Bevacizumab, a humanized monoclonal antibody against VEGF-A, was the first VEGF pathway antagonist used in clinical trials to test the hypothesis that modulation of aberrantly expressed components of the VHL pathway would be associated with clinical activity in clear cell RCC. In a three-arm phase 2 study, patients with metastatic clear cell RCC whose disease had progressed after prior cytokine therapy were randomized to receive either one of two dose levels of bevacizumab (10 mg/kg or 3 mg/kg administered every 2 weeks intravenously) or placebo (Table 50–7) (Yang et al, 2003a). **An interim efficacy analysis performed after 116 patients (of a planned 240 patients) were enrolled in the study demonstrated a significantly longer progression-free survival (PFS) in patients assigned to 10 mg/kg bevacizumab compared with those receiving placebo (4.8 vs 2.5 months, *P* < .001)** (Fig. 50–5). There was no corresponding improvement in OS, although the crossover design used in this trial (patients progressing on placebo were allowed to cross over to the bevacizumab arm) may have influenced this outcome. The overall response rate in patients receiving bevacizumab was modest (objective response rate of 10%, all in patients assigned to the 10 mg/kg dose). The agent was well tolerated, with bleeding, hypertension, fatigue, and proteinuria being some of the more common adverse events reported. Single-agent bevacizumab has not been compared with either cytokines (often used in first-line treatment before the advent of VEGF pathway antagonists) or other VEGF pathway antagonists such as sunitinib in prospective trials.

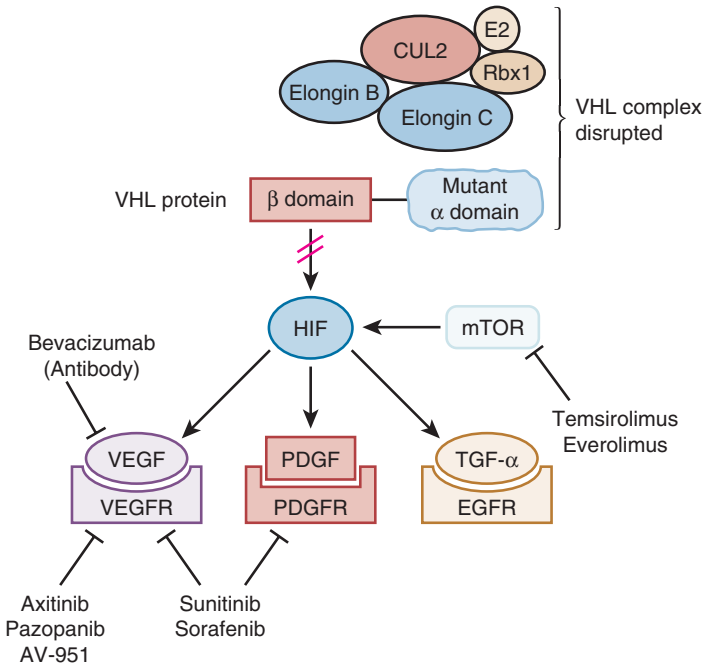

Figure 50–4. Targeting the VHL pathway in clear cell renal cell carcinoma. Loss of VHL activity leads to accumulation of HIF and several proangiogenic and growth factors that can serve as targets for anticancer drugs. HIF can also be upregulated by mTOR, which promotes HIF translation. (Adapted from Linehan WM, Bratslavsky G, Pinto PA, et al. Molecular diagnosis and therapy of kidney cancer. Annu Rev Med 2010;61:329–43.)

Several strategies for improving the efficacy of bevacizumab have been explored, including combination with cytokines (interferon-α) and other targeted agents (e.g., erlotinib, a small molecule inhibitor of epidermal growth factor receptor tyrosine kinase activity). A single-arm phase 2 study of bevacizumab plus erlotinib showed promising activity with an overall response rate of 25% (higher than would be expected with bevacizumab alone based on historical data) and median PFS of 11 months (Hainsworth et al, 2005). However, a subsequent randomized phase 2 study failed to demonstrate the superiority of this combination (median PFS 9.9 months) over bevacizumab alone (median PFS 8.5 months, *P* = .58) (Bukowski et al, 2007). Two large randomized phase 3 studies have compared the combination of bevacizumab and interferon-α to interferon-α alone (Table 50–8). **In a Cancer and Leukemia Group B study (CALGB 90206) of 752 patients with previously untreated metastatic clear cell RCC randomized to one of two treatment arms, a higher response rate (25.5% vs. 13.1%, *P* < .0001) and PFS (8.5 months vs. 5.2 months, *P* < .0001) were observed in**

Table 50–7.

Summary of Selected Studies of Bevacizumab-Based Regimens in Metastatic Renal Cell Carcinoma

STUDY	AGENT(S)	PHASE	STUDY POPULATION	NO. OF PATIENTS	OVERALL RESPONSE RATE (RECIST)*	MEDIAN PFS (MO)*	MEDIAN OS (MO)*
Yang et al, 2003a	Bev (10 mg/kg) vs. Bev (3 mg/kg) vs. placebo	Randomized, 3-arm phase 2	Cytokine-refractory clear cell	116	10% vs. 0% vs. 0%	**4.8 vs. 3.0 vs. 2.5**	
Escudier et al, 2007b	Bev + IFN-α vs. IFN-α	Randomized phase 3	Previously untreated clear cell	649	**31% vs. 13%**	**10.2. vs. 5.4**	NR vs. 19.8

patients assigned to bevacizumab plus interferon-α compared with those receiving interferon-α alone (Rini et al, 2008a). **A multicenter European trial (AVOREN) with a similar design also reported similar results with PFS (10.2 vs. 5.4 months, *P* = .0001) and objective response rate (31% vs. 13%) favoring the combination arm** (Fig. 50–6) (Escudier et al, 2007b). Updated survival data from both trials were recently reported, demonstrating no improvement in overall survival associated with the addition of bevacizumab to interferon (Escudier et al, 2010; Rini et al, 2010). While neither study permitted crossover of patients assigned to interferon-α at progression, a significant number of patients (>60%) subsequently received anticancer therapy off protocol, potentially confounding overall survival analysis. Both trials reported a higher incidence of some grade 3 adverse events such as hypertension, fatigue, anorexia, and asthenia in patients receiving combination therapy. Both the CALGB and Avoren trials were large, well-designed, and well-conducted multicenter studies that suggest that the addition of bevacizumab to interferon may be associated with clinical benefit (i.e., improvement in PFS). However, these trials did not include an arm with bevacizumab alone (owing to insufficient evidence of single-agent activity at the time these trials were designed to justify a bevacizumab-only arm), making it difficult to determine if inclusion of interferon in this regimen, with its attendant toxicities, adds meaningful clinical benefit. Interestingly, the median PFS observed in the combination arm of the CALGB trial (8.5 months) is similar to that observed with bevacizumab alone in a phase 2 trial of previously untreated patients with clear cell RCC (Bukowski et al, 2007). Lastly, bevacizumab (either alone or in combination with interferon) has not been compared prospectively with VEGF receptor (VEGFR) antagonists such as sunitinib, arguably the current standard of care for most newly diagnosed patients with metastatic clear cell RCC. **Bevacizumab is not widely used as a single agent in the initial therapy for metastatic clear cell RCC but may have a role in patients who have failed standard therapy with first-line VEGFR antagonists, either alone or in combination with other agents, particularly interferon. Ongoing and future trials may help determine the best use of this agent in the overall management of patients with clear cell RCC.**

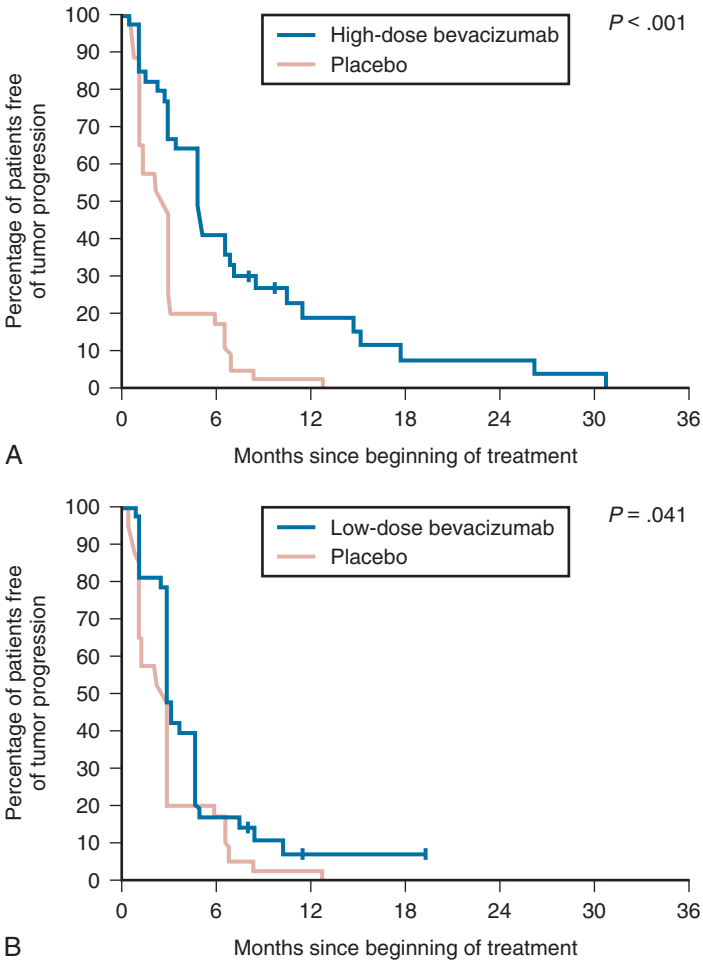

Figure 50–5. Kaplan-Meier analysis of 39 patients assigned to high-dose bevacizumab (10 mg/kg, **A**) and of 37 patients assigned to low-dose bevacizumab (3 mg/kg, **B**) compared with 40 patients assigned to receive placebo. (From Yang JC, Haworth L, Sherry RM, et al. A randomized trial of bevacizumab, an anti-vascular endothelial growth factor antibody, for metastatic renal cancer. N Engl J Med 2003a;349:427–34.)

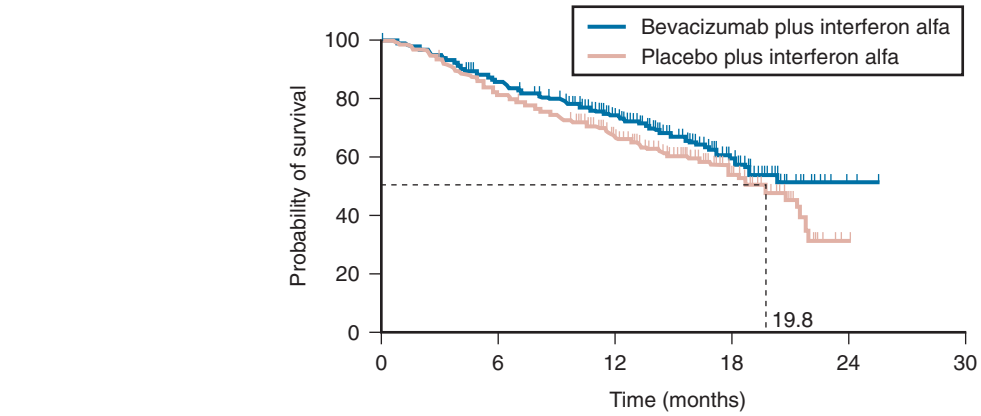
Sorafenib



Sorafenib is an oral receptor kinase inhibitor with activity against VEGFR2, PDGF receptor-β, and raf-1. A phase 2 trial using a randomized discontinuation design provided initial evidence that sorafenib is active in RCC (see Table 50–8) (Ratain et al, 2006). Two hundred and two patients were enrolled on this trial, and all of them received 400 mg of sorafenib twice daily for the first 12 weeks. Sixty-five patients who demonstrated stable disease at the end of this period (defined in this trial as within ± 25% of baseline) were then randomized to either continued treatment with sorafenib or to placebo. Patients randomized to sorafenib had a superior PFS (24 weeks) versus

Figure 50–6. Kaplan-Meier analysis of **(A)** overall survival and **(B)** progression-free survival in 649 patients assigned to receive interferon-α alone or in combination with bevacizumab. (From Escudier B, Pluzanska A, Koralewski P, et al. Bevacizumab plus interferon alfa-2a for treatment of metastatic renal cell carcinoma: a randomised, double-blind phase III trial. Lancet 2007b;370:2103–11.)

those receiving placebo (6 weeks, $P = .0087$). A global, multicenter, placebo-controlled randomized phase 3 trial with 903 patients (the TARGET study) was subsequently undertaken to evaluate the efficacy of sorafenib in patients with metastatic RCC who had previously received cytokine therapy (Fig. 50–7) (Escudier et al, 2007a). **This trial echoed the results seen in the phase 2 trial, with patients randomized to receive sorafenib experiencing a longer PFS (median 5.5 months) versus those receiving placebo (2.8 months, $P < .01$) at a planned interim analysis.** After this interim analysis patients progressing on placebo were allowed to cross over to receive sorafenib. **Mature survival data from this trial were recently presented and demonstrated no significant difference in OS between the two groups (17.8 months for sorafenib vs. 15.3 months with placebo, $P = .146$) in an intent-to-treat analysis** (see Fig. 50–7) (Escudier et al, 2009a). However, if patients who crossed over from placebo to sorafenib were censored, the survival data demonstrated a statistically significant advantage favoring sorafenib (median OS 17.8 vs. 14.3 months, $P = .029$). Results from this exploratory "pre-crossover" survival analysis suggest that the survival end point may have been influenced by the crossover design. Overall response rate to sorafenib in this trial was relatively low, with 10% of patients experiencing a partial response; however, more than 70% of patients receiving sorafenib had some degree of tumor regression. **The side effect profile of sorafenib is comparable to that of other agents in this class and includes hypertension, fatigue, rash, hand-foot syndrome, and diarrhea. The efficacy of sorafenib in the first-line setting was investigated in a randomized phase 2 study that assigned 189 previously untreated patients with metastatic clear cell RCC to receive either sorafenib or interferon-α** (Escudier et al, 2009b). **Although patients receiving sorafenib had a higher likelihood of achieving tumor regression (68% vs. 39%), PFS in the two groups was nearly identical (median 5.7 months for sorafenib vs. 5.6 months for interferon, P = NS)** (Table 50–9). **Although sorafenib is FDA-approved for the treatment of advanced kidney cancer, its precise role in the management of these patients remains to be determined in view of the plethora of VEGFR antagonists currently available or under investigation.** Dose-intensive regimens of sorafenib (up to 800 mg twice daily) are being explored in an attempt to enhance

the efficacy of this agent, but to date there is no convincing evidence that higher doses offer additional clinical benefit. **Currently, sorafenib is infrequently used in the first-line setting.** Anecdotal evidence and small case series suggest that patients whose disease has progressed on other VEGFR inhibitors may respond favorably to sorafenib, and the agent is commonly used in patients whose disease has progressed on sunitinib or similar agents.

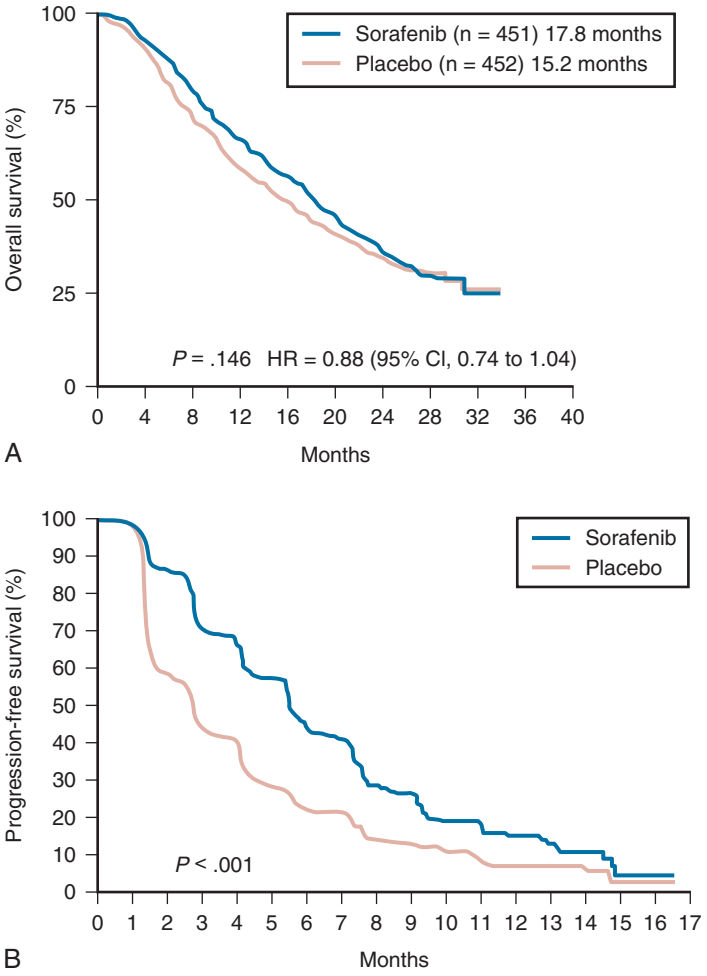

Figure 50–7. Kaplan-Meier analysis of overall survival (**A**) and progression-free survival (**B**) in 903 metastatic renal cell carcinoma patients randomized to sorafenib or placebo. Sorafenib for treatment of renal cell carcinoma: final efficacy and safety results of the phase III treatment approaches in renal cancer global evaluation trial. J Clin Oncol 2009a;27:3312–18; and Escudier B, Eisen T, Stadler WM, et al. Sorafenib in advanced clear-cell renal-cell carcinoma. N Engl J Med 2007a;356:125–34.)

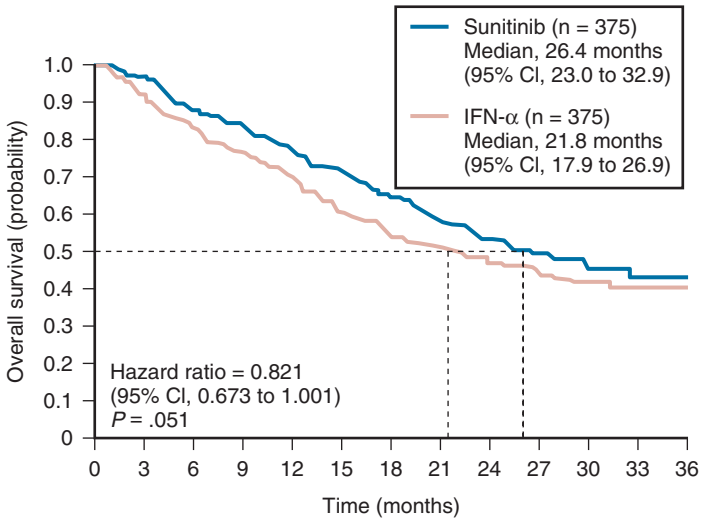
Sunitinib



Sunitinib is currently the most widely used oral VEGFR kinase inhibitor in the initial treatment of metastatic clear cell RCC. It is a potent inhibitor of VEGFR2, PDGFR-β, c-*KIT*, and fms-like tyrosine kinase-3. As with sorafenib, simultaneous targeting of VEGF and PDGF pathways by this agent is likely to act synergistically in inhibiting tumor angiogenesis, by directly disrupting VEGF-mediated vascular endothelial development and proliferation and by interfering with vascular pericyte function, which is dependent on the integrity of PDGF signaling. Initial evaluation of sunitinib was undertaken with two single-arm open-label phase 2 trials in patients with metastatic RCC, most of whom had previously received cytokine therapy (Motzer et al, 2006a, 2006b). Sunitinib was administered orally at a dose of 50 mg/day during the first 4 weeks of a 6-week cycle on both trials (see Table 50–9). Remarkably high overall response rates (30% to 40%) with a median PFS of more than 8.5 months were observed in these trials, leading to the approval of this agent for treatment of advanced RCC by the FDA. A landmark phase 3 randomized trial comparing sunitinib with interferon-α as first-line therapy in patients with metastatic clear cell RCC further demonstrated the activity of sunitinib in this patient population (Motzer et al, 2007). In this study, 750 patients were randomized to receive either sunitinib or interferon-α. **An interim analysis based on independent, third-party radiologic assessment demonstrated a significantly superior PFS (median 11 months vs, 5 months, *P* = .001) and overall response rate (31% vs. 6%, *P* = .001) favoring the sunitinib arm** (Fig. 50–8). **Gastrointestinal events, particularly diarrhea, dermatologic manifestations such as rash and hand-foot syndrome, constitutional symptoms such as fatigue and asthenia, and hypertension were the most commonly adverse events associated with sunitinib, whereas bone marrow suppression, decline in left ventricular ejection fraction, and hypothyroidism were other notable side effects. Sunitinib also performed better than interferon in a quality of life assessment conducted as part of the study. Mature survival data from this study were recently reported and demonstrated superior OS in the sunitinib study arm based on an intent-to-treat analysis (median OS 26.4 vs. 21.8 months, *P* = .051)** (Motzer et al, 2009). **Based on these data,**

J Clin Oncol 2009;27:3584–90; and Motzer RJ, Hutson TE, Tomczak P, et al. Sunitinib versus interferon alfa in metastatic renal-cell carcinoma. N Engl J Med 2007;356:115–24.)

sunitinib has become the most widely used agent in the initial management of metastatic clear cell RCC patients in the United States.

Other VEGF Pathway Antagonists

Agents such as sunitinib and sorafenib have activity against a wide array of target molecules, some of which may not be relevant in clear cell RCC. Although these agents are relatively well tolerated when compared with conventional cytotoxic chemotherapy, dose reductions and termination of treatment due to toxicity are not infrequently warranted in patients receiving these drugs. **A variety of newer agents with selective activity against the VEGFR family have recently gained attention as a possible means of diminishing the side effects associated with therapy without compromising efficacy** (Table 50–10). **Axitinib** is an oral small molecule tyrosine kinase inhibitor of VEGFR1, VEGFR2, and VEGFR3. In a phase 2 trial of axitinib in 52 patients with advanced kidney cancer, an overall response of 44%, including two complete responses (4%), and a median time to progression of 15.7 months were reported (Rixe et al, 2007). Most patients treated on this study displayed some degree of tumor shrinkage, and many had been pretreated with either IL-2 or interferon. Diarrhea, fatigue, and hypertension were the most commonly encountered grade 3 and 4 events and were amenable to medical management in most patients. Several other agents with selective activity against the VEGFR family are also under investigation. One agent in this class, **pazopanib,** was the subject of a recent randomized, double-blind, placebo-controlled phase 3 trial in patients with metastatic clear cell RCC who had received no or one prior cytokine-based therapy (Sternberg et al, 2010). In the 405 patients randomized (2:1) to receive either pazopanib or placebo, PFS (median 9.4 months vs. 4.2 months, *P*

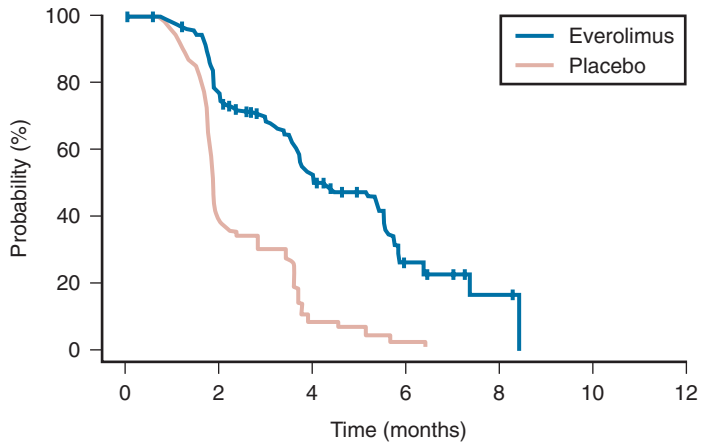
= .0000001) and response rates (30% vs. 3%) clearly favored the pazopanib study arm. Furthermore, reported toxicities were mild, with very few grade 3 and 4 adverse events encountered. **Tivozanib (AV-951),** yet another inhibitor of VEGFR1 to VEGRF3, has been evaluated in a phase 2 randomized discontinuation trial with demonstration of activity in RCC as well as an appealing adverse event profile (Bhargava et al, 2009). **The approach directed at a single type of growth factor receptor has the potential to provide a strategy for precisely targeting a component of the VHL pathway in clear cell kidney cancer while avoiding the toxicity of multiple kinase inhibitors. Prospective randomized trials of selective VEGFR inhibitors are required to determine if these agents offer tangible advantages over currently FDA-approved agents.**

Inhibitors of the Mammalian Target of Rapamycin



mTOR is a key intracellular protein that is a component of several signaling cascades including those mediating the effects of some growth factors. **It appears to play a role in regulating translation and stability of HIF-1α, and preclinical models have suggested that growth inhibition occurring in response to mTOR inhibitors correlates with a block in HIF-1α translation** (Hudson et al, 2002; Thomas et al, 2006). Two analogues of sirolimus, **temsirolimus** and **everolimus,** have been clinically evaluated with demonstrable activity in RCC.

A phase 2 trial of **temsirolimus** evaluated three different doses (25 mg, 75 mg, and 250 mg per week administered intravenously) in 111 patients assigned randomly to one of the dose levels (Table 50–11). The overall response rate observed on this trial was modest (7%, including one patient with a complete response), and the median PFS was 15 months (Atkins et al, 2004). Responses and PFS appeared to be independent of temsirolimus dose. An exploratory subgroup analysis based on stratification of patients according to MSKCC risk groups revealed that patients in the poor-risk group had a longer median OS compared with historical controls receiving interferon-α (8.2 vs. 4.9 months). Based on this observation, a three-arm randomized phase 3 trial of 626 patients with three or more predefined poor risk features was undertaken (Hudes et al, 2007). Patients with previously untreated metastatic kidney cancer of all histologic subtypes were eligible and randomized to receive temsirolimus alone (25 mg intravenously every week), interferon-α alone (up to 18 million units subcutaneously three times a week) or temsirolimus (15 mg intravenously every week) plus interferon-α (6 million units subcutaneously three times a week). PFS was superior in both temsirolimus-containing arms compared with interferon alone (median 3.8 months vs. 1.9 months). **Importantly, the trial also demonstrated a significantly higher OS in the temsirolimus arm compared with the interferon-only arm (median OS 10.9 vs. 7.3 months, *P* = .008), while the addition of temsirolimus did not appear to significantly alter OS compared with interferon alone (median OS 8.4 vs. 7.3 months, *P* = .70)** (Fig. 50–9). Temsirolimus was fairly well tolerated, and most

Number at risk							
Everolimus	272	132	47	8	2	0	0
Placebo	138	32	4	1	0	0	0

Figure 50–10. Kaplan-Meier estimates of progression-free survival in 410 patients with metastatic renal cell carcinoma randomized to everolimus or placebo. (From Motzer RJ, Escudier B, Oudard S, et al. Efficacy of everolimus in advanced renal cell carcinoma: a double-blind, randomised, placebo-controlled phase III trial. Lancet 2008b;372:449–56.)

common adverse events such as mucositis, fatigue, rash, hyperglycemia, hypophosphatemia, hypercholesterolemia, and pulmonary complications were amenable to medical and/or supportive measures. **Based on these data, temsirolimus was approved by the U.S. FDA for the treatment of patients with metastatic RCC, and the agent is a reasonable front-line choice in patients presenting with poor-risk features.**

Everolimus is an orally bioavailable inhibitor of mTOR. It was the subject of a phase 3 trial in patients with metastatic clear cell RCC whose disease had progressed after therapy with sunitinib, sorafenib, or both (Motzer et al, 2008b). Patients were randomized to receive either everolimus, 10 mg once daily (n = 272), or placebo (n = 138) (see Table 50–11). **The trial was stopped after an interim analysis demonstrated superior PFS in the everolimus arm (median 4 months) compared with the placebo arm (median 1.9 months)** (Fig. 50–10). At the time of this analysis, median survival had not been reached in the everolimus group and was 8.8 months for the placebo group; OS was not significantly different in the two groups. **Although the agent offers only a modest improvement in PFS in patients progressing on first-line VEGFR antagonists, it is nonetheless a reasonable therapeutic option and has been approved by the U.S. FDA for this indication.**

Combination and Sequential Therapy with Agents Targeting the VHL Pathway

Combinations of two or more classes of agents with activity centered on different components of the VHL pathway provides an attractive strategy that might serve to increase efficacy as well as eliminating potential mechanisms of resistance. **A major limitation of this approach is the overlapping toxicity profile of several drugs, necessitating significant dose reductions of individual drugs** (Feldman et al, 2009; Patel et al, 2009). Ongoing trials will determine if the synergy engendered by combination therapy can adequately offset the effects of dose reduction.

Given the profusion of agents with single-agent activity in RCC, identifying the optimal sequencing of these agents is a question of considerable importance. A randomized study has demonstrated that everolimus can prolong PFS compared with placebo in patients who have progressed on first-line VEGFR antagonists (Motzer et al, 2008b). Smaller retrospective analyses have suggested that a proportion of patients who have progressed on one VEGF pathway inhibitor may benefit from a second agent targeting the same pathway (Rini et al, 2008b; Tamaskar et al, 2008). Carefully designed clinical trials are required to identify the most

effective strategies for sequencing multiple agents, as well as to categorize patients most likely to benefit from a given sequence based on molecular characterization of their tumors.

Other Treatment Options in Patients with Clear Cell Renal Cell Carcinoma

Chemotherapy

Conventional cytotoxic chemotherapy has been largely ineffective in the management of clear cell RCC. Numerous chemotherapeutic agents including 5-FU, platinum compounds, gemcitabine, vinblastine, and bleomycin have been evaluated as single agents in this disease but have failed to demonstrate clinically meaningful activity; a wide array of combination chemotherapy regimens have fared little better (Haas et al, 1976; Hahn et al, 1977; Zaniboni et al, 1989; Mertens et al, 1993, 1994; Amato, 2000; Rini et al, 2000, 2005; Stadler et al, 2006). **Comprehensive meta-analyses of chemotherapy trials in RCC indicate the overall response rate is 5.5% to 6.0%** (Yagoda et al, 1995). Although the mechanisms underlying this profound chemoresistance have not been fully elucidated, overexpression of the multidrug resistance gene *(MDR)* has been proposed as one possible culprit (Fojo et al, 1987). However, the addition of MDR inhibitors such as toremefine, cyclosporine, and verapamil to conventional chemotherapeutic agents has failed to improve their efficacy, suggesting that other, as yet unrecognized, factors may be at play (Braybrooke et al, 2000). **Cytotoxic chemotherapy has no role in the current management of most patients with clear cell RCC.** One situation in which chemotherapy may bear further investigation is in patients whose tumors demonstrate a sarcomatoid component; a small case series has suggested promising activity for gemcitabine-based chemotherapy in this setting, prompting further study of this approach (Nanus et al, 2004).

Hormonal Therapy

Hormonal therapy had been the subject of trials in RCC in the 1970s and 1980s, preceding the advent of cytokines. These studies were prompted by both the lack of effective therapies for kidney cancer and by the belief that a male preponderance (kidney cancer occurs approximately twice as frequently in males) implied a hormonal basis for this malignancy. Hormonal agents such as medroxyprogesterone have been noted to induce tumor regressions in a small minority of patients, but overall response rates are too low (approximately 2%) to have meaningful clinical impact in most patients (Schomburg et al, 1993; Harris, 1983; Medical Research Council Renal Cancer Collaborators, 1999; Braybrooke et al, 2000). **Progestational and other hormonal agents have no role in the current management of renal cell cancer.**

SYSTEMIC THERAPY FOR NON–CLEAR CELL VARIANTS OF RENAL CELL CARCINOMA

Non–clear cell subtypes of kidney cancer are relatively rare (constituting approximately 15% of all kidney cancer) and have been the subject of few prospective studies. Given the unavailability of agents of proven efficacy in papillary, chromophobe, and other rare histologic subtypes, patients with non–clear cell renal tumors often receive agents with activity in clear cell RCC.

Recent advances in our understanding of some subtypes of RCC are bound to lead to a more rational approach to their management. As with clear cell RCC, hereditary forms of papillary and chromophobe RCC may hold the key to the identification of critical molecular events leading to these tumors both in familial and sporadic settings (Linehan, 2003; Linehan et al, 2009). Hereditary papillary renal cancer (HPRC) is a familial condition characterized by the predisposition of affected individuals to develop bilateral, multifocal papillary type I RCC. **HPRC is characterized by the presence of activating germline mutations in the tyrosine kinase domain of the proto-oncogene c-*MET*, which is located on chromosome 7; this is usually accompanied by nonrandom duplication of the chromosome containing the mutated allele** (Schmidt et al, 1997, 1998, 1999, 2004; Zhuang et al, 1998; Linehan, 2003; Linehan et al, 2009). c-MET is a cell surface receptor that is normally activated on binding its ligand, hepatocyte growth factor (HGF) but is rendered constitutionally active in the presence of mutations in the kinase domain of this protein (Bottaro et al, 1991; Dharmawardana et al, 2004; Peruzzi and Bottaro, 2006; Giubellino et al, 2009). The HGF/c-MET pathway is involved in regulating a variety of biologic functions, including cell growth, proliferation, and motility (Fig. 50–11) (Jeffers et al, 1998; Giubellino et al, 2009). Somatic c-MET alterations have been noted in a proportion of patients with sporadic papillary RCC, with activating mutations identified in approximately 13% of papillary tumors in one series. Trisomy 7 (both *HGF* and c-MET are located on chromosome 7) has been described in more than two thirds of papillary tumors and may represent an alternative mechanism contributing to activation of the c-MET pathway (Kovacs et al, 1991; Henke and Erbersdobler, 2002).

VEGFR inhibitors active in clear cell RCC do not seem to be effective in papillary RCC. Sorafenib and sunitinib were shown to have minimal activity in retrospective studies of papillary RCC patients (Choueiri et al, 2008a). Prospective phase 2 trials with sunitinib have demonstrated that this agent is associated with low response rates (5% to 10%) in papillary RCC. The Southwest Oncology Group reported an 11% overall response rate with erlotinib, an oral EGFR inhibitor, in 52 patients with metastatic papillary RCC with a 6-month PFS of only 29%. More recently, the realization that c-MET activation may play an important role in some forms of papillary RCC has led to the evaluation of foretinib (formerly known as XL880 and GSK1363089), a novel tyrosine kinase inhibitor with activity against c-*MET* and VEGFR2 in this RCC subtype. A multicenter, open-label phase 2 trial studied two dosing regimens (an intermittent regimen in which the drug was administered orally at a dose of 240 mg/day for the first 5 days of every 14-day cycle and a continuous or daily dosing regimen at a dose of 80 mg/day) in patients with metastatic papillary RCC and those with bilateral multifocal disease (Srinivasan et al, 2009). A recent interim analysis in the first 53 patients enrolled on trial (including seven HPRC patients with germline c-*MET* mutations and bilateral multifocal tumors) has been reported in abstract form. Of 44 evaluable patients in both dosing regimens, 6 had a confirmed partial response (objective response rate 14%) and an additional 34 (77%) had stable disease as their best response. Striking responses were seen in some patients, including regression of renal tumors in patients with bilateral multifocal disease. The adverse event profile associated with this drug is similar to that observed with other VEGFR antagonists. Patients on this trial will be retrospectively stratified based on the presence or absence of c-MET pathway activation (germline or somatic c-*MET* mutation or trisomy 7 or 7q31 amplification in

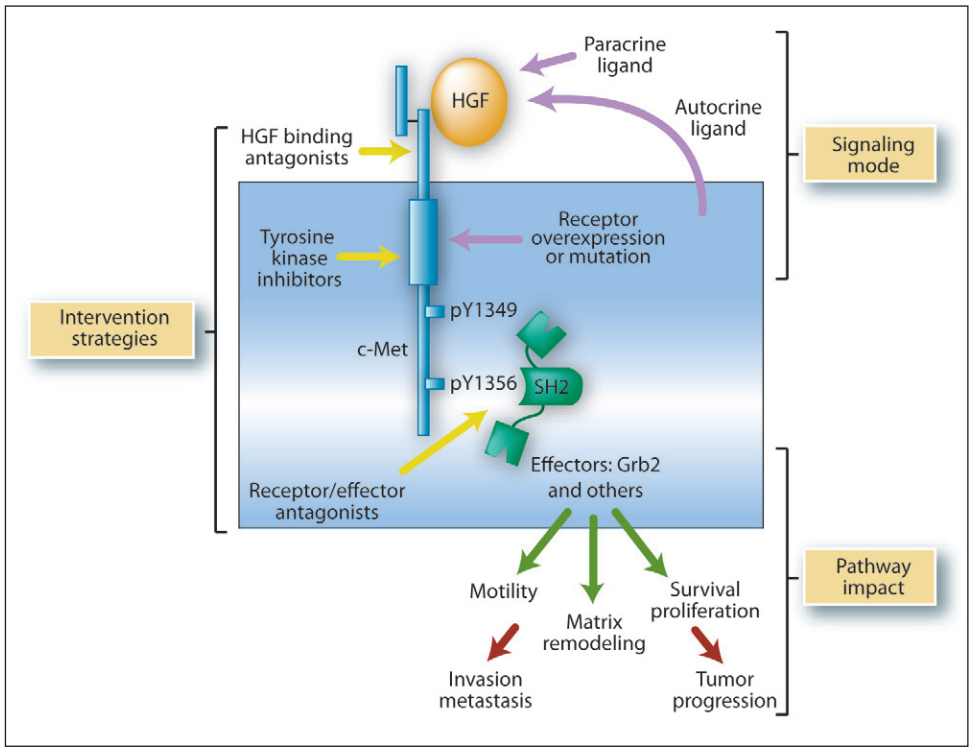

Figure 50–11. c-MET oncogenic signaling pathway. Important downstream biochemical and biologic consequences of c-MET activation (by HGF binding or by constitutive activation of the receptor tyrosine kinase activity by mutation) are represented. The c-MET ligand (HGF), c-MET tyrosine kinase activity, and downstream effectors (such as Grb-2) are potential targets for drugs in tumors with aberrant pathway activation. (From Peruzzi B, Bottaro DP. Targeting the c-Met signaling pathway in cancer. Clin Cancer Res 2006;12:3657–60.)

tumor tissue) to help explore the correlation between c-MET activation and response to foretinib. Foretinib and other agents targeting the c-MET pathway warrant further evaluation in patients with papillary RCC.

An exploratory subgroup analysis of patients enrolled in large randomized phase 3 study evaluating the efficacy of temsirolimus versus interferon in "poor prognosis" patients suggests that mTOR inhibitors may have activity in some non–clear cell variants. Approximately 20% of the patients enrolled in this trial had non–clear cell histologies (predominantly papillary RCC). The outcome of 37 patients with non–clear cell RCC treated with temsirolimus (both OS and PFS) was found to be better than that of 36 patients receiving interferon in this subgroup analysis. Although these data suggest that temsirolimus may have activity in some non–clear cell variants, these conclusions are limited by the fact that this is a subgroup analysis (Dutcher et al, 2009). Prospective studies evaluating the efficacy of mTOR inhibitors are required to clarify the role of these agents in different subsets of RCC.

Cytotoxic chemotherapy has been used with modest success in collecting duct carcinoma, a rare kidney cancer variant with similarities to urothelial malignancies. In a series of 23 patients with metastatic collecting duct carcinoma, a response rate of 26% (including one complete response) was reported with a regimen comprising gemcitabine and carboplatin. Median PFS (7.1 months) and OS (10.5 months) were modest (Oudard et al, 2007). **In summary there is no standard approach of proven efficacy for most patients with non–clear cell RCC, although some promising approaches are being evaluated. Enrollment in suitable trials should be considered for all patients with non–clear cell RCC.**

Renal Cysts
Renal Cortical Adenoma
Metanephric Adenoma
Oncocytoma
Angiomyolipoma
Cystic Nephroma and Mixed Epithelial/Stromal Tumor
Leiomyoma
Other Benign Renal Tumors

Benign renal neoplasms constitute a rather large and heterogeneous group of renal lesions that can be found in the kidney. These include the simple renal cyst, selected complex renal cysts, cortical and metanephric adenomas, angiomyolipoma, oncocytoma, the rarer cystic nephroma, mixed epithelial/stromal tumor, and leiomyoma, as well as other, even more esoteric tumor types. Management approaches to these lesions can vary widely, from no management for the simple renal cyst to selective embolization for larger angiomyolipomas and surgical extirpation for solid renal masses when the differential diagnosis includes renal cell carcinoma (RCC). With the increased use of cross-sectional abdominal imaging for renal-specific as well as other nonspecific complaints, it is expected that the identification of both benign and malignant renal tumors will continue to increase in the coming years (Patard, 2009). Moreover, with the increase use of, and refinements to, renal mass biopsy, the management of both benign and malignant renal neoplasms is still evolving in a way that the indications for intervention, and the type of intervention, may change significantly in the coming years (Lane et al, 2008; Campbell et al, 2009). Now, with advanced multidimensional imaging techniques, as well as minimally invasive, nephron-sparing surgical approaches, percutaneous ablative approaches, and the concept of active surveillance in the armamentarium of the practicing urologist, management of all renal lesions, including those that are presumptively benign in etiology, continues to evolve (Raj et al, 2007; Benway and Bhayani, 2009; Murphy et al, 2009).

At present, however, the urologist is left primarily with imaging studies such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) to assess whether a renal lesion is benign or malignant before therapeutic decisions are made. And unless the mass has clear radiographic features that suggest a benign etiology, such as clear evidence of fat seen with most angiomyolipomas or the smooth walls and lack of enhancement of a simple or minimally complex cyst, the vast majority of benign renal lesions are diagnosed only after definitive therapy such as surgical intervention has been implemented. There are several clinical features that have been linked to an increased likelihood of a renal mass having a benign etiology, including smaller size, female sex, and older age, but none of these factors can be relied on to avoid intervention if a specific pretherapy diagnosis cannot be made (Kutikov et al, 2006; Snyder et al, 2006; Glassman et al, 2007; Lane et al, 2007; Beisland et al, 2009; Murphy et al, 2009).

In this chapter the most common benign renal neoplasms that occur in the kidney are identified. The discussion is then focused on the etiology and natural history, clinical presentation, imaging characteristics, and treatment options, when treatment is indicated.

RENAL CYSTS

In much the same way as the molecular biology of RCC was elucidated through the study of familial genetic syndromes such as von Hippel-Lindau disease, the molecular basis for cyst formation has been further elucidated through the genetic analysis of familial renal cystic syndromes, such as autosomal dominant polycystic kidney disease (ADPKD). **Through these studies researchers have identified that loss of specific genes, such as *PKD1* and/or *PKD2* (polycystins) lead to cyst formation in patients with ADPKD. Polycystin-1 and polycystin-2 form a complex that represents a critical ion channel in the kidney, the loss of which results in cyst formation through the loss of intracellular calcium dysregulation and dysfunction of the primary renal cilia, a poorly understood organelle that is in part responsible for normal renal development** (Pei, 2003; Weimbs, 2007; Ibraghimov-Beskrovnaya and Bukanov, 2008). Whether these genetic changes are common to sporadic forming "benign" renal cystic disease remains to be proven, but many of the phenotypic and genetic changes noted in the kidneys of patients with familial cystic disease syndromes have been identified in sporadic cystic disease (Qian et al, 1996; Pei, 2001).

Perhaps the best description of the natural history of sporadic renal cysts can be found in the recently updated study by Terada and associates (2008). In this study of 61 patients with simple renal cysts and a mean of 10 years of follow-up, the authors noted that the cysts increased in both size and number over time. The average increase in size of the cysts was 1.9 mm per year, but the authors also noted that the rate of size increase decreased with age. Interestingly, two cysts developed renal neoplasms during the course of the study and no differences were noted in the clinical characteristics of the cysts that developed neoplasms from those

that did not. **Regarding the risk factors for the development of cysts, increasing age, male gender, presence of hypertension, and the presence of renal insufficiency were all associated with the development of sporadic renal cysts** (Terada et al, 2004). **Renal cysts remain the most common benign renal lesions, representing more than 70% of asymptomatic renal masses.** They can be solitary or multiple and unilateral or bilateral (Terada et al, 2002).

In addition to sporadic cystic disease of the kidney, and the cysts that occur with familial syndromes such as ADPKD and autosomal recessive polycystic disease, cysts are also known to occur in association with end-stage renal disease in patients on dialysis (Bisceglia et al, 2006). **There appears to be a higher incidence of RCC associated with the development of acquired renal cystic disease, much like that seen with von Hippel-Lindau disease and tuberous sclerosis, such that the pathogenesis of these cystic lesions may be quite different from that seen with sporadic simple or minimally complex cysts** (Truong et al, 2003).

Renal cystic lesions can be imaged through a variety of radiographic techniques, including ultrasonography, CT, as well as MRI. On ultrasonography, simple renal cysts have a smooth wall, are fluid filled with no internal echoes, and have evidence of posterior wall enhancement. Evidence of internal echoes, calcifications or nodularity in the wall, or internal septa on ultrasonography suggest a more complex cyst that might be worthy of further imaging that includes intravenous administration of a contrast agent (Quaia et al, 2008; Eknoyan, 2009).

The Bosniak classification for renal cystic lesions, as reviewed in Table 51–1, is perhaps the most useful and widely employed method for characterizing renal cystic lesions and for assessing the likelihood of the presence of a concomitant malignancy within the cyst (Israel and Bosniak, 2005; Warren and McFarlane, 2005). In general, Bosniak class I, II, and IIF cysts are likely to represent benign lesions, thus requiring either no therapy or just continued radiographic follow-up, in the case of class IIF lesions (Fig. 51–1). These recommendations are based on a number of series published in the

Table 51–1.
Bosniak Classification of Renal Cysts

BOSNIAK CLASSIFICATION	IMAGING CHARACTERISTICS	INCIDENCE OF MALIGNANCY	THERAPY
I	Simple cyst with a hairline thin wall that does not contain septa, calcifications, or solid components. It measures water density in Hounsfield units and does not enhance with intravenous administration of a contrast agent.	1.7%	No therapy or follow-up required
II	Cyst may contain a few hairline thin septa and fine calcifications, or a short segment of slightly thickened calcification may be present in the wall or septa. Uniformly high-attenuation lesions <3 cm (so-called high-density cysts) are well marginated and do not enhance with intravenous administration of a contrast agent.	18.5%	No therapy or follow-up required
IIF	Cysts may contain multiple hairline thin septa or minimal smooth thickening of their wall or septa. Their wall or septa may contain calcifications that may be thick and nodular, but no measurable contrast enhancement is present. These lesions are generally well marginated. Totally intrarenal nonenhancing high-attenuation renal lesions ≥3 cm are also included in this category.	18.5%	Repeat imaging to assess stability of size and radiographic characteristics
III	"Indeterminate" cystic masses have thickened irregular or smooth walls or septa in which measurable contrast enhancement is present.	33%	Excision or ablation
IV	Clearly malignant cystic masses can have all the criteria of category III but also contain enhancing soft tissue components.	92.5%	Excision or ablation

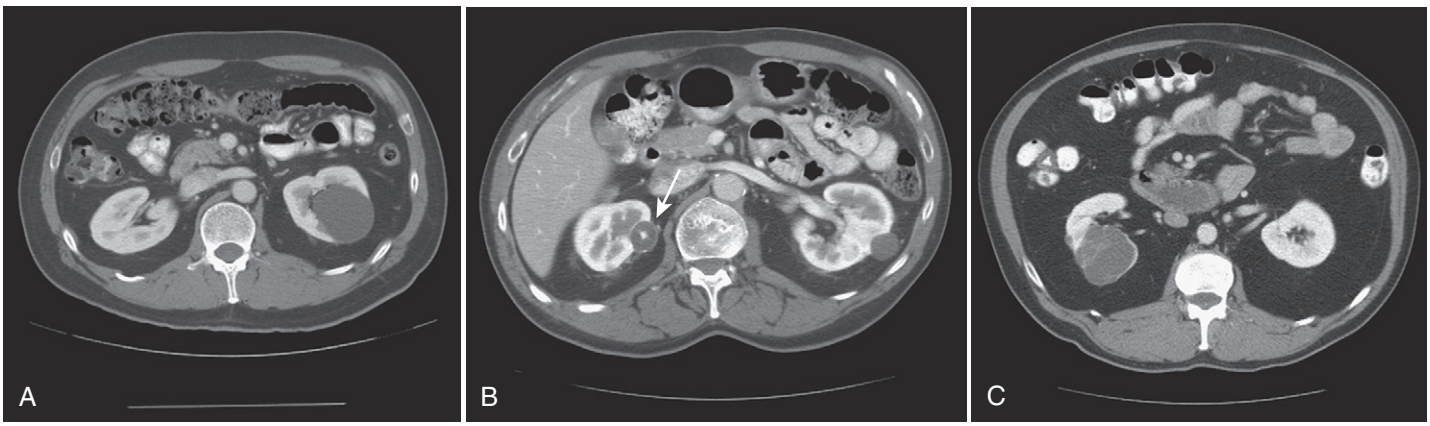

Figure 51–1. **A,** CT scan of a Bosniak I renal cyst. **B,** CT scan of a Bosniak II renal cyst. Note internal calcification. **C,** CT scan of a Bosniak IIF renal cyst. Several thin irregular septations are present within the cyst. (Copyright 2009, C.G. Wood.)

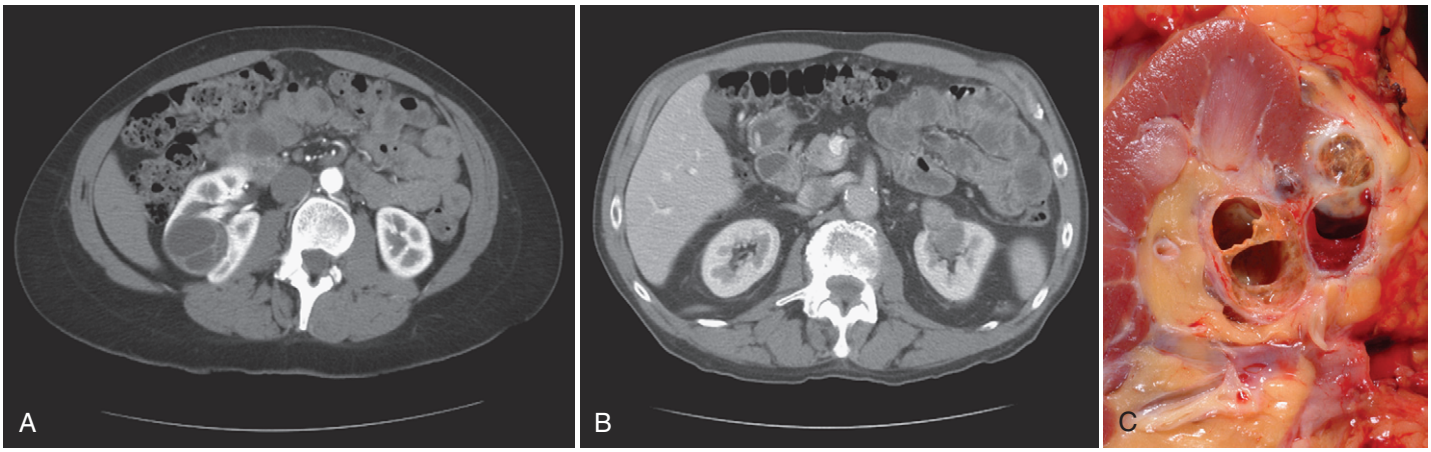

Figure 51–2. **A,** CT scan of a Bosniak III renal cyst. Thick, irregular septations are present within the cyst. **B,** CT scan of a Bosniak IV renal cyst, with a solid enhancing nodule. **C,** Bivalved Bosniak IV renal cyst demonstrating a solid component that proved to be conventional renal cell carcinoma. literature by Bosniak and others that include both radiographic as well as pathologic follow-up (Warren and McFarlane, 2005).

Because of the higher risk of malignancy associated with Bosniak class III and IV lesions, therapy is recommended (Fig. 51–2). The definitive therapy would be surgical excision, although ablative therapies such as cryotherapy or radiofrequency ablation of cystic masses have been reported (Raman et al, 2009) (see Chapter 49).

The overwhelming majority of simple or minimally complex cysts require no further follow-up or therapy once diagnosed (Eknoyan, 2009). Rarely, benign cystic lesions of the kidney can grow to such a large size that they can cause pain or other symptomatology, including hypertension (Porpiglia et al, 2009; Zerem et al, 2009). Symptoms can also occur as a consequence of hemorrhage within the cyst or spontaneous/traumatic cyst rupture (Hughes et al, 1995; Rainio et al, 2006; Ishikawa et al, 2008; Vaidyanathan et al, 2008).

A variety of therapeutic interventions have been described for benign symptomatic cystic lesions of the kidney. These include aspiration, surgical resection, cyst decortications, as well as sclerotherapy with a variety of different agents (Cho et al, 2008; Ham et al, 2008; Baysal and Soylu, 2009; Canguven et al, 2009; Choi et al, 2009; Porpiglia et al, 2009). Although none of these approaches seems to be better than the others described, it is noted that with aspiration and sclerotherapy there is a higher incidence of cyst recurrence and multiple treatments may be needed to satisfactorily ablate the cystic lesion. A word of caution is warranted regarding the treatment of peripelvic cysts: given their proximity to the vital structures of the kidney, including the renal vessels and collecting system, laparoscopic, rather than percutaneous, approaches may be associated with a higher safety margin and better efficacy (Okumura et al, 2003; Camargo et al, 2005).

Key Points: Renal Cysts

- Renal cysts remain the most common of benign renal lesions, representing more than 70% of asymptomatic renal masses.
- The overwhelming majority of simple or minimally complex cysts require no further follow-up or therapy once diagnosed.
- The Bosniak classification for renal cystic lesions is perhaps the most useful and widely employed method for characterizing renal cystic lesions and assessing the likelihood of the presence of a concomitant malignancy within the cyst.

RENAL CORTICAL ADENOMA

The designation and management of purportedly benign renal cortical adenomas remains a subject of controversy in the urologic literature. These lesions are small, solid cortical renal lesions that are thought to have a benign course (Renshaw, 2002). **Histologically, renal adenomas appear as small, well-circumscribed lesions characterized by uniform basophilic or eosinophilic cells with benign-appearing nuclear and cellular features, arranged as tubulopapillary or purely papillary growth. The incidence of renal adenomas increases with age and male sex, and these tumors also have been associated with acquired renal cystic disease that results in end-stage renal failure** (Leroy et al, 2001; Denton et al, 2002; Snyder et al, 2006; Ferda et al, 2007). The incidence of renal adenomas in autopsy series ranges from 7% to 23%, although antemortem pathologic diagnosis of renal adenoma is much less common, in part owing to the pathologist's concern that there are no reliable histopathologic, ultrastructural, or immunohistochemical criteria to distinguish benign from malignant lesions of the kidney (Licht, 1995). **In fact, in a more recent study in which immunohistochemical analyses were used to further characterize renal adenomas, it was suggested that these lesions may be linked to the development of papillary RCC and represent a biologic link and continuum as a premalignant precursor** (Wang et al, 2007). In this study, researchers examined 542 nephrectomy specimens obtained over 8 years. Seven percent of these demonstrated evidence of renal adenoma; and of these, 47% were associated with a concomitant papillary RCC. Adenomas that arose in the setting of papillary RCC tended to be multiple (61%). Eighty-two percent of adenomas found in the study had a similar immunohistochemistry staining profile as papillary RCC, staining positive for α-methyl-coenzyme A racemase. In other studies, renal adenomas shared similar cytogenetic profiles to papillary RCC, such as trisomy of chromosomes 7 and 17, thus suggesting a biologic link between the two neoplasms (Brunelli et al, 2003a, 2003b).

The overwhelming majority of renal adenomas remain asymptomatic, are undetectable radiographically due to their small size (<1 cm), and require no further therapy. Size of the neoplasm has historically been utilized to differentiate renal adenoma from more malignant neoplasms of the kidney. Thoenes and colleagues (1986) provided a reassessment of the histologic classification of renal tumors and defined renal adenoma as a tumor with nuclear grade I and a diameter of at least 1 cm. For many years, a "3-cm rule" was pervasive in the urologic literature, dating back to the original autopsy studies by Bell (1938) when he noted that only 1 of 38 renal cortical tumors had associated metastases whereas 70 of 106 tumors larger than 3 cm were associated with metastases.

The diagnosis of renal adenoma remains controversial; many believe that all solid renal epithelium-derived masses are potentially malignant and therefore should undergo treatment (Renshaw, 2002).

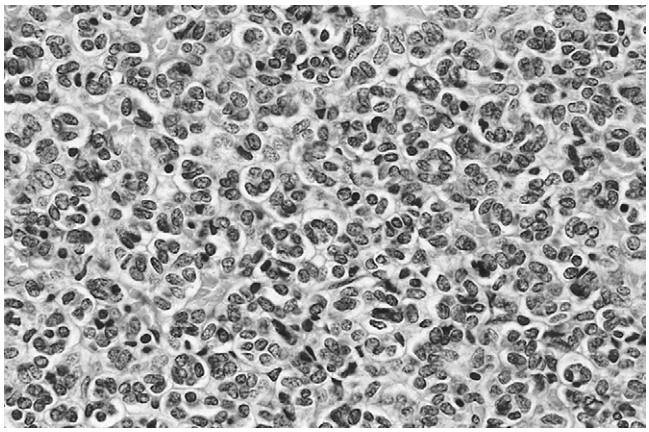

Figure 51–3. Classic metanephric adenoma with small, intensely basophilic cells arranged in an acinar pattern.

Key Points: Renal Cortical Adenoma

- The diagnosis of renal adenoma remains controversial; many believe that all solid renal epithelium-derived masses are potentially malignant and therefore should undergo treatment.
- Renal adenomas may be linked to the development of papillary RCC and represent a biologic link and continuum as a premalignant precursor.
- The incidence of renal adenomas increases with age and male sex, and these tumors also have been associated with acquired renal cystic disease resulting in end-stage renal failure.

METANEPHRIC ADENOMA

In 1995 Davis and colleagues reported 50 cases of an unusual and novel renal mass lesion with distinctive histologic features and a benign clinical course despite occasional symptomatic presentation and large tumor size. In this series, mean tumor size was 5.5 cm (up to 15 cm) and nearly half of the patients presented with flank pain, gross hematuria, or a palpable mass. Six additional patients presented with polycythemia, and hypercalcemia has also been reported in association with this tumor type, which was designated *metanephric adenoma (*Davis et al, 1995; Mahoney et al, 1997; Kuroda et al, 2003b). Metanephric adenoma was officially accepted as a primary benign renal tumor based on consensus from the Heidelberg classification (Kovacs et al, 1997). A higher male-to-female ratio was initially reported in the series of Davis and colleagues (1995), but it is likely that **there is actually a female predominance as has been reported in other series** (Jones et al, 1995; Snyder et al, 2006; Bastide et al, 2009). Incidental presentation is most common, and peak incidence is in the fifth decade of life (Renshaw, 2002). Polycythemia can be seen in 10% of patients and appears to be due to the production of erythropoietin and other cytokines by the tumor (Yoshioka et al, 2007; Bastide et al, 2009). Radiographically these tumors can have peripheral or central calcifications and may be hypovascular on contrast-enhanced CT and hyperechoic on ultrasonography (Bastide et al, 2009).

On microscopic examination these tumors consist of very small, often highly basophilic epithelial cells that form small acini and occasionally tubular or papillary structures within a predominantly acellular stroma (Fig. 51–3). Davis and colleagues (Renshaw, 2002) argued that metanephric adenoma might be histologically related to epithelial Wilms tumor because they believed that it exhibited histologic similarities to the metanephric, hamartomatous elements of nephroblastomatosis. Along these lines, it is interesting to note that many of these tumors exhibit evidence of regression in the form of scarring or calcification. In addition, Muir and colleagues (2001) have shown positive staining for the Wilms tumor protein WT1 and an immunohistochemical staining profile that suggests a histogenetic relationship to Wilms tumor. An alternative theory for the origin of metanephric adenoma was proposed by Brown and associates (1997), who found gain of chromosomes 7 and 17 by fluorescent in-situ hybridization in 8 of 11 of these tumors. These findings suggest a clonal neoplastic disorder potentially related to papillary RCC, but others have argued that this series may have been contaminated by inclusion of some cases of papillary RCC, which can be difficult to differentiate from metanephric adenoma (Brunelli et al, 2003a). Arroyo and colleagues (2001) showed that metanephric adenomas are part of a spectrum of related tumors, bridging metanephric stromal tumors, metanephric adenofibromas, and Wilms tumor. Pesti and colleagues (2001) have described a putative tumor suppressor gene for metanephric adenoma at chromosome 2p13. Various histologic stains have been evaluated to help distinguish metanephric adenoma from other renal neoplasms. **The Wilms tumor marker WT1 is frequently expressed in metanephric adenoma** (Muir et al, 2001; Bosco et al, 2007). **α-Methylacyl-CoA racemase (AMACR) is poorly expressed in metanephric adenoma but highly expressed in papillary RCC** (Olgac et al, 2006), **whereas S-100 protein expression is very high in metanephric adenoma, weak in Wilms tumor, and absent in papillary RCC** (Azabdaftari et al, 2008). Skinnider and colleagues (2005) demonstrated the potential utility of an expression panel to help differentiate papillary RCC and metanephric adenoma using a panel of cytokeratins 7, 8, 18, and 19 and vimentin. **Using these various markers appears to have improved the diagnostic yield of percutaneous biopsy and fine-needle aspiration** (Bosco et al, 2007; Patel et al, 2009), **but the index of initial suspicion needs to be high for biopsy to be considered.**

Only one case of metastasis has been described in association with classic metanephric adenoma into a regional lymph node,

and death related to this entity has not been reported (Renshaw, 2002). However, Picken and colleagues (2001) have described malignant stromal elements associated with a metanephric neoplasm of the kidney in a 21-year-old woman who died of progressive cancer, and they have proposed that there may be a spectrum of metanephric tumors that includes rare, aggressive variants. Atypical histologic features and multifocality in childhood have also been reported (Jain et al, 2007; Kohashi et al, 2009). **Given the rarity of this tumor and the lack of highly predictive clinical or radiographic criteria, metanephric adenoma remains primarily a pathologic diagnosis. If radiographic findings raise the index of suspicion, then percutaneous core biopsy with fine-needle aspiration may prove helpful in establishing a diagnosis for nephron-sparing treatment or observation, but most patients will require surgical excision because of concern for malignancy** (Fig. 51–4).

Key Points: Metanephric Adenoma

- Metanephric adenoma is a recently described, rare benign mass that radiographically may be indistinguishable from RCC.
- It is typically found incidentally, has a female predominance, and has a peak incidence in the fifth decade of life.
- The diagnosis is often made after surgical excision and can be confirmed with immunostain panels for cytokeratins, WT1, S-100, and AMACR.

ONCOCYTOMA

Renal oncocytoma is the most common benign tumor that appears as an enhancing renal mass on cross-sectional imaging and is presumed to be RCC until surgical excision, representing one of the ultimate challenges in preoperative diagnosis for the urologist. It accounts for 3% to 7% of kidney tumors (Morra and Das, 1993). Oncocytoma initially became accepted as a distinct entity after a report of 13 cases in 1976 by Klein and Valensi. Multiple additional reports since that time, including more recent genotyping studies, confirm it to be a benign histology with a distinct cell of origin and genetic abnormalities (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Perez-Ordonez et al, 1997; Amin et al, 1997; Dechet et al, 1999; Chao et al, 2002; Kuroda et al, 2003a). Cases of metastatic disease have been reported, yet these are considered exceptionally rare and may represent cases of malignant degeneration or pseudometastases (Paner et al, 2005; Oxley et al, 2007).

Grossly these tumors are mahogany or tan, homogeneous, and well circumscribed with a pseudocapsule and typically a central stellate scar (Fig. 51–5). Microscopically the cells are round or polygonal and arranged in a nested growth pattern. **The cells are uniform and highly eosinophilic, owing to an abundance of mitochondria** (Renshaw, 2002). In up to one third of cases, hemorrhage, extension into perinephric fat, cellular atypia, prominent nucleoli, and pleomorphism may be seen, yet the clinical behavior in these cases is within what is expected with a benign course (Amin et al, 1997; Perez-Ordonez et al, 1997). The most common genetic abnormality is loss of chromosome 1p (Lindgren et al, 2004; Paner et al, 2007). Other common cytogenetic findings include loss of the Y chromosome and chromosome 14q and rearrangements of 11q13 (Schwerdtle et al, 1997; Chao et al, 2002; Polascik et al, 2002; Lindgren et al, 2004). **The chromosomal abnormalities typically seen in RCC are not seen in renal oncocytomas, further reinforcing the**

Figure 51–4. CT scan showing a metanephric adenoma in a middle-aged woman. (Copyright 2009, S.F. Matin.)

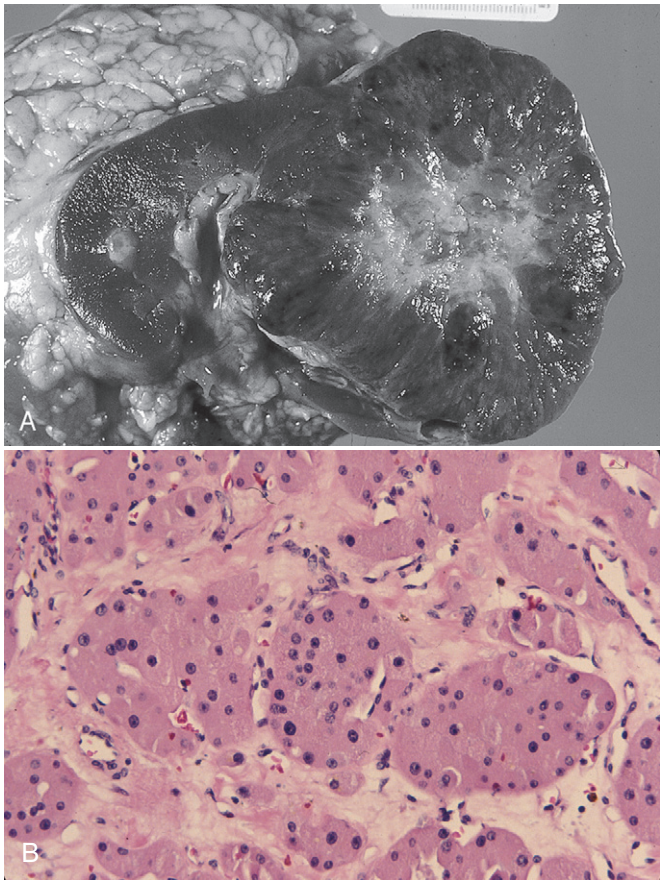

Figure 51–5. **A,** Bivalved renal oncocytoma demonstrating central scar. **B,** Oncocytoma with large eosinophilic cells arranged in distinct nests.

concept that these tumors are genotypically distinct from RCC (Minor et al, 2003). **However, histologically, the greatest dilemma arises from distinguishing chromophobe and clear cell RCC with eosinophilic characteristics from oncocytoma.** Hale colloidal iron staining is the classic differentiating marker for oncocytoma, but it can have nonspecific staining and be difficult to interpret (Leroy et al, 2000). Cytokeratin profiles are helpful in distinguishing these histologic findings (Skinnider et al, 2005; Adley et al, 2006). Expression of cytokeratin-7 is seen in 66% of chromophobe RCC and only 5% of oncocytomas, and parvalbumin is expressed in 100% of chromophobe RCC and 47% of oncocytomas (Leroy et al, 2000; Adley et al, 2006). A variety of other markers have been recently described to differentiate oncocytoma from RCC, particularly chromophobe RCC, but the clinical utility for most of these has not yet been fully developed. These include Pax-2, expressed in metanephric tissues and vital for renal tubule development; pattern of claudin-7 and 8 expression, tight junction proteins expressed in distal nephron epithelium; a vimentin expression pattern; c-*KIT* expression; and S-100 (Pan et al, 2004; Lin et al, 2006; Hes et al, 2007; Rocca et al, 2007; Lechpammer et al, 2008; Gupta et al, 2009; Osunkoya et al, 2009). An "optimal" panel for distinguishing between chromophobe and clear cell RCC and oncocytoma was recommended by Liu and colleagues in 2007, consisting of a combination of three markers (vimentin, glutathione-S-transferase-α, and epithelial cell adhesion molecule). These investigators achieved 100% sensitivity and 100% specificity for the differential diagnosis of chromophobe carcinoma, oncocytoma, and clear cell carcinoma (Liu et al, 2007). The feasibility of molecular signatures and gene profiling is being evaluated as potentially useful tests for the accurate diagnosis of tumors such as oncocytoma (Schuetz et al, 2005; Yang et al, 2006), but such studies are not yet a clinical reality.

As noted previously there are several distinct similarities to chromophobe RCC, which also is derived from the distal renal tubules. **Chromophobe RCC, particularly the eosinophilic variant, and oncocytoma are histologically similar and their distinction often requires additional pathologic testing** (Weiss et al, 1995; Renshaw, 2002). The commonality of these two tumors is further evidenced in patients with Birt-Hogg-Dubé syndrome, in whom both oncocytomas and chromophobe RCC develop, in addition to cutaneous fibrofolliculomas and spontaneous pneumothoraces (Pavlovich et al, 2005; Toro et al, 2008). Some of the renal tumors display a histology between these two tumors, prompting some to speculate that chromophobe RCC and oncocytoma represent points in a spectrum of neoplasia (Chao et al, 2002; Linehan, 2003; Pavlovich et al, 2005; Toro et al, 2008).

The greatest clinical dilemma remains the inability to confidently differentiate between renal oncocytoma and RCC on clinical or radiographic testing. Both have a similar age at presentation, have a male-to-female predominance, and are similarly sized at presentation. Although oncocytomas were more likely to be asymptomatic at presentation, most RCC are also diagnosed incidentally in the current era, eliminating this clinical scenario as a differentiator (Davis et al, 1991; Licht et al, 1993; Lieber, 1993; Amin et al, 1997; Perez-Ordonez et al, 1997; Dechet et al, 1999). **The typical spoke-wheel pattern seen on angiography or the stellate scar on cross-sectional imaging may bring up the question of a renal oncocytoma, but these findings have a poor predictive value by themselves** (Davidson et al, 1993; Licht et al, 1993; Licht, 1995). On MRI, oncocytomas may have distinct T1 and T2 signal patterns that can be suggestive but these are not definitive findings (Harmon et al, 1996). T2-weighted images on MRI do not differentiate oncocytoma from RCC (Dann et al, 2006). For lesions undergoing surveillance, the growth rates of RCC and oncocytoma are similar, so growth kinetics also do not help differentiate these tumors either (Chawla et al, 2006; Crispen and Uzzo, 2007; Siu et al, 2007). In 4% to 13% of cases, tumors are multicentric, are bilateral, or have a metachronous presentation (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Amin et al, 1997; Perez-Ordonez et al, 1997; Dechet et al, 1999; Tickoo et al, 1999; Minor et al, 2003). Familial renal oncocytomatosis was initially described (Weirich et al, 1998) in five families in which it presented at a young age as multicentric, bilateral and recurrent oncocytomas. Nonfamilial forms of bilateral multifocal oncocytomas resembling oncocytomatosis can also occur (Fig. 51–6). A recent cytogenetic evaluation of a patient with apparently sporadic oncocytomatosis and hybrid tumors showed different chromosomal losses than the Birt-Hogg-Dubé syndrome (Al-Saleem et al, 2004).

Recent clinical studies highlight the differing incidence of oncocytoma based on age and gender. Cao and colleagues (2005) **and** Skolarus and colleagues (2008) **showed an increasing incidence of oncocytoma in older patients presenting with a small incidentally discovered renal mass. Two different reports highlight that younger females are nearly twice as likely as their male**

Figure 51–6. CT scan of a patient with multiple bilateral oncocytomas. (Copyright 2009, S.F. Matin.)

counterparts to have a benign tumor, which includes oncocytoma and angiomyolipoma but is probably largely driven by the higher rates of angiomyolipoma in women (Cao et al, 2005; Snyder et al, 2006).

Historically fine-needle aspiration or core biopsy was compromised by high false-negative or nondiagnostic specimens, given the difficulty in differentiating oncocytoma with RCC subtypes (Weiss et al, 1995; Campbell et al, 1997). **However, the diagnostic accuracy of percutaneous biopsy has markedly improved, particularly when a core biopsy is done in addition to a fine-needle aspiration and bolstered with the use of immunostains** (Liu and Fanning, 2001; Barocas et al, 2006; Lebret et al, 2007; Volpe et al, 2007; Kummerlin et al, 2008; Schmidbauer et al, 2008), **prompting some investigators to revisit the role of the biopsy in the management of some patients with an incidental renal tumor** (Shah et al, 2005; Lebret et al, 2007; Volpe et al, 2007). When multiple tumors are present, one must consider the possibility of RCC coexisting with oncocytoma, which in some series has been shown to be as high as 32% (Davis et al, 1991; Licht et al, 1993; Licht, 1995; Gudbjartsson et al, 2005). Consideration of biopsy in these cases must be thoughtfully considered to provide a sampling of all sites of disease that are of concern.

Treatment options for a known oncocytoma range from observation to thermal ablation, laparoscopic or open partial nephrectomy, and even radical nephrectomy depending on the clinical scenario and uncertainty regarding the diagnosis (Licht, 1995; Romis et al, 2004; Gudbjartsson et al, 2005; Crispen and Uzzo, 2007). **If oncocytoma is highly suspected and surgery is indicated, a nephron-sparing approach is preferred given the benign nature of these lesions and the very low probability of recurrence** (Licht, 1995; Romis et al, 2004; Gudbjartsson et al, 2005). **Frozen section analysis is usually not sensitive enough to differentiate the eosinophilic appearance of oncocytomas with eosinophilic RCCs and should not be used to guide surgical strategy.** Thermal ablation, although sometimes reported as a treatment option, commits the patient to long-term radiographic surveillance, given the lower success rates of these procedures and the unknown long-term outcomes, tests that would be considered unnecessary should surgical excision be performed. In most cases the treatment options are isolated to observation, particularly for the older or sicker patient, and surgical resection, particularly for the younger healthier patient.

Key Points: Oncocytoma

- Renal oncocytoma is a common benign renal tumor that is clinically and radiographically indistinguishable from RCC.
- There may be a higher incidence of oncocytoma in older patients with a small renal mass as opposed to younger patients.
- Oncocytomas are derived from the distal renal tubules, similar to chromophobe RCC, and may represent a spectrum of neoplasia as evidenced in the Birt-Hogg-Dubé genetic syndrome. However, there is no evidence that oncocytomas undergo malignant transformation in sporadic cases.
- If oncocytoma is suspected preoperatively, a percutaneous core biopsy in addition to fine-needle aspiration may reliably provide a diagnosis when core tissue is available for additional immunostain panels.
- Recent advancements in immunostain panels have greatly improved the diagnostic accuracy of pathologic diagnosis from pathologic specimens and even core biopsy specimens.
- Frozen section analysis at the time of surgery may not reliably distinguish oncocytoma from RCC and should not be used to guide surgical strategy.

ANGIOMYOLIPOMA

Angiomyolipoma accounts for less than 10% of renal tumors, with autopsy series and ultrasound-screened populations showing a 0.3% and 0.13% incidence in the general population (Eble, 1998). It is a benign neoplasm consisting of thick-walled aneurysmal vessels, smooth muscle, and varying levels of mature adipose tissue (Tamboli et al, 2000; Nelson et al, 2002; Bissler et al, 2004). Initially considered to be a form of hamartoma or choristoma, recent evidence suggests a neoplastic origin with evidence of a monoclonal, rather than polyclonal, source (Green et al, 1996; Sepp et al, 1996; Kattar et al, 1999). Angiomyolipoma is now considered to be of neural crest origin, possibly derived from perivascular epithelioid cells (PEC). Originally described in 1911 by Fischer, its current name was given by Morgan in 1951 (Eble, 1998). The tumor strongly expresses estrogen receptor-β as well as androgen receptor, is predominantly found in females, and is rare before puberty, suggesting a potential hormonal influence (Boorjian et al, 2008).

The typical sporadic presentation is of a middle-aged woman with a single asymptomatic tumor. Sporadic angiomyolipomas appear to have a slow growth rate and are usually detected incidentally (Seyam et al, 2008). **Angiomyolipoma is the most common renal neoplasm associated with spontaneous perirenal hemorrhage, closely followed by RCC** (Zhang et al, 2003). Skolarus and colleagues (2008) suggested that there may be a decreased incidence of sporadic angiomyolipoma with increasing age. These tumors are most often sporadic but can also be associated with the autosomal dominant tuberous sclerosis complex (TSC). **Twenty to 30 percent of angiomyolipomas are in patients with TSC, and approximately 50% of patients with TSC develop angiomyolipomas** (Eble, 1998; Neumann et al, 1998; Tamboli et al, 2000; Lendvay et al, 2003; Minor et al, 2003). TSC-associated angiomyolipomas typically present at a younger age (mean age 30 years); there is less female-to-male predominance (2:1) with multiple, bilateral, and symptomatic tumors (Eble, 1998; Neumann et al, 1998; Lendvay et al, 2003). Because of the variable penetrance of the *TSC* mutation, the classic triad of seizures, adenoma sebaceum, and mental retardation may not be present because this mutation is seen in a minority of patients (Steiner et al, 1993). Patients with TSC also develop renal cysts and may be at higher risk of developing RCC. Lymphangioleiomyomatosis is also significantly associated with renal involvement in TSC (Rakowski et al, 2006).

Similar to RCC, most angiomyolipomas are now diagnosed incidentally during workup of unrelated complaints (Lemaitre et al, 1997; Seyam et al, 2008). The literature correlating tumor size and symptoms, however, is derived prior to this era, when most angiomyolipomas were diagnosed after the development of symptoms. The Wunderlich syndrome, or massive retroperitoneal hemorrhage, representing the most significant complication of renal angiomyolipoma, was reported in up to 10% of patients and could be associated with significant morbidity and potential mortality if not promptly treated (Oesterling et al, 1986; Steiner et al, 1993;

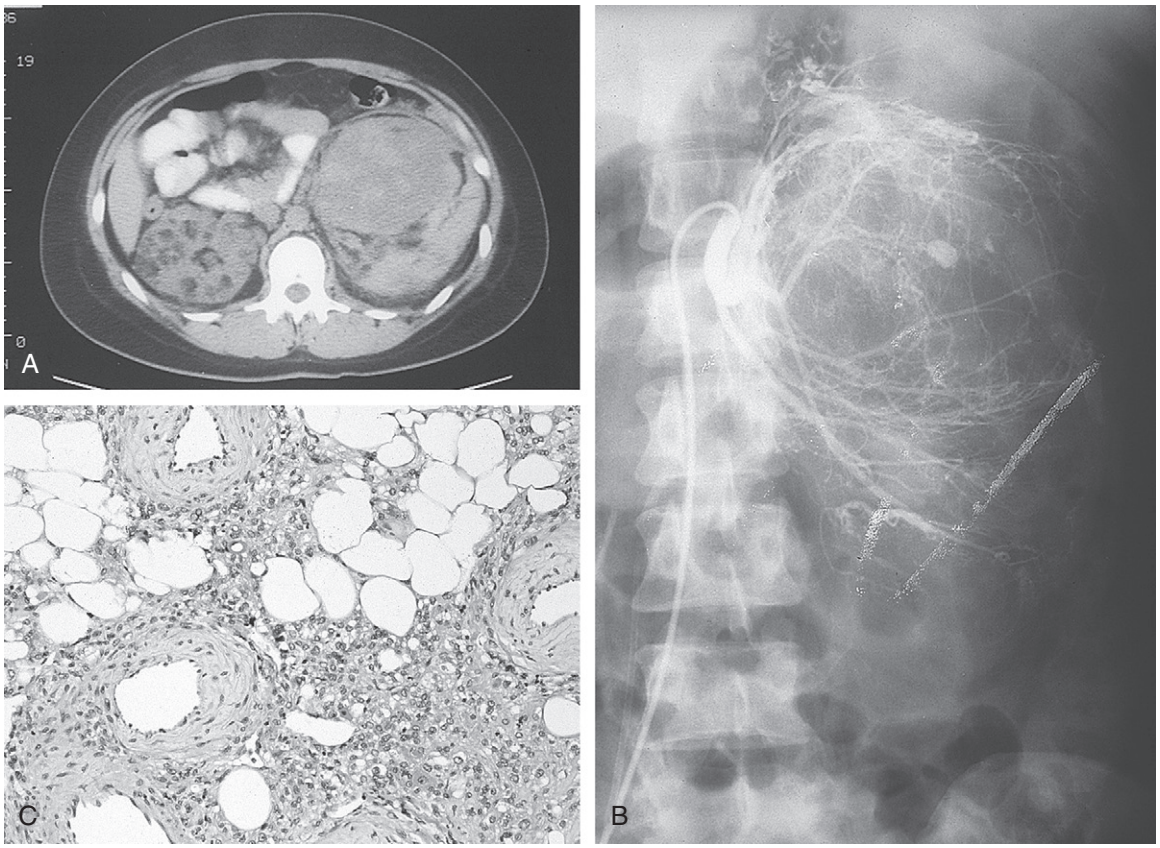

Figure 51–7. **A,** CT scan demonstrating large bilateral renal angiomyolipomas in a patient with tuberous sclerosis. **B,** Renal angiogram shows increased vascularity and aneurysmal dilation characteristic of angiomyolipoma. **C,** Typical microscopic appearance of angiomyolipoma with admixture of mature adipose tissue, smooth muscle, and thick-walled blood vessels.

Eble, 1998). The most common cause of spontaneous retroperitoneal hemorrhage is angiomyolipoma, followed by RCC (Zhang et al, 2003). Pregnancy appears to increase the risk of hemorrhage from angiomyolipoma, a factor that can influence clinical decision making (Eble, 1998).

Angiomyolipoma is the only benign renal tumor that is confidently diagnosed on cross-sectional imaging (Fig. 51–7). **The presence of fat (confirmed on nonenhanced thin-cut CT by a value of –20 Hounsfield Units [HU] or less) within a renal lesion is considered the diagnostic hallmark** (Jinzaki et al, 1997; Lemaitre et al, 1997; Bosniak et al, 1998; Simpfendorfer et al, 2009). **Findings of more than 20 pixels with attenuation less than –20 HU and of more than 5 pixels with attenuation less than –30 HU have been shown to have a positive predictive value of 100%** (Simpfendorfer et al, 2009). Ultrasonography shows a well-circumscribed, highly echogenic lesion with shadowing (Siegel et al, 1996; Lemaitre et al, 1997). On angiography (or CT-angiography) aneurysmal dilation is found in 50% of angiomyolipomas (Lemaitre et al, 1997). The size of the aneurysms has been reported to correlate with the risk of rupture (Yamakado et al, 2002). MRI can be used in difficult cases or in lieu of CT, with findings on fat-suppressed images being highly suggestive of the diagnosis.

Despite the radiographic hallmarks of angiomyolipoma the diagnosis can be confused in the three following situations: confusion with liposarcoma, possibility of fat-containing RCC, and possibility of a fat-poor angiomyolipoma resembling an RCC. Large angiomyolipomas can be confused with retroperitoneal liposarcomas, which are very rare. A good quality, high-resolution CT however will invariably show several features that are characteristic of angiomyolipoma, the primary one being a small indentation of the renal parenchyma even when the tumor envelops the kidney (Fig. 51–8), whereas liposarcomas will compress or only extrinsically push the

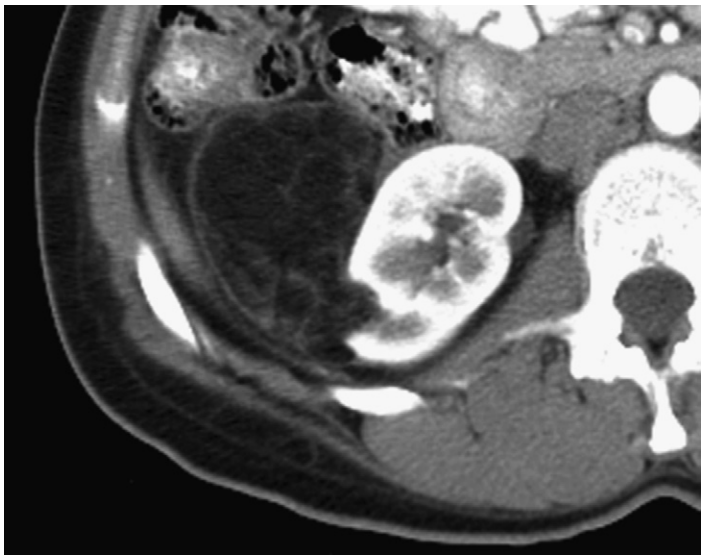

Figure 51–8. CT scan of angiomyolipoma with parenchymal indentation. (Copyright 2009, S.F. Matin.)

renal parenchyma (Clark and Novick, 2001; Wang et al, 2002). Although RCC containing fat density has also been reported, these extremely rare cases also contained calcifications, a finding usually almost never seen with angiomyolipoma (Henderson et al, 1997; Lemaitre et al, 1997; Roy et al, 1998). Most recently a report of two cases of RCC with very small amounts of intratumoral fat but without calcification was reported, adding to two other reported cases in the literature (Hayn et al, 2009). Fat-poor angiomyolipoma, seen in 14% of cases or more, is much more difficult to diagnose, owing to the paucity of mature adipose tissue (Lemaitre et al, 1997; Kim et al, 2004; Milner et al, 2006). Lane and colleagues (2008) showed that fat-poor angiomyolipoma was more commonly single, smaller, and found in older patients. Various imaging modalities have attempted to accurately identify these lesions preoperatively and differentiate them from RCC, with mixed success. On CT many appear to have hyperattenuation on noncontrast imaging and have a homogeneous and prolonged enhancement pattern (Jinzaki et al, 1997; Kim et al, 2004; Hafron et al, 2005; Milner et al, 2006; Silverman et al, 2007). **Detailed pixel distribution analysis cannot differentiate between fat-poor angiomyolipoma and RCC** (Catalano et al, 2008). Ultrasonography can show a hyperechoic or isoechoic lesion, suggesting a fat-poor angiomyolipoma (Jinzaki et al, 1997). **Because of the nonspecific nature of these findings most patients are often treated as having a presumed RCC. However, these radiographic findings may prompt the attentive urologist to consider a percutaneous biopsy if the suspicion is raised by imaging. Percutaneous biopsy can play an important role in diagnosis in these cases, because a core biopsy should be eminently accurate in the diagnosis of angiomyolipoma** (Lebret et al, 2007; Silverman et al, 2007).

Although an invariably benign nature of angiomyolipoma is well accepted, extrarenal occurrences are occasionally seen and have been reported in the hilar lymph nodes, retroperitoneum, and liver, with direct extension into the venous system (Eble, 1998; Türker Köksal et al, 2000; Gögüs et al, 2001; Nelson and Sanda, 2002; Lin et al, 2003; Bissler and Kingswood, 2004; Akcali et al, 2006; Haritharan et al, 2006; Blick et al, 2008; Schade et al, 2008). Even in these cases a benign clinical course follows, indicating multicentric origin rather than malignancy with metastasis. Many angiomyolipomas exhibit regions of cellular atypia, and the pathologic differential diagnosis can include a number of subtypes of sarcoma, including fibrosarcoma, leiomyosarcoma, and liposarcoma, depending on the relative amounts of adipose, vascular, or smooth muscle tissue present (Wang et al, 2002). **Positive immunoreactivity for HMB-45, a monoclonal antibody raised against a melanoma-associated antigen, is characteristic for angiomyolipoma and can be used to differentiate this tumor from sarcoma and other tumors** (Eble, 1998). There have been two reports of high-grade and eventually lethal leiomyosarcoma arising within an angiomyolipoma. Christiano and colleagues (1999) have described a highly pleomorphic angiomyolipoma that was associated with the development of multiple pulmonary nodules, the majority of which stained positive for HMB-45 (Ferry et al, 1991). They believed that this case represented a malignant transformation of angiomyolipoma, which, if it does occur, must be exceedingly rare. **However, these cases may also have represented the more recently described entity of epithelioid angiomyolipoma. In 1997, Eble and colleagues published their experience of five patients who had angiomyolipoma with a predominant epithelioid component; and more recently this malignant epithelioid variant of angiomyolipoma that can metastasize has been further described in patients with and without TSC, many of whom succumbed to the disease** (Pea et al, 1998; L'Hostis et al, 1999; Martignoni et al, 2000; Cibas et al, 2001; Menè et al, 2001; Nelson and Sanda, 2002; Saito et al, 2002; Bissler and Kingswood, 2004; Huang et al, 2007; Limaiem et al, 2008; Matsuyama et al, 2008; Moudouni et al, 2008; Zanelli et al, 2008; Kato et al, 2009). This phenotype is characterized by epithelioid cells that are cytokeratin negative and HMB-45 positive. Whether this extremely rare variant represents malignant degeneration of a preexistent angiomyolipoma or a de-novo tumor without a benign precursor remains unknown.

For optimal management of angiomyolipoma, treatment must be individualized. **The management should take into account the size of the tumor, presence of symptoms, and patient factors.** In particular, the risk of hemorrhage must be weighed during the evaluation. In general, most symptomatic angiomyolipomas have been relatively large and most studies in the literature have focused on a 4-cm cut point (Steiner et al, 1993; Nelson and Sanda, 2002). On the basis of an extensive literature review, Oesterling and coworkers (1986) reported that 82% of patients with angiomyolipomas larger than 4 cm in diameter were symptomatic, with 9% in hemorrhagic shock at the time of presentation; in contrast, patients with smaller tumors were symptomatic 23% of the time. Echoing these findings, Dickinson and colleagues (1998) reported that all 18 patients with angiomyolipomas smaller than 4 cm in their series were asymptomatic, whereas 7 of 13 patients with angiomyolipomas of 4 to 8 cm and 5 of 6 patients with tumors larger than 8 cm required intervention, primarily related to pain or bleeding. These observations have been confirmed and extended by a number of investigators (Blute et al, 1988; Steiner et al, 1993; Lemaitre et al, 1995; De Luca et al, 1999; Seyam et al, 2008). Steiner and colleagues (1993) reported that patients with angiomyolipomas larger than 4 cm were symptomatic 52% of the time, with 30% requiring surgical intervention, whereas patients with smaller tumors never required surgery and were asymptomatic 76% of the time. Although it was primarily retrospective, limited follow-up with a mean of 4 years was available for 24 patients with 28 tumors in this series. Interval growth was documented in 6 of 13 tumors with diameter of more than 4 cm and in 4 of 15 tumors smaller than 4 cm. A slower growth rate and a low risk of hemorrhage for smaller tumors was also supported by Kennelly and colleagues (1994), who observed 17 angiomyolipomas with tumor size of less than 4 cm for a mean of 3.8 years. Similarly, De Luca and colleagues (1999) studied 32 incidentally discovered angiomyolipomas smaller than 5 cm in diameter and found that 92% remained asymptomatic and unchanged in size. **Even so, occasional larger angiomyolipomas undergoing observation, some for up to 18 years, can remain asymptomatic** (Kennelly et al, 1994; Hadley et al, 2006; Danforth et al, 2007), **reinforcing the concept that size represents a continuum of risk, not an absolute phenomenon, and highlighting the need for individualized tailoring of treatment recommendations.** Multicentric angiomyolipomas and those in patients with tuberous sclerosis represent a special group that has demonstrated increased growth rates of approximately 20% per year, in contrast to a mean growth rate of 5% per year for solitary, sporadic angiomyolipomas (Steiner et al, 1993; Nelson and Sanda, 2002; Harabayashi et al, 2004; Seyam et al, 2008).

Although no large prospective studies evaluating the long-term outcomes of angiomyolipomas have been performed, the information reviewed here allows one to propose general guidelines for

management. Asymptomatic, smaller tumors, which by convention have been those with a diameter less than 4 cm, can be observed expectantly, with repeat initial imaging at 6 to 12 months to define the growth rate and clinical significance. Repeat imaging can be lengthened once stability is established, with follow-up performed only annually or biannually for smaller tumors (Oesterling et al, 1986; De Luca et al, 1999; Matin et al, 2008). **Intervention should be considered for larger tumors, particularly if the patient is symptomatic, taking into account the patient's age, comorbidities, and other related factors. Women of childbearing age and patients with limited access to surveillance or to emergency care should also consider a proactive approach** (Nelson and Sanda, 2002). **A nephron-sparing approach, by either selective embolization or open or laparoscopic/robotic partial nephrectomy, is clearly preferred in patients with angiomyolipomas requiring intervention. Preservation of renal tissue remains a priority in those with TSC or multicentric angiomyolipoma and particularly in patients with underlying renal insufficiency.** The feasibility and efficacy of partial nephrectomy by either wedge resection or enucleation in patients with angiomyolipoma is well established, with preservation of renal function achieved even in patients with large lesions in a solitary kidney (Fazeli-Matin and Novick, 1998; Boorjian et al, 2007; Minervini et al, 2007). Selective embolization is reported by some to be the preferred modality, and data from 76 patients in six series have documented long-term success in most cases (Nelson and Sanda, 2002; Harabayashi et al, 2004). However, a substantial proportion of patients experienced persistent or recurrence of symptoms or hemorrhage and most of these required repeated procedures, including embolization or surgery (Hamlin et al, 1997; Han et al, 1997; Kehagias et al, 1998; Mourikis et al, 1999; Nelson and Sanda, 2002; Lenton et al, 2008). The overall complication rate with embolization in these series was 10%, similar to rates of partial nephrectomy (Boorjian et al, 2007), and included hemorrhage, abscess formation, or sterile liquefaction of the tumor requiring percutaneous drainage or surgical intervention. **These data highlight the need for extended follow-up after selective embolization, which would not be required after partial nephrectomy** (Nelson and Sanda, 2002). **Selective embolization should be considered as first-line therapy in patients with acute or potentially life-threatening hemorrhage, because surgical exploration in this setting is often associated with total nephrectomy** (Pappas et al, 2006; Chang et al, 2007). Ablative therapies such as radiofrequency ablation (Prevoo et al, 2008) and cryoablation (Bachmann et al, 2005; Byrd et al, 2006; Littrup et al, 2007; Caviezel et al, 2008) have also been utilized for the treatment of angiomyolipoma, but follow-up remains short, the evaluation of success remains poorly defined, and the duration for continued radiographic surveillance is unknown, thus committing the patient to multiple, long-term imaging. Ablative therapies may have their best role for the treatment of patients with TSC who have multicentric angiomyolipomas or older patients with comorbidities who require treatment and are not candidates for embolization.

Key Points: Angiomyolipoma

- Angiomyolipoma is the only benign renal tumor confidently diagnosed on cross-sectional imaging by the presence of fat on nonenhanced thin-cut CT. Fat-poor angiomyolipoma may still be confused with RCC but if it is suspected preoperatively then percutaneous biopsy is eminently capable of providing the diagnosis, with positivity for HMB-45 typically seen with angiomyolipoma.
- Angiomyolipoma is the most common renal tumor associated with spontaneous hemorrhage, followed by RCC.
- Treatment must be individualized, based on the presentation, pregnancy status, tumor size, and renal function.
- The treatment of choice in cases of acute hemorrhage is selective renal angioembolization.
- Treatment options for elective management of larger angiomyolipomas include selective renal angioembolization and open or minimally invasive partial nephrectomy. Embolization is associated with a high rate of secondary procedures.

CYSTIC NEPHROMA AND MIXED EPITHELIAL/STROMAL TUMOR

Although considered separate entities by the 2004 World Health Organization classification of renal neoplasms, cystic nephroma and mixed epithelial/stromal tumors of the kidney (MEST) are rare benign renal neoplasms that have overlapping clinical, morphologic, and immunohistochemical characteristics (Lopez-Beltran et al, 2006; Turbiner et al, 2007; Lane et al, 2008; Montironi et al, 2008). Recent demonstration of striking similarities between global gene expression profiles in cystic nephroma and MEST further strengthens the notion that these two entities represent opposite ends of the spectrum of the same biologic process (Zhou et al, 2009). **Female predilection and history hormonal ablation therapy in male patients, combined with the frequent expression of estrogen and progesterone receptors, suggest that the sex-steroid hormones might play a role in the pathogenesis of these rare lesions** (Turbiner et al, 2007; Lane et al, 2008; Montironi et al, 2008; Stamatiou et al. 2008).

Cystic Nephroma

Cystic nephroma is a characteristic renal lesion with a bimodal age distribution and a benign clinical course (Tamboli et al, 2000). Diagnostic peaks occur primarily in the first 2 to 3 years of life, predominantly in males, and again in the fourth and fifth decades with a significant (8:1) female prevalence (Madewell et al, 1983; Upadhyay and Neely, 1989; Castillo et al, 1991; Stamatiou et al, 2008; Kuzgunbay et al, 2009). As with other renal lesions, presenting signs can include abdominal mass, pain, and hematuria, but the majority of cystic nephromas are incidental findings (Madewell et al, 1983; Kuzgunbay et al, 2009). Several familial cases have been reported in the literature, and there have been anecdotal reports of sarcoma and clear cell carcinoma arising from cystic nephroma (Bal et al, 2005; Omar et al, 2006; Raj et al, 2006; Ashley and Reinberg, 2007).

Radiologically, most cystic nephromas are solitary, centrally located, and widely variable in size (mean 9 cm) and commonly demonstrate curvilinear calcifications, herniation into the renal collecting system, and septal enhancement (Fig. 51–9A, B) (Madewell et al, 1983; Turbiner et al, 2007). **Consequently, reliable radiologic differentiation between cystic nephroma and cystic RCC in adults or Wilms tumor in children is not possible** (Vujanic et al, 2000).

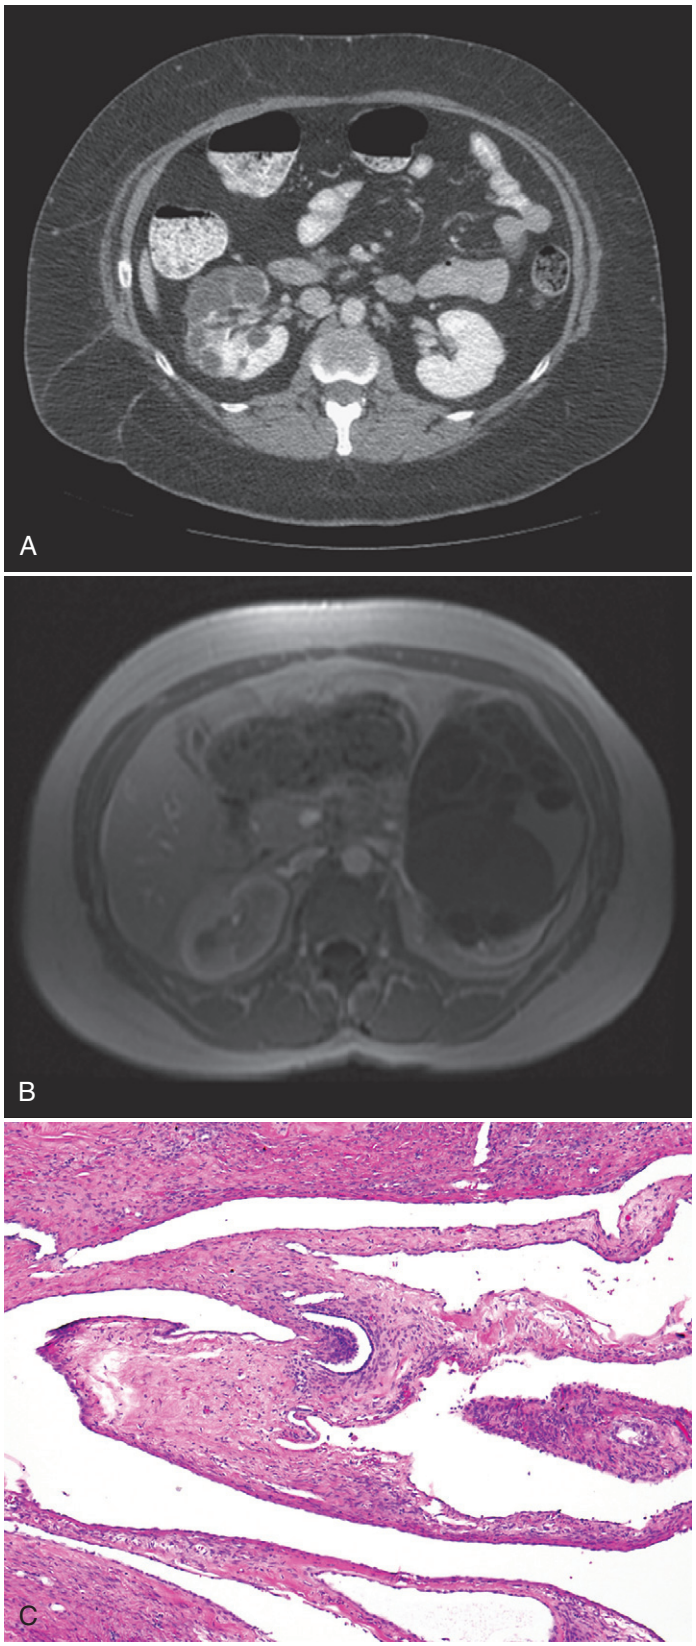

Figure 51–9. Cystic nephroma. CT **(A)** and MR **(B)** images do not allow reliable distinction from cystic renal cell carcinoma or cystic Wilms tumor. **C,** The variably sized cystic spaces are lined by flattened epithelium (low magnification). (Copyright 2009, V. Margulis.)

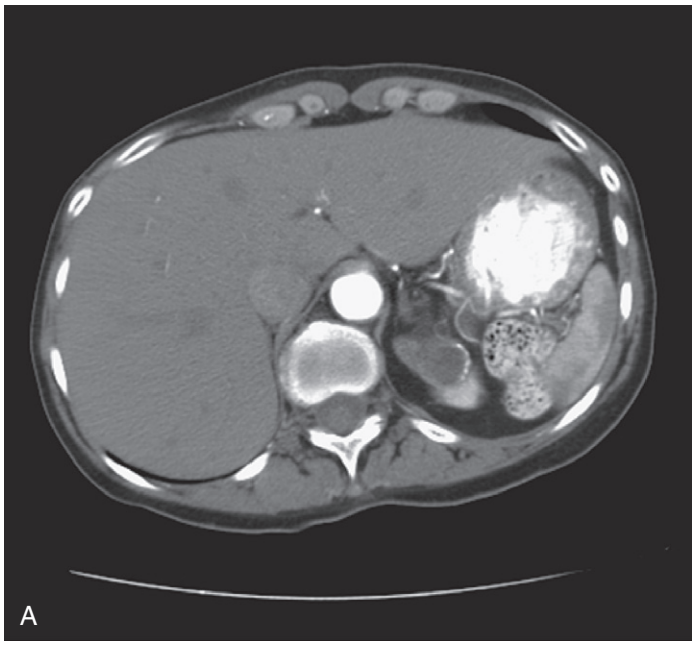
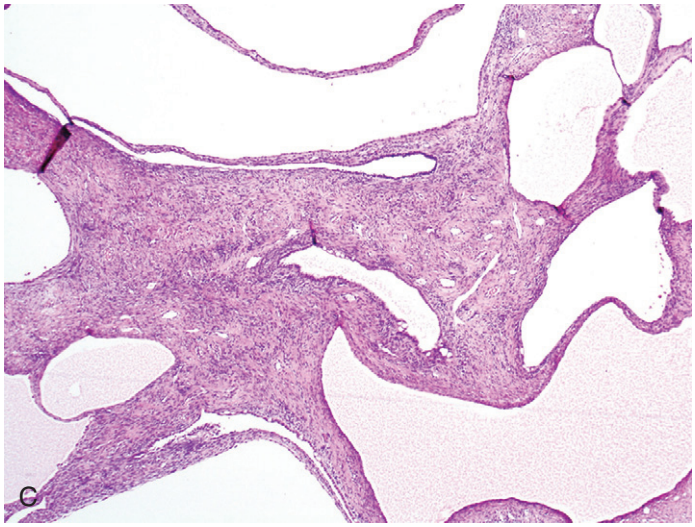
Histologically, cystic nephromas are well encapsulated by a thick fibrous pseudocapsule and are composed of cysts lined by flattened, cuboidal, or hobnail epithelium (see Fig. 51–9C). The stromal component can range from dense paucicellular collagen to markedly cellular fascicles of spindle cells, closely resembling ovarian stroma (Tamboli et al, 2000). Immunohistochemical studies reveal affinity of the epithelial component for cytokeratins, whereas stromal components frequently stain positive for CD10, calretinin, inhibin, estrogen, and progesterone receptors (Turbiner et al, 2007; Montironi et al, 2008).



Because of concern for cystic Wilms tumor, most children with cystic nephromas continue to be managed by radical nephrectomy, whereas a nephron-sparing approach with partial nephrectomy, if feasible, is an attractive option in adults.

Mixed Epithelial/Stromal Tumor



MEST is a rare benign adult renal neoplasm with a variable admixture of epithelial and mesenchymal components (Adsay et al, 2000). Previously these tumors have been described as congenital mesoblastic nephroma, leiomyomatous renal hamartoma, solid and cystic biphasic tumor, cystic hamartoma, solitary multilocular cyst, and adult metanephric stromal tumor (Adsay et al, 2000; Pierson et al, 2001; Mai et al, 2007). **Similar to cystic nephromas, MEST exhibits striking female predominance with a diagnostic peak in the fourth decade. The majority of women diagnosed with MEST had a history of receiving estrogen replacement therapy, and the only male patient in the largest MEST series had a long history of androgen deprivation therapy for prostate cancer** (Adsay et al, 2000). Presenting signs and symptoms of MEST are similar to those of cystic nephroma with the majority detected incidentally (Adsay et al, 2000; Turbiner et al, 2007; Montironi et al, 2008).

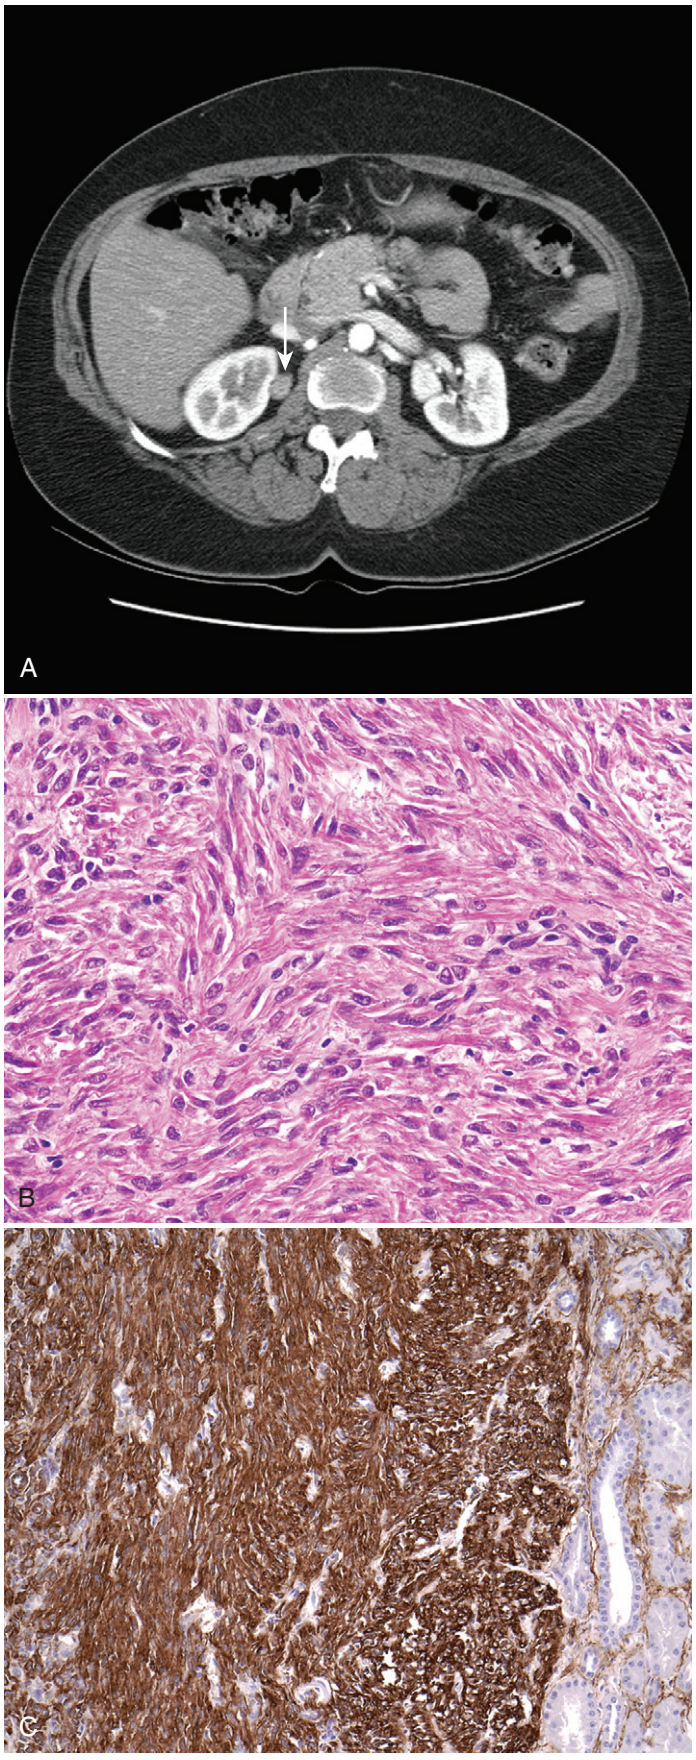
Radiologic appearance of MEST is of a complex cystic renal mass, typically classifying these tumors as Bosniak class III to IV lesions, indistinguishable from cystic RCC (Fig. 51–10A) (Adsay et al, 2000). A typical MEST has a benign clinical course, but recently a case of malignant transformation to a sarcomatoid carcinoma and several cases of local recurrence of a malignant stromal component with a dismal clinical course have been described (Adsay et al, 2000; Nakagawa et al, 2004).

Grossly, MEST appears encapsulated and ranges from 2 to 24 cm (mean 6 cm) (Adsay et al, 2000; Mai et al, 2007). Involvement of renal hilum and compression of the pelvicalyceal system is common, but gross infiltration of adjacent renal parenchyma is not seen (see Fig. 51–10B). The mesenchymal component is characterized by spindle cells showing variable degrees of smooth muscle, fibroblastic, or myofibroblastic differentiation with interspersed collagen bundles. The epithelial components vary from regular tubules to complex tubulopapillary structures with or without cystic dilatation, lined by cuboidal to flattened epithelium that may show clear cell changes and have a characteristic hobnail appearance (see Fig. 51–10C) (Adsay et al, 2000; Antic et al, 2006; Turbiner et al, 2007; Montironi et al, 2008). As in cystic nephroma, the epithelial components stain positive for cytokeratins whereas estrogen and progesterone receptor staining has been observed in the majority of the mesenchymal elements of MEST (Adsay et al, 2000).

A preoperative diagnosis of MEST should be considered in perimenopausal women receiving hormone therapy; however, because radiologic differentiation from RCC is not reliable, surgical intervention, preferably with a nephron-sparing approach should be offered to appropriately selected patients.

Key Points: Cystic Nephroma and Mixed Epithelial/Stromal Tumor

- These tumors are at opposite ends of the spectrum of the same biologic process with overlapping clinical, morphologic, and immunohistochemical characteristics.
- There is a female predilection, and a history of hormonal ablation therapy is noted in male patients.
- Frequent expression of estrogen and progesterone receptors in tumor tissue is reported.
- Clinical distinction from RCC or cystic Wilms tumor is not possible.
- If feasible, a nephron-sparing approach with partial nephrectomy is the preferred management strategy.



LEIOMYOMA

Leiomyomas are rare, benign tumors that may arise from smooth muscle cells anywhere along the genitourinary tract (Tamboli et al, 2000). In the kidney these tumors most commonly arise from the renal capsule, but renal pelvis and renal vein sites of origin have been reported (Wells et al, 1981; Steiner et al, 1990; O'Brien et al, 1992; Rao et al, 2001). **Leiomyomas are found at autopsy with a frequency of 4.2% to 5.2%, but only a minority are discovered clinically, representing approximately 1.5% of all benign renal tumors treated surgically** (Romero et al, 2005). As with other renal lesions, in the age of widespread utilization of computerized tomographic abdominal imaging, the vast majority of leiomyomas are found incidentally (Romero et al, 2005; Derchi et al, 2008).

Renal leiomyomas have a characteristic appearance of a small exophytic renal mass with or without enhancement arising from renal capsule, but conclusive radiologic differentiation from RCC is not possible (Fig. 51–11A) (Steiner et al, 1990; Derchi et al, 2008).

Grossly, leiomyomas are well encapsulated and range from purely cystic to mixed solid/cystic or solid in appearance. Histologic examination reveals intersecting fascicles of smooth muscle with no evidence of hypercellularity, pleomorphism, mitotic activity, or necrosis (see Fig. 51–11B) (Steiner et al, 1990; Tamboli et al, 2000). Immunohistochemical stains confirm the smooth muscle nature of the tumor with strong diffuse positive staining for smooth muscle markers desmin and caldesmon (see Fig. 51–11C) (Romero et al, 2005). **Large lesions have traditionally been**

Figure 51–10. Mixed epithelial and stromal tumor. **A,** CT scan characteristics are not distinguishable from renal cell carcinoma. **B,** Gross photograph of a partial nephrectomy specimen demonstrating a well-circumscribed mass composed of variably sized cysts separated by thick white septa. **C,** Medium-power magnification shows cysts lined by hobnailed cells and spindle cell stroma. managed with radical nephrectomy, but nephron-sparing approaches should be considered for peripherally located small lesions.

Key Points: Leiomyoma

- The characteristic appearance is of a small solid renal mass arising from the renal capsule.
- Radiologic differentiation from RCC is not possible.
- Nephron-sparing approaches are preferred when technically possible.

OTHER BENIGN RENAL TUMORS

A multitude of rare benign tumors derived from the various mesenchymal components of the kidney have been described and include multiple histiotypes, such as fibromas, lipomas, lymphangiomas, and hemangiomas (Ligato et al, 1999; Tamboli et al, 2000). Current radiologic methods do not allow for conclusive differentiation of these benign tumors from malignant renal lesions, and surgical excision is often needed for pathologic confirmation.

Among these, noteworthy is reninoma, which is a benign tumor of the renal juxtaglomerular cell apparatus (Wong et al, 2008). With fewer than 100 cases reported in the literature, females in the third and fourth decade are most commonly affected (Martin et al, 2001; Rubenstein et al, 2002; Wong et al, 2008). **Clinical presentation is dominated by hypersecretion of renin and includes hypertension and hypokalemia and associated symptoms such as polydipsia, polyuria, myalgia, and headaches** (Schonfeld et al, 1991; Rubenstein et al, 2002). The radiologic appearance is that of a small (<3 cm) solid hypovascular renal mass; and surgical excision, preferably sparing the remaining renal parenchyma, results in rapid decline of plasma rennin levels, normalization of blood pressure, and resolution of the associated symptoms (Dunnick et al, 1983; Schonfeld et al, 1991; Tanabe et al, 2001). Histologic examination reveals sheets of polygonal to spindle-shaped cells with indistinct cell borders, abundant eosinophilic cytoplasm, and minimal atypia (Martin et al, 2001). Strong immunostaining for factor VIII and factor VIII–related antigens is characteristic and confirms derivation from endothelial cell lineage (Sanfilippo et al, 1982). Although a benign clinical course is expected, one case of malignant reninoma has been documented in the literature (Duan et al, 2004).

Renal leiomyoma. **A,** CT scan with characteristic appearance of a small renal mass arising from the renal capsule. **B,** Medium-power magnification shows uniform spindle cells with thin cigar-shaped nuclei, without any pleomorphism. **C,** Strong positive immunohistochemical staining with smooth muscle actin in the leiomyoma. Note lack of smooth-muscle actin staining in the normal renal tubules on the right. (Copyright 2009, V. Margulis.)

Key Points: Other Benign Renal Tumors

- Numerous rare benign tumors derived from the various mesenchymal components of the kidney have been described.
- Radiologic differentiation from renal malignancy is not possible.
- Reninoma, a benign tumor of the renal juxtaglomerular cell apparatus, is an important but rare cause of secondary hypertension and hypokalemia.

Incidence and Etiology
Pathology
Benign Lesions
Malignant Lesions
Diagnosis
Staging
Management
Metastatic Disease

Retroperitoneal tumors are relatively rare lesions yet of interest to the urologist because they present in a key anatomic location and often involve urologic organs. Because of their location these lesions usually demonstrate indolent growth and present as relatively large lesions. Although some lesions are benign the majority are malignant and are best treated by surgical extirpation when possible. This often requires the excision of involved organs, most often the kidney. Beyond the obvious effort to obtain negative surgical margins during removal, optimal treatment strategies are difficult to systematize owing to the inability to accrue sufficient prospective evidenced-based data. Additionally, much of the available data is intertwined with surveys and treatment approaches to sarcomas of extremities.

The clinical approach to these lesions from the perspective of assessment and surgery is fairly standard. Anthracycline chemotherapy is the basis of treatment, and the advantages and limitations of this approach have been further defined by recent treatment series. The exact role and efficacy for radiation therapy in these lesions continues to be explored. The role for targeted therapy is being investigated.

INCIDENCE AND ETIOLOGY

Retroperitoneal sarcomas are relatively rare lesions that comprise nearly 15% of the soft tissue sarcomas that occur annually and thus account for approximately 2000 cases per year (Jemal, 2009). Surveillance, Epidemiology, and End Results (SEER) data from the U.S. National Cancer Institute have identified 2.7 cases per 100,000 individuals at a steady rate over the past 30 years (Porter, 2006). Actually, fewer than half of all retroperitoneal tumors are sarcomas. Fifteen to 20 percent are benign lesions such as lipomas, and the remainder consist of primary lymphoma or primary urologic tumors such as germ cell lesions (Jemal et al, 2002). Presentation is usually in the sixth decade of life, but the age range is broad (Gronchi et al, 2009). There is a slight male predominance, and two thirds of patients have high-grade malignancy. Approximately 10% will present with metastatic disease, with lung and liver the most common sites of spread (Lewis, 1998).

Although histologic types may span any age range, rhabdomyosarcoma tends to cluster in younger patients, even excluding the pediatric population, whereas malignant fibrous histiocytoma is seen in older patients. Gastrointestinal stromal tumor has been more thoroughly recognized recently, and appropriate characterization is key because targeted therapeutic approaches are available for this lesion.

The etiology of retroperitoneal sarcoma is poorly understood. The etiology of sarcoma has been attributed to prior radiation exposure and toxins, yet it is difficult to account for this in the majority of cases. Approximately 0.1% of patients who receive radiation therapy may develop a sarcoma at the treatment site. The most common lesion associated with radiation is malignant fibrous histiocytoma. Some association exists between dioxin exposure and the development of sarcoma, but prolonged periods of exposure and significant latency were also noted (Hardell and Sandstom, 1979).

PATHOLOGY

Retroperitoneal sarcomas arise primarily from soft tissues of fibrous and adipose origin as well as muscle, nerve, and lymphatic tissue. These tissues are derived from primitive mesenchyme from the mesoderm with some contribution from neuroectoderm (Economou, 1987). Their location allows for a rather long indolent preclinical course during which time the tumor can grow to significant proportions. This growth may result in local areas of necrosis or liquefaction as the tumor outstrips its vascular supply.

In classic reviews of these lesions the common tissue distribution in descending order is liposarcoma, leiomyosarcoma, and fibrosarcoma, followed by other histologies (McGrath et al, 1984; Karakousis et al, 1985, Jacques et al, 1990; Storm and Mahvi, 1991; Rossi et al, 1993). Malignant fibrous histiocytoma is expressed more prominently in contemporary series; however, owing to intensive pathologic interest in defining this disorder, many tumors previously described as variants of fibrosarcoma or liposarcoma have been reclassified as malignant fibrous histiocytoma (Rööser et al, 1991; Pezzi et al, 1992). Therefore fibrosarcoma has been replaced in frequency order by this condition.

Additionally, several previously characterized leiomyosarcomas are now correctly identified as gastrointestinal stromal tumors. By various histologic and immunohistochemical stratification it became apparent that these tumors were less like smooth muscle and more similar to cells of the myenteric nervous system. It is now believed that these tumors probably originate from stem cells

Genetic Alterations in Retroperitoneal Tumors

TUMOR	ABERRATION	GENE(S) INVOLVED
Alveolar rhabdomyosarcoma	t(2;13) ($q^{35};q^{14}$)	*PAX3-FKHR*
	t(1;13) ($p^{36};q^{14}$)	*PAX7-FKHR*
Myxoid/round cell liposarcoma	t(12;16) ($q^{13};p^{11}$)	*TLS-CHOP*
Atypical lipomatous tumor/well-differentiated liposarcoma (ALT/WDLPS)	Supernumerary ring chromosomes; giant marker chromosomes	Amplification of region 12q14-15, Including *MDM2, CDK4, HMGA2, SAS, GL1*
Dedifferentiated liposarcoma	Same as for ALT/WDLPS	Same as for *ALT/WDLPS*
Sporadic gastrointestinal stromal tumor	Activating kinase mutations	*KIT* or *PDGFRA*

that differentiate toward an interstitial cell of Cajal phenotype (Table 52–1) (Quek and George, 2009).

The molecular pathology of sarcomas is complex, and many lesions demonstrate the theme of specific chromosomal translocations creating a fusion chimeric transcription factor. A sophisticated understanding of these changes has been further developed in lesions less commonly seen in the adult retroperitoneum. A partial list of these alterations is presented in Table 52–2. These factors interact with the upstream regulatory component of a gene and can significantly affect the expression of that gene at the messenger RNA level. The nucleic acid binding domain of the chimeric transcription factor confers target specificity within the tissue genome while the transcription factor portion of this novel protein determines the transactivation potential and expression level of the target gene (Crozat et al, 1993; Ladanyi, 1995; Panagopoulos et al, 1996; Tschoep et al, 2007; Torsten and West, 2010). The description of this pathologic mechanism predated a similar finding recently described in prostate cancer.

Additionally, the development of extra abnormal chromosomes (ring chromosomes and giant rods) involving chromosome 12 can result in the amplification of certain gene products such as *MDM2* and *SAS*. *MDM2* can be involved in TP53 inactivation, which can contribute to carcinogenesis (Berner et al, 1996; Elkahloun et al, 1996). Series of investigations regarding soft tissue leiomyosarcoma have revealed exceptionally complex, multiple gene alterations that are not easily categorized. These molecular insights into the pathology of sarcoma have not translated into therapeutic targets as readily as the gastrointestinal stromal tumors histology but may provide approaches for future therapeutic strategies directed at these lesions (Van Roggen and Hogendoorn, 2000; Nielson and West, 2010).

Gastrointestinal stromal tumors demonstrate activated c-*KIT* mutations in 8% to 88% of lesions. Additionally, analogous gain of function mutations were demonstrated in platelet-derived growth factor receptor-α (PDGFR-α). These mutations suggested a role for targeted therapy in these lesions (Heinrich et al, 2003; Corless et al, 2004).

Gene expression profiling has also been explored in sarcomas, which allows the identification of some putative biomarkers in the study of these lesions and has suggested that malignant fibrous histiocytoma, rather than a separate entity, may represent a common end point of several different sarcomas (Tschoep, 2010).

BENIGN LESIONS

Lipomas

Lipomas consist almost entirely of mature fat and are uncommonly found in the retroperitoneum. They are probably the most common soft tissue tumor in humans. Most of these lesions occur superficially, but they may occur in other areas, such as the retroperitoneum. Deep lipomas within the retroperitoneum are usually not as well circumscribed as their superficial counterparts and can conform to irregular spaces in this body space (DeWeerd and Dockerty, 1952; Mowat and Clark, 1961). The adipocytes are normal or slightly larger in appearance and have a well-developed vascular network. There is very little in the way of nuclear irregularity. Differing levels of fibrous connective tissue can be found in these lesions. The rim of the lipocyte is reactive for S-100 protein. Although the majority of these masses are idiopathic, they can occasionally be a manifestation of steroid lipomatosis.

Pelvic lipomatosis, although not a distinct tumor per se, was first described in 1959 as an overgrowth of fat in the perivesical and perirectal area. It is a hyperplastic rather a neoplastic entity that can create a space-occupying lesion. Approximately two thirds of patients are African-American, and women are rarely affected (Heyns, 1991). The growth is diffuse rather than nodular, and often it is difficult to distinguish it from normal adipose tissue. The condition may be associated with cystitis glandularis (Yalla et al, 1975). The general clinical course is slowly progressive and may result in the need for urinary diversion (Klein et al, 1988). Occasionally, fat necrosis in these lesions can be mistaken for sarcomatous degeneration (Andac et al, 2003).

Myelolipoma

Myelolipoma is a tumor-like growth of mature fat and bone marrow elements. Although it usually occurs in the adrenal gland it can be seen as an isolated pelvic lesion (Chen et al, 1982; Sanders et al, 1995). It is distinct from extramedullary hematopoietic tumors, which are usually multiple and generally associated with mild proliferative diseases and skeletal disorders. These generally occur in patients older than age 40 years and are rarely greater than 5 cm (Fowler et al, 1992; Mukherjee et al, 2010). They are usually noted as incidental findings on imaging. The adrenal gland can create inferior renal displacement due to a radiolucent mass. Pathologically it may display the features of a lipoma or have a darker appearance if myeloid elements predominate. Adrenal myolipoma development may be secondary to prolonged stress and excessive stimulation with adrenocorticotropic hormone.

Leiomyoma

These generally rare lesions are seen in a distribution that represents smooth muscle tissue in the body. They are overwhelmingly found in the female genital tract but have also been reported in the urinary bladder. There are occasional reports of these tumors in the retroperitoneum, where they can grow asymptomatically to a considerable size. Leiomyomas stain positive for desmin, which separates them from their malignant counterpart. Extension of these lesions from the uterus into the vascular system can create tumor thrombi not unlike those seen with renal lesions (Clement, 1988).

MALIGNANT LESIONS

Liposarcoma

Liposarcomas are among the most common of primary retroperitoneal tumors and are distinguished by their often large dimensions and range of subtypes. These lesions have their peak incidence between ages 40 and 60 (Kindblom et al, 1975). They account for 10% to 15% of sarcomas, and approximately 20% of these lesions arise in the retroperitoneum. One unfortunate clinical feature of these lesions is their usual tendency to recur, often within the first 6 months after surgery. The principal tissue type is usually recapitulated at the time of recurrence. The rate of metastasis depends on the degree of tumor differentiation, with nearly 90% of poorly differentiated tumors metastasizing (Enterline et al, 1960; Spittle et al, 1971; Weiss and Rao, 1992).

Significant advances in cytogenetics have allowed the reclassification of these lesions on a molecular basis. Well-differentiated and dedifferentiated lesions are a continuum of lesions based on the genetic abnormality of giant and ring chromosomes usually involving chromosome 12. Gene amplification, particularly of *MDM2,* drives their pathology (Pilotti et al, 1998; Forus et al, 2001). Myxoid and round cell lesions (poorly differentiated myxoid) are another continuum that have fusion transcripts caused by translocations in chromosomes 16 and 12 as their principal pathologic feature. Pleomorphic liposarcomas are rare and poorly understood (Dal Cin et al, 1997).

Unlike benign lipomas, liposarcomas may bear little resemblance to classic fat-filled structures. The gross lesion is usually described as having a "fish flesh" appearance and, although generally encapsulated, it can often display invasive characteristics. Besides the retroperitoneum, these lesions arise in the deep soft tissues of the proximal extremities. They generally present as very large lesions when originating from the retroperitoneum.

Myxoid liposarcomas are the most common type and usually occur in the lower extremity. They account for 50% of sarcomas and represent a large proportion of retroperitoneal lesions. The peak presentation is in the fifth decade. These tumors display a background of stellate mesenchymal cells and a prominent capillary pattern often described as a "chicken wire" appearance. The distinct cell is the lipoblast, which is similar to the fetal adipocyte. These cells are noted by a lipid vacuole that scallops the nucleus. This creates the lipoma-like appearance of these lesions, which can demonstrate fusion proteins (TLS-CHOP) on molecular analysis. Higher-grade lesions tend to demonstrate a higher number of *TP53* mutations (Deitos et al, 1997). The round cell subtype is also referred to as a lipoblastic variant and is distinguished by sheets of round cells with lipoblastic differentiation. These lesions are considered the most aggressive part of the spectrum of myxoid lesions.

Well-differentiated liposarcomas most resemble lipomas and are usually designated as low grade. They are a common sarcoma of later life. Subvariants include the lipoma-like, inflammatory, sclerosing, and differentiated types. The first three variants are often confused with benign processes such as scarring or inflammation, whereas the differentiated subtype is often noted in long-standing retroperitoneal lesions and considered higher grade. Generally these lesions are now considered as a group with dedifferentiated lesions because they share genetic similarities.

Pleomorphic liposarcomas comprise 10% to 15% of liposarcomas and are defined as high-grade malignant variants with very bizarre nuclei and huge lipoblasts.

Leiomyosarcoma

Leiomyosarcomas account for less than 10% of all soft tissue sarcomas yet a significant percentage of retroperitoneal sarcomas because almost half of them appear in this region. They have a 2:1 female-to-male presentation and generally occur in middle age (mean age 60 years). The molecular pathology of these lesions has not been reduced to any common pathway and demonstrates a tremendous amount of variation on cytogenetic and molecular analysis. The tumors are usually categorized by site of origin (soft tissue, vascular, or superficial), although many of the soft tissue lesions are believed to originate from smaller blood vessels. On imaging examinations, however, they appear to have moderate to low vascularization.

Grossly, low-grade leiomyosarcomas can be difficult to distinguish from leiomyomas but higher-grade lesions display a more infiltrative fleshlike appearance (Shmookler and Lauer, 1983). Low-grade lesions are often distinguished from leiomyomas by their chromatin pattern and the number of mitoses (more than five mitoses per high-power field) present in the specimen.

Again, a continuum exists in the pathologic progression of these smooth muscle lesions; therefore the cut point between benign, moderate, and high grade may sometimes be arbitrary. There is little evidence of sarcomatous degeneration from benign leiomyomas. The characteristic pathologic finding of a leiomyosarcoma is malignant spindle cells with "cigar"-shaped nuclei. The muscle fascicles interweave. These tumors immunohistochemically stain for smooth muscle myosin, vimentin, and actin and less often for desmin. They stain negative for S-100. Ultrastructural features include bundles of thin cytofilaments, which can help distinguish leiomyosarcomas from other lesions.

A rare retroperitoneal variant of these tumors are leiomyosarcomas that originate from the great vessels (Demers et al, 1992). These occur predominantly in women. Tumors of the iliac vessels usually present as lower extremity edema, whereas those of the inferior vena cava can display findings consistent with Budd-Chiari syndrome (Cardell et al, 1971). Resection of these lesions is recommended when anatomically feasible. Survival, however, is usually less than 2 years, and many inferior vena caval tumors are unresectable because of the intrahepatic location of many of these lesions.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma was originally described in 1963 and has come to be the predominant histologic diagnosis for currently reported soft tissue sarcomas (Ozello et al, 1963). It was first defined as a sarcoma of primary histiocytic origin, but it is now believed that it is a lesion derived from fibroblast differentiation. Many pleomorphic variants of fibrosarcoma, liposarcoma, and

rhabdomyosarcoma have been reclassified into this category. With the thorough evaluation of a tumor specimen, distinct regions of leiomyosarcoma, liposarcoma, and other soft tissue sarcomas may be identified. In such cases the tumor may be defined by those findings and the mention of an associated malignant fibrous histiocytoma pattern (Weiss, 1982). These lesions are most often seen on the extremities and are less common in the retroperitoneum. Their molecular pathology is unclear. An analysis of these lesions in the retroperitoneum suggests that many of these could be reclassified as a dedifferentiated liposarcoma and that they may represent a common end point for several tissue types (Coindre et al, 2003; Tschoep et al, 2007). Storiform-pleomorphic, myxoid, giant cell, and inflammatory subtypes of malignant fibrous histiocytoma may coexist in a particular lesion.

The storiform-pleomorphic variant has a distinct but not pathognomonic pinwheel pattern caused by the collagen pattern of curling fascicles of cells. It is the most common variant, usually comprising 40% to 60% of most series. Although this pattern may predominate, it may not be present throughout the lesion in question. Areas of collagen or foamy cells may also be encountered. The nuclei tend to be irregular and large with discernible mitosis. The constellation of tissue histology and nuclear irregularities in addition to the inflammatory components differentiate this lesion from benign entities.

Myxoid malignant fibrous histiocytoma comprises 25% of this overall tumor type. It is often difficult to distinguish it from liposarcoma; however, the myxoid subtype has little neutral fat but is rich in mucopolysaccharide residing in intracytoplasmic vacuoles.

Malignant fibrous histiocytoma, giant cell type, is distinguished by large benign-appearing osteoclasts. Multinucleated giant cells and the stroma comprise the malignant components of this lesion. If cartilage or osteoid is detected, these lesions are classified as a soft tissue osteosarcoma, which usually has a poorer prognosis than malignant fibrous histiocytoma.

Fibrosarcoma

Fibrosarcomas are malignant tumors of fibroblast origin. They have a range of gradation and grossly display a classic "fish flesh" pattern with hemorrhage and necrosis. Low-grade lesions can display a herringbone/spindle-shaped histologic pattern. On retrospective review these lesions are often reclassified as malignant fibrous histiocytoma or as a desmoid lesion (aggressive fibromatosis). Therefore these lesions represent a smaller proportion of primary retroperitoneal tumors than previously reported. There is a greater incidence of blood-borne metastases from this tumor to the lung and bones (Bizer, 1971).

Rhabdomyosarcoma

Rhabdomyosarcoma comprises a minor percentage of reported retroperitoneal sarcomas yet is a significant lesion in pediatric oncology as well as pediatric tumors associated with the genitourinary system. These lesions are generally classified as embryonal, botryoid, alveolar, or pleomorphic, with a spindle cell subtype more recently described within the embryonal type (Horn and Enterline, 1958; Cavazzana et al, 1992). The pathology of these lesions is associated with chromosomal abnormalities and the fusion transcripts associated with these translocations.

Embryonal rhabdomyosarcoma comprises more than half of all rhabdomyosarcomas and has a large array of anatomic locations, including the genitourinary tract and retroperitoneum. It can range from very well to poorly differentiated lesions and can express the multiple stages of muscle development. Botryoid lesions are an anatomic variant of the embryonal type and generally found in hollow viscera. The spindle cell subtype is noted for its favorable clinical behavior.

Alveolar rhabdomyosarcoma accounts for approximately 20% of all rhabdomyosarcomas and tends to occur more frequently in the extremities. The tumor is arranged in aggregates of round or oval cells that create irregular spaces reminiscent of alveoli. They can be classified into subtypes based on fusion gene transcripts *(PAX-FKHR)*. These tissues may be surrounded by fibrous septa, and areas of necrosis are not uncommon.

Pleomorphic rhabdomyosarcoma comprises 5% of adult rhabdomyosarcomas and generally occurs in older patients. It usually is found in the extremities and is not unlike malignant fibrous histiocytoma in its appearance. The absence of cross striations makes diagnosis difficult. With all rhabdomyosarcomas, immunostaining for desmin, myoglobin, and muscle-specific actin is useful.

Malignant Hemangiopericytoma

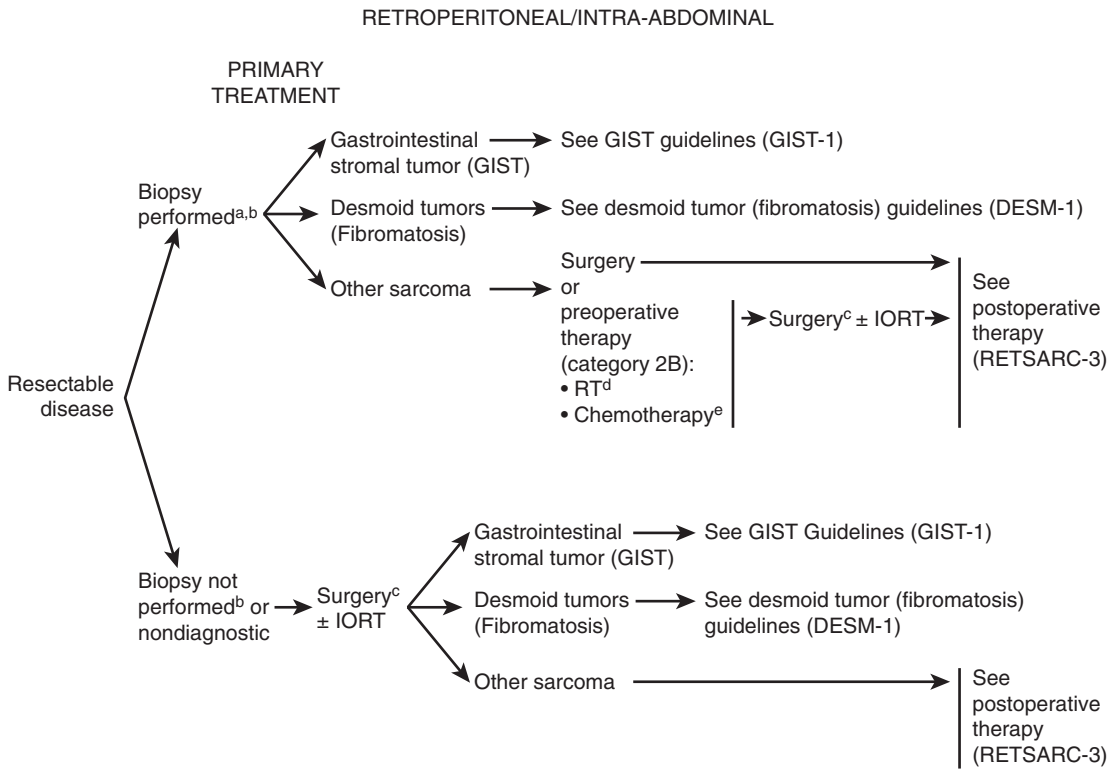
These rare lesions originate from pericytes, which are unique cells that arborize about small vessels and capillaries. Their contractile properties allow them to control microvascular flow and permeability. Fewer than 200 of these lesions have been described, yet 25% of them have occurred in the retroperitoneum or pelvis. They are usually well circumscribed and, if possible, complete surgical excision is warranted. Hemangiopericytomas display a rich vascular pattern and stain positive for factor VIIIa. They are negative for desmin and actin. The clinical behavior of these lesions is difficult to predict, but metastases may develop in 20% to 50% of cases. Those lesions with more than four mitoses per 10 high-power field have a worse prognosis (Enzinger and Smith, 1976; Zirkin 1977).

DIAGNOSIS

Because of their slow growth and anatomic location, retroperitoneal tumors (usually sarcomas) tend to grow to a large size before they are detected. In one series of soft tissue sarcomas the average size at diagnosis for extremity lesions was 5 cm, whereas retroperitoneal lesions were 16.5 cm (Hueman et al, 2008); thus such lesions can often be enormous by usual pathologic standards. Although the age at presentation is distributed across a large spectrum, the majority of patients are diagnosed with retroperitoneal tumors in the sixth decade of life. Because the progression of symptoms is slow there is usually a lag time of 5 months from initial symptoms to diagnosis. The principal clinical finding is an abdominal mass and abdominal pain (60% to 80%) (McGrath, 1984). Many patients also experience nausea and vomiting and weight loss (20% to 30%). Neurologic findings are noted in 30% of patients (Cohan et al, 1988). Lower extremity edema is seen in 17% to 20% of patients whereas urinary symptoms are surprisingly rare, occurring in 3% to 5% of patients in most series.

Physical examination will generally demonstrate a protuberant abdomen that may be accompanied by an appearance of extremity wasting. Lymphadenopathy is not usually associated with retroperitoneal sarcomas (<5%) (Fong et al, 1993). Lower extremity edema and/or increased abdominal wall venous markings suggest the presence of vena cava compression or obstruction.

Diagnostic imaging is imperative to delineate the anatomic limits of the lesion and assess the integrity and function of



adjacent organs. This is most appropriately demonstrated with cross-sectional imaging (Neifeld et al, 1982; Chang et al, 1987). Important issues to address with this modality are bilateral renal function, the presence or absence of visceral metastases, and lymphadenopathy. Attention should also be given to the axial skeleton. Tumor involvement of neural foramina suggest unresectability of the lesion. Germ cell tumors, which should be suspected in young men and diagnosed through a thorough physical examination and testicular ultrasound examination, are usually distinguished on computed tomography (CT) from other primary retroperitoneal lesions. This is also generally true for lymphomas. CT, however, is not particularly diagnostic for the multiple tumor histologies of primary retroperitoneal tumors except for a liposarcoma with high fat content.

Cross-sectional imaging has largely supplanted a multiple-study approach to staging, and the application of magnetic resonance arteriography allows for the delineation of vascular involvement by these uncommon lesions. From a practical standpoint, CT and magnetic resonance imaging are complementary rather than redundant and should be employed as needed (Bland et al, 1987). The majority of information necessary for appropriate staging should be obtainable through a CT scan with and without contrast enhancement and chest imaging.

The role for preoperative biopsy is controversial. In some cases imaging will not provide a reasonable diagnosis, in which case a biopsy prior to definitive resection may be required (Barth et al, 1992). Most surgeons agree that surgical exploration is the next most appropriate step for a mass suspected of being a sarcoma and that a preoperative biopsy should be reserved for cases in which a diagnosis will change therapy, such as the need for neoadjuvant imatinib mesylate for gastrointestinal stromal tumors or protocols of neoadjuvant chemotherapy for germ cell tumors or lymphomas (Windham and Pisters, 2005). When a biopsy is performed, a CT-guided core biopsy is the preferred approach. In the case of gastrointestinal stromal tumors a biopsy may be made endoscopically, which is preferable because these lesions are vascular and tend to fragment (Fig. 52–1) (Rabin et al, 2009).

STAGING

The principal staging system used for soft tissue sarcoma is the American Joint Committee on Cancer (AJCC) system (Table 52–3). Alternate systems are the French Federation of Cancer Centers Sarcoma Group system and the National Cancer Institute system. Staging is driven in large part by tumor grade, which in the revised AJCC system is three tier. Tumor grading is determined by several factors, including atypical mitosis, cytoplasmic and nuclear pleomorphism, and necrosis (Leyvraz and Costa, 1988; Kulander et al, 1989). Grade 1 lesions are denoted by few mitoses, acellularity, minimal alterations of the nucleus, and absent or few nucleoli. Scoring often takes into consideration other factors such as tumor size and patient age. Grade 2 lesions display small- to moderate-sized nucleoli, moderate nuclear pleomorphism, irregular chromatin distribution, and a moderate amount of mitoses. Areas of

T2b	Deep tumor		Any T	N1	M0	Any G
Regional Lymph Nodes (N)						
NX	Regional lymph nodes cannot be assessed	IV	Any T	Any N	M1	Any G
N0	No regional lymph node metastasis					
N1	Regional lymph node metastasis					
Distant Metastases (M)						
M0	No distant metastasis					
M1	Distant metastasis					
Histologic Grade						
GX	Grade cannot be assessed					
G1	Grade 1					
G2	Grade 2					

*Superficial tumor is located exclusively above the superficial fascia.
†Invasion of the fascia; deep tumor is located exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia.

necrosis may be noted in the microscopic field. Grade 3 lesions are characterized by numerous mitoses, gross chromatin clumping, moderate or considerable necrosis, and variation in nuclear morphology. The distinction between T1 and T2 lesions is made at 5 cm, but for matters of retroperitoneal lesions all are considered deep.

MANAGEMENT

Surgery

Extirpative surgery is the principal and most effective form of therapy for primary retroperitoneal tumors. Preoperative planning to assess the extent of the disease is essential because successful surgery is defined by complete excision of the mass with adequate margins of normal tissue. A complete resection rate between 38% and 78% (average 55%) is reported in many large series (Sindelar et al, 1993; Karakousis and Velez, 1996; Lewis et al, 1998; Stoeckle et al, 2001; Gronchi et al, 2004). In several large series of retroperitoneal sarcomas, univariate and multivariate analysis of independent treatment variables has been reported. In more than 280 patients completeness of resection was the single most important positive predictive feature (Bevilacqua et al, 1991; Catton et al, 1994; Singer et al, 1995; Anaya et al, 2009, Bonvalot et al, 2009). Intermediate or high tumor grade is a strong negative feature (Bevilacqua et al, 1991; Anaya et al, 2009). In most reported series, intermediate- and high-grade lesions comprise 55% to 70% of the tumors described. Tumor histology, tumor size, or patient age were not significant factors in survival in multiple-variable analysis (Wurl et al, 2000; Ferrario and Karakousis, 2003). Therefore carefully planned and skillfully executed surgical therapy is critical for any chance at long-term success (Malerba et al, 1999; Bautista et al, 2000).

Operative Technique

The classic approach for surgery on these lesions is described through long midline or chevron incisions. The tumors are usually right sided or left sided; however, a few actually rise from the midline. A full flank position such as that employed for renal stone surgery is discouraged because it can limit exposure to the full retroperitoneum or abdomen (Storm and Mahvi, 1991; McGrath, 1984). Because these lesions are not compartmentalized by the retroperitoneum they can cross many anatomic boundaries. It is important, therefore, to determine the potential for resectability, beyond that presupposed through imaging. This is first accomplished by developing a subadventitial plane along the lateral borders of the great vessels extending dorsally between the spine and psoas and quadratus muscles. In this manner one can determine if the tumor has spread along a spinal nerve route and into the spinal foramina or even farther into the spinal cord. If this is the case, the tumor is generally considered unresectable. It has also been suggested that the lateral incision of the peritoneum into the deep body wall is important to explore on a level posterior to the spinous processes. If the operator's fingers can bimanually palpate the tumor, this sarcoma is considered resectable.

It is imperative in the preoperative period that both the patient and the surgeon realize the potential need for en-bloc resection of affected organs. This can include vascular structures as well as the kidney and a portion of the diaphragm, liver, stomach, gallbladder, spleen, pancreas, and gut. In a review of several series, up to 68% of operations required resection of an adjacent organ to ensure adequate negative margins. The most frequently resected organs are listed in decreasing order in Table 52–4. In one review (Russo et al, 1997) it was reported that 20% of patients undergoing surgery for a retroperitoneal sarcoma required nephrectomy. The majority of them (72%) underwent this during their initial

Table 52–4.

Frequency of Resection of Specific Organs in Surgery for Retroperitoneal Tumors

Dalton et al, 1989	116	54	21	72	13

resection. The usual reason for nephrectomy was total encasement of the organ, followed by dense adherence to the kidney and less often by direct invasion of the renal unit. Although a Dacron graft can be employed to replace a portion of resected aorta there is debate among surgeons with regard to the need for venous reconstruction. Many believe that the venous collateral vessels that develop secondary to vena caval compression are adequate to allow for appropriate drainage from otherwise vascular-compromised organs. There has been a greater trend toward major blood vessel reconstruction in an attempt to achieve complete resection of retroperitoneal lesions, but this must be done with careful preoperative planning (Song et al, 2009). In such cases, vascular patency was maintained in approximately 80% of patients, with the majority of thromboses occurring within the first month postoperatively.

A special case is the presence of a leiomyosarcoma of a major vessel such as the inferior vena cava. This has been addressed by inferior vena caval ligation, primary or patch repair, or tube grafting (Hollenbeck et al, 2003). A local recurrence occurred in 33% of patients, and distant disease was noted in 48%. The 3- and 5-year disease-specific survival rates were 76% and 33%. When bowel viability is questionable that segment should be resected if possible. An area of caution is in the resection of the femoral nerve, which may be considered in cases of deep involvement of the psoas (Jones et al, 2009). In one series, 6 of 10 patients developed fractures during long-term follow-up as a result of falls related to absent active knee extensors. Although many visceral organs can be resected, unresectability is usually denoted by sarcomatosis, nerve root involvement, pelvic side wall involvement, malignant ascites, or the presence of distant metastasis (McGrath 1984; Storm and Mahvi, 1991; Karakousis and Velez, 1996).

When defining the operative field it is often necessary to release multiple intra-abdominal adhesions. This must be performed meticulously because an enterotomy and subsequent fistula formation can cause major morbidity. Tactile as well as visual perceptions aid in avoiding violation of the bowel. In addition, the use of sharp, curved Mayo scissors rather than Metzenbaum scissors may aid in avoiding this complication. During the dissection of a large tumor mass it is often necessary to shift the location of the dissection when one particular area becomes difficult owing to concerns of a clear margin or the potential for vascular damage. A centripetal dissection allows one to dissect those areas that are amenable to dissection and that in turn may free up a previously more constrained area of the operative field (Fernandez-Trigo and Sugarbaker, 1993). Morbidity and mortality rates for contemporary surgical series are acceptable. An operative mortality of 2% to 7% with morbidity rates of 6% to 25% is the norm. Hemorrhage, intra-abdominal abscess, and enterocutaneous fistula are the most commonly described complications.

Another surgical technique is the modified thoracoabdominal approach, which has been developed and popularized by Skinner (1977). Those familiar with the technique believe that it allows maximum exposure to the posterior retroperitoneum, which is often a difficult area to assess through a midline incision. Additionally, it provides access and control to the ipsilateral great vessels above the diaphragm. Whether a left- or right-sided procedure is performed, excellent exposure can be developed in the contralateral retroperitoneal region without difficulty.

Several recent studies have also suggested the potential value of aggressive surgery in retroperitoneal soft tissue sarcoma, which includes the resection of clinically normal-appearing organs such as the ipsilateral renal unit (Gronchi et al, 2009; Bonvalot et al, 2010). Although it was demonstrated that this could be done with a reasonable margin of safety and lower local recurrence rates (28% vs. 48%), there was no difference in overall survival rates between aggressive and less aggressive surgery. Furthermore, as one might expect, an increase in overall morbidity was noted as more normal organs were resected. Widespread adoption of such an approach has not been recommended until prospective studies demonstrate an advantage.

Surgical Outcome

The classic overall survival for patients presenting with retroperitoneal sarcomas is poor. In a multi-institutional review the 2-, 5-, and 10-year mean survival rates for patients with this disease were 56%, 34%, and 18%, respectively (Storm and Mahvi, 1991). Recent series suggest 2-year survivals of more than 70% and 5-year survivals of 50% to 60% in patients without metastases (Lewis et al, 1998; Stoeckle et al, 2001). The effective surgical management of retroperitoneal tumors has been limited by their size at presentation, which often results in secondary organ involvement. This has a poor impact on the ability to achieve negative surgical margins even with the resection of adjacent organs. Historically, a complete surgical resection with negative margins was achieved in 50% to 60% of patients. The more recent series demonstrate complete resection rates in the 60% to 80% range, which may be due to improvements in imaging, preoperative planning, and surgical technique.

Those patients who achieve a complete resection display superior survival to those patients with incomplete resection of their tumors (Table 52–5). This is also supported in a laboratory model (Tsivian et al, 2002). In an analysis of microscopic margins, however, positive margins at this level of pathologic resolution had little impact on recurrence-free survival (Stojadinovic et al, 2002; Anaya et al, 2009).

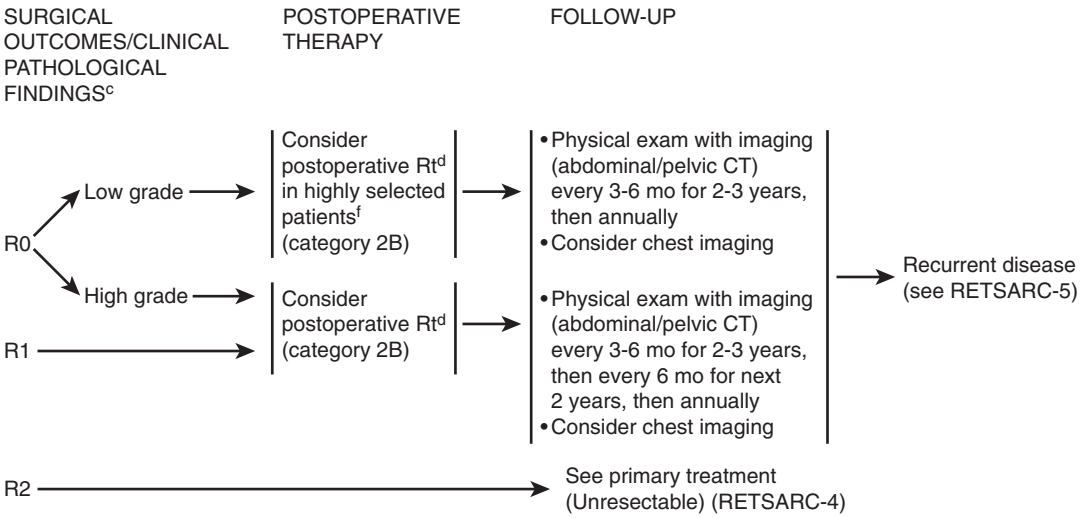
On average the 5-year survival of patients with completely resected tumors is 54% compared with 17% for incomplete resections; at 10 years this difference is 45% to 17%. Thus a nearly 40% survival advantage is seen at 5 to 10 years in those patients with complete surgical resection of their lesion. Tumor recurrence after complete surgical resection, however, is significant. There is a 72% chance of local recurrence at 5 years and a 90% chance of recurrence at 10 years in most series. These data imply fairly poor survival at 15 years (Storm and Mahvi, 1991; Thomas et al, 2009).

Reoperative surgery for the treatment of recurrent retroperitoneal sarcoma can be of value. Over 60% of patients may experience a complete resection (Lewis et al, 1998). In one series, 30 patients with a previous complete resection of the primary lesion experienced local tumor recurrence at a mean interval of 23 months, and 60% of these patients were rendered free of disease after reoperative surgery. To accomplish this, 33% of these patients required the resection of adjacent viscera. Those patients who achieved a complete resection with a second operation had a 33-month median survival compared with a 14-month median survival in those patients who did not experience a second complete resection (Wang et al, 1994). In a recent series, 79% of patients achieved palliation of tumor-related symptoms on first resection of a recurrence and survival was improved with a complete or incomplete resection compared with biopsy only (Grobmyer et al, 2009). Second or third recurrences occurred over shorter intervals and were less likely to be completely resectable. Tumor grade was the most important determinant of long-term survival.

The role of subtotal resection has never been clearly established, yet some data suggest that this may have some positive value compared with palliative or debulking surgery. The argument for the possible value of incomplete resection has been made in the management of liposarcomas. In a series of 55 patients, 75% received symptom relief from their surgery and partial resection compared with biopsy or exploration alone, which had a significant impact on increased survival (26 vs. 4 months) (Shibata et al, 2001). In another report, 22 patients with complete resection of tumor displayed a similar median survival to 15 patients with subtotal resection (median survival > 120 months), compared with those only having a partial palliative resection or exploration (12 to 20 months) (Shiloni et al, 1993). An aggressive surgical approach in cases in which near-complete resection can be obtained has also been advocated by others (Karakousis and Velez, 1996). In general, partial debulking does not confer a survival advantage for retroperitoneal sarcoma except perhaps in the case of lower-grade liposarcoma (Anaya et al, 2009).

Palliative surgery for unresectable disease has to be determined on a case-to-case basis. The usual consideration is gastrointestinal obstruction or pain. In one large series of palliative attempts, perioperative mortality was 9% and complications occurred in 29% of patients (Yeh et al, 2005). Alternate options include radiation therapy, chemotherapy, and supportive care.

Considering the relative rarity of retroperitoneal sarcomas it is reasonable to consider if such lesions should be exclusively treated at high-volume centers. In a review of 260 soft tissue sarcomas treated over a 3-year period, 86 were treated at one center while the remainder were managed at 38 other centers (Bhangu et al, 2004; Bonvalot et al, 2010). The rate of local recurrence was 19% at the specialty center and 39% in aggregate at the other hospitals. Survival was significantly different between groups for larger (>5 cm) and high-grade lesions. Similarly, in a registration study of over 4000 soft tissue sarcomas treated at more than 200 centers in Florida, 68.1% were treated at low-volume centers and the remainder at seven other sites (Gutierrez et al, 2007). There were significant differences in 30- and 90-day mortality and improved survival for high-grade lesions, lesions larger than 10 cm, and retroperitoneal sarcomas (39 vs. 31 months, $P = .011$). On multivariate analysis, center effect was a significant independent predictor of improved survival (odds ratio = 1.292, $P = .047$).



Postoperative monitoring of patients with primary retroperitoneal sarcoma has been established by authority opinion based on the rapidity of recurrence, the advantage of re-resection, and the lethality of this condition. It would be appropriate to perform abdominal and pelvic CT, chest imaging, and biochemistry profile with a complete blood cell count every 3 to 6 months for 2 to 3 years. A lengthening of this follow-up interval may be considered only after 3 years. Data support the concept that close follow-up allows for early detection and less bulky recurrences that allow for more successful salvage surgery (Fig. 52–2) (Gupta et al, 2000).

The effect of tumor grade on patient survival cannot be underestimated. Low-grade lesions display a 50% survival advantage over intermediate- and high-grade lesions at 5 years (74% to 24%) and a 30% survival at 10 years (42% to 11%). This is demonstrated even in the presence of total surgical resection. Although staging systems generally demonstrate three or four tumor grades, outcomes generally dichotomize into high grade and low grade. In an attempt to better stratify outcomes an effort has been made to establish prognosis in retroperitoneal sarcoma by histology (Anaya et al, 2009, 2010). More than 300 patients treated over a decade were categorized as having atypical lipomatous tumor, nontypical lipomatous tumor (liposarcoma), and other tumors. This provided outcome stratification for all three groups and applied to primary and recurrent lesions. On multivariable analysis, liposarcoma and "other" histologic processes were independent predictors of survival. The concordance ratio was approximately 0.74. This analysis has been incorporated into a retroperitoneal sarcoma–specific postoperative nomogram in which age, tumor size (>15 cm), type of presentation, multifocality, completeness of resection, and histology are independent predictors of overall survival, with a concordance index of 0.73 (Fig. 52–3) (Anaya et al, 2010; Ardoino et al, 2010).

Although aggressive surgical resection of retroperitoneal sarcoma serves as the foundation of therapy for this condition, the high local recurrence rate and eventual mortality from this disease has prompted the exploration of adjuvant therapeutic modalities.

Radiation Therapy

Radiation therapy has been used successfully in extremity sarcoma, and therefore it is reasonable to consider it for local control in retroperitoneal sarcoma. Unfortunately, the total dose is often limited by radiosensitive structures in the tumor bed. Radiation therapy may be delivered in the neoadjuvant, intraoperative, and adjuvant settings. It may be administered as external-beam therapy or brachytherapy. A preoperative approach is attractive because the viscera are often displaced by the tumor volume and a lack of surgical adhesions further reduces dose to the bowel. Additionally, the effective radiation dose is lower in the preoperative setting. The feasibility of administering radiation in the neoadjuvant setting has been demonstrated in several small series (Gieschen et al, 2001; Jones et al, 2002; Petersen et al, 2002). Unfortunately, many series will combine this with brachytherapy or intraoperative radiation and therefore not give a meaningful sense of the toxicity of neoadjuvant therapy alone. In a series of 40 patients

[c]See Principles of Surgery (SARC-C)

Postoperative nomogram for survival of patients with retroperitoneal sarcoma treated with curative intent. Ann Oncol 2010;21[2]:397–402.)

receiving preoperative or postoperative therapy, significantly more complications were noted in the postoperative cohort (Zlotecki et al, 2005). In another review of 72 patients who received preoperative therapy, 46% had a 5-year disease-specific survival and those who completed therapy and had a macroscopically complete resection demonstrated a 60% disease-specific survival (Pawlik et al, 2006). Attempts at phase 3 trials have been limited by poor accrual (Kane, 2006).

Some small studies have evaluated combination neoadjuvant radiation with chemotherapy usually doxorubicin-based treatment. In one study of 23 patients, 26% of patients demonstrated a clinical and pathologic complete response. In another investigation, 90% of patients who underwent a laparotomy after irradiation and chemotherapy had an R0 or R1 resection (Pisters et al, 2003). The feasibility of this approach has been demonstrated, yet phase 2 trials are needed.

Intraoperative radiation therapy is feasible and has the advantages of administering a dose in a single large fraction. The largest series using this technique are somewhat confounded by the use of external-beam irradiation as well (Sindelar et al, 1993; Gieschen et al, 2001). In both studies, local control rate was significantly higher in the intraoperative radiation therapy group. At 8 years, the phase 3 trial demonstrated a significant difference (20% vs. 80%) in local control but toxicity was significantly higher in the cohort receiving intraoperative radiation therapy.

Chemotherapy

Multimodal therapy for extremity sarcoma has provided an inference for the role of chemotherapy in retroperitoneal lesions. The majority of large-scale chemotherapy trials, however, comprise patients with extremity disease, so these findings may not be directly applicable. Overall, the argument for adjuvant therapy seems reasonable because the potential for distant recurrence is significant with retroperitoneal lesions. The data in this regard have been somewhat contradictory, yet a meta-analysis of these studies suggests a slight advantage of 4% overall survival for the use of adjuvant doxorubicin therapy to decrease the risk of death and recurrence in patients with high-grade lesions (Gilbeau et al, 2002; Pervaiz et al, 2008). Such therapy is associated with toxicity, however, and has mixed acceptance for retroperitoneal lesions (Zalupski et al, 1993).

The association of c-*KIT* mutations and alterations in PDGFR-α suggest a role for tyrosine kinase inhibitors and other targeted therapy in gastrointestinal stromal tumors. One trial of adjuvant imatinib therapy for high-risk, completely resected gastrointestinal stromal tumors demonstrated a significant 1-year relapse-free survival advantage (97% vs. 83%), and other trials are in progress (Gold et al, 2006).

METASTATIC DISEASE

Approximately 20% of patients with soft tissue retroperitoneal sarcoma will present with metastatic disease. Those patients who experience recurrence after treatment for localized disease generally do so by 60 months. Recurrence is demonstrated at multiple sites (47%), or it is local (30%). Isolated pulmonary lesions occur in approximately 20% of patients. Three-year survival in patients undergoing complete excision of lung-only lesions is 38%.

Doxorubicin is the foundation for chemotherapy in advanced sarcoma (Gottlieb et al, 1975; Borden et al, 1987). The general response rate is 20% to 25%, but sustained complete responses are uncommon. Median survival is 7.7 to 12 months (Santoro et al, 1995). Other classic agents demonstrating activity include dacarbazine, ifosfamide, methotrexate, and cyclophosphamide. In several phase 3 studies, however, combination treatments were not superior to single-agent doxorubicin (Yap et al, 1980; Antman et al, 1993; Edmonson et al, 1993). Other phase 3 studies have not demonstrated superior response yet do show significant increased toxicity (myelosuppression and cardiac) with the addition of other agents (Santoro et al, 1995). Another combination regimen of mesna, doxorubicin (Adriamycin), ifosfamide, and dacarbazine (MAID) has been successful in neoadjuvant programs for sarcomas of the extremities compared with historical controls, yet less data are available with regard to other soft tissue sites. In general, salvage therapy for patients has been associated with poor responses and little in the way of advantages in quality of life (O'Sullivan and Bell, 2003; O'Sullivan et al, 2003).

More recently, gemcitabine has been investigated as an initial agent in advanced disease and for salvage therapy. As a single agent the results have been disappointing, with response rates below 5% in either setting (Okuno et al, 2003; Svancarova et al, 2002). The combination of gemcitabine and docetaxel in patients with unresectable leiomyosarcoma, however, demonstrated a 10% complete response and an overall response of 53%. It was believed to be a tolerable and active combination in treated and untreated patients (Hensley et al, 2002).

Disseminated intraperitoneal spread of disease is very difficult to treat. A novel approach is the application of photodynamic therapy (Bauer et al, 2001). In a preliminary report, patients underwent surgical debulking and were treated with porfirmer sodium (Photofrin) and laser light. Of an initial 11 patients, 5 demonstrated no evidence of disease over a range of 2 to 17 months. The advancement of such technologies and the implementation of small molecule therapy may provide improved outcomes for such patients in the future.

In advanced gastrointestinal stromal tumors the response to classic combination chemotherapy is negligible (Edmonson et al, 2002). Imatinib demonstrated an overall objective response rate of 53.7% and stable disease in 27.9% of patients (Demetri et al, 2002). Follow-up has demonstrated a median time to progression of 24 months and median overall survival of 57 months (Blanke et al, 2008). Sunitinib, another small-molecule tyrosine kinase inhibitor that affects multiple kinases, has demonstrated activity in imatinib-refractory/intolerant patients (Demetri et al, 2009). The success of targeted therapy in this lesion has encouraged further research using novel targeted therapy in other forms of metastatic retroperitoneal disease.

BASIC AND CLINICAL BIOLOGY

An upper urinary tract tumor can be defined as any neoplastic growth that affects the lining of the urinary tract from the calyces to the distal ureter. These tumors display behaviors that are similar to those of tumors arising in bladder, but they also have many characteristics that separate them from those tumors. For example, unlike bladder urothelial cancers, upper urinary tract cancers are relatively less common and are associated with several familial syndromes. They are more difficult to visualize directly and to reach with topical therapies; and, given the anatomic difference between the upper and lower urinary tracts in terms of muscle thickness and other factors, they may have different prognoses.

EPIDEMIOLOGY AND ETIOLOGY

Incidence and Mortality Rates

The etiology, natural history, pathology, detection, and staging of urothelial tumors are presented in Chapters 80, 81, and 82. Only the features that differentiate upper tract tumors from bladder tumors and that are pertinent to treatment are revisited here.

Upper urinary tract urothelial tumors involving the renal pelvis or ureter are relatively uncommon, accounting for 5% to 7% of all renal tumors and about 5% of all urothelial tumors (Fraley, 1978; Melamed and Reuter, 1993; Jemal et al, 2004). Because renal pelvic tumors generally are not reported separately, worldwide statistics vary substantially between nations and are not accurate. However, the highest incidence appears to occur in Balkan countries, where urothelial cancers represent 40% of all renal cancers.

The frequency of urothelial tumors of the upper tract is increasing, even though the tumors represent only a small percentage of all urothelial neoplasms (McCarron et al, 1982; Richie, 1988; Williams, 1991; Herr, 1998; Messing and Catalona, 1998; Munoz and Ellison, 2000; David et al, 2009). The peak incidence of upper tract tumors is 10 per 100,000 per year, occurring in the age range of 75 to 79 years. Fortunately, synchronous bilateral urothelial upper urinary tract tumors are very rare (Holmang and Johansson, 2004). In one series from Sweden the percentage of upper tract tumors that were bilateral was 1.6%, preceded in 80% of cases by a bladder cancer diagnosis. There may be a decreasing incidence of bilaterality secondary to the prohibition of phenacetin-containing analgesics in the 1960s. An evaluation of data from 1973 to 1996 with use of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database showed 9057 cases, 5379 of the renal pelvis and 3678 of the ureter. In comparison of age-adjusted annual incidence rates, an increase in ureteral neoplasms from 0.69 to 0.73 per 100,000 person-years was found but no change in the incidence of renal pelvic tumors was apparent. In addition, the rate of in-situ neoplasm increased from 7.2% to 23.1%. **The incidence of ureteral and renal pelvis tumors in the United States from 1985 to 1994 was 0.73 and 1.0 each per 100,000 person-years, respectively, based on the SEER database** (Munoz and Ellison, 2000). **The 5-year disease-specific survival was 75% overall and 95%, 88.9%, 62.5%, and 16.5% for in-situ, localized, regional, and distant disease, respectively.** Several factors account for this increase in survival for patients with upper tract tumors. Survival of patients with the more prevalent transitional cell carcinoma (TCC) of the bladder is improved owing to more effective diagnosis and treatment. This produces a length-time bias of longer time at risk for development of upper tract tumors. The National Cancer Data Base (NCDB) for the United States for the years 1993 to 2005 identified a total of 334,480 bladder cancers, 15,105 renal pelvis cancers, and 10,128 ureteral cancers (David et al, 2009). There was a significant increase in high-grade tumors in each of the sites during those years. The percentage of early stage tumors increased for both the renal pelvis and the ureter. However, overall, there was no change in survival during those years. Upper tract urothelial tumors are rarely diagnosed at autopsy but rather present clinically during the patient's lifetime (Resseguie et al, 1978). It also appears that the true incidence of upper tract tumors is increasing as the population ages. Patients with upper tract cancer are generally older than patients with bladder tumors (Melamed and Reuter, 1993). Upper tract tumors rarely present before the age of 40 years, and the mean age at presentation is 65 years (Anderstrom et al, 1989). **In conclusion there appears to be a slight increase in the U.S. national**

incidence of ureteral cancers during the past 2 decades. Fortunately, this has been associated with a slight improvement in the overall and disease-specific survival of patients with upper tract malignant neoplasms.

Key Point: Upper Tract Urothelial Tumors

- The frequency of urothelial tumors of the upper tract is increasing.

Variations by Sex and Race

Men are about twice as likely to develop upper urinary tract tumors as are women (Greenlee et al, 2000). In addition, whites are about twice as likely as African-Americans to develop upper tract tumors (Greenlee et al, 2000). On the other hand, SEER data suggest that disease-specific annual mortality is greater in black men than in white men (7.4% vs. 4.9%) and greater in women than in men (6.1% vs. 4.4%) (Munoz and Ellison, 2000). As is the case with bladder cancer, women who develop upper urinary tract cancer are 25% more likely than men to die of their disease (Greenlee et al, 2000). Accurate data regarding racial differences in mortality are not available.

Upper Urinary Tract Tumors after Known Bladder Cancer

On the basis of SEER data from the period 1973 to 1996, Rabbani and colleagues (2001) reported that upper urinary tract cancers developed in 657 of 91,245 cases of bladder cancer with adequate follow-up (median 4.1 years). The relative risk for upper urinary tract tumors for white men and women was 64.2% and 75.4% at or before 2 years, 44.3% and 40.5% at 2 to 5 years, 50.8% and 42.1% at 5 to 10 years, and 43.2% and 22.2% at more than 10 years, respectively. These authors concluded that the incidence of upper tract cancers is stable on long-term follow-up and that upper tract surveillance must remain rigorous for an extended period. **The incidence of upper tract recurrence has been shown to be higher in patients with carcinoma in situ than in patients with noninvasive papillary TCCs and in patients treated with cystectomy for carcinoma in situ rather than for invasive cancer** (Solsona et al, 1997; Premoli et al, 2006; Slaton et al, 1999). **Upper urinary tract recurrence is also more likely to occur with high-grade bladder cancer (hazard ratio [HR] 2.16), in T1 versus Ta disease (HR 1.16), and in patients with trigonal or periureteral presentation (HR 1.76)** (Wright et al, 2009). On pathologic evaluation, recurrence is most likely to be superficial (Ta, T1, Tis) and to occur in the distal ureter only (47%). However, this finding has not been reported in all series. For example, in patients with Ta, T1, and Tis bladder cancers treated with bacille Calmette-Guérin (BCG), Herr and colleagues (1996) reported a 21% upper tract recurrence rate after a median interval of 7.3 years; the majority of tumors were invasive, and 38.8% of patients with recurrence died of their upper urinary tract disease.

Etiology and Risk Factors

Balkan Nephropathy. Balkan nephropathy is characterized by a degenerative interstitial nephropathy occurring in Balkan countries. Afflicted families display a much higher incidence of upper urinary tract TCC, in some areas 100 to 200 times greater than in nonaffected individuals (Petkovic, 1975). Curiously, bladder cancer incidence is not affected. Tumors are generally of low grade and are more frequently multiple and bilateral than are upper tract TCCs due to other causes (Radovanovic et al, 1985). Balkan nephropathy is familial but not obviously inherited, suggesting an environmental etiology that has yet to be identified. **Recent studies suggest that dietary exposure to aristolochic acid may be responsible** (Grollman et al, 2007). Interestingly, family members who leave home early in life may not be affected (Radovanovic et al, 1985). **Overall, the incidence of this syndrome may be declining** (Stefanovic et al, 2008). **However, poorer outcomes are still seen in women (HR 2.2), with tumor size larger than 3 cm (HR 2.8), and with stage T3 or T4 disease (HR 3.1)** (Dragicevic et al, 2007).

Smoking. Cigarette smoking appears to be the most important of the modifiable risk factors for upper urinary tract cancer, producing an incidence three times that seen in nonsmokers. It appears that this risk is dose related, with a rate as high as 7.2 times normal for long-term (>45 years) smokers (McLaughlin et al, 1992). Former smokers also have a twofold increased risk compared with age-matched persons with no smoking history. This risk declines only partially after smoking ceases. In addition, the risk from smoking seems more often to lead to ureteral rather than to renal pelvic tumors.

Coffee Consumption. A relative risk of 1.8 times normal has been described in individuals who consumed more than seven cups of coffee per day (Ross et al, 1989). However, after controlling for cigarette smoking, this risk decreased to 1.3.

Analgesics. Analgesic abuse is a well-documented risk factor associated with the development of upper urinary tract cancers (Johansson et al, 1974; Morrison, 1984; McCredie et al, 1986). In one study, 22% of patients with renal pelvic tumors and 11% of patients with ureteral tumors reported a history of analgesic abuse with a latency period of approximately 2 years (Steffens and Nagel, 1988). Renal papillary necrosis and phenacetin consumption also appear to be independent but synergistic risk factors. Each alone resulted in relative risk factors of 6.9 and 3.6, respectively, but together increased risk 20 times (McCredie et al, 1986). Although phenacetin is the most well-described causative agent in analgesic nephropathy, most patients have reported taking combination preparations that included caffeine, codeine, acetaminophen, and aspirin or other salicylates (De Broe and Elseviers, 1998). Histologic findings associated with analgesic abuse include thickening of the basement membrane (pathognomonic) and papillary scarring. Thickening of the basement membrane has been demonstrated in 15% of patients with upper urinary tract tumors and should alert the physician to the presence of analgesic abuse and the subsequent risk of contralateral involvement (Palvio et al, 1987). The degree of papillary scarring also appears to be closely related to tumor grade, although not with the development of squamous metaplasia or squamous cancer (Stewart et al, 1999).

Arsenic. Excess inorganic arsenic in drinking water from artesian wells is a major health hazard in certain parts of the world and is associated with an increased risk of upper tract urothelial tumors in addition to other diseases (Tan et al, 2008). Chronic exposure to arsenic in southwestern Taiwan has long been associated with a form of peripheral vascular disease known as blackfoot disease that causes dry gangrene of the extremities. Throughout all regions of Taiwan an increased rate of upper tract urothelial tumors has been noted. These tumors behave in a similar fashion to other upper urinary tract tumors of similar grade and stage. However, there is a distinct female predominance of the upper

tract tumors seen in Taiwan in contrast to the male predominance seen in all other areas of the world. Some have postulated that the women may be exposed to arsenic fumes during cooking by steam heat over boiling water. If this is correct it implies an inhaled risk as well as the risk of ingestion from drinking water with high arsenic content.

Occupation. A significantly increased risk for upper urinary tract tumors has been reported for persons employed in chemical, petroleum, and plastic industries (relative risk of 4); patients with exposure to coal or coke (relative risk of 4); and patients with exposure to asphalt or tar (relative risk of 5.5) (Jensen et al, 1988). Aniline dyes, β-naphthylamine, and benzidine have been implicated as causative agents, and tumors can occur at long intervals (up to 15 years or more) after exposure.

Chronic Inflammation, Infection, or Exposure to Chemotherapeutic Agents. The development of squamous cell cancer (and less commonly adenocarcinoma) has been shown to be related to chronic bacterial infection associated with urinary stones and obstruction (Godec and Murrah, 1985; Spires et al, 1993). In addition, exposure to cyclophosphamide, an alkylating agent, also appears to confer an increased risk (Brenner and Schellhammer, 1987).

Heredity. Several familial syndromes have been associated with the development of upper tract TCC (Frischer et al, 1985; Orphali et al, 1986; Lynch et al, 1990). Lynch syndrome II, for example, is characterized by the early development of colonic tumors (without polyposis) and extracolonic neoplasms, including upper tract urothelial tumors. Unlike with nonhereditary cancers, these patients are typically younger (mean, 55 years) and are more likely to be female (Lynch et al, 1990).

NATURAL HISTORY

Location and Distribution of Tumors

Ureteral tumors occur more commonly in the lower than in the upper ureter. Overall, about 70% of ureteral tumors occur in the distal ureter, 25% in the midureter, and 5% in the proximal ureter (Anderstrom et al, 1989; Messing and Catalona, 1998). This phenomenon may be a reflection of downstream implantation. One area of consensus is that removal of the entire ureter is mandatory when upper urinary tract cancers are removed by nephroureterectomy. Bilateral involvement (either synchronous or metachronous) occurs in 1.6% to 6.0% of sporadic upper tract TCCs (Babaian et al, 1980; Murphy et al, 1981; Kang et al, 2003).

Patients with upper urinary tract tumors are at risk for development of bladder cancer, with an estimated incidence that varies in multiple reports from 15% to 75% within 5 years of the development of the upper tract cancer (Kakizoe et al, 1980; Huben et al, 1988; Anderstrom et al, 1989; Hisataki et al, 2000; Miyake et al, 2000; Kang et al, 2003). **This high incidence of metachronous bladder involvement suggests that routine bladder surveillance should be performed.** Why are upper tract cancers followed by bladder cancers more often than bladder cancers are followed by upper tract cancers? Theories include downstream seeding, longer exposure time to carcinogens in the bladder, and greater number of urothelial cells in the bladder that are subject to random carcinogenic events. Studies have suggested that in high-grade cancers (with associated *TP53* gene mutations), which also tend to be more rapidly recurrent, specific gene mutations noted in upper tract cancers are also demonstrated in subsequent bladder cancers (Harris and Neal, 1992; Lunec et al, 1992; Habuchi et al, 1993). In contrast, microsatellite studies in low-grade upper tract cancers, which tend to recur less rapidly in the bladder, have suggested genetic discordance between these upper tract tumors and subsequent bladder cancers in 46% of cases (Takahashi et al, 2000).

Upper tract cancers have traditionally been reported to develop in 2% to 4% of patients with bladder cancer, with a mean interval to recurrence of 17 to 170 months (Oldbring et al, 1989; Solsona et al, 1997; Rabbani et al, 2001). **Risk factors that have been reported to predict a higher likelihood of the development of upper tract cancers after bladder cancer treatment include stage, grade, multiplicity of tumors in the bladder, presence of ureteral reflux, presence of recurrent carcinoma in situ in the bladder after BCG treatment, multifocal carcinoma in situ in the bladder at the time of cystectomy, and presence of bladder cancers arising close to a ureteral orifice** (Zincke et al, 1984; Herr et al, 1992; Hudson and Herr, 1995). Two long-term follow-up series have reported that upper tract recurrence after bladder cancer diagnosis may be much higher than previously thought, occurring in approximately 25% of cases. This phenomenon may be the result of selection of patients, with more high-grade and dysplastic tumors reported in these series (Herr et al, 1996; Solsona et al, 1997).

Delayed recurrence is more common in the ureter than in the renal pelvis and appears to occur earlier (at 40 vs. 67 months). In patients treated with BCG for carcinoma in situ of the bladder, upper urinary tract cancer is even more common (about 30% of cases) and appears to occur distally (in the distal, juxtavesical, and intramural portions of the ureter), especially in those patients subjected to cystectomy whose disease is refractory to BCG. Therefore, in cases of high-risk bladder cancer (high-grade T1 disease or carcinoma in situ), imaging of the upper urinary tract should probably be performed annually as part of routine follow-up (Herr et al, 1996).

Upper tract urothelial cancers are often associated with a poor prognosis. Up to 19% of patients with upper tract TCC have been reported to present initially with metastatic disease (Akaza et al, 1970). **However, one recent study based on a four-institution review suggested that although upper tract urothelial cancers were more often invasive and more often poorly differentiated than bladder cancers, in pathologically matched cohorts recurrence with less aggressive disease, progression to more advanced disease, and death occurred with equal frequency among patients with upper tract and lower tract (bladder) urothelial cancers** (Catto et al, 2007). **Several studies have suggested that renal pelvic tumors have a better overall prognosis and 5-year disease-specific and recurrence-free survival than do ureteral tumors** (Park et al, 2004). **However, overall prognosis of upper tract tumors seems to be principally related to tumor stage and to a lesser degree to tumor grade.** In one series, 5-year survival was 100% for Ta and Tis, 91.7% for T1, 72.6% for T2, and 40.5% for T3 tumors. Multivariate analysis in this series showed that tumor stage ($P = .0001$) and age of the patient ($P = .042$) were the only statistically significant predictors of survival (Hall et al, 1998a).

Progression to Muscle Invasion and Metastases

The thin muscle layer of the renal pelvis and ureter probably allows earlier penetration of invasive upper tract tumors through the thinned muscle layer than is seen in bladder cancers (Cummings, 1980; Richie, 1988). In a recent report, 164 patients with

upper tract tumors were compared with 2197 patients with bladder cancer. High-grade and deeply invasive TCC occurred in 28.2% of bladder cancers compared with 39.5% of upper tract tumors (Stewart et al, 2005). The renal parenchyma itself may be a barrier to the spread of stage T3 cancers, whereas periureteral tumor extension is a risk factor for early tumor dissemination (Batata and Grabstald, 1976; Guinan et al, 1992a). This anatomic phenomenon may be at least part of the explanation as to why renal pelvic tumors appear to have a better prognosis than ureteral tumors. In one large series of 611 patients treated at 97 hospitals, the 5-year survival rates of patients with stage T3 tumors of the renal pelvis and ureter were 54% and 24%, respectively (Guinan et al, 1992a).

Patterns of Spread

TCCs of the upper urinary tract may spread in several different ways, including direct invasion into the renal parenchyma or surrounding structures, lymphatic or vascular invasion, and epithelial spread by seeding or direct extension. It is clear that high-grade tumors demonstrate a greater propensity to invade and that renal parenchymal invasion is the most significant predictor of the development of metastases (95%), followed by vascular invasion (83%) and lymphatic invasion (77%) (Davis et al, 1987).

Epithelial. To describe the clonal nature of urothelial tumors of the bladder and upper tract, two theories of the nature of this phenomenon have been proposed. The monoclonality theory describes the multiple tumors as the descendants of a single genetically transformed cell that populates the urothelium. In contrast, the field theory assumes a diffuse "cancerization" that is the result of exposure to a carcinogen and results in the independent development of nonrelated tumors at different sites. Although the majority of the evidence supports the monoclonality theory, most of this evidence has resulted from the study of advanced invasive cancers. It seems that a small but significant proportion of multifocal cancers are, in fact, derived from different clones (Hafner et al, 2002).

Epithelial spreading may occur in both antegrade (most common) and retrograde manners. Antegrade seeding is thought to be the most likely explanation for the high incidence of recurrence in patients in whom a ureteral stump is left in situ after nephrectomy and incomplete ureterectomy (Johnson and Babaian, 1979).

Lymphatic. Lymphatic spread from the upper urinary tract extends to the para-aortic, paracaval, and ipsilateral common iliac and pelvic lymph nodes (Batata and Grabstald, 1976). This extension, of course, depends on the location of the primary tumor and is directly related to the depth of invasion of the primary tumor. Whether lymphadenectomy should be performed routinely and the extent of lymphadenectomy remain controversial (Nakazono and Muraki, 1993; Komatsu et al, 1997). In a series of nephroureterectomy and lymph node dissection, Secin and associates (2005) reported positive lymph nodes in 20% of cases (mean number of lymph nodes sampled, 7.3; range, 1 to 17). Death from disease was 25% for patients with N0 tumors compared with 66.7% in the N1-2 group ($P < .001$). In this series the presence of suspicious lymph nodes on preoperative imaging studies was the only preoperative predictor of lymph node metastasis on multivariate analysis ($P = .02$).

Hematogenous. The most common sites of hematogenous metastases from upper tract tumors are the liver, lung, and bone (Batata et al, 1975). Although it is very rare, direct extension into the renal veins and vena cava may occur in renal pelvic tumors (Jitsukawa et al, 1985; Geiger et al, 1986).

PATHOLOGY

The majority of upper tract tumors are urothelial cancers. Of these, the majority are transitional cell in origin; squamous cell cancers and adenocarcinomas represent a small minority (Bennington et al, 1975; Vincente et al, 1995; Flanigan and Kim, 2004).

Normal Upper Tract Urothelium

The urothelial lining of the upper urinary tract closely approximates that of the bladder except for the markedly reduced thickness of the muscle layer and the abutting of the urothelium to the renal parenchyma proximally. The epithelial layer is continuous from the level of the calyces to the distal ureter. It has been postulated that the urothelial layer may even "extend" into the collecting ducts, raising the possibility that collecting duct renal cancers may be closely related to urothelial cancers and perhaps better treated by agents used for urothelial cancers (Orsola et al, 2005). This observation needs further confirmation.

Renal Pelvis and Calyces. The walls of the calyces and the pelvis contain fibrous connective tissue and two layers of smooth muscle and are lined on their inner surfaces by transitional epithelium (Dixon and Gosling, 1982) (Figs. 53–1 and 53–2). Thin muscle layers originate in the minor calyces and form a spiral, helical arrangement (Fig. 53–3).

Ureter. The ureter demonstrates two continuous thin muscle layers with a loosely spiraled internal layer and a more tightly

Figure 53–1. Low-magnification view of a section through the kidney. The renal medulla ends in the pointed renal papilla. Urine empties into the Y-shaped space made up of the renal calyces (the arms of the Y) and the pelvis (the base of the Y).

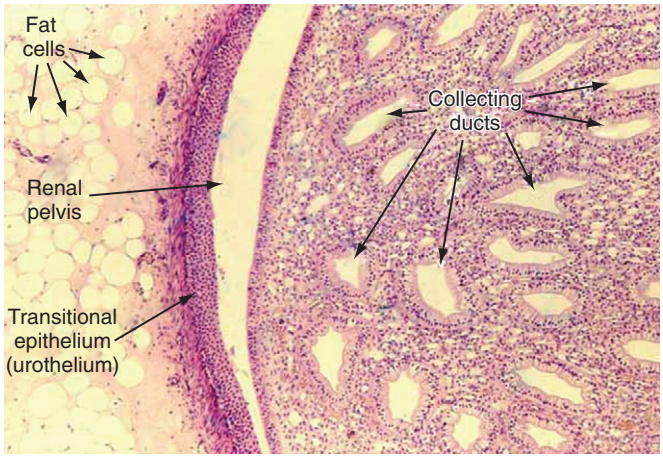

Figure 53–2. This image shows several large collecting ducts near the end of a medullary pyramid (i.e., close to their opening into the pelvis). The transitional epithelium of the renal pelvis is continuous with that of the ureters and bladder.

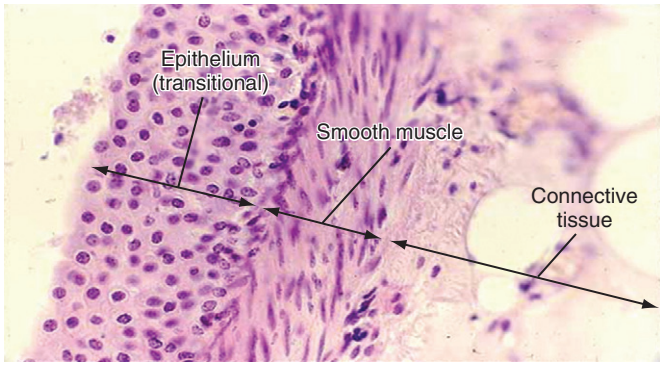

Figure 53–3. In this specimen from the renal pelvis the connective tissue immediately beneath the epithelium is inconspicuous, obscured by a layer of smooth muscle (note elongated nuclei). Beneath the smooth muscle is loose connective tissue, including conspicuous adipocytes.

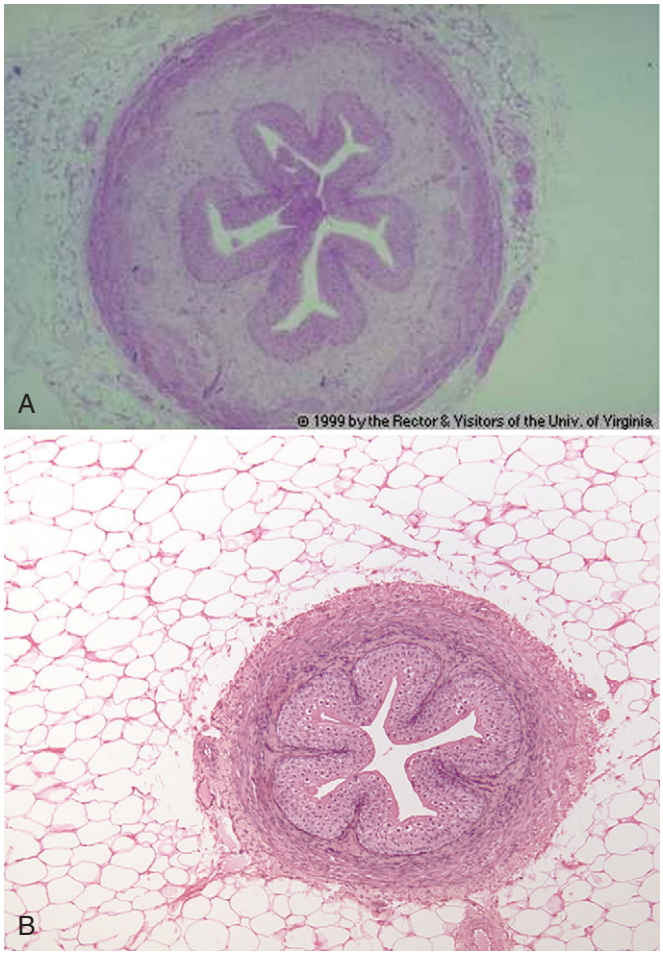

Figure 53–4. **A** and **B,** Cross section of ureter. The ureter has an irregular lumen, which is lined by transitional epithelium. Under the epithelium is a connective tissue layer and, beneath that, three layers of smooth muscle: inner longitudinal, middle circular, and outer longitudinal. (**A,** © 1999, Rector & Visitors of the University of Virginia.)

spiraled external layer. In the lower third of the ureter, a third outer longitudinal layer is present. All three layers merge with the three layers (inner longitudinal, middle circular, and outer longitudinal) of the bladder wall, which run longitudinally, transversely, and obliquely. Beneath the outer muscle coat is the serosa, made up of loose connective tissue and containing blood vessels and lymphatics (Hanna et al, 1976; Notley, 1978) (Figs. 53–4 and 53–5).

Abnormal Urothelium

Metaplasia and Dysplasia. **Several studies have suggested that upper tract urothelial cancers progress through histologic changes from hyperplasia to dysplasia to frank carcinoma in situ in a significant proportion of patients** (Heney et al, 1981; McCarron et al, 1982). Carcinoma in situ may be patchy and may extend proximally to the collecting ducts of the kidney (Mahadevia et al, 1983). More severe urothelial dysplastic changes are associated with a greater risk for tumor recurrence in the distal ureter and bladder and a reduced prognosis.

Benign Lesions: Inverted Papillomas and von Brunn Nests. Inverted papillomas, although generally considered benign lesions, often have been shown to be associated with either synchronous or

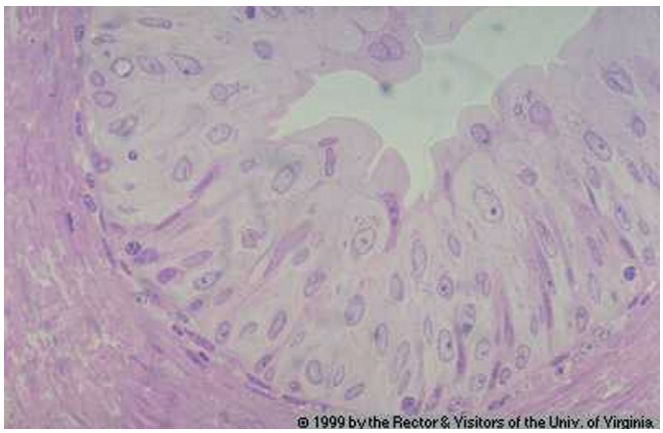

Figure 53–5. Transitional epithelium and loose connective tissue that compose the mucosa of the urinary tract. Transitional epithelium superficially resembles nonkeratinized stratified squamous epithelium, but note that the epithelial cells nearest to the apical (outer) surface are not flattened but cuboidal. Transitional epithelium is a stratified epithelium characterized by the fact that the most apical cells are the roundest and largest in diameter. It is designed to be able to increase its surface area as the lumen is dilated by urine. (© 1999, Rector & Visitors of the University of Virginia.)

metachronous upper tract urothelial tumors (Renfer et al, 1988; Stower et al, 1990; Chan et al, 1996; Cheville et al, 2000). One series demonstrated an 18% incidence of malignancy associated with inverted papilloma of the ureter (Grainger et al, 1990). Other studies have suggested that there are two types of urinary inverted papilloma. The lesions of type 1 behave in a benign fashion, whereas those of type 2 may have a malignant potential. Because there is currently no way to distinguish between these two types, it has been advised that follow-up for all cases of inverted papilloma be continued for at least 2 years after initial diagnosis (Asano et al, 2003). Similarly, these findings suggest close surveillance of the upper tracts for malignancy is warranted when inverted papilloma is diagnosed.

Transitional Cell Carcinoma. TCC makes up more than 90% of upper urinary tract tumors, may present as papillary or sessile lesions, and may be unifocal or multifocal. On histologic examination these lesions are similar to TCCs of the bladder, but the relative thinness of the muscle layer of the renal pelvis and ureter makes invasion through the muscle coat an earlier event. Carcinoma in situ, as in the bladder, can be particularly difficult to identify and can vary in appearance from a whitish plaque to epithelial hyperplasia or a velvety red patch due to increased submucosal vascularity (Melamed and Reuter, 1993). Progression to muscle invasion or invasion into the renal parenchyma or adventitial tissues may occur and is more likely, given the relative thinness of the muscle coat of the upper tracts.

Non–Transitional Cell Carcinoma. Non-TCCs of the upper tracts represent a wide spectrum of lesions, from benign to highly malignant. The most common of these are squamous cell cancers and adenocarcinomas.

Squamous Cell Cancers. Squamous cell cancers make up 0.7% to 7.0% of upper urinary tract cancers (Babaian and Johnson, 1980; Blacker et al, 1985). They are frequently associated with a condition of chronic inflammation or infection or with analgesic abuse (Stewart et al, 1999). These tumors occur six times more frequently in the renal pelvis than in the ureter and are generally moderately to poorly differentiated and more likely to be invasive at the time of presentation.

Adenocarcinomas. Adenocarcinomas account for less than 1% of all renal pelvic tumors and are typically associated with long-term obstruction, inflammation, or urinary calculi (Stein et al, 1988; Spires et al, 1993). These tumors typically present at advanced stage and display a poor prognosis.

Micropapillary Variant. A micropapillary variant of TCC in the bladder is associated with aggressive behavior and poor outcome. This histologic subtype is very rare in the upper urinary tract. Holmang and associates (2006) described 26 patients with this entity in the upper urinary tract. Twenty-two patients had stage T3 disease at presentation, and carcinoma in situ or lymphovascular invasion was noted in 64% and 81% of cases, respectively. Five-year survival was only 26.9%, and overall the disease-specific mortality was 77%.

Other Miscellaneous Tumors. Fibroepithelial polyps (benign) (Musselman and Kay, 1986; Blank et al, 1987) and neurofibromas (benign) (Varela-Duran, 1987) are uncommon lesions that are typically treated by simple excision.

Multiple types of sarcomas have also been reported to involve the upper urinary tracts, including leiomyosarcomas (Madgar et al, 1988), plasmacytomas (Igel et al, 1991), and angiosarcomas (Coup, 1988). Because of the rare nature of these tumors they are typically treated by excision with adjuvant therapy that is based on the experience with tumors of similar histology occurring elsewhere in the body.

PROGNOSTIC FACTORS

Stage. **Stage is currently the most important predictor of survival in patients with upper tract urothelial tumors** (Png et al, 2008). The most commonly used staging system is the TNM system (see later section on staging). Upper tract cancers can spread by direct invasion, mucosal seeding, and hematologic and lymphatic routes. Prognosis decreases as stage increases; the most significant decrease in survival is observed in T3 tumors that have penetrated into the perirenal or periureteral fat (Grabstald et al, 1971).

Grade. The traditional grading system used for bladder cancer is also applicable to upper urinary tract tumors. Broder's original system, modified by Ash, grades tumors from grade 1 to grade 4: grade 1 tumors are primarily papillomas, and grade 4 tumors are highly anaplastic and poorly differentiated tumors (Melamed and Reuter, 1993). The World Health Organization's system, proposed by Mostofi, eliminates papillomas and grades tumors from grade 1 to grade 3. Recently, tumor grading has been divided into low grade and high grade (Epstein, 1998). Papillomas and papillary urothelial neoplasms of low malignant potential are also described. **Certainly, tumors of high grade are more likely to invade into the underlying connective tissue, muscle, and surrounding tissues. Tumors of high grade are also more likely to be associated with concomitant carcinoma in situ.**

Location. There remains disagreement as to whether the location of an upper tract tumor affects prognosis. Several studies have suggested that renal pelvic tumors have a better prognosis than ureteral cancers (Park et al, 2004). In contrast, others have argued that when renal pelvic and ureteral tumors are matched for stage there is no significant difference in prognosis (Hall et al, 1998b).

Associated Carcinoma in Situ. **As in bladder cancer, carcinoma in situ of the upper tract is associated with a poor prognosis and a likelihood of future development of invasive urothelial cancers.** Carcinoma in situ of the distal ureter is most common in patients with bladder carcinoma in situ treated with BCG (30% likelihood).

Lymphovascular Invasion. **Lymphovascular invasion has been suggested to be an independent prognostic factor for disease-specific survival in upper tract TCC.** In a Japanese study, 173 consecutive patients undergoing surgical treatment of upper tract TCC had lymphovascular invasion determined (Kikuchi et al, 2005). Lymphovascular invasion was found in 30% of cases and was more frequent in advanced pathologic stage. Overall 5- and 10-year survival rates were 84.9% and 80.4%, respectively, in the absence of lymphovascular invasion compared with 40.2% and 21.1% with lymphovascular invasion. In three recent single-center and two multicenter series including a total of 1841 patients with upper tract tumors, the prevalence of lymphovascular invasion varied from 23.7% to 37.8%. Lymphovascular invasion correlated with increasing tumor stage and grade and with disease recurrence and disease-specific survival (Akao et al, 2008; Bolenz et al, 2008; Lin et al, 2008; Chung et al, 2009). In multivariate analysis, lymphovascular invasion was an independent and stronger predictor of recurrence and survival than were tumor stage or grade. Kikuchi and colleagues (2009) reported on a large international, 13-center collaborative series of 1453 patients who underwent radical nephroureterectomy for upper tract urothelial tumors. The overall prevalence of lymphovascular invasion was 24%. Lymphovascular invasion correlated with tumor grade stage, lymph node status, and tumor necrosis. In multivariate analysis, lymphovascular invasion was an independent predictor

of disease recurrence and survival for patients with either negative lymph nodes or unknown nodal status. However, lymphovascular invasion was not an independent predictor of outcome for patients with positive lymph nodes. Further prospective, large-scale studies are needed to confirm these observations. As with bladder and other solid organ cancers, lymphovascular invasion is the presumed mechanism that leads to regional lymph node and to systemic hematogenous metastases.

Molecular Biology (Chromosome Abnormalities) and Markers. The molecular and genetic basis of upper tract TCCs appears to be similar to that of TCCs of the bladder. These events have been better described in bladder cancers and are reported in detail in Chapter 80. Briefly, the genetic events leading to the development of upper tract tumors seem to be associated with the overexpression of tumor suppressor genes, including *TP53* (on chromosome 17p), the retinoblastoma gene (*RB*) on chromosome 13q, and several gene foci on chromosome 9 (including the genes for CDKN2C [formerly p18] and CDKN2A [formerly p16] proteins located at 9p21 and 9p32-33). It is generally thought that chromosome 9 abnormalities occur early in the development of these cancers but are not typically associated with high-grade and dysplastic changes, whereas *TP53* is more often associated with increased grade and dysplasia. It would also seem, however, that by the time the tumor has been able to invade into the lamina propria both genetic events are likely to have occurred (Spruck et al, 1994). Zigeuner and associates (2004) reported that decreased TP53 immunoreactivity and TP53 overexpression in upper tract tumors were associated with advanced tumor stage and poor prognosis. However, the findings were not independent of stage and grade in multivariate analysis. Eltz and associates (2008) provided a comprehensive review of molecular markers in upper tract urothelial tumors.

TP53. The TP53 nuclear protein staining of cytology specimens obtained ureteroscopically appears to correlate well with the presence of upper tract TCC. In one study, of 36 TP53-positive specimens 28 had simultaneous evidence of upper tract TCC; 80% of the remaining patients who were evaluated serially also had confirmed TCC. All 14 TP53-negative studies occurred in patients with no sign of concurrent malignant disease on ureteroscopy (Keeley et al, 1997b).

c-MET. Recently the roles of c-*MET* and *RON,* members of the *MET* proto-oncogene family of tyrosine kinases, have been studied in upper urinary tract tumors (Compérat et al, 2008). c-*MET* overexpression correlated with vascular invasion and a worse clinical outcome, whereas that of *RON* did not correlate with outcome.

COX-2. Abnormal expression of cyclooxygenase-2 (COX-2) has been reported in many forms of human cancer, including bladder urothelial cancer. Kang and coworkers (2008) reported abnormal expression of COX-2 in stromal cells of upper urinary tract cancers correlated with high tumor stage and grade and poor prognosis.

CDKN1B. CDKN1B (formerly p27), a cyclin-dependent kinase inhibitor, has also been shown to predict the prognosis of upper tract tumors. In one study, low levels of CDKN1B staining were indicative of a worse disease-specific survival (Kamai et al, 2000).

Loss of Heterozygosity. Loss of heterozygosity at 9p21 has been observed in bladder cancer and now in upper tract TCC by microsatellite instability analysis. It has been shown that TCC can occur in patients with hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. Patients with this syndrome show genomic lesions in DNA mismatch repair genes (Amira et al, 2003). Furthermore, an inverted growth pattern of cancer has also been associated with microsatellite instability, with a sensitivity and specificity of 0.82 in one study. This finding suggests that microsatellite instability may serve as a marker for inverted growth in upper urinary tract cancers (Hartmann et al, 2003). Ho and coworkers (2008) have reported that a urine-based assay testing for a total panel of 77 markers for microsatellite instability in 30 patients detected 83.3% of cases of an upper urinary tract tumor.

Ploidy-Flow Cytometry. Tumor ploidy has been shown to correlate with survival in upper tract tumors. In one study, tumor aneuploidy was associated with poor 5- and 10-year survival rates of 25% and 0%, respectively (Blute et al, 1988).

Overexpression of Hypoxia-Inducible Factor-1α (HIF-1α). **HIF-1α is a transcription factor that plays an important role in cellular hypoxia adaptation. In a series of patients with upper tract urothelial cancer, positive HIF-1α expression was found in two thirds of cases (was absent in normal urothelium). HIF-1α was significantly associated with high T stage, nodal stage, and grade as well as cancer-specific survival (HR 2.23, *P* = .004)** (Ke et al, 2008).

Other Markers. Rapid urine tests for urothelial malignant neoplasms have been studied extensively for the purpose of identifying lower urinary tract tumors. Less is known about their value in upper tract cancers. Urinary levels of NMP22, a nuclear matrix protein–based marker, have been found to be elevated in patients with upper tract cancer (Carpinito et al, 1996). Although the sensitivity of this test for determining the presence of low-grade tumors is probably higher than that of cytology, the specificity is low. Recently, urine fluorescence in-situ hybridization (FISH) was reported to have a sensitivity of 87.5% and a specificity of 80% for detection of upper tract tumors in a small series (Akkad et al, 2007).

In one series, an analysis of fibrinogen-fibrin degradation products (AuraTek FDP) was compared with the bladder tumor antigen (BTA) test and urine cytology. In this study, the accuracy of the FDP test was 83% compared with 62% for BTA and 59% for cytology (Siemens et al, 2003). Telomerase activity has been shown to be present in most (>95%) upper tract urothelial cancers. It can be detected in exfoliated urinary specimens in a high percentage of patients and thus may prove to be a potentially useful marker (in addition to conventional cytology) to identify upper tract cancers (Wu et al, 2000).

DIAGNOSIS

Symptoms and Signs

The most common presenting symptom of upper tract urothelial tumors is hematuria, either gross or microscopic. This occurs in 56% to 98% of patients (Murphy et al, 1981; Guinan et al, 1992a; Raabe et al, 1992). Flank pain is the second most common symptom, occurring in 30% of tumors. This pain is typically dull and believed to be secondary to a gradual onset of obstruction and hydronephrotic distention. In some cases, pain can be acute and mimic renal colic, typically ascribed to the passage of clots that acutely obstruct the collecting system. These common symptoms of localized disease (hematuria, dysuria) and of advanced upper tract tumors (weight loss, fatigue, anemia, bone pain) are similar in type and frequency to those of bladder cancer. However, flank pain due to obstruction by tumor or clot is more prevalent in upper tract tumors, having been reported in 10% to 40% of cases (Babaian and Johnson, 1980; McCarron et al, 1983; Richie, 1988; Williams, 1991; Melamed and Reuter, 1993). Flank pain in patients with upper tract tumors does not correlate with either locally advanced tumor stage or worse prognosis, as is

the case with bladder cancer. About 15% of patients are asymptomatic at presentation and are diagnosed when an incidental lesion is found on radiologic evaluation. Patients may also present with symptoms of advanced disease, including flank or abdominal mass, weight loss, anorexia, and bone pain. Nearly all upper tract tumors are diagnosed during the patient's life, and therefore upper tract urothelial cancer represents a rare autopsy finding (Ressequie et al, 1978).

Radiologic Evaluation

Although intravenous pyelography has been the traditional means for diagnosis of upper tract lesions, computed tomographic (CT) urography is increasingly performed today. CT is easier to perform and less labor intensive than intravenous pyelography. It also has a higher degree of accuracy in determining the presence of renal parenchymal lesions. On the other hand, small urinary filling defects (<5 mm) may be missed between the "cuts" of the traditional CT scan. More recently, CT urography has been performed to obtain a three-dimensional image of the upper tracts. This technique appears to be equal to intravenous pyelography in imaging the ureters and renal pelvis (McTavish et al, 2002). With CT urography, the sensitivity for detecting upper tract malignant disease has been reported to approach 100%, with a specificity of 60% and a negative predictive value of 100% (Caoili et al, 2002). CT urography does, however, expose the patient to higher doses of radiation.

Radiolucent filling defects, obstruction or incomplete filling of a part of the upper tract, and nonvisualization of the collecting system are the typical findings suggestive of an upper urinary tract tumor. Filling defects, which account for 50% to 75% of cases, typically require the intravenous administration of contrast material to be identified (Murphy et al, 1981; Fein and McClennan, 1986). The differential diagnosis of these defects includes blood clot, stones, overlying bowel gas, external compression, sloughed papilla, and fungus ball. Stones can be ruled out most easily by confirmation of calcification by renal ultrasonography or CT. TCCs have an average density of 46 Hounsfield units (HU) and a range of 10 to 70 HU (Lantz and Hattery, 1984). This is in contrast to an average of 100 HU seen in radiolucent uric acid stones (range, 80 to 250 HU). Thus CT can be useful in distinguishing between these two common causes of radiolucent filling defect on excretory urography or retrograde ureterography. The impact of hydronephrosis and nonvisualization for renal pelvis tumors versus ureteral tumors as indicators of a higher stage is uncertain. Nonvisualization is reported in 20% of renal pelvis tumors, only 33% of which are invasive (McCarron et al, 1983). Nonvisualization is reported in 37% to 45% of ureteral tumors and carried a 60% risk of invasion in one series (McCarron et al, 1983). In other reports there is no correlation of nonvisualization and stage (Batata and Grabstald, 1976; Anderstrom et al, 1989). Hydronephrosis with or without an associated filling defect is linked with invasion in 80% of ureteral tumors (McCarron et al, 1983; Cho et al, 2007).

Radiolucent, noncalcified lesions may require additional evaluation by retrograde urography or ureteroscopy, with or without biopsy and cytology. Overall, retrograde urography has an accuracy of 75% in diagnosis of an upper tract malignant neoplasm (Murphy et al, 1981). An incompletely filled or obstructed renal infundibulum or calyx, occurring in 10% to 30% of cases, again typically requires retrograde urography or ureteroscopy to confirm the diagnosis. Obstruction of the urinary tract is a poor prognostic sign for tumor invasion (Babaian and Johnson, 1980).

Evaluation of the contralateral kidney is important not only because of possible bilaterality of the disease but also because it allows a determination of the functionality of the contralateral kidney. This is an extremely important part of the management process. At times, a split-function renal scan may be helpful in determining the contribution of both the "diseased" and the presumed "normal" kidney to the patient's overall renal function.

Some have suggested that ultrasonography has sensitivity equal to that of urography in evaluating patients with painless gross hematuria for upper tract malignant disease (Yip et al, 1999; Data et al, 2002). For staging purposes, CT or magnetic resonance imaging (MRI) is most useful in determining the extent of invasion, an associated mass lesion outside the collecting system, and the presence of lymph node or distant metastases (Milestone et al, 1990). CT is also more sensitive than conventional radiography in determining minimally radiopaque substances, making it useful in identifying urine excreted by poorly functioning areas of kidney (as in obstructed areas) (Kenney and Stanley, 1987). The greatest downside of CT or MRI is in the detection of small lesions that may be lost in volume averaging. In one series, CT predicted TNM stage in 60% of patients; it understaged 16% and overstaged 24% (Scolieri et al, 2000).

Cystoscopy

Because upper urinary tract tumors are often associated with bladder cancers, cystoscopy is mandatory in the evaluation to exclude coexistent bladder lesions.

Ureteroscopic Evaluation and Biopsy

The technical advances achieved in the realm of endoscopic equipment have made the flexible and rigid ureteroscope a key part of the evaluation (and treatment) of upper urinary tract tumors. **Diagnostic accuracy can be improved from approximately 75% with excretory or retrograde urography alone to 85% to 90% when it is combined with ureteroscopy** (Streem et al, 1986; Blute et al, 1989). Although pyelovenous and pyelolymphatic migration has been reported with ureteroscopy, this phenomenon appears to be uncommon and should not preclude its use (Lim et al, 1993).

As with bladder tumors, 55% to 75% of ureteral tumors are low grade and low stage (Cummings, 1980; Richie, 1988; Williams, 1991). **Also, like bladder cancers, approximately 85% of renal pelvic tumors are papillary and the remainder sessile.** Invasion of the lamina propria or muscle (stage T1 or T2) occurs in 50% of papillary and in more than 80% of sessile tumors. Overall, therefore, 50% to 60% of renal pelvic tumors are invasive into either the lamina propria or muscle. In ureteral tumors, invasion is also more common than in bladder tumors (Anderstrom et al, 1989; Williams, 1991).

In addition to visualization of the tumor, ureteroscopy allows more accurate biopsy of suspected areas, with either biopsy forceps or brushing. Good histologic correlation (78% to 92%) between the ureteroscopic biopsy specimen and the final pathologic specimen has been established (Keeley et al, 1997c; Guarnizo et al, 2000). It appears that fresh samples obtained ureteroscopically provide the best chance of predicting eventual pathologic findings. In one study, a cell block from biopsy specimens was prepared when a visible tumor was present, and grades of ureteroscopic biopsy specimens were compared with grades and stages of surgical specimens in 42 cases. Of 30 low- or moderate-grade

specimens, 29 (90%) proved to be low- or moderate-grade TCC; 11 of 12 high-grade specimens (92%) proved to be high-grade TCC, and 8 (67%) were invasive (T2 or T3) (Keeley et al, 1997c). In contrast, the urologist's impression of the tumor grade based on ureteroscopic appearance is likely to be correct in only 70% of cases, suggesting that biopsy is also needed to further define this important aspect of staging (El-Hakim et al, 2004).

Because of the small size of ureteroscopic biopsy specimens, a precise correlation with eventual tumor *stage* is difficult. Therefore, in predicting the tumor stage, a combination of the radiographic studies, the visualized appearance of the tumor, and the tumor grade provides the surgeon with the best estimation of eventual tumor stage. Although, as stated earlier, grading of the tumors may be fairly accurate, staging is much more problematic. Of 40 urothelial tumors staged in one series (40% in the renal pelvis, 20% in the proximal ureter, and 40% in the distal ureter), ureteroscopic grade matched surgical grade in 78% of cases and was less than surgical grade in the remaining 22%. Lamina propria was present in 68% of biopsy specimens (62% of cup biopsies and 100% of loop biopsies), but tumors thought to be Ta were upstaged to T1 to T3 in 45% of cases at the time of complete resection of the lesion (Guarnizo et al, 2000). Therefore, accurate tumor grading on ureteroscopic biopsy is critical in estimating tumor stage. In one series, a biopsy specimen showing grade 3 tumor accurately predicted tumor stage in more than 90% of cases (Skolarikos et al, 2003).

Is ureteroscopy (with or without biopsy) necessary in all cases of suspected upper tract tumors? No. In fact, ureteroscopy should probably be reserved for situations in which the diagnosis remains in question after conventional radiographic studies and for those patients in whom the treatment plan may be modified on the basis of the ureteroscopic findings, for example, endoscopic resection. Although there is no evidence that ureteroscopy diminishes the prognosis of a patient destined to proceed to nephroureterectomy, and although the risks of tumor seeding, extravasations, and dissemination are low in experienced hands, these risks are real and should preclude ureteroscopy when it is unnecessary (Hendin et al, 1999).

Antegrade Endoscopy

In some cases of upper tract tumors, percutaneous access to the renal pelvis may be required for diagnosis or treatment. In such cases, antegrade urography and uroscopy may be useful for tumor resection, biopsy, or simple visualization. Larger-caliber scopes that can be passed into the renal pelvis in this manner may be particularly helpful in resecting or debulking larger volumes of tumor in this area (Streem et al, 1986; Blute et al, 1989). One must remember, however, that tumor cell implantation in the retroperitoneum and along the nephrostomy tube tract has been reported after these procedures (Tomera et al, 1982; Huang et al, 1995).

Role of Cytology and Other Tumor Markers

Urine cytology is a specific tool that is useful in the diagnosis of upper tract carcinomas. On the other hand, the sensitivity of cytology remains an issue. In general, the sensitivity of voided urine (or bladder wash) cytology is directly related to tumor grade. Overall accuracy estimates of the sensitivity of cytology have ranged from about 20% for grade 1 tumors to 45% and 75% for grade 2 and grade 3 tumors, respectively (Murphy and Soloway, 1982; Konety and Getzenberg, 2001).

Even if a voided cytology specimen is abnormal in a patient with an upper tract filling defect, one must be cautious in determining the site of origin of the malignant cells. Ureteral catheterization for collection of urine or washings may provide more accurate cytologic results. However, even in this setting, a substantial false-negative or false-positive result (22% to 35%) can be expected (Zincke et al, 1976). It would appear that saline washing provides a better cell yield and improves cytologic results secondary to the release by hydroscopic forces of loosely adherent cells from the urothelium. Still better accuracy can be achieved by brush biopsy through a retrograde catheter or ureteroscope. Sensitivity in the 90% range with specificity approaching 90% may be possible with these techniques (Streem et al, 1986; Blute et al, 1989). Brush biopsies have, however, also been reported to result in severe complications, including massive hemorrhage and perforation of the urinary tract with extravasation (Blute et al, 1981).

It appears that the exposure of urothelial cells to ionic, high-osmolar contrast agents as in retrograde pyelography may worsen cytologic abnormalities. Thus, it is probably prudent to obtain cytologic specimens before the use of these agents (Terris, 2004).

Early results suggest that FISH also may be useful in the diagnosis of upper tract urothelial tumors. In a study of 21 consecutive upper urinary tract urothelial cancer patients and 10 healthy controls using FISH probes for chromosomes 3, 7, 17, and the *CDKN2A* (9p21) gene, overall sensitivity of FISH was significantly higher than that of cytology while specificity for both was 100% (Luo et al, 2009).

STAGING

The staging of upper urinary tract tumors parallels the staging of bladder tumors and is presented in Chapter 80.

TNM Staging System

The TNM classification and staging system is the most commonly used. A comparison of the American Joint Committee on Cancer (AJCC) staging system and the TNM system is presented in Table 53–1.

The histologic characteristics and biology of upper tract tumors still affect treatment decisions, technologic improvements notwithstanding. The entity of benign papilloma, which responds favorably regardless of the extent of treatment, is well described in older series of upper tract tumors (Bloom et al, 1970; Batata and Grabstald, 1976). The existence of similar low-grade papillomas of low-grade malignant potential in the bladder remains controversial (Cheng et al, 1999; Cheng and Bostwick, 2000; Oyasu, 2000). It is unclear whether the differences between upper tract papillomas and bladder papillomas are biologic or semantic. **Approximately 85% of renal pelvis tumors are papillary;** the remainder are sessile. This distribution is similar to that of bladder tumors. However, the stage of upper tract tumors is T1 or T2 in approximately 50% of papillary and 80% of sessile lesions, respectively (Cummings, 1980; Richie, 1988; Williams, 1991). Thus, 50% to 60% of renal pelvis tumors are invasive, in contrast to most bladder tumors, which are noninvasive; 55% to 75% of ureteral tumors are low grade and low stage, but invasion is still more common than among bladder tumors (Anderstrom et al, 1989; Williams, 1991). Patients with upper urinary tract tumors present most often in the sixth or seventh decade of life and thus are

Table 53–1.

AJCC and TNM Staging and Classification Systems for Upper Urinary Tract Tumors

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades the muscularis.
T3	Tumor invades periureteral fat (for renal pelvis only). Tumor invades beyond muscularis into perinephric fat or the renal parenchyma.
T4	Tumor invades adjacent organ or through the kidney into the perinephric fat.
Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases
N1	Metastasis to a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

AJCC Staging System	TNM Classification System
0	T0
I	Ta, Tis, T1, N0, M0
II	T2, N0, M0
III	T3, N0, M0
IV	T4 or any T, N+, M+

AJCC, American Joint Committee on Cancer.

generally older than patients with bladder tumors (Melamed and Reuter, 1993).

Tumors of the renal pelvis are slightly more common than ureteral tumors (Batata and Grabstald, 1976; Richie, 1988; Maulard-Durdux et al, 1996). Ureteral tumors occur in the distal, middle, and proximal segments in 70%, 25%, and 5% of cases, respectively (Babaian and Johnson, 1980; Anderstrom et al, 1989; Williams, 1991; Messing and Catalona, 1998). **After conservative treatment, ipsilateral upper tract tumor recurrence is common in a proximal to distal direction and is seen in 33% to 55% of cases** (Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983). Recurrence proximal to the original lesion is rare.

Key Point: Upper Tract Tumor Recurrence

- Multiple upper tract recurrences are common in a proximal to distal direction.

This high rate of ipsilateral recurrence is due in part to a multifocal field change, which is even more pronounced than in bladder cancer. Areas of atypia, dysplasia, or carcinoma in situ are reported in 60% to 95% of specimens after nephroureterectomy for renal pelvis tumor (Johansson et al, 1976; Kakizoe et al, 1980; Heney et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Melamed and Reuter, 1993). Molecular techniques demonstrate that downward seeding of tumor accounts for some recurrences (Harris and Neal, 1992). Tumor multifocality does not lessen survival of patients independent of stage (Messing and Catalona, 1998).

Metachronous bilateral upper tract tumors are rare. In a review of all 768 cases of upper tract tumor reported in western Sweden from 1971 to 1998, the rate of metachronous bilateral tumors was 3.1% and was associated with increased age and short survival time after the event (Holmang and Johansson, 2006).

The occurrence of bladder tumors after upper tract tumors, and vice versa, is another expression of the field change, multifocal risk that affects initial treatment decisions. Carcinoma in situ is present in the distal ureter at the time of cystectomy in 7% to 25% of cases (Melamed and Reuter, 1993; Solsona et al, 1997; Herr, 1998); 15% to 50% of all cases of upper tract tumor occur in patients with a history of bladder tumor (Batata and Grabstald, 1976; Babaian and Johnson, 1980). The incidence of upper tract tumor after bladder tumor is 2% to 4% with a mean time to occurrence of 70 months (Shinka et al, 1988; Oldbring et al, 1989; Melamed and Reuter, 1993; Herr et al, 1996). Upper tract tumors are reported in 3% to 9% of patients after cystectomy for bladder cancer in older series (Zincke and Neves, 1984; Mufti et al, 1988).

Particular insight into the contemporary risk for upper tract tumor after treatment of bladder cancer is provided in several large series (Solsona et al, 1997; Herr, 1998; Rabbani et al, 2001; Mullerad et al, 2004; Sved et al, 2004; Canales et al, 2006; Tran et al, 2008; Wright et al, 2009). Herr (1998) found that among 307 patients with bladder tumor observed for a median of 12 years there was an overall incidence of upper tract tumors of 23%. The cumulative risks for upper tract tumors were 10%, 26%, and 34% at 5 years, 5 to 10 years, and 15 years, respectively. Upper tract tumors occurred in 26% of another subgroup of 87 patients with bladder tumor observed for more than 15 years. Delayed upper tract tumors were more common in the ureter than in the renal pelvis and appeared at a median follow-up of 56 months. Median time to delayed ureteral versus renal pelvis tumors was 40 months versus 67 months, respectively. Ureteral tumors occurred in 29% of 66 patients who were successfully treated with intravesical BCG for carcinoma in situ. In a subset of 105 patients who underwent cystectomy for BCG-refractory carcinoma in situ, ureteral carcinoma in situ was present in the distal, juxtavesical, and intramural portions of the ureter in 35%, 68%, and 81% of cases, respectively. In a retrospective study from the same center, treatment outcome in patients with upper tract tumor was worse in patients with a prior history of bladder cancer (superficial or invasive) independent of upper tumor stage (Mullerad et al, 2004). Similarly, Sved and colleagues (2004) reported upper tract tumors in 2% of patients (5 of 235) observed for a mean of 42 months after radical cystectomy for bladder cancer. Upper tract tumor was diagnosed at a mean follow-up of 39.6 months, because of hematuria in four cases, and on routine intravenous urography in the remaining case. Presence of tumor in the prostatic urethra of the cystectomy specimen was the only initial tumor feature that was associated with a higher risk of subsequent upper tract tumor. This may be a predictor of a higher risk of multifocal tumor in such cases. Outcome was poor with disease-related mortality in four of the cases. In contrast, in a review of 91,245 patients with bladder

cancer from the SEER database for 1973 to 1996, upper tract tumor occurred in 657 patients (0.7%) at a median follow-up of 4.1 years (Rabbani et al, 2001). These patients had lower tumor stage and improved disease-specific survival than did patients with primary upper tract tumors. Canales and coworkers (2006) found that patients with two or more stage Ta bladder cancer recurrences within 12 months were at increased risk for upper tract tumors and that surveillance of the upper tracts is indicated. In an update on the earlier study by Herr and associates (1996), Tran and associates (2008) found that the risk for upper tract recurrence after cystectomy for bladder cancer was 4% and 7% at 3 years and 5 years, respectively. Patients who had any tumor in the ureter at the time of cystectomy, including only carcinoma in situ, were at greatest risk for upper tract recurrence. Wright and colleagues (2009) reviewed 99,338 patients with bladder cancer in the SEER registry from 1988 to 2003. Upper tract tumors occurred in 0.8% of patients, at a median time of 33 months. Seventy-one percent of these were seen within 5 years, and only 6% of the total occurred after 10 years. On multivariate analysis high-grade and non–muscle-invasive bladder tumors correlated with a higher risk for subsequent upper tract tumors. The latter point likely relates to a lower mortality rate from the original bladder cancer and thus a greater competing risk for upper tract disease.

Solsona and colleagues (1997) reported that carcinoma in situ was present in the distal ureter in 25% of 138 cystectomies performed for bladder carcinoma in situ, compared with only 2.3% and 2.9% among 786 and 179 cases of stage Ta to T1 versus stage T2 disease, respectively. This may indicate that bladder carcinoma in situ carries a higher risk of multifocal disease than do other forms of bladder tumor.

The incidence of bladder tumor after treatment of upper tract tumor is 20% to 75% (Batata and Grabstald, 1976; Kakizoe et al, 1980; Nocks et al, 1982; Huben et al, 1988; Anderstrom et al, 1989; Sakamoto et al, 1991; Williams, 1991; Melamed and Reuter, 1993; Hisataki et al, 2000; Kang et al, 2003; Matsui et al, 2005). Bladder tumor after upper tract tumor occurs earlier than the reverse, at a median of 21 months versus 86 months afterward, respectively. Both bladder tumor and contralateral upper tract tumor after initial unilateral upper tract tumor are examples of the multifocal nature of urothelial tumor. In one study, subsequent bladder tumors appeared earlier than did contralateral upper tract tumors (Kang et al, 2003). Renal insufficiency was associated with a higher risk of contralateral upper tract tumor.

The occurrence of bladder tumor after treatment of upper tract tumor may be due to a field effect, distal tumor seeding, or both. Association of a higher bladder tumor incidence after upper tract tumor multifocality supports a role of distal seeding (Matsui et al, 2005). However, reports of distinct tumor clones by microsatellite analysis support a field effect (Takahashi et al, 2001). The paradoxical finding that the risk of subsequent bladder tumor is inversely related to upper tract tumor size and stage may reflect a higher and earlier risk of death from the primary tumor in these cases. In the reports by Hisataki and coworkers (2000), Matsui and associates (2005), and Terakawa and colleagues (2008), increased upper tract tumor stage at the time of nephroureterectomy correlated with a higher risk for subsequent bladder tumor. In a recent European multicenter study reported by Novara and coworkers (2008) prior bladder tumor before upper tract tumor was the only independent risk factor for bladder tumor after nephroureterectomy in multivariant analysis. Raman and associates (2007) reported that the grade, but not the stage, of the prior upper tract tumors correlated with the pathologic findings of the subsequent bladder tumors.

Three particular forms of upper tract urothelial tumors, those seen in Balkan nephropathy, those associated with analgesic abuse, as well as those seen in arsenic-endemic regions of Taiwan, each have an even higher tendency to multiple and bilateral recurrences than do sporadic tumors (Markovic, 1972; Petkovic, 1975; Mahoney et al, 1977; Johansson and Wahlquist, 1979; Melamed and Reuter, 1993; Stewart et al, 1999; Tan et al, 2008). The typically low-grade nature of the tumors and the frequent renal insufficiency seen in Balkan nephropathy underscore the importance of conservative treatment when possible. The degree of scarring of renal papillae seen in phenacetin abuse correlates in a dose-dependent manner with the risk of high tumor grade and progression. Calcification of renal papillae after analgesic abuse is associated with development of squamous carcinoma of the renal pelvis (Stewart et al, 1999).

There is a strong correlation of grade and stage for upper tract tumors. **The single most important determinant of outcome is tumor stage** (Tables 53–2 and 53–3) (Bloom et al, 1970; Grabstald et al, 1971; Batata et al, 1975; Wagle et al, 1975; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983; Huben et al, 1988; Anderstrom et al, 1989; Guinan et al, 1992b; Terrell et al, 1995; Messing and Catalona, 1998).

Key Points: Staging of Upper Tract Tumors

- Staging of upper tract tumors parallels that of bladder cancer.
- Stage is the most important determinant of outcome.

The primary tumor characteristics that suggest invasion, the high incidence of ipsilateral multifocal abnormality, and the risk of recurrence distal to the primary lesion are all offered in support of radical excision of large, proximal, and likely invasive tumors of the upper tract. Conversely, the same risks of multiple recurrence and the fact that tumor stage is the main determinant of outcome support conservative nephron-sparing surgery in many cases.

Upper tract tumors spread in the same ways as bladder tumors do, through lymphatic and hematogenous routes and by direct extension into contiguous structures. Thus, **the common metastatic sites are the lungs, liver, bones, and regional lymph nodes.** Preoperative evaluation for the extent of disease includes chest radiography, abdominal CT, liver function tests, and occasional bone scintigraphy. The thin muscle layer of the renal pelvis and ureter may allow earlier penetration of invasive upper tract tumors than is seen in bladder neoplasms (Cummings, 1980; Richie, 1988). However, this is not a valid reason for radical versus conservative treatment if a lesion is either noninvasive or invasive and organ confined (stage T2) (Gittes, 1980). The renal parenchyma may be a barrier, slowing distant spread of stage T3 renal pelvis tumors. In contrast, periureteral tumor extension carries a high risk of early tumor dissemination along the periureteral vascular and lymphatic supply. Improved survival of patients with stage T3 renal pelvis tumors versus ureteral tumors has been reported by several investigators (Batata and Grabstald, 1976; Guinan et al, 1992a; Park et al, 2004). Guinan and colleagues confirmed this observation among 611 patients treated at 97 hospitals and in a collection of 250 cases reported in the literature (Guinan et al, 1992a). The 5-year survival rates for patients with stage T3 tumors of the renal pelvis and ureter were 54% and 24%, respectively. In a multivariate analysis, patients with ureteral tumors had a higher local and distant failure rate than did those with renal pelvis tumors of the same stage and grade (Park et al, 2004). Renal pelvis and upper ureteral tumors spread initially to para-aortic and paracaval nodes, whereas distal ureteral tumors spread to pelvic nodes (Batata et al, 1975; Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983; Jitsukawa et al, 1985; Geiger et al, 1986).

TREATMENT

The treatment of upper tract urothelial tumors has undergone significant changes. **The relatively low frequency of these lesions and the lack of prospective randomized trials do not permit absolute conclusions about treatment impact on outcomes.** In the past, treatment recommendations were based, at least in part, on practical limitations in follow-up and detection of local disease recurrence. Technologic improvements in imaging and, most important, direct endoscopic visualization of all levels of the urinary tract allow earlier and more accurate initial diagnosis and treatment and improved follow-up. Treatment may be based primarily on the risk the tumor poses and on the efficacy of a specific treatment rather than on other considerations. The specific indications and techniques for each form of treatment (open vs. laparoscopic radical nephroureterectomy; open vs. retrograde endoscopic vs. percutaneous renal-sparing tumor ablation) are addressed later in this chapter. However, the following introductory considerations apply.

The least invasive and least ablative treatment necessary for safe control of the tumor is preferred. Most upper tract urothelial tumors are not large or bulky. Thus, laparoscopic surgery is ideal, at least for the renal portion of radical nephroureterectomy when the tumor warrants removal of the entire renal unit (see later). A variety of approaches with various combinations of laparoscopic and open techniques are employed for distal ureterectomy. Low-grade noninvasive upper tract tumors are managed initially by ablative renal-sparing surgery. Retrograde ureteroscopy and ureteropyeloscopy are preferred when tumor size, number, and access allow complete tumor ablation. Percutaneous antegrade tumor ablation is chosen when the anatomy and the tumor do not allow complete ablation through a retrograde approach.

Open Nephron-Sparing Surgery for Renal Pelvis Tumors: Pyelotomy and Tumor Ablation and Partial Nephrectomy

Indications

Open conservative surgery may be applied in selected cases when nephron sparing for preservation of renal function is required (Gittes, 1966, 1980; Petkovic, 1972a, 1972b; Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; Wallace et al, 1981; Tomera et al, 1982; McCarron et al, 1983; Zincke and Neves, 1984; Bazeed et al, 1986; Ziegelbaum et al, 1987; Messing and Catalona, 1998). Tumor in a solitary kidney, synchronous bilateral tumors, and predisposition to form multiple recurrences, as in endemic Balkan nephropathy, are all reasons to consider nephron sparing (Fig. 53–6). Pyeloscopy as an initial diagnostic component to open conservative surgery has been supplanted by retrograde or

Figure 53–6. Patient with an invasive tumor of the upper calyx of a solitary kidney. The patient elected an upper pole partial nephrectomy.

percutaneous antegrade renal endoscopy (Huffman et al, 1985). Direct endoscopic visualization of the lesion and biopsy with cup forceps or brush establish a definitive diagnosis and tumor grade (Gill et al, 1973). The brush biopsy has renewed value because tissue obtained by small cup biopsy forceps used through narrow-caliber flexible endoscopes is limited. Preoperative determination of the stage of renal pelvis tumors remains difficult. Large size, broad base, and nonpapillary pattern favor tumor invasiveness. These improvements in initial diagnosis and assessment of tumor stage and grade allow more specific treatment, including conservative surgery when it is indicated.

The documented risk of wound implantation by tumor is low after open conservative surgery if simple precautions are followed to minimize spillage (Gittes, 1980; Tomera et al, 1982; McCarron et al, 1983). Modern percutaneous antegrade renal surgery allows resection of virtually any lesion formerly treated by open pyeloscopy, and the risk of tumor spillage is even lower (see following discussion).

Technique

Preoperative arteriography is not routinely obtained. However, it may be helpful before partial nephrectomy of rare hypervascular renal pelvis tumors. The affected segmental renal artery may be embolized or more easily identified at the time of surgery on the basis of the arteriogram.

The patient is placed in either a full flank or a torque position, as shown in Chapter 54. The full flank position provides optimal exposure to the renal pelvis for pyelotomy and excision of a large noninvasive tumor. The torque position allows both anterior and posterior exposure to the renal pedicle for partial nephrectomy. An extrapleural, extraperitoneal flank, or thoracoabdominal incision is made. Removal of a portion of the 11th or 12th rib provides maximal exposure to the kidney and aids in mobilization of the upper pole and in gaining access to the renal vessels. Removal of a rib is especially helpful in obese patients or in those with a high kidney. An incision off the tip of the 12th rib suffices in thin patients with a low kidney and is accompanied by less potential wound discomfort or morbidity. After the incision is completed, the Gerota fascia is opened posteriorly and the entire kidney is mobilized. The renal vessels and the ureter are each isolated with a vessel loop.

The wound is packed with dry sponges to isolate the kidney before any intrarenal incisions are made. For pyelotomy and tumor excision the renal pelvis and the major calyceal infundibula are exposed by dissecting the hilar and renal sinus fat as for an extended pyelolithotomy. A gentle curvilinear incision is made in the renal pelvis, and the tumor is excised; the base is cauterized with electrocautery, laser, or argon beam coagulator. Finally, the pelvis is closed with 4-0 chromic catgut or other absorbable suture.

The techniques of partial nephrectomy for renal pelvis tumors are essentially the same as those described in Chapter 54, with the added proviso of taking care to minimize the risk of tumor spillage. The involved segment of the intrarenal collecting system is clamped before removal of the tumor-bearing portion of the kidney is begun. The collecting system of the renal remnant is closed with absorbable 4-0 suture. Identified individual bleeding points are oversewn with 4-0 vascular Prolene or polydioxanone suture. Additional hemostasis is provided by use of electrocautery and the argon beam coagulator on the raw parenchymal surface. The edges of the renal defect and the adjoining renal capsule are approximated over Surgicel bolsters with 2-0 chromic catgut suture.

A suction drain is placed in the renal bed in all cases. A temporary urinary diversion stent is not used routinely unless difficulty is encountered in closing the collecting system.

Results

The reported overall risk of tumor recurrence in the ipsilateral renal pelvis after initial pyelotomy or partial nephrectomy varies from 7% to 60% (Mazeman, 1976; Murphy et al, 1980, 1981; Wallace et al, 1981; McCarron et al, 1983; Zincke and Neves, 1984; Ziegelbaum et al, 1987; Messing and Catalona, 1998). The risk of recurrence after conservative surgery increases with tumor stage from less than 10% for grade 1 to 28% to 60% for grades 2 and 3. The moderate to high risk of recurrence primarily reflects the inherent multifocal atypia and field change of the renal pelvis (Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983). The possibility of incomplete initial treatment of the primary tumor cannot be totally excluded.

Estimates of overall and cancer-specific survival after conservative surgery of renal pelvis tumors are hampered by the lack of prospective, controlled, randomized trials and the small numbers of affected patients. The inherent bias introduced by selection of patients for conservative treatment based on medical comorbidities is another variable. Murphy and associates (1980) reported 5-year survival of 75% and 2-year survival of 46% after conservative surgery in patients with grade 1 and grade 2 renal pelvis tumors, respectively. McCarron and associates reported rates of cures, cancer-related deaths, and deaths due to unrelated causes of 33% each in nine patients who underwent conservative surgery (McCarron et al, 1983). **Radical nephroureterectomy and dialysis still offer the best chance of cure and survival in patients with a large, invasive, high-grade, organ-confined renal pelvis tumor (T2N0M0) in a solitary kidney** (Gittes, 1980; McCarron et al, 1983).

Open Radical Nephroureterectomy

Indications

Radical nephroureterectomy with excision of a bladder cuff is recommended for large, high-grade, invasive tumors of the renal pelvis and proximal ureter (Batata and Grabstald, 1976; Skinner, 1978; Babaian and Johnson, 1980; Cummings, 1980; Murphy et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). Radical surgery also retains a role in treatment of medium-grade, noninvasive tumors of the renal pelvis and upper ureter when they are large, multifocal, or rapidly recurring despite maximal efforts at conservative surgery.

Key Point: Indications for Radical Nephroureterectomy

- The treatment of large, invasive tumors of the renal pelvis and proximal ureter is radical nephroureterectomy with removal of a bladder cuff.

Technique

Choice of Incision. Radical nephroureterectomy may be performed through a variety of approaches. The choice of incision is largely one of the surgeon's preference and is based on the

surgeon's experience, the patient's body habitus and medical comorbidities, and the size of the kidney. The operation may be performed through one incision with the patient placed in a flank torque position, as shown in Chapter 54 and as described in the section on open nephron-sparing surgery (Fig. 53–7). In male patients the genitalia are included in the surgical field so that the bladder catheter may be accessed during the procedure. An extrapleural, extraperitoneal, thoracoabdominal incision is begun over the 11th or 12th rib or off the tip of the 12th rib, as described earlier. In contrast to the incision for partial nephrectomy, for which adequate exposure to the kidney is the primary concern, the lower ureter and the bladder must also be exposed for nephroureterectomy. Thus, the middle and anterior portions of the skin incision angle down toward the pelvis rather than in a subcostal direction (see Fig. 53–7). The peritoneum may be opened at any time to increase exposure as necessary. The thoracoabdominal approach offers the best exposure to the kidney but may cause a greater degree of postoperative atelectasis than the anterior subcostal approach. This may be an important consideration in patients with chronic lung disease.

The operation may also be performed through a single long midline incision and intraperitoneal exposure. However, exposure to the kidney is limited from this approach, particularly for left-sided tumors.

Alternatively, the patient may be positioned supine with a small roll placed behind the rib cage on the affected side. The nephroureterectomy is performed through an upper anterior subcostal incision and a lower quadrant Gibson incision as for renal transplantation. A lower midline or Pfannenstiel incision may be substituted (Fig. 53–8). A lower midline incision avoids dividing muscles, is fast, and provides direct exposure to the prevesical space. However, a Gibson incision provides easier exposure to the distal ureter. Nephrectomy may be difficult from an anterior subcostal approach in obese patients.

Radical Nephrectomy. The entire kidney, along with all the perinephric fat and the Gerota fascia, is fully mobilized (Figs. 53–9 and 53–10). The renal vessels are dissected and individually secured and divided in a standard manner. The authors prefer at least one 0 silk tie and 4-0 vascular Prolene suture ligature on an RB needle for each renal artery and renal vein. Combinations of ties plus large hemoclips may be substituted for the suture ligature. The adrenal is a not-infrequent site of metastasis for urothelial tumor. Traditionally, the ipsilateral adrenal gland has been included with the specimen. However, as in the case of renal cell

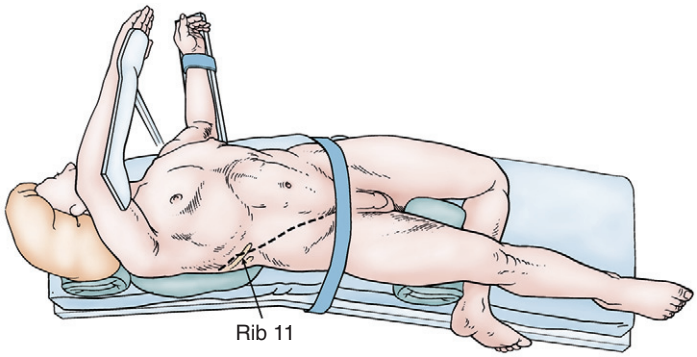

Figure 53–7. Patient in torque flank position for radical nephroureterectomy through a single thoracoabdominal incision. The shoulder girdle is rotated into a full flank position. The pelvic girdle is rolled back nearly to a supine position. All potential pressure points are carefully padded.

Figure 53–8. Radical nephroureterectomy may be performed through a long midline incision or through a subcostal plus Gibson, lower midline, or Pfannenstiel incision. The patient is supine, and the table is mildly flexed. Placement of a small roll under the edge of the rib cage is helpful. (From Sagalowsky AI. Renal transplantation and autotransplantation. In: Marshall F, editor. The textbook of operative urology. Philadelphia: WB Saunders; 1996:320–30.)

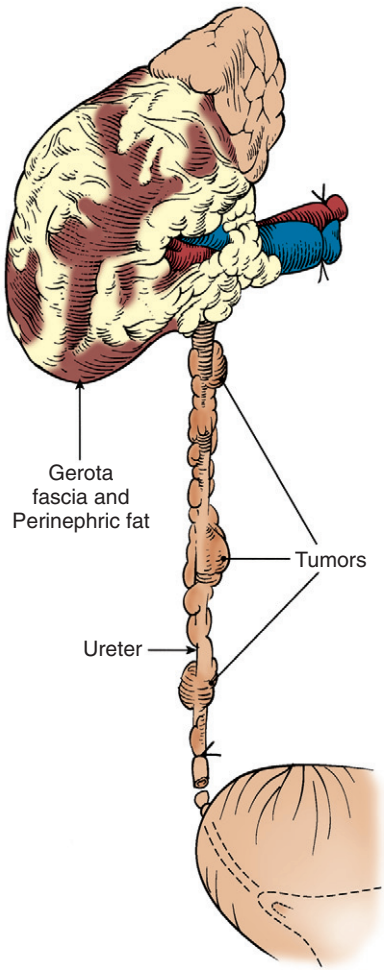

Figure 53–9. Radical nephroureterectomy specimen including the kidney, Gerota fascia, and perinephric fat, with or without the ipsilateral adrenal gland. Note that the ureter is divided distally in the pelvis between ties for a separate distal ureterectomy.

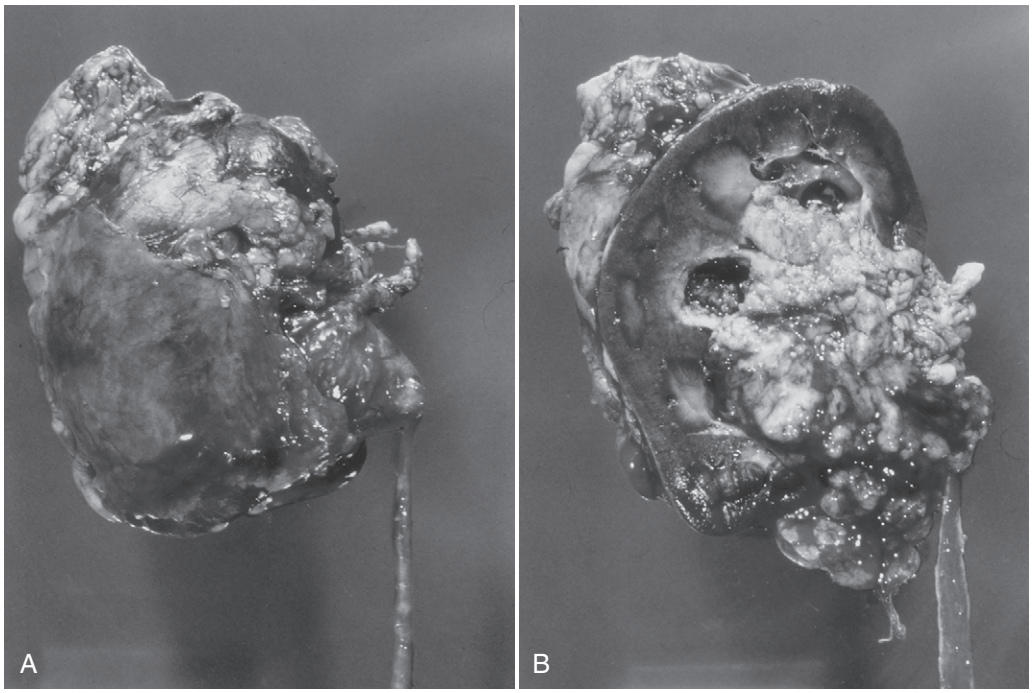

Figure 53–10. **A,** Intact nephroureterectomy specimen for a large renal pelvis tumor. **B,** Bivalved specimen reveals the tumor.

carcinoma, **adrenalectomy adds little to the cure for upper tract tumors.** One may omit adrenalectomy if the gland appears normal on preoperative imaging studies and is grossly normal at the time of surgery and if the disease seems localized within the renal pelvis. However, adrenalectomy is prudent for maximal control if locally advanced disease is discovered.

Management of Distal Ureter and Bladder Cuff

Complete distal ureterectomy with a bladder cuff is necessary with nephroureterectomy and represents a distinct portion of the case, whether an open or laparoscopic approach to the kidney is used. General principles include intact complete ureteral excision with controlled occlusion of the ureteral orifice. **The entire distal ureter, including the intramural portion and the ureteral orifice, is removed.** Failure to completely remove the entire distal ureter and ureteral orifice is associated with a high rate of tumor recurrence. The ureter may be kept in continuity with the kidney to obviate the risk of tumor spillage from the lumen. However, the attached kidney is cumbersome, and this technique is not necessary as long as the distal ureter is divided between ties or clips at a location that is free of gross abnormality. Following are the options available for management of the distal ureter, whether an open or laparoscopic approach is used. If a laparoscopic approach is chosen, the incision can be placed to facilitate both intact specimen extraction and dissection of the distal ureter. One should keep in mind that TCC is a tumor that has the potential to seed nonurothelial surfaces and that maintenance of a "closed system" is important, especially with high-grade tumors.

Traditional Open Distal Ureterectomy

This operation can be done through Gibson, low midline, and Pfannenstiel incisions, depending on the patient's anatomy and the extent of proximal ureteral dissection required. Transvesical, extravesical, and combined approaches have been described. The transvesical approach is the most reliable approach for ensuring complete ureteral excision. An anterior cystotomy may be made and intravesical and extravesical dissection performed as for ureteral neocystostomy (Fig. 53–11); 1 cm of bladder mucosa is included circumferentially around the ureteral orifice. The defect in the bladder wall at the ureteral hiatus is closed in two layers from within the bladder with interrupted 2-0 or 3-0 absorbable suture on the muscle and 4-0 suture on the mucosa. The anterior cystotomy is closed carefully in two layers with running 3-0 absorbable suture. The urethral catheter is maintained for 5 to 7 days; a suprapubic catheter is not routinely used. A flat suction drain is left in the perivesical space.

Complete distal ureterectomy may be performed entirely by extravesical (Fig. 53–12) dissection of the distal ureter and the intramural portion within the bladder wall all the way to the ureteral orifice. The need for a cystotomy is avoided with this approach. The ureter is tented up, and the bladder mucosa is divided between clamps. The defect in the bladder wall is closed in layers, as described previously. Care must be taken to ensure a complete dissection of the intramural portion of the ureter and to avoid contralateral injury from excessive traction.

Transurethral Resection of the Ureteral Orifice

This approach, also referred to as the pluck technique, should be reserved for proximal, low-grade tumors (Abercrombie et al, 1988; Palou et al, 1995). The patient is placed in the lithotomy position, and the ureteral orifice and intramural ureter are aggressively resected to the extravesical space (Fig. 53–13). The patient is then positioned for the nephrectomy portion of the procedure, in which dissection must extend down to the perivesical space. The advantage is avoidance of a second incision in performing an open nephroureterectomy. Walton and coworkers (2009) showed equivalent oncologic outcomes in a long-term retrospective study comparing this to traditional bladder cuff techniques. The advantages are less apparent with laparoscopic nephrectomy, in which an incision is necessary for specimen extraction, and this can be used

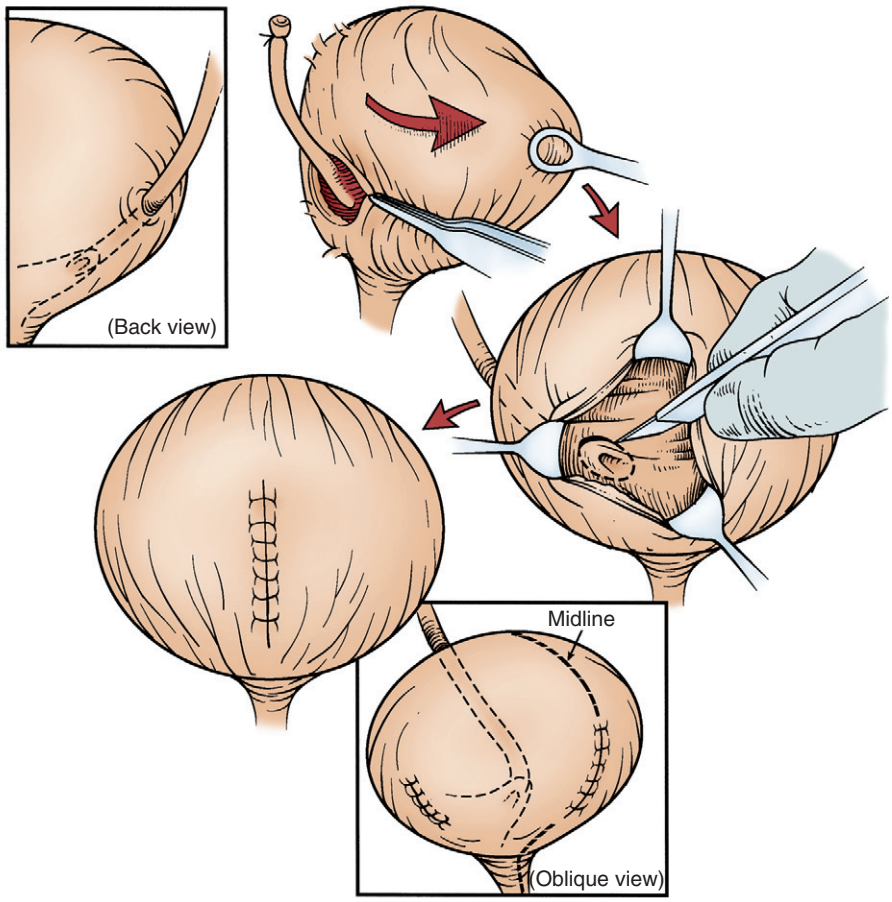

Figure 53–11. Complete distal ureterectomy with bladder cuff is performed by combined extravesical and transvesical dissection.

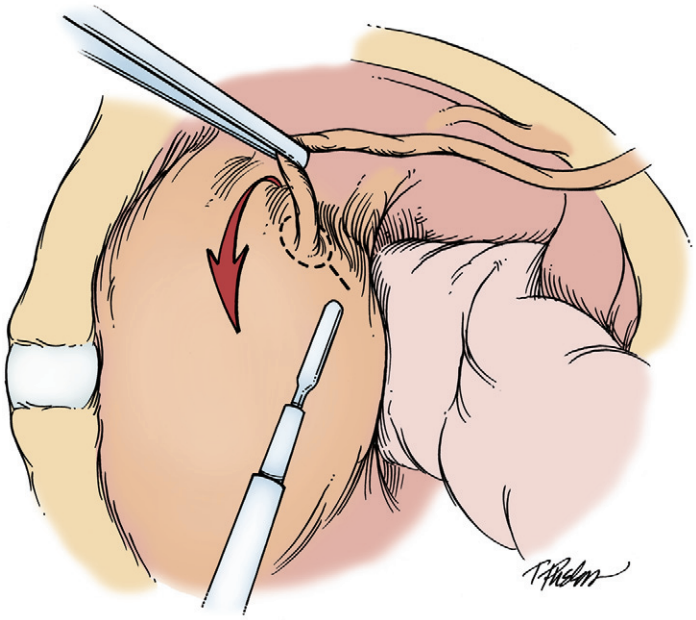

Figure 53–12. Complete distal ureterectomy by extravesical approach. Traction is placed, everting the orifice outside the bladder. Care must be taken to ensure complete removal and to avoid injury to the contralateral ureteral orifice.

for dissection of the distal ureter. In addition there is exposure of nonurothelial surfaces, which may predispose to local recurrence, especially with more dysplastic tumor (Jones and Moisey, 1993; Arango et al, 1997).

Intussusception (Stripping) Technique

Several variations of this procedure have been described (McDonald, 1953; Clayman et al, 1983; Roth et al, 1996; Angulo et al, 1998). Basically, a ureteral catheter is placed in the ipsilateral ureter at the beginning of the procedure. The nephrectomy portion of the procedure is carried out, and the ureter is dissected as far distally as possible. The ureter is then ligated and transected with the ureteral catheter secured to the proximal end of the distal ureter (Fig. 53–14). After nephrectomy, the patient is moved to the lithotomy position; the ureter is intussuscepted by traction into the bladder, and a resectoscope is used to excise the bladder cuff and free the ureter from the bladder. Concerns with this technique are presented by Giovansili and associates (2004), who described a failure rate of 18.7% in which there may have been disruption of the ureter and the need for an additional surgical incision.

Transvesical Ligation and Detachment Technique

This technique most closely mimics the open technique. Before the nephrectomy portion of the procedure, the patient is placed in the low lithotomy position, a ureteral catheter is placed, and two suprapubic 3-mm trocars (Fig. 53–15) are placed transvesically. The ureter is tented up, and a loop ligature is placed around the catheter and the orifice, creating a "closed" system. A Collins knife circumscribes the ureteral orifice, and further dissection is facilitated by the grasper, which provides traction until the extravesical

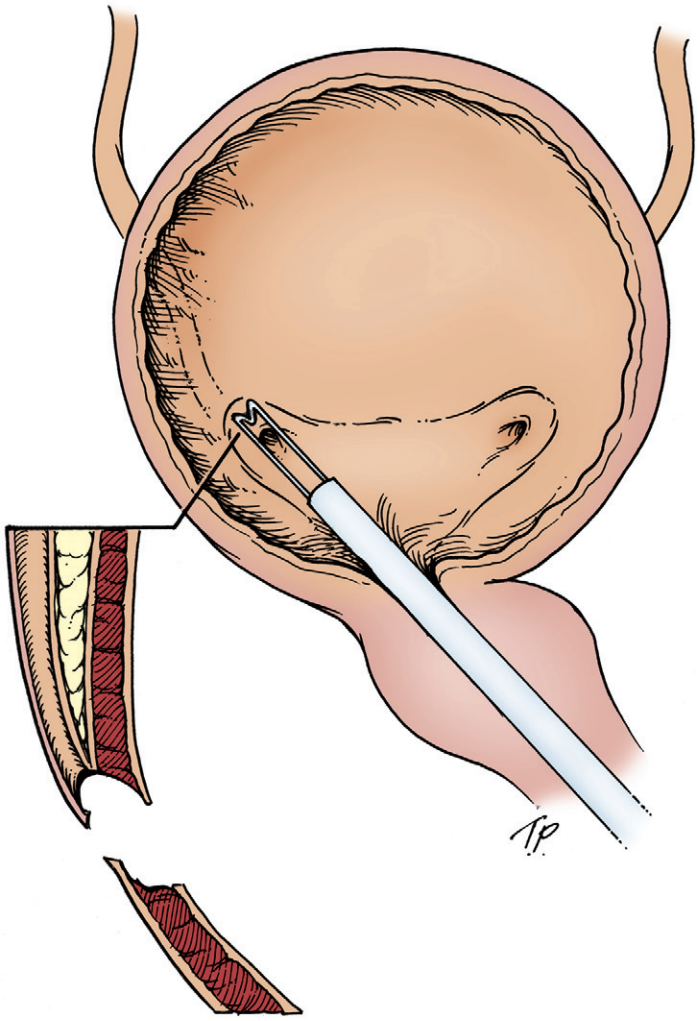

Figure 53–13. The entire orifice and intramural ureter are resected transurethrally until the extravesical fat is seen. This portion is usually done at the beginning but can be done at the end of the procedure.

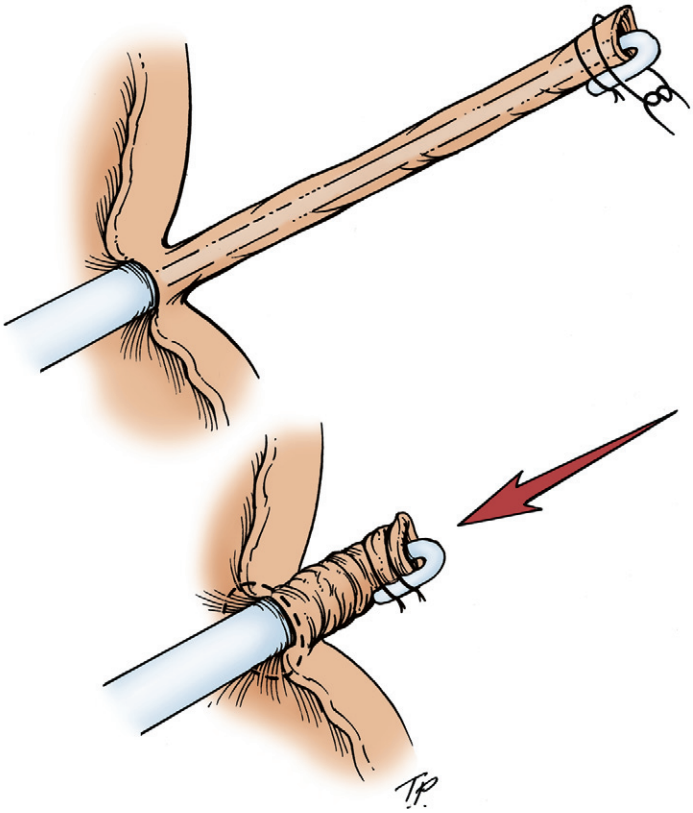

Figure 53–14. With the intussusception technique, a ureteral catheter is placed at the beginning of the case. After nephrectomy the ureter is divided and the catheter is secured to the distal portion of the ureter. The patient is moved to the lithotomy position, and the ureter is intussuscepted into the bladder with retrograde traction. A resectoscope is used to excise the attached orifice.

space is reached. There has been excellent clinical success reported with this technique (Gill et al, 1999), but it can be technically difficult. Agarwal and associates (2008) described a technique that appears similar but dissects the ureter only to the extravesical space.

Total Laparoscopic Technique

Flexible cystoscopy is performed before the laparoscopic portion of the case, and a Bugbee electrode is used to cauterize the orifice and intramural ureter completely. Cauterization of the intramural portion of the ureter is important for identification of the distal limits of the dissection during the laparoscopic portion of the procedure. A 20- or 22-Fr Foley catheter is placed before proceeding to the laparoscopic portion. The nephrectomy and ureteral dissection are carried down to the detrusor muscle. Antegrade traction is placed on the ureter, everting the orifice out of the bladder, and an endovascular stapling device is placed as distally as possible (Fig. 53–16). A flexible cystoscope can be placed at this time if there is any question of the adequacy of the specimen or concern of disturbance of the contralateral ureteral orifice. The endovascular stapling device is then deployed, laying two rows of staples on the bladder and specimen sides. This allows a closed system after division of the ureter.

Management of Distal Ureter—Considerations

Much controversy surrounds the management of the distal ureteral cuff during nephroureterectomy. No study has shown a clear advantage of any single technique (Macejko et al, 2008). However, it is universally accepted that the ureter must be removed in its entirety. Failure to do so places the patient at an unacceptable risk for distal recurrence, especially with high-grade tumors. Because of the rarity of the disease and other factors it is unlikely that a study will be designed to resolve this issue. There is some concern of the use of techniques that violate the closed system, especially with high-grade/stage and lower ureteral tumors. In addition, total laparoscopic techniques appear to be associated with a higher local recurrence rate, possibly due to retained ureter in the bladder (Romero et al, 2007). When considering an approach, the surgeon should take into account tumor location, potential for seeding, patient factors, and personal experience.

Lymphadenectomy

Regional lymphadenectomy is included with radical nephroureterectomy. For renal pelvis and proximal or middle ureteral tumors the ipsilateral renal hilar nodes and the adjacent para-aortic or paracaval nodes are resected. This dissection adds little time or morbidity to the surgery. On occasion, lymphadenectomy is more hazardous in patients with severe atherosclerosis of the aorta or grossly positive and fixed nodes. Node dissection is limited or omitted in these cases.

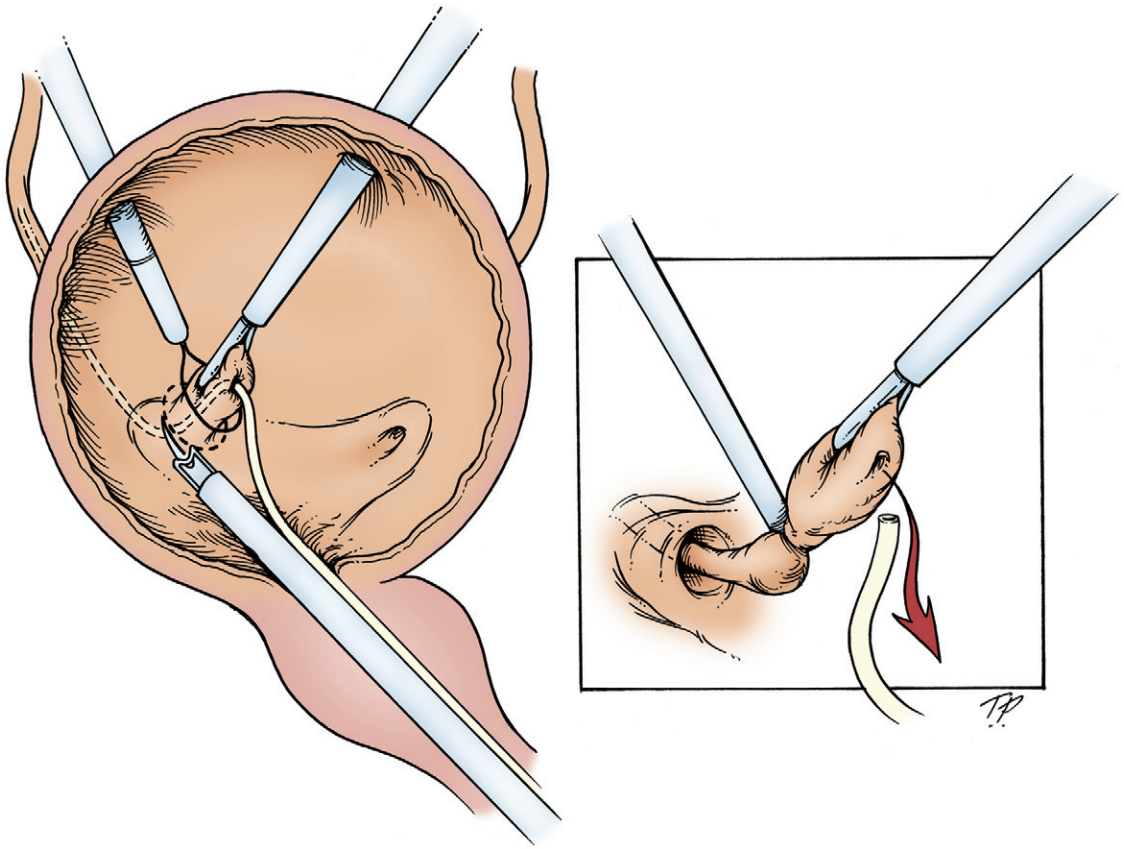

Figure 53–15. A ureteral catheter is placed, and two laparoscopic ports are placed transvesically. The ureteral orifice is tented up; a loop is placed around the orifice to occlude the opening and to place traction on the ureter. A Collins knife then facilitates the dissection to the extravesical space.

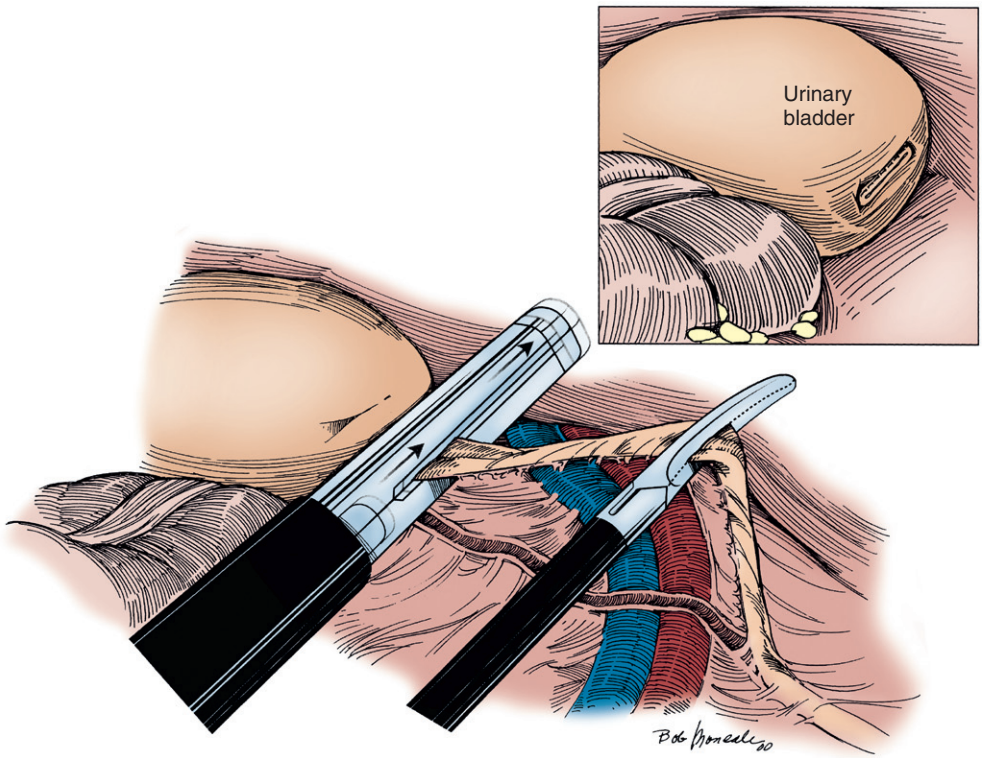

Figure 53–16. The ureter is dissected extravesically to the ureteral orifice. Lateral traction is placed on the ureter, everting the orifice, and the endovascular stapling device is placed at the distal margin, providing simultaneous ligation and division of the distal ureter at the level of the bladder. A cystoscope can be placed to ensure that the entire ureter is removed.

Key Point: Lymphadenectomy with Radical Nephroureterectomy

- Regional lymphadenectomy is included with radical nephroureterectomy.

Results

The outcome strongly correlates with tumor stage and grade as summarized in Tables 53–2 and 53–3, compiled from numerous series. The role of complete distal ureterectomy with excision of a bladder cuff in radical nephroureterectomy for upper tract tumors is well established. The risk of tumor recurrence in a remaining ureteral stump is 30% to 75% (Bloom et al, 1970; Strong et al, 1976; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Kakizoe et al, 1980; Mullen and Kovacs, 1980; McCarron et al, 1983). This risk is likely to remain or even to increase as the use of radical nephroureterectomy becomes more selective for patients, mainly those with higher risk tumors. All patients who underwent an extravesical dissection and tenting up of the ureter in the series by Strong and associates (1976) retained a portion of the ureter and the ureteral orifice; this demonstrates that the transvesical dissection of the ureter must be thorough to avoid such an error. Complete ureterectomy with a bowel cuff should accompany nephroureterectomy of a renal unit draining into a urinary diversion. Mufti and coworkers (1988) reported a tumor recurrence rate of 37.5% when the ureteroenteric anastomosis was not removed.

The need or benefit of radical nephroureterectomy versus simple nephrectomy or conservative nephron-sparing surgery is less well defined. Radical nephroureterectomy is recommended as providing optimal chance for survival in numerous series (Batata et al, 1975; Johansson and Wahlquist, 1979; Murphy et al, 1980; McCarron et al, 1983; Zungri et al, 1990). Batata and colleagues (1975) reported that radical nephroureterectomy provided a 5-year survival rate of 23% among patients with locally advanced disease (stage T3 to T4, N1 to N2). Johansson and Wahlquist (1979) reported survival advantage at 5 years for radical versus simple nephrectomy of 84% versus 51%, respectively, and of 74% versus 37%, respectively, for patients with high-stage tumors only. McCarron and associates (1983) reported that the subgroup of patients with large, high-grade, but organ-confined disease obtained the most benefit from radical versus conservative surgery. The death rate due to tumor was 29% versus 89% for the radical and conservative surgery groups, respectively. In the series reported by Murphy and associates (1980), radical surgery conferred a survival advantage over conservative surgery at 5 years of 88% versus 75% for grade 1 tumors and of 90% versus 46% for grade 2 tumors. The retrospective, uncontrolled nature of all these series limits the conclusions that may be drawn. In summary, radical nephroureterectomy is warranted for patients with high-grade invasive disease that is organ confined (stage T1 to T2, N0) or is only locally advanced (stage T3 to T4, N0 to N2, M0). Tumor-free survival rates are high after radical nephroureterectomy for organ-confined disease and are guarded to poor for locally advanced disease. Treatment decisions in patients with compromised renal function must balance the potential beneficial effect of radical surgery on control of the tumor versus the morbidity, mortality, and quality of life risks associated with dialysis.

Regional lymphadenectomy is a recommended accompaniment of radical nephroureterectomy for upper tract tumors in multiple reports (Grabstald et al, 1971; Batata et al, 1975; Batata and Grabstald, 1976; Skinner, 1978; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Cummings, 1980; Heney et al, 1981; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998; Brausi et al, 2007; Kondo et al, 2007; Abe et al, 2008). However, the authors in nearly every one of these series find little therapeutic value from lymphadenectomy, and almost every patient with node-positive disease develops early distant metastases. In the series by Batata and Grabstald (1976), 5-year survival was seen in 23% of patients with completely resected stage T3 to T4, N1 to N2 disease. One of the limitations in assessing the role of lymph node dissection for radical nephroureterectomy is that, as with the treatment of renal cell carcinoma, the lymphatic drainage for renal pelvis tumors is not precise and thus the boundaries of lymphadenectomy are unclear. Investigators in recent series have readdressed these issues. Kondo and colleagues (2007) compared outcomes after radical nephroureterectomy for 45, 36, and 88 patients who underwent complete regional, incomplete regional, or no lymphadenectomy, respectively. Overall cancer-specific survival did not correlate with more extensive lymphadenectomy. However, with multivariate analysis a statistically significant benefit was seen with complete lymphadenectomy and higher lymph node counts for patients with stage pT3-4 disease. In a recent retrospective, uncontrolled series Brausi and associates (2007) compared outcomes in 82 patients with stage pT2-4 upper tract tumors who underwent lymphadenectomy with removal of more than five nodes at the time of radical nephroureterectomy or no lymphadenectomy in 44 and 42 cases, respectively. In both univariate and Cox proportional hazard analysis the T stage and performance of lymph node dissection correlated with disease recurrence and disease-specific survival. In a larger contemporary series, Abe and associates (2008) compared outcomes in 166 patients and 146 patients who did or did not undergo lymphadenectomy, respectively, at the time of renal surgery for upper urinary tract tumor. In multivariate analysis, pathologic lymph node status, as well as grade and stage, correlated with cause-specific survival. Among the group who underwent lymphadenectomy survival was similar for those with fewer than six and more than six nodes removed. Survival for patients with resected negative nodes was higher than for those who did not undergo lymphadenectomy (stage pNx). **The rationale for continuing regional lymphadenectomy is that it adds little time or morbidity to the surgery, is important for prognosis, and may occasionally have therapeutic value.** Earlier diagnosis in contemporary experience may identify more patients with limited nodal metastases who might benefit from radical surgery. Patients with proven nodal disease are obvious candidates for more careful follow-up and for trials exploring the role of adjuvant therapy.

Laparoscopic Radical Nephroureterectomy

The indications for laparoscopic nephroureterectomy are the same as those for open nephroureterectomy. Laparoscopic nephroureterectomy can be performed by transperitoneal, retroperitoneal (Hattori et al, 2005), and hand-assisted approaches (Landman et al, 2002; Stifleman et al, 2000). All show a significant decrease in morbidity compared with an open surgical approach for appropriately selected patients. All laparoscopic techniques involve two distinct portions of the procedure: nephrectomy and excision of the distal ureter with intact specimen extraction for accurate staging. Management of the distal ureter is described previously in the chapter. One should bear in mind several factors with

laparoscopic nephroureterectomy, including the risk of tumor seeding from both the ureter and the bladder. For these reasons, removal of an intact specimen is desirable. The incision should be strategically placed for both extraction of the specimen and dissection of the distal ureter. Because an incision is necessary regardless of the approach chosen, some techniques for avoidance of a second incision for the distal ureter described previously have less utility.

Technique

Transperitoneal Laparoscopic Nephroureterectomy

Laparoscopic Removal of Kidney Down to Midureter. The patient is placed supine with the ipsilateral hip and shoulder rotated approximately 20 degrees (Fig. 53–17). The patient is secured to the table and can be easily moved from the flank position (nephrectomy portion) to the modified supine position (open portion) by rotating the operative table. The ipsilateral flank and urethra are prepared and draped, and a Foley catheter is placed before insufflation of the abdomen.

The abdomen is insufflated, and three or four trocars are placed as outlined in Figure 53–18, with the first usually being the lateral trocar. Subsequent trocars are placed under direct vision. With this configuration, the camera is kept at the umbilicus for the entire procedure. The upper midline and lateral trocars are used by the surgeon for the dissection of the kidney and the proximal half of the ureter. The lower midline and lateral trocars are used for the dissection of the distal ureter. A 3-mm trocar just below the xiphoid can be helpful in retracting the spleen and liver for left- and right-sided lesions, respectively. The exception is with obese patients, when shifting of the trocars may be necessary to provide optimal visualization (Fig. 53–19). If a hand-assist approach is chosen, the hand port site should be placed so that it can be used for the dissection of the distal ureter and open bladder cuff as indicated.

The table is rotated so the patient is in the flank position. The peritoneum is incised along the white line of Toldt from the level of the iliac vessels to the hepatic flexure on the right and to the splenic flexure on the left. The colon is moved medially by releasing the renocolic ligaments while leaving the lateral attachments of the Gerota fascia in place to prevent the kidney from "flopping" medially. The colon mesentery should be mobilized medial to the great vessels to facilitate dissection of the ureter, renal hilum, and local lymph nodes as needed.

Proximal Ureteronephrectomy. The proximal ureter is identified, just medial to the lower pole of the kidney, and dissected toward the renal pelvis. If an invasive ureteral lesion is suspected, the dissection should include a wide margin of tissue. The renal hilum is identified, and its vessels are exposed with a combination of blunt and sharp dissection. The artery is ligated and divided by use of a gastrointestinal stapling device with a vascular load or multiple clips. The renal vein is then divided in a similar fashion (Fig. 53–20). With vascular control ensured, the kidney is dissected free, either inside or outside the Gerota fascia, depending on the tumor location and stage. For upper pole lesions thought to invade the parenchyma, the ipsilateral adrenal should be removed.

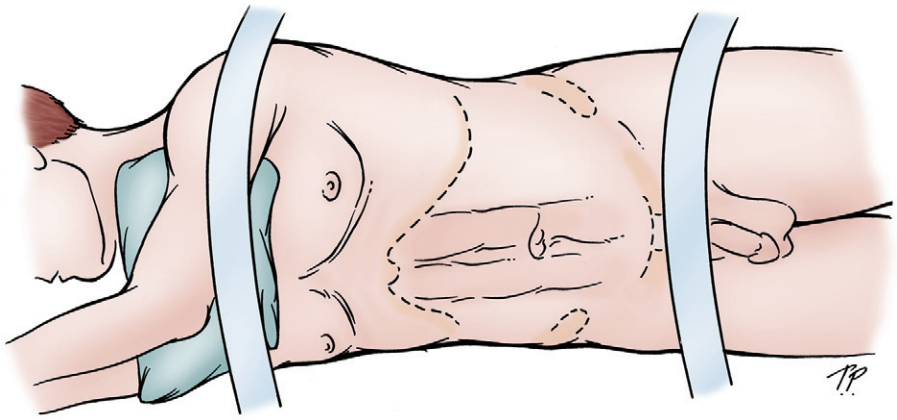

Figure 53–17. The patient is positioned on the table in a modified lateral decubitus position with the ipsilateral flank rotated up 15 degrees. The patient is secured to the table at the chest, waist, and lower extremity. This setup allows the patient to be moved to the full flank or supine position with simple rotation of the operating table. (From Jarrett TW. Laparoscopic nephroureterectomy. In: Bishoff JT, Kavoussi LR, editors. Atlas of laparoscopic retroperitoneal surgery. Philadelphia: WB Saunders; 2000. p. 105.)

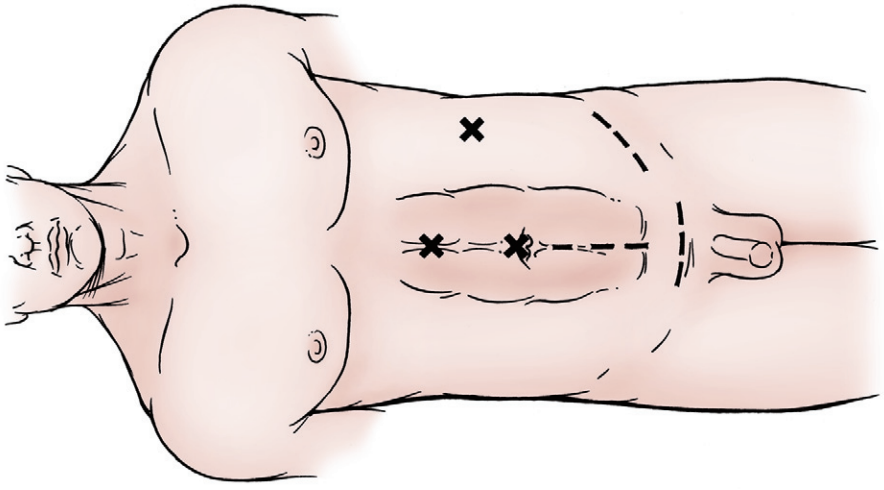

Figure 53–18. Port configuration for laparoscopic-assisted nephroureterectomy. Three ports are generally used for the kidney and upper ureteral dissection. A fourth midline port between the umbilicus and symphysis can be placed, if needed, for further ureteral dissection. The incision is then strategically placed to allow the distal ureteral dissection and specimen removal. The choice of incision largely depends on patient factors and level of dissection reached during the laparoscopic portion of the procedure. A low abdominal (midline or Pfannenstiel) incision is favored if the dissection is below the iliac vessels. A Gibson-type incision will give exposure of the more proximal ureter, if necessary.

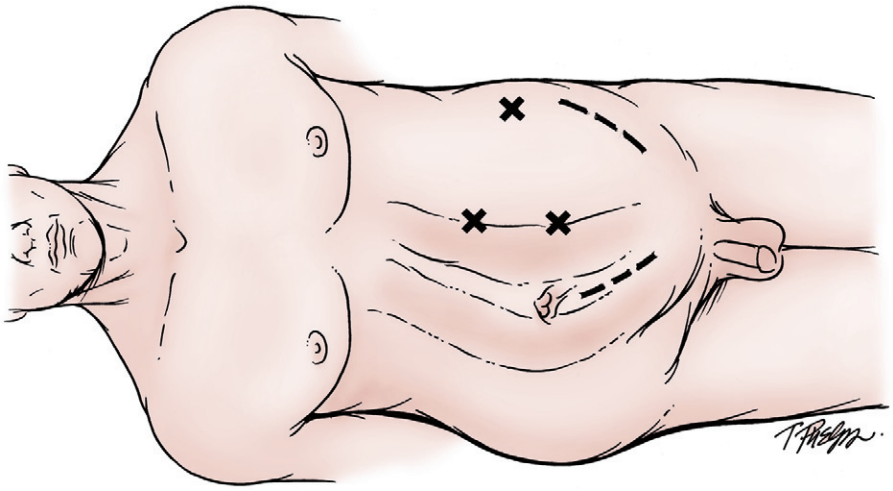

Figure 53–19. For obese patients undergoing laparoscopic-assisted nephroureterectomy the trocars are shifted laterally to accommodate the increased distance from the kidney.

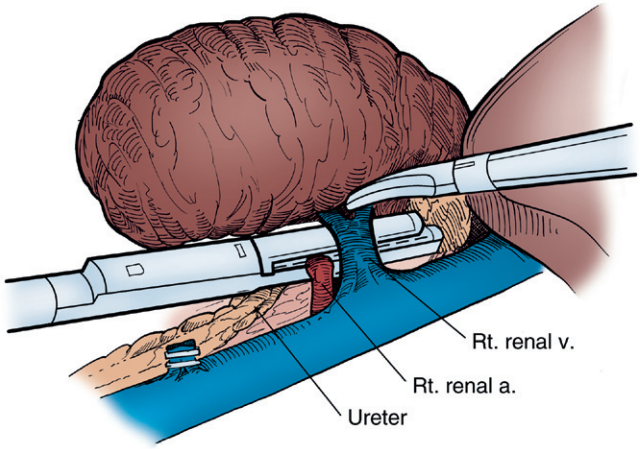

Figure 53–20. The vessels of the renal hilum are carefully dissected, and the endovascular stapling device, with a vascular load, is used to simultaneously ligate and divide the vessels in a controlled environment. (From Jarrett TW. Laparoscopic nephroureterectomy. In: Bishoff JT, Kavoussi LR, editors. Atlas of laparoscopic retroperitoneal surgery. Philadelphia: WB Saunders; 2000. p. 112.)

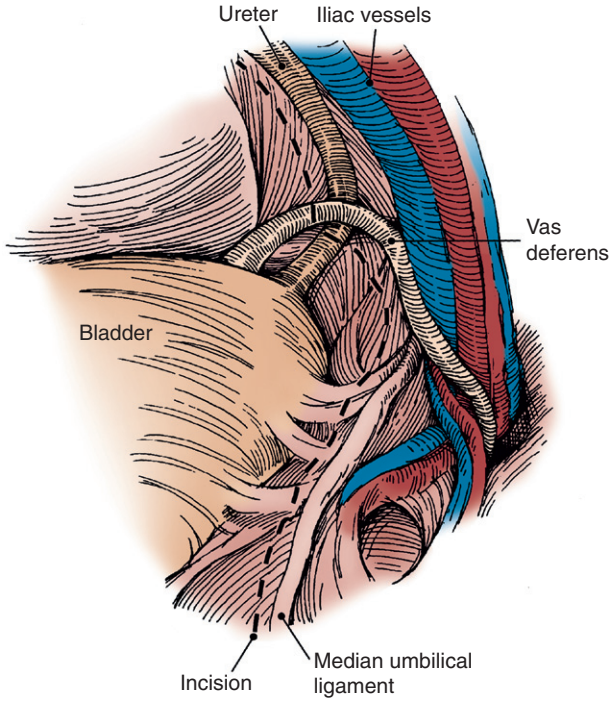

Figure 53–21. The peritoneal incision is continued below the iliac vessels medial to the median umbilical ligament and lateral to the bladder. The vas deferens is divided between clips in the male patient. In the female patient the round ligament is divided, giving full exposure of the distal ureter to the bladder.

The ureteral dissection is continued distally, keeping in mind that the ureteral blood supply is generally anteromedially located in the proximal third, medially located in the middle third, and laterally located in the distal third. Dissection of the lower half may require placement of the fourth trocar. In the area of primary disease, surrounding tissue should be left to provide an adequate tumor margin. The ureteral dissection is continued as far as is technically feasible. If the distal limits of the dissection are below the level of the iliac vessels, the remainder of the procedure can easily be completed through a lower abdominal incision. The specimen is placed in the pelvis, and the renal bed is inspected meticulously for bleeding. At this time, the 10-mm port sites are closed before proceeding to the open portion of the case.

Open Distal Ureterectomy with Excision of Bladder Cuff. The patient is now moved to the supine position, which can usually be done without re-preparation, and a low midline Pfannenstiel or Gibson incision is made (see Fig. 53–18). The choice of incision largely depends on the tumor location, the body habitus of the patient, and the most caudal level of ureteral dissection attained during the laparoscopic portion. The Gibson incision is preferable when the distal ureter cannot be freed laparoscopically to the level of the iliac vessels. The open distal ureterectomy is described in the section on open techniques.

Dissection of the Distal Ureter. If one is to consider a total laparoscopic procedure or to minimize the open distal portion, the ureteral dissection needs to continue to the level of the bladder. The patient is placed in the Trendelenburg position to move the bowel contents out of the pelvis. The peritoneal incision is extended from the level of the iliac vessels into the pelvis lateral to the bladder and medial to the medial umbilical ligament (Fig. 53–21). The vas deferens in male patients and the round ligament in female patients is clipped and divided. The ureter can now be traced between the bladder and the medial umbilical ligament down to its origin at the bladder. The bladder cuff may be dissected extravesically, freeing the ureter from the surrounding detrusor

muscle. Flexible cystoscopy at this point may be helpful in confirming complete ureterectomy and patency of the contralateral ureteral orifice.

Results

The first laparoscopic nephroureterectomy was performed in 1991 by Clayman and associates. Since that time the technical aspects and safety of laparoscopic procedures have been well established. There are multiple published series of laparoscopic nephroureterectomy with varying techniques (Chung et al, 1996; Keeley and Tolley, 1998; Salomon et al, 1999; Shalhav et al, 2000; Jarrett et al, 2001; Stifleman et al, 2001; Bariol et al, 2004; Hsueh et al, 2004; Matin and Gill, 2005; Wolf et al, 2005). Each varies with regard to approach (transperitoneal vs. retroperitoneal), management of the distal ureter by open removal, transurethral resection, and total laparoscopic management. As with other laparoscopic renal procedures there is no clear-cut benefit of any one approach with regard to morbidity, cosmesis, or return to activity. All, however, show a benefit with regard to morbidity compared with open surgery.

The efficacy of laparoscopic nephroureterectomy is being established for cancer control. With intermediate and long-term follow-up, cancer-related outcomes appear comparable to those of the open counterpart (McNeill et al, 2000). El Fettouh and colleagues (2002), in a multi-institutional study with 116 patients, showed the local and bladder recurrence rates to be 2% and 24%, respectively. The rate of distant metastasis was 9%, and positive margins were seen in 4.5% of cases. More recently, Berger and associates (2008) showed a 5-year cancer-specific survival of 80%, 70%, 68%, 60% and 0% for stage Ta/Tis, T1, T2, T3, and T4 lesions, respectively. Schatteman and associates (2007) similarly showed cancer-specific survival rates of 100%, 86%, 100%, 77%, and 0% for stage Ta, T1, Tis, T3, and T4 lesions. In both studies there was a worsening prognosis with increasing tumor stage. Long-term data are available from Muntener and associates (2007a), who studied 37 patients with follow-up of 60 to 148 months. In this study, 11 patients had disease progression and died of TCC 7 to 59 months after the operation. Tumor stage was the only factor significantly associated with disease recurrence. Waldert and coworkers (2009) compared open to laparoscopic outcomes and showed no significant difference in cancer outcomes and the advantage of lower morbidity for well-selected patients.

Local recurrence and port-site seeding are major concerns. There have been five reported instances of port-site seeding involving TCC of the upper urinary tract. Two of these cases were discovered after simple nephrectomy for presumed benign disease in which the principles of surgical oncology were inadvertently not followed (Ahmed et al, 1998; Otani et al, 1999). Three instances were for intended nephroureterectomy for high-grade disease (Ong et al, 2003; Matsui et al, 2004; Barrett, verbal communication, September 1998). Muntener and associates (2007b) reported a single case of local recurrence among 166 cases. In this instance there was obvious violation of the ipsilateral urinary tract, noted perioperatively. Although the potential for seeding exists, it does not appear any higher than that for the open surgical counterpart as long as good surgical principles are followed.

In summary there does not appear to be a significant difference between laparoscopic and open nephroureterectomy when the principles of surgical oncology are followed. Management of the bladder cuff still has shown variability and a tendency toward higher recurrences with minimally invasive approaches. Lymphadenectomy can be performed laparoscopically and should be utilized based on the clinical situation.

Open Segmental Ureterectomy

Ureteroureterostomy

Indications. **Segmental ureterectomy and ureteroureterostomy are indicated for noninvasive grade 1 and grade 2 tumors of the proximal ureter or midureter that are too large for complete endoscopic ablation and for grade 3 or invasive tumors when nephron sparing for preservation of renal function is a goal.**

Technique. The patient is placed in a modified flank position for lesions of the proximal ureter or in a supine position with a roll under the ipsilateral lumbar space for midureteral tumors. An angular extraperitoneal incision from the tip of the 12th rib toward the pelvis provides good exposure to the midureter. The ureter is identified, mobilized, and secured with vessel loops proximally and distally. The approximate location of the lesion is known from preoperative imaging and ureteroscopy. The tumor is palpated, and the ureter is ligated 1 to 2 cm proximal and distal to the tumor (Fig. 53–22A). The involved ureteral segment is excised and sent for frozen-section analysis to confirm the diagnosis, grade, and stage and to verify that both ends of the ureter are tumor free. A regional lymphadenectomy is performed. The ureter is repaired by mobilizing both ends to allow a tension-free anastomosis. A defect of up to 4 cm is amenable to ureteroureterostomy in most cases. The entire kidney may be mobilized downward to provide additional length to the proximal ureter when necessary. The periureteral blood supply is preserved as the ureter is mobilized. The ureteral ends are spatulated and anastomosed with interrupted absorbable 4-0 sutures (see Fig. 53–22B and C). A ureteral stent is placed as the anastomosis is in progress, and a closed-suction drain is placed in the retroperitoneal space near but not touching the repair (see Fig. 53–22D).

Distal Ureterectomy and Direct Neocystostomy or Ureteroneocystostomy with a Bladder Psoas Muscle Hitch or a Boari Flap

Indications. **Complete distal ureterectomy is recommended for tumors in the distal ureter that cannot be removed completely by endoscopic means** (Bloom et al, 1970; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Pagano, 1984; Johnson et al, 1988; Anderstrom et al, 1989; Williams, 1991; Messing and Catalona, 1998). Larger, high-grade, organ-confined, invasive lesions comprise the majority of these tumors.

Technique. The patient is placed in the supine position. It is desirable to include the genitalia in the surgical field so that a bladder catheter may be placed and accessible during the procedure. A Gibson, Pfannenstiel, or lower midline incision provides good exposure to the distal ureter and bladder for the ureteral excision and the repair. The distal ureterectomy is performed as described in the section on radical nephroureterectomy. Extra care is warranted to avoid spillage of known tumor in the distal ureteral segment.

The choice of a nonrefluxing or refluxing anastomosis is controversial (Pagano, 1984). The nonrefluxing anastomosis may limit infections as well as seeding of the upper tract with tumors from the bladder. The refluxing anastomosis may facilitate follow-up surveillance of the upper tract with imaging studies and ureteroscopy.

Direct ureteroneocystostomy may be possible if only a short segment of the juxtavesical and intramural ureter is removed. Additional techniques are required when the entire distal ureter

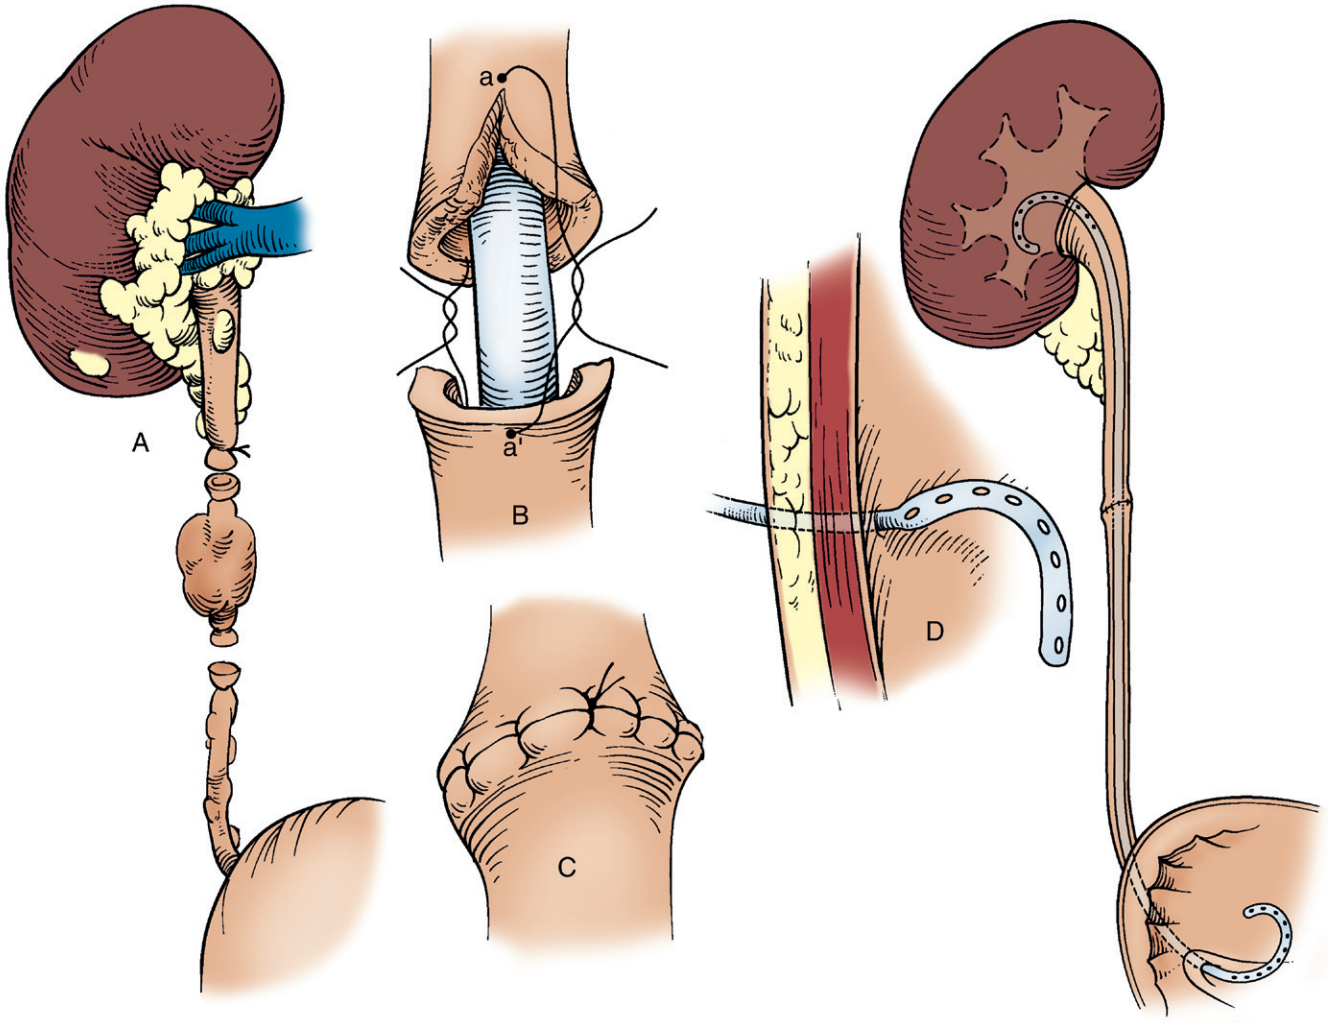

Figure 53–22. **A,** Segmental ureterectomy between ties for a large, invasive tumor of the midureter. **B** and **C,** Ureteroureterostomy of spatulated ends of the ureter. The repair is performed over an internal stent. **D,** Completed repair with closed-suction drain in retroperitoneal space.

is removed. The first choice is a bladder psoas muscle hitch. The superior vesical attachments on the opposite side of the bladder are freed. An anterior cystotomy is made, and the bladder is mobilized upward over the iliac vessels to the psoas muscle at the level of the iliac crest (Fig. 53–23A and B). The bladder is secured to the psoas muscle and tendon with a row of interrupted 2-0 chromic sutures. Entrapment of the genitofemoral nerve is avoided. The ureteral end is spatulated and brought through an opening in the uppermost portion of the bladder. Angulation must be avoided at the ureteral hiatus. A nonrefluxing anastomosis is performed by placing the ureter in a mucosal trough or tunnel if there is sufficient ureteral length (see Fig. 53–23C). The anastomosis is completed with interrupted 4-0 chromic sutures. A ureteral stent, a urethral catheter, and a closed-suction drain in the perivesical space are placed in all cases (see Fig. 53–23D). The anterior cystotomy is closed in two layers with 3-0 absorbable suture. Insertion of a suprapubic catheter is optional.

The bladder psoas muscle hitch provides considerable length if the bladder is of normal size and compliance. However, if an even greater gap must be bridged, a Boari flap from the anterior bladder wall combined with a psoas muscle hitch will reach the proximal ureter (Figs. 53–24 and 53–25). If the need for a Boari flap is anticipated, the incisions for the flap should be marked before making the cystotomy and psoas hitch. The spatulated end of the ureter is anastomosed to the cephalad end of the bladder flap, as described previously. The bladder tube is folded and closed in two layers with running 3-0 absorbable suture.

Subtotal Ureterectomy

Indications. Some tumors may require removal of long segments of the ureter by virtue of multifocality and number. However, the tumor grade and stage may not warrant nephroureterectomy. In addition, nephron sparing may be necessary because of compromised function of the contralateral kidney.

Technique. Complete ileal ureteral substitution may be performed as described in Chapter 85. The proximal ileal segment is anastomosed to the renal pelvis, and the distal ileum is connected to the bladder. Ileal interposition may be performed to repair a long midureteral defect when neither ureteroureterostomy nor bladder mobilization is feasible. A suitable length of ileum to bridge the gap is selected. The ileum is narrowed over a 14-Fr catheter held along the mesenteric edge of the bowel to approximate the diameter of the ureter. Discarding excess bowel from the antimesenteric edge decreases problems with mucus plugging, preserves intestinal blood supply, and allows more efficient peristalsis of urine across the ileal segment. The vermiform appendix has also

A closed-suction drain, ureteral stent, and bladder catheter are placed *(not shown)*.

been used for segmental ureteral substitution (Goldwasser et al, 1994). A preoperative bowel preparation is indicated when possible use of intestine is anticipated.

Finally, total ureterectomy, renal autotransplantation to the iliac fossa, and pyelocystostomy are options when the entire ureter is involved with multiple tumors (Pettersson et al, 1984). However, modern endoscopic techniques provide less invasive means of tumor control with lower morbidity in most cases.

Results

In the past, some authors recommended radical nephroureterectomy for all patients with upper tract urothelial tumors (Skinner, 1978). Others suggested segmental ureterectomy only for patients with low-grade, noninvasive tumors of the distal ureter (Babaian and Johnson, 1980). The cumulative results from the series in Tables 53–2 and 53–3 for patients with upper tract tumors of the renal pelvis or ureter reveal that **outcome strongly correlates with tumor stage and grade. Moreover, the results are similar for radical or nephron-sparing surgery.** The outcomes for only ureteral tumors are shown in Tables 53–4 and 53–5. Again, overall survival strongly correlates with stage and grade regardless of the extent of surgical treatment. Overall 5-year survival is excellent for patients with grade 1 and grade 2 noninvasive ureteral tumors. Five-year survival remains approximately 50% for patients with stage T2 disease but falls dramatically for stage T3. McCarron and associates (1983) reported 5-year survival of 64%

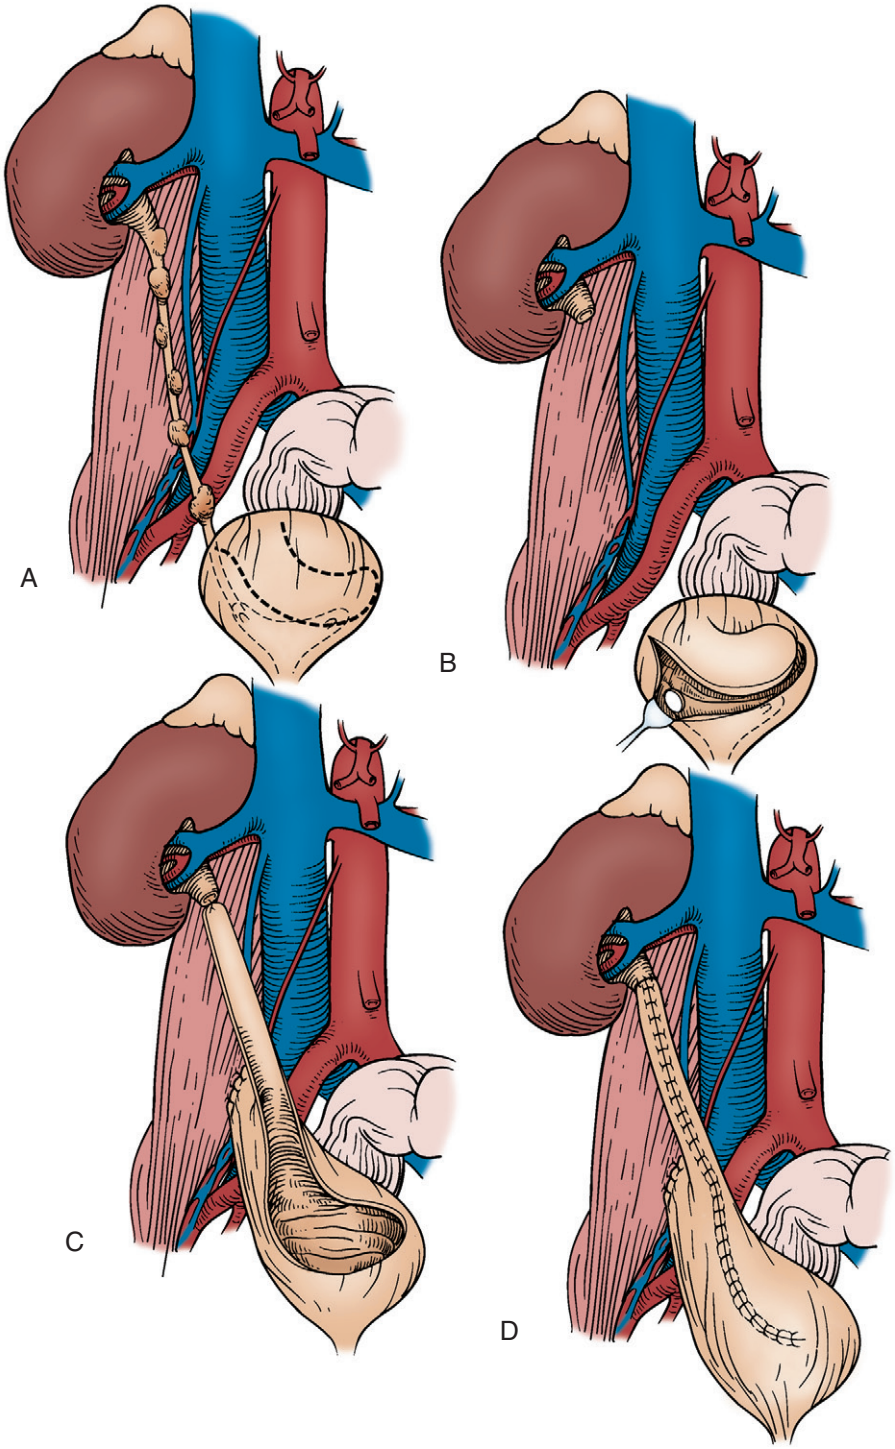

Figure 53–24. **A,** Subtotal ureterectomy required for nephron sparing in a patient with multiple diffuse ureteral tumors. **B,** A spiral flap is fashioned from the anterior bladder wall. **C,** The psoas hitch plus Boari flap reaches the remaining proximal ureter. **D,** Completed anastomosis and bladder closure. for patients with stage Ta tumors treated by either segmental ureterectomy or endoscopic tumor ablation. In the same series, 5-year tumor-free survival was 66% and 50% for stage T1 and T2 tumors, respectively, treated with segmental or distal ureterectomy. Anderstrom and colleagues (1989) reported no tumor-related deaths and only one recurrence among 21 patients treated with segmental ureterectomy for low-grade, noninvasive ureteral tumors who were observed for a median of 83 months.

Booth and associates (1980) reported 5-year survival of 72% versus 31% among 144 patients with ureteral tumors having either superficial or deep ureteral muscle invasion, respectively. This observation has not been duplicated in other series. The concept is of doubtful validity owing to the thin nature of the ureteral wall.

One of the few reports of 5-year cancer-specific survival by stage for patients with ureteral tumors comes from Grabstald and coworkers (1971). Disease-specific survival was 64% and 100% for stage Ta to T1 and stage T2 disease, respectively. All deaths were due to unrelated causes. In contrast, for patients with stage T3 disease, cancer-specific survival was only 7% and the death rate due to tumor was 87%.

The risk of ipsilateral recurrence after conservative treatment of ureteral tumors is 33% to 55% (Mazeman,

Results of Segmental Resection for Localized Ureteral Tumors

STUDY	NO. OF PATIENTS	LOCAL RECURRENCE (%)	FOLLOW-UP (mo)
Johnson and Babaian, 1979	6	16.6	44
Zungri et al, 1990	35	8.5	86
Maier et al, 1990	17	17.6	41.4
Wallace et al, 1981	7	14.3	93.6
Anderstrom et al, 1989	21	4.7	83

1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; McCarron et al, 1983; Williams, 1991). Most recurrences are distal to the original lesion, but proximal recurrences are also seen (Strong et al, 1976). The risk for recurrence and the need for follow-up are lifelong (Herr, 1998). Grossman (1978) reported a stage T2 local recurrence in a patient 16 years after segmental ureterectomy and ureteroureterostomy for a grade 1, stage Ta, midureteral tumor. The authors have seen a recurrence of a grade 2, stage Ta tumor in the distal ureter 18 years after segmental ureterectomy of a grade 1, stage Ta tumor of the proximal ureter (Sagalowsky, unpublished data, 1999).

The following are general recommendations for treatment of ureteral tumors in patients with good contralateral renal function. **Segmental ureterectomy is offered for grade 1 to grade 2, stage Ta to stage T1 tumors of the proximal ureter or midureter that are not amenable to complete ablation by endoscopic means because of size or multiplicity. Segmental excision also is offered for grade 1 to grade 2, stage T2 tumors of the proximal ureter or midureter. Distal ureterectomy and neocystostomy are offered for low-grade, low-stage tumors that are not controlled by endoscopic means. Ureteral excision may also be suitable for some high-grade, locally invasive tumors of the distal ureter.**

Laparoscopic Distal Ureterectomy and Reimplant

Various laparoscopic techniques for distal ureterectomy and reimplant have been reported (Rouprêt et al, 2007). **The indications are the same as those for the open counterpart and reserved for low-risk distal tumors. The distal ureter is dissected down to the ureteral orifice and the proximal end anastomosed to the bladder using standard techniques. The early reports are encouraging, but strict adherence to oncologic principles must be followed.**

Endoscopic Treatment

Basic Attributes

Hugh Hampton Young described the first endoscopic evaluation of the upper urinary tract in 1912. Subsequent advances in technology allow us to reach all parts of the urinary tract with minimal morbidity through antegrade and retrograde approaches. Diagnosis and treatment of upper tract TCC have become possible with these improvements because tumor biopsy and ablation by various energy sources are possible even through the smallest instruments. In addition, miniaturization has made follow-up surveillance of the upper tract more practical with the use of smaller ureteroscopes, which usually do not require previous stenting, or with active dilation of the distal ureter.

Tumors of the upper urinary tract can be approached in a retrograde or antegrade fashion. The approach chosen depends largely on the tumor location and size. In general, a retrograde ureteroscopic approach is used for low-volume ureteral and renal tumors. An antegrade percutaneous approach is preferred for larger tumors of the upper ureter or kidney and for those that cannot be adequately manipulated in a retrograde approach because of location (e.g., lower pole calyx) or previous urinary diversion. In cases with multifocal involvement, combined antegrade and retrograde approaches can be considered (Figs. 53–26 and 53–27).

The basic principles for treatment of TCC of the upper urinary tract are similar to those for the bladder counterpart (Fig. 53–28). The tumor is sampled and ablated by electrocautery or laser energy sources. A staged procedure should be considered for high-volume disease or disease that is thought to represent high pathologic grade or stage. In such cases, when subsequent nephroureterectomy most likely will be necessary for cure, only biopsy and partial ablation are performed to minimize the risks of perforation or major complications. Endoscopic management is completed only after the pathologic examination shows that the patient is an acceptable candidate for continued minimally invasive endoscopic management. If the pathologic process is unresectable, of high grade, or invasive, the patient should proceed immediately to nephroureterectomy, provided he or she is medically fit. Patients who undergo renal-sparing therapy must be committed to a lifetime of follow-up with radiographs and endoscopy.

Ureteroscopy and Ureteropyeloscopy

The ureteroscopic approach to tumors was first described by Goodman in 1984 and is generally favored for ureteral and smaller renal tumors. With the advent of small-diameter rigid and flexible ureteroscopes, tumor location is less of a limiting factor than it used to be. **The advantage of a ureteroscopic approach is lower morbidity than that of the percutaneous and open surgical counterparts, with the maintenance of a closed system. With a closed system, nonurothelial surfaces are not exposed to the possibility of tumor seeding.**

Figure 53–26. Retrograde pyelogram of a patient with a solitary kidney and multifocal low-grade tumors, which required both antegrade and retrograde approaches.

The major disadvantages of a retrograde approach are related to the smaller instruments required. Smaller endoscopes have a smaller field of view and working channel. This limits the size of tumor that can be approached in a retrograde fashion. In addition, some portions of the upper urinary tract, such as the lower pole calyces, cannot be reliably reached with working instruments. Smaller instruments limit the ability to remove large tumors and to obtain deep specimens for reliable staging. Retrograde ureteroscopy is difficult in patients with prior urinary diversion.

Key Point: Ureteroscopy

- Ureteroscopy offers lower morbidity and a closed-system approach to the tumor.

Technique and Instrumentation. A wide variety of ureteroscopic instruments are available, each with its own distinct advantages and disadvantages. In general, rigid ureteroscopes are used primarily for the distal ureter and midureter. Access to the upper ureter and kidney with rigid endoscopy is unreliable, especially in the male patient. Larger, rigid ureteroscopes provide better visualization because of their larger field of view and better irrigation. Smaller rigid ureteroscopes (8 Fr) generally do not require active dilation of the ureteral orifice (Fig. 53–29A).

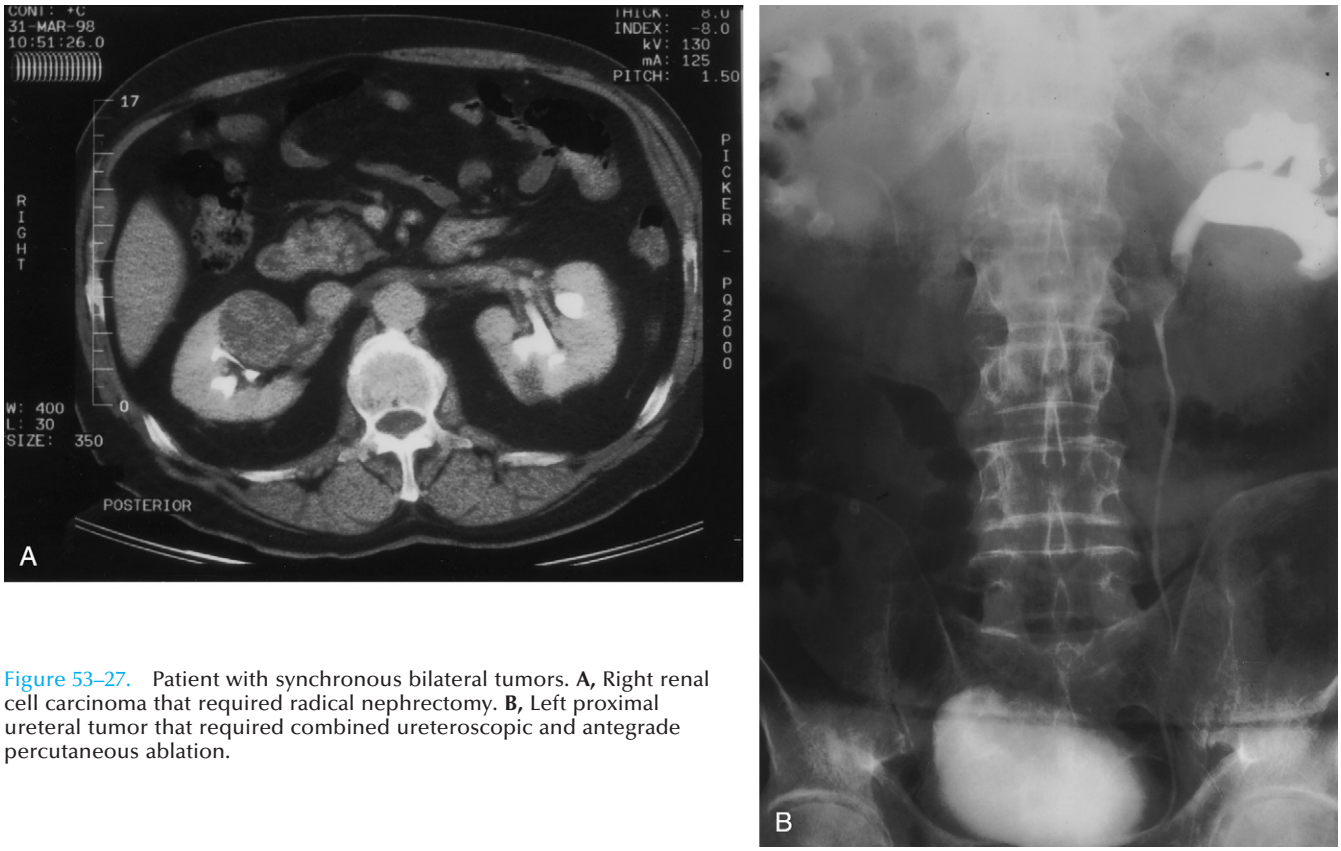

Figure 53–27. Patient with synchronous bilateral tumors. **A,** Right renal cell carcinoma that required radical nephrectomy. **B,** Left proximal ureteral tumor that required combined ureteroscopic and antegrade percutaneous ablation.

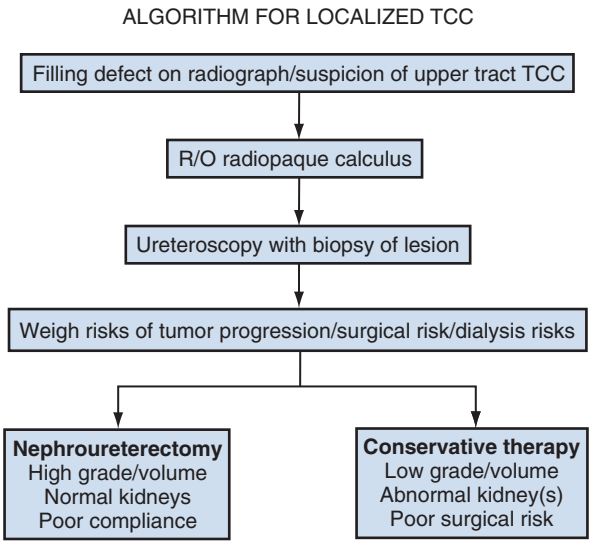

Figure 53–28. Algorithm for endoscopic approach to upper tract transitional cell carcinoma (TCC).

Newer-generation, flexible ureteropyeloscopes are available in sizes smaller than 8 Fr to allow simple and reliable passage to most portions of the urinary tract (Abdel-Razzak and Bagley, 1993; Grasso and Bagley, 1994; Chen and Bagley, 2000; Chen et al, 2000). These are generally preferred in the upper ureter and kidney, where the rigid ureteroscope cannot be reliably passed. **Flexible ureteroscopes, however, have technical limitations, such as a small working channel, that limit irrigant flow and the diameter of working instruments. Further limitations of flexible ureteroscopy include reduced access to certain areas of the kidney, such as the lower pole, where the infundibulopelvic angle may limit passage of the scope, and prior urinary diversion** (Fig. 53–29B).

Endoscopic Evaluation and Collection of Urine Cytology Specimen. Cystoscopy is performed and the bladder inspected for concomitant bladder disease. The ureteral orifice is identified and inspected for lateralizing hematuria. A small-diameter (6.9 or 7.5 Fr) ureteroscope is passed directly into the ureteral orifice, and the distal ureter is inspected for any trauma from a previously placed guide wire or dilation. A guide wire is then placed through the ureteroscope and up the ureter to the level of the renal pelvis under fluoroscopic guidance. The flexible ureteroscope is used to visualize the remaining urothelium. **When a lesion or suspicious area is seen, a normal saline washing of the area is performed before biopsy or intervention** (Bian et al, 1995). If the ureter does not accept the smaller ureteroscope, active dilation of the ureter is necessary.

Special circumstances include prior urinary diversion and tumor confined to the intramural ureter. With cases of prior urinary diversion, identification of the ureteroenteric anastomosis is difficult and may require antegrade percutaneous passage of a guide wire down the ureter before endoscopy. The wire can be retrieved from the diversion, and the ureteroscope can be passed in a retrograde fashion. The nephrostomy tract does not need to be fully dilated in this setting. Wagner and associates (2008) described their experience with endoscopic monitoring of patients with ureteral carcinoma in situ after radical cystectomy. A second type of case is tumor in the intramural ureter. When a tumor protrudes from the ureteral orifice, complete ureteroscopic

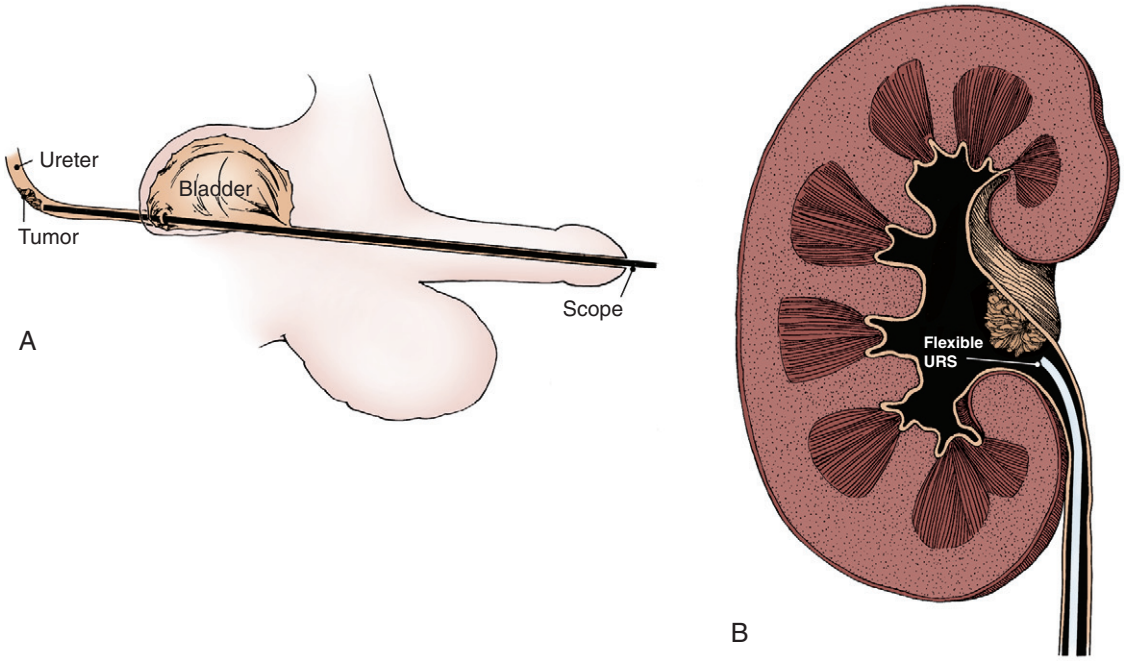

Figure 53–29. **A,** Rigid ureteroscopic approach. **B,** Flexible ureteroscopic approach. URS, ureteroscope.

ablation of the tumor or aggressive transurethral resection of the entire most distal ureter can be done with acceptable results (Palou et al, 2000).

Biopsy and Definitive Treatment. Three general approaches can be used for tumor ablation: bulk excision with ablation of the base, resection of the tumor to its base, and diagnostic biopsy followed by ablation with electrocautery or laser energy sources. Regardless of technique used, special attention to biopsy specimens is necessary. Specimens are frequently minute and should be placed in fixative at once and specially labeled for either histologic or cytologic evaluation (Tawfiek et al, 1997).

Ureteroscopic Techniques. The tumor is debulked by use of either grasping forceps or a flat wire basket engaged adjacent to the tumor (Fig. 53–30A). Next, the tumor base is treated with either electrocautery or laser energy sources. This technique is especially useful for low-grade papillary tumor on a narrow stalk. The specimen is sent for pathologic evaluation.

A ureteroscopic resectoscope is used to remove the tumor (Fig. 53–30B). Only the intraluminal tumor is resected, and no attempt is made to resect deep (beyond the lamina propria). Extra care is necessary in the midureter and upper ureter, where the wall is thin and prone to perforation. Ureteral resectoscopes are approximately 12 Fr and require more extensive dilation of the ureteral orifice. With larger volume disease of the distal ureter, Jarrett and associates (1995a) described extensive dilation of the ureter followed by resection with a long standard resectoscope. **The tumor is adequately sampled with forceps and sent to the pathology laboratory for diagnostic evaluation. The tumor bulk is then ablated to its base with laser or electrosurgical energy** (Fig. 53–30C and D). Multiple biopsy specimens are often required when small, flexible 3-Fr biopsy forceps are used. Electrocautery delivered through a small Bugbee electrode (2 or 3 Fr) can be used to fulgurate tumors. However, the variable depth of penetration can make its use in the ureter dangerous, and circumferential fulguration should be avoided because of the high risk of stricture formation. More recently, laser energy with either neodymium:yttrium-aluminum-garnet (Nd:YAG) (Smith et al, 1984; Schilling et al, 1986; Schmeller and Hofstetter, 1989; Carson, 1991) or holmium:YAG (Bagley and Erhard, 1995; Razvi et al, 1995; Matsuoka et al, 2003; Suoka et al, 2003) sources has been popular. Each has characteristic advantages (Fig. 53–31) and can be delivered through small, flexible fibers (200 or 365 μm) that fit through small, flexible ureteroscopes without significant alteration of irrigant flow or scope deflection.

Key Point: Biopsy and Ablation

- The lesion is sampled first for cytology and for histopathologic staging, if possible; then it is ablated.

The holmium:YAG laser is well suited for use in the ureter. The tissue penetration is less than 0.5 mm, which allows tumor ablation with excellent hemostasis and minimal risk of full-thickness injury to the ureter. Its shallow penetration may, however, make its use cumbersome with larger tumors, especially in the renal pelvis. Settings most commonly used for the holmium:YAG laser are energy of 0.6 to 1 J with frequency of 10 Hz. The Nd:YAG laser has a tissue penetration of up to 5 to 6 mm, depending on laser settings and duration of treatment. In contrast to the holmium:YAG laser, which ablates tumor, the Nd:YAG laser works by coagulative necrosis with subsequent sloughing of the necrotic tumor. The safety margin is significantly lower and can limit its use in the ureter, where the ureteral wall is thin. Settings most commonly used for the Nd:YAG laser are 15 W for 2 seconds for ablation of tumor and 5 to 10 W for 2 seconds for coagulation.

A ureteral stent is placed for a variable duration to aid with the healing process. Large tumors usually require multiple treatment sessions during several months.

Results. Multiple series have shown the safety and efficacy of ureteroscopic treatment of upper tract TCC (Elliott et al, 1996;

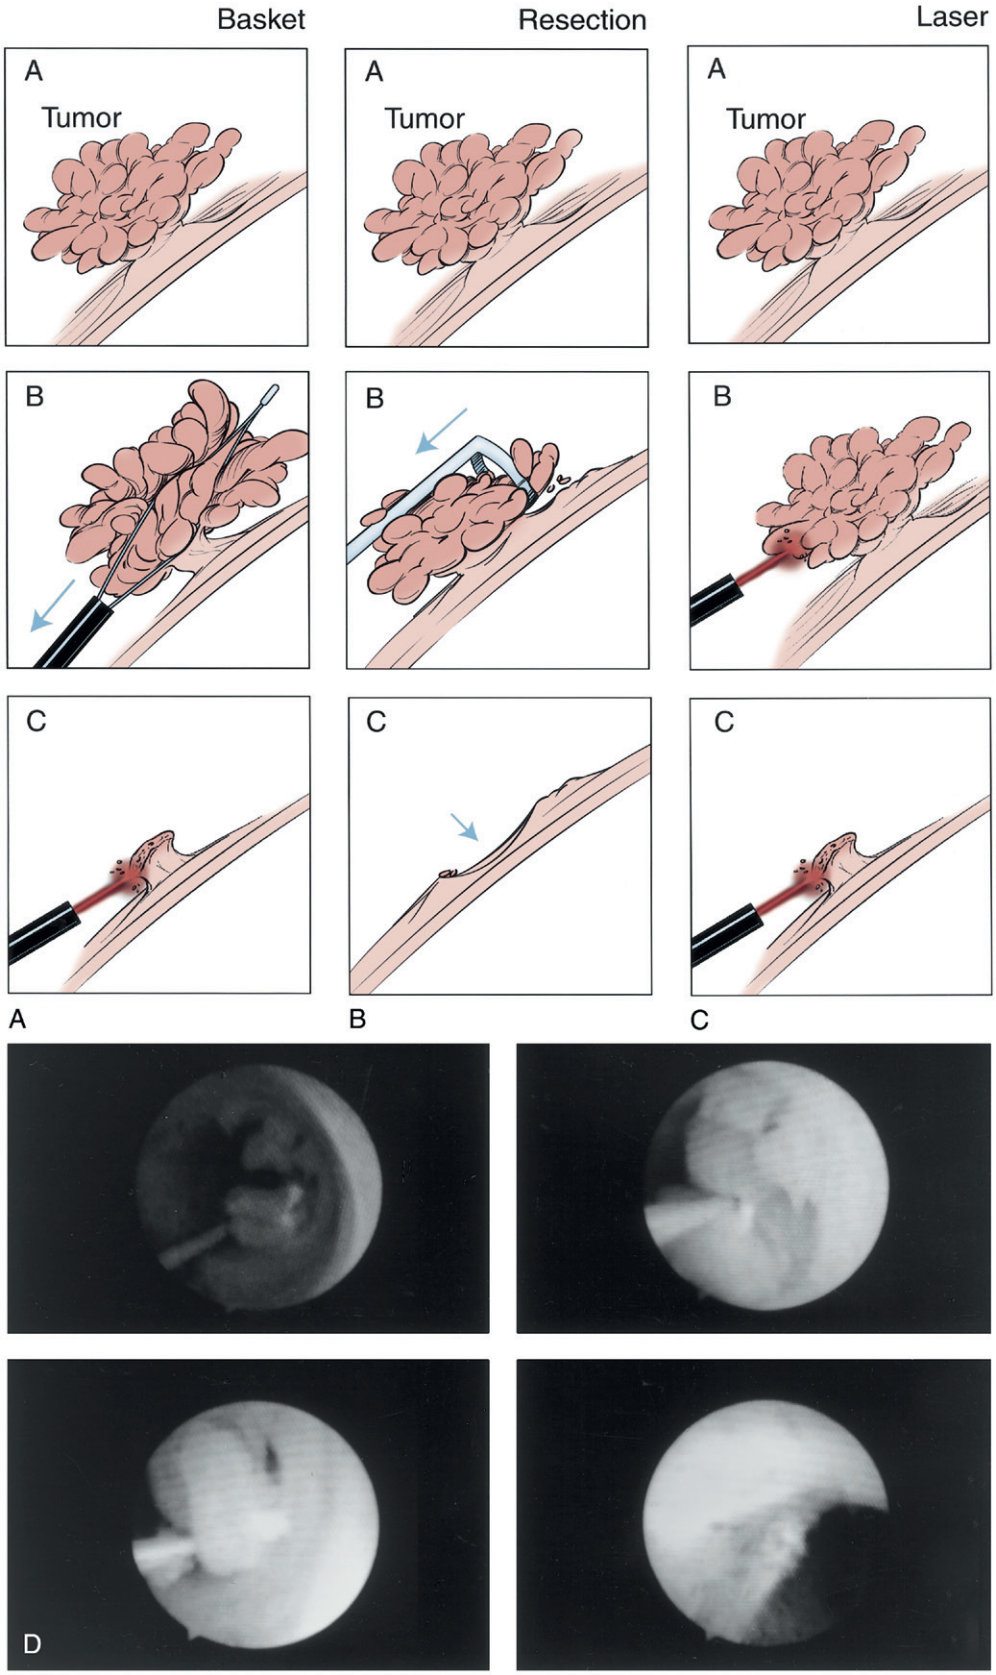

Figure 53–30. Techniques for ureteroscopic treatment of ureteral and renal tumors. **A,** The tumor is identified and removed piecemeal by grasping forceps to its base. **B,** Alternatively, a flat wire basket can be deployed alongside the tumor. The tumor is engaged and removed, with care taken not to avulse the adjacent ureter. With either of these technique, the base is treated with electrocautery or a laser energy source. **C,** The tumor is identified and removed by a ureteroscopic resectoscope. The technique differs from the technique for bladder tumors in that only intraluminal tumor is resected. No attempt is made to resect deep, as with a bladder tumor. The scope is not arching deep into the tissue. **D,** The tumor is sampled for diagnostic purposes. The bulk of the tumor is then ablated with electrosurgical or laser energy. Laser energy is generally preferred because it has more reliable delivery of energy and depth of penetration. The two most commonly used energy sources are holmium:yttrium-aluminum-garnet and neodymium:yttrium-aluminum-garnet.

NXUX, nephroureterectomy.

Englemeyer and Belis, 1996; Martinez-Pineiro et al, 1996; Keeley et al, 1997a, 1997b; Iborra et al, 2003). In a literature review of 205 patients (Tawfiek and Bagley, 1997), the overall recurrence rates for ureteral and renal pelvic lesions were 33% and 31.2%, respectively, and the risk of bladder recurrence was 43%. In the largest series (Keeley et al, 1997a) there was a single cancer death directly attributed to recurrent upper tract disease. As with any TCC, the most important prognostic indicator for tumor recurrence was grade. Keeley and associates (1997c) showed a recurrence rate of 26% for grade 1 tumors and 44% for grade 2 tumors, which roughly correlated with previously established recurrence rates for open conservative surgery.

More recent literature shows the long-term feasibility of the ureteroscopic approach, but concerns over the high rate of ipsilateral recurrences remain (Table 53–6). Daneshmand and colleagues (2003) reported a large number of recurrences with an overall ipsilateral recurrence rate of 90% with three to four recurrences per patient. Sowter and associates (2007) showed an ipsilateral recurrence rate of 74%. Thompson and colleagues (2008) studied 83 patients who underwent endoscopic management of tumors, 76 of which were ureteroscopic. The overall recurrence rate was 55%. Nephroureterectomy eventually was performed in 33%. This is important in considering patients with a normal contralateral kidney. Patients must be counseled in the need for lifetime follow-up and possible treatment of ipsilateral recurrence.

Complications were uncommon and usually related to the patient's comorbidities. Complications specific to ureteroscopic therapy included ureteral perforation, which can be managed with indwelling ureteral stent, and ureteral stricture. Stricture formation rate ranged from 5% to 13% (Elliott et al, 1996; Martinez-Pineiro et al, 1996; Keeley et al, 1997a). The complication rates have dropped in more contemporary series, most likely related to smaller endoscopes, improved laser energy sources, and refinements in endoscopic techniques.

Two major concerns of the ureteroscopic approach are the accuracy of ureteroscopic biopsies and the limitations of biopsies, especially with regard to staging (Huffman, 1988). Retrospective reviews of patients who underwent ureteroscopic biopsy followed by nephroureterectomy found the accuracy of ureteroscopic diagnosis to be 89% to 94% and the pathologic grading to match the open surgical technique in 78% to 92% (Keeley et al, 1997a; Guarnizo et al, 2000). From prior studies, we know that there is an excellent correlation between grade of lesion and stage (Chasko et al, 1981; Heney et al, 1981). This holds true for the ureteroscopic approach (Keeley et al, 1997c) because 87% of patients with grade 1 or grade 2 tumors had noninvasive disease (stage Ta or T1) whereas 67% of patients with grade 3 tumors had invasive disease (stage T2 or T3). This information supports the notion that tumor grade is the most important prognostic factor; and although stage cannot be directly assessed, noninvasive disease can be expected in most cases of low-grade tumor.

A final concern is whether ureteroscopy promotes progression or spread of disease to other urothelial surfaces or metastatic sites. There have been reports of increased tumor appearance in refluxing ureters of patients with bladder tumors (de Torres Mateos et al, 1987) and in the ipsilateral urinary tract and bladder of patients after ureteroscopic treatment. However, Kulp and Bagley (1994) reported on 13 patients who underwent multiple ureteroscopic treatments followed by nephroureterectomy; they found no unusual propagation of TCC in the specimens. Concerns that ureteroscopy may promote metastatic spread were raised by Lim and associates (1993), who found tumor cells in renal lymphatics after ureteroscopy. However, Hendin and colleagues (1999) reported no increased risk of metastatic disease in a group of patients who underwent ureteroscopy before nephroureterectomy compared with a group undergoing nephroureterectomy alone.

Percutaneous Approach

The percutaneous approach was first described by Tomera and coworkers in 1982 and is generally favored for larger tumors located proximally in the renal pelvis or proximal ureter. **The main advantage of the percutaneous approach is the ability to use larger instruments that can remove a large volume of tumor** in any portion of the renal collecting system. Because deeper biopsy specimens are obtained, tumor staging as well as grading is usually possible. In addition, a percutaneous approach may avoid the limitations of flexible ureteroscopy, especially in complicated calyceal systems or areas difficult to access, such as the lower pole calyx or the upper urinary tract of patients with urinary diversion. With a percutaneous approach, the established nephrostomy tract can be maintained for immediate postoperative nephroscopy and administration of topical adjuvant therapy.

The main disadvantages are the increased morbidity compared with ureteroscopy and the potential for tumor seeding outside the urinary tract. Establishment of the nephrostomy tract has inherent risks, and the procedure usually requires inpatient admission. Distinct risks related to a percutaneous approach are loss of urothelial integrity and exposure of nonurothelial surfaces to tumor cells. This open system provides the possibility of tumor implantation in the nephrostomy tract.

Technique and Instrumentation

Establishment of the Nephrostomy Tract. Cystoscopy is performed, and an open-ended ureteral catheter is positioned in the pelvis. Contrast material is injected to define the calyceal anatomy,

and a percutaneous nephrostomy tract is established through the desired calyx (Fig. 53–32). Tumors in peripheral calyces are best approached with direct puncture distal to the tumor (Fig. 53–33). Disease in the renal pelvis and upper ureter is best approached through an upper or middle pole access to allow scope maneuvering through the collecting system and down the ureteropelvic junction. The tract is dilated by either sequential (Amplatz) or balloon dilation to accommodate a 30-Fr sheath. Correct positioning of the nephrostomy tract is crucial to the success of the procedure and should be done by the urologist or by the radiologist after direct consultation with the operating surgeon.

A nephroscope is inserted, and the ureteral catheter is grasped, brought out the tract, and exchanged for a stiff guide wire, thus providing both antegrade and retrograde control. Complete nephroscopy is performed with rigid and flexible endoscopes when necessary. Any suspicion of upper ureteral involvement warrants antegrade ureteroscopy.

Biopsy and Definitive Therapy. **After identification, the tumors are removed by one of the following four techniques** (Fig. 53–34). In the first technique, which uses a cold-cup biopsy forceps through a standard nephroscope, the bulk of the tumor is grasped by forceps and removed in piecemeal fashion until the base is reached (see Fig. 53–34A). A separate biopsy of the base is performed for staging purposes, and the base is cauterized with a Bugbee electrode and cautery. Low-grade papillary lesions on a thin stalk are easily treated in this manner with minimal bleeding.

Alternatively, a cutting loop from a standard resectoscope is used to remove the tumor to its base (see Fig. 53–34B). Once again, the base should be resected and sent separately for staging purposes. This approach is more effective for larger, broad-based tumors for which simple debulking to a stalk is not possible.

For the third technique, which uses flexible or rigid endoscopes, the tumor is sampled and treated with holmium:YAG or Nd:YAG

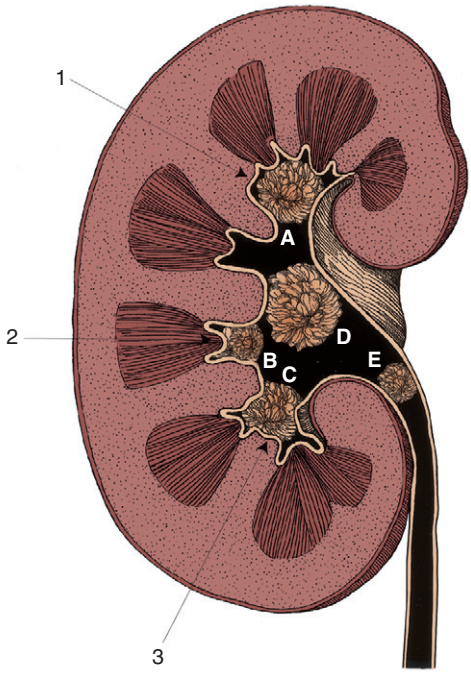

Figure 53–32. Nephrostomy tract puncture site. Position of the nephrostomy is imperative for successful percutaneous resection of transitional cell carcinoma of the renal collecting system and upper ureter and requires careful preoperative evaluation of radiographs for tumor location. Tumors in peripheral calyces (A to C) are best approached by direct puncture as far distally in the calyx as possible. Tumors in the renal pelvis (D) and upper ureter (E) are best approached by puncture to an upper (1) or middle (2) calyx, which allows the scope to be maneuvered in the renal pelvis and down the ureter. Tumors in the lower calyx are approached by lower calyx puncture (3).

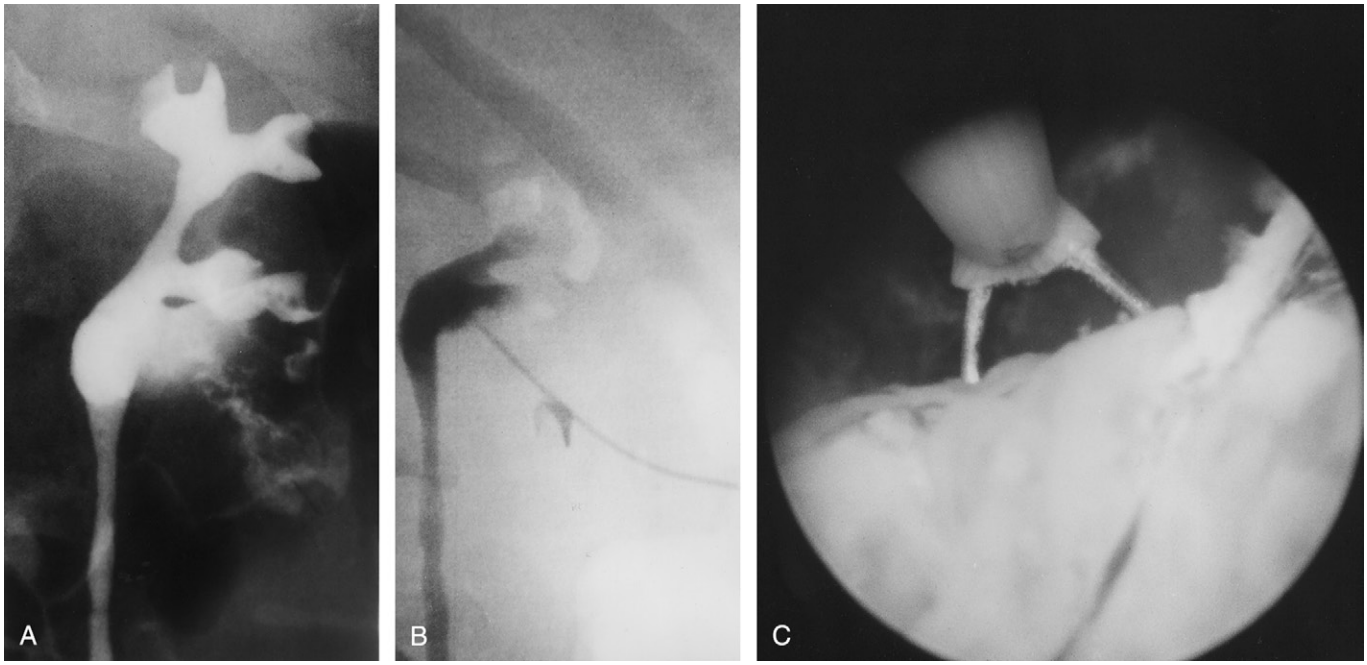

Figure 53–33. **A,** Retrograde pyelogram of a man with transitional cell carcinoma of the lower calyx in a solitary kidney. **B,** Access distal in the calyx allows a clear view of the tumor. **C,** Subsequent resection.

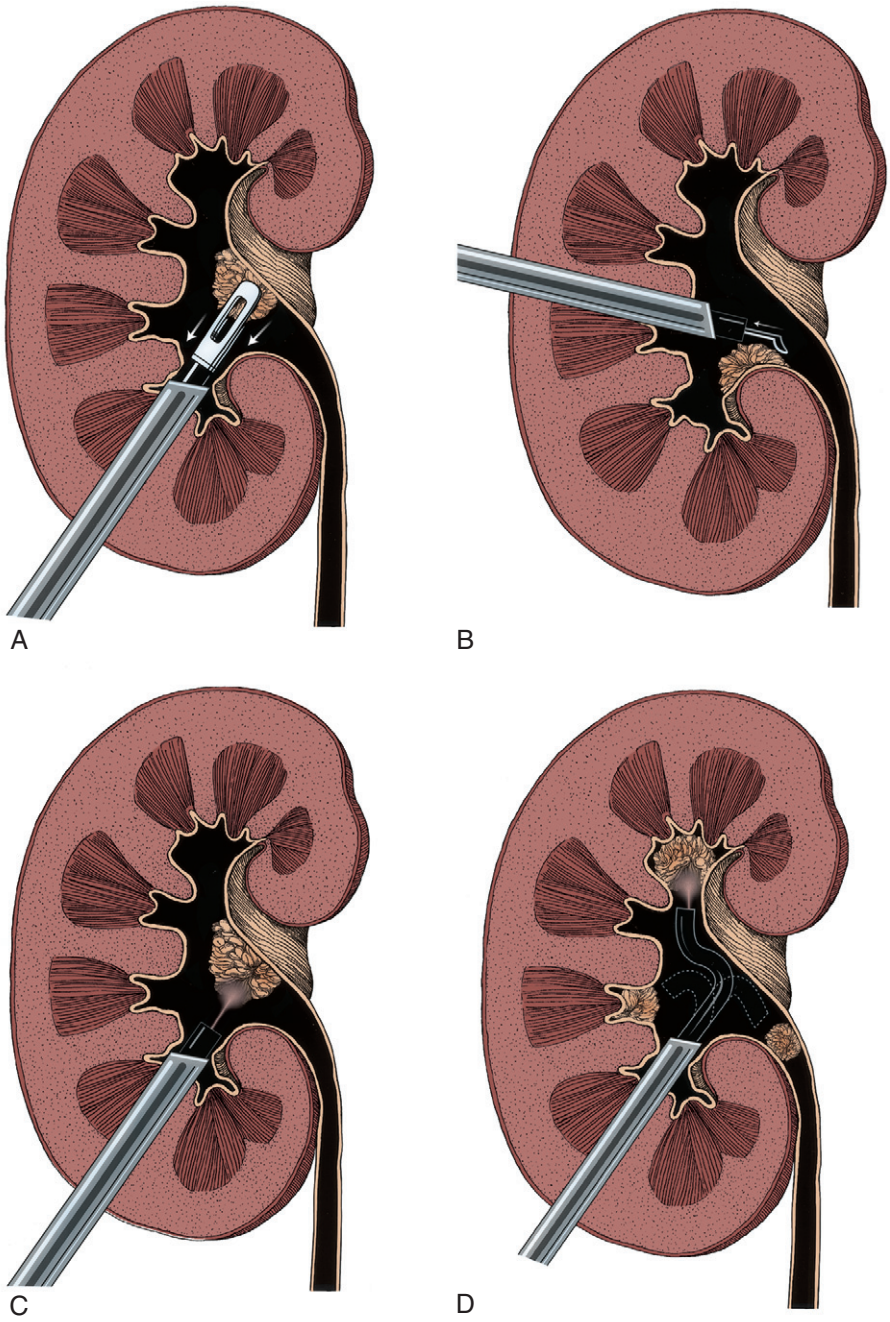

Figure 53–34. Techniques for percutaneous removal of transitional cell carcinoma of the renal collecting system. **A,** The tumor is identified and debulked by forceps to its base. The base is sampled and sent separately for evaluation. This technique works well for papillary tumors on a narrow stalk. Broad-based tumors may cause excessive bleeding and are best approached with resection or laser therapy. **B,** With use of a standard resectoscope the tumor is identified and resected to its base. Special care should be taken to avoid resection into major renal vasculature. The tumor is identified, sampled for diagnostic purposes, and treated by holmium or neodymium laser sources. This can be done through a standard nephroscope **(C)** or with a flexible cystoscope **(D).**

laser at 25 to 30 W (see Fig. 53–34C and D). Tissue may also be obtained with a small snare used for gastrointestinal polyps.

Regardless of approach, a nephrostomy tube is left in place. This access can be used for second-look follow-up nephroscopy to ensure complete tumor removal (Fig. 53–35). Nephroureterectomy is indicated if the pathologic examination shows high-grade or invasive disease.

Second-Look Nephroscopy. Follow-up nephroscopy is performed 4 to 14 days later to allow adequate healing. The tumor resection site is identified, and any residual tumor is removed. If no tumor is identified, the base should be sampled and treated by cautery or the Nd:YAG laser (15 to 20 W and 3-second exposures). The nephrostomy tube can be removed several days later if all tumors have been removed. If the patient is being considered for adjuvant topical therapy, a small, 8-Fr nephrostomy tube is left to provide access for instillations. Some authors advocate third-look nephroscopy before removal of the nephrostomy tube (Jarrett et al, 1995b).

Results. Because of the rarity of the disease there are limited retrospective series (Table 53–7) with adequate numbers and follow-up from which to draw reasonable conclusions (Jarrett et al, 1995b; Patel et al, 1996; Clark et al, 1999; Goel et al, 2003; Palou et al, 2004; Rouprêt et al, 2006). In a literature review of 84 patients, Okada and colleagues (1997) found an overall recurrence rate of 27%. Tumor grade strongly predicted outcomes; Jarrett and associates (1995b) showed the recurrence rate for grades 1, 2, and 3 lesions to be 18%, 33%, and 50%, respectively. The only cancer-related mortalities in this series were in patients with high-grade disease. Lee and colleagues (1999) reviewed their 13-year experience with percutaneous management, comparing 50 patients who underwent percutaneous management with 60 patients who

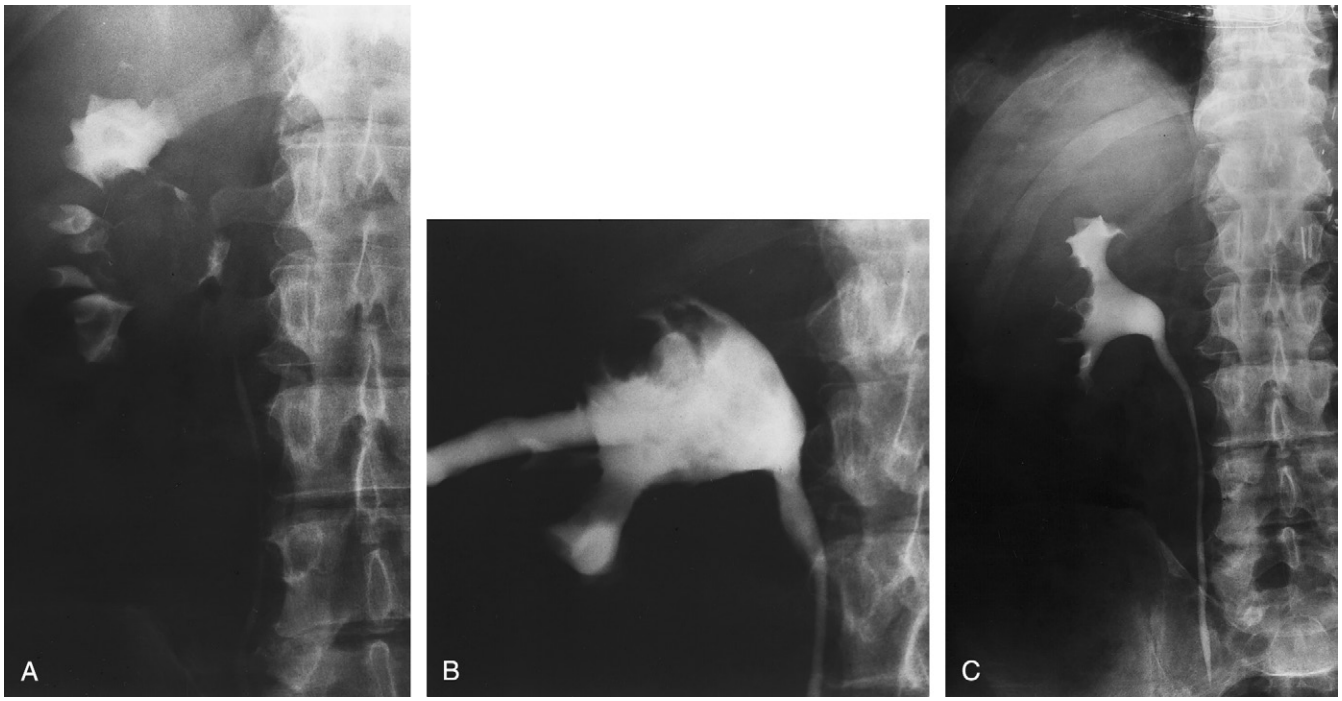

Figure 53–35. **A,** A 65-year-old man presented with a solitary kidney and a 5-cm renal pelvis tumor. **B,** Nephrostogram after patient underwent staged resection. **C,** Three-month follow-up retrograde pyelogram after completed resection. The patient showed grade 1 transitional cell carcinoma without invasion to submucosa.

Rouprêt et al, 2007	24	8 (32)	20	18-188

NXUX, nephroureterectomy.

underwent nephroureterectomy, and found no significant difference in overall survival. As expected, patients with low-grade disease did well regardless of modality and patients with high-grade disease did poorly regardless of treatment option.

Most would agree from the literature that percutaneous management is acceptable in patients with low-grade (grade 1) disease regardless of the status of the contralateral kidney, provided the patient is committed to lifelong endoscopic follow-up. Patients with grade 3 disease do poorly regardless of modality chosen but should probably undergo nephroureterectomy to maximize cancer therapy (provided they are medically fit). The largest area of controversy surrounds the use of percutaneous management for patients with grade 2 disease and a normal contralateral kidney. Jabbour and associates (2000) retrospectively evaluated 24 patients and found a disease-specific survival of 95% overall and 100% and 80% for stage Ta and stage T1 lesions, respectively. This study shows an acceptable result with conservative treatment of noninvasive grade 2 disease. With more invasive lesions, the potential for disease progression and metastatic disease is significant and nephroureterectomy should be considered.

Complications from percutaneous management of tumors are similar to those for benign renal processes and include bleeding, perforation of the collecting system, and secondary ureteropelvic junction obstruction. Complications increase in number and severity with higher tumor grade (Jarrett et al, 1995b). This finding is probably due to the more extensive pathologic process and treatments necessary to eradicate the tumor. Unlike ureteroscopic resection, the percutaneous method can stage tumors and, as expected, stage increases with tumor grade.

A major concern of the percutaneous approach is the potential seeding of nonurothelial surfaces with tumor cells. Although there have been multiple reported cases of nephrostomy tract infiltration with high-grade tumors (Tomera et al, 1982; Slywotzky and Maya, 1994; Huang et al, 1995; Oefelein and MacLennan, 2003; Treuthardt et al, 2004), there were no reported occurrences in the three largest series (Jarrett et al, 1995b; Patel et al, 1996; Clark et al, 1999). Tract seeding is a possibility but appears to be an uncommon event.

Isolated Upper Tract Cytologic Abnormality or Urinary Marker

On occasion, one is faced with a patient who has an isolated abnormal cytologic finding or other urinary marker from the upper urinary tract. **By definition, the patient should have normal intravenous urography and retrograde pyelography, normal cystoscopy, and normal biopsy findings from the bladder and urethra.** Radical nephroureterectomy was performed in the past for a unilateral cytologic abnormality of the upper tract to eliminate presumed carcinoma in situ. This practice is not recommended (Gittes, 1980; McCarron et al, 1983;

Williams, 1991; Messing and Catalona, 1998). Upper tract cytology suffers from the same limitations in specificity as does bladder cytology. Furthermore, properly collected upper tract samples are of limited volume and cell count compared with bladder washings. Any source of inflammation, such as urinary infection or calculus, may produce a false-positive result. A subsequent cytologic abnormality from the contralateral side during follow-up is not rare in cases of true-positive results from early carcinoma in situ (Murphy et al, 1974; Khan et al, 1979). A variety of urinary markers are being studied to aid in detection of urothelial tumor recurrence. At this time, both urine FISH and urine nuclear matrix protein show particular promise.

Ureteropyeloscopy is indicated in such cases because the yield for direct visualization of small lesions is superior to that of retrograde pyelography. An attempt to perform biopsy and confirm the diagnosis is indicated before treatment is considered. A consistently abnormal finding on upper tract cytology may signify carcinoma in situ. Current treatment options are limited. Instillation of topical immunotherapy or chemotherapy may be performed through ureteral catheters or a small percutaneous nephrostomy. However, the contact time of the agent with the urothelium is minimal. Reports of efficacy are uncontrolled and anecdotal. Frequent-interval reevaluation with urinalysis, bladder cytology, cystoscopy every 3 months and retrograde pyelography or ureteropyeloscopy every 6 months is indicated for 1 to 2 years. However, one must avoid overtreatment and excessive evaluation and instrumentation of a patient who may have had a single false-positive result.

Adjuvant Therapy

After Organ-Sparing Therapy

Any procedure short of nephroureterectomy has a higher local recurrence due to the established risk of ipsilateral recurrence. Several approaches are available to minimize these risks. They fall into two basic categories: instillation of immunotherapeutic or chemotherapeutic agents and brachytherapy of the nephrostomy tract.

Instillation Therapy. Instillation therapy can be accomplished in several ways. Accepted techniques include antegrade instillation through a nephrostomy tube (Fig. 53–36) and retrograde instillation directly into a ureteral catheter or by reflux in a patient with an indwelling ureteral stent or iatrogenically created vesicoureteral reflux. Patel and Fuchs (1998) described a convenient technique of outpatient instillation through a ureteral catheter placed suprapubically. Regardless of the technique chosen, administration to the upper urinary tract should be done under low pressure and in the absence of active infection to minimize the risk of bacterial sepsis or systemic absorption of the agent.

Results. **The same agents used to treat urothelial carcinoma of the bladder are used to treat tumors of the upper urinary tract. Many studies have described small, retrospective, uncontrolled series of patients undergoing therapy with thiotepa** (Elliott et al, 1996; Patel et al, 1996), **mitomycin** (Eastham and Huffman, 1993; Weston et al, 1993; Martinez-Pineiro et al, 1996; Keeley et al, 1997a; See, 2000), **and BCG** (Table 53–8) (Smith et al, 1987; Studer et al, 1989; Eastham and Huffman, 1993; Sharpe et al, 1993; Jarrett et al, 1995b; Hayashida, 2004; Rastinehad et al, 2009). Although the cumulative experience appears encouraging, no individual study has shown statistical improvement with relation to survival and recurrence rates. Possible reasons for this include (1) insufficient numbers to show clinical significance because of the relative rarity of the disease; (2) tumors of the upper urinary tract, which have a tumor biology different from that of their bladder counterparts; and (3) an inadequate delivery system that, unlike in the bladder, does not allow uniform delivery of the agent with adequate dwell time to enable a clinical response. Furthermore, in the report by Hayashida and colleagues (2004) with intrarenal perfusion of BCG, despite initial return of cytology results to normal, 50% of patients (5 of 10) developed disease recurrence after a mean follow-up of 50.9 months, and all of these suffered cancer-specific mortality. There is no doubt that more studies are required to settle this issue. The attempt to decrease multiple recurrences in the upper tract is reasonable in well-selected patients.

The most common complication of instillation therapy is bacterial sepsis. To minimize this problem, patients must be evaluated for active infection before each treatment and only a low-pressure delivery system should be used. Agent-specific complications of

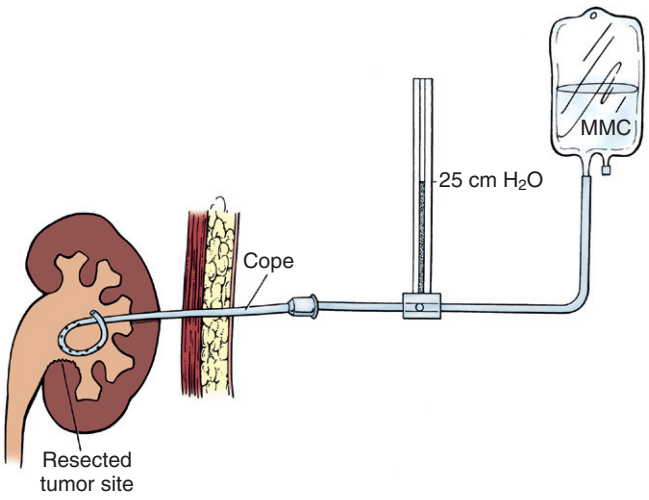

Figure 53–36. Setup for administration of topical immunotherapy or chemotherapy to the upper urinary tract through a previously placed nephrostomy tube. Therapy is instilled by gravity with a mechanism that prevents excessive intrarenal pressures. High pressures have been linked to complications of systemic absorption and bacterial sepsis. MMC, mitomycin C.

Jarrett et al, 1995	19	19	33	10	55

BCG, bacille Calmette-Guérin; DOD, dead of disease.

the various therapies include ramification of systemic absorption of the agent. Bellman and colleagues (1994) described upper urinary tract complications of percutaneous BCG instillation. Granulomatous involvement of the kidney in the absence of systemic signs of BCG infection was most commonly seen. Mukamel and associates (1991) saw an inordinate decrease in renal function for patients receiving BCG who had vesicoureteral reflux.

Brachytherapy. Brachytherapy to the nephrostomy tract through iridium wire or delivery system was described by Patel and coworkers (1996) and Nurse and colleagues (1989). There were no instances of tract recurrences in this series, although the authors acknowledged the rarity of the event. The only major complication attributed to the brachytherapy was cutaneous fistula formation requiring nephroureterectomy.

After Complete Excision

Radiation Therapy. The rationale for focal radiation therapy is to decrease the risk of local relapse after radical surgery for locally advanced non–organ-confined disease (stage T3 to T4, N+). Most series concluding that postoperative irradiation is beneficial are small or even anecdotal, uncontrolled, and retrospective (Holtz, 1962; Brady et al, 1968; Leiber and Lupu, 1978). In one series with 41 patients, postoperative radiation therapy decreased local recurrence but had no effect on distant relapse or survival (Brookland and Richter, 1985). Maulard-Durdux and associates (1996) retrospectively reviewed 26 patients who received 46 Gy to the wound bed after radical surgery for upper tract tumors. Tumors were grade 2 in 40% and grade 3 in 60% of cases. Tumor stage was T2, T3, and N+ in 42%, 58%, and 35% of cases, respectively. Five-year survival is shown in Table 53–9. Overall 5-year survival was 49%, with 30% remaining disease free. All patients with local relapse also had distant relapse, leading the authors to conclude that adjuvant radiation therapy is not beneficial.

The largest experience addressing this issue is that reported by Hall and associates (1998b). A retrospective review of 252 patients with upper tract tumors who were observed for a median of 64 months was performed. Radical nephroureterectomy was performed in 77% of cases. Initial tumor stage was T3 in 19% and T4 in 10% of cases; 50% and 52%, respectively, of patients with stage T3 and stage T4 tumors received 40 Gy to the wound bed postoperatively. Disease-specific and overall 5-year survival was 41% and 28%, respectively, for patients with stage T3 disease. Actuarial 5-year disease-specific survival for stage T3 with or without adjuvant radiation therapy was 45% and 40%, respectively. Median survival was 6 months for stage T4 disease. There were no long-term survivors in this group. Local relapse occurred in only 9% of the entire series and was seen only in patients with stage T3 and stage T4 disease. Among the patients who received adjuvant radiation, isolated local relapse without distant metastases occurred in only 10% and 4% of stage T3 and stage T4 cases, respectively. Thus **radical nephroureterectomy alone provides a high rate of local control. Adjuvant radiation for high-stage disease does not decrease local relapse or protect against a high rate of distant failure.**

Table 53–9.

5-Year Survival after Postoperative Adjuvant Radiation Therapy for Upper Tract Urothelial Tumors

Data from Maulard-Durdux C, Dufour B, Hennequin C, et al. Postoperative radiation therapy in 29 patients with invasive transitional cell carcinoma of the upper urinary tract: no impact on survival? J Urol 1996;155:115–7.

Systemic Chemotherapy. **The major limitation to long-term survival for patients with locally advanced upper tract tumors is distant relapse with metastatic disease. Both induction (neoadjuvant) and adjuvant systemic therapy with agents used for proven metastatic disease** (see following discussion) **are reasonable. However, there are no controlled trials that establish the efficacy of either induction or adjuvant chemotherapy in this setting.** The small number of cases treated with adjuvant chemotherapy are anecdotal and preclude definitive conclusions of efficacy.

Key Point: Metastatic Disease

- Distant relapse with metastatic disease is the main limitation in survival of patients, not local recurrence.

Follow-Up

Issues in Assessing for Recurrence

The propensity of upper tract tumors for multifocal recurrence and metastatic spread with more dysplastic lesions makes follow-up complicated. Postoperative evaluation must routinely include evaluation of the bladder, the ipsilateral (if organ-sparing therapy was chosen) and contralateral urinary tracts, and the extraurinary sites for local and metastatic spread. A follow-up regimen is thus dependent on the time from surgery, the approach chosen (organ sparing vs. radical), and the potential for metastatic spread. General recommendations for time intervals are listed in Figure 53–37.

General Procedures

All patients should be assessed at 3-month intervals the first year after they are rendered tumor free by endoscopic or open surgical approaches (Keeley et al, 1997a). This schedule is largely based on work with bladder TCC that shows that most tumor recurrences after bladder resection develop in the first year (Varkarakis et al, 1974; Loening et al, 1980). The upper urinary tract is more difficult to monitor, and delayed recognition of upper tract tumor recurrence may lead to disease progression and poor results (Mazeman, 1976). Evaluation should include history, physical examination, urinalysis, and office cystoscopy because of the high risk of bladder recurrences in patients treated both conservatively and with nephroureterectomy (Mazeman, 1976). If the patient requires endoscopic evaluation of the upper urinary tract, cystoscopy can be done in conjunction with that procedure.

Urine cytology may be helpful in assessing for upper tract recurrence, especially for high-grade tumors (Murphy et al, 1981). The utility, however, is decreased with less dysplastic tumors (Grace et al, 1967; Sarnacki et al, 1971; Zincke et al, 1976). The same tumor markers under study for bladder TCC

- Physical examination, urine cytology (only for high-grade lesions) and cystoscopy
  - Every 3 months–first year
  - Every 6 months thereafter–years 2 through 3
  - Yearly–thereafter
- Contralateral imaging (IVU or retrograde pyelography)–yearly
- Ipsilateral endoscopy (patients undergoing organ-sparing therapy)–
  - Every 6 months–first several years
  - Yearly–thereafter
- Metastatic evaluation–necessary in all patients with significant risk of disease progression (i.e., high grade or invasive disease)
  - Physical examination, chest x-ray, comprehensive metabolic panel with liver enzymes
    - Every 3 months–first year
    - Every 6 months–years 2 through 3
    - Yearly–years 4 and 5
    - After 5 years–evaluation of urothelium only
  - Computed tomography or MRI of abdomen and pelvis–
    - Every 6 months–years 1 and 2
    - Yearly–years 3 through 5
  - Bone scan–only for elevated alkaline phosphatase level or symptoms of bone pain

Figure 53–37. Follow-up begins after open surgery or when the patient is rendered tumor free by endoscopic management. The commencement of follow-up may be altered according to the potential for disease progression.

are promising for upper urinary tract TCC (Brown, 2000). One marker that may be preferentially more involved in upper tract TCC than in bladder TCC is the DNA mismatch repair gene *MSH2* (Leach et al, 2000).

Specific Procedures

Bilateral disease, either synchronous or metachronous, is seen in 1% to 4% of patients (Petkovic, 1975; Babaian and Johnson, 1980; Murphy et al, 1981), and thus imaging of the contralateral kidney is required on a regular basis. Yearly intravenous urography is usually sufficient. However, retrograde pyelography may be necessary if the patient is not a candidate for injection of contrast medium or if intravenous urography is not diagnostic. CT or ultrasonography is helpful in distinguishing stones from soft tissue densities. Further evaluation of filling defects on imaging studies usually requires ureteroscopic evaluation.

If an organ-sparing approach is chosen, the ipsilateral urinary tract must be assessed as well as the remainder of the urinary tract. The frequency and duration of the follow-up assessments depend largely on the grade and stage of the lesion, but they are usually every 6 months for several years and annually thereafter. Radiographic evaluation of the upper tracts alone is not adequate because Keeley and colleagues (1997a) showed that 75% of early tumor recurrences were visible endoscopically and not radiographically. With tumors approached in a percutaneous fashion, immediate follow-up nephroscopy can be performed through the established nephrostomy tract.

In the past, the burden of repeated endoscopic evaluation of the upper urinary tracts was a major deterrent to conservative therapy. The use of smaller, 7.5-Fr flexible ureteroscopes has greatly eased the burden of follow-up because ureteroscopes can be reliably passed up the ureter without the need for dilation of the ureteral orifice or prior stenting. Others have advocated resection of the ureteral orifice to facilitate subsequent surveillance ureteroscopy in the office setting (Kerbl and Clayman, 1993). Even though technology has somewhat facilitated follow-up, both physician and patient must be committed to nephron-sparing treatment.

Metastatic Restaging

Metastatic restaging is required in all patients at significant risk for disease progression to local or distant sites. This group includes those with high-grade or high-stage disease. Metastatic restaging is generally not necessary for low-grade disease when the risks of invasive and subsequent metastatic disease are negligible. Included in metastatic restaging is imaging of the ipsilateral renal bed for recurrence with cross-sectional imaging. Follow-up restaging includes chest radiograph, liver function tests, cross-sectional body imaging, and selective use of bone scintigraphy based on an understanding of natural disease history and metastatic pathways (Korman et al, 1996).

Treatment of Metastatic Disease

Outcomes are poor in patients with metastatic urothelial tumors of the upper urinary tract. **The systemic chemotherapy regimens offered for treatment are the same as those used for TCC of the bladder.** These regimens are discussed in Chapter 82. Only limited data on response rates of advanced upper tract tumors to chemotherapy are available because of the rarity of these lesions. Prospective randomized trials comparing chemotherapeutic regimens for upper tract tumors are not feasible for this reason. Patients with advanced upper tract tumors are excluded from most trials on treatment of advanced bladder cancer. Therefore, one must extrapolate likely chemotherapy response rates for upper tract disease from observations in bladder cancer trials. However, the need for effective use of perioperative chemotherapy for patients with locally advanced and metastatic upper tract tumors remains great. In a study of 184 patients accrued over three consecutive time intervals from 1986 to 2004 at M. D. Anderson Cancer Center, the median recurrence-free survival was 2.4 years and did not improve over time (Brown et al, 2006). The decline in renal function after nephroureterectomy in these mostly elderly patients may compromise the ability to administer effective postoperative chemotherapy and is yet another reason to consider neoadjuvant chemotherapy for patients with upper tract tumors and evidence of regional lymph node metastases.

The MVAC (methotrexate/vinblastine/doxorubicin [Adriamycin]/cisplatin) regimen continues to have the highest response rate (Sternberg et al, 1989). However, complete responses are rare, and the duration of response is limited, with overall survival of 12 to 24 months. Toxicity is high and dose limited in some patients. For all these reasons there is considerable ongoing investigation with newer agents, including paclitaxel, ifosfamide, carboplatin, and gemcitabine, used in various combinations and sequences (Roth et al, 1994; Bajorin et al, 1998; Redman et al, 1998; Vaughn et al, 1998; Kaufman et al, 2000; Lorusso et al, 2000). Many of these show initial overall response rates similar to the response rate to the MVAC regimen and lower toxicity. Occasional major responses are seen (Fig. 53–38). However, thus far, complete responses are rare, and neither durability of response nor survival is better than that seen with the MVAC regimen. In summary, upper tract

Key Points: Chemotherapy

- The chemotherapy for advanced upper tract TCC is the same as for bladder cancer.
- Controlled trials limited to upper tract tumors are not practical because of the low prevalence of disease.

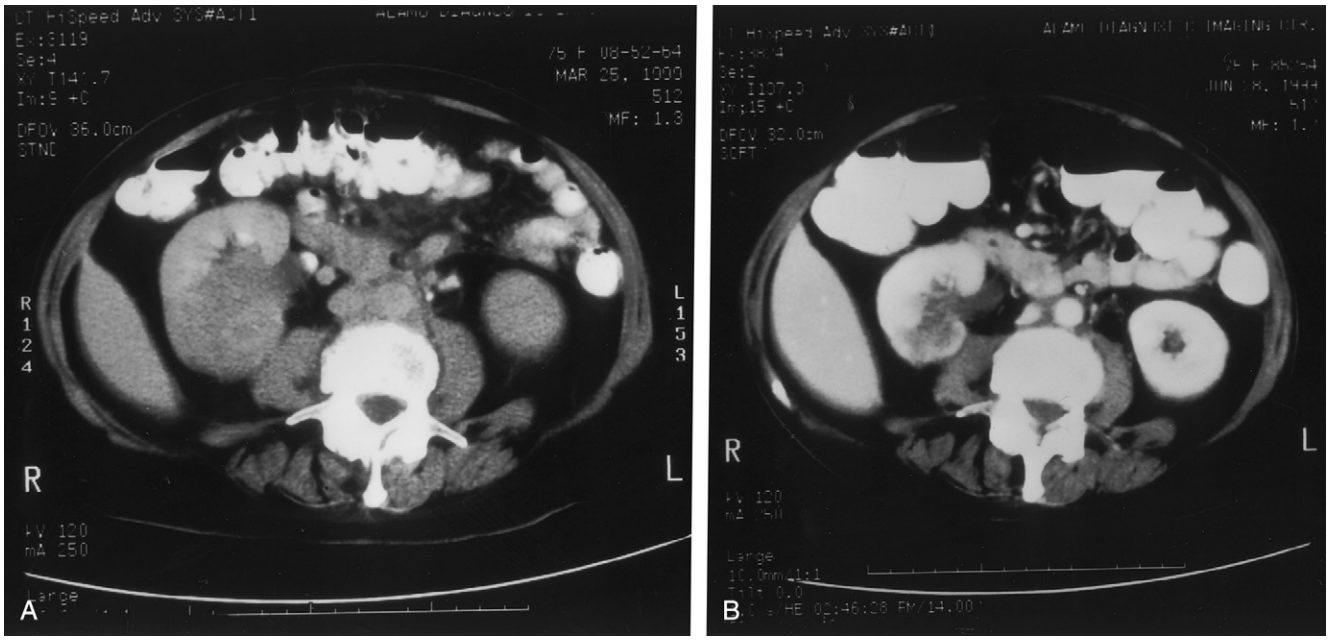

Figure 53–38. A patient presented with a large, biopsy-proven transitional cell carcinoma of the kidney as well as lung and axillary metastases. **A,** Initial appearance of the renal tumor. **B,** Marked shrinkage of the tumor after four courses of paclitaxel-gemcitabine chemotherapy. The lung and axillary metastases disappeared, and nephroureterectomy was performed. During the next year, the patient developed a brain metastasis. (Courtesy of Dr. Randall Singleton.)

urothelial cancer, like bladder cancer, is chemosensitive. It is to be hoped that additional improvements in treatment efficacy and safety are forthcoming, with further experience with new chemotherapeutic regimens. Alternative strategies, such as biologic response modifiers and gene therapy, also should be explored.

Complications of Open Renal Surgery

HISTORY

The history of open renal surgery is characterized by the spirit of innovation, investigation, and excellence that distinguishes modern urology (Table 54–1). Despite progress in minimally invasive techniques and other alternatives, open renal surgery remains a vital field that continues to benefit from refinement and research. Open surgery is an essential component of the contemporary, cutting-edge surgical armamentarium.

SURGICAL ANATOMY

General

Knowledge of regional anatomy is vital to safe and efficient renal surgery (Figs. 54–1 to 54–4 on the Expert Consult website). The renal capsule, perinephric fat, Gerota fascia (renal fascia), and paranephric fat are important landmarks in staging and surgery of renal malignancy (see Fig. 1–27).

Renal Vasculature

Arterial

The origin of the right renal artery is beneath the left renal vein and it typically passes posterior to the inferior vena cava (IVC) (Fig. 54–5; see also Fig. 1–33). **During transabdominal left radical nephrectomy, knowledge of this anatomic relationship may prevent inadvertent ligation of the right renal artery** (Fig. 54–6; see Fig. 54–7 on the Expert Consult website). The inferior adrenal artery and a branch that supplies the renal pelvis and ureter arise from the renal artery. In the majority of cases the renal artery branches in the distal third of the vessel or the renal sinus.

The kidney is divided into four segments (superior, anterior, posterior, inferior) that are supplied by one or more segmental renal arteries, which are end arteries (Fig. 54–8 on the Expert Consult website). **Ligation or occlusion of a segmental artery, or any of its branches, leads to devitalization of renal tissue.** Intraoperatively, one can administer methylene blue dye and occlude the segmental arteries to define the borders of the vascular segments. Despite variation in the origin of the branches supplying the renal segments, the anatomic pattern of the segments is constant (Graves, 1954). Three planes between the vascular segments can be demonstrated (see Fig. 54–8 on the Expert Consult website) and are important for intrarenal surgery. In theory, incision in the plane between the anterior and posterior segments affords reduced blood loss (Brodel, 1900) and has been described for anatrophic nephrolithotomy (Smith and Boyce, 1968). This plane, located on the posterior surface of the kidney, is not to be confused with the "Brodel white line," a whitish linear depression on the lateral aspect of the anterior surface of some kidneys formed by fusion of anterior and posterior columns of Bertin, which demarcates a highly vascular area (Brodel, 1900) (Fig. 54–9).

Typically, the first division of the renal artery creates the anterior and posterior segmental branches (see Fig. 1–30A and B). The posterior segmental branch of the main renal artery arises proximal to the hilum, passes posterior to the renal pelvis, and supplies the posterior renal segment. Classically, a crossing vessel responsible for ureteropelvic junction (UPJ) obstruction is an aberrant posterior segmental artery passing anterior to the UPJ. The anterior segmental branch of the main renal artery divides into four divisions: the apical (superior) segmental artery, the anterior superior segmental artery, the anterior inferior segmental artery, and the basilar (inferior) segmental artery. These are also referred to as the apical, upper, middle, and lower anterior segmental arteries, respectively. These segmental arteries then divide further into lobar arteries (associated with each renal pyramid) and further into two or three interlobar arteries (Fig. 54–10). The interlobar arteries travel through the renal medulla alongside either side of the pyramids. They divide at the corticomedullary junction into arcuate arteries that give rise to the interlobular arteries that travel radially to the capsule. They give off numerous side branches en route, including the afferent arterioles.

Venous

In parallel to the renal arterial system, the renal venous system progresses from the interlobular veins to the arcuate, interlobar, lobar, and segmental veins (see Fig. 1–32). The segmental veins

Table 54–1.

Important Advances in Open Renal Surgery

YEAR	INNOVATION
1869	Gustav Simon performed the first nephrectomy in a human to treat a ureterovaginal fistula, after first demonstrating that dogs are able to survive with a solitary kidney (Simon, 1870).
1878	Kocher and Langham use a midline incision to accomplish an anterior transperitoneal nephrectomy (Kocher and Langham, 1878).
1881	Morris performed the first nephrolithotomy (Morris, 1881).
1884	Wells performed an inadvertent partial nephrectomy while removing a perirenal fibrolipoma (Wells, 1884).
1887	Czerny carried out the first planned partial nephrectomy to treat a renal tumor (Herr, 2008).
1891	Kuster completed the first successful dismembered pyeloplasty (Kuster, 1896–1902).
1903	Grégoire performed the first procedure resembling a radical nephrectomy, described as an en-bloc resection of a kidney, perirenal fat, adrenal gland, and lymphatic tissue for cancer (Grégoire, 1903).
1913	Berg employed a transverse abdominal incision and mobilization of the colon to safely control the renal pedicle. He also obtained control of the renal veins and made a cavotomy to extirpate caval tumor thrombi (Berg, 1913).
1922	Rehn performed caval resection with reimplantation of the contralateral renal vein (Rehn, 1922).
1932	Rosenstein performed a palliative partial nephrectomy for renal cancer in a patient with contralateral renal insufficiency, defining an indication for nephron-sparing surgery (Rosenstein, 1921).
1959, 1960	Kerr and Klotz described renal hypothermia to minimize ischemic damage while prolonging available operative time for partial nephrectomy (Kerr et al, 1960; Herr, 2008).
1973	Libertino and Zinman described revascularization of the totally occluded renal artery (Zinman and Libertino, 1973).
1998	Libertino described use of a minimally invasive approach for cardiopulmonary bypass for vena cava thrombectomy (Fitzgerald et al, 1998).

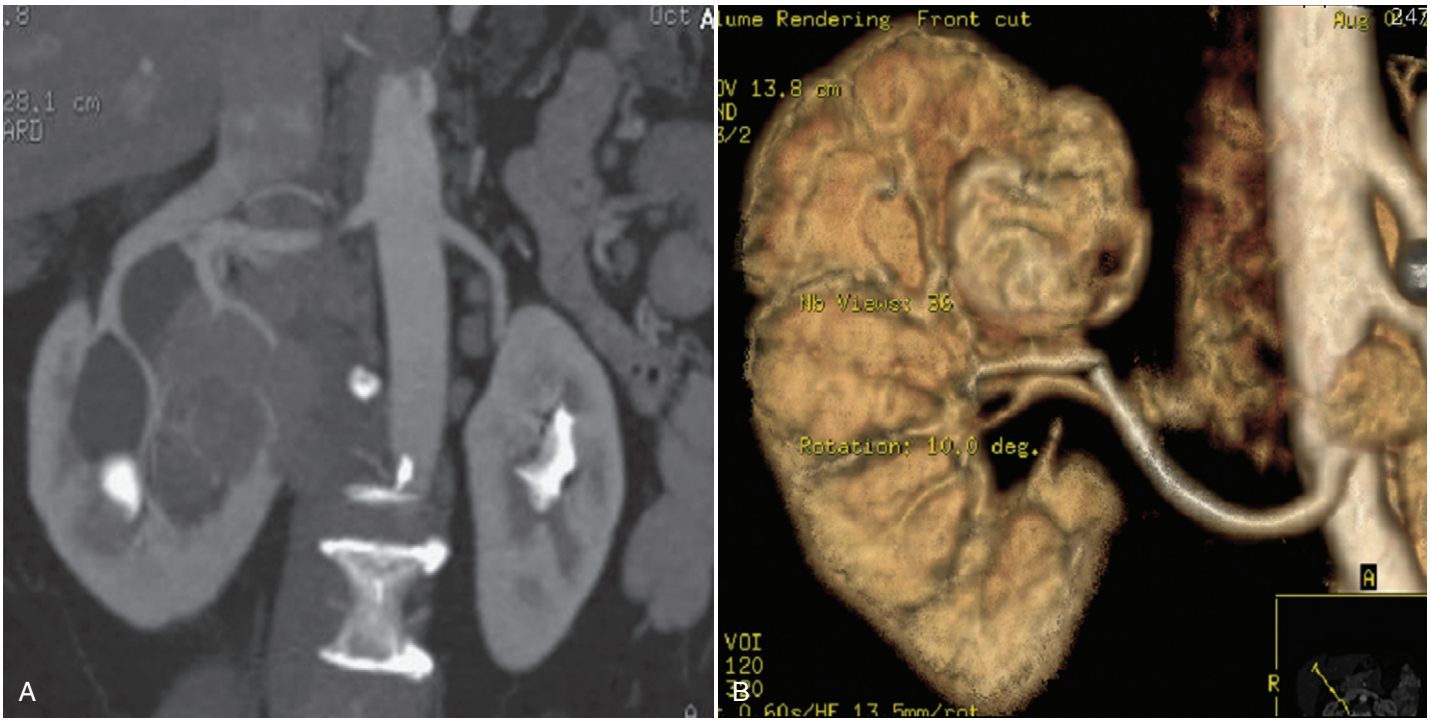

Figure 54–5. Arterial anatomy can be well defined using CT **(A)** and three-dimensional reconstruction **(B)**.

combine to form three to five venous tributaries, the confluence of which forms the main renal vein near the hilum. Each kidney is typically drained by a single renal vein that courses anterior to the renal artery and joins the lateral aspect of the vena cava. The left renal vein is longer than the right, making the left kidney attractive for donor nephrectomy. The left renal vein typically passes anterior to the aorta.

Unlike the arterial structure of the kidney, the renal venous system is characterized by a rich anastomotic network between the various renal segments. One may ligate and divide segmental veins without compromising drainage. The right renal vein does not receive significant branches. Tributaries draining into the main left renal vein include the gonadal vein, the left adrenal vein, and one or two large lumbar veins, all of which can be injured during mobilization of the left renal vein. Because of these collateral vessels, one is at liberty to ligate the left renal vein at the caval junction without eliminating venous return.

Anomalies of Renal Vasculature

Frequent anatomic variation in the renal vasculature contributes to the complexity of open renal surgery. Multiple renal arteries, which typically arise from the

Figure 54–11. Horseshoe kidney with multiple arterial branches well defined with three-dimensional imaging.

aorta or iliac arteries, are the most common variation, occurring in 25% to 30% of the population (Merklin and Michels, 1958; Boijsen, 1959; April, 1997). Supernumerary hilar renal arteries originate at the aorta adjacent to the renal artery and traverse the renal hilum, whereas polar renal arteries originate at a greater distance from the main renal artery and enter the renal parenchyma directly. Ectopic and horseshoe kidneys more frequently have supernumerary renal arteries (Fig. 54–11).

Venous anomalies occur less frequently. Supernumerary renal veins occur less commonly on the left than right (Merklin and Michels, 1958). The most common variation is duplication of a renal vein (6%) (April, 1997). Retroaortic left renal veins occur in approximately 2% of patients. Circumaortic renal veins are present in 1.6% to 6.0% of the population (Kottra and Castellino, 1970).

One must be vigilant to identify these infrequent anomalies during preoperative evaluation or intraoperative dissection.

Lymphatics

Lymphatics parallel the arterial system from the renal cortex into the sinus and then empty into hilar nodes associated with the renal vein (see Figs. 1–34 [on the Expert Consult website] and 1-35). There is communication between parenchymal lymphatics and those of the renal capsule and perinephric fat. From the first description of renal lymphatic drainage in 1935 to modern day lymphatic dissections the complexity of renal lymphatic drainage beyond the hilum has been apparent (Parker, 1935; Assouad et al, 2006). For the surgeon, the most important characteristic of renal lymphatics is variability in drainage. More so than in malignancies of the penis, testis, bladder, and prostate, the role of regional lymphadenectomy in kidney cancer remains controversial.

Key Points: Surgical Anatomy

- The origin of the right renal artery is beneath the left renal vein. It typically passes posterior to the IVC. During transabdominal left radical nephrectomy, knowledge of this anatomic relationship may prevent inadvertent ligation of the right renal artery.
- The kidney is divided into four segments (superior, anterior, posterior, inferior) that are supplied by one or more segmental renal arteries, which are end arteries. Ligation or occlusion of a segmental artery, or any of its branches, leads to devitalization of renal tissue.
- The renal venous system is characterized by a rich anastomotic network between the various renal segments. One may ligate and divide segmental veins without compromising drainage.
- The right renal vein does not receive significant branches. Tributaries draining into the main left renal vein include the gonadal vein, the left adrenal vein, and one or two large lumbar veins, all of which can be injured during mobilization of the left renal vein. Because of these collateral vessels, one is at liberty to ligate the left renal vein at the caval junction without eliminating venous return.
- Frequent anatomic variation in the renal vasculature contributes to the complexity of open renal surgery. Multiple renal arteries, which typically arise from the aorta or iliac arteries, are the most common variation, occurring in 25% to 30% of the population.

PREOPERATIVE EVALUATION AND PREPARATION

A thorough preoperative evaluation is essential to safe open renal surgery. The preoperative evaluation is directed at patient selection, staging of disease, identification and optimization of medical comorbidities, imaging, preoperative procedures such as renal artery embolization, and prevention of surgical morbidity. Patient selection and clinical staging of renal disease are covered in other chapters of this text.

Identification and Optimization of Cardiovascular and Pulmonary Comorbidities

Open renal surgery often requires prolonged nonphysiologic positioning with attendant impingement of cardiovascular and pulmonary function. The flank position may impede ventilatory capacity as well as decrease venous return to the heart, with resultant reduction in cardiac output. Patients may have significant bleeding, fluid shifts, or increased oxygen demand, which can result in imbalance in oxygen supply and demand. Preoperative evaluation including laboratory and imaging studies, along with judicious specialist consultation is essential (Table 54–2).

Cardiovascular

Some patients will benefit from referral to a consulting cardiologist for consideration of resting 12-lead electrocardiogram, noninvasive evaluation of left ventricular function, noninvasive stress testing, medication adjustments, or preoperative coronary revascularization (coronary artery bypass graft or percutaneous coronary intervention). **Patients with unstable coronary syndromes, decompensated heart failure, significant arrhythmias, or severe valvular disease should be evaluated and treated by a cardiologist before noncardiac surgery** (Fleisher et al, 2007). It is incumbent on the urologist to identify these patients and others who are at risk of cardiovascular complications and to refer them for evaluation by a specialist.

In addition, patients with known coronary artery disease or signs or symptoms suggestive of new coronary artery disease should receive a preoperative cardiac assessment (Fleisher et al, 2007). **In asymptomatic patients, referral should be made based on a history and physical examination** (Lee et al, 1999; Fleisher et al, 2007). The history should elucidate symptoms of cardiovascular disease, risk factors for cardiac disease, and pertinent medications (Table 54–3). The Revised Cardiac Risk Index (RCRI), a simple validated index to predict cardiovascular complications, was developed at a tertiary care facility for prediction of cardiac risk of major noncardiac surgery in patients 50 years of age or older (Lee et al, 1999). The RCRI, which is composed of six independent predictors of cardiac complications, identifies patients at risk of cardiac complications (Table 54–4) and may be helpful for preoperative risk stratification.

Pulmonary

In noncardiothoracic surgery, risk factors for postoperative pulmonary complications include chronic

Table 54–3.

Pertinent Cardiovascular History

Shortness of breath, dyspnea on exertion, or paroxysmal nocturnal dyspnea
Angina
Orthostatic intolerance
Bleeding diathesis
Coronary artery disease, including previous myocardial infarction
Heart failure

obstructive pulmonary disease, age older than 60 years, inhaled tobacco use, American Society of Anesthesiologists (ASA) class II or higher, functional dependence (i.e., inability to perform activities of daily living or need for equipment and assistance for some activities of daily living), congestive heart failure, pulmonary hypertension, and hypoalbuminemia (Qaseem et al, 2006; Bapoje et al, 2007). The urologist should screen for these risk factors and refer the patient for preoperative pulmonary evaluation and risk reduction.

Even in the absence of baseline risk factors, open renal surgery itself may disturb a patient's pulmonary equilibrium and render him or her at risk for postoperative pulmonary complications. For instance, transection of upper abdominal and flank muscles, removal of ribs, impairment of diaphragm function through nerve or muscular injury, pneumothorax, hemothorax, and pleuritic pain may all contribute to pulmonary difficulties. **Prolonged surgery (>3 hours) is an independent predictor of pulmonary complications, as is either thoracic or upper abdominal surgery** (Qaseem et al, 2006).

Pulmonology consultation, preoperative pulmonary function testing, chest radiography, or arterial blood gas analysis may benefit patients who are at risk of pulmonary complications. Preoperative interventions such as smoking cessation 6 to 8 weeks before surgery and inspiratory muscle training may reduce the risk of pulmonary complications (Bapoje et al, 2007). In patients with significant pulmonary risk factors or impairment an anterior surgical approach in the supine position might be preferable to the flank approach (Novick, 2007). Risk can be ameliorated after surgery by deep breathing exercises or incentive spirometry and by selective rather than routine use of nasogastric drainage (Qaseem et al, 2006; Bapoje et al, 2007).

Renal Evaluation

Although a definitive discussion of renal impairment and its impact on surgical decision making is beyond the scope of this chapter, assessment of renal function is mandatory before open renal surgery. As discussed later in the section on partial nephrectomy, preservation of renal function is a vitally important aspect of contemporary renal surgery. Knowledge of preoperative renal dysfunction is essential.

Initial renal evaluation should include urinalysis and measurement of serum creatinine concentration. **The serum creatinine value is the most widely used surrogate marker of glomerular filtration rate (GFR) but is not ideal.** Changes in the serum creatinine level can reflect a change in GFR but may also represent a change in production of creatinine or tubular secretion of creatinine. A better estimate of GFR is provided by 24-hour creatinine clearance (CrCl), which reflects the volume of plasma that is cleared of creatinine per minute. Because creatinine is also cleared by tubular secretion in addition to filtration, the 24-hour CrCl tends to overestimate GFR. GFR can also be estimated by renal radionuclide imaging. For instance, renal scan with technetium-99 diethylenetriaminepentaacetic acid (DTPA) can provide an estimate of GFR but its use is limited in patients with renal insufficiency. **A commonly used method, which is favored by the senior author, is to estimate GFR using the Modification of Diet in Renal Disease (MDRD) Study equation** (Levey et al, 1999):

$$\text{GFR (mL/min/1.73 m}^2) = 186 \times (S_{Cr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African-American})$$

If extirpative renal surgery is anticipated to render the patient at high-risk of dialysis dependence, preoperative nephrology referral and placement of hemodialysis access, such as a Tesio catheter (Medical Components, Harleysville, PA), are advisable. Patients must be made aware that the risks of open renal surgery include chronic kidney disease, dialysis dependence, and the systemic consequences of renal insufficiency.

Imaging

Modern imaging permits a thorough anatomic evaluation of the urinary tract before open renal surgery. It is essential to identify anatomic variants before surgery such as supernumerary renal arteries, retroaortic left renal vein, circumaortic renal vein, duplicated collecting system, and renal ectopia. A variety of imaging

modalities are available, including intravenous pyelography, retrograde pyelography, ureteroscopy, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), renal arteriography, and renal venography.

Three-dimensional (3D) volume-rendered CT is a valuable tool in the evaluation of patients undergoing renal surgery (Coll et al, 1999; Derweesh et al, 2003). **CT can demonstrate vital information including the anatomy of the renal vasculature, orientation of the kidney, and characteristics of renal tumors, including location, depth of penetration into the kidney, relationship with collecting system, and segmental arterial supply to the tumor** (Coll et al, 1999) (Figs. 54–12 to 54–14). CT is also able to characterize other surgically relevant processes, including renal arterial disease, nephrolithiasis, and hydroureteronephrosis (Herts, 2005).

The importance of imaging to open renal surgery is likely to increase with time. Future possibilities include image-guided open surgery, the objective of which is to provide surgeons enhanced visualization of the surgical field by merging data from preoperative images with an intraoperative view (Benincasa et al, 2008). In addition, simulation of complex nephron-sparing surgery based on 3D imaging may be possible (Wunderlich et al, 2000).

Angioembolization

Since its introduction in the early 1970s, renal artery embolization (RAE) has been employed for palliation of inoperable renal tumors, to control bleeding, and as part of multimodal treatment of hypervascular metastatic disease (Almgard et al, 1973). In addition, RAE is used as a preoperative adjunct to resection of locally advanced renal tumors, with or without metastases (Paster et al, 1975) (Fig. 54–15).

Proposed benefits of preoperative RAE include shrinkage of an arterialized tumor thrombus to ease surgical removal, reduced blood loss, facilitation of dissection due to tissue plane edema, ability to ligate the renal vein before the renal artery at time of nephrectomy, and modulation of the immune response (Klimberg et al, 1985; Bakal et al, 1993; Kalman and Varenhorst, 1999; Schwartz et al, 2007; Wotkowicz and Libertino, 2007; Wszolek et al, 2008). Ligation of the renal vein before the renal artery is useful in the setting of hilar tumors, tumors with significant medial extension, or considerable perihilar adenopathy (Schwartz et al, 2007; Wotkowicz and Libertino, 2007; Wszolek et al, 2008). Before ligating the renal vein, one should characterize the completeness of embolization to prevent unnecessary blood loss in cases of incomplete embolization. In the senior author's experience this assessment can be made by evaluating renal venous return during surgery. In addition, angioembolization can also be useful for renal tumors associated with large arteriovenous malformations that are having a deleterious hemodynamic impact (Figs. 54–16 and 54–17).

There may be a survival benefit to preoperative RAE. In a case-control study, preoperative RAE and nephrectomy was associated with a survival benefit when compared with nephrectomy alone (Zielinski et al, 2000). In comparison to matched controls, preoperative RAE was associated with improved overall survival at 5 years (62% vs. 35%, $P = .01$) and 10 years (47% vs. 23%, $P = .01$). This possible survival benefit has not been demonstrated in a prospective trial.

Although there is no conclusive evidence that RAE has any immunotherapeutic benefit it is plausible that angioinfarction may augment the immune response to the renal tumor (Kalman and Varenhorst, 1999). There are reports of regression of metastases from renal cell carcinoma after RAE and nephrectomy (Mohr and Whitesel, 1979; Swanson et al, 1983). The postinfarction syndrome that is nearly universal may be cytokine mediated. Several studies have shown that RAE is immunomodulatory, with

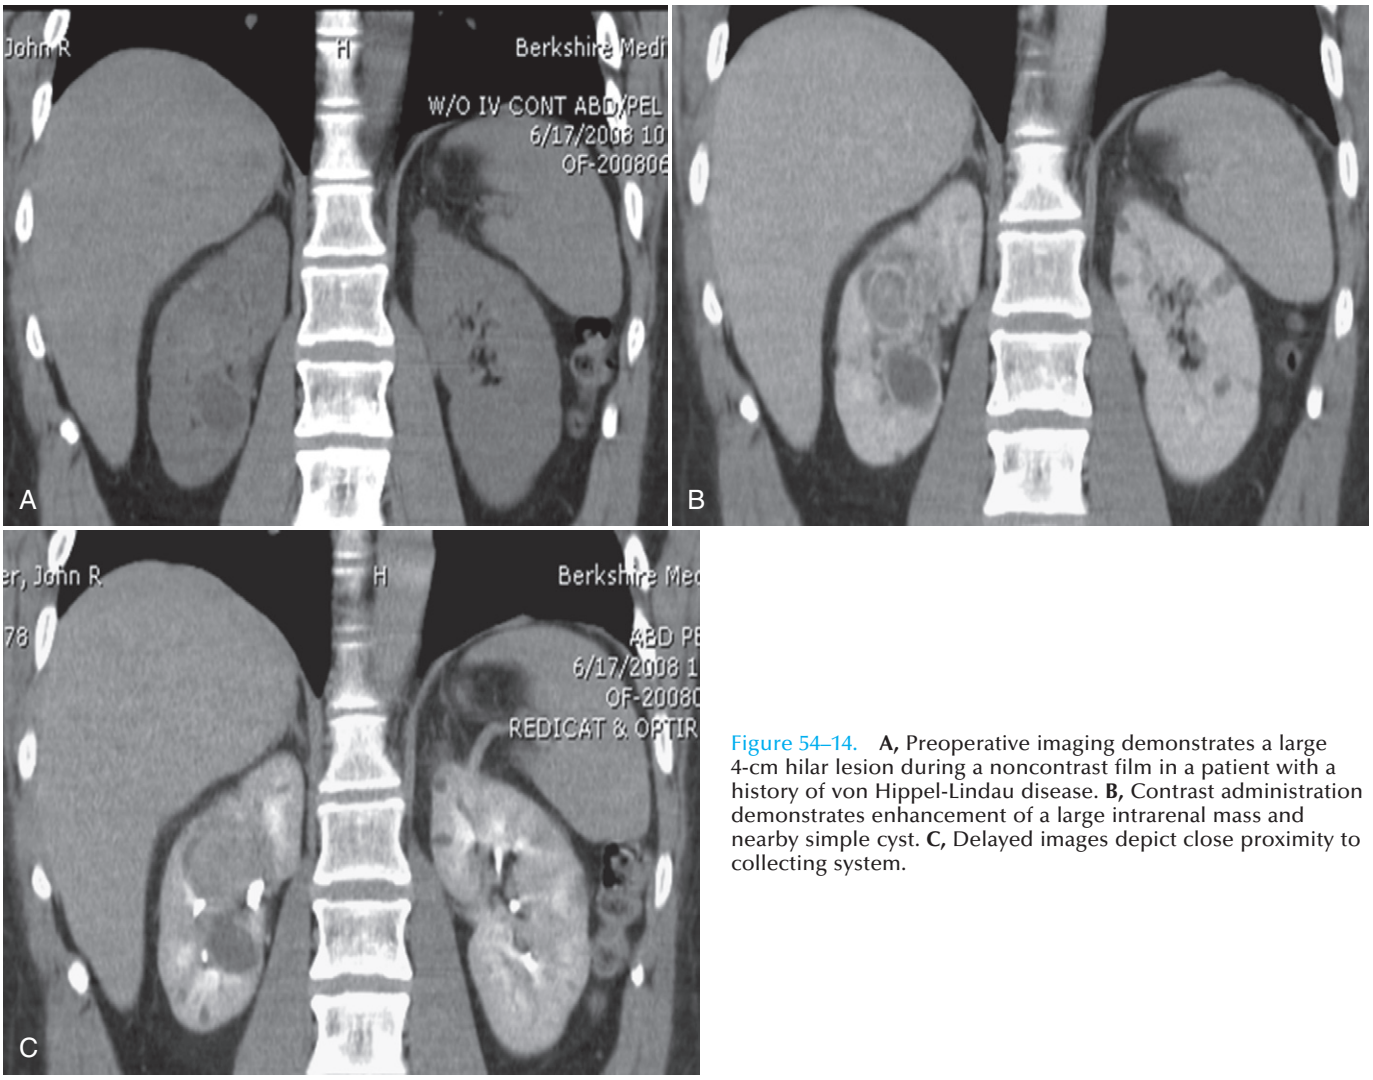

Figure 54–14. **A,** Preoperative imaging demonstrates a large 4-cm hilar lesion during a noncontrast film in a patient with a history of von Hippel-Lindau disease. **B,** Contrast administration demonstrates enhancement of a large intrarenal mass and nearby simple cyst. **C,** Delayed images depict close proximity to collecting system.

documented changes in natural killer cell activity (Bakke et al, 1982), increased cell-mediated cytotoxicity (Johnson and Kalland, 1984), and alteration in lymphocyte proliferation (Nakano et al, 1983). There are no modern molecular data to support these findings.

The postinfarction syndrome, which is characterized by flank pain, nausea, and fever, occurs in approximately three fourths of patients and is the most frequently cited complication of RAE (Schwartz et al, 2007). Other complications, including incomplete embolization, coil migration, and groin hematoma, occurred in fewer than 5% of patients (Schwartz et al, 2007). Rarely cited complications include hyponatremia (Huang et al, 2003), paraplegia due to occlusion of spinal arteries, or inadvertent angioinfarction of other organs such as the colon (Roy et al, 1999).

The data regarding preoperative RAE are limited, without any randomized trials evaluating the technique. As a result, in some institutions, surgeons rarely employ preoperative RAE (Boorjian et al, 2007). It is the practice of the senior author to perform preoperative RAE for large renal tumors with hypervascular characteristics or IVC tumor thrombus (Wotkowicz and Libertino, 2007). The ideal timing of nephrectomy after embolization is unclear (Craven et al, 1991; Weckermann et al, 1992; Kalman and Varenhorst, 1999; Schwartz et al, 2007). At the Lahey Clinic, surgery usually is timed 4 weeks after angioinfarction. An imaging study to assess the cranial limit of tumor thrombus is repeated shortly before the operation. Although prospective trials are needed to evaluate the role of preoperative RAE in the treatment of renal cell carcinoma, the senior author has found it a useful preoperative adjunct in the management of locally advanced RCC.

Surgical Site Infection Prophylaxis

A preoperative urinalysis and culture should be obtained for all patients undergoing open renal surgery. Patients with urinary tract infection or bacteriuria should be treated with culture-guided antibiotics before surgery, with the goal of sterilizing the urine or reducing the bacterial count if the urine cannot be sterilized (Wolf et al, 2008).

In the absence of active infection or bacteriuria, judicious antimicrobial prophylaxis may reduce the risk of surgical site infection and systemic sepsis. In cases in which the urinary tract is not entered, such as radical nephrectomy, antibiotics should be targeted to skin flora (e.g., a first-generation cephalosporin or clindamycin). The American Urological Association (AUA) advises that in these clean cases the use of antibiotics should be limited to

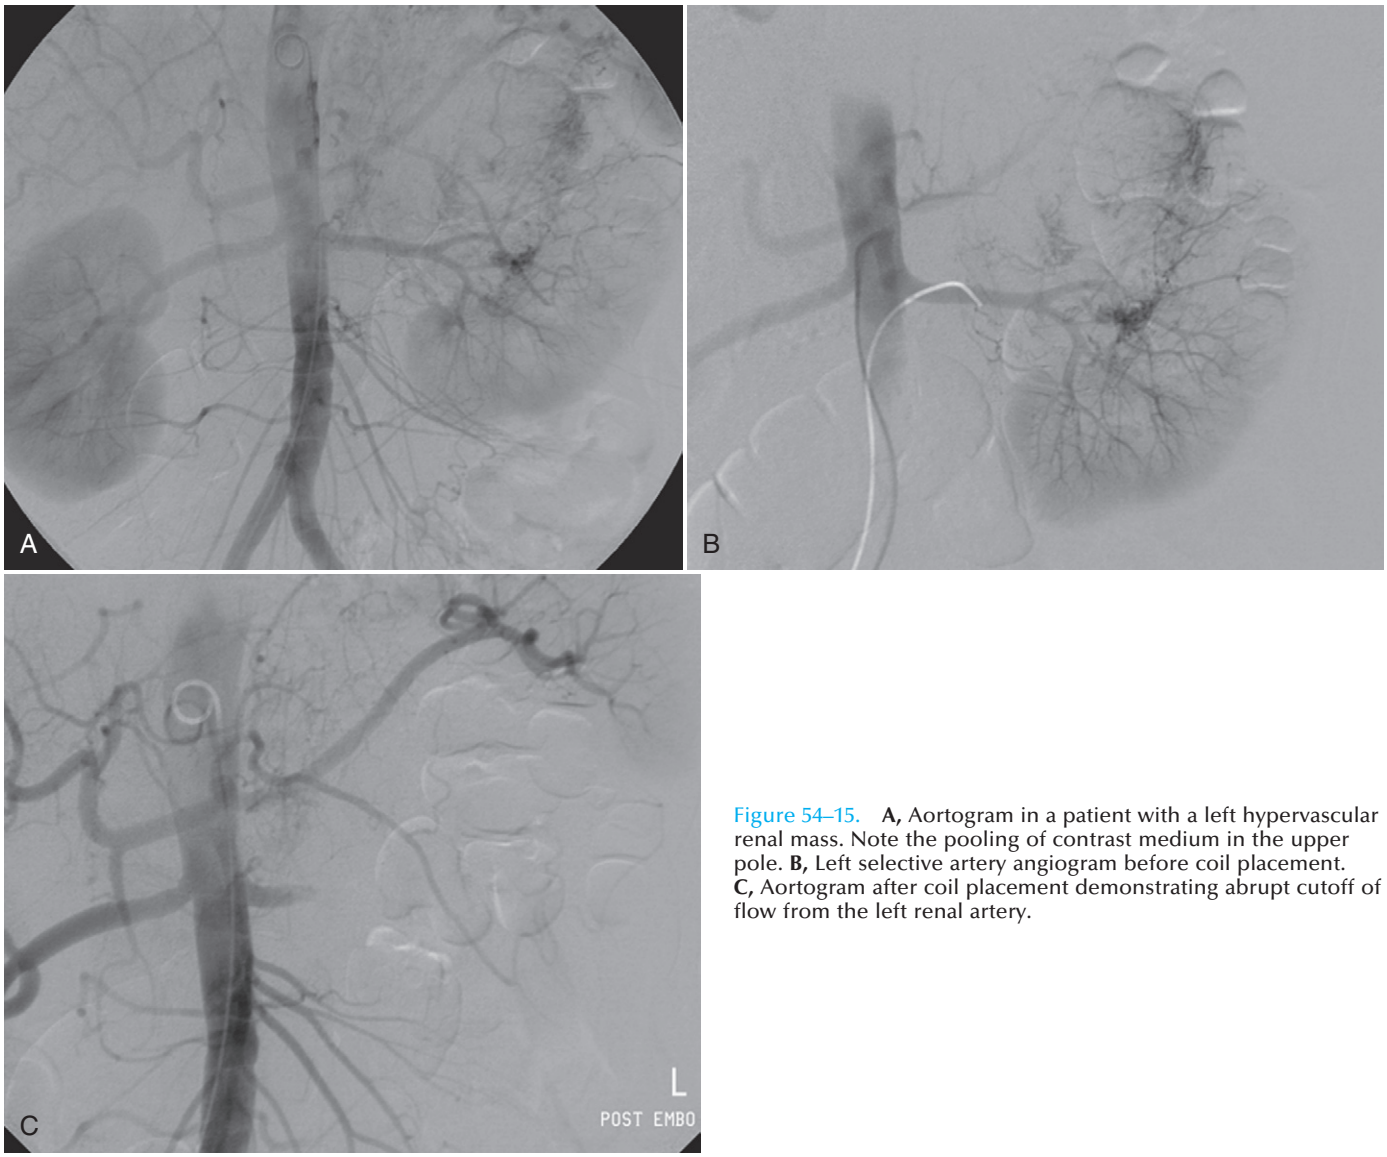

Figure 54–15. **A,** Aortogram in a patient with a left hypervascular renal mass. Note the pooling of contrast medium in the upper pole. **B,** Left selective artery angiogram before coil placement. **C,** Aortogram after coil placement demonstrating abrupt cutoff of flow from the left renal artery.

patients with risk factors (Table 54–5) (Wolf et al, 2008). In renal surgery in which the urinary tract is entered both skin and genitourinary flora should be covered (with a first- or second-generation cephalosporin or aminoglycoside with metronidazole or clindamycin, or ampicillin/sulbactam, or fluoroquinolone) (Wolf et al, 2008).

Open renal surgery is often complex and time consuming. Antibiotics should be readministered during surgery after one to two half-lives to ensure adequate drug levels are maintained until wound closure (Bratzler and Houck, 2005). Antibiotic prophylaxis should not continue beyond 24 hours (Bratzler and Houck, 2005).

In addition to antibiotics, sterile technique is employed to reduce the rate of surgical site infection. Although there is no conclusive evidence to support hair removal as a method of reducing surgical site infection, the authors recommend clipping hair at the incision site before sterile preparation of the field (Tanner et al, 2006). It is the practice of the senior author to use povidone-iodine scrub and paint, although one study has found paint alone to be equivalent to scrub and paint for abdominal surgery (Ellenhorn et al, 2005). One should avoid alcohol-containing products because of flammability (Armstrong et al, 2001). Finally, proper surgical technique with regard to tissue handling, hemostasis, avoidance of unnecessary hypothermia, and excision of devitalized tissues is an essential component of infection prevention (Mangram et al, 1999).

Venous Thromboembolism Prophylaxis

There is a paucity of date to guide prophylaxis for venous thromboembolism (VTE) in open renal surgery. Although both the AUA and American College of Chest Physicians (ACCP) guidelines recommend pharmacologic VTE prophylaxis in open renal surgery, the data supporting these recommendations are imperfect (Geerts et al, 2008; Forrest et al, 2009). The ACCP recommends routine VTE prophylaxis in all open urologic procedures, although this recommendation is largely based on data from other surgical specialties and radical retropubic prostatectomy. The ACCP recommends preoperative use of graduated compression stockings along with intermittent pneumatic compression devices, pharmacologic prophylaxis after surgery (low-dose unfractionated heparin, low-molecular-weight heparin, or fondaparinux), or both. In patients at high risk of bleeding, the ACCP advises pharmacologic

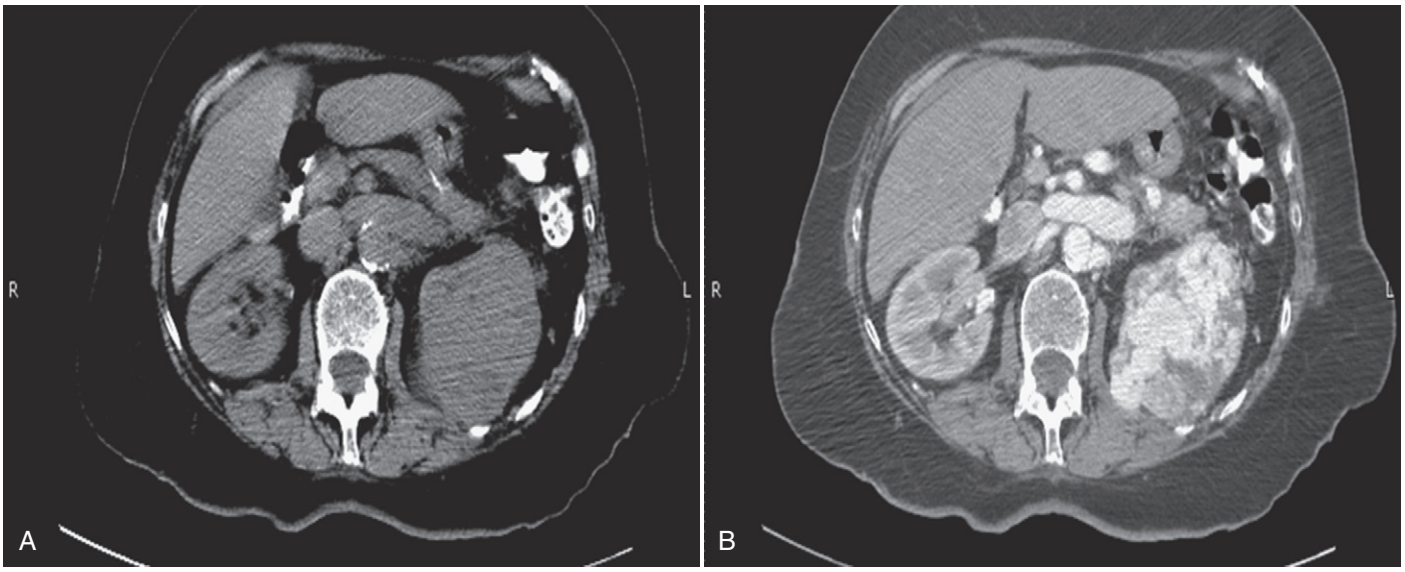

Figure 54–16. Noncontrast **(A)** and contrast-enhanced **(B)** CT images of a patient with high output cardiac failure secondary to arteriovenous malformation associated with left renal cell carcinoma. Notice the equal contrast intensity of the aorta, left renal artery, and left renal vein.

therapy once the bleeding risk has diminished. **The AUA recommends use of mechanical prophylaxis in all patients undergoing open surgery and consideration of pharmacologic prophylaxis in patients with elevated risk for VTE** (Tables 54–6 and 54–7).

It is the authors' practice to apply intermittent pneumatic compression devices before open renal surgery for all patients. In the opinion of the senior author there is not sufficient evidence to support routine use of pharmacologic VTE prophylaxis given the associated risk of hemorrhage. At the Lahey Clinic addition of pharmacologic prophylaxis is determined on a case-by-case basis by subjectively assessing an individual's risk of VTE (see Tables 54–6 and 54–7). In partial nephrectomy, a procedure with significant risk of hemorrhage, pharmacologic prophylaxis is avoided in the vast majority of cases at the Lahey Clinic. This practice is supported by a retrospective review from Memorial Sloan-Kettering Cancer Center that describes a low prevalence (1.5%) of clinically apparent VTE after radical or partial nephrectomy (Pettus et al, 2006). This is an order of magnitude lower than the estimated 15% to 40% rate of asymptomatic VTE (i.e., found on screening) on which the current ACCP recommendations are based (Geerts et al, 2008). The clinical significance of asymptomatic VTE is unclear.

Table 54–5.

Risk Factors for Surgical Site Infection

Alteration in Host Defense
Advanced age
Anatomic anomalies of the urinary tract
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Alteration in Pathogen
Externalized catheters
Colonized endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Table 54–7.

Venous Thromboembolism: Risk Factors

Surgery
Trauma (major or lower extremity)
Immobility, paresis
Malignancy
Cancer therapy (hormonal therapy, chemotherapy, or radiotherapy)
Venous compression (tumor, hematoma, arterial abnormality)
Previous venous thromboembolism
Increasing age
Pregnancy and the postpartum period
Estrogen-containing oral contraception or hormone replacement therapy
Selective estrogen receptor modulators
Erythropoiesis-stimulating agents
Acute medical illness
Heart or respiratory failure
Inflammatory bowel disease
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Obesity
Smoking
Varicose veins
Central venous catheterization
Inherited or acquired thrombophilia

Data from Geerts and colleagues (2008) and Forrest and colleagues (2009).

Key Points: Preoperative Evaluation and Preparation

- Patients with unstable coronary syndromes, decompensated heart failure, significant arrhythmias, or severe valvular disease should be evaluated and treated by a cardiologist before noncardiac surgery.
- Patients with known coronary artery disease or signs or symptoms suggestive of new coronary artery disease should receive a preoperative cardiac assessment. In asymptomatic patients, referral should be made based on a history and physical examination (e.g., Revised Cardiac Risk Index).
- In noncardiothoracic surgery, risk factors for postoperative pulmonary complications include chronic obstructive pulmonary disease, age older than 60 years, inhaled tobacco use, ASA class II or higher, functional dependence, congestive heart failure, pulmonary hypertension, and hypoalbuminemia.
- Prolonged surgery (>3 hours) is an independent predictor of pulmonary complications, as is thoracic and upper abdominal surgery.
- Pulmonology consultation, preoperative pulmonary function testing, chest radiography or arterial blood gas analysis, smoking cessation, and inspiratory muscle training may be of benefit.
- Measurement of serum creatinine concentration is the most widely used surrogate marker of GFR but is not ideal. The method favored by the senior author is to estimate GFR using the MDRD Study equation.
- CT can demonstrate vital information, including the anatomy of the renal vasculature, orientation of the kidney, and characteristics of renal tumors, including location, depth of penetration into the kidney, relationship with collecting system, and segmental arterial supply to the tumor.
- Proposed benefits of preoperative RAE include shrinkage of an arterialized tumor thrombus to ease surgical removal, reduced blood loss, facilitation of dissection due to tissue plane edema, ability to ligate the renal vein before the renal artery at the time of nephrectomy, and modulation of the immune response.
- The postinfarction syndrome, which is characterized by flank pain, nausea, and fever, occurs in approximately three fourths of patients and is the most frequently cited complication of RAE.
- A preoperative urinalysis and culture should be obtained for all patients undergoing open renal surgery.
- The AUA recommends use of mechanical prophylaxis in all patients undergoing open surgery and consideration of pharmacologic prophylaxis in patients with elevated risk for VTE. This is controversial.

SURGICAL APPROACHES

Safe, effective open renal surgery is predicated on good functional exposure of the kidney. The kidney is a retroperitoneal structure in close proximity to the great vessels, pancreas, spleen, liver, colon, and duodenum. These neighbors serve as landmarks to guide dissection, as well as potential sources of complications and impediment to adequate exposure. An incision that is too small or inappropriately placed will increase the difficulty of open renal surgery and may adversely impact patient outcomes.

Good functional exposure permits the surgeon to perform the planned procedure, diminishes the risk of injury to surrounding structures, and permits definitive treatment of an intraoperative complication, such as injury to a great vessel (Libertino, 1998). Proper exposure limits the amount of required retraction, which can be a source of injury to surrounding structures such as the liver or spleen (Cooper et al, 1996).

One must balance numerous variables when selecting a surgical approach to the kidney. **The ideal surgical approach is one that is tailored not only to the operation being performed but also to the anatomy as defined on preoperative imaging, previous surgical history, body habitus, and presence of limiting factors such as kyphoscoliosis or pulmonary disease** (Libertino, 1998).

The primary approaches to the kidney are the subcostal, supracostal, and transcostal flank incisions, the thoracoabdominal approach, the dorsal lumbotomy, as well as the midline, paramedian, and subcostal anterior approaches (Table 54–8).

Flank Approaches

The flank approaches are undertaken with the patient in lateral decubitus position with flexion of the table. Flexion tightens the skin and muscles of the flank and improves exposure by increasing the distance between the iliac crest and costal margin. Positioning for the flank approaches can impede pulmonary function and venous return to the heart, with resultant deficits in ventilation and cardiac output (Longnecker, 2007). When the table is flexed with the kidney bar elevated, ischemic injury to a previously operated on contralateral kidney may result (Matin and Novick, 2001). Flank approaches may not be ideal in patients with preexisting cardiopulmonary deficits or kyphoscoliosis. Each of the flank approaches can result in injury to the intercostal nerves with denervation and paresis of the flank musculature, leading to chronic postoperative pain or flank bulge in 3% to 49% of patients (Ward et al, 1974; Chatterjee et al, 2004). Gravity will tend to move the abdominal panniculus of an obese patient away from the operative field, a distinct advantage of the flank approaches.

Table 54–8.

Approaches to the Kidney: Salient Features

APPROACH		APPLICATIONS AND ADVANTAGES	DISADVANTAGES AND POTENTIAL COMPLICATIONS
Flank	Subcostal	Useful for surgery on lower renal pole, ureteropelvic junction, and upper ureter, as well as simple nephrectomy, nephrostomy tube insertion, and drainage of perinephric abscess Extraperitoneal approach prevents peritoneal contamination Abdominal panniculus falls away from incision	Poor option for radical or partial nephrectomy and in patients with significant scoliosis or who will not tolerate flank position (e.g., severe pulmonary comorbidity) Provides poor access to renal hilum and renal vasculature Exposure possibly hindered by the iliac crest and subcostal nerve Risks chronic flank pain and bulge and ischemic injury to a postoperative contralateral kidney
	Supracostal	Useful for radical nephrectomy for modest-sized tumor and partial nephrectomy Extraperitoneal, extrapleural approach Good renal, suprarenal, and retroperitoneal exposure Permits pivoting of the 11th or 12th rib on a single articulating surface posteriorly without removal of a rib Abdominal panniculus falls away from incision	Poor option for patients with significant scoliosis or who will not tolerate flank position (e.g., severe pulmonary comorbidity) Longer operative time Risks chronic flank pain and bulge and ischemic injury to a postoperative contralateral kidney
	Transcostal	Same as supracostal	Same as supracostal Morbidity due to rib resection
Thoracoabdominal		Useful for radical nephrectomy and partial nephrectomy of large renal masses, especially those of the upper pole Valuable for right-sided tumors in which the liver and hepatic veins would reduce exposure and make vascular control difficult using a different approach (Chute et al, 1949; Clarke et al, 1958; Khoury, 1966; Middleton and Presto, 1973; Libertino, 1998) Useful for radical nephrectomy for renal tumors with venous extension and those involving adjacent structures (e.g., liver, spleen, or pancreas) as well as for excision of suprarenal masses (Libertino, 1998) Provides maximal suprarenal exposure Permits synchronous biopsy or resection of pulmonary lesions	Longer operative time Greater potential pulmonary morbidity (Novick, 2007) Damage to phrenic nerve (Novick, 2007)

Table 54–8.

Approaches to the Kidney: Salient Features—cont'd

APPROACH		APPLICATIONS AND ADVANTAGES	DISADVANTAGES AND POTENTIAL COMPLICATIONS
Dorsal lumbotomy		Useful for simple nephrectomy for small atrophic kidney, simultaneous bilateral simple nephrectomies in end-stage renal disease, pyeloplasty, pyelolithotomy and upper ureterolithotomy, and open renal biopsy Rapid Affords fresh tissue planes in patients with numerous prior abdominal or flank procedures No muscles are transected; only posterior fascial layers are incised, leading to strong wound closure and less incisional pain With detachment of the costovertebral ligament the 12th rib can be retracted widely, rendering resection of the rib unnecessary (Gardiner et al, 1979; Novick, 2007)	Poor option for radical or partial nephrectomy, for large or superiorly displaced kidneys, and for procedures requiring extensive ureteral mobilization (e.g., long stricture) Morbid obesity and musculoskeletal irregularity may limit access between the iliac crest and 12th rib (Novick, 2007) Previous retroperitoneal surgery may cause obliteration of the normal planes of dissection rendering the approach less favorable Poor control of the renal vessels
Anterior	Subcostal (extraperitoneal or transperitoneal)	Useful for open renal biopsy, nephrectomy and renovascular surgery Favorable approach for upper pole tumors and in patients with a wide subcostal angle (Chute et al, 1967) Provides good access to the superior and lateral aspect of kidney; the transperitoneal approach permits good access to the renal hilum The extraperitoneal approach diminishes risk of ileus and intra-abdominal injury	The extraperitoneal approach provides limited access, especially to the pedicle The transperitoneal approach may risk ileus, adhesions and bowel obstruction The left transperitoneal anterior subcostal approach has been associated with splenic injury (Mejean et al, 1999)
	Chevron	Useful for renovascular surgery and renal tumors extending into the vena cava Useful in obese patients and in those with a wide subcostal angle Provides outstanding access to both kidneys, renal pedicles, and the great vessels	Ileus, adhesions, and possible bowel obstruction Transection of the abdominal wall muscles may lead to pain and morbidity
	Midline transperitoneal	Useful for trauma, renovascular surgery, reconstructive procedures (e.g., ileal ureter), and bilateral procedures Rapid Provides good access to renal pedicle Practical in patients with a narrow subcostal angle	Ileus, adhesions, and possible bowel obstruction
	Paramedian (extraperitoneal or transperitoneal)	Same as midline Provides added strength with two-layer fascial closure	Ileus, adhesions, and possible bowel obstruction (transperitoneal) Limited exposure of the kidney (extraperitoneal)

It is imperative to understand the anatomy of the flank before employing these approaches (see Figs. 1–3, 1–4, 1–5, and 1–8). There are three principal flank approaches: subcostal, supracostal, and through the bed of a resected rib.

Subcostal Flank Approach

This approach offers good exposure of the renal parenchyma and upper ureter. It is an advantageous approach for surgery on the lower renal pole, UPJ, and upper ureter (e.g., ureterocalicostomy, pyeloplasty, and stone surgery). Simple nephrectomy, insertion of a nephrostomy tube, and drainage of a perinephric abscess may all be accomplished through a subcostal flank incision. Because the approach is extraperitoneal, contamination of the peritoneal cavity is avoided. Access to the renal hilum and vascular pedicle is poor, which is the most salient disadvantage of this approach. The subcostal flank approach is not appropriate for radical or partial nephrectomy (Libertino, 1998). The incision may be caudal to the kidney, hampering access to the upper pole, renal pelvis, and hilum (Novick, 2007). Exposure may be further hindered by the iliac crest and subcostal nerve, the anterior division of the 12th thoracic nerve.

After induction of anesthesia, insertion of an endotracheal tube, and introduction of a Foley catheter into the urinary bladder to monitor urine output, the patient is placed in the lateral position. The head is supported to maintain proper alignment of the cervical spine. The tip of the 12th rib should be positioned over the kidney bar (Fig. 54–18). The patient's back should be nearly flush with the edge of the table to ensure unfettered access by the surgeon. To preserve stability and prevent forward roll, the dependent leg is flexed at the hip and knee and the top leg is kept straight. A pillow is placed between the knees. An axillary roll is deployed just caudal to the axilla to prevent compression or injury of the axillary neurovascular bundle. Other pressure points, including the upper foot, are padded with foam. The

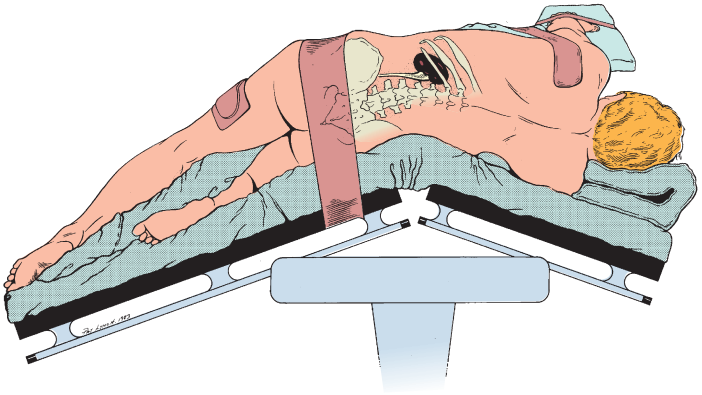

Figure 54–18. Position of the patient for the flank approach. Note the axillary pad. The kidney rest may be elevated if further lateral extension is needed.

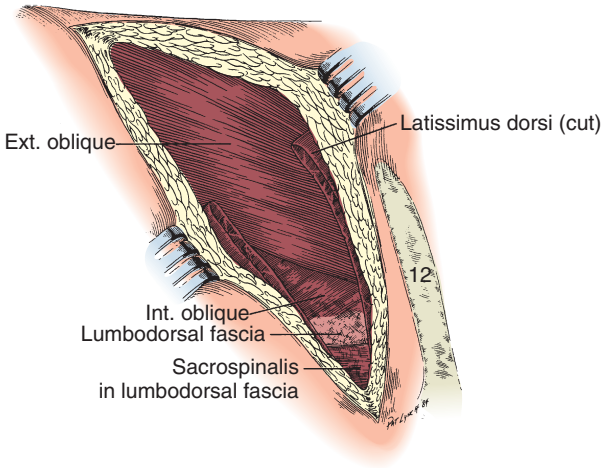

Figure 54–20. Left subcostal incision. The latissimus dorsi muscle has been divided to expose the lumbodorsal fascia and the posterior aspects of the abdominal muscles.

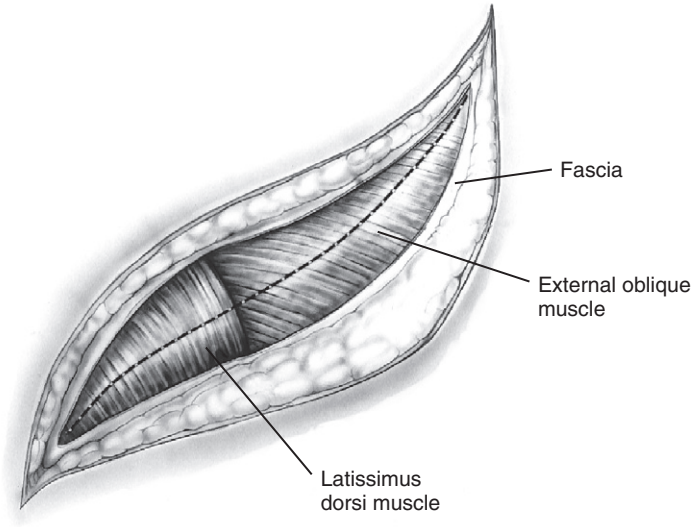

Figure 54–19. Superficial incision through flank. (From Libertino JA. Reconstructive urologic surgery. 3rd ed. Philadelphia: Mosby; 1997.)

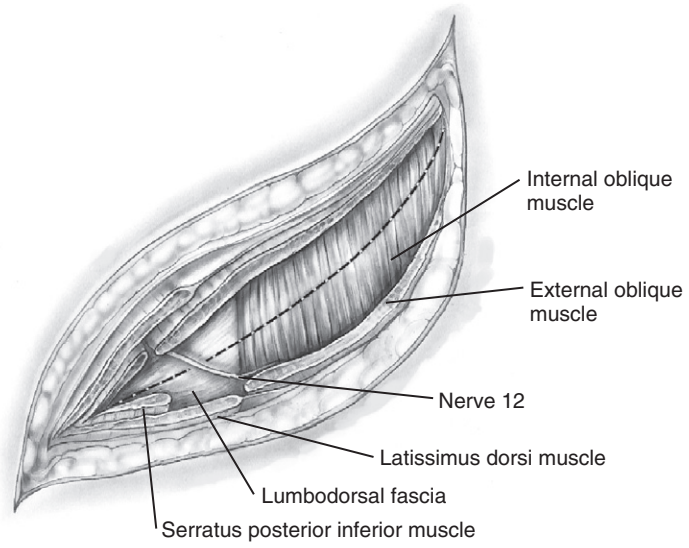

Figure 54–21. Dissection through flank muscles. (From Libertino JA. Reconstructive urologic surgery. 3rd ed. Philadelphia: Mosby; 1997.)

nondependent arm should be placed on a padded Mayo stand so that the arm is horizontal with slight forward rotation at the shoulder. The bed is flexed until the flank muscles are under stretch. A kidney bar can be employed if necessary. The bed is placed in Trendelenburg position so that the flank is rendered parallel to the floor. The patient is secured to the mobile part of operating table with 2-inch wide adhesive tape, which fixes the patient in place while allowing adjustment of flexion.

After sterile preparation and draping, the skin incision begins at the costovertebral angle, approximately at the lateral border of the sacrospinalis muscle just inferior to the 12th rib. The incision is made a fingerbreadth below and parallel to the 12th rib and is carried onto the anterior abdominal wall. In an attempt to avoid the subcostal nerve, the incision can be curved gently downward at the midaxillary line. If needed, the incision can be extended caudally or medially to the lateral border of the rectus abdominis.

The incision is carried sharply through the subcutaneous tissue, exposing the fascia of the latissimus dorsi and external oblique muscles (Fig. 54–19). Electrocautery is used to incise the muscles in the line of the incision (Fig. 54–20), starting with the latissimus dorsi posteriorly. The serratus posterior inferior muscles, which insert into the lower four ribs, are also encountered in the posterior portion of the wound and transected. In the anterior aspect of the wound the external oblique muscle is divided. These maneuvers expose the fused lumbodorsal fascia, which gives rise to the internal oblique and transversus abdominis muscles. The lumbodorsal fascia and internal oblique muscle are divided (Fig. 54–21). By using two fingers inserted into an opening created in the lumbodorsal fascia at the tip of the 12th rib, the peritoneum is swept medially as the transversus abdominis is split digitally. The subcostal nerve should be identified between the internal oblique and transversus abdominis muscles and spared (Figs. 54–22 and 54–23).

To maximize exposure in the posterior aspect of the incision, one may incise the posterior angle of the lumbodorsal fascia, exposing the sacrospinalis and quadratus lumborum muscles. Dividing the costovertebral ligament permits superior retraction of the 12th rib if enhanced exposure is deemed necessary. A

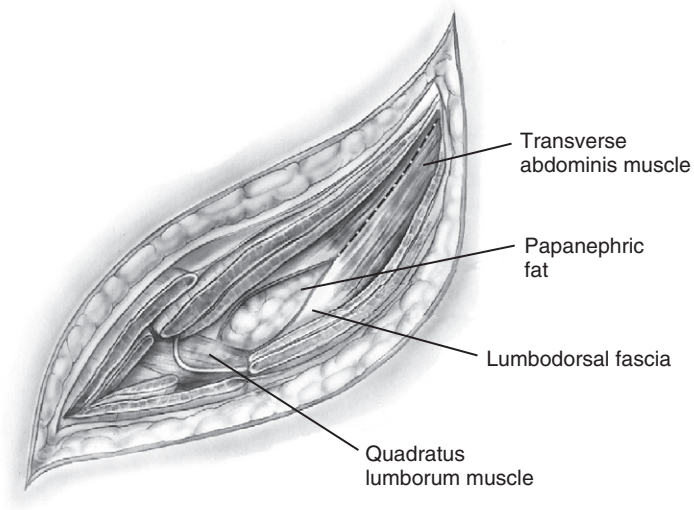

Figure 54–22. Opening lumbodorsal fascia to gain entrance to retroperitoneum. (From Libertino JA. Reconstructive urologic surgery. 3rd ed. Philadelphia: Mosby; 1997.)

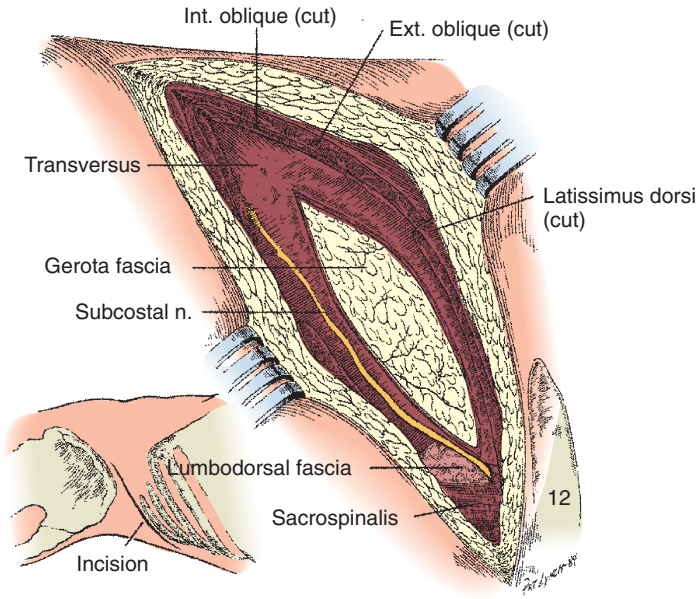

Figure 54–23. The lumbodorsal fascia and transverse muscles have been divided to expose the Gerota fascia. The subcostal nerve and vessels pierce the lumbodorsal fascia posteriorly and course forward on the transverse muscle.

Bookwalter (Codman & Shurtleff, Raynham, MA) flank retractor is used for exposure.

To facilitate wound closure, the kidney bar is lowered and the table is partially taken out of flexion. The wound is closed in layers using No. 2 Nylon. The transversus abdominis and internal oblique muscles are closed in one layer. The lumbodorsal fascia is reapproximated, followed by the external oblique, serratus posterior inferior, and latissimus dorsi muscles. The skin edges are reapproximated with staples or subcuticular 2-0 polyglactin (Vicryl). A closed drainage system or Penrose drain should be externalized through a small counterincision below the wound. After applying a sterile dressing to the wound, the authors place the Penrose drain into a collection bag designed for urinary stomas, which is secured

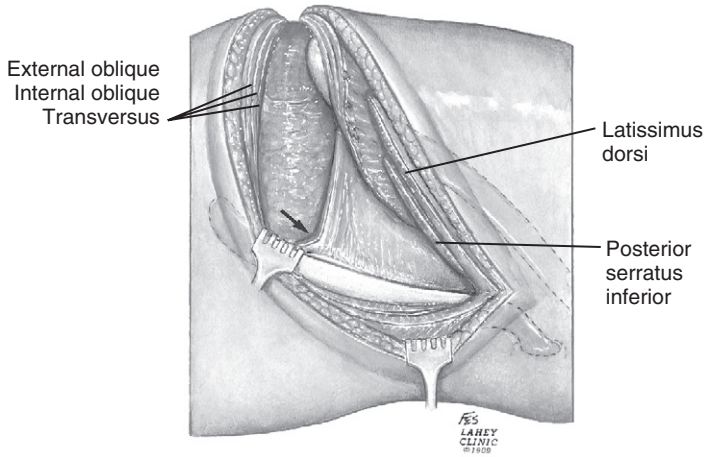

Figure 54–24. Relationship of flank musculature to supracostal area. (© The Lahey Clinic.)

to the abdominal wall. This allows drainage to be easily recorded and protects the skin from the drain output.

Supracostal Flank Approach

The supracostal flank incision is favored at the Lahey Clinic for most modest-sized renal tumors and most partial nephrectomies (Fig. 54–24). When properly executed it affords an extraperitoneal, extrapleural approach to the kidney with excellent exposure of the renal and suprarenal areas. In addition, this approach permits the 11th or 12th rib to pivot posteriorly without removing a rib. Turner-Warwick (1965), who popularized the approach, believed that the supracostal approach provides maximal posterior exposure, simplifies wound closure, and is less morbid than a transcostal incision requiring rib resection. More recently, an 8-cm modified mini-flank supra-11th rib incision has been described as a safe, effective approach to radical or partial nephrectomy for renal cortical tumors (Diblasio et al, 2006).

The level of the incision is determined by the patient's anatomy, location of the lesion, and the operation planned. For partial nephrectomy the level of incision is determined by the position of the kidney in relation to the ribs as seen on preoperative radiographic studies and by the location and size of the tumor.

The patient is positioned as described for the subcostal flank incision. A skin incision at the superior aspect of the 12th or 11th rib is made, beginning at the lateral border of the sacrospinalis muscle and continuing until the lateral border of the ipsilateral rectus abdominis muscle. The incision is carried sharply through the subcutaneous tissue. The latissimus dorsi and serratus posterior inferior muscles are transected in the posterior aspect of the wound, revealing the intercostal muscles.

The external and internal oblique muscles are divided. The lumbodorsal fascia is opened at the tip of the rib to avoid both peritoneum and pleura. Moving medially, the transversus abdominis muscle is divided carefully while sweeping the peritoneum medially and inferiorly. The diaphragm is exposed by transection of the transversalis muscle. The pleura is identified between the divided transverses abdominis muscle and the diaphragm and can be mobilized superiorly.

The lateral aspect of the sacrospinalis is identified and is either incised or retracted to permit access to the neck of the rib and its attachments. Division of the intercostal muscles should start at the most distal aspect of the rib and proceed toward the spine.

The corresponding intercostal nerve is identified and spared. To avoid the neurovascular bundle the intercostal muscles are divided in close proximity to the superior aspect of the rib. The plane between the chest wall and pleura is developed by entering the investing fascia surrounding the intercostal nerve, which allows an extrapleural dissection (Fig. 54–25). The slips of the diaphragm attached to the inferior ribs are transected. Proceeding posteriorly, the intercostal or transverse costal ligament is divided, which permits free movement of the 12th rib (supra 12th) or the 11th and 12th rib (supra 11th).

Proper closure restores separation between the thoracic and abdominal cavities. At time of closure, local anesthetic can be used to perform an intercostal nerve block under direct vision. As described by Turner-Warwick (1965), the detached diaphragm is externalized through the intercostal space and sutured to the free edge of the intercostal muscles and to the inferior cut edge of the serratus posterior inferior muscle. The edges of the transected latissimus dorsi muscle are reapproximated while incorporating the upper margin of the serratus posterior inferior muscle. A drain is externalized through a separate stab incision.

Over time, the senior author has modified the closure of the supracostal incision. The diaphragm is closed primarily and not externalized. A rib punch is used to create a hole in the rib above and below the incision. A No. 2 Nylon suture, which is passed through the ribs and the diaphragm, is used to restore integrity of the chest wall. The latissimus dorsi, serratus posterior inferior, and intercostal muscles are closed in a single layer.

Transcostal Flank Approach

The classic flank approach involves resection of the 11th or 12th rib and entrance into the retroperitoneum through the bed of the resected rib (Hess, 1939; Hughes, 1949; Bodner and Briskin, 1950). It provides similar exposure to the supracostal incision but is a more complicated and more morbid incision. This transcostal approach fell out of favor at the Lahey Clinic decades ago with the advent of the supracostal approach.

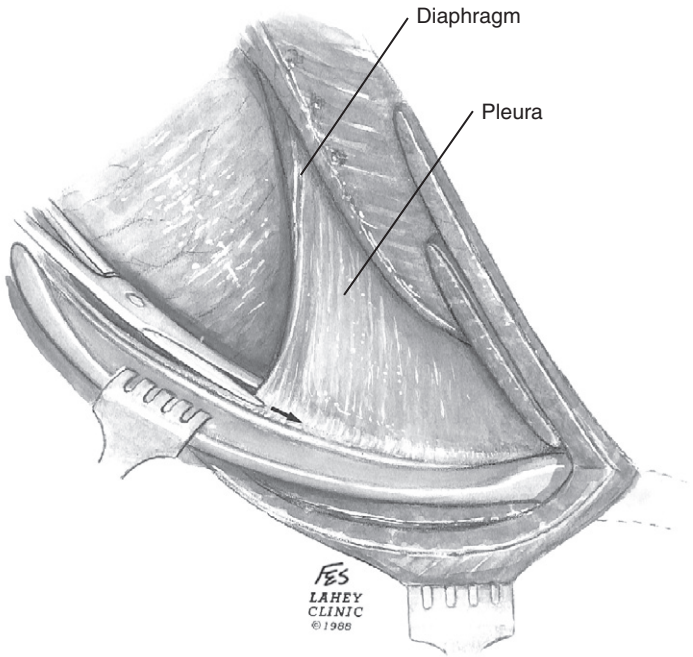

Figure 54–25. Following the intercostal nerve to remain extrapleural back to the intercostal ligament. (© The Lahey Clinic.)

The site of incision is determined by the position of the kidney and the location of disease. Typically, for a lower pole tumor a supra-12th rib incision is adequate. For mid and upper pole tumors, a supra-11th incision is often satisfactory. On a urogram a horizontal line that traverses the hilum of the kidney will intersect with the rib that should be resected. In cases requiring upper pole access the surgeon should approach the kidney through the rib above the one indicated by the horizontal line transversing the hilum.

The patient is placed in the flank position. A trans-12th rib approach will be described. The skin is incised directly over the 12th rib from the lateral border of the sacrospinalis muscle and continuing until the lateral border of the ipsilateral rectus abdominis muscle. The latissimus dorsi, serratus posterior inferior, and external oblique muscles are divided with electrocautery over the center of the 12th rib, exposing the periosteum. The periosteum is incised with a knife. A periosteal elevator is employed to separate the rib from its periosteum. One must be vigilant to preserve the neurovascular bundle.

The exposed rib is resected with a rib cutter as posterior as possible. Rongeurs help remove additional rib and sharp fragments. Bone wax is used to obtain hemostasis and a smooth surface. The anterior attachments of the rib are divided, permitting the rib to be excised.

One enters the retroperitoneum by incising the posterior layer of periosteum at the tip of the rib. As the incision is extended laterally along the length of the rib bed, a finger is used to sweep away the pleura and peritoneum. The internal oblique is divided with cautery. Proceeding anteriorly, the transversus abdominis is then split with fingers. As in other flank approaches, effort should be made to preserve the 12th nerve coursing between the internal oblique and transverse muscles. The pleura is sharply separated from the fascia under the 11th rib above. The diaphragmatic attachments to the thoracoabdominal wall are divided. With sharp dissection the peritoneum is released from the transverse fascia to improve exposure.

In cases of 11th rib resection, the pleural reflection will be in the posterior aspect of the wound atop the diaphragm. One can mobilize the pleura superiorly by dividing its attachments to the diaphragm, or the two can be mobilized together by dividing the diaphragm.

To close the wound, the kidney rest is lowered and flexion is partially reduced. The incision is closed in layers. If an inadvertent pleural tear was created, an 8-Fr "dart" chest drain (Arrow International, Reading, PA) is placed and the pleural defect is closed using 2-0 silk. Infiltration of local anesthetic into the fascia around the intercostal nerves is helpful for analgesia. Drains are brought out through a separate stab incision.

Thoracoabdominal Approach

The thoracoabdominal approach (Fig. 54–26) is used for the management of large renal masses, suprarenal or upper pole masses, renal tumors with venous extension, as well as tumors involving adjacent structures (Mortensen, 1948; Chute et al, 1949; Cooper et al, 2002). The incision provides maximal suprarenal exposure. It is particularly useful on the right side, where the liver and hepatic veins impede exposure and make control of the renal pedicle difficult. This transpleural incision may be associated with additional pulmonary morbidity compared with the other flank or anterior approaches (Novick, 2007), but the incision permits

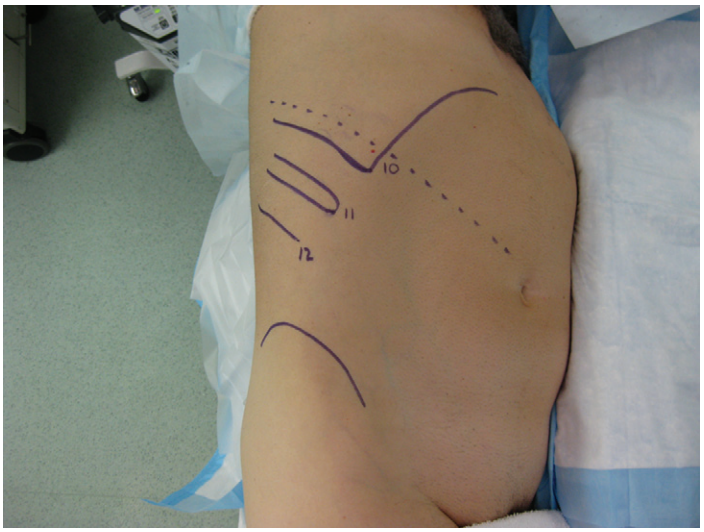

Figure 54–26. Thoracoabdominal incision at the supra-tenth border with patient in lateral decubitus position.

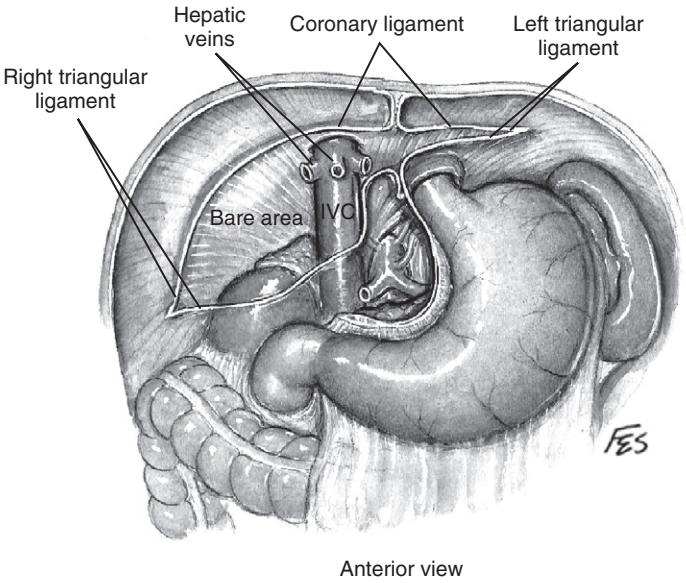

Figure 54–27. Relationship of liver and triangular and coronary ligaments to vena cava. IVC, inferior vena cava. (© The Lahey Clinic.)

resection of very large tumors, including those that involve adjacent structures (Buse et al, 2006). The phrenic nerve may be injured in this approach, compromising diaphragmatic function.

For this approach the flank position is modified to permit access to the anterior abdominal wall. The patient is positioned in a semi-oblique manner with a rolled blanket or beanbag supporting the flank. The legs are positioned similar to the traditional flank position. The pelvis is rotated in a more horizontal position than in the flank incisions, at an angle of approximately 75 degrees rather than 90 degrees from level.

The level of the incision is determined by the nature of the tumor, including size and relationship to surrounding structures such as the liver. In the experience of the senior author, approaching through the 9th or 10th interspace provides sufficient exposure in the majority of cases. For particularly large tumors or those involving the liver, an incision through the 8th interspace may be required. Dividing the intercostal ligament is an essential maneuver to obtain good exposure.

The skin incision begins at the lateral aspect of the sacrospinalis muscle over the 10th or 11th rib and travels obliquely across the anterior abdominal wall to the midpoint of the contralateral rectus abdominis muscle above the umbilicus. Alternatively, the incision can be carried caudally toward the symphysis pubis. The subcutaneous tissues are divided with cautery.

In patients with involvement of the IVC the abdominal portion of the wound should be opened first to permit exploration for evidence of metastatic disease. Otherwise, the chest and abdomen can be opened in the order of preference of the surgeon. The rectus abdominis, external oblique, latissimus dorsi, and serratus inferior posterior muscles are divided. The internal oblique and transversus abdominis muscles are transected. The underlying peritoneum is opened, and the peritoneal cavity is explored.

The chest is entered. The costal cartilage is transected. While staying close to the superior border of the rib, the intercostal muscles are divided. This exposes the underlying pleura and diaphragm. The pleura is opened sharply, taking care to avoid the lung. The costovertebral ligament is divided. The diaphragm is opened from its thoracic surface. Starting anteriorly and proceeding posteriorly, the diaphragm is opened in a curvilinear fashion staying about two fingerbreadths from the chest wall to avoid injuring the more central phrenic nerve.

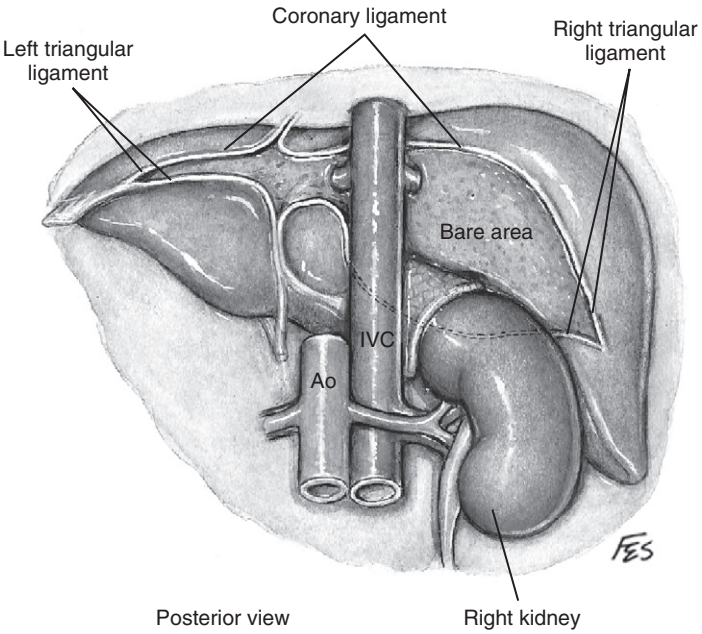

Figure 54–28. Posterior view of relationship of liver and triangular and coronary ligaments to vena cava. IVC, inferior vena cava; Ao, aorta. (© The Lahey Clinic.)

The liver or spleen is gently retracted upward. Additional hepatic mobility can be obtained by dividing the coronary ligament and the right triangular ligament of the liver (Figs. 54–27 and 54–28). For right-sided tumors, the kidney and great vessels are approached by mobilizing the colon medially and kocherizing the duodenum (Fig. 54–29). For tumors on the left, the colon and the tail of the pancreas are mobilized, providing excellent exposure of the renal pedicle.

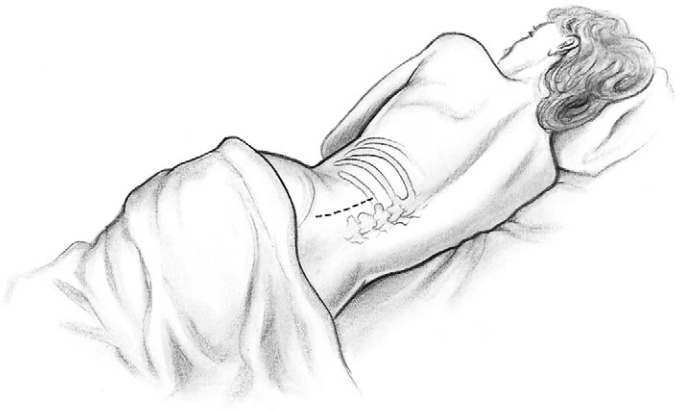

Figure 54–32. Lateral decubitus position for lumbodorsal approach. (© The Lahey Clinic.)

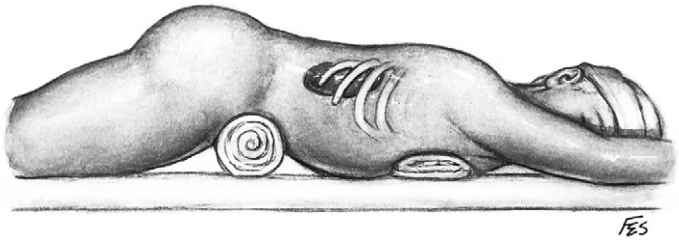

Figure 54–33. Prone position for lumbodorsal approach. (© The Lahey Clinic.)

After the procedure the posterior peritoneum is closed with running 2-0 polyglactin. The continuity of the diaphragm is restored with 2-0 silk, with the knots tied on the abdominal surface. When necessary the diaphragm can be repaired with a polytetrafluoroethylene (PTFE) patch (W. L. Gore and Associates, Medical Products Division, Flagstaff, AZ). The integrity of the rib cage is restored by reapproximating the costal arch with No. 2 Nylon. An 8-Fr "dart" chest drain is placed and attached to a Pleur-Evac drainage system (Teleflex, Research Triangle Park, NC). The pleura and intercostal muscles are reapproximated using 2-0 polyglactin, taking care to incorporate the diaphragm toward the medial surface. The anterior peritoneum is closed with 2-0 polyglactin. The abdominal wall muscles and rectus sheaths are reapproximated with 1-0 polydioxanone (PDS). The subcutaneous tissue is brought together with 3-0 plain suture. Staples are used to close the skin. A Penrose drain is externalized through a separate stab incision.

Dorsal Lumbotomy

The lumbodorsal approach is useful for simple nephrectomy for a small atrophic kidney, simultaneous bilateral simple nephrectomies, renal biopsy, pyeloplasty, pyelolithotomy and upper ureterolithotomy, and other procedures on the renal pelvis or upper ureter (Andaloro and Lilien, 1975; Gardiner et al, 1979; Novick, 1980) (see Figs. 54–30 and 54–31 on the Expert Consult website). The incision is particularly advantageous in patients with extensive prior abdominal or flank operations because it avoids dissection in scarred or adhesed planes. Because muscles are retracted rather than transected, patients benefit from less pain and a strong closure (Gil-Vernet, 1964; Gardiner et al, 1979). Postoperative flank bulges are less common than with the flank approaches. Rib resection is not necessary because exposure is adequate with division of the costovertebral ligament and rib retraction (Gardiner et al, 1979; Novick, 2007). The lumbodorsal approach is appropriate neither for large kidneys nor for those that are superiorly displaced. The incision provides limited exposure of the ureter and is thus not ideal for operations requiring dissection beyond the upper ureter. The lumbodorsal approach allows marginal access to the renal hilum that may adversely impact control of the renal vasculature. This is the most significant shortcoming of the approach.

For a unilateral procedure the patient is placed in the lateral decubitus position with the table minimally flexed (Fig. 54–32). In the case of a bilateral procedure the patient is placed prone with the table partially flexed to broaden the distance between the iliac crest and 12th rib (Fig. 54–33). Supports under the sternum and pubis permit movement of the anterior abdominal wall with respiration.

The dorsal lumbotomy is an anatomic approach to the kidney, with incision of fascial planes rather than muscle (see Fig. 54–3). A vertical skin incision is made from the inferior border of the 12th rib to the iliac crest, in line with the lateral border of the sacrospinalis muscle. The subcutaneous tissues are divided, exposing the latissimus dorsi muscle. The aponeurosis of the latissimus dorsi is separated from the posterior layer of the lumbodorsal fascia where it overlies the sacrospinalis muscle. The posterior layer of the lumbodorsal fascia, a strong fascial covering, is incised, which allows the sacrospinalis muscle to be retracted medially. The costovertebral ligament is divided, which permits superolateral retraction of the 12th rib, which improves access superiorly. The fused middle and anterior layers of the lumbodorsal fascia are divided, permitting the quadratus lumborum muscle to be

retracted medially (Fig. 54–34). The ilioinguinal nerve should be identified and spared. Entry into the paranephric space is achieved by incising the transversalis fascia. Division of the perinephric fascia reveals the kidney.

The incision is closed by returning the muscles to anatomic position and by reapproximating the lumbodorsal fascia. Some advocate closure of the lumbodorsal fascia in two layers, although reapproximation of the fascia overlying the sacrospinalis muscle as a single layer may be adequate (Menon, 1998). A drain should be externalized.

Anterior Approaches

The anterior incisions can be used for either transperitoneal or extraperitoneal access to the kidney (Fig. 54–35). The transperitoneal anterior approaches offer good access to the renal pedicle at the expense of a longer postoperative ileus and risk of future small bowel obstruction due to intra-abdominal adhesions. Seprafilm (Genzyme Corporation, Cambridge, MA), a sodium hyaluronate and carboxymethylcellulose membrane, can be used to decrease the risk of adhesions. The extraperitoneal anterior approaches provide inferior exposure and are of limited utility.

Anterior Midline

An anterior midline incision is the incision of choice for management of renal trauma because it permits exploration for associated intraperitoneal injuries. It can also be employed for renovascular surgery, reconstructive procedures including ileal ureteral replacement, and bilateral renal procedures.

With the patient in the supine position, a midline skin incision is made from the xiphoid process to the symphysis pubis, curving around the umbilicus. After dividing the subcutaneous tissues with electrocautery, the linea alba is sharply incised to expose the underlying preperitoneal fat and peritoneum. The peritoneum is grasped with two smooth forceps and elevated to reduce risk of bowel injury. The peritoneum is sharply opened between the two forceps. A finger is inserted into the peritoneal cavity and is used to tent the peritoneum away from bowel as the incision is extended with scissors. The ligamentum teres should be divided and suture ligated.

Control of the renal pedicle can be obtained directly through the posterior parietal peritoneum or by medial reflection of the colon. On the left, the approach involves a vertical incision in the posterior peritoneum below the ligament of Treitz. This space contains the anterior surface of the aorta, the crossing left renal vein, and often the inferior mesenteric vein and gonadal vessels. The superior mesenteric artery should be on the anterior surface of the aorta and is usually 1 to 2 cm cephalad to the left renal vein. Gentle dissection along the hilum at this level provides good vascular control. A second approach to the left renal hilum is through the lesser sac. In this approach, the gastrocolic omentum is divided and entered. The transverse colon can then be retracted inferiorly. The peritoneum below the pancreas can be incised. The vessels are identified (Fig. 54–36). It is the authors' preference to incise the colon along the white line of Toldt and reflect the colon anteromedially. This permits access to the renal pedicle both anteriorly and posteriorly. The artery can be isolated posteriorly and the venous system identified and controlled anteriorly.

Similarly, the right kidney can be reached directly by incision of the hepatic flexure and a Kocher maneuver to free the duodenum and reflect it medially. Further incision along the white line of Toldt frees the colon, permitting exposure of the anterior Gerota fascia. After the duodenum is reflected, the anterior surface of the vena cava is exposed. Care is taken not to injure the pancreas, gonadal vein, adrenal vein, or accessory renal vessels. The main renal vein is mobilized. Posterior to the renal vein along its superior margin lies the renal artery (Fig. 54–37), which normally runs a retrocaval course. The renal artery can be isolated here or between the vena cava and aorta when greater length is required.

After the procedure is complete, the peritoneum is closed with 2-0 polyglactin. The fascia is closed with polypropylene (Prolene) or polydioxanone. After bringing the subcutaneous tissues together with 3-0 plain sutures, the skin edges are reapproximated with staples or subcuticular 2-0 polyglactin. A Penrose drain is externalized through a separate stab incision.

Anterior Paramedian

The paramedian approach, which is a straightforward incision with a strong closure, is occasionally employed but provides limited exposure to the kidney. A paramedian skin incision is made approximately 3 cm lateral to the midline. The subcutaneous tissues are divided with electrocautery. The anterior rectus sheath is divided. By sharply transecting the transverse tendinous intersections, one is able to reflect the belly of the muscle medially. The posterior rectus sheath and transversalis fascia are then divided in the line of the incision.

By developing the plane between the peritoneum and transversalis fascia from diaphragm to iliac crest, one can make an extraperitoneal approach to the kidney, although this offers marginal renal access (Tessler et al, 1975). Alternatively, the peritoneum is opened and the kidney is approached as described earlier.

The peritoneum is closed with 2-0 polyglactin. The fascia is closed with polypropylene or polydioxanone. After bringing the subcutaneous tissues together with 3-0 plain sutures, the skin edges are reapproximated with staples or subcuticular 2-0 polyglactin. A Penrose drain is externalized through a separate stab incision.

Anterior Subcostal

The transperitoneal anterior subcostal incision can be employed for both radical and partial nephrectomy, especially for upper pole tumors. With extension of the incision to the lateral border of the contralateral rectus abdominis muscle, the transperitoneal anterior subcostal approach can be used for renovascular surgery. The extraperitoneal subcostal incision has limited utility in adults owing to marginal access to the renal pedicle. It is rarely employed.

The patient is placed in the supine position. The skin is incised from the tip of the 11th rib to the contralateral rectus abdominis muscle, starting two fingerbreadths below the costal margin. The subcutaneous tissues are divided with electrocautery, exposing the external oblique muscle laterally and the rectus sheath medially. After dividing fibers of the latissimus dorsi muscle in the lateral aspect of the wound, the external oblique muscle is transected. The anterior rectus sheath is opened, and the rectus abdominis muscle is retracted medially or divided. The internal oblique muscle, transversus abdominis muscle, posterior layer of the rectus sheath, and the transversalis fascia are divided. This exposes the underlying peritoneum.

For the extraperitoneal approach the peritoneum is reflected from the transversalis fascia using blunt dissection. The retroperitoneal space is entered laterally while retracting the peritoneum and its contents medially. In the more commonly employed transperitoneal approach the peritoneum is opened. The ligamentum teres is encountered in the midline, divided, and suture ligated. The kidneys are approached as described earlier.

The peritoneum is closed with 2-0 polyglactin. The fascia is closed with 1-0 polydioxanone. After bringing the subcutaneous tissues together with 3-0 plain sutures, the skin edges are reapproximated with staples or subcuticular 2-0 polyglactin. A Penrose drain is externalized through a separate stab incision.

Chevron Incision (Bilateral Subcostal Approach)

The chevron incision, essentially a bilateral anterior subcostal approach, is advantageous for renovascular surgery and radical nephrectomy with IVC tumor thrombectomy. Exposure of the renal pedicles and great vessels is outstanding. The incision starts at the tip of the 11th rib, extends approximately two fingerbreadths below and parallel to the costal margin, curves superiorly

in the midline, travels parallel to the contralateral costal margin, and terminates at the tip of the contralateral 11th rib.

After dividing the subcutaneous tissues with electrocautery, the latissimus dorsi muscle, external oblique muscle, anterior rectus sheath, rectus abdominis muscle, internal oblique muscle, transversus abdominis muscle, posterior rectus sheath, and transversalis fascia are divided. The peritoneum is opened, dividing the ligamentum teres as described previously.

The peritoneum is closed with 2-0 polyglactin. The fascia is closed with 1-0 polydioxanone or 2-0 nylon. After bringing the subcutaneous tissues together with 3-0 plain sutures, the skin edges are reapproximated with staples or subcuticular 2-0 polyglactin. A Penrose drain is externalized through a separate stab incision.

Key Points: Surgical Approaches

- Good functional exposure permits the surgeon to perform the planned procedure, diminishes risk of injury to surrounding structures, and permits definitive treatment of an intraoperative complication, such as injury to a great vessel.
- The ideal surgical approach is one that is tailored not only to the operation being performed but also to the anatomy as defined on preoperative imaging, previous surgical history, body habitus, and presence of limiting factors such as kyphoscoliosis or pulmonary disease.
- The salient features of the surgical approaches to the kidney are summarized in Table 54–8.

SURGERY FOR BENIGN DISEASE

Simple Nephrectomy

Indications

Simple nephrectomy, removal of the kidney within the Gerota fascia, is employed to manage nonmalignant diseases of the kidney. Indications for simple nephrectomy include durable nonfunction or poor function of a kidney due to obstruction, infection, trauma, stones, nephrosclerosis, vesicoureteral reflux, polycystic kidney, or congenital dysplasia. Nephrectomy is undertaken when reconstructive procedures have failed or are contraindicated due to poor function of the renal unit, advanced age, or significant comorbidity. Simple nephrectomy of a functional kidney may be employed to relieve intractable symptoms or associated problems, such as bleeding, pain, hypertension, or persistent infection. Simple nephrectomy is an accepted treatment for renovascular hypertension that is refractory to other organ-sparing therapies.

Preoperative Evaluation and Preparation

In addition to a genitourinary history, one must ascertain the patient's full medical history, with a special focus on cardiovascular, pulmonary, and surgical history. Factors influencing choice of incision should be elucidated on history and examination, including body habitus and sites of prior abdominal or flank operations. One must be cognizant of a patient's renal status and the anticipated function that will remain after surgery. Estimation of global renal function as previously described is essential. Determination of differential renal function by radionuclide scan is advisable, particularly if renal dysfunction or abnormal split function is suspected.

Techniques

Simple nephrectomy can be performed through the flank and anterior abdominal approaches as described earlier. The approach can be either extraperitoneal or transperitoneal. Removal of atrophic kidneys with end-stage disease can also be accomplished through a dorsal lumbotomy incision (Andaloro and Lilien, 1975; Novick, 1980). **For all approaches the key steps of a simple nephrectomy are the approach, mobilization of the kidney, division of the artery followed by the vein, division of the ureter, removal of the kidney, and closure.**

Standard Flank Approach. A flank approach (Fig. 54–38) is preferable in patients with multiple prior anterior abdominal operations and in obese patients. An extraperitoneal approach is preferred in patients with an infected renal unit or numerous prior transperitoneal procedures. The kidney can be approached extraperitoneally through the subcostal route, although consideration should be given to a supracostal approach depending on the patient's anatomy.

The perinephric space is entered. To avoid inadvertent entry into the peritoneum a vertical incision is made in Gerota fascia on the lateral aspect of the kidney, revealing the underlying perinephric fat. The kidney is mobilized sharply by developing a plane between the renal capsule and the perinephric fat. If there have been numerous episodes of pyelonephritis or prior renal operations, developing this plane can be challenging. Inadvertent entrance into the renal capsule should be avoided. When developing the plane at the lower pole the ureter is identified but not yet ligated. Downward traction on the kidney permits the upper pole to be mobilized. The adrenal gland is left in position.

With the use of lateral traction on the kidney to expose the hilum, the vascular pedicle is dissected free from surrounding fat and lymphatics. The renal hilum can be approached either anteriorly or posteriorly. In the anterior approach, gonadal, adrenal, and lumbar branches draining into the left renal vein are ligated and divided. The mobilized renal vein is retracted to reveal the renal artery located posteriorly (see Figs. 54–8 and 54–39). The left renal artery should be differentiated from the superior mesenteric artery by ensuring that the renal artery emanates from the lateral aspect of the aorta and by palpating the superior mesenteric artery before ligating the renal artery. The renal artery is ligated away from the hilum using two medium vascular Hem-o-Lok clips on the stump side and a 2-0 silk tie on the specimen side. The artery is divided proximal to the silk tie. The arterial stump is then suture ligated with 2-0 silk. After division of the renal artery, the renal vein is similarly ligated and divided. In the posterior approach the artery is encountered before the renal vein and is ligated and divided before mobilization of the vein. The ureter is doubly clamped and divided. The specimen is removed. The distal aspect of the transected ureter is suture ligated with 2-0 polyglactin.

Ideally, the renal artery and vein are ligated individually as described previously, because taking the vessels en bloc may increase risk of arteriovenous fistula (Lacombe, 1985; Okamoto et al, 2001). In cases complicated by severe fibrosis and scarring, one may not be able to safely control the vessels individually, in which case en-bloc ligation and division may be necessary. A drain is brought out through a separate stab incision.

Subcapsular. In patients with a history of significant renal infection or prior renal surgery, severe inflammation and scarring may obliterate the usual tissue planes within the Gerota fascia, rendering mobilization of the kidney unsafe and inefficient. In these

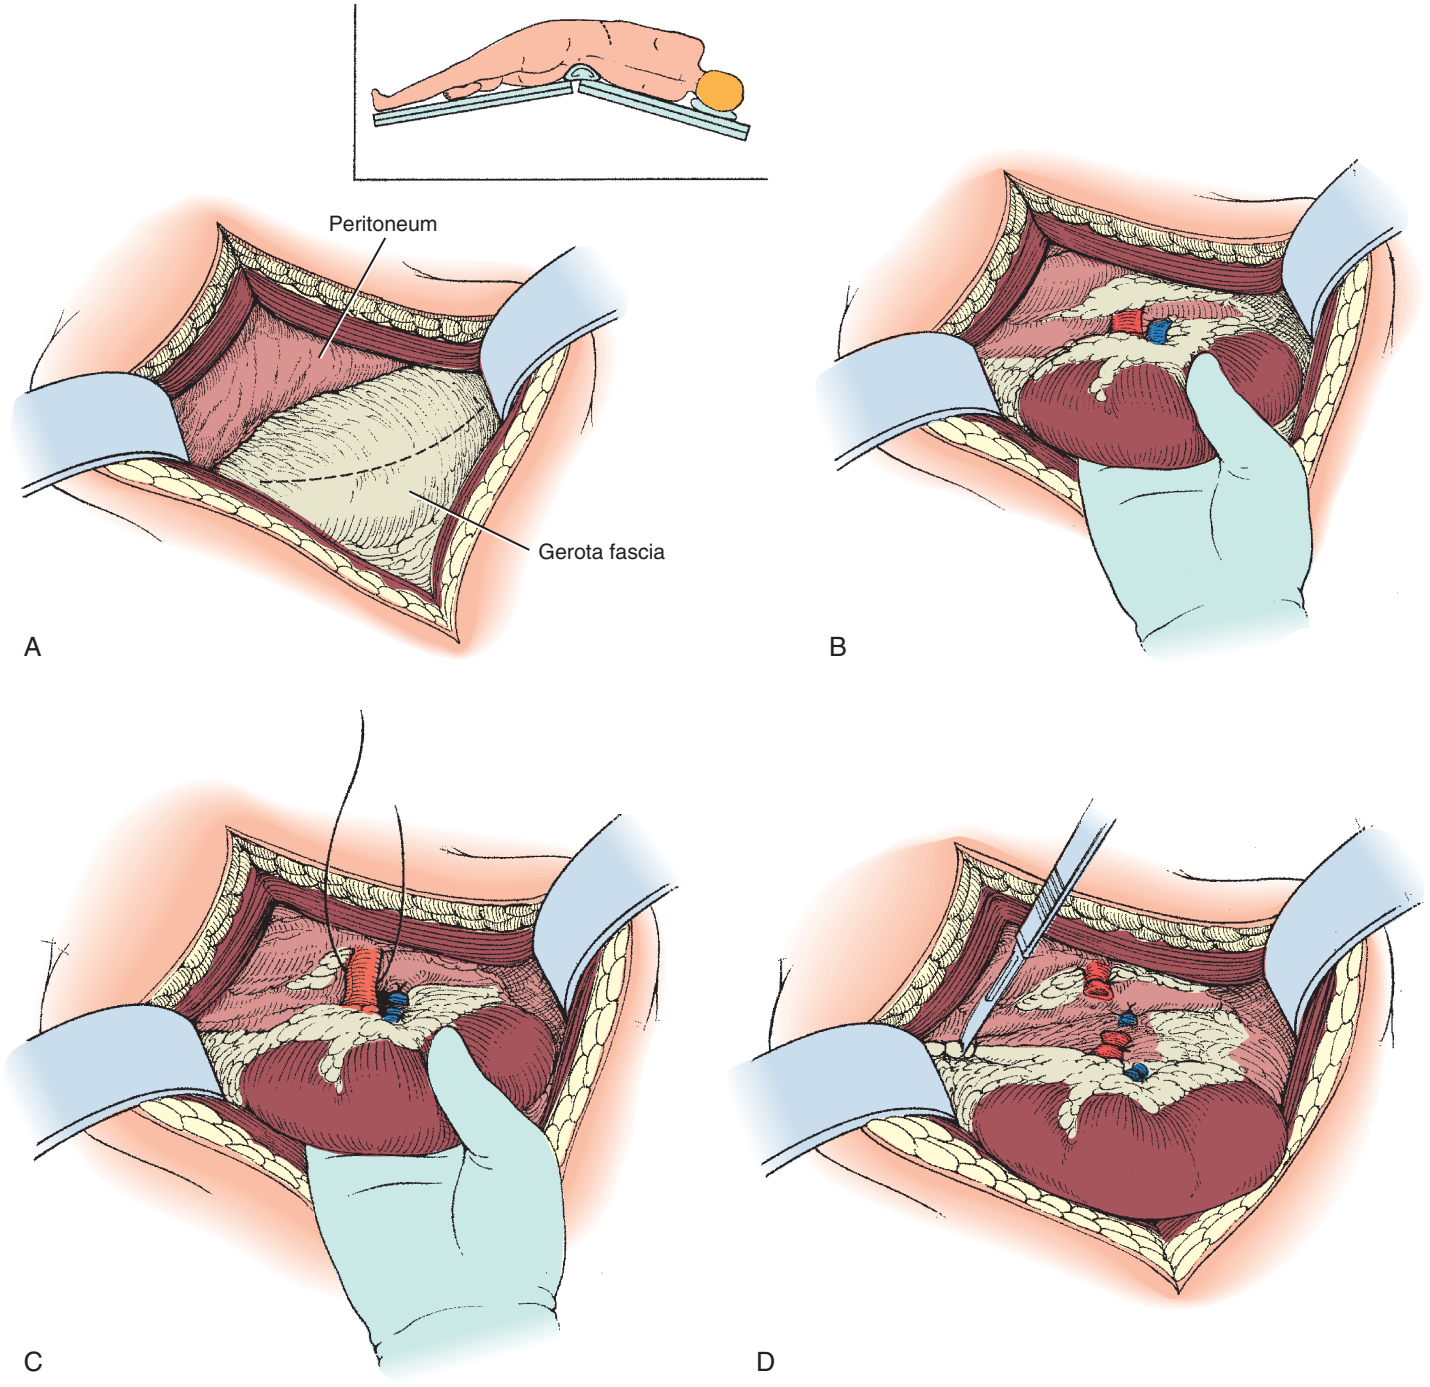

Figure 54–38. **A** to **D,** Technique of simple left nephrectomy through an extraperitoneal flank incision.

cases a subcapsular nephrectomy is indicated (Kimbrough and Morse, 1953; Kittredge and Fridge, 1958) (Fig. 54–40).

Subcapsular nephrectomy can be an arduous procedure. In patients who had prior renal surgery, care should be taken in entering the retroperitoneal space because the perirenal fat may be attenuated and the parenchyma can be unintentionally incised when opening the transversalis fascia. After entry into retroperitoneal space and determination that scarring precludes traditional simple nephrectomy, the renal capsule is incised longitudinally over the convex surface of the kidney.

Holding sutures of 2-0 polyglactin or Allis clamps are placed on the anterior aspect of the renal capsule for traction. While gently pulling on the anterior edge of the renal capsule and proceeding toward the hilum, sharp dissection is used to free the capsule from the underlying parenchyma. When the capsular flap has been raised adequately to expose the hilum, the parenchyma of the kidney is retracted laterally to expose the renal vessels. The artery and vein are ligated and divided in succession. The ureter is ligated and divided. The kidney is removed. Any devascularized perirenal tissue is excised. A drain is essential.

Transperitoneal Anterior Abdominal Approach. A transperitoneal anterior abdominal approach is used to perform simple nephrectomy in patients with renal trauma, flank scarring from prior operations, for bilateral nephrectomies, and in patients who are

unable to tolerate the flank position. After making a transperitoneal midline incision or anterior subcostal incision, the Gerota fascia and the renal hilum are approached as described earlier. A Bookwalter retractor is employed. The Gerota fascia is entered medially and the hilum secured before mobilizing the kidney. On the left, retraction of the left renal vein inferiorly exposes the left renal artery, which is then ligated with 2-0 silk (see Fig. 54–39). For right nephrectomy, the right renal artery is ligated between the aorta and IVC (see Fig. 54–8). After securing the artery the renal vein is ligated and divided. After ligating the renal artery a second time, it is divided. The kidney is then mobilized within the Gerota fascia, the ureter is ligated and divided, and the specimen is removed. A drain is brought out through a separate stab incision.

Key Points: Simple Nephrectomy

- Simple nephrectomy, removal of the kidney within the Gerota fascia, is employed to manage nonmalignant diseases of the kidney.
- For all approaches the key steps of a simple nephrectomy are the approach, mobilization of the kidney, division of the artery followed by the vein, division of the ureter, removal of the kidney, and closure.

Renovascular Surgery

Background

Renal artery surgery was first described in 1949 by Dos Santos for atherosclerotic disease utilizing a dedicated renal endarterectomy to treat an occlusive plaque. By restoring flow to the affected renal unit it became apparent that patency could be accomplished by removal of the intima and media of the arterial system. The drawbacks to this approach stemmed from the weakness of the native adventitia and the incidence of intimal flaps leading to postoperative aneurysms and restenosis. To maximize the repair surgeons soon came to recognize the benefits of vein patch renal angioplasty, thereby limiting narrowing and dilation. Transaortic endarterectomy was explored as an alternative option, allowing simultaneous repair; however, the high rates of recurrent stenotic disease precluded it becoming a mainstay in therapy (Libertino, 1992).

Renal endarterectomy and repair with saphenous vein or synthetic graft can be a suitable option for short well-defined segments of mural dysplasia. Recurrent stenosis is often attributed to residual microscopic mural disease not appreciated at the time of surgery. The authors prefer to treat renal stenotic lesions using aortorenal bypass procedures. If the saphenous vein is unavailable, cephalic vein or PTFE is recommended. In some instances the aorta is too diseased for reimplantation and alternate arterial conduits are chosen, as described later.

Etiology

The primary disease entities necessitating revascularization include atherosclerosis (75%) and fibrous dysplasia

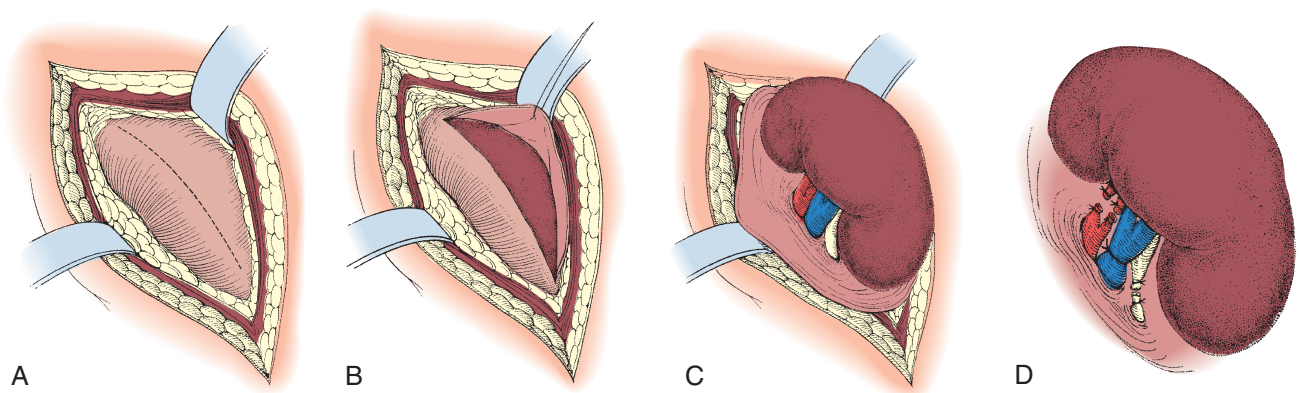

Figure 54–40. **A** to **D,** Technique of subcapsular nephrectomy.

(25%). Patients can present with hypertension and renal insufficiency when the lesion is chronic. Less than 3% of the hypertensive population has a renovascular etiology versus an estimated 18% to 20% in patients undergoing cardiac angiography and 35% to 50% of patients with aortic occlusive disease (Olin et al, 1990; Anderson et al, 1994; Rihal et al, 2002). Hypertension is a direct result of activation of the renin-angiotensin-aldosterone system, whereas renal impairment (ischemic nephropathy) is secondary to reduced perfusion pressure and loss of glomerular filtration capacity.

Atherosclerosis. In general, atherosclerosis affects patients in the sixth to seventh decades of life. The diagnosis of renovascular hypertension caused by atherosclerosis is being discovered in younger patients, which may be attributable to increased imaging studies. Atherosclerosis may be limited to the renal artery in 15% to 25% of patients but tends to be part of a generalized process affecting the major arterial branches of the aorta. Bilateral disease is present in up to 40% of patients (Fig. 54–41). Unilateral disease is more common in the left renal artery with contralateral disease present in 40% at the 4-year mark (Libertino et al, 1988). Although renal arteries are end arteries by anatomic definition, the slow onset of atherosclerosis permits development of collateral vessels, resulting in minimal clinical symptoms.

Mural Dysplasia. Fibrous dysplasia is progressive and more common in children and young adults. Segmental stenotic sections develop secondary to hyperplasia of smooth muscle and the associated layers of the arterial wall. Various categories exist under the broad definition of fibrous dysplasia.

Primary intimal fibroplasia accounts for 10% of lesions and occurs in children and young adults. The process can develop in contralateral kidneys or other vessels in a progressive nature. Angiographically the disease has smooth, focal stenosis involving the proximal or middle portion of renal vessels or branches (Fig. 54–42).

Medial fibroplasia accounts for 75% to 80% of fibrous lesions primarily in women between 25 and 50 years of age. With angiography, arteries demonstrate a "string of beads" in the distal two thirds of the main renal artery and its branches (Fig. 54–43). Multiple microaneurysms can also be appreciated. An estimated 33% demonstrate progression, whereas complete occlusion is rare.

Perimedial (subadventitial) fibroplasia accounts for 10% to 15% of fibrous lesions and is limited to the renal arteries. Angiographically the appearance is similar to that of medial fibroplasia but there are no microaneurysms and extensive collateral circulation is present (Fig. 54–44). Without intervention this entity leads to severe stenosis and progressive obstruction with ischemic nephropathy. The disease often afflicts young females.

Fibromuscular hyperplasia is an extremely rare lesion, accounting for less than 5% of mural dysplasia in children and young adults. These lesions progress over time. Although most of these

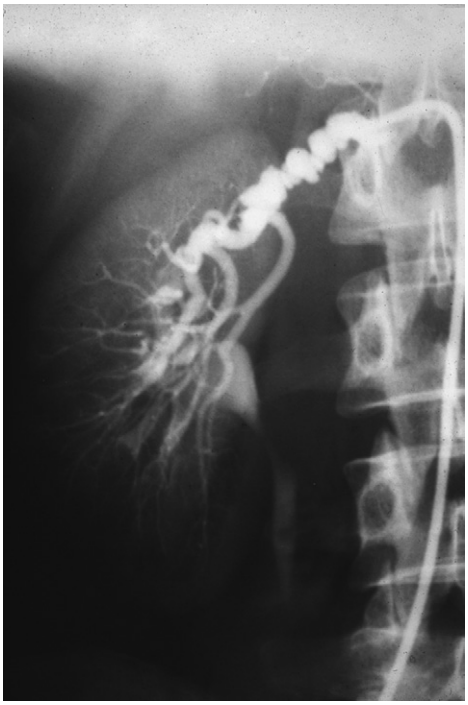

Figure 54–43. Selective right renal angiogram demonstrating medial fibroplasia "beads on a string" in a solitary right kidney.

lesions can mimic one another the final diagnosis should be made after histologic examination when possible.

Renal Aneurysms. Aneurysmal disease can lead to progressive renal damage and hypertension. By definition these lesions may be true (congenital or acquired) or false from trauma. Angiographically they can be divided into saccular, dissecting, fusiform, and intrarenal. Saccular forms occur in the main renal artery or at the anterior-posterior branch point and are the most common (Fig. 54–45). Dissecting aneurysms result from a disruption of the internal elastic membrane in certain populations (e.g., atherosclerosis, intimal fibrodysplasia, and perimedial fibrodysplasia). Fusiform aneurysms are noncalcified and common in younger hypertensive patients with fibromuscular dysplasia (Fig. 54–46).

Intrarenal aneurysms are considered congenital and account for one fifth of aneurysmal disease affecting the kidney (Fig. 54–47). In some instances they may develop secondary to atherosclerosis, mural dysplasia, trauma, inflammation (arteritis), or needle biopsy. Intervention is warranted for lesions larger than 2 cm or those associated with hypertension. Lesions can rupture and dissect leading to ischemia or may contribute to thrombus formation and warrant intervention (revascularization or coil placement). Women in childbearing age with evidence of aneurysms are urged to undergo repair secondary to risk of rupture and associated high rates of maternal and fetal mortality (Figs. 54–48 and 54–49) (Yang and Hye, 1996; Centenera et al, 1998).

Embolic Disease. Embolic disease affecting the arterial tree is often secondary to migration of cardiac thrombus from underlying atrial fibrillation, acute myocardial infarction, ventricular aneurysms, subacute bacterial endocarditis, mitral valve disease, prosthetic valves, and cardiac tumors (myxomas). Paradoxical emboli can arise from VTE via patent foramen ovale. Iatrogenic emboli can arise during manipulation of atherosclerotic vessels during aortic surgery or angiographic procedures. Emboli commonly migrate to the left renal artery because of its acute angle from the aorta.

Management of emboli is often time dependent in terms of renal salvage, and patients are best treated with thrombolysis or percutaneous transcatheter embolectomy. Emboli affecting

solitary kidneys or both kidneys need to be treated by thrombolysis (e.g., streptokinase) and catheter embolectomy. Surgical intervention is based on clinical response to conservative measures and the complexity of the case.

Trauma. Blunt or penetrating renal trauma, iatrogenic in some cases, can rarely cause acute renal artery thrombosis. Blunt trauma more frequently involves the left renal artery. Isolated injury is infrequent, and most of these patients have other associated injuries (extremity or rib fractures with pneumothorax or hemothorax or hepatic and splenic lacerations or contusions). Because of its rigidity the intima is torn, resulting in hemorrhage and propagation of thrombus. The adventitia and media, which are more elastic, will stretch. In general, patients with traumatic renal artery thrombosis only should undergo an attempt at surgical repair in the presence of a solitary kidney or bilateral occlusion. Unfortunately, therapy for traumatic renal artery thrombosis is often unsuccessful even when performed within a short time after the injury.

Arteriovenous Malformations. Arteriovenous malformations may be congenital or acquired with a wide range of symptoms. High-output cardiac failure from arteriovenous malformations in renal cell carcinomas have been described (Crawford et al, 1979). In cases of renal tumors, preoperative angioembolization may help restore cardiac integrity before nephrectomy (see Figs. 54–16 and 54–17). Iatrogenic causes include renal artery biopsy, partial nephrectomy, radiofrequency ablation, and cryotherapy. Percutaneous approaches are highly successful for treating these lesions. Open surgery is rarely required for these renovascular lesions and when indicated is often in the form of a nephrectomy.

Takayasu Disease. Takayasu inflammatory disease is characterized by localized periarteritis with mononuclear infiltration, multinucleated giant cells, and disruption of elastic arterial wall fibers. Although the disease has been primarily associated with patients of Asian descent, it is now known to coexist in the Western world. Takayasu arteritis typically affects young women (80% of affected patients are younger than 35 years old). Takayasu disease was initially described for its ocular findings. Clinicians later discovered that its arterial lesions were more widespread than initially thought. For diagnostic and surgical reasons it has been classified angiographically into four categories based on the location of the lesions: (1) aortic arch and its great vessels, (2) descending thoracic and upper abdominal aorta, (3) simultaneous involvement of categories 1 and 2 (65% of all cases), and (4) pulmonary artery with or without categories 1 through 3. Of the cases reported in the literature, 50% are associated with hypertension. Renal artery disease is most common, followed by proximal hypertension caused by coarctation of the aorta and loss of arterial elasticity (Fig. 54–50) (Ishikawa, 1978).

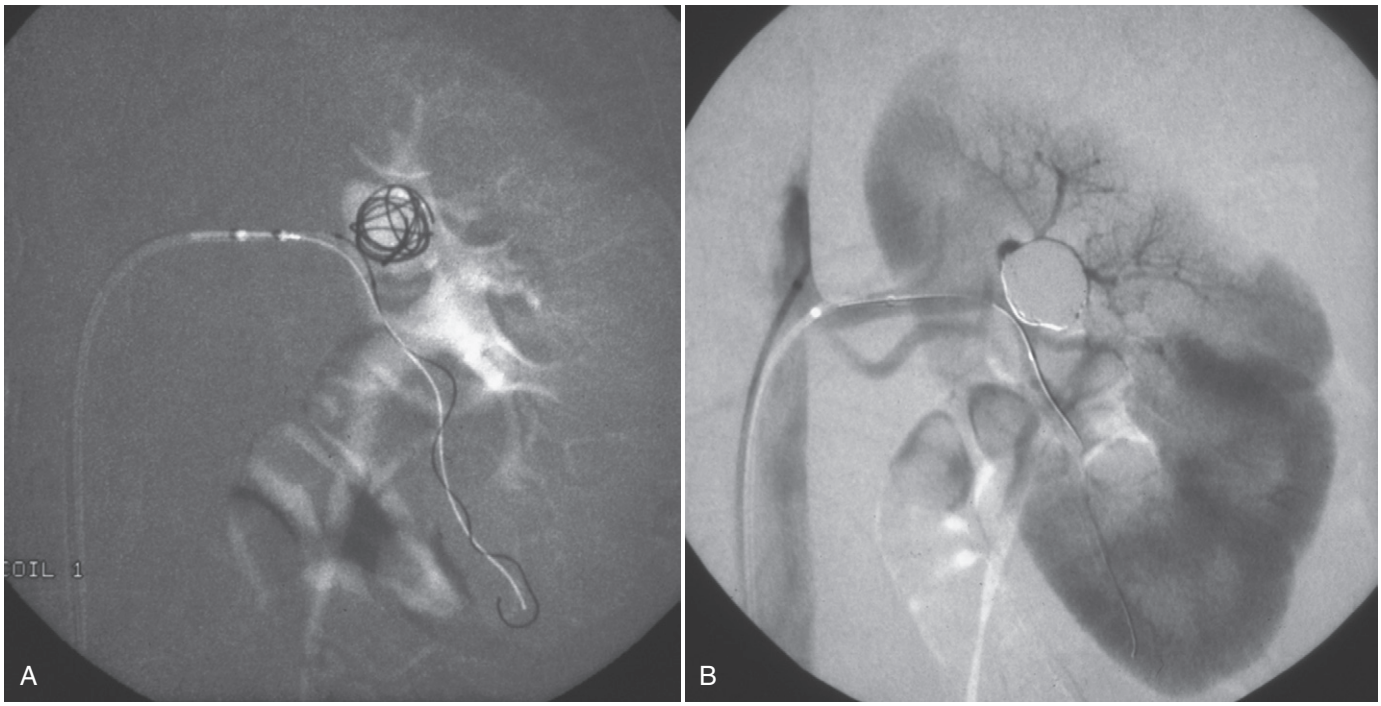

Figure 54–49. **A,** Selective angiography and coiling of aneurysm. **B,** Repeat angiogram demonstrating no flow to aneurysm.

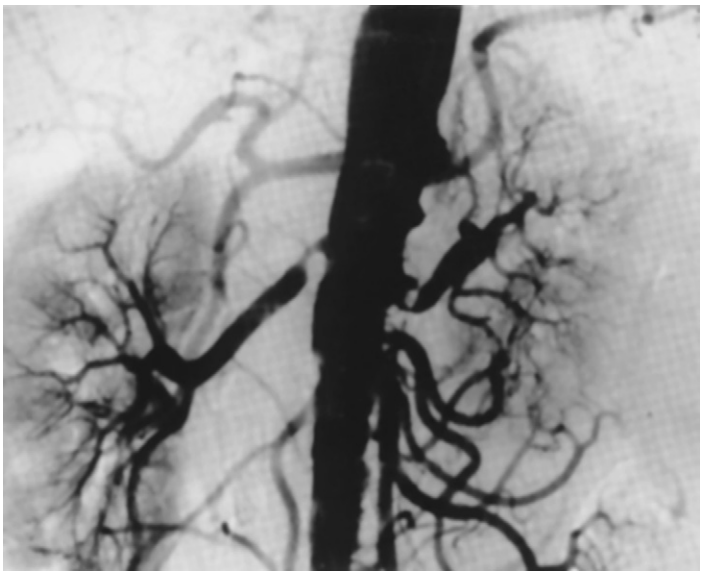

Figure 54–50. Bilateral renal artery stenosis caused by Takayasu disease. (From Libertino JA. Reconstructive urologic surgery. 3rd ed. Philadelphia: Mosby; 1997.)

Neurofibromatosis. Neurofibromatosis is a hereditary disease characterized by café-au-lait spots, cutaneous fibromas, and neurofibromas. Hypertension associated with neurofibromatosis is usually caused by pheochromocytoma or, more rarely, by coarctation of the aorta. Arterial lesions associated with neurofibromatosis have been reported occasionally since the first published report in 1905. Renovascular hypertension associated with neurofibromatosis has been described in 20 cases, 18 of which were in children. The vascular lesions are characterized by intimal endothelial nodules in the vessel wall. The aorta is frequently involved, and the renal arteries may demonstrate long areas of stenosis, which are probably best treated by revascularization procedures rather than by angioplasty.

Management Options

The gradual decline in renal revascularization procedures is a testament to improved medical management and appropriate population based on imaging screening protocols. Advances in percutaneous transluminal angioplasty and renal artery stent development have lessened the need for open renal bypass surgery, respectively.

Medical Therapy. By the time of referral most patients have been on multiple drug therapy (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers and β-adrenergic blockers) targeted at the renin-angiotensin and aldosterone cascades. ACE inhibitors manage hypertension and provide a means to predict who will benefit from surgery (e.g., ACE inhibitor test, captopril-furosemide renogram). Medical management is best targeted at lesions least likely to progress to complete occlusion and ischemic nephropathy, such as medial fibroplasia.

It is important to reiterate that although ACE inhibitors can improve hypertension there is little evidence to support their role in delaying progression of occlusive disease process. An inadvertent consequence of ACE inhibitors is a reduction in GFR by eliminating angiotensin II–induced efferent arteriolar constriction. In patients with bilateral disease or solitary kidneys there will be a paradoxical increase in blood pressure secondary to increased renin secretion and azotemia.

Interventions. Indications for surgical or percutaneous (angioplasty or stenting) intervention are listed in Table 54–9**. In general, patients who have elevated creatinine levels, poor functional studies, or unfavorable histology are unlikely to benefit from revascularization.**

Patients with high significant risk factors are better suited with endovascular repair. Percutaneous approaches (angioplasty and

Table 54–9.

Indications for Surgical or Percutaneous Intervention

Hypertension not responsive to multimodal medical therapy
ACE-I or ARB induced GFR reduction or elevation of creatinine concentration
Congestive heart failure (recurrent and difficult to manage)
Favorable renal biopsy (salvageable glomeruli)
Creatinine concentration less than 4.0 mg/dL
Evidence of collateral circulation and renal size >7 cm
Positive nuclear function study
Doppler resistive index <0.80
Lateralization of renin on renal vein sampling
Progressive occlusion

ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; GFR, glomerular filtration rate.

stenting) are ideal approaches for short, nonostial, nonoccluded lesions in the proximal or mid main renal artery often found in fibromuscular dysplasia. As a general rule, stents can be used for bilateral atherosclerotic disease or solitary kidneys in patients unable to tolerate open surgery. Open repair is indicated in failed endovascular repairs or when concomitant aortic repair is undertaken.

Preoperative Evaluation. In general, renovascular candidates can be divided into two groups: atherosclerosis and mural dysplasia. The former population is older with multiple comorbidities. The high incidence of concomitant carotid and coronary artery disease warrants evaluation with angiography or 3D CT angiograms. Preoperative revascularization via percutaneous stenting is preferable to limit morbidity associated with recovery. Simultaneous procedures are ill advised and performed under the rarest of circumstances. Percutaneous procedures have a 1% to 3% incidence of dissection requiring open repair, and the authors therefore recommend full workup in case conversion is necessary. Recommended noninvasive options for evaluation include duplex Doppler ultrasonography, captopril-enhanced renal scans, and magnetic resonance angiography. Although angiography remains the gold standard the nephrotoxic risk may be too high.

Endovascular Procedures. Percutaneous transluminal angioplasty was first performed in 1964 by Dotter and Judkins for peripheral vascular disease and expanded to the renal arterial system by Gruntzing and Hopff 10 years later (Dotter and Judkins, 1964; Gruntzig and Hopff, 1974). Technical advances and an aging population have resulted in aortic and renal open revascularization rates decreasing 73% from 1998 to 2001 while percutaneous procedures increased by 173% (Knipp et al, 2004).

Percutaneous transluminal angioplasty is now a widely used technique for treatment of patients with renal artery disease. Little controversy exists about its role in the treatment of patients with fibromuscular dysplasia. The results reported are excellent and are comparable to those obtained by surgical revascularization. In up to 30% of patients, mural dysplasia involves the arterial branch points, which increases the technical difficulties of balloon dilation and often renders it impossible to perform.

Several factors influence the success of transluminal angioplasty in patients with atherosclerotic renal artery stenosis. In this population, the success rate associated with nonostial lesions is 80% to 85%. For unilateral ostial lesions and lesions that originate within the aorta, patency rates average only 30% to 35%. Patients with total renal artery occlusion, bilateral involvement, and renal artery aneurysms are not considered candidates for percutaneous transluminal renal angioplasty (PTRA) because of historically poor response rates (Novick, 1994).

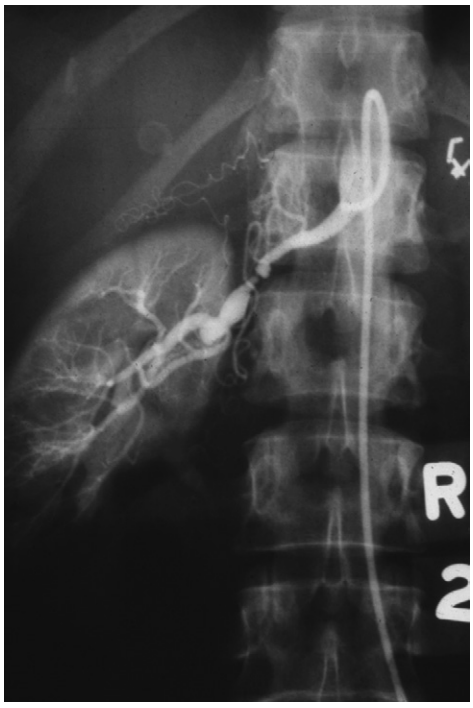

Figure 54–52. Right renal angiogram demonstrating significant mid renal artery stenosis from subadventitial disease. Note extensive adrenal collateral and distal reconstitution.

Complications associated with PTRA were reported in 10% of patients. The most frequently reported complications are main renal artery dissection, thrombosis and occlusion, segmental artery infarction, and hematoma (Eklof et al, 2009). Pseudoaneurysms are also a recognized risk. Thus, although the procedure is performed under local anesthesia, all patients must be considered as preoperative for open repair. With this in mind, patients require a comprehensive preoperative evaluation and postoperative observation. In addition, it is the authors' practice to have an operating room available and urology and anesthesiology teams aware of the procedure in the event open repair is required.

Open Surgical Repair.

AORTORENAL BYPASS. The widespread popularity of the aortorenal bypass graft for renal artery disease stems from its technical ease of insertion and favorable short-term and long-term patency rates (see Fig. 54–51 on the Expert Consult website). The procedure eliminates the hazardous dissection of the juxtarenal aorta required with endarterectomy, and overall patency rates range from 94% to 99% (Libertino et al, 1980). **Almost all disease processes affecting renal artery patency, particularly the fibrodysplasias, may be bypassed with an aortorenal graft** (Figs. 54–52 and 54–53). One notable exception is severe atherosclerotic disease that renders the aorta an unsafe vessel from which to obtain blood flow. In this instance, alternative bypass procedures are indicated (Libertino and Selman, 1982).

The autogenous saphenous vein has emerged as the preferred graft in adults and is the most common graft material used for restoration of renal blood flow at the Lahey Clinic. Saphenous vein is readily available and closely approximates the size of the renal artery. The intima is less thrombogenic than prosthetic material and accommodates the creation of a precisely contoured anastomosis with a delicate thin-walled

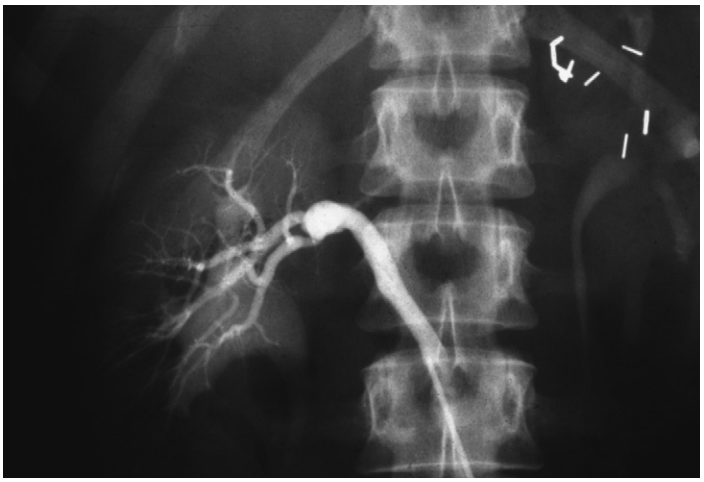

Figure 54–53. Postoperative angiogram demonstrating patent right renal artery after end-to-end saphenous vein aortorenal bypass.

distal renal artery. Patent anastomoses can be achieved with 2- to 3-mm lumen branches beyond the major bifurcation. When saphenous vein is not available, the authors' prefer to use cephalic vein or PTFE graft (Libertino and Zinman, 1980).

In children, autogenous hypogastric artery is the most favorable graft material with which to revascularize the renal artery. Its size approximates that of the renal artery, and its intima is free of fibromuscular disease. The saphenous vein should never be used in this population because it is too small and readily undergoes aneurysmal dilation. Conversely, the hypogastric artery in older adults is usually heavily involved with atheroma and thus is not a suitable graft material.

PROCUREMENT OF SAPHENOUS VEIN

The procurement of an adequate segment of the greater saphenous vein is critical to the success of the bypass procedure. Meticulous technique in exposure and excision of the vein is essential to prevent mural trauma and ischemia and associated stenosis and dilatation in the long term. The contralateral vein is harvested, allowing two surgical teams to work simultaneously. The vein is mobilized through a single long incision in the upper thigh beginning parallel and caudal to the groin crease (Fig. 54–54). When the femoral artery is palpable, the incision is made directly over the pulsation; otherwise, the incision is 2 to 3 cm lateral and caudal to the ipsilateral pubic tubercle. After the junction of the saphenous and femoral veins has been exposed the incision is extended toward the knee directly over the vein. Finger dissection between the vein and the overlying skin is helpful to ensure accurate placement of the incision, to prevent the development of potentially necrotizing skin flaps. The ideal graft is 20 cm long with an outside diameter of 4 to 6 mm. Excess vein should always be available for revision of any intraoperative technical problems that may occur during anastomosis. The areolar tissue is not dissected from the specimen, and the adventitia is left undisturbed. To decrease transmural ischemia the vein graft remains in situ until the renal vessels are mobilized and it is ready to be used. If the graft is removed prematurely, it is placed in cold lactated Ringer solution or autologous blood, even if only for a short time. The caudal end of the vein is cannulated with a Marks needle secured with a fine silk. The vein is flushed with dilute heparinized saline solution, and the cephalic end is secured with a microvascular Schwartz clamp (Fig. 54–55). The vein is distended to a

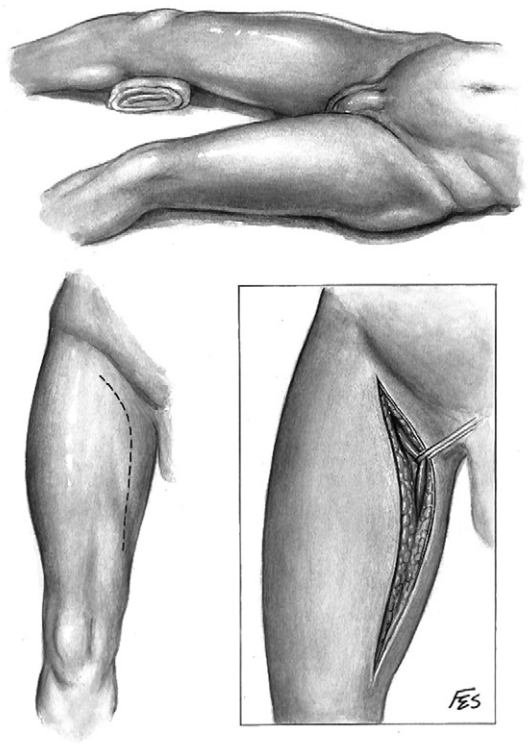

Figure 54–54. Procurement of saphenous vein. (© The Lahey Clinic.)

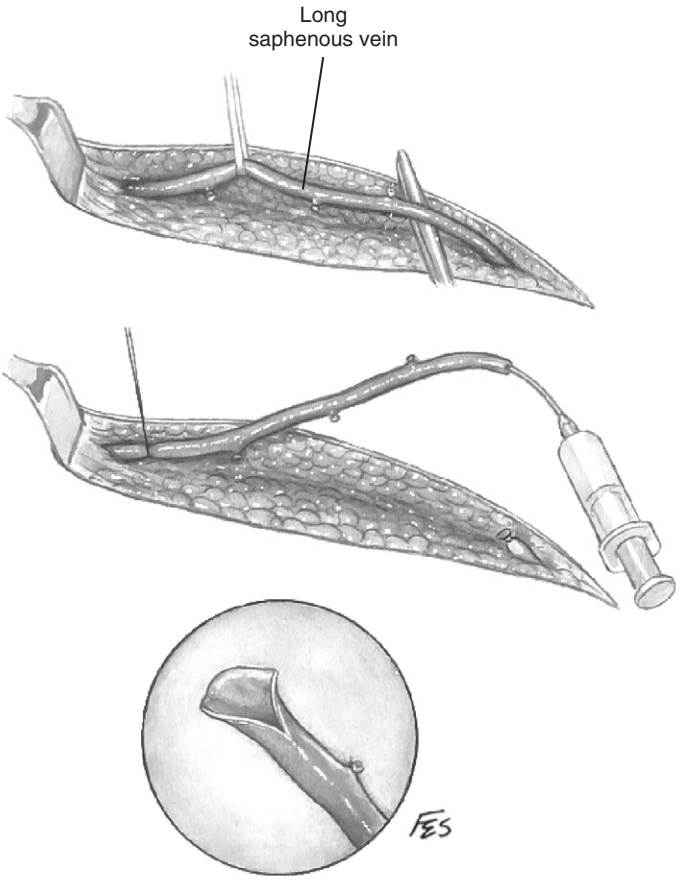

Figure 54–55. Harvesting of saphenous vein. (© The Lahey Clinic.)

minimal diameter of 5 to 6 mm and transected with Potts scissors. The in-situ vein remnant is secured with a silk suture ligature. The thigh incision is not closed until the bypass procedure is completed to ensure that any delayed bleeding resulting from heparinization is identified and controlled.

TECHNIQUE FOR INSERTION OF SAPHENOUS VEIN GRAFT

Systemic heparin is administered about 30 minutes before clamping the arteries. The saphenous vein graft should be oriented properly to avoid misalignment during implantation. The proximal end with Marks needle is transected with Potts scissors. Either an end-to-end or end-to side anastomosis may be performed distally, depending on the anatomy encountered. For aortorenal bypass the proximal anastomosis is obviously always end to side. A distal end-to-end anastomosis is preferred because it permits the best laminar flow.

The aorta, having been exposed widely from the level of the renal arteries to the inferior mesenteric artery, is gently palpated to locate a suitable soft location for the anastomosis. A medium-sized side-biting vascular clamp is placed on the anterolateral portion of the infrarenal aorta in a tangential manner. A vertical 13- to 16-mm aortotomy is made without excising the aortic wall or attempting to perform localized endarterectomy. The former is unnecessary because intraluminal aortic pressure will spread the edges of the linear aortotomy to the appropriate dimensions when the clamp is released. The vein graft is anastomosed to the aorta with two continuous sutures of 5-0 polypropylene after it has been spatulated (Fig. 54–56). A microvascular clamp is placed on the end of the saphenous vein graft, and the aortic clamp is released. The graft is permitted to lie anterior to the vena cava on the right side or anterior to the renal vein on the left side. Although it is preferable to leave the vein too long rather than too short, it should not be so long as to bend into an acute angle at any point. The renal artery is secured distally with a smooth-jawed microvascular clamp(s) placed on either the main artery or a segmental branch. The proper site for the arterial anastomosis is selected. An end-to-end anastomosis is performed using continuous or interrupted sutures of 6-0 polypropylene (see Fig. 54–51 on the Expert Consult website). When the recipient vessel is 3 mm or less in diameter, interrupted sutures are used exclusively. Likewise, an interrupted suture line is used in children to prevent "purse-string stenosis" as their vessels grow. Although the authors usually perform an interrupted anastomosis even in adults, continuous suture lines may be run between interrupted sutures at four quadrants without the danger of "purse-string stenosis." Bleeding from needle holes at the anastomosis can usually be controlled with thrombogenic mesh such as Surgicel (Ethicon, Somerville, NJ). Multiple grafts can be employed when disease affects kidneys with more than one renal artery (Fig. 54–57; see Figs. 54–51 and 54–58 on the Expert Consult website).

Native saphenous vein and arterial autografts have been shown in many clinical studies to preserve glomerular function, and patency has been confirmed with postoperative angiography. PTFE grafts have been shown to be a feasible option in renal revascularization with concomitant aortic replacement. Customized grafts can compensate for discrepancies in anastomotic sizes. Seven-year patency rates of over 95% have been reported by Paty and associates (2001) in more than 400 revascularization procedures.

ALTERNATIVES TO AORTORENAL BYPASS

HYPOGASTRIC AUTOGRAFTS

The authors often make use of the internal iliac artery to repair lesions of the segmental renal arteries. Extensive collateral flow to the pelvis enables one to use this arterial conduit. An anterior subcostal with modified Gibson incision is the senior author's preferred approach. Alternatively, an anterior midline incision may by used for both renal artery mobilization and harvesting of the internal iliac artery. Evidence of atherosclerosis in the graft is a contraindication. Vessel loops are placed at proximal and distal branch point locations (Fig. 54–59). The artery is harvested by a second team as the primary team is nearing completion of their bench component. The hypogastric artery and branches are tailored to accommodate the branch points of the disease segments, and end-to end anastomoses are performed using 6-0 and 7-0 polypropylene suture (Fig. 54–60). The kidney is then autotransplanted into the groin as described in later sections.

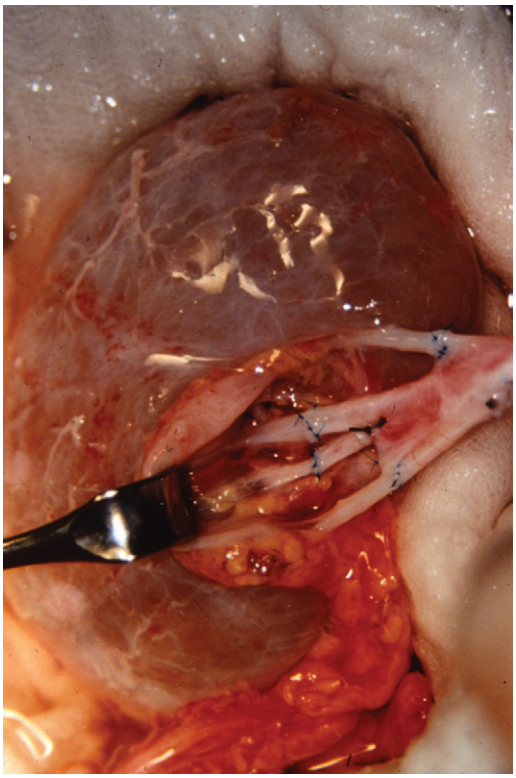

Figure 54–60. Distal anastomoses using 6-0 and 7-0 polypropylene suture followed by renal autotransplantation.

SPLENORENAL ARTERIAL BYPASS

Patients with diffuse atherosclerosis, significant aortic disease or prior aortic surgery, and left renal arterial disease are candidates for a splenorenal artery bypass. Preoperative lateral and oblique angiography should confirm the absence of disease of the celiac axis. CT reconstructions in combination with MRI have replaced angiography in some cases. Calcification of the distal splenic artery is a rare finding that would obviously preclude its use for repairs. The native state of the splenic artery provides an ideal location for bypass requiring only one anastomosis. Intraoperative use of ultrasound is suggested to establish blood flow rates, and at least 125 mL per minute is recommended.

The initial exposure is through a supracostal 11th incision. This incision permits a retroperitoneal approach without entry into the pleural cavity. The planes between the adrenal and kidney (within Gerota fascia) posterosuperiorly and between the kidney and pancreas anteromedially are entered with sharp dissection using tenotomy scissors. Manipulation of the pancreas should be avoided when identifying the splenic artery at its superior border. The artery is next mobilized from the splenic hilum to the celiac plexus without violating the peritoneal space (Fig. 54–61). Branches to the pancreas are ligated using 4-0 silk suture, and a Schwartz clamp is placed at the origin of the splenic artery. One may increase the caliber of the lumen using a Fogarty balloon, Gruntzig balloon catheter, or coronary artery dilators. The artery is next divided in close proximity to the hilar bifurcation point. Collateral blood flow from the short gastric eliminates the need for a splenectomy.

The left kidney is mobilized within the retroperitoneum. The authors recommend isolating the arterial supply via the posterior approach to avoid the superior mesenteric artery. Once adequate length is obtained the vessels are anastomosed in an end-to-end

fashion with interrupted or continuous 6-0 polypropylene sutures (Fig. 54–62). After completion of the anastomoses, Surgicel may be placed to promote hemostasis around needle entry points. Saphenous vein interposition grafts can be employed to eliminate tension between the splenic and left renal artery if necessary (Fig. 54–63).

Postoperatively, patients are maintained on heparin. Postoperative Doppler studies or a ^{99m}Tc-mercaptoacetyltriglycine (MAG3) renogram may be used to evaluate renal perfusion. Complications include thrombosis and graft failure. Pancreatitis and associated pancreatic pseudocysts have occurred in a small subset of over 175 splenorenal bypass patients treated at the Lahey Clinic.

HEPATORENAL AND GASTRODUODENAL ARTERY BYPASS

The indications for alternatives to aortorenal bypass for right-sided lesions are similar to those for the contralateral side and can be managed with hepatorenal or gastroduodenal saphenous bypass grafts as have been described by the authors' group (Libertino and Lagneau, 1983, Libertino et al, 1976). The common hepatic artery arises from the celiac plexus coursing laterally above the head of the pancreas until the confluence of the portal vein complex before branching into ascending and descending limbs. The ascending portion lies medial to the biliary tree and in front of the portal vein before branching into the right and left proper hepatic arteries. The descending limb becomes the gastroduodenal artery and can also be used in certain situations.

Variation within the hepatic arterial tree is almost twice that in the renal system, with an estimated 48% of living liver donors having aberrant vasculature (Hiatt et al, 1994). In addition to a sound understanding of the anatomy the surgeon must be patient during dissection of the porta hepatis, making every effort to spare all arterial components. Accessory arteries will hypertrophy in response to the loss of the common hepatic artery.

Unlike on the left side, the transabdominal approach is necessary for right-sided repairs. The right renal artery is identified and dissected under the IVC as close to the aorta as possible. The common and proper hepatic arteries are isolated and clamps placed before dividing the gastroduodenal artery. A 10- to 12-mm arteriotomy is made in the inferior wall of the hepatic artery at the ostium of the gastroduodenal artery. A reversed autogenous saphenous vein graft is sewn between this and the renal artery using interrupted or continuous 6-0 polypropylene (Fig. 54–64; see Fig. 54–65 on the Expert Consult website).

ILEORENAL BYPASS

In rare instances a patient requiring open surgical revascularization may not be able to undergo aortorenal, splenorenal, or hepatorenal bypass surgery and an alternative such as the ileorenal bypass may be needed (Fig. 54–66). Unfortunately most patients with significant atherosclerosis of the renal aorta have equivalent disease at the level of the common iliac arteries. Progression of iliac atherosclerosis may lead to chronic ischemia of kidneys undergoing this form of revascularization. A midline incision is made, and a saphenous vein graft harvest performed. The

corresponding colon is mobilized along the line of Toldt from the splenic or hepatic flexure to the iliac vessels. Utilization of the contralateral iliac artery is an option if significant ipsilateral disease is present. Vessel loops and vascular clamps are used in standard fashion to perform an end-to-side anastomosis at the iliac vessel and end-to-end technique at the renal artery using 6-0 polypropylene suture (Figs. 54–67 and 54–68; see Fig. 54–69 on the Expert Consult website).

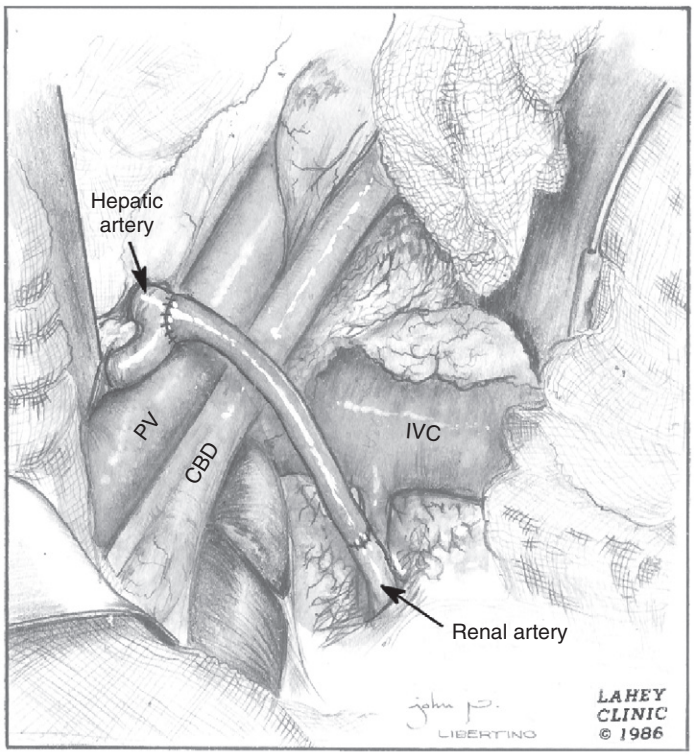

Figure 54–64. Diagram of hepatic artery to right renal artery end-to-end anastomosis using a saphenous vein graft that overlies the porta hepatis. CBD, common bile duct; IVC, inferior vena cava; PV, portal vein. (© The Lahey Clinic.)

THORACIC AORTORENAL BYPASS

If the splenic artery is heavily atherosclerotic, a thoracic aortorenal bypass is an option. The subdiaphragmatic supraceliac and descending thoracic aorta is often free of atherosclerosis and can serve as an alternative for renal vascular reconstruction using a saphenous vein graft. Preoperative angiography to rule out disease at this level is essential. Novick (2007) describes using a supra–9th rib incision extending across the midline for left-sided lesions. The cephalad extent of the incision provides great exposure of the thoracic aorta and left renal artery. The left colon is reflected

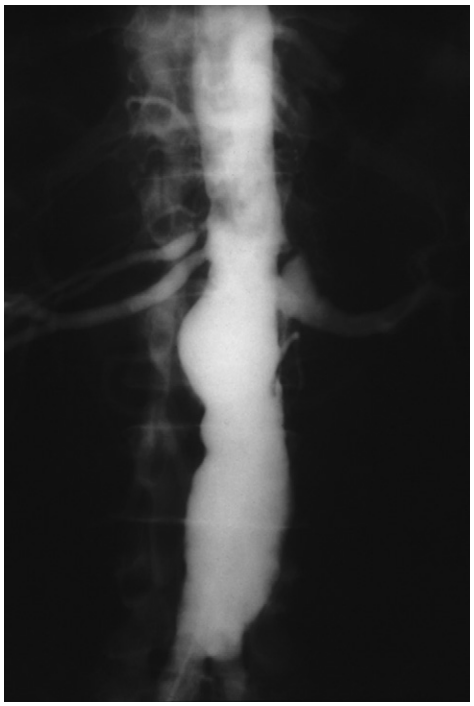

Figure 54–68. Preoperative aortogram demonstrating multiple right renal arteries with stenosis at the aortorenal junction.

medially in standard fashion to expose the renal artery in the retroperitoneum. After exposure of the thoracic aorta a DeBakey clamp is used to partially occlude a lateral segment before making a small aortotomy. A reversed autogenous saphenous vein graft is then sewn in an end-to-side fashion. Systemic heparinization is not employed because the aortic flow is preserved (Fig. 54–70). The hiatus in the diaphragm is extended by 2 cm laterally, permitting passage of the saphenous vein behind the pancreas into the retroperitoneal space. An end-to-end anastomosis is performed to the left renal artery. For right-sided lesions the subdiaphragmatic supraceliac and lower thoracic aorta can be accessed via an anterior bilateral incision. The steps are repeated in a similar fashion to the left-sided approaches.

Thoracic inlet revascularization of the renal system has several advantages. The high flow thoracic aorta in conjunction with the relatively acute angle of the proximal graft is hemodynamically advantageous and decreases the thrombogenicity that would be associated with sluggish arterial flow. The ability to perform the anastomosis without complete aortic cross clamping avoids systemic heparinization and spinal cord ischemia. Renal ischemia is limited to the time necessary to perform the distal vein-to-renal artery anastomosis, which rarely exceeds 25 minutes. Autogenous graft material limits the immune response associated with synthetic material.

Novick (2007) reports resolution or improvement of hypertension in 86% of his surgical population with preservation or enhanced renal function in 95% within the same group of 23 patients. All patients demonstrated extensive atherosclerosis of the abdominal aorta and celiac artery stenosis precluding hepatic and splenic bypass.

MESENTERORENAL BYPASS

The superior mesenteric artery has been utilized in conjunction with a saphenous vein interposition graft leaving the marginal artery of Drummond responsible for collateral circulation between

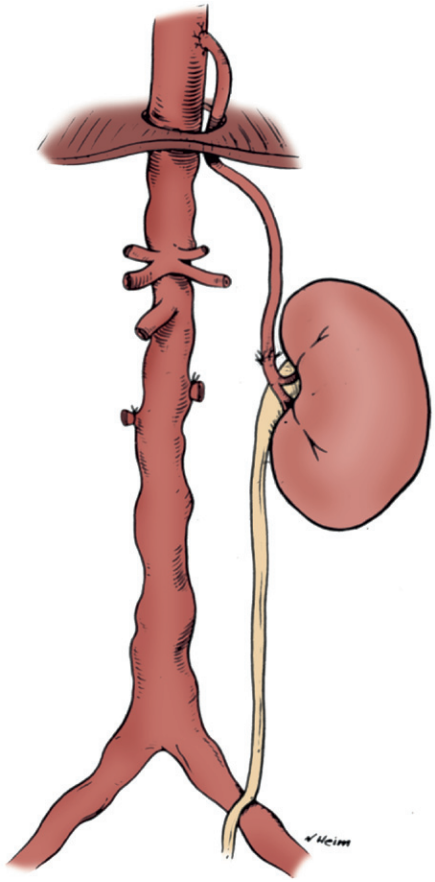

Figure 54–70. Technique of left thoracic aortorenal revascularization.

the celiac and inferior mesenteric artery. Novick (2007) describes significantly enlarged superior mesenteric arteries associated with complete infrarenal aortic occlusion in which extensive collateral circulation provided insurance against bowel ischemia. Midline incisions provide excellent exposure for both right and left renal arteries. Exposure of the suprarenal aorta is obtained by cephalad retraction of the pancreas and first portion of the jejunum and medial refection of the mesocolon. The superior mesenteric artery can be palpated 2 to 3 cm above the renal arteries. This artery is mobilized 2 to 3 cm beyond the takeoff of the aorta. A reversed saphenous vein interposition graft is anastomosed end to side along the lateral aspect of the superior mesenteric artery. An end-to-end anastomoses is performed from the graft to the right or left renal artery (Fig. 54–71).

RENOVASCULAR SALVAGE SURGERY. Despite the successful patency rates that have been achieved with endovascular approaches, occasional patients remain who will need an open salvage procedure in the setting of postoperative complications or recurrent disease (Lacombe and Ricco, 2006). Surgical dissection is complicated by inflammatory changes. Renal artery stents preclude thromboembolectomy. Wide resection with interposition vein patch angioplasty is the primary choice with alternate bypass as a reserve option. Fibromuscular revisions fare better than atherosclerotic ones owing to less inflammatory reaction and a generally healthier population.

REVASCULARIZATION OF AN OCCLUDED RENAL ARTERY

Predictors of functional return after revascularization of an ischemic renal unit have been elucidated. **The kidney with a**

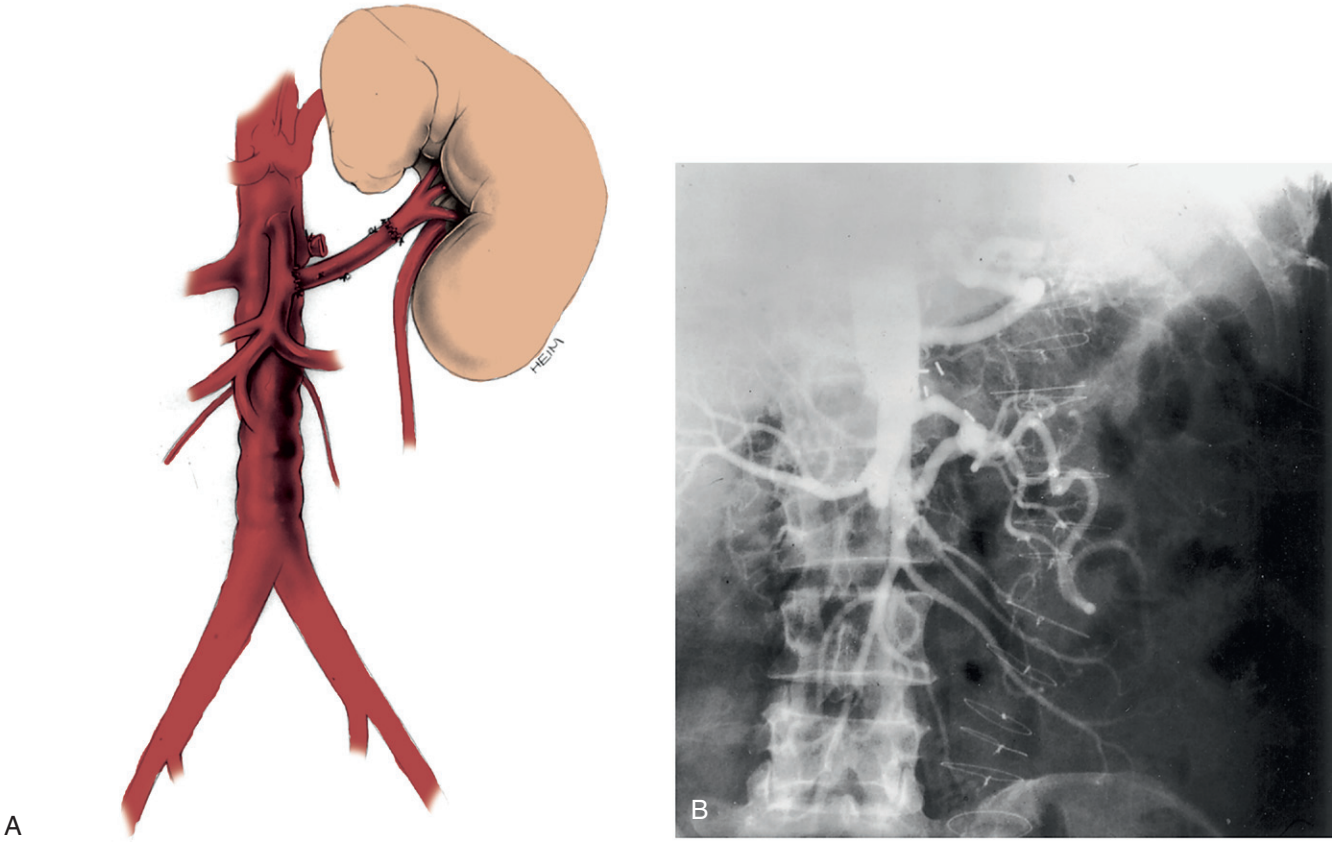

Figure 54–71. **A,** Technique of superior mesenterorenal bypass to the left kidney with a saphenous vein graft. **B,** Aortogram in a patient who underwent left mesenterorenal saphenous vein bypass shows excellent flow to the left kidney.

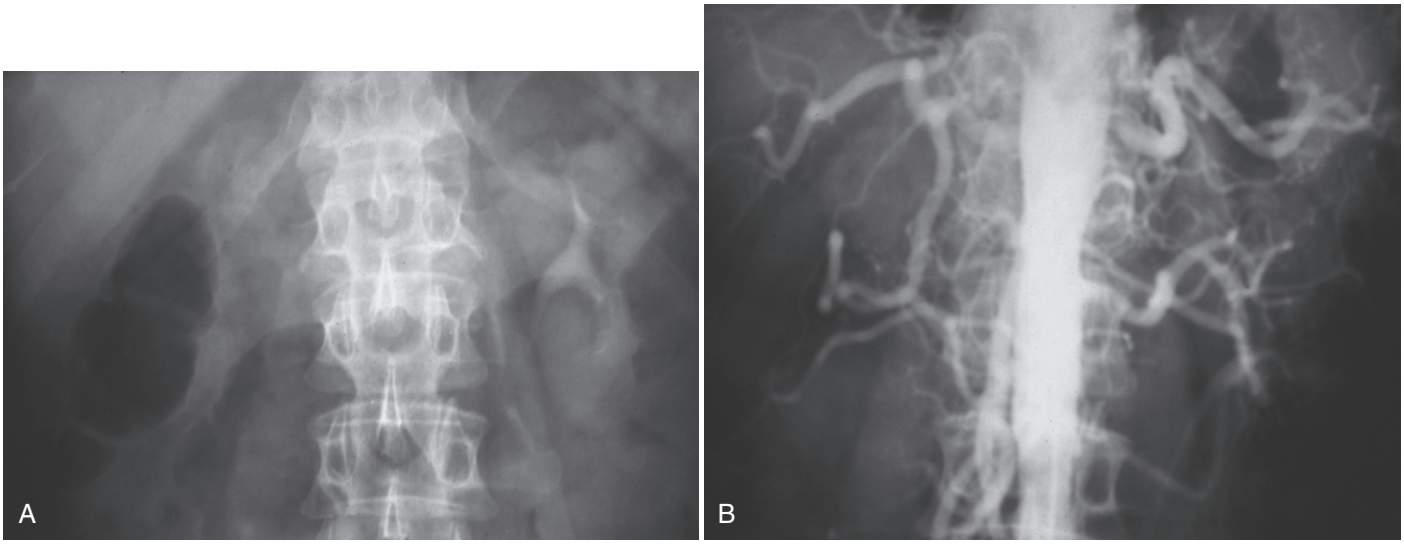

Figure 54–72. **A,** Preoperative intravenous pyelogram demonstrating functional left system with no contrast medium in the right system. **B,** Preoperative angiogram demonstrating complete occlusion of the right renal artery with extensive collateral vessels.

totally occluded renal artery may be revascularized when the following criteria are fulfilled: angiographic demonstration of a nephrogram, proximal occlusion with retrograde filling of distal circulation by perihilar collateral vessels, intraoperative back-bleeding from a renal arteriotomy distal to the occlusion, and demonstration on intraoperative frozen section or preoperative biopsy of an intact glomerular architecture (Zinman and Libertino, 1973, 1977; Libertino et al, 1980) (Figs. 54–72 and 54–73).

OUTCOMES AND COMPLICATIONS. Although open renovascular surgery has seen a significant decline in numbers, the success rates justify the role it continues to play in the treatment of renovascular hypertension. In more than 300 procedures performed at the

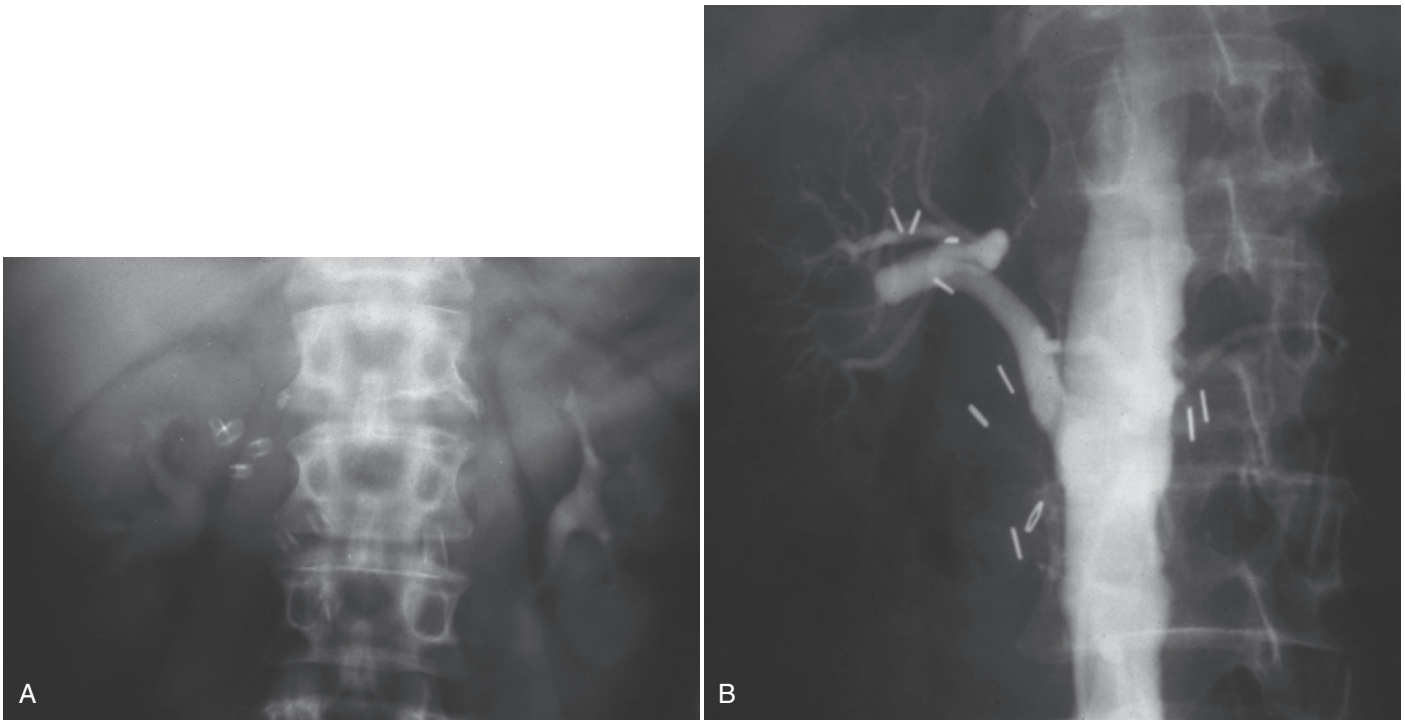

Figure 54–73. **A,** Postoperative intravenous pyelogram with contrast enhancement in the right collecting system. **B,** Postoperative angiogram with restoration of flow to the right kidney.

Lahey Clinic the overall success rate is 85%, and other contemporary series produce similar results (Lawrie et al, 1989; Libertino et al, 1992). The surgeon who performs open renovascular surgery is now confronted with a greater number of failed percutaneous approaches, which tend to have lower revascularization success rates. These procedures can be technically demanding and should be performed by persons with a strong background in vascular surgery.

Early complications include hemorrhage, thrombosis, subintimal dissection, false aneurysm, and distal branch vessel embolization. Postoperative bleeding is often attributable to surgical technique or overzealous anticoagulation. Covering the anastomoses with thrombogenic material such as Surgicel can limit bleeding. Perihilar vasculature is often collateralized and deserves attention during mobilization. False aneurysm formation can lead to delayed bleeding, as can infected suture lines. Postoperative thrombosis if recognized early enough is best treated with anastomotic revision.

Intimal dissection can occur in significantly atherosclerotic vessels during suture placement. Sutures that pass from intima to adventitia in theory have a lower chance of disrupting plaque. Atheroemboli can travel after clamping or unclamping a diseased aorta, resulting in a pulseless extremity requiring thromboembolectomy.

Extirpative Surgery. Reconstructive surgery is preferable to nephrectomy, considering that the kidney is fundamentally healthy and both atheromatous and mural diseases are potentially bilateral entities. The major determinant in favor of nephrectomy is poor viability or nonviability of the affected renal unit. In the presence of failed medical therapy and significant medical comorbidity a nephrectomy should be the primary therapy. Patients with complete occlusion of previous placed grafts may undergo a trial of streptokinase or tissue plasminogen activator if the occlusion is discovered early enough (<6 hours). Nephrectomy may be the treatment of choice for restenosis after reconstruction when the occlusion is unresponsive to tissue plasminogen activator and there is marginal function. Nephrectomy is also a suitable option for those with extensive unilateral arterial disease at the segmental level (multiple branch-point lesions) in the setting of normal contralateral renal function.

Partial nephrectomy in this situation is based on the premise that the disease process is localized and that preservation of normal remaining nephrons is worth the increased operative time and surgical risk. Patients with branch lesions that produce segmental ischemia and localized overproduction of renin may be treated by arterial bypass when the segmental branch is large enough; by arteriotomy and dilation, especially in pediatric patients; or by partial nephrectomy with an upper, lower, or midsegmental renal resection. Knowledge of the segmental blood supply to the kidney is essential for proper performance of partial nephrectomy.

Midpolar partial nephrectomy may be useful in patients with segmental lesions that affect the superior or inferior branches of the anterior segmental renal artery (Fig. 54–74). Selective arteriography is essential to understand the arrangement and distribution of the anterior and posterior arterial branches. Venography and segmental venous renin assays are obtained from the venous branches draining the affected tissue. These tests are helpful when main renal vein renin levels do not lateralize.

Extracorporeal Renal Surgery and Autotransplantation

Background

The first successful renal autotransplant was recorded by J. D. Hardy in 1963 for ureteral disease. Since that time the indications for "renal bench" surgery have broadened and have resulted in

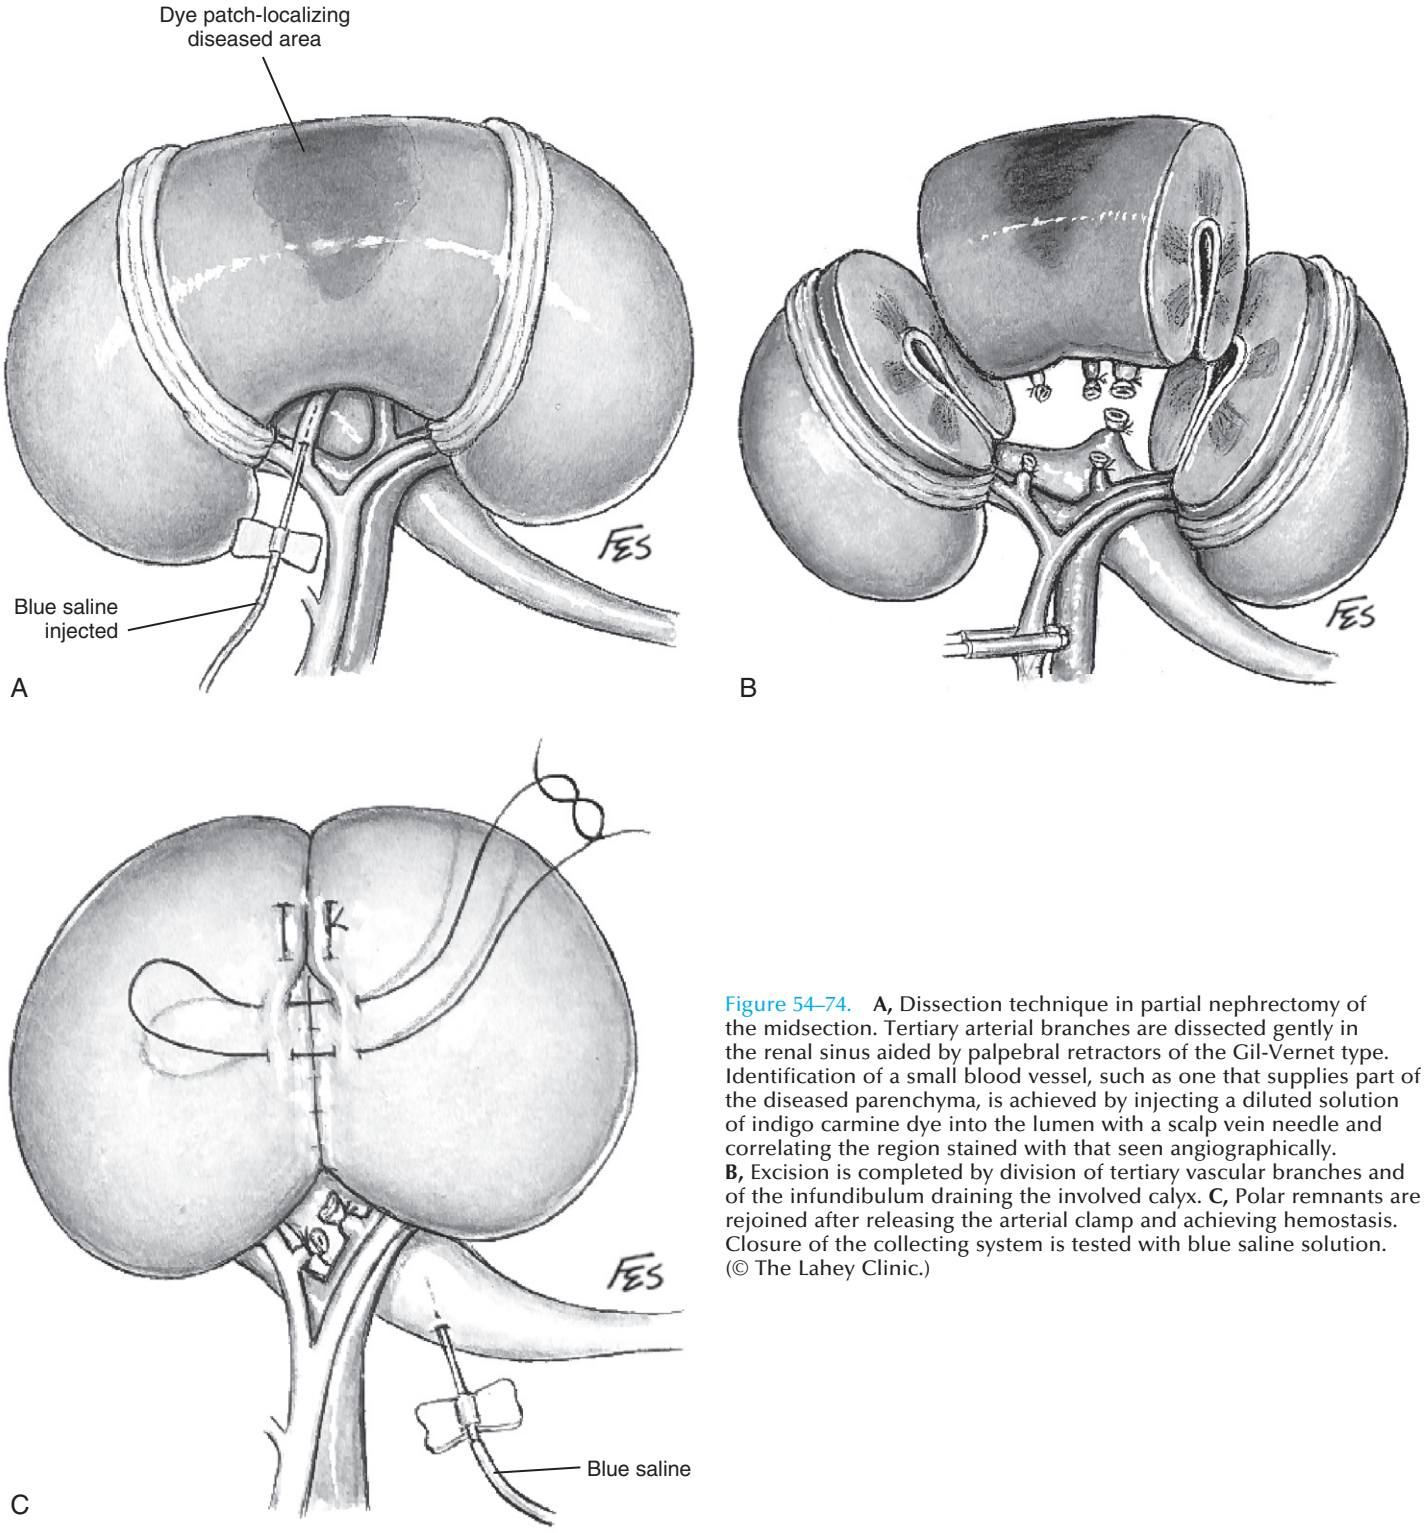

Figure 54–74. **A,** Dissection technique in partial nephrectomy of the midsection. Tertiary arterial branches are dissected gently in the renal sinus aided by palpebral retractors of the Gil-Vernet type. Identification of a small blood vessel, such as one that supplies part of the diseased parenchyma, is achieved by injecting a diluted solution of indigo carmine dye into the lumen with a scalp vein needle and correlating the region stained with that seen angiographically. **B,** Excision is completed by division of tertiary vascular branches and of the infundibulum draining the involved calyx. **C,** Polar remnants are rejoined after releasing the arterial clamp and achieving hemostasis. Closure of the collecting system is tested with blue saline solution. (© The Lahey Clinic.)

improved clinical outcomes (Ota et al, 1967; Husberg et al, 1975; Putnam et al, 1975; Wotkowicz and Libertino, 2004). Complex renovascular disease, renal tumors, and staghorn calculi have been the mainstay of the authors' experience. Extracorporeal partial nephrectomy was described more than 30 years ago for renal cell tumors and provides an alternative to dialysis in select patients. Laparoscopy has also been added to the field to help limit morbidity and speed recovery (Fabrizio et al, 2000; Meng et al, 2003).

Many of the initial feasibility studies were performed in canine models and gradually expanded to the human population (Belzer et al, 1970). Vascular repair of complex intrarenal disease is performed using native veins of saphenous, splenic, and iliac origin or hypogastric arterial grafts. The last is often best suited to pediatric or young adult populations with limited size discrepancy and a lack of atherosclerotic disease. Technical advances with respect to surgical magnification have expanded the indications. **Overall**

Key Points: Renovascular Surgery

- The primary disease entities necessitating revascularization include atherosclerosis (75%) and fibrous dysplasia (25%).
- Patients can present with hypertension and renal insufficiency when the lesion is chronic. Less than 3% of the hypertensive population has a renovascular etiology versus an estimated 18% to 20% of patients undergoing cardiac angiography and 35% to 50% of patients with aortic occlusive disease.
- Causes include atherosclerosis, mural dysplasia, renal aneurysms, embolic disease, trauma, arteriovenous malformations, Takayasu disease, and neurofibromatosis.
- Indications for surgical or percutaneous (angioplasty or stenting) intervention are listed in Table 54–9.
- In general, patients who have an elevated creatinine concentration, poor functional studies, or unfavorable histology are unlikely to benefit from revascularization.
- Almost all disease processes affecting renal artery patency, particularly the fibrodysplasias, may be bypassed with an aortorenal graft. Other options include hypogastric autografts, splenorenal arterial bypass, hepatorenal and gastroduodenal artery bypass, ileorenal bypass, thoracic aortorenal bypass, and mesenterorenal bypass.
- The autogenous saphenous vein has emerged as the preferred graft in adults.
- The kidney with a totally occluded renal artery may be revascularized when the following criteria are fulfilled: angiographic demonstration of a nephrogram, proximal occlusion with retrograde filling of distal circulation by perihilar collateral vessels, intraoperative back-bleeding from a renal arteriotomy distal to the occlusion, and demonstration on intraoperative frozen section or preoperative biopsy of an intact glomerular architecture.
- The major determinant in favor of nephrectomy is poor viability or nonviability of the affected renal unit.

renal insult associated with these complex procedures has been limited with advances in hypothermic perfusates commonly used in transplantation, which provide an isotonic external milieu (Belzer et al, 1992). **In limiting membrane transport the metabolic requirements decrease while maintaining cellular integrity. In addition the cold solution shrinks parenchyma, leading to better vascular and collecting system exposure** (Novick et al, 1979).

Indications

Most arterial disease requiring bench approaches have extension at and beyond the anterior and posterior division branch points (Fig. 54–75). Stenotic lesions and aneurysms may be resected and repaired with interposition saphenous vein grafts. Multiple branch lesions may be amenable to hypogastric artery interposition utilizing the branches of the internal iliac artery when atherosclerosis is absent. Renal tumors have also been removed utilizing an ex-vivo approach in select patient populations (solitary kidneys), with limited small volume series in the literature (Fig. 54–76) (van der Velden et al, 1992). The ureter can be affected by the numerous processes (trauma, iatrogenic, and inflammatory) that lead to urinary obstruction or extravasation. Left untreated, these patients develop chronic infections and eventual renal failure. Recurrent nephrolithiasis can lead to ureteral stenosis secondary to repeat trauma from ureteroscopy and scarring from percutaneous approaches. **Indications for autotransplantation include tumors in solitary kidneys, recurrent staghorn calculus and concomitant renovascular disease, sterile urine and recurrent nephrolithiasis causing damage to a ureter, calculi associated with congenital abnormalities, or extensive ureteral stricture. Transitional cell carcinoma of the renal pelvis or ureter in solitary kidneys can be managed with this approach.**

Although an ileal segment interposition graft can obviate the need for ureteroscopy, the long-term metabolic sequelae are not

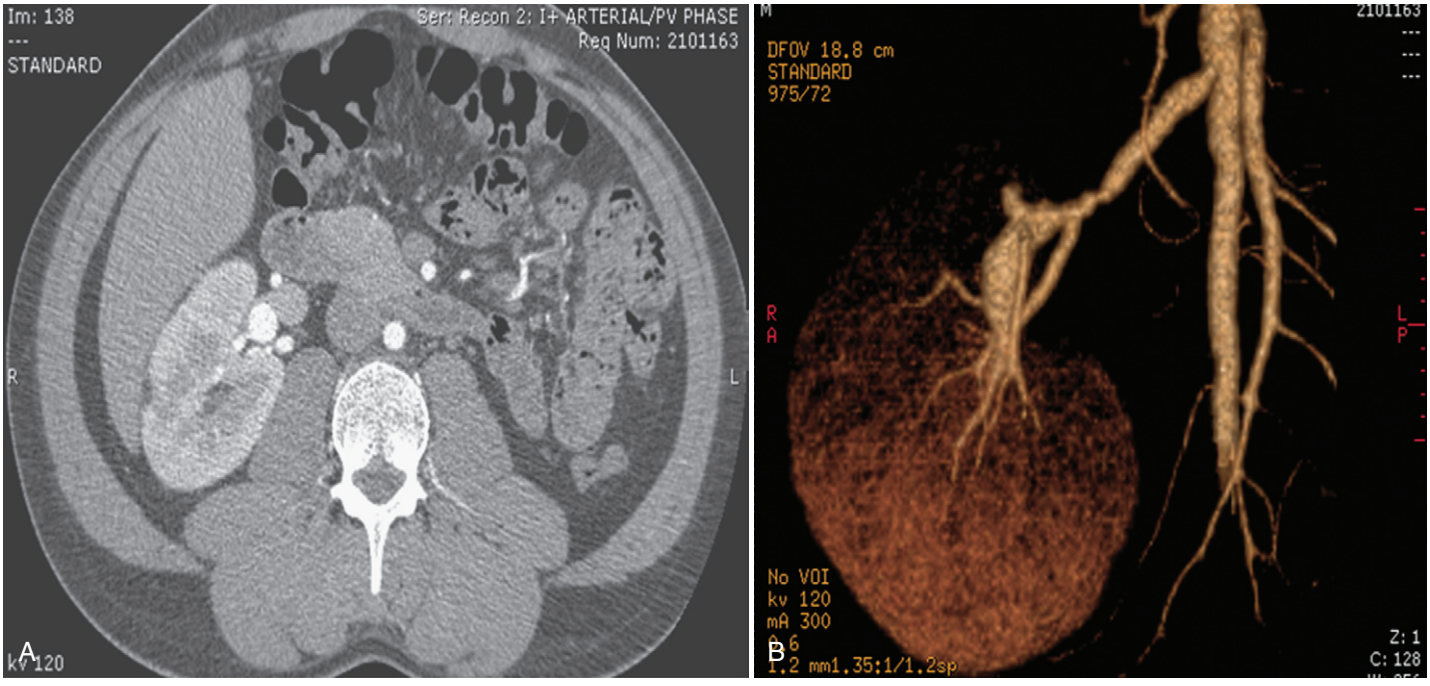

Figure 54–75. **A,** CT scan in a 33-year-old man with an atrophic left kidney and fibromuscular dysplasia and a 2.4-cm aneurysm in the right kidney and uncontrolled hypertension. **B,** Three-dimensional reconstruction demonstrates location of renal artery aneurysm.

insignificant (Chung et al, 2006). Autotransplantation, pyelovesicostomy, and a Boari flap can minimize reflux and allow passage of stones (Olsson and Idelson, 1980).

Autotransplantation is an acceptable option for complicated tumors in solitary kidneys and bilateral malignancies. A pyelovesicostomy is recommended to facilitate easy surveillance. Patients with traumatic arterial injuries can also be treated with autotransplantation.

Preoperative Evaluation and Preparation

In addition to preoperative screening, renal and pelvic anatomy are evaluated with dedicated 3D CT angiography, paying specific attention to the iliac vessels. The hypogastric artery and associated branches are ideal conduits for complex multiple-vessel repairs given their size, which is similar to the native renal artery branches. Renal functional scans (e.g., MAG3) should document at least 15% to 25% of the global renal function before surgery. Kidneys with extensive small vessel disease and compromised parenchyma are limited by poor flow dynamics and decreased filtration capabilities and are not candidates for renal autotransplantation. Patients with chronic renal insufficiency or solitary kidneys must consent for placement of vascular dialysis catheters before surgery, and the authors' nephrology colleagues are made aware of this procedure.

Surgical Procedure

The advantages of renal bench surgery include a bloodless field and optimal exposure of the vascular tree and collecting systems. The ideal length of cold ischemic time should be no greater than 5 to 6 hours. Ex-vivo repair also allows the integrity of the anastomosis to be tested before reimplantation. The technical aspects of bench surgery are demanding and should be performed in high-volume centers with surgeons experienced in vascular and transplantation surgery. The authors prefer a flank approach for an adrenal-sparing donor nephrectomy with preservation of the proximal one third of the ureter. The kidney is completely mobilized and vessel loops passed around the main renal artery and vein. Renal vessels and ureter are dissected to provide maximum length (Fig. 54–77). Mannitol may be given before ligation and division of the vasculature to promote diuresis. Hypothermic University of Wisconsin solution is the authors' choice for perfusate on removal and initiation of extracorporeal surgery (Belzer et al, 1992). Once the feasibility of the extracorporeal repair has been determined a second team can reposition the patient supine and expose the ipsilateral fossa for reimplantation via a Gibson incision. A single midline incision is another approach that allows access to both operative sites and keeps the ureter in continuity. After the vessels are taken the abdominal wall serves as a bench for microvascular repair or removal of tumor.

Once the renal vessels have been ligated the kidney is flushed with hypothermic solution and placed in an ice-slush solution to minimize ischemia. For vascular anastomosis 5-0 and 6-0 polypropylene is preferred; however, finer suture can be used with surgical magnification. Both native and graft vessels are intermittently flushed with heparinized saline to minimize clot formation. Arterial spasm can be alleviated with papaverine flushes. The integrity of the anastomosis is evaluated with flushing of hypothermic solution (see Figs. 54–78 [on the Expert Consult website] and 54–79).

For flank approaches a standard curvilinear Gibson incision provides access to the iliac fossa and vessels. Cautious dissection and ligation of surrounding lymphatics is imperative to prevent postoperative lymphocele formation and to minimize the risk of suture line infections. The external vein is mobilized cephalad to the junction where the internal iliac artery crosses over. The venous anastomosis between the renal vein and external iliac vein is completed with continuous or running 5-0 polypropylene in an end-to-side fashion. A disease-free internal iliac artery is anastomosed with continuous or interrupted 6-0 polypropylene to the renal artery end to end. If there is evidence of disease not detected with preoperative imaging then an end-to-side approach is advisable to limit stenosis, recognizing that perfusion pressures may be lower secondary to flow turbulence. Intraoperative ultrasonography can be performed to assess inflow. Surgicel may be wrapped around the anastomosis to ensure hemostasis at needle sites, which tend to ooze once systemic anticoagulation is initiated after surgery. The ureter is reimplanted using an extravesical Grégoire-Lich anastomosis or a Leadbetter-Politano tunneled reimplant using absorbable suture (Figs. 54–80 and 54–81). A psoas hitch and/or Boari flap may be required for extremely short ureters. A 6-Fr transplant double-J stent is next placed across the anastomosis. A Penrose drain or 7-Fr Jackson-Pratt drain is left for 24 to 48 hours.

Postoperative Care and Complications

Elevated lactate dehydrogenase levels can also indicate the presence of a renal infarct. A MAG3 scan can be obtained to evaluate uptake and excretion, but the majority of kidneys repaired ex vivo show immediate and somewhat prolonged periods of acute tubular necrosis. Patients will need to be on systemic heparin therapy during the immediate postoperative period, which increases the risk of hemorrhage and anastomosis rupture. Vascular leaks or thrombosis occur in 1% to 2% of transplants and need urgent surgical revision. Peritransplant fluid collections are of concern and need to be evaluated and treated. Collections discovered between weeks 1 and 3 are usually urinomas and occur in 4% to 5% of transplanted kidneys. Depending on severity they can be managed with revision of the ureteroneocystotomy or stent placement. Fluid collections presenting at 3 to 6 months represent lymphocele formations and occur in 5% to 10% of patients. Presenting symptoms include ureteral obstruction with rising creatinine concentration and iliac vein compression with lower extremity edema. Small lymphoceles can be managed conservatively whereas larger ones require more invasive procedures, such as percutaneous drainage or sclerosing agents. When percutaneous approaches fail, a peritoneal window can be created laparoscopically to facilitate permanent drainage. Patients with infected urine and extravasation can progress to abscess formation, suture line infection, and graft loss.

Outcomes

Numerous investigators have reported acceptable outcomes with extracorporeal surgery and renal autotransplantation. The authors' success rate is 90% in more than 25 autotransplants, primarily for renovascular disease. Other contemporary series demonstrated similar results with resolution of hypertension in over 90% of patients with preserved or improved renal function, respectively (Jordan et al, 1985; Novick et al, 1990a; Wotkowicz and Libertino, 2004).

These outcomes support the role of autotransplantation for renovascular disease. Numerous case reports and small series demonstrate the feasibility of the procedure for additional indications as listed previously.

Partial Nephrectomy for Benign Disease

In addition to treating malignant disease, which is discussed later in the chapter, partial nephrectomy can also be used for localized

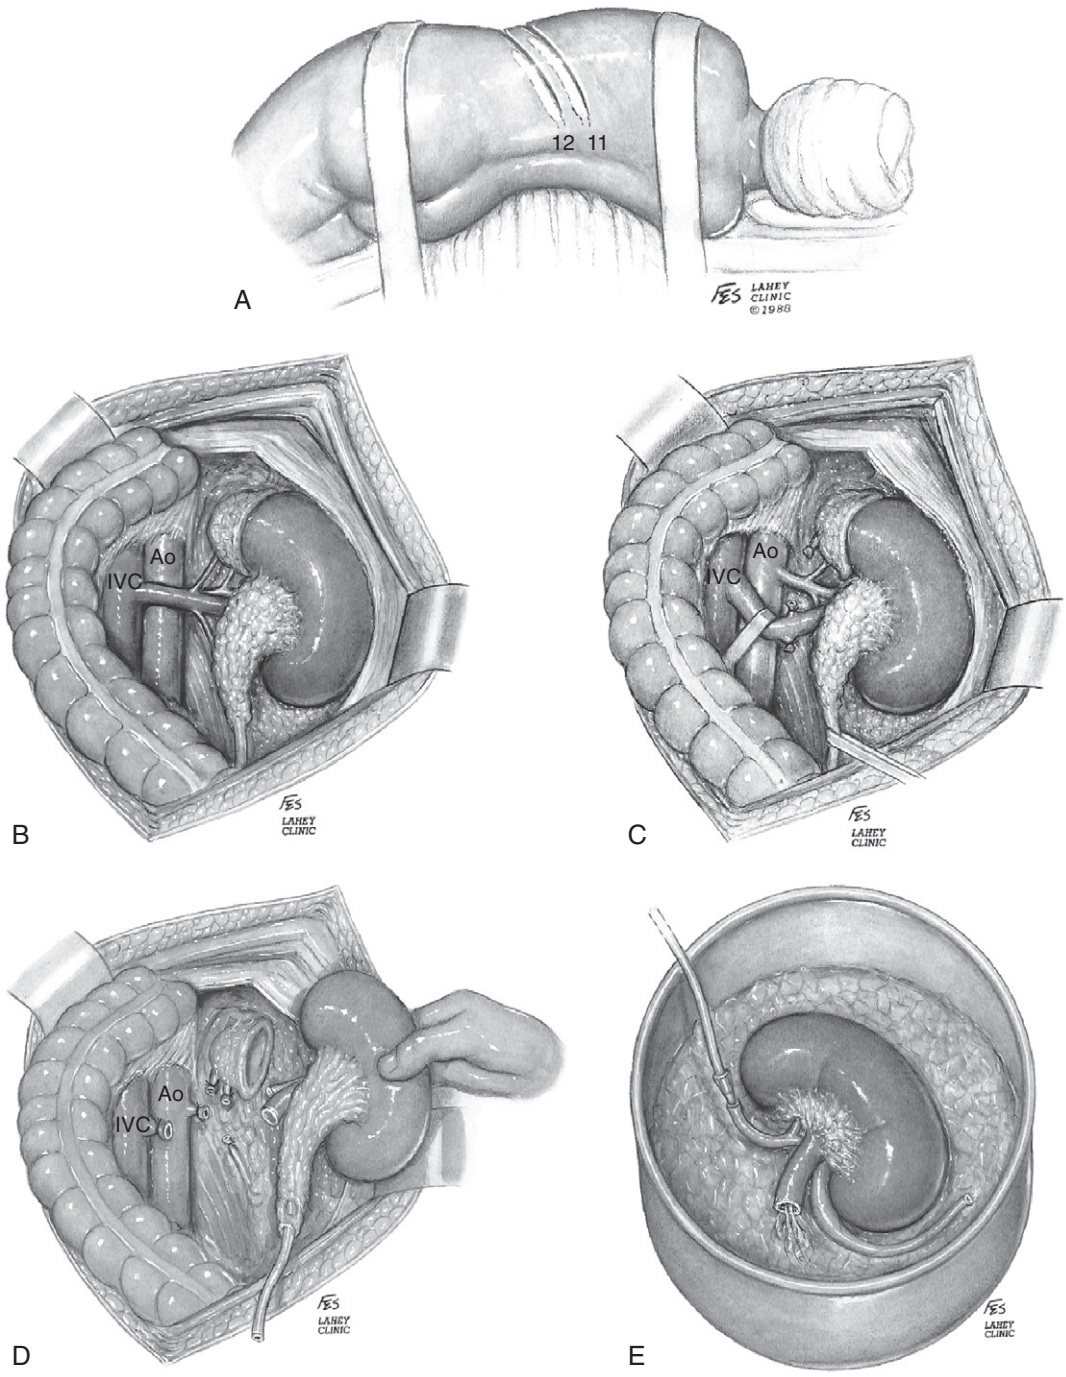

Figure 54–77. Nephrectomy for autotransplant is shown. **A,** Patient is placed in the flank position. An 11th rib supracostal incision maximizes renal exposure. **B,** Dissection of the left kidney demonstrates exposure of the renal vein to its origin at the vena cava (IVC). **C,** After ligation of the adrenal and gonadal vessels, the renal vein is mobilized to expose the renal artery. **D,** Division of the renal vessels is at the origin of the aorta (Ao) and vena cava. The ureter is transected below the pelvic brim. Care is taken not to maintain adventitial tissue or ureter. **E,** Chilled preservation solution (heparinized lactated Ringer solution) is perfused through the renal artery. (© The Lahey Clinic.)

benign disease of the kidney (Leach and Lieber, 1980). The indications include hydronephrosis with parenchymal atrophy or atrophic pyelonephritis in a duplicated renal segment; calyceal diverticulum complicated by infection, stones, or both; calculus disease with obstruction of the lower pole calyx or segmental parenchyma disease with impaired drainage (Papathanassiadis and Swinney, 1966; Bates et al, 1981); renovascular hypertension due to segmental parenchymal damage or noncorrectable branch renal artery disease (Aoi et al, 1981; Parrott et al, 1984); traumatic renal injury with irreversible damage to a portion of the kidney (Gibson et al, 1982); and removal of a benign renal tumor, such as an angiomyolipoma or oncocytoma (Maatman et al, 1984).

In a partial nephrectomy for suspected malignancy the renal capsule is excised along with the specimen. **In benign disorders a flap of renal capsule can be reflected off the diseased parenchyma and used in renorrhaphy** (Figs. 54–82 and

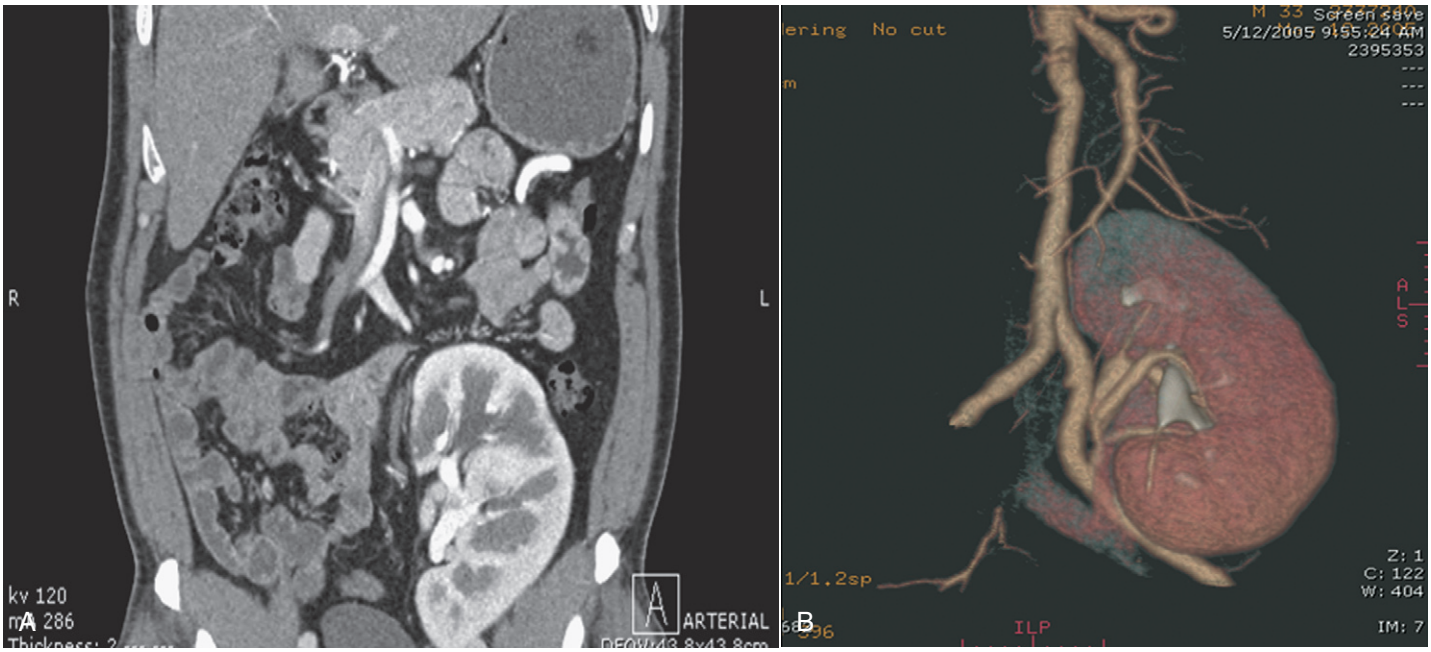

Figure 54–79. **A,** Follow-up CT scan 3 years after operation demonstrates good renal function and lack of aneurysm. The patient takes no antihypertensive medication. **B,** Three-dimensional reconstructions demonstrate no aneurysmal dilation.

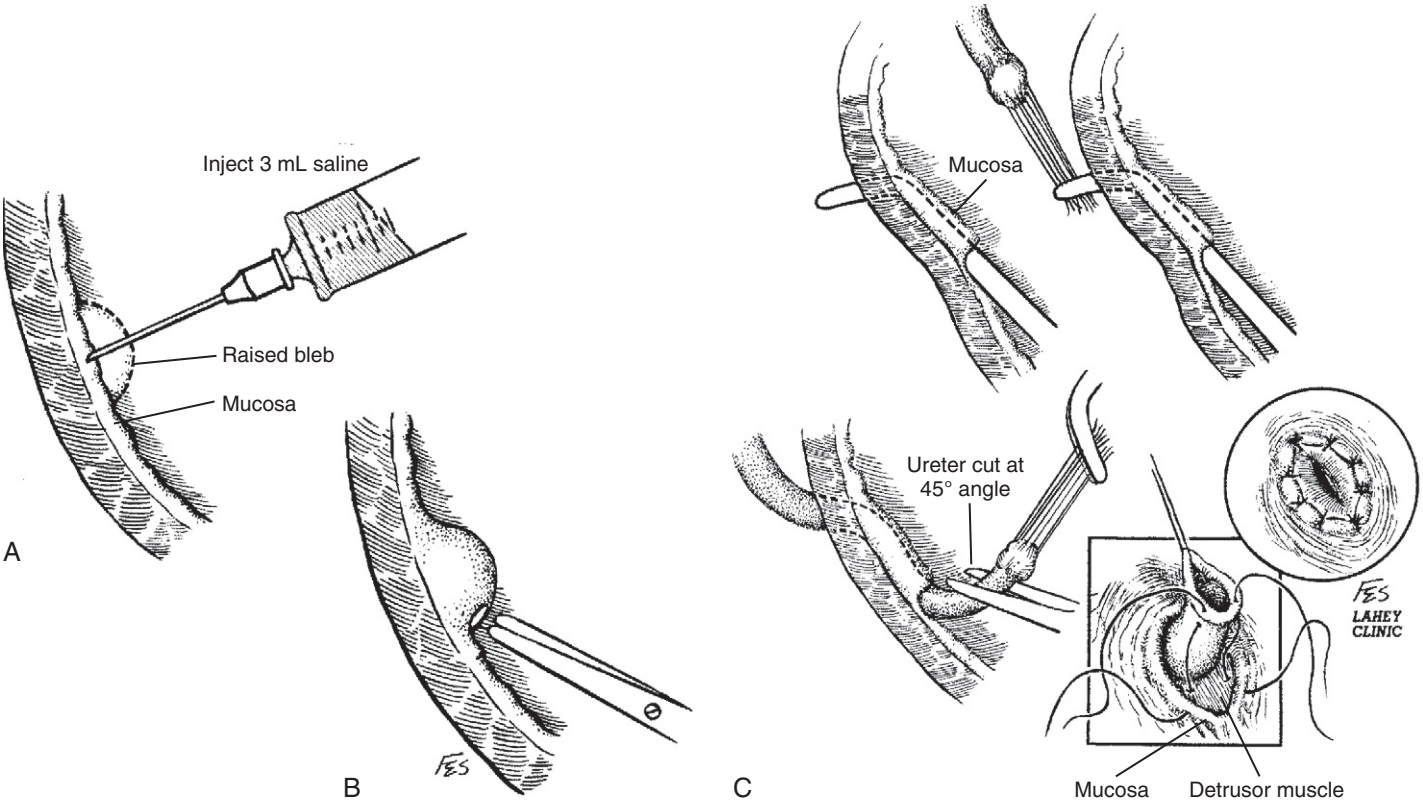

Figure 54–80. Modification of the Politano-Leadbetter technique is shown. **A** and **B,** The submucosal tunnel is created. Injection of 3 mL of saline raises the mucosal layer and permits earlier dissection. **C,** Right-angle clamp is placed along the mucosal tunnel. (© The Lahey Clinic.)

54–83). The remaining techniques are the same as those described for malignant disease.

Heminephrectomy can be carried out in a duplicated collecting system. The division between the specimen and what will be remnant parenchyma is evident from atrophy of the diseased segment or can be delineated by pyelotubular backflow after distending the affected collecting system with blue dye. Segmental arterial and venous branches to the diseased portion of the kidney are ligated and divided. Clamping of the artery supplying the nondiseased segment is usually unnecessary. Renorrhaphy

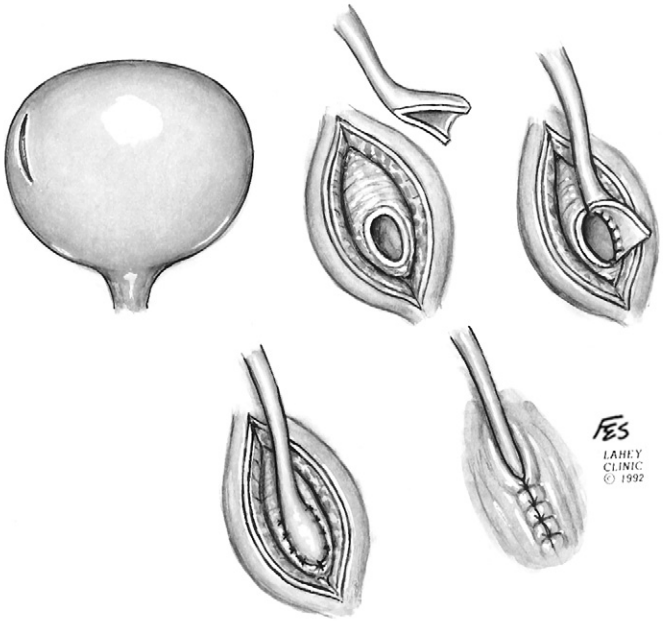

Figure 54–81. The Grégoire-Lich technique of extravesical ureteroneocystostomy is shown. (© The Lahey Clinic.)

proceeds as described for malignancy, although the remnant collecting system in a duplex system will not have been violated and therefore will not require repair.

Stone Surgery

Open surgery for nephrolithiasis is rare, making up less than 2% of stone procedures in contemporary practice (Kerbl et al, 2002; Matlaga and Assimos, 2002). Appropriate candidates for open stone surgery have failed less invasive techniques such as extracorporeal shockwave lithotripsy or endoscopic treatment, have anatomic abnormalities precluding less invasive treatment, or have an exceedingly complex stone array.

Pyelolithotomy

Pyelolithotomy can be effective in removing a small stone burden. This is rarely performed as a solitary procedure because efficacious minimally invasive techniques are more commonly employed. The kidney is approached through a flank or extraperitoneal anterior subcostal incision. The Gerota fascia is opened. The kidney is mobilized within the Gerota fascia and reflected medially to expose the posterior surface. The ureter is located inferiorly and tracked superiorly past the UPJ to the hilum. A U-shaped incision is made on the pelvis, avoiding the UPJ. A forceps is passed through the pyelotomy and is used to remove the stones. A nephroscope also can be employed to inspect the collecting system. A ureteral catheter is passed in an antegrade fashion to ensure that the ureter is free of stone debris. The pelvis is closed with a 4-0 absorbable suture, a Penrose drain is externalized, and the wound is closed in layers.

Extended Pyelolithotomy and Radial Nephrolithotomy

For larger stones and staghorn calculi, a pyelolithotomy can be extended into the sinus after dissecting intrasinus fat away from the pelvis and infundibula. The U-shaped incision will start at the base of an inferior calyx and end at the base of a superior calyx. The stone is separated from the urothelium and removed with forceps. One can dilate an infundibulum to remove a large calyceal component of the stone. In cases in which a calyceal stone is too large to remove through the infundibulum, a radial nephrotomy can be done to extract the stone. The stone is localized by palpation through the capsule, and a radial capsulotomy is sharply made over the stone. The parenchyma is bluntly opened, and the stone is extracted with forceps. The nephrotomy is closed with 2-0 polyglactin suture and Surgicel bolster.

Anatrophic Nephrolithotomy

Knowledge of the segmental renal arterial circulation is fundamental to anatrophic nephrolithotomy. The parenchyma is divided at the border between anterior and posterior vascular segments, permitting removal of complex staghorn calculi.

A supracostal approach is advantageous. The Gerota fascia is opened and the kidney is mobilized. The hilum is sharply dissected, exposing the main renal artery and posterior segmental artery. The renal pelvis and ureter do not need to be mobilized. The arterial branch to the posterior segment is clamped. As the posterior segment whitens, administration of methylene blue permits identification of the border between the anterior and posterior segments, which marks a relatively avascular plane. The line is scored with cautery.

The main renal artery is occluded. The kidney is placed in an ice slush bath and allowed to cool. The capsule is sharply incised

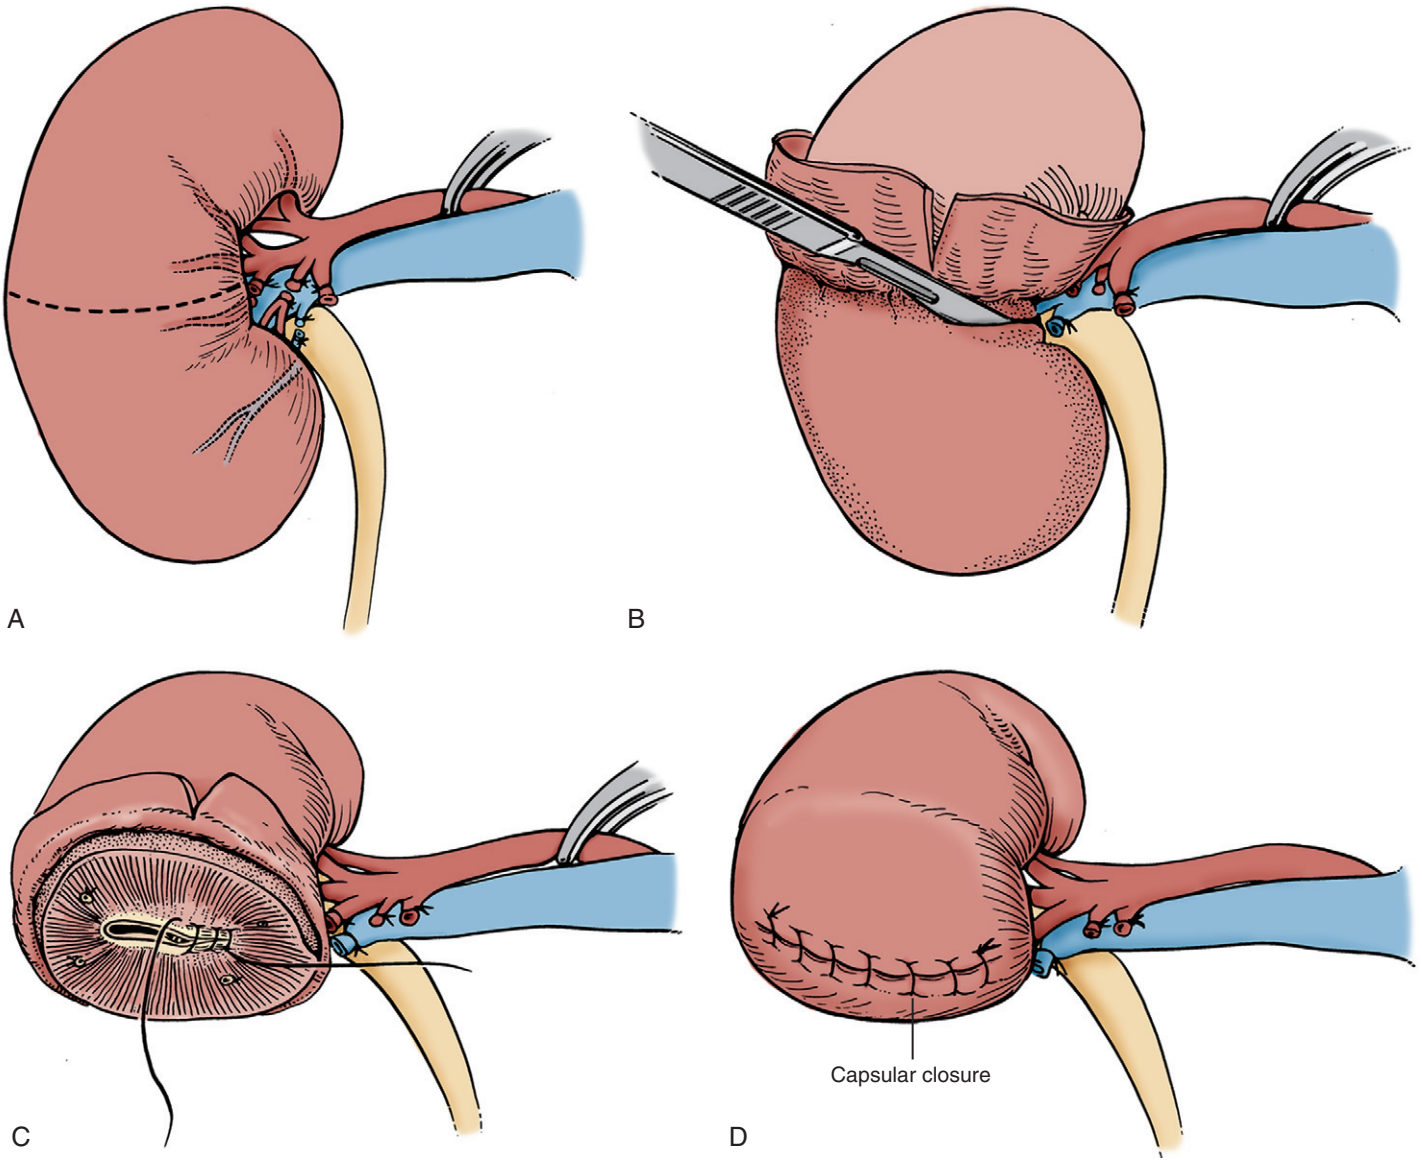

Figure 54–83. **A** to **D,** Technique of transverse renal resection for a benign disorder. The renal capsule from the diseased parenchyma is preserved and used to cover the transected renal surface.

along the border between the anterior and posterior segments, being careful to avoid the poles, which have a separate blood supply. The parenchyma is separated bluntly between the anterior and posterior segments. The renal pelvis and calyces are sharply incised, and the stone is removed. Intraoperative ultrasonography, fluoroscopy, and nephroscopy can be employed to ensure stone clearance.

A ureteral stent is placed in an antegrade fashion. The renal pelvis is reapproximated with a running 3-0 monocryl suture. Blood flow is restored to the kidney. Any bleeding vessels are sutured with 2-0 or 3-0 polyglactin. The renal capsule is closed with a running, locking 2-0 polyglactin suture. A Surgicel bolster can be employed. A Penrose drain is externalized through a separate stab excision.

Excision of Simple Renal Cysts

Simple renal cysts are characterized radiographically by thin walls; lack of septation, calcifications, or solid components; and lack of enhancement (Israel and Bosniak, 2005). Asymptomatic cysts are a common incidental radiographic finding. Mass effect from large cysts can cause symptoms or obstruction. Surgical excision of the cyst may be required and is usually handled laparoscopically (Fig. 54–84).

In the unusual circumstance that open surgery is required the kidney is approached through an extraperitoneal flank, dorsal lumbotomy, or anterior approach. The best approach is determined by the size and location of the cyst. After the Gerota fascia is opened, the perirenal fat surrounding the cyst and nearby parenchyma is mobilized. The field is packed to protect surrounding tissues in the event of spillage. A needle is used to aspirate the contents of the cyst, which are sent for cytologic evaluation and culture. The cyst is entered sharply with scissors. The wall of the cyst is excised near normal parenchyma, leaving a few millimeters of cyst wall to be oversewn. Biopsy of the cyst base is performed if there is intraoperative suspicion for malignancy. If frozen section is consistent with malignancy, partial nephrectomy is performed. Otherwise, the cut edges are oversewn with 2-0 polyglactin suture

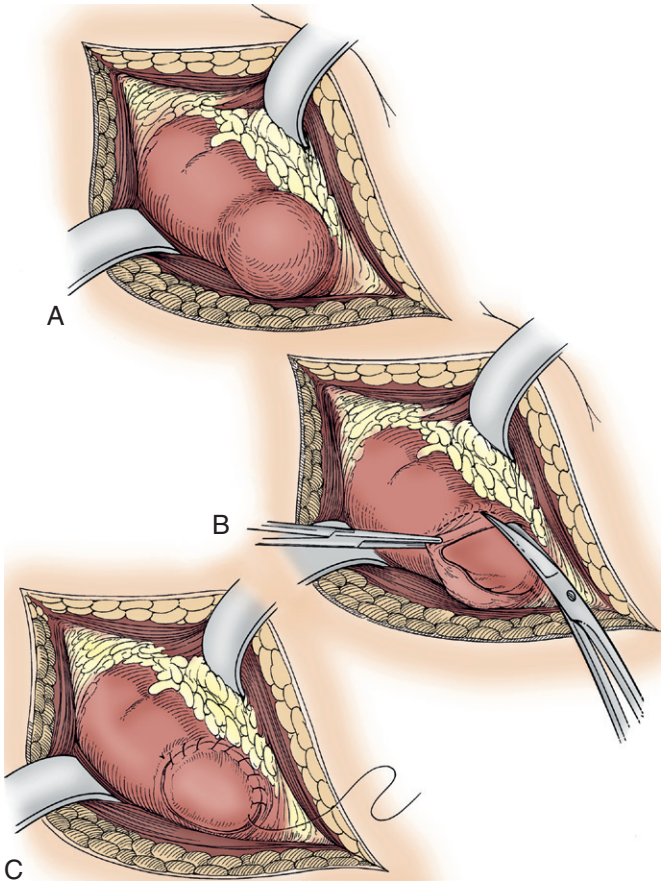

Figure 54–84. **A** to **C,** Technique of excision of renal cyst.

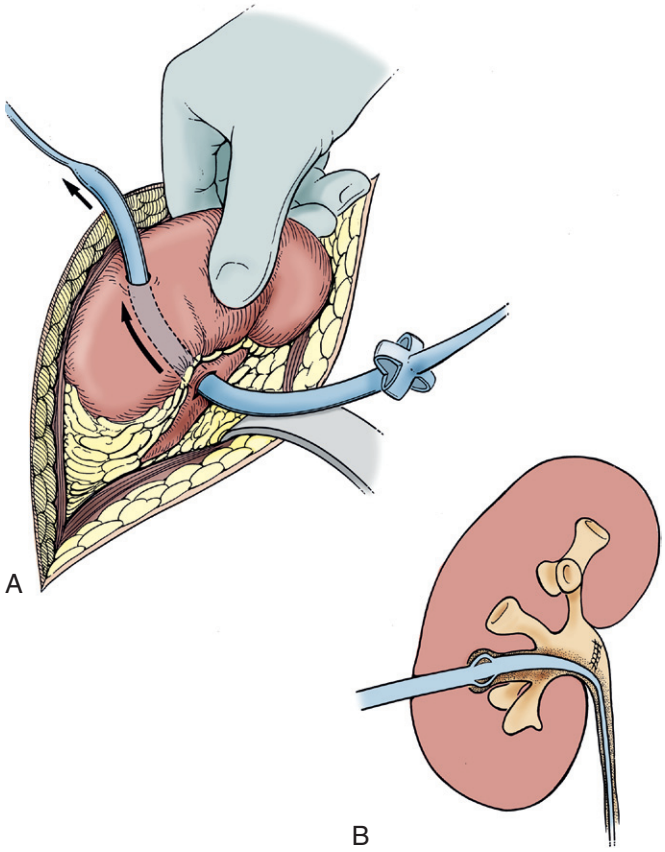

Figure 54–85. **A** and **B,** Technique of open nephrostomy tube insertion.

for hemostasis. Cautery is employed as needed and can be used in the spray mode to cauterize the lining of the cyst. For infected cysts, a drain is externalized.

Open Nephrostomy

With the widespread adoption of percutaneous nephrostomy drainage and endoscopic placement of ureteral stents, open insertion of a nephrostomy tube has become rare. **When endoscopic and percutaneous approaches have failed, open nephrostomy can be lifesaving** (Fig. 54–85). A nephrostomy tube may also be inserted as an adjunct to an open reconstructive procedure such as pyeloplasty or ureterocalicostomy (Willscher and Conway, 1987).

The kidney is approached through a retroperitoneal flank incision. The Gerota fascia is opened laterally. The kidney is mobilized within the Gerota fascia and reflected medially to expose the posterior surface. The ureter is located inferiorly. Dissection proceeds superiorly along the ureter to the renal pelvis. Two 2-0 polyglactin stay sutures are placed in the renal pelvis a safe distance away from the UPJ. With a hooked scalpel, a 2-cm incision is made parallel to the long axis of the kidney between the holding sutures, avoiding the UPJ.

A silk suture is passed through the tip of a Malecot catheter. A Randall stone forceps is passed through the pyelotomy into a lower pole calyx. The tip of the forceps is aimed at the convex border of the kidney, because a nephrostomy on the anterior or posterior surface of the kidney has a higher risk of hemorrhage from damage to intrarenal vessels. While pressure is applied with the forceps, the tip of the forceps is palpated at the convex border of the kidney. A radial capsulotomy is made over the tip of the forceps. The tract through the parenchyma is widened slightly by opening the forceps, which is then used to grasp the silk suture. The forceps is gently withdrawn back through the pyelotomy, while reducing the wings of the Malecot catheter by pulling on the distal aspect of the tube. The tube is thus drawn through the tract, placing the tip in the lower calyx. The silk suture is removed. Rather than using a curved clamp and a Malecot catheter, one can use a Willscher nephrostomy tube, which is equipped with a stylet to puncture the parenchyma.

The tube is sutured to the renal capsule using a 3-0 absorbable purse-string or figure-of-eight suture. The tube is externalized through a separate anterior flank stab incision, ensuring that the tube does not kink. It should not exit beneath a supine patient.

The pyelotomy is closed with a running 4-0 monocryl suture, and the holding sutures are removed. The nephrostomy tube is secured to the skin using a heavy silk suture. A Penrose drain is placed in the region of the repaired pyelotomy and externalized through an additional stab incision. The wound is closed in layers.

Postoperative care of the tube is directed at prevention and treatment of obstructed drainage. The tube should be gently irrigated if it is not draining appropriately. If irrigation does not restore flow or if irrigant exits around the catheter insertion site, antegrade nephrostography should be performed to assess tube position. It is essential to adequately secure the tube at the skin level to prevent dislodgement. The tube should be replaced under fluoroscopic guidance every 6 to 8 weeks, or more frequently if the patient is prone to stone encrustation.

Renal Biopsy

Since the first description of percutaneous renal biopsy nearly 60 years ago (Iversen and Brun, 1951), the role of open renal biopsy has gradually diminished. Generally, open renal biopsy is indicated when a percutaneous biopsy might be associated with excessive risk, such as in patients with a solitary kidney or uncorrected coagulopathy. Open surgery enables hemostasis and provides more tissue for evaluation than percutaneous biopsy. Laparoscopy also permits hemostasis and should be considered before open surgery. The authors have not performed an open renal biopsy at the Lahey Clinic since 1975.

The kidney is approached through a dorsal lumbotomy or subcostal flank incision. The right kidney, which is more inferior, more readily lends itself to biopsy and is preferred. After the Gerota fascia is entered the perirenal fat surrounding the lower pole is mobilized. Two fine absorbable stay sutures are placed in the renal capsule. A third stay suture is placed between them into the parenchyma. An elliptical incision is made in the renal capsule around the third suture, measuring 0.5 to 1.0 cm by 1.0 to 2.0 cm. A wedge biopsy is then performed by deepening the elliptical incision on an angle toward the center of the specimen. The biopsy should include renal cortex and medulla, although deep biopsies risk entry into the collecting system and should be avoided. The capsule is closed primarily using the stay sutures. A Surgicel bolster can be employed. Excellent hemostasis should be assured before the wound is closed in layers.

SURGERY FOR MALIGNANCY

Radical Nephrectomy

Indications and Evaluation

Radical nephrectomy involves the en-bloc removal of the kidney outside the Gerota fascia together with the ipsilateral adrenal gland as well as complete regional lymphadenectomy from the crus of the diaphragm to the aortic bifurcation (Robson et al, 1969; Skinner et al, 1971). **Whereas partial nephrectomy is the treatment of choice for T1 tumors when feasible, radical nephrectomy remains the definitive therapy for T2 or larger tumors.**

Clinical staging of renal cell carcinoma involves radiologic evaluation of tumor size, extension beyond the Gerota fascia and into adjacent structures, venous involvement, and evaluation for nodal and metastatic disease. Renal cell carcinoma is staged with the 2010 American Joint Committee on Cancer (AJCC) TNM staging classification (Tables 54–10 and 54–11). Preoperative radiographic studies such as ultrasonography, CT, and MRI are important. Through preoperative imaging, one is able to determine the clinical stage of the tumor, define the anatomy of the affected kidney, and assess the structure or function of the contralateral kidney. All patients should undergo a metastatic evaluation including a chest radiograph and an abdominal CT scan. A bone scintiscan is indicated in patients with bone pain or elevated serum levels of alkaline phosphatase. Preoperative renal, cardiac, and pulmonary evaluations are essential, as described earlier.

Tumor thrombus involving the IVC should be suspected in patients with lower extremity edema, varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or nonfunction of the involved kidney. MR venography is the authors' preferred study for evaluating the presence and the distal extent of involvement of the IVC (Pritchett et al, 1987; Goldfarb et al, 1990) (Fig. 54–86). The use of invasive inferior vena cavography is limited to those patients with a nondiagnostic MR venogram or ultrasound evaluation, in those in whom MRI is contraindicated, and in patients who underwent preoperative angioinfarction with coils that would produce scatter leading to poor quality MR images (Fig. 54–87). Transesophageal echocardiography (Treiger et al, 1991; Glazer and Novick, 1997) and transabdominal Doppler ultrasonography (McGahan et al, 1993) are also useful. **In patients with known IVC tumor thrombus the authors perform intraoperative transesophageal**

Table 54–10.

TNM Staging of Renal Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
T1	Tumor ≤7 cm in greatest dimension, limited to the kidney
T1a	Tumor ≤4 cm in greatest dimension, limited to the kidney
T1b	Tumor >4 cm but not >7 cm in greatest dimension limited to the kidney
T2	Tumor >7 cm in greatest dimension, limited to the kidney
T2a	Tumor >7 cm but ≤10 cm in greatest dimension, limited to the kidney
T2b	Tumor >10 cm, limited to the kidney
T3	Tumor extends into the major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond the Gerota fascia
T3a	Tumor grossly extends into the renal vein or its segmental (muscle-containing) branches or invades perirenal and/or renal sinus fat but not beyond the Gerota fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond the Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

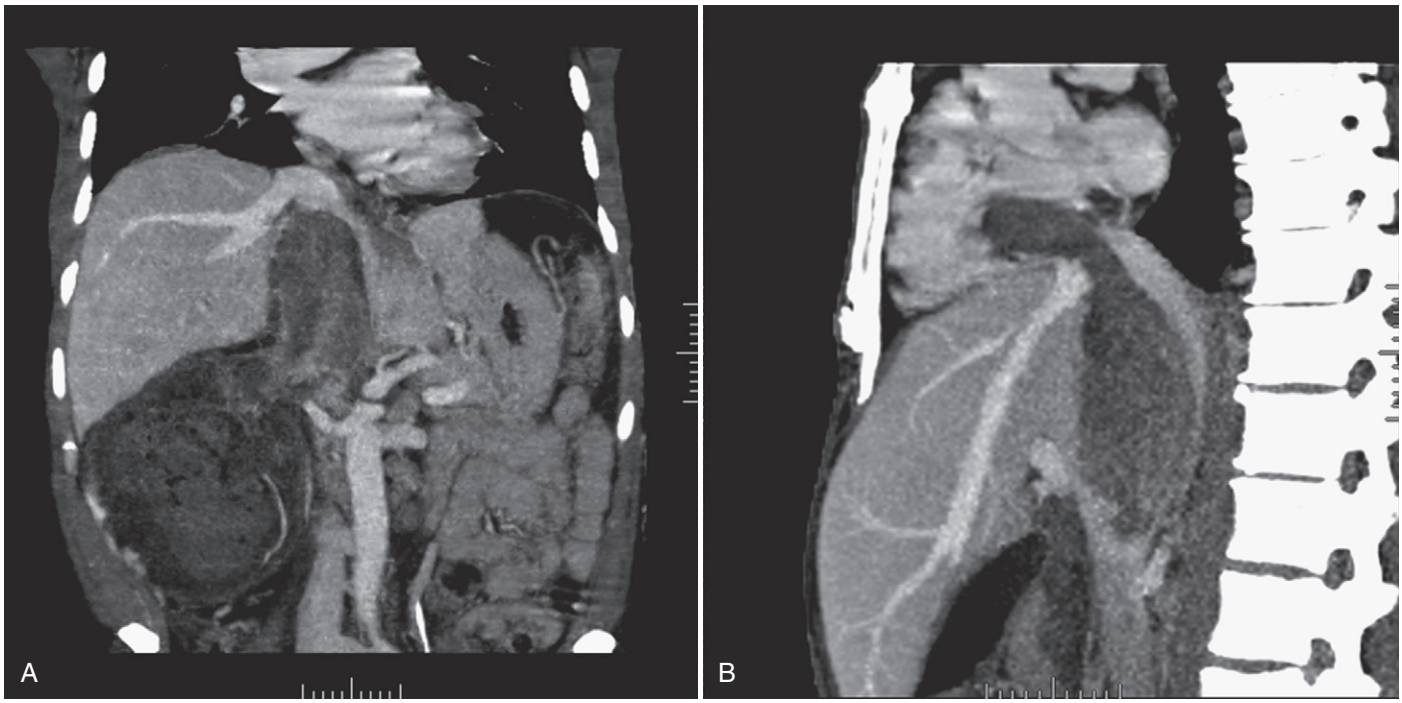

Figure 54–86. **A,** Coronal MR image demonstrates tumor extending to the level of the diaphragm. **B,** Sagittal MR reconstruction demonstrates thrombus that extends farther into the right atrium. The patient would eventually require cardiopulmonary bypass and deep hypothermic circulatory arrest.

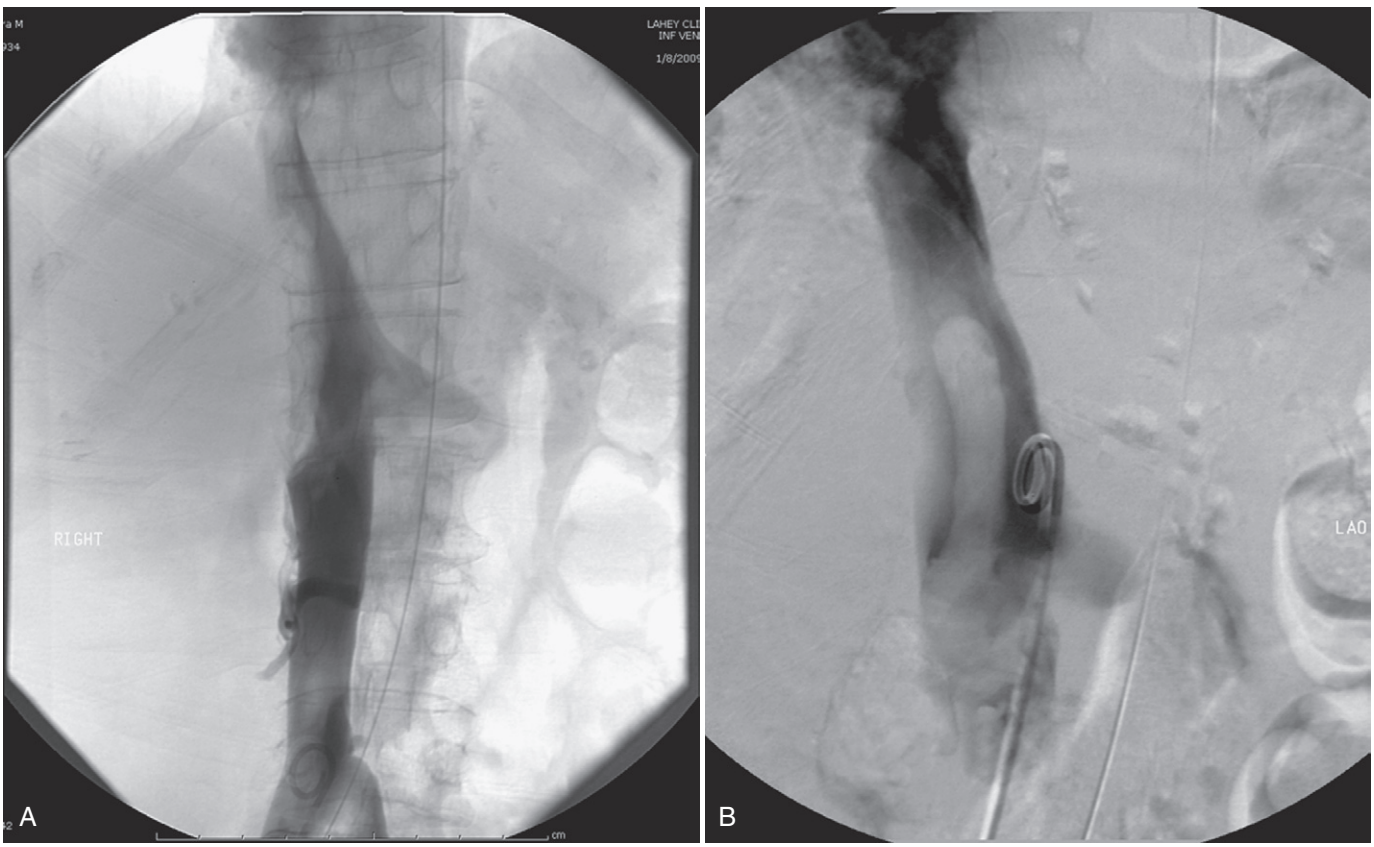

Figure 54–87. **A** and **B,** Preoperative cavogram demonstrating filling defect at the T10 level consistent with tumor thrombus in a patient with a large right renal mass. The patient required cardiopulmonary bypass and deep hypothermic circulatory arrest.

echocardiography to evaluate the distal extent of the tumor thrombus before making the incision.

As discussed earlier, the senior author favors preoperative angioinfarction for large renal tumors with hypervascular characteristics or IVC tumor thrombus (Wotkowicz and Libertino, 2007). Proposed benefits of preoperative RAE include shrinkage of an arterialized tumor thrombus to ease surgical removal and reduce blood loss. **When cardiopulmonary bypass (CPB) with deep hypothermic circulatory arrest is anticipated, surgeons at some institutions will also perform preoperative coronary angiography** (Belis et al, 1989; Novick et al, 1990b). **Coronary lesions can be repaired concurrently during CPB.**

Technique

The key elements of radical nephrectomy include the surgical approach, early ligation of the renal artery and vein, removal of the kidney outside the Gerota fascia, removal of the ipsilateral adrenal gland, and a complete regional lymphadenectomy extending from the crus of the diaphragm to the aortic bifurcation.

Surgical approaches are determined by tumor location and size, body habitus, prior surgical history, and surgeon preference. Although simple nephrectomy is often accomplished through an extraperitoneal approach, radical nephrectomy is best performed through a transperitoneal incision. This permits abdominal exploration for metastatic disease and access to the pedicle before significant manipulation of the tumor. The senior author prefers either an anterior or a thoracoabdominal approach.

Anterior Approach. A transperitoneal anterior midline, anterior subcostal, or chevron incision is made. The abdomen is systematically examined for metastatic disease. The approach for left and right tumors is described.

Right. The right kidney is approached by taking down the hepatic flexure and incising the peritoneal reflection along the right paracolic gutter. This permits the colon to be reflected medially in a plane anterior to the Gerota fascia. A Kocher maneuver, in which the lateral peritoneal reflection of the duodenum is incised and the duodenum reflected medially, is used subsequently to expose the underlying IVC and pararenal aorta (see Fig. 54–90). These maneuvers typically provide adequate access to the right renal pedicle and great vessels.

The right renal vein, which is relatively short and does not typically receive large tributaries, is mobilized. The gonadal vein enters the IVC and is ligated before the dissection of the right renal vein to avoid troublesome bleeding. The right renal artery lies posterior to the renal vein along its superior margin and normally runs a retrocaval course (see Fig. 54–37). The renal artery can be isolated to the right of the vena cava. Alternatively, in cases of a large medial tumor or significant nodal disease in the hilum, the renal artery can be controlled between the vena cava and aorta (Fig. 54–88).

Left. On the left side the white line of Toldt is incised and the colon is reflected medially to expose the great vessels. Division of the splenocolic ligaments reduces traction on and injury to the spleen. This approach permits access to the renal pedicle both anteriorly and posteriorly, which is the authors' preference. The left renal artery can be isolated posteriorly and the venous system identified and controlled anteriorly.

The left renal vein passes anterior to the aorta and is longer than the right renal vein. Unlike the right side it receives gonadal, adrenal, and lumbar tributaries, which are ligated and divided. **Identifying the left renal artery from the posterior approach is recommended to avoid inadvertent ligation**

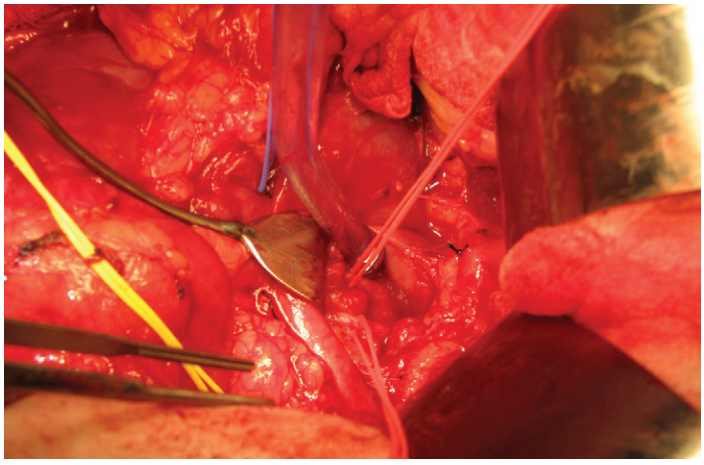

Figure 54–88. Two right renal arteries are isolated with red vessel loops at the interaortocaval junction. The vein retractor is retracting the inferior vena cava, and the Yankauer suction is displacing the left renal vein cephalad.

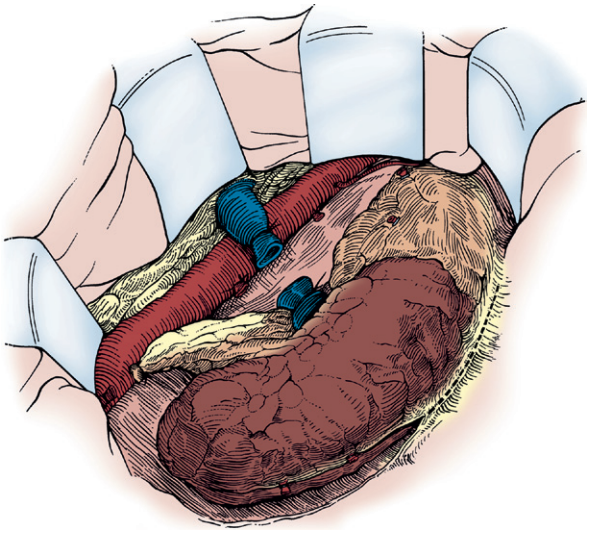

Figure 54–90. After the pedicle is secured and the ureter divided, the kidney is mobilized outside the Gerota fascia. (Reproduced with permission from Novick AC, Streem SB, Pontes E, editors. Stewart's operative urology. 2nd ed. Baltimore: Williams & Wilkins; 1989.)

of the superior mesenteric artery, which is on the anterior surface of the aorta 1 to 2 cm cephalad to the left renal vein. Alternatively, the artery can be isolated from an anterior approach by retracting the mobilized vein. The artery is mobilized toward the aorta, ligated, and divided. Two large Hemo-Lok clips and a 0 silk suture ligature are used to secure the main renal artery with a silk tie on the specimen side, followed by the vein (see Fig. 54–89 [on the Expert Consult website] and Figs. 54–90 and 54–91). Preoperative arterial embolization permits venous ligation to be performed first, which is occasionally necessary in complex dissections.

Mobilization of Kidney and Completion of the Case. After dividing the renal pedicle, the kidney is mobilized outside the Gerota fascia with blunt and sharp dissection. Any remaining vascular attachments are ligated with nonabsorbable sutures and divided. The ureter is ligated and divided. The kidney and adrenal gland are removed. A Penrose drain is placed in the empty renal fossa and

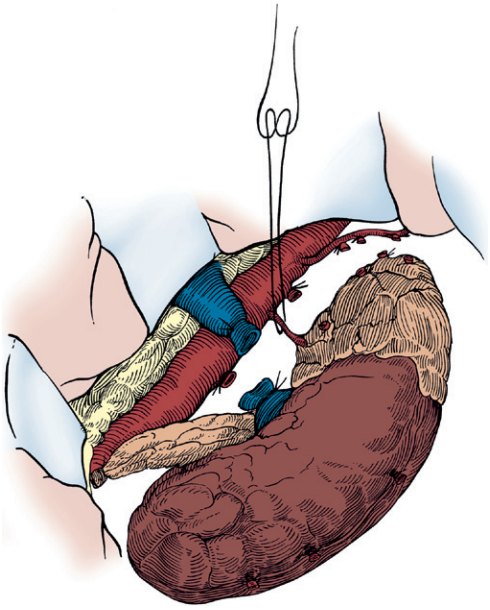

Figure 54–91. Remaining medial vascular attachments are secured and divided to complete the nephrectomy. (Reproduced with permission from Novick AC, Streem SB, Pontes E, editors. Stewart's operative urology. 2nd ed. Baltimore: Williams & Wilkins; 1989.)

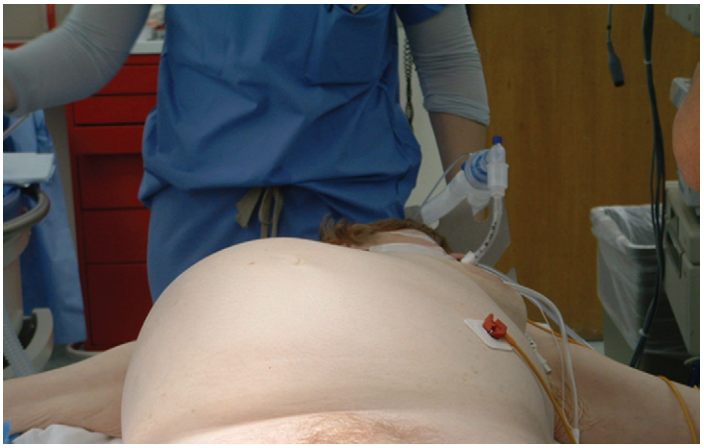

Figure 54–92. Patient with right flank mass positioned supine.

externalized through a separate stab incision. The abdomen is closed in layers as previously described.

Thoracoabdominal Approach. **For large renal tumors, especially those of the upper pole, the thoracoabdominal approach is preferable to an anterior approach** (Fig. 54–92; see Fig. 54–93 on the Expert Consult website). On the right side the liver is retracted cephalad. The hepatic flexure of the colon and the duodenum are reflected medially, exposing the IVC, the renal pedicle, and the anterior surface of the kidney (Figs. 54–94 to 54–96). The renal artery and vein are handled as described for the anterior approach. The ureter and right gonadal vein are ligated and divided. The kidney is mobilized outside the Gerota fascia down to the psoas fascia. The additional vascular attachments to the upper pole tumor and adrenal gland are exposed by medial retraction of the IVC along with caudal and lateral retraction of the kidney. They are ligated and divided. A curved-shaped clamp is passed along the superior portion of the adrenal gland to

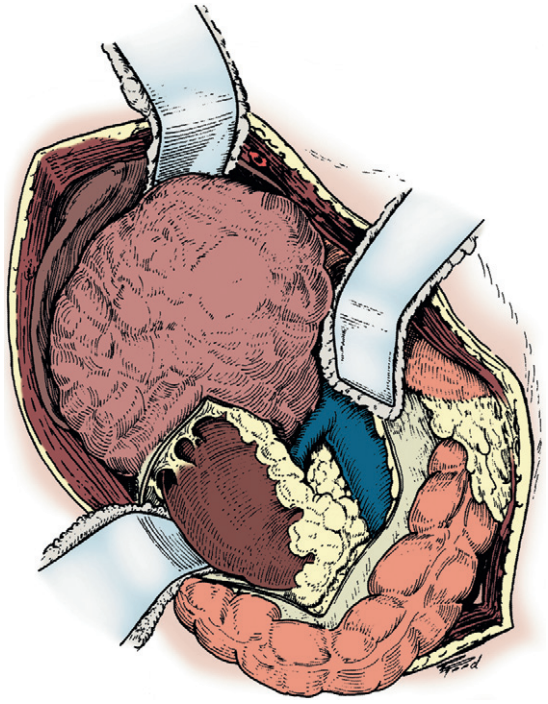

Figure 54–94. Exposure of large right upper pole tumor through a thoracoabdominal incision. (Reproduced with permission from Novick AC, Streem SB, Pontes E, editors. Stewart's operative urology. 2nd ed. Baltimore: Williams & Wilkins; 1989.)

gain control of the phrenic vessels using a 0 silk suture ligature. The specimen is mobilized fully away from the liver and removed en bloc.

On the left side the splenic flexure and the descending colon are mobilized. After the left renal pedicle is secured the kidney is mobilized outside the Gerota fascia. The upper border is dissected from the spleen, and the medial border is dissected from the tail of the pancreas. The ureter is ligated, and the specimen is removed.

Ipsilateral Adrenalectomy

Ipsilateral adrenalectomy may be associated with increased morbidity, adrenal insufficiency, and longer operative times. In 511 patients, Tsui and colleagues failed to demonstrate a correlation between tumor size and adrenal involvement, although presence of the tumor in the upper pole was a prognostic factor for adrenal involvement. Mordhorst and associates suggested that an adrenal-sparing approach should be taken in patients with tumors of less than 8 cm and no evidence of lymph node or organ metastasis. **Contrary to the classic description of radical nephrectomy, removal of the ipsilateral adrenal gland is not routinely necessary unless the tumor either extensively involves the kidney or is located in the upper portion of the kidney** (Sagalowsky et al, 1994).

Regional Lymphadenectomy

Complete regional lymphadenectomy, a traditional component of radical nephrectomy, encompasses removal of lymphatic tissue from the crus of the diaphragm to the aortic bifurcation. The lymph nodes can be removed en bloc with the kidney and adrenal gland or separately after completing the nephrectomy.

One enters and proceeds along a plane close to the adventitia of the aorta, which permits removal of all periaortic lymph tissue. One must be vigilant to avoid injury to the celiac trunk and

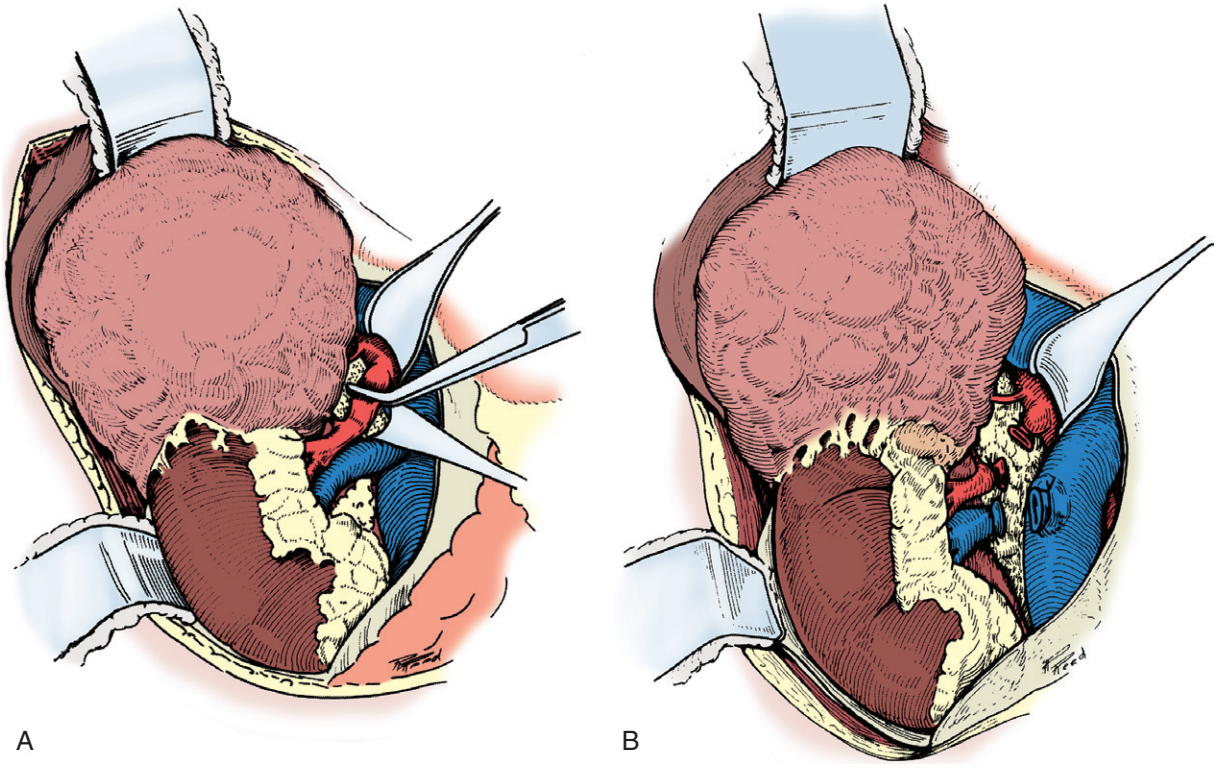

Figure 54–95. **A** and **B,** The renal artery and vein are secured and divided. (Reproduced with permission from Novick AC, Streem SB, Pontes E, editors. Stewart's operative urology. 2nd ed. Baltimore: Williams & Wilkins; 1989.)

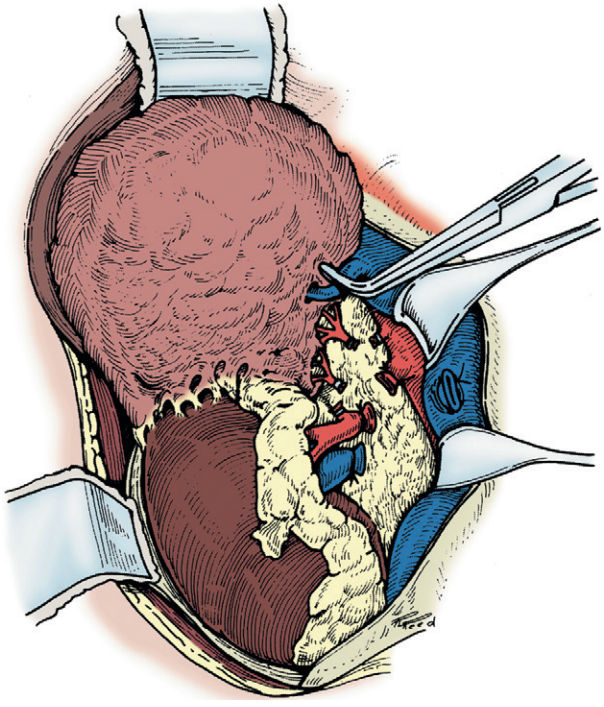

Figure 54–96. The vena cava is retracted medially to expose the remaining superior vascular attachments, which are secured and divided. (Reproduced with permission from Novick AC, Streem SB, Pontes E, editors. Stewart's operative urology. 2nd ed. Baltimore: Williams & Wilkins; 1989.)

superior mesenteric artery, which emanate from the anterior aorta. Proceeding downward to the origin of the inferior mesenteric artery, the sympathetic ganglia and nerves are removed together with the lymphatic tissue. The cisterna chyli, which is located medial to the right crus, is secured along with entering lymphatic vessels. After lymphadenectomy, the surgical field is copiously irrigated with sterile water. The argon laser beam can be helpful for hemostasis in extensive lymphadenectomies. Penrose drains are left for at least 48 hours.

Although lymphadenectomy is a recognized component of pathologic staging, the impact of lymphadenectomy on progression-free and overall survival is controversial. The European Organization for Research and Treatment of Cancer (EORTC) trial 30881, a randomized trial comparing radical nephrectomy with lymphadenectomy to radical nephrectomy alone in patients with clinical N0M0 renal cell carcinoma, did not demonstrate a survival benefit (Blom et al, 2009). The role of lymph node dissection in patients with locally advanced disease, clinical suspicion of nodal disease, or metastatic disease is unclear. There may be a subset of patients with micrometastatic lymph node involvement who can benefit from lymphadenectomy (Giuliani et al, 1990). Prospective trials of patients at higher risk of lymph node metastasis are needed.

Venous Extension and Tumor Thrombectomy

Renal cell carcinoma is associated with venous tumor thrombus in 4% to 10% of cases (Schefft et al, 1978). **In the absence of metastases, an aggressive surgical approach with curative intent is justified.** Five-year survival rates of 40% to 68% have been reported after radical nephrectomy and tumor thrombectomy (Libertino et al, 1987; Neves and Zincke, 1987; Skinner et al, 1989; Novick et al, 1990b). Although the level

Key Points: Radical Nephrectomy

- Although partial nephrectomy is the treatment of choice for T1 tumors when feasible, radical nephrectomy remains the definitive therapy for T2 or larger tumors.
- The key elements of radical nephrectomy include the surgical approach, early ligation of the renal artery and vein, removal of the kidney outside the Gerota fascia, removal of the ipsilateral adrenal gland, and a complete regional lymphadenectomy extending from the crus of the diaphragm to the aortic bifurcation.
- Identifying the left renal artery from the posterior approach is recommended to avoid inadvertent ligation of the superior mesenteric artery, which is on the anterior surface of the aorta 1 to 2 cm cephalad to the left renal vein.
- For large renal tumors, especially those of the upper pole, the thoracoabdominal approach is preferable to an anterior approach.
- Removal of the ipsilateral adrenal gland is not routinely necessary unless the tumor either extensively involves the kidney or is located in the upper portion of the kidney.
- The impact of lymphadenectomy on progression-free and overall survival is controversial.

of IVC involvement is not predictive of survival, tumor thrombus limited to the renal vein is associated with improved survival compared with thrombus in the IVC (Moinzadeh and Libertino, 2004). The most favorable outcomes are achieved when the tumor does not involve the perinephric fat or regional lymph nodes (Cherrie et al, 1982). Although there are several systems for categorizing venous tumor thrombi based on the distal extent of the thrombus, a rational and commonly employed scheme that is preferred by the senior author is shown in Figure 54–97 and Table 54–12.

Renal Vein Tumor Thrombus (Level I). Tumor thrombus in the renal vein often can be approached using the techniques of a standard radical nephrectomy. The kidney, great vessels, and renal pedicle are exposed, mobilized, and controlled through a thoracoabdominal incision. After ligation of the renal artery the tumor thrombus is gently palpated to ensure that no further extension into the vena cava is present. Preoperative angioinfarction permits ligation of the venous system before taking the artery, which can occasionally be helpful.

The kidney is dissected free, leaving the renal vein as the only attachment point (see Figs. 54–98 and 54–99 on the Expert Consult website). Two Satinsky or carotid clamps are placed in close apposition to each other at the junction of the renal vein and IVC, sparing any lumbar tributaries (see Fig. 54–100 on the Expert Consult website). With a scalpel, the IVC is transected proximal to both clamps, leaving them on the IVC. The proximal clamp is removed, which leaves a margin of caval wall for reconstruction with the distal clamp still in place. The caval defect is closed with running 4-0 polypropylene suture, with caution taken to minimize reduction of the IVC diameter (see Fig. 54–101 on the Expert Consult website). Surgicel may be placed over the repair for additional hemostasis.

Perirenal or Infrahepatic Tumor Thrombus (Level II). Transesophageal echocardiography is performed before making the incision to evaluate the cephalad extent of tumor thrombus (Fig. 54–102). Radical nephrectomy with removal of a perirenal or infrahepatic IVC thrombus is best approached through a chevron incision. For very large tumors involving the upper pole of the kidney a thoracoabdominal incision may be used instead. Most often these lesions are resected without CPB.

The colon is reflected medially, and a Kocher maneuver is employed to mobilize the duodenum. A Bookwalter retractor is used for exposure. The caudate lobe of the liver can be exposed and a sweetheart retractor placed under it, taking caution to identify and safeguard the porta hepatis. Control of the IVC is obtained with limited manipulation to prevent embolization of tumor thrombus. Rummel tourniquets are placed above and below the thrombus and around the contralateral renal vein (see Figs. 54–103 and 54–104 on the Expert Consult website). The renal artery, associated lumbar and minor hepatic veins, as well as the contralateral renal vein are isolated and circumferentially dissected. One can sacrifice perforating veins to the caudate lobe of the liver, which permits the IVC to be separated from the caudate lobe and exposes several more centimeters of IVC (Novick, 2007).

The renal artery and the ureter are ligated and divided. The specimen is mobilized outside the Gerota fascia, leaving the renal vein as the sole attachment. Preoperative renal angioinfarction may produce an inflammatory response that precludes safe early mobilization of the renal artery. In this instance the authors defer ligation of the renal artery until the tumor thrombectomy has been completed.

Venous occlusion is obtained with the previously placed Rummel tourniquets. An alternative is to use a Satinsky clamp on the IVC and a bulldog vascular clamp on the contralateral renal vein (Novick, 2007). A longitudinal anterior cavotomy is made, and the thrombus is freed from the caval wall to the level of the renal vein ostium using a spatula and gentle manipulation. In most cases the thrombus is not attached to the wall of the cava. The IVC is gently flushed with heparinized saline and evaluated for residual fragments. The infrarenal clamp is released transiently to purge the system of debris and limit the risk of embolus. Alternatively the suprarenal clamp can be released while applying positive pulmonary pressure to flush the cava free of fragments. The cavotomy is closed with a continuous 4-0 polypropylene suture (Figs. 54–105 and 54–106 on the Expert Consult website). Radical nephrectomy is carried out after closure of the vena cava has been completed.

Whereas the senior author prefers to incise the anterior wall of the cava, an alternative is to open the anterior surface of the renal vein over the thrombus and extend the venotomy posteriorly with scissors (Fig. 54–107). With gentle downward traction the tumor thrombus is extracted from the cava through the venotomy, which is repaired as described previously.

Occasionally the tumor thrombus invades the wall of the IVC necessitating caval wall resection. The lumen can be safely narrowed by half and closed primarily. To maintain the lumen in larger resections the cava can be reconstructed with PTFE or a pericardial graft in cases in which the chest is opened (Sarkar et al, 1998) (Fig. 54–108). When necessary, a segment of IVC can be excised without reconstruction. Resection of the infrarenal vena cava is usually safe and relies on the extensive venous collateral network that develops in the setting of tumor thrombus, particularly through the lumbar drainage system. **In right radical nephrectomy with tumor thrombectomy the suprarenal vena cava can be resected, but only if the left renal vein has been ligated distal to its venous tributaries (i.e., gonadal, lumbar, and adrenal veins). These veins then provide venous drainage from the left kidney. Given the lack of venous tributaries on the right side the**

Table 54–12.
Classification of Venous Tumor Thrombus Extension

LEVEL	DISTAL EXTENT OF THROMBUS
I	Limited to renal vein
II	Infrahepatic inferior vena cava
III	Retrohepatic inferior vena cava in proximity to renal veins
IV	Supradiaphragmatic inferior vena cava or right atrium

suprarenal vena cava should not be resected for a left-sided tumor unless one provides alternative venous drainage for the right kidney with autotransplantation or a saphenous vein graft to the splenic, portal, or inferior mesenteric vein.

Bland tumor thrombus completely occluding the cava can be managed with staple interruption to limit the risk of pulmonary embolism. Resection or ligation of the IVC should be prefaced by efforts to preserve the integrity of the lumbar drainage system.

Intrahepatic and Suprahepatic Tumor Thrombus (Levels III and IV). The literature supports extirpative surgery for these tumors provided patients have a decent Eastern Cooperative Oncology Group (ECOG) performance status score and that there is not extensive locoregional invasion or metastatic disease (Staehler and Brkovic, 2000; Ficarra et al, 2001; Parekh et al, 2005; Blute et al, 2007; Klatte et al, 2007; Terakawa et al, 2007). **Radical nephrectomy with excision of an intrahepatic or suprahepatic IVC thrombus is a challenging procedure requiring special techniques including CPB owing to the difficulty of obtaining vascular control above the tumor thrombus.** Using traditional or minimally invasive bypass, which was pioneered at the Lahey Clinic, safe resection with excellent oncologic outcome is possible (Cummings et al, 1979; Foster et al, 1988; Skinner et al, 1989; Novick et al, 1990b; Burt, 1991; Fitzgerald et al, 1998; Ciancio et al, 2002; Wotkowicz et al, 2006).

Conventional Circulatory Bypass. Transesophageal echocardiography is performed after induction of anesthesia to assess the distal extent of the thrombus. **In general, the authors recommend CPB with deep hypothermic circulatory arrest for a thrombus within 2 cm of the hepatic veins and cephalad** (Shahian et al, 1990). After a chevron incision is made the abdomen is evaluated for evidence of metastatic disease. Once respectability has been confirmed a median sternotomy is made (Fig. 54–109). The duodenum is kocherized. A Langenbeck maneuver, in which the right triangular and coronary ligaments of the liver are divided, is performed. This permits the right lobe of the liver to be rotated medially and cephalad, which exposes the retrohepatic IVC up to the diaphragm (Figs. 54–110 to 54–112).

The kidney is completely mobilized outside the Gerota fascia, with minimal traction to prevent embolism of the tumor thrombus. The gonadal vein and ureter are taken with Hem-o-Lok clips or 0 silk ties. The superior pole and adrenal are mobilized in a routine fashion along with the associated phrenic vessels. The last portion of dissection is the hilum. As stated earlier, isolating the

renal artery from the posterior approach is recommended especially for left-sided tumors, given the risk of injury to the superior mesenteric artery. The main renal artery should be palpated in patients who had preoperative angioinfarction. If a pulse is present, the artery should be treated as unoccluded. The renal artery is taken with two large Hem-o-Lok clips and 0 silk suture ligatures, leaving the renal vein as the sole attachment (see Fig. 54–113 on the Expert Consult website). Few cases proceed in as straightforward a manner as described, because inflammation may make anatomic planes challenging to discern and the venous collateral vessels may be daunting.

The infrarenal vena cava and contralateral renal vein are exposed. The dissection is extended inferiorly to the bifurcation

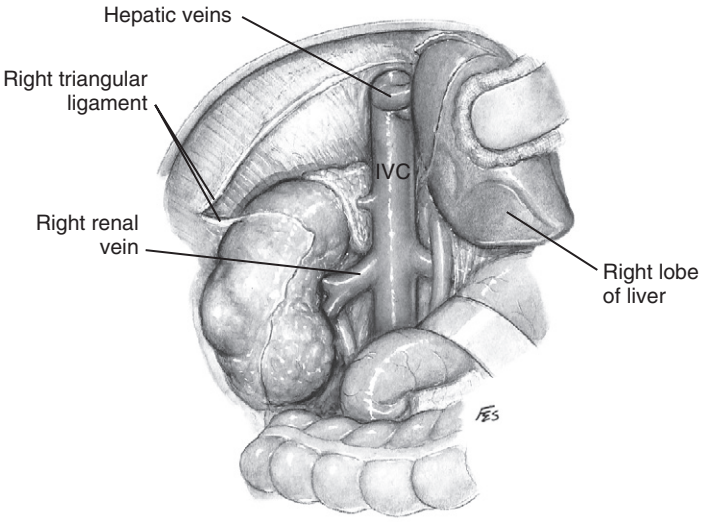

Figure 54–112. Access to vena cava by the Langenbeck maneuver. IVC, inferior vena cava. (© The Lahey Clinic.)

of the common iliac veins when bland or tumor thrombus extends there. Meticulous hemostasis is obtained before heparinization and initiation of CPB.

The patient is heparinized. The aortic arch and superior vena cava are cannulated. CPB is initiated (Fig. 54–114). A right atriotomy provides distal control of the tumor thrombus, which minimizes the risk of embolization. When the heart fibrillates, the aorta is clamped and crystalloid cardioplegic solution is infused. Inflow blood temperature is reduced as low as 10° C, resulting in deep hypothermia. The head and abdomen are packed in ice. After 15 to 30 minutes, a core temperature of 18° C to 20° C is achieved. Flow through the perfusion machine is stopped. Approximately 95% of the blood volume is drained into the pump, leaving no flow to any organ. Hypothermic circulatory arrest can be maintained for at least 40 minutes without incurring a cerebral ischemic event (Svensson et al, 1993). This interval can be extended by maintenance of "trickle" blood flow at a rate of 5 to 10 mL/kg/min (Mault et al, 1993) or by adjunctive retrograde cerebral perfusion (Pagano et al, 1995).

An anterior cavotomy is made using Potts forward and reverse scissors. The cavotomy should circumscribe the ostium of the renal vein and extend to the minor hepatic veins above the caudate lobe of the liver. The field will be nearly bloodless. For tumor extending into the right atrium the atrium is also opened (Fig. 54–115). The thrombus is extracted with the patient in Trendelenburg position and using positive-pressure respiration. If possible, the tumor thrombus is removed intact along with the kidney, although the thrombus may need to be removed in pieces if it is friable or adherent to the caval wall (Fig. 54–116). When necessary, a Fogarty catheter is passed from the atrium into the hepatic veins to retrieve portions of tumor thrombus. The authors ensure that tumor thrombus removal is complete by performing venacavoscopy with a flexible cystoscope. The cavotomy is closed with a double-armed 4-0 polypropylene running suture. The atriotomy is closed. Radical nephrectomy is carried out while rewarming to 37° C and coming off bypass. The patient is decannulated. Protamine is administered to reverse the heparin. Any leaking areas on the IVC are repaired with interrupted 4-0 polypropylene sutures. The abdomen is drained, and chest tubes are placed. Fresh frozen plasma, platelets, and desmopressin are used if needed to treat coagulopathy.

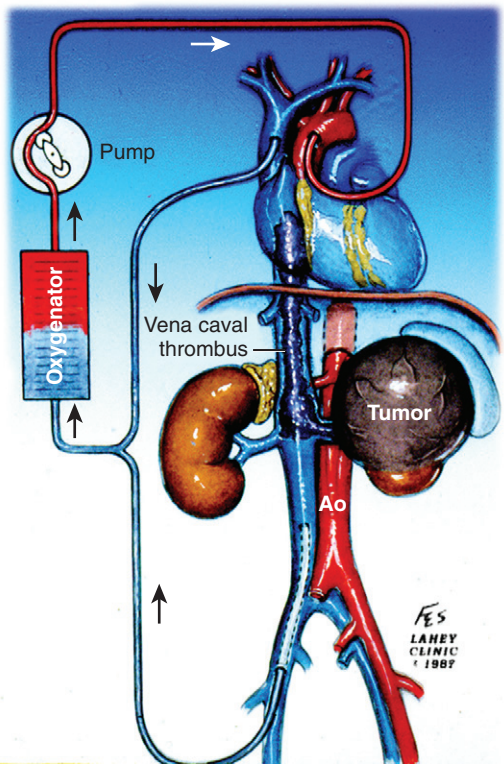

Figure 54–114. Traditional median sternotomy approach with cannulation of the aortic arch, superior vena cava, and right femoral vein for cardiopulmonary bypass. Ao, aorta. (© The Lahey Clinic.)

Minimally Invasive Cardiopulmonary Bypass. Since 1998, the authors have used a minimally invasive approach to CPB originally developed for aortic valve replacement (Fig. 54–117; see Figs. 54–118 to 54–126 on the Expert Consult website) (Cosgrove and Sabik, 1996; Fitzgerald et al, 1998). Unlike the traditional approach the kidney is not mobilized as extensively before heparinization and bypass. A chevron incision is used. The colon is mobilized, and the IVC is exposed using the Kocher and Langenbeck maneuvers.

The right subclavian artery is mobilized via an infraclavicular incision followed by a 2-inch right parasternal incision at the heads of the third and fourth ribs with resection of the rib cartilage and ligation of the right internal thoracic artery. Periosteum, muscles, and pleura are preserved for closure. The right pericardium is opened, exposing the superior vena cava and right atrium, and a Finochietto retractor is placed. Systemic heparinization is initiated as an 8-mm synthetic graft is sewn to the right subclavian artery for arterial return, while a two-stage venous cannula is positioned into the right atrium for venous outflow. CPB and circulatory arrest are initiated, and the patient is cooled. A right atriotomy is made to gain distal control of the thrombus and prevent passage into the pulmonary circulation. Tumor thrombus is removed from the cava, and a gauze pad is passed through the cava to the cardiothoracic team for removal of any loose debris (see Fig. 54–125 on the Expert Consult website). The remainder of the operation proceeds as described previously for a traditional median sternotomy.

Alternatives to Cardiopulmonary Bypass

VENOVENOUS BYPASS. **Patients with nonadherent supradiaphragmatic tumor thrombi that do not extend into**

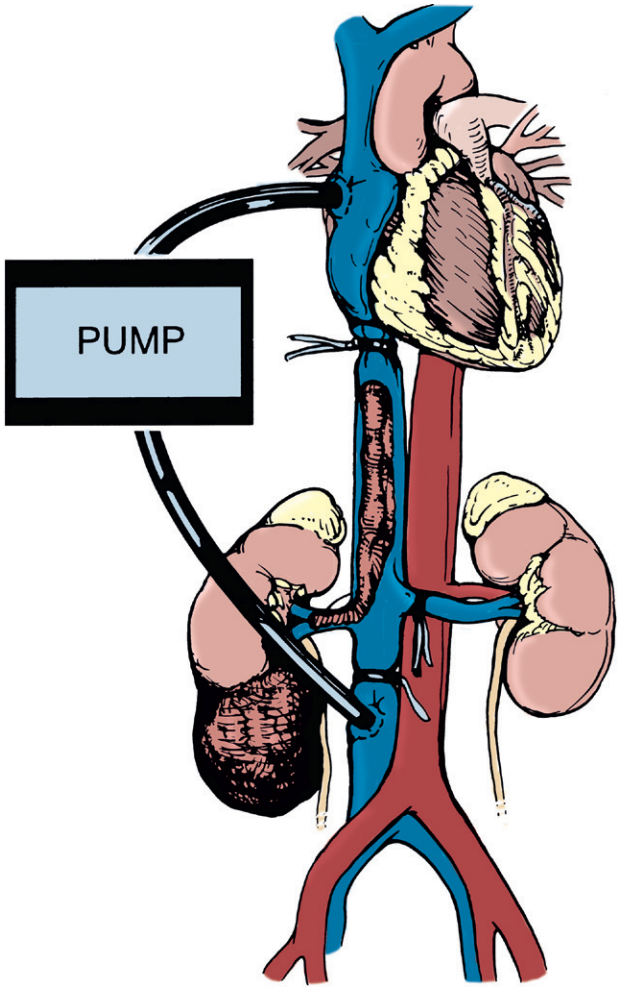

Figure 54–127. Technique of venovenous bypass for removal of supradiaphragmatic vena caval tumor thrombus.

the right atrium can be managed with venovenous bypass using a caval-atrial shunt (Foster et al, 1988; Burt, 1991). The intrapericardial vena cava, infrarenal vena cava, and contralateral renal vein are temporarily occluded. Cannulae are inserted into the right atrium or axillary vein and the femoral veins or infrarenal vena cava. Bypass is initiated using a primed pump to maintain flow to the right side of the heart (Fig. 54–127). This avoids the decline in cardiac output due to the reduced preload associated with occlusion of the intrapericardial and infrarenal vena cava. The cavotomy is made and the thrombectomy performed. **Bleeding from the hepatic venous system, which can be brisk, is managed with a Pringle maneuver, cross clamping the hepatic veins, or both.** Bleeding from the lumbar veins, which originates from the uncontrolled azygous and hemiazygous systems, is difficult to control and is a major downside of this technique. The cava is repaired and the nephrectomy performed as previously described. This technique helps to avoid some of the complexities of CPB with deep hypothermic circulatory arrest, albeit at the risk of hepatic venous bleeding.

EXTENSIVE LIVER MOBILIZATION AND OTHER TECHNIQUES. Extensive liver mobilization, employed for decades at the Lahey Clinic, is another approach to avoid CPB (see Fig. 54–128 on the Expert Consult website) (Libertino, 1987; Ciancio et al, 2007). The liver is mobilized to the left after the division of the ligamentum teres, falciform ligament, triangular ligament, and superior coronary ligament of the liver. This provides excellent access to the retrohepatic portion of the vena cava, leaving on the major hepatic veins in continuity after a Pringle maneuver is performed. The surgeon palpates and milks the tumor thrombus caudally to the level of the hepatic veins, and a standard cavotomy is performed.

D'Ancona and associates (2005) describe the removal of a suprarenal tumor thrombus using extracorporeal circulation and deep hypothermic arrest without violation of the thoracic cavity. After exposure of the vena cava the liver is retracted inferiorly to expose the pericardium at the level of the diaphragm. A pericardial window permits cardiac defibrillation. Extracorporeal circulation is established via the right femoral artery, right femoral vein, and subclavian vein. Core hypothermia to 20° C is achieved before circulatory arrest is begun. Infrahepatic and suprahepatic longitudinal incisions provide access for thrombus removal.

Chowdhury and associates (2007) discuss another alternative for intra-atrial tumor thrombus utilizing CPB, mild hypothermia, and an intermittent cross clamping of the supraceliac aorta to avoid the risks associated with circulatory arrest.

Outcomes. The incidence of complications in treating tumors of this magnitude has decreased with refinements in surgical techniques, intraoperative monitoring, and postoperative critical care (Boorjian et al, 2007; Wotkowicz and Libertino, 2007). Prolonged pulmonary support and renal replacement therapy may be necessary. The authors' minimal access technique, used in more than 30 patients, avoids median sternotomy with equivalent oncology outcomes. Eliminating the median sternotomy reduces the dose of postoperative analgesics, avoids reoperative sternotomy in patients with a prior coronary artery bypass, and results in a shorter operative time, shorter hospital stays, and decreased transfusion and mechanical ventilatory support (Wotkowicz et al, 2006).

Cytoreductive Nephrectomy and Metastasectomy

Palliative nephrectomy is often performed for tumors that are very large with significant extrarenal disease in an effort to decrease

Key Points: Venous Extension and Tumor Thrombectomy

- Renal cell carcinoma is associated with venous tumor thrombus in 4% to 10% of cases. In the absence of metastases an aggressive surgical approach with curative intent is justified.
- In patients with known IVC tumor thrombus, intraoperative transesophageal echocardiography can be done to evaluate the distal extent of the tumor thrombus before making an incision.
- When CPB with deep hypothermic circulatory arrest is anticipated, surgeons at some institutions will also perform preoperative coronary angiography. Coronary lesions can be repaired concurrently during CPB.
- When reconstructing the IVC the lumen can be safely narrowed by half and closed primarily. To maintain the lumen in larger resections the cava can be reconstructed with a pericardial graft or PTFE.
- When performing right radical nephrectomy with tumor thrombectomy the suprarenal vena cava can be resected, but only if the left renal vein has been ligated distal to its venous tributaries (i.e., gonadal, lumbar, and adrenal veins).
- Given the lack of venous tributaries on the right side, the suprarenal vena cava should not be resected for a left-sided tumor unless one provides alternative venous drainage for the right kidney with autotransplantation or a saphenous vein graft to the splenic, portal, or inferior mesenteric vein.
- Radical nephrectomy with excision of an intrahepatic or suprahepatic IVC thrombus is a challenging procedure requiring special techniques, including CPB, owing to the difficulty of obtaining vascular control above the tumor thrombus. CPB with deep hypothermic circulatory arrest is recommended for a thrombus within 2 cm of the hepatic veins and cephalad.
- The Lahey minimally invasive approach to CPB eliminates the median sternotomy, reduces the dose of postoperative analgesics, avoids reoperative sternotomy in patients with a prior coronary artery bypass, and results in a shorter operative time, shorter hospital stays, and decreased transfusion and mechanical ventilatory support.
- Alternatives to CPB may include venovenous bypass and extensive liver mobilization.

symptoms. In contrast, cytoreductive nephrectomy is performed with the goal of improving cancer outcome. A combined analysis of two trials (Southwest Oncology Group S8949 and EORTC 30947) elucidated the benefits of cytoreductive nephrectomy and revealed a survival benefit for interferon-alfa combined with nephrectomy versus interferon alone (Lara et al, 2009; Mickisch et al, 2001). Additional studies show potential for cytoreductive nephrectomy in combination with tyrosine kinase inhibitors (sunitinib [Sutent] and sorafenib) (Thomas et al, 2009). Analyses indicate that excellent preoperative performance status (ECOG 0 to 1 or Karnofsky performance status <80) and lung-only metastatic disease are good prognostic variables (Tables 54–13 and 54–14). Proponents of cytoreductive therapy cite anecdotal cases of spontaneous metastasis resolution, referred to as the Lazarus effect. A reduction in angiogenesis and growth factors after nephrectomy may enhance the efficacy of systemic immunotherapy compared with immunotherapy without prior cytoreductive nephrectomy. Unresectable lung lesions can serve as markers for chemotherapy efficacy and may be resected if their volume decreases significantly. In the authors' experience the presence of disease outside the chest and poor performance status are contraindications for surgical intervention, unless for pure palliative purposes such as with intractable edema, ascites, cardiac dysfunction, associated pain, or hematuria.

First described by Barney and Churchill in 1939, the resection of pulmonary metastasis remains an effective treatment for select patients. Utilizing a thoracoabdominal approach for the radical

Eastern Cooperative Oncology Group (ECOG) Status

GRADE	ECOG
0	Fully active, able to carry on all pre-disease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature (e.g., light housework and office work)
2	Ambulatory and capable of all self care but unable to carry out any work activities Up and about more than 50% of waking hours
3	Capable of only limited self care Confined to bed or chair more than 50% of waking hours
4	Completely disabled Cannot perform any self care Totally confined to bed or chair
5	Dead

Table 54–14.

Karnofsky Performance Score

SCORE	DESCRIPTION
100	Normal no complaints; no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or to do active work
60	Requires occasional assistance but is able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospital admission is indicated although death not imminent
20	Very sick; hospital admission necessary; active supportive treatment necessary
10	Moribund, fatal processes progressing rapidly
0	Dead
Ranges	
80-100	Able to carry on normal activity and to work. No special care needed
50-70	Unable to work. Able to live at home and care for most personal needs
0-40	Unable to care for self. Requires institutional or hospital care

nephrectomy and metastasectomy, the authors resect anterior lower lobe lesions using Doyle clamps and endovascular staplers. Favorable prognostic factors for isolated pulmonary metastasis include preoperative performance status, completeness of resection, number of lesions (less than six), limited lymph node involvement, and disease-free interval. Properly selected patients may have 5-year survival rates exceeding 50% (Hofmann et al, 2005). Metastasectomy in nonpulmonary sites such as the liver and brain are controversial and should be considered investigational. Preoperative imaging using biologic markers, such as monoclonal antibodies to carbonic anhydrase IX, may better help to identify occult metastatic disease and better stratify these patients with complex disease (Divgi et al, 2007) (Fig. 54–129).

Partial Nephrectomy for Malignant Disease

From its 19th century roots, nephron-sparing surgery has emerged as a sophisticated and continually ground-breaking component of contemporary open renal surgery. Partial nephrectomy is a demanding endeavor that involves complete resection of a tumor with a negative margin, with maximal preservation of functioning renal parenchyma. Although radical nephrectomy is oncologically sound, technically straight forward, and boasts a favorable perioperative complication rate, the more challenging nephron-sparing approach is indicated in a growing number of patients.

Indications

Traditionally, the treatment of choice for renal cortical tumors was radical nephrectomy. Partial nephrectomy was reserved for patients in whom radical nephrectomy would result in dependence on dialysis, such as those patients with a solitary kidney, bilateral or familial renal tumors, or chronic renal insufficiency. In recent years, indications for nephron-sparing surgery have broadened. **Partial nephrectomy has supplanted radical nephrectomy as the treatment of choice for T1 renal tumors when feasible, even in the absence of identifiable renal insufficiency or threat** (Russo et al, 2002; Russo and Huang, 2008). Partial nephrectomy provides the same long-term oncologic results as radical nephrectomy for tumors of 7 cm or less (Fergany et al, 2000; Russo et al, 2002; Dash et al, 2006; Pahernik et al, 2008).

For tumors other than T1, partial nephrectomy may be indicated in patients with a contralateral kidney that is threatened by stone disease, chronic infection, renovascular disease, vesicoureteral reflux, or systemic diseases that threaten renal function such as hypertension or diabetes mellitus (Licht et al, 1994). In recent years, the adverse consequences of chronic renal insufficiency, even in the absence of dialysis, have become clear. Urologists are increasingly aware of the importance of preservation of renal function. The literature does not support partial nephrectomy for patients with a tumor that is T2 or higher with a normal contralateral kidney.

Contraindications to open partial nephrectomy include lymph node metastasis because the prognosis for these patients is poor. Biopsy of enlarged or suspicious-looking lymph nodes should be done before the renal resection is initiated. For renal cortical tumors in a solitary kidney with venous extension, partial nephrectomy with tumor thrombectomy may be feasible, but this remains investigational (Tollefson et al, 2005).

Nephron-Sparing Surgery and the Adverse Effects of Renal Insufficiency

In the past, partial nephrectomy was not thought to be necessary in patients with a normal contralateral kidney, owing to a mistaken belief that patients with a normal contralateral kidney would suffer no ill effect from radical nephrectomy. This idea dates back to the 19th century. In 1869, Simon performed the first nephrectomy in a human for a benign condition (Simon, 1870). He did so only after first removing a kidney in 30 dogs, thereby demonstrating that survival with a solitary kidney is possible. Nevertheless, 140 years later, it is apparent that the deficit in glomerular filtration due to radical nephrectomy can have far-reaching negative consequences.

The majority of patients with renal cortical tumors have unrecognized comorbid medicorenal disease. In a pathologic review of radical nephrectomy specimens, only 10% of specimens had normal renal parenchyma adjacent to the tumor (Bijol et al, 2006). More than 60% of patients had pathologic evidence of medicorenal disease and nearly 30% had demonstrable renal arteriosclerosis. In a study from Memorial Sloan-Kettering Cancer Center, 26% of patients with renal cortical tumors who underwent surgery had a preoperative estimated GFR less than 60 mL/min/1.73 m^2 despite having two apparently normal kidneys and a serum creatinine concentration in the normal range (Huang et al, 2006).

In comparison to partial nephrectomy, radical nephrectomy is associated with a higher risk of postoperative renal insufficiency (Lau et al, 2000; McKiernan et al, 2002). In a retrospective study from Memorial Sloan-Kettering Cancer Center regarding patients with a renal cortical tumor 4 cm or smaller, normal preoperative serum creatinine concentration,

and two intact kidneys, radical nephrectomy was an independent risk factor for new onset of chronic kidney disease. The 3-year probability of freedom from new onset of GFR less than 60 mL/min/1.73 m^2 was 80% after partial nephrectomy but only 35% after radical nephrectomy ($P < .01$) (Huang et al, 2006).

There is a dose-response association between chronic kidney disease and hospitalizations, cardiovascular events, and death (Go et al, 2004). **Recent efforts have demonstrated that radical nephrectomy may be associated with increased cardiovascular events and decreased survival.** A study combining Surveillance, Epidemiology and End Results (SEER) cancer registry data with Medicare claims demonstrated that radical nephrectomy, in comparison to partial nephrectomy, is associated with a higher risk of overall mortality (HR 1.38, $P < .01$) and a 1.4-fold higher number of cardiovascular events ($P < .05$) (Huang et al, 2009). For patients younger than 65 years old with single unilateral renal cortical tumors measuring 4 cm or less with a normal contralateral kidney, data from the Mayo Clinic suggests that radical nephrectomy is associated with decreased overall survival in comparison to partial nephrectomy (response rate [RR] = 2.16; $P = .02$) (Thompson et al, 2008).

Partial Nephrectomy is Underutilized

Despite the growing number of small renal masses and ample evidence in favor of the oncologic efficacy of partial nephrectomy for T1 tumors and the potential adverse impact of radical nephrectomy, a large percentage of tumors amenable to partial nephrectomy are still removed with radical surgery (Nuttall et al, 2005; Hollenbeck et al, 2006). In a study from a tertiary care center, more than 70% of renal cortical tumors smaller than 4 cm were treated by laparoscopic radical nephrectomy in 2002 (Scherr et al, 2003). In a nationwide sample from 1988 to 2002, partial nephrectomy comprised fewer than 8% of operations for renal tumors (Hollenbeck et al, 2006). In another sample, only 20% of renal cortical tumors measuring 2 to 4 cm were treated with partial nephrectomy (Miller et al, 2006). The desire to use a minimally invasive modality may be contributing to excessive use of radical surgery (Scherr et al, 2003). This imbalance needs to be rectified.

Open Partial Nephrectomy: An Increasingly Challenging Endeavor

Because the majority of renal cortical lesions are now discovered incidentally on cross-sectional imaging, tumors of 4 cm or less now make up the principal share of newly diagnosed masses (Nguyen et al, 2006). Despite this general trend, in the senior author's experience the lesions referred for open partial nephrectomy have become more complex. Lesions managed with open partial nephrectomy at the Lahey Clinic are now larger, more often hilar, more central, deeper, and involve the collecting system to a greater degree than in the past. This observation is consistent with experience at other tertiary care centers. When compared with the era before laparoscopy, tumors undergoing open partial nephrectomy in the laparoscopic era at the Cleveland Clinic are more often in a solitary kidney (40.0% vs. 15.6%), centrally located (55.6% vs. 37.3%), and higher grade (Fuhrman 3 or 4) (43.1% vs. 27.8%, each $P < .01$) (Weight et al, 2008).

The increasing complexity of open partial nephrectomy is attributable, at least in part, to widespread adoption of minimally invasive techniques (e.g., laparoscopic radical and partial nephrectomy, cryoablation, and radiofrequency ablation) (Weight et al, 2008). In a multi-institutional comparison of 1800 open and laparoscopic partial nephrectomies, patients undergoing open partial nephrectomy had larger tumors, which were more centrally located and more often malignant. Patients undergoing open surgery were more often symptomatic at presentation and more frequently had impaired renal function, worse performance status, and solitary kidney (Gill et al, 2007).

New surgical techniques, which will be integrated into the technical descriptions in this chapter, have been adopted so the nephron-sparing approach can be applied to these increasingly complex masses with limited impact on renal function. Contemporary open partial nephrectomy is a cutting-edge operation that is rooted in powerful evidence favoring both oncologic efficacy and renal preservation.

Preoperative Evaluation and Preparation

Patients undergoing partial nephrectomy should have an extensive preoperative workup as described earlier in the chapter, including cardiac, pulmonary, and renal evaluation. Autologous blood donation should be offered to patients because perioperative blood transfusion may be necessary. A preoperative urine culture is mandatory. It is the practice of the senior author to treat bacteriuria, even if asymptomatic, before surgery. Urine should be sterile before partial nephrectomy given the risk of entry into the collecting system. Patients should be intravascularly fluid replete before surgery. Although it is no longer the authors' practice to admit patients for volume resuscitation on the day before partial nephrectomy, it is the belief of the senior author that patients benefit from vigorous intravenous hydration on the morning of surgery.

Before partial nephrectomy, evaluation of patients with renal cortical tumors should include imaging to identify locally extensive or metastatic disease. Preoperative imaging should also delineate relevant regional anatomy, intrarenal anatomy, and vasculature to minimize blood loss and damage to adjacent renal parenchyma. Invasive renal arteriography has largely been replaced by noninvasive 3D CT angiography, which offers excellent anatomic detail. 3D CT integrates information from arteriography, venography, excretory urography, and conventional two-dimensional CT into a single imaging modality (Fig. 54–130). In addition to tumor staging, 3D reconstructions of contrast-enhanced CT angiograms, MR images, or MR venograms are useful for planning site and extent of planned resection and to determine proximity to the renal hilum, intrarenal vasculature, and collecting system (Fig. 54–131). 3D CT accurately demonstrates involvement of the collecting system by tumor (Derweesh et al, 2003).

In general, the authors prefer not to administer an intravenous contrast load within 1 week of surgery. Appropriate precautions including oral *N*-acetylcysteine, vigorous hydration with normal saline, and use of low osmolality contrast agents should be taken in patients at risk of contrast nephropathy (Barrett and Parfrey, 2006). After administration of a contrast medium, renal function is reevaluated before partial nephrectomy to exclude contrast nephropathy.

Bilateral Tumors

Bilateral tumors represent a special circumstance that is considered a firm indication for nephron-sparing surgery. The simpler partial nephrectomy is performed first. A MAG3 renogram is used to document preservation of renal function in the postoperative kidney. Once the patient has fully recovered from the initial surgery, the more complicated partial or radical nephrectomy is performed on the contralateral kidney.

Fundamentals of Partial Nephrectomy

Open partial nephrectomy is a technically demanding procedure. **Although individual techniques may vary, the fundamental steps begin with the surgical approach, vascular control, and mobilization of the kidney. After complete excision of the tumor with maximal preservation of normal parenchyma and minimization of ischemic injury, renorrhaphy is completed. Renorrhaphy includes hemostasis, watertight closure of the collecting system, and repair of the renal defect.** The basic techniques are outlined here, followed by a more detailed discussion of the various types of partial nephrectomy.

Approach. Good functional exposure through a properly selected incision is essential to the success of the procedure. For partial nephrectomy the incision should be chosen to optimize exposure of the tumor, kidney, and renal pedicle. The authors most often employ an extrapleural, extraperitoneal supra-11th rib incision. The level of incision is determined by the position of the kidney in relation to the ribs as seen on preoperative radiographic studies and by the location and size of the tumor. The thoracoabdominal approach is useful in large or upper pole tumors. Partial nephrectomy can also be accomplished through an anterior subcostal incision, although this typically affords inferior exposure. The rib-resecting approach is not employed. In rare circumstances, extracorporeal partial nephrectomy with autotransplantation is necessary, in which case a supracostal 11th rib incision is used to harvest the kidney and a semilunar Gibson incision is used to autotransplant the kidney.

Figure 54–130. Three-dimensional CT reconstruction demonstrating hilar tumor and peripheral tumor.

Prompt Vascular Control and Mobilization of the Kidney. **With few exceptions, the first priority in partial nephrectomy is identification, dissection, and nonocclusive control of the renal artery and vein with vessel loops** (see Fig. 54–132 on the Expert Consult website). This protects the renal pedicle in the ensuing dissection and, in emergencies, permits the surgeon to rapidly occlude the renal artery to stop life-threatening hemorrhage. One may be able to safely resect small, peripheral renal tumors without first obtaining control of the main renal artery.

The ureter is identified and encircled with a vessel loop. Dissection of the ureter is carried superiorly to the renal pelvis, with special care to avoid devascularization. The uninvolved portion of the kidney is mobilized within the Gerota fascia, while the perirenal fat overlying the tumor is left undisturbed. The kidney must be adequately mobilized to permit resection of a renal tumor with negative margins and minimal injury to adjacent vasculature, parenchyma, and collecting system.

Fully Perfused Partial Nephrectomy: A New Model of Nephron Sparing. Although clamping of the renal artery and vein may reduce the technical difficulty of the procedure by providing a nearly bloodless field, this maneuver leads to renal ischemia that may adversely affect renal function (Thompson et al, 2007). At the Lahey Clinic, the senior author prefers to perform fully perfused partial nephrectomy.

Duration of renal ischemia is the strongest modifiable risk factor for renal insufficiency after partial nephrectomy (Lane et al, 2008). In patients with a solitary kidney, clamping is associated with greater risk of urine leak, renal failure, and

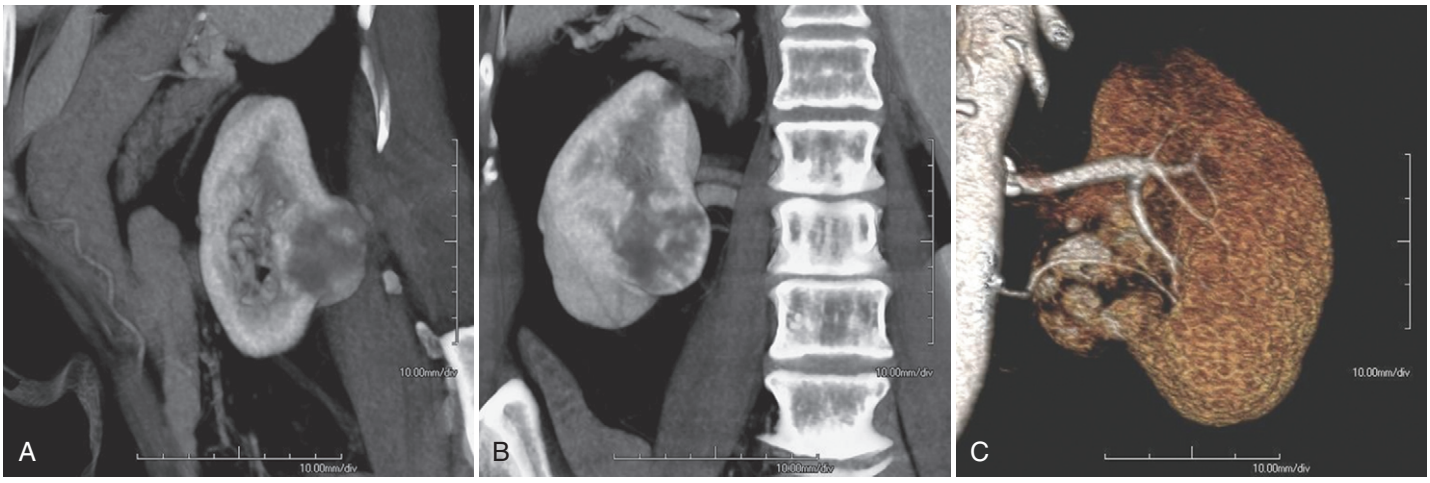

Figure 54–131. **A,** Contrast-enhanced CT scan demonstrating right renal mass. **B,** Three-dimensional reconstruction demonstrates a large intrarenal component to the mass. **C,** Arterial reconstruction shows lower pole renal artery in close proximity to the renal mass.

temporary dialysis (Thompson et al, 2007). The senior author considers clamping of the pedicle to be antithetical to the philosophy of nephron-sparing surgery. The authors perform the majority of open partial nephrectomies with the kidney fully perfused. In a retrospective review of 112 patients with a solitary kidney or preoperative renal dysfunction (serum creatinine concentration >1.5 mg/dL) who underwent partial nephrectomy by the senior author, only 18% required arterial clamping (Smith et al, 2008). **The fully perfused partial nephrectomy technique may result in excellent sparing of renal function.** The majority of patients had either no change in serum creatinine concentration (37%) or a less than a 50% change (46%). Others have advocated a similar approach when feasible (Russo and Huang, 2008).

In the nonclamping method, a vessel loop is placed around the renal artery after it has been mobilized but the vessels are never clamped or compressed. Although this nonclamping technique has frequently been coupled with enucleation, a method of excision characterized by minimal blood loss and trauma to surrounding parenchyma, the senior author has expanded nonclamping to more difficult tumors requiring complex resection. In a retrospective review of 273 patients at the Lahey Clinic who underwent fully perfused partial nephrectomy, 37% of tumors were 4 cm or smaller and 33% were hilar or central. There were multiple tumors in 17% of patients, and 26% of patients had a solitary kidney (Kurteva et al, 2008). The median estimated blood loss was 685 mL (mean 1100 mL). With fully perfused partial nephrectomy, the authors believe the risk of durable deficit in renal function is lowered, as demonstrated in patients with solitary kidneys or preoperative renal dysfunction, albeit at the cost of an increased risk of blood loss and a higher level of technical difficulty (Kurteva et al, 2008).

On rare occasions, some form of transient compression may be required to aid in tumor excision, pelvicalyceal suture repair, and hemostasis. Even in cases of brisk bleeding, the authors prefer not to clamp the main renal artery with instruments or tourniquets, given the threat of ischemia and the small but real risk of intimal damage, thrombosis, and loss of the kidney. It is often sufficient to have the assistant gently compress the renal parenchyma adjacent to the cut surface or use a Kitner to compress the bleeding vessel while the surgeon places shallow 4-0 monocryl figure-of-eight sutures into the transected vessels.

Traditional Partial Nephrectomy with Vascular Clamping. Although the authors have largely abandoned vascular clamping, partial nephrectomy has traditionally been performed with temporary occlusion of the main renal artery or a segmental artery supplying the tumor. Proposed benefits of clamping include limitation of intraoperative bleeding, improved visualization, and reduction in renal tissue turgor, which may improve access to intrarenal structures (Novick, 2007).

When clamping of the renal artery is required, in-situ renal hypothermia is used to protect against ischemic renal injury (Novick, 2007). Surface cooling of the kidney with ice slush allows up to 3 hours of safe ischemia without permanent renal injury. The entire kidney should be covered with ice slush for 10 to 15 minutes immediately after the renal artery is occluded and before the partial nephrectomy is begun (Fig. 54–133). This amount of time is needed to obtain core renal cooling to a temperature (approximately 20° C) that optimizes in-situ renal preservation. During excision of the tumor, invariably, large portions of the kidney are no longer covered with ice slush; and in the absence of adequate prior renal cooling, rapid rewarming and ischemic renal injury can occur. Cooling by perfusion of the kidney with a cold solution instilled through the renal artery is not recommended because of the theoretical risk of tumor dissemination. Mannitol is given intravenously 5 to 10 minutes before temporary renal arterial occlusion. Systemic or regional anticoagulation to prevent intrarenal vascular thrombosis is not necessary (Novick, 2007).

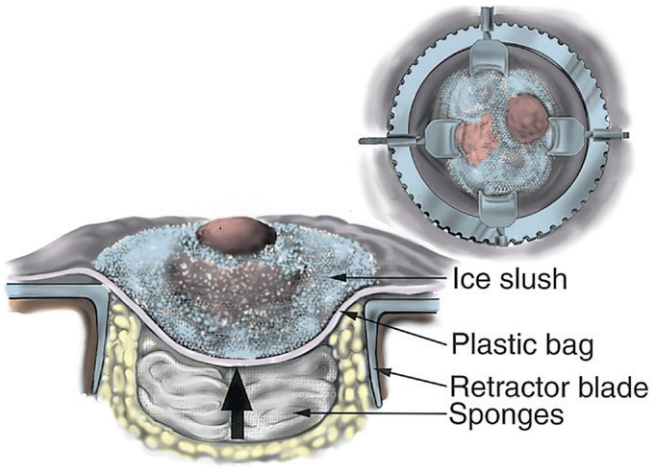

Figure 54–133. Elevation of the mobilized kidney to skin level is demonstrated by placement of sponges under the plastic bag containing the kidney and ice slush.

Even with the artery clamped it is preferable to leave the renal vein patent to reduce ischemia and permit identification of venous bleeding. When large veins are transected, such as in large centrally located tumors, some find it necessary to clamp the renal vein (Novick, 2007).

Tumor Excision. The goal of partial nephrectomy is complete excision of the tumor with negative margins and maximal preservation of benign adjacent parenchyma. Various techniques can be employed to remove the tumor, including enucleation, polar segmental nephrectomy, transverse resection, wedge resection, and extracorporeal partial nephrectomy with renal autotransplantation (see later for a detailed discussion). When performing partial nephrectomy for a suspected malignancy, the overlying renal capsule is not preserved for renorrhaphy but is excised along with the tumor.

Complete resection must be ensured in the operating room. Local recurrence may be due to incomplete resection of the primary lesion or synchronous lesions that were unrecognized at the time of surgery. Intraoperative ultrasonography is used to delineate tumor from normal parenchyma and may help localize intrarenal lesions that are not visible or palpable from the surface of the kidney (Assimos et al, 1991; Campbell et al, 1996) (see Fig. 54–134 on the Expert Consult website; see also Fig. 54–135). Intraoperative ultrasonography is especially useful in the patient with von Hippel-Lindau disease with multiple lesions. The tumor should be inked and cut by the pathologist to be certain that the capsule has not been violated. Intraoperative biopsies should be obtained from the tumor bed if the capsule has been violated. Frozen sections should be examined, and additional tissue should be excised if the frozen section reveals persistent tumor. The width of a tumor-free resection margin has no biologic or prognostic significance (Castilla et al, 2002).

Renorrhaphy: Hemostasis, Closure of the Collecting System, and Repair of the Renal Defect. After excision of the tumor the transected blood vessels on the renal surface are secured with figure-of-eight 4-0 monocryl sutures. The argon beam coagulator can be

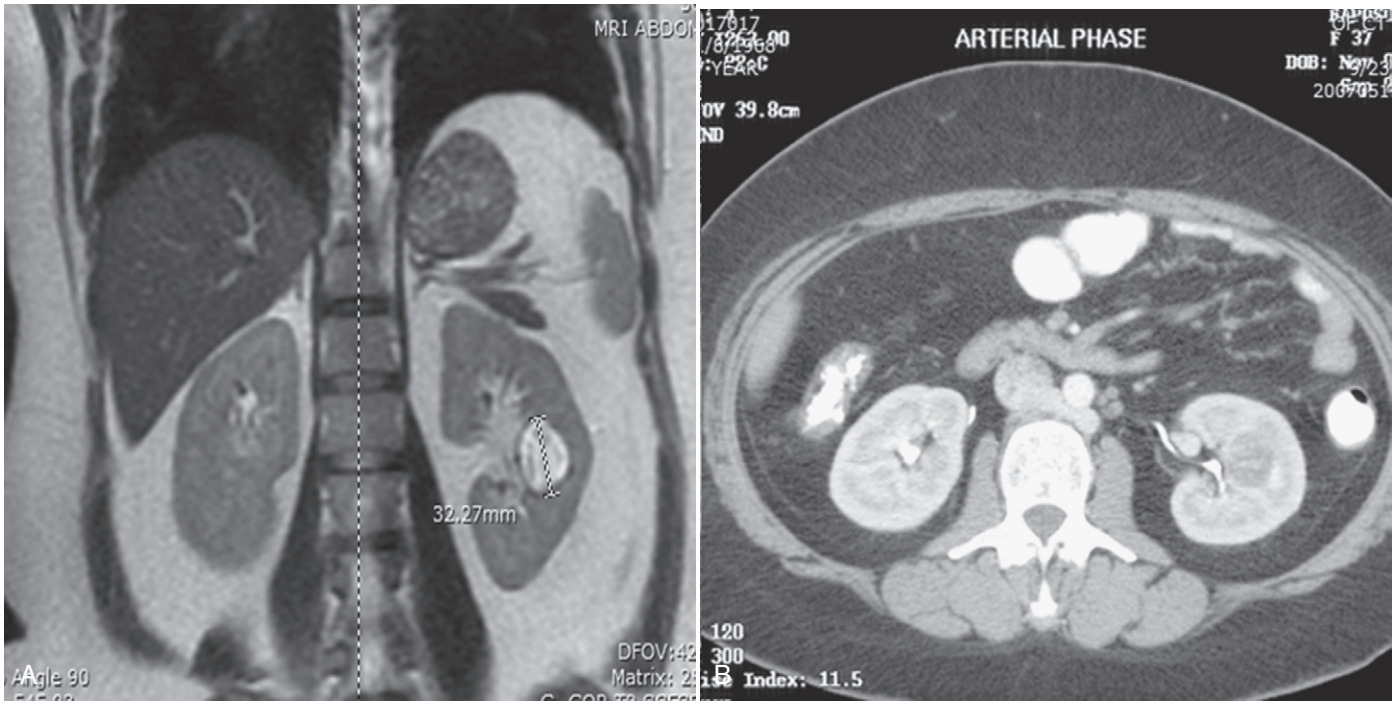

Figure 54–135. **A** and **B,** Preoperative MR and CT images show a left 3-cm enhancing hilar mass closely abutting the collecting system.

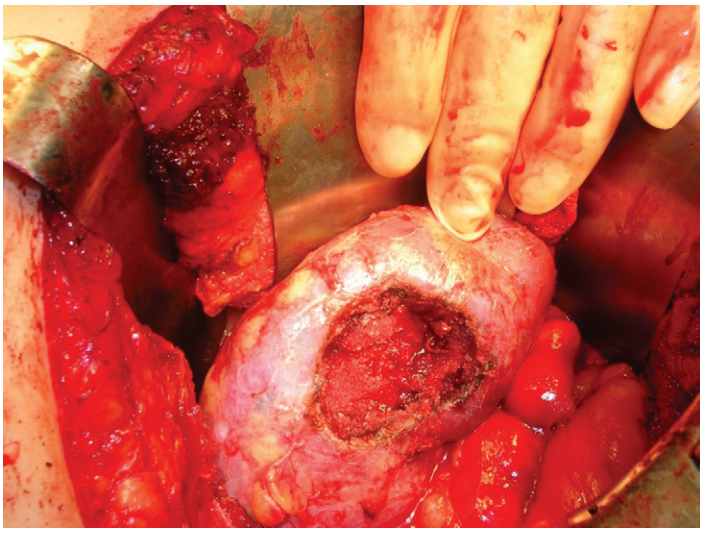

Figure 54–136. Floseal is used to provide hemostasis after removal of the tumor and to identify areas of collecting system leaks after intravenous administration of indigo carmine.

used to achieve hemostasis on the cut renal surface. At the Lahey Clinic, use of Floseal hemostatic matrix (Baxter International, Deerfield, IL) has obviated use of the argon beam coagulator, which can disrupt the figure-of-eight sutures or devitalize the collecting system (Fig. 54–136).

Collecting system defects can be identified by administration of methylene blue or indigo carmine, either intravascularly or directly into the renal pelvis, to dye the urine (see Fig. 54–137 on the Expert Consult website). The collecting system is closed with interrupted or running 4-0 monocryl suture. A ureteral stent can be placed in a retrograde fashion at the start of the procedure if significant repair of the intrarenal collecting system is anticipated. Alternatively, before repair of the collecting system, a wire can be placed antegrade into the bladder through the opening in the collecting system followed by a double-J stent (see Fig. 54–138 on the Expert Consult website).

After closure of the renal vasculature and collecting system, a hemostatic bolster composed of rolled Surgicel is placed at the base of the defect. Floseal hemostatic matrix is applied to the resection site around the bolster. The cortical edges are approximated over the bolster with simple, pledgeted interrupted 2-0 polyglactin sutures (Fig. 54–139; see Fig. 54–140 on the Expert Consult website). The suture line should be tension free, and the kidney should be reconstructed in such a way that the renal pedicle is not kinked. If the renal artery was clamped, circulation is restored after the renorrhaphy is complete. Nephropexy to the posterior musculature with interrupted 2-0 polydioxanone may prevent postoperative migration or rotation of the remnant kidney (Fig. 54–141). A retroperitoneal drain is externalized through a counter incision and is left in place approximately 1 week, or longer if it is draining urine.

Recently, the senior author has utilized an alternative method of approximating the cortical edges that is adapted from the laparoscopic technique. Interrupted 2-0 polyglactin sutures are used to approximate the cortical margins, which are secured in a novel, knotless fashion (see Fig. 54–142 on the Expert Consult website). The suture is secured at the first cortical surface with a Weck ligating clip (Pilling Weck Canada, L.P., Markham, ON, Canada), followed by a Lapra-Ty clip (Ethicon Endosurgery, Cincinnati, OH). A Weck clip is then placed on the suture where it exits the other cortical surface. It is cinched snugly into position, causing the cortical margins to come together, and secured with a second Lapra-Ty clip. This may permit tighter closure of the cortical margins than the traditional repair, provide good closure of parenchyma over the repaired collecting system, and eliminate the need for a bolster.

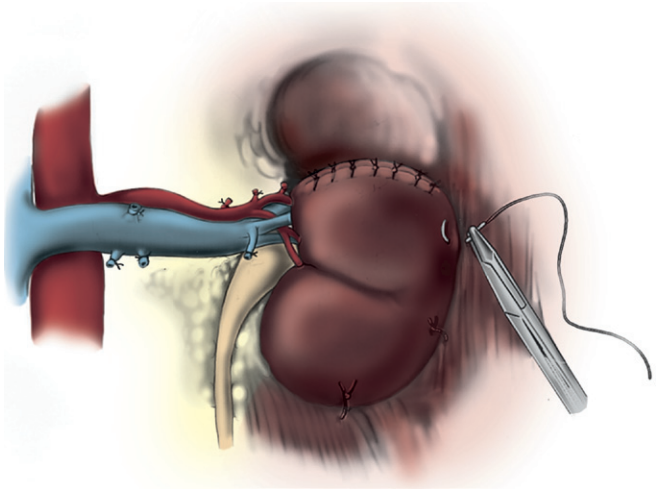

Figure 54–141. Nephropexy of the remnant kidney to the retroperitoneum is achieved with several interrupted sutures.

Techniques of Tumor Excision

Enucleation. Pure enucleation involves removing a renal tumor with blunt dissection along the natural plane provided by the tumor pseudocapsule. Although this technique is convenient and is associated with minimal blood loss, several studies have demonstrated that tumor may extend beyond the pseudocapsule and might therefore be left behind after a pure enucleation. For instance, an analysis of 82 radical nephrectomy specimens for tumors measuring less than 4 cm demonstrated that nearly 20% of specimens had tumor beyond the pseudocapsule, at a mean of 0.5 mm from the capsule. No cancer was found to extend beyond 5 mm, and fewer than 3% extended beyond 4 mm (Li et al, 2003). Other studies have also suggested a higher risk of leaving cancer in the kidney when pure enucleation is performed (Rosenthal et al, 1984; Marshall et al, 1986; Blackley et al, 1988). In response, some authors have advocated using pure enucleation followed by ablation of the tumor base with argon beam or laser energy, such as with the neodymium:yttrium-aluminum-garnet (Nd-YAG) laser, to destroy remaining tumor cells (Kutikov et al, 2008).

Given the risk of incomplete resection with pure enucleation, it is the practice of the senior author to enucleate tumors along with a thin rim of grossly normal renal parenchyma. It is a rapid, precise technique with the benefit of limited blood loss and excellent preservation of normal parenchyma. The kidney is approached and mobilized as described previously, leaving the perirenal fat overlying the tumor intact. The limits of the tumor are defined by palpation and ultrasonography. An incision is made in the renal capsule around the base of the tumor, using the coagulation setting of the Bovie device (see Fig. 54–143 on the Expert Consult website). The Bovie device is inserted into the cut renal capsule and the tumor is circumferentially inscribed. A small tenotomy scissor is used to divide the renal parenchyma. A Penfield spatula is used to retract the normal parenchyma from the specimen. Small vessels in the cortex are palpated with the Frazer pediatric suction device by gently moving it along the cut surface of the parenchyma. These vessels are then grasped with a delicate Gerald forceps, coagulated, and divided with the tenotomy scissors (see Fig. 54–144 on the Expert Consult website). Cautery should not be used deeper than the corticomedullary junction or near the collecting system because it will cause ischemic damage. Nonhealing of the collecting system due to cautery injury may result in a urinary fistula.

Closer to the base of the lesion the tumor is meticulously dissected with the surgeon's thumb protecting the specimen. Larger intrarenal vessels are clamped with pediatric right-angle clamps, divided, and ligated (see Fig. 54–145 on the Expert Consult website). Frozen sections are obtained to be certain that the margins are negative. If there is any question about the margin, additional tissue at the margins is resected and reevaluated. The specimen is inked, and the integrity of the capsule is determined. Floseal is applied to the cut surface of the kidney. In the absence of renal artery clamping, indigo carmine can be given intravenously (see Fig. 54–146 on the Expert Consult website). An opening in the collecting system is identified by the appearance of a blue dot on the surface of the Floseal, which is then closed with 4-0 monocryl suture (see Fig. 54–138). If possible, the renal parenchyma should be closed over the opening in the collecting system. Otherwise, perinephric fat or omentum can be used to cover the renal parenchymal defect. The perinephric fat is approximated over the kidney. This is accomplished without clamping the renal artery or manual compression of the parenchyma. A Penrose drain is externalized through a separate stab incision.

Deep-seated tumors can be resected using a similar approach. After the tumor is located with ultrasound, a Y-shaped incision is made in the parenchyma over the tumor. The incision is opened, and the tumor is dissected meticulously from the kidney using the techniques described earlier. The incision is then closed with absorbable suture (see Fig. 54–147 on the Expert Consult website).

Polar Nephrectomy. Polar nephrectomy is useful for tumors confined to the upper or lower pole of the kidney. The kidney is approached and mobilized as previously explained. The authors typically use a vessel loop to obtain nonocclusive control of the segmental artery supplying the tumor and perform the polar nephrectomy with the kidney fully perfused, as described earlier. The limits of the resection are determined by the tumor rather than by the territory supplied by the segmental apical or basilar artery. This technique permits resection of a polar tumor with a

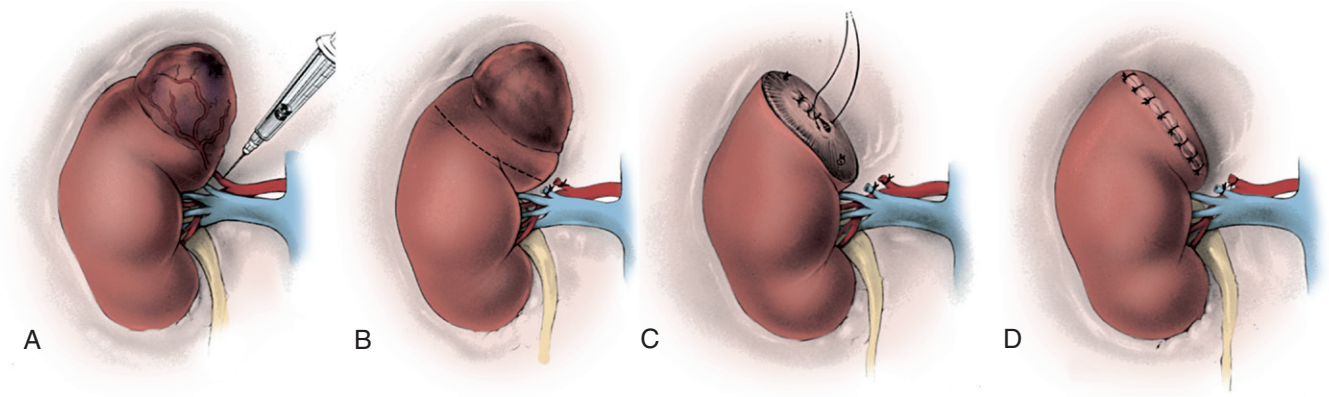

Figure 54–148. **A** to **D,** Technique of segmental (apical) polar nephrectomy with preliminary ligation of apical arterial and venous branches. (From Novick AC. Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

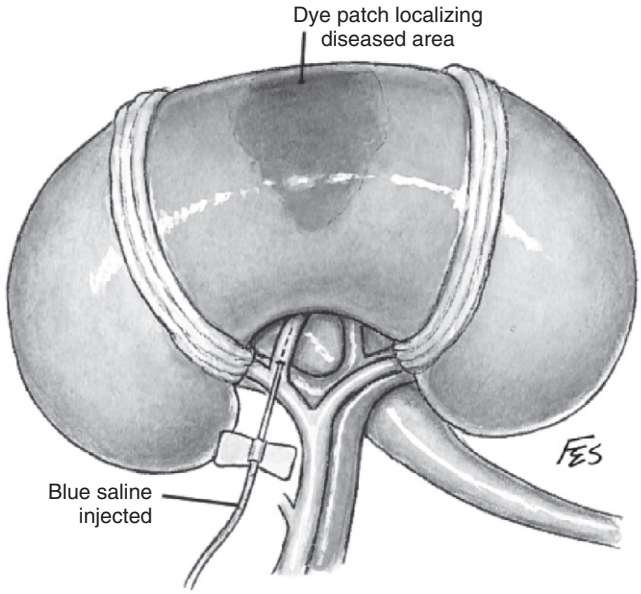

Figure 54–149. Identification of the small blood vessel, such as one that supplies part of the diseased parenchyma, is achieved by injecting a diluted solution of indigo carmine dye into the lumen with a scalpel vein needle and correlating the region stained with that seen angiographically. (© The Lahey Clinic.)

thin margin of normal parenchyma and preservation of uninvolved polar parenchyma.

A more traditional approach is to isolate, ligate, and divide the segmental apical or basilar artery, leaving the remainder of the kidney perfused (Fig. 54–148). The corresponding venous branch is also divided. A line marking the ischemic segment will appear. If this ischemic line is not apparent, injection of methylene blue into the distal aspect of the ligated artery will delineate the involved renal segment (Fig. 54–149). The renal cortex is incised at the line of ischemia, which should be at least several millimeters away from the visible edge of the tumor. Renal parenchyma is divided with a small tenotomy scissor. A neurosurgical spatula is used to provide exposure. Whereas renal parenchyma is easily divided, vessels and collecting system structures are sturdier and elastic. With careful technique, this difference can aid in identification of vessels and the collecting system structures before they are divided. By placing gentle tension on the polar segment to be excised, the gap between specimen and remnant kidney is enlarged, which helps identify larger blood vessels before they are transected. The polar segment is removed. Renorrhaphy with hemostasis, closure of the collecting system, and repair of the renal defect proceeds as described earlier. Surgicel is placed at the base of the defect. If the cortical margins cannot be approximated to each other, a hemostatic bolster is employed.

Knowledge of the renovascular anatomy is essential for polar nephrectomy. If the segmental artery supplying the tumor has been identified with a preoperative CT angiogram, it can be isolated and controlled with a minimal amount of dissection. Alternatively, one is obligated to dissect the main renal artery and identify the various branches. The main renal artery often enters the upper third of the kidney and branches downward to supply the rest of the kidney. In upper pole partial nephrectomy it is therefore possible to damage the main renal artery during tumor excision or occlude a segmental artery supplying the lower portion of the kidney during renorrhaphy.

Heminephrectomy. Heminephrectomy, also referred to as a transverse resection, is used to remove large tumors that extensively involve the upper or lower portion of the kidney (see Figs. 54–150 and 54–152 on the Expert Consult website; see also Fig. 54–151). It is the authors' preference to perform transverse resections without clamping to maintain perfusion to what will be the remnant parenchyma. The kidney is approached and mobilized as previously described. The main renal artery is isolated and surrounded with a vessel loop. With nonocclusive control of the renal artery the parenchyma is sharply divided, leaving several millimeters of grossly normal parenchyma around the tumor (Fig. 54–153). Transected vessels are controlled with shallow 4-0 monocryl figure-of-eight sutures. If needed, bleeding can be slowed transiently by gentle manual compression on the cut parenchyma of the kidney. For more severe bleeding the bleeding vessel can be compressed digitally or with a Kitner. Alternatively, Libertino clamps can be briefly applied until hemostasis has been obtained (Fig. 54–154). Renorrhaphy proceeds as previously described.

A more traditional approach is to perform a major transverse resection with arterial clamping and renal hypothermia. Before clamping the main renal artery, major branches of the renal artery and vein supplying the tumor-bearing portion of the kidney are identified in the renal hilum, ligated, and divided (Fig. 54–155). Renal artery clamping and tissue hypothermia are then obtained. Once adequate hypothermia has been obtained, the transverse resection proceeds as described previously.

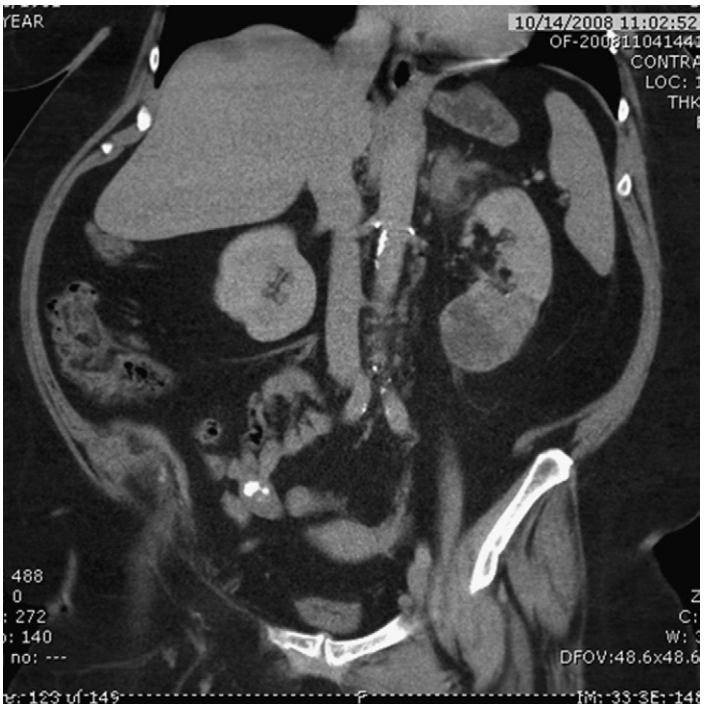

Figure 54–151. Left renal mess noted on CT scan.

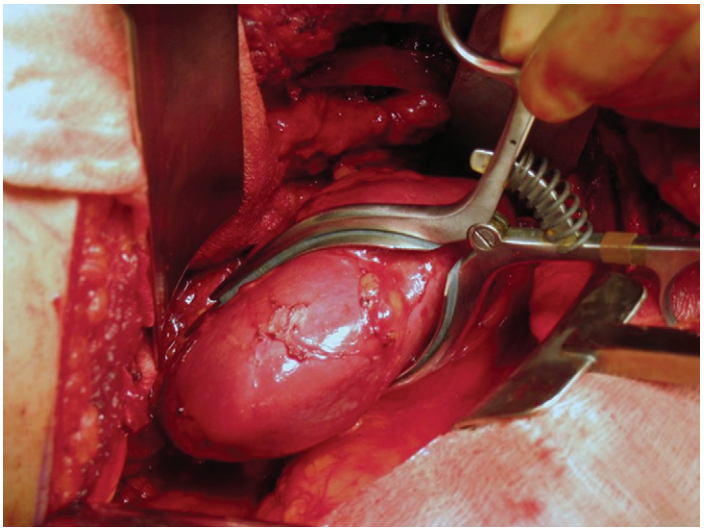

Figure 54–154. Large kidney clamps can be helpful for heminephrectomy and large polar masses.

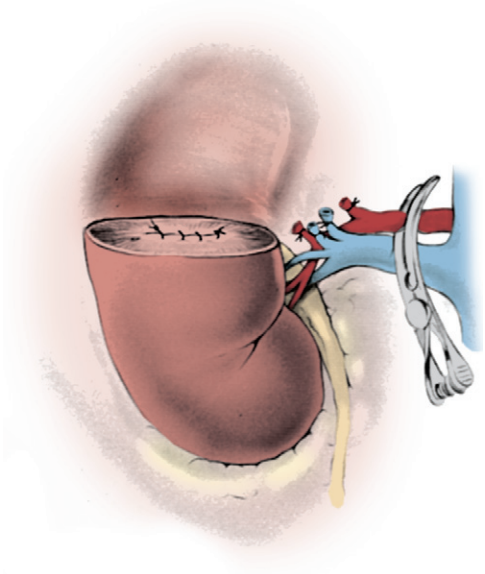

Figure 54–153. Technique of transverse resection for a tumor involving the upper half of the kidney. (From Novick AC. Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

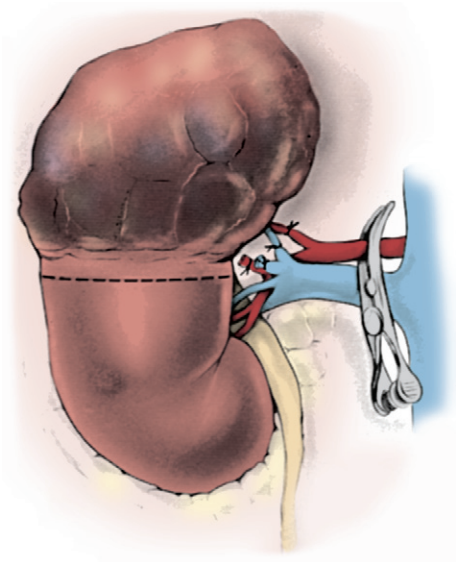

Figure 54–155. Technique of transverse resection for a tumor involving the upper half of the kidney. (From Novick AC: Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

The relevant renovascular anatomy should be identified on a preoperative CT angiogram. The posterior segmental renal artery can be injured during transverse resection. The basilar renal artery, which typically arises from the anterior segmental renal artery, may occasionally arise from the posterior segmental artery. In that case, injury to the posterior segmental artery would devascularize a major portion of the remnant kidney during an upper pole transverse resection (Fig. 54–156).

Midsegmental Partial Nephrectomy. Midsegmental partial nephrectomy is a complicated and rarely employed nephron-sparing technique that is utilized for predominantly endophytic

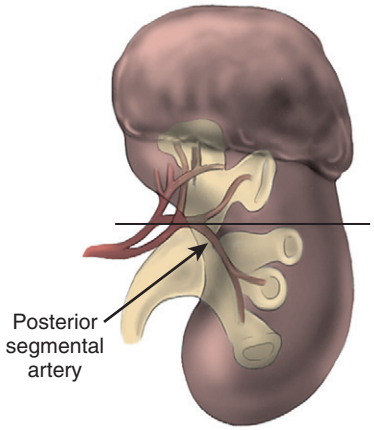

Figure 54–156. Injury to the posterior segmental renal arterial branch must be avoided.

interpolar tumors. The kidney is approached and mobilized as described. The hilar structures are dissected free from each other and cleaned of adherent fat. The arterial branches are carefully identified. Vessel loops or loose loops of silk are placed around the primary and secondary arterial branches supplying the segment of parenchyma to be removed. The secondary arterial branches are injected with a dilute solution of indigo carmine or methylene blue, which demarcates the territory supplied by the vessels. If the demarcated area includes the tumor with an acceptable margin, the appropriate segmental arteries are ligated. The corresponding veins are doubly tied and divided. The caliceal infundibulum draining the targeted tissue is transected and ligated.

The main renal artery is clamped and surface hypothermia is obtained as previously described. A fingertip is placed under the midparenchyma to protect the hilar vessels. With a scalpel, a central section of the kidney that includes the tumor and a clean margin is excised from the convex through to the concave surfaces of the kidney (Fig. 54–157). Hemostasis is obtained with figure-of-eight sutures of 4-0 monocryl. The collecting system is closed. No calyces of the remaining lower or upper pole should be left open. The clamp is removed from the main renal artery. The cut surfaces and hilar branches are checked for significant bleeding. The two poles are approximated with horizontal mattress sutures (Fig. 54–158). During renorrhaphy, one must ensure that the blood vessels supplying the remnant kidney are free of significant angulation or kinking.

Wedge Resection. Wedge resection can be employed to excise large tumors that are predominantly located on the surface of the kidney and that are not limited to the upper or lower pole. A wedge shape that contains the tumor along with several millimeters of grossly normal renal parenchyma is removed. Wedge resection is traditionally performed with clamping of the renal artery and surface hypothermia, although it is the authors' practice to avoid clamping whenever possible. The parenchyma is divided by a combination of sharp and blunt dissection, as previously described. The tumor is excised. The collecting system and vasculature are repaired as previously described.

Surgicel is placed at the base of the defect, which is then obliterated by closing the kidney on itself using simple interrupted 2-0 polyglactin sutures to approximate the cut cortical edges (Fig. 54–159). Alternatively, if closing the kidney would produce tension on the suture line or kinking of the blood supply, the base of the renal defect is covered with perirenal fat, which is sutured to the parenchymal margins with interrupted 4-0 monocryl sutures. The renal artery is then unclamped.

Central Tumors. Centrally located tumors present unique challenges for partial nephrectomy given their proximity to the hilum and the collecting system (see Fig. 54–160 on the Expert Consult website). The kidney is approached and mobilized as described. With central tumors extending into the renal hilum there may be no overlying perirenal fat to preserve. As mentioned previously, very deep-seated tumors can be resected without clamping by making a Y-shaped incision in the parenchyma overlying the tumor (see Figs. 54–147 and 54–161 on the Expert Consult website). The tumor and a thin rim of normal parenchyma is meticulously dissected and extracted from the kidney using the techniques described in the enucleation section. The incision is closed with absorbable suture.

A more conventional technique for tumors adjacent to the hilum is to perform partial nephrectomy with temporary occlusion of both the renal artery and vein using individual vascular clamps. Before clamping the main renal artery, segmental renal vessels adjacent to the tumor that supply the uninvolved portion of kidney are dissected away from the tumor and preserved. Because intrarenal venous branches freely anastomose, providing collateral venous drainage, one may divide small venous branches to access central tumors in the renal hilum without causing ischemia. In this way the main renal vein can be mobilized and

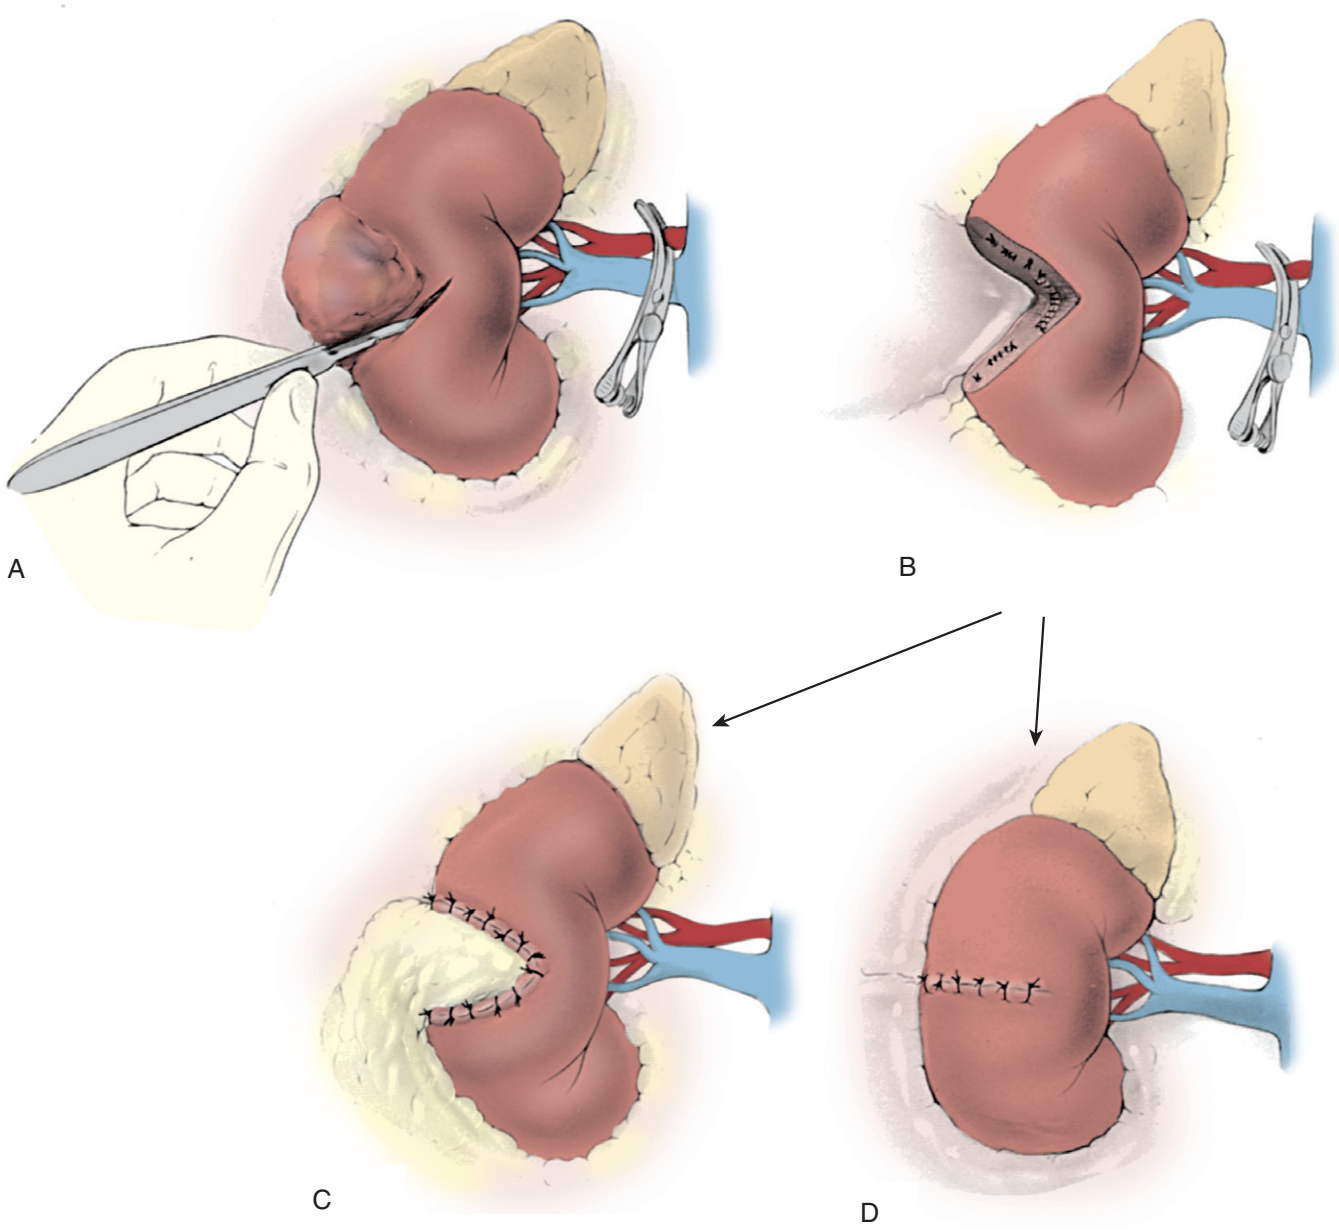

Figure 54–159. **A** to **D,** Technique of wedge resection for a peripheral tumor on the surface of the kidney. The renal defect may be closed on itself or covered with perirenal fat. (From Novick AC. Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

retracted in a fairly extensive fashion to expose a central tumor (Fig. 54–162). Segmental arterial branches that directly supply the tumor are divided. The renal artery and vein are clamped, and the kidney is cooled. The tumor is excised using a combination of blunt and sharp dissection as described previously. These tumors should be removed with neighboring renal sinus fat and with a 3- to 4-mm margin of surrounding normal parenchyma where feasible. Hilar tumors may border the central collecting system; this may limit the margin of normal tissue. Renorrhaphy proceeds with the previously described methods. The vessels are unclamped. As mentioned previously, one must be vigilant to avoid injury to the posterior segmental renal artery

Extracorporeal Partial Nephrectomy and Autotransplantation. Extracorporeal partial nephrectomy with autotransplantation of the renal remnant can facilitate excision of large complex tumors involving the renal hilum (see Fig. 54–76). Proposed benefits of an extracorporeal approach include excellent exposure, a bloodless surgical field, maximal conservation of renal parenchyma, and greater protection of the kidney from prolonged ischemia. The technique, which is associated with longer operative time, need for renovascular and ureteral anastomoses, and risk of renal insufficiency, is infrequently employed and is discussed previously in this chapter.

COMPLICATIONS OF OPEN RENAL SURGERY

Although much can be done to avoid surgical complications, some complications are due to the nature of the disease being treated and may be unavoidable. Meticulous attention to preoperative evaluation, surgical technique, and postoperative care will minimize avoidable morbidity and mortality. Complications are to be

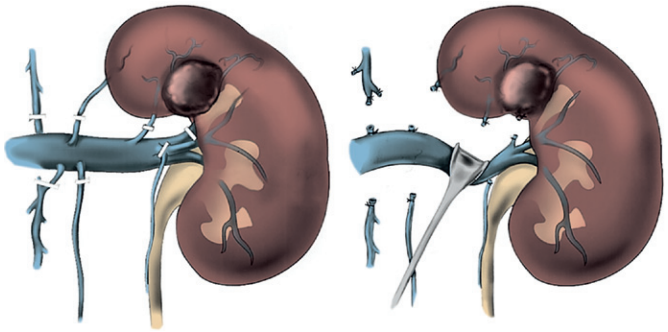

Figure 54–162. Mobilization of the left renal vein to obtain better exposure of the tumor in the renal hilum by ligation and division of small renal venous branches.

Key Points: Partial Nephrectomy for Malignant Disease

- Partial nephrectomy has supplanted radical nephrectomy as the treatment of choice for T1 renal tumors when feasible, even in the absence of identifiable renal insufficiency or threat.
- For tumors other than T1, partial nephrectomy may be indicated in patients with a contralateral kidney that is threatened by stone disease, chronic infection, renovascular disease, vesicoureteral reflux, or systemic diseases that threaten renal function such as hypertension or diabetes mellitus.
- Bilateral tumors represent a special circumstance that is considered a firm indication for nephron-sparing surgery.
- The majority of patients with renal cortical tumors have unrecognized comorbid medicorenal disease. In comparison to partial nephrectomy, radical nephrectomy is associated with a higher risk of postoperative renal insufficiency. There is a dose-response association between chronic kidney disease and hospitalizations, cardiovascular events, and death. Radical nephrectomy may be associated with increased cardiovascular events and decreased survival.
- A large percentage of tumors amenable to partial nephrectomy are still removed with radical surgery.
- The fundamental steps of partial nephrectomy include the surgical approach, vascular control, mobilization of the kidney, complete excision of the tumor with maximal preservation of normal parenchyma, minimization of ischemic injury, and renorrhaphy, which includes hemostasis, watertight closure of the collecting system, and repair of the renal defect.
- The goal of partial nephrectomy is complete excision of the tumor with negative margins and maximal preservation of benign adjacent parenchyma. Various techniques can be employed to remove the tumor, including enucleation, polar segmental nephrectomy, transverse resection, wedge resection, and extracorporeal partial nephrectomy with renal autotransplantation.
- Partial nephrectomy has traditionally been performed with temporary occlusion of the main renal artery or a segmental artery supplying the tumor. Duration of renal ischemia is the strongest modifiable risk factor for renal insufficiency after partial nephrectomy. The fully perfused partial nephrectomy technique may result in improved sparing of renal function.

avoided at all costs, but they also should be regarded as an invaluable teaching tool for surgeons in training.

Patients with significant comorbidity may be at higher risk of complications, and some procedures are inherently perilous. Ideal surgical outcomes and safety should be relentlessly pursued, but the risk of complications should not deter surgeons from performing an indicated operation for a patient in need. Unlike vigilance and confidence, timidity and apprehension on the part of a surgeon do not benefit the patient.

Pulmonary and Thoracic Complications

Pulmonary complications of open renal surgery include atelectasis, pneumothorax, pneumonia, and injury to the lung parenchyma. As discussed previously, use of the flank positions can have deleterious effects on cardiopulmonary function. Postoperative atelectasis, which is cited as a common cause of postoperative fever, is best managed with early ambulation, vigilant fluid management, deep breathing, and incentive spirometry. Atelectasis and pneumonia may be prevented by postoperative pulmonary toilet, including incentive spirometry, bronchodilators when indicated, and postural drainage.

In addition, the pleura or parenchyma of the lung can be injured during open renal surgery, especially through a thoracoabdominal or flank incision. When the pleura is injured, the authors prefer to leave a 8-Fr "dart" chest drain one or two rib levels above the incision. On the contrary, after a nephrectomy with wedge resection of the lung for metastasectomy, a standard-caliber chest tube is used.

When an air leak is not anticipated, a well-described alternative to a chest tube is to evacuate the air from the pleural cavity with a red rubber catheter while the anesthesiologist hyperinflates the lungs. With hyperinflation and suction on the catheter, air and fluid in the hemithorax are forced out through the catheter, which is then removed as a preplaced purse-string suture is tied. Chest films are obtained in the postanesthesia care unit. A significant pneumothorax (15%-20%) or tension pneumothorax requires standard (28 to 32 Fr) chest tube placement. The less common complications of urinothorax or hemothorax are best managed with drainage of the chest and treatment of the root causes of urine leak and bleeding, respectively.

Injured lung parenchyma can be identified by gently pouring water over the parenchyma while the anesthesiologist hyperinflates the lungs. One can oversew the injured areas with 3-0 chromic sutures while the lungs are hyperinflated. Alternatively, a wedge resection of the injured lung using a gastrointestinal stapler can be performed. In the absence of definitive injury to the lung parenchyma, a clinically significant pneumothorax will rarely occur.

Diaphragmatic palsy is a hazard of any approach that puts the phrenic nerve at risk of injury. In addition, renal tumors may be adherent to and require partial resection of the diaphragm, especially when performing a thoracoabdominal incision. Small- to medium-sized defects can be repaired with figure-of-eight 2-0 silk sutures. A PTFE patch can be used to reconstruct larger defects along with chest tube drainage. Omental flaps interposed between the diaphragm and abdominal organs provide additional vasculature to promote healing.

Renal Complications

Renal insufficiency is a risk of any renal surgery, from ischemic injury from vascular clamping, excision of functional renal tissue,

or renal unit loss. Hemodialysis, either temporary or permanent, may be necessary. As discussed earlier, duration of renal ischemia is the strongest modifiable risk factor for renal insufficiency after partial nephrectomy (Lane et al, 2008). In addition, clamping of the renal artery is associated with greater risk of urine leak, renal failure, and temporary dialysis (Thompson et al, 2007).

Ligation of the right renal vein during radical nephrectomy and IVC thrombectomy will result in failure of the right renal unit due to lack of venous collateral vessels. On the left, the renal insufficiency should be transient and resolve once adequate venous collateral vessels have developed (Clark, 1961; Pathak, 1971).

Urine leak is a risk of any renal surgery involving entrance into the colleting system, such as partial nephrectomy. This complication should resolve with placement of a ureteral stent, and urinomas should be managed with percutaneous drainage.

Neurologic Complications

Patients undergoing CPB and circulatory arrest are at risk for cerebral ischemic insults when the total arrest time exceeds 40 minutes. Retrograde cerebral perfusion and "trickle" maintenance blood flow (5 to 10 mL/kg/min) can be employed when the ischemic period is expected to be long. When the foramen ovale remains patent, tumor thrombus that dislodges can cause massive stroke. After a single instance of this devastating complication, the authors abandoned the median sternotomy technique to gain distal control via the minimally access approach, which was hoped to reduce the risk of embolism of the thrombus.

Compression neurapraxia is a recognized complication of the flank position for nephrectomy (Garland and Moorhouse, 1952). In addition, intraoperative hypothermia, which is used in IVC thrombectomy, is a risk factor for development of nerve injury (Graham et al, 1981). Nerve injury due to intraoperative positioning is caused by stretch, ischemia, or compression. Risk factors include thin body habitus, diabetes mellitus, existing neuropathy, peripheral vascular disease, malnutrition, and intraoperative hypothermia or hypotension (Winfree and Kline, 2005). Particular care should be taken, especially in high-risk patients, to properly pad and position all areas at risk (Winfree and Kline, 2005). The authors advocate a team approach with the anesthesiologists for positioning and make an effort to reposition the arms every 2 to 3 hours during prolonged operations.

The bulk of neurapraxia injuries resolve with conservative measures. Postoperative complaints should be addressed with physical therapy and neurology evaluations if symptoms persist or worsen. Pain is treated with analgesics. Physical therapy will help preserve range of motion and joint flexibility in the presence of motor deficits. The physical examination and electromyography findings should normalize over time, although surgical intervention may be indicated if the deficit does not improve.

The flank approaches risk injury to the intercostal nerves and subcostal nerve, which can result in denervation and paresis of the flank musculature. Consequences can include chronic pain or flank bulge, as discussed earlier.

Intra-Abdominal Complications

Abdominal complications include injury to adjacent structures such as the colon, liver, spleen, pancreas, and duodenum. Injury to the bowel can be a devastating complication of renal surgery. Intraoperative vigilance can help prevent and recognize bowel injury, which should be repaired and drained. Adhesions from prior surgery increase the risk of injury to the small bowel. The small bowel can suffer injury when packed away under a retractor. The authors close simple serosal tears or enterotomies with interrupted polyglactin 3-0 sutures in a two-layered Lembert fashion. When necessary, small bowel resection is performed using gastrointestinal staplers and a side-to-side anastomosis. The large bowel can be injured when it is mobilized, especially during adhesiolysis or resection of locally advanced tumors invading the colon or mesocolon.

Right radical nephrectomy requiring Kocher mobilization can lead to injuries of the second or third portions of the duodenum. A duodenal injury should be treated with sharp debridement of nonviable tissue. Two-layered closure in Lembert fashion with an omental patch is the optimal closure to limit leaks and provide additional blood support for healing. Complete mobilization of the small bowel mesentery can maximize exposure of the duodenum and the degree of medial reflection. Use of moist sponges and gentle retraction will limit undue pressure. The same approach should be taken on left-sided tumors to minimize damage to the fourth portion of the duodenum and the tail of the pancreas.

Left-sided tumors requiring mobilization and division of the splenorenal ligament can lead to inadvertent splenic injury. Simple lacerations can be addressed with electrocautery or the argon laser. Larger defects can be managed with bolster repairs utilizing Surgicel or Gelfoam. Omental patches can provide additional support. Persistent bleeding necessitates splenectomy. The spleen is first mobilized anterior and medially, and the short gastric vessels are ligated with 2-0 silk sutures or controlled with Harmonic shears (Ethicon Endo Surgery, Inc., Cincinnati, Ohio). The splenic artery and vein should be ligated individually with suture ligatures of 2-0 silk. Postoperative immunizations to encapsulated bacteria are given before discharge.

Liver lacerations can be very troublesome depending on the location. Superficial lacerations can be managed with electrocautery or an argon beam laser. Alternatively, hemostatic bolsters of Surgicel can be sewn over defects. In the case of severe bleeding from liver injury, partial hepatectomy with assistance of hepatobiliary surgeons may be necessary.

Pancreatic injuries for the most part tend to result from inadequate mobilization or excess traction during exposure. Pancreatic injuries recognized at the time of surgery require that the capsule of the pancreas be closed with nonabsorbable suture and drained with a Jackson-Pratt suction device. In the rare instance that a pancreatectomy is necessary, a consult with hepatobiliary or general surgeons should be obtained. The tail of the pancreas, which can be injured in left nephrectomy, can be resected in a straightforward manner. The pancreas is mobilized and the tail resected with a gastrointestinal stapler. The resected edge may be oversewn with nonabsorbable nylon or polypropylene suture and use of a Surgicel bolster.

Postoperative ileus with significant pain should alert one to possible pancreatitis. Conservative management with parental nutrition and bowel rest remains the primary therapy. A pancreatic fistula usually presents as acute pancreatitis and is confirmed by measuring the amylase level and pH of the draining fluid. Serum chemistries should be obtained and CT performed to delineate the extent of disease. Pancreatic leak is managed by percutaneous or surgical drainage of the fluid collection, hyperalimentation, and administration of somatostatin until the drainage ends or requires surgical management. Most fistulas close spontaneously with adequate drainage. Early drainage of peripancreatic collections can limit pseudocyst or abscess formation. Surgical closure by excision of the fistulous tract and construction of an anastomosis between the pancreas and a Roux-en-Y limb of

the jejunum is only occasionally necessary in patients with prolonged drainage.

Prolonged ileus and small bowel obstruction are potential complications of any surgery, especially the transperitoneal approach.

Incisional Complications

Incisional hernias can be a vexing complication. Anterior midline hernias may result from a technical error in failing to identify and reapproximate the rectus fascia. Patients with multiple prior incisions may be best served by closure with mesh or retention sutures.

Flank bulges after nephrectomy are often not hernias but rather result from paresis of the flank musculature due to intercostal or subcostal nerve injury. An effort should be made to spare the intercostal nerve, which lies between the internal oblique and the transverse abdominal muscles, by padding and retracting the nerve out of the surgical field.

Flank incisional hernias are rare and may result from inappropriate closure of the fascia of the oblique muscles. A fascial defect is often palpable. Closing flank incisions in multiple layers will reduce the incidence of hernia.

Partial or complete dehiscence of the operative wound can occur in 1% to 4% of midline incisions and less than 1% of all flank incisions. Most occur between postoperative days 6 to 8 when tensile strength is relatively weak. Risk factors include poor surgical technique, immunosuppression, malnutrition, poorly controlled diabetes, and sepsis (Riou et al, 1992). The key to management of this complication is prevention with a well-planned incision and solid tissue approximation. Retention sutures should be considered in those patients at risk. A complete revision with retention sutures and synthetic mesh reinforcement should be considered in treating wound dehiscences.

Infectious Complications

Preoperative antibiotics are administered per guidelines discussed in earlier sections. Superficial wound infections are treated by opening the wound to allow purulent material to drain. Deep wound infections, and those accompanied by cellulitis or systemic symptoms, are treated with drainage and antibiotics. Small wounds can be managed with wet-to-dry packing two to three times per day to allow for secondary intention healing. Larger wounds with intact fascia heal faster with vacuum devices.

Asymptomatic lymph or serous collections in the surgical site are best managed conservatively. Infection or respiratory impingement from mass effect are indications to percutaneously drain the collection. Infected hematomas or urinomas should be drained. Prolonged drainage should raise the possibility of a retained foreign body or enteric fistula.

Vascular Injury and Hemorrhage. Blood loss in renal surgery can be significant due to the high percentage of cardiac output delivered to the kidneys. Preparation is essential. Cross-matched blood should be available. Two larger-bore peripheral intravenous catheters and an arterial catheter are standard. Any patient with an extensive cardiac or pulmonary history is managed with a pulmonary artery catheter to facilitate fluid management and determine the need for inotropic support. Vascular instruments should be open before the initial incision is made. Preoperative images should be reviewed for anomalous vasculature.

Injury to the main renal artery often will require proximal exposure at the aortic takeoff to get adequate control. In patients without significant atherosclerotic disease a side clamp can be placed for temporary occlusion until a 4-0 polypropylene repair suture can be placed. Inadvertent injury to the aorta is best repaired with gentle pressure over the aortotomy and polypropylene figure-of-eight repair sutures. Very small holes are best treated with Surgicel, absorbable gelatin sponge such as Gelfoam, or microfibrillar collagen such as Avitene, along with gentle pressure and patience. Segmental branch injuries can be difficult to manage and may require excellent hilar exposure with proximal control for clamping.

The vascular nature of renal tumors and the presence of venous tumor thrombus can lead to extensive venous collateral patterns. These veins are fragile and easily torn. Lumbar tributaries lie in difficult positions and may be injured before they are detected. If the distal end can be identified, the authors like to use a small Allis clamp for hemostasis with figure-of-eight polypropylene sutures. If complete circumferential control cannot be gained, a small snap can be used along with a gentle twisting motion followed by suture ligation. In the rare instance that a lumbar vein retracts into the deep musculature of the retroperitoneum, a large figure-of-eight suture is placed through the muscle in wide bites. Likewise, these vessels can retract into the foramina of vertebral bodies requiring figure-of-eight sutures into the vertebral periosteum. Large lesions with parasitizing vessels can bleed extensively and may be best treated with tumor extirpation and a damage control approach to bleeding after exposure is increased.

Injuries to the IVC are manageable if recognized early with adequate exposure. As a general rule the key principle is to avoid making more than one hole at a time. When a venotomy is encountered the initial move is get proximal and distal control with gentle pressure using one's fingers or sponge sticks. An Allis clamp(s) can be used for hemostasis and a running polypropylene suture can be placed. For larger rents one can temporary occlude the vena cava using Fogarty clamps.

Postoperative bleeding after open renal surgery may be characterized by pain, signs of shock, abdominal or flank swelling, and drainage of blood through the incision or a drain site. Potential sources of postoperative bleeding include the kidney itself, the renal pedicle, and unrecognized injury to the spleen, the liver, or a mesenteric vessel. In some cases it may be best to explore the surgical site, evacuate the hematoma, and obtain hemostasis. In the event of diffuse bleeding from a clotting disorder it may be necessary to temporarily pack the wound with gauze, which can then be removed after 24 to 48 hours. Arteriovenous malformations are an additional significant complication of renal surgery that may present in a delayed fashion. They can often be treated percutaneously (Fig. 54–163). Patients should be given blood and fluid replacement as needed.

Key Points: Complications

- Although much can be done to avoid surgical complications, some complications are due to the nature of the disease being treated and may be unavoidable.
- Meticulous attention to preoperative evaluation, surgical technique, and postoperative care will minimize avoidable morbidity and mortality.

Surgical treatment is central to addressing many urologic conditions affecting the kidneys. Decades of experience have demonstrated the efficacy and durability of operative excision for malignancies, as well as reconstruction for obstruction. Unfortunately, traditional open surgical approaches, although extremely effective, are associated with significant postoperative discomfort and recuperation. Studies also demonstrate permanent body surface alterations with flank incisions resulting in significantly larger postoperative surface area and volume changes on the operated flank compared to the noninvolved flank. Indeed, patients report dissatisfaction with the body changes occurring in up to 60% of flank incisions (Chatterjee et al, 2004; Kobayashi et al, 2004).

Minimally invasive surgical approaches were born out of the desire to address secondary issues related to surgery, including incisional pain, convalescence, and cosmesis. Initially applied to treat stone disease, advances in video technology and surgical tools have now been used to treat the most complex of renal pathologies, with less morbidity compared to standard operative approaches. Clayman and associates initiated this revolution in renal surgery in 1990 when they introduced the laparoscopic nephrectomy (Clayman et al, 1991). This was performed in an octogenarian with a kidney mass, and although the procedure took over 7 hours, its impact on postoperative recovery was immediately apparent. Subsequently, this approach has been applied to treat every aspect of operative renal disease.

Multiple studies have demonstrated that laparoscopic renal surgery provides recuperative as well as cosmetic advantages in contrast to open surgery (Kerbl et al, 1994a; Dunn et al, 2000; Gill et al, 2003). **With experience, this is now routinely accomplished without compromise to surgical outcomes**. As such, the laparoscopic technique has evolved into the preferred alternative in treating surgical diseases of the kidney. This chapter will discuss indications, present techniques, review results, and outline potential complications of laparoscopy applied to the kidney.

PATIENT EVALUATION AND PREPARATION

Basic laparoscopic principles are thoroughly discussed in Chapter 9. Patient selection and preparation for renal surgery is similar to that for comparable open surgery. A pertinent history and physical are necessary to identify potential issues that could arise during surgery. **Prior abdominal, retroperitoneal, or renal surgery is not a contraindication to laparoscopic surgery; however, type and extent of prior abdominal surgery**

will drive trocar location, as well as choice of transperitoneal or extraperitoneal access (Chen et al, 1998; Cadeddu et al, 1999). In addition, degree of obesity may influence the type of access and location of trocars (Fugita et al, 2004; Hedican et al, 2004; Kapoor et al, 2004). Surgeon experience and available equipment will facilitate or deter use of the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) in treating renal pathology. Informed consent is obtained with a detailed discussion of potential complications including the potential for open conversion.

Coagulopathies should be corrected to minimize chances of intraoperative or postoperative bleeding. With the increased use of cardiac stenting, more patients are on chronic antiplatelet therapy. A conversation should occur with the patient's cardiologist to plan cessation of therapy to minimize risk of perioperative coronary artery thrombosis. If necessary, complex laparoscopic renal procedures have been performed while patients continue aspirin therapy. Uremic patients with prolonged bleeding time may benefit from desmopresssin acetate (desamino-D-arginine vasopressin [DDAVP] 0.3 to 0.4 μg/kg) given intravenously an hour before surgery to improve platelet function (Mannucci et al, 1983). A side effect of this therapy, iatrogenic hyponatremia, has been reported (Pruthi et al, 2002).

Laboratory and imaging studies are obtained as indicated by each patient's medical history. Patients should have blood typed and screened. Cross matching of blood is at the discretion of each surgeon and based on operative experience and complexity of the procedure. Bowel preparation is helpful to improve visualization and working space.

Imaging studies that define the pathology should be available in the operative suite to define anatomy and, along with operative site marking, minimize the risk of wrong side surgery. Angiography, embolization, and stent placement are not routine and related to each individual procedure.

Anesthesic Considerations in Laparoscopy

The majority of laparoscopic renal procedures require a general anesthetic, and a patient's pulmonary and cardiac function must tolerate this anesthetic approach (Monk and Weldon, 1992). The pneumoperitoneum can impact upon patients with severe cardiopulmonary disease by compromising ventilation and venous return (Arthure, 1970; Hodgson et al, 1970; Nunn 1987; Lew et al, 1992). Patients with chronic pulmonary disease may not be able to compensate for the pneumoperitoneum-induced hypercarbia and may require working at lower pressures, use of helium as an insufflant, or open conversion (Monk and Weldon, 1992; Wolf et al, 1996; Makarov et al, 2007). The use of valveless trocar systems has also been associated with less carbon dioxide absorption (Herati et al, 2009).

Considerations in Obese Patients

Obesity is not a contraindication for laparoscopic surgery, but can make retraction and identification of anatomic structures challenging. It is for these reasons that laparoscopy in obese patients is associated with an increased risk of open conversion when compared with nonobese patients (Fazeli-Matin et al, 1999). In addition, although complication rates for laparoscopy in obese patients are higher when compared with laparoscopy in the general population (Mendoza et al, 1996), pulmonary and wound complications are lower with laparoscopy when compared with an open approach (Kapoor et al, 2004; Montgomery et al, 2005). Other factors to account for in the obese population include the increased distance to the operative field, which calls for modifying trocar location and number, as well as the use of longer instrumentation (Doublet and Belair, 2000; Jacobs et al, 2000). Consideration must also be given to the weight of the pannus, which may raise the intra-abdominal pressure and limit working space. The potential for rhabdomyolysis, a rare but devastating complication in the obese as well as very muscular individuals, must also be considered (Troppmann and Perez, 2003).

SURGICAL APPROACHES AND OBTAINING ACCESS

There are now five laparoscopic approaches to renal surgery: transperitoneal, retroperitoneal, hand-assisted, robotic, and laparoendoscopic single-site surgery (LESS)/natural orifice transluminal endoscopic surgery (NOTES). Each approach can have discrete advantages and limitations depending upon the clinical situation and surgeon familiarity. To date there have been no studies that have shown a definitive recuperative advantage of any one of these approaches. Potential differences in cosmesis may exist, but have also not been well studied to date.

Transperitoneal Laparoscopy

The transperitoneal approach is the traditional and most widely used method of addressing renal pathology. It provides the largest working space, facilitates orientation by providing readily identifiable anatomic landmarks, affords greater versatility in angles and direction of laparoscopic trocars and instruments, and can result in the smallest size and number of ports. The equipment is mature and techniques are well defined and, like any approach, it requires significant expertise in instrument manipulation and suturing.

Patient Positioning and Trocar Placement

For most transperitoneal renal surgery, the patient is initially positioned supine for intravenous (IV) access, the induction of general anesthesia, and endotracheal intubation. A bladder catheter and orogastric tube are placed for decompression of the bladder and stomach during insufflation, trocar placement, and dissection. Sequential compression stockings are placed for deep venous thrombosis prophylaxis. When performing transperitoneal procedures, including robotic and LESS surgeries, patients are positioned in a 30- to 45-degree flank-up position. Care is taken to pad

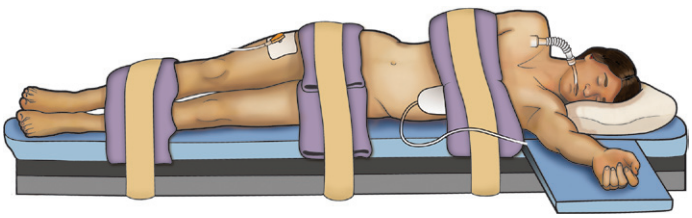

Figure 55–1. The patient is placed in a modified flank position, with the operative side tilted up 30 to 45 degrees using a gel roll or a rolled blanket supporting the back. The lower arm is placed on a padded armrest, and the other arm is flexed at the elbow and rested over the chest. Wide cloth or silk tape is used to secure the patient to the operating table to allow for table rotation during the surgery.

all pressure points. The patient is secured to the operating table to allow lateral tilting of the table (Fig. 55–1). Tilting the table away from the affected kidney will help move bowel out of the operative field. There is no need to flex the table or use a kidney rest as there is with open surgery. The equipment in the operating room is situated to maximize the use of space and allow all members of the surgical team to view the procedure (Fig. 55–2). During the skin preparation and draping, the entire flank and abdomen are included in case conversion to an open procedure is required.

Once a pneumoperitoneum is established, three to five trocars are initially placed to complete the dissection (Fig. 55–3). There are a variety of trocar configurations that are effective for each procedure.

A 12-mm trocar is placed lateral to the rectus at the level of the umbilicus; this trocar is used for instrumentation and the passage of sutures, bulldog clamps, or staplers to secure and divide hilar vessels. In short patients, this may be placed in the midline, halfway between the umbilicus and pubis. **A 10-mm trocar is placed at the umbilicus for the camera, and a 5- or 10-mm port is inserted in the midline 2 cm below the xiphoid process.** In obese patients, all trocar sites are moved laterally (see Fig. 55–3C). Additional trocars for retraction may be needed for visualization or assist with organ entrapment (Fig. 55–4).

Retroperitoneal Laparoscopy

The retroperitoneal approach mimics open surgery because the peritoneal cavity is avoided. A potential space is created to visualize the surgical field. It may be preferred for selected cases of laparoscopic partial nephrectomy, cyst marsupialization, pyeloplasty, renal biopsy, or in patients who have had peritonitis or who have undergone multiple prior abdominal surgeries.

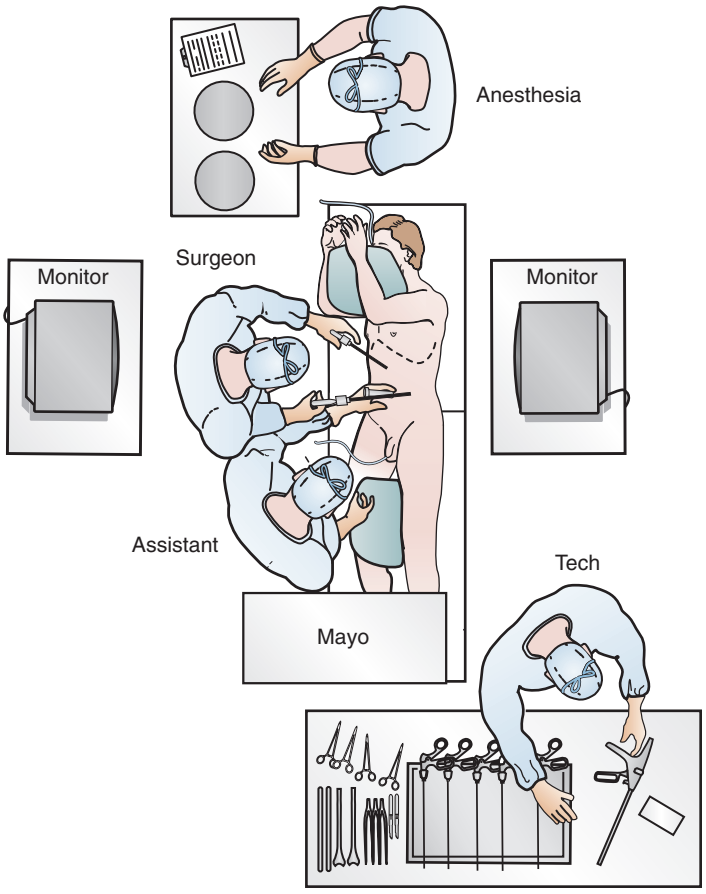

Figure 55–2. The operating room configured for left nephrectomy. Two monitors allow the assistant to follow the procedure. The scrub tech is positioned to easily assist with instrument passage and exchange.

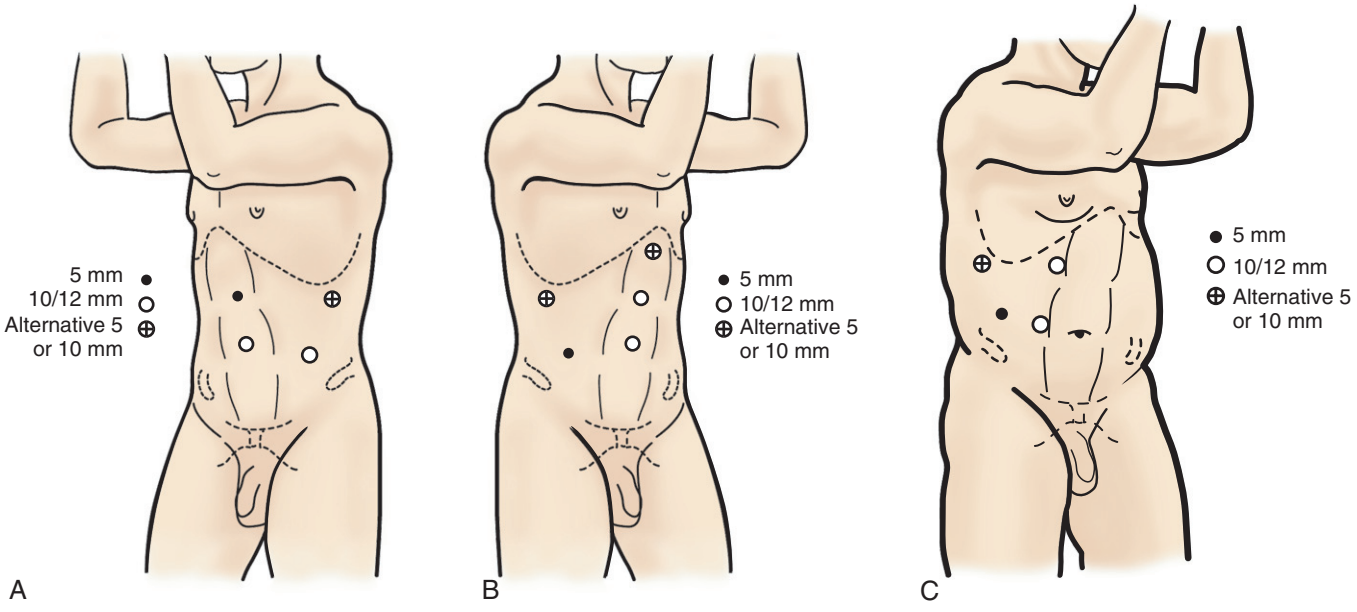

Figure 55–3. Trocar sites for left-sided **(A)** and right-sided **(B)** procedures. A 12-mm trocar is placed lateral to the rectus at the level of the umbilicus, a second 10-mm trocar is placed at the umbilicus, and a 5-mm trocar is inserted in the midline between the umbilicus and the xiphoid process. **C,** In obese patients, all trocars are shifted laterally. Optional accessory subcostal, subxiphoid, and low midline trocar positions, which may be helpful for retraction, are also shown.

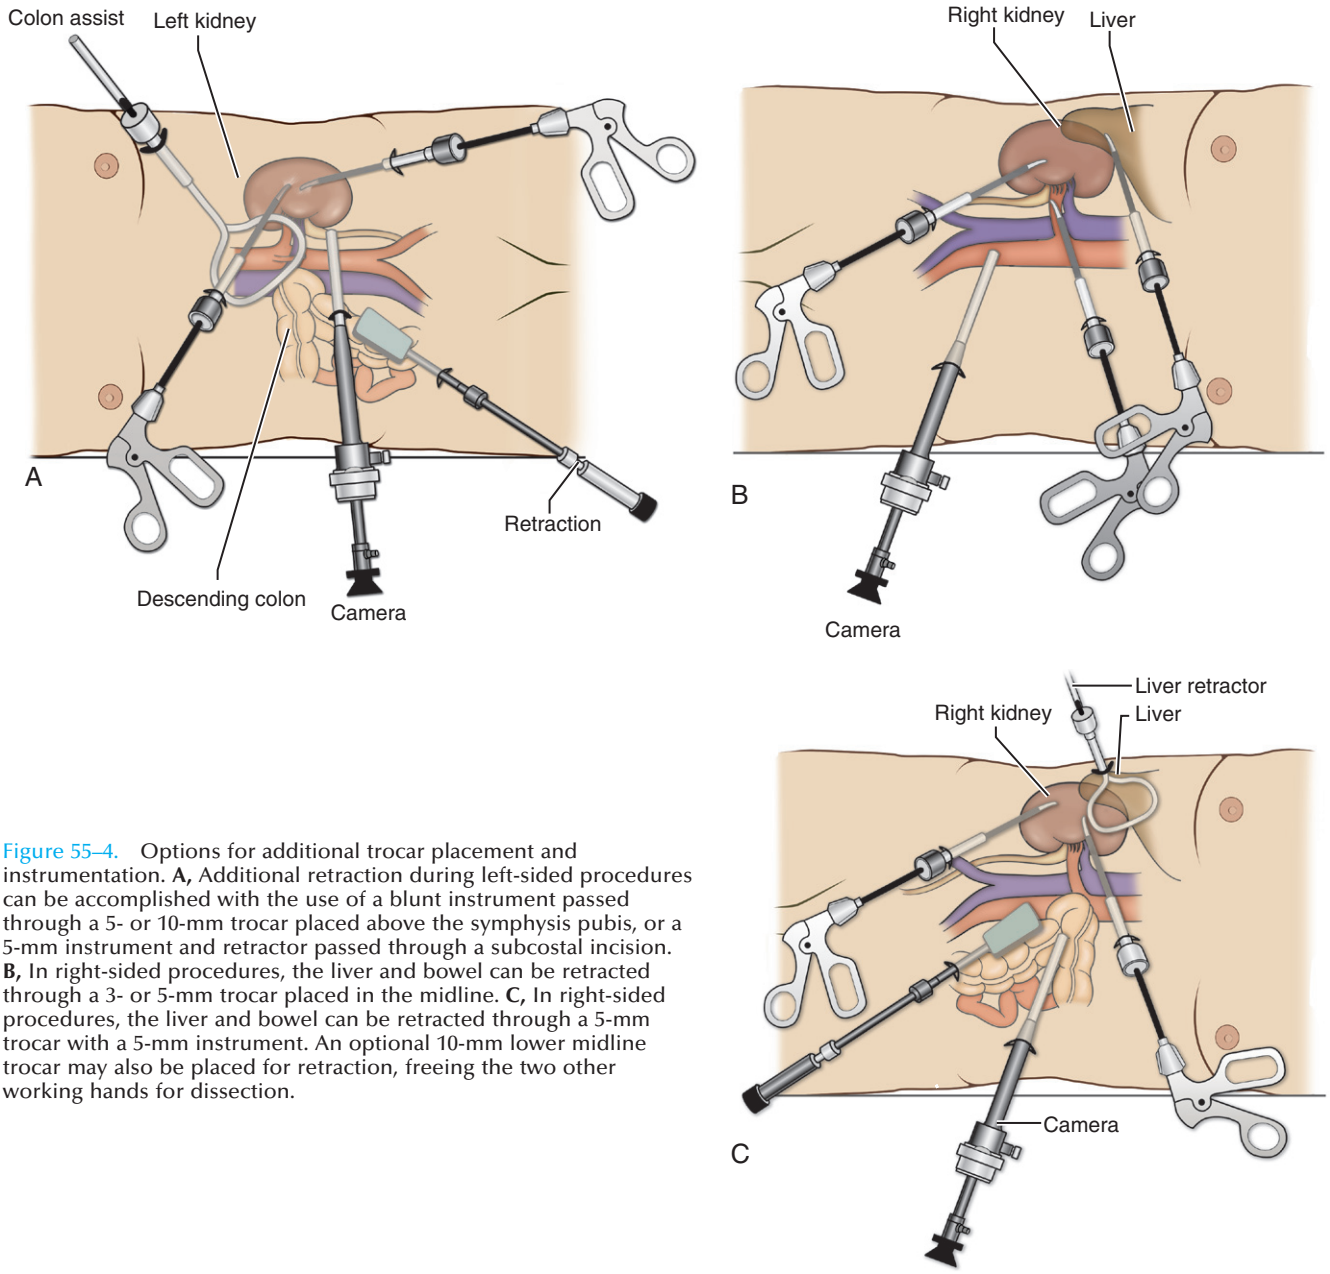

Figure 55–4. Options for additional trocar placement and instrumentation. **A,** Additional retraction during left-sided procedures can be accomplished with the use of a blunt instrument passed through a 5- or 10-mm trocar placed above the symphysis pubis, or a 5-mm instrument and retractor passed through a subcostal incision. **B,** In right-sided procedures, the liver and bowel can be retracted through a 3- or 5-mm trocar placed in the midline. **C,** In right-sided procedures, the liver and bowel can be retracted through a 5-mm trocar with a 5-mm instrument. An optional 10-mm lower midline trocar may also be placed for retraction, freeing the two other working hands for dissection.

Patient Positioning and Trocar Placement

Using this approach, patients are placed in a full-flank position. Modest table flexion can help increase the distance between the ribs and iliac crest to facilitate trocar placement. An axillary roll is required, as well as care in securing the patient to the bed. Arms may be secured on pillows or a purpose-built armrest. A 15-mm transverse incision is made in the posterior axillary line, midway between the tip of the 12th rib and the iliac crest (Fig. 55–5A). After deepening the dissection downward through the lumbodorsal fascia, the retroperitoneum is entered, and a working space may be developed using blunt dissection with the tip of a finger in the space between the psoas muscle and the kidney (Fig. 55–5B). A simple balloon created from two fingers of a size-8 or -9 glove may then be inserted and filed with CO_2 or saline to further develop the retroperitoneal working space (Fig. 55–5C). A blunt tip trocar is then passed through the incision, and the trocar cuff is expanded and cinched to the skin to prevent leakage of CO_2 (Fig. 55–5D). An alternative entry approach involves entry with the 0-degree lens and visual obturator through the initial incision (Fig. 55–6A). Entry into the retroperitoneum may be confirmed by the appearance of the characteristic yellow retroperitoneal fat, insufflation is initiated, and blunt dissection using only the laparoscope is performed to develop a working space (Fig. 55–6B). Caution must be used not to enter too anteriorly because inadvertent **peritoneal entry or colon injury may occur; entering too posteriorly may result in bleeding from the quadratus lumborum or psoas muscles.** Once the working space is established through either approach, pertinent structures may be identified for orientation and additional trocars placed. Typically, a 5-mm trocar is placed just off the tip of the 12th rib, and a 12-mm trocar is placed posteriorly and superiorly relative to the camera port (see Fig. 55–5A).

The greatest limitations of the retroperitoneal approach are the limited working space and more subtle anatomic landmarks. The smaller working space limits the distance between trocars,

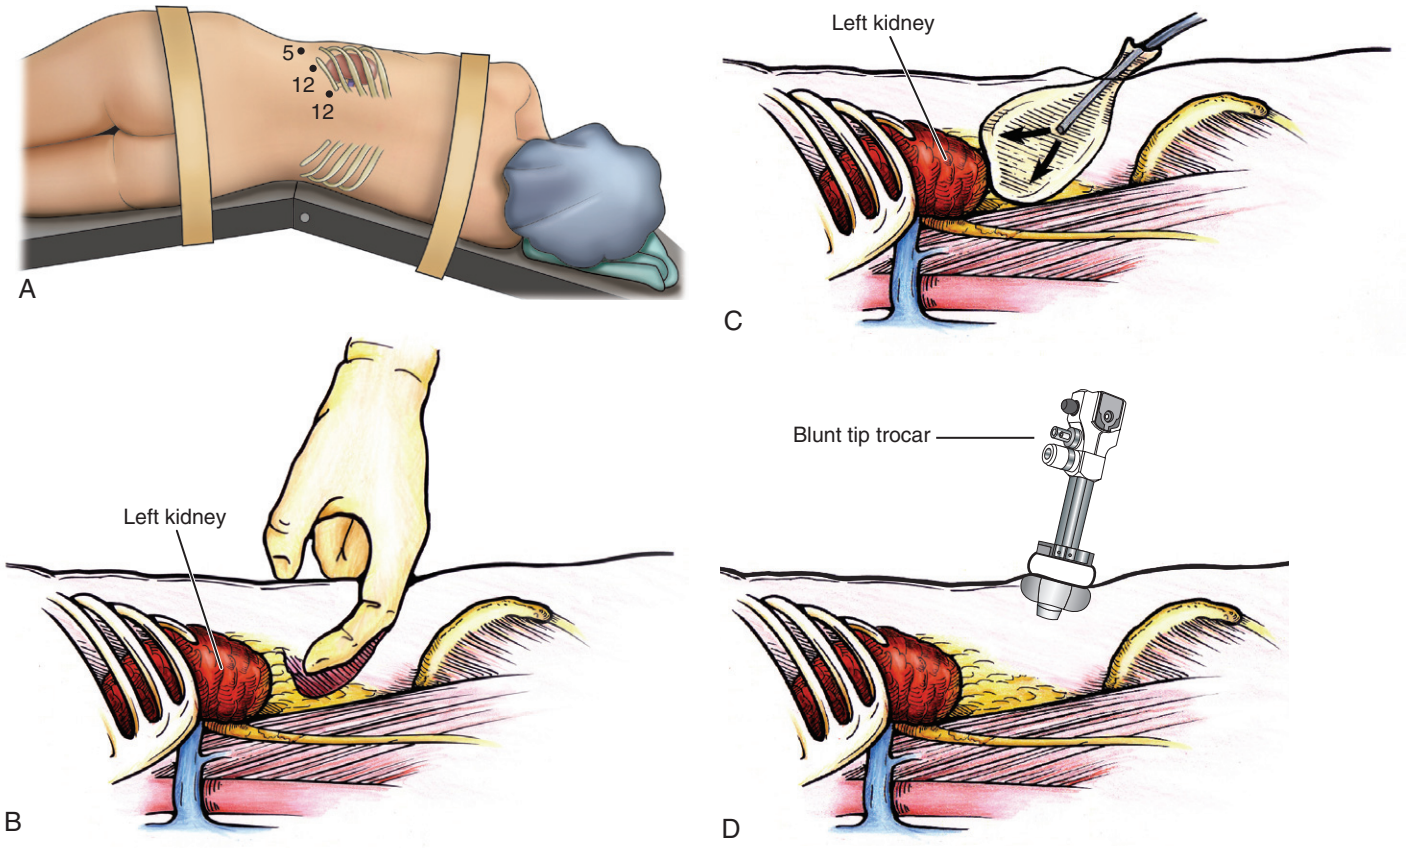

Figure 55–5. Trocar placement for retroperitoneal kidney surgery. **A,** With the patient in the full lateral position, the hips flexed, and the kidney rest elevated, a 15-mm incision is made 2 cm below the tip of the 12th rib, between the rib and the anterior superior iliac spine. **B,** The index finger is inserted through the incision and used for blunt dissection to create a hole from the skin through the muscle into the retroperitoneal space. If the finger is in the correct position, the surgeon should feel the smooth surface of psoas muscle and the lower pole of the kidney covered by Gerota fascia. **C,** To quickly create the working space, insert a balloon created from the finger of a size 8 or 9 glove, secured with silk suture over a simple red rubber catheter. The balloon is then filled with 600 to 800 mL of saline. **D,** A Blunt Tip Trocar (U.S. Surgical, Norwalk, CT) is used to seal the trocar site. Because of its low profile, it will not obstruct the view or take up useful space in the retroperitoneum. The balloon/collar configuration eliminates the need for sutures and allows 360-degree rotation.

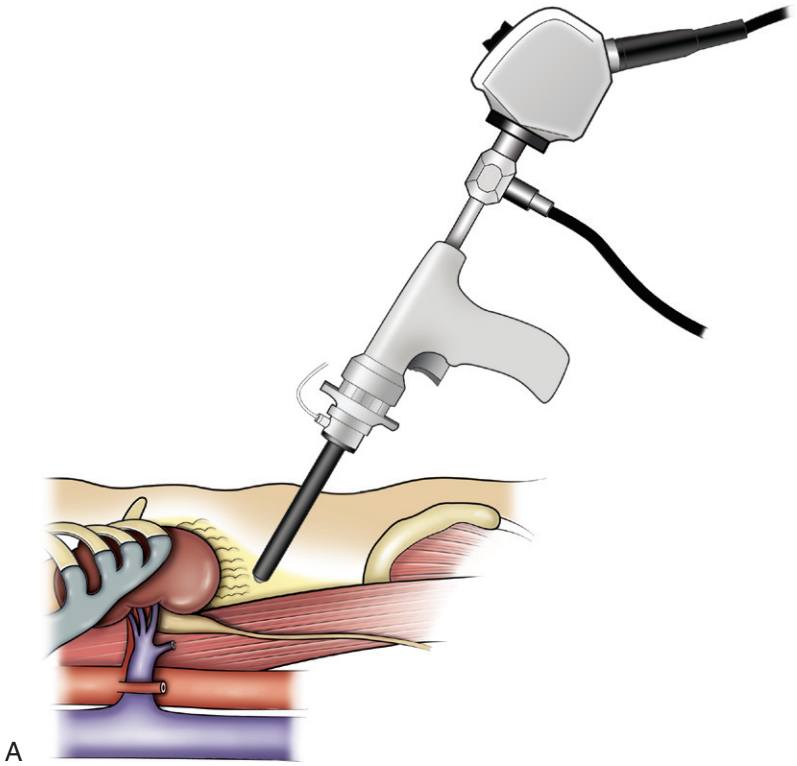
potentially leading to awkward hand positioning. Also, the pathology is much closer to the lens, and frequent smudging of the tip may occur. If additional space is needed during the procedure, initial retroperitoneal access can be expanded to a transperitoneal approach through opening the peritoneum under direct vision. Despite these limitations, the retroperitoneal approach may be preferred in some cases, and with adequate experience, a wide variety of laparoscopic renal surgery may be performed.

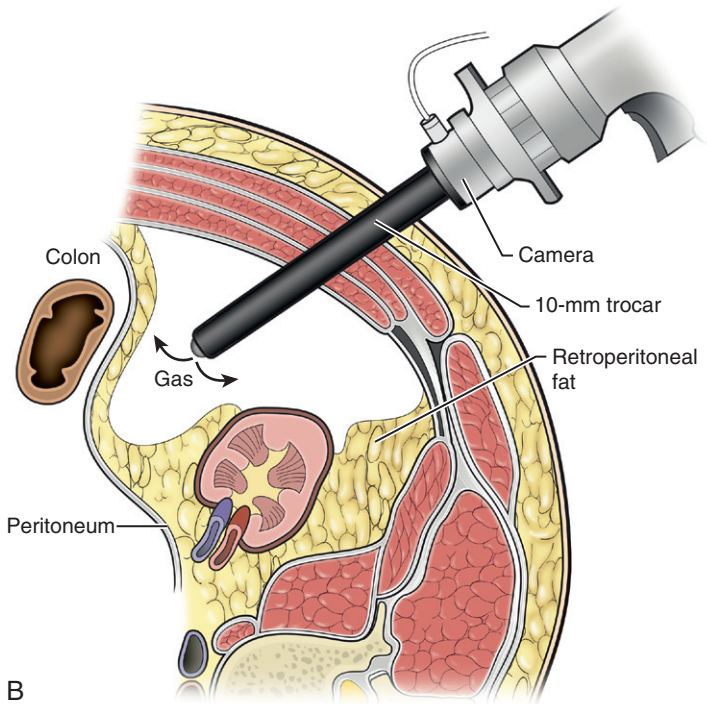
Hand-Assisted Laparoscopy

Hand assistance offers a bridge between open surgery and laparoscopy (Nakada et al, 1997). It offers more intuitive assistance from the human hand with dissection and retraction, simultaneously providing tactile feedback to the surgeon. Several manufacturers make devices for this purpose. An incision large enough for the hand must be created and can also be used as an extraction site. This incision site is usually larger than one used for intact extraction during pure laparoscopic surgery. This technique may be advantageous for the novice laparoscopic surgeon and in patients with significant scaring about the kidney, or if a difficult dissection is anticipated. Hand assistance may also be employed in the event of an emergency, such as bleeding, by extending a trocar site and placing a hand port to assist in repair of an injury or vascular control. Indications are identical to those for laparoscopic nephrectomy or laparoscopic partial nephrectomy.



Patient Positioning and Trocar Placement

The patient is positioned just as for pure laparoscopic kidney surgery. The initial incision is for the hand port that is made through the skin and fascia and into the peritoneal cavity. Location will depend on handedness of the surgeon, operative side, and body habitus of the patient (Figs. 55–7 and 55–8). Care must be taken to avoid making the incision too large, because gas may escape, making the procedure more difficult due to decreased working space. Once the hand-assisted device is placed, the peritoneum is insufflated, and the additional trocars may be placed under direct vision by placing the camera through the hand port.



There are some limitations in location of port placement, and the hand may potentially get in the way of visualization or dissection instrumentation. Some leakage of gas may occur about the device, resulting in difficulty in maintaining the pneumoperitoneum. These devices exert 30 to 100 mm Hg of pressure on the arm, which may account for surgeons developing tingling, numbness, or pain in the forearm or hand (Monga et al, 2004).

Robotic-Assisted Laparoscopy

The da Vinci computer–aided surgical system has been used to perform what has commonly become known as robotic surgery. This device uses a computer system and a series of mechanical arms to translate surgeon movements familiar to open surgery to

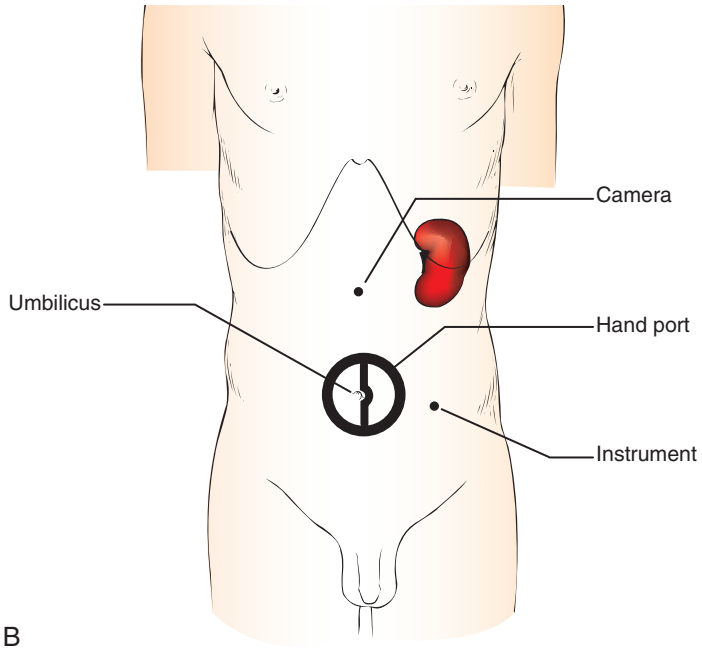
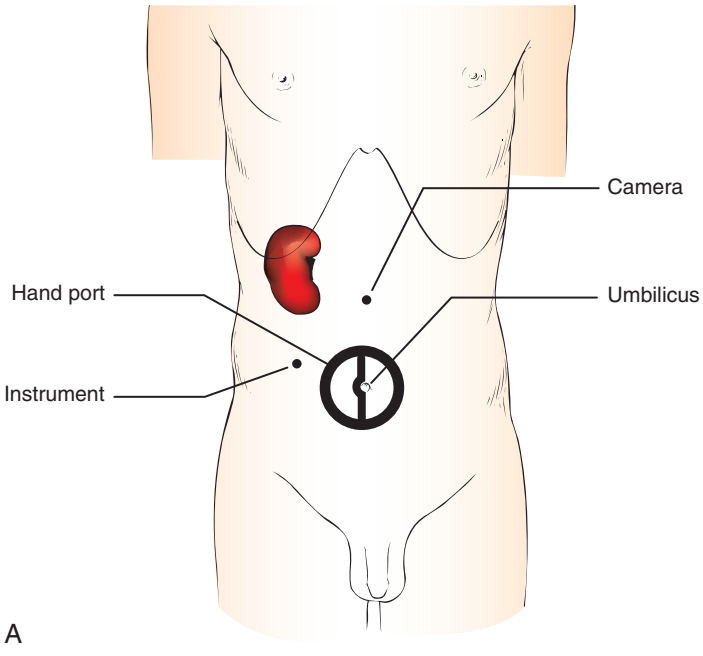
Figure 55–6. **A,** Standing behind the patient, the surgeon initially develops a space bluntly between the psoas muscle and the kidney using the visual obturator with the 0-degree laparoscope through it. **B,** Together, they are used to bluntly push the peritoneum medially, creating a working space large enough to allow placement of additional trocars.



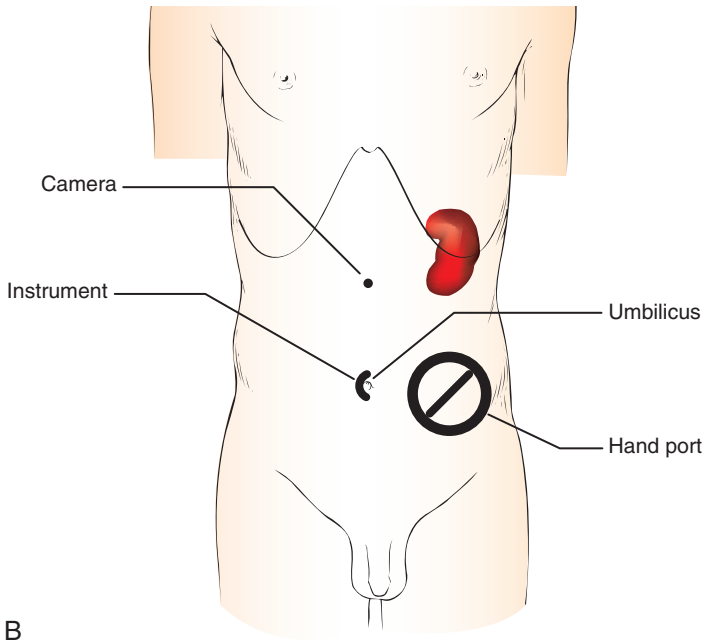
a laparoscopic platform. As such, instrument movement of right and left is preserved, as opposed to pure laparoscopic surgery where it is reversed. Also, hand-eye association is preserved and, a dual lens system provides 3-dimensional (3D) depth perception. The addition of instrument articulation facilitates dissection and suturing for those lacking laparoscopic abilities. These additions have obviated the need for high-level laparoscopic skills, in some instances to allow more surgeons to offer a minimally invasive approach to their patients.

Patient Positioning and Trocar Placement

Patient positioning will depend, in part, upon tumor location if partial nephrectomy is to be undertaken. In addition, the timing of docking the robot must be considered because with the robot docked, table rotation will not be possible. The entire procedure may be performed with the aid of the robot, or the initial part of the operation may be performed using standard laparoscopy, with use of the robot only for tumor excision and renorrhaphy.



A



B

Figure 55–7. Port placement for a right-handed surgeon for hand assistance. **A,** For a right-sided kidney, the hand-assisted device is placed in the right lower quadrant for insertion of the left hand, and dissection is performed with instruments in the right hand placed through an umbilical trocar. The camera is placed several centimeters above the umbilicus in the midline. On the right side, retraction of the liver is usually necessary to allow visualization and dissection of the renal hilum. A liver or bowel retractor can be placed through a subcostal trocar to assist with visualization or irrigation/aspiration. **B,** For the left kidney, the hand-assisted device and left hand are placed though a periumbilical incision and dissection is performed with the right hand using an instrument placed in the subcostal margin just medial to the nipple. The camera is placed several centimeters lateral to the edge of the actual hand-assisted device (not the edge of the incision). Additional assistance can be delivered through the most lateral trocar site.

A

B

Figure 55–8. Port placement for a left-handed surgeon for hand assistance **A,** When operating on the right kidney, a left-handed surgeon places the hand-assisted port in the periumbilical location for insertion of the right hand. The working port for the left hand is placed lateral to the rectus muscle, in line with or just inferior to the level of the umbilicus. The camera is placed through a lateral trocar in the anterior axillary line. Additional assistance with retraction of the liver can be accomplished through a subcostal trocar. **B,** For a left-handed surgeon operating on the left kidney the hand-assisted port is placed in the left lower quadrant for insertion of the right hand. The left hand works with the instrument passed through an umbilical trocar, and the camera is placed midway between the umbilicus and the xiphoid process. Additional assistance with retraction or aspiration can be accomplished through a fourth trocar placed at the subcostal margin.

Most authors prefer a flank position with the table modestly flexed (Aron et al, 2008; Deane et al, 2008; Benway et al, 2009). As the robotic procedure requires more trocars than standard laparoscopy, this allows more adequate spacing of instruments and less clashing of the robotic arms. Inclining the table may provide additional space at the back of the patient for the robot and other equipment (Fig. 55–9).

Robotic trocars plus the additional assistant and camera ports are typically used for the procedure. A port-in-port technique of robotic-assisted partial nephrectomy (RaPN) has also been described, wherein the righthand and lefthand working ports are actually standard 12-mm laparoscopic ports (Aron et al, 2008). The robotic 8-mm ports are inserted through these 12-mm ports to perform RaPN. This arrangement can be advantageous in event of an intraoperative complication or robotic malfunction, wherein emergent conversion to pure laparoscopic surgery is necessary. The robot can be undocked expeditiously and standard LPN performed in the usual fashion without requiring additional time to insert new ports or working through 8-mm robotic ports that preclude passage of the necessary CT-1 or CT-X needles.

A three-arm configuration includes four to five total trocars, a 12-mm periumbilical camera port, an 8-mm subcostal robotic trocar in the anterior axillary line, an 8-mm robotic trocar in the posterior axillary line placed above the iliac crest, and one 12-mm assistant trocar in the low midline to allow passage of sutures, bulldog clamps, suction, or retraction. An additional 12-mm subxiphoid trocar may be used, if necessary, for additional retraction or passage of bulldog clamps if the angle is more optimal (Fig. 55–10A). A four-arm configuration involves five to six total trocars, using the same general configuration as the three-arm technique, but shifting the robotic trocars slightly to avoid clashing of the arms (Fig. 55–10B).

The shortcomings of the device include the initial capital investment and ongoing disposable expenses that make robotic procedures more expensive than other laparoscopic approaches. In case of instrument malfunction, the surgeon must either have laparoscopic skills or abort and perform the surgery in an open manner. Robotic cases also require a skilled bedside assistant and use more, and potentially larger, port sites, whereas most laparoscopic renal procedures can be completed in a solo fashion using a mechanical endoscope holder and two working trocars.

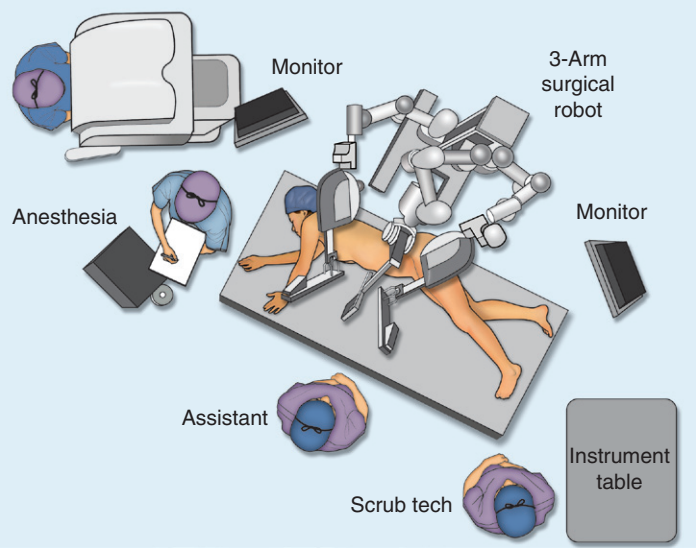


Figure 55–9. Operating room configured for left-sided robotic-assisted laparoscopic partial nephrectomy.

Laparoendoscopic Single-Site Surgery (LESS) and Natural Orifice Transluminal Endoscopic Surgery (NOTES)

Laparoendoscopic single-site (LESS) surgery describes laparoscopic techniques that consolidate all ports within a single skin incision, often concealed within the umbilicus (Box et al, 2008). It has evolved to improve upon cosmesis associated with standard laparoscopic surgery and uses commercially available multichannel working ports placed in the umbilicus or below the lower abdominal hair line to minimize postoperative visible scars. Initial clinical cases of virtually every type of extirpative and reconstructive urologic procedures have now been performed by LESS surgery.

Patient Positioning and Trocar Placement

Because LESS surgery remains a procedure in evolution, there is no widely accepted method of positioning or gaining access. Modified and full-flank positioning have been described and are identical to standard transperitoneal or retroperitoneal kidney surgery,

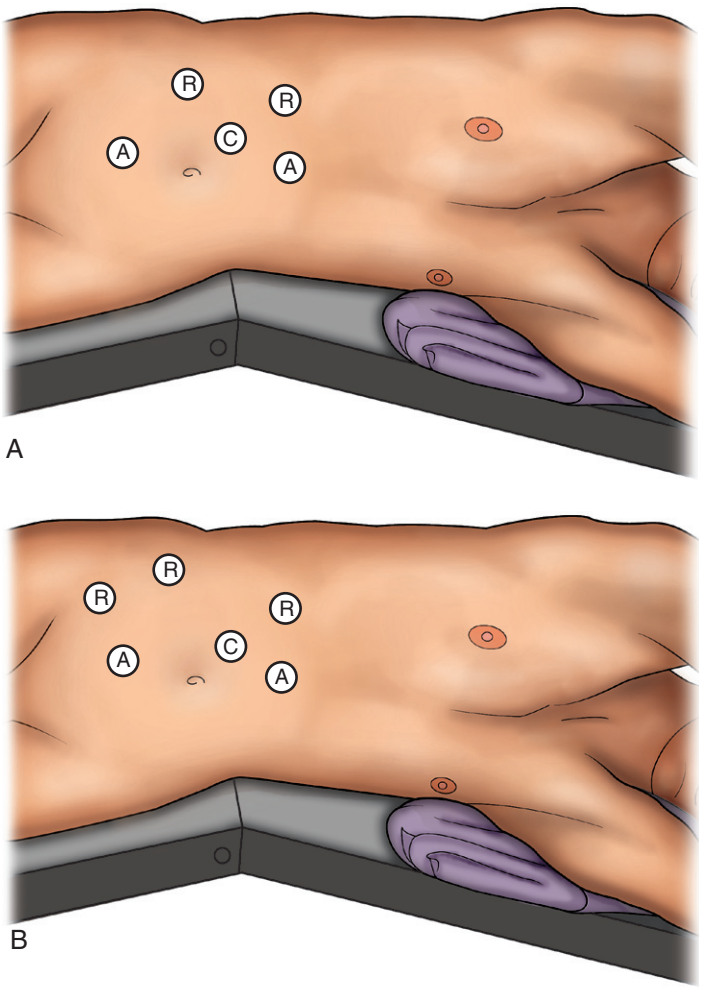

Figure 55–10. Trocar placement for robotic-assisted laparoscopic renal surgery. **A,** Three-arm system configuration. **B,** Four-arm system configuration. A, assistant trocars, R, robotic trocars, C, camera port.

respectively. Once pneumoperitoneum has been established, one may cluster multiple traditional low-profile trocars close together within a single, small extraction incision (Fig. 55–11). Alternatively, newer purpose-specific access devices (Fig. 55–12) may be used in combination with conventional laparoscopic or flexible instrumentation. The devices are secured using preplaced fascial sutures or with an inner and outer ring drawn together with a cylindrical sleeve. Characteristics of single-site access options are described in Table 55–1.

Figure 55–11. Laparoendoscopic single-site surgery performed using three low-profile trocars inserted through a single small extraction incision. A flexible laparoscope and flexible instrumentation may be used. (From Tracy CR, Raman JD, Cadeddu JA, Rane A. Laparoendoscopic single-site surgery in urology: where have we been and where are we heading? Nat Clin Pract Urol 2008;5:561–8.)

These approaches are technically challenging and the most difficult of the minimally invasive techniques. To date, no differences in postoperative morbidity or recovery have been reported (Raman et al, 2009). Advances in instrumentation may increase applicability and dissemination into mainstream urologic practice.

NOTES involves using a natural orifice to perform the entire operation. In the gastrointestinal (GI) and surgical literature, the mouth, vagina, and rectum have been used to remove organs such as the appendix and gall bladder (Rao et al, 2006; Zorron et al, 2007; Palanivelu et al, 2008). In urology, to date experience with pure NOTES surgery in humans is limited (Kaouk et al, 2009). Several authors have reported hybrid approaches with NOTES and standard laparoscopic techniques, using the vagina as an access and extraction site for nephrectomy (Branco et al, 2008; Alcaraz et al, 2010; Sotelo et al, 2010).

SIMPLE NEPHRECTOMY

Benign Indications

Laparoscopic simple nephrectomy is indicated in the treatment of most benign renal diseases. **Renovascular hypertension that is not correctable with medication or angiographic repair** may be managed with a simple nephrectomy. Patients with **chronic pain syndromes** may benefit from nephrectomy, including **symptomatic acquired renal cystic disease, autosomal dominant polycystic kidney disease (ADPKD), chronic hydronephosis not amenable to surgical repair, loin pain/hematuria syndrome. Chronic infectious processes** that are recalcitrant to antibiotic therapy may also be approached laparoscopically, including **chronic pyelonephritis, xanthogranulomatous pyelonephritis (XGP), and renal tuberculosis**. These conditions are associated with a higher rate of conversion to open surgery due to perinephric inflammatory changes and loss of tissue planes (Gupta et al, 1997; Bercowsky et al, 1999). In some cases, subcapsular nephrectomy

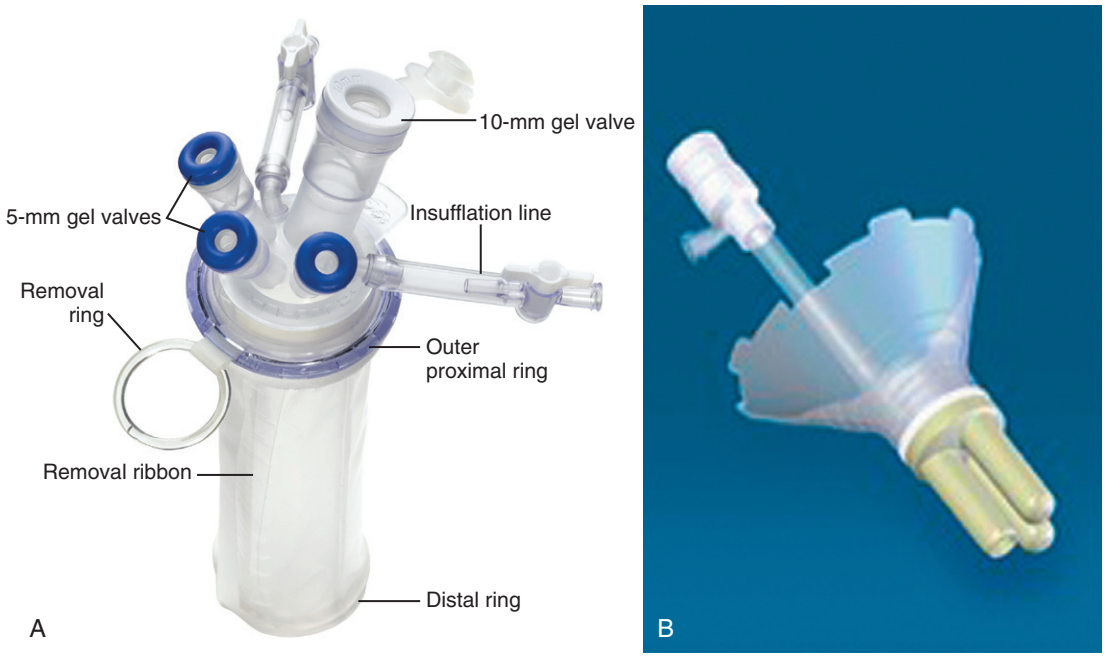

Figure 55–12. Purpose-specific devices for laparoendoscopic single-site surgery. **A,** The TriPort system (Advanced Surgical Concepts, Bray, Ireland). **B,** The Uni-X system (Pnavel Systems, Cleveland, OH). Both allow for passage of multiple instruments through a single incision.

Table 55–1.

Access Options for Laparoendoscopic Single Site (LESS) Surgery

ACCESS TYPE	DESCRIPTION
Keyhole	Use of three closely approximated periumbilical trocars placed side by side in a single skin incision or three separate incisions No additional device required Typically used with articulating camera and specialized instrumentation Insufflation through trocar
TriPort (Advanced Surgical Concepts, Bray, Ireland)	Open or closed access, may be used with multiple incision sizes (5-mm to hand-assisted incision) Anchored by inner (intra-abdominal) and outer rings drawn together with cylindrical sleeve 3-Port (one 12-mm and two 5-mm) configuration or 4-port (two 12-mm and two 5-mm) configuration available (Quadport) Insufflation through valve housing
Uni-X (Pnavel Systems, Cleveland, OH)	Open access technique, requires 2-cm fascial incision Anchored with preplaced fascial sutures Single port encompassing three 5-mm access ports Typically used with articulating camera and specialized instrumentation Insufflation through valve housing
Gelport (Applied Medical, Rancho Santa Margarita, CA)	Open access technique, requires 2.5- to 5-cm fascial incision Anchored by inner and outer rings drawn together with cylindrical sleeve Can accommodate all trocar sizes May allow for wider spacing of trocars Insufflation through trocar placed through device

may be necessary to complete the procedure. Hand assistance may also be of benefit and avoid open conversion in cases with dense scar tissue formation or inflammatory reaction (Rosoff et al, 2006). Successful retroperitoneal laparoscopic simple nephrectomy has also been reported in 30 of 31 patients with nonfunctioning kidneys secondary to tuberculosis (Lee et al, 2002). Other benign conditions that may call for nephrectomy include patients with a multicystic dysplastic kidney or a symptomatic failed renal transplant. Again, in this later case, a subcapsular dissection may be required.

Procedure

Reflection of the Colon

For a left nephrectomy and all renal surgery, the line of Toldt is incised from below the lower pole of the kidney inferiorly to above the spleen superiorly (Fig. 55–13). The inferior limit of this incision may be extended inferiorly, if the bowel does not move sufficiently. The lienocolic ligament should be incised to allow the spleen to fall medially along with the pancreas and the colon (see Fig. 55–13). Care must be taken to avoid injuring the diaphragm

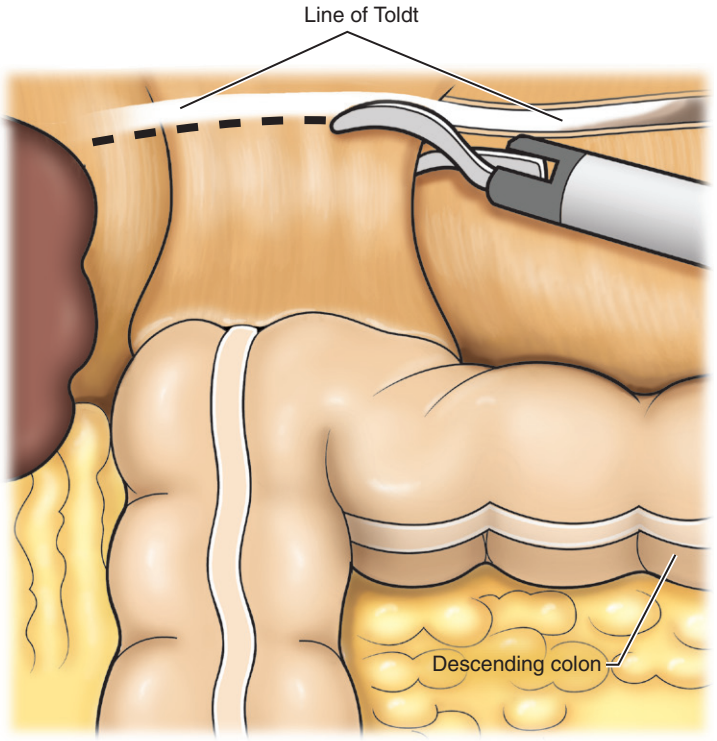

Figure 55–13. Incision of the white line of Toldt with endoshears, bipolar cautery, or ultrasonic energy allows reflection of the colon. Continuing superiorly allows incision of the lienocolic ligament, facilitating reflection of the spleen, pancreas, and colon.

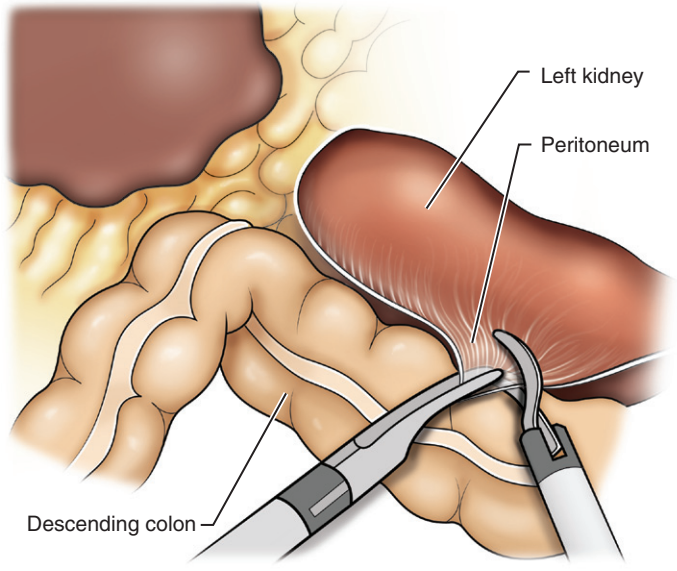

Figure 55–14. Medial traction on the colon helps identify additional colorenal attachments and assists in differentiating the undersurface of the large bowel mesentery. Care must be taken at this step to avoid creating a mesenteric window.

with this maneuver. The thin colorenal attachments are incised and the colon is swept medially (Fig. 55–14). Care should be taken to avoid making a hole in the mesentery. Mesenteric fat has a brighter hue of yellow compared with the retroperitoneal or Gerotas fat, which allows for identification of the correct plane of

dissection. If the operative field is not adequately visualized, a paddle retractor may be placed in an additional lower midline trocar to aid in retracting the colon, pancreas, and spleen medially (see Fig. 55–4A). Blunt and sharp dissection is necessary to move these structures off the anterior surface of the kidney and hilum.

During a right-sided nephrectomy, the peritoneal incision is carried medially and parallel to the lateral border of the venacava and duodenum. A lateral (anterior axillary line) or high midline port may be needed to retract the liver anteriorly (see Fig 55–4B and C). Care must be taken to avoid thermal injury to the duodenum and gall bladder during incision of the peritoneum. Medial traction on the colon reveals colorenal attachments that must be divided to complete the colon dissection. Again, a low midline retractor may be helpful for visualization. A Kocher maneuver may be required to fully expose the medial portion of the kidney and the connective tissue overlying the renal hilum (Fig. 55–15).

Dissection of the Ureter

Once the colon has been adequately mobilized, the psoas muscle and tendon should be identified. Following this structure medially, the gonadal vessels are usually first encountered. These should be swept medially and the ureter is usually located just deep to these vessels. Peristalsis of the ureter can help differentiate between these two structures. **Once identified, the ureter is elevated and followed proximally to the lower pole of the kidney. The ureter is not divided at this time, because it can be used to help elevate the kidney** (Fig. 55–16). The tissue posterior to the ureter and lower pole of the kidney is swept anteriorly to further expose the psoas muscle. Care should be taken to try and stay above the psoas fascia to minimize postoperative thigh numbness. The instrument in the subxyphoid trocar is used to slide under the kidney all the way to the sidewall. This allows the surgeon to lift the kidney and place medial lymphatic and vascular attachments on stretch.

Identification of the Renal Hilum

Safe dissection of the renal hilum requires medial retraction of the colon and bowel by gravity or an additional retractor, as well as anterior retraction of the kidney, lifting it out of the renal fossa. With the ureter and lower pole of the kidney elevated, vessels entering the renal hilum can be identified and bluntly dissected using the tip of the irrigator-aspirator. **Firm elevation of the lower pole assists in identification and dissection of the renal hilar vessels** (Fig. 55–17). This is accomplished by gently placing the lateral grasper under the ureter and kidney until it abuts the abdominal sidewall. It is important to be sure that the

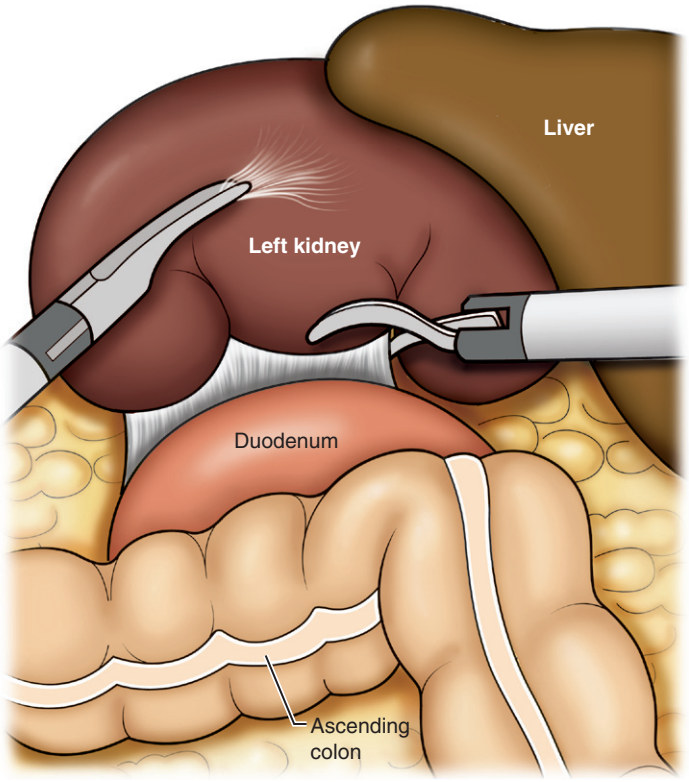

Figure 55–15. On the right side, the colon is reflected, and a Kocher maneuver may be performed to completely expose the kidney and the renal hilum.

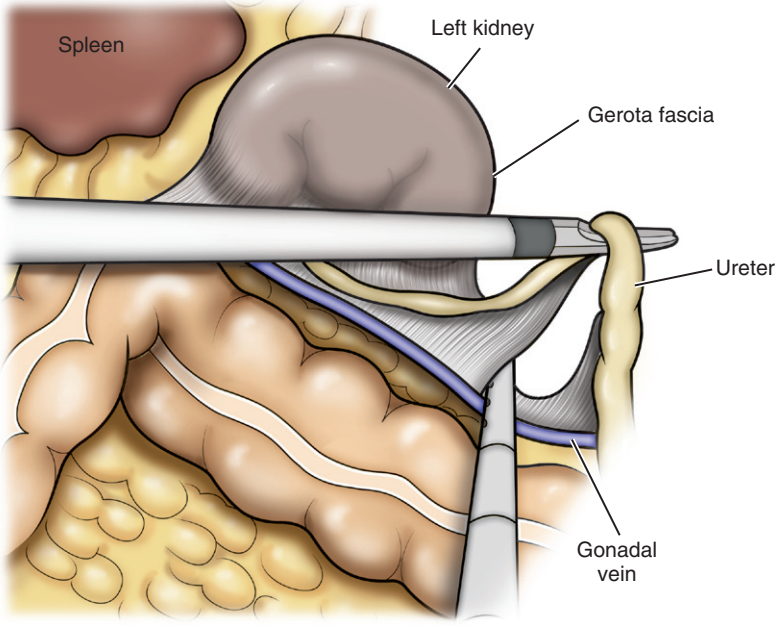

Figure 55–16. A curved dissector, in the left hand, is placed beneath the ureter and used to provide anterolateral elevation. On the right side the angle of insertion from the gonadal to the vena cava can be a source of significant bleeding if torn during elevation.

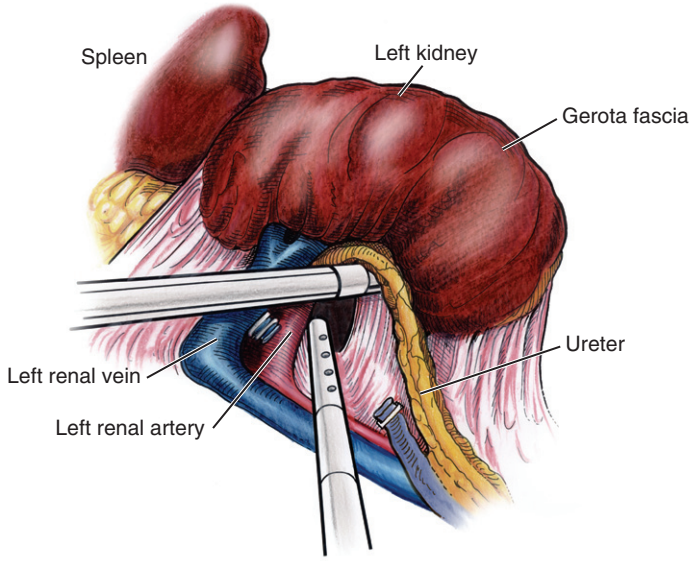

Figure 55–17. The lower pole of the kidney and ureter are firmly retracted anterolaterally, placing the hilum on stretch. The left gonadal vein has been ligated and divided.

grasper is against the muscle and not into the renal parenchyma. A gentle, layer-by-layer dissection is performed with the irrigator-aspirator until the renal vein is uncovered. There is usually an anterior bundle of connective tissue that needs to be incised in order to fully expose and visualize the vein. Gonadal, lumbar, and accessory venous branches can be clipped and divided as necessary.

Securing the Renal Blood Vessels

By clearing off inferior attachments and lymphatics, one can identify the renal artery. If the irrigator-aspirator tip is not precise enough for meticulous dissection, a hook electrode can be used to dissect the lymphatic vessels free of the vein and artery. **With an endovascular gastrointestinal anastomosis (GIA) stapler, the artery is divided first, followed by the vein** (Fig. 55–18). We prefer to use staples in this area because three rows of staples will be left on the vessel stump and are unlikely to be dislodged during subsequent dissection. In some instances clips may be needed. We prefer to use at least five clips on the patient side, when possible.

Isolation of the Upper Pole

Once the hilar vessels have been divided, the dissection continues posteriorly and superiorly to the upper pole. The adrenal gland is preserved in cases of simple nephrectomy by staying close to the upper pole (Fig. 55–19). This is accomplished by incising the Gerota fascia anteriorly, just above the hilum. Gerota fat is then gently peeled off circumferentially above the upper pole of the kidney. At this point during the dissection, it may be necessary to clip and transect the ureter. This allows the kidney to be rotated anteriorly above the liver (right) or spleen (left) to facilitate incision of the uppermost attachments under direct vision. In cases of extreme fibrosis, a subcapsular nephrectomy can be performed once the artery and vein have been controlled (Moore et al, 1998). Long, blunt instruments, such as the closed stapler or the 10-mm Ligasure Atlas (Valleylab, Boulder, CO) are particularly well suited for reaching and freeing the upper pole attachments.

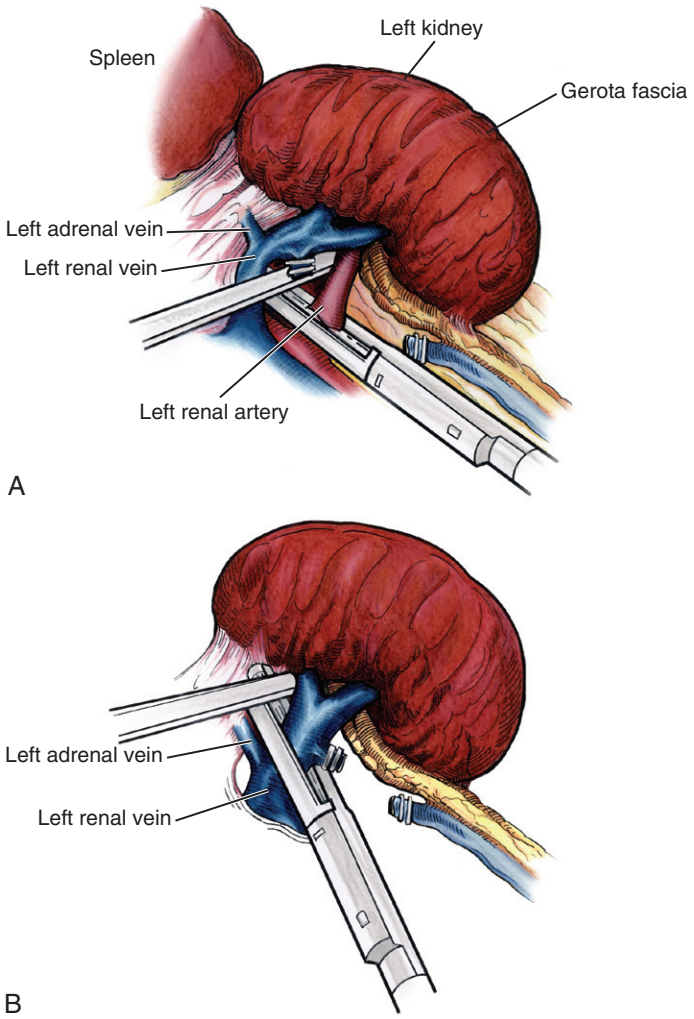

Figure 55–18. **A,** First, the renal artery is stapled using an endovascular gastrointestinal anastomosis (GIA) stapler. **B,** The renal vein is secured lateral to the adrenal vein with the GIA stapler. If clips are used on the gonadal or adrenal vessels, the surgeon must be careful to exclude them from the jaws of the stapler.

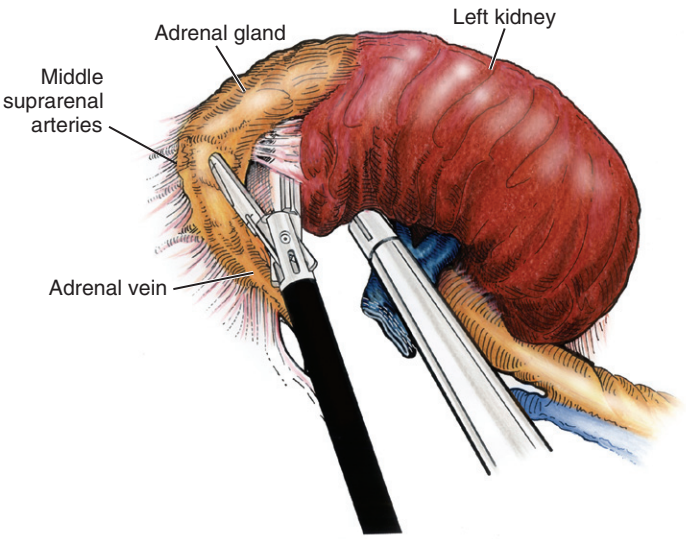

Figure 55–19. The adrenal gland can be preserved during simple nephrectomy or radical nephrectomy as indicated by dissecting it from the superior pole of the kidney.

Organ Entrapment and Extraction

The kidney can be removed intact or through morcellation. When morcellation is performed, the specimen should be placed into a sturdy entrapment sac (Urban et al, 1993). This minimizes the risk of rupture during mechanical morcellation of the tissue (Landman et al, 2000; Pautler et al, 2002). Using ring forceps and a Kocher clamp, the kidney and collecting system can be morcellated and removed in small pieces (Fig. 55–20). Alternatively, the kidney can be removed intact through an incision after placement into a sac (Fig. 55–21). The kidney can be worked out of an extended trocar site or Pfannenstiel incision. For trocar sites greater than 5 mm, it is helpful to place the closure sutures before removing the kidney. Once the sutures are placed, trocars can be reinserted for kidney entrapment and removal.

Postoperative Management

The orogastric tube is removed at the conclusion of the procedure. The patient can begin a diet as tolerated. The Foley catheter should be removed once the patient is comfortably ambulating. The patient is discharged when tolerating a regular diet. Unrestricted activity can usually be resumed according to the patient's comfort.

Results

The postoperative results of laparoscopic nephrectomy are comparable to that of open surgery, with much less pain and shorter convalescence. **Postoperative pain control requirements are approximately four times less than with traditional open incisions. Hospital stays have been decreased by 50%, and the time to full convalescence has been reported to be markedly less than with open removal.** In early series, the mean operative times were greater than 300 minutes. However, with advances in techniques, experience, and equipment, current operative times have decreased dramatically (Kerbl et al, 1994a, 1994b; Nicol et al, 1994; Parra et al, 1995; Baba et al, 1996; Rassweiler et al, 1998).

RENAL CYSTIC DISEASE

Renal cysts are extremely common and are present in more than one third of patients more than 50 years old (Laucks and McLachlan, 1981; Carrim et al, 2003). **They rarely require surgical intervention, but indications include cyst-associated pain, infection, or obstruction** (Hoenig et al, 1997; Wolf, 1998; Roberts et al, 2001; Doumas et al, 2004; Camargo et al, 2005). The increased use of cross-sectional imaging has also increased the detection of indeterminate renal cystic lesions and complex renal cysts, bringing an increased number to the attention of urologists. Classification schema have been developed to help clinicians make determinations regarding management, the most popular being the Bosniak system (Table 55–2) (Israel and Bosniak, 2005). Although these schema can be extremely useful, they are not diagnostic, and surgery may be required in some cases to exclude malignancy.

Indications

First-line therapy and diagnosis of symptomatic renal cysts often involves percutaneous image-guided needle aspiration, with or without the use of a sclerosing agent, to prevent recurrence. If symptoms temporarily resolve and recur when fluid reaccumulates, this increases the likelihood that surgical treatment will be successful in resolving the pain (Rané et al, 2004). Caution should be exercised in use of cyst aspiration and sclerosing agents in peripelvic cysts, because fibrosis may occur (Wehle and Grabstald, 1986; Hulbert et al, 1988; Santiago et al, 1998; McDougall, 2000).

In addition to causing pain, cysts may compress the renal parenchyma or other adjacent organs, cause ureteral obstruction and obstructive uropathy, spontaneously bleed, cause hypertension, or become infected. Laparoscopic decortication or unroofing may be used to treat these cysts, which are typically simple in character (Fig. 55–22). Cysts with complex appearance, such as thickened septa, calcification, or enhancement (Bosniak class III-IV), may be explored and sampled laparoscopically to rule out renal cell carcinoma due to their increased risk of harboring

Table 55–2.

Renal Cyst Classification Based on Updated Bosniak Criteria

TYPE	DESCRIPTION	RECOMMENDED MANAGEMENT
I	A benign simple cyst with a hairline thin wall that does not contain septa, calcifications, or solid components. It measures water density and does not enhance.	No follow-up necessary
II	A benign cyst that may contain a few hairline thin septa in which "perceived"* enhancement may be present. Fine calcification or a short segment of slightly thickened calcification may be present in the wall or septa. Uniformly high-attenuation lesions (3 cm) (so-called high-density cysts) that are well marginated and do not enhance are included in this group.	No follow-up necessary
IIF	Cysts that may contain multiple hairline thin septa or minimal smooth thickening of their wall or septa. Perceived enhancement of their septa or wall may be present. Their wall or septa may contain calcification that may be thick and nodular, but no measurable contrast enhancement is present. These lesions are generally well marginated. Totally intrarenal nonenhancing high-attenuation renal lesions >3 cm are also included in this category.	Follow-up imaging required
III	"Indeterminate" cystic masses that have thickened irregular or smooth walls or septa in which measurable enhancement is present. These are surgical lesions, although some will prove to be benign (e.g., hemorrhagic cysts, chronic infected cysts, and multiloculated cystic nephroma), some will be malignant, such as cystic renal cell carcinoma and multiloculated cystic renal cell carcinoma.	Surgical treatment
IV	These are clearly malignant cystic masses that can have all the criteria of category III, but also contain enhancing soft tissue components adjacent to, but independent of, the wall or septum. These lesions include cystic carcinomas and require surgical removal.	Surgical treatment

From Israel GM, Bosniak MA. An update of the Bosniak renal cyst classification system. Urology 2005;66:484–8.

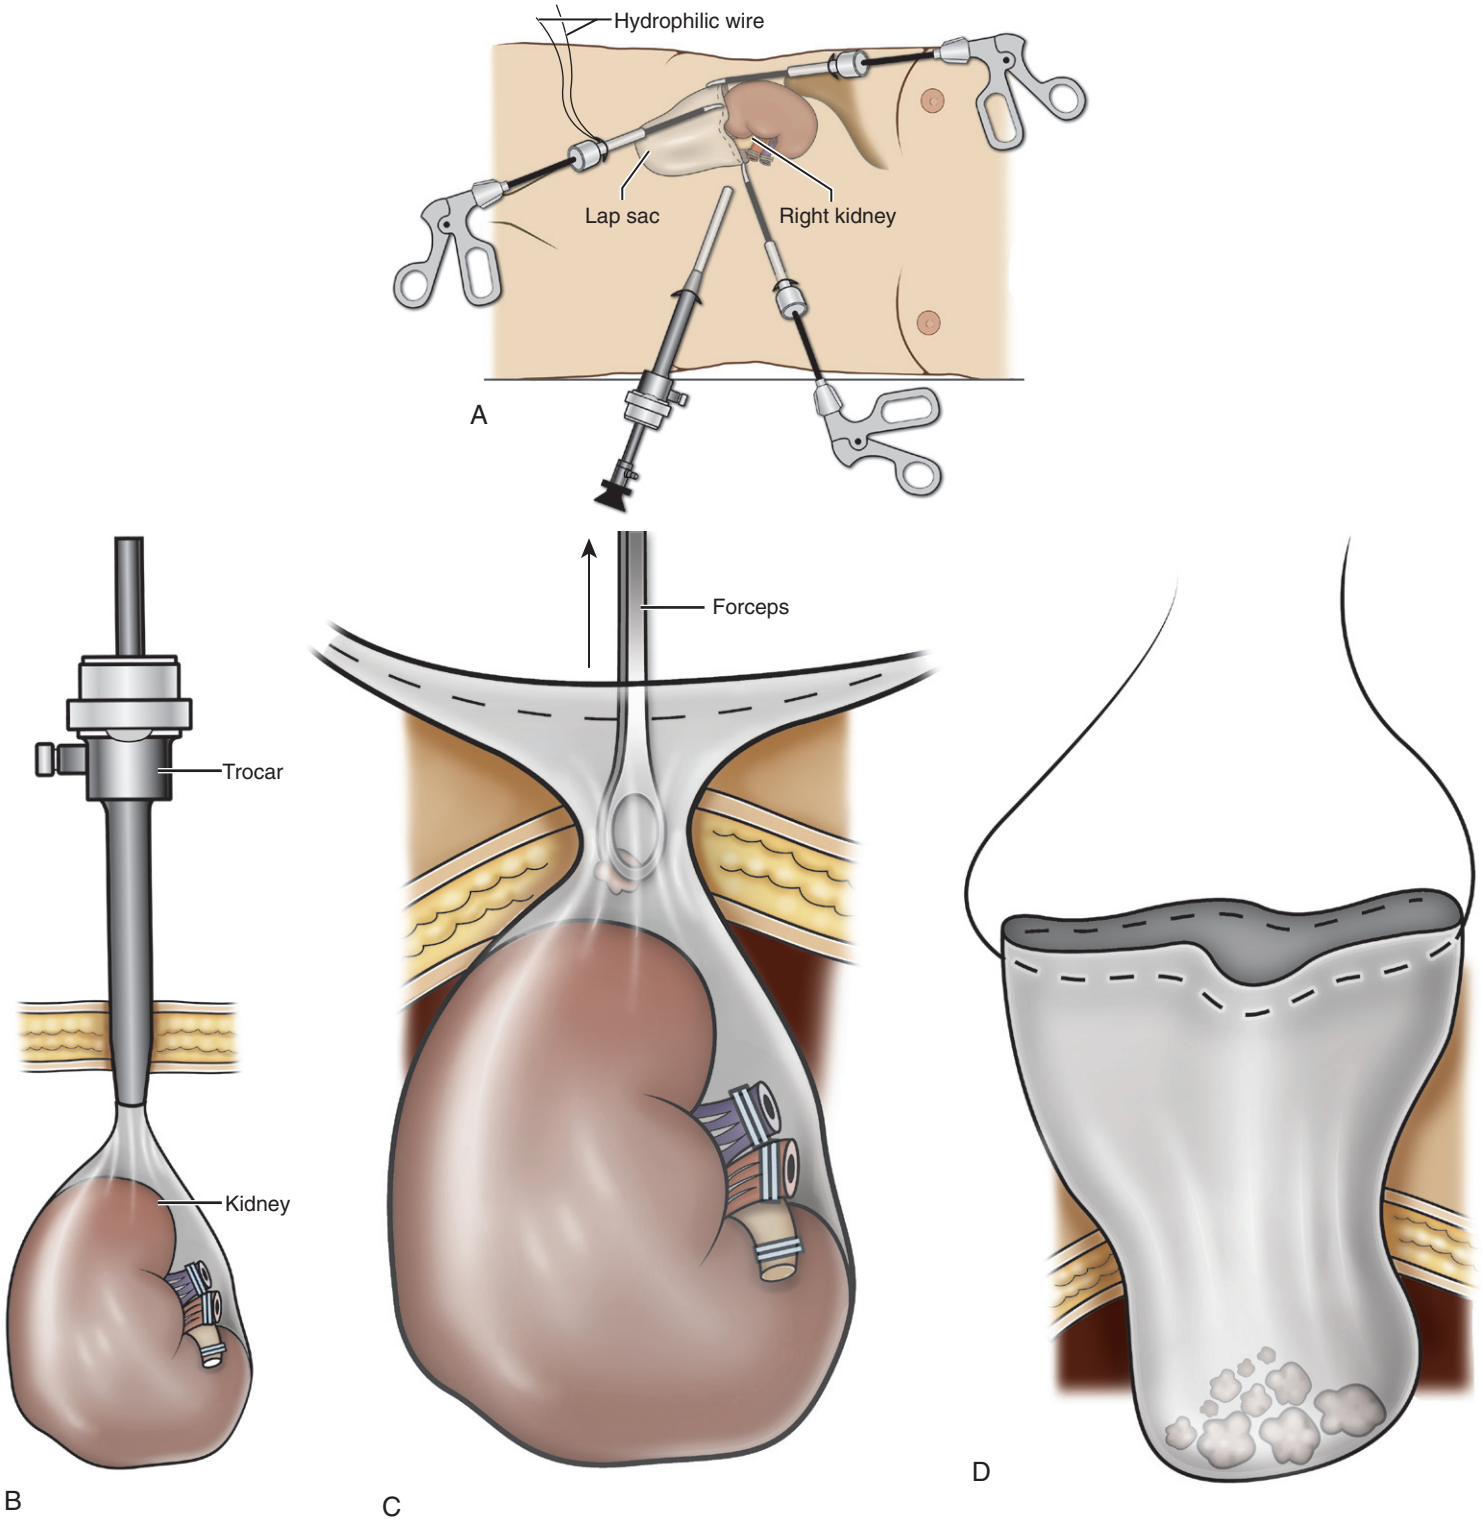

Figure 55–20. Removal of the morcellated specimen. **A,** The LapSac (Cook Urological, Spencer, IN) entrapment sac is introduced through the lateral 10-mm trocar site after passing a hydrophilic wire through the opening of the LapSac. The entrapment sac is then released within the abdomen. The wire facilitates opening the bag and placement of the specimen. A lateral 5- or 3-mm port may be necessary to assist with holding placement of the specimen inside the LapSac. **B,** Once the specimen is within the LapSac, the wire is removed, the bag cinched closed, and the opening withdrawn through the 10-mm trocar site. **C,** The entrapment sac is pulled tightly up against the abdominal wall, with two hands pushing part of the specimen to appear through the opening of the LapSac. After the site is carefully draped, manual morcellation with ring forceps or a Kelly clamp can be used. **D,** The entrapment sac is removed once the remaining specimen fragments are small enough to be extracted through the trocar site. Only the tissue visible from the opening is grasped. Blind passes into the bag may injure surrounding bowel segments.

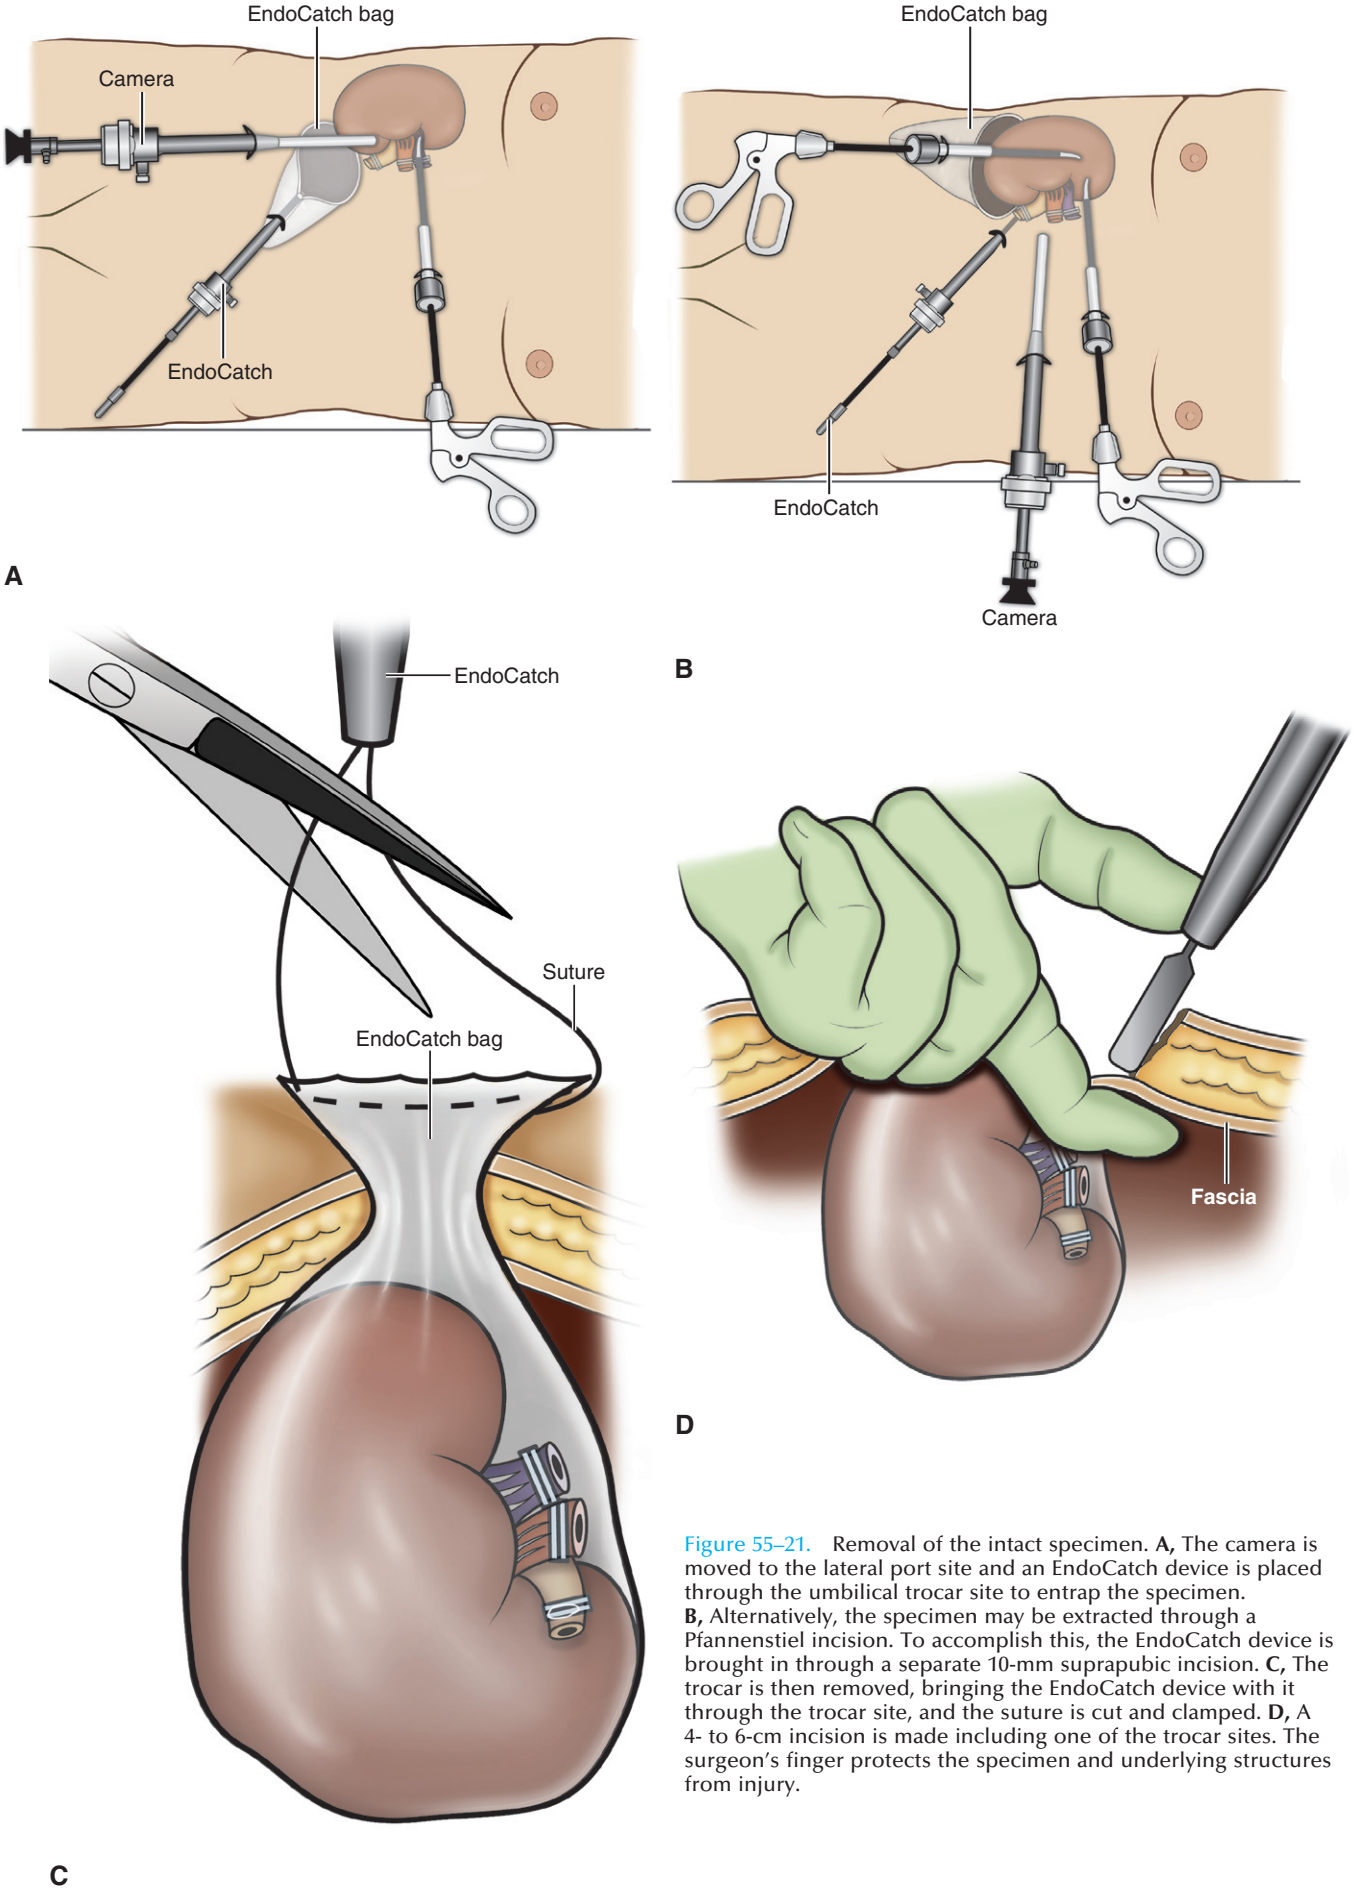

Figure 55–21. Removal of the intact specimen. **A,** The camera is moved to the lateral port site and an EndoCatch device is placed through the umbilical trocar site to entrap the specimen. **B,** Alternatively, the specimen may be extracted through a Pfannenstiel incision. To accomplish this, the EndoCatch device is brought in through a separate 10-mm suprapubic incision. **C,** The trocar is then removed, bringing the EndoCatch device with it through the trocar site, and the suture is cut and clamped. **D,** A 4- to 6-cm incision is made including one of the trocar sites. The surgeon's finger protects the specimen and underlying structures from injury.

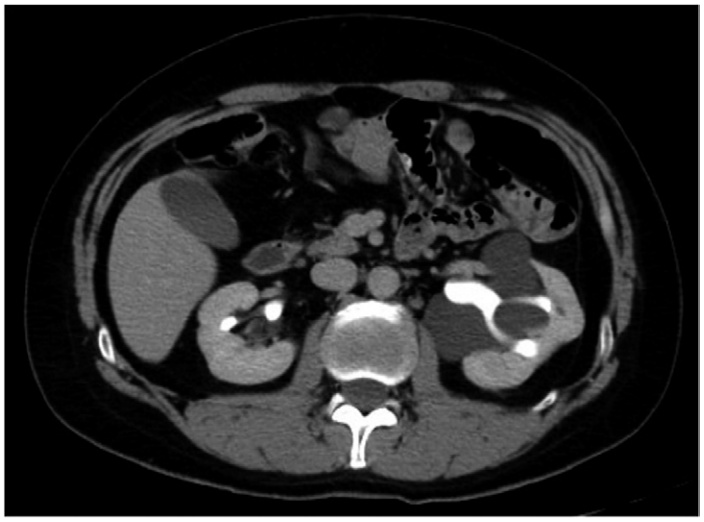

Figure 55–22. Axial CT scan in delayed phase after IV contrast administration, demonstrating peripelvic cysts in a patient who presented with left flank pain.

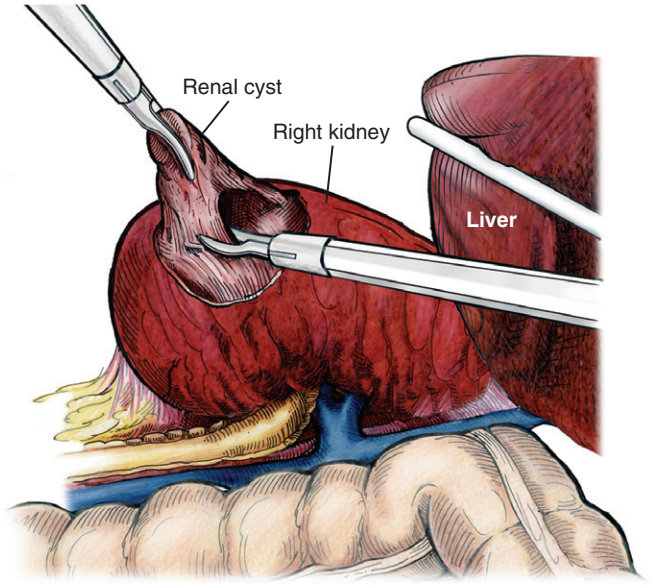

Figure 55–23. The cyst fluid is aspirated with a laparoscopic aspiration needle. After decompression of the cyst, the wall can easily be grasped and manipulated. The cyst is elevated with a grasper and scissors or ultrasonic shears to circumferentially excise the cyst wall. The edge of the cyst is carefully inspected, and biopsies are performed using the 5-mm laparoscopic biopsy forceps as needed.

malignancy (Cloix et al, 1996; Santiago et al, 1998). Options include cryoablation, enucleation, partial nephrectomy, or radical nephrectomy. If there is any question of cyst proximity to the collecting system, cystoscopy and placement of an open-ended ureteral catheter may be performed to ensure the integrity of the collecting system after cyst excision.

A subset of patients with autosomal dominant polycystic kidney disease (ADPKD) may develop cyst-associated pain. Laparoscopic cyst decortication, marsupialization, or unroofing can be of benefit to these patients by offering a minimally invasive treatment that is successful in relieving pain in up to 83% of cases (Lifson et al, 1998; Dunn et al, 2001; Lee et al, 2003). In patients with end-stage renal disease, bilateral synchronous laparoscopic nephrectomy may be performed in patients with enlarged, symptomatic, or infected kidneys (Gill et al, 2001; Rehman et al, 2001; Bendavid et al, 2004; Desai et al, 2008). Because an incision will be required to remove kidneys that are often quite enlarged, a hand port may be placed in the midline and used bilaterally to facilitate the dissection (Rehman et al, 2001; Jenkins et al, 2002).

Procedure

Depending on cyst location, a transperitoneal or retroperitoneal approach may be used as previously described. Intraoperative ultrasonography may be used to identify the cyst or cysts in question. It is usually easier to dissect out the cyst wall before evacuating fluid. The wall of the cyst can then be grasped and excised, cutting along the junction between the cyst wall and the renal parenchyma (Fig. 55–23). If suspicious lesions are noted in the base, biopsies may be taken using the 5-mm biopsy forceps. If no evidence of malignancy is seen, the remaining cyst wall may be fulgarated with either electrocautery or the argon beam coagulator. Care should be taken when ablating the surface, because inadvertent entry into the collecting system can easily occur (Cherullo et al, 1999). Moreover, these surfaces can be friable and prone to significant bleeding. Packing with hemostatic agents or suturing may be necessary. One should have a low level of suspicion for entry into the collecting system and, as such, a low threshold for leaving a drain (Fig. 55–24). If malignancy is noted, extirpative surgery or cryoablation may be used to treat the remainder of the lesion.

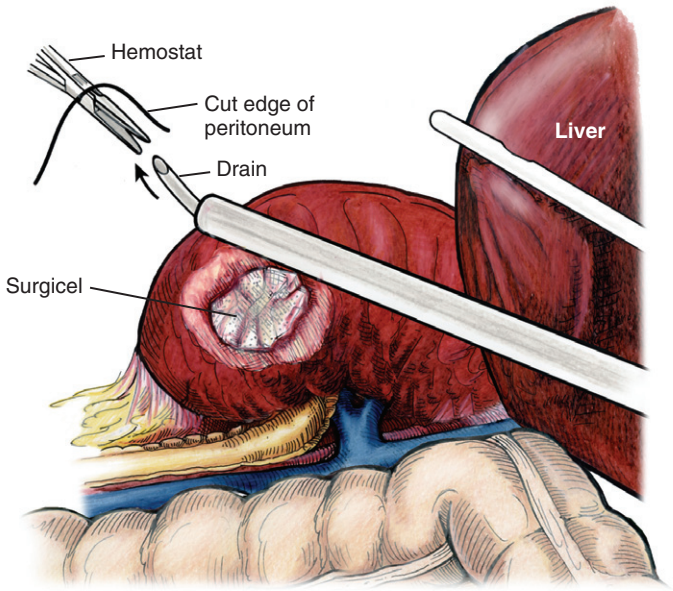

Figure 55–24. Drain placement after renal cyst excision. If the collecting system has been entered, it is closed and a drain placed. To insert the drain, a hemostat is passed through a small stab incision in the side and advanced into the abdominal cavity under direct vision. A drain is placed through a trocar site and advanced toward the open hemostat using the trocar to direct the drain. The colon is brought back over the kidney and attached to the sidewall to "reperitonealize" the kidney and drain.

When treating central or perihilar cysts, it may not be feasible to remove a large portion of the cyst wall. In these cases, it is helpful to place a pedicle of autologous fat into the defect to act as a wick (Nieh and Bihrle, 1993).

Results

Laparoscopic treatment of symptomatic renal cysts has been found to be effective in both decompression and pain control. A study evaluating treatment durability at a mean follow-up of 26 months demonstrated a 100% pain-free rate in patients treated for a solitary symptomatic renal cyst (Lifson et al, 1998). In a separate study with a mean follow-up of 60 months, 80% to 90% of patients have complete resolution of pain after laparoscopic cyst decortication. In patients with ADPKD, additional benefits of cyst decortication have been noted, including decreased blood pressure (Dunn et al, 2001; Lee et al, 2003). Recurrence of pain in this group is higher than with simple cysts, and durability is moderate (Brown et al, 1996). No significant changes in renal function were noted postoperatively.

Patients undergoing surgery for cystic renal disease are inherently a heterogeneous group, made up of patients with simple renal cysts, complex or indeterminate cysts, and ADPKD. Interpretation of incidence reports of renal cell carcinoma in these series must take this fact into account. That said, the reported incidence of renal cell carcinoma in cystic lesions is between 3% and 20% (Rubenstein et al, 1993; Lifson et al, 1998; Roberts et al, 2001; Limb et al, 2002).

RENAL BIOPSY FOR MEDICAL RENAL DISEASE

Histologic information is a key component in making treatment decisions and for prognosis in patients with proteinuria or unexplained renal insufficiency (Morel-Maroger, 1982; Gault and Muehrcke, 1983; Manaligod and Pirani, 1985). Although the modality of choice is typically ultrasound-guided percutaneous renal biopsy, laparoscopic biopsy may be preferred in certain situations, such as failed percutaneous biopsy, renal anatomic anomalies, risk of bleeding complications, morbid obesity, multiple renal cysts, or solitary kidneys.

Procedure

The patient is placed in the full-flank position with the table flexed to increase working space between the costal margin and the iliac crest. Retroperitoneal access is preferred and obtained using techniques described later in this chapter. Renal biopsy is accomplished with the use of two trocars. With blunt dissection, Gerota fascia is opened, and the lower pole of the kidney is exposed (Fig. 55–25A). **In obese patients, intraoperative ultrasonography may be required to localize the kidney when copious retroperitoneal or perinephric fat is present.** A 5-mm biopsy forceps is used to take samples of cortical tissue; hemostasis is achieved with the argon beam coagulator; and adjunctive hemostatic measures are used as necessary (Fig. 55–25B).

Results

A multi-institutional series reporting on outcomes of laparoscopic renal biopsy in 74 patients over 9 years showed a mean operative time of 123 minutes, mean estimated blood loss of 67 cc, and discharge within 24 to 48 hours unless other preexisting medical conditions required a longer stay (Shetye et al, 2003). Tissue obtained from 96% of patients was adequate for diagnosis, with a complication rate of 13.5%. The authors concluded that laparoscopic renal biopsy may be performed safely with a high success

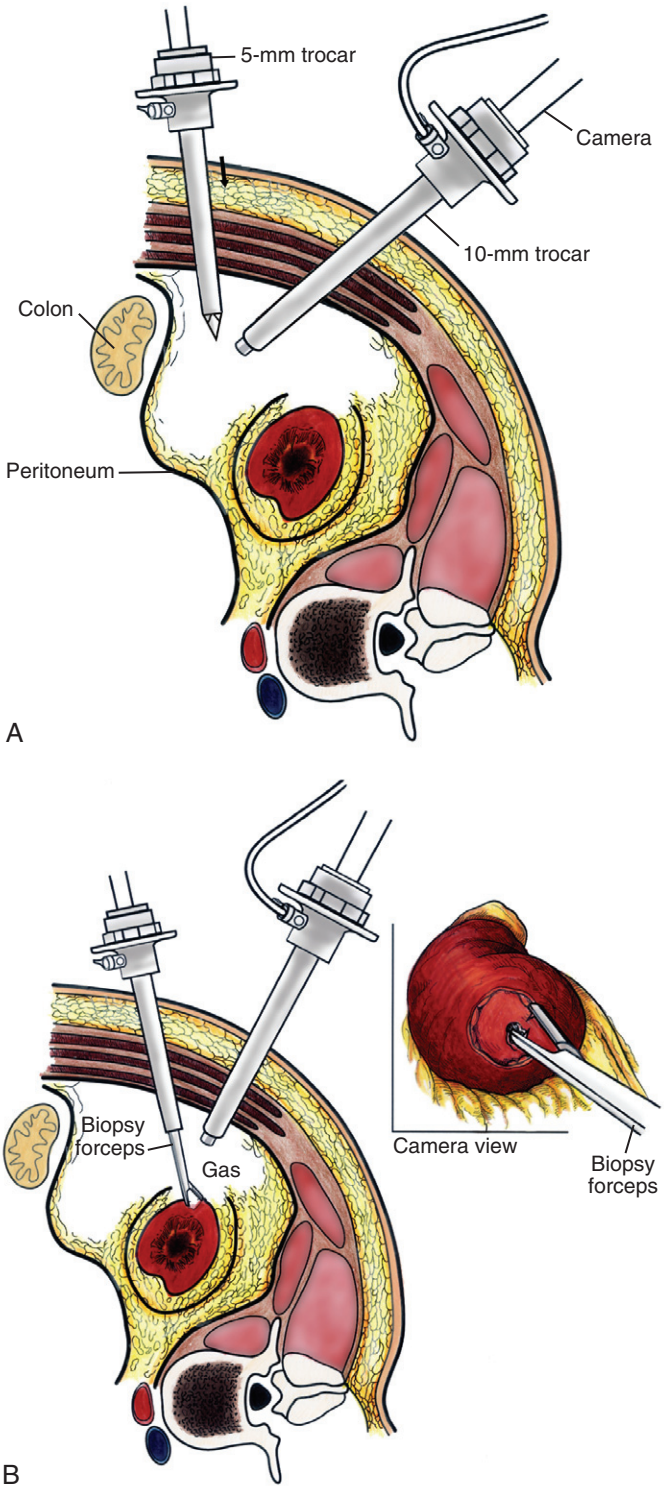

Figure 55–25. **A,** After establishing a working space, a 5-mm trocar is placed under direct vision. The working instruments are passed through this port. The camera can be used to assist with dissection and is frequently cleaned to maintain adequate visualization. **B,** Gerota fascia is opened with the use of the scissors. A 5-mm two-tooth laparoscopic biopsy forceps is used to take two to three samples from the lower pole of the kidney.

rate, and, that as experience grows, the complication rate and operative duration would likely decrease. In another series of 17 patients, using balloon dilatation to create the working space demonstrated 100% success in obtaining renal tissue adequate for diagnosis. Mean operative time was 35 minutes (excluding anesthesia time), complication rate was 11%, and 15 of 17 patients were discharged within 24 hours. **In published series of laparoscopic renal biopsy, hemorrhage is the most common complication. Caution should be used in resumption of anticoagulation in patients who require it postoperatively. If signs or symptoms of postoperative anemia or hypovolemia occur, a low threshold should be used to evaluate the patient with computed tomography (CT).**

PYELOLITHOTOMY, NEPHROLITHOTOMY, AND URETEROLITHOTOMY

Advances in stone therapy have made pyelolithotomy, nephrolithotomy, and ureterolithotomy almost obsolete. However, a select subgroup of stone patients will benefit from these approaches. Depending on local demographics and incidence of stone disease, the **indications for laparoscopic stone extraction may vary but primarily include patients with renal stones who are undergoing simultaneous laparoscopic pyeloplasty** (Ball et al, 2004; Stein et al, 2008). **In these patients, a flexible cystoscope may be passed through one of the trocars to remove stones. A laparoscopic grasper may also be used to remove stones, but patients should always undergo a complete nephroscopy to ensure stone clearance. Other patients who may benefit include those with unusual anatomy (pelvic kidney)** (Chang and Dretler, 1996; Harmon et al, 1996; Hoenig et al, 1997), **stones resistant to fragmentation** (Jordan et al, 1997), **and failed extracorporeal shock wave lithotripsy (ESWL), ureteroscopy, or percutaneous procedures.**

Treating stone disease in ectopic kidneys can be particularly challenging. Ectopic kidneys frequently have anomalous vasculature, and therefore access into the collecting system carries a higher risk of bleeding. Laparoscopy may be used to assist in the placement of percutaneous access to minimize the risk of bleeding complications (Eshghi et al, 1985; Tóth et al, 1993; Troxel et al, 2002).

A retrospective comparative study of 12 patients who underwent percutaneous nephrolithotomy (PCNL), and 16 patients who underwent laparoscopic retroperitoneal pyelolithotomy, revealed no benefit to the laparoscopic approach. Laparoscopy was also associated with longer operative time, longer recovery, inferior cosmesis, and required more advanced skills (Goel and Hemal, 2003). The authors concluded that PCNL should remain the gold standard for treating large renal stones, unless the patient is undergoing surgery for concomitant pathology.

Robotic approaches to stone disease have also been described for the treatment of staghorn calculi, with or without simultaneous pyeloplasty. In a study of 12 patients undergoing robotic extended pyelolithotomy, 11 were stone free after surgery as assessed by postoperative CT scan. Mean operative time was 158 minutes, with mean estimated blood loss of 100 cc (Badani et al, 2006).

Laparoscopic anatrophic nephrolithotomy has been reported in animal models and small case series (Kaouk et al, 2003; Simforoosh et al, 2008). Initial reports are encouraging, but, to date, renal functional outcomes in humans have not been evaluated with nuclear renal scans. Further studies are required to assess the feasibility of this procedure.

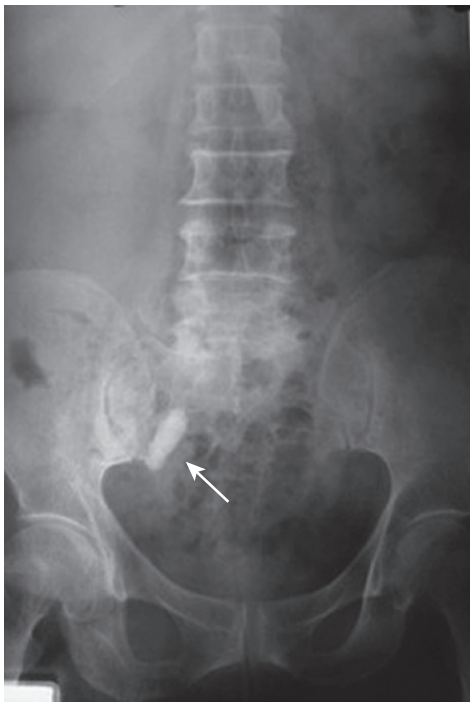

Figure 55–26. Abdominal radiograph demonstrating a large, impacted, distal right ureteral stone that was addressed with ureterolithotomy.

Large or impacted ureteral stones may be managed laparoscopically with ureterolithotomy (Fig. 55–26). In a series of 93 patients undergoing this procedure, successful stone removal was achieved in 85 patients, with eight failures due to inability to locate the stone (Gaur et al, 2002). Mean operative time was reported as 80 minutes, and in many of the patients, the ureter was left open, leading to shorter operative time but more complications with prolonged urinary leakage. Other authors have also reported this approach for impacted or large ureteral stones (Hemal et al, 2003). In this series of 31 patients, success was reported in all cases, no stent was used, and closure of the ureterolithotomy in all cases resulted in a prolonged urinary leakage rate of 6.5% at 48 hours.

NEPHROPEXY

Renal ptosis, although rare, is a real cause of chronic flank or upper abdominal pain. The precise origin of symptoms is unknown, but is likely secondary to either transient ischemia or urinary obstruction (Moss, 1997). It is usually defined as the descent of the kidney by more than two vertebral bodies, but before a definitive diagnosis is made, objective proof that is associated with pain should be obtained. The typical patient with a ptotic kidney is a young, thin female who complains of pain while in an upright position. **Supine and erect intravenous pyelography (IVP) can be used for diagnosis, with the finding of interest being descent of the symptomatic kidney by two vertebral bodies** (Fig. 55–27)**. Nuclear imaging may also quantify obstruction of blood flow or drainage in the upright position. Color Doppler sonography in both the supine and upright positions can also be used to evaluate differential blood flow.** If a ptotic kidney is present, the expected

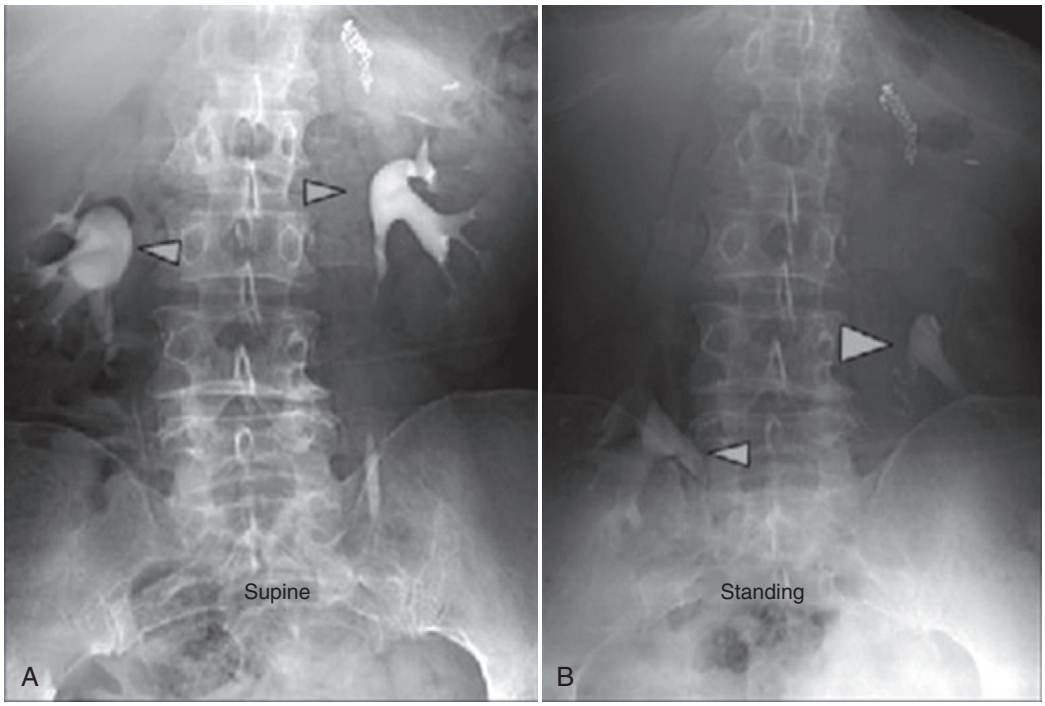

Figure 55–27. Intravenous pyelogram demonstrating bilateral ptotic kidneys in the supine **(A)** and standing **(B)** positions. (From El-Moula MG, Izaki H, Kishimoto T, et al. Laparoscopic nephropexy. J Laparoendosc Adv Surg Tech A 2008;18:230–6.)

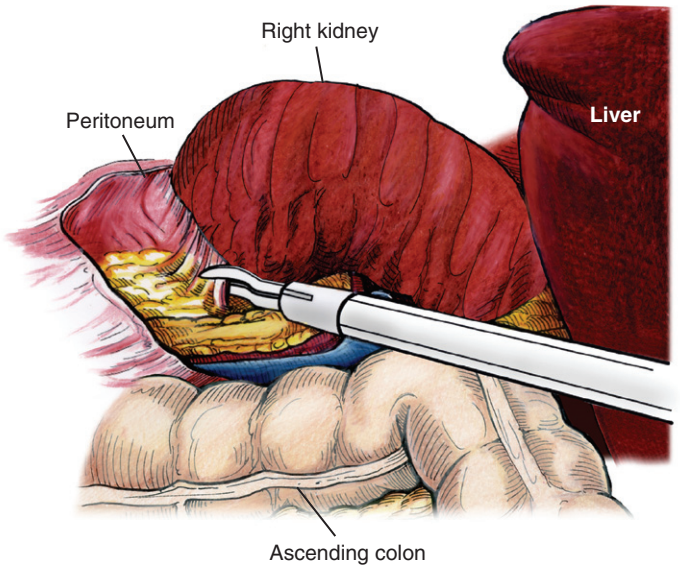

Figure 55–28. The kidney is stripped of overlying Gerota fascia down to the surface of the renal capsule. All remaining attachments are divided, allowing full mobility for repositioning.

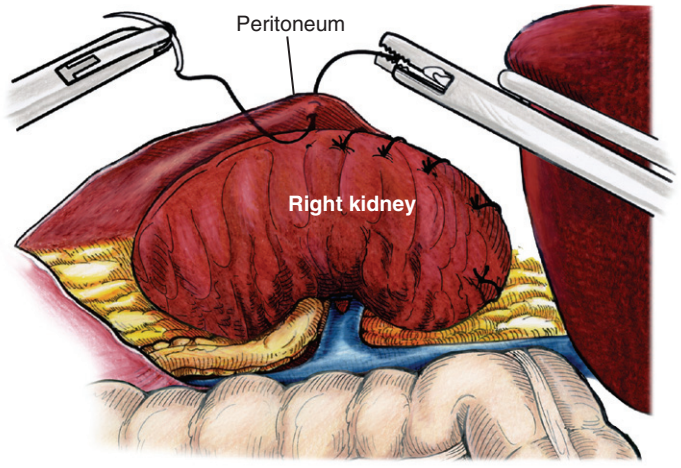

Figure 55–29. Nephropexy. Once the kidney is free of lateral and posterior attachments, multiple 2-0 sutures are placed into the capsule and the lateral edge of the fascia overlying the abdominal wall. Sutures may also be placed between the anterior renal capsule and the parietal peritoneum for additional support.

finding would be diminished blood flow while in the erect position. **Before surgical repair, obstruction, decreased blood flow, or significant descent correlating with pain should be documented.**

Procedure

Surgical repair is performed using either a standard transperitoneal or retroperitoneal approach to fully mobilize the affected kidney and expose the fascia overlying the psoas and quadratus lumborum muscles (Chueh et al, 2002; Matsui et al, 2004) (Fig. 55–28). Beginning at the upper pole, interrupted sutures are placed to secure the lateral edge of the renal capsule to the fascia overlying the muscle (Fig. 55–29). Sutures may also be placed between the anterior renal capsule and the parietal peritoneum for additional support. Using sutures with preplaced Lapra-Ty clips (Ethicon Endosurgery, Cincinnati, OH), the initial pass is made through the fascia or peritoneum, and a second clip is placed on the suture after the pass through the kidney. An alternative technique describes the use of tension-free vaginal tape to secure the kidney (Hübner et al, 2004). By placing the needles such that the tape is passed around the lower pole of the kidney and out through the abdominal wall, the kidney is secured. Sometimes this is found in

conjunction with a ureteropelvic junction obstruction that should be adressed simultaneously (Boylu et al, 2009).

Results

A retrospective study of 30 patients undergoing laparoscopic nephropexy with a median follow-up of 5.9 years demonstrated improvement in all patients, 11 with complete relief of symptoms (Plas et al, 2001). Significant improvement in renal function was measured by renal scan in 9 of 10 patients undergoing the study postoperatively. Two patients developed a recurrent ptotic kidney with greater than 5 cm of descent documented by IVP. An additional study of 48 patients, with a median follow-up of just more than 8 years, revealed that 94% of patients had no signs of significant ptosis on postoperative imaging, and 91% of patients had improvement in their pain symptoms (Gözen et al, 2008). Mean operative time was 95 minutes, and mean estimated blood loss was 50 cc. Patient satisfaction was high, and the authors concluded that laparoscopic nephropexy provided a minimally invasive approach to these patients with good long-term clinical outcomes.

CALYCEAL DIVERTICULECTOMY

Patients with symptomatic calyceal diverticula containing stones can be managed laparoscopy. ESWL and ureteroscopy may be employed, but due to infundibular stenosis, stone clearance rates are low (Jones et al, 1991; Pang et al, 1992; Stream et al, 1992). **The principles of treatment include the removal of stones and widening of the infundibular stenosis to prevent urine stasis or ablation of the diverticula cavity.** In the past, symptomatic calyceal diverticula have been managed with partial nephrectomy, with marsupialization and fulgaration of the diverticulum, and occasionally simple nephrectomy. More recently, percutaneous treatment has been used, but stones or symptoms may recur if the cavity is not fully ablated (Donnellan et al, 1999). **A laparoscopic approach may be indicated with large, peripheral diverticula, or for centrally located diverticula with proximity to the renal hilum.**

Procedure

The location of the diverticula will be the primary driver for choosing either a transperitoneal or retroperitoneal approach. Once the renal dissection is completed, locating the diverticulum may prove difficult. The presence of dense adhesions on the surface of the kidney overlying the divericulum may be present along with a "dimpling" effect on the renal capsule. Intraoperative ultrasonography may also be used to aid in the location of the divertiulum or to confirm a suspected location. Once localized, the overlying parenchyma is incised and opened to expose the diverticulum, which is subsequently opened with cautery. Stones may then be removed, and the argon beam coagulator or monopolar cautery device can be used to fulgarate the diverticular lining. The collecting system is closed with suture, and perirenal fat may be placed into the defect to further decrease the likelihood of recurrence. A drain is usually left in place.

Results

Published reports on laparoscopic calyceal diverticulectomy are limited to small series and case reports. Excellent results have been reported by numerous authors, demonstrating the definitive nature of this treatment modality (Miller et al, 2002; Gluckman et al, 1993; Ruckle and Segura et al, 1994; Harewood et al, 1996; Wolf, 2000; Canales and Monga, 2003; Wyler et al, 2005). Probably due to the rarity of this surgery, complications are also rare and have not been reported yet in the literature.

NEPHROLYSIS

Chyluria is caused by lymphatic rupture or fistulous connection into the pyelocalyceal system. It is a rare problem worldwide but is commonly seen in tropical countries when filariasis (*Wuchereria bancrofti* or *Brugia malayi*), the most common cause, is endemic (Tandon et al, 2004). Rarely, schistosomiasis may also be a cause of chyluria, and nonparasitic chyluria is rare. Other reported etiologies include tuberculosis (Wilson and White, 1976), idiopathic lymphorenal fistula (Eisner et al, 2009), prior surgery (Kim and Joudi, 2009), pregnancy (Onyeije et al, 1997), thoracic duct obstruction (Garrido et al, 1995), mesenteric adenitis (Cohen et al, 1984), renal vasculitis (El-Reshaid et al, 1998), and metanephric adenoma (McNeil et al, 2008).

Diagnosis

Patients typically present with milky white urine and may have nephrotic range proteinuria. Initial evaluation includes urinalysis and culture, urine for chyle, and complete blood count to check for eosinophila. Evaluation to localize the fistula may include cystoscopy with retrograde pyelogram, CT, magnetic resonance imaging (MRI), or lymphangiography (Fig. 55–30).

Treatment

Chyluria is often self-limited, and many patients may be managed conservatively. In filariasis-associated cases, this involves treatment with a course of diethylcarbamazine (DEC) in combination with a low-fat diet (Tandon et al, 2004). Retrograde instillation of silver nitrate or povidone iodine into the collecting system as a sclerosing agent has also been described, and these agents are commonly used as first-line treatment with comparable success rates of approximately 80% (Dalela et al, 2004a; Goel et al, 2004). When conservative management fails or if cases are particularly severe, surgical intervention is undertaken.

Procedure and Results

Nephrolysis involves the complete mobilization of the kidney and skeletonization of the renal hilar vessels and upper ureter with ligation of the lymphatic channels. The procedure may be performed laparoscopically by either a transperitoneal or retroperitoneal approach and ensures complete lymphatic dissociation of the affected kidney (Chiu et al, 1995, Gomella et al, 1998). The use of an omental wrap around the hilum has also been described to provide an additional barrier against recurrence (Dalela et al, 2004b). Authors commonly performing this procedure report excellent success rates—approaching 100%.

RADICAL NEPHRECTOMY

Indications for Malignancy

Laparoscopic approaches to malignancy have been performed for over 20 years. The indications for radical nephrectomy are similar to those for open surgery. Kidneys with tumors as large as 25 cm

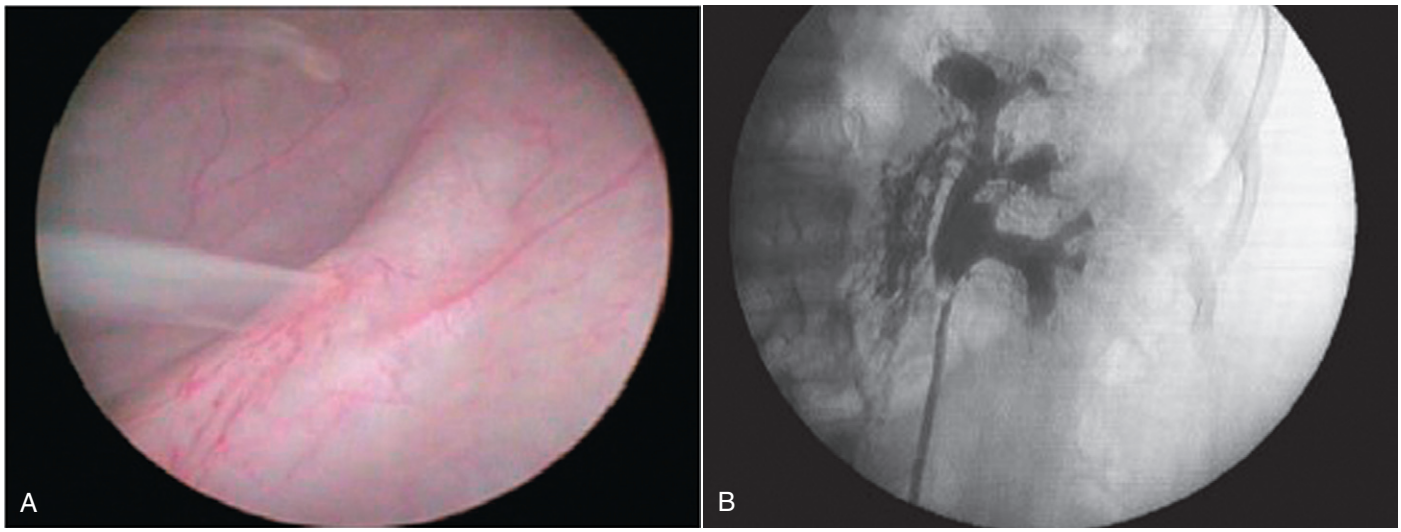

Figure 55–30. Chyluria. **A,** Cystoscopy demonstating milky white efflux from the left ureteral orifice. **B,** Retrograde pyelogram demonstrating lymphorenal fistula. (From Eisner BH, Tanrikut C, Dahl DM. Chyluria secondary to lymphorenal fistula. Kidney Int 2009;76:126.)

have been successfully removed laparoscopically, and cytoreductive nephrectomy has been performed in patients with metastatic disease (Walther et al, 1999). Moreover, tumors with low- level caval thrombi have also been removed (Martin et al, 2008).

Transperitoneal

Procedure

Access and trocar placement are similar to what has been described for simple nephrectomy. With larger masses, caval involvement or organ invasion, additional trocars or a hand port may be needed. The procedure for laparoscopic radical nephrectomy (LRN) is essentially identical to laparoscopic simple nephrectomy. The main distinguishing feature is that Gerota fascia is left intact during dissection. The adrenal may be removed en bloc with the kidney when indicated (Fig. 55–31A). Alternatively, this fascia is opened over the upper medial aspect of the kidney when adrenal-sparing nephrectomy is performed (Fig. 55–31B). Suspect lymph nodes may be removed, and a full hilar or retroperitoneal dissection can be carried out if deemed necessary. Excision of part of adjacent muscle or involved organs, such as the pancreas, liver, spleen, and bowel, has also been reported (Molina et al, 2004).

Results

Long-term cancer-specific survival data is now widely available from multiple centers around the world that perform laparoscopic radical nephrectomy (Table 55–3). Five- and 10-year outcomes show oncologic equivalence to open radical nephrectomy in treatment of renal cancer. Indeed, LRN has become the standard of care for most renal malignancies.

A multi-institutional study from centers performing LRN compared the surgical and disease-specific outcomes between open and laparoscopic radical nephrectomy, with long-term follow-up (Portis et al, 2002). Median follow-up was 54 months, and recurrence-free survival was 91% and 92%, respectively, for the two groups at 5 years. The 5-year cancer-specific survival was 98% for the laparoscopic cohort and 92% for the open cohort.

A comparative analysis of 67 patients undergoing LRN, with 54 patients undergoing open radical nephrectomy, evaluated perioperative and oncologic outcomes (Permpongkosol et al, 2005). The LRN group showed a longer mean operative time (256 vs. 193 minutes). However, this finding likely reflects the learning curve for laparoscopy, because the first 34 patients and last 33 patients in the LRN group had a significant operative time difference. Complications occurred in 15% of patients in the LRN and open groups, and blood transfusions were required in 6% and 20% of the patients, respectively. Most importantly, **the calculated disease-free survival rates for laparoscopic and open radical nephrectomy were 95% and 89%, respectively, at 10 years. The actuarial survival rates for laparoscopic and open radical nephrectomy were 87% and 75%, respectively, at 10 years.** These differences were not found to be statistically significant.

Most recently, 10-year oncologic outcomes data following LRN were reported. Recurrence-free, cancer-specific, and overall survival rates were 86%, 92%, and 65%, respectively, at 10 years postnephrectomy (Berger et al, 2009). **Of 73 patients undergoing LRN, no patient developed local recurrence, and 6 (8.2%) developed metastatic disease at a mean time to recurrence of 74 months.** Although outcomes in this study were not compared with an open radical nephrectomy cohort, results are quite comparable to those for open surgery.

Perioperative outcomes in contemporary groups undergoing laparoscopic and open radical nephrectomy have also been extensively studied. In a series of 54 laparoscopic and 34 open radical nephrectomies, no differences in age, body mass index (BMI), American Society of Anesthesiologists (ASA) score, tumor size, specimen weight, or operative time were noted (Gill et al, 2000). **The laparoscopic approach was shown to have less blood loss, shorter hospital course, lower analgesic requirement, and shorter return to convalescence.** Complications were noted in 13% of patients in the laparoscopic group and 24% of patients in the open group. Similar findings have been previously reported by multiple authors (Kerbl et al, 1994a; McDougall et al, 1996; Hemal et al, 2007).

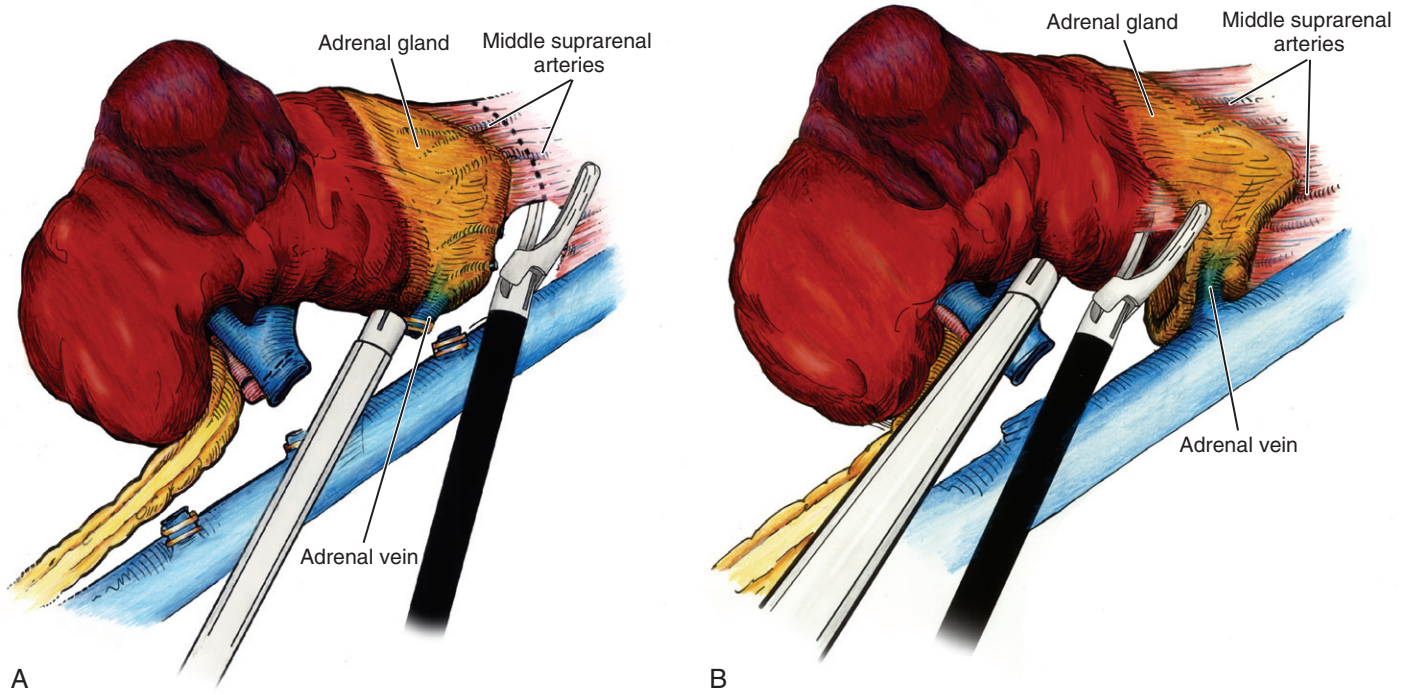

Figure 55–31. **A,** Inclusion of the adrenal gland during right laparoscopic radical nephrectomy can be readily accomplished using ultrasonic or bipolar shears to control the multiple arterial branches to the adrenal gland. Inferior retraction of the specimen facilitates exposure of this surgical plane. **B,** Adrenal-sparing, right radical nephrectomy. Use of a blunt instrument above the hilum to put anterior and inferior traction on the kidney helps to expose the correct plane and place the connective tissue on stretch. Ultrasonic or bipolar shears are again useful to avoid any bleeding that may be encountered in this plane.

Retroperitoneal

Procedure

The patient is positioned, and trocars are placed for retroperitoneal access as described earlier in the chapter. After identifying the psoas muscle and tendon, medial dissection in this plane will reveal the ureter. Elevation of the ureter will allow visualization and subsequent elevation of the lower pole of the kidney. This will place the main renal vessels on stretch, facilitating their dissection. The arterial pulsation may be indirectly visualized through overlying connective tissue, and just as with the transperitoneal approach, gentle layer-by-layer dissection with the suction-irrigator will allow the renal vessels to come more directly into view. Use of the right-angle dissector will allow the artery to be circumferentially freed from the surrounding tissue, and the endovascular stapler or clips are used to divide the artery and vein sequentially. When operating on the left kidney, a lumber vein will typically require dissection, ligation, and division to allow unencumbered access to the main hilum. **Care must be taken to continuously reorient to anatomic relationships to ensure that the inferior vena cava is not mistakenly identified as the renal vein**. The kidney may be removed intact or after morcellation, as previously described.

Results

When compared with transperitoneal laparoscopic radical nephrectomy, outcomes of the retroperitoneal approach are quite similar with regard to complication rates, analgesic requirements, hospital course, and return to convalescence.

A randomized study comparing transperitoneal and retroperitoneal laparoscopic approaches was performed in 102 patients (52 transperitoneal, 50 retroperitoneal) with a mean tumor size of 5 cm (Desai et al, 2005). No difference was seen in blood loss, narcotic requirement, hospital stay, or complication rate. However, there was a significant difference noted in operative time, which favored the retroperitoneal approach (150 vs. 207 minutes). A second randomized study of 40 patients compared the number and size of trocars, pathologic stage, blood loss, operative time, complication rate, and hospital stay (Nambirajan et al, 2004). No statistical difference was noted in any of these outcomes, including operative time.

Hand-Assisted

Procedure

The patient is positioned, and the hand port and trocars are placed as previously described. The steps in hand-assisted laparoscopic nephrectomy (HALN) are similar to those for pure laparoscopic surgery, but the nondominant hand is used throughout for retraction and dissection. To incise the white line of Toldt, the nondominant hand retracts the colon medially while the dominant hand uses an endoscopic scissors to divide the attachments (Fig. 55–32). The irrigator-aspirator is then used to help identify and dissect the correct plane posterior to the large bowel mesentery and anterior to Gerota fascia. The surgeon's hand and fingers may be used to simultaneously place lateral traction on the kidney and medial traction on the bowel, helping to demonstrate the correct plane. For a left nephrectomy, the hand may also be used to gently retract the spleen and pancreas medially while the lienorenal

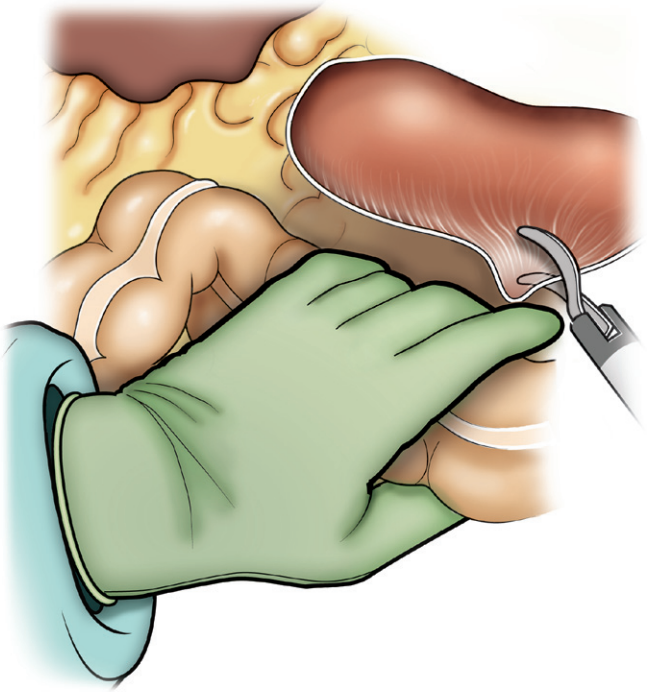

Figure 55–32. The nondominant hand is used to retract the colon medially and to dissect tissue planes, while the dominant hand uses endoscopic scissors to divide colon attachments.

attachments are divided. Similarly, on the right, the hand is used to retract the liver anteriorly, exposing the upper pole and facilitating its dissection.

After the colon is sufficiently mobilized, the psoas muscle is identified, which will allow the ureter to be elevated. On the left, the gonadal vein is typically elevated in the packet along with the ureter, but on the right, the gonadal vein is reflected medially. With the ureter elevated, the hand can bluntly dissect and elevate the entire kidney off the psoas muscle, and the ureter is then followed up to the renal hilum. The fingers are then used to place anterolateral traction on the kidney, while the thumb pushes the bowel and mesentery medially. The hilum should begin to come into view at this point, and the irrigator-aspirator can be used to gently dissect the overlying connective tissue while the hand is used to keep the vessels on stretch. Once the vessels are sufficiently skeletonized, the endovascular stapler or clips are used to ligate and divide the artery and vein sequentially (Fig. 55–33A and B). The lateral and superior attachments may then be divided, using a Ligasure device or harmonic scalpel while the hand keeps them on traction. The hand should not be used to dissect the adrenal gland free from the upper pole of the kidney, because this will typically result in bleeding. Ultrasonic energy, Ligasure, or bipolar cautery may be used to divide the fragile attachments between the kidney and the adrenal gland, just as with pure laparoscopy.

A rolled laparotomy sponge is often placed through the hand port at the beginning of the procedure to assist with retraction, absorb blood, and to allow the surgeon to hold pressure if needed. In addition, the tip of the irrigator-aspirator can be placed into the compressed sponge to facilitate suction when needed. It is critical to remember removal of the sponge at the end of the case. The previously made hand-port incision allows rapid removal of sponge and the intact specimen. However, hand-port metastases have been reported, and it is recommended to place the specimen in a removal device before extraction to prevent any possibility of direct contact with wound edges.

The inserted hand can also facilitate closure of trocar sites greater than 10 mm with a suture-passing device. **Wound complications such as hernias and infections have been reported at the hand-port site, with hernias typically presenting 3 months or more after surgery and with an overall 4% incidence** (Okeke et al, 2002; Wolf, 2005). Care must be taken to copiously irrigate and close the hand-port incision, ideally closing the peritoneum separately from the fascia to minimize chance of hernia.

Results

Most outcomes are comparable between pure laparoscopy and the hand-assisted technique including efficacy, operative times, complication rates, narcotic requirements, length of hospital stay, and return to convalescence. Some comparative studies between laparoscopic and hand-assisted techniques have demonstrated that the hand-assisted procedures can require shorter operative times, but patients had more abdominal pain and wound complications (Nelson and Wolf, 2002).

Comparative studies between HALN and standard laparoscopic approaches have shown that choice of approach does not impact on oncologic outcome. Gabr and colleagues (2009) studied and compared 147 patients who underwent standard laparoscopic nephrectomy and 108 who underwent hand-assisted laparoscopic nephrectomy. Patients were followed for a mean of 35.2 months, and multivariate analysis showed that the approach did not impact recurrence-free, cancer-specific, or overall survival. A multi-institutional study of 95 patients undergoing HALN evaluated the impact of tumor size on outcome (Stifelman et al, 2003). Patients were grouped into those with tumors larger than 7 cm and those with tumors smaller than 7 cm. Short-term outcomes at mean follow-up of 12 months were not different between the two groups, including positive margin rate, local recurrence, and metastasis. An additional short-term outcome study investigating a series of 60 patients undergoing HALN for T1 or T2 tumors demonstrated no recurrence or trocar site seeding at mean follow-up of 11 months (Patel and Leveillee, 2003).

RADICAL NEPHRECTOMY: SPECIAL CONSIDERATIONS

Large Tumors

Experience with laparoscopy for large tumors (>7 cm) has grown substantially as confidence with renal laparoscopy has increased (Steinberg et al, 2004; Hemal et al, 2007; Berger et al, 2008; Rosoff et al, 2009). Large tumors present several surgical challenges. The bulk of the mass can decrease working space and alter normal anatomic landmarks. This can result in disorientation with potential injury to surrounding structures. Continuous intraoperative reference to preoperative imaging as well as use of ultrasonography is helpful. Flexible endoscopes may be used to see around structures. The weight of large tumors may cause the surgeon to apply additional force for manipulation, potentially resulting in tumor rupture. It may be beneficial to use a hand port in these instances or additional trocars. Consideration may also be given to lymphadenectomy with larger tumors as indicated.

En Bloc Stapling

En bloc stapling of the renal hilum has been reported from several centers. An evaluation of 80 patients with mean follow-up of 35.2

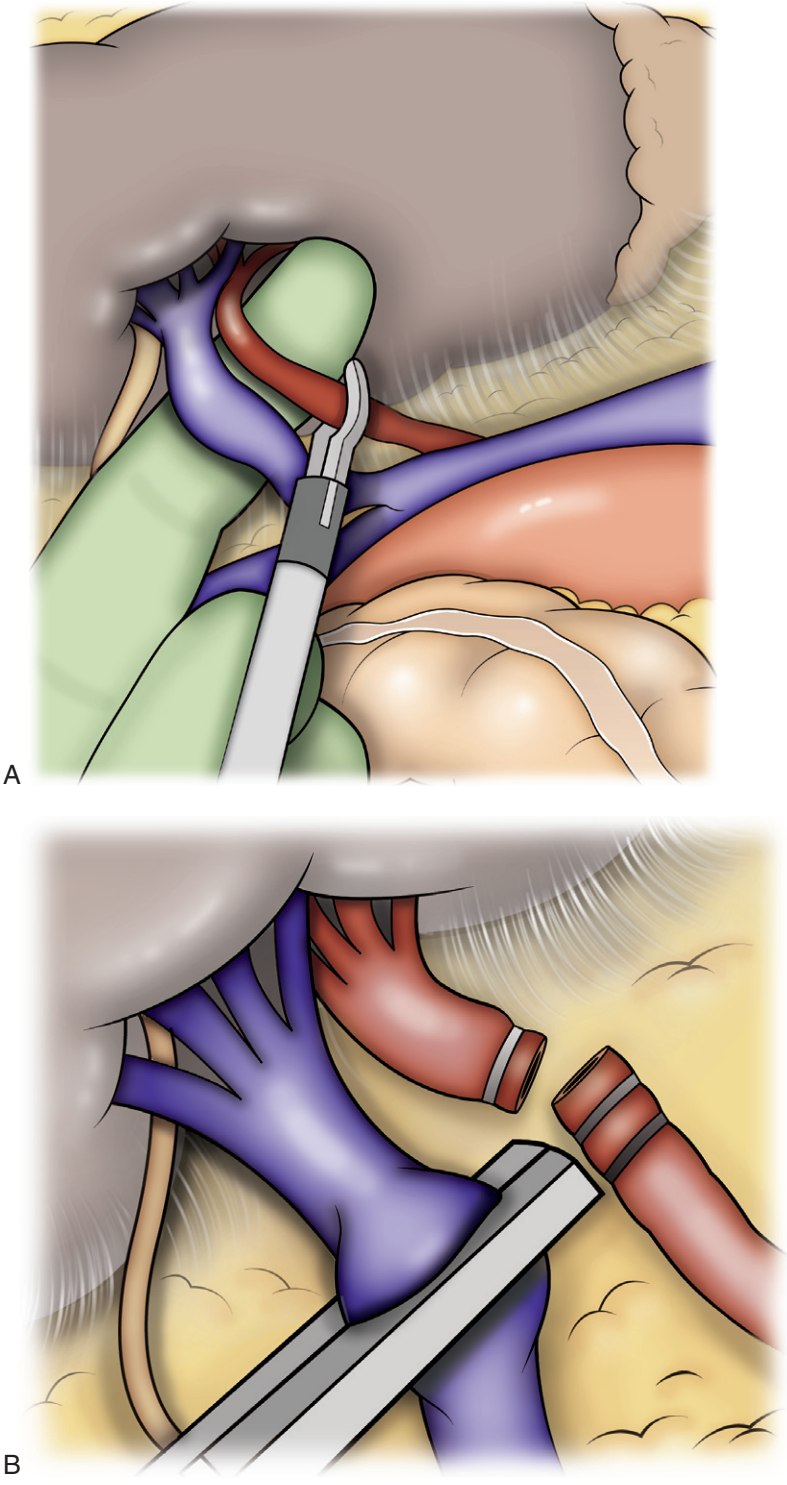

Figure 55–33. **A,** With the renal hilum on stretch and the bowel retracted medially to expose the vessels, the fingers can be used to palpate the renal artery and guide a stapler or clip applier to secure and divide the artery. **B,** Once the artery is divided, the renal vein is freed circumferentially and divided with an endovascular stapler.

months after either open or laparoscopic radical nephrectomy, with routine use of en bloc hilar stapling, demonstrated no clinical evidence of arteriovenous fistula (White et al, 2007). Half of the patients also underwent CT arteriography at a minimum interval of 12 months postoperatively, and no patient had radiographic evidence of arteriovenous fistula. Another study evaluated patient outcomes in 433 patients undergoing laparoscopic radical nephrectomy or nephroureterectomy, of whom 26 (6%) underwent en bloc stapling only when hilar dissection was deemed "difficult" by the surgeon (Rapp et al, 2004). No cases of arteriovenous fistula were noted at a mean follow-up of 26 months. However, the authors noted that arteriovenous fistula may be a more long-term complication after en bloc hilar stapling, and thus longer follow-up is needed to properly assess these patients.

Port-Site Recurrence

Since its inception, a concern for port-site seeding and recurrence continues to be raised for performance of laparoscopic surgery for urologic malignancy. In an international survey of 20 centers

performing 2604 laparoscopic radical nephrectomies, no port-site seeding was reported (Micali et al, 2004). A recent review of all reported cases of port-site seeding in laparoscopy for urologic malignancy revealed a total of 28 cases. The majority involved aggressive upper tract transitional cell carcinoma, and six involved renal cell carcinoma (Eng et al, 2008). The etiology of port-site recurrence is thought to be multifactorial and related to tumor aggressiveness, immune status of the patient, local wound factors, and surgical technique. The effect of pneumoperitoneum, aerosolization of tumor cells, insufflation gas type, and laparoscopic wound closure techniques have been studied by multiple authors and is noncontributory (Ikramuddin et al, 1998; Tsivian et al, 2000; Gupta et al, 2002; Burns et al, 2005; Halpin et al, 2005; Jingli et al, 2006). As with open surgery, the most common etiology is technical error and associated tumor spillage. Animal studies demonstate that direct contact between tumor and port-site enhances tumor growth (Bouvy et al, 1996), and the use of an impermeable specimen retrieval bag is recommended in all cases. Although the overall incidence of port-site metastasis is low—estimated at 0.09% to 0.18% (Micali et al, 2004; Rassweiler et al, 2003)—care should be taken in specimen handling and extraction to help minimize risk factors over which the surgeon has the most control.

Specimen Extraction

An area of controversy surrounding specimen extraction has been morcellation due to the concerns for inadequate pathology and staging, peritoneal or port-site seeding, bag rupture, and recurrence. Although there is an advantage in terms of shorter incision length, there has been no benefit demonstrated in postoperative analgesic requirement (Hernandez et al, 2003). A multi-institutional study of the safety and efficacy of specimen morcellation in 188 patients with clinical stage T1 or T2 renal cell carcinomas revealed 11 patients with recurrent disease (10 metastatic to lungs or viscera and 1 patient with port-site, renal fossa, and lymph node recurrence) (Wu et al, 2009). This demonstrates that mechanical morcellation may be safely performed in selected patients. However, the ability to properly stage the patient remains in question, with studies demonstrating conflicting results. The feasibility of pathologic evaluation has been studied in comparative fashion by evaluating both fresh and formalin-fixed specimens before and after morcellation (Landman et al, 2000). No alteration in determination of histology, grade, or local invasiveness of tumor was seen. Only specimen size could not be assessed following morcellation. A separate study on 23 morcellated specimens concluded that pathologic tumor stage in both renal cell and transitional cell carcinoma is severely limited by morcellation and must rely partially on diagnostic imaging for lesion size, capsule, and renal vein involvement (Rabban et al, 2001). Additionally, the incidence of pathologic stage T3a tumors was evaluated retrospectively in a series of 1781 patients and found to be 7.2% overall (Granberg et al, 2007). Imaging in the overwhelming majority of these patients did not predict stage pT3a disease. The authors concluded that without imaging that can more reliably predict fat invasion, accurate staging would be difficult if morcellation is performed.

If the specimen is to be morcellated, the surgeon should strictly adhere to proper technique including the use of a purpose-built sac, adequate draping, and change of gowns, gloves, and instruments after morcellation. The LapSac (Cook Urological, Spencer, IN) has been shown to be impermeable to bacteria and tumor cells, even after its use for morcellation (Urban et al, 1993). The sac is prepared by passing a moistened hydrophilic wire alternating through every third hole in the sac, which is then rolled from the bottom up and passed through a 12-mm trocar site. The trocar is replaced leaving the wire and drawstrings outside the trocar. Graspers are used to place the specimen in the sac, which is held open by the wire, and the wire is removed (Wakabayashi et al, 2003). The drawstrings are grasped and brought through the periumbilical incision along with the neck of the sac, which is held tightly against the abdomen. Enlarging the trocar site by 1 cm will allow small amounts of tissue to protrude through the mouth of the sac. The morcellation process is performed with a ring forceps, working with alternating bites on the protruding tissue. Deep passes with the forceps should be avoided to prevent unintentional incorporation of bowel into the forceps. Pneumoperitoneum should also be maintained during the process to allow monitoring of the sac intracorporeally to avoid injury to structures resting against the sac or sac perforation.

Lymphadenectomy

Lymphadenectomy at the time of nephrectomy, open or laparoscopic, remains controversial. It has been shown that presence of two or more adverse pathologic predictors (grade, sarcomatoid features, tumor size, stage, and necrosis) results in a higher likelihood of lymph node metastasis (Blute et al, 2004). In addition, patients with preoperatively or intraoperatively suspicious lymph nodes have been shown to have improved survival (median of 5-month benefit) when undergoing a lymph node dissection compared with those who did not (Pantuck et al, 2003). A retrospective study of 50 patients undergoing LRN alone versus 50 undergoing LRN with laparoscopic lymph node dissection (LND) determined that 10% of the patients undergoing LND had positive nodes (Chapman et al, 2008). All patients were preoperatively node negative by cross-sectional imaging evaluation, and those with positive nodes all had high-grade lesions, stages T3 or T4. However, a randomized study comparing groups undergoing radical nephrectomy, with or without lymphadenectomy at the time of surgery, has demonstrated no survival benefit of lymph node dissection in patients with clinically negative lymph nodes (Blom et al, 2009).

It is clear that not every patient with renal cell carcinoma requires lymphadenectomy. However, a subset of patients with suspicious lymph nodes may derive benefit from lymphadenectomy. Of note, there is no consensus on the extent of node dissection to be performed. The additional group that may benefit includes those with higher-stage tumors in the absence of suspicious lymph nodes, although survival data to support lymphadenectomy in this population is lacking.

Local Recurrence

The incidence of isolated local recurrence after nephrectomy with curative intent is approximately 1.8% (Itano et al, 2000; Margulis et al, 2009). Isolated local recurrence is defined as recurrence in the ipsilateral retroperitoneal lymph nodes, renal fossa, or adrenal gland without evidence of distant metastasis (Fig. 55–34). In a study of 54 patients with isolated local recurrence managed with open surgical resection, median recurrence-free and cancer-specific survival of 11 and 61 months, respectively, were observed (Margulis et al, 2009). Perioperative systemic therapy with various combinations of immunotherapy, chemotherapy, and targeted tyrosine kinase inhibitors was used in 69% of cases. Given their rarity, published laparoscopic experience in surgically addressing these recurrences is quite limited to date. A series of five patients

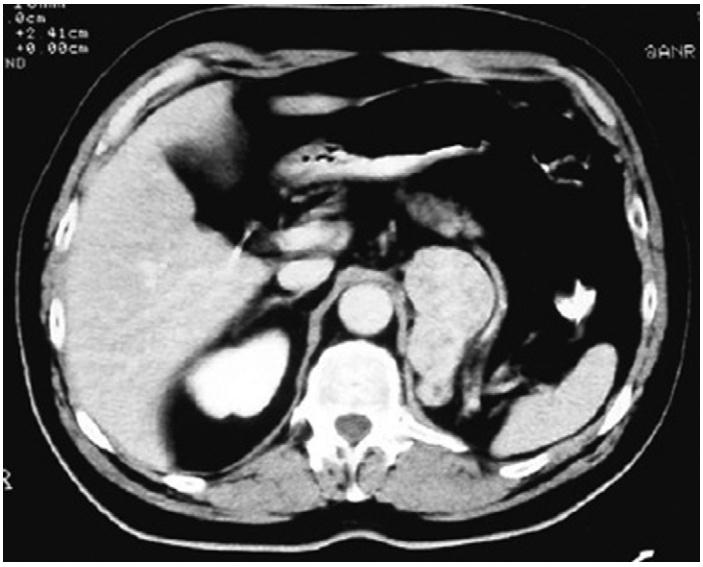

Figure 55–34. Renal fossa recurrence. (From Nóbrega de Jesus CM, Silva Casafus FA, Agostinho AD. Surgical treatment of renal cell carcinoma recurrence at the renal fossa following radical nephrectomy. Sao Paulo Med J 2008;126:194–6.)

(one open conversion for vena caval invasion) undergoing a hand-assisted approach to isolated local recurrence has demonstrated that the procedure may be safely performed in selected patients (Bandi et al, 2008). At a mean follow-up of 43 months, cancer-specific and disease-free survival rates were 60% and 20%, respectively. The small number of patients in this report makes the results difficult to interpret. An open surgical resection can offer durable local control and cancer-specific survival in carefully selected patients; larger comparative laparoscopic series with sufficient follow-up are clearly needed to determine the efficacy of laparoscopy in these scenarios.

Renal Vein and Caval Tumor Thrombus

Several centers have now published their experiences with laparoscopy for renal cancers with associated tumor thrombus into the renal vein or inferior vena cava (Desai et al, 2003; Hsu et al, 2003; Martin et al, 2008; Guzzo et al, 2009). After complete laparoscopic mobilization of the kidney and ligation of the renal artery, a laparoscopic DeBakey procedure, vessel loop, or hand assistance is typically employed to "milk" the tumor thrombus distally toward the kidney. This allows either the endovascular stapler to be deployed proximal to the thrombus, or a laparoscopic Satinsky clamp to be placed to isolate a cuff of the vena cava such that the cuff may be excised to allow intact specimen extraction. When using a hand port, the vena cava may then be oversewn using proline suture. The use of intraoperative ultrasonography has also been described to aid in assessing the location of the proximal extent of the tumor thrombus (Hsu et al, 2003). To date, the approach has been limited to low-level caval thrombi, but results have been comparable with the open surgical experience.

Cytoreductive Nephrectomy

Patients with advanced renal cell carcinoma may require cytoreductive nephrectomy before the initiation of systemic secondary therapies. A comparative study of open versus laparoscopic cytoreductive nephrectomy in a selected group of patients with metastatic disease—but without local invasion, venous involvement, or bulky adenopathy—demonstrated similar one-year survival between the two groups (61% vs. 65%) (Rabets et al, 2004). In addition, the laparoscopic group had less blood loss, shorter hospital stay, and shorter interval between surgery and the initiation of systemic therapy (36 vs. 61 days). Other studies have shown similar results (Eisenberg et al, 2006; Matin et al, 2006a), although the shorter interval to systemic therapy has not been consistently observed.

Surgical Salvage after Failed Ablative Therapies

Nephrectomy following ablation is technically challenging due to resulting loss of tissue planes surrounding the lesion. A multi-institutional review of treatment outcomes for primary radiofrequency ablation (RFA) or cryotherapy revealed residual or recurrent disease in a median of 8.7% of patients (Matin et al, 2006b). Although a subgroup of these patients will undergo successful salvage ablative therapy, some may not be candidates for repeat ablation due to disease progression, tumor size, or failed repeat ablation. A report of 10 patients undergoing salvage surgery in this patient population has shown that laparoscopic nephrectomy was only possible in 4 patients, and the remainder required either open partial or radical nephrectomy (Nguyen et al, 2008). Extensive perinephric fibrosis was cited as the main factor complicating surgery.

PARTIAL NEPHRECTOMY

Kidney tumors are increasingly being diagnosed incidentally, at a small size and early stage, in asymptomatic healthy patients (Jayson et al, 1998; Leslie et al, 2003). Although the majority of imaging-detected incidentally found renal lesions are benign simple cysts, one must be vigilant to not miss an early renal cancer. **Recent data regarding the prevalence of unsuspected, early-stage chronic kidney disease underscore an important point: Renal functional preservation and nephron-sparing strategies are important considerations when making management decisions in patients with a small renal mass (SRM)** (Huang et al, 2006)**.** The desire to provide a minimally invasive alternative to treat patients with small renal masses led to the application of laparoscopic techniques to nephron-sparing surgery.

The first transperitoneal laparoscopic partial nephrectomy (LPN) was reported in 1993 by Winfield and colleagues, with the retroperitoneal approach introduced one year later (Gill et al, 1994). Initially, LPN was applied to treat small clinical T1a exophytic renal masses (Fig. 55–35). With increasing laparoscopic confidence and experience, the indications of LPN have been expanded to almost all patients with challenging tumor anatomy in complex clinical settings.

Expanded Indications

Clinical Stage T1b Tumors (4 to 7 cm)

LPN was initially restricted to patients with tumors less than or equal to 4 cm in size. Technical advances in laparoscopic techniques, along with demonstration of equivalent results to open surgery for T1a tumors, provided the groundwork for approaching

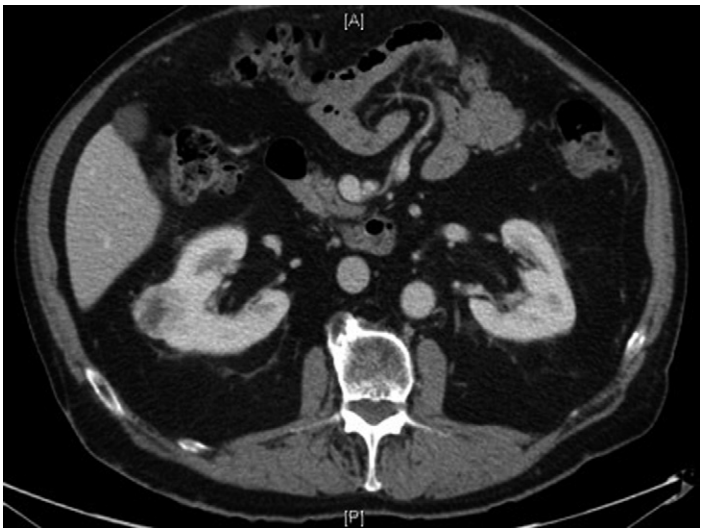

Figure 55–35. CT scan with IV contrast demonstrating a partially exophytic midpole clinical T1a lesion in the right kidney.

larger lesions (Leibovich et al, 2004; Dash et al, 2006; Mitchell et al, 2006). Simmons and colleagues (2009) reported perioperative outcomes of LPN in 58 patients for T1b tumors. Mean tumor size was 6 cm, and 55% of tumors were centrally located. Although patients with pT1b tumors more often underwent pelvicalyceal repair ($P = .004$) and heminephrectomy ($P < .001$), they had similar operative time, blood loss, and hospital stay but longer warm ischemia time than patients with tumors less than 4 cm. Tumor size greater than 4 cm did not increase risk for positive cancer margins, intraoperative complications, or postoperative urologic complications. Of note, in patients with tumors less than 2 cm, 2 to 4 cm, and 4 to 7 cm (stage ≥III), chronic kidney disease (CKD) existed preoperatively in 31%, 35%, and 44% of patients, respectively, and postoperatively in 52%, 53%, and 63%, respectively (P = ns). This underscores the importance of attempting to provide a nephron-sparing approach to all patients. **Given adequate laparoscopic experience and judicious patient selection, the perioperative outcomes of LPN for clinical T1b tumors greater than 4 cm appear comparable to those achieved for clinical T1a tumors less than or equal to 4 cm.**

Laparoscopic Heminephrectomy

Finelli and colleagues (2005) compared outcomes of laparoscopic heminephrectomy (excising greater than 30% of renal parenchyma) in 41 patients, with a contemporary group of 41 consecutive patients who underwent LPN with less than 30% resection. Except for a longer ischemia time (39 vs. 33 minutes) in the heminephrectomy cohort, there were no differences between the two groups regarding blood loss, operation room (OR) time, analgesic requirement, hospital stay, postoperative serum creatinine, and overall complications. All surgical margins were negative. Specific technical considerations inherent to laparoscopic heminephrectomy include routinely performing deeper renal parenchymal resections, transection of sizable intraparenchymal blood vessels, and intentional entry into the pelvicalyceal system. The primary goals of laparoscopic heminephrectomy and LPN are the same: achieve negative surgical margins, perform clipping or suture repair to secure renal vessels, and where necessary, repair the collecting system while minimizing ischemia time.

Central and Hilar Tumors

Central tumors are defined as those abutting or invading the central renal sinus fat and/or the collecting system on preoperative CT. These tumors deeply infiltrate the renal parenchyma, and their excision requires intentional entry into and potentially suture-repair of the pelvicalyceal system along with complex parenchymal reconstruction, all within the time constraints of renal ischemia. The technical complexity of such cases depends upon the location of the individual tumor, and the type of suturing angles available for laparoscopic instruments in the dominant and nondominant hand. Frank and colleagues (2006) compared experience with LPN for 154 central tumors with LPN for 209 peripheral tumors. Although blood loss was similar, central tumors were associated with somewhat longer operative time, ischemia time, and hospital stay, and more early postoperative complications. There was only one positive margin for cancer in each group. These data reflect the initial outcomes of the LPN experience; at this writing, the authors routinely perform LPN for central tumors without any increase in operative morbidity as noted above.

Hilar tumors, defined as tumors located in the renal hilum in direct contact with the renal artery and/or vein on cross-sectional imaging, were initially considered by many to be a contraindication to LPN. In 2005, an initial experience with LPN outcomes for hilar tumors in 25 patients was reported (Gill et al, 2005). Mean tumor size was 3.7 cm (range 1 to 10.3). LPN was successful in all cases, without any open conversions or operative reinterventions. Postoperative hemorrhage occurred in three early patients. Preoperative 3D video reconstruction of triphasic spiral CT was important in detailing the number, interrelationship, anatomical course, and position of the renal vessels in relation to the tumor.

Tumor in a Solitary Kidney

Partial nephrectomy for tumor in a solitary kidney, open or laparoscopic, is challenging. The margin for error is small because a complication could result in temporary dialysis, or worse, render the patient anephric. In the largest reported series of patients (n = 22) undergoing LPN for a tumor in a solitary kidney mean warm ischemia time was 29 minutes (Gill et al, 2006). Two patients (9%) were electively converted to open surgery. Median pre- and postoperative serum creatinine (1.2 and 1.5 mg/dL, respectively) and estimated glomerular flow rate (eGFR) (67.5 and 50 mL/min/1.73 m^2, respectively) reflected changes of 33% and 27%, respectively, which correlates with approximately 25% nephron volume loss. One kidney was lost due to hemorrhage. The authors concluded that LPN for tumor in a solitary kidney was feasible.

Multiple Tumors

Increasingly, nephron-sparing surgery (NSS) is the preferred treatment for patients with multiple, small ipsilateral tumors, due to the potential for contralateral recurrence. LPN has been applied in this clinical setting as well. Steinberg and colleagues (2004) published their experience in 13 patients (92% of patients had an imperative indication for nephron preservation) undergoing laparoscopic NSS for two or more ipsilateral renal tumors. LPN was performed in six patients either by itself, or in conjunction with cryotherapy. At a mean follow-up of 16.4 months (range 1 to 54), no ipsilateral recurrences were noted. When performing LPN for multiple tumors, depending upon their geographic proximity, tumor excision can be performed either en bloc or individually. With the short-term oncologic outcome data available to date, LPN, when judiciously combined with cryotherapy, can provide

clearance of the ipsilateral tumor burden, while keeping ischemia time to a minimum.

Cystic Tumors

LPN for radiographically suspicious cystic tumors is technically more challenging due to the potential for inadvertent cyst rupture and tumor spillage. Spaliviero and colleagues (2005) compared 50 patients undergoing LPN for a cystic renal lesion with 50 consecutive patients undergoing LPN for a solid renal mass. LPN was successful in all cases, and intraoperative complications were similar in the two groups. All surgical margins were negative. However, one patient in the cystic tumor group developed retroperitoneal recurrence at 1 year, despite an unremarkable intraoperative course and negative histological margins. The authors concluded that extreme caution and careful technique is necessary to avoid inadvertent cyst rupture and local tumor spillage.

Other Indications

LPN has also been performed in the following unique clinical settings: adrenal involvement from an upper pole tumor requiring excision with concomitant adrenalectomy (Ramani et al, 2003), repair of concomitant renal artery disease (Steinberg et al, 2003), tumor in congenitally anomalous kidney, such as horseshoe kidney (Tsivian et al, 2007), in obese patients (Romero et al, 2008), and after prior ipsilateral renal surgery (Turna et al, 2008).

Procedure

Technical Issues

The principal technical challenge during LPN stems from the complexity of laparoscopic tumor excision and sutured renal reconstruction in a time-sensitive manner. **The primary objectives are to complete tumor excision with negative margins, obtain hemostasis, and minimize warm ischemia time.** Successful LPN for complex tumors requires an in-depth understanding of 3D renal anatomy, real-time appreciation of visual cues during laparoscopy, and facility with precise and relatively efficient suturing.

Transperitoneal LPN

The transperitoneal approach offers many features that are crucial for performance of advanced LPN: larger working space, more familiar landmarks, greater versatility of instrument angles, and technical ease of suturing. The initial portion of the procedure is performed as previously described for transperitoneal LRN.

Tumor Localization and Excision

Once the initial dissection is complete, including isolation of the hilar vessels, intraoperative ultrasonography is used to confirm location, width, and depth of the tumor (Fig. 55–36). Ultrasonography may also be used to confirm absence of additional lesions in the kidney. The Gerota fascia is entered away from the lesion to expose the renal capsule. Using the monopolar scissor, the capsule is scored circumferentially around the tumor (Fig. 55–37), and the hilum is then clamped using laparoscopic bulldog clamps (Fig. 55–38). The scored line may then be incised using cold shears (Fig. 55–39), and with the assistance of a suction-irrigator device to provide both countertraction and a clear operative field, the tumor excision is completed. In some patients, adherent fat will necessitate a subcapsular dissection to identify the visual borders of the tumor.

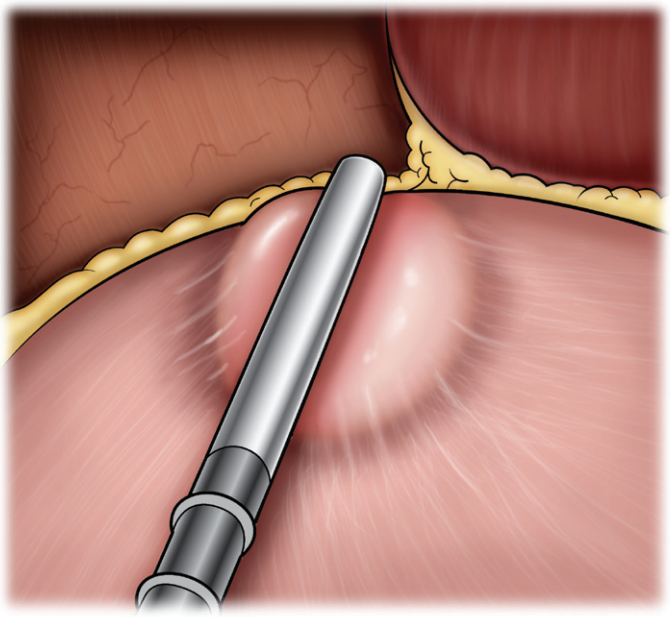

Figure 55–36. Intraoperative ultrasonography is used to confirm location, width, and depth of the tumor.

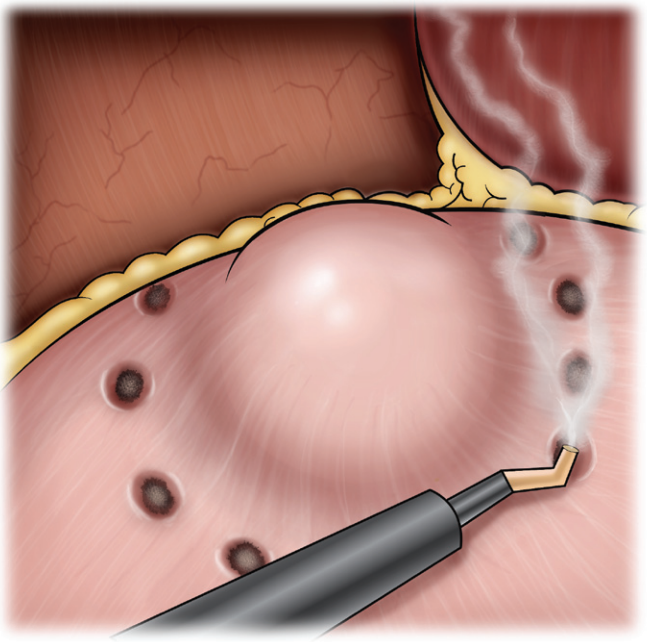

Figure 55–37. After Gerota fascia is cleared to expose the lesion and the renal capsule. Using the monopolar scissor or hook cautery, the capsule is scored circumferentially around the tumor.

Hemostasis

Achieving hemostasis is very important during LPN. Several strategies have been advocated for this purpose. The most widely employed technique to achieve hemostasis of the partial nephrectomy bed is by primarily using freehand laparoscopic suturing with or without adjunctive biologic hemostatic/sealant agents, or a Surgicel bolster (Johnson and Johnson, New Brunswick, NJ) (Fig. 55–40). Alternatively, surgical clips can be used while coming across the surface of the parenchyma. A number of tissue sealants

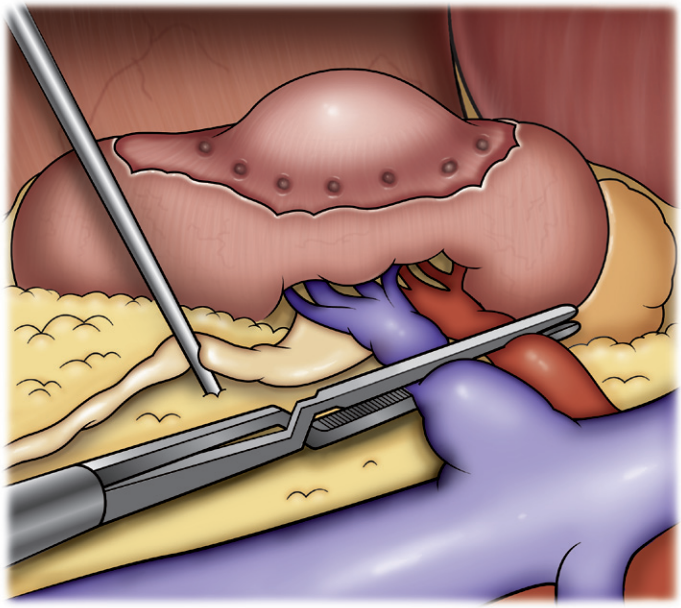

Figure 55–38. Once the margin around the tumor has been scored, the hilum is clamped either en bloc using a laparoscopic Satinsky clamp, or the artery and vein are clamped separately using bulldog clamps.

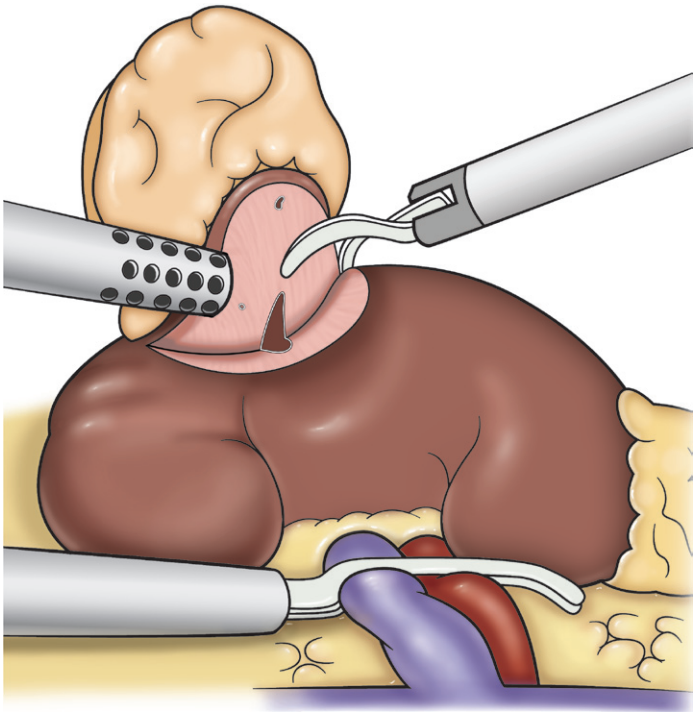

Figure 55–39. The scored margin around the tumor is incised using cold shears with the renal hilum clamped. The suction-irrigator provides both countertraction and helps to maintain a clear operative field and adequate margin of normal renal tissue.

are available: gelatin matrix thrombin sealant (Floseal; Baxter, Deerfield, IL), fibrin glue (Tisseel; Baxter), polyethylene glycol hydrogel (Coseal; Baxter), cyanoacrylate glue (Dermabond; Ethicon, Somerville, NJ), and Bioglue (CryoLife, Atlanta, GA).

During LPN for selected small, superficial, exophytic tumors, various thermal (radiofrequency, microwave, ultrasonic) and novel alternative (laser, water-jet) energy sources have been employed for hemostasis clinically and in the laboratory. Herrell and Levin (2005) evaluated the TissueLink radiofrequency device (TissueLink Medical, Dover, DE) during unclamped LPN in 25 human cases. Fibrin glue was used as a hemostatic adjunct. There were no intraoperative complications. Mean estimated blood loss was 98 mL (range 10 to 337). This device could potentially have a role in unclamped LPN for small, peripheral, and exophytic tumors. Lasers have been used as an energy source for performing unclamped LPN in the animal model. The potassium-titanyl-phosphate laser (KTP) (GreenLight PVP; Laserscope, San Jose, CA) and the holmium : yttrium aluminum garnet (Ho : YAG) laser have been employed with initial success (Lotan et al, 2004; Hindley et al, 2006; Liu et al, 2006). Moinzadeh and colleagues (2005) also evaluated the water-jet device (Helix Hydro-jet; Erbe-USA, Marietta, GA) to perform LPN without renal hilar control in the calf model. They were able to perform 18 of 20 cases without hilar control, with a mean estimated blood loss of 174 mL. Further technological improvements are necessary to achieve reliable hemostasis using these technologies.

Hilar Control

Select superficial, exophytic, noninfiltrating tumors can be excised during LPN without hilar clamping. However, tumors that are larger, deeper, central, or hilar require a substantial LPN, necessitating transient hilar clamping to provide a bloodless operative field. Guillonneau and colleagues (2003) compared LPN with (n = 12) and without (n = 16) hilar clamping using ultrasonic shears and bipolar cautery. The authors concluded that hilar clamping provided decreased blood loss, shorter operating time, and superior surgical performance. From a technical standpoint, hilar control can be achieved by using bulldog clamps individually on the renal artery and vein, or by using a Satinsky clamp across both vessels to achieve en bloc hilar clamping.

Renal hypothermia

Three techniques have been described for laparoscopic renal hypothermia: surface cooling with ice slush, instillation of cold saline through a retrograde ureteral catheter, and intra-arterial perfusion of cold saline or lactated Ringer solution (Gill et al, 2003; Landman et al, 2003; Janetschek et al, 2004). Although all of these techniques are clinically feasible and reasonably effective, they are rarely employed during clinical LPN. This is not only because of their complexity, but also because the majority of tumors subjected to LPN do not currently require an inordinately long period of warm ischemia.

Collecting System Repair

Central tumors abutting the renal sinus fat and collecting system may require deliberate entry into the pelvicalyceal system (PCS) to ensure negative surgical margins during tumor excision. For this reason, PCS entry is a common occurrence in contemporary LPN practice. Retrograde injection of dilute indigo carmine through a 5-Fr ureteral catheter inserted into the renal pelvis can be used to help identify the site of PCS entry and confirm repair. Prospective comparison of perioperative outcomes in 27 LPN with pelvicalyceal entry to 37 LPN with no pelvicalyceal entry (Desai et al, 2003) revealed similar operating room (OR) time, tumor excision time, and blood loss. However, PCS suture repair was associated with a somewhat longer warm ischemia time and hospital stay. None of the patients undergoing PCS suture repair developed a urinary leak. The results of this early study showed that intentional entry into the PCS system for central tumors could be safely and effectively repaired (Fig. 55–41). Suture repair of the PCS with a running

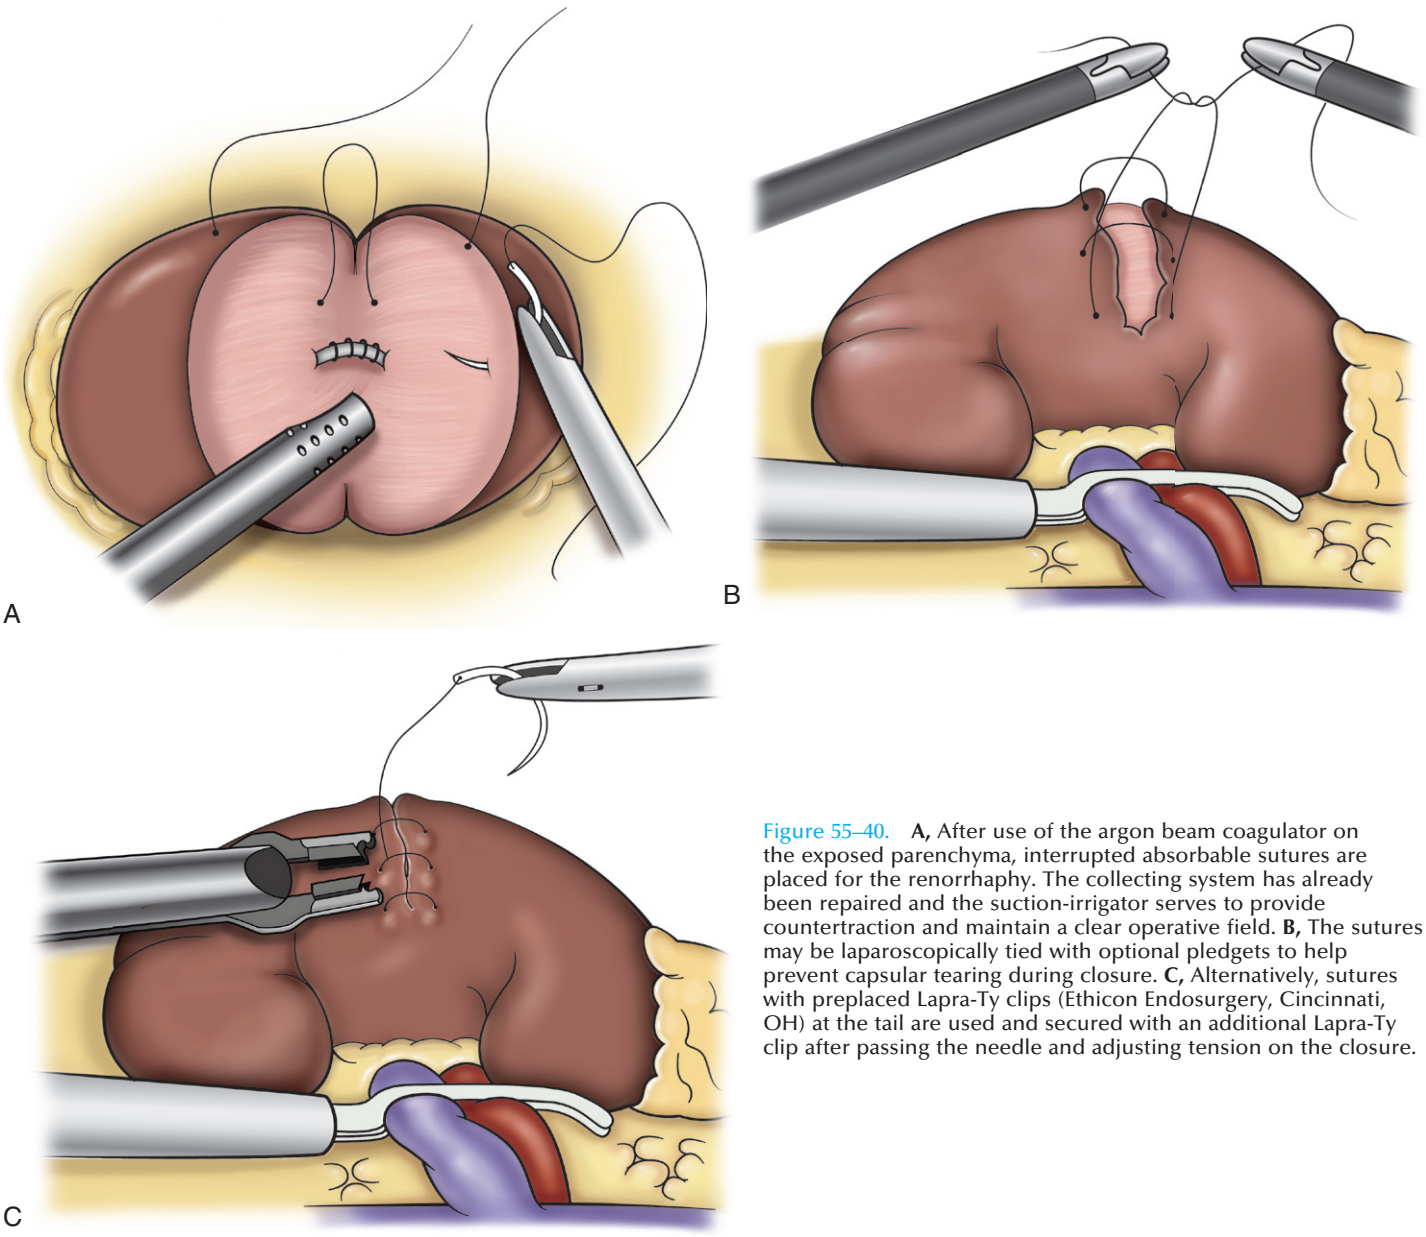

Figure 55–40. **A,** After use of the argon beam coagulator on the exposed parenchyma, interrupted absorbable sutures are placed for the renorrhaphy. The collecting system has already been repaired and the suction-irrigator serves to provide countertraction and maintain a clear operative field. **B,** The sutures may be laparoscopically tied with optional pledgets to help prevent capsular tearing during closure. **C,** Alternatively, sutures with preplaced Lapra-Ty clips (Ethicon Endosurgery, Cincinnati, OH) at the tail are used and secured with an additional Lapra-Ty clip after passing the needle and adjusting tension on the closure.

3-0 polyglactin suture can be accomplished, and the integrity of the repair tested with retrograde injection of dilute methylene blue. Alternatively, one may close the renal capsule over the defect. In either case, a drain should be placed for postoperative monitoring.

Retroperitoneal LPN

Although most LPN surgeons prefer the transperitoneal approach for most tumors, some employ the retroperitoneal approach, which has advantages for select posteriorly located upper pole apical tumors. After entry into the retroperitoneum and establishment of a working space as previously described, the kidney may be lifted anteriorly off the psoas muscle to allow visualization of the arterial pulsation. The dissection of the renal hilum can then proceed to facilitate bulldog clamp placement when deemed necessary. Tumor localization and excision, hemostatic control, collecting system repair, and renorraphy are performed as described for the transperitoneal approach. In a comparison of 32 retroperitoneal with 19 transperitoneal LPN, choice of approach was based on tumor location (Wright and Porter, 2005). The retroperitoneal approach was associated with shorter operating time, decreased blood loss, quicker return of bowel function, and shorter hospitalization. These authors preferred the retroperitoneal approach for polar and posterolateral masses, while the transperitoneal approach was preferred for anterior and medial lesions. Another comparison of 100 transperitoneal with 63 retroperitoneal LPN demonstrated that blood loss, perioperative complications, postoperative serum creatinine, analgesic requirements, and histological outcomes were comparable in the two groups (Ng et al, 2005). As such, the choice of LPN approach is dictated primarily by surgeon experience and tumor location. Other factors include tumor size, number of tumors, number of arteries supplying the kidney, amount of visceral fat surrounding the kidney, and route

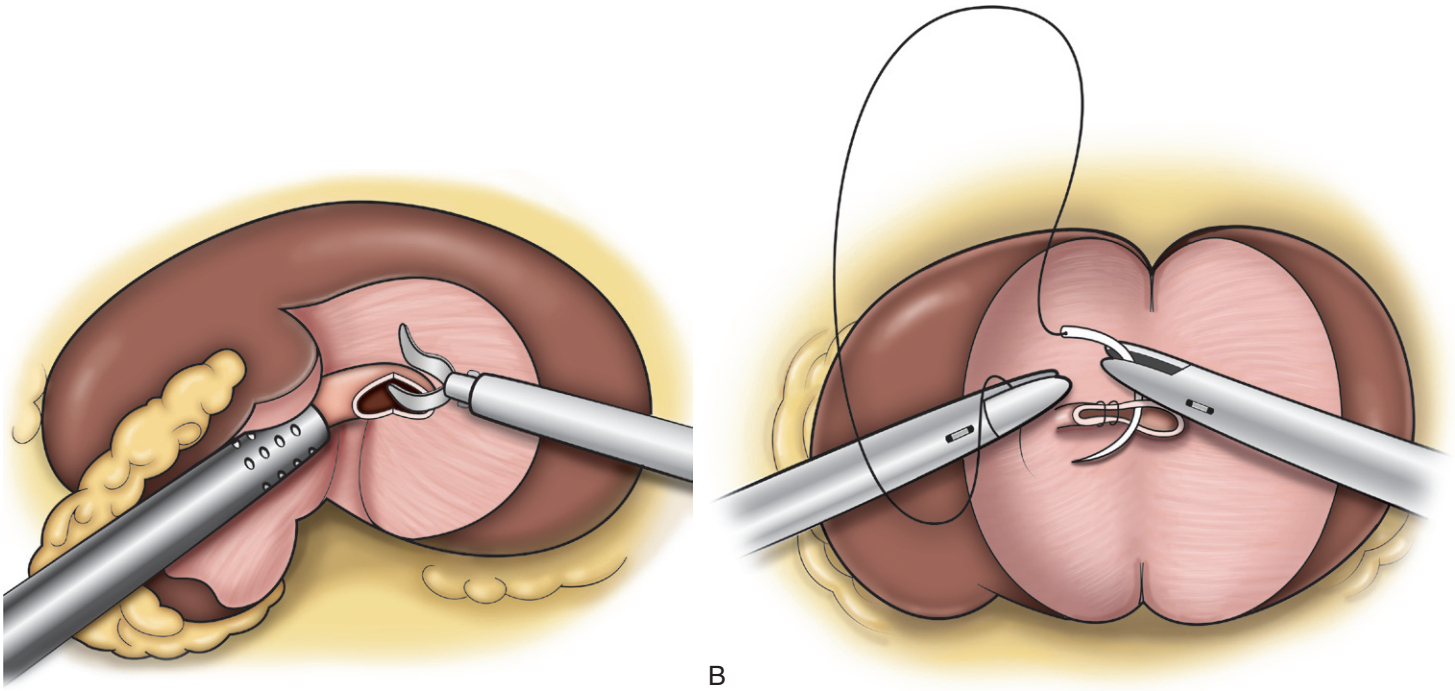

Figure 55–41. **A,** When deep resection is required, the collecting system will often be transected. With occlusion of the renal vessels, these defects can easily be identified and closed using absorbable sutures. The cut edge of the collecting system is identified with the tip of the needle and elevated. **B,** An interrupted figure-of-eight suture or running suture is used to completely close the collecting system. The integrity of the repair can be determined by intravenous indigo carmine administration or retrograde instillation, if a ureteral catheter was placed at the beginning of the case. Care must be taken not to destroy the suture, if argon beam coagulation of the parenchyma surface will be performed.

of any prior open surgery on the quadrant of interest. The transperitoneal approach for all renal tumors is usually easier, except those that are located posteriorly or posteromedially on the upper pole.

Early Unclamping LPN Technique

The standard LPN technique involves en bloc hilar clamping of the renal artery and vein followed by cold endoshear excision of the tumor with adequate margins. Control of transected intrarenal blood vessels and pelvicalyceal repair are obtained with an initial, central, running suture. Subsequent parenchymal reconstruction involves parenchymal mattress sutures tied over a bolster, with adjunctive use of biologic hemostatic agent. Thus the entire renal repair is performed in the ischemic kidney, with the hilar vessels clamped.

More recently, an early unclamping technique has been developed in an attempt to decrease ischemia time (Nguyen and Gill, 2008). In this technique, the renal hilum is clamped only for the duration of tumor excision and placement of the initial, central, running suture. In conjunction with suturing, clips are used selectively for preemptive control of the larger intrarenal blood vessels before transection. The hilum is then unclamped, reperfusing the kidney. All subsequent suturing in the partial nephrectomy bed to ensure parenchymal hemostasis and pelvicalyceal repair is now performed in the perfused, revasularized kidney. This includes specific figure-of-eight sutures to control any remaining active arterial and/or venous bleeding sites. Horizontal mattress sutures are also placed, if indicated, to undersew various clips, thereby excluding them from immediate proximity to the underlying pelvicalyceal system. If desired, the partial nephrectomy bed can be covered with biologic, hemostatic, or adhesive agents. Given that this technique allows hemostasis to be visually confirmed in the perfused kidney, the compression bolster is rarely used in contemporary practice. The benefits of early unclamping are twofold: (1) it decreases ischemia time, and (2) it leads to decreased incidence of postoperative hemorrhage.

Robotic-Assisted Partial Nephrectomy

Robotic-assisted PN (RaPN) is being explored at several centers with the aim of facilitating the precise intracorporeal suturing necessary during LPN. In its early days, RaPN remains a procedure in evolution (Gettman et al, 2004; Caruso et al, 2006; Kaul et al, 2007; Rogers et al, 2008).

The responsibilities of the table-side assistant include clamping the renal hilum, providing suction and retraction to maintain a clean operative field, delivery and cutting of sutures, and clip placement as needed. The console-side surgeon performs tumor excision, hemostatic suturing, and pelvicalyceal and parenchymal suture reconstruction robotically. Upon completion of renal reconstruction, the hilum is unclamped, and additional parenchymal sutures are placed, as needed, to ensure hemostasis. The robot is undocked and laparoscopic exit completed. The early unclamping LPN technique may be easily adapted for use during RaPN with good success.

Since 2004, several centers have reported initial experiences with RaPN (Gettman et al, 2004; Caruso et al, 2006; Kaul et al, 2007; Rogers et al, 2007). As such, the technical feasibility of RaPN has been established. More recently, initial data comparing outcomes with LPN have become available in a matched-pair analysis comparing RaPN and LPN (Aron et al, 2008). Patients were matched for age, gender, body mass index (BMI), ASA score, tumor side, tumor size, tumor location, and specific technique employed (early vs. conventional unclamping). Perioperative outcomes were

similar between the RaPN and LPN cohorts with regard to estimated blood loss, warm ischemia time, OR time, and length of stay. Renal functional outcomes, transfusion rate, and complication rates were also comparable. Two RaPN cases required conversion to standard LPN. In a subset analysis of patients undergoing the early unclamping technique, the LPN cohort had a shorter warm ischemia time (14 vs. 21 minutes, $P = .05$), despite larger tumors in the LPN cohort (3 cm vs. 2.4 cm, $P < .01$). The authors concluded that RaPN, an evolving procedure, is technically feasible and safe, albeit with a longer ischemia time compared to LPN in the initial experience. Analysis of a larger number of cases is necessary to determine the relative merits of RaPN. However, it is likely that the growing familiarity of urologists with robotic surgery will facilitate the application of minimally invasive nephron-sparing surgery in a larger cohort of patients. Unfortunately, the robotic approach is associated with increased cost and cosmetic inferiority due to the need for additional access ports.

WARM ISCHEMIA

The limit of safe renal warm ischemia time has historically been considered to be 30 minutes. Although supported by canine and anecdotal clinical data, no scientifically rigorous clinical study has defined an ischemic dose-response curve to date. Indeed, recent data suggests that up to 90 minutes may be reasonable (Orvieto et al, 2005). Until this issue is better understood, all efforts should be made to keep warm ischemia time as short as possible. With regard to surgical renal ischemia, various myths abound due to insufficient data.

Pneumoperitoneum

There is ongoing debate regarding the effects of pneumoperitoneum on renal functional outcomes. It has been demonstrated that 20 mm Hg of intraperitoneal pressure can cause decreased renal cortical capillary perfusion, increased renal venous outflow resistance, and transient oliguria in pigs (Shuto et al, 1995). In contrast, a report by Cisek and colleagues (1998) showed that 6 hours of 20-mm Hg pneumoperitoneum in pigs, rendered renally insufficient with prior left nephrectomy and right heminephrectomy, had no long-term impact on renal function. The debate regarding the negative impact of pneumoperitoneum remains unresolved; however, these studies suggest that when applied for less than 6 hours in patients with normal preoperative renal function, its ultimate impact is likely negligible and reversible. There is general consensus, however, that pneumoperitoneum during laparoscopic surgery should not be maintained with sustained pressures of greater than 20 mm Hg. Attempts at completely eliminating potential effects of pneumoperitoneum on the kidney have also been reported with donor nephrectomy using gasless laparoscopy (Watanabe et al, 2002), but it is unclear whether there are any long-term benefits of this approach.

Renal Artery-Only versus Artery-Plus-Vein Clamping

It is theorized that artery-only clamping during partial nephrectomy would allow retrograde venous blood flow with potentially partial oxygenation to the renal parenchyma. In a solitary kidney pig model, Orvieto and associates (2007) found that artery-only clamping resulted in lower serum creatinine rises, during postoperative days 1 to 3, than in animals that underwent complete hilar occlusion. Interestingly, this effect was not observed in animals that underwent laparoscopic surgery. It was concluded that artery-only clamping provided immediate postoperative benefit, and that this benefit was likely offset by pneumoperitoneum-induced venous compression during laparoscopy. In contrast, the same group found a benefit to artery-only clamping in a case-control study of patients undergoing LPN with artery-only ($n = 25$) versus simultaneous clamping of the artery and vein ($n = 53$) (Gong et al, 2008). A significant decrease in serum creatinine and creatinine clearance was observed in those patients undergoing simultaneous clamping of the artery and vein compared to preoperative levels. This effect was not observed in those undergoing artery-only clamping. Additionally, there were no statistically significant differences observed in either blood loss or positive margin rate between the groups. These findings need validation in larger patient cohorts. From a practical standpoint, leaving the renal vein unclamped can lead to increased intraoperative renal parenchymal bleeding, which can obscure the surgical field, leading to increased blood loss and prolonged ischemia time. In the majority of partial nephrectomy cases at the authors' institutions, both the renal artery and vein are clamped routinely to achieve vascular control and optimize visualization during tumor excision and renorrhaphy.

Manual Compression of Renal Parenchyma versus Vascular Clamping

Some advocate the use of manual compression of the kidney during tumor excision and renorrhaphy, while others contend that vascular clamping is preferable. Manual compression can be effective for small exophytic tumors, although the renal vasculature should always be accessible to allow emergent clamping in the case of hemorrhage. No controlled clinical study examining this issue has been conducted. Issues to consider include the possibility of tissue trauma due to excessive compression, and the limitation of this approach to peripheral tumors during open and hand-assisted laparoscopic procedures only. Manual compression techniques would not be feasible in partial nephrectomy of central, hilar, or large tumors, or for pure laparoscopic surgery.

Intermittent versus Continuous Clamping

Controversy exists regarding the possible deleterious effects of intermittent perfusion by sequential clamping and unclamping during partial nephrectomy. Intermittent ischemic "preconditioning" has been extensively studied as a method for protecting against ischemic organ injury, especially in liver surgery (Centurion et al, 2007; Saidi et al, 2007). Wilson and colleagues (1971) compared renal function in canine kidneys subjected to intermittent versus continuous occlusion for 1 to 2 hours. Occlusion and reperfusion times were 15 minutes and 3 minutes, respectively, repeated for 2 hours of occlusion time. In subjects with intermittent occlusion, GFR was significantly decreased after 7 days compared with continuous occlusion subjects. Contrary to these findings, Frank and colleagues (1993) found that rats undergoing cycled occlusion-reperfusion (15 minutes occlusion followed by 5 minutes reperfusion) for 45 minutes had lower serum creatinine levels and decreased pathologic evidence of tubular

injury at 3 days compared with the continuous occlusion subjects. Another study confirmed a protective effect of intermittent ischemic preconditioning in rats, and established the optimal occlusion and reperfusion intervals at 15 and 10 minutes, respectively (Wu et al, 2009). It is possible that species differences may account for discrepancies within the literature. No clinical trials of renal ischemic preconditioning have been conducted; only anecdotal reports guide practice. Because of insufficient and conflicting data regarding intermittent clamping, ischemic preconditioning is not recommended.

Parenchymal Clamping

Several authors have published their initial experiences in a small number of patients using techniques of parenchymal clamping in selected patients with peripheral renal cortical tumors (Verhoest et al, 2007; Simon et al, 2009). Use of a parenchymal clamp can allow the surgeon to induce ischemia only in the immediate area surrounding the tumor. All patients in these two studies had negative surgical margins, and no changes in renal function were reported. The potential benefits of this technique are multiple: It facilitates a bloodless operative field in the area of the tumor; the majority of the normal parenchyma is spared from ischemic injury; and the time-sensitivity of tumor excision and renorrhaphy is markedly reduced. However, the limitation of the technique is that only selected patients with peripherally located tumors are candidates. Larger numbers of patients are necessary to validate this technique, but due to the reduction in time sensitivity, parenchymal clamping may allow a larger cohort of surgeons to perform LPN with increased confidence.

Solitary Kidney May Be "More Tolerant" to Ischemic Injury

It is known that contralateral normally-functioning kidneys will hypertrophy to compensate for decreased function after unilateral nephrectomy. The extent of this response has been shown to be species- and age-dependent (Funahashi et al, 2009). Fried and colleagues (1984) studied functional recovery in rats with or without nephrectomy 2 weeks before a 40-minute ischemic insult. Nephrectomized rats demonstrated improved inulin clearance at 48 hours compared with non-nephrectomized controls. In contrast, Stackl and colleagues (1983) failed to show a difference in renal blood flow (RBF) or GFR in rabbits with or without preischemic nephrectomy. For obvious reasons, a human clinical study of this effect is impossible. Clinical anecdotal evidence points to the possibility that solitary kidneys may be more resistant to ischemic injury. It is plausible that some aspect of this increased tolerance to ischemic injury is attributable to the increased intraoperative vigilance and postoperative support measures taken in this high-risk patient cohort.

LAPAROSCOPIC PARTIAL NEPHRECTOMY: CONTEMPORARY OUTCOMES

An 1800-patient retrospective multi-institutional study compared a mature series of 1029 OPN cases with the initial LPN cases for solitary T1 tumors less than or equal to 7cm (Gill et al, 2007). Tumors in the OPN group were larger (3.3 vs. 2.6 cm), and more often located centrally (53% vs. 34%) or in a solitary kidney ($P < .001$ for all comparisons). LPN had less blood loss, and shorter operative time, hospital stay, and convalescence ($P < .001$ for all comparisons). Overall postoperative complications (25% vs. 19%) and conversion to radical nephrectomy (1% vs. 0%) were somewhat greater in the LPN group. Importantly, LPN and OPN were similar with regard to intraoperative complications (1.8% vs. 1%), positive surgical margins for cancer (1.6% versus 1%), 3-year oncological outcomes, and 3-year renal functional outcomes. However, LPN had a 10-minute longer ischemia time (30 vs. 20 minutes), and somewhat higher postoperative hemorrhage (4.2% vs. 2%) and reintervention rate.

With increasing LPN experience and standardization of the early unclamping technique, contemporary LPN outcomes have improved significantly. Specifically, the two remaining concerns for higher postoperative hemorrhage and longer ischemia time with LPN have now been addressed, leading to significantly decreased ischemia time and reduced occurrence of post-operative hemorrhage. The initial report of the early unclamping technique in LPN has decreased ischemia to a mean of 13.9 minutes (55% reduction), and reduced postoperative hemorrhage rate to 2% (Nguyen and Gill, 2008).

Gill and colleagues (2010) reported a single-surgeon series of 800 laparoscopic partial nephrectomy (LPN) cases encompassing a 9-year period (1999 to 2008). The authors divided the entire cohort into three chronologic eras: era I: 1999 to 2003 ($n = 276$), era II: 2004 to 2006 ($n = 289$), and era III: 2007 to 2008 ($n = 235$). **On comparing eras I, II, and III, tumors in the most recent era were larger, more commonly greater than or equal to 4 cm and central, and, less often, peripheral and less than 4 cm (*P* value significant for all). Despite such increasing tumor complexity, mean warm ischemia times were shorter in the most recent era: 32 minutes, 32 minutes, and 14 minutes, respectively, ($P < .0001$). Also, overall, postoperative and urologic complications were significantly lower in the most recent era. Finally, renal functional outcomes were superior in era III, as documented by lesser percent decreases in estimated GFR (18%, 20%, and 11%, respectively).**

Kamoi and Gill also retrospectively compared 150 contemporary patients undergoing OPN (2006 to 2008) with 150 contemporary patients undergoing LPN (2007 to 2008) (author's unpublished data). Notably, all OPNs were performed by one surgeon experienced with open procedures, and all LPNs were performed by one surgeon experienced with laparoscopy procedures. LPN patients had a shorter ischemia time (21 vs. 13 minutes, $P < .0001$); more LPN patients had ischemia time of less than or equal to 20 minutes (52% vs. 97%); and fewer had an ischemia time greater than 30 minutes (9% vs. 0%; $P < .0001$ for both). Postoperative complications were fewer in the LPN group (19% vs. 8.7%; $P = .01$), including hemorrhage (3.3% vs. 2.7%; $P =$ ns) and urine leak (7.3% vs. 1.3%; $P = .02$). Patients undergoing elective PN had similar outcomes, and those undergoing imperative PN or PN in a solitary kidney had superior renal functional outcomes in the LPN cohort, probably because of the reduced ischemic insult during LPN. A recent study compared 86 off-clamp LPN with traditional clamped LPN (Herati et al, submitted). Significant differences ($P < .05$) in the off-clamp group relative to the on-clamp group included shorter operative time (132 vs. 146 minutes), a higher proportion of exophytic lesions (51% vs. 28%), smaller tumor volume (26 vs. 41 cm^3), and fewer hilar tumors (15% vs. 29%). Short-term elevation in serum creatinine was significantly

less (6% vs. 29%) although long-term significance of this finding is unknown. There were no significant differences in blood loss, transfusion rate, or complications. As experience improves, an increasing number of procedures may be performed off clamp.

These new data indicate that, despite increasing tumor complexity, three key outcomes of contemporary LPN (ischemia time, complications, and renal function) have improved significantly and now approach outcomes of open partial nephrectomy.

Positive Surgical Margin

The clinical significance of a pathologic positive surgical margin after partial nephrectomy, whether laparoscopic or open, has prompted several studies evaluating outcomes specifically in these patients. In a group of 1344 patients undergoing open partial nephrectomy, positive surgical margins were noted in 77 cases (5.5%) (Yossepowitch et al, 2008). The 10-year probability of freedom from local recurrence and progression to metastatic disease was 93% for both. There were no significant differences noted between those with positive and negative margins. Several laparoscopic surgeons have reported similar results. Of 511 patients undergoing LPN for renal cell carcinoma, 9 patients (1.8%) had a positive surgical margin (Permpongkosol et al, 2006a). Two underwent completion nephrectomy with no evidence of residual tumor, one patient with von Hippel-Lindau disease died of metastatic disease at 10 months, and six patients were observed to have no evidence of recurrence at mean follow-up of 32 months. **Although these data demonstrate that many patients with pathologically positive margins may be observed, negative surgical margins should always be the goal in any oncologic procedure.**

Long-Term Outcomes

Long-term data on LPN are now available (Table 55–4), and appear similar to open partial nephrectomy (OPN). **Five-year cancer-specific survival after LPN is 100%** (Lane et al, 2007). Most recently, a retrospective comparative study of 7-year outcomes compared 77 patients undergoing LPN with 310 patients undergoing open partial nephrectomy (OPN) for single clinical stage T1 (≤7 cm) tumors between 1999 and 2001 (Lane and Gill, 2010). Cancer recurred infrequently, and only rarely caused mortality, after either LPN or OPN. At 7 years, metastasis-free survival was 97.5% and 97.3% ($P = 0.47$) after LPN and OPN, respectively. After accounting for baseline differences between the cohorts, using propensity score–matching, 7-year metastasis-free survival was similar after LPN and OPN. On multivariate analysis, predictors of all-cause mortality included advancing age ($P < .0001$), comorbidity ($P < .0001$), preoperative renal dysfunction ($P = .0001$), but not tumor size ($P = .6$) or operative approach (LPN vs. OPN, $P = .06$). **The authors concluded that LPN and OPN provide similarly excellent long-term overall and cancer-specific survival, with the vast majority (97%) of patients experiencing metastasis-free survival.**

In experienced hands, LPN now is equivalent to OPN, with shorter ischemia times, and equivalent complication rates and renal functional outcomes. As a result, several centers routinely offer LPN for the majority of tumors (Permpongkosol et al, 2006b; Kamoi et al, submitted). These include technically challenging SRMs, including tumors which are hilar, central, completely intrarenal, larger (4 to 7 cm, pT1b) or located in a solitary kidney (Turna et al, 2008).

LAPAROSCOPIC ABLATIVE TECHNIQUES

As the incidence of the small renal mass has increased with the prevalence of cross-sectional imaging, a stage migration has occurred such that a rising number of patients are presenting with low-stage disease. Although the standard of care for these lesions remains surgical excision, due to cancer-specific survival rates in excess of 95% (Frank et al, 2005; Lane et al, 2007), cryoablation and radiofrequency ablation (RFA) have emerged as alternative treatment options for patients with a small renal mass. High-intensity focused ultrasonography, microwave therapy, and high-intensity radiation have also been investigated. The primary goals of these techniques are complete tumor destruction while minimizing morbidity. The potential advantages include less blood loss, less dissection, and fewer complications. Indications are similar for all of the ablative technologies and include lesions in patients with significant comorbidities, solitary kidneys, and hereditary renal cell carcinoma. The percutaneous approach is preferred for treatment of small renal masses due to its lower morbidity, but in some instances may not be possible due to tumor location or proximity to adjacent organs. For these reasons, laparoscopy is required for direct visualization and manipulation to make treatment delivery feasible. As cryoablation and RFA are the most prevalent in clinical applications, these ablative techniques will be discussed here in further detail.

Cryoablation

Laparoscopic cryoablation may be delivered using either a transperitoneal or retroperitoneal approach, with the decision resting primarily on tumor location. The kidney is mobilized using a three-port technique, and Gerota fascia is opened in a manner similar to that employed for LPN. The fat overlying the tumor may be excised and placed in a specimen bag for extraction and pathologic analysis. Biopsy samples of the tumor itself may also be taken with a 14- or 18-gauge biopsy needle for pathologic diagnosis. Placement of the cryoablation probes into the tumor can be performed percutaneously, leaving the ports free for instrumentation. Direct visualization of probe placement and depth of placement are confirmed with the laparoscope and intraoperative ultrasonography, respectively. Number and spacing of probes is dictated by probe-specific ablative diameter, and they should be positioned to ensure cryolesion overlap, typically parallel to one another in a triangular or quadratic configuration. The tip of the probes should be advanced just beyond the deepest margin of the tumor.

Cryoablation is believed to work by two distinct mechanisms: at the cellular level by intracellular ice formation and solute damage, and at the vascular level, secondary to thrombosis and subsequent coagulative and ischemic necrosis. It uses thin probes cooled with compressed gas, such as argon or carbon dioxide, to achieve very low temperatures. Tissue destruction and necrosis occur consistently at temperatures at or below –19.4° C and temperatures of –20° C are achieved 3.1 mm inside of the leading edge of a 3.2-cm iceball (Campbell et al, 1998; Chosy et al, 1998). Typically, an active double freeze-thaw cycle is used to enhance tumor destruction (Gill et al, 1998; Nakada et al, 1998). Clamping of the renal artery during freezing, to theoretically avoid the heat-sink effect of renal blood flow, has been shown to make no difference in the freezing effect (Orihuela et al, 1999).

Table 55–4.

Oncologic Outcomes of Laparoscopic Partial Nephrectomy

A. Comparative Series Analyzing Laparoscopic and Open Partial Nephrectomy

NR, not reported; RCC, renal cell carcinoma.

The progress of the ice-ball formation may be monitored in real time using intraoperative ultrasonography, and the iceball should extend approximately 1 cm beyond the edge of the tumor. Keeping in mind that the progress of the iceball cannot be abruptly stopped, caution should be exercised to avoid contact of the iceball with the renal collecting system, ureter, renal vasculature, or adjacent organs. After the freeze-thaw cycles are complete, the probes are removed with a gentle twisting motion. If any bleeding occurs, it can usually be controlled by applying pressure, or, if necessary, hemostatic agents such as fibrin glue or Floseal.

Radiofrequency Ablation

Similar to cryoablation, RFA may be administered laparoscopically using either a transperitoneal or retroperitoneal approach. After ultrasound confirmation of tumor location and size, the RFA probe is introduced into the tumor, and the tines are deployed to a diameter that ensures ablation of the tumor and a 1-cm margin of normal renal tissue. The size of the thermal lesion is determined by temperature- or impedance-based monitoring. **The probe uses an alternating current of high-frequency radio waves, causing ion vibration. The resistance in the tissue causes generation of sufficient heat to result in thermal tissue damage—tumor coagulation, protein denaturation, and cell membrane disintegration all occur** (Goldberg et al, 2000; Aron and Gill, 2007). Immediate histopathology after RFA shows hypereosinophila and pyknosis, which is subsequently replaced by coagulative necrosis within days to weeks (Crowley et al, 2001). To achieve these effects, optimal temperatures for ablation range between 60° C and 100° C and avoid tissue vaporization, which may occur at temperatures over 105° C (Goldberg et al, 2000; Crowley et al, 2001).

Unfortunately, unlike cryoablation, real-time ultrasonography cannot be used to monitor the thermal lesion induced by RFA. RFA itself may interfere with ultrasound imaging, and the affected tissue does not have any immediate change in echotexture. Color Doppler ultrasonography has been evaluated during RFA, but does not reliably contribute to monitoring the lesion (Crowley et al, 2001). Although MRI has been used to monitor the changing appearance of ablated lesions at the time of percutaneous treatment (Lewin et al, 2004), there is no current imaging technique that effectively monitors the progress of RFA lesions intraoperatively. Questions have been raised about temperature-based monitoring of the lesion, due to the observation that temperatures measured at the limit of the ablated area are actually 20° C to 30° C cooler than what is measured by the probe thermocouples. A potential solution involves the use of independent temperature probes to monitor temperature at the edge of the desired treatment area (Wingo et al, 2008). This allows a more definitive end point in the ablation cycle. Alternatively, an impedance-based system may be used. Instead of direct temperature measurement, this method relies on tissue impedance; sufficiently desiccated tissue becomes an insulator, and at an impedance level of 200 Ω, further progression of the thermal lesion is unlikely to occur (Lewin et al, 1998).

Imaging Follow-up

While cross-sectional imaging serves as the mainstay to determine treatment efficacy, there is debate about how to interpret the appearance of ablated lesions on postoperative imaging studies. Lack of enhancement on postprocedure CT scan or MRI is generally considered to define success for both cryoablation and RFA. Studies evaluating the appearance of cryolesions by CT or MRI demonstrated that peripheral rim enhancement is a common finding after laparoscopic cryoablation, and not necessarily cause for concern as demonstrated by follow-up percutaneous biopsy of these lesions (Remer et al, 2000; Bolte et al, 2006; Beemster et al, 2008). Cryolesions were generally noted to decrease in size over time, up to 94% at one year (Remer et al, 2000). Nonenhancing infiltrated fat may also be noted in the area overlying the lesion. Findings to elicit cause for concern for residual or recurrent disease were new rim enhancement, internal enhancement, or increase in size of the cryolesion. RFA lesions followed with MRI tend to be hypointense with a surrounding bright rim on T2-weighted imaging, and hyperintense on T1-weighted images. Tumor recurrence by most authors is defined as hyperintense soft tissue signal within the ablation zone, along its margin on T2-weighted images, or in areas of abnormal contrast enhancement within the treated region on the postcontrast images. Over time, RFA lesions also involute, causing a decrease in their size as measured by MRI or CT.

Treatment Outcomes

Several studies have reported promising short-term outcomes of laparoscopic cryoablation (Gill et al, 2000; Cestari et al, 2004). A study of 59 patients undergoing laparoscopic cryoablation, with a median tumor size of 2.5 cm and median follow-up of 26.8 months, documented 2 patients with tumor recurrence (Lawatsch et al, 2006). In a study of 81 patients undergoing laparoscopic cryoablation, 31 were presented with a minimum 3-year follow up (Weld et al, 2007). Biopsy of these lesions demonstrated that 61% were malignant and 39% were benign. Follow-up imaging performed at 1, 3, 6, 12, 24, and 36 months showed one patient who developed return of enhancement that was suspicious for recurrence at 36 months.

A comparison of 66 patients undergoing laparoscopic or percutaneous cryoablation demonstrated equivalent oncologic control at 30-months mean follow-up with no progression to metastasis (Malcolm et al, 2009). However, the percutaneous approach had a significantly higher primary treatment failure rate (25% vs. 3.8%). These patients either underwent salvage treatment or were observed with serial imaging. A similar comparative study of 37 patients with median follow-up of approximately 12 months demonstrated no difference in recurrence (4.2% vs. 5.3%) or need for re-treatment between the laparoscopic and percutaneous groups (Finley et al, 2008).

A multi-institutional study of RFA and cryoablation outcomes in 616 patients demonstrated residual or recurrent disease in 13.4% of patients undergoing RFA and 3.9% of patients undergoing cryoablation (Matin et al, 2006). Overall, 8.7% of patients failed primary therapy, and, after salvage ablative therapy, the failure rate was reduced to 4.2%. The authors noted that the majority of failures were detected after less than 3 months, and that cross-sectional imaging should be obtained 3 to 4 times at spaced intervals for the first year after undergoing treatment. A subsequent meta-analysis of patients undergoing partial nephrectomy, ablative therapies, or observation noted a higher risk of recurrence in patients undergoing cryoablation (RR = 7.45) or RFA (RR = 18.23) when compared with partial nephrectomy (Kunkle et al, 2008). Treatment failure was also linked to tumor size. However, no significant difference in rates of progression to metastatic disease was observed, regardless of treatment modality (Kunkle et al, 2008). Other studies have demonstrated that endophytic status may be linked to treatment failure after laparoscopic cryoablation, perhaps explained by increased difficulty with

ultrasound-guided targeting of the lesion without direct visualization afforded by exophytic lesions (Wright et al, 2007).

Complications

A multi-institutional experience with 148 laparoscopic cryoablation procedures on 144 patients reported a complication rate of 15.5% (Laguna et al, 2009). Significant independent predictors of negative outcomes and complications included tumor size, preexisting cardiac disease, and female gender. Although larger tumor size and cardiac disease would intuitively lead one to predict increased complication rate, the association of female gender is unclear. A second multi-institutional study investigated complications of both percutaneous and laparoscopic cryoablation and radiofrequency ablation of small renal tumors (Johnson et al, 2004). A total of 139 cryoablations were performed along with 133 RF ablations. An overall 11% complication rate was observed with 1.8% classified as major, 9.2% as minor. Major complications included significant hemorrhage, ileus, uteropelvic junction (UPJ) obstruction necessitating nephrectomy, urinoma, conversion to open surgery, and death (aspiration pneumonia). In the laparoscopic group (90 patients), a 9% complication rate was reported, with the most common complication being pain or paresthesia at the ablation probe insertion site.

LAPAROENDOSCOPIC SINGLE-SITE (LESS) SURGERY OF THE KIDNEY

Clinical Experience of Renal LESS Surgery

Initially reported for nephrectomy in the urologic literature (Raman et al, 2007), LESS has now been used to perform a variety of transumbilical procedures. Adjunctive 3-mm subxiphoid ports and 2-mm needlescopic ports have been required in some cases for liver retraction and laparoscopic suturing, respectively. Reported operative times and complication rates have been comparable to traditional laparoscopic approaches.

After gaining substantial experience with LESS techniques, several authors have now reported the use of LESS with more time-sensitive surgeries such as donor nephrectomy and partial nephrectomy. A retrospective comparative study between 17 LESS donor nephrectomies and 17 matched patients undergoing a standard laparoscopic approach has now been reported (Canes et al, 2010). All LESS procedures were completed with the use of a purpose-specific access device; at the discretion of the surgeon, an adjunctive 2-mm needlescopic port was used to aid in retraction, hilar dissection, and extraction (Fig. 55–42). Mean warm ischemia time was longer in the LESS group (3 vs. 6.1 minutes), while blood loss and operative times were similar. The median length of harvested renal artery, vein, and ureter were 3.2 cm, 3.6 cm, and 14.9 cm, respectively, in the LESS cohort; measurements for standard laparoscopy were not reported. Complications included one corneal abrasion and one postoperative allograft thrombosis. A more rapid return to convalescence was noted in the LESS donor nephrectomy group, with fewer days on oral pain medication, faster return to work, and days to "100% recovery" (self determined). LESS Pfannenstiel donor nephrectomy has also been reported and may add to the cosmetic benefit afforded by the single-site approach (Andonian et al, 2009). Prospective studies are certainly needed to determine if this approach is warranted in this patient population.

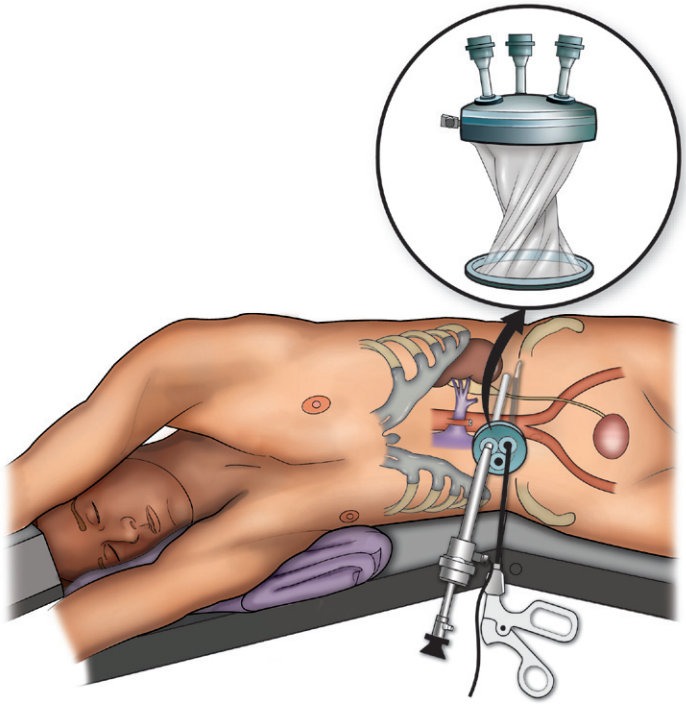

Figure 55–42. Laparoendoscopic single-site surgery donor nephrectomy using a purpose-specific device with multichannel instrument access. A 2-mm instrument is also used to aid in retraction, hilar dissection, and extraction.

An initial series of LESS partial nephrectomy was reported in four patients with a median tumor size of 3-cm (range, 1 to 5.9 cm) (Aron et al, 2009). Median operating time was 270 minutes, and median blood loss was 150 cc. Median warm ischemia time was 20 minutes (range 11 to 29 minutes), and median hospital stay was 3 days. One patient had postoperative hemorrhage and pulmonary embolism.

The two largest LESS series each encompass 100 patients, where LESS has been employed to perform a variety of urologic surgeries (Desai et al, 2009; White et al, 2009). The cases performed have included nephrectomy (simple, partial, radical, and donor), nephroureterectomy, renal cyst excision, renal tumor cryoablation, pyeloplasty, ureteroneocystostomy, ileal ureter, adrenalectomy, hysterectomy, varicocelectomy, radical prostatectomy, transvesical simple prostatectomy, radical cystectomy, sacral colpopexy, and mesh sling removal. These series demonstrate the breadth of urologic procedures that can be performed with LESS techniques.

Raman and colleagues (2009) reported the first comparative study between traditional laparoscopic and LESS applications. The investigators compared 11 LESS nephrectomies with 22 standard laparoscopic nephrectomies. The groups were matched at a 2:1 ratio for patient age, surgical indication, and tumor size. Similar outcomes between the two groups were noted regarding operative time (122 vs. 125 minutes), analgesic use, length of stay, and complication rate.

Robotic LESS (R-LESS) Surgery

The da Vinci-S Robotic System (Intuitive Surgical, Sunnyvale, CA) has been used in conjunction with a Tri-Port single-port access device to perform radical prostatectomy, pyeloplasty, and radical nephrectomy (Kaouk et al, 2009). A 12-mm 3D camera and 5-mm

grasper were placed through the Tri-Port, while an additional 8-mm port was placed alongside the port in the same incision for another robotic instrument. Operative times (radical prostatectomy = 5 hours, pyeloplasty = 4.5 hours, radical nephrectomy = 2.5 hours), estimated blood loss (80 to 250 cc), and hospital stay (2 days) were acceptable. Significant "clashing" of robotic arms was noted. R-LESS surgery has also been performed using the GelPort laparoscopic access system (Stein et al, 2010). The authors reported more adequate spacing for the robotic instruments and easier assistant access. However, the need for novel purpose-specific, possibly flexible, robotic instrumentation or platforms was noted in both studies.

The prospect of LESS surgery is potentially attractive from the patient perspective, with possible benefit in decreasing postoperative pain and improving cosmesis. This may be especially true in the case of extirpative surgery, when an extraction site is required or if cosmesis is of particular concern. However, these potential benefits have not yet been proven in prospective trials. Moreover, although a large body of surgical literature clearly demonstrates benefits of traditional laparoscopy versus open surgical techniques for analgesic requirements, length of stay, return to convalescence, and cosmesis, the benefits of LESS versus traditional laparoscopy remain in question at this time. Larger comparative series between traditional laparoscopic techniques and LESS are required to further study outcomes relevant to each specific procedure and to evaluate for potential benefits.

COMPLICATIONS OF LAPAROSCOPIC RENAL SURGERY

Complications are an unavoidable consequence of surgical practice and even the most experienced clinicians will face problems. Organic factors related to the patient, operating room environment, and chaotic forces can lead to an untoward event. Thus efforts at prevention through knowledge of each given procedure and its potential pitfalls should be maximized. Moreover, patient education about the risks of surgery is essential.

Patient selection is important to minimize risk of complications. This needs to be paired with each surgeon's experience and ability. Several situations require caution when considering a laparoscopic approach. True contraindications include an uncorrected coagulopathy, untreated infection, and hypovolemic shock (Capelouto and Kavoussi, 1993). **Previous surgery is not a contraindication to laparoscopic renal surgery. Prior abdominal surgery may have caused intra-abdominal adhesions and increased the possibility of injury to bowel during insufflation, trocar placement, or dissection.** The initial entry site in these patients should be away from scars and prior surgical fields. Open trocar placement or a retroperitoneal approach, may be necessary to minimize access injuries (Hasson, 1971). Extraperitoneal access may also help avoid adhesions. If additional space is required, the peritoneum may be opened under direct vision.

Patients with large, dilated loops of bowel from either functional or obstructive ileus should be approached cautiously, because the dilated intestinal segments can limit the working space and may be injured during access, dissection, and trocar site closure (Borten, 1986).

Care is taken to keep anatomic orientation at all times, because confusion in landmarks can lead to catastrophic consequences. Prior surgery or bulky pathology can alter normal anatomic relationships. It is thus necessary to have preoperative imaging studies available in the room. Intraoperative ultrasonography can be a valuable tool to help identify structures. When visual clues are inadequate to allow safe progress, palpation by hand assistance may provide additional information. Alternatively, open conversion may be indicated.

When complications occur, the consequences can often be minimized through early recognition and appropriate intervention. Laparoscopic renal surgery shares several potential risks with traditional open approaches; however, there are differences in the type and presentation of these complications. It must be kept in mind that all situations are individual, and unique problems may arise and call for innovative actions.

General complications of laparoscopic surgery have been covered in Chapter 9, however, specific pitfalls require review. Reported complications from laparoscopic kidney surgery are reviewed in Table 55–5. The combined incidence of bowel injury in the urologic literature is 0.8%, and injury may occur at any point during the dissection (Schwartz et al, 2010). When reflecting the colon or duodenum, avoid thermal energy adjacent to the bowel. This is the most common cause of unrecognized injury and may not be diagnosed until postoperative day 3 to 5. When recognized, superficial thermal injuries may be oversewn with 3-0 silk suture to imbricate the affected area. Transmural injuries should be debrided and, as with primary sharp injury, may be closed primarily in two layers. The area should be irrigated thoroughly and inspected to rule out a through and through injury. Drain placement is optional and oral intake is held until bowel function has returned.

Table 55–5.

Reported Complications of Laparoscopic Kidney Surgery

Vascular injury
Adjacent organ injury (liver, spleen, pancreas, bowel, stomach, diaphragm)
Wound infection
Abscess
Seroma
Wound dehiscence
Internal hernia
Incisional hernia
Pulmonary complications (pneumothorax, pulmonary edema, pleural effusion, pneumonia)
Pulmonary embolism
Deep vein thrombosis
Neuromuscular pain
Postoperative bleeding/transfusion
Atrial fibrillation
Myocardial infarction
Adrenal insufficiency
Testicular infarction or ischemia
Epididymitis
Ureteral stricture
Nonelective open conversion
Chylous ascites
Urinoma
Completion nephrectomy (after partial nephrectomy)
Tumor fragmentation
Renal insufficiency (transient or chronic)
Delayed bleeding
Urinary tract infection
Urinary retention

One of the most devastating complications occurring as a result of laparoscopic surgery is unrecognized bowel injury (Fig. 55–43). **Only a small portion of the laparoscopic instrument is in the visual field so that injuries can occur out of the surgeon's view during introduction or retraction.** In the urologic literature, the overall incidence of bowel injury during laparoscopic surgery of the retroperitoneum, both recognized and unrecognized, is 0.65% (Schwartz et al, 2010). **Unrecognized injuries result in high-grade complications in 100% of cases in series reporting on laparoscopic bowel injuries.** Blunt, sharp, and cautery dissection account for the majority of bowel injuries (60%), while access-related injuries are far less common (6%). **The presentation of bowel injuries in patients undergoing laparoscopy differs from that described with open surgery. Patients with unrecognized bowel injury after laparoscopy typically present with persistent and increased trocar-site pain at the site closest to the bowel injury. The area around this site becomes edematous and doughy in consistency. Signs and symptoms may also include abdominal distention, nausea, diarrhea, anorexia, low-grade fever, persistent bowel sounds, and a low or normal white blood cell count. The patient's condition can rapidly deteriorate to hemodynamic instability and death, if the injury is not recognized and treated** (Bishoff et al, 1999). CT with oral contrast is the initial diagnostic modality of choice (Cadeddu et al, 1997), and open exploration is usually required to evacuate bowel spillage and perform the necessary repair. In rare cases, when a controlled fistula develops, conservative management with bowel rest and hyperalimentation may be used, but this can take months to resolve.

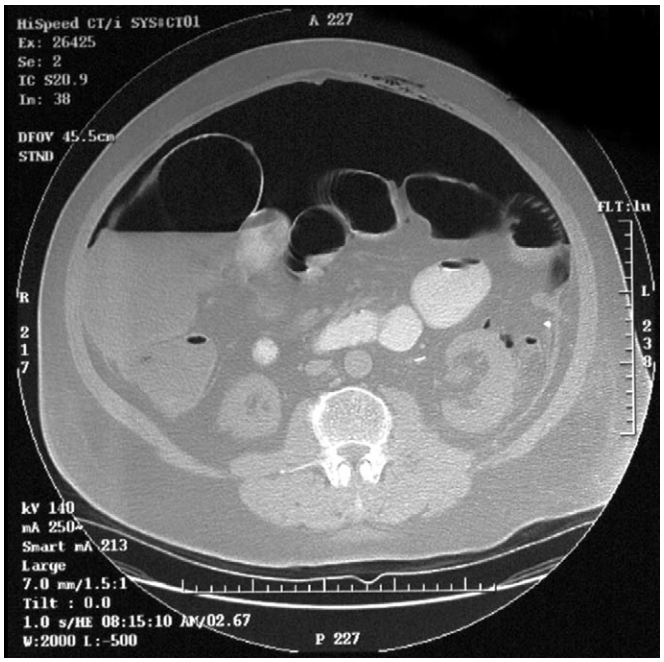

Figure 55–43. CT scan taken 9 days after partial nephrectomy when the patient presented to the clinic for routine follow-up complaining of distention and worsening abdominal pain for the past 3 days, low-grade fever, leukopenia, and pain out of proportion at a single trocar site. CT shows dilated loops of large bowel and significant amounts of free air. Exploration revealed a small perforation in the cecum.

In reflecting the bowel on the left side, care must be taken to avoid making a hole in the mesentery. Any mesenteric defects should be closed as postoperative bowel herniation is possible (Regan et al, 2003). During closure of the mesentery, care also should be taken to avoid compromising the vascular supply to the colon. Retractors not in the operative field may also injure the bowel, and one should check for inadvertent injury at the conclusion of the procedure.

Vascular injuries are the most common complication of urologic laparoscopy (Permpongkosol et al, 2007). Life-threatening vascular injuries can occur during laparoscopic renal surgery and usually occur during dissection of the renal hilum. Injury to arteries, veins, branches, and accessory vessels can result in bleeding that may require conversion to open surgery. The renal vein can have multiple branches that can easily be torn. Care should be taken in assuring ligation and transection without tension. Venous bleeding can be brisk. Many times, applying direct pressure with gauze for several minutes will be sufficient to control bleeding. Resist the temptation to continually explore the area of venous bleeding, if all is quiescent once the gauze is removed. On the right side, the vena cava can be injured. Avulsion of the gonadal or adrenal vein can cause significant bleeding. If a hole is visible, placement of a clip or suture may be attempted once a grasper has controlled the situation. Blind clip placement or suturing can lead to a worsening of the situation and additional complications. Again, direct pressure with gauze over several minutes may abate bleeding. Dissection may continue with the gauze in place.

Arterial injuries can occur when structures are not fully identified before transection. Also, past pointing of scissors can cut an underlying vessel. If the opening is identified, suture placement or clips may be used for control. A hand may be placed in a lower abdominal midline incision to hold pressure if bleeding is brisk. In this manner, laparoscopic suturing or open conversion can proceed in a controlled manner.

Cases of inadvertent stapling of important anatomic structures have been reported. The vena cava and aorta have been mistaken for the renal vessels (McAllister et al, 2004). Several instances of transection of the small mesenteric artery (SMA) or contralateral renal vessels have also occurred. This can occur readily with the novice who is unfamiliar with the retroperitoneal approach. Unfortunately, many of these are not recognized intraoperatively and mortality is high. The best way to avoid this is through continuous anatomic orientation and vigilant self-questioning.

Equipment failure can result in bleeding. A multi-institutional review of endovascular stapler complications showed a malfunction rate of 1.7% (10/565), with eight cases involving the renal vein and two cases the renal artery (Chan et al, 2000). Blood loss resulting from the malfunction was between 200 to 1200 cc. Conversion to open surgery for hemostasis was required in 20% of the malfunction cases. The etiology of stapler failure was due directly to the instrument in three cases and due to preventable causes in seven cases. Preventable causes included stapling over clips or incomplete transection due to incorrect placement. **The abdominal cavity should be inspected for bleeding at the conclusion of surgery. Common areas of postoperative intra-abdominal bleeding include the bed of the dissection, adrenal gland, mesentery, gonadal vessels, and ureteral stump.**

Postoperative hemorrhage can occur following partial nephrectomy. Hypotension with associated tachycardia and a drop in hematocrit may imply postoperative bleeding. **Following partial nephrectomy, an arteriovenous malformation or pseudoaneurysm may form** (Benway et al, 2009; Shapiro et al,

2009). **These patients present with persistent gross hematuria, hypotension, and tachycardia.** If there is a question, CT scanning may be appropriate in identifying the source of bleeding; **however, in the majority of patients, immediate renal angiography with embolization of the bleeding site is indicated.**

Persistent urine leakage may occur following a partial nephrectomy or cyst ablation. Unless there is distal obstruction to the site of leakage, most will resolve with conservative therapy after several weeks (Meeks et al, 2008). After approximately one week, a controlled fistula develops, and the drain can be taken off continous suction and checked intermittantly to be sure fluid is not accumulating. If conservative management fails, such as in cases of distal obstruction, additional intervention may be required, such as percutaneous drainage of a urinoma or ureteral stent and bladder decompression.

Upper pole renal dissection can result in diaphragmatic injury. This is usually immediately recognized because peak airway pressures suddenly increase, and ventilation of the patient becomes difficult. The diaphragm can be seen billowing on endoscopic inspection. Immediate treatment is needed to prevent a tension pneumothorax. The diaphragm can be sutured directly while a central line catheter is placed into the ipsilateral anterior second intercostals space and placed to a water seal. At the conclusion of the procedure, the patient is ventilated, a chest radiograph obtained, and, if resolved, the catheter is removed. When significant gas remains, a chest tube can be inserted (Del Pizzo et al, 2003; Aron et al, 2007).

On the left side, splenic and pancreatic injuries may occur. Bleeding from the spleen is usually controlled with topical agents and argon beam coagulations (Canby-Hagino et al, 2000; McGinnis et al, 2000). Injuries to the pancreas may be insidious, and inspection is needed at the conclusion of surgery. Superficial pancreatic injuries are observed with drain placement. Deeper injuries may require formal repair or isolation of the segment with a GIA stapler (Varkarakis et al, 2004). Right-sided dissections may cause injury to the liver or gall bladder. Liver injuries are managed with topical therapy and argon beam coagulation. Gall bladder injuries are best managed by cholecystectomy.

Patients undergoing laparoscopic renal surgery are at risk of intravascular volume overload if fluid replacement is not modified relative to open surgery. The laparoscopic approach is associated with far less insensible fluid loss compared with open procedures, and there is also a vascular-mediated oliguria. As such, urine output should not be a barometer of fluid status. Typically, intravenous fluids should be minimized with the exception of laparoscopic donor nephrectomy. Aggressive replacement can cause volume overload in patients with diminished cardiac reserve and can result in postoperative congestive heart failure. Poor urine output or hemodynamic instability in the postoperative period should initiate an evaluation to rule out bleeding; if the work-up is negative, diuresis can be induced if clinically indicated.

Several authors have reported cases of chronic pain syndrome or nerve injury after laparoscopic radical nephrectomy. Patients may experience a burning discomfort in the ipsilateral flank; paresthesias around port sites or over the thigh and upper extremity can occur (Wolf et al, 2000; Oefelein and Bayazit, 2003). In a series of 381 laparoscopic donor nephrectomies, ipsilateral orchialgia was reported in 10% of patients (Kim et al, 2003). Onset of pain occurred at a mean of 5 days after surgery (range 6 to 52 months) and at 6 months; 50% had complete spontaneous resolution. Thigh paresthesias may be avoided by preserving the psoas fascia during posterior renal dissection. Additional reported complications include incisional hernia after intact specimen removal, port-site hernia, prolonged ileus, pulmonary embolus, and pneumonia.

In a multi-institutional review of 185 patients, Gill and coworkers (1995) reported an overall complication rate of 12% for benign disease, with 5% of patients requiring conversion to open surgery. In their series, the incidence of complications decreased markedly with increasing experience. **In fact, 70% of the complications occurred during the first 20 cases at each institution. A learning curve of approximately 20 laparoscopic nephrectomy cases is also supported by other reports** (Keeley and Tolley, 1998; Rassweiler et al 1998; Fahlenkamp et al, 1999). In a recently reported series of partial nephrectomies, the complication rate continued to decrease even after 750 cases. This implies a longer learning curve for more complex procedures.

In a series of 482 laparoscopic nephrectomies (444 procedures for benign disease) performed by 20 surgeons at 14 different European medical centers, a 6% overall complication rate was reported, with 10% of the cases converted to open surgery (Rassweiler et al, 1998). **The majority of patients converted to open surgery had infectious causes of renal abnormality as the leading indication for kidney removal.** Bleeding was the most common cause of open conversion in these cases, followed by the surgeon's inability to visualize the renal hilum for dissection.

In series comparing open, hand-assisted, and laparoscopic nephrectomy for malignancy, the complication rates were 10%, 17%, and 12% respectively (P = .133) (Chan et al, 2001; Shuford et al, 2004).

Two comparative studies examining complication rates in the elderly population, greater than 75 and greater than 80 years, respectively, found no difference in surgical or long-term morbidity when compared with younger patient populations (Varkarakis et al, 2004b; Thomas et al, 2009). In patients at high risk for perioperative complications, as determined by an American Society of Anesthesiologists score greater than or equal to 3, there were no significant differences in complication rates between hand-assisted, laparoscopy, and open radical nephrectomy (Baldwin et al, 2003).

PENETRANCE OF LAPAROSCOPIC RENAL SURGERY FOR THE COMMUNITY UROLOGIST

A recent study using information gathered from the SEER-Medicare–linked database showed the serious underutilization of laparoscopic and nephron-sparing techniques (Miller et al, 2008). Of 4872 radical nephrectomies performed for kidney cancer between 1997 and 2002, only 515 (10.6%) were performed laparoscopically. After controlling for variables such as demographics, tumor size, and comorbidities, surgeon-attributable factors were consistently the most significant predictor of the type of surgery performed. Stated otherwise, the surgeon's practice style was the determining factor for the surgical approach, not patient characteristics or characteristics of the renal cancer. This conclusion should be cause for some alarm in the urologic community. Laparoscopic procedures such as cholecystectomy and appendectomy are quite commonplace and were rapidly adopted by general surgeons. Historically, urologists have been receptive to new technology, a fact most recently demonstrated by the rapid increase in the number of robotic prostatectomies performed in the United States. However, the same does not hold true for laparoscopic nephrectomy, despite its longevity and proven benefits. This

would suggest significant barriers to the diffusion of laparoscopy specifically for renal surgery. A complex array of reasons may account for this observation, including the differential incidence of kidney and prostate cancer, marketing of robotics, referral patterns, consumer demand, etc. (Richstone et al, 2008). As physicans, we must be aware of barriers that affect the use of procedures with proven and meaningful patient benefits, and work toward dismantling them such that every patient may gain from progress in our field.

SUMMARY

Laparoscopy has emerged as the preferred treatment modality for many types of renal pathology. Patients have undoubtedly gained from the benefits laparoscopy offers in terms of perioperative morbidity without sacrificing therapeutic outcomes. As surgical tools continue to evolve, even more minimally invasive options such as laparoendoscopic single-site surgery and natural orifice transluminal endoscopic surgery may become more pervasive and potentially offer additional perioperative benefit to patients.

Key Points

- Laparoscopy can be used to treat the majority of renal pathology with equal efficacy as open surgery while providing less pain, shorter convalescence, and optimal cosmesis.
- Basic principles of oncologic surgery must be maintained when using a laparoscopic approach to treat renal tumors.
- Unrecognized bowel injuries are associated with high mortality, because the presentation of bowel injuries in patients undergoing laparoscopy differs from that described with open surgery. Presentation is typically characterized by normal to low white blood count (WBC), focal abdominal pain (often worst at the trocar site nearest the injury), mild ileus, and lack of fever.

Ablative Therapy for Renal Tumors

Wesley M. White, MD ● Jihad H. Kaouk, MD

Cryoablation
Radiofrequency Ablation
Surgical Technique
Oncologic Outcomes
Complications
Future Trends
Conclusions

The management of renal cell carcinoma has undergone a paradigm shift over the last two decades. The widespread use and refinement of modern imaging during this period has led to a dramatic increase in the number of incidentally discovered and low-stage renal lesions (Jayson and Sanders, 1998; Volpe et al, 2004). This fortunate trend has allowed urologists to explore alternative and less invasive forms of therapy, among them nephron-sparing surgery and renal ablative technologies (Colombo and Kaouk, 2007; Pinto, 2009). Cancer-specific survival, preservation of renal function, avoidance of treatment-related morbidity, and patient-centered quality-of-life outcomes now constitute the ultimate goals for management of early-stage renal cell carcinoma.

The preponderance of evidence-based data champions the role of partial nephrectomy in the treatment of localized unilateral small renal masses (Herr, 1999; Fergany et al, 2000). Nephron-sparing surgery, in this setting (tumors < 4 cm), offers comparable oncologic outcomes (>95% cancer-specific survival) as compared with radical nephrectomy and is associated with improved preservation of renal function, superior cardiac outcomes, and improved overall survival (Thompson et al, 2008; Huang et al, 2009; Zini et al, 2009). Moreover, nephron-sparing surgery avoids overtreatment of indolent or benign tumors, a particularly germane concern, because nearly 20% of malignant-appearing, small renal masses are pathologically benign (Frank et al, 2003). For these reasons, open partial nephrectomy is currently considered the gold standard treatment for radiographically enhancing small renal masses (Novick, 2004).

Despite its aforementioned long-term advantages, open partial nephrectomy is nevertheless associated with significant short-term morbidity, namely substantial postoperative pain, prolonged hospitalization, and a protracted convalescence (Gill et al, 2007). Because a large proportion of patients who are candidates for partial nephrectomy demonstrate concomitant co-morbidities or are of advanced age, this short-term morbidity must be taken into consideration during patient counseling, and less invasive alternatives, if appropriate, should be discussed.

Laparoscopic partial nephrectomy (LPN) replicates the principles of open nephron-sparing surgery but with less attendant surgical morbidity (Gill et al, 2002). Indeed, laparoscopic partial nephrectomy offers markedly improved convalescence and equivalent disease-free survival as compared with open partial nephrectomy (Aron and Gill, 2007; Andonian et al, 2008; Marszalek et al, 2009). However, laparoscopic partial nephrectomy remains a technically challenging procedure with significantly higher complication rates, even among experienced surgeons at centers of excellence (Gill et al, 2007). Further, renal hilar occlusion is nearly universally required during LPN to minimize blood loss and facilitate tumor resection in a bloodless field. In expert hands, warm ischemia times during LPN approach 30 minutes (Kural et al, 2009; Thomas et al, 2009). Although controversial and dependent on the inherent renal function status, warm ischemia times that approach or exceed 30 minutes may place the kidney at considerable risk for postischemic injury (Thompson et al, 2007; Lane et al, 2008).

Irrespective of the surgical approach chosen, nephron-sparing surgery is underutilized in the United States owing to the comparative risks and attendant technical demands associated with the procedure (Abouassaly et al, 2009). Recent Surveillance, Epidemiology, and End Results (SEER) data found that partial nephrectomy is performed in only 11.1% of patients, with the remaining 88.9% undergoing radical nephrectomy (Miller et al, 2008). Furthermore, when adjusted for patient demographics and tumor size, surgeon preference was significantly more important than patient characteristics with regard to the type of operation selected.

Energy-based, in-situ tumor ablation was developed in an attempt to broaden the minimally invasive treatment options available to patients with ostensibly localized, low-stage renal tumors (Goel and Kaouk, 2008a). Focal ablative therapy confers myriad advantages compared with extirpative surgery. Principally, renal tumor ablation is associated with fewer complications, less morbidity, and a shortened convalescence (Desai et al, 2005). Second, prospective studies have demonstrated no significant impact on renal function following treatment (Shingleton and Sewell, 2003; Raman et al, 2008). Although a modicum of parenchymal loss does occur, renal hilar occlusion is not performed during tumor ablation, and postischemic injury is therefore avoided. Next, ablation offers considerable treatment flexibility. That is, tumors may be treated open, laparoscopically, or percutaneously with the approach tailored to the specifics of the patient and tumor (Rukstalis et al, 2001; Deane and Clayman, 2006).

Finally, renal tumor ablation is technically less demanding to perform than either open or laparoscopic partial nephrectomy. Complex reconstruction is not required following treatment, and dissection and isolation of the renal hilum is not requisite. Given these advantages, ideal candidates for ablative treatment have traditionally included patients with small multifocal tumors, those with one or more tumors in a solitary kidney in which surgical warm ischemia would place the kidney at risk, and those who desired treatment but were not appropriate candidates for extirpative surgery (Lehman and Landman, 2008).

Although well tolerated and technically less challenging than alternative extirpative options, concern exists regarding the oncologic efficacy of ablative techniques. A recent meta-analysis demonstrated a higher relative risk of local recurrence with cryoablation (RR = 7.45) and radiofrequency ablation (RR = 18.23) as compared with partial nephrectomy, but with no significant difference in progression to metastatic disease between the three groups (Kunkle et al, 2008). However, nonuniform criteria were used to define tumor recurrence in these series and pathology was not obtained for all specimens.

Evolving technology that includes treatment guidance systems, more robust operator experience, and improved patient selection may position renal ablative technologies as a treatment of choice for small renal masses. Probe ablative treatments are considerably less invasive than open partial nephrectomy, are less technically challenging and more easily learned than laparoscopic partial nephrectomy, and are associated with fewer complications as compared with open or laparoscopic partial nephrectomy.

Key Points: Management of the Small Renal Mass

- Widespread use of cross-sectional imaging has led to a dramatic increase in the number of incidentally discovered, low-stage renal lesions.
- Nephron-sparing surgery offers comparable cancer-specific survival and superior overall survival when compared with radical nephrectomy for small renal masses.
- In-situ ablative technologies including cryoablation and radiofrequency ablation were developed as a minimally invasive nephron-sparing alternative to extirpative surgery.

CRYOABLATION

Mode of Action and Experimental Data

The concept of applying cold temperatures to destroy tissue is credited to an English physician, Dr. James Arnott (1797 to 1883). Using a combination of ice and salt, he was able to topically palliate tumors of the cervix and breast with variable success. Over the course of the ensuing decades, investigators developed more sophisticated, reproducible, and pragmatic methods of handling and applying topical cryogens (Gage, 1998). In 1963, a neurosurgeon from New York, Dr. Irving S. Cooper, introduced a probe capable of achieving a controlled temperature of –196° C in deep-seated tissues (Cooper, 1963). Using pressurized liquid nitrogen, this self-contained probe was employed to ablate otherwise inoperable brain tumors, as well as portions of the thalamus in patients with Parkinson disease. Cooper's innovative concept ushered in a new era in cryosurgery in which larger volumes of tissue in less accessible locations could be successfully and reproducibly ablated.

Although Cooper's experience provided the proof in principle for cryoablation, its practical application for abdominopelvic tumors was not immediately realized. Early cryogen delivery systems could not unfailingly control the extent of tissue death owing to a generalized lack of cryoprobe sophistication and an unreliable system of monitoring the freezing process (Weber and Lee, 2005). As such, irreparable collateral damage was often a consequence of treatment, and the technique was transiently abandoned. It was not until the development of cryoablation under real-time image guidance with intraoperative ultrasonography that the procedure became a safe and pragmatic treatment choice.

The application of intraoperative ultrasonography during cryosurgery addressed many of its aforementioned short-comings (Onik et al, 1984, 1985). First, ultrasonography offered an excellent method for evaluating the patient's anatomy. The relative size and location of the area to be treated could be visualized and documented, and the entirety of the organ could be evaluated for occult metastatic disease. Second, precise probe placement could be assured by following its echogenic tip under ultrasound guidance. Lastly and most importantly, the freezing process could finally be monitored in real time by observing the formation and propagation of the highly echogenic leading edge of the iceball (Fig. 56-1). Because animal studies had already confirmed a close correlation between the sonographically visible iceball and the zone of cell death, surgeons now had a reliable and reproducible method of targeting and destroying tumors without attendant collateral damage (Steed et al, 1997; Campbell et al, 1998; Weber et al, 1998).

Following treatment under image guidance, the next significant breakthrough with cryoablation was the introduction of argon gas–driven treatment systems (Rewcastle et al, 1999). Through the mid- to late 1990s, cryoablation was performed exclusively with liquid nitrogen-based systems that were relatively inefficient. Newer argon gas systems were developed, ones that use the Joule-Thomson principle (low temperatures are achieved by the rapid expansion of high-pressure, inert gas) to generate temperatures of –185.7° C within the treatment tissues. These systems require shorter treatment times and allow for smaller, more proficient

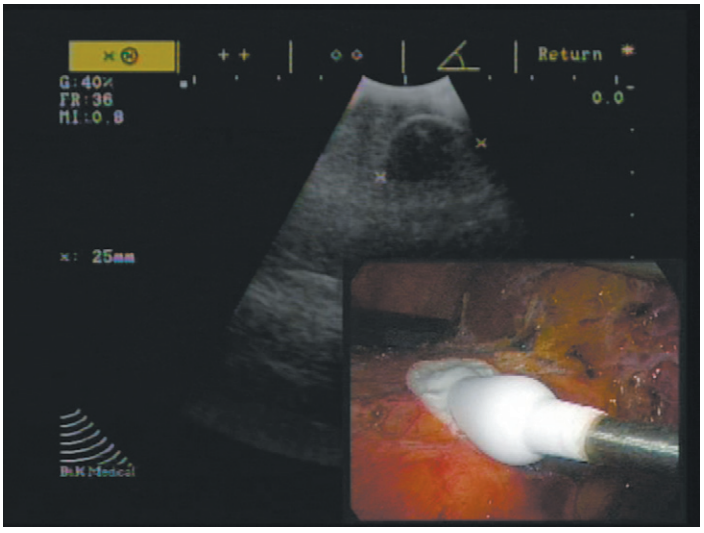

Figure 56–1. Intraoperative ultrasound image during renal tumor laparoscopic cryoablation. Note the hyperechoic semicircular edge with a posterior shadow of the developing iceball. *Inset:* laparoscopic view of the cryoablated mass with the cryoprobe positioned in the center of the tumor that is covered with ice.

cryoprobes that can be employed laparoscopically with fused ultrasound guidance or percutaneously under computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound guidance. The majority of commercially available cryoablation units (CryoHit, Galil Medical, Plymouth Meeting, PA; CryoCare, CryoCare CS, Endocare, Irvine, CA; SeedNet, Oncura, Philadelphia, PA) now employ argon gas–based systems as described.

The mechanism of tissue injury with cryoablation is multifaceted, reflecting direct cellular damage during the freezing phase and indirect reperfusion injury during the thawing phase (Mazur, 1977; Ishiguro and Rubinsky, 1994; Hoffman and Bischof, 2002). During rapid freezing or freezing at extremely low temperatures, ice crystals form within the intracellular spaces, causing cell death by direct injury to either the cellular membrane or structures within the cell. With gradual freezing, extracellular ice formation creates an osmotic gradient that results in intracellular fluid moving into the extracellular space. The result of this fluid shift is dehydration, cell membrane rupture, and subsequent cell death. During the thawing phase, reperfusion injury occurs that results in microcirculatory failure and small-vessel thrombosis (Weber et al, 1997; Kahlenberg et al, 1998). Although speculative, this may represent the dominant mechanism of cell kill during cryosurgery. The summative pathologic consequence of treatment is coagulative necrosis and fibrous scar formation.

The adequacy and reproducibility of tissue destruction during cryoablation is dependent upon several parameters:

1. *Treatment Temperature.* Based on experimental evidence, it is clear that a certain threshold temperature must be reached in order to effect adequate tumor destruction. Although susceptibility to cryoablation is dependent upon the tissue treated, it is widely estimated that the critical temperature for irreparable tissue destruction is between –20° C and –50° C (Neel, 1971; Tatsutani et al, 1996; Woolley et al, 2002). In general, normal renal parenchyma is destroyed at –19.4° C with tumor cells requiring lower temperatures, likely owing to their more fibrous nature (Chosy et al, 1998; Larson et al, 2000). Tissue with high-collagen and elastin content appear to be the most resilient to freezing (Shepherd and Dawber, 1984). For this reason, the renal collecting system and renal vasculature tolerate cryoablation without appreciable long-term adverse effects (Sung et al, 2003). Conversely, the urethra, bowel, and ureter are more cryosensitive and are thus subject to stricture, sloughing, and perforation if protective measures are not employed (Wong et al, 1997). With the use of modern cryoablation units, core treatment temperatures of –130° C to –150° C are achieved. **Currently, the minimum preferred target temperature during renal cryoablation is at or below –40° C.**
2. *Double Freeze-Thaw Cycle.* In-vivo animal studies initially demonstrated adequate cell kill in normal tissue employing a single freeze-thaw cycle (Weber et al, 1997). However, when applied to tumor cells in small animal models, the single freeze-thaw cycle was found to be inferior to a double freeze-thaw cycle with respect to adequacy of tissue ablation and local tumor control. This finding was confirmed by Woolley and associates (2002) who prospectively compared treatment outcomes in 16 female dogs who underwent either a single or double freeze-thaw cycle. A significantly larger and more adequate area of liquefaction necrosis was noted following a double freeze-thaw cycle. **As such, a double freeze-thaw cycle is currently the standard of care during renal tumor cryoablation.**
3. *Determining an Adequate Ablation Zone.* Campbell and colleagues (1998) demonstrated that the aforementioned threshold temperature of –40° C (as evidenced by tissue necrosis) was achieved 3.1 mm inside the edge of the evolving iceball. To guarantee that the tumor is completely ablated with a margin of normal tissue, the iceball is generally carried 5 to 10 mm beyond the edge of the tumor when viewed under real-time imaging (Gill et al, 2000). In addition, thermosensors may be positioned at the tumor margin to ensure that adequate treatment temperatures (–40° C) are achieved at the periphery (Rukstalis et al, 2001). The ability to shape the iceball by placing multiple probes at different locations and to deliver varying amounts of flow through these probes such that target temperatures are consistently achieved constitutes a distinct advantage over single-probe ablation devices such as radiofrequency ablation (Weber and Lee, 2005). **Currently, cryoablation of renal tumors should be performed under real-time imaging with the treatment area approximately 1 cm beyond the margin of the tumor.**
4. *Duration of Treatment.* Little data exists regarding the optimal duration of freezing during cryoablation. Auge and colleagues (2006) performed a prospective study in nine female farm pigs in which cryoablation was performed for either 5, 10, or 15 minutes. When the specimens were examined histologically, the pigs treated for 5 minutes demonstrated inadequate tissue necrosis and experienced more postprocedural bleeding. Pigs that were treated for 15 minutes exhibited uniform and consistent necrosis but with a high rate of tissue fracture. The pigs treated in the 10-minute cohort demonstrated adequate cell kill and minimal complications. Although the optimal duration of freezing is not known, **in our clinical experience, most tumors can be adequately treated with an initial freeze cycle of 8 to 10 minutes and a second freeze cycle of approximately 6 to 8 minutes.**
5. *Active versus Passive Thaw.* Modern argon-based cryoablation units employ helium gas to actively thaw tissue following iceball formation. Alternatively, the flow of argon gas may be discontinued and the tissue allowed to passively thaw without the use of helium. Although active thawing is clearly more efficient and translates into shorter overall operative times, scant data is available regarding the superiority of tissue destruction with active versus passive thawing (Desai and Gill, 2002). Experimental data from Woolley and colleagues (2002) suggests no difference in the degree or reproducibility of tissue destruction with active or passive thaw processes. Conversely, Klossner and colleagues (2007) examined variables that impacted cryosurgical outcomes using human prostate PC-3 and LNCaP cultures and found passive thawing yielded greater tissue destruction owing to

Key Points: Cryoablation

- Cryoablation employs argon gas–based systems to achieve treatment temperatures of less than –40° C.
- Cryoablation of renal tumors should be performed under real-time imaging with the treatment area approximately 1 cm beyond the margin of the tumor.
- A double freeze-thaw cycle is currently the standard of care during renal tumor cryoablation.

increased solute effects and increased recrystallization at temperatures between –20° C and –30° C. Unfortunately, no prospective clinical data exists that specifically addresses the issue. **We prefer to use a passive thaw following our initial freeze cycle such that temperatures of less than –40° C are maintained for a longer period of time. We employ an active thaw following the second freeze cycle such that potential bleeding can be more rapidly addressed following probe removal.**

RADIOFREQUENCY ABLATION

Mode of Action and Experimental Data

Cushing and Bovie (1928) introduced the Bovie knife, an instrument that employed pulsed or continuous monopolar radiofrequency current to cauterize or cut tissue, respectively. Although this forerunner to modern electrocautery revolutionized and defined contemporary surgical techniques, it also provided the foundation for present-day radiofrequency ablation (RFA).

Radiofrequency energy effects cell kill by transferring alternating radiofrequency current (450 to 1200 kHz) through insulated interstitial needle electrodes (Raj et al, 2003). This energy transfer generates ionic friction and agitation within tissue that results in heating (Organ, 1976-1977; LeVeen, 1997; Rehman et al, 2004). When tissue is heated in excess of 60° C, irreversible coagulative necrosis and tissue desiccation occurs (Hsu et al, 2000). Much like cryoablation, the adequacy and reproducibility of tissue destruction during RFA is dependent upon several parameters:

1. *Amount of RF Energy/Treatment Temperature:* The volume of tissue necrosis is directly correlated to the total amount of RF energy deposited into the tissue less local and systemic heat loss (Zevas and Kuwayama, 1972; McGahan and Dodd, 2001). As stated, alternating RF current creates cellular agitation and, as a result of electrical impedance of the tissue, local heating. Provided that electrical impedance remains low, an expanding sphere of tissue damage emanates outward from the treatment probe. If current is administered too rapidly or the amount of RF energy applied is too high, charring occurs, which reduces the water content of the tissue, abruptly increases impedance, decreases energy transfer, and halts the heating process (Djavan et al, 2000; Finelli et al, 2003). The lesion volume is then either smaller than desired or lacks uniformity. In general, treatment temperatures well above 105° C are avoided for this reason (Goldberg et al, 2000). **In clinical practice, a mean treatment temperature of 105° C is preferred** (Carraway et al, 2009).
2. *Duration of RF Treatment:* In general, irreversible protein denaturation and cell kill occurs if a temperature of 46° C is maintained for 1 hour, or 50° C is maintained for between 4 to 6 minutes (Goldberg and Dupuy, 2001). Tissue destruction is nearly instantaneous when treatment temperatures exceed 60° C. As most modern RFA treatment systems consistently achieve temperatures at or above 100° C, the duration of treatment would not appear to be a defining parameter. With modern temperature-based and impedance-based generators, the duration of ablation is largely determined by the treatment system and the size of the lesion. **Although no clinical data explicitly addresses the optimal duration of RF treatment, tumors less than 2 cm are typically treated with two cycles of 5 minutes; tumors 2 to 3 cm are treated with two cycles of 7 minutes; and tumors greater than 3 cm are treated with two cycles of 8 minutes** (Park et al, 2006a).
3. *Wet versus Dry RF:* Radiofrequency energy can be applied using needles placed directly into tissue (dry RFA), or with ionic solutions perfused into tissues to decrease carbonization and act as an energy conductor (wet RFA). Early dry RFA systems were highly successfully in treating small lesions but encountered tissue impedance and an attendant lack of efficacy in treating lesions greater than 4 cm. In the late 1990s, Lorentzen and colleagues (1997) and Goldberg and colleagues (1996) independently introduced the concept of driving chilled saline through the shaft of the treatment needle (wet RFA). By cooling the tip of the probe, they discovered that tissue charring immediately adjacent to the electrode was minimized; impedance and ionic agitation was preserved as a consequence, and a larger overall treatment lesion was ultimately created. The success of wet RFA in producing a reliably larger area of necrosis was confirmed in subsequent studies (Collyer et al, 2001; Leveillee and Hoey, 2003; Pereira et al, 2004). Internally cooled ablation probes and the use of hypertonic saline have both been proposed as an alternative to cooled saline and have demonstrated mixed success (Miao et al, 1997; Muvner et al, 2002).
4. *Single-Tine versus Multitine Electrode:* The original RF needle electrodes were dry RF devices, with varying amounts of insulation at the distal tip governing the approximate size of the treatment lesion. That is, the size of the lesion and the approximate depth of treatment could be modified by exposing varying amounts of tissue to the uninsulated needle. However, the initial ablation probes were capable of treating tumors no greater than 2 cm (McGahan et al, 1993). Larger tumors or the acquisition of an adequate tumor margin required additional treatment probes or re-treatment of overlapping regions. In an attempt to achieve a larger overall treatment volume, LeVeen (1997) introduced an insulated monopolar probe with multiple uninsulated prongs that function as RF antennae for the wider dispersion of current. These prongs are deployed in an even fashion to create a spherical lesion. When high impedance is encountered at one prong, current is redirected to areas of lower impedance. **Clinical validation studies have demonstrated more complete necrosis and superior treatment outcomes with multitine electrodes** (Rossi et al, 1998; Curley et al, 2000; Rehman et al, 2004).
5. *Monopolar versus Bipolar RF:* RF energy can be delivered through bipolar or monopolar electrodes. Monopolar RF devices achieve this effect by dispersing current from the device through the patient to a grounding pad on the skin of the patient. Conversely, bipolar RF devices generate current between two electrodes (one active and one negative) in the target tissue. The purported advantage of bipolar energy is that significantly higher temperatures are induced compared with those of monopolar devices (Nakada et al, 2003). It is unclear whether this theoretical advantage translates into improved operative outcomes.
6. *Heat-Based versus Impedance-Based Generators:* RF energy can be delivered using impedance or temperature-based feedback. As is implied by the name, impedance-based systems (Cool-tip, Valleylab, Boulder, CO; RF 3000, Boston Scientific, Natick, MA) constantly monitor the level of impedance at the tip(s) of the electrode(s) and terminate treatment when

"infinite impedance" is encountered. This implies complete desiccation and charring such that electrical current is unable to pass through tissue. Conversely, temperature-based systems (RITA Model 1500X, AngioDynamics, Queensbury, NY) determine completion of treatment when the tissues adjacent to the probe have reached a target temperature for a predetermined duration of time. Experimental data is contradictory. Rehman and colleagues (2004) noted areas of incomplete necrosis with impedance-based systems and complete necrosis with temperature-based systems. However, a dedicated animal study by Gettman and colleagues (2002a) demonstrated similar efficacy in ablating renal tissue with the two types of generators. **There is no explicit clinical data that supports the superiority of impedance or temperature-based systems.**

7. *"Heat-Sink" Phenomenon:* Treatment efficacy is dependent on the total amount of RF energy applied to the tissue, multiplied by local tissue interactions, less systemic and local heat loss (the "bioheat transfer equation") (Pennes, 1948; Goldberg et al, 2000). When the target zone is highly vascularized or is adjacent to large vessels, thermal energy is preferentially dispersed to the comparatively cooler blood within these vessels. This heat-sink effect may therefore spare tumor cells in close proximity to large blood vessels and lead to treatment failures. In response to this shortcoming, investigators within and outside urology have evaluated and employed methods to temporarily interrupt blood flow to the target organ (Corwin et al, 2001; Chang et al, 2004). The collective experience with hepatovascular occlusion (by transcatheter arterial embolization/balloon occlusion or the Pringle maneuver) during RFA has been favorable with significantly larger treatment areas and improved overall outcomes (Curley et al, 1999; Rossi et al, 2000). Success with renovascular occlusion has not yet been demonstrated. No significant difference in lesion size was noted between the clamped and unclamped cohorts in two separate studies (Corwin et al, 2001; Marcovich et al, 2002). Given the risk of postischemic injury and the technical complexity of hilar dissection and cross-clamping, renal vascular occlusion is not routinely performed during RFA.
8. *Treatment under Image Guidance:* Perhaps the most significant limitation of RFA, to date, has been the inability to reliably monitor treatment under image guidance. With cryoablation, the evolving iceball can be monitored in real time and its hyperechoic edge used as direct clinical evidence of treatment adequacy. Owing to the low intrinsic contrast between untreated and ablated tissue, as well as the formation of gas bubbles during heating, monitoring the RF ablation zone with ultrasonography, CT, and/or MRI has proven difficult (Rendon et al, 2001; Renshaw, 2004). Certainly, accurate probe positioning can be achieved with intraoperative ultrasonography (laparoscopic RFA) or under ultrasonography, CT, or MRI guidance (percutaneous RFA). However, once the probe is appropriately positioned, the desired treatment zone becomes entirely dependent on the deployed diameter and configuration of the electrode. And although impedance and temperature-based feedback ensures tissue destruction at the tip(s) of the electrode(s), the global geometric treatment area cannot be directly appreciated as readily as with cryoablation. In order to compensate for these "indirect" cues and to ensure a negative treatment margin, an ablation zone 5 to 10 mm beyond the maximum radiographic tumor diameter is preferred (Carraway et al, 2009).

Key Points: Radiofrequency Ablation

- Transfer of RF energy generates ionic friction and agitation within tissue that results in heating. When temperatures exceed 60° C, irreversible coagulative necrosis and tissue desiccation occurs.
- Myriad probe configurations and treatment systems are available.
- Treatment cannot be monitored under image-guidance owing to the low intrinsic contrast between untreated and ablated tissue, as well as the formation of gas bubbles during heating.

SURGICAL TECHNIQUE

Transperitoneal/Retroperitoneal Laparoscopic Renal Cryoablation/ Radiofrequency Ablation

See Chapter 55 for these modalities.

Percutaneous Renal Cryoablation/ Radiofrequency Ablation under Ultrasonography, CT, or MRI

Percutaneous tumor ablation can be performed under conscious sedation with local anesthesia or under general endotracheal anesthesia. Controversy exists regarding the optimal method of sedation. General endotracheal anesthesia allows controlled respiration during probe placement that may translate into more accurate targeting and improved overall outcomes. Conversely, conscious sedation minimizes the morbidity of the procedure and allows the procedure to be performed on an outpatient basis. Following induction, a 16-Fr urinary catheter is placed and intravenous antibiotics are administered. The patient is positioned on the CT or MRI gantry in the prone or flank position.

Intravenous contrast (iodinated or gadolinium contrast, depending on the imaging technique chosen and the patient's renal function) is administered and the lesion identified and characterized. A 20-gauge "finder needle" or access sheath is placed near the expected location of the tumor, and imaging is repeated to confirm localization. It is important to note the depth of the finder needle for subsequent biopsy and probe placement. Using this finder needle as a guide, an 18-gauge Tru-Cut (Cardinal Health, Dublin, OH) core biopsy needle is inserted percutaneously, and positioning is again confirmed with repeat imaging. Specimens are obtained and sent for permanent section. The cryoprobe(s) or RFA probe is/are next inserted in a manner similar to that of the core biopsy needle. Cryoprobe positioning and positioning of the RFA probe, and prongs are again confirmed with repeat imaging. Treatment is carried out in a fashion similar to that described for laparoscopic cryoablation/radiofrequency ablation (Fig. 56-2). Again, a "track burn" can be performed with percutaneous RFA. With percutaneous cryoablation, the cryoprobe is removed and repeat imaging performed to evaluate for potential bleeding. With either technique, a postablation contrasted imaging study is performed to determine the adequacy of treatment.

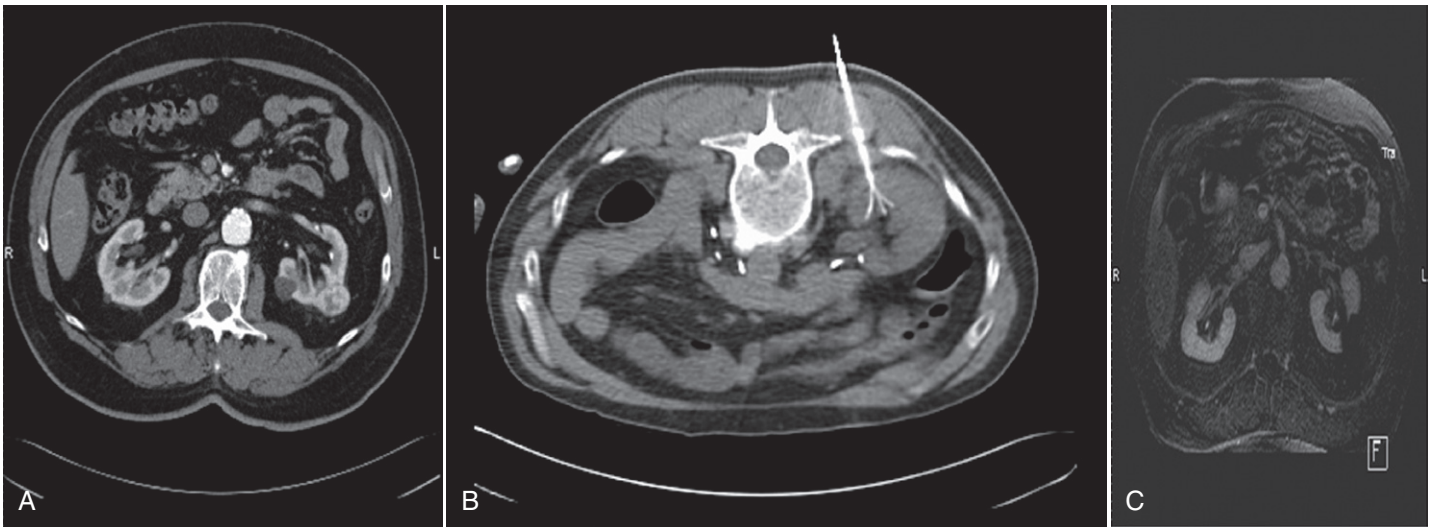

Figure 56–2. **A,** Preoperative CT scan noting a 2.4-cm solid enhancing mass in the left kidney. **B,** Intraoperative CT scan with the patient in prone position and a multitine radiofrequency ablation needle deployed into the renal mass. **C,** Postoperative CT scan at 6 months follow-up showing complete ablation of the left renal mass as demonstrated by the lack of enhancement at the site of the preexisting renal tumor.

Patients who underwent percutaneous ablation under conscious sedation are discharged in a same-day fashion. If the patient required general endotracheal anesthesia or in those patients with significant comorbidities, overnight admission is standard. Again, a CT of the abdomen without contrast is obtained prior to discharge.

Interpretation of Success and Follow-up after Tumor Ablation

Interpretation of treatment success following renal tumor ablation remains a controversial subject. Much of this confusion stems from a lack of uniformity with regard to follow-up protocols (frequency of follow-up and the type of imaging study chosen), as well as a lack of consensus regarding radiographic parameters of success and the role of renal biopsy. **The aggregate duration of follow-up with either cryoablation or RFA is inadequate to determine if radiographic follow-up alone is a sufficient surrogate of treatment efficacy** (Boorjian and Uzzo, 2009). Routine postablative biopsy may serve a role in corroborating radiographic findings. **However, the interpretation of biopsy findings following ablation is highly contentious, and the overall utility of biopsy in this setting is unresolved.** Selective biopsy is appropriate and indicated in cases of suspected recurrence. Given these ambiguities, urologists who employ ablative technologies should be familiar with existing and ongoing evidence-based literature and must place these findings in the context of clinical judgment and the overall well being of the patient.

Radiographic Interpretation of Success. As no pathologic margins are rendered with in-situ ablation, imaging characteristics serve as a surrogate marker of treatment efficacy. In general, the **complete loss of contrast enhancement on follow-up CT or MRI is considered evidence of complete tissue destruction and attendant treatment success** (Matsumoto et al, 2004; McAchran et al, 2005). **If a lesion demonstrates persistent contrast enhancement following treatment or requires more than one ablation session to achieve loss of contrast enhancement, this is considered incomplete ablation** (Matin et al, 2006). **Conversely, if a lesion demonstrates an initial complete loss of contrast enhancement and later demonstrates enlargement of the lesion and/or contrast enhancement, this is considered local tumor recurrence or progression** (Novick et al, 2009).

In addition to contrast-related characteristics, lesions that undergo cryoablation or RFA demonstrate characteristic but strikingly different appearances on follow-up imaging. **The majority of lesions treated with cryoablation demonstrate a greater than 50% reduction in size in the first year following treatment** (Deane and Clayman, 2006; Kawamoto et al, 2009). This contraction is due to cellular breakdown and phagocytosis. Conversely, **lesions treated with RFA often do not demonstrate postablative contraction, and failure to do so should not be interpreted as a treatment failure. Enlargement of a lesion, regardless of the treatment modality or the enhancement characteristics, should be construed as an ominous sign of local tumor recurrence** with biopsy and/or treatment (observation vs. repeat ablation vs. extirpative surgery) dictated by the size and location of the lesion, the response to the original treatment, and the patient's overall and renal functional status.

Recommended Radiographic Follow-up Protocol. The optimal radiographic follow-up regimen is not yet defined. The plurality of high-volume centers have determined that **CT with intravenous contrast or MRI with gadolinium contrast should be performed at 3 months, 6 months, 9 months, 12 months, 18 months, and 24 months following treatment** (Deane, 2006; Matin et al, 2006; Carraway et al, 2009; Crouzet et al, 2009). **Imaging should be repeated annually thereafter.** There is no available data that cites the superiority of MRI or CT in routine follow-up although some experts contend that CT better distinguishes tumor margins and enhancement in the evaluation of renal tumors (Cadeddu, 2008). Ultrasonography is not routinely employed to evaluate lesions following ablation.

Role of Pre- and Postablation Biopsy. One of the chief criticisms of in-situ renal ablation has been the inability to render definitive pathologic evidence of treatment success. Efficacy with ablative technologies is therefore predicated solely on indirect radiographic cues as previously discussed. In an attempt to address this issue

and substantiate the role of postablation radiographic evaluation, biopsy of the lesion before and after treatment has been advocated (Kunkle and Uzzo, 2008).

Historically, biopsy of suspected renal cell carcinoma (RCC) has rarely been performed prior to treatment owing to perceived diagnostic inaccuracies in specimen interpretation, as well as the high overall diagnostic accuracy of cross-sectional imaging (Wang and Wood, 2009). Unfortunately, this reticence to perform biopsy prior to extirpative surgery has likewise carried over to cryoablation and RFA. A recent meta-analysis performed by Kunkle and Uzzo (2008) demonstrated that preablation biopsy was performed in 83.2% of cryoablation cases and 62.2% of RFA cases ($P < .0001$). Among those that underwent biopsy and subsequent ablation, 53.9% demonstrated pathologic evidence of RCC. The remaining 46.1% of lesions were either benign (12.7%) or indeterminate (33.5%). In light of these ambiguities, accurately interpreting cancer specific outcomes following cryoablation and RFA is extremely challenging. **To establish a diagnosis and provide uniformity and improved outcomes-based data, the American Urological Association Small Renal Mass (AUA SRM) Guidelines Panel recently recommended that tumor biopsy be universally performed at the time of ablation** (Novick et al, 2009).

Much of the controversy surrounding the oncologic efficacy of ablative technologies has centered on the inherent reliability of postoperative cross-sectional imaging to accurately predict disease-free status. It was originally thought that the high overall diagnostic accuracy of CT or MRI in predicting malignancy preoperatively would translate into equally accurate predictions of postablation tumor destruction or tumor recurrence. However, recent studies have questioned this bias and invoked uncertainty regarding the utility and adequacy of radiographic imaging as the sole surrogate of treatment success, especially following RFA.

In 2002, Rendon and colleagues (2002) performed laparoscopic or percutaneous RFA prior to partial or radical nephrectomy in 10 patients (11 tumors), with a mean tumor size of 2.4 cm. Hematoxylin and eosin (H&E) staining demonstrated residual viable tumor in 7 of the 11 tumors that underwent treatment. Four years later, Park and colleagues (2006b) reported on three patients who underwent delayed nephrectomy at a mean follow-up of 18 months following RFA. Intervention was performed due to new enhancement at the periphery of the treated lesion in two cases and treatment-related ureteropelvic junction obstruction in the remaining patient. No evidence of residual tumor was noted in any of the specimens.

Weight and colleagues (2008) attempted to correlate the radiographic appearance of ablated renal masses with pathological outcomes. The group examined a total of 109 renal lesions in 88 patients who underwent percutaneous RFA and 192 lesions in 176 patients who underwent laparoscopic cryoablation. At 6 months following treatment, radiographic success (no evidence of contrast enhancement) was noted in 90% of patients who underwent cryoablation and in 85% of patients who underwent RFA. Biopsy at 6 months was then performed in 134 lesions (45%). Pathologic evidence of success was 93.8% with cryoablation and only 64.8% with RFA. Of note, 6 of the 13 patients who underwent RFA and demonstrated viable residual tumor on follow-up biopsy demonstrated no contrast enhancement on follow-up imaging. Conversely, all cryoablation patients who had residual tumor on follow-up biopsy demonstrated definitive contrast enhancement. The authors concluded that radiographic imaging results following cryoablation correlated well with pathologic results, whereas a poor correlation was noted between radiographic imaging and pathologic results following RFA. Routine biopsy following RFA was advocated by the authors.

Although the Weight and colleagues study (2008) was criticized for potential selection bias, it nevertheless highlights the long-standing dilemma of post-RFA biopsy interpretation. **Standard H&E staining may be misleading immediately following RFA, because cellular architecture is largely preserved despite cell death** (Margulis et al, 2004). The duration of this "architectural preservation" is unknown. Stern attempted to address this issue by performing tumor biopsy of 20 radiographically negative lesions at least 1 year following RFA (Stern et al, 2008). No evidence of disease was noted. The authors concluded that RFA imparts definitive cellular necrosis, and radiographic imaging results correlate well with histopathology. **Given such conflicting information, the ultimate utility of H&E staining following RFA remains unknown.**

Cell viability stains, primarily reduced nicotinamide adenine dinucleotide (NADH) diaphorase, have been proposed as an alternative and more accurate method of determining cell death following tumor ablation. Much like the aforementioned H&E studies, results with NADH staining have been conflicting. Marcovich and coworkers (2003) performed a porcine study in which renal tumors were ablated and later resected and examined histologically. Tumor architecture was variably preserved on H&E staining (as previously discussed) but no NADH diaphorase staining was noted (implying complete cell death). Conversely, Matlaga and colleagues (2002) performed biopsy following RFA in 10 patients and noted an absence of NADH activity in 8 patients. The remaining two patients stained positive for NADH but technical (maximum treatment temperature of 41° C) and tumor-related (8-cm lesion) confounders may account for these failures. Michaels and colleagues (2002) likewise performed RFA in 15 patients and noted positive NADH staining in 4 of 5 tumors that underwent completion nephrectomy. **The inherent value and accuracy of NADH staining following RFA remains controversial.**

Key Points: Follow-up After Tumor Ablation

- Interpretation of treatment success following renal tumor ablation remains a controversial and divisive subject.
- Complete loss of contrast enhancement on follow-up CT or MRI is considered evidence of complete tissue destruction and attendant treatment success.
- The majority of lesions treated with cryoablation demonstrate a greater than 50% reduction in size in the first year following treatment. Lesions treated with RFA often do not demonstrate postablative contraction and failure to do so should not be interpreted as a treatment failure.
- Enlargement of a lesion, regardless of the treatment modality or the enhancement characteristics, should be construed as an ominous sign of local tumor recurrence.
- The American Urological Association Small Renal Mass Guidelines Panel recently recommended that tumor biopsy be universally performed at the time of ablation.
- The accuracy and utility of H&E and NADH staining following RFA is controversial.

ONCOLOGIC OUTCOMES

The interpretation of oncologic outcomes following renal tumor ablation is challenging. In general, ablative technologies have been thought to offer inferior cancer control compared to better-established extirpative alternatives. A recent meta-analysis demonstrating a higher relative risk of recurrence with cryoablation and RFA would seem to support this (Kunkle et al, 2008). However, the majority of published studies on cryoablation and RFA have enrolled small numbers of patients and employed disparate operative and follow-up protocols. As was explained, pathology is either not obtained or is difficult to interpret, and the reliability of radiographic imaging remains unknown. A veritable litany of commercially available and ever-evolving treatment systems and probes have further compounded the issue. Perhaps most importantly, collective follow-up is too short to derive meaningful conclusions. Much like radiation treatment for prostate cancer, a **discussion of oncologic efficacy regarding ablative technologies must focus less on defined and immediately gratifying end points, such as margin status, and more on long-term markers of success, such as metastasis-free survival, cancer-specific survival, and quality-of-life outcomes.** In an attempt to minimize inherent flaws with single institutional series, we have elected to present oncologic outcomes in a more evidence-based and systematic fashion. Individual salient studies of cryoablation and RFA are found in Tables 56–1 and 56–2.

Local Recurrence-Free Survival (LRFS)

Recent meta-analyses have evaluated the risk of local tumor recurrence following cryoablation and RFA (Kunkle et al, 2008; Novick et al, 2009). Local recurrence was defined as "any disease presence in the treated kidney or associated renal fossa posttreatment" and for ablation studies was defined as "any localized disease remaining in the treated kidney at any point after the first ablation." The AUA SRM Guidelines Panel examined 10 studies of cryoablation and 10 studies of RFA and determined a local recurrence-free survival of 90.6% (83.8% to 94.7%) for cryoablation and 87.0% (83.2% to 90%) for RFA. **When compared to alternative extirpative treatments, both cryoablation and RFA demonstrated significantly higher rates of local recurrence despite a shorter overall duration of follow-up.** There was no significant difference in local recurrence-free survival between cryoablation and RFA.

Kunkle and colleagues (2008) performed a landmark meta-analysis in which treatment outcomes with partial nephrectomy, cryoablation, RFA, and active surveillance were evaluated. A total of 99 studies and 6,471 tumors were included in the analysis. The relative risk of local recurrence was significantly higher with cryoablation (RR = 7.45) and RFA (RR = 18.23), respectively, when compared to partial nephrectomy. This same group performed a follow-up subanalysis including 1,375 renal tumors (47 total published series from 45 institutions) that underwent cryoablation ($n = 600$) or RFA ($n = 775$) alone (Kunkle and Uzzo, 2008). The rate of local tumor progression was 5.2% following cryoablation and 12.9% following RFA. The risk of local recurrence was significantly higher in the RFA cohort on univariate ($P = .001$) and multivariate ($P = .003$) analysis.

Metastatic Recurrence-Free Survival (MRFS)

The AUA SRM Guidelines Panel additionally examined the risk of metastatic recurrence, which was defined as "any disease presence in the body other than in the treated kidney or associated renal

fossa post-treatment." Mean metastatic recurrence-free survival was 95.3% (91.1% to 97.5%) for cryoablation and 97.5% (94.8% to 98.8%) for RFA (Novick et al, 2009). Interestingly, **there was no significant difference in metastatic recurrence-free survival between the ablative technologies and alternative extirpative treatments** including open partial nephrectomy and laparoscopic radical nephrectomy. There was a significant difference in MRFS in favor of laparoscopic partial nephrectomy. The authors did note that duration of follow-up was inadequate to draw conclusions and selection bias may have confounded the analysis.

In Kunkle's initial meta-analysis, the relative risk of metastatic disease was not significantly different between cryoablation, RFA, active surveillance, and partial nephrectomy (Kunkle et al, 2008). Subsequent analysis of ablation patients alone demonstrated progression to metastatic disease in 1% of patients who underwent cryoablation and 2.5% of patients who underwent RFA ($P = .06$) (Kunkle and Uzzo, 2008).

Cancer-Specific Survival (CSS)

The AUA meta-analysis additionally examined the risk of dying from RCC following cryoablation (six studies were included) or RFA (eight studies were included). **CSS was 95.2% (89.2% to 97.9%) with cryoablation and 98.1% (95.2% to 99.2%) with RFA.** CSS was significantly higher with laparoscopic partial nephrectomy than for cryoablation but there was no significant difference in CSS between LPN and RFA. There was no significant difference in CSS between cryoablation and RFA. Again, selection bias and short duration of follow-up may confound these results.

Overall Survival

Mean overall survival rate following cryoablation was 95.8% (87.2% to 98.7%) and 93.7% (85.4% to 97.4%) for RFA. **There was no significant difference in overall survival between cryoablation and RFA.** Again, limited follow-up and selection bias may confound these results.

Cryoablation versus RFA

Any debate regarding the superiority of cryoablation versus RFA is subject to the same faults, confounders, and ambiguities as the aforementioned comparisons between in-situ tumor ablation and extirpation. Beyond issues of ill-defined radiologic and pathologic end points, there is considerable variability in patient selection, tumor size and location, technique, and approach (laparoscopic vs. percutaneous), as well as inherent bias for a particular ablative modality. To our knowledge, there is no data that directly compares percutaneous and laparoscopic cryoablation to its respective RFA counterparts.

Hegarty and colleagues performed the only published comparative study of cryoablation and RFA in 2006. This retrospective cohort study was performed to determine complications, impact on renal function, follow-up imaging, and oncologic outcomes comparing 164 laparoscopic cryoablation procedures and 82 percutaneous RFA procedures. There was no significant difference in tumor size between the two groups, but the RFA cohort demonstrated more central tumors and tumors in solitary renal units. Radiographic evidence of disease persistence or recurrence was noted in 1.8% of patients who underwent cryoablation and in 11.1% of patients who underwent RFA. There was no significant impact on renal function with either modality. At a median follow-up of 3 years, the CSS for cryoablation was 98%; at a median follow-up of 1 year, the CSS for RFA was 100%. Although the study was successful in articulating the need for improved comparative analysis, its results are difficult to fully embrace given the incongruent patient cohorts and treatment approaches.

Ultimately, the results of the three recent meta-analyses discussed previously offer the most insight into the comparative

oncologic merit and potential limitations of cryoablation and RFA (Kunkle et al, 2008; Kunkle and Uzzo, 2008; Novick et al, 2009). **Although some data is conflicting, it appears that there is no significant difference in the risk of local tumor recurrence, disease progression/metastasis, cancer-specific survival, and overall survival between the two modalities.**

Laparoscopic versus Percutaneous Renal Tumor Ablation

One proposed explanation for the higher local recurrence rate with RFA in some series centers on the adequacy of tumor ablation by the percutaneous approach. Indeed, the vast majority of cryoablation procedures are approached laparoscopically, while nearly 90% of RFA procedures are performed percutaneously (Deane, 2006; Carraway et al, 2009). Crouzet and colleagues (2009) retrospectively compared 244 laparoscopic renal cryoablation procedures with 63 percutaneous renal cryoablation procedures. Patient and tumor characteristics were similar with both cohorts. There was a trend toward prior renal surgery or a solitary renal unit with percutaneous cryoablation. There was no significant difference in renal functional outcomes between the two groups. Duration of hospitalization was shorter in the percutaneous cohort. With a minimum follow-up of 2 years, the percutaneous cohort demonstrated a higher incomplete treatment rate and the need for re-treatment. There was no difference in overall survival, CSS, and recurrence-free survival between the two groups. Similar studies comparing laparoscopic and percutaneous tumor ablation have confirmed these findings (Derweesh et al, 2008; Hinshaw et al, 2008; Hui et al, 2008; Malcolm et al, 2009).

In contradistinction to these studies, Finley and colleagues (2008) reported their 4-year experience with laparoscopic and percutaneous renal cryoablation in 37 patients with 43 tumors. Operative time and duration of hospitalization were significantly shorter with the percutaneous approach, and there was no significant difference in the number of incomplete ablations.

Key Points: Oncologic Outcomes

- The interpretation of oncologic outcomes following renal tumor ablation is challenging.
- When compared to alternative extirpative treatments, both cryoablation and RFA demonstrate significantly higher rates of local recurrence, despite a shorter overall duration of follow-up.
- There is no apparent significant difference in metastatic recurrence-free survival between the ablative technologies and alternative extirpative treatments.
- Any discussion of oncologic efficacy regarding ablative technologies must focus less on defined and immediately gratifying end points, such as margin status, and more on long-term markers of success, such as metastasis-free survival, cancer-specific survival, and quality-of-life outcomes.
- Although some studies demonstrate inferior local recurrence rates with RFA when compared with cryoablation, these results are controversial and subject to considerable debate. There is no apparent difference in cancer-specific or overall survival between the two modalities.

Researchers have investigated exclusive use of general anesthesia and advanced navigational systems as mechanisms to improve outcomes with percutaneous ablation (Gupta et al, 2009; Haber et al, 2009).

COMPLICATIONS

Complications with in-situ tumor ablation are relatively low. A recent meta-analysis compared urologic and nonurologic complications following cryoablation, radiofrequency ablation, and alternative extirpative approaches (Novick et al, 2009). Major urologic complications were defined as postoperative hemorrhage requiring transfusion or intervention, urinary leak, abscess, and unanticipated loss of renal function. **The incidence of major urologic complications with renal cryoablation was 4.9% (range 3.3% to 7.4%). Postoperative hemorrhage is the most commonly cited major adverse risk,** with ureteral obstruction, splenic hematoma, and perirenal abscess additionally reported. **The risk of major urologic complications with RFA is 6.0% (4.3% to 8.2%).** Reported major complications with RFA include ureteral obstruction, pyelocalyceal injury, bowel injury, pancreatic injury, and/or gross hematuria requiring intervention. Of note, **the risk of major urologic complications was lower with ablative techniques than with either laparoscopic or open partial nephrectomy, and there was no significant difference in urologic complications with cryoablation versus RFA.**

Major nonurologic complications occurred in 4.9% (3.4% to 7.2%) of cryoablation patients and in 4.4% (3.2% to 6.2%) of RFA patients. Of note, nonurologic complications were significantly more common with cryoablation than with RFA or open partial nephrectomy. This higher complication rate with cryoablation may reflect the older patient population in the cryoablation cohort. **Commonly cited minor complications with cryoablation and RFA include pain and paresthesia at the probe insertion site, urinary tract infections, and self-limited hematuria.**

Conversion was defined in the meta-analysis as a deviation from the intended surgical procedure or approach. The overall conversion rate for cryoablation was 3.5% with bleeding, adhesions, and respiratory difficulty cited as common reasons for conversion. The conversion rate for RFA was 1.6% with proximity to bowel as the only cited reason. Of note, only one RFA study was included in the analysis. Deriving meaningful conclusions regarding the superiority of RFA versus cryoablation with regard to conversions is therefore difficult.

The cited rate of transfusion with cryoablation is 3.2% (2.0% and 20%) and is 2.4% (1.4% to 40%) with RFA. Indeed, the most commonly encountered complication with cryoablation is bleeding, especially in the setting of tumor or renal fracture (up to 17% of patients with renal fracture require transfusion). Lehman and colleagues (2008) additionally noted that tumors greater than 3.0 cm in size were significantly more likely to require a blood transfusion (38%). Bleeding following RFA is relatively uncommon given the ability to perform a hemostatic "track burn" on probe withdrawal.

Reintervention was defined in the meta-analysis as any unplanned operation occurring during or after the planned renal surgery. Reintervention occurred in 2.6% (1.5% to 4.3%) of cryoablation patients and 3.2% (1.9% to 5.1%) of RFA patients. **The risk of reintervention was significantly higher in patients undergoing laparoscopic partial nephrectomy than with either ablative technique.**

Key Points: Complications Following Tumor Ablation

- The incidence of major urologic complications with renal cryoablation is estimated at 4.9%. Postoperative hemorrhage is the most commonly cited major adverse risk.
- The risk of major urologic complications with RFA is 6.0%. Bleeding is not a significant risk factor following RFA.
- The risk of major urologic complications is lower with ablative techniques than with either laparoscopic or open partial nephrectomy. There is no significant difference in urologic complications between cryoablation and RFA.
- Commonly cited minor complications with cryoablation and RFA include pain and paresthesia at the probe insertion site, urinary tract infections, and self-limited hematuria.

FUTURE TRENDS

Extracorporeal High-Intensity Focused Ultrasonography (HIFU)

As an acoustic wave is propagated through tissue, a portion of its energy is absorbed and converted into heat (Madersbacher et al, 1995; Vricella et al, 2009). When ultrasound beams are tightly concentrated, temperature levels approach or exceed the threshold for cell kill (65° C to 85° C) within this focused field, while adjacent tissue is spared. At high enough intensities (>3500 W/cm^3), cavitation and microbubble formation occurs that yields extremely high temperatures and a mechanically disrupting "shock wave" effect similar to that seen with extracorporeal shock wave lithotripsy (Kieran et al, 2007). Cavitary forces are extremely difficult to control during HIFU and are generally avoided.

HIFU employs a transducer that is used for treatment and monitoring. The ultrasound beams are focused geometrically through the transducer by employing an acoustic lens or a concave shape. Under real-time guidance, the HIFU beam is focused on the treatment zone and a defined area is ablated. The transducer can then be refocused to ablate a larger overall volume of tissue. Treatment times can be lengthy with a mean reported duration of nearly 5½ hours (1.5 to 9 hours) (Köhrmann et al, 2002; Marberger et al, 2005; Häcker et al, 2006). Myriad parameters, including focal length, type of transducer employed, and type of treatment system, have been investigated and are beyond the scope of this chapter.

Certainly, the promise of a noninvasive ablative technology that offers favorable and reproducible outcomes is extremely attractive. However, existing studies have yielded mixed results. Vallancien and colleagues (1993) performed a pilot study in which eight patients underwent targeted transcutaneous HIFU ablation followed by specimen excision. Approximately 10% of the cohort exhibited skin burns, and all specimens demonstrated pathologic evidence of viable tumor. Marberger and colleagues (2005) evaluated 18 renal units treated with HIFU followed by specimen extraction. Similar to the findings of Vallencien, incomplete ablation was noted in all cases. Häcker and colleagues (2006) additionally assessed the efficacy of HIFU by treating normal portions of 24 kidneys prior to preplanned completion radical nephrectomy. Coagulative necrosis was sporadic and inconsistent with the number of treatments applied. Again, skin burns were noted in two patients. Purported explanations for these collective incomplete treatments have included poor targeting secondary to respiratory movement and acoustic interference (acoustic shadowing, reverberation, and refraction), as well as system limitations including limited focal zone depth and an inability to monitor treatment progression in real time. Recently, laparoscopic HIFU has been investigated in an attempt to circumvent issues related to targeting, acoustic interference, and respiratory movement (Klingler et al, 2008). Results are anecdotal but favorable. **In summary, outcomes with renal HIFU have proven inferior to alternative ablative technologies, and its use in this regard should be considered investigational.**

Radiation Therapy

Historically, radiation therapy has been considered ineffective in the treatment of renal cell carcinoma. Although RCC is widely considered "radioresistant," it is unclear if this assertion is justifiable. It remains unclear if poor outcomes with radiation therapy for RCC are due to an inherent resistance to radiation or due to limitations with radiation delivery (Camphausen and Coia, 2008). Modern external beam radiation systems are inadequately designed to deliver high doses in a focal manner. With conventional treatment systems, high-dose radiation is associated with significant radiation scatter and attendant damage to adjacent tissues. Brachytherapy is better tailored for focal ablation, but its logistic application (seed placement in the kidney) for renal indications remains impractical.

Stereotactic radiosurgery (SRS) employs 3-dimensional coordinates to target and focally ablate tissue using high-dose external beam radiation. As opposed to conventional radiation delivery techniques, modern stereotactic treatment systems compensate for respiratory movement and radiation scatter by automatically tracking, detecting, and correcting for tumor and/or organ movement without interrupting the treatment or repositioning the patient. This tracking system is image guided and dependent on a constant reference point (fiducial marker) that is continually recognized by the linear accelerator. High-dose radiation beams move in real time with the respiratory cycle and are therefore extremely accurate (Ponsky et al, 2007). Not only is radiation scatter minimized, but higher doses may be applied in a focal manner that effectively ablates masses in the kidney without compromising overall renal function. The most commonly used stereotactic radiosurgical system is termed CyberKnife (Accuray, Palo Alto, CA). The CyberKnife is a 6-MV frameless linear accelerator mounted on a computer-controlled robotic arm. An image-guidance system as described above is employed to continually monitor movement of the target organ and deliver high-dose radiation in a focused fashion.

Ponsky and colleagues (2003) evaluated stereotactic radiosurgery in the treatment of renal tissue. Eight pigs underwent bilateral renal irradiation using the CyberKnife treatment system. Treatment doses of between 24 to 40 Gy were administered. The pigs were sacrificed 4 to 8 weeks following ablation. The treatment zone demonstrated complete tissue ablation with no collateral damage to adjacent tissue. Building on this initial animal experiment, Ponsky subsequently performed a Phase I study on three human patients with a mean renal tumor size of 2.03 cm. A total of 16 Gy were administered in a fractionated fashion. Patients were followed for 8 weeks, after which a partial nephrectomy was performed (a so-called treat and cut study). No adverse events or radiation toxicities were noted. Examination for pathology demonstrated residual RCC in two patients and no evidence of

viable tumor in the remaining patient. However, low doses were used in this initial feasibility study, and dose escalation trials are ongoing.

Svedman and colleagues (2006) performed a retrospective study evaluating the efficacy and safety of stereotactic radiosurgery in the management of inoperable or metastatic primary renal cell carcinoma. Thirty patients with 82 lesions underwent treatment with varied dose/fractionation schedules. At a median follow-up of 52 months, complete response was noted in 21% of patients, with another 58% demonstrating a partial/stable response. Overall survival was 32 months.

Certainly, the responsiveness of RCC to stereotactic radiosurgery in the aforementioned trials argues against its radioresistant reputation. **Although its use should still be considered experimental, with improved treatment protocols and well-designed prospective trials, SRS may ultimately play a significant role in the treatment of RCC.**

Microwave Thermotherapy (MWT)

MWT delivers energy through flexible antennae that are inserted directly into the target lesion. Microwave energy creates an electromagnetic field that causes rapid ion oscillation and frictional heat. Although ostensibly similar in design and technique to RFA, MWT is capable of achieving treatment temperatures (>60° C) with greater rapidity. Moreover, MWT is not limited by tissue charring and desiccation and is able to achieve high treatment temperatures over a broader area. These advantages may translate into more efficient treatments and improved cell kill. Although theoretical, there is also some evidence that MWT is less susceptible to the heat-sink phenomenon and may therefore be applied in the treatment of highly vascular lesions (Liang and Wang, 2007).

MWT was initially designed for the percutaneous treatment of hepatocellular carcinoma and has enjoyed considerable success in this capacity. Its use in the management of renal tumors remains investigational, with sporadic feasibility studies supporting its use. MWT was initially employed during unclamped open partial nephrectomy to create an avascular plane prior to tumor resection. More recently, MWT has been investigated as a therapeutic in-situ renal ablative device. Clark and colleagues (2007) performed a Phase I study in which 10 patients underwent MWT of suspected RCC at the time of radical nephrectomy. When examined pathologically, ablation lesions as large as 5.7 cm × 4.7 cm × 3.8 cm were achieved with complete and uniform tissue necrosis. The authors advocated "treat and leave" studies to confirm their findings. In 2008, Liang and colleagues published their series of 12 patients who underwent percutaneous MWT under ultrasound guidance (a so-called treat and leave protocol). All patients demonstrated pathologically proven unilateral renal cell carcinomas that were less than 4 cm, not adjacent to the collecting system or bowel, and were accessible through a percutaneous approach. One or two antennae were employed (depending on tumor size) to ablate the renal lesion, and thermocouples were used to monitor treatment temperatures in real time. No significant adverse events were reported following treatment. All patients underwent follow-up imaging at 1 day, 1 month, 3 months, and 6 months following treatment. At a median follow-up of 11 months, no cancer recurrence was noted on imaging.

MWT offers considerable promise as yet another minimally invasive ablative technology. However, until prospective studies are available, its use should remain investigational.

Laser Interstitial Thermal Therapy (LITT)

LITT employs specialized laser fibers to delivery energy directly into tissue. These fibers emit laser light that is converted to heat. Treatment temperatures of greater than 55° C are achieved, and tissue necrosis results. Thus far, LITT has relied on neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers and diode lasers. Results have been difficult to interpret owing to the small number of treated patients and a lack of clinical follow-up (Dick et al, 2002; Gettman et al, 2002b; Williams et al, 2000). **The use of LITT remains investigational.**

Navigational Systems

In an attempt to better localize, control, and predict the area of treatment during percutaneous cryoablation, novel navigational and targeting systems have been developed. Haber and colleagues (2009) performed percutaneous renal cryoablation of 13 lesions in 10 patients using a stereotactic navigational system (CT-Nav; Keolis, La Tronche, France) designed to direct renal biopsy and probe placement. Patients underwent preoperative CT scan with a preplaced tracking sensor taped to the body of the patient. Using a stereoscopic infrared camera, the tracking sensor was located three-dimensionally and a tracking handle used to guide probe placement. The mean calculated error in targeting with use of the navigational device was 4.2 mm. The most significant variability occurred in the cephalad/caudad axis consistent with respiratory movement. Although purely experimental, these tracking and targeting systems may represent a significant advance in the percutaneous application of ablative technologies.

Single Port Surgery/NOTES

Developed as an extension of standard laparoscopy, laparoendoscopic single-site (LESS) surgery seeks to minimize patient discomfort, shorten convalescence, and improve cosmesis by placing all instruments through a 2 cm incision, sometimes concealed in the umbilicus (Kaouk et al, 2008).

In 2008, Goel and colleagues published their clinical experience with single-port access renal cryoablation (SPARC) in six patients with small renal masses (Goel and Kaouk, 2008b). Using either a transperitoneal or retroperitoneal approach, all procedures were successfully completed without intraoperative complications. A subsequent publication from the same group cited eight total single-port cryoablation procedures (White et al, 2009). Mean tumor size was 2.64 cm. Mean operative time was 171 minutes. Two patients required postoperative blood transfusions. No recurrences were noted on follow-up imaging. The authors stated that renal ablative procedures may represent an attractive and natural transition into single-port surgery as limited dissection and reconstruction are needed.

Natural orifice translumenal endoscopic surgery (NOTES) employs a natural orifice, such as the vagina, bladder, stomach, or colon, as the entry point to the peritoneal cavity. Ostensibly, NOTES should offer superior cosmesis and decreased pain compared to conventional laparoscopy. However, operating through a natural orifice is technically very challenging with only two NOTES extirpative urologic procedures successfully completed (Kaouk et al, 2009). Much like single-port surgery, NOTES is ideally suited for ablative procedures that require minimal dissection and

reconstruction. Crouzet and colleagues (2009) reported bilateral transgastric and transvesical renal cryoablation in two female farm pigs. All four procedures were successfully completed without the need for additional ports. There were no intraoperative complications.

Chemoablation and Combined Chemoablation with RFA

The percutaneous injection of 95% ethanol to ablate renal cysts was originally described by Bean in 1981. This conceptual approach was later applied in the treatment of hepatocellular carcinoma with moderate success. Clayman and colleagues later evaluated injectable 95% ethanol, 24% hypertonic saline gel, and 50% acetic acid gel alone or in combination with RFA in a porcine study (Rehman et al, 2004). The authors demonstrated inadequate tissue necrosis with any of the injectables alone but noted enhanced tissue necrosis with the use of chemoablative agents in conjunction with RFA. The combined use of hypertonic saline with RFA produced the largest overall lesions. A second study from Fotiadis and colleagues (2007), in the United Kingdom, evaluated combined RFA and ethanol injection in 27 patients (28 total tumors) with a mean tumor size of 2.87 cm. Absolute ethanol was injected into the tumor just prior to RFA treatment. At a mean follow-up of approximately 18 months, 27 of 28 tumors were completely ablated with one (21 tumors) or two (6 tumors) treatments. No local recurrence or metastases occurred. **Currently, injectable chemoablation agents are difficult to reproducibly control and provide inferior tissue necrosis. Combined RFA/injectable chemoablation remains investigational.**

Targeted Embolization and Ablation

Owing to the heat-sink phenomenon with RFA, highly vascular central lesions or lesions positioned adjacent to the renal hilum are often inadequately ablated. Studies estimate treatment failures as high as 40%. In an attempt to address conductive heat loss, investigators have performed selective arterial embolization prior to RFA (Yamakado et al, 2006; Gebauer et al, 2007; Mahnken et al, 2009). Theoretically, selective embolization should allow for more homogenous heating and improved tissue necrosis. **Clinical reports are sporadic and anecdotal. Therefore the use of targeted angioembolization prior to RFA remains investigational.**

CONCLUSIONS

The role of in-situ ablation in the management of small renal masses is rapidly evolving. Once considered experimental and appropriate only for patients with significant comorbidities, cryoablation and radiofrequency ablation are currently considered viable alternatives to extirpative management. In-situ ablation confers less treatment-related morbidity than either open or laparoscopic partial nephrectomy and offers superior renal preservation compared with open or laparoscopic nephrectomy. Cryoablation and RFA are technically less challenging than other nephron-sparing approaches and may allow general urologists without advanced laparoscopic training to selectively provide their patients with a minimally invasive nephron-sparing treatment. Results from recent meta-analyses demonstrate inferior local tumor control compared with partial and radical nephrectomy, but with equivalent or superior cancer-specific and overall survival. Interpretation of treatment success remains challenging with existing protocols, and long-term follow-up is needed to confirm these findings. No prospective literature currently exists that addresses the superiority of cryoablation or RFA. Some evidence exists that percutaneous tumor ablation offers incomplete primary treatment, but with improved recovery and decreased morbidity. Without question, prospective, comparative trials with uniform radiographic and pathologic follow-up are needed to address many of these uncertainties. Ultimately, the decision to treat a small renal mass with an ablative technology should take into account tumor-related characteristics, patient demographics and comorbidities, and the values and desires of the patient.

Pathophysiology, Evaluation, and Medical Management of Adrenal Disorders

Alexander Kutikov, MD • Paul L. Crispen, MD • Robert G. Uzzo, MD

Historical Background
Adrenal Anatomy and Embryology
Adrenal Physiology
Adrenal Disorders
Evaluation of Adrenal Lesions in Urologic Practice

The adrenal glands are small and deceptively simple. Formerly known as the suprarenal glands, given their location above the kidneys, this paired triangular organ sits at an anatomical crossroads in the upper abdomen adjacent to major vessels, nerves, and other vital organs, which they help to monitor and regulate. The complexities of adrenal endocrine and neurocrine function only recently have been more fully recognized. Indeed, **adrenals are now known to be central to homeostasis.** Moreover, pathology involving the glands is responsible for major human ailments.

Given the varied systemic adrenal functions and dysfunctions, medical management is primarily within the purview of endocrinologists, nephrologists, and cardiologists. Similarly, surgical management of adrenal diseases historically has been divided among urologists, general surgeons, surgical oncologists, and, more recently, endocrine surgeons with referral patterns often dependent on traditions established at individual institutions. With the urologist's advanced minimally invasive surgical skills, comfort with both retroperitoneal anatomy and surgical approaches to retroperitoneal organs, and the close relationship between renal and adrenal pathophysiology, **it is natural that the evaluation and surgical management of adrenal disorders remain firmly in the domain of practicing urologic surgeons.**

HISTORICAL BACKGROUND

The diminutive adrenal glands were easily overlooked by early physicians. Distinguished anatomists such as Galen, da Vinci, and Vesalius omitted the adrenal glands in their descriptions of the retroperitoneum. Bartholomaeus **Eustachius was the first to describe the organs in the mid-16th century** (Scott, 1990). Not until the mid-19th century was the critical importance of the adrenal recognized when **Thomas Addison,** an English physician, described a series of patients with the condition of **adrenal insufficiency** that now carries his name. He linked the disease to the adrenal glands upon careful inspection of the organs at autopsy (Addison, 1855). Soon thereafter, **Charles Brown-Sequard,** through a series of animal experiments demonstrated that **bilateral adrenalectomy uniformly resulted in death,** suggesting that the adrenals were indispensable to the survival of the host (Brown-Sequard, 1856). William Osler was the first to report treatment of Addison disease with hormonal replacement in 1896. He administered crude extract from the adrenal glands of pigs to a patient with Addison disease and produced significant weight gain in this one individual (Oliver and Sharpey-Schafer, 1895). In the ensuing half-century "adrenalin" was discovered, and its production was localized to the adrenal medulla (Oliver and Sharpey-Schafer, 1895). The ability of adrenaline to produce a sustained rise in blood pressure was subsequently determined (Abell and Crawford, 1897). Moreover, the failure of this substance, later termed "epinephrine" to sustain life following bilateral adrenalectomy underscored the complexity and multifunctionality of the adrenal gland and established Addison disease as an ailment of the adrenal cortex (Scott, 1990; Porterfield et al, 2008). Discovery and **isolation of cortisol from the adrenal gland** in the 1930s and subsequent work on its use to treat rheumatoid arthritis produced a **1950 Nobel Prize** in Physiology and Medicine for Edward Kendall, Philip Hench, and Tadeus Reichstein (Scott, 1990). Aldosterone was ultimately isolated from the bovine adrenal in 1952 (Grundy et al, 1952). The latter part of the 20th century witnessed a rapid transformation in our understanding and treatment of adrenal disorders lead by pioneers such as Jerome Conn, Lawson Wilkins, Grant Liddle, and Earl Sutherland (Scott, 1990).

ADRENAL ANATOMY AND EMBRYOLOGY

Overview

The adrenal glands are paired retroperitoneal organs composed of a cortex and medulla. Gross examination reveals a distinct spiculated mustard-yellow–colored cortex that is distinct from the surrounding perinephric fat and the inner medulla, which can be

distinguished macroscopically on cross section by its central brown color (see Figs. 57–1 and 57–2 on the Expert Consult website). The normal adrenal gland weighs an average of 4 to 5 g each and range in size from 4 to 6 cm in length and 2 to 3 cm in width (Mitty, 1988; Silverman and Lee, 1989; Avisse et al, 2000). Morphologically, the right adrenal gland is triangular in shape while the left adrenal gland is crescent shaped (Avisse et al, 2000). They may sit either immediately superior to the kidney, "capping" the upper pole, or superior medially to the upper pole, "cradled" by the kidney just above the renal vessels. Once understood, this difference can be appreciated by either computed tomography (CT) scan or magnetic resonance imaging (MRI) and is a relevant surgical distinction, particularly in patients with substantive perinephric fat and on the left side when identifying the adrenal vein.

Embryology

The adrenal cortex and the medulla are two embryologically and functionally distinct units. The cortex is derived from the intermediate mesoderm of the urogenital ridge (Mitty, 1988; Barwick et al, 2005). Beginning in the 5th week of gestation, mesenchymal cells located at the urogenital ridge and the root of the mesentery proliferate and form the cortex of the fetal adrenal gland. During the 6th and 7th weeks of gestation, additional mesothelial cells surround the fetal adrenal cortex, which will later form the adult adrenal cortex (Mitty, 1988; Barwick et al, 2005). By the end of the 8th week of gestation the mesothelial cells forming the cortex are encapsulated by connective tissue and have separated from the peritoneal mesothelium. In distinction, the adrenal medulla is derived from neural crest cells, located in adjacent sympathetic ganglia, which migrate into the medial aspect of the fetal adrenal cortex by the 9th week of gestation (Kempna and Fluck, 2008). The neural crest cells continue to invade the adrenal cortex until they achieve a central position surrounding the adrenal vein by the 18th week of gestation. This embryologic relationship explains the brown stippling of the adrenal cortex.

At birth, the fetal adrenal gland is twice the weight of an adult adrenal gland, but has not completed development. After birth, the fetal cortex begins to atrophy and will be completely resorbed by 12 months of age (Mitty, 1988). As the fetal cortex is being resorbed, the zona glomerulosa and fasciculata of the adult cortex continue to develop, but the zona reticularis will not complete differentiation until 3 years of age, reflecting the relative late importance of sex steroid production by this part of the adrenal cortex (Barwick et al, 2005; Kempna and Fluck, 2008).

Cases of unilateral adrenal agenesis are rare and are often associated with unilateral renal agenesis (Nakada et al, 1988; Else and Hammer, 2005). However, because adrenal and renal development are separate processes, this association is likely spurious and is the result of limited radiographic evaluation of the ipsilateral adrenal gland in cases of renal agenesis. **Most often, adrenal gland development occurs normally in the absence of ipsilateral renal unit development, malrotation, or malascent. In these cases, the adrenal glands are often discoid in shape and located in their normal position within the retroperitoneum** (Mitty, 1988).

More common anomalies of adrenal gland development include accessory adrenal tissue and adrenal heterotopia. Accessory renal tissue, also known as adrenal rests, can be composed of cortical or medullary tissues. Due to the close proximity of the adrenal gland and genitourinary organ development, adrenal rests can be found anywhere along the path of gonadal descent within the retroperitoneum. Although adrenal rests can be found in up to 50% of neonates, the tissue typically atrophies and is found in only approximately 1% of adults (Barwick et al, 2005). In cases of congenital adrenal hyperplasia (CAH), adrenal rest within the testis may become hyperplastic and present as a testicular mass. This is an important consideration prior to performing an orchiectomy for a testicular mass in patients with CAH. Adrenal heterotopia results from incomplete separation of primitive adrenal mesoderm from adjacent organs such as the liver or kidney, resulting in partial or complete incorporation of the gland into the adjacent organ.

Anatomy

The right and left adrenal glands are located within Gerota fascia at the levels of the 11th and 12th ribs and share several important anatomic relationships, including being located cephalad to the upper pole of the kidneys and anterior to the crus of the diaphragm. The right adrenal is bounded medially by the inferior vena cava and anteriorly by the liver, while the left adrenal gland is bounded medially by the aorta and anteriorly by the stomach, pancreas, and splenic vessels. The close juxtaposition of these organs to the adrenal explains why lesions of adjacent organs, such as leiomyomas of the greater curvature of the stomach, may be confused for an adrenal mass.

As with most endocrine organs, the blood supply to the adrenal gland is redundant. Although variable, the arterial supply of each adrenal gland may arise from three main sources: superior adrenal arteries (branches from the inferior phrenic arteries), middle adrenal arteries (direct visceral branches from the aorta), and inferior adrenal arteries (branches from the ipsilateral renal artery (see Fig. 57–1). The main adrenal arteries then branch to form a subcapsular plexus. From the subcapsular plexus some branches continue directly to the medulla, while others form sinusoids supplying the adrenal cortex. On the venous side, medullary veins coalesce to form the adrenal vein, which is surrounded by medullary tissue within the adrenal gland. The short right adrenal vein drains directly into the vena cava. On the left, the adrenal vein is long compared with the right and is joined by the inferior phrenic vein prior to draining into the left renal vein. The overlapping of both arterial and venous anatomy makes partial adrenalectomy possible with little risk of subsequent adrenal infarction. The principal lymphatic drainage of the adrenal glands is through the paracaval lymph nodes on the right and the para-aortic lymph nodes on the left.

The autonomic innervation of the adrenal glands includes predominantly preganglionic sympathetic fibers off the sympathetic trunk directly to the chromaffin cells of the adrenal medulla, while postganglionic fibers originating from the splanchnic ganglia provide innervation to the adrenal cortex. Parasympathetic innervation to the adrenal cortex and medulla is not well defined; however, animal models suggest that parasympathetic branches originating from the vagus nerve may be present.

Histology

Each adrenal gland is enclosed within a fibrous capsule (see Fig. 57–2). Directly beneath the capsule is the cortex, which comprises three zones: the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa consists of small polyhedral cells with scant eosinophilic cytoplasm and dark round nuclei. The essential function of the glomerulosa is the production of mineralocorticoids, predominantly aldosterone. The broad layer of large pale cells arranged in vertical columns beneath the zona

glomerulosa is the zona fasciculata responsible for the production of glucocorticoids such as cortisol. The zona reticularis, the innermost layer of the cortex, consists of round dark staining cells and predominantly produces sex steroids, such as adrenal estrogens and androgens (Mitty, 1988; MacLennan et al, 2003) (Table 57–1).

Key Points: Anatomy and Embryology

- The adrenal glands are composed of two embryologically and functionally distinct components: the cortex and the medulla (the former endocrine, the latter neurocrine).
- The arterial supply of the adrenal glands is variable and can arise from several sources. However, the venous drainage is more predictable with the right adrenal vein emptying into the inferior vena cava and the left adrenal vein draining into the left renal vein in the majority of patients.

ADRENAL PHYSIOLOGY

Other than their juxtaposed anatomic associations, the adrenal cortex and the adrenal medulla are best conceptualized as two distinct organs, the former endocrine and the latter neurocrine.

Adrenal Cortex Physiology

As part of a multistep synthetic pathway, numerous enzymes of the adrenal cortex catalyze conversion of essential steroid hormones from the common precursor cholesterol. Low-density lipoprotein (LDL) serves as the primary source of cholesterol for the adrenal (Arlt and Stewart, 2005). **Ratios and types of enzymes in each zone of the adrenal cortex vary, resulting in different hormonal products for each region** (Fig. 57–3) (Rainey, 1999).

Steroid hormone receptors are absent on cellular membranes of target tissues. Instead, steroids diffuse passively into the cell and bind to their respective receptors intracellularly. Gene transcription is then modulated by direct binding of the hormone receptor complex to target DNA (Arlt and Stewart, 2005). As discussed previously, the three main zones of the adrenal cortex are zona glomerulosa, zona fasciculata, and zona reticularis with each zone primarily responsible for mineralocorticoid (100 to 150 mcg/day), glucocorticoid (10 to 20 mg/day), and androgen synthesis (>20 mg/day), respectively (Arlt and Stewart, 2005).

Table 57–1.
Primary Effects of Mineralocorticoids

ACTION	EFFECT	SITE OF ACTION
Renal sodium reabsorption	Increased blood volume Increased blood pressure Decrease in urine sodium	Distal tubule Connecting segment Collecting duct
Renal chloride reabsorption	Increase in serum chloride Decrease in urine chloride	Distal tubule Connecting segment Collecting duct
Renal potassium secretion	Decrease in serum potassium Increase in urine potassium	Distal tubule Connecting segment Collecting duct
Renal proton secretion	Increased urine NH_4	Collecting duct—a result of sodium reabsorption

NH_4, ammonia.

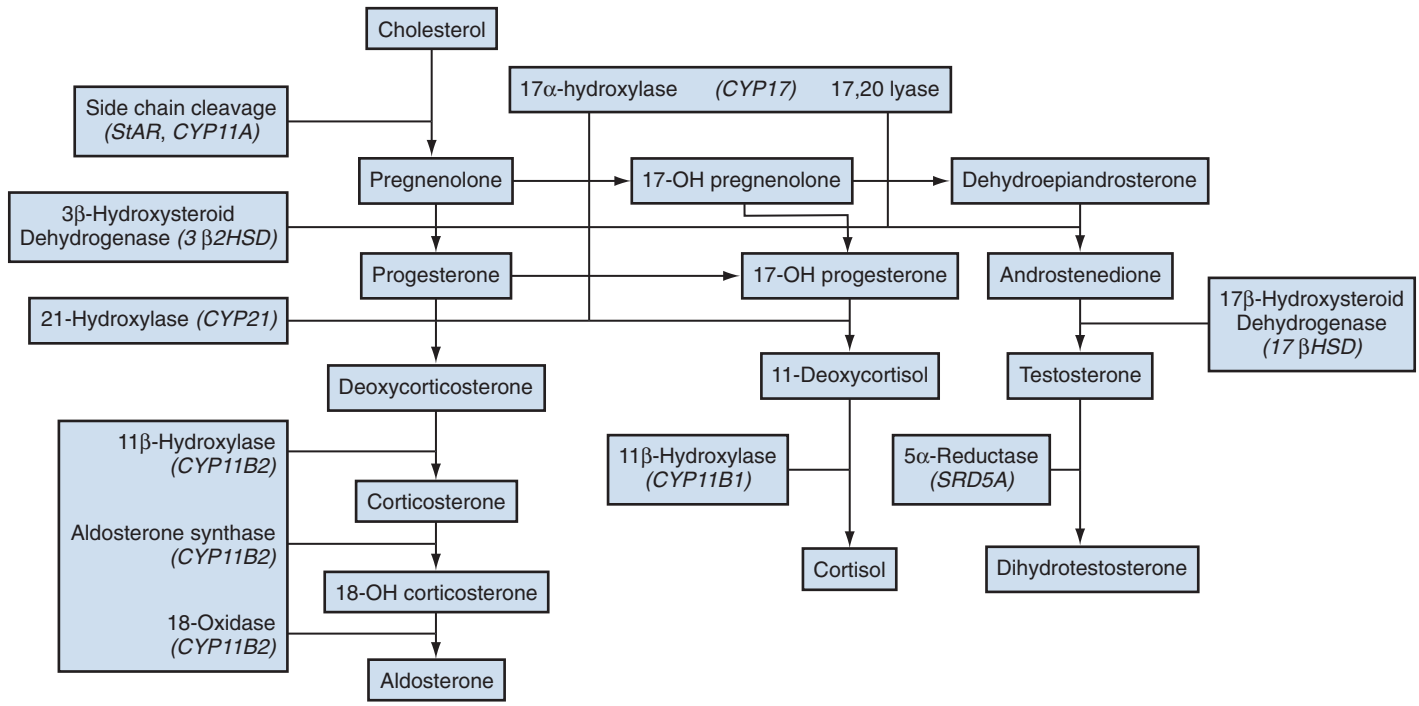

Figure 57–3. Steroid hormone synthesis beginning with cholesterol and resulting in mineralocorticoid, glucocorticoid, and androgen production in the adrenal cortex. Enzymes are listed in boxes and genes in parentheses. (From Hyun G, Kolon TF. A practical approach to intersex in the newborn period. Urol Clin N Am 2004;31:435–43.)

Zona Glomerulosa

The zona glomerulosa is the outermost region of the adrenal cortex and is the only zone of the adrenal gland that contains the enzyme aldosterone synthase (CYP11B2). As a result, the glomerulosa cells of this tissue are **the sole source of aldosterone**—the primary human mineralocorticoid (Rainey, 1999). Aldosterone regulates electrolyte metabolism by stimulating epithelial cells of the distal nephron to reabsorb Na^+ and Cl^-, while secreting H^+ and K^+. Although aldosterone levels have a profound effects on total body Na^+, concentration of the ion does not change, whereas reabsorbtion of sodium is accompanied by reuptake of free water. Therefore aldosterone primarily affects total body volume and not sodium concentration (White, 1994; Arlt and Stewart, 2005). Electrolyte balance in epithelial cells of the submaxillary salivary glands and the large intestine are also under mineralocorticoid control; however, the physiologic importance of this phenomenon is likely minimal (Bastl and Hayslett, 1992).

Aldosterone levels are primarily regulated by angiotensin II through the renin-angiotensin-aldosterone system and directly by serum potassium levels. A rise in adrenocorticotropic hormone (ACTH) can also increase aldosterone secretion, but this is a much less potent stimulus (White, 1994; Arlt and Stewart, 2005). For this reason the zona glomerulosa is the only region of the adrenal cortex that does not atrophy upon pituitary failure (Hubbard et al, 1990). Atrial natriuretic peptide is the main inhibitory regulator of aldosterone secretion providing an important link between cardiac, adrenal and renal function; although, somatostatin, dopamine, and others may also play a role (Spat and Hunyady, 2004). A working knowledge of the renin-angiotensin-aldosterone system is critical in conceptualizing and managing hyperaldosteronism. The pathophysiology of this pathway is discussed in the section on Conn syndrome.

Zona Fasciculata

The zona fasciculata is the site of glucocorticoid production due to zonal expression of 17α-hydroxylase, 21-hydroxylase, and 11β-hydroxylase enzymes (see Fig. 57–3) (Arlt and Stewart, 2005). **Cortisol is the primary glucocorticoid in humans, and its secretion is under tight control of the ACTH.** As such, cortisol and ACTH are a part of a classic hormonal negative feedback system that features the hypothalamus, the pituitary gland, and the adrenal. The physiology of this axis is discussed in more detail in the section on Cushing syndrome (Jacobson, 2005). Production of cortisol by the adrenal follows a strict circadian schedule with the majority of the hormone being secreted in the early morning (Jacobson, 2005). Glucocorticoids are essential to life and modulate complex physiologic pathways that include metabolism, immunity, maintenance of intravascular volume, regulation of blood pressure, and complex modulation of the central nervous system with significant effects on mood, sleep, and potentially memory (Arlt and Stewart, 2005) (Table 57–2).

Zona Reticularis

The zona reticularis is the innermost zone of the adrenal cortex. The presence of 17α-hydroxylase and 17,20-lyase results in the production of dehydroepiandrosterone (DHEA), sulfated DHEA (DHEA-S) and androstenedione to this region, although some androgen synthesis also occurs in the zona fasciculata. Adrenal androgen secretion appears to be under control of ACTH, and, like cortisol, exhibits circadian patterns (Arlt and Stewart, 2005). DHEA, DHEA-S, and androstenedione comprise the greatest portion of steroid hormone that is produced by the adrenals (>20 mg/day), but appear to be the least important for adult physiologic homeostasis (Nguyen and Conley, 2008); however, **pharmacologic manipulation of adrenal androgen production remains a viable and increasingly targeted strategy for advanced prostate cancer** (see Chapter 133). Moreover, aberrations in production of these hormones during development are responsible for significant pathology and result in the clinical entity known as congenital adrenal hyperplasia (CAH) (Finkelstein and Shaefer, 1979; Hubbard et al, 1990). CAH is discussed in detail in Chapter 110.

Table 57–2.

Primary Effects of Glucocorticoids

EFFECTS	CLINICAL IMPLICATIONS
Enhance skeletal and cardiac muscle contraction	Absence results in weakness
Cause protein catabolism	Excess results in muscle wasting and weakness
Inhibit bone formation	Excess decreases bone density
Inhibit collagen synthesis	Excess causes thin skin and fragile capillaries
Increase vascular contractility and decrease permeability	Absence makes it difficult to maintain blood pressure
Have anti-inflammatory activity	Exogenous steroid is useful in treating inflammatory diseases
Have anti-immune system activity	Exogenous steroids are useful in promoting transplant tolerance and in treating autoimmune disorders
Maintain normal glomerular filtration (GFR)	Absence reduces glomerular filtration rate

From Howards SS, Carey RM. The adrenals. In: Gillenwater JY, Grayhack JT, Howards SS, Duckett JW, editors. Adult and pediatric urology. 2nd ed. Chicago: Year Book; 1991.

Adrenal Medulla Physiology

The **adrenal medulla** comprises less than 10% of total adrenal mass. Neither its function nor its embryology are related to the neighboring cortex. Instead, this portion of the adrenal, which **lies at the center of the gland, is an integral part of the autonomic nervous system.** Chromaffin cells of the medulla are innervated by preganglionic sympathetic fibers of T-11 through L-2, making them analogous to cells of the sympathetic ganglia. The medulla secretes epinephrine (80%), norepinephrine (19%), and dopamine (1%). These substances, collectively known as catecholamines, are produced from the amino acid tyrosine and modulate the systemic stress response (Fig. 57–4) (Robertson, 1990; de Diego et al, 2008). The effects of these catecholamines are mediated through their binding to adrenoreceptors located on target organs. The nature of these effects depend on the adrenoreceptor types or subtypes located and stimulated on a particular end organ (Table 57–3) (Robertson, 1990; Guimaraes and Moura, 2001). Interestingly, the enzyme phenylethanolamine-*N*-methyl transferase (PNMT), which catalyzes the conversion of norepinephrine to epinephrine, is relatively unique to the adrenal medulla (the brain and organ of Zuckerkandl also express this enzyme). The function of this enzyme is potentiated by the presence of glucocorticoids, thereby creating one of the few physiologic links between the adrenal cortex and the medulla. **Localization of PNMT to the adrenal medulla explains**

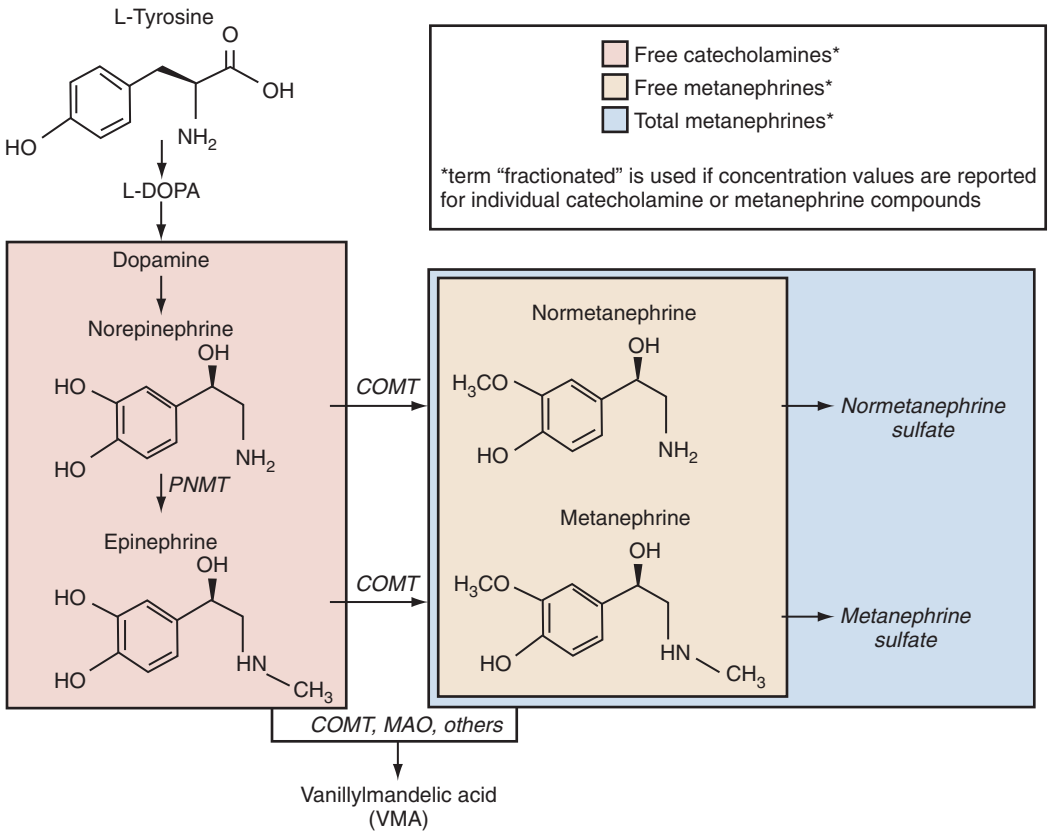

Figure 57–4. Summary of catecholamine metabolism. The figure simplifies the metabolic pathway of norepinephrine and epinephrine degradation to highlight those metabolic products that play a role in routine clinical practice. Key enzymes involved in catalysis of metabolic conversions are indicated in italic font. COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase; PNMT, phenylethanolamine-*N*-methyltransferase. NB: The central role that the MAO enzyme plays in catecholamine degradation is not fully reflected in this figure, because most metabolites that are produced by MAO catalysis are not routinely measured in laboratory assessments for pheochromocytoma.

why the gland is the primary source of systemic epinephrine, despite the presence of similar chromaffin cells elsewhere in the sympathetic nervous system (Robertson, 1990). Similar to the physiology that controls norepinephrine release at synaptic nerve terminals, the storage and release of adrenal catecholamines involves intracellular vesicles. Liberation of these vesicles through exocytosis results in release of adrenal catecholamines into the blood stream (Eisenhofer et al, 2004b).

The metabolism of catecholamines is complex and some controversy still exists about the physiologic relevance of each pathway (Eisenhofer et al, 2004b). The majority of adrenal catecholamine metabolism occurs at the scene of production in cells of the adrenal medulla themselves (Eisenhofer et al, 2003a). **For clinical purposes, three metabolites (metanephrine, normetanephrine, and vanillylmandelic acid) and two enzymes (catechol-O-methyltransferase and monoamine oxidase) are important.** Metanephrine and normetanephrine result from respective methylation of epinephrine and norepinephrine by catechol-*O*-methyltransferase (COMT). Although large amounts of this enzyme are present in the liver and kidneys, the majority of adrenal catecholamine metabolites are methylated by COMT within the cells of the adrenal medulla (Eisenhofer et al, 2003a). Indeed, **over 90% of metanephrine (epinephrine metabolite) and some 20% or more of normetanephrine (a norepinephrine metabolite) in the blood stream are derived from the adrenal medulla.** Therefore a measurable rise in the level of these metabolites is very useful when diagnosing potential pheochromocytomas (see

Key Points: Physiology

- Adrenal cortex and the adrenal medulla are best conceptualized as two distinct organs, the former endocrine and the latter neurocrine.
- Three main zones of the adrenal cortex are zona glomerulosa, zona fasciculata, and zona reticularis, with each zone primarily responsible for mineralocorticoid, glucocorticoid, and androgen synthesis, respectively.
- Ratios and types of enzymes in each zone of the adrenal cortex vary, resulting in different hormonal products for each region.
- Aldosterone levels are primarily regulated by angiotensin II through the renin-angiotensin-aldosterone system and directly by serum potassium levels. ACTH is less important in regulation of this region's function; therefore zona glomerulosa is the only region of the adrenal cortex that does not atrophy upon pituitary failure.
- Cortisol is the primary glucocorticoid in humans, and its secretion is under tight ACTH control.
- Pharmacologic manipulation of adrenal androgen production is an increasingly targeted strategy for treatment of advanced prostate cancer.
- Substances collectively known as catecholamines—epinephrine, norepinephrine, and dopamine—are produced from the amino acid tyrosine and modulate the systemic stress response.

Table 57–3.

Primary Effects of Catecholamines

EFFECTOR ORGANS	RECEPTOR TYPE	RESPONSES	MOST RELEVANT CLINICAL MANIFESTATIONS
Eye			
Radial muscle, iris	α_1	Contraction (mydriasis) + +	Blurry vision
Ciliary muscle	β_2	Relaxation for far vision +	
Heart			
SA node	β_1, β_2	Increase in heart rate + +	Palpitations, angina
Atria	β_1, β_2	Increase in contractility and conduction velocity + +	Palpitations, angina
AV node	β_1, β_2	Increase in automaticity and conduction velocity + + +	Palpitations, angina
His-Purkinje system	β_1, β_2	Increase in automaticity and conduction velocity + + +	Palpitations, angina
Ventricles	β_1, β_2	Increase in contractility, conduction velocity, automaticity, and rate of idioventricular pacemakers + + +	Palpitations, angina
Arterioles			
Coronary	α_1, α_2, β_2	Constriction +; dilations + +	Angina
Skin and mucosa	α_1, α_2	Constriction + + +	Pallor
Skeletal muscle	α, β_2	Constriction + +; dilations + +	Hypertension
Cerebral	α_1	Constriction (slight)	Stroke
Pulmonary	α_1, β_2	Constriction +; dilations + +	Edema
Abdominal viscera	α_1, β_2	Constriction + + +; dilations +	E.g., bowel ischemia
Salivary glands	α_1, α_2	Constriction + + +	
Renal	α_1, α_2, β_1, β_2	Constriction + + +; dilations +	Renal failure
Veins (systemic)	α_1, α_2, β_2	Constriction + +; dilations + +	Orthostatic hypotension
Lung			
Tracheal and bronchial muscle	β_2	Relaxation +	
Bronchial glands	α_1, β_2	Decreased secretion; increased secretion	
Stomach			
Motility and tone	α_1, α_2, β_2	Decrease (usually) +	Early satiety, discomfort
Sphincters	α_1	Contraction (usually) +	
Intestine			
Motility and tone	α_1, α_2, β_1, β_2	Decrease +	Constipation, ileus
Sphincters	α_1	Contraction (usually) +	
Secretion	α_2	Inhibition	Constipation
Gallbladder and ducts	β_2	Relaxation +	Gallstones
Kidney			
Renin secretion	α_1, β_2	Decrease +; increase ++	
Urinary bladder			
Detrusor	β_2	Relaxation (usually) +	Urinary retention
Trigone and sphincter	α_1	Contraction + +	Urinary retention
Ureter			
Motility and tone	α_1	Increase	
Uterus	α_1, β_2	Pregnant; contraction; relaxation Nonpregnant; relaxation	
Sex organs, male	α_1	Ejaculation + +	
Skin			
Pilomotor muscles	α_1	Contraction + +	
Sweat glands	α_1	Localized secretion +	Sweating
Spleen capsule	α_1, β_2	Contraction + + +; relaxation +	
Skeletal muscle	β_2	Increased contractility; glycogenolysis; K^+ uptake	Hyperglycemia, glycosuria
Pancreas			
Acini	α	Decreased secretion +	
Islets (β cells)	α_2	Decreased secretion + + +	Hyperglycemia, glycosuria
	β_2	Increased secretion +	Hypoglycemia
Fat cells	α_2, β_1, β_2	Lipolysis + + + (thermogenesis)	Feeling warm
Salivary glands	α_1	K^+ and water secretion +	
	β	Amylase secretion +	
Lacrimal glands	α	Secretion +	Lacrimation
Pineal gland	β	Melatonin synthesis	
Posterior pituitary	β_1	Antidiuretic hormone secretion	Decreased diuresis

Highest (+ + +) to lowest (+) intensity of adrenergic nerve activity in the control of various organs and functions listed. Where (+) is not given, intensity is not specified.

section on Assessment of Function of Adrenal Masses) (Eisenhofer et al, 1995). In the urine, the majority of these metabolites are excreted in a sulfonated form. Furthermore, monoamine oxidase (MAO) and other enzymes subsequently participate in the conversion of catecholamine metabolites to vanillylmandelic acid (VMA), the primary catecholamine metabolic end product that is largely formed by the liver. Nonadrenal catecholamines from the sympathetic nervous system are similarly converted to VMA (Eisenhofer et al, 2004b). Figure 57–4 summarizes the most clinically relevant aspects of the catecholamine metabolism pathway.

ADRENAL DISORDERS

Disorders of Increased Adrenal Function

Cushing Syndrome

Introduction and Epidemiology. **Hypercortisolism secondary to excessive production of glucocorticoids by the adrenal cortex is defined as Cushing syndrome** (Orth and Liddle, 1971). The disease is rare and occurs in 2 to 5 of every million people per year (Lindholm et al, 2001; Findling and Raff, 2005). Diagnosis and treatment of Cushing syndrome is multifaceted, often requiring cooperation of internists, endocrinologists, neurosurgeons, and adrenal surgical experts (Newell-Price et al, 2006). The urologist must understand the comprehensive pathophysiology of hypercortisolism and have particularly advanced expertise in the aspects of this complex disease for which adrenalectomy is required.

Pathophysiology

Introduction. The zona fasciculata of the adrenal cortex secretes more than 20 mg of cortisol every day (Arlt and Stewart, 2005). Regulation of this secretion is controlled through the hypothalamic-pituitary-adrenal (HPA) axis (Jacobson, 2005). A fluent understanding of this classic neuroendocrine negative feedback system is critical for the successful management of every Cushing patient.

Normal Hypothalamic-Pituitary-Adrenal (HPA) Axis Physiology. **Corticotrophic cells of the anterior pituitary secrete ACTH, also known as corticotrophin, under the influence of neuronal innervations from the hypothalamus.** Synthesis of ACTH is a result of cleavage of the pro-opiomelanocortin (POMC) precursor molecule. Physiologically, the most important promoter of ACTH release is corticotropin-releasing hormone (CRH), but oxytocin and vasopressin also play a role (Jacobson, 2005; Sam and Frohman, 2008). **Stress, whether physiologic or psychologic, appears to be the most important variable in modulating activity of the HPA axis** (Jacobson, 2005).

ACTH is not only responsible for promoting production of glucocorticoids and androgens by the adrenal cortex, but it also plays a critical role in maintaining adrenal cortical vitality. Indeed, without ACTH (e.g., when its secretion is suppressed by exogenous steroid intake), all but the mineralocorticoid-producing cells of the adrenal cortex arrest hormone production and undergo apoptosis (Arlt and Stewart, 2005; Jacobson, 2005). In addition to ACTH, splanchnic nerves that innervate the adrenals also appear to affect glucocorticoid production (Jacobson, 2005).

Glucocorticoids bind receptors in the hypothalamus and the pituitary and complete the negative feedback loop by inhibiting production of CRH and ACTH by these structures, respectively (Jacobson, 2005). Figure 57–5 summarizes the salient features of the HPA axis.

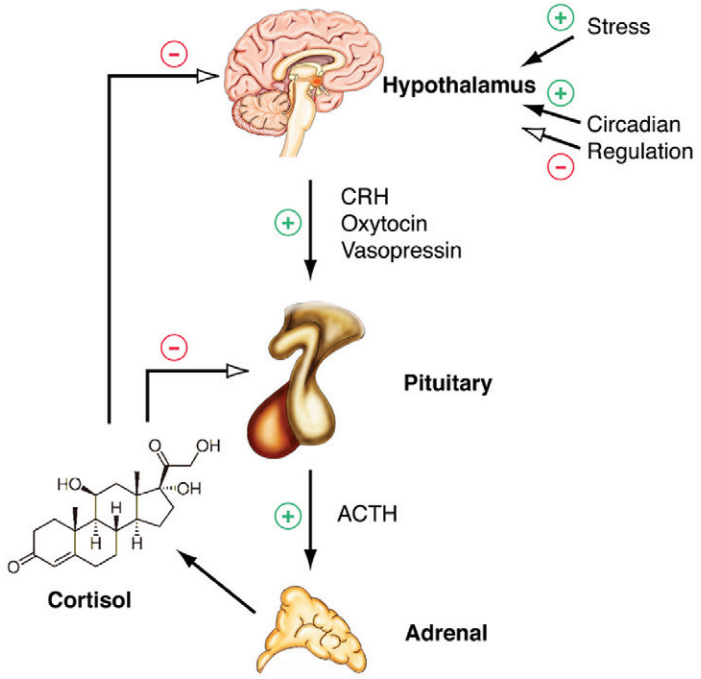

Figure 57–5. The hypothalamic-pituitary-adrenal axis and feedback loop. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

It is important to understand that CRH secretion is under tight control of the hypothalamic suprachiasmic nucleus and follows circadian patterns. The highest level of cortisol in healthy subjects is detected in the mornings, while the nadir is observed at approximately 11 PM. Even small perturbations of this physiologic rhythm are considered pathologic (Jacobson, 2005; Sam and Frohman, 2008).

Overview of Cushing Syndrome. Given the sophistication of the HPA axis, hypercortisolism can result from a number of different pathologies that result in oversecretion of cortisol by the adrenal glands. **Causes of Cushing syndrome can be divided into three main groups: (1) exogenous, (2) ACTH-dependent, and (3) ACTH-independent** (Fig. 57–6). Exogenous Cushing syndrome is a result of iatrogenic glucocorticoid administration. ACTH-dependent disease results from an elevated serum corticotropin level due to pathology extrinsic to the adrenal gland and accounts for up to 85% of cases of endogenous Cushing syndrome. **ACTH-independent hypercortisolism, on the other hand, results from unregulated overproduction of glucocorticoids by the adrenal(s) and is relatively rare.** The adrenal surgeon has long been involved in management of ACTH-independent disease, but with advent of laparoscopy, adrenal surgery for ACTH-dependent Cushing syndrome is becoming more commonplace (Porterfield et al, 2008).

Exogenous Cushing Syndrome. **Exogenous Cushing syndrome is the most common cause of hypercortisolism in patients of the Western world** (Newell-Price et al, 2006). Synthetic glucocorticoids are frequently employed in treatment of many conditions, and Cushing syndrome can result even from the administration of even low doses of exogenous steroids administered orally, topically, or by inhaled preparations (Hopkins and Leinung, 2005; Newell-Price et al, 2006). A careful patient history is therefore essential in the evaluation of all patients with Cushing syndrome. The clinician also must be cognizant of the possibility

that the patient is either unaware of his or her steroid use (e.g., use of herbal remedies, nasal sprays) or is surreptitiously self-administering glucocorticoids (e.g., for performance enhancement) (Hopkins and Leinung, 2005).

ACTH-Dependent Cushing Syndrome

OVERVIEW. **ACTH-dependent hypercortisolism accounts for 80% to 85% of endogenous Cushing syndrome. Approximately 80% of ACTH-dependent disease is due to primary pituitary pathology and is known as Cushing *disease*. Ectopic ACTH production is the other main cause of ACTH-dependent hypercortisolism** (Newell-Price et al, 2006). Ectopic CRH syndrome is a third cause of ACTH-dependent Cushing syndrome and is extremely uncommon (see Fig. 57–6) (Orth, 1995).

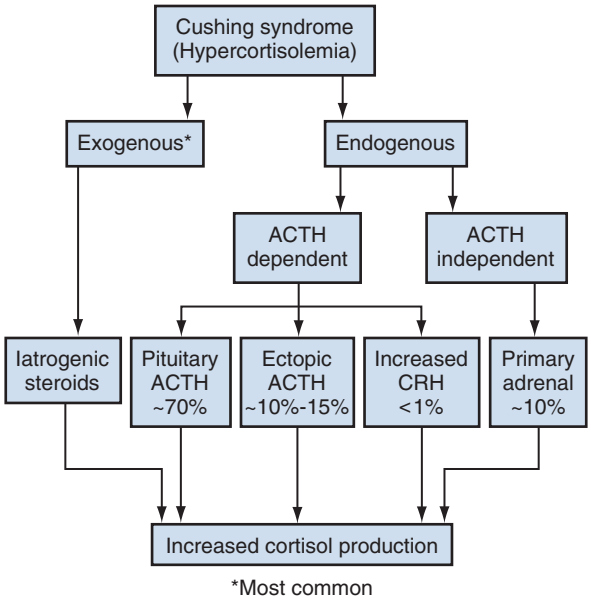

Figure 57–6. Clinically relevant causes of excess cortisol production. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

CUSHING DISEASE. **Described by the neurosurgical pioneer Harvey Cushing in 1932, Cushing disease causes hypercortisolism through excessive secretion of ACTH by the pituitary gland** (Cushing, 1932). The condition accounts for nearly 70% of endogenous Cushing syndrome. The most common culprit is a corticotropin-producing microadenoma. Large macroadenomas of 1 cm in size or greater are found in only about 5% of cases (Newell-Price et al, 2006). Fifteen percent of functional pituitary adenomas exhibit the ability to secrete ACTH (Shimon and Melmed, 1998). Hyperplasia of ACTH-producing cells and pituitary carcinoma can also oversecrete ACTH but are extremely rare (Orth, 1995). Up to two thirds of individuals with Cushing disease are female (Scott and Orth, 1990).

ECTOPIC ACTH SYNDROME. **Production of ACTH by nonpituitary tumors can also result in hypercortisolism. These corticotropin-producing tissues are nearly always malignant and account for approximately 10% of Cushing syndrome** (Porterfield et al, 2008). Liddle and associates first described the phenomenon in the early 1960s and termed it "ectopic ACTH syndrome" (Meador et al, 1962; Scott and Orth, 1990). The timing and onset of hypercortisolism varies and can precede the diagnosis of an extra-adrenal malignancy by many years, resulting in diagnostic difficulties and the clinical conundrum, whereby a subclinical pituitary adenoma is suspected but not radiographically identified (Aniszewski et al, 2001). Moreover, hypercortisolism in end-stage debilitated cancer patients is almost certainly underdiagnosed (Orth, 1995). As a result of higher ACTH levels, the adrenal glands of patients with ectopic ACTH syndrome are generally more markedly hyperplastic and thereby larger than those of patients with Cushing disease (Jenkins et al, 1999). Table 57–4 summarizes primary malignancies implicated in ectopic ACTH production, which notably includes pheochromocytoma.

ECTOPIC CRH. Production of CRH by malignancies is extremely rare and is responsible for less than 1% of cases of Cushing syndrome. Bronchial carcinoma is the most common culprit, and

concurrent ACTH secretion is not unusual (Carey et al, 1984; Orth, 1995).

ACTH-INDEPENDENT CUSHING SYNDROME. **Uncontrolled hypersecretion of cortisol by adrenal tissues accounts for a minority of endogenous hypercortisolism and is classified as ACTH-independent Cushing syndrome.** Adrenal neoplasms and rare forms of bilateral adrenal disease are responsible for this group of conditions (Lacroix and Bourdeau, 2005; Newell-Price et al, 2006).

ADRENAL TUMORS. **Cortisol-secreting benign adenomas of the adrenal gland are responsible for approximately 10% of Cushing syndrome** and often result from a dominant unilateral hyperplastic nodule, although multifocal bilateral functional adrenal hyperplasia may also occur. Less than 10% of adrenal masses are bilateral and often present a diagnostic challenge (Lacroix and Bourdeau, 2005; Porterfield et al, 2008; Young et al, 2008). Radiographically undetectable benign adrenal cortisol-producing lesions may also be responsible for cases of subclinical Cushing syndrome (Rossi et al, 2000). Cortisol production by adrenocortical carcinomas account for approximately 8% of patients with Cushing syndrome (Lindsay and Nieman, 2005a).

ACTH-INDEPENDENT MACRONODULAR ADRENAL HYPERPLASIA (AIMAH). ACTH-independent bilateral macronodular adrenal hyperplasia (AIMAH) gives rise to less than 1% of Cushing syndrome. The condition is characterized by multiple large (up to 4 cm) nodules replacing the glands with each adrenal weighing over 60 g (Lacroix and Bourdeau, 2005; Iacobone et al, 2008). Weights in excess of 200 g have been reported for each gland affected by AIMAH (Swain et al, 1998). It is essential that this disease entity must be distinguished from adrenal enlargement caused by chronic adrenal stimulation in ACTH-dependent Cushing syndrome, whereas radiographics of the adrenals appear similar in both conditions. Bilateral macronodular hyperplasia is observed as a feature of the McCune-Albright syndrome, which also includes polyostotic fibrous dysplasia, dermatologic manifestations, and other endocrine abnormalities (Lacroix and Bourdeau, 2005).

PRIMARY PIGMENTED NODULAR ADRENOCORTICAL DISEASE (PPNAD). Like AIMAH, primary pigmented nodular adrenocortical disease (PPNAD) is exceedingly rare, accounting for less than 1% of cases of Cushing syndrome. Unlike AIMAH, however, the adrenal glands in this condition remain normal in size and exhibit black or brown cortical nodules (Young et al, 1989). The cortical tissue surrounding the nodules is atrophic and the adrenal medulla is free of disease (Lacroix and Bourdeau, 2005). Approximately half of PPNAD is found in patients with the autosomal-dominant Carney complex, which is also responsible for spotty skin and mucous membrane lesions, and a variety of neoplasms that include Sertoli-cell tumors. The other half of cases of PPNAD are nonhereditary with no known cause (Lacroix and Bourdeau, 2005).

Clinical Characteristics

Classical Cushing Syndrome. **Clinical characteristics of Cushing syndrome vary considerably among affected patients. Many of the classic symptoms of hypercortisolism, such as central obesity, moon faces, buffalo hump, proximal muscle weakness, easy bruisability, and abdominal striae, are non-specific. It is the combination of these and other clinical signs that should raise suspicion and prompt potential screening for Cushing syndrome** (Findling and Raff, 2005). **Cushing syndrome also results in systemic symptomatology, such as central obesity, dyslipidemia, insulin resistance, and hypertension, that is identical to the highly-prevalent metabolic syndrome** (Pivonello et al, 2005, 2008). Figure 57–7 depicts the effects of glucocorticoids on organ systems, and Table 57–5 summarizes signs and symptoms of the disease and indicates their frequency. Screening for Cushing syndrome is usually beyond the scope of urologic practice; however, it is important for urologists to appreciate the **relatively common occurrence of hypogonadal hypogonadism in men with Cushing syndrome.** A low threshold for initiating a hypercortisolism workup should exist in these men with libido or erectile problems, low testosterone, and low gonadotropin levels (Findling and Raff, 2005; Pivonello et al, 2008). **Up to 50% of patients with Cushing syndrome exhibit urolithiasis;** therefore stone formers with cushinoid features also deserve a hypercortisolemia evaluation. Interestingly, definitive treatment of Cushing syndrome in these patients reduces the risk of stone formation, but does not bring the risk back to that of the general population (Faggiano et al, 2003).

Subclinical Cushing Syndrome. Subclinical Cushing syndrome is a relatively new disease entity that describes hypercortisolemia in the absence of an overt cushinoid phenotype. Obvious clinical signs of Cushing syndrome are absent, and the diagnosis is made when a metabolic workup for an incidentally-discovered adrenal mass reveals hypercortisolemia (Sippel and Chen, 2004). In the past, the disease entity was referred to as "pre-Cushing syndrome," "noncushingoid Cushing syndrome," and "preclinical Cushing syndrome"; however, the term "subclinical Cushing" has gained acceptance. Recently, the term "subclinical autonomous glucocorticoid hypersecretion" also has been introduced (Tsagarakis et al, 2006). Classically, the disease entity applies to patients who are found to have elevated cortisol levels upon a metabolic workup of an adrenal incidentaloma. **Nearly 10% of patients in one large series of adrenal incidentalomas were found to have the condition** (Mantero et al, 2000). Patients can also fall under the umbrella of this diagnosis when Cushing syndrome

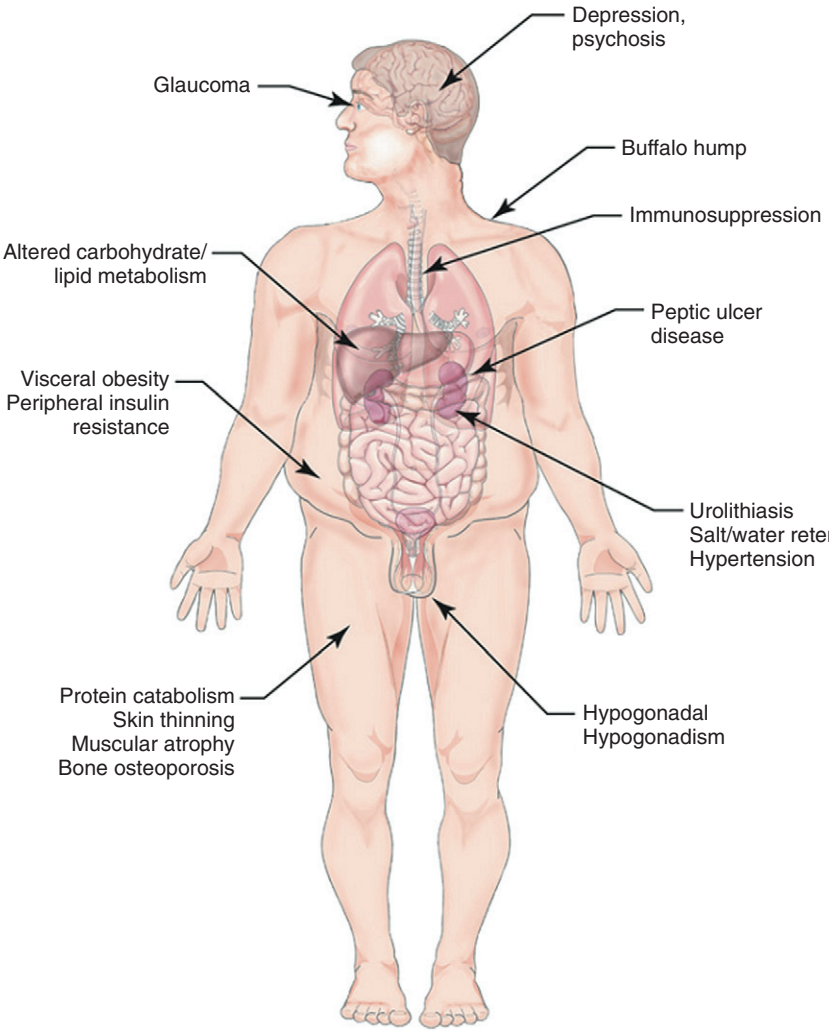

Figure 57–7. Diverse effects of hypercortisolism on organ systems.

is discovered during screening. For instance, when patients with type II diabetes and poor glucose control are screened for hypercortisolism, some 2% have subclinical Cushing syndrome (Catargi et al, 2003).

Adrenalectomy in the setting of subclinical Cushing may improve glucose control, hypertension, and result in weight loss (Midorikawa et al, 2001; Mitchell et al, 2007). Surgical indications and benefits for subclinical Cushing syndrome, however, are still a matter of debate (Sippel and Chen, 2004; Tsagarakis et al, 2006). Some authors argue that adrenalectomy should be performed only in patients who are potentially symptomatic and exhibit clinical signs, such as hypertension, obesity, glucose intolerance, or osteopenia. Others propose that surgery must be offered to all patients in order to prevent the sequelae of hypercortisolism (Sippel and Chen, 2004; Pivonello et al, 2005; Tsagarakis et al, 2006). Patients with subclinical Cushing syndrome may be at higher risk for postadrenalectomy adrenal insufficiency than those patients with non-cortisol-secreting adrenal pathologies, because functionality of the contralateral gland may be suppressed (Tsagarakis et al, 2006).

Diagnostic Tests. The diagnosis of Cushing syndrome is one of the most complex and difficult tasks in clinical endocrinology and most often falls outside of the realm of medical or surgical urological practice (Findling and Raff, 2005). Nevertheless, the urologist must be familiar with these diagnostic strategies and how they relate to the etiology of hypercortisolism. Moreover, the urologist who offers adrenalectomy must be well versed in the basic metabolic evaluation for Cushing syndrome in patients with adrenal masses.

Establishing the Diagnosis of Cushing Syndrome. When the diagnosis of Cushing syndrome is suspected, the clinician can choose among several laboratory studies. **The two evaluations performed most frequently are the 24-hour urinary free cortisol evaluation and the overnight low-dose dexamethasone suppression test (LD-DST). The sensitivity of the former test, however, may not be adequate for screening patients with incidentalomas** (Nieman et al, 2008). **Late-night salivary cortisol is a test that is becoming increasingly popular.** Second-line tests include the 2-day LD-DST and midnight plasma cortisol testing (Arnaldi et al, 2003; Newell-Price et al, 2006, Nieman et al, 2008; Pivonello et al, 2008). The physiologic principles underlying these tests are important to understand and are described in this section (Findling and Raff, 2005). The section Evaluation of Adrenal Pathology in Urologic Practice outlines practical algorithms for the metabolic evaluation of adrenal lesions. Tests such as random serum cortisol, plasma ACTH level, urinary 17-ketosteroid level, insulin tolerance testing, and loperamide testing have fallen out of favor and are no longer recommended (Nieman et al, 2008).

Administration of low-dose dexamethasone followed by measurement of serum cortisol the next morning probes the patient's glucocorticoid negative feedback

system. In subjects without hypercortisolism, dexamethasone acts on the corticotrophic cells of the anterior pituitary, suppresses ACTH production, and thereby results in a reduction of serum cortisol levels (Findling and Raff, 2005). A key element to understanding this test is that despite the "low-dose" designation, the dosage of dexamethasone administered for this study corresponds to three- to fourfold levels of physiologic glucocorticoid. Importantly, the exogenous dexamethasone is not detected by the serum cortisol assay. The fact that patients with ACTH-independent Cushing syndrome and those with ectopic ACTH secretion fail to suppress cortisol production during such testing is intuitive; however, the reason for the failure of patients with ACTH-producing pituitary adenomas (Cushing disease) to suppress cortisol secretion following low-dose dexamethasone administration is less obvious. The phenomenon is best understood by the relative insensitivity of pituitary adenomas to the inhibitory effects of glucocorticoid stimulation (Raff and Findling, 2003). In summary, a patient's failure to suppress cortisol levels following an overnight low-dose dexamethasone administration is indicative of Cushing syndrome. **This test does not delineate the etiology of hypercortisolism, but simply suggests its presence.** Administration of low-dose dexamethasone over a 48-hour period is less practical and is reserved for second-line testing.

Urinary free cortisol evaluation is a 24-hour direct measurement of free bioavailable cortisol. Unlike serum cortisol testing, which measures both free and bound cortisol, urinary cortisol measurements are independent from the variables that influence corticosteroid-binding globulin levels (Arnaldi et al, 2003). Moreover, the test is an integrated measurement of cortisol secretion over a 24-hour period. This feature of the study is critical, because serum cortisol levels exhibit some circadian variation even in many patients with Cushing syndrome (Orth, 1995). **The urologist must be cognizant that this test may not possess sufficient sensitivity for diagnosis of subclinical Cushing syndrome, and the Endocrine Society recommends against it for metabolic evaluation of adrenal incidentalomas** (Nieman et al, 2008).

Late-night salivary cortisol and midnight plasma cortisol measurements take advantage of a common feature of all causes of Cushing syndrome—a perturbation and in some cases complete disruption in the diurnal variation of cortisol levels. The abnormality, even in very mild cases of Cushing syndrome, is the inability to suppress cortisol levels at night. As previously mentioned, peak morning cortisol levels in patients with Cushing syndrome are often within the normal range; however, persistent elevation at night may signal the loss of diurnal variance associated with Cushing. While midnight plasma cortisol measurements are clinically impractical in an outpatient setting, late-night salivary cortisol measurements are becoming a popular diagnostic tool for identification of hypercortisolism (Raff and Findling, 2003; Findling and Raff, 2005).

It is important to note that other conditions can stimulate the hypothalamic-pituitary-adrenal axis and emulate Cushing syndrome (Table 57–6); **therefore endocrinologic expertise is recommended when definitively diagnosing hypercortisolism** (Nieman et al, 2008).

Identifying the Cause of Cushing Syndrome. Once Cushing syndrome is diagnosed, its etiology must be localized. Due to the nuanced complexity of this process, some authors believe that this is best done by endocrinologists at major referral centers (Newell-Price et al, 2006). Briefly, the algorithm is as follows.

First, ACTH-dependent disease must be distinguished from the ACTH-independent causes. This is done by measurement of serum ACTH. Low serum ACTH points to ACTH-independent pathology, and abdominal imaging is indicated to identify the adrenal source. If the adrenals are unremarkable on cross-sectional imaging, exogenous steroids as a cause of Cushing syndrome, or much less commonly PPNAD, must be suspected (Arnaldi et al, 2003). Interestingly, the presence of PPNAD often can be confirmed by a delayed "paradoxical rise" in the 24-hour urinary cortisol sampling following dexamethasone administration (Lacroix and Bourdeau, 2005). Up to 10% of patients with adrenal Cushing syndrome have bilateral adrenal lesions (Lacroix, 2008). Adrenal venous sampling may be helpful in this setting (Young et al, 2008).

Table 57–6.

Causes of Hypercortisolism in the Absence of Cushing Syndrome

Conditions
Some clinical features of Cushing syndrome may be present
Pregnancy
Depression
Alcohol dependence
Glucocorticoid resistance
Morbid obesity
Poorly controlled diabetes mellitus
Unlikely to have any clinical features of Cushing syndrome
Physical stress (hospitalization, surgery, pain)
Malnutrition, anorexia nervosa
Intense chronic exercise
Hypothalamic amenorrhea
CBG excess (increased serum but not in urine cortisol)

Whereas Cushing syndrome is unlikely in these conditions, it may rarely be present. If there is a high clinical index of suspicion, the patient should undergo testing, particularly those within the first group.

Adapted from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. J Clin Endocrinol Metab 2008;93(5):1526–40.

The true diagnostic difficulty lies in distinguishing Cushing disease from the ectopic ACTH syndrome for patients who have high serum ACTH levels. This problem stems from the fact that both pituitary microadenomas and ACTH-producing tumors can be very difficult to localize with modern imaging. Meanwhile, incidental imaging findings in the lungs, pancreas, and pituitary are relatively common, often clouding the diagnostic waters (Newell-Price et al, 2006). For instance, 10% of the general population exhibit an abnormality upon imaging of the pituitary gland, while some 50% of patients with Cushing disease have no abnormality on pituitary MRI (Fig. 57–8) (Arnaldi et al, 2003; Porterfield et al, 2008).

Direct measurements of ACTH in a downstream venous plexus that drains the pituitary—the inferior petrosal sinus—following CRH stimulation has become the gold standard approach for distinguishing ectopic ACTH production from Cushing disease. High levels of ACTH in the inferior petrosal sinus, when compared to those in peripheral blood, indicate Cushing disease, while levels similar to peripheral plasma suggest an ectopic ACTH source (Findling and Raff, 2006; Porterfield et al, 2008).

High-dexamethasone suppression testing was used in the past to differentiate pituitary and ectopic ACTH sources, but the value of the test is limited. The study is based on the principle that high enough doses of dexamethasone should suppress ACTH production by pituitary adenomas, while ectopic ACTH production continues despite the high-dose

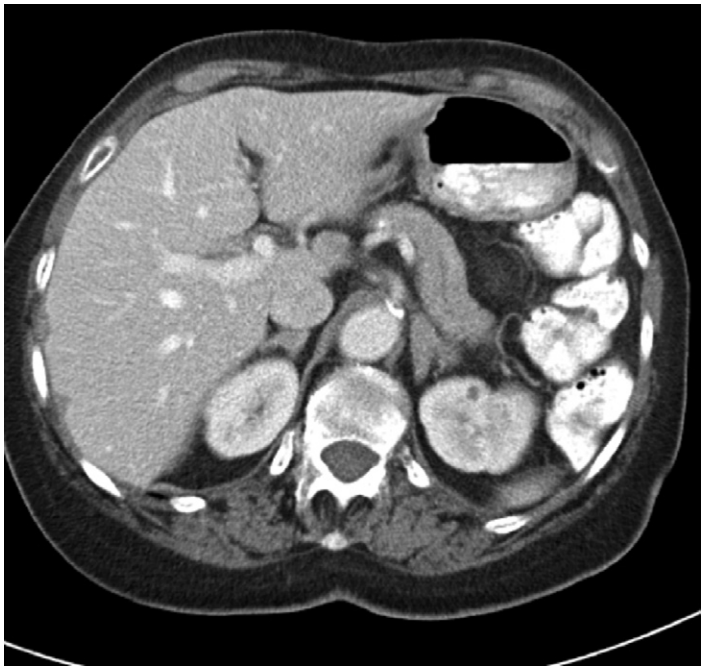

Figure 57–8. Bilateral adrenal enlargement in a patient with advanced metastatic adenocarcinoma of the pancreas.

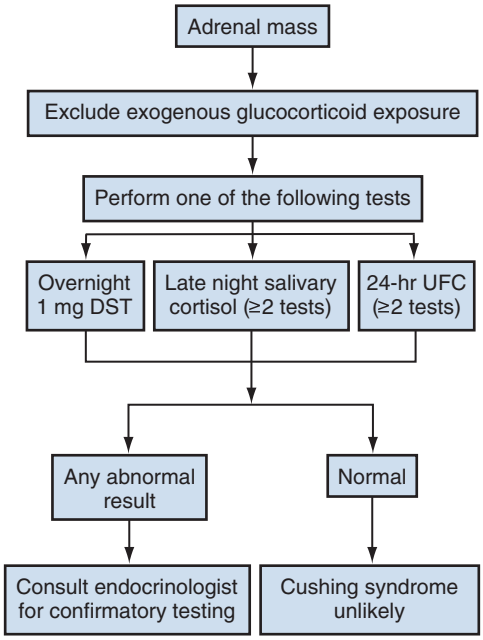

Figure 57–9. Testing algorithm for ruling out hypercortisolemia secondary to an adrenal mass. In case of a positive result during late-night salivary cortisol or 24-hour urinary–free cortisol evaluations, repeat testing is often prudent. DST, dexamethasone suppression test; UFC, urinary–free cortisol.

glucocorticoid administration (Arnaldi et al, 2003). Unfortunately, it is now clear that some nonpituitary ACTH-producing tumors possess the glucocorticoid receptor and also reduce ACTH production upon high-dose dexamethasone administration (Aron et al, 1997; Raff and Findling, 2003). Currently, high-dexamethasone suppression testing is not routinely employed (Fig. 57–9) (Findling and Raff, 2006; Porterfield et al, 2008).

Treatment. The treatment of Cushing syndrome must be approached as a multidisciplinary endeavor. Primary care physicians, endocrinologists, neurosurgeons, and the adrenal surgical experts must effectively communicate not only with the patient but also with each other. Treatment goals involve correction of hypercortisolemia, restoration of the hypothalamic-pituitary-adrenal axis, and management of Cushing syndrome sequelae (Porterfield et al, 2008).

Exogenous Cushing Syndrome. Correction of exogenous Cushing syndrome, when appropriate, must be handled with proper care. Cessation of glucocorticoid administration must be gradual, so that hypothalamic-pituitary-adrenal axis has ample time to recover. The process can take weeks to months and varies greatly from patient to patient. The physician must be aware of the clinical entity known as "steroid withdrawal syndrome" where the patient cannot tolerate steroid dose reduction despite apparent normalization in hypothalamic-pituitary-adrenal axis testing (Hopkins and Leinung, 2005).

ACTH-Dependent

CUSHING DISEASE. **The current standard of care for ACTH-secreting pituitary adenomas is transsphenoidal surgical resection** (see Fig. 57–10 on the Expert Consult website). **Unfortunately, cure is seen in only 60% to 80% of patients** (Newell-Price et al, 2006; Pivonello et al, 2008). **Furthermore, long-term follow-up is necessary, because up to 25% of individuals relapse** (Patil et al, 2008). Macroadenomas are additionally resistant to neurosurgical treatment, and less than 15% of patients are cured following excision of tumors 1 cm in size or greater (Newell-Price et al, 2006). Following resection, a severe addisonian state is common, and careful glucocorticoid replacement is necessary in the year following surgery (Utz et al, 2005). Hypopituitarism after resection of a pituitary adenoma is a known complication, with rates varying from less than 5% to greater than 50% for the various pituitary metabolic products in various surgical series. Careful patient monitoring by expert endocrinologists is essential (Utz et al, 2005; Porterfield et al, 2008). Neurosurgic reoperation following initial failure is challenging and success rates vary. Moreover, the risk of hypopituitarism also significantly rises with secondary resections (Utz et al, 2005; Porterfield et al, 2008). Salvage radiation therapy is an option, but the patient must be warned about significant delays in reduction of ACTH secretion and the possibility of hypopituitarism (Estrada et al, 1997; Utz et al, 2005; Porterfield et al, 2008).

The urologist must be involved when adrenalectomy is contemplated or required. **Currently bilateral adrenalectomy is most often recommended when at least one attempt to treat the primary tumor has failed. It is also necessary in rare instances when hypercortisolism is life-threatening and swift definitive treatment is mandatory.** The advantages of the procedure include a lack of postoperative hypopituitarism and an extremely high success rate with rapid resolution of hypercortisolism (Vella et al, 2001; Chow et al, 2008; Lacroix, 2008). Nevertheless, lifelong mineralocorticoid and glucocorticoid replacement is required in all patients. **Moreover, the patients are at risk for progressive growth of their pituitary adenoma, mainly resulting in complications such as ocular chiasm compression, oculomotor deficiencies, and, rarely, a rise in intracranial pressure** (Assie et al, 2007). **This results in the Nelson-Salassa syndrome (also known as Nelson syndrome), which is found in 8% to 29% of patients following bilateral adrenalectomy in large series.** Prophylactic radiation therapy has been shown to prevent the phenomenon in some but not all published reports (Gil-Cárdenas et al, 2007). Currently, routine use of prophylactic radiotherapy to prevent Nelson syndrome following

bilateral adrenalectomy is controversial (Porterfield et al, 2008). **When counseling patients regarding bilateral adrenalectomy for ACTH-dependent Cushing syndrome, the urologist must also warn of the rare possibility of residual, functioning adrenal tissue remaining following the procedure** (Kemink et al, 1992).

ECTOPIC ACTH SYNDROME. Resection of the primary ACTH-producing tumor is the single best therapeutic approach to normalizing cortisol levels in patients with ectopic ACTH syndrome. In large series, however, primary tumor resection is only possible in approximately 10% of patients (Aniszewski et al, 2001). **For patients with unresectable primary tumors or whose primary ACTH-producing tissue cannot be identified (up to 35% of cases), bilateral adrenalectomy with lifelong replacement therapy is an excellent therapeutic option** (Aniszewski et al, 2001; Porterfield et al, 2008).

ACTH-Independent. Patients with unilateral cortisol-secreting adrenal masses are treated with ipsilateral adrenalectomy. Partial adrenalectomy is possible when preservation of adrenal tissue is deemed essential (Walz, 2004). Case reports of bilateral partial adrenalectomies for cortisol-producing masses exist in the literature (Inoue et al, 2006). The current standard of care for AIMAH and PPNAD patients is bilateral adrenalectomy with lifelong replacement therapy. Success with unilateral resection of the largest gland in AIMAH patients also has been reported (Iacobone et al, 2008).

Medical Treatment of Hypercortisolism. Medical therapy for hypercortisolism is employed for bridging a patient to surgery or when surgical intervention is not possible. Medications that block enzymes of steroid synthesis, such as metyrapone, aminoglutethimidine, trilostan, ketoconazole, and etomidate are often employed. Mitotate, a medication that is discussed in further detail in the section Adrenal Carcinomas, can also be used (Porterfield et al, 2008). In the future, inhibitors of 17α-hydroxylase (cyp17), such as aberaterone, may also be of some utility; however, at this point such use of these drugs remains largely unexplored (Attard et al, 2009). Medical treatment of hypercortisolemia requires significant expertise and should be left to expert endocrinologists.

Prognosis. Life expectancy for patients with Cushing syndrome falls short of those of patients with normal cortisol levels. Normalization of hypercortisolemia may reduce but not eradicate this risk (Swearingen et al, 1999; Pivonello et al, 2005). Aggressive management of cardiovascular risk factors under the watchful eyes of experienced medical experts is paramount even in patients whose laboratory values return to normal following successful treatment.

Key Points: Cushing Syndrome

- Serum cortisol levels are under tight control. In healthy subjects peaks occur in the morning, while the nadir is observed at approximately 11:00 PM.
- Adrenal tumors that secrete cortisol cause ACTH-independent Cushing syndrome and account for approximately 10% of Cushing syndrome that is not caused by steroid intake.
- Patients with undiagnosed Cushing syndrome can present to the urologist with hypogonadal hypogonadism or with urolithiasis.
- Testing of adrenal masses for cortisol hypersecretion is mandatory.

Summary. Cushing syndrome is a complex disorder that requires a multidisciplinary approach. The urologist plays a critical role in management of the hypercortisolemic patient when unilateral or bilateral adrenalectomy is required. A thorough understanding of relevant pathophysiology is necessary not only for diagnosis and treatment, but also for appropriate perioperative counseling of patients with Cushing syndrome.

Primary Aldosteronism

Introduction and Epidemiology. Dr. Jerome Conn first described primary aldosteronism in 1955 in a 34-year-old female presenting with hypertension and hypokalemia (Conn, 1955). Urine assays demonstrated a markedly elevated level of mineralocorticoid activity. The patient's condition greatly improved following the removal of a 4-cm unilateral adrenal tumor. Since this initial case report, several subtypes of primary aldosteronism, which require distinct evaluation and treatment, have been identified. Given the prevalence of primary aldosteronism, which ranges from 5% to 13% of hypertensive patients in contemporary series, urologists must be familiar with appropriate diagnostic and management strategies (Mulatero et al, 2004; Rossi et al, 2006a; Young, 2007a).

Pathophysiology. The renin-angiotensin-aldosterone-system (RAAS) is a key regulator of blood pressure and extracellular fluid volume (Fig. 57–11). The release of renin from the juxtaglomerular cells is the rate-limiting step in the RAAS cascade. Under normal physiologic conditions, renin release is stimulated by several conditions including low renal perfusion pressure, increased renal sympathetic nervous activity, and low sodium concentration sensed by the macula densa (Gibbons et al, 1984). Renin then cleaves angiotensinogen to angiotensin I, which in turn is cleaved by angiotensin-converting enzyme to angiotensin II. Angiotensin II functions as both a potent vasoconstrictor and triggers the release of aldosterone from the zona glomerulosa. Additional regulators of aldosterone release include potassium and ACTH. **In primary aldosteronism, aldosterone secretion is independent of the RAAS, and plasma renin levels will be suppressed.** This finding is in contrast to patients with secondary

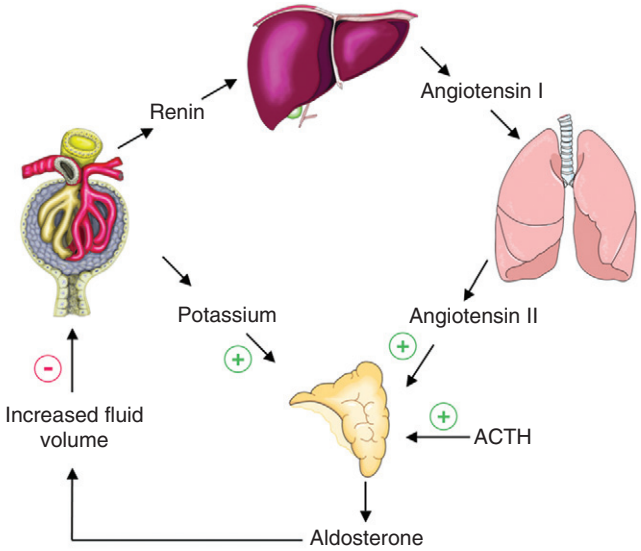

Figure 57–11. Renin-angiotensin-aldosterone-system. Under normal conditions, aldosterone secretion is under the control of angiotensin II, serum potassium levels, and adrenocorticotropic hormone (ACTH). In primary aldosteronism, aldosterone is autonomously released, resulting in decreased plasma renin levels.

hyperaldosteronism, where elevated renin levels are the cause of elevations in aldosterone secretion. This distinction between plasma renin levels in primary and secondary hyperaldosteronism is a critical concept used when screening for primary aldosteronism (see Diagnosis section later).

Following release from the adrenal cortex, aldosterone increases sodium reabsorption and potassium secretion in the distal nephron (Nyirenda and Padfield, 2007). Hypernatremia does not occur as sodium reabsorption is accompanied by water uptake, thereby maintaining isotonicity. The resultant volume expansion is limited by mineralocorticoid escape. Mineralocorticoid escape is mediated by pressure-natriuresis, atrial natriuretic peptide secretion, and changes in electrolyte transporters in the distal nephron, which result in limiting volume expansion to approximately 1.5 kg or less (Burnett et al, 1985; Yokota et al, 1994; Knepper et al, 2003).

Although the finding of increased plasma aldosterone and decreased plasma renin activity is common to all patients with primary aldosteronism, individual subtypes of the disorder have distinct underlying pathophysiology. Differentiation between subtypes of primary aldosteronism is essential to ensure proper treatment. The causes of primary aldosteronism are presented in Figure 57–12. Idiopathic hyperplasia and aldosterone-producing adenomas are by far the most common subtypes encountered, accounting for over 95% of cases. Although idiopathic hyperplasia is the most common subtype diagnosed, the prevalence of aldosterone-producing adenomas may be greater than previously thought due to lack of routine lateralization studies in patients diagnosed with primary aldosteronism (Mulatero et al, 2004).

The underlying pathophysiology of idiopathic hyperplasia, also referred to as bilateral adrenal hyperplasia, remains unknown. Macronodular hyperplasia is rarely the cause, with most cases attributed to micronodular hyperplasia (Schirpenbach and Reincke, 2007). Clinically, patients with idiopathic hyperplasia have less severe hypertension and are less likely to be hypokalemic compared with patients with aldosterone-producing adenomas (Rossi et al, 2006a). Whereas both adrenal glands are responsible for increased aldosterone production in idiopathic hyperplasia, unilaterally adrenalectomy is not therapeutic. Unilateral adrenal hyperplasia is distinctly uncommon, but when appropriately diagnosed is potentially curable with adrenalectomy following confirmation of lateralizing aldosterone secretion (see Subtype Differentiation section). In comparison with idiopathic hyperplasia, aldosterone-producing adenomas are associated with more profound hypertension and hypokalemia (Rossi et al, 2006a).

Less common causes of primary aldosteronism include adrenal cortical carcinomas, ectopic aldosterone producing tumors, and familial hyperaldosteronism (FH). Primary aldosteronism associated with adrenal cortical carcinoma is rare, representing less than 1% of cases of primary aldosteronism and 2.5% to 5% of adrenal cortical carcinomas (Ng and Libertino, 2003; Seccia et al, 2005). Ectopic aldosterone-producing tumors are extremely rare and should raise suspicion for the presence of accessory adrenal tissue or adrenal heterotopia (Abdelhamid et al, 1996).

Two types of FH have been described, type I and type II (Mulatero et al, 2004). FH type I, also known as glucocorticoid-remediable aldosteronism, is an autosomal-dominant genetic disorder driven by the chimeric fusion of the promoter region of the 11β-hydroxylase gene (*CYP11B1*) and the coding region of the aldosterone synthase gene (*CYP11B2*). This combination results in aldosterone synthase activity being controlled by ACTH. Thus aldosterone is secreted according to the circadian rhythm of ACTH instead of the RAAS (Lifton et al, 1992). Patients with FH type I will often have early-onset refractory hypertension and a family history of early onset hypertension or cerebral vascular accidents (Litchfield et al, 1998; McMahon and Dluhy, 2004). FH type II is a genetically heterogeneous disease with an autosomal-dominant inheritance pattern. Effected families will demonstrate either idiopathic hyperplasia or aldosterone-producing adenomas that are clinically and morphologically indistinguishable from sporadic cases of primary aldosteronism. Linkage analysis suggests that mutations in the 7p22 region are responsible for FH type II in some families (Mulatero et al, 2004; So et al, 2005).

Clinical Characteristics. The diagnosis of primary aldosteronism is usually made during the third to sixth decades of life. There are no specific symptoms of primary aldosteronism with the vast majority of patients being diagnosed during the evaluation of hypertension. The degree of hypertension is typically graded as moderate to severe with the mean blood pressure of 184/112 noted in a retrospective series of 262 patients with primary aldosteronism (Young and Klee, 1988). In the prospective series by Rossi and colleagues (2006a), which evaluated the prevalence of primary aldosteronism in 1125 newly diagnosed hypertensive patients, the mean blood pressure (154/98) was significantly higher than in patients without primary aldosteronism (147/95) (Rossi et al, 2006a). The association between primary aldosteronism and the severity of hypertension has been demonstrated by Mosso and colleagues (2003), who noted a 2%, 8%, and 13% prevalence of primary aldosteronism in hypertensive patients stratified by stage 1 (140 to 159/90 to 99), stage 2 (160 to 179/100 to 109), and stage 3 (>180/>110) hypertension, respectively.

Although hypokalemia has been classically described as a common finding in primary aldosteronism, in contemporary

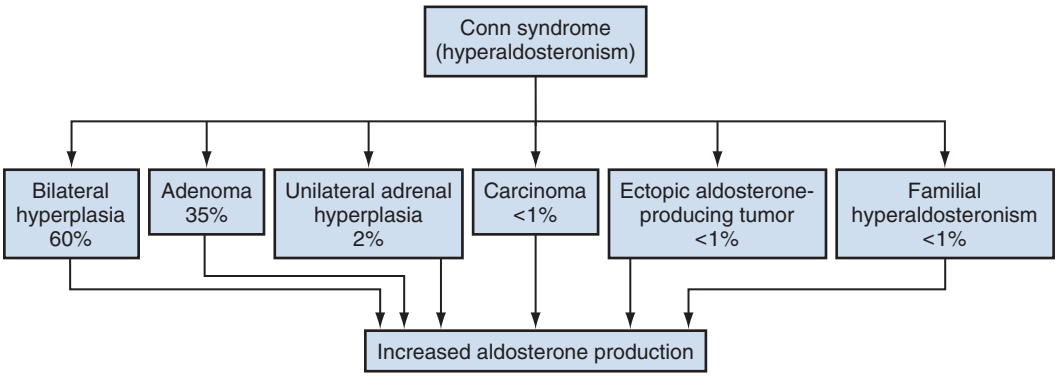

Figure 57–12. Subtypes of primary aldosteronism. (Adapted from Young WF. Primary aldosteronism: renaissance of a syndrome. Clin Endocrinol [Oxf] 2007;66:607–18.)

series, between 63% and 91% of newly diagnosed patients are normokalemic at the time of diagnosis (Mulatero et al, 2004). In a minority of patients, hypokalemia is associated with symptoms including headaches, polydipsia, palpitations, polyuria, nocturia, and muscle weakness (Young, 2007a). Due to mineralocorticoid escape, hypernatremia is an uncommon finding in primary aldosteronism with serum sodium levels similar to other forms of hypertension (Rossi et al, 2006a; Young, 2007a).

Cardiovascular and renal damage is a concern for all patients with hypertension and underlies the need for treatment. The incidence and severity of target organ damage appears to be increased in patients with primary aldosteronism compared with other forms of hypertension. Cardiac abnormalities, including left ventricular filling and diastolic dysfunction, increased left ventricular mass measurement, and prolonged QP interval have all been associated with primary aldosteronism (Rossi et al, 1996; Tanabe et al, 1997). These findings may help to explain the significant increase of cardiovascular events noted in patients with primary aldosteronism by Milliez and colleagues. In a retrospective series of 589 patients with hypertension, patients with primary aldosteronism were 4 times more likely to be diagnosed with a stroke, 6.5 times more likely to be diagnosed with a myocardial infarction, and 12 times more likely to be diagnosed with atrial fibrillation compared with patients with essential hypertension (Milliez et al, 2005; Gonzaga and Calhoun, 2008). The increased risk of cardiovascular disease may be associated with the increased prevalence of metabolic syndrome that has been noted in this patient population (Fallo et al, 2006). Additionally, patients with primary aldosteronism demonstrate increased rates of proteinuria when compared with patients with essential hypertension (Fox et al, 2006; Rossi et al, 2006b).

Diagnostic Tests. The diagnosis of primary aldosteronism is made in a systematic fashion and involves screening, confirmatory testing, and subtype differentiation. Indications for screening are listed in Table 57–7. The accurate diagnosis of primary aldosteronism and subtype differentiation is critical due to the associated increased risk of target organ damage and the potential of surgical cure in appropriately selected patients.

Screening. Prior to initiating screening, hypokalemia should be corrected and all contraindicated medications discontinued. Although patients can continue the majority of antihypertensive agents during screening, mineralocorticoid receptor antagonists are contraindicated and should be stopped at least 6 weeks prior to testing (Seifarth et al, 2002; Young, 2007a). Patients requiring these agents for control of severe hypertension should be transitioned to agents, such as α_1-receptor blockers or long-acting calcium channel blockers, with minimal effects on screening test results (Rossi et al, 2008a). Other antihypertensive agents can alter screening values, but not to the extent that mandates their discontinuation (see Fig. 57–32).

Screening for primary aldosteronism begins by obtaining a morning (between 8 and 10 AM) plasma aldosterone concentration (PAC) and plasma renin activity (PRA) (Funder et al, 2008). From these tests, the PAC and aldosterone to renin ratio are used to screen for autonomous aldosterone secretion. Whereas the aldosterone to renin ratio is dependent on PRA, it is recommended that the lowest PRA value be set at 0.2 ng/mL/hr to avoid falsely elevated ratios (Rossi et al, 2006a). The plasma aldosterone concentrations and aldosterone to renin ratios that define a positive screen and suggest the diagnosis of primary aldosteronism are subject to laboratory variability, thus standard thresholds have not been established. The National Institutes of Health (NIH) Consensus Statement (2002) on the management of the clinically inapparent adrenal mass suggests cutoffs of greater than 30 for the aldosterone to renin ratio and greater than 20 ng/dL for the plasma aldosterone concentrations. However, other institutions have recommended lowering the cutoffs to greater than 20 and greater than 15 ng/dL, respectively (Young, 2007a; Rossi et al, 2008a). Although lowering the thresholds for a positive screening test may increase the rate of false-positive results, all positive tests must be confirmed with further testing prior to making the diagnosis of primary aldosteronism.

Measurement of PRA can be time consuming and varies between different laboratories. For this reason, plasma renin concentration has been evaluated as a possible replacement for PRA in screening for primary aldosteronism (Ferrari et al, 2004; Perschel et al, 2004). Although initial series evaluating the utility of plasma renin concentration in primary aldosteronism screening have demonstrated promise, these findings require further standardization and validation prior to the widespread use (Young, 2007a; Rossi et al, 2008b).

Confirmatory Testing. Following a positive screening test, a confirmatory test must be performed prior to securing the diagnosis of primary aldosteronism. Of the patients with positive screening tests, only 50% to 70% will be diagnosed with primary aldosteronism on confirmatory testing (Mosso et al, 2003; Seiler et al, 2004; Giacchetti et al, 2006). As with screening for primary aldosteronism, proper patient preparation is required with the correction of hypokalemia and discontinuation of mineralocorticoid receptor antagonists. Of the confirmatory tests available, three evaluate for the suppression of aldosterone following sodium loading, and one evaluates for the suppression of the aldosterone to renin ratio following the administration of an angiotensin-converting enzyme inhibitor. The underlying theory behind the sodium loading tests is that loading will decrease plasma renin and aldosterone production in patients without autonomous aldosterone secretion (Mattsson and Young, 2006). The selection of the confirmatory test used depends on individual patient characteristics and physician preferences. Blood pressure should be monitored closely in all patients during confirmatory testing.

The fludrocortisone suppression test requires the administration of the synthetic mineralocorticoid fludrocortisone (0.1 mg every 6 hours) and sodium chloride (2 g every 8 hours) for 4 days. Following 4 days of fludrocortisone and sodium loading, plasma aldosterone concentrations are measured in the upright position. Failure to suppress plasma aldosterone concentrations to less than 6 ng/dL is diagnostic of primary aldosteronism. Once considered the gold standard in the diagnosis of primary aldosteronism, the fludrocortisone suppression test has been supplanted by the oral sodium loading test and the intravenous infusion test due to the

Table 57–7.

Indications for Primary Aldosterone Screening

Hypertension with hypokalemia
Resistant hypertension (three or more oral agents with poor control)
Adrenal incidentaloma with hypertension
Early-onset hypertension (<20) or stroke (<50 years)
Severe hypertension (≥160/≥110)
Whenever considering secondary causes of hypertension (i.e., pheochromocytoma or renovascular disease)
Unexplained hypokalemia (spontaneous or diuretic induced)
Evidence of target organ damage disproportionate to degree of hypertension

risks of severe hypertension and hypokalemia (Schirpenbach and Reincke, 2007).

The oral sodium loading test is conducted by administering a high-sodium diet for 3 days, followed by 24-hour urine measurements of aldosterone, sodium, and creatinine. Supplemental sodium chloride can be given to ensure the intake of at least 12.8 g of sodium per day. Twenty-four-hour sodium should be greater than 200 mmol to ensure adequate sodium loading. The diagnosis of primary aldosteronism is then made when the 24-hour aldosterone is greater than 12 µg per day.

The intravenous saline infusion test spares the patient from several days of sodium loading by the administration of 2 L of 0.9% sodium chloride intravenously over 4 hours. The infusion is performed in the morning after an overnight fast, while the patient is in a recumbent position. Following the intravenous infusion of saline, plasma aldosterone concentrations are measured, with a level of greater than 5 ng/dL being diagnostic of primary aldosteronism, and levels greater than 10 ng/dL are suggestive of aldosterone-producing adenomas (Mulatero et al, 2005; Young, 2007a).

The captopril suppression test is performed by administering 25 to 50 mg of the angiotensin-converting enzyme inhibitor captopril, followed by the measurement of plasma aldosterone concentrations while the patient remains recumbent. Suppression of the RAAS should be noted in patients without primary aldosteronism following the acute administration of captopril, while those with autonomous aldosterone secretion will have persistently elevated plasma aldosterone concentrations greater than 15 ng/dL (Young and Klee, 1988). Further standardization and validation of the captopril suppression test is needed before it is used routinely to confirm the diagnosis of primary aldosteronism when sodium loading tests are available. At this time, the captopril suppression is recommended for patients with cardiac and renal disease, which prohibits sodium loading (Giacchetti et al, 2008).

Subtype Differentiation. Following the diagnosis of primary aldosteronism, attention is then paid to defining the etiology of autonomous aldosterone secretion. Subtype differentiation of primary aldosteronism is essential in selecting the appropriate therapy, because surgical therapy is only successful for select subtypes (Table 57–8). **In patients who are not surgical candidates, subtype differentiation is of little consequence because medical therapy will be instituted; thus these patients can forgo further evaluation, and medical management can be initiated** (Fig. 57–13). **Given the rarity of FH type I, genetic screening should not be performed in all patients. However, patients with a family history of primary aldosteronism, early age of onset (<20 years), or patients with a family history of cerebral vascular accidents at a young age should be considered for genetic testing** (Fig. 57–14). An adrenal CT scan should be obtained in

Table 57–8.

Subtypes of Primary Aldosteronism

SURGICALLY CORRECTABLE	NOT CORRECTABLE BY SURGERY
Aldosterone-producing adenoma	Bilateral adrenal hyperplasia
Primary unilateral adrenal hyperplasia	Familial hyperaldosteronism type I
Ovarian aldosterone-secreting tumor	Familial hyperaldosteronism type II
Aldosterone-producing carcinoma	

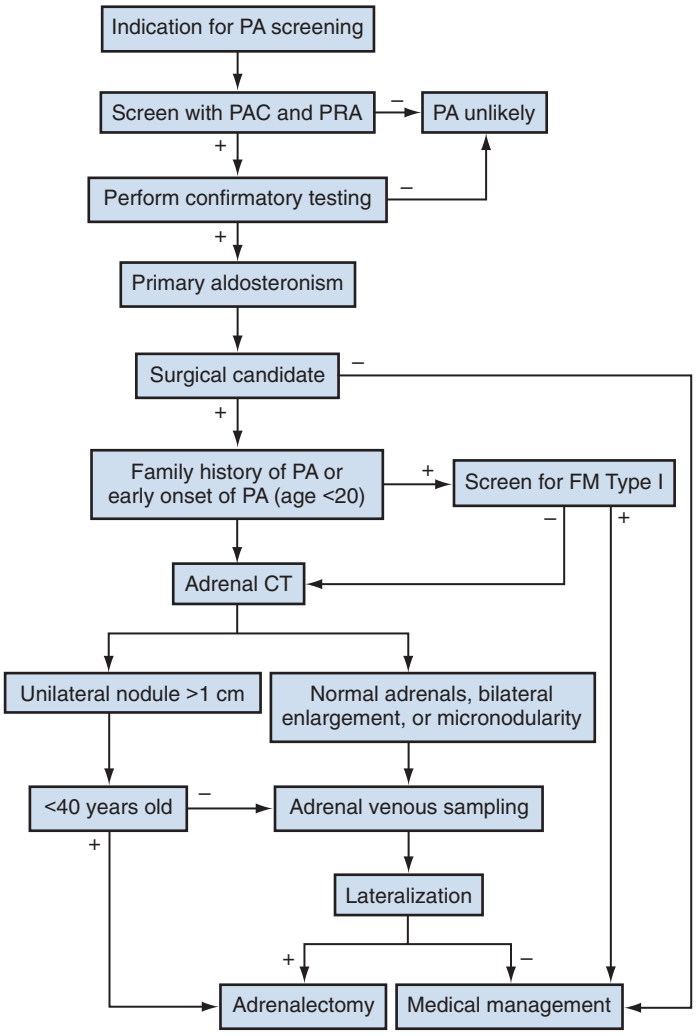

Figure 57–13. Primary aldosteronism diagnosis and treatment algorithm. CT, computed tomography; FM, familial hyperaldosteronism; PA, primary aldosteronism; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

all patients with primary aldosteronism who are potential surgical candidates.

Although imperfect in delineating the subtype of primary aldosteronism, an adrenal CT scan should be obtained to evaluate for the presence of adrenal nodules. Radiographic characteristics of aldosterone-producing adenomas include the presence of a unilateral low-density non-enhancing lesion of less than 10 Hounsfield units (HU), with an average size of 1.6 to 1.8 cm and a normal-appearing contralateral adrenal gland. However, given that approximately 20% of aldosterone-producing adenomas will be less than 1 cm in size, lateralization is not based on CT findings alone (Simon and Palese, 2008). Radiographic characteristics of idiopathic hyperplasia can include the presence of multiple unilateral or bilateral adrenal nodules, bilateral adrenal enlargement with increased limb size, or the presence of normal-appearing glands. The combination of the small-size, aldosterone-producing adenomas, and the potential for the presence of nonfunctional adrenal adenomas makes CT imaging flawed in delineating lateralization of aldosterone hypersecretion. Because MRI does not offer an advantage in delineating primary aldosteronism subtypes, and is associated with increased cost, routine use is not currently recommended.

To establish lateralization of aldosterone secretion in surgical candidates, adrenal vein sampling should be performed. By establishing lateralization, one can differentiate between subtypes of primary aldosteronism and identify patients in which adrenalectomy is potentially beneficial. **The value of adrenal vein sampling in evaluating the presence of lateralized aldosterone secretion was illustrated by** Young and colleagues (2004), **who noted that 22% of patients would have been incorrectly excluded from adrenalectomy, and 25% would have been inappropriately recommended to undergo adrenalectomy based on CT findings instead of adrenal vein sampling studies.** As with all other evaluations performed for primary aldosteronism, proper patient selection, patient preparation, and an accurate interpretation of results are essential (Young and Stanson, 2009). A decision-making strategy when performing adrenal vein sampling is depicted in Figure 57–15.

After appropriate patient selection, adrenal vein sampling is performed in the morning after an overnight fast. Percutaneous access to the femoral vein is obtained, and catheter tips are positioned to collect samples from three sites: the right adrenal vein, left adrenal vein, and inferior vena cava (IVC) (see Fig. 57–15A). Samples are then evaluated for aldosterone and cortisol concentrations. Appropriate specimen collection from the adrenal vein is determined by comparing the cortisol concentrations from the adrenal vein samples to the cortisol concentration from the IVC sample, which should be less. The ratio of adrenal vein cortisol to IVC cortisol should be greater than 1.1 : 1 to 5 : 1, depending upon the use of ACTH stimulation (Young and Stanson, 2009). If ACTH stimulation is used, a higher ratio is expected in properly collected samples. Adrenal vein sampling that demonstrates adrenal vein to IVC ratios below the cutoff, on either side, should be considered "nonselective" and discarded. An adrenal vein to IVC ratio above the cutoff, bilaterally, is considered "selective," and comparisons between aldosterone concentrations can be made to determine the presence of lateralization.

Lateralization of aldosterone secretion is determined by comparing the aldosterone to cortisol ratios of the dominant to

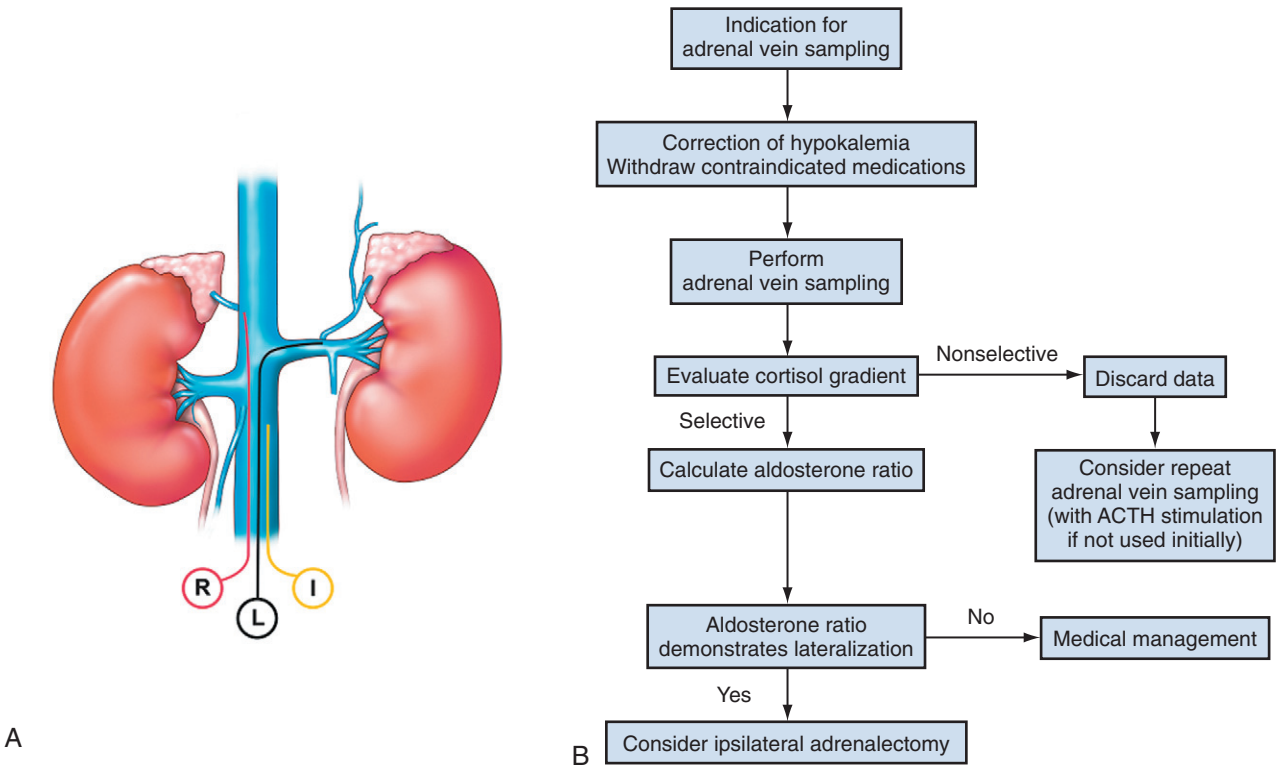

Figure 57–15. Adrenal vein sampling protocol. **A,** Proper catheter positioning for sampling R, right adrenal vein sample; L, left adrenal vein sample; I, inferior vena cava (IVC) sample. **B,** Following sample collection, the cortisol gradient is evaluated using the ratios $R_{cortisol}/I_{cortisol}$ and $L_{cortisol}/I_{cortisol}$. If the cortisol gradients confirm appropriate sample collection, lateralization of aldosterone secretion can be evaluated. Lateralization of aldosterone secretion is determined by the ratio of aldosterone secretion of the dominant to the nondominant adrenal gland while correcting for ipsilateral cortisol secretion using the formula $(A_{dominant}/C_{dominant})/(A_{nondominant}/C_{nondominant})$, where A = plasma aldosterone concentration [PAC] and C = cortisol. ACTH, adrenocorticotropic hormone.

nondominant sides using the formula $(A_{dominant}/C_{dominant})/(A_{nondominant}/C_{nondominant})$. Aldosterone secretion is considered to be lateralized if the ratio is greater than 2 to 4:1, depending on the use of ACTH stimulation (Rossi et al, 2008a; Young and Stanson, 2009). When performed and interpreted correctly, adrenal vein sampling has a sensitivity of 95% and specificity of 100% in detecting lateralized autonomous aldosterone secretion (Young et al, 2004).

The routine use of ACTH stimulation during adrenal vein sampling is controversial. Potential advantages of ACTH stimulation include minimizing stress-induced fluctuations in aldosterone secretion, maximizing the cortisol gradient, and maximizing the aldosterone secretion from aldosterone-producing adenomas (Young, 2007a; Young and Stanson, 2009). In a prospective study investigating these potential benefits, ACTH stimulation was noted to facilitate the ascertainment of proper specimen collection when evaluating the cortisol gradient between adrenal and IVC specimens. However, the authors also noted that ACTH stimulation was also associated with a small risk (3% to 12%) of incorrectly assigning the side of lateralization of aldosterone-producing adenomas, and a moderate risk (36% to 37%) of incorrectly classifying aldosterone-producing adenomas as idiopathic hyperplasia (Seccia et al, 2009).

When adrenal vein sampling is inconclusive due to sampling error, alternative studies are available that may help guide treatment decisions, including nuclear scintigraphy, postural stimulation testing, and measurement of cortisol metabolites. Of these modalities, only nuclear scintigraphy can provide both functional and anatomic data, which is necessary when considering surgical intervention.

^{131}I-6β-iodomethyl-norcholesterol (NP59) is a cortisol analog that can label adrenal cortical cells in order to evaluate for areas of hypersecretion (Heinz-Peer et al, 2007). Prior to injection of the radiotracer, saturated potassium iodine (Lugol solution) is administered to protect the thyroid from uptake of free ^{131}I. Additionally suppression of ACTH with dexamethasone (1 mg every 6 hours for 7 days) is necessary. Evaluation of radiotracer uptake is begun 4 days after NP59 injection and may continue through day 10. Characteristics that suggest the presence of aldosterone-producing adenomas include unilateral uptake of radiotracer less than 5 days after injection, while bilateral uptake is suggestive of idiopathic hyperplasia (Simon and Palese, 2008). The ability to detect a hyperfunctioning adenoma using NP59 is directly proportional to the tumor size and function, with a diminished ability to detect lesions less than 1.5 cm in size (Hogan et al, 1976; Nomura et al, 1990; Mansoor et al, 2002).

The posture stimulation test is designed to distinguish between aldosterone-producing adenomas and idiopathic hyperplasia based on changes in plasma aldosterone concentration levels in response to changes in posture. The test is performed by comparing plasma aldosterone concentration levels after the patient has been recumbent overnight, and again after 4 hours of being upright. In theory, the increase of angiotensin induced with being upright leads to an increase of plasma aldosterone concentration in normal patients that is two- to fourfold greater when compared with recumbent levels. In comparison, patients with idiopathic hyperplasia will demonstrate an increase of at least 33% over baseline, while patients with aldosterone-producing adenomas or FH type I will not demonstrate an increase of plasma aldosterone concentration levels with changes in posture (Ganguly et al, 1973; Young, 2007a). Although the test can be helpful in distinguishing between aldosterone-producing adenomas and idiopathic hyperplasia, it does not provide information regarding the location of the adenoma (right vs. left). Additionally, the reliability of the posture stimulation test is limited by the observation that 30% to 50% of aldosterone-producing adenomas demonstrate an increase of plasma aldosterone concentration, while 20% of idiopathic hyperplasia patients do not demonstrate any elevation with postural changes (Mulatero et al, 2004; Schirpenbach and Reincke, 2007).

Another potential method for differentiating aldosterone-producing adenomas from idiopathic hyperplasia is the measurement of 18-hydroxycortisone (18-OH-B). 18-OH-B is formed by the 18-hydroxylation of corticosterone and may be the immediate precursor of aldosterone. Elevated 18-OH-B (>100 ng/dL) suggests an aldosterone-producing adenoma, while levels of less than 100 ng/dL suggest idiopathic hyperplasia (Biglieri and Schambelan, 1979). However, the accuracy of this test in distinguishing aldosterone production from an adenoma versus hyperplasia is thought to be less than 80%. Additionally, the test does not provide information about tumor location (right vs. left) in cases of functional adenomas (Young and Klee, 1988).

Treatment and Prognosis. The goal of treatment in primary aldosteronism is to control and prevent the morbidity associated with mineralocorticoid access. Therefore the treatment strategies used in therapy aim to remove the source of mineralocorticoid access or block the effect of aldosterone on target organs (Young, 2007a). Treatment strategies for primary aldosteronism are primarily dependent on subtype classification and surgical candidacy (see Fig. 57–13). Patients who are acceptable surgical candidates and have been diagnosed with a surgically correctable subtype of primary aldosteronism can be offered unilateral adrenalectomy, while other patients can be managed effectively with medical therapy.

In patients with confirmed lateralizing aldosterone secretion, adrenalectomy should be considered. Given the small size of aldosterone-producing adenomas, the majority of patients are candidates for a laparoscopic adrenalectomy. In patients suspected of having hypersecretion of aldosterone associated with adrenal cortical carcinoma, an open procedure may be recommended (Kebebew et al, 2002; Gonzalez et al, 2005; Schlamp et al, 2007). **Improvements in blood pressure are noted in the majority of patients undergoing adrenalectomy for primary aldosteronism, with 33% to 73% of patients not requiring antihypertensives postoperatively** (Sawka et al, 2001; Meyer et al, 2005; Schirpenbach and Reincke, 2007). Several predictors of persistent hypertension following adrenalectomy for primary aldosteronism have been described, including age greater than 50 years, the use of two or more antihypertensive agents preoperatively, having a first-degree relative with hypertension, prolonged duration of hypertension prior to adrenalectomy, and renal insufficiency (Celen et al, 1996; Sawka et al, 2001). In patients less than 40 years of age with a unilateral adenoma greater than 1 cm, a unilateral adrenalectomy can be performed without adrenal vein sampling due to the rarity of incidental adenomas in this population (Schirpenbach and Reincke, 2007; Young, 2007a; Zarnegar et al, 2008). In the immediate postoperative period, plasma aldosterone concentration and aldosterone to renin ratios should be evaluated to ensure biochemical cure. Additionally, patients should maintain a high-sodium diet and be monitored for hyperkalemia for several weeks following surgery (Mattsson and Young, 2006; Funder et al, 2008).

Medical treatment of primary aldosteronism is indicated in patients with nonsurgically correctable subtypes and those who are not surgical candidates. **Aldosterone receptor antagonists, spironolactone and eplerenone, are successful in**

lowering the blood pressure and are the antihypertensive agents of choice in patients with primary aldosteronism. Spironolactone therapy is initiated at doses of 25 to 50 mg per day and can be titrated up to 400 mg per day, depending on blood pressure, serum potassium levels, and side effects. Side effects of spironolactone include gynecomastia, impotence, and menstrual disturbances. Eplerenone may provide a more favorable side-effect profile compared with spironolactone, due to increased selectivity for the aldosterone receptor. Treatment should be initiated with 25 mg twice per day and titrated up to 100 mg per day. Despite treatment with an aldosterone receptor antagonist, other antihypertensive agents will often be needed. Additionally, several lifestyle modifications may contribute to the success of medical therapy, including weight loss, maintaining a low- sodium diet, and a regular exercise program (Young, 2007a).

Unlike other forms of primary aldosteronism, FM type I can be treated with oral glucocorticoids. Glucocorticoid administration will reduce ACTH release, leading to decreased aldosterone production in this select group of patients. In FM type I patients whose blood pressure is not controlled with glucocorticoids alone, or those who develop iatrogenic Cushing syndrome, the addition of an aldosterone receptor antagonist should be considered (Funder et al, 2008).

Summary. Successful identification and treatment of primary aldosteronism is critical due to the increased risk of cardiovascular morbidity associated with the diagnosis. Because primary aldosteronism comprises several distinct subtypes that significantly impact management strategy, subtype differentiation is critical prior to surgical intervention.

Key Points: Primary Aldosteronism

- Most patients with primary aldosteronism in contemporary series are normokalemic.
- Primary aldosteronism is associated with an increased risk of end organ damage compared to essential hypertension.
- Accurate subtype differentiation is essential to ensure appropriate treatment of primary aldosteronism.

Pheochromocytoma

Introduction and Epidemiology. Pheochromocytoma is a tumor of the catecholamine-producing cells of the adrenal medulla. Approximately 1 to 2 per 100,000 individuals are diagnosed annually with pheochromocytoma, albeit reports on incidence vary (Bravo and Tagle, 2003). Given its rarity, it is estimated that pheochromocytoma is responsible for only approximately 0.5% of cases of hypertension (Lenders et al, 2005). **Among patients with incidental adrenal masses, approximately 5% will have a pheochromocytoma** (Mantero et al, 2000; Young, 2000). Indeed, incidentally discovered lesions now account for 10% to 25% of all pheochromocytomas diagnoses (Bravo and Tagle, 2003; Lenders et al, 2005).

Some 1% to 25% of pheochromocytomas originate outside of the adrenal gland (Fig. 57–16). These extra-adrenal pheochromocytomas are known as paragangliomas, because they arise from paraganglia, a network of chromaffin-producing neural crest tissue that anatomically parallels the sympathetic and parasympathetic ganglia (Scott et al, 1990; Ilias and Pacak, 2004). Paragangliomas can arise in the head, neck, thorax, abdomen, and pelvis (including bladder). The chromaffin bodies that lie between the aortic bifurcation and the root of the inferior mesenteric artery are known as the organ of Zuckerkandl, and are a common site for paragangliomas (Scott et al, 1990). Of note, some authors reserve the term paraganglioma for tumors only in the head and neck, locations where extra-adrenal pheochromocytomas tend to be nonfunctional (Neumann et al, 2004).

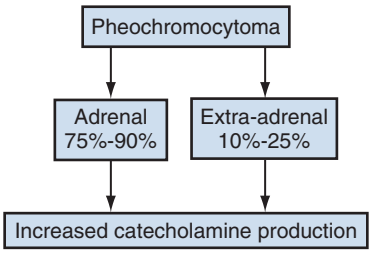

Figure 57–16. Causes of excess catecholamines.

Pathophysiology

Overview. As discussed in the Adrenal Physiology section, cells of the adrenal medulla are analogous to the chromaffin cells of the sympathetic ganglia. Unlike sympathetic ganglia cells, however, cells of the adrenal medulla, and therefore of adrenal pheochromocytomas, possess the enzyme phenylethanolamine-*N*-methyl transferase (PNMT), which gives them the ability to synthesize epinephrine from norepinephrine (Eisenhofer et al, 2004b). Pheochromocytomas vary in their enzymatic composition and in their ability to self-metabolize the catecholamines within each tumor's secretory vesicles. Therefore there is great variability in the amount and ratio of catecholamines secreted by pheochromocytomas (Eisenhofer et al, 2001). Indeed these differences in norepinephrine, epinephrine, and dopamine secretion explain the heterogeneity in clinical behavior of pheochromocytomas. For instance, patients with the rare tumors that secrete primarily epinephrine (usually limited to those that arise from the adrenals or from the organ of Zuckerkandl), tend to experience syncopal or hypotensive episodes due to epinephrine's vasodilatory action through the β_2 receptor, while those patients with predominantly norepinephrine-secreting tumors (e.g., patients with von Hippel–Lindau syndrome [VHL]) present with hypertension and sweating, given the compound's affinity for the vasoconstricting α-adrenoreceptor (Pacak, 2007).

Pathophysiology of Hereditary Pheochromocytoma. Familial cases account for nearly one third of pheochromocytomas (Benn and Robinson, 2006). **Indeed, a significant percentage of cases that initially appear sporadic are later deemed hereditary upon genetic testing. In a 2002 report, Neumann and colleagues** (2002) **demonstrated that 24% of patients (*n* = 271) who presented with isolated pheochromocytoma and lacked any significant family history exhibited a germ-line mutation that predisposed them to the disease.** At least five genes—*RE*arranged *T*ransfection proto-oncogene *(RET)*, von Hippel–Lindau *(VHL)*, neurofibromatosis type 1 *(NF1)*, and mitochondrial succinate dehydrogenase subunits D and B genes *(SDHD, SDHB)*, are now associated with familial pheochromocytomas. Some investigators believe that these genetic abnormalities all modulate neuronal apoptosis and are related through signal transduction pathways downstream from the nerve growth factor (NGF) (Nakamura and Kaelin, 2006). Nevertheless, the phenotypes produced by each gene mutation are quite diverse. Table 57–9 summarizes the clinical features associated with each gene mutation.

In general urologic practice, VHL is the most relevant syndrome associated with pheochromocytoma, because these patients

Table 57–9.

Hereditary Forms of Pheochromocytoma

SYNDROME	CLINICAL CHARACTERISTICS	RISK OF PHEOCHROMOCYTOMA	GENE	CHROMOSOME/ INHERITANCE	PROTEIN	% GERM-LINE MUTATION IN APPARENTLY SPORADIC CASES	RATE OF MALIGNANT DISEASE
Multiple endocrine neoplasia type 2A	• Medullary cancer of thyroid • Hyperparathyroidism • Cutaneous lichen • Amyloidosis	50%	*RET*	10q11.2 Autosomal dominant	Tyrosine kinase receptor	<5	3
Multiple endocrine neoplasia type 2B	• Medullary cancer of thyroid • Multiple neuromas • Marfanoid body habitus • Rare hyperparathyroidism	50%	*RET*	10q11.2 Autosomal dominant	Tyrosine kinase receptor	<5	3
von Hippel-Lindau syndrome type 2	• Renal cell carcinomas and renal cysts • CNS and retinal hemangioblastomas • Pancreatic cysts • Epididymal cystadenomas • Endolymphatic cyst tumors	10%-20%	*VHL*	3p25.26 Autosomal dominant	pVHL19 pVHL30	2-11	5
Neurofibromatosis type 1	• Neurofibromas • Café-au-lait skin spots	1%	*NF1*	17q11.2 Autosomal dominant	Neurofibromin	Unknown	11

Data from Dluhy RG. Pheochromocytoma—death of an axiom. N Engl J Med 2002;346(19):1486–8; and Lenders JW, Eisenhofer G, Mannelli M, Pacak K. Phaeochromocytoma. Lancet 2005;366(9486):665–75.

usually are already under urologic care due to their propensity to develop renal cell carcinoma (RCC). Patients with VHL and no family history of pheochromocytoma are classified as having the type 1 variant of the syndrome, while type 2 patients are those who carry a family history of pheochromocytoma. Additionally, the type 2 variant of VHL is further subdivided. Type 2A patients are those with concomitant RCC, and type 2B patients are those who do not exhibit evidence of renal malignancy (Walther et al, 1999). A type 2C variant is defined as patients with pheochromocytoma in the setting of a VHL mutation, but no other stigmata of the VHL syndrome (Hes et al, 2003). Interestingly, a genotype phenotype has been established with VHL-associated pheochromocytomas (type 2), whereby these patients are more likely to exhibit a missense mutation of the VHL gene (Walther et al, 1999). Whereas VHL type 2C patients appear to maintain HIF regulation, pheochromocytoma pathogenesis may occur through HIF-independent pathways (Nakamura and Kaelin, 2006). Furthermore, pheochromocytomas in patients with VHL, unlike those in cases of sporadic or multiple endocrine neoplasia 2 (MEN2)-related disease, tend to produce less epinephrine. As a result, metanephrine (but not normetanephrine) levels in these patients are nearly always normal (Eisenhofer et al, 1999; Walther et al, 1999; Pacak, 2007).

Pathophysiology of Malignant Pheochromocytoma. Malignant pheochromocytoma is an aggressive life-threatening neoplasm. **Currently, malignancy can only be defined by the presence of clinical metastases. Pathologic appearance and even local invasion are of only limited value in determining metastatic potential of a given lesion** (Scholz et al, 2007). A number of pathologic criteria to differentiate benign from malignant disease have been proposed, but, to date, there is no single histologic criterion agreed upon (Thompson, 2002; Kimura et al, 2005; Pacak et al, 2007; Scholz et al, 2007). Some pathologic criteria employ immunohistochemical strategies including Ki-67 staining, which may be the best indicator of malignancy thus far; although, it has not yet been validated due to methodologic heterogeneity (Kimura et al, 2005; Pacak et al, 2007).

Malignant pheochromocytoma in patients with MEN-2 and VHL is exceedingly rare (see Table 57–9). The *SDHB* mutation is the single genetic abnormality most strongly associated with malignancy. In one international series, 11 of 32 patients with this mutation exhibited clinically malignant pheochromocytoma (Neumann et al, 2004).

Clinical Characteristics

Overview. **Classically, pheochromocytoma has been called the "10% tumor": 10% extra-adrenal, 10% familial, 10% bilateral, 10% pediatric, and 10% malignant** (Scott et al, 1990; Dluhy, 2002; Lenders et al, 2005). **However, this rule has been challenged repeatedly. As already mentioned, up to 25% of pheochromocytomas can be extra-adrenal** (Ilias and Pacak, 2004). **Similarly, familial cases account for up to 30% of tumors at presentation** (Benn and Robinson, 2006). **Malignancy is rare in both sporadic cases of adrenal pheochromocytoma (up to 5%) and in most cases of hereditary disease** (see Table 57–9). **However, for unclear reasons, it occurs in over one third of patients with extra-adrenal disease** (Lenders et al, 2005). **Nonhereditary cases of pheochromocytoma are most often diagnosed in the fourth and fifth decades of life, while familial tumors tend to occur at a younger age** (Lenders et al, 2005). Despite being uncommon, pediatric pheochromocytoma is the most frequently encountered endocrine neoplasm in children. Up to 40% of such tumors are familial, and over 20% are bilateral (Pacak et al, 2007; Havekes et al, 2009). For reasons that are unclear, tumors arising from the right adrenal are more common, tend to be larger, and recur more frequently than those that arise in the left gland (Amar et al, 2005b).

Paroxysmal hypertension is the classic presenting symptom in patients with pheochromocytoma. Nevertheless, such episodic spikes in blood pressure are only documented in approximately 30% to 50% of patients and can occur in the backdrop of baseline essential hypertension. The remainder of patients demonstrate persistently elevated blood pressure, and a minority are entirely normotensive (Scott et al, 1990). **The triad of headache, episodic sudden perspiration, and tachycardia is a classic hallmark of pheochromocytoma** (Bravo and Tagle, 2003). Table 57–10 lists common clinical signs and symptoms of pheochromocytoma. More than 20% of patients can be asymptomatic (Adler et al, 2008). Indeed, depending on the catecholamine milieu of each tumor, its ability to self-metabolize the catecholamine reserve, and the patient's varied response to catecholamine surges, symptomatology can drastically differ from patient to patient (Pacak, 2007). This heterogeneity in mode of presentation, symptomatology and difficulty in establishing firm diagnostic criteria for pheochromocytoma is illustrated by an autopsy series that includes 54 patients over 50 years from the Mayo Clinic, where more than 75% of tumors were not suspected prior to the patient's death (Sutton et al, 1981).

Clinical Characteristics of Hereditary Pheochromocytoma. Hereditary pheochromocytomas occur at a younger age and tend to be multifocal and/or bilateral at presentation (Adler et al, 2008). Table 57–9 summarizes the clinical features of each gene mutation. Pheochromocytomas in patients with MEN-2 nearly always arise from the adrenal gland, while tumors in patients with VHL and neurofibromatosis-1 (NF1) are outside the adrenal in approximately 12% and 6% of cases, respectively (Lairmore et al, 1993; Walther et al, 1999; Benn and Robinson, 2006; Karagiannis et al, 2007). *SDHB* and *SDHD* mutations mostly result in extra-adrenal and often multifocal phenotypes; nevertheless, solitary adrenal masses, as a result of these genetic abnormalities, may also arise (Neumann et al, 2004; Pacak et al, 2007). Unlike other hereditary forms of pheochromocytoma, mutations in the *SDHB* gene is associated with a very high risk of malignancy (Neumann et al, 2004). As mentioned previously, pheochromocytomas in patients with VHL mainly secrete norepinephrine and lack significantly

Table 57–10.

Clinical Manifestations of Pheochromocytoma

	FREQUENCY
Headache	60%-90%
Palpitations	50%-70%
Sweating	55%-75%
Pallor	40%-45%
Nausea	20%-40%
Flushing	10%-20%
Weight loss	20%-40%
Tiredness	25%-40%
Psychologic symptoms (anxiety, panic)	20%-40%
Sustained hypertension	50%-60%
Paroxysmal hypertension	30%
Orthostatic hypotension	10%-50%
Hyperglycemia	40%

elevated epinephrine secretion. As a result, normetanephrine, but not metanephrine, levels are elevated in these patients (Eisenhofer et al, 1999; Walther et al, 1999; Pacak, 2007).

Clinical Characteristics of Malignant Pheochromocytoma. Metastatic disease is much more common in extra-adrenal lesions (Scholz et al, 2007). The *SDHB* mutation is the one genetic abnormality that is strongly associated with metastatic disease (see Table 57–9). Classically, the majority of patients with an *SDHB* abnormality exhibit extra-adrenal disease; however, a significant proportion of patients (28% of patients in one series) have adrenal lesions at presentation (Neumann et al, 2004). Malignant lesions are more likely to exhibit elevated dopamine levels and tend to be larger (>5 cm); however, as mentioned previously, in the absence of metastatic deposits, a preclinical diagnosis of malignant potential is not possible (John et al, 1999; Lenders et al, 2005). Bone, lungs, liver, and lymph nodes constitute the most common sites of metastases (Scholz et al, 2007).

Metastatic pheochromocytoma can be present at diagnosis or be detected during surveillance after excision of the primary tumor. Most metastases are discovered within 5 years of the original diagnosis, but metastatic spread more than 15 years following initial excision has been reported (Eisenhofer et al, 2004a; Lenders et al, 2005).

Diagnostic Tests. Biochemical testing is the first step in the evaluation of patients suspected of pheochromocytoma. If metabolic testing is positive, appropriate imaging is undertaken to localize the source of the catecholamine excess (Adler et al, 2008). Timely and appropriate diagnosis of pheochromocytoma continues to be a clinical challenge (Zendron et al, 2004; Harding et al, 2005; Yu et al, 2009). In urologic practice, diagnosis of pheochromocytoma typically begins with the evaluation of an adrenal mass as a catecholamine hypersecreting lesion. Given the potentially catastrophic consequences of misdiagnosis, the possibility of pheochromocytoma must also be considered in patients with a known history of malignancy, and with a solitary adrenal mass in those whom a metastatic adrenal lesion is suspected (Weismann et al, 2006; Adler et al, 2007). Clinical evaluation depends on both radiographic imaging and, more importantly, on biochemical testing.

Imaging. Here we briefly discuss imaging of pheochromocytoma. Please refer to Imaging of Adrenal Masses section for further details on adrenal imaging.

CROSS-SECTIONAL IMAGING. On cross-sectional imaging, adrenal pheochromocytomas appear as well-circumscribed lesions. **Given their rich vascularity and low lipid content, pheochromocytomas typically measure an attenuation of greater than 10 HU on unenhanced CT (mean ≈35 HU). This property affords the ability to differentiate them from lipid-rich adenomas** (Motta-Ramirez et al, 2005). Furthermore, pheochromocytomas can be distinguished from lipid-poor adenomas using CT contrast washout strategies. Although nonspecific, pheochromocytomas, unlike adenomas, do not exhibit rapid contrast washout on delayed imaging (Szolar et al, 2005), rare examples of low-density pheochromocytomas that exhibit an unenhanced attenuation of less than 10 HU and demonstrate brisk contrast washout have been reported (Blake et al, 2003; Blake et al, 2005). Such examples, underscore the importance of a complete metabolic evaluation for every adrenal mass. In the past, iodinated intravenous (IV) contrast was believed to be a possible trigger for a hypertensive crisis. No evidence exists to support this misconception (Pacak, 2007).

Similar to CT, magnetic resonance imaging is an excellent imaging modality for characterizing adrenal lesions. Again, differentiation of pheochromocytoma from adenoma centers on an assessment of the lesion's lipid content. Unlike lipid-rich adenomas, pheochromocytomas do not exhibit signal dropout on out-of-phase sequences (Namimoto et al, 2001). Classically, bright signal intensity on T2-weighted imaging (best seen on fat suppression sequences)—termed the "light bulb" sign—was believed to be diagnostic for pheochromocytoma. It is now clear that this imaging characteristic is neither specific nor sensitive enough to secure a diagnosis and must be interpreted with caution (Varghese et al, 1997; Elsayes et al, 2005).

FUNCTIONAL IMAGING

METAIODOBENZYLGUANIDINE (MIBG) SCINTIGRAPHY

MIBG is a small-molecule analogue of norepinephrine. When tagged with either ^{131}I or ^{123}I, MIBG scintigraphy has been used since the 1980s to evaluate patients with pheochromocytoma. ^{123}I-MIBG, the preferred radiographic agent, affords a high sensitivity (83% to 100%) and superb specificity (95% to 100%) for identification of pheochromocytoma (Ilias and Pacak, 2004). Details regarding this imaging modality are discussed in the Imaging section. Here, we review clinical applications of MIBG.

MIBG is an integral part of a thorough workup for patients with extra-adrenal, metastatic, or recurrent pheochromocytoma. It is also often employed to localize diseases in patients with biochemical evidence of pheochromocytoma but negative cross-sectional imaging. Nevertheless, currently no consensus exists on the role of MIBG in the most common and urologically most relevant clinical scenario—a solitary adrenal mass on cross-sectional imaging in the setting of a biochemical evaluation indicative of pheochromocytoma (Pacak et al, 2007; Koch, 2009). Advocates for MIBG testing argue that in this context, MIBG affords the opportunity to verify that the mass in question is indeed a pheochromocytoma and that metastatic disease was not missed on cross-sectional imaging (Ilias and Pacak, 2004). Some clinical data, however, suggest that MIBG in this situation can safely be omitted, because it only serves to confirm what is already known and does not alter management (Miskulin et al, 2003; Bhatia et al, 2008; Greenblatt et al, 2008). Nevertheless, MIBG imaging for large (>5 cm) tumors is likely prudent in order to assess for presence of metastatic disease prior to surgery and thereby counsel the patient appropriately (Lenders et al, 2005). Rarely, MIBG scanning may also be employed in cases where metabolic workup of an adrenal mass reveals exclusive excess of norepinephrine and normetanephrine, but not epinephrine or metanephrine. In such unusual circumstances, MIBG can, at times, demonstrate that the actual functioning lesion is extra-adrenal (Pacak et al, 2007).

OTHER FUNCTIONAL IMAGING MODALITIES

Whole-body functional imaging with MIBG has its limitations. For instance, tumors in patients with *VHL* and *SDHB* gene mutations may exhibit cold MIBG scans (Timmers et al, 2007b; Havekes et al, 2008). Furthermore, aggressive metastatic lesions may lose their ability to accumulate MIBG (Havekes et al, 2008). As discussed under Imaging, several modalities using radiolabeled somatostatin analogues and PET radiopharmaceuticals have been developed to serve as alternatives to MIBG in these instances. Most have limited clinical utility; however, PET imaging with ^{18}F-dopamine has gained acceptance at some institutions (Timmers et al, 2007a). Furthermore, FDG-PET was recently shown as a useful clinical tool for patients with the *SDHB* mutation (Fig. 57–17) (Timmers et al, 2007b).

Biochemical Evaluation

OVERVIEW. Catecholamines and their metabolites, including metanephrines, are conjugated with a sulfate moiety in the

Test Characteristics for Diagnosis of Pheochromocytoma from a Large Multicenter Cohort Study (*n* = 858, 214 Patients with Pheochromocytoma and 644 Controls)

	Sensitivity, %		Specificity, %	
	Hereditary	Sporadic	Hereditary	Sporadic
Plasma-free metanephrines	97 (74/76)	99 (137/138)	96 (326/339)	82 (249/305)
Catecholamines	69 (52/75)	99 (126/137)	89 (303/339)	72 (220/304)
Urine-fractionated metanephrines	96 (26/27)	97 (76/78)	82 (237/288)	45 (73/164)
Catecholamines	79 (54/68)	91 (97/107)	96 (312/324)	75 (159/211)
Total metanephrines	60 (27/45)	88 (61/69)	97 (91/94)	89 (79/89)
Vanillylmandelic acid	46 (30/65)	77 (66/86)	99 (310/312)	86 (132/153)

From Lenders J, Pacak K, Walther M, et al. Biochemical diagnosis of pheochromocytoma: which test is best? J Am Med Assoc 2002;287(11):1427–34, Table 3.

bloodstream. The term "free" refers to compounds that are not conjugated and lack this sulfate group. In the past, assays that measured "total" amounts of catecholamine metabolites were employed. These assays were not able to discriminate between "free" and "sulfonated" compounds, and were largely inferior in their test characteristics compared with current methods (Eisenhofer et al, 2003a). Moreover, in the past, assays did not always distinguish compound subtypes and reported the aggregate level of catecholamines or metanephrines. Today, the term "fractionated" is used when the laboratory report details not only the amount of each compound type (e.g., metanephrines), but also the relative concentrations of each compound (e.g., normetanephrine and metanephrine) (Eisenhofer et al, 2004b) (Table 57–11).

CATECHOLAMINE TESTING. Catecholamines—dopamine, norepinephrine, and epinephrine—are produced by pheochromocytomas in varying amounts. Release of these compounds into the bloodstream is often paroxysmal. In the past, measurement of both urinary and serum catecholamine levels was the mainstay for evaluation of pheochromocytoma. Due to the sensitivity (≈85%) and specificity (≈85%) of these tests, this strategy has been largely replaced by measurements of levels of metanephrines—the methylated metabolites of catecholamines (Lenders et al, 2002; Lenders et al, 2005). Measurement of urinary catecholamines, nevertheless, is still recommended in conjunction with urinary–fractionated metanephrine testing (Young, 2007b).

METANEPHRINE TESTING. *O*-Methylation of catecholamines is catalyzed by the catechol-*O*-methyltransferase (COMT) enzyme. *O*-Methylation of norepinephrine produces normetanephrine, while epinephrine's methylation results in formation of metanephrine. Together normetanephrine and metanephrine are known as metanephrines (see Fig. 57–4) (Eisenhofer et al, 2001). Historically, formation of metanephrines was believed to take place by COMT in the liver and kidneys after catecholamines were released into the peripheral circulation by the tumor. Now it is clear that the vast majority of metanephrine synthesis occurs within the adrenal medulla and/or pheochromocytoma and only then do they enter the bloodstream (Eisenhofer et al, 1998; Eisenhofer et al, 2004b). **Because this conversion of catecholamines to metanephrines is an uninterrupted process within pheochromocytomas, measurement of plasma concentration of metanephrines is a much more sensitive means of tumor detection than the measurement of rises in plasma catecholamines, which may be paroxysmal** (Eisenhofer et al, 2003a, b). Today, measurement of metanephrine levels in plasma or urine represents the foundation for pheochromocytoma diagnosis and is extremely sensitive (Fig.

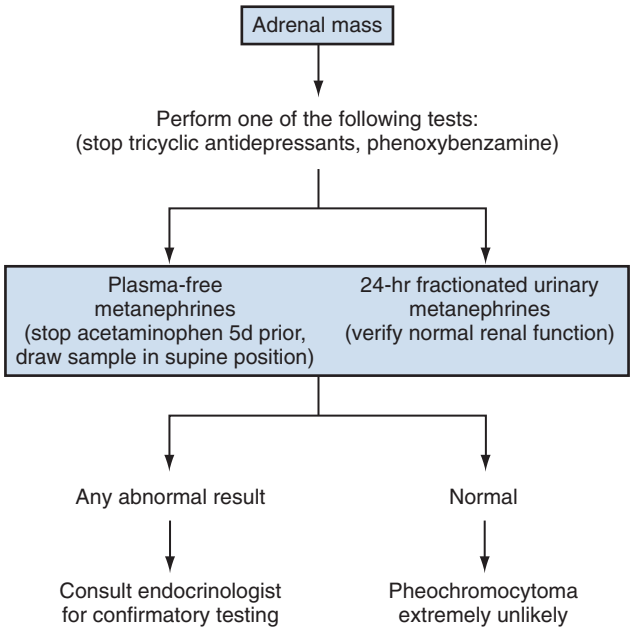

Figure 57–18. Testing algorithm to evaluate adrenal mass for catecholamine secretion.

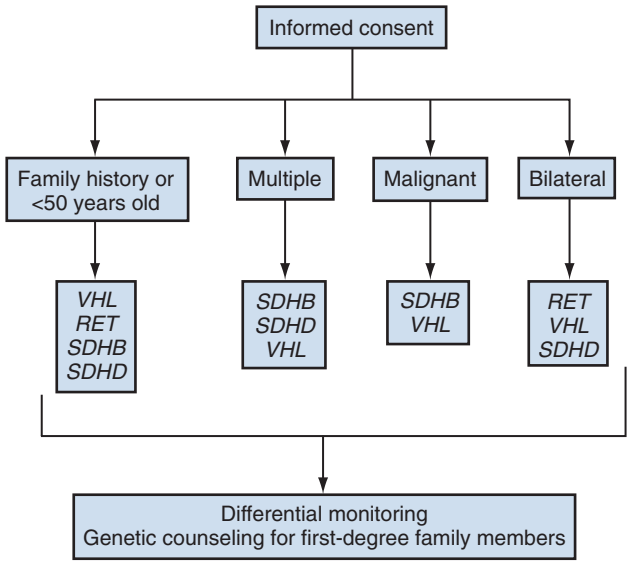

Figure 57–19. Algorithm for genetic screening of patients with pheochromocytoma with risk factors for hereditary disease. (From Pacak K. Preoperative management of the pheochromocytoma patient. J Clin Endocrinol Metab 2007;92:4069–79.)

57–18). Controversy exists regarding whether measurement of plasma-free metanephrines versus urinary–fractionated metanephrines should be used as the initial test (Lenders et al, 2002; Sawka et al, 2003; Young, 2007b; Eisenhofer et al, 2008). Please refer to the section Assessment of Function of Adrenal Masses: Testing for Catecholamine Hypersecretion for a complete discussion of the two testing strategies. Traditionally, when tests for fractionated urine or total metanephrines are ordered, urine catecholamine levels are also obtained (Eisenhofer et al, 2003a).

VMA TESTING. Because vanillylmandelic acid (VMA) is the primary end metabolite of catecholamines, its measurement in urine has long been used for diagnosis of pheochromocytoma. Nevertheless, synthesis of VMA requires deamination of catecholamines, or their metabolites, by the monoamine oxidase (MOA) enzyme, and occurs not only in the adrenal medulla but also in the sympathetic nervous system. Moreover, the sympathetic nervous system lacks the ability to produce epinephrine, due to the absence of the PNMT enzyme, and therefore only contributes to the serum level of normetanephrine (from norepinephrine) but not metanephrine (from epinephrine). Therefore the relative rise of VMA levels in the presence of a pheochromocytoma is much less dramatic than the rise seen in the levels of metanephrines, and the sensitivity of urine VMA levels is therefore low (below 65% in some series) (Lenders et al, 2005). However, the specificity of the test is high, especially in nonfamilial cases (99%) (Lenders et al, 2002).

CLONIDINE SUPPRESSION TESTING. Clonidine, an α_2 agonist, suppresses catecholamine (specifically norepinephrine) production by the sympathetic nervous system but not by pheochromocytoma. Comparison of normetanephrine levels before and after clonidine administration has been shown to yield results with favorable test characteristics (Eisenhofer et al, 2003b). This evaluation is suggested by some experts for secondary testing in patients with pheochromocytoma who exhibit mild or borderline elevations in metanephrine levels. When embarking on clonidine suppression testing, one must be cognizant that clonidine administration can result in significant hypotension in certain patients (Eisenhofer et al, 2003b).

CHROMOGRANIN A TESTING. Chromogranin A belongs to a group of compounds known as granins, which exist in the secretory vesicles of the neuroendocrine and the nervous systems. Elevation of serum chromogranin A levels has been documented in patients with pheochromocytoma. Although the sensitivity of the test for detecting pheochromocytoma is suboptimal (≈85%), some have suggested that chromogranin A–level evaluation has a role for confirmatory testing in patients who have mild or moderate (less than a fourfold) elevation in free-plasma metanephrine levels (Bravo and Tagle, 2003; Algeciras-Schimnich et al, 2008). Chromogranin A is renally cleared, and the specificity of the test decreases significantly in patients with glomerular filtration rates less than 80 mL/min (Bravo and Tagle, 2003).

Screening for Hereditary Pheochromocytoma. A hereditary pattern is responsible for more than one third of pheochromocytomas. Furthermore, nearly one quarter of patients who appear to have sporadic nonfamilial disease at diagnosis demonstrate germline mutations upon genetic testing (Neumann et al, 2002; Benn and Robinson, 2006). Despite this, the consensus of The First International Symposium on Pheochromocytoma in 2005 did not endorse universal genetic testing in all patients diagnosed with pheochromocytoma. Instead, this panel of experts established guidelines for screening and evaluation for pheochromocytoma. Figure 57–19 summarizes how clinical history and disease characteristics at presentation should guide genetic testing. Others have suggested similar algorithms (Amar et al, 2005a). All patients under age 50 deserve genetic testing for the *RET*, *VHL*, *SDHB*, and *SDHD* gene mutations (Pacak, 2007). Routine testing for the *NF1* gene is not recommended in patients who do not meet clinical criteria for neurofibromatosis (Plouin and Gimenez-Roqueplo, 2006b). Before initiating genetic testing, the patient should be counseled about implications and benefits of genetic testing. Professional genetic counseling is strongly recommended (Pacak, 2007).

Treatment

Overview. Pheochromocytoma is a surgical disease. Complete resection of the tumor is advised whenever possible (Khorram-Manesh et al, 2005). Laparoscopic adrenalectomy constitutes the

standard of care for most tumors; although open approaches have been advocated for large and/or surgically difficult tumors (Pacak et al, 2007). Please see Chapter 58 regarding surgical considerations when treating patients with pheochromocytoma. The urologist must be familiar with the peri-operative management of catecholamine-producing tumors before taking the patient to the operating room. Lifelong follow-up is necessary for all patients. Patients with familial and malignant disease require a tailored approach that should include cardiology, endocrinology, and, if needed, medical oncology.

Preoperative Management

OVERVIEW. Catecholamine release during intraoperative tumor manipulation can result in hazardous blood pressure elevation and cardiac arrhythmias. In the era before routine initiation of preoperative catecholamine blockade, some reported mortality rates as high as 50% (Pacak et al, 2001b). **In 2005, the First International Symposium on Pheochromocytoma recommended that all patients with pheochromocytoma and an abnormal metabolic evaluation undergo preoperative catecholamine blockade, including patients who do not exhibit evidence of blood pressure elevation and lack classic symptomatology** (Pacak, 2007). Contemporary series demonstrate mortality rates of less than 3%, which has been attributed in part to optimized anesthetic care and routine preoperative blockade (Lenders et al, 2005). In the absence of appropriately conducted clinical studies comparing preoperative management strategies, no level I evidence exists regarding optimal pre- or perioperative management (Pacak, 2007). Here, we review pre-operative blockade strategies relevant to aggressive α blockade, a central theme recommended by the team from the National Institutes of Health. Option 1 in Figure 57–20 summarizes their approach. We also outline an alternative strategy (see Fig. 57–20, option 2) that focuses on calcium channel blockade and that has been popularized by other authors (Ulchaker et al, 1999). Other permutations on approaches to preoperative catecholamine blockade exist but are less widely discussed in the literature (Pacak, 2007).

Thoughtful preoperative cardiac evaluation is paramount, because patients with pheochromocytoma are at risk for cardiomyopathy. Some experts recommend routine pre-operative echocardiography (Kinney et al, 2002). We suggest that the patient undergo either a cardiology or an anesthesia consultation prior to surgery.

ALPHA BLOCKADE. **Phenoxybenzamine is the most common α blocker used for preoperative catecholamine blockade of pheochromocytoma.** The agent irreversibly blocks the α receptor. As such, intraoperative catecholamine surges generally do not override its actions, because reversal of the blockade is only possible through synthesis of new receptor molecules (Pacak, 2007). Phenoxybenzamine is started 7 to 14 days prior to surgery. Oral dosing of 10 mg twice daily is initiated and titrated by increases of 10 to 20 mg to a blood pressure of 120 to 130/80 mm Hg in a seated position. Mild postural hypotension with systolic pressures greater than 80 mm Hg is acceptable (Kinney et al, 2002). Experience shows that final dosing of 1 mg/kg is usually sufficient to achieve adequate blockade (Pacak, 2007). In children, 0.2 mg/kg (maximum dose of 10 mg) four times daily with increases in 0.2 mg/kg increments is recommended (Lenders et al, 2005). Due to the irreversible nature of α blockade, following tumor resection patients may require transient blood pressure support (Pacak, 2007).

Selective reversible α_1 blockers, such as terazosin, doxazosin, or prazosin, are used at some centers in lieu of or in combination with phenoxybenzamine. Although these agents may have fewer side effects than phenoxybenzamine, data regarding their efficacy is contradictory (Lenders et al, 2005; Pacak, 2007).

BETA BLOCKADE. Beta blockade should be used with caution in patients with pheochromocytoma; however, its use is at times necessary due to reflex tachycardia and arrhythmias that can result upon initiation of α blockade. **It is important to understand that β blockade should never be started prior to appropriate α blockade.** Indeed, in the absence of α blockade, β antagonists cause a potentiation of the action of epinephrine on the α_1 receptors, due to blockade of the arteriolar dilation at the β_2 receptor. For this reason, selective β_1 adrenoreceptor blockers, such as atenolol and metoprolol, are generally preferred. Dosing for these agents is summarized in Figure 57–20 (Pacak, 2007).

CATECHOLAMINE SYNTHESIS BLOCKADE. Alpha-methyltyrosine, better known as metyrosine, blocks the rate-limiting step in the biosynthesis of catecholamines by inhibiting the tyrosine hydroxylase enzyme and thereby preventing the conversion of tyrosine to L-dihydroxyphenylalanine (L-DOPA) (see Fig. 57–4) (Pacak et al, 2001b). Approximately 3 days are necessary to achieve full clinical effect following initiation of this agent. Because blockade of catecholamine synthesis is incomplete, the use of metyrosine is generally coupled with α blockade by phenoxybenzamine. Use of this agent largely depends on institutional preferences and availability. Some centers avoid routine use of this agent and reserve it for refractory or metastatic patients due to its central nervous system side effects, including sedation, mood depression, and galactorrhea. Extrapyramidal symptoms resembling parkinsonism can result and require cessation of phenoxybenzamine use if present (Pacak et al, 2007). Dosing and titration strategies are summarized in Figure 57–20.

CALCIUM CHANNEL BLOCKADE. Calcium channel blockade in the context of catecholamine excess lowers blood pressure by generating smooth muscle relaxation (Ulchaker et al, 1999). The use of agents such as nicardipine has been suggested by some as an adjunct to traditional α-blockade therapy in refractory patients. Other groups, however, report that sole use of calcium channel blockers (see Fig. 57–20, option 2) is sufficient for safe pheochromocytoma resection (Ulchaker et al, 1999; Lebuffe et al, 2005). Indeed, advocates of this strategy argue that this approach avoids reflex tachycardia and postoperative hypotension that is seen with use of phenoxybenzamine (Ulchaker et al, 1999). The team from the National Institutes of Health suggests that this strategy (Fig. 57–20, option 2) be reserved for patients with only mild symptomatology at presentation (Pacak, 2007).

INTRAVASCULAR VOLUME MANAGEMENT. Restoration of intravascular volume is perhaps the most important component of preoperative management of patients with pheochromocytoma. Intake of salt and fluid is encouraged once catecholamine blockade has been initiated (Lenders et al, 2005). Moreover, most centers admit patients the day before surgery and initiate aggressive intravenous fluid resuscitation. The last dose of phenoxybenzamine and/or metyrosine is usually given on the night prior to surgery, and the next morning's dose is held. This approach minimizes potentially prolonged hypotension following tumor resection (Pacak, 2007).

Postoperative Management.

In the immediate postoperative period, the patient must be actively monitored. If phenoxybenzamine was employed for preoperative α blockade, hypotension is common, given the lasting effects of the agent (Pacak et al, 2001b). Moreover, in a high catecholamine state, α_2-adrenoreceptor stimulation inhibits insulin release. The withdrawal of this adrenergic stimulus following tumor resection, may result in rebound hyperinsulinemia and subsequent hypoglycemia (Kinney et al, 2002).

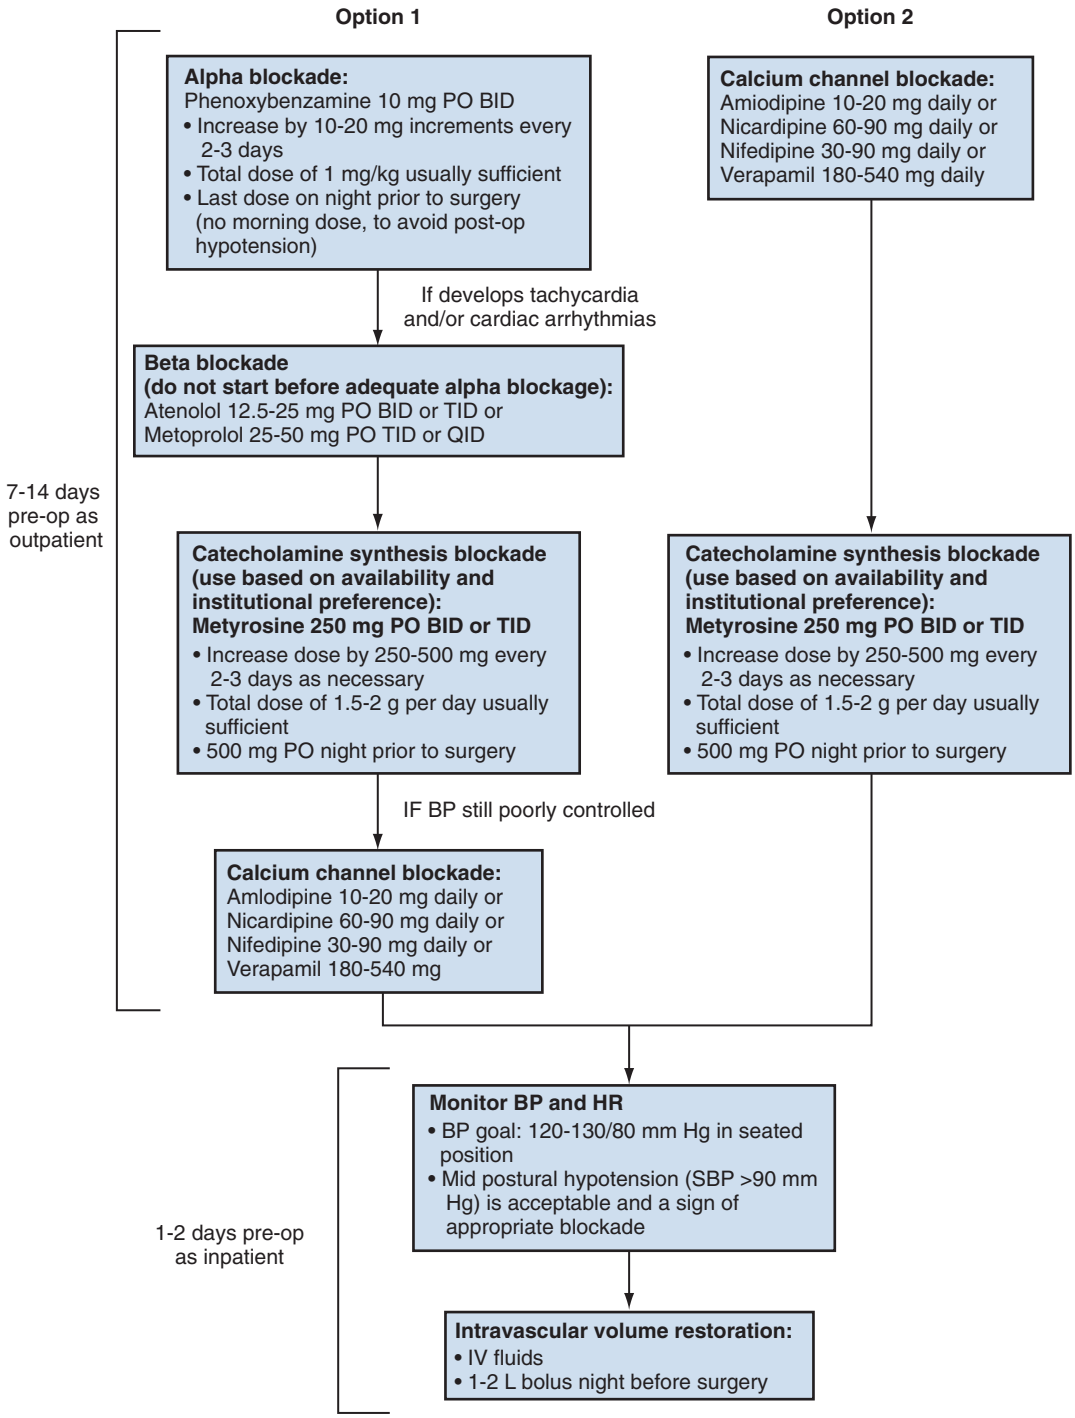

Figure 57–20. Preoperative medical management in patients with pheochromocytoma. BP, blood pressure; HR, heart rate; IV, intravenous. (Adapted from Pacak K. Preoperative management of the pheochromocytoma patient. J Clin Endocrinol Metab 2007;92:4069–79.)

Hence, given the necessity for close monitoring, some experts advise overnight admission to the intensive care unit following pheochromocytoma resection (Lenders et al, 2005).

Follow-up. Repeat metabolic testing should be performed approximately 2 weeks after adrenalectomy to document normalization of chromaffin cell function (Pacak et al, 2007). In patients in whom metanephrine levels remain elevated, MIBG imaging may be helpful. MIBG uptake by previously unseen metastases may now be unveiled following resection of the primary tumor (Plouin and Gimenez-Roqueplo, 2006a).

Long-term vigilant postoperative follow-up of patients with pheochromocytoma is essential (Lenders et al, 2005; Pacak et al, 2007). **Lifelong screening for recurrence is recommended by some experts, because 10-year recurrence rates are as high as 16% in some series of fully resected lesions** (Amar et al, 2005b; Plouin and Gimenez-Roqueplo, 2006a). Indeed, recurrent disease has been noted in patients more than 15 years following resection of the original tumor (Plouin et al, 1997; Goldstein et al, 1999). Annual biochemical follow-up is mandatory for all patients with resected pheochromocytoma (Eisenhofer et al,

2004a; Lenders et al, 2005). No consensus on follow-up protocols exists; however, biochemical testing at 6 months after surgery, followed by annual testing, has been suggested (Pacak et al, 2001b, 2007). Post-operative cross-sectional imaging is reasonable to document tumor resection and appropriate healing of the resection bed. Need for subsequent imaging should be guided by results of biochemical testing (Pacak et al, 2001b).

Treatment of Hereditary Pheochromocytoma. Patients with hereditary pheochromocytoma require a unique approach. Given that for patients with MEN-2 and VHL, the risk of malignancy is low (see Table 57–9) while risk of bilateral disease is significant, partial cortical-sparing adrenalectomy has been advocated. This strategy is employed to avoid lifelong hormonal replacement, with its associated morbidity (Løvås et al, 2002; Yip et al, 2004; Diner et al, 2005). Successful surgical outcomes require advanced surgical expertise and careful preoperative radiographic planning (Mitterberger et al, 2006). Nevertheless, the patient must be counseled that hormonal replacement may still be necessary despite a seemingly successful cortex-sparing procedure. Life-threatening addisonian crisis can also occur despite close postoperative monitoring (Yip et al, 2004; Asari et al, 2006). Close long-term biochemical and radiographic follow-up is essential, whereas recurrence rates are poorly defined but appear to be significant (Yip et al, 2004; Asari et al, 2006).

Treatment of Malignant Pheochromocytoma. Currently therapy for metastatic pheochromocytoma is largely palliative. Surgical metastatectomy of resectable disease is the standard of care; however, little evidence exists to demonstrate that it prolongs patient survival or is more effective for symptomatic relief than medical treatment with α/β blockade and α-methyl-paratyrosine (Eisenhofer et al, 2004a; Lenders et al, 2005; Pacak, 2007). Local palliative tumor control is also described using ablation techniques and embolization (Pacak et al, 2001a; Eisenhofer et al, 2004a).

Given selective uptake of MIBG by pheochromocytoma cells, systemic treatment of metastatic patients with radioactive ^{131}I-MIBG may be instituted. Before initiation of therapy, MIBG uptake by tumor targets should be demonstrated with traditional MIBG imaging (Scholz et al, 2007). Symptomatic response is seen in up to 2 of 3 patients. Over 40% of patients exhibit a reduction in catecholamine levels. Tumor volume reduction occurs in approximately 30% of patients, but complete responses are seen in less than 5% (Loh et al, 1997; Scholz et al, 2007). High-dose therapy has been reported. Rose and colleagues (2003) described a multi-institutional study where 12 patients were treated with ^{131}I-MIBG at 2 to 3.5 times its usual dose. Although toxicity was not trivial, 25% of patients ($n = 3$) exhibited a lasting complete response. Two of these patients had both bony and soft tissue metastatic lesions. Given significant toxicity, routine use of high-dose MIBG radiotherapy continues to be controversial (Lenders et al, 2005; Pacak et al, 2007; Scholz et al, 2007).

The best-studied chemotherapy regimen for malignant pheochromocytoma entails a combination of cyclophosphamide, vincristine, and dacarbazine (CVD). Although response rates can be significant (over 50% radiographic tumor response and nearly 75% biochemical response), they are generally short-lived (2 years) (Scholz et al, 2007; Huang et al, 2008). Chemotherapy is primarily used in patients who have failed MIBG therapy, or in those whose tumors do not demonstrate MIBG uptake on initial MIBG imaging studies. Combination therapy with CVD and MIBG has been explored, but, to date, its risks and benefits remain poorly defined (Scholz et al, 2007).

Prognosis. Following surgical resection, patients with pheochromocytoma generally do exceedingly well. Surgical mortality rates in the current era are less than 3% (Lenders et al, 2005). Hypertension usually resolves following resection, but not in all cases (Plouin et al, 1997). **Despite excellent prognosis, the disease can recur many years following resection in up to 16% of patients, necessitating vigilant lifelong follow-up** (Plouin et al, 1997; Goldstein et al, 1999; Eisenhofer et al, 2004a; Amar et al, 2005b). In one large series, patients with extra-adrenal disease (hazard ratio [HR] 11.2), hereditary pheochromocytomas (HR 3.4), right adrenal tumors (HR 3.1), bilateral tumors (HR 1.4), and larger tumors (HR 1.2 per cm of diameter) were more likely to recur. **Some 50% of the recurrences were malignant** (Amar et al, 2005b).

Some patients with metastatic disease progress rapidly, while others exhibit nonaggressive disease and can live in excess of 20 years (Huang et al, 2008). Bone metastases appear to carry the most benign prognosis (Pacak, 2007; Scholz et al, 2007). For all-comers, 5-year survival statistics vary but are believed to be approximately 50% (John et al, 1999; Lenders et al, 2005; Pacak et al, 2007; Scholz et al, 2007).

Summary. Pheochromocytoma is a rare catecholamine-producing tumor. Awareness of its potential presence and familiarity with its management are critical for every urologist. Misdiagnosis or management is often associated with dire consequences. Pheochromocytoma must be considered in every adrenal mass and referral to a tertiary care facility made if the physician is unfamiliar with the care of these complex patients.

Key Points: Pheochromocytoma

- Nearly 25% of cases of pheochromocytoma that initially appear sporadic are later deemed hereditary upon genetic testing.
- Testing for urinary or serum metanephrines (normetanephrine and metanephrine) represents the underpinning of modern biochemical testing for pheochromocytoma.
- Malignancy of pheochromocytoma can be defined only by presence of metastases. Pathologic appearance is unreliable. Long-term follow-up is paramount, since recurrences are reported even after 15 years following the initial resection of a localized lesion.
- Familiarity with perioperative management of patients with pheochromocytoma is paramount.

Disorders of Decreased Adrenal Function

Introduction and Epidemiology

Adrenal insufficiency, also known as Addison disease, is a condition whose management typically is beyond the scope of most urologic practices. Nonetheless, a working knowledge of the condition is essential for the urologic surgeon, because it may result from either resection or pharmacologic inhibition of functioning adrenal tissues. Failure to consider and diagnose is potentially lethal and therefore warrants review. **Indeed, if not anticipated and appropriate proactive therapies instituted, addisonian crises following simultaneous or staged bilateral adrenalectomy can result in death** (Asari et al, 2006).

Adrenal insufficiency may be due to primary adrenal failure or secondary to extra-adrenal mechanisms. Its estimated prevalence is 39 to 60 per million (Oelkers, 1996).

Pathophysiology

In the Western world, the most frequent cause of primary adrenal insufficiency is autoimmune adrenalitis. This condition can occur in isolation or as a constellation of pathologies known as autoimmune polyendocrine syndrome (APS), where adrenal insufficiency coexists with hypoparathyroidism, autoimmune thyroid disease, hypogonadism, diabetes, and other autoimmune conditions. Depending on the extent of endocrinologic involvement, APS is classified as either type 1 or the more common type 2 (Arlt and Allolio, 2003). In developing countries, as was true in the age of Thomas Addison, tuberculosis remains the major etiology of adrenal failure (Løvås and Husebye, 2005). Other infectious causes, such as cytomegalovirus in the setting of HIV infection and rare fungal adrenalities, can also destroy the adrenal cortex. Bilateral adrenal hemorrhage or infiltrative diseases, such as amyloidosis, sarcoidosis, along with hemochromatosis may also affect the function of the glands (Oelkers, 1996). Bilateral metastatic disease involving the adrenals, while classically described as a potential cause of adrenal insufficiency, is a very rare cause of clinically significant Addison disease (Lutz et al, 2000). In urologic practice, relevant clinical scenarios include simultaneous or staged surgical loss of bilateral adrenal tissue following treatment of adrenal or renal disease, and pharmacologic adrenalectomy with inhibitors of steroid hormone synthesis, such as ketoconazole, or new 17α-hydroxylase (CYP-17) inhibitors, such as aberiterone (Arlt and Allolio, 2003).

Secondary adrenal insufficiency is caused by abnormalities in the pituitary gland or, less frequently, the hypothalamus. Tumors, radiation, autoimmune conditions, pituitary apoplexy (also known as Sheehan syndrome, when it occurs peripartally), and trauma are less common causes of the condition. Rare congenital conditions marked by a metabolic error in the production of pituitary hormones, including ACTH, are rare causes of secondary Addison disease (Arlt and Allolio, 2003). Figure 57–21 summarizes the major causes of Addison disease. Importantly, given that aldosterone secretion by the adrenals does not depend on ACTH, the zona glomerulosa continues to function appropriately in patients with secondary adrenal insufficiency. **Mineralocorticoid deficiency is therefore only present in patients with primary Addison disease** (White, 1994).

Exogenous chronic administration of glucocorticoids accompanied by suppression of the hypothalamic-pituitary-adrenal axis, resulting in secondary adrenal insufficiency is particularly relevant to the surgeon (Krasner, 1999). Although overt adrenal crises due to this clinical scenario are exceedingly rare, the possibility exists in surgical patients on chronic steroids (Axelrod, 2003). Postoperatively the urologist must also be cognizant of hypothalamic-pituitary-adrenal axis failure in critically-ill patients. This condition, recently termed "critical illness–related corticosteroid insufficiency" is an important, albeit controversial, clinical entity (Marik et al, 2008; Marik, 2009).

Clinical Characteristics

Clinical signs and symptoms of Addison disease are generally nonspecific and constitutional in most outpatients, who may complain of profound fatigue and anorexia for many months prior to definitive diagnosis. Hyperpigmentation, a hallmark of primary adrenal insufficiency, results from high serum concentrations of ACTH in response to increased hypothalamic release of pro-opiomelanocortin (POMC)-derived peptides that stimulate the melanocortin (MC-1) receptor of the skin (Arlt and Allolio, 2003). Table 57–12 summarizes the clinical manifestations of adrenal insufficiency.

Acute adrenal insufficiency, or adrenal crisis, is a life-threatening condition often preceded by hypotension unresponsive to fluid resuscitation. Patients are easily and often misdiagnosed with an acute abdomen, whereas abdominal pain, nausea, vomiting, and fever frequently accompany hypovolemia in these individuals. Pediatric patients can exhibit hypoglycemic seizures (Arlt and Allolio, 2003; Bouillon, 2006).

Adrenal insufficiency (an addisonian state) following adrenalectomy in the setting of a normally functioning contralateral adrenal gland is unlikely, but possible.

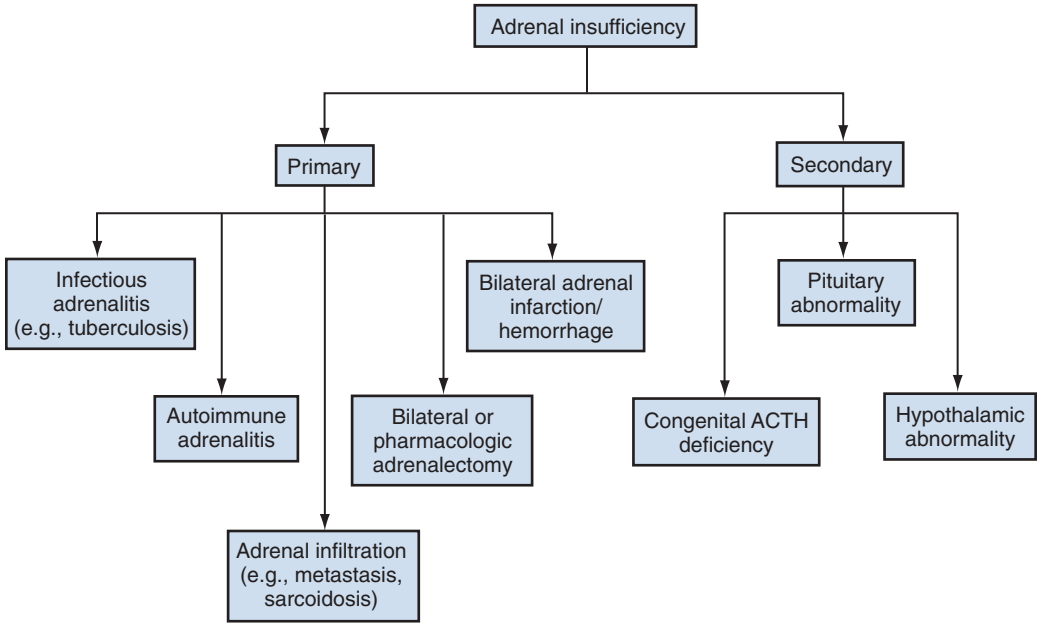

Figure 57–21. Causes of adrenal insufficiency. ACTH, adrenocorticotropic hormone.

Table 57–12.

Clinical Manifestations of Adrenal Insufficiency

SYMPTOMS	PATHOPHYSIOLOGY
Fatigue, lack of energy or stamina, reduced strength	Glucocorticoid deficiency, adrenal androgen deficiency
Anorexia, weight loss (in children failure to thrive)	Glucocorticoid deficiency
Gastric pain, nausea, vomiting (more frequent in primary adrenal insufficiency)	Glucocorticoid deficiency, mineralocorticoid deficiency
Myalgia, joint pain	Glucocorticoid deficiency
Dizziness	Mineralocorticoid deficiency, glucocorticoid deficiency
Salt craving (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Dry and itchy skin (in women)	Adrenal androgen deficiency
Loss or impairment of libido (in women)	Adrenal androgen deficiency
Signs	
Skin hyperpigmentation (primary adrenal insufficiency only)	Excess of pro-opiomelanocorticoid-derived peptides
Alabaster-colored pale skin (secondary adrenal insufficiency only)	Deficiency of pro-opiomelanocortin-derived
Fever	Glucocorticoid deficiency
Low blood pressure (systolic RR < 100 mm Hg), postural hypotension (pronounced in primary adrenal insufficiency)	Mineralocorticoid deficiency, glucocorticoid deficiency
Raised serum creatinine (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Hyponatremia	Mineralocorticoid deficiency, glucocorticoid deficiency (leading to SIADH)
Hyperkalemia (primary adrenal insufficiency only)	Mineralocorticoid deficiency
Anemia, lymphocytosis, eosinophilia	Glucocorticoid deficiency
Increased thyroid stimulating hormone (primary adrenal insufficiency only)	Glucocorticoid deficiency (or autoimmune thyroid failure)
Hypercalcemia (primary adrenal insufficiency only)	Glucocorticoid deficiency (mostly concurrent hyperthyroidism)
Hypoglycemia	Glucocorticoid deficiency
Loss of axillary or pubic hair (in women), absence of adrenarche or pubarche in children	Adrenal androgen deficiency

From Arlt W, Allolio B. Adrenal insufficiency. Lancet 2003;361(9372):1881–93.

This is especially true for patients who are undergoing adrenalectomy for a cortisol-secreting lesion, because functionality of the contralateral gland can be suppressed (Tsagarakis et al, 2006). **Furthermore, patients with a history of contralateral partial or radical nephrectomy clearly represent a high-risk group. The integrity of the adrenal gland on the side of previous surgery may be compromised, or that gland may be altogether absent. Close examination of preoperative imaging and review of old operative and pathology reports, as to the status of the adrenal gland in the previous surgical field, is paramount.**

Diagnostic Tests

The diagnosis of primary adrenal insufficiency is primarily made on clinical grounds, with a high index of suspicion given a patient's history, exam, and laboratory evaluation. It is ultimately secured by measurements of morning serum cortisol and ACTH. Patients with primary Addison disease exhibit abnormal aldosterone and renin levels. Confirmatory testing involves assessing the adrenal response to ACTH stimulation in the form of the corticotropin test. The majority of patients with autoimmune adrenalitis demonstrate detectable levels of anti–21-hydroxylase antibodies (Oelkers et al, 1992; Arlt and Allolio, 2003).

The appropriate workup for secondary adrenal insufficiency often requires sophisticated probing of the hypothalamic-pituitary-adrenal axis that goes beyond the scope of this text and requires endocrinologic expertise. In-depth reviews of the topic are available (Oelkers et al, 1992; Oelkers, 1996).

Treatment

The treatment of Addison disease involves adrenal hormonal repletion. Cortisol is replaced with hydrocortisone (15 to 25 mg per day) or with cortisone acetate (25 to 37.5 mg per day). To mimic physiologic circadian glucocorticoid cycling, the majority (half or two thirds) of the daily dosing is given in the morning, with the rest administered in one or two doses later in the day (Arlt and Allolio, 2003). Mineralocorticoid replacement is only required for patients with primary adrenal insufficiency, and is achieved with fludrocortisone 0.05 to 0.2 mg daily (Løvås and Husebye, 2005). Supplementation of adrenal androgens is advised by some experts (dehydroepiandrosterone 25 to 50 mg daily), but is often limited to those who experience constitutional complaints despite adequate glucocorticoid and mineralocorticoid supplementation (Arlt and Allolio, 2003). Careful monitoring of patients on hormone replacement for adrenal insufficiency is required and is often best left to experienced endocrine experts.

The necessity of perioperative stress-dose steroid administration continues to be controversial. Although continuing the patient's usual steroid dose is usually sufficient, given the negligible downside of perioperative steroid coverage and the potential catastrophic consequences of failure to prevent an adrenal crisis, surgeons continue to administer stress-dose steroids perioperatively. Tables 57–13 and 57–14 summarize contemporary recommendations (Salem et al, 1994; Krasner, 1999; Axelrod, 2003). Again, because aldosterone physiology is not altered in these patients, mineralocorticoid replacement is unnecessary (White, 1994).

Prognosis

The impact on life expectancy in cases of primary adrenal insufficiency has not been established; however, a significant impact on a patient's quality of life has been demonstrated (Løvås et al, 2002). Many patients complain of decreased energy, loss of libido, and psychologic maleffects (Arlt and Allolio, 2003). Secondary adrenal insufficiency due to hypopituitary disease is an established cause of premature death (Tomlinson et al, 2001).

Table 57–13.

Perioperative Glucocorticoid Dosing in Patients on Chronic Steroid Therapy

DEGREE OF SURGICAL STRESS	DEFINITION	GLUCOCORTICOID DOSE
Minor	Procedure under local anesthesia and less than 1 hour in duration (e.g., inguinal hernia repair)	Hydrocortisone 25 mg or equivalent
Moderate	Procedure such as vascular surgery of a lower extremity or a total joint replacement	Hydrocortisone 50 to 75 mg or equivalent This could be continuation of usual daily steroid dose (e.g., prednisone 10 mg per day) and hydrocortisone 50 mg intravenously during surgery
Major	Procedure such as esophagogastrectomy or operation on cardiopulmonary bypass	Usual glucocorticoid (e.g., prednisone 40 mg or the parenteral equivalent within 2 hours before surgery) and hydrocortisone 50 mg intravenously every 8 hours after the initial dose for the first 48 to 72 hours of the postoperative period

Data from Salem M, Tainsh RE Jr, Bromberg J, et al. Perioperative glucocorticoid coverage. A reassessment 42 years after emergence of a problem. Ann Surg 1994;219(4):416–25; and Axelrod L. Perioperative management of patients treated with glucocorticoids. Endocrinol Metab Clin North Am 2003;32(2):367–83.

Table 57–14.

Relative Potency of Common Glucocorticoid Preparations

NAME	BIOLOGIC HALF-LIFE (hr)	RELATIVE ANTI-INFLAMMATORY POTENCY	APPROXIMATE ADULT PHYSIOLOGIC REPLACEMENT DOSE (mg/day)
Hydrocortisone (cortisol)	8-12	1	20
Cortisone acetate		0.8	25
Prednisone	18-36	4	5
Prednisolone		4	5
Methylprednisolone		5	4
Triamcinolone		5	4
Dexamethasone	36-54	25-50	0.5

Summary

In urologic practice, adrenal insufficiency can result from simultaneous or staged surgical excision or pharmacologic ablation with steroid–hormone synthesis blockade agents. Diagnosis requires a high index of suspicion. Any patient having undergone ipsilateral partial or radical nephrectomy and presenting for contralateral surgery represents an at-risk population. Obtaining old operative or pathology reports and examining cross-sectional imaging for the presence or absence of adrenal tissue is essential in this setting. Postoperative adrenal insufficiency must be considered in patients on chronic glucocorticoid therapy or in the critically ill. There should be a low threshold to consult advanced endocrinologic expertise given the complexity and the potentially grave consequences of the condition.

Key Points: Adrenal Insufficiency

- Mineralocorticoid deficiency is present only in patients with primary Addison disease (e.g., autoimmune adrenalitis, surgical absence of adrenal tissue). Abnormalities in the pituitary gland or, less frequently, the hypothalamus (e.g., in patients with suppressed ACTH secretion due to chronic steroid use) do not result in suppression of aldosterone production.
- Any patient who has undergone ipsilateral partial or radical nephrectomy presenting for contralateral renal or adrenal surgery is at risk for a postoperative adrenal crisis. Obtaining old operative or pathology reports and examining cross-sectional imaging for the presence or absence of adrenal tissue is essential in this setting.

Disorders of Abnormal Adrenal Function

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a disorder that is characterized by low cortisol production due to a metabolic enzymatic abnormality in the cholesterol-steroid biosynthesis pathway (see Fig. 57–3). The disorder is autosomal recessive and associated with a deficiency in the enzyme 21-hydroxylase in over 95% of cases. In the absence of negative feedback, ACTH production by the pituitary is increased, resulting in hyperplasia of the adrenal cortex and overproduction of adrenal androgens (Merke and Bornstein, 2005). Diagnosis of the condition is most often established in childhood and is discussed in detail in Chapter 110. Patients with known CAH, as well as carriers of the *CAH* gene, appear to have a high propensity for developing benign adrenal cortical adenomas but are not at known increased risk for malignant adrenal lesions (Jaresch et al, 1992; Barzon et al, 2007). Patients with undiagnosed nonclassical 21-hydroxylase deficiency can present with adrenal neoplasms later in life (Ravichandran et al, 1996; Nigawara et al, 2008). Given the relatively low incidence, genetic screening of patients with adrenal incidentalomas has not demonstrated an increased incidence of undiagnosed CAH. Therefore screening of incidentaloma patients for CAH is not indicated (Kjellman et al, 1999; Barzon et al, 2003; Wagnerova et al, 2008).

Adrenal Lesions

Malignant

Adrenal Carcinoma

Introduction and Epidemiology. Adrenocortical carcinoma (ACC) is a rare malignancy with an incidence of 0.5 to 2 per million (Aubert et al, 2002; Roman, 2006; Fassnacht and Allolio, 2009). It has a bimodal age distribution that peaks in children in the first decade of life and adults in the fourth to fifth decades of life, although most patients with ACC are adults, with a slight female predominance of 1.5 to 2.1 (Roman, 2006). Several important differences exist between the pediatric and adult ACC populations, including symptoms at presentation, staging systems used, and prognosis. Compared with the adult population, children with ACC will more often present with lower-stage functional tumors, which is associated with improved survival (Liou and Kay, 2000).

The majority of ACCs are sporadic and unilateral; however, 2% to 6% of patients will present with bilateral disease that may be associated with a hereditary disorder (Ng and Libertino, 2003). Although the etiology of sporadic ACC remains unknown, several syndromes are associated with an increased incidence of ACC, including Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome, Carney complex, multiple endocrine neoplasia type 1, and McCune-Albright syndrome. Although the underlying molecular defect of these syndromes has advanced our understanding of the tumorigenesis of ACC, significant improvements in treatment regimens and survival are yet to be realized. Currently, surgical resection remains the cornerstone of treatment and, when localized, offers the best chance of cure; however, multimodal therapy including systemic chemotherapy and radiation therapy are often required for locally advanced and metastatic disease.

Pathophysiology. **Two hereditary disorders, Li-Fraumeni and Beckwith-Wiedemann syndrome, have provided valuable insight into the tumorigenesis of sporadic ACC. Loss of TP53 function, as found in Li-Fraumeni syndrome, has been noted in 20% to 33% of sporadic ACC cases compared with 0% to 6% of adrenal cortical adenomas. Increased insulin-like growth factor (IGF) expression, as found in Beckwith-Wiedemann syndrome, has been noted in up to 90% of sporadic cases of ACC, compared with only 8.5% of adrenal cortical adenomas** (Herbet et al, 2009). **These findings suggests that loss of TP53 function and increased IGF expression represent late events in the tumorigenesis of sporadic ACC. Additional alterations of several oncogenes and peptides have been associated with the ACC, including squamous cell carcinoma–related oncogene (SCCRO), inhibin, activin, epidermal growth factor receptor, and vascular endothelial growth factor (VEGF)** (Boulle et al, 1998; Kolomecki et al, 2001; Beuschlein et al, 2004; Sarkaria et al, 2004).

Clinical Characteristics. Incidental detection of adrenal cortical carcinoma has increased with the routine use of cross-sectional imaging; however, the majority of patients still present with advanced disease and tumor-related symptoms. Figure 57–22 shows a CT image of a large right-sided ACC. **Tumor-related symptoms of ACC can be secondary to local or systemic disease burden and/or hypersecretion of adrenal hormones, which has been noted in 50% to 79% of adult and 90% of pediatric ACCs** (Roman, 2006). Adrenal cortical carcinomas that are associated with the hypersecretion of adrenal hormones are characterized as being functional. However, the presence of a functional tumor does not always lead to clinical symptoms, as in the case of tumors that secrete high concentrations of steroid precursors. This is especially relevant given the increasing sensitivity of assays used when evaluating serum hormone levels. Furthermore, it is common to have several hormones secreted by a single tumor, and it has been theorized that a tumor's functional status and hormones secreted may change throughout the tumor's development and growth (Phan, 2007).

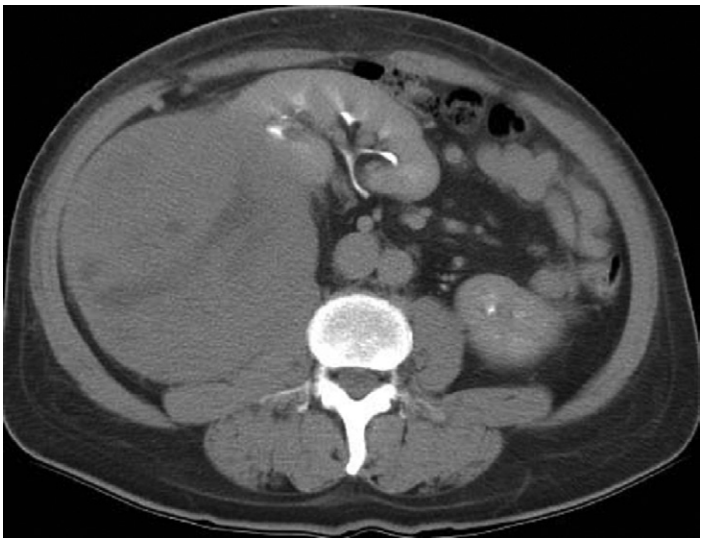

Figure 57–22. Axial cut in excretory phase of a computed tomography scan demonstrating a large right adrenal carcinoma. The right kidney is shifted anteriorly and medially. Similar-sized masses that arise from the kidney itself generally do not displace the renal unit. Importantly, even at this large size the adrenal carcinoma appears relatively homogeneous and well circumscribed—features deceptively camouflaging its deadly biologic potential. Surgical resection demonstrated a 25-cm, stage II (pT2N0M0), localized adrenocortical carcinoma (ACC). (Courtesy of Dr. David Y.T. Chen, Fox Chase Cancer Center, Philadelphia, PA.)

Table 57–15.

Functional Breakdown of Adrenal Cortical Carcinomas

Nonfunctional	21%-50%
Functional	50%-79%
Cushing syndrome	33%-53%
Cushing syndrome + virilization	20%-24%
Virilization alone	10%-20%
Feminization	6%-10%
Hyperaldosteronism	2.5%-5%

The most common hormone secreted by adrenal cortical carcinoma is cortisol, resulting in the clinical manifestations of Cushing syndrome (Table 57–15). Hypercortisolism in ACC is ACTH-independent, and the Cushing-associated virilization has been noted to be more pronounced compared with that resulting from functional adenomas. The observed increase in virilization may be due to increased rates of cosecretion of 17-ketosteroids and de-hydroepiandrosterone (DHEA) in patients with ACC (Roman, 2006). Androgen-secreting tumors in women can lead to virilization, characterized by male-pattern baldness, hirsutism, and oligoamenorrhea, which are typically related to elevated 17-ketosteroids. When virilization is present in the absence of elevated 17-ketosteroids, free testosterone hypersecretion from an adrenal or ovarian source should be considered. Feminization in

men, characterized by testicular atrophy and gynecomastia, may result from peripheral conversion of androstenedione to estrogen and is highly suggestive of malignancy when present. Although hypersecretion of aldosterone is rarely associated with ACC, when present, it is associated with profound hypertension and hypokalemia. Moreover, the symptoms of hypertension and hypokalemia are more likely secondary to other adrenal steroids produced by ACC, rather than the hypersecretion of aldosterone. Although considered functional, ACCs can present with high levels of steroid precursors, such as androstenedione and 17α-hydroxyprogesterone, which may not cause any overt clinical symptoms (Fassnacht and Allolio, 2009). Nonfunctional ACC may present with more generalized tumor related symptoms, such as abdominal fullness, back pain, nausea, vomiting, or other constitutional symptoms.

Diagnostic Tests. Suspicion for adrenal cortical carcinomas is based on clinical symptoms or radiographic findings and warrants the complete extent of disease evaluation, given the implications of this malignancy. Evaluating the functional status of adrenal tumors suspicious for ACC is essential, not only for making the diagnosis of ACC but also for consideration of postoperative cortisol replacement and the potential use of tumor secreted hormones as markers during postoperative surveillance. **When considering the functional status of a tumor suspicious for adrenal cortical carcinomas, glucocorticoid, mineralocorticoid, catecholamine, sexual steroid, and steroid precursor excesses should be evaluated** as outlined in Table 57–16.

The radiographic characteristics of an adrenal tumor provide valuable information regarding the lesion's malignant potential, and may be obtained using several modalities including CT, MRI, and FDG-PET imaging. **On cross-sectional imaging, adrenal cortical carcinomas tend to be larger than benign adrenal tumors with an average size of 10 to 12 cm on presentation. Indeed over 90% of ACCs are greater than 5 cm** (Ng and Libertino, 2003; Fassnacht and Allolio, 2009). In incidentally detected adrenal tumors, size is a relative indicator of malignancy, with 4% to 5% of tumors less than 4 cm, 10% of tumors larger than 4 cm, and 25% of tumors greater than 6 cm found to be adrenal carcinomas (Sturgeon and Kebebew, 2004; Walz et al, 2005). Given the relationship between adrenal tumor size and malignancy, it is currently recommended that adrenal tumors greater than 4 to 6 cm be surgically excised (Schteingart et al, 2005). Although a complete metastatic evaluation should be completed for all adrenal tumors suspicious for adrenal cortical carcinomas, the presence of lymphadenopathy and local tumor extension into the inferior vena cava and other adjacent organs are ominous indicators of locally advanced or distant metastatic disease. The most common sites of metastases in adrenal carcinoma are the lung and liver. Therefore metastatic evaluation at presentation should include cross-sectional imaging of the chest, abdomen, and pelvis. Evaluation for bone and central nervous system metastases need only be performed in patients with site-specific symptoms. **Common radiographic characteristics of adrenal carcinomas on CT imaging include the presence of irregular borders, irregular enhancement, calcifications, and necrotic areas with cystic degeneration. Mean attenuation on noncontrast CT scan in ACC is significantly higher (39 HU) compared with adenomas (8 HU).** Moreover, they will not demonstrate the contrast washout characteristics of benign adrenal adenomas (Szolar et al, 2005; Roman, 2006) (see Imaging section).

MRI provides valuable information when evaluating adrenal tumors. ACCs appear isointense relative to the liver or spleen on T1-weighted images and demonstrate intermediate to increased intensity on T2-weighted images. On gadolinium-enhanced images, adrenal carcinomas demonstrate marked contrast uptake (Ilias et al, 2007). In cases of suspicion for venous tumor thrombus, MRI can be an essential tool in detecting the presence of a tumor clot and delineating its extent.

Experience with FDG-PET in evaluating adrenal tumors suspicious for ACC is limited. In currently available series, all malignant adrenal tumors demonstrated FDG uptake (Tenenbaum et al, 2004). However, given the established value of CT and MRI in distinguishing benign from malignant disease and the limited experience with FDG-PET, the routine use of FDG-PET in evaluating adrenal tumors cannot be recommended at this time.

When diagnosing adrenal cortical carcinomas, percutaneous needle biopsy is generally not performed prior to surgical excision due to a clinically unacceptable risk of needle-tract seeding (Fassnacht et al, 2004; Schteingart et al, 2005). In cases of surgically resectable disease, the information obtained from biochemical and radiographic evaluation should be enough to justify extirpation. The primary indication for needle biopsy is in cases of unresectable, locally advanced, or metastatic disease, to confirm the diagnosis prior to systemic medical therapy.

Pathologic Evaluation. Although the presence of distant metastasis and local invasion are clear indications of malignancy, the differentiation between benign and malignant neoplasms in organ-confined tumors can be pathologically challenging (Fig. 57–23). The Weiss criteria, developed in 1984, have been established to distinguish benign from malignant adrenal tumors using nine pathologic features (Weiss, 1984). The classification system is based on tumor structure, cytology, and invasion (Table 57–17. The presence of three or more of the Weiss criteria are associated with malignancy, with a sensitivity of 100% and a specificity of 96% (Aubert et al, 2002). In cases of pediatric adrenal tumors, and in adult adrenal tumors that demonstrate oncocytic features, the Weiss criteria should be employed with caution, and alternative diagnostic criteria are recommended (Lau and Weiss, 2009).

Staging. In 2004, the Union Internationale Contre Cancer and World Health Organization created a staging system for ACC

Table 57–16.

Functional Evaluation of Adrenal Tumors Suspicious for Adrenal Cortical Carcinoma

TYPE OF ADRENAL HYPERSECRETION	FUNCTIONAL EVALUATION
Glucocorticoid excess	Low-dose dexamethasone suppression test or Late night salivary or 24-hour urine cortisol
Sexual steroids and steroid precursors	DHEA-S 17-OH-progesterone Androstenedione Testosterone 17β-estradiol (only in men and postmenopausal women)
Catecholamine excess	Serum or urinary metanephrines
Mineralocorticoid excess	Aldosterone to renin ratio (only in patients with hypertension or hypokalemia)

DHEA-S, dehydroepiandrosterone sulphate.

Sebo, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.)

Table 57–17.

Weiss Pathologic Criteria for Differentiating Benign and Malignant Adrenal Tumors

High nuclear grade (Furman grade 3 to 4)
High mitotic rate (greater than 5 mitoses per HPF)
Presence of atypical mitoses
Character of cytoplasm (low percentage of clear cells)
Diffuse architecture of tumor cells
Presence of necrosis
Invasion of venous structures
Invasion of sinusoidal structures
Invasion of tumor capsule

Table 57–18.

Staging of Adrenocortical Carcinoma Including Stage at Diagnosis and 5-Year Survival Data

STAGE	2004 UICC/WHO	AT DIAGNOSIS	5-YEAR SURVIVAL
1	T1N0M0	3%-4%	33%-66%
2	T2N0M0	29%-46%	20%-58%
3	T1-2N1M0 T3N0M0	11%-19%	18%-24%
4	T1-4N0-1M1 T3N1M0 T4N0-1M0	39%-49%	<5%

T1 = <5 cm; T2 = >5 cm; T3 = infiltration of surrounding adipose tissue; T4 = invasion into adjacent organs.
UICC, Union Internationale Contre Le Cancer; WHO, World Health Organization.

(Table 57–18) (DeLellis et al, 2004). Stage I and II tumors are confined to the adrenal gland and are distinguished by a size cutoff of 5 cm. Stage III disease includes tumor extension into adjacent adipose tissue or having regional lymph node involvement. Stage IV disease includes tumors invading adjacent organs and the presence of distant metastatic disease. A modified staging system has recently been proposed by the European Network for the Study of Adrenal Tumors (ENSAT), in an attempt to improve the prognostic accuracy of the 2004 WHO staging system. The ENSAT staging system maintains the tumor-node-metastasis (TNM)

classifications used in the 2004 staging system (version 6); however, stage III disease includes patients with positive lymph nodes (N1), infiltration of surrounding tissues (T3-4) and venous tumor thrombus, while stage IV disease is reserved for any tumor associated with distant metastatic disease (Fassnacht et al, 2009). Further changes in the staging of ACC may be forthcoming with the release of the 2009 American Joint Committee on Cancer Staging Manual.

Management. Unfortunately, the majority of patients with adrenal cortical carcinomas present with advanced disease (see Table 57–18), and those who do have localized disease are at a high risk of local recurrence and metastatic progression. For this reason, treatment of ACC often includes multimodal therapy directed by a team of surgeons, medical oncologists, endocrinologists, and radiation oncologists. **Despite aggressive surgical resection, adrenal carcinoma is associated with a high rate (60% to 80%) of recurrent disease** (Pommier and Brennan, 1992; Stojadinovic et al, 2002; Meyer et al, 2004). Thus adjuvant therapy is often administered, frequently involving both local and systemic modalities. Unfortunately, the impact of adjuvant therapy on survival is not established, making the routine administration of adjuvant treatments controversial. Given the low incidence of ACC, no randomized prospective trials have been completed to evaluate the efficacy of current treatment regimens; thus existing treatment strategies are based on the collective experience of nonrandomized retrospective series.

SURGERY. Complete surgical excision is essential in the management of adrenal cortical carcinomas and offers the best chance of cure, control of symptoms secondary to hypersecretion of adrenal hormones, and other tumor-related symptoms. En bloc resection of surrounding organs involved with locally advanced disease should be performed whenever possible. Regional retroperitoneal lymph node dissection can provide additional disease control and staging information. Cases of venous tumor thrombus involving the IVC may require vascular bypass techniques, IVC replacement, and/or IVC interruption. Given the extent of resection frequently required, open abdominal/retroperitoneal exploration is commonly employed. Smaller radiographically organ- confined disease can be approached laparoscopically, but should be performed with caution due to the risk of tumor spillage (Kebebew et al, 2002; Gonzalez et al, 2005; Schlamp et al, 2007). **In cases of metastatic adrenal carcinoma, cytoreductive removal of the primary tumor and debulking metastatectomy should be considered if greater than 90% of the disease burden can be removed** (Schteingart et al, 2005). **Although debulking surgery may not improve survival, it may alleviate tumor-related side effects and facilitate additional therapies** (Fassnacht et al, 2004)**. Local or distant disease recurrences, following initial resection, should be considered for surgical excision and have been associated with improved survival in retrospective series** (Meyer et al, 2004). Locally recurrent disease and select metastatic lesions may be treated with ablative therapy using radiofrequency ablation or angioembolization, if surgical excision cannot be performed (Wood et al, 2003; Schteingart et al, 2005; Soga et al, 2009).

Follow-up should include CT examination of the chest, abdomen, and pelvis every 3 months for the first 2 years. The value of routine PET imaging in disease surveillance has not been established. In patients with evidence of functional tumors, measurement of the initially elevated hormones postoperatively may help to reveal early disease recurrence despite negative radiographic studies. After a disease-free interval of 2 years, surveillance should continue, but the frequency of imaging may decrease (Fassnacht et al, 2004; Schteingart et al, 2005).

RADIATION. Currently there is a limited role for radiation therapy in the treatment of primary adrenal cortical carcinomas; however, radiation therapy remains the treatment of choice in the management of bone and CNS metastasis (Schteingart et al, 2005). Adjuvant radiation has been noted to decrease local recurrence rates following complete tumor resection, with reported local recurrence rates of 14% and 79%, with and without adjuvant radiation therapy, respectively (Fassnacht et al, 2004; Polat et al, 2009). Unfortunately, a significant improvement in disease-free or overall survival was not observed. Patients believed to benefit the most from adjuvant radiation therapy are those without evidence of metastatic disease and positive or indeterminant surgical margins.

MEDICAL THERAPY. Mitotane is an oral synthetic derivative of the insecticide dichlorodiphenyltrichloroethane (DDT) and is the most commonly used chemotherapeutic agent in the treatment of adrenal cortical carcinoma. The agent has demonstrated clinical benefit in the adjuvant setting following surgical resection and in patients with metastatic disease (Phan, 2007). Three mechanisms of action of mitotane against ACC have been proposed, including the direct cytotoxicity of cells in the adrenal cortex, oxidative damage through the production of free radicals, and/or inhibition of enzymes involved with steroid synthesis (Fassnacht and Allolio, 2009). Due to the adrenolytic effect of mitotane, steroid replacement is typically necessary during therapy. In addition to adrenal insufficiency, common side effects include gastrointestinal upset, lethargy, depression, feminization in males, rash, elevation of hepatic enzymes, elevation of hormone-binding globulins, hypothyroidism, dyslipidemia, and thrombocytopenia. Given its significant adverse effect profile and its marginal therapeutic benefit, administration must be closely monitored and dosage titrated according to patient tolerability and serum levels (Fassnacht and Allolio, 2009).

The efficacy of adjuvant mitotane following surgical resection has been evaluated by several small retrospective series with varying results. A more contemporary retrospective series by Terzolo and colleagues (2007) evaluated the impact of adjuvant mitotane on recurrence-free survival and overall survival in 177 patients with ACC. A significant increase in recurrence-free survival and overall survival was noted in patients receiving mitotane compared with controls, after multivariate adjustments. Additionally, treatment-related toxicity appeared acceptably low. Currently, significant questions remain regarding the routine use of adjuvant mitotane following surgical resection, including which patients will derive the greatest benefit from adjuvant therapy and what is the optimal dosage and duration of adjuvant mitotane therapy (Terzolo et al, 2007, 2009).

In patients who are not candidates for complete tumor debulking, surgery should not be performed because it will delay systemic therapy. Currently, mitotane remains the primary systemic therapy, either as a single agent or in combination with other cytotoxic drugs for adrenal cortical carcinomas. **As a single agent, overall responses to mitotane range from 14% to 36%, with few studies demonstrating a significant survival benefit** (Roman, 2006; Phan, 2007). **A series by** Khan and colleagues (2000), **investigating the combination of mitotane and streptozotocin, noted a response rate of 36%. In a report by** Berruti (2005), **a response rate of 49% was noted with the combination of mitotane, etoposide, doxorubicin, and cisplatin.** These series have led to the currently ongoing randomized First International Randomized Trial

in Locally Advanced and Metastatic Adrenocortical Carcinoma Treatment (FIRM-ACT) trial, in which patients with advanced ACC are randomized to receive mitotane in combination with streptozotocin or etoposide, doxorubicin, and cisplatin. With the known limited success of first-line mitotane therapy for advanced disease, salvage therapy is often required. Multiple ongoing trials are investigating targeted therapies and other agents in patients who progress following first-line systemic therapy (Roman, 2006; Fassnacht and Allolio, 2009).

Control of symptoms secondary to the hypersecretion of hormones is often necessary in patients with metastatic disease. Although mitotane has adrenolytic activity, given its delayed onset of action and associated toxicity, other agents are often necessary to help control symptoms of hormone hypersecretion. Adrenostatic drugs, such as ketoconazole, metyrapone, aminoglutethimide, and etomidate have been used to decrease circulating levels of cortisol in symptomatic patients (Fassnacht et al, 2004).

Prognosis. Overall 5-year survival in adrenal cortical carcinomas is poor, ranging from 20% to 47% (Fassnacht and Allolio, 2009; Roman, 2006). The observed poor prognosis associated with ACC reflects the advanced stage frequently noted at presentation, the high rate of recurrent disease in patients with localized disease, and the limited efficacy of current systemic treatment regimens. Five-year survival based on tumor stage is presented in Table 57–18. In addition to advanced stage, several clinicopathologic features have been associated with decreased survival, including tumor size greater than 12 cm, high mitotic rate, tumor necrosis, atypical mitotic figures, and high Ki-67 staining (Fassnacht and Allolio, 2009). The impact of a tumor's functional status on outcome has been widely debated and remains controversial (Luton et al, 1990; Favia et al, 2001; Chen et al, 2004; Vaughan, 2004).

Pediatric ACC. The presentation, staging, and prognosis of pediatric adrenal cortical carcinomas differ from that in adults (Liou and Kay, 2000). More than 90% of ACCs in children are functional at the time of presentation, with virilization being the most common clinical manifestation occurring in 55% to 70% of patients. Unlike adults, the female to male ratio is equal in children under the age of 12, while the female to male ratio sharply increases to 6:1 in children aged 13 to 20. Genetic syndromes should be considered in pediatric cases of adrenal carcinoma, particularly Li-Fraumeni syndrome, because a high rate of *TP53* mutations has been noted in prior series. The staging system in pediatric patients defines stage I and II tumors as being completely excised with negative margins and with a tumor weight of greater than 200 g differentiating stage I and II disease. Stage III disease is defined by the presence of microscopic or macroscopic residual disease following surgical resection or inoperable tumors, while stage IV disease is defined by the presence of hematogenous metastasis. The overall 5-year survival rate is 54.2%, with several clinicopathologic features associated with diminished survival, including tumors weighing more than 400 g, tumor size greater than 10.5 cm, necrosis, frequent and atypical mitotic bodies, and presentation after 5 years of age (Michalkiewicz et al, 2004).

Summary. Adrenal cortical carcinoma is a rare malignancy requiring multispecialty care. Given the aggressive natural history of the disease, ACC must be considered in the differential diagnosis in all patients presenting with an adrenal tumor, particularly if greater than 6 cm. Evaluation of tumor functional status is critical for preoperative planning and supportive care, even in asymptomatic patients. Complete surgical resection of the primary tumor and any associated metastatic lesions should be performed whenever possible. Adjuvant therapy or enrollment into a clinical trial should be considered in most patients, given the high rate of local recurrence and metastatic progression despite complete surgical resection. Systemic therapy with mitotane therapy alone, or in combination with other cytotoxic agent, is recommended as first-line therapy in patients with metastatic ACC. Unfortunately, the prognosis for patients with ACC is poor, and improved therapeutic regimens are needed to improve outcomes.

Key Points: Adrenal Cortical Carcinoma

- Increasing adrenal tumor size is significantly associated with an increased risk of malignancy.
- The majority of adrenal cortical carcinomas will be functional at the time of presentation.
- Multimodal treatment, surgical resection, radiation therapy, and systemic chemotherapy is often necessary for patients with adrenal cortical carcinoma.

Neuroblastoma. Neuroblastoma, a malignancy derived from the cells of the neural crest, which give rise to the adrenal medulla and sympathetic ganglia, is the most common solid extracranial tumor of childhood. Chapter 137 is dedicated to the clinical and pathologic features of this entity (Park et al, 2008).

Metastases

Introduction and Epidemiology. **The adrenal glands are a common site of metastases.** Large autopsy series have demonstrated that over 25% of patients with melanoma and lung carcinoma have metastases to their adrenals (Bullock and Hirst, 1953). Renal cell carcinoma, breast cancer, medullary thyroid carcinoma, contralateral adrenocortical carcinoma, gastrointestinal malignancies, prostate adenocarcinoma, cervical cancer, basal cell, pancreatic tumors, cholangiocarcinoma, urothelial carcinoma, squamous cell carcinoma, seminoma, thymoma, chronic myelogenous leukemia, and other malignancies can all exhibit metastatic deposits within the adrenals (Bullock and Hirst, 1953; Lenert et al, 2001). Indeed diagnostic challenges arise when an adrenal incidentaloma is discovered in patients with a known malignancy. **It has been estimated that in patients with a history of a previous malignancy, over 50% of newly discovered adrenal lesions are metastatic** (Lenert et al, 2001; Frilling et al, 2004). Current imaging modalities supplemented by adrenal biopsy, when necessary, can frequently differentiate metastases from a primary adrenal tumor.

Renal cell carcinoma can involve the adrenal by direct invasion or systemic metastases (Lau, 2003; Antonelli, 2006). O'Malley and colleagues (2009) provide a recent review of these data as they relate to the need for adrenalectomy during surgery for RCC. Management of solitary metastases to the adrenal from other malignancies often falls within the purview of the practicing urologist. **Indeed, for some malignancies, specifically melanoma and non–small cell lung carcinoma, a survival benefit has been suggested in patients who undergo resection of an isolated adrenal metastasis** (Mercier et al, 2005; Collinson et al, 2008; Mittendorf et al, 2008; Tanvetyanon et al, 2008).

Pathophysiology and Clinical Characteristics. Remarkably few patients with metastatic disease to the adrenal gland exhibit evidence of adrenal insufficiency. Indeed, although an addisonian state secondary to metastatic carcinoma was described by Addison in his original series, the scenario is exceedingly rare (Addison, 1855; Lutz et al, 2000). Some reports suggests that bulky (>4 cm)

bilateral disease is necessary to produce biochemical evidence of adrenal insufficiency (Lutz et al, 2000). The statement that adrenal insufficiency exists in 20% of patients with metastatic RCC is, at times, quoted in the urologic literature. This supposition is based on an isolated report from the 1980s (involving a cohort of 15 patients) that, to our knowledge, has only been published in abstract form (Schorr et al, 1986). Indeed, patients with advanced malignancy may exhibit symptoms of an addisonian state (i.e., nausea, vomiting, fatigue, weight loss, etc.) in the absence of biochemical evidence of adrenal insufficiency (Lutz et al, 2000).

Diagnostic Tests. Radiographically metastatic lesions, similar to benign adenomas, appear well circumscribed, homogeneous, and most often lack areas of macroscopic necrosis (Boland et al, 2008). Nevertheless, metastatic disease almost always can be differentiated from the typical adrenal adenoma based on its lack of substantial lipid content. As is discussed in the Imaging section of this chapter, metastatic lesions exhibit greater than 10 HU in attenuation on noncontrast imaging and fail to demonstrate significant contrast loss on adrenal "washout" studies (Fig. 57–24) (Boland et al, 2008). Furthermore, adrenal biopsy can be helpful with newly found adrenal lesions in the setting of a known history of malignancy when imaging is equivocal. Unlike with metastases to the kidney, which are frequently associated with widespread metastatic disease, metastases to the adrenals can occur early and may be the sole focus of radiographically identifiable disease, making therapeutic resection feasible. (See Adrenal Biopsy section for more details.)

Nonetheless, a standard metabolic workup is warranted to rule out functionality of any new adrenal lesion (Lenert et al, 2001). Indeed, some small series report no difference in the incidence of metabolically active tumors, when patients with and without a history of extra-adrenal malignancy are compared (Tsvetov et al, 2007). Importantly, reports of pigmented pheochromocytomas being mislabeled as metastatic melanoma exist in the literature (Lenert et al, 2001).

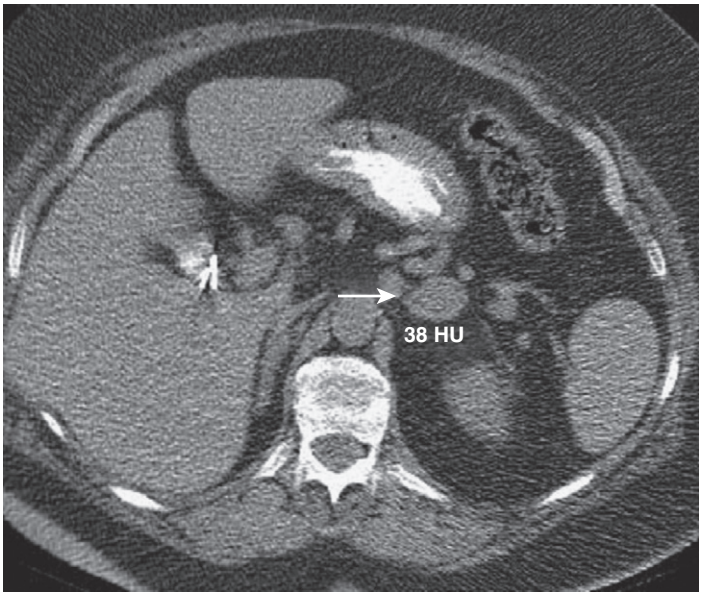

Figure 57–24. Unenhanced CT of a patient with a left adrenal metastasis from right-sided renal cell carcinoma (RCC) that was resected several years earlier. At presentation, unenhanced imaging revealed a lesion with an attenuation of greater than 10 Hounsfield units (HU), indicating that the adrenal mass was not a lipid-rich adenoma. Washout study (not shown) revealed poor contrast washout, significantly reducing the possibility that the lesion was a lipid-poor adenoma. Metabolic evaluation ruled out pheochromocytoma. Laparoscopic adrenalectomy confirmed metastatic RCC.

Treatment and Prognosis. Resection of metastases to the contralateral or ipsilateral adrenal gland from renal cell carcinoma is advocated in the context of a cytoreductive approach for a select group of patients. Nevertheless, benefits to adrenal metastatectomy are as yet unproven in a prospective fashion. Moreover, the role of resection may change with antiangiogenic targeted therapies (Lau, 2003; Antonelli, 2006; O'Malley et al, 2009). **Treatment of metastatic disease of the adrenals in patients with nonurologic malignancies requires a multidisciplinary approach. The urologist must work closely with the patient's primary medical oncologist regarding the surgical and biologic prudence of resection.** Lenert and colleagues (2001) have reported their experience with adrenalectomy for solitary adrenal metastases from over 20 separate primary malignancies. Currently, the best data regarding adrenal metastasectomy exist for patients with non–small cell lung carcinoma and melanoma (Branum et al, 1991; Mittendorf et al, 2008).

In patients with non–small cell lung cancer, adrenal metastases are most frequently encountered in the setting of systemic disease. An isolated adrenal metastasis is rare, and may be due to nonhematogenous lymphatic spread (Tanvetyanon et al, 2008). Surgical resection of solitary adrenal metastases has been associated with 5-year overall survival rates of over 25% (Mercier et al, 2005; Strong et al, 2007; Tanvetyanon et al, 2008). Although the prognosis following resection in patients with metachranous metastasis and longer disease-free intervals is thought to be better than in those patients found to have an isolated adrenal metastasis at the time of their initial diagnosis, a meta-analysis from 2008 demonstrated that the 5-year overall survival is equivalent in both groups (Tanvetyanon et al, 2008). In patients with metastatic melanoma, adrenalectomy has been reported to be associated with long-term survival and even rare regression of distant disease (Branum et al, 1991; Collinson et al, 2008). Nevertheless, data is limited to retrospective reports describing highly selected patient populations (Mittendorf et al, 2008).

Summary. Metastatic disease to the adrenal is common and must be suspected when patients with a history of malignancy are found to have adrenal incidentaloma. Radiographic and functional studies are essential and often secure the diagnosis. Percutaneous biopsy is safe but its success depends on the size and location of the lesion and the technical aspects of the procedure. Adrenalectomy for patients with solitary adrenal metastasis is a viable option for a select group of individuals.

Key Points: Adrenal Metastases

- Metastatic disease to the adrenals is common, yet it appears that bilateral and bulky disease (>4 cm) is necessary to produce biochemical evidence of adrenal insufficiency.
- More than 50% of newly discovered adrenal lesions in patients with a history of previous malignancy represent metastatic disease; nevertheless, metabolic work-up in these patients is recommended.

Malignant Pheochromocytoma. Malignant pheochromocytomas are discussed in the section Disorders of Increased Adrenal Function: Pheochromocytoma.

Benign

Adenoma

Introduction and Epidemiology. Adenomas are the most common neoplasms arising from the adrenal gland and are most often associated with the cortex. These lesions are found in approximately 6% of patients at autopsy (Kloos et al, 1995). Clinically adrenal adenomas are most often incidentally discovered on cross-sectional imaging obtained for other indications and are thus termed "incidentalomas." More than 85% of adrenal neoplasms incidentally discovered on imaging are ultimately clinically proven to be adenomas (Young, 2000, 2007b). **The incidence of adenomas rises with age, as inferred from the observation that incidentalomas are found in less than 0.5% of individuals in their 20s and in up to 7% of those 70 years of age or older** (Young, 2000). Similar trends are observed in historical autopsy series (Commons and Callaway, 1948; Russell et al, 1972). Despite benign behavior, a small percentage of adrenal adenomas can exhibit metabolic activity, and, as such, can represent "surgical" lesions. The essential evaluation of the small adrenal mass requires differentiating the nonfunctional benign adenoma from functional or malignant lesions.

Pathophysiology and Clinical Characteristics. Adenomas possess a yellowish color on gross pathological examination due to presence of abundant lipid. Histologically, they may be difficult to distinguish from adrenal adenocarcinomas. As discussed above (see Table 57–17), pathologists use a set of criteria proposed by Weiss along with modern immunohistochemical methods to differentiate the two clinical entities (Weiss, 1984; Aubert et al, 2002; Sasano et al, 2006).

Adrenal adenomas are by definition benign and the vast majority are metabolically silent. An analysis of the 13 largest series of incidental adrenal masses (n = 2005) reveals that nearly 90% (n = 1779) of these lesions are clinically benign adenomas. Of these, only 127 lesions (7.1% of adenomas) exhibited metabolic activity, 107 (6% of adenomas) hypersecreted glucocorticoids, and 20 (1.1% of adenomas) were functioning hyperaldosteronomas. The overwhelming majority (93%) of adenomas displayed no evidence of metabolic activity (Young, 2000, 2007b). Hypersecretion of sex steroids by benign adrenal adenomas is exceedingly rare but has been reported. Interestingly, these rare lesions may secrete testosterone and possess Reinke crystals, normally identified in testosterone-producing Leydig cells of the testes (Ryan et al, 1995). The implications of glucocorticoid and mineralocorticoid hypersecretion by adrenal adenomas are discussed in detail in the sections Cushing Syndrome and Primary Aldosteronism, respectively. Finally, it has been hypothesized that nonfunctional adrenal adenomas may be associated with physiologic derangements, such as insulin resistance and left ventricular dysfunction; however, such reports are isolated to small single-institution series and await confirmation (Midorikawa et al, 2001; Ermetici et al, 2008).

The growth kinetics of adrenal adenomas is reviewed below (see discussion on incidentalomas). In brief, an analysis of 18 reported series following over 850 patients with adrenal incidentalomas revealed that the vast majority of these benign masses remain stable in size; however, approximately 9% of lesions increased by more than 1 cm in diameter over a mean follow-up of 3 years (Barzon et al, 2003). The size and growth of adrenal lesions are discussed in detail in a later section of this chapter.

The current literature suggests that adenomas that are initially metabolically inert are unlikely to gain function. An analysis of 18 published series, reporting over 1100 incidental adrenal masses (not all of them adenomas) revealed that only 1.7% became metabolically active in follow-up, including 0.65% that developed subclinical Cushing syndrome, 0.3% with subsequent overt Cushing syndrome, and 0.05% who were identified as becoming functional secretors of catecholamines. No lesion produced new onset hyperaldosteronism during endocrinologic reevaluation (Barzon et al, 2003).

Diagnostic Tests. The evaluation of incidental adrenal lesions, the primary way that adenomas come to clinical attention, is discussed in detail elsewhere in this chapter. In this section, we review the salient points of the clinical workup, as it relates to adenomas. The goal in evaluating any adrenal lesion is twofold: (1) rule out the possibility of malignancy and (2) document metabolic inactivity of the lesion in question.

Noncontrast CT scan is arguably the most valuable imaging study for the diagnosis of an adrenal adenoma. Computed tomography affords accurate measurements of a lesion's density, uniformity, and size. The vast majority of adrenal adenomas are smooth-bordered, homogeneous tumors that are less than 4 cm in diameter (Grumbach et al, 2003). High intracytoplasmic lipid content is unique to adenomas, and this attribute affords accurate differentiation of adenomas from other adrenal lesions on cross-sectional imaging. **According to an NIH 2002 consensus panel, an adrenal mass with an attenuation of less than 10 Hounsfield units (HU) on unenhanced CT is "strongly suggest[ive of] a benign adrenal adenoma"** (Grumbach et al, 2003). Indeed, a large contemporary series of resected adrenal masses from Cleveland Clinic demonstrated 100% specificity when the threshold of less than 10 HU was applied to lesions in this cohort (Hamrahian et al, 2005). The 100% specificity for adenoma was retained if only masses equal to 4 cm were considered and the threshold was raised to 20 HU (Hamrahian et al, 2005). Nevertheless, not all adenomas have sufficient intracytoplasmic fat content to result in attenuation below 10 HU on noncontrast CT. Approximately 30% of adrenal adenomas register a density greater than 10 HU on unenhanced computed tomography (Korobkin et al, 1998; Pena et al, 2000; Szolar et al, 2005). However, even in these cases a diagnosis of adenoma is still possible employing the "washout" technique, whereby loss of attenuation of the lesion is noted on delayed contrast-enhanced CT imaging. Lesions that "washout" more than 40% to 60% of gained enhancement can be identified as adenomas with specificity that approaches 100% (Fig. 57–25) (Korobkin et al, 1998; Pena et al, 2000; Szolar et al, 2005; Heinz-Peer et al, 2007). MRI also can be used to successfully characterize adrenal adenomas. Chemical-shift ratios relating to in- and out-of-phase imaging substitute for CT attenuation values. Refer to the Imaging section for further details on imaging of adrenal adenomas (Outwater et al, 1996; Hussain and Korobkin, 2004; Heinz-Peer et al, 2007).

Classically, incidentalomas are evaluated for excess cortisol and catecholamine secretion. In patients with history of hypertension, hyperaldosteronemia also should be ruled out (Grumbach et al, 2003). Adenomas themselves only have the potential to secrete cortisol or aldosterone; therefore, strictly speaking if a diagnosis of adenoma is unequivocal on imaging, metabolic workup for pheochromocytoma risks false-positive results given the imperfect specificity of testing. Nevertheless, current recommendations suggest serum or urine metanephrine testing for all adrenal lesions (Grumbach et al, 2003; Young, 2007b). Indeed, pheochromocytomas that mimic adenomas on imaging have been reported validating the

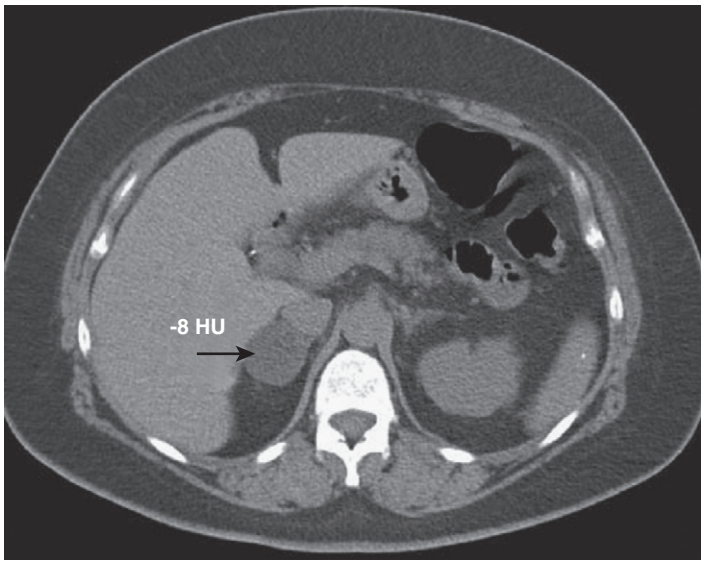

Figure 57–25. Axial cut of an unenhanced computed tomography scan in a patient with a 3.5-cm, right, lipid-rich adrenal adenoma, demonstrating an attenuation of less than 10 Hounsfield units (HU).

recommendation for metanephrine testing of all adrenal lesions (Blake et al, 2003). Despite the 2002 NIH consensus statement that all adrenal lesions greater than 1 cm should undergo a metabolic evaluation, current literature suggests that greater than 80% of adrenal masses are not appropriately radiographically or functionally evaluated in routine clinical practice (Eldeiry and Garber, 2008).

Treatment. **Adenomas that are metabolically active should undergo resection in acceptable surgical candidates.** In patients with nonfunctional adenomas, the size of lesion and its growth characteristics dictate management. Notwithstanding benign imaging features, experts suggest that resection of all adrenal masses greater than 6 cm is prudent given that adenomas of this size are rare and the risk of malignancy is substantial. The one exception to this may be a definitively diagnosed adrenal myelolipoma (Grumbach et al, 2003). Others argue that a cutoff of 4 cm should be used (Young, 2007b). Lesions that are not resected should undergo at least initial radiographic follow-up to ascertain growth kinetics. Reimaging at 6, 12, and, potentially, 24 months has been recommended in order to verify benign clinical biology and indolent growth (Grumbach et al, 2003; Young, 2007b). Suspicious and unusual tumors may necessitate imaging at earlier or more frequent intervals or removal (Young, 2007b). As already discussed, although reports in the literature vary, on average approximately 2% of incidentalomas that are initially metabolically silent result in superphysiologic hormone production during follow-up (Barzon et al, 2003). Despite this low rate of "metabolic transformation," the most recent consensus statement by a panel of NIH-convened experts suggests that annual metabolic hormonal screening for the first 3 to 4 years following diagnosis is prudent, especially for masses that are equal to 3 cm in diameter (Grumbach et al, 2003). Nevertheless, given lack of strong data supporting this recommendation, the need for metabolic reevaluation of adrenal adenomas in patients who show no clinical signs of hormonal hypersecretion remains controversial (Barry et al, 1998; Bulow et al, 2006; Young, 2007b).

Prognosis. Normalization of serum cortisol levels following resection of adenoma likely reduces but does not eradicate heightened cardiovascular risk in patients with Cushing syndrome (Swearingen et al, 1999; Pivonello et al, 2005). For patients with hyperaldosteronism, serum aldosterone and blood pressure often return to normal within 3 months of adrenalectomy (Young, 2007a), although those with baseline essential hypertension may remain medication-dependent. Generally, patients with nonfunctional adrenal adenomas appear to be unaffected by their diagnoses. **A large surveillance series from the Mayo Clinic (n = 231) demonstrated that no patients succumbed to a condition that could be ascribed to adrenal pathology after a mean follow-up of 7 years** (Barry et al, 1998).

Summary. Adrenal adenomas account for more than 80% of incidental adrenal neoplasms. Due to their abundance of intracellular lipid, these lesions possess characteristic imaging features. More than 90% of these lesions are metabolically silent and require no treatment; however, all should be subjected to an initial metabolic evaluation. Lesions greater than 4 to 6 cm and metabolically-active lesions should be resected in patients who are appropriate surgical candidates.

Key Points: Adenoma

- Incidence of adrenal adenoma rises with age.
- Approximately 7% of adrenal adenomas exhibit metabolic hyperactivity. Those that are metabolically inert at diagnosis only rarely (<2%) gain function on follow-up.
- Radiographic diagnosis of adrenal adenoma pivots on its high lipid content.

Oncocytoma

Introduction and Epidemiology. Oncocytomas are familiar to the urologist given their relatively common renal origin (Chang and Harawi, 1992). Oncocytic tumors can also arise from the salivary gland and the endocrine organs. Adrenal lesions are exceedingly rare (Bisceglia et al, 2004), with approximately 50 cases having been reported in the literature (Juliano et al, 2008).

Pathophysiology and Clinical Characteristics. Like oncocytic tumors in other organs, histologically oncocytic adrenal lesions are characterized by mitochondria-rich, large, eosinophilic cells with abundant granulations (Chang and Harawi, 1992). The pathogenesis of oncocytic neoplasias is poorly understood (Chang and Harawi, 1992). Females have been reported to be affected 2.5 times more frequently than males, and left-sided lesions outnumber those in the right adrenal 3.5 to 1. Tumors can grow up to 20 cm, and at least two cases have been reported in pregnancy (Bisceglia et al, 2004; Juliano et al, 2008). Most lesions that are documented in the literature are metabolically inactive; however, some oncocytic adrenal neoplasms (n = 6, or approximately 10% of all cases reported) hypersecrete sex steroids, cytokines, and/or cortisol (Akatsu et al, 2008; Juliano et al, 2008; Lee et al, 2008). Classically, these lesions have been considered benign (Vaughan and Blumenfeld, 2007); however, over 30% of reported lesions have been classified as malignant with an additional 23% having been designated as pathologically indeterminant (Juliano et al, 2008). These reports include a lesion that locally invaded the inferior venal cava (El-Naggar et al, 1991).

Diagnostic Tests and Treatment. Because the diagnosis of adrenal oncocytic tumor is nearly always made upon surgical resection, the evaluation and treatment of oncocytic lesions follows the same strategy as that of other adrenal masses. On imaging, adrenal oncocytic lesions are not reported to regularly possess the central stellate scar that may characterize such cases in the kidney (Lee

et al, 2006). The optimal treatment for malignant oncocytic lesions is unknown; however, in at least one report, metastatectomy and radiation treatment for local recurrence may play a role (Juliano et al, 2008).

Prognosis. Given the emerging appreciation for the heterogeneity of the biologic behavior of adrenal oncocytic lesions, the prognosis of patients with these lesions is uncertain but leans toward the more benign. Some reports suggest that even patients with widely metastatic disease can exhibit slow disease progression with long-term survival (Juliano et al, 2008).

Summary. **Adrenal oncocytic tumors are extremely rare neoplasms. Despite predominantly benign classical descriptions, a proportion of lesions can exhibit malignant potential.**

Key Point: Oncocytoma

- Unlike renal oncocytomas, a large proportion of adrenal lesions are malignant.

Myelolipoma

Introduction and Epidemiology. Myelolipomas are rare, benign, metabolically silent lesions that arise primarily from the adrenal gland and arise in patients in all age groups (Han et al, 1997). Based on historical autopsy series, the incidence of these lesions is estimated at less than 0.1% percent (Olsson et al, 1973; Bishop et al, 2006). Some reports suggest that 15% of all myelolipomas are extra-adrenal, with up to a half of these arising in the presacral area. Thoracic, retroperitoneal, pelvic, renal, hepatic, and gastric lesions have all been reported (Patel et al, 2006).

Pathophysiology. **Myelolipomas appear to result from clonal stem cell proliferation and are composed of an unusual mixture of mature adipose tissue and relatively normal trilineage hematopoietic elements** (Bishop et al, 2006). Overabundance of megakaryoctyes has been reported. Unlike normal bone marrow, cellularity within myelolipomas varies greatly and does not decrease with increasing patient age. These lesions do not appear to contribute hematopoietic cells to the circulation, which may be due to irregularities in stromal support and a lack of appropriate microvasculature. Specifically, normal capillary venous sinuses that are critical to functional bone marrow are nearly always absent in myelolipomas (Bishop et al, 2006).

Experimentally, myelolipoma generation has been induced in the adrenals of rats following injection with necrotic tumor tissues and ACTH (Seyle and Stone, 1950). This observation has resulted in the hypothesis that myelolipomas are a result of an adrenal stress response. Additional theories exist, and the etiology of these unusual tumors remains unknown (Han et al, 1997; Bishop et al, 2006).

Clinical Characteristics. Men and women are affected with relatively equal frequency. The tumor does not appear to have a predilection for either the right or left adrenal. Bilateral lesions have been reported (Bishoff et al, 1997; Han et al, 1997; Russell et al, 2000). Tumors vary greatly in size, and can grow in excess of 10 cm. In a single institutional series of 21 lesions, the average tumor size was 5.1 cm (Han et al, 1997). As with most retroperitoneal tumors, these lesions are usually asymptomatic, although some proportion of patients do present to medical attention with abdominal or flank pain (Han et al, 1997). Spontaneous rupture of myelolipomas has been reported; however, this event is rare. Indeed, the mean tumor size of myelolipomas that ruptured exceeds 10 cm (range 6.3 to 14.7 cm) (Russell et al, 2000).

Classically, myelolipomas are metabolically nonfunctional lesions. Nevertheless, over two dozen cases are present in the literature in which myelolipomas are associated with adrenal metabolic hyperactivity. The most common abnormality appears to be hypercortisolemia (Hisamatsu et al, 2004). In the majority of patients, the myelolipoma is not the source of excess hormone production but coexists with a hyperfunctional adrenal adenoma. Indeed, some have suggested that these cases substantiate the early animal model where rat adrenal hyperstimulation with pituitary extract resulted in myelolipoma formation (Seyle and Stone, 1950; Hisamatsu et al, 2004).

Diagnostic Tests. In the majority of cases, diagnosis of myelolipoma can be made accurately on cross-sectional imaging. **Computed tomography reveals a well-circumscribed adrenal lesion with varying amounts of mature adipose tissue (30 HU) interdigitated with higher-density myeloid components, which enhance upon contrast administration** (Fig. 57–26). Over a quarter of the lesions may exhibit evidence of

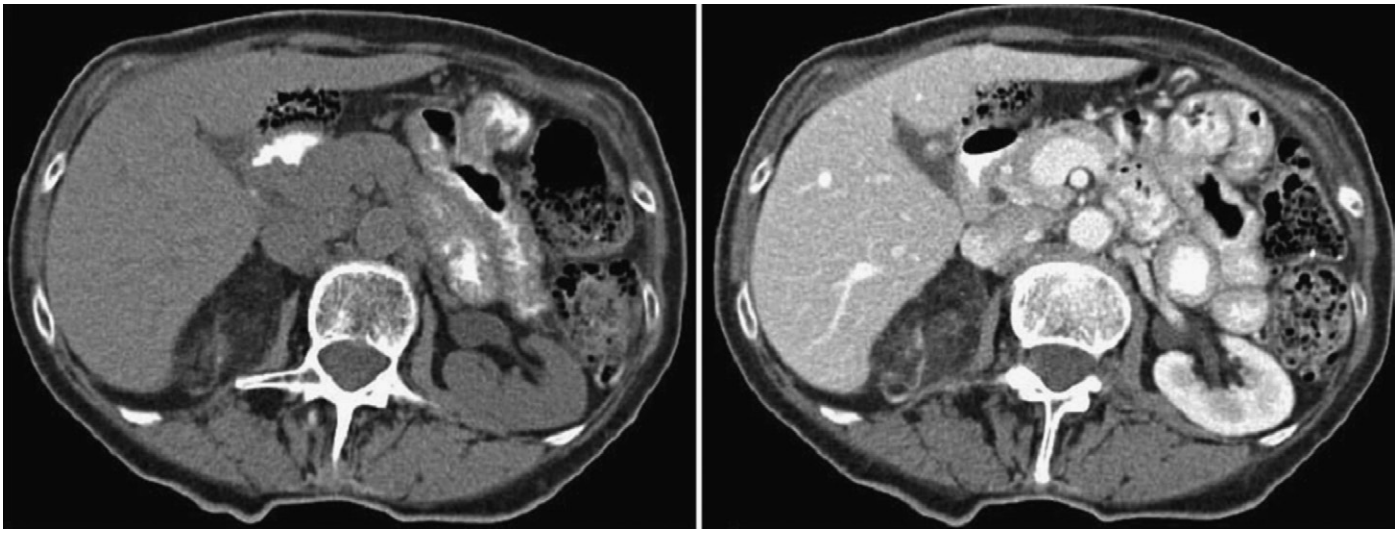

Figure 57–26. Pre- and postcontrast axial cuts of a CT scan demonstrating a right 6- × 3.5-cm adrenal myelolipoma in a 76-year-old, otherwise asymptomatic female. (Courtesy of Dr. Rosalia Viterbo, Fox Chase Cancer Center, Philadelphia, PA.)

calcifications, and a large proportion have areas of hemorrhage (Kenney et al, 1998). Macroscopic adipose tissue can also be easily identified within myelolipomas on magnetic resonance imaging (Cyran et al, 1996). **The presence of macroscopic fat in an adrenal mass is virtually diagnostic of a myelolipoma.** Nevertheless, exceedingly rare exceptions exist, and adrenal lipomas, teratomas, angiomyolipomas, metastases, and liposarcomas with macroscopic fat on imaging have been reported (Han et al, 1997; Lam and Lo, 2001). Careful interpretation of cross-sectional imaging is mandatory to distinguish an adrenal myelolipoma from an upper pole renal angiomyelolipoma. In contrast to the benign appearance of a myelolipoma, liposcarcomas tend to be aggressive lesions that lack regular borders and have a propensity for infiltrating surrounding tissues (Schaeffer and Kavoussi, 2005). When the diagnosis is in doubt, some experts believe that percutaneous biopsy may be helpful (Han et al, 1997).

As discussed earlier, although myelolipomas are themselves metabolically silent, they have been associated with metabolically active adenomas and pheochromocytomas that may not be readily differentiated on imaging. Therefore it is not unreasonable to perform a standard adrenal metabolic workup in the rare patient that is diagnosed with a myelolipoma (Daneshmand and Quek, 2006; Patel et al, 2006). Nevertheless, some experts believe a metabolic workup is only necessary when the index of suspicion for a concomitant metabolically active tumor is high (Han et al, 1997). The National Institutes of Health Consensus Panel on adrenal incidentaloma concluded that myelolipoma can be regarded as an exception to the mandatory metabolic work-up of a newly discovered adrenal mass (Grumbach et al, 2003).

Treatment. **Classically asymptomatic myelolipomas are treated conservatively.** No standard protocols for reimaging exist, but serial reevaluation with ultrasonography or CT every several years has been suggested (Han et al, 1997). **Surgery is usually reserved for symptomatic lesions** (Schaeffer and Kavoussi, 2005).

Prognosis. Tumor growth rates vary. Not only do some lesions remain stable, but some may actually decrease in size over time (Han et al, 1997). Based on available literature, resections are considered definitive. As discussed previously, although spontaneous rupture of myelolipomas has been reported, this event appears to be extremely rare and, on average, has been reported in lesions greater than 10 cm in size (range 6.3 to 14.7 cm) (Russell et al, 2000).

Summary. Myelolipoma is a rare lesion of the adrenal gland that contains hematopoietic elements and mature adipose tissues. Extra-adrenal lesions have also been reported. In general, lesions do not require resection and follow a benign clinical course.

Key Points: Myelolipoma

- Myelolipoma possess tissue components identical to healthy bone marrow.
- Clinical course is benign and surgery is indicated only for extremely large or symptomatic lesions.

Ganglioneuroma

Introduction and Epidemiology. Ganglioneuromas are extremely rare benign neuroectodermal neoplasms that are composed of ganglion and Schwann cells (Enzinger and Weiss, 1995). Although uncommon, the diagnosis must be considered during the evaluation of an adrenal mass (Maweja et al, 2007). In one large series (n = 88), 21% of cases arose from the adrenal gland itself. Other sites of origin included the mediastinum (39%), retroperitoneum (31%), and isolated cases in the pelvis and neck (Enzinger and Weiss, 1995). The tumor appears to have a predilection for the young, with only 20% of cases affecting individuals over age 40, and some 50% of cases found in patients between 10 and 29 years of age (Enzinger and Weiss, 1995).

Pathophysiology/Clinical Characteristics. Ganglioneuromas are benign, but isolated case reports of ganglioneuromas undergoing malignant transformation are reported (Enzinger and Weiss, 1995). Furthermore, cases of peripheral nerve sheath tumors (PNST) arising within ganglioneuromas, and composite tumors of ganglioneuroma and pheochromocytoma, also exist in the literature (Radin et al, 1997). Interestingly, reports of ganglioneuroma cells in lymph nodes surrounding an apparently benign tumor exist, and some authors presume that such cases represent neuroblastomas that have matured (Enzinger and Weiss, 1995).

Tumors can grow extremely large and have a propensity to encase vessels without impinging on the vessel lumen (Radin et al, 1997). Ganglioneuromas have been reported to secrete vasoactive intestinal polypeptide (VIP), and some patients complain of diarrhea (Enzinger and Weiss, 1995). Nevertheless, the majority of individuals with ganglioneuromas are largely asymptomatic (Radin et al, 1997).

Diagnostic Tests. On both enhanced and unenhanced CT, ganglioneuromas exhibit attenuation less than that of muscle (Radin et al, 1997). Calcifications within the tumor are not uncommon and have been reported present in as many as a third of ganglioneuromas (Enzinger and Weiss, 1995; Radin et al, 1997). Some authors suggest that a metabolically silent adrenal mass with unenhanced attenuation of less than 40 HU and presence of stippled calcifications should raise suspicion for a ganglioneuroma (Maweja et al, 2007).

Treatment/Prognosis. Because the diagnosis of ganglioneuroma is nearly always made upon resection, natural history of unresected gangioneuromas has not been clearly defined. Nevertheless, the urologist must be aware that the tumors can grow quite large and can surround critical structures such as retroperitoneal vessels (Radin et al, 1997).

Summary. Ganglioneuromas are rare tumors that can arise from the adrenal gland. Diagnosis is largely pathologic and the clinical course is nearly always benign.

Key Point: Ganglioneuroma

- Ganglioneuromas are rare, benign tumors that tend to occur in the young and can grow to encase critical structures.

Adrenal Cysts

Introduction/Epidemiology. Adrenal cysts have been noted in 0.064% to 0.18% of patients in autopsy series and account for 1% to 5% of incidentally detected adrenal lesions (Elsayes et al, 2004; Guo et al, 2007; Song et al, 2008). Cystic adrenal lesions can be diagnosed throughout life and as early as the prenatal period. Cyst size can range widely from several millimeters to greater than 20 cm, with either unilocular or multilocular components. Although the majority of adrenal cysts are unilateral, bilateral cysts have been noted in 8% to 10% of cases (Rozenblit et al, 1996). An increased incidence of adrenal cysts has been noted in women, with a peak incidence between the third and sixth decades of life (Sanal et al, 2006). Several medical conditions have been

associated with adrenal cysts, including polycystic renal disease, Klippel-Trenaunay-Weber syndrome, and Beckwith-Wiedemann syndrome (Erickson et al, 2004).

Pathophysiology. **Four histologic types of adrenal cysts have been described, including pseudocysts, endothelial, epithelial, and parasitic cysts.** Among these, the most common are pseudocysts and endothelial adrenal cysts. Adrenal pseudocysts do not possess a cellular lining and are believed to be the result of previous intra-adrenal hemorrhage or infarction. Endothelial cysts include lymphangiomatous and angiomatous subtypes. Epithelial cysts can be further characterized as glandular and embryonal cysts. Paracystic adrenal cysts may occur in association with disseminated *Echinococcus* infections; however, it is extremely rare for a parasitic adrenal cyst to be the only site of infection (Otal et al, 1999; Guo et al, 2007).

It can be difficult to distinguish a benign adrenal cyst from cystic adrenal neoplasms. This is especially true of adrenal neoplasms with associated hemorrhage or cystic degeneration, which may radiographically resemble an adrenal pseudocyst. In a series of 41 adrenal lesions macroscopically characterized as cysts, 7 were associated with adrenal neoplasms, including 2 adrenal cortical carcinomas, 2 adenomas, and 3 pheochromocytomas (Erickson et al, 2004). Furthermore, 6 of the 7 adrenal neoplasms in this series were associated with adrenal pseudocysts. **A review of multiple series accounting for 515 adrenal cysts noted that 7% of the lesions were associated with malignancy, all of which were pseudocysts** (Neri and Nance, 1999). Additionally, cases of cystic adrenal carcinoma and pheochromocytomas have been reported (Rozenblit et al, 1996). Compared with benign cysts, cystic adrenal neoplasms tend to be larger (>7 cm) and have thicker walls. When considering the reported incidence of malignancy associated with adrenal cysts it should be noted that histology in most series is based upon surgical specimens, so the incidence of malignancy may be overestimated because small radiographically benign lesions likely remain unresected.

Clinical Characteristics. Although most adrenal cysts are diagnosed incidentally, some become large in size and are symptomatic on presentation. The origin of large adrenal cysts is often difficult to distinguish from other organs, including the kidney, pancreas, spleen, and liver (Otal et al, 1999).

Diagnostic Tests. Although the majority of adrenal cysts are benign, and nonfunctional, routine endocrinologic evaluation should be performed to exclude active lesions. Due to the relative rarity of adrenal cysts, well-defined diagnostic criteria have not been established. The suggested radiographic criteria for diagnosing an adrenal cyst include a well-defined, sharply marginated mass of fluid attenuation without any evidence of enhancement (Fig. 57–27). Cysts with higher fluid attenuation (>30 HU) may be attributed to hemorrhage, intracystic debris, or calcification (Rozenblit et al, 1996; Sanal et al, 2006). The presence of peripheral calcifications has been noted in 15% to 70% of adrenal cysts (Song et al, 2008). Calcifications are typically rimlike, but occasionally will be nodular in appearance (Rozenblit et al, 1996). When evaluated with MRI, simple cysts will appear hypointense on T1-weighted images and hyperintense on T2-weighted images. Unfortunately, radiographic criteria alone cannot rule out malignancy in adrenal cystic lesions, thus cyst aspiration or surgical excision is often performed to rule out malignancy. Aspiration of cystic adrenal lesions should only be performed after chemical evidence of pheochromocytoma has been excluded. Adrenal cyst aspiration may be both diagnostic and potentially therapeutic in select patients (Pradeep et al, 2006). If aspiration is performed, the collected fluid should be sent for Gram stain, cytology, triglycerides, cortisol, and amylase (for left-sided cysts). Additionally, a contrast injection of the cyst cavity (cystogram) can be performed at the time of aspiration to evaluate the cyst wall texture.

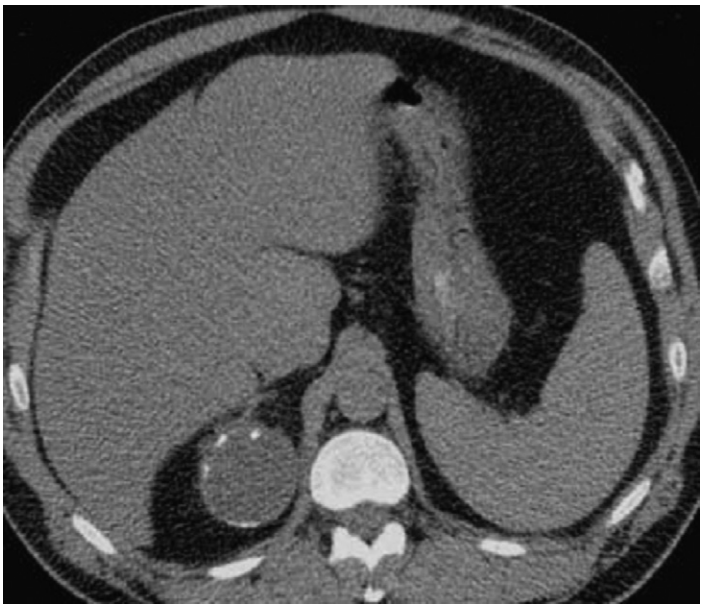

Figure 57–27. Unenhanced CT of a right adrenal cyst. Stippled calcifications within the cyst wall are not unusual in these lesions, as can be seen in this particular lesion.

Treatment. Factors influencing the treatment of adrenal cysts include functional status, chances of incidental malignancy, and cyst-related symptoms. With the known, albeit low, risk of associated malignancy with cystic adrenal lesions, active surveillance must be done with caution. Small, asymptomatic thin-walled lesions containing homogeneous near-water attenuation may be safely observed, and future surveillance of cystic lesions is warranted (Rozenblit et al, 1996). Adrenal cysts that are heterogeneous, large, thick walled, or symptomatic warrant further evaluation and surgical excision. Because of the known risk of associated malignancy, simple decortication is not advocated and should be undertaken with caution. Due to the inadequacies of radiographic evaluation, surgical resection remains the standard of care in patients with a normal-appearing contralateral adrenal gland.

Prognosis. The prognosis and subsequent follow-up following resection of an adrenal cyst is dependent upon histology. Benign adrenal cysts warrant follow-up to monitor potential reaccumulation, and warrant re-treatment if symptoms return. Adrenal cysts associated with malignancy require follow-up in accordance to the malignant histology detected.

Summary. Adrenal cysts are rare, and their diagnosis can be challenging. Symptomatic adrenal cysts should be surgically removed, while small nonfunctional asymptomatic lesions with benign radiographic appearance may be treated conservatively with regular follow-up.

Key Point: Adrenal Cysts

- Due to the known chance of associated malignancy, observation of adrenal cysts must be done with caution.

Benign Pheochromocytoma. Benign pheochromocytomas are discussed in the section Disorders of Increased Adrenal Function: Pheochromocytoma.

EVALUATION OF ADRENAL LESIONS IN UROLOGIC PRACTICE

In urologic practice, the evaluation of adrenal pathology is typically in the setting of patients referred with a diagnosis of a new adrenal mass or in existing patients in whom a new adrenal mass is discovered incidentally. Occasionally, patients are identified by astute clinicians based on clinical symptoms in the absence of prior radiographic identification of an adrenal lesion. This section of the chapter reviews clinically relevant evaluation and management of adrenal masses. It is important to note that the pregnant patient diagnosed with an adrenal mass requires a carefully planned, multidisciplinary, tailored approach. This subject matter is beyond the scope of this chapter; however, reviews on this topic are available (Harrington et al, 1999; Lindsay and Nieman, 2005b, 2006; Klibanski et al, 2006).

Overview of the Adrenal Incidentaloma

Adrenal incidentalomas are unsuspected adrenal masses greater than 1 cm in diameter identified on cross-sectional imaging performed for seemingly unrelated causes. Strictly speaking, patients who are undergoing a staging evaluation for another malignancy or who are later found to have symptoms relating to the adrenal lesion are excluded from the term "adrenal incidentaloma," given the possible relationship of the primary indication for the study and the adrenal lesion (Young, 2000, 2007b; Mazzaglia and Monchik, 2009). **The frequency of adrenal incidentalomas is relatively high, with contemporary imaging series reporting an incidence of approximately 5%,** (Song et al, 2008) **similar to that found in historical autopsy data** (Commons and Callaway, 1948; Russell et al, 1972). **The incidence of the incidental adrenal mass increases with age, with a risk of less than 0.5% in individuals in their 20s and up to 7% in those 70 years of age or older** (Young, 2000).

It is important to emphasize that "incidental" does not mean "insignificant." Table 57–19 summarizes collective data available regarding pertinent clinical characteristics of over 2000 newly discovered adrenal lesions and demonstrates that **nearly 20% of adrenal incidentalomas are found to be potential surgical lesions.** The two characteristics of primary clinical relevance are imaging and metabolic activity or functional status. Biopsy is rarely indicated but can be a useful tool in specific clinical circumstances. This section of the chapter describes in details the clinical indications and processes of imaging, biopsy, and metabolic testing.

Table 57–19.

Characteristics of Incidental Adrenal Masses as Described in a Systematic Review of Published Series of Adrenal Incidentalomas That Include ≥20 Patients (Total *n* = 2005)

ADRENAL LESION	PERCENT OF TOTAL (*n* = 2005)
Metabolically active	11.2%
Cortisol-producing adenoma	5.3%
Aldosterone-producing adenoma	1.0%
Pheochromocytoma	5.1%
Malignant	7.2%
Adrenocortical carcinoma	4.7%
Metastasis	2.5%
TOTAL POTENTIALLY SURGICAL LESIONS	18.4%

Data from Young WF Jr. Management approaches to adrenal incidentalomas. A view from Rochester, Minnesota. Endocrinol Metab Clin North Am 2000;29(1):159–85, x; and Young WF Jr. The incidentally discovered adrenal mass. N Engl J Med 2007b;356(6):601–10.

Imaging of Adrenal Masses

Imaging Modalities

Appropriate management and follow-up of the adrenal incidentaloma largely depends on ordering the proper test, carrying out accurate image-acquisition protocols, and interpreting the information obtained. Urologists must be well versed in adrenal imaging modalities and limitations and be able to speak knowledgeably to their radiology colleagues. Numerous imaging modalities can be used to assess both morphologic and functional features of adrenal masses. This section will summarize the salient features of each imaging modality as they pertain to characterization of adrenal incidentalomas. Please also refer to the Adrenal Lesions section of this chapter for details regarding imaging characteristics of each specific type of adrenal lesion.

Ultrasonography. Ultrasonography is a suboptimal imaging modality for detecting and fully characterizing adrenal lesions. Nevertheless, many incidentalomas will be discovered on ultrasound imaging performed for unrelated reasons. Indeed, in parts of the world where ultrasonography is employed as the primary imaging modality, the majority of adrenal incidentalomas are discovered using this modality (Bhargav et al, 2008). Moreover, in series where ultrasonography is responsible for identifying individuals with adenomas, right-sided lesions appear to be more common, whereas ultrasonography is less sensitive in identifying left-sided adrenal lesions than those in the right gland, based on anatomic differences. On the right, the IVC and liver provide a better window to the adrenal gland by ultrasonography, whereas on the left, the adrenal can be overlooked or mistaken as part of the splenic, pancreatic, para-aortic lymphatic, or gastric anatomy (Barzon et al, 2003).

Computed Tomography and Magnetic Resonance Imaging. Imaging with computed tomography (CT) and magnetic resonance (MR) permit cross-sectional and reconstructed anatomical image characterization of the adrenals and serve as the cornerstone for adrenal evaluation. Size, laterality, homogeneity, density, vascularity (enhancement and washout), and anatomic relationships can be accurately assessed using these modalities. Indeed, the size of an adrenal lesion, a characteristic reliably assessed by cross-sectional imaging, is a primary factor driving management decisions (see discussion in Size and Growth section). Often the differential diagnosis of an adrenal lesion can be immediately narrowed based on their imaging characteristics. For instance, the presence of macroscopic fat identifies an adrenal myelolipoma, while large heterogeneous masses that invade surrounding structures are most indicative of adrenal adenocarcinomas (Cyran et al, 1996). Adrenal cysts and acute or subacute hemorrhage also exhibit characteristic imaging findings (Burks et al, 1992). **Nevertheless, most adrenal incidentalomas are small homogeneous masses with regular**

contours that cannot be immediately given a pathologic label. Further characterization of these common lesions relies on the ability of modern cross-sectional imaging to identify the presence of intracytoplasmic lipid that differentiates a benign adrenal adenoma from other adrenal pathology (Korobkin et al, 1996b). Although adenomas can be differentiated from nonadenomas based on this single imaging characteristic, the need for a metabolic workup is not eliminated based upon identification of lipid within an adrenal mass. Radiographic differentiation between metabolically functional and nonfunctioning adenomas has been investigated and, to date, no reliable radiographic test or characteristic is sensitive enough to obviate endocrinologic evaluation based solely on imaging (Korobkin et al, 1996b; Fujiyoshi et al, 2003; Hussain and Korobkin, 2004).

Unenhanced CT. **An unenhanced CT scan is the first, and perhaps single best, and most easily interpreted test for intracellular lipid and therefore can diagnose an adrenal adenoma in more than 70% of cases. Low attenuation (<10 HU) on unenhanced CT corresponds to high intracytoplasmic lipid content and is diagnostic for an adrenal adenoma** (Lee et al, 1991; Korobkin et al, 1996b). Using a threshold of 0 or less HU, there is 100% specificity for an adrenal adenoma, meaning that if the lesion meets this criterion, it is always an adenoma. Unfortunately, the sensitivity of noncontrast CT density measurements is imperfect, meaning that not all adenomas will meet this criterion. Indeed only 41% of adenomas exhibit an attenuation of 0 HU (Boland et al, 1998), and therefore a threshold of 10 HU is currently used. This cutoff affords a sensitivity of 71% and a specificity of 98% for the diagnosis of adrenal adenomas (Boland et al, 1998; Boland et al, 2008). In other words, 98% of lesions that exhibit an attenuation of 10 HU or less on nonconstrast CT are adrenal adenomas, while less than 30% of adrenal adenomas are lipid-poor (also known as "atypical adenomas") and exhibit an attenuation of greater than 10 HU. Similar test characteristics have been confirmed in purely surgical series (Hamrahian et al, 2005). In urologic practice, this criterion on unenhanced CT is quite useful, because the vast majority of renal imaging for stones or lesions of the upper urinary tracts includes an unenhanced precontrast phase. Despite the high specificity of the 10 HU cutoff, few low-density (<10 HU) pheochromocytomas have been reported, underscoring the importance of a metabolic workup for all adrenal lesions (Blake et al, 2003; Blake et al, 2005). It should be mentioned that in an era of digital radiology, density measurements of adrenal lesions can easily be measured at the time of evaluation for definitive evaluation, even when the interpreting radiologist may not provide the values in their dictation. Diligence in this regard by the clinician is essential to avoid additional unnecessary imaging tests, even if improperly recommended.

Enhanced CT. Some adrenal masses may be discovered on contrast-enhanced imaging without the benefit of precontrast films. Unfortunately, the diagnostic information that can be obtained from attenuation values of these single-phase studies (approximately 1 minute after the contrast bolus) is limited. Unlike unenhanced CT, there is tremendous overlap in postcontrast attenuation values of adenomas and nonadenomas (Korobkin et al, 1996a; Szolar and Kammerhuber, 1998).

Recently, some authors demonstrated that enhanced CT may indeed contain diagnostic information that is helpful in identifying lipid-rich adenomas when histogram analysis of the lesion's region of interest (ROI) is performed. This technique is available on most modern workstations, and it graphs the quantity of pixels in an ROI against their attenuation value (Boland et al, 2008). Some suggest that if more than 10% of pixels exhibit a density below 0 HU, the lesion is likely an adenoma (Bae et al, 2003). Nevertheless, this technique is not yet fully validated (Boland et al, 2008).

CT Washout Study. **Approximately 30% of adrenal adenomas exhibit an attenuation of greater than 10 HU on unenhanced CT due to their lower lipid content. These "atypical adenomas" are indistinguishable from nonadenomas using noncontrast CT density measurements alone** (Boland et al, 1998)**. Fortunately lipid-poor adenomas possess identical properties to lipid-rich adenomas regarding their rapid loss (washout) of enhancement following CT contrast load** (Caoili et al, 2000; Pena et al, 2000). Indeed in the last decade, "washout" of contrast enhancement has become a routine technique to differentiate lipid-poor adenomas from other adrenal lesions (Korobkin et al, 1998; Szolar and Kammerhuber, 1998; Szolar et al, 2005). An absolute percent washout (comparing noncontrast values to 15-minute postcontrast density values) of greater than 60%, or a relative percent washout (comparing arterial phase density measurements to 15-minute postcontrast density values) of greater than 40% on delayed (washout) imaging, are indicative of adenoma (Fig. 57–28) (Caoili et al, 2002; Boland et al, 2008). Remarkably, test characteristics for these CT washout studies approach nearly perfect sensitivity and specificity parameters (Boland et al, 2008). Figure 57–29 summarizes when CT washout studies should be used and how the percent washout is calculated.

Reports on washout studies using a 10-, instead of a 15-minute, delay exist. Originally, a relative percent washout (RPW) of greater than 50% was believed to be necessary to diagnose adenomas using such protocols (Pena et al, 2000). However, more recent reports suggest that just as with a 15-minute delayed study, an RPW of greater than 40% is sufficient (Blake et al, 2005). Nevertheless, despite the potential added efficiency of a 10-minute study, the 15-minute delayed protocols are most often employed (Boland et al, 2008).

Given these data, it is imperative that the knowledgeable urologist orders a proper adrenal CT study to include noncontrast 5-mm images through the adrenal with enhanced (1-minute postbolus imaging) and 15-minute washout imaging, and speaks to the radiologists to assure the test uses the proper protocol. In the absence of a properly performed test, nondiagnostic images may lead to a recommendation for subsequent unnecessary and anxiety-provoking tests.

MR Imaging. Similar to adrenal imaging by CT, magnetic resonance imaging of the adrenal incidentaloma relies on its ability to accurately quantify the lesion's lipid content. **While CT uses unenhanced attenuation to identify lipid-rich adenomas, MRI harnesses the interference between signal collected from fat and water tissue to evaluate for intracellular lipid content** (Hussain and Korobkin, 2004). **On such opposed phase chemical-shift imaging, signal intensity loss on out-of-phase sequences, when compared to in-phase imaging, signifies the presence of intracellular lipid and definitively identifies the lesions in question is an adenoma** (Korobkin et al, 1996b; Namimoto et al, 2001). The loss of signal intensity can be quantified by several methods (for example, using the spleen as an internal reference); however, in clinical practice, qualitative assessments are most often employed (Outwater et al, 1996; Fujiyoshi et al, 2003; Boland et al, 2008). Most reports demonstrate that the test characteristics of MR chemical shift imaging are similar to those of unenhanced CT, albeit

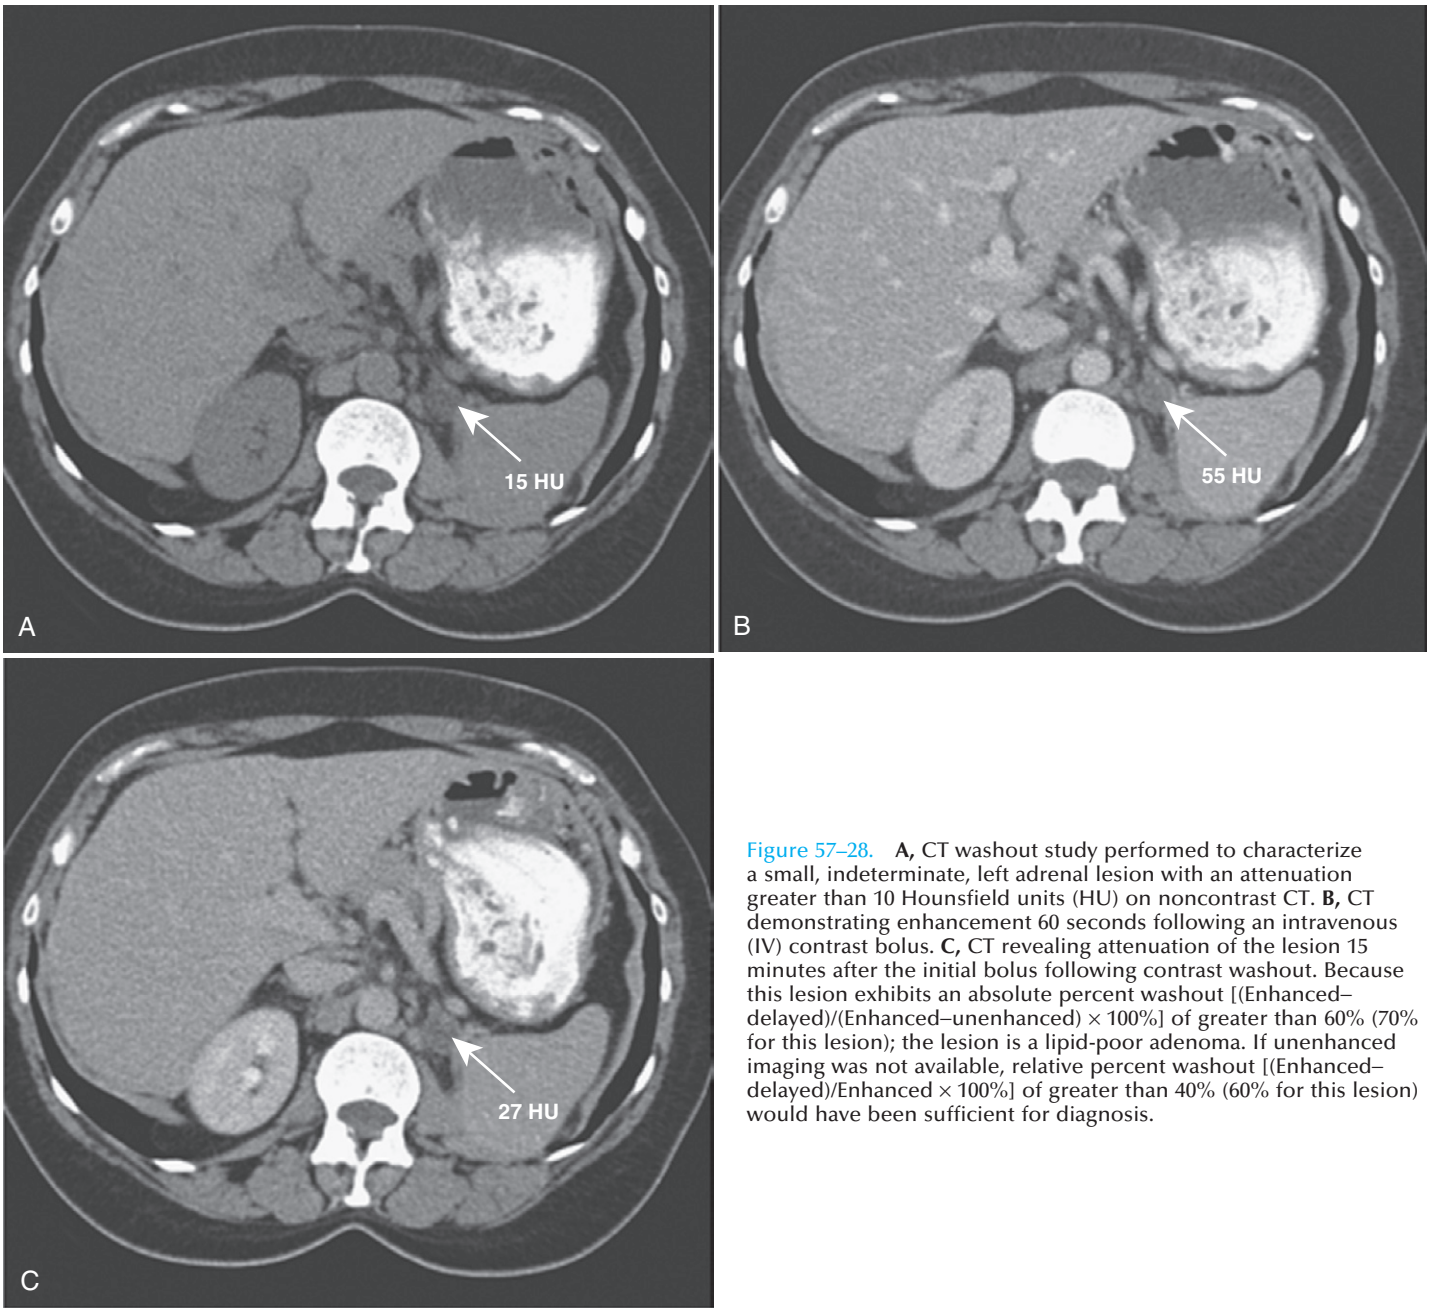

Figure 57–28. **A,** CT washout study performed to characterize a small, indeterminate, left adrenal lesion with an attenuation greater than 10 Hounsfield units (HU) on noncontrast CT. **B,** CT demonstrating enhancement 60 seconds following an intravenous (IV) contrast bolus. **C,** CT revealing attenuation of the lesion 15 minutes after the initial bolus following contrast washout. Because this lesion exhibits an absolute percent washout [(Enhanced–delayed)/(Enhanced–unenhanced) × 100%] of greater than 60% (70% for this lesion); the lesion is a lipid-poor adenoma. If unenhanced imaging was not available, relative percent washout [(Enhanced–delayed)/Enhanced × 100%] of greater than 40% (60% for this lesion) would have been sufficient for diagnosis.

significantly more expensive. Several reports suggest that MRI may be superior in characterizing *lipid-poor* adenomas than unenhanced CT (Haider et al, 2004; Israel et al, 2004). **Nevertheless, CT washout studies are considered the gold standard and appear to surpass opposed phase chemical-shift MR imaging in their sensitivity for identifying adenomas** (Caoili et al, 2000; Hussain and Korobkin, 2004; Park et al, 2007; Boland et al, 2008). **It is important to note that gadolinium-enhanced MR washout studies do not exhibit the diagnostic strength of iodine-based CT washout studies, and are not currently employed in clinical practice.** This shortcoming of MR imaging may be explained by the fact that gadolinium-induced signal intensity is less dose-dependent than enhancement from iodinated contrast on computed tomography imaging (Hussain and Korobkin, 2004).

Functional Imaging. The high diagnostic accuracy provided by biochemical evaluation and cross-sectional radiographic imaging of adrenal incidentalomas limits the indications for the routine use of functional imaging. However, functional adrenal imaging can provide valuable information when the origin of the adrenal tumor is unclear or when malignancy is highly suspected but has not been confirmed with other diagnostic modalities (Avram et al, 2006; Gross et al, 2009).

Radionuclide scintigraphy with the radiolabeled cholesterol analogue ^{131}I-6β-iodomethyl-norcholesterol (NP59) can help determine whether or not an adrenal lesion originated in the adrenal cortex or is from another source, because adrenocortical cells demonstrate increased uptake of the cholesterol analog. Based upon the pattern of NP59 uptake, adrenal adenomas can be distinguished from other space-occupying lesions of the adrenal gland

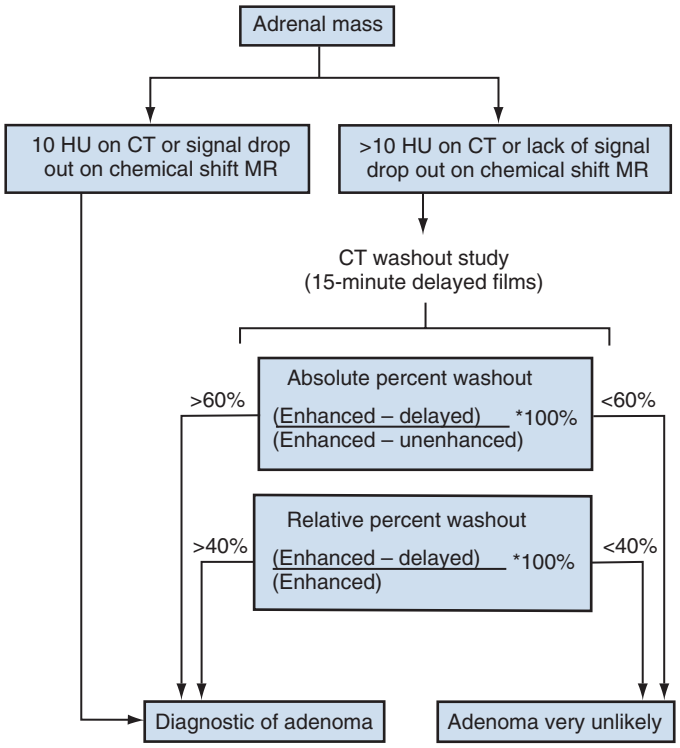

Figure 57–29. Summary of evaluation of adrenal mass using modern cross-sectional imaging.

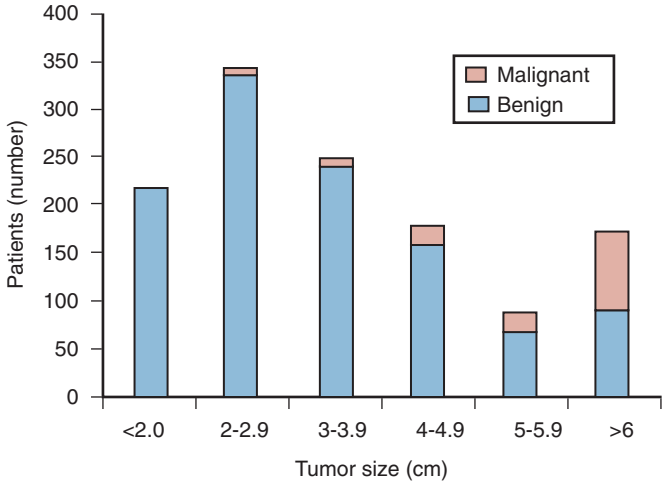

Figure 57–30. Distribution of benign versus malignant adrenal masses based on lesion size (total $n = 1322$). (Adapted from Barzon L, Sonino N, Fallo F, et al. Prevalence and natural history of adrenal incidentalomas. Eur J Endocrinol 2003;149:273–85.)

with high sensitivity and specificity (Kloos et al, 1995; Kloos et al, 1997). Although the characterization of lesions greater than 2 cm is limited with planar scintigraphy, the use of single photon emission-computed tomography (SPECT) may enhance the ability of NP59 to detect smaller lesions (La Cava et al, 2003). Despite the apparent benefits of NP59 scintigraphy in detecting adrenal adenomas, the test is time consuming and is not currently approved by the U.S. Food and Drug Administration. Moreover, it cannot reliably exclude the presence of adrenal cortical carcinoma (Tauchmanova et al, 2004).

Another radiotracer used to identify tumors of adrenocortical origin is ^{11}C-metomidate. Metomidate is an inhibitor of 11β-hydroxylase and aldosterone synthase that is preferentially taken up by adrenocortical cells (see Fig. 57–3). Although several studies have demonstrated the ability of ^{11}C-metomidate PET to correctly identify tumors of adrenocortical origin, the test is significantly limited by its inability to differentiate benign adrenal adenomas from adrenal cortical carcinomas (Minn et al, 2004; Hennings et al, 2006).

The role of functional imaging for the diagnosis of pheochromocytoma is limited given that most pheochromocytomas can be accurately diagnosed with cross-sectional imaging and metabolic evaluation for catecholamines and their metabolites. Therefore ^{131}I-metaiodobenzylguanidine (^{131}I-MIBG) imaging has a limited role in the routine evaluation of adrenal incidentalomas. MIBG is a functional and structural analog of norepinephrine that is incorporated into catecholamine storage vesicles. Increased uptake of MIBG suggests the presence of a chromaffin tumor, such as a pheochromocytoma or paraganglioma. In a small series of 23 patients with nonfunctioning adrenal masses, ^{131}I-MIBG scintigraphy was performed prior to pathologic evaluation and demonstrated a sensitivity of 100% and a specificity of 94% in identifying the presence of pheochromocytomas and paragangliomas (Maurea et al, 2001). Although there are alternatives to MIBG imaging for the detection of pheochromocytomas, including ^{18}F-dopamine PET and the somatostatin analogue ^{111}In-octreotide, their utility in the routine evaluation of adrenal incidentalomas has not been evaluated to date (Mayo-Smith et al, 2001; Timmers et al, 2007a).

The differentiation of benign and malignant adrenal tumors may be facilitated with the use of PET. Multiple reports have demonstrated a high sensitivity (93% to 100%) and specificity (80% to 100%) using ^{18}F-fluorodeoxyglucose (^{18}F-FDG) PET to identify malignant adrenal tumors, including adrenal cortical carcinomas and metastatic lesions to the adrenal (Yun et al, 2001; Blake et al, 2006; Chong et al, 2006). However, the use of ^{18}F-FDG-PET is best reserved for cases in which CT imaging and clinical data are inconclusive (Boland et al, 2008).

Key Points: Imaging

- Low attenuation on unenhanced CT (<10 HU) corresponds to high intracellular lipid and is extremely specific for identification of adrenal adenoma.
- MR imaging is similar in its test characteristics to unenhanced CT.
- CT washout studies are considered the gold standard for adrenal imaging. Rapid loss of contrast enhancement can differentiate even lipid-poor adenomas (~30% of adenomas) from other lesions. Gadolinium-enhanced MR washout studies do not exhibit the diagnostic strength of iodine-based CT washout studies and are not currently employed in clinical practice.

Size and Growth

The retroperitoneal space allows for relatively asymptomatic growth of most adrenal lesions, which may reach beyond 20 cm in size before clinically manifesting. Nevertheless, at presentation, the median radiographic diameter of an adrenal incidentaloma is approximately 3 cm (Mantero et al, 2000). **A relationship does exist between the size of an adrenal lesion and its malignant potential with larger masses more likely to exhibit adverse clinical and pathologic features** (Angeli et al, 1997). Figure 57–30 summarizes the

relationship between adrenal mass size and its risk of malignancy in over 1300 reported incidentalomas (Barzon et al, 2003). Masses less than 4 cm are considered to possess low malignant potential (2% are adrenal carcinomas) and, if nonfunctional, can be observed safely (Grumbach et al, 2003; Cicala et al, 2008). **Masses that exceed 6 cm should be considered malignant until proven benign, which generally requires definitive resection. Management of incidentalomas between 4 and 6 cm is more controversial. In this intermediate size range, the rate of malignancy is estimated to be only 6%** (Cicala et al, 2008)**. Nonetheless, in otherwise healthy individuals with acceptable perioperative risk profile, most experts recommend 4 cm as the cutoff diameter that warrants resection** (Barry et al, 1998; Mantero et al, 2000; Young, 2000, 2007b; Thompson and Young, 2003). In the largest adrenal incidentaloma series to date ($n = 1004$), Mantero and colleagues (2000) reported that the 4-cm cutoff afforded a 93% sensitivity and 42% specificity for detecting malignancy. Sensitivity dropped to 74% and specificity rose to 73% when a 6-cm cutoff was applied. It is important to note that the relationship between the radiographic and pathologic size of an adrenal lesion is imperfect, with pathologic assessment usually resulting in a larger measurement (Cerfolio et al, 1993; Kouriefs et al, 2001).

The urologic oncologist must remember that the incidence of benign adrenal adenomas increases with age; therefore adrenal lesions in younger patients, even those less than 4 cm, must be managed with greater caution than similar lesions in an older age group. Likewise, lesions greater than 4 cm in older patients with significant comorbidities may be better served with observation than resection (Young, 2007b). Moreover, the radiographic characteristics of individual adrenal lesions (regularity of borders, enhancement) must be considered in addition to the lesion's size when deciding whether to treat. In the absence of level I evidence, large population-based reports must be integrated with sound clinical judgment.

The growth kinetics of unresected adrenal lesions should be followed; although, most lesions that are resected due to an increased growth kinetics ultimately prove benign. In a prospectively followed multi-institutional Swedish cohort ($n = 229$, median follow-up 25 months), 7.4% ($n = 17$) of masses grew at least 5 mm, with 5.2% ($n = 12$) adding at least 1 cm to their diameter. All patients who underwent resection because of an increase in lesion size exhibited benign pathology (Libe et al, 2002). Similarly, an earlier review of the literature ($n = 873$) revealed that at a mean follow-up of 3 years, 9% of adrenal incidentalomas grew over 1 cm in diameter while a smaller number decreased in size. In this series, only one lesion proved malignant. The authors concluded that the rate of malignant transformation of adrenal incidentalomas is approximately 1 in 1000 (Barzon et al, 2003). **Reimaging at 6, 12, and, as possible, at 24 months is currently recommended in order to verify oncologic indolence** (Grumbach et al, 2003; Young, 2007b). Suspicious and unusual tumors may require imaging at earlier or more frequent intervals, while small (<2 cm) homogeneous, well-circumscribed, nonfunctional lesions can be followed less closely (Young, 2007b). **A rather arbitrary criterion of 1-cm growth has been proposed as an indication for resection; however, the patient must be counseled that the chance of malignancy is low if growth kinetics are flat** (Young, 2007b).

Key Points: Size and Growth

- Masses >6 cm should be considered malignant until proved otherwise. Although management of masses between 4 and 6 cm is controversial, thought leaders in the field advise that in otherwise healthy individuals masses 4 cm or larger should be resected.
- Kinetics of growth should be followed. Current recommendation is to resect masses that grow over 1 cm; however, incidence of malignancy among these patients is low.

Biopsy of Adrenal Masses

Overview

The role for adrenal biopsy has been limited for the following reasons: (1) modern imaging in the context of clinical characteristics affords superb diagnostic capabilities, (2) histologically adenomas cannot be reliably differentiated from adrenal carcinomas, and (3) adrenal biopsy is not without risk (Thompson and Young, 2003; Young, 2007b). Nevertheless, it is useful to review data that is available with regard to safety and diagnostic utility of adrenal biopsy, and the procedure can occasionally be a useful tool in the diagnostic armamentarium of the adrenal surgeon.

Test Characteristics of Biopsy

Welch and colleagues (1994) reported on 277 percutaneous biopsies performed at the Mayo Clinic. Most biopsies in the series were performed in patients with a known nonadrenal malignancy. The authors report a sensitivity of 81% and specificity of 99%. The accuracy of right-sided biopsies was higher than those on the left (94% vs. 87%). Larger biopsy needles (18 or 19 gauge) resulted in better diagnostic yield and equivalent complication rates when compared with biopsies performed with smaller needles.

The reported positive predictive value of adrenal biopsy is high, meaning that a positive biopsy for malignancy has a high correlation on final pathology. This is especially relevant in patients with a history of an unrelated primary, and in whom an adrenal metastasis is suspected (Silverman et al, 1993; Harisinghani et al, 2002). Although the overall specificity is imperfect, in the same clinical scenario, the test's negative predictive value is nevertheless impressive when nondiagnostic biopsies are excluded (Silverman et al, 1993; Harisinghani et al, 2002). In a series of 225 adrenal biopsies performed in patients with a known primary malignancy at the Massachusetts General Hosptial, 18% of biopsies demonstrated adrenal tissue without evidence of malignancy. The authors reported the negative predictive value of these negative biopsies based on lack of tumor growth at follow-up, autopsy findings, or a rebiopsy result of 100%; although selection and research biases may have existed (Harisinghani et al, 2002). In skilled hands, nondiagnostic biopsies appear infrequent when the majority of sampling is performed with 18-gauge needles (Paulsen et al, 2004).

The probability of a positive adrenal biopsy for metastatic disease appears highest in patients with known lung (>90%) and renal cell carcinomas (80%) (Mazzaglia and Monchik, 2009). In contrast, an adrenal mass in a patient without a previous history of malignancy and without evidence of a synchronous nonadrenal mass is highly unlikely to be present as a metastasis (Lutz et al, 2000). Biopsy in this setting is rarely helpful. Instead, other

criteria, such as radiographic morphology and size, must be used to characterize adrenal masses in such patients (Thompson and Young, 2003; Mazzaglia and Monchik, 2009).

Complications of Biopsy

The complication rates of adrenal biopsies in some large series are as low as 2.8% (Welch et al, 1994). Bleeding is the most common postbiopsy issue with pneumo-/hemothoraces also being reported (Silverman et al, 1993; Welch et al, 1994; Quayle et al, 2007). Needle-track seeding in patients with adrenocortical carcinoma remains a concern, and some authors suggest that biopsy should be avoided in patients in whom adrenal carcinoma is suspected (Quayle et al, 2007). Surgically, there has been a suggestion that biopsy, especially if followed by hemorrhage, can complicate or even prevent laparoscopic resection (Quayle et al, 2007).

The NIH consensus statement mandates that the possibility of pheochromocytoma is metabolically excluded prior to biopsy, whereas percutaneous biopsies of pheochromocytomas have been reported to result in life-threatening hypertensive crises (Grumbach et al, 2003; Quayle et al, 2007). Interestingly, inadvertent biopsy of pheochromocytomas has resulted in no ill effects in some patients (Quayle et al, 2007); however, in real-world practice due diligence to rule out pheochromocytoma prior to biopsy is prudent (Mazzaglia and Monchik, 2009).

Clinical Utility of Biopsy

Despite the fact that adrenal biopsies—when used to differentiate benign from metastatic disease—afford favorable accuracy, some clinicians argue that most adrenal biopsies performed today are unnecessary (Quayle et al, 2007; Mazzaglia and Monchik, 2009). For instance, Quayle and colleagues retrospectively reviewed their experience with patients who were sent to their tertiary referral center following an adrenal biopsy performed in the community. They concluded that in no case did the biopsy affect their clinical management. Moreover, these and other investigators have raised the issue of radiology reports recommending adrenal biopsies or stating that the lesions are "amenable" to biopsy. The authors suggested that such language in radiology reports must be strongly discouraged, because it leads to unnecessary and, at times, deleterious procedures by physicians who are not familiar with standard management of the adrenal mass (Quayle et al, 2007; Mazzaglia and Monchik, 2009).

In conclusion, adrenal biopsy should be pursued only when limitations of imaging have been reached and when the physician and patient are certain that the result of biopsy will influence management. Indeed, perhaps the biggest role for adrenal mass biopsy is in patients with primary malignancies that have potentially recurred in the adrenal gland and whose management will be affected by the biopsy results. Figure 57–31 summarizes the salient points that must be considered when making a decision regarding whether to perform a biopsy of a patient's adrenal mass.

Key Points: Biopsy of Adrenal Masses

- When used to differentiate benign from metastatic disease, adrenal biopsy carries favorable test characteristics.
- Always exclude possibility of pheochromocytoma before biopsy.

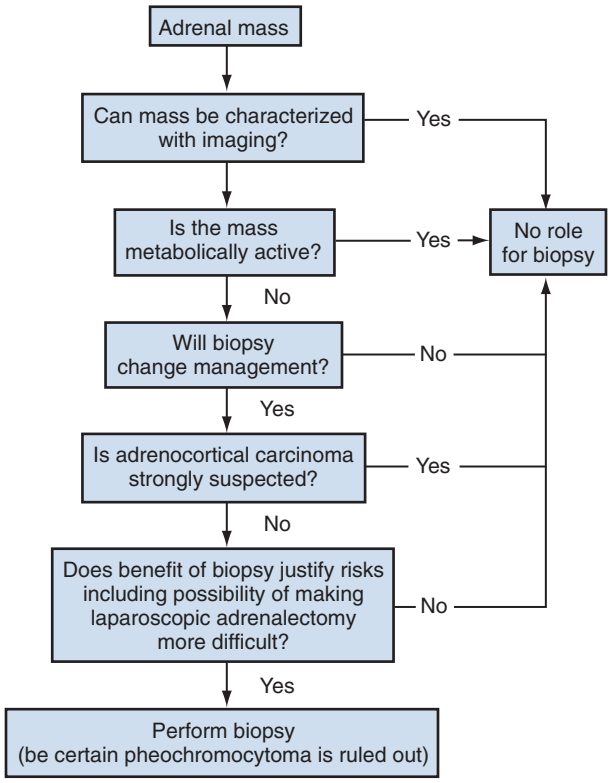

Figure 57–31. Algorithm summarizing decision making regarding whether to subject the patient to an adrenal biopsy. Perhaps the most clinically valuable role for adrenal mass biopsy is in patients with primary malignancies that have potentially recurred in the adrenal gland and whose management will be affected by the biopsy results.

Assessment of Function of Adrenal Masses

Overview

The NIH consensus statement recommends metabolic testing for all adrenal incidentalomas (Grumbach et al, 2003). **This recommendation is supported by the observation that more than 10% of adrenal incidentalomas are metabolically active** (see Table 57–19). **Current practice is to test all new adrenal masses for cortisol and catecholamine hypersecretion. In patients with a history of hypertension, aldosterone hypersecretion should also assessed** (Grumbach et al, 2003; Young, 2007b). Despite this recommendation as a standard of care, routine clinical practice remains inadequate in this domain, whereas it is estimated that greater than 80% of adrenal masses do not receive appropriate evaluation (Eldeiry and Garber, 2008).

Testing for Cortisol Hypersecretion

A systematic review of the literature reveals that 5% to 8% of adrenal incidentalomas produce excessive glucocorticoids (Young, 2000; Barzon et al, 2003). The NIH consensus guidelines state that all adrenal lesions should be tested for glucocorticoid hypersecretion (Grumbach et al, 2003). **Three first-line tests are available to screen patients with incidentalomas for Cushing syndrome: (1) an overnight low-dose dexamethasone suppression test (OST), (2) a late-night salivary cortisol test, and (3) a 24-hour urinary–free cortisol evaluation**

(UFC). A meta-analysis of the published literature demonstrates that these tests afford relatively equivalent accuracy; however, the UFC and the OST are supported by more abundant evidence than the late-night salivary cortisol approach (Elamin et al, 2008). **Nonetheless, reports suggest that UFC is not sufficiently sensitive to detect subclinical Cushing syndrome** (Tsagarakis et al, 2006; Mitchell et al, 2007). Indeed, recent practice guidelines from the The Endrocrine Society, recommend the use of either the OST or the late-night salivary cortisol test to screen patients with adrenal incidentalomas as part of a complete endocrinologic evaluation (Nieman et al, 2008). The section on Cushing syndrome reviews the physiologic rationale for both first-line testing discussed here and other testing that may be necessary. In this section, we review practical considerations of evaluating adrenal incidentalomas for excess glucocorticoid secretion within the scope of urologic practice. As mentioned in prior sections, the physician must verify that exogenous steroids, including creams and nasal sprays, are not in use by the patient prior to testing.

Overnight Low-Dose Dexamethasone Suppression Test. Administration of low-dose dexamethasone followed by measurement of serum cortisol probes the patient's glucocorticoid negative feedback system (see section on Cushing syndrome for discussion of physiology). A patient's failure to suppress cortisol levels following low-dose dexamethasone administration is indicative of Cushing syndrome (Findling and Raff, 2005).

Despite the test's arguably complex physiologic considerations, its administration is remarkably simple. **The patient is given a prescription for 1 mg of dexamethasone and instructed to take it between 11 PM and 12 AM (Newell-Price et al, 2006). The next morning, a serum cortisol is obtained between 8 AM and 9AM.** In patients without hypercortisolemia, the cortisol level should be suppressed below 5 mcg/dL (140 nmol/L). Specificity at this threshold is greater than 95% (Nieman et al, 2008). The trade-off, however, is sensitivity. In some reports up to 18% of patients with Cushing syndrome exhibited false-negative results (Findling et al, 2004). Therefore, a threshold-suppressed cortisol level of 1.8 mcg/dL (50 nmol/L) has been suggested, raising the sensitivity to over 90% (Findling et al, 2004) with a specificity of 80% (Nieman et al, 2008). The test's performance is similar to other first-line tests used to diagnose Cushing syndrome and is recommended as an alternative to the late-night salivary cortisol test for initial screening of incidentalomas (Elamin et al, 2008; Nieman et al, 2008).

Unlike the 24-hour urinary–free cortisol testing, OST is not affected by the patient's glomerular flow rate (GFR). Table 57–20 lists the most common pharmacologic agents that can alter testing. **Most importantly, the urologist must be aware that the test can yield as high as a 50% false-positive rate in women using oral contraceptives, because the contraceptives increase total (but not bioavailable) cortisol levels by raising the patient's cortisol-binding globulin concentrations** (Nickelsen et al, 1989). Administration of low-dose dexamethasone over a 48-hour period is less practical but may improve accuracy and is preferred by some endocrinologists.

Late-Night Salivary Cortisol. Late-night cortisol measurements probe the perturbation and, in some cases, complete disruption in the diurnal variation of cortisol levels that is seen in Cushing syndrome. The abnormality, even in very mild cases of Cushing syndrome, is the inability to suppress cortisol levels at night (Raff and Findling, 2003; Findling and Raff, 2005). Because late-night serum cortisol measurements are impractical, salivary testing has gained acceptance, because salivary cortisol levels reflect near real-time serum cortisol levels. Measurements of cortisol in saliva samples collected between 11 PM and midnight or at bedtime should not exceed 145 ng/dL when the tandem mass spectrometry (LC-MS/MS) assay is used (Nieman et al, 2008). The sensitivity and specificity of the test exceeds 90% and is similar to both UFC and OST; however, a large meta-analysis concluded that the data supporting salivary cortisol testing, to date, is inferior to the data available for UFC and the OST (Elamin et al, 2008; Nieman et al, 2008). Furthermore, the test's utility in diagnosing subclinical Cushing syndrome has been questioned (Nunes et al, 2009).

Unacceptably high false-positive rates may occur in patients with depression, altered sleep patterns, and chronic illness, because normal circadian variation in cortisol levels can be altered in these individuals. Tobacco use can affect salivary cortisol levels and should be avoided on the day of testing (Nieman et al, 2008). Some clinicians instruct patients to avoid oral food or liquid intake, brushing teeth, or undergoing stimulating activity within 30 minutes of salivary collection. Collection is rescheduled if the patient feels ill (Nunes et al, 2009). Some experts advise repeating salivary testing at least twice, regardless of the initial result (Nieman et al, 2008).

24-Hour Urinary–Free Cortisol Evaluation. Urinary–free cortisol evaluation is a 24-hour direct measurement of free bioavailable cortisol. This test is an integrated measurement of cortisol secretion over a 24-hour period and does not depend on variables

Table 57–20.

Pharmaceuticals That Affect Testing for Cushing Syndrome

Drugs That Accelerate Dexamethasone Metabolism by Induction of CYP 3A4
Phenobarbital
Phenytoin
Carbamazepine
Primidone
Rifampin
Rifapentine
Ethosuximide
Pioglitazone
Drugs That Impair Dexamethasone Metabolism by Inhibition of CYP 3A4
Aprepitant/fosaprepitant
Itraconazole
Ritonavir
Fluoxetine
Diltiazem
Cimetidine
Drugs That Increase CBG and May Falsely Elevate Cortisol Results
Estrogens
Mitotane
Drugs That Increase UFC Results
Carbamazepine
Fenofibrate (increase if measured by HPLC)
Some synthetic glucocorticoids (immunoassays)
Drugs that inhibit 11β-HSD2 (licorice, carbenoxolone)

This should not be considered a complete list of potential drug interactions. Data regarding CYP3A4 obtained from http://medicine.iupui.edu/flockhart/table.htm.
From Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. J Clin Endocrinol Metab 2008;93(5):1526–40.

that influence corticosteroid-binding globulin levels (e.g., oral contraceptives) (Arnaldi et al, 2003). This study has been recommended as an initial test to screen patients with incidentalomas for Cushing syndrome (Orth, 1995); however, some recent evidence suggests that the study may not be sensitive enough to detect subtle glucocorticoid metabolism perturbations in patients with cortisol-secreting adrenal lesions (Terzolo et al, 2005; Tsagarakis et al, 2006; Mitchell et al, 2007). **Practice guidelines issued by the Endocrine Society in 2008 recommend that the dexamethasone suppression test or the late-night salivary cortisol test supplant the 24-hour urinary–free cortisol evaluation in initial metabolic screening of patients with incidentalomas** (Nieman et al, 2008). Nevertheless, this test remains the test of choice in pregnant patients. In the second and third trimester, cutoff values two- to threefold above the normal laboratory threshold must be used to account for the physiologic hormonal changes associated with pregnancy (Nieman et al, 2008).

As in all 24-hour urine collections, the patient is instructed to discard the morning's first voided urine and begin to collect all subsequent voided samples. The last sample that is collected is the first morning's void of the following day. Collection and analysis of two separate samples from each patient is advised. The test is most accurate in patients with a GFR greater 60 mL/min because false-negative results may arise in patients with poor renal function (Nieman et al, 2008). Creatinine levels in the collection must be checked to verify completeness of the collection.

As for all tests, sensitivity and specificity of the UFC depend on the population that is being tested and the normal cutoff values that are selected. Normal cutoff values of approximately 50 mcg to 100 mcg per 24 hours of urine volume are usually used, but these vary depending on the laboratory where the test is performed and the assay employed (Orth, 1995; Lin et al, 1997; Pecori Giraldi et al, 2007). Again, cutoff values in the second and third trimester of pregnancy must be raised approximately threefold to account for physiologic changes. As stated previously, the sensitivity of UFC for patients proven to exhibit hypercortisolism secondary to an adrenal adenoma has been reported to be as low as 85% (Invitti et al, 1999), while the specificity of the test in a population of patients with suspected Cushing syndome appears to be in the 90% range (Pecori Giraldi et al, 2007).

Testing for Aldosterone Hypersecretion

Hypersecretion of aldosterone by adrenal masses is extremely rare, with only approximately 1% of adrenal adenomas responsible for Conn syndrome (Young, 2000). Nevertheless, recent data demonstrates that nearly 5% of newly hypertensive patients may harbor an aldosterone-secreting adenoma (Rossi et al, 2006a). Indeed, testing of hypertensive patients with adrenal lesions for hyperaldosteronemia is clinically recommended. Testing of nonhypertensive patients, however, currently is not recommended. The section on Primary Aldosteronism describes the physiologic rationale for each test. In this section, we review the practical implications of evaluating adrenal incidentalomas for excess aldosterone secretion.

In the past, low serum potassium level has been used as a screening tool to assess for presence of aldosterone hypersecretion. Despite this prior teaching, contemporary series reveal that less than 40% of patients with hyperaldosteronism exhibit hypokalemia (Mulatero et al, 2004). **Today the screening test of choice for Conn syndrome is a morning plasma aldosterone (ng/dL) to renin (ng/mL/hr) ratio (ARR). An ARR of 20 (some suggest 30) along with a concomitant aldosterone concentration above 15 ng/mL are indicative of Conn syndrome** (Grumbach et al, 2003; Mulatero et al, 2004; Vierhapper, 2007; Young, 2007b). **The concurrent elevated aldosterone level appears important for cases in which the ARR is elevated simply due to a low renin level.** The test's characteristics have not been fully defined; however, sensitivities and specificities in the 90th percentile have been reported (Montori and Young, 2002; Young, 2007a).

Blood samples should be drawn between 8 AM and 10 AM, preferably in the sitting position. Note that this timing is also ideal for drawing the morning cortisol level for low-dose dexamethasone suppression testing. Some experts believe that hypokalemia may result in false-positive studies due to physiologic aldosterone elevation, and, therefore, patients with low potassium levels should undergo repletion prior to testing (Young, 2007a). **Potassium-sparing diuretics such as amiloride, and especially mineralocorticoid receptor blockers such as spironolactone, alter the renin-angiotensin-aldosterone system and will affect test results. These agents should be stopped approximately 6 weeks prior to testing** (Young, 2007a). Also, historically, there has been great concern about ARR reliability in patients who are on other antihypertensive medications. Indeed, until recently, cessation of all antihypertensive therapy was recommended for a minimum of several days prior to ARR testing. Data now suggest that this may be unnecessary. Figure 57–32 summarizes the effects of various antihypertensive agents on aldosterone and renin levels and on the ARR. The urologist must remember that patients on β blockers, who continue therapy through testing, may show a false-positive rise in ARR. Interpretation in these cases should be unaffected because the concurrent aldosterone level remains within normal limits (Young, 2007a). Nevertheless, some experts recommend cessation of β blockade prior to testing (Seifarth et al, 2002). Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs)

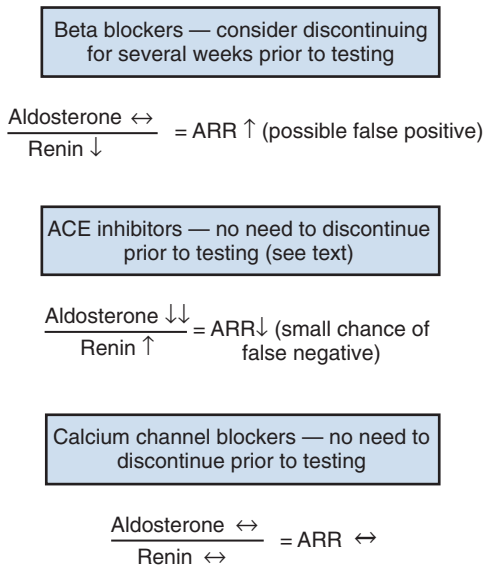

Figure 57–32. Effect of antihypertensives on screening for hyperaldosteronism. Potassium-sparing diuretics and mineralocorticoid receptor blockers are not included in the figure, because they greatly alter the renin-angiotensin-aldosterone axis and should be stopped at least 6 weeks prior to aldosterone renin ratio (ARR) testing. The ARR must be interpreted in the context of the aldosterone and renin levels (see text).

can lower aldosterone levels while raising renin levels in normal subjects. The ARR in patients with and without hyperaldosteronism, who are on these medications, has been shown to fall. Cessation of ACE inhibitors and ARBs, however, is not required. First, aldosterone levels are unlikely to fall in patients with hypersecreting adrenal lesions in the setting of ACE inhibitor/ARB use, due to the fact that this hypersecretion is independent of the renin-angiotensin-aldosterone system. Second, undetectable renin levels can be used as an additional screen for the diagnosis of hyperaldosteronism. Indeed, renin levels rise in normal subjects, and undetectable renin concentrations should be used as a trigger for secondary (confirmatory) testing even in the setting of an ARR within the normal limits (Seifarth et al, 2002; Young, 2007a).

Confirmatory testing is mandatory in patients who test positive during the initial screen for Conn syndrome. Briefly, this testing involves a 72-hour oral sodium challenge followed by measurements of a 24-hour urinary aldosterone level. The intravenous saline infusion test and the fludocortisone suppression tests are also used for confirmatory testing by some experts, although the latter test has fallen out of favor (Mulatero et al, 2004; Young, 2007a). We strongly recommend that the patient be referred to an experienced endocrinologist at this point in his or her care. Once hyperaldosteronism is confirmed, further workup with adrenal vein sampling may be necessary. Please refer to the Primary Aldosteronism section for further discussion.

Testing for Adrenal Sex Steroid Hypersecretion

Hypersecretion of adrenal sex steroids by adrenal masses, especially incidentalomas, is exceedingly rare. The most common adrenal mass that hypersecretes sex steroid is an adrenal carcinoma that concomitantly exhibits cortisol hypersecretion (Wajchenberg et al, 2000; Cordera et al, 2003). Tumors that exclusively hypersecrete androgens, both testosterone and/or 17-ketosteroids, have been reported primarily in women. Approximately 50% of such lesions ultimately prove benign (Cordera et al, 2003; Moreno et al, 2004). **Routine testing of incidentalomas for sex hormones is currently not recommended** (Grumbach et al, 2003; Stanczyk, 2006; Young, 2007b).

Previously, for patients who presented with virilization, dexamethasone suppression testing was used to differentiate adrenal androgen excess from an ovarian androgen source; however, this approach has proven unreliable and has been largely replaced by radiographic imaging strategies (Derksen et al, 1994; Cordera et al, 2003).

Testing for Catecholamine Hypersecretion

Pheochromocytoma is found in approximately 5% of patients who present for adrenal incidentaloma. Therefore all patients, including those in whom metastatic disease is suspected, should undergo functional testing to rule out pheochromocytoma (Adler et al, 2007; Young, 2007b). The section on Pheochromocytoma describes the physiologic rationale for each test. Here we discuss the practical details regarding testing.

Free-fractionated plasma metanephrines and the 24-hour urinary–fractionated metanephrine tests constitute the mainstay for pheochromocytoma testing, given their superb sensitivity and suitable specificity. Indeed, the 2005 International Symposium on pheochromocytoma concluded that one of these two tests should be used for initial diagnosis and screening for pheochromocytoma (Grossman et al, 2006; Pacak et al, 2007). Currently there is an ongoing debate regarding which one of these tests is superior (Young, 2007b; Eisenhofer et al, 2008).

Plasma-Free Metanephrines. The measurement of plasma-free (fractionated) metanephrines has gained popularity due to ease of testing and excellent test characteristics. In a study of over 850 patients ($n = 214$ with pheochromocytoma, $n = 644$ without pheochromocytoma), Lenders and colleagues (2002) concluded that the test is superior to all other methods for diagnosing and excluding pheochromocytoma. Investigators in this multicenter study showed that the test affords nearly perfect sensitivity in cases of sporadic (99%) and familial (97%) pheochromocytoma. Specificity was reported to be 82% for sporadic and 96% for familial cases (Lenders et al, 2002). Indeed, the test's low specificity (reported as low as 77%) in patients older than 60, may lead to false-positive results. For this reason, some experts advise against first-line use of plasma-free metanephrines in all patients with incidentalomas (Sawka et al, 2003; Young, 2007b). Nevertheless, supporters of the test contend that the true specificity of the test is closer to 92% and that insufficient evidence exists to prove superiority of urinary testing and to eliminate plasma-free metanephrines from routine first-line use (Eisenhofer et al, 2008). Further arguments for and against using plasma-free metanephrines are summarized in Table 57–21.

Ideally, patients should not consume food or liquids after midnight prior to the study. Caffeinated beverages must be avoided especially (Lenders et al, 2002). **Acetaminophen can produce a false-positive result due to cross reactivity in the assay and should be stopped for at least 5 days prior to testing. Tricyclic antidepressants and phenoxybenzamine should also be stopped, because these have been shown to be**

Table 57–21.

Relative Merits for and against Using Plasma-Free Metanephrines and Urinary-Fractionated Metanephrines in Diagnosis of Pheochromocytoma

URINARY FRACTIONATED METANEPHRINES	PLASMA-FREE METANEPHRINES
Well-established, widely available test	Relatively new test with limited availability
Urinary concentrations (200-2000 nmol) make analysis relatively easy	Plasma concentrations (0.1-0.5 nmol) can make analysis difficult
Easy for clinicians to implement with minimal expenditure of time and effort	Blood collections require some time and effort by medical staff
Twenty-four–hour collections can be inconvenient for patients	Blood sampling relatively more convenient for patients
Problems with reliability of incomplete timed urine collections	Collection and handling of blood samples can be better regulated
Difficult to control dietary and daily life influences on symphathoadrenal function	Influences of diet and sympathoadrenal function more easily controlled
In children, 24-hour collections are difficult to interpret without age-appropriate reference intervals	In children blood sampling may be stressful, but results are more easily interpreted without age-appropriate reference intervals
Urine collections may be inappropriate in patients with renal failure	Test is applicable in patients with renal failure

From Grossman A, Pacak K, Sawka A, et al. Biochemical diagnosis and localization of pheochromocytoma: can we reach a consensus? Ann N Y Acad Sci 2006;1073:332–47.

responsible for false-positive results (Eisenhofer et al, 2003b). Usual antihypertensive therapy can be continued. Although β blockade can potentially result in a false-positive test result, the current recommendation is to stop the medication only on repeat testing (Eisenhofer et al, 2003b). Ideally, the serum sample should be drawn in the supine position following at least 20 minutes of supine rest. Position is especially important if a positive result has been obtained and confirmatory testing is being performed (Grossman et al, 2006).

The upper limit of normal for the test is usually set at 0.61 nmol/L (112 ng/L) for normetanephrine and 0.31 nmol/L (61 ng/L) for metanephrine (Lenders et al, 2002; Eisenhofer et al, 2003; Pacak et al, 2007). Elevation beyond 2.2 nmol/L (400 ng/L) for normetanephrine and/or 1.2 nmol/L (236 ng/L) for metanephrine is substantial and is highly indicative of pheochromocytoma. Lesser elevation in plasma-free metanephrine levels require repeat testing (Eisenhofer et al, 2003b). No consensus exists regarding the best strategy for repeat testing; however, such strategies as repeating plasma-free metanephrine under ideal conditions (supine for 20 minutes, off β blockers, etc.), performing urinary–fractionated metanephrine testing, evaluating for elevated chromogranin A levels, and subjecting the patient to clonidine suppression testing have all been suggested (Eisenhofer et al, 2003b; Lenders et al, 2005; Algeciras-Schimnich et al, 2008). At this point in the patient's care, we strongly suggest involving an experienced endocrinologist.

24-Hour Urinary–Fractionated Metanephrines. Some experts believe that 24-hour urinary–fractionated metanephrines along with fractionated urinary catecholamine testing represent the best first-line test for pheochromocytoma (Perry et al, 2007; Young, 2007b). When measured with tandem mass spectrometry, and when an elevation in either metanephrine (>1531 nmol/day), normetanephrine (>4001 nmol/day), or total metanephrines (>1563 nmol/day) level is considered as a positive result, sensitivity for detecting pheochromocytoma is reported to exceed 97% with a specificity of approximately 91%. Supporters contend that given this specificity, the test is superior to plasma-free metanephrines, because it avoids unnecessary false-positive results, especially in patient populations with relatively low pretest probabilities, such as those with incidentaloma (Sawka et al, 2003, Perry et al, 2007; Young, 2007). Nevertheless, critics argue that high specificity is achieved by raising reference limits, potentially compromising sensitivity (Eisenhofer et al, 2008). Furthermore, they point to results of Lenders and colleagues (2002) that showed urinary–fractionated metanephrine to be inferior to plasma-free metanephrines. Given strong opinions on both sides of the argument, the 2005 International Symposium on Pheochromocytoma failed to reach a consensus regarding the superiority of either test (Grossman et al, 2006; Pacak et al, 2007). Table 57–21 summarizes some additional arguments for and against urinary metanephrine testing.

As in all 24-hour urine collections, the patient is instructed to discard the morning's first voided urine and begin to collect all subsequent voided samples. The last sample that is collected is the first morning's void of the following day. Creatinine levels in the collection must be checked to verify completeness of the collection. The test is most accurate in patients with normal renal function. Tricyclic antidepressants and phenoxybenzamine should be stopped.

Follow-up

A small percentage (approximately 2%), of metabolically silent adrenal incidentalomas are reported to show new metabolic activity during follow-up evaluation (Barzon et al, 2003). **The most recent consensus statement by a panel of experts recommends annual metabolic hormonal screening for the first 3 to 4 years following diagnosis, especially for masses that are 3 cm in diameter** (Grumbach et al, 2003). Nevertheless, given a lack of strong data for this recommendation, the need for metabolic reevaluation of adrenal adenomas in patients who show no clinical signs of hormonal hypersecretion remains controversial (Barry et al, 1998; Bulow et al, 2006; Young, 2007b).

Key Points: Assessment of Function of Adrenal Masses

- All adrenal incidentalomas demand a metabolic evaluation.
- Annual follow-up for 3 to 4 years is recommended for metabolically silent masses; however, de-novo development of metabolic activity is rare.

Summary of Surgical Indications

Every urologist must clearly understand the indications for surgical intervention in patients with adrenal pathology. The decision making and management algorithm for patients with adrenal incidentalomas are summarized in Figure 57–33. Table 57–22 also details the major surgical indications for resection of the adrenal gland. The table also includes existing recommendations for adrenal resection during radical nephrectomy (O'Malley et al, 2009).

Table 57–22.

Summary of Surgical Indications for Adrenalectomy

Functional adrenal mass
• Cortisol hypersecretion
• Pheochromocytoma
• Aldosterone hypersecretion
Mass > 4 cm (see Imaging of Adrenal Masses: Size and Growth) with exception of myelolipoma
Mass with imaging findings that are suggestive of malignancy (lipid-poor, heterogeneous, irregular borders, infiltrates surrounding structures, etc.)
Adrenal incidentaloma that grow greater than 1 cm on follow-up imaging
Extremely large and/or symptomatic myelolipoma (see Adrenal Lesions: Benign: Myelolipoma)
Isolated adrenal metastasis (multidisciplinary decision making required)
During radical nephrectomy for renal cell carcinoma if:
• Adrenal abnormal or not visualized due to large renal tumor size on imaging
• Large (≥7 cm) upper pole mass
• Vein thrombus to level of adrenal vein
Failed neurosurgical treatment of Cushing disease, requiring bilateral adrenalectomy
Select patients with ectopic adrenocorticotropic hormone (ACTH) syndrome, requiring bilateral adrenalectomy
ACTH-independent macronodular adrenal hyperplasia (AIMAH)
Primary pigmented nodular adrenocortical disease (PPNAD)

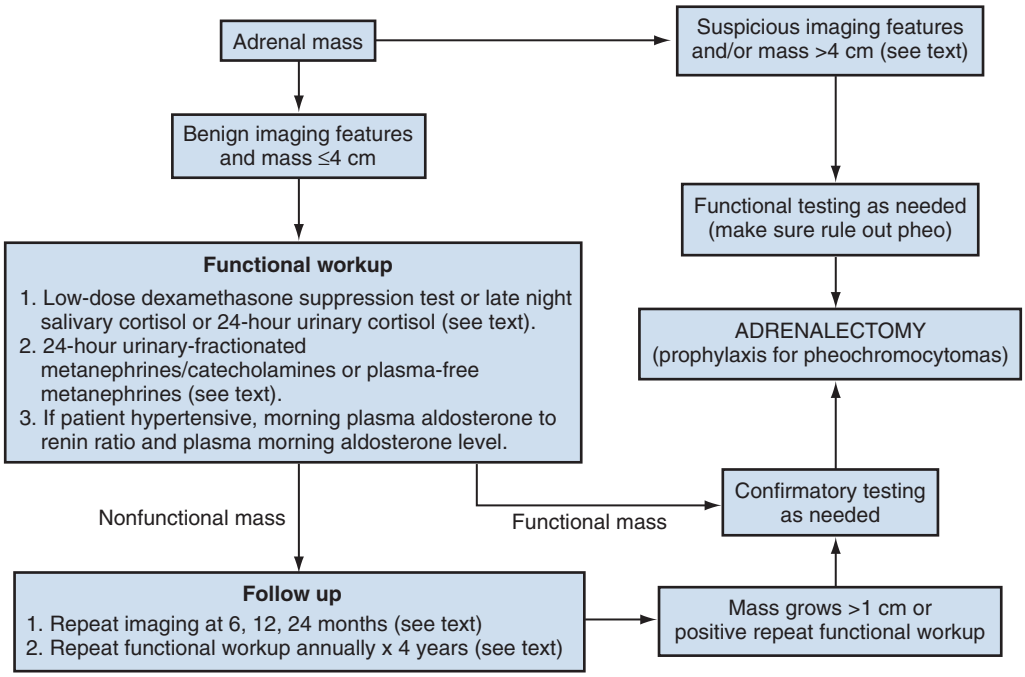

Figure 57–33. Management algorithm for newly diagnosed incidental adrenal mass.

CONCLUSIONS

The adrenal glands have long been recognized for their essential role in regulation of critical homeostatic functions. Indeed, these deceptively simple glands are central to a myriad of essential life-sustaining human functions. Despite the frequency of incidental adrenal lesions, relative to other essential organs, the adrenal glands are infrequent primary initiators of human diseases. Nonetheless, clinically significant abnormalities of the adrenal gland require a systematic multidisciplinary approach. With the urologist's advanced minimally invasive surgical skills, comfort with both retroperitoneal anatomy and surgical approaches to retroperitoneal organs and the close relationship between renal and adrenal pathophysiology, it is natural that he or she participate in the evaluation of adrenal disorders and provide primary surgical management for these patients.

Special Considerations
Nonsurgical Alternatives

Surgery of the adrenal gland consists of operative procedures to correct endocrine abnormalities or to treat malignant disease. As outlined in Chapter 57, various adrenal disorders can be identified and treated medically. When medical therapy is ineffective or does not exist for a particular adrenal disease, surgery becomes necessary.

Traditional open adrenal surgery has been performed since the late 19th century. Various techniques and anatomic approaches have been described for adrenalectomy, but the essential surgical principles have remained unchanged for a century. The introduction of laparoscopic adrenalectomy has revolutionized adrenal surgery and largely supplanted the open approach. However, we are not yet ready to relegate open adrenal surgery to the history books. There is a diminished but vital role for open adrenal surgery in the management of invasive adrenal carcinoma. Furthermore, all urologic surgeons should be familiar with the open techniques in the event that emergent open surgical conversion is necessary.

The future of adrenal surgery is evolving. New technology, such as robotics and percutaneous ablation, is being developed. These minimally invasive nonsurgical approaches may obviate the skills of the surgeon. Nevertheless, it is important that the urologist be part of the treatment team, either as direct practitioner of the technique or as a direct consultant guiding therapy.

HISTORY

The first adrenalectomy was performed by Thornton in 1889 for a large tumor in a 36-year-old woman (Thornton, 1890). At the time, Thornton was unaware of the adrenal origin of the patient's disease and removed the adrenal en bloc with the kidney. Sargent performed the first planned adrenalectomy in 1914 for a large adrenal adenoma. Charles Mayo (1927) performed the first flank adrenalectomy for pheochromocytoma in 1927. As was often the case in these early forays, Mayo was not aware of the exact nature of the pathologic process with which he was dealing and assumed that he was removing an aberrant retroperitoneal nerve.

Young (1936) described the posterior approach using a "hockey stick" incision to access both adrenal glands simultaneously. The thoracoabdominal incision for management of large retroperitoneal masses was first described by Chute and colleagues (1949). In 1965, Turner-Warwick developed and described a supracostal transdiaphragmatic variation of Young's posterior approach.

Gagner performed the first laparoscopic adrenalectomy in 1991 (Gagner et al, 1992). He used a transperitoneal approach to gain access to the adrenal gland. Also in 1992, Gaur developed and described the first device for balloon dilation of the retroperitoneum. Retroperitoneal access has been developed for both flank (Gasman et al, 1998) and posterior (Baba et al, 1997) approaches.

SURGICAL ANATOMY

The adrenal glands are situated in the retroperitoneum within the Gerota fascia. The right adrenal gland tends to lie more cephalad than the left adrenal gland. The anatomic borders of the right adrenal gland are the liver anteriorly, the vena cava medially, the right kidney laterally and inferiorly, and the diaphragm along its superior and posterior aspects. The medial aspect of the right adrenal gland will often be retrocaval, and the right adrenal vein will enter the inferior vena cava in a posterolateral position.

The left adrenal gland is bordered by the aorta medially, the stomach and body of the pancreas anteriorly, the kidney inferiorly, the spleen superiorly, and the diaphragm posteriorly. The left adrenal gland is often more elongated than the right adrenal gland and will lie in a more superomedial position to the kidney. This tends to place the gland closer to the left renal hilum, and these structures must be accounted for during dissection. The anatomic relationships of the adrenal glands are summarized in Fig. 58–1.

The arterial blood supply to the adrenal gland can be variable but tends to derive from three major sources on each side. Each

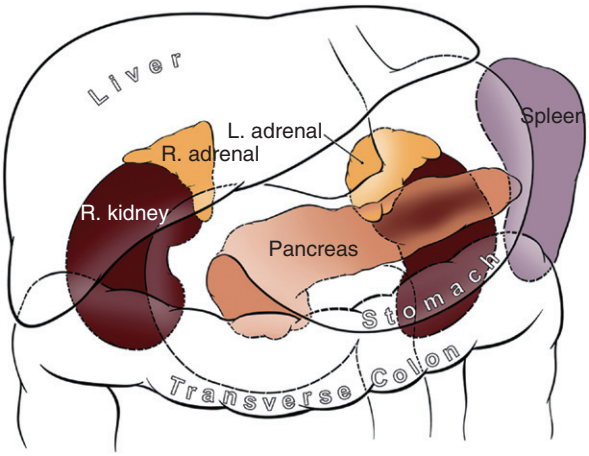

Figure 58–1. Regional anatomy of adrenal glands.

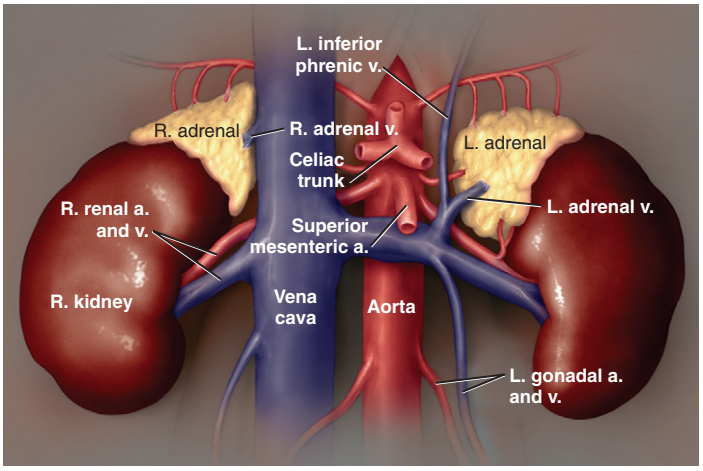

Figure 58–2. Vascular supply of adrenal glands.

adrenal gland receives branches from its ipsilateral inferior phrenic artery (superior adrenal arteries), aorta (middle adrenal arteries), and renal artery (inferior adrenal arteries). The venous drainage is typically simple; a single adrenal vein drains into the vena cava directly on the right and into the left renal vein on the left. Accessory veins (5% to 10%) that drain into the right renal vein, right hepatic vein, or inferior phrenic vein can be present (Fig. 58–2).

Lymphatic drainage from the adrenal glands consists of a lateral aortic lymph node chain extending from the diaphragm to the ipsilateral renal artery.

CLINICAL INDICATIONS AND SELECTION OF PATIENTS

Clinical Indications

The clinical indications for adrenalectomy are summarized in Table 58–1. The pathophysiology, diagnosis, and treatment of these diseases are detailed in Chapter 57.

Exclusion Criteria

Severe coagulopathy and poor cardiopulmonary performance status are absolute contraindications to adrenalectomy by any technique. As far as laparoscopy is concerned, the shrinking number of contraindications attests to the high level of skill exhibited by pioneering laparoscopic surgeons. These relative contraindications include previous open surgery, tumor size, obesity, and adrenal cortical carcinoma.

Table 58–1.

Clinical Indications for Adrenalectomy

Primary aldosteronism (solitary adenoma versus bilateral adrenal hyperplasia)
Cushing syndrome
Pheochromocytoma
Adrenal adenoma
Myelolipoma
Adrenal cyst
Metastatic tumor
Adrenocortical carcinoma
Neuroblastoma (pediatric)
Incidentally discovered adrenal mass or “incidentaloma”

Table 58–2.

Surgical Options (Open Adrenalectomy)

DISEASE	APPROACH
Primary hyperaldosteronism	Posterior (left or right) Modified posterior (right) 11th rib (left > right) Posterior transthoracic
Cushing adenoma	11th rib (left or right) Thoracoabdominal (large) Posterior (small)
Cushing disease (bilateral hyperplasia)	Bilateral posterior Bilateral 11th rib (alternating)
Adrenal carcinoma	Thoracoabdominal 11th rib Transabdominal
Bilateral adrenal ablation	Bilateral posterior
Pheochromocytoma	Transabdominal chevron Thoracoabdominal (large, usually right) 11th rib
Neuroblastoma	Transabdominal 11th rib

From Vaughn ED. Adrenal surgery. In: Marshall F, editor. Operative urology. Philadelphia: WB Saunders; 1996. p. 222.

Indications for Open Surgery

The current indications for open adrenalectomy are few but important. First, **adrenal cortical carcinoma with radiographic evidence of extra-adrenal tumor invasion of adjacent organs may benefit from maximal surgical exposure. Similarly, the extension of adrenal vein tumor thrombus into the inferior vena cava necessitates a more invasive approach.** Finally, in developing countries, the resources for laparoscopic surgery may be lacking, and the open approach will be preferred out of necessity. The choice of open surgical approach is dictated by the surgeon’s experience and the pathologic process in question. Table 58–2 summarizes the best surgical approach for a given adrenal disease.

Past Surgical History

Is open surgery indicated when there is a history of previous surgery close to the adrenal gland? The laparoscopic approach can be tailored to deal with past surgical history; a patient with previous transabdominal surgery could have a retroperitoneal laparoscopic procedure (Caddedu et al, 1999), and a history of previous open flank surgery could be addressed by performing a transperitoneal laparoscopic procedure. Furthermore, Gill and colleagues (2001) have reported their experience with a transthoracic laparoscopic approach that may be ideally suited for this situation. The thoracic cavity is entered thorascopically, the diaphragm is divided, and the adrenal gland is approached superiorly.

Size

Tumor size is a relative contraindication to laparoscopic surgery. In the initial experience of many laparoscopists, a cutoff of 5 or 6 cm was chosen because of the increased risk of treating an adrenal cortical carcinoma. Subsequently, ample empirical evidence has accumulated to suggest that specimen size is not necessarily a contraindication to laparoscopic adrenalectomy. MacGillivray and colleagues (2002) noted no difference in operative time, blood loss, complication rate, and hospital stay among 12 patients with large tumors (mean, 8.2 cm; range, 6 to 12 cm) and 36 patients with small tumors (mean, 2.5 cm; range, 0.4 to 5.6 cm).

In contrast, Hobart and colleagues (2000) noted increased operative time (205 minutes vs. 158 minutes; $P = .07$), increased blood loss (400 mL vs. 113 mL; $P = .009$), higher complication rate (21.4% vs. 8.9%; $P = .21$), and higher open conversion rate (14.3% vs. 2.2%; $P = .14$) in comparing 14 large tumors (mean, 8 cm) with 45 small tumors (mean, 2.2 cm). However, Hobart did find that operative time, blood loss, hospital stay, narcotic use, and complication rate were lower with laparoscopic adrenalectomy than with traditional open adrenalectomy for large tumors. Although a higher morbidity could be expected with larger tumors, morbidity was still less than with open surgery.

Conversion to open surgery is most often due to infiltrative adrenal cortical carcinoma. In the largest series, conversion occurred electively after initial laparoscopic exploration and not because of hemorrhage or other emergent causes. MacGillivray and colleagues (1996) concluded that **preoperative computed tomographic scanning can identify those infiltrative tumors that are likely to be invasive carcinoma.**

MacGillivray and coworkers (2002) and Henry and colleagues (1999) recommend an upper size limit of 12 cm for laparoscopic adrenalectomy. However, keep in mind that computed tomographic scanning can underestimate specimen size by as much as 16% (Lau et al, 1999).

Obesity

With a worldwide epidemic of obesity, it is an increasingly common occurrence to operate on morbidly obese patients. Rather than obesity being a relative contraindication, laparoscopy may offer a less morbid alternative for adrenalectomy on obese patients. Comparing results between obese patients (body mass index greater than 30) who underwent laparoscopic adrenal or renal surgery and those who underwent open surgery, Fazeli-Matin and colleagues (1999) noted that patients who underwent laparoscopic surgery had fewer complications (18% vs. 47%; $P = .21$), less blood loss (50 mL vs. 300 mL; $P = .03$), less narcotic use ($P = .01$), and shorter hospital stay (<24 hours vs. 5.5 days; $P = .01$). However, these surgeries were performed by a veteran laparoscopist, and obesity may remain a relative contraindication for less experienced surgeons.

Adrenal Cortical Carcinoma

Laparoscopic adrenalectomy on adrenal cortical carcinoma can be a daunting task. Adrenal carcinomas tend to be larger (>6 cm). Henry and colleagues (2002) noted that of 150 consecutive laparoscopic adrenalectomies, none of the smaller (<4 cm) tumors ($N = 102$) was malignant. In contrast, 12.5% of tumors larger than 4 cm ($N = 48$) were malignant. Using a 6-cm cutoff, Prager and coworkers (2004) noted that 21.2% of tumors larger than 6 cm were malignant versus 1.9% of lesions smaller than 6 cm. Also, the prospect of invasion by infiltrative lesions into surrounding structures can prohibit successful laparoscopic surgery. However, if computed tomography indicates that no local invasion is present and the lesion is not excessively large, laparoscopic adrenalectomy is possible.

Known adrenal vein or vena caval involvement is an absolute contraindication to laparoscopic surgery. However, in one case report, Kim and colleagues (2004) described an intraoperatively discovered adrenal vein thrombus with a 7-cm adrenal mass. With use of atraumatic vascular clamps, the renal vein was entered, and the intact tumor thrombus was removed en bloc with the adrenalectomy specimen.

Cancer control is dependent on adherence to the same oncologic principles as in open surgery. Wide local excision with perirenal fat is necessary for good local control to be obtained. Adrenal cortical carcinoma tends to be an aggressive disease, and locoregional recurrence can develop as often as 60% (Vassilopoulou-Sellin and Schultz, 2001). Most reports of postoperative adrenal cortical carcinoma recurrence have been in case reports. Henry and colleagues (2002) published a summary of 12 cases of carcinoma recurrence in the medical literature. In 25% of the cases, the authors admitted to specimen disruption during the case.

PREOPERATIVE MANAGEMENT

It is important to correct any electrolyte abnormalities that may result from an endocrinologically active adrenal tumor. Most notably, aldosteronoma can result in hypokalemia that may require potassium repletion and administration of a potassium-sparing diuretic. Hypertension should also be treated before surgery.

With a pheochromocytoma, α-adrenergic blockade should be started 2 weeks before surgery. Phenoxybenzamine is most often used for adrenergic blockade prior to surgery. Some patients with tachycardia may benefit from concurrent β blockade. Alternatively, an α_1-selective blocker such as prazosin or doxazosin can be used. Intraoperatively, high blood pressure can be treated with nitroprusside or a short-acting β blocker like esmolol. Volume repletion is important to prevent the postoperative hypotension secondary to loss of tonic vasoconstriction after removal of a pheochromocytoma.

Patients with Cushing syndrome require correction of electrolyte abnormalities and hyperglycemia before surgery. These patients may benefit from administration of adrenolytic agents such as mitotane or aminoglutethimide.

Potential errors in preoperative preparation are summarized in Table 58–3.

Table 58–3.
Errors in Preparation of Patients for Adrenal Surgery

Primary Aldosteronism
Potassium repletion
Blood pressure control
Cushing Syndrome
Inhibition of glucocorticoid production when there is severe manifestation with metyrapone
Control of diabetes
Preoperative antibiotics
Operative steroid administration
Incidentalomas
Anesthetic preparation for pheochromocytoma; 5% have normal diagnostic studies
Adrenal Carcinoma
Consent for adjacent organ removal
Failure to identify vena cava involvement
Pheochromocytoma
Preoperative catecholamine blockade
Volume expansion
Anesthetic consultation

Modified from Vaughn ED. Complications of adrenal surgery. In: Taneja SS, Smith RB, Ehrlich RM, editors. Complications of urologic surgery: prevention and management. 3rd ed. Philadelphia: WB Saunders; 2001. p. 363.

A mechanical bowel preparation can be helpful for open or laparoscopic transperitoneal surgery. Retroperitoneal surgery may not require this bowel preparation. All patients should receive appropriate preoperative antibiotics. A nasogastric or orogastric tube can be placed to decompress the bowel, especially helpful for transperitoneal cases. The placement of a urinary catheter to help measure urine output and to decompress the bladder is essential.

OPEN ADRENALECTOMY

Open adrenalectomy can be performed through either a transperitoneal or retroperitoneal approach. The transperitoneal approaches include midline, subcostal, and thoracoabdominal. The retroperitoneal approaches include flank and posterior lumbodorsal. The advantages of the transperitoneal approaches are better exposure for larger tumors and excellent access to the great vessels and retroperitoneum. The main disadvantages are prolonged ileus and difficult exposure in morbidly obese patients. The retroperitoneal approach results in less ileus and may result in shorter hospital stays. There is a smaller operative field, and access to larger tumors and surrounding involved organs may be difficult. The best surgical approach for a given adrenal disease is indicated in Table 58–2.

Flank Retroperitoneal Approach

Right Side. The patient is placed in flank position with the right side facing up (Fig. 58–3). The bed is placed in maximal flexion, and the kidney rest is deployed to accentuate the space between the costal margin and iliac crest. Palpation is used to identify the course of the 11th rib. The skin and fat overlying the 11th rib are incised, and the fascia and muscle overlying the rib are divided. (Fig. 58–4).

Once the anterior surface of the rib is exposed, the anterior periosteum is cauterized, and the periosteal elevator is used to scrape it off the anterior rib surface. The edges of the periosteum

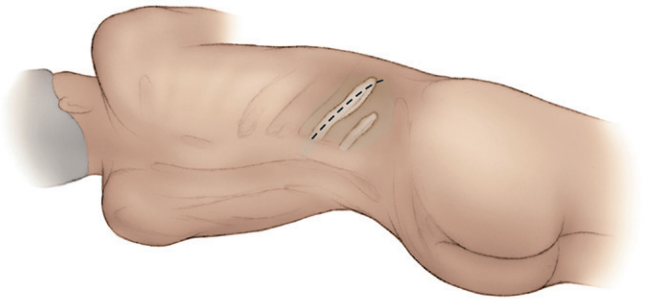

Figure 58–3. Surgical incision over 11th rib for flank adrenalectomy. The patient is in flexion, with the kidney rest deployed to maximally expose the right retroperitoneum.

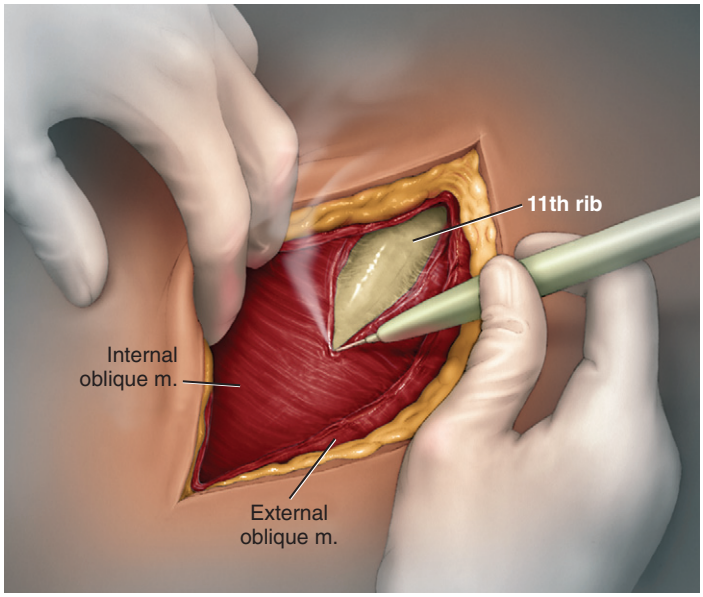

Figure 58–4. Flank approach. Incision of muscle overlying 11th rib.

on the superior and inferior aspects of the rib should now be visible. The periosteal elevator is used to develop a plane between the posterior rib surface and the posterior leaf of the periosteum. The Doyen instrument and surgical cautery are used to strip the periosteum off the rib from the tip of the rib back toward the paraspinal muscles. With the rib cutter, the 11th rib is excised (Fig. 58–5). A rongeur can be used to remove any sharp remnants on the rib stump. Cautery or bone wax can be used to render the marrow hemostatic.

Next, the neurovascular bundle is identified and freed with sharp and blunt dissection to avoid injury during subsequent dissection and closure (Fig. 58–6). The lumbodorsal fascia is entered sharply with Metzenbaum scissors, and blunt dissection is used to dissect the peritoneum off the transverse fascia anteriorly. The flank muscles and their accompanying fasciae are divided anteriorly—the external oblique, internal oblique, and transverse abdominal. Next, the posterior muscle diaphragmatic attachments are divided with cautery. The pleura is sharply and bluntly dissected off the superior edge of the 12th rib.

The plane between the Gerota fascia and the peritoneum can be started with the cautery or sharp dissection. Once it is identified, this plane can be maximally developed with blunt dissection. The peritoneum needs to be freed from the superior aspect of the

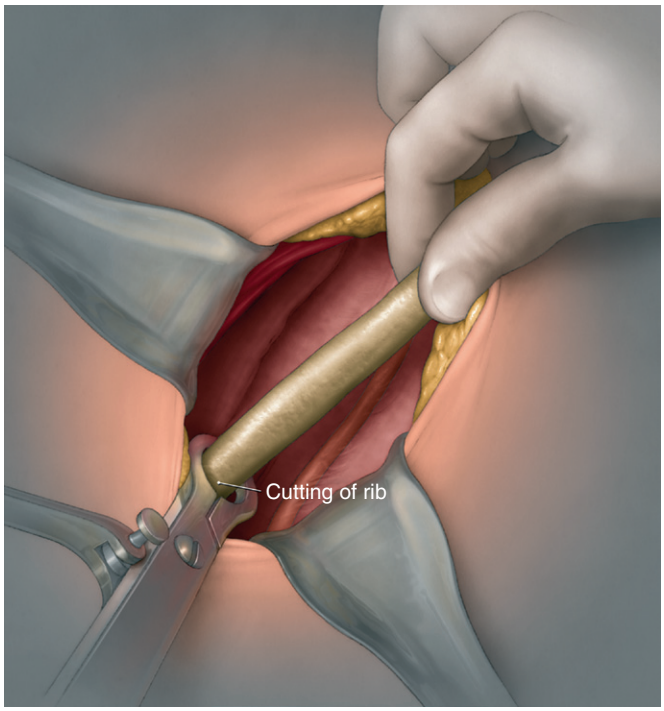

Figure 58–5. Flank approach. Excision of 11th rib.

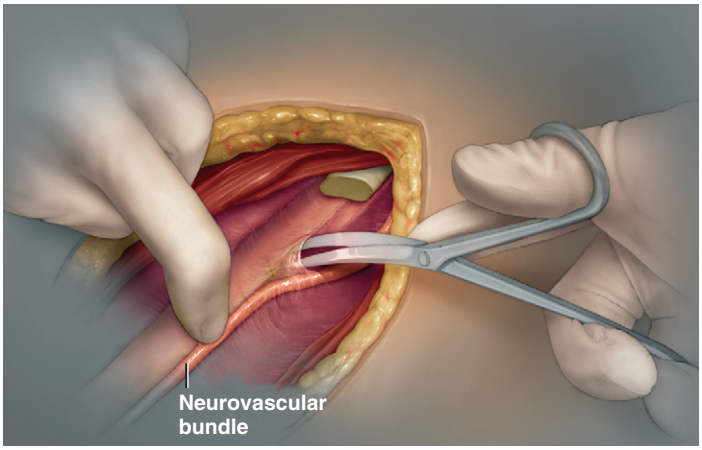

Figure 58–6. Flank approach. Mobilization of the intercostal neurovascular bundle from the 11th rib. This is performed with a combination of blunt dissection with a Kittner dissector and sharp dissection with Metzenbaum scissors.

Gerota fascia as well. Once the peritoneum is mobilized, on the right side, the vena cava can be visualized, and with cephalad dissection, the adrenal gland and renal vein can be seen as well. Placement of a self-retaining retractor is essential for maximal exposure to be obtained.

Dissection of the adrenal gland typically begins along the medial border of the gland with the vena cava. The overlying peritoneum is divided, and blunt dissection is used to expose the plane between the medial surface of the adrenal gland and the lateral surface of the vena cava. The adrenal vein is often difficult to identify until this plane is developed. The adrenal vein is dissected out with a right-angled instrument such as a Mixter forceps. Surgical ties or clips can be placed to ligate the adrenal vein. In our opinion, surgical ties are more reliable than standard titanium clips. However, locking surgical clips may be substituted for added security. There are numerous arterial branches to the gland that can be ligated and divided individually. Alternatively, many authors attest to the utility of the harmonic scalpel in hemostatically dividing arterial attachments. Once this is done, the psoas muscle is often visible posteriorly. Superior attachments are divided with the aid of surgical cautery or harmonic scalpel. Downward traction on the kidney assists with this dissection. Inferomedial attachments to the kidney are taken with sharp or cautery hook dissection.

Dissection of the left adrenal gland is similar except that the aorta is visualized, and the adrenal vein originates from the renal vein. Other authors have described supracostal technique with intentional violation of the pleura. This approach may be helpful for larger tumors.

Closure of the incision consists of a two-layer closure with a running No. 1 polydioxanone suture. The deep layer consists of the transverse abdominal muscle, internal oblique muscle, and fascia. The outer layer consists of the external oblique muscle and fascia. Skin closure can be completed with surgical staples or absorbable subcuticular suture.

Lumbodorsal Posterior Approach

The main advantage of this approach is the ability to easily access both adrenal glands for bilateral surgery. The disadvantages include a limited operative field and respiratory limitation. If bleeding is extensive, it can be difficult to control from this position. The posterior approach requires prone positioning of the patient with arms extended cephalad. The procedure has been extensively modified over time—with or without rib resection, transthoracic through the diaphragm, or diaphragm sparing. A rib-resecting, diaphragm-sparing approach is described.

Right Side. An incision is made along the course of the right 11th rib (Fig. 58–7). This is taken down to the periosteum, and the rib resection is performed in a manner similar to that described for flank incision. The diaphragm is dissected off the underlying peritoneum and liver. The peritoneum is then dissected off the Gerota fascia, which is retracted inferiorly. If a bilateral procedure is undertaken, a Finochietto retractor can be used to assist in bilateral exposure (Fig. 58–8). With division of the final hepatic attachments, the adrenal gland becomes visible. The vena cava often becomes visible at this point, and the right adrenal vein is easily identified at its posterolateral origin. After division of arterial branches to the adrenal that course behind the vena cava and anterior to the paraspinal muscles, the adrenal gland can be mobilized posteriorly away from the paraspinal muscles, exposing the anterior vena cava. Given the small operative field, manual retraction of the kidney to assist dissection is not usually possible. Fortunately, division of the vascular attachments is relatively simple, and direct manipulation of the adrenal gland is possible. **The posterior approach should not be used for large tumors or adrenocortical carcinoma.**

Subcostal Anterior Approach

The anterior approach is useful for larger tumors and can be extended to the contralateral side as a chevron incision for treatment of bilateral lesions (Fig. 58–9). This approach also affords excellent exposure of the great vessels, in the event that lymph nodes or venous tumor thrombus needs to be addressed.

Left Side. The patient is placed supine on the surgical table. If needed, a body roll can be placed under the back at the level of the costal margin to accentuate the costal margin. A skin incision

Figure 58–7. Posterior approach—possible incisions for lumbodorsal incisions.

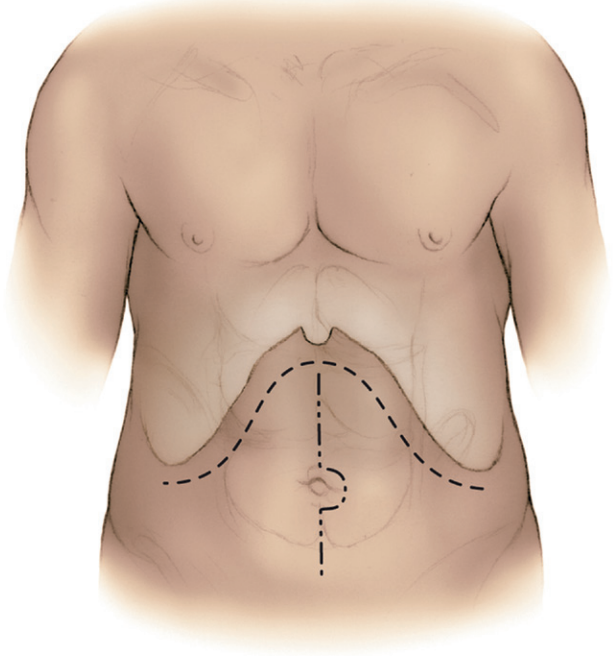

Figure 58–9. Anterior approach. The transperitoneal approach may be attempted through a midline incision or subcostal incision. The subcostal incision can be extended into a full chevron for bilateral adrenalectomy or if a large unilateral tumor is encountered.

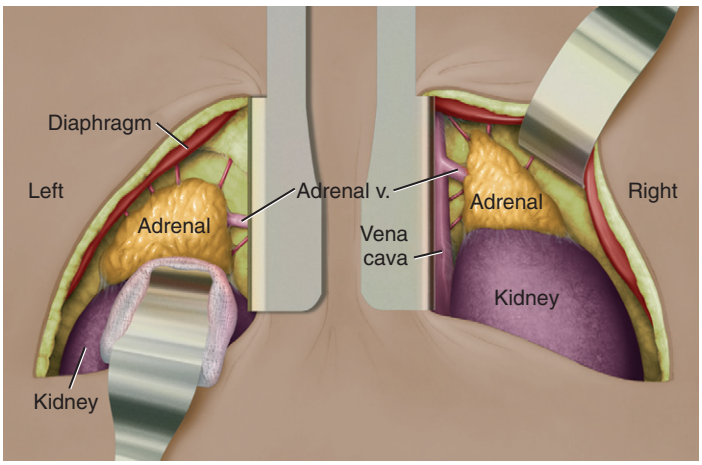

Figure 58–8. Bilateral posterior approach—anatomic relations to the adrenal gland as seen from behind.

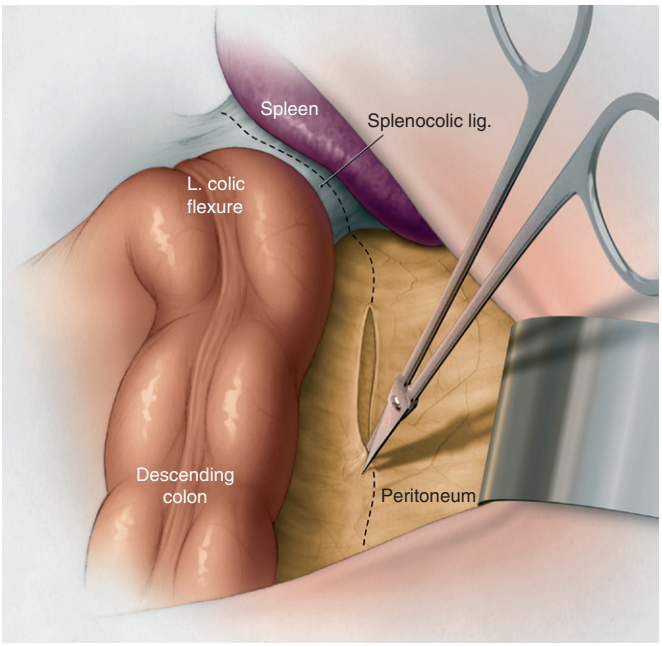

Figure 58–10. Anterior approach. Peritoneum lateral to left colon is incised at the line of Toldt and extended cephalad to the splenocolic ligament and inferiorly.

is made approximately two fingerbreadths below the costal margin. This incision is extended medially to the midline or beyond, depending on the degree of exposure needed. The external oblique, internal oblique, and transverse abdominal muscles, and their corresponding fasciae, are divided laterally; the rectus muscle and the rectus sheath are divided medially. The peritoneum is entered sharply, and the falciform ligament is divided after it is clamped and ligated with a large-gauge vascular tie (No. 0 or 1 silk). The line of Toldt is incised, and the left colon is mobilized medially. The splenic flexure is taken down by dividing the splenocolic ligament (Fig. 58–10). Division of the lienorenal ligament will allow medial mobilization of the spleen. The tail of the pancreas may come into view at this point. In a thin individual, the adrenal may be visible at this point. The left adrenal vein is identified on dissecting out the left renal vein (Fig. 58–11). After ligation and division of the left adrenal vein, medial attachments to the aorta can be taken with the harmonic scalpel or with careful dissection and ligation of small arterial vessels while gentle lateral traction is placed on the gland. The lateral and inferior attachments to the kidney can be taken by blunt and sharp dissection off of the renal

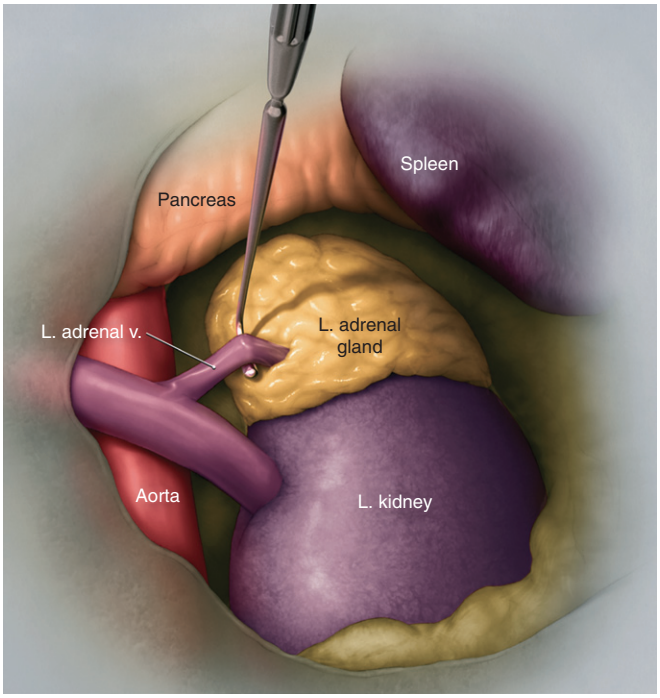

Figure 58–11. Anterior approach. The left adrenal vein is dissected out and ligated.

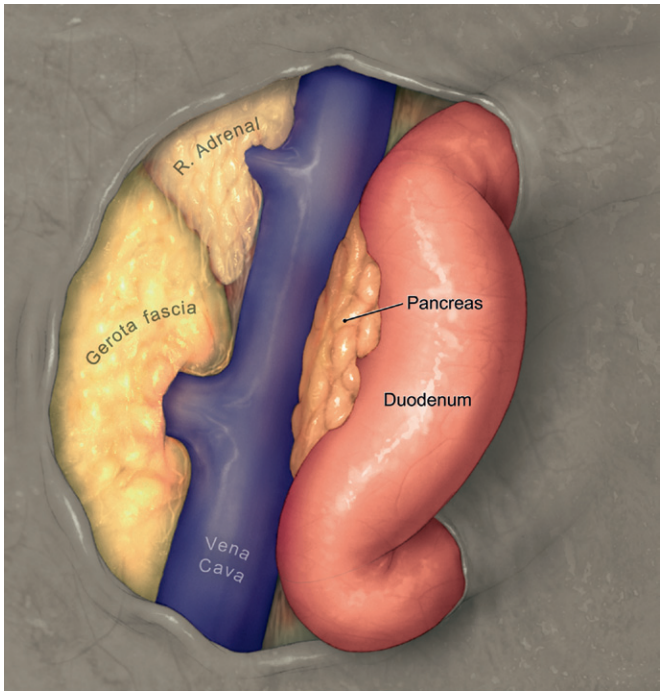

Figure 58–12. Kocher maneuver. The peritoneum is incised, and sharp dissection and blunt dissection are used to mobilize the second stage of the duodenum away from the renal hilum.

capsule. Care must be taken to avoid hitting upper pole renal vascular attachments. After removal of the left adrenal gland, closure of the incision is performed with a running No. 1 polydioxanone suture in two layers. The deep layer consists of the transverse abdominal muscle, transverse fascia, internal oblique muscle and fascia, and posterior rectus sheath, and the superficial layer consists of the external oblique muscle and fascia, and the anterior rectus sheath.

For right-sided tumors, the dissection is similar except for the need to dissect the duodenum medially by the Kocher maneuver (Fig. 58–12).

Thoracoabdominal Approach

This approach is a maximally invasive way to ensure superb surgical exposure of the retroperitoneum, adrenal gland, and great vessels. However, this exposure comes at a price: increased incisional pain, prolonged ileus, pulmonary morbidity, and a chest tube. **The thoracoabdominal approach is reserved for large or invasive adrenal carcinomas.**

Right Side. The patient is placed in an oblique position with the upper torso at a 45-degree angle to the table and the lower body flat on the table. A body roll is used to achieve the 45-degree position, and the right arm is placed in a sling with the arm bent at the elbow (Fig. 58–13). The left arm is secured to an arm board. The incision is made through the eighth or ninth intercostal space (Fig. 58–14), dividing the intercostal muscles and fasciae. The costal cartilage is divided with the surgical cautery. The incision is carried farther through the anterior and posterior rectus sheaths and the rectus abdominal muscle. The pleura is entered, and the lung is packed away with laparotomy sponges (Fig. 58–15). The diaphragm is divided with the cautery. Do not cut directly to the center of the diaphragm because the phrenic nerve can be damaged. Once the diaphragm is divided, a Finochietto

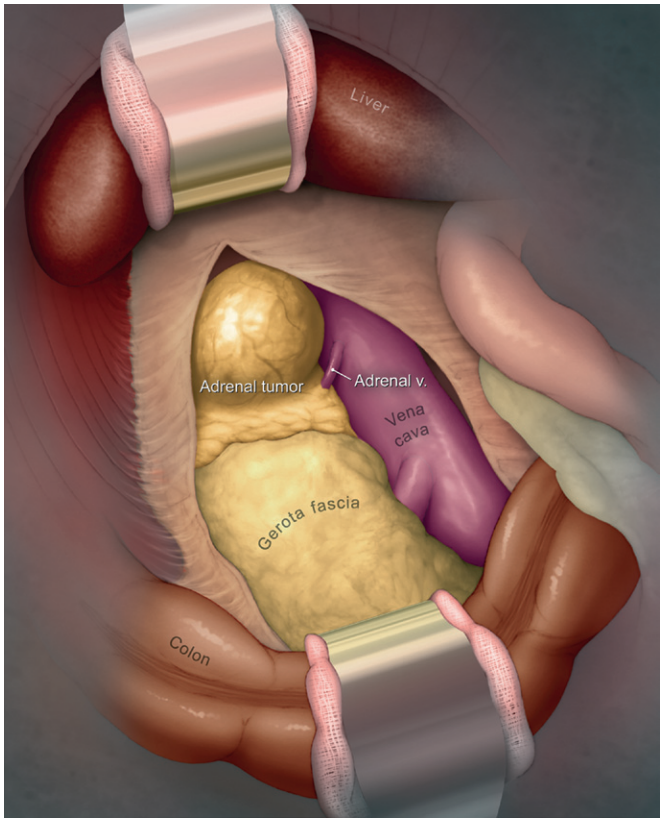

Figure 58–16. Thoracoabdominal approach. Exposure of the adrenal.

self-retaining retractor is placed to expose the surgical area. The rest of the dissection is similar to that of the previously described techniques. The relationship of the thoracoabdominal incision to the adrenal gland is illustrated in Figures 58–16 and 58–17.

Closure of the incision requires closure of the diaphragm and reapproximation of the ribs. The diaphragm is closed with interrupted figure-of-eight stitches with nonabsorbable suture. A chest tube is placed before the anterior thorax is closed. The anterior thorax is closed with several interrupted No. 0 chromic sutures on blunt-tip liver needles around the superior border of the eighth

rib and inferior border of the ninth rib. A No. 0 Prolene suture on a tapered needle is placed through the cut costal cartilage to bring the costal margin together. The chest tube is placed to a water seal and suction.

LAPAROSCOPIC ADRENALECTOMY

Transperitoneal Approach

Transperitoneal laparoscopic adrenalectomy can be performed through either an anterior supine approach or a lateral approach. In general, the anterior supine approach allows bilateral adrenalectomy without having to reposition the patient. The lateral position is advantageous because greater workspace is available secondary to gravity-assisted retraction of the bowel. The flank approach is described in detail.

Left Side. The patient is positioned in a modified flank position. The patient is angled back about 30 to 45 degrees. After insufflation of the abdomen, four trocars are placed along the left costal margin (Fig. 58–18). The line of Toldt is incised and the left colon medially mobilized (Fig. 58–19). The lienorenal and splenocolic ligaments are divided. The lateral and superior attachments of the spleen can be divided to facilitate medial mobilization of the spleen if necessary. In many cases, the spleen may fall away sufficiently by gravity without having to extend the dissection above the spleen. The renal vein and adrenal vein are dissected free (Fig. 58–20). The left adrenal vein is dissected out, ligated, and divided (Fig. 58–21). Surgical clips are used to control the adrenal vein. It is advisable to leave two clips on the body side of the vein and one on the specimen side. Adrenal arterial supply is divided as the adrenal is dissected free (Fig. 58–22). The harmonic scalpel is effective for performing this dissection. The remaining attachments to the kidney are divided bluntly and with the hook cautery (Fig. 58–23). The specimen is placed in an endoscopic sac and extracted (Fig. 58–24).

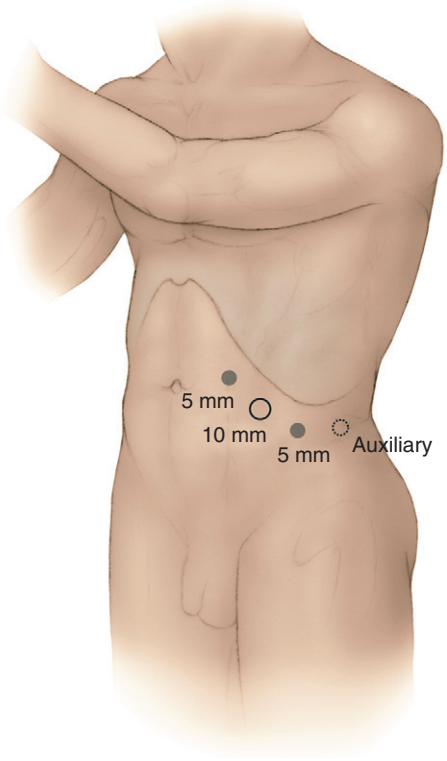

Figure 58–18. Four-trocar configuration for left transperitoneal laparoscopic adrenalectomy.

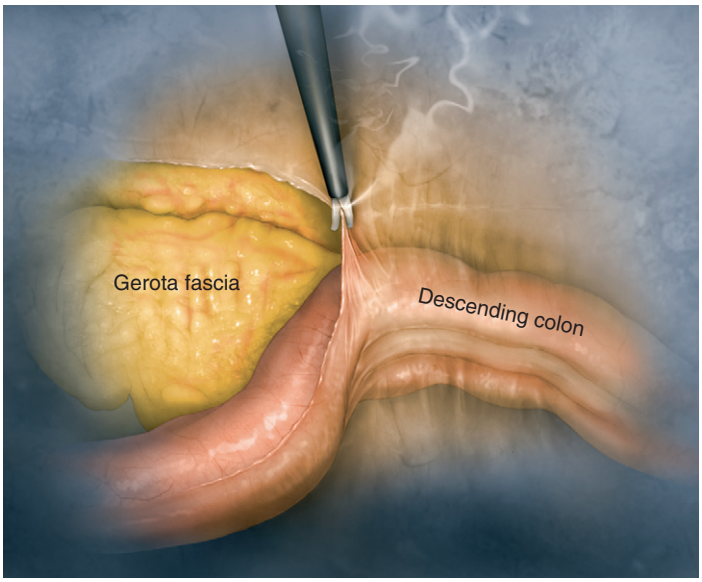

Figure 58–19. Transperitoneal laparoscopic adrenalectomy. Incision of the line of Toldt and medial dissection of the left colon with cautery endoscopic scissors.

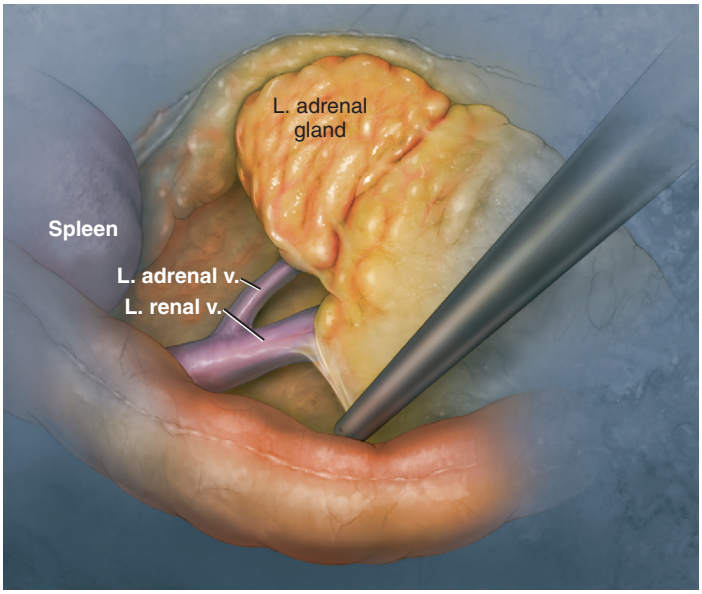

Figure 58–20. Transperitoneal laparoscopic adrenalectomy. Exposure and dissection of the renal vein and left adrenal vein.

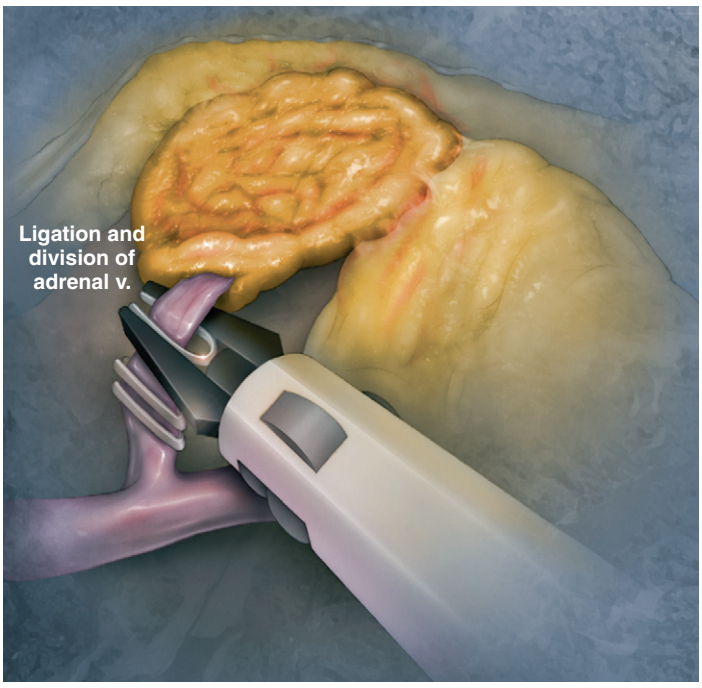

Figure 58–21. Transperitoneal laparoscopic adrenalectomy. Ligation and division of left adrenal vein.

The operative field is examined with the insufflation pressure turned down to 5 mm Hg. If it is hemostatic, the trocar sites are closed with absorbable suture. A drain usually does not need to be placed.

On the right side, the approach is similar. However, the duodenum must be dissected away by the Kocher maneuver. As on the left side, a four-trocar configuration is used (Fig. 58–25). The most medial trocar is used for liver retraction. A 2-mm trocar can be used with a 2-mm locking grasper to fashion a self-retaining retractor of the liver (Fig. 58–26).

Retroperitoneal Approach

Left Side. The patient is placed in flank position with the left side up. The patient is placed in flexion, and the kidney rest is deployed to accentuate the left flank. A 12-mm incision is made near the tip of the 12th rib under the 11th rib. The underlying muscle and fasciae are divided with cautery until the lumbodorsal fascia is visible or palpable. The lumbodorsal fascia is divided with cautery or Metzenbaum scissors, and blunt finger dissection is

used to develop a plane between the posterior Gerota fascia and the psoas fascia. With this plane developed, a retroperitoneal dissection balloon is placed and inflated. Typically, a laparoscope can be placed down the hollow shaft of the dissection balloon to visually confirm the accurate anatomic placement of the balloon between the kidney and psoas. A balloon-tip trocar is placed into the defect and secured in position. After insufflation of the retroperitoneum, a 5- or 10-mm trocar is placed at the angle of the paraspinal muscle and the origin of the 12th rib. A 5- or 10-mm trocar is placed about two fingerbreadths above the iliac crest near the anterior superior iliac spine (Fig. 58–27).

The renal hilum is usually located fairly rapidly in the retroperitoneal approach by direct visualization of arterial pulsations. The left adrenal vein can be isolated from its origin on the left renal vein (Fig. 58–28). The left adrenal vein is dissected out and ligated with surgical clips and divided (Fig. 58–29). The left adrenal gland is then dissected out as described previously; small arterial branches can be clipped or divided hemostatically with a harmonic scalpel. The specimen is placed in a specimen bag and extracted. The trocar sites are closed with absorbable suture after hemostasis is ensured. The right adrenalectomy is performed in similar fashion; anatomic relations of this approach are illustrated in Fig. 58–30.

HAND-ASSISTED SURGERY

The advantage of hand assistance stems from the addition of tactile sensation. This may result in faster dissection and added security in the event of bleeding complications. Also, the learning curve may be shorter with hand assistance. Only case reports exist regarding hand-assisted laparoscopic adrenalectomy. This may be

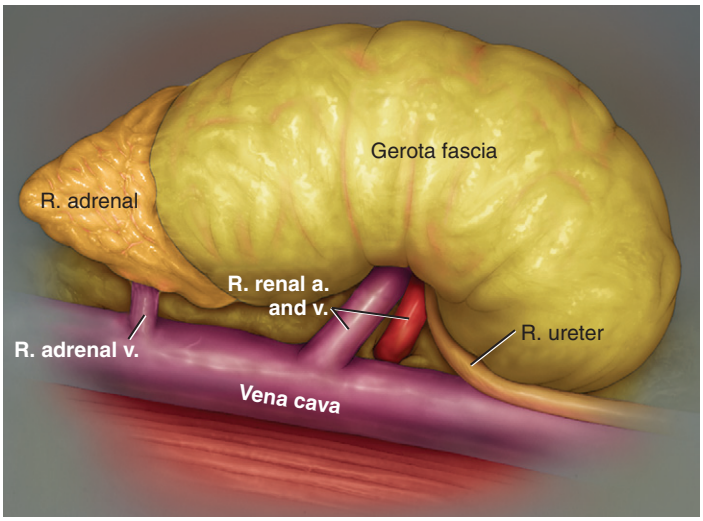

Figure 58–30. Anatomic view of right adrenal gland from laparoscopic retroperitoneal approach.

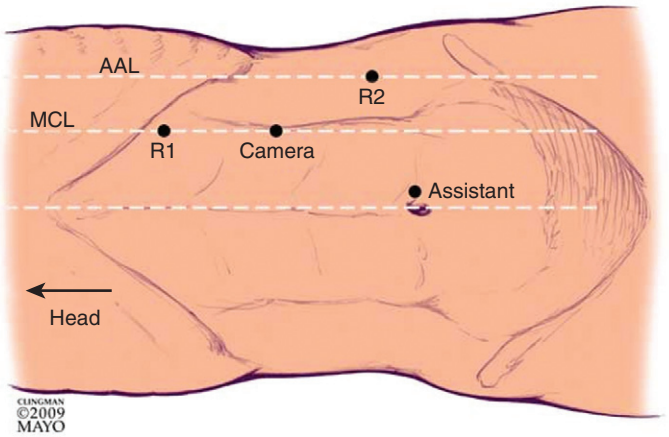

Figure 58–31. Left robotic adrenalectomy trocar placement. A total of four ports are placed. One 12-mm camera port, one 12-mm assistant port, and the two 8-mm robotic arm ports. especially advantageous for large adrenal tumors that may require an incision for extraction. Bilateral tumors may also be treated in this fashion.

ROBOTIC SURGERY

There is growing interest in applying robotic technology to adrenal surgery. Currently, the da Vinci Surgical Robotic System (Intuitive Surgical, Sunnyvale, CA) is the only commercially available product to perform these procedures. Desai and colleagues reported the first case of robotic adrenalectomy in 2002. Since the initial case report, there have been many larger experiences that show that robotic adrenalectomy is safe and effective.

It remains to be seen if robotic adrenalectomy is superior to laparoscopy. The advantages of robotics should be the superior three-dimension visualization and hand-like dexterity of the robotic arms to perform the microdissection of the plane between the adrenal and the great vessels. However, these technical advantages do not appear to translate to any tangible benefit in operative outcomes. In a quality-of-life study comparing laparoscopic to robotic adrenalectomy, Brunaud and colleagues (2004) demonstrated no major difference in all parameters assessed. Likewise, in a prospective randomized study comparing laparoscopic and robotic adrenalectomy, Morino and colleagues (2004) showed that laparoscopic surgery was actually superior to robotic adrenalectomy in operative time, morbidity, and cost. Winter and colleagues (2006) reported on 30 consecutive adrenalectomies and showed that the cost was higher for robotic surgery ($12,977 vs. $11,599), but this was not statistically significant.

Robotic Adrenalectomy Technique

This transperitoneal technique is a variant on the laparoscopic approach. The patient is placed in flank position. After the patient is prepared and draped, pneumoperitoneum is established in the same manner as laparoscopic surgery. Based on the side treated, a total of 4 to 5 trocars are placed as outlined by diagrams. The remainder of the dissection and excision of the adrenal gland are similar to the laparoscopic surgery. To facilitate access to the upper areas of the retroperitoneum, the robot is docked at an angle at the head of the table as outlined in diagram. The third robotic

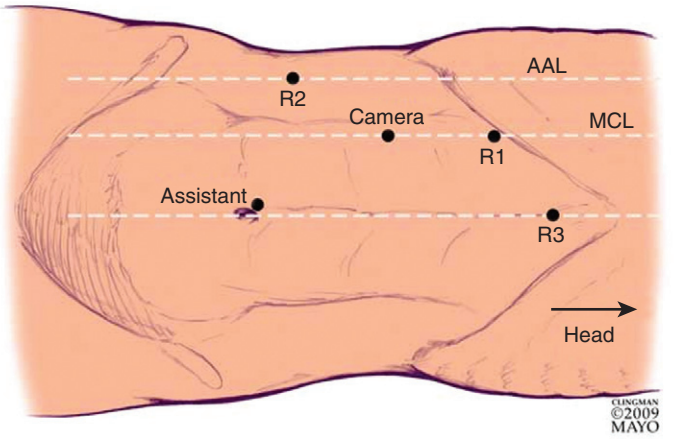

Figure 58–32. Right robotic adrenalectomy trocar placement. A total of five ports are placed. One 12-mm camera port, one 12-mm assistant port, and two 8-mm robotic arm ports. To retract the liver, a third robotic arm is available, or a 3- or 5-mm trocar may be placed with a retraction device such as a locking Babcock clamp or fan retractor. AAL, anterior axillary line; MCL, mid clavicular line. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

arm or a locking forceps can be used to elevate and retract the liver during right adrenalectomy (Figs. 58–31 to 58–33).

INTRAOPERATIVE ULTRASONOGRAPHY

It can be difficult, at times, to locate the adrenal gland, especially if the patient is obese and there is a lot of intra-abdominal fat. Without tactile feedback, unless the lesion is grossly evident, it can be difficult to localize the adrenal gland during surgery. Ultrasonography of the adrenal gland is extremely difficult as an extracorporeal technique. The ability to directly apply the ultrasound probe to the operative area under laparoscopic guidance facilitates identification of the adrenal gland. Furthermore, **intraoperative ultrasonography can help identify the adrenal vein,** especially on the left side.

Brunt and colleagues (1999) used intraoperative ultrasonography in 28 adrenalectomies and had 100% success in identifying

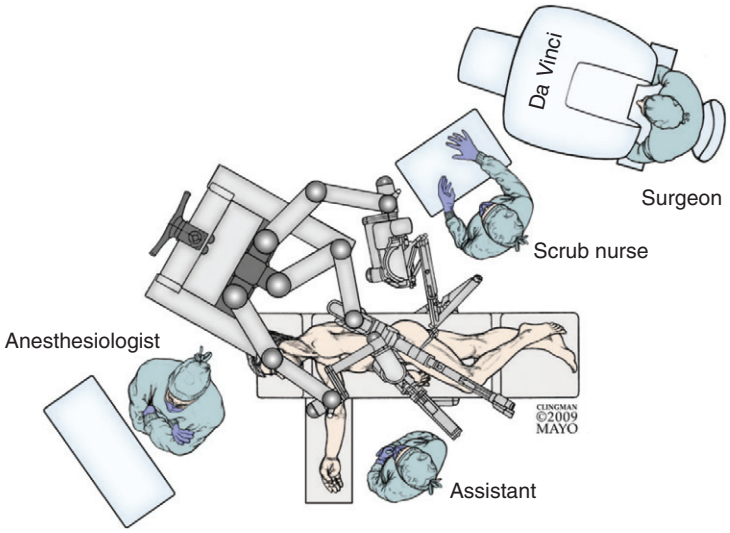

Figure 58–33. Surgical room set-up for left robotic adrenalectomy. The slave unit of the robot is brought in over patient's left shoulder as indicated in the diagram. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

the adrenal gland. Lucas and colleagues (1999) had similar success with 42 adrenalectomies.

Intraoperative ultrasonography is especially helpful in laparoscopic partial adrenalectomy. It can delineate the tumor within the adrenal gland to facilitate adrenal-sparing surgery. Pautler and colleagues (2002) successfully performed laparoscopic partial adrenalectomy on seven patients with ultrasound assistance. There were no complications and no open conversions.

POSTOPERATIVE MANAGEMENT

Electrolyte values are checked the night of surgery and each morning; this is especially important for patients with Conn or Cushing syndrome. The urinary catheter can usually be removed on the first postoperative day when the patient is ambulatory. If a nasogastric tube was placed for open surgery, it can be removed with return of bowel sounds. Diet resumption is usually started on the first postoperative day for laparoscopic surgery, and when bowel sounds resume for open surgery.

Blood pressure is carefully evaluated for hypertension or hypotension. Unexplained hypotension, confusion, lethargy, nausea, vomiting, or fever could represent addisonian crisis (adrenal insufficiency). **Adrenal insufficiency is most commonly seen after surgery for Cushing syndrome, because of contralateral cortisol suppression.** Stress-dose steroid administration may be necessary. Corticosteroid replacement and mineralocorticoid (fludrocortisone) may be required for the long term. Hospital stay may be prolonged by the necessary adjustment of antihypertensive medications and steroids.

OUTPATIENT AND SHORT-STAY LAPAROSCOPIC ADRENALECTOMY

In select patients who underwent uneventful surgery, same-day or less than 24-hour hospital discharge has been attempted. Gill and colleagues (2000) were able to discharge 9 of 27 patients who underwent laparoscopic adrenalectomies within 8 hours of surgery. One patient was readmitted for abscess formation. Edwin and colleagues (2001) described 13 patients with aldosteronoma who underwent laparoscopic adrenalectomy. All were discharged within 3 to 6 hours of surgery. None was readmitted. The satisfaction of patients was high for all but one patient who had poorly controlled pain after discharge. Rayan and Hodin (2000) performed 19 laparoscopic adrenalectomies and were able to discharge 47% of patients within 24 hours.

OUTCOMES

Retrospective studies demonstrate a clear advantage to laparoscopic surgery over open surgery in terms of analgesia, hospital stay, blood loss, and complication rate. The laparoscopic surgeries typically had longer operative times than the open surgery did. There are no randomized prospective studies comparing laparoscopic with open adrenalectomy. In a rare nonrandomized prospective study, Prager and colleagues (2004) assigned patients to laparoscopic or open surgery on the basis of a cutoff of 6 cm; lesions smaller than 6 cm were removed laparoscopically. As one would expect, operative times, complication rate, and blood loss were higher in the open surgery group. It is difficult to compare these two groups fairly because the patients assigned to open surgery had larger tumors and a higher incidence of malignant disease (1.9% vs. 29.1%) than the laparoscopic cohort did.

Comparison of retroperitoneal with transperitoneal laparoscopy tended to favor the retroperitoneal approach. Bonjer and colleagues (1997) showed an advantage in operative time (75 minutes vs. 150 minutes; $P = .005$), blood loss (20 mL vs. 150 mL; $P = .01$), postoperative analgesia (6 mg vs. 20 mg of morphine sulfate; $P = .003$), and hospital stay (4 vs. 6 days; $P = .027$) for retroperitoneal over transperitoneal approach. Suzuki and colleagues (2001) also found less blood loss, shorter convalescence, and faster resumption of oral intake with retroperitoneal surgery than with anterior and lateral transperitoneal procedures. Interestingly, Bonjer and colleagues initially attempted to perform a prospective randomized study, but patients expressed strong preference for retroperitoneal surgery.

Is laparoscopic adrenalectomy too costly? In the current era of soaring medical costs, the cost effectiveness of laparoscopic surgery must be proven to justify its use. Initially, the cost of laparoscopic adrenalectomy was much higher than the cost of open surgery. Thompson and colleagues (1997) noted that hospital charges for laparoscopic adrenalectomy were $1000 higher than for open adrenalectomy. With increased use of disposables and with growing surgical experience, the costs are becoming manageable. Hobart and colleagues (1999) have shown that with 2-mm instrumentation, laparoscopic adrenalectomy resulted in 17.9% less cost than open adrenalectomy. The laparoscopic adrenalectomy had an 18.1% increased intraoperative cost but a 63.4% less postoperative cost. In Spain, Ortega and colleagues (2002) calculated that laparoscopic adrenalectomy was not more expensive in terms of direct surgical cost (€6306 vs. €7581; P = NS). However, hospital stay was significantly shorter and cheaper (€742 vs. €1191; $P = .004$). Interestingly, the most expensive part of the entire therapeutic process was the preoperative hospitalization for diagnostic workup. In the United States, most diagnostic tests are carried out on an ambulatory outpatient basis, and these costs would be considerably less. Aside from the direct cost of surgery and hospitalization, laparoscopic adrenalectomy is often less expensive than long-term medical therapy for certain adrenal disorders. In Canada, aldosteronoma management with surgery represents a savings of C$31,132 over the lifetime of each patient (Sywak and Pasieka, 2002).

Table 58–4.

Operative Complications of Adrenal Surgery

Hemorrhage	Adjacent Organ Injury
Inferior vena cava	Pneumothorax
Adrenal vein	Pancreas
Lumbar vein	Liver
Hepatic vein	Spleen
Vascular	Stomach
Ligation of renal artery branch	Colon
Ligation of mesenteric artery	Kidney
Inferior vena cava involvement	

From Vaughn ED. Complications of adrenal surgery. In: Taneja SS, Smith RB, Ehrlich RM, editors. Complications of urologic surgery: prevention and management. 3rd ed. Philadelphia: WB Saunders; 2001. p. 366.

COMPLICATIONS

Operative Complications (Table 58–4)

As expected, adrenal surgery, both open and laparoscopic, can involve injury to adjacent organs. Hemorrhage is a potentially catastrophic complication of adrenal surgery. Bleeding can result from injury to the adrenal vein, inferior vena cava, lumbar vein, or renal vein. These injuries are managed initially by application of direct pressure to the injury. Grasping a small injury with an Allis clamp and closing it with suture or by placement of a vascular clamp for a larger vena cava injury may be curative. For laparoscopic cases, the management is more of a problem. In the early days of laparoscopic adrenalectomy, open conversion was the typical consequence of vascular injury. However, with increasing experience with laparoscopic suturing techniques, these injuries are often managed as in the open surgery.

Nonhemorrhagic vascular injuries can occur as well. An upper pole renal artery branch can be divided inadvertently during dissection. If the branch is small and supplies a minimal portion of the kidney, it can be ignored. More substantial injuries may require a revascularization attempt. If the patient has a large tumor, there can be distortion of the regional anatomy, and inadvertent ligation of the superior mesenteric vein is possible. This is a potentially fatal injury, and one must have a high index of suspicion to restore vascular supply to the bowel as soon as possible.

The adjacent organs can be injured during dissection of the adrenal gland. The liver can be injured during right adrenalectomy. Liver lacerations can be treated with argon beam coagulation and application of hemostatic agents such as methyl cellulose. More serious injuries may require hemostatic sutures with a blunt-tip liver needle. The spleen can be injured during left adrenalectomy. As with hepatic injury, argon beam coagulation and hemostatic agents can be used to control bleeding. If this is not sufficient, splenorrhaphy can be attempted. If these measures are unsuccessful, splenectomy may be necessary. It is important to remember to give pneumonia vaccination to these patients during postoperative care.

The pancreas can be injured during surgery on either the right or left adrenal gland. If an injury to the tail of the pancreas occurs, distal pancreatectomy may be performed. If the injury is to the pancreatic duct, this may be repaired and surgical drains left. If there is uncertainty of pancreatic injury, leaving closed-suction surgical drains behind is advisable. Postoperative drainage high in triglycerides is indicative of pancreas injury. Management consists of bowel rest with parenteral nutrition. The administration of octreotide can decrease pancreatic secretions while the pancreas heals.

The proximity of the kidney to the adrenal gland can be a problem in cases of large adrenal cortical carcinomas. **It is imperative for all patients undergoing surgery for large adrenal masses to be counseled about the possibility of concurrent en bloc nephrectomy.**

During 11th-rib flank adrenalectomy, it is not unusual for pleural injury to be incurred. These injuries can be repaired with a purse-string chromic suture and a red rubber catheter to water seal. Expulsion of air from the pleura followed by cinching of the purse-string usually repairs the defect. Postoperative chest radiography should be routinely performed after flank or thoracoabdominal nephrectomy. If a significant pneumothorax is present, a chest tube should be placed.

With pheochromocytoma, blood pressure fluctuations can be life-threatening. The anesthesiologist typically manages high blood pressure with short-acting β blockade, α blockers, or nitroprusside. Arrhythmias are usually treated with β blockers. When the adrenal vein is ligated, there can be a sudden drop in blood pressure. It is important to inform the anesthesiologist just before the adrenal vein is ligated to avoid any nasty surprises. Fluid repletion and pressors may be necessary to bring the pressure to normal.

Postoperative Complications

Table 58–5 summarizes the postoperative complications that can occur. Disease-specific complications must be accounted for to ensure an uneventful postoperative course.

Patients with primary hyperaldosteronism require close monitoring of potassium levels because they can be either hypokalemic or hyperkalemic. Hyperkalemia, secondary to contralateral adrenal zona glomerulosa suppression, should be managed medically with the typical hyperkalemia regimens. Hypokalemia can persist in the immediate period after adrenalectomy, and this should be corrected with potassium repletion. In patients who had only one adrenal gland to begin with, mineralocorticoid replacement with fludrocortisone is essential.

Patients with Cushing syndrome will require steroid replacement after surgery, until the contralateral gland recovers function. Measurements of plasma cortisol can be useful in determining when steroid replacement can be tapered. Furthermore, these patients have increased risk of fracture secondary to osteoporosis, hyperglycemia, and poor wound healing.

Patients with pheochromocytoma may have hypotension secondary to α blockade. These patients need to be monitored closely until α blockade wears off, often in the intensive care unit. If α blockade was not used preoperatively, as it is done at the Cleveland Clinic, intensive care stay is unnecessary in most cases.

Laparoscopy versus Open Adrenalectomy

Brunt (2002) compiled the complication statistics of 50 laparoscopic studies and 48 open studies to evaluate the impact of laparoscopy on adrenalectomy. To limit selection bias, open surgical series with adrenal cortical carcinoma cases were excluded. Laparoscopy resulted in a lower complication rate (10.9% vs. 25.2%; $P \leq .0001$) than did open adrenalectomy. Specifically, **pulmonary, wound, and infectious complications were statistically less common with laparoscopic surgery.** There were also fewer injuries to adjacent organs (0.7% vs. 2.4%; $P = .05$). Splenic injuries decreased dramatically in incidence (laparoscopic,

Table 58–5.
Postoperative Complications of Adrenal Surgery

Primary Aldosteronism
Hypokalemia: secondary to continued potassium loss immediately postoperative
Hyperkalemia: secondary to failure of contralateral adrenal to secrete aldosterone
Cushing Syndrome
Inadequate steroid replacement leading to hypocorticoidism
Fracture secondary to osteoporosis
Hyperglycemia
Poor wound healing
Increased risk of infections
Pheochromocytoma
Hypotension secondary to α-adrenergic blockade after tumor removal
Generic Complications
Hemorrhage
Inferior vena cava
Adrenal arteries
Pneumothorax
Pancreatitis
Pneumonia
Hiccups

0.2%; open, 2.0%). A number of factors account for this decrease, including division of the splenocolic and lienorenal ligaments under magnification and the assistance of gravity in retracting the spleen rather than manual retraction. With retroperitoneal surgery, the spleen would not even be in the surgical field to be injured. A decrease in cardiac complications was observed, but some of the improvement in complication rate was thought to be attributable to improvements in perioperative management of vasoactive tumors. The most common complication of laparoscopic adrenalectomy is bleeding (4.7%). Bleeding is also the most common reason for open conversion of laparoscopic adrenalectomy (30%). Bleeding results from vascular injury to the adrenal vein, injury to the vena cava, direct injury to the adrenal gland, renal capsular tear, or surgical clip dislocation.

SPECIAL CONSIDERATIONS

Pediatric

There are relatively few cases of laparoscopic adrenalectomy for pediatric patients. The small body habitus of the patients makes surgery more technically challenging. Neuroblastoma is the most common adrenal tumor in this age group, and this tumor tends to be large and infiltrative, complicating laparoscopic extraction.

Nevertheless, laparoscopic surgery has been successfully performed on pediatric patients. The first case was performed on a small asymptomatic neuroblastoma identified by mass screening of children in Japan (Yamamoto et al, 1996). Comparing open with laparoscopic biopsies and excisions, Iwanaka and colleagues (2001) showed that laparoscopy was associated with shorter hospitalization and rapid resumption of diet. Bilateral laparoscopic adrenalectomy can be performed safely as well (Schier et al, 1998).

In financial terms, laparoscopic adrenalectomy is cost saving when postoperative stay is accounted for (Stanford et al, 2002). Even though laparoscopic adrenalectomy was more expensive as a procedure ($12,941 vs. $4,714; $P < .001$), the overall cost difference between the two procedures was statistically insignificant.

Pregnancy

The pregnant patient can present with an endocrinologically active adrenal tumor. Pheochromocytoma must be distinguished from preeclampsia or pregnancy-induced hypertension, a more medically accurate term. The main distinguishing factors are the absence of proteinuria in pheochromocytoma and the fact that pregnancy-induced hypertension tends to occur in the third trimester. When pheochromocytoma is diagnosed late in pregnancy, the pregnancy can be taken to term with medical management and the child delivered by cesarean section. If pheochromocytoma is diagnosed in the first or second trimester, the risk of surgery must be weighed against the risk of the pheochromocytoma to the pregnancy (Martinez Brocca et al, 2001).

Laparoscopic adrenalectomy can be successfully performed on a pregnant patient. Several reports exist of successful surgery. Maneuvers to minimize risk include keeping insufflation pressure below 15 mm Hg, using open Hasson technique to gain access, and monitoring fetal heart rate and maternal arterial blood gases.

Partial Adrenalectomy

The main indications for partial adrenalectomy are solitary adrenal gland, bilateral disease, and patients with familial syndromes. Pheochromocytoma has been treated with partial adrenalectomy, especially in patients with von Hippel-Lindau syndrome (Al-Sobhi et al, 2002; Baghai et al, 2002), familial pheochromocytoma, or multiple endocrine neoplasia type IIA (Sackett and Bambach, 2003; Brauckhoff et al, 2004). Aldosteronomas have been removed laparoscopically (Sasagawa et al, 2000; Jeschke et al, 2003).

Partial adrenalectomy is usually performed with an endoscopic stapler. Dividing the adrenal vein does not affect viability of the adrenal gland, so it can be taken with the mass. However, Sasagawa and colleagues (2000) described a technique using the ultrasonic scalpel. Intraoperative ultrasonography can help identify the mass to facilitate surgery (Pautler et al, 2002).

NONSURGICAL ALTERNATIVES

Radiofrequency Ablation

Radiofrequency ablation has been used successfully to treat adrenal lesions, primarily adrenal metastases (Rohde et al, 2003) or metastases of adrenal cortical carcinoma (Abraham et al, 2003; Wood et al, 2003) and malignant pheochromocytoma. In the largest series to date, Mayo-Smith and Dupuy (2004) described performing 13 procedures on 12 patients without incident. These procedures can be safely and comfortably employed on an outpatient or overnight-stay basis. However, life-threatening hypertension has been reported in one case of adrenal ablation (Chini et al, 2004). The lesion may have been a pheochromocytoma. Unfortunately, no pathologic examination or preoperative workup for vasoactive adrenal masses was performed. Presumably, **catecholamine release can be caused by thermal injury to the adrenal in the absence of pheochromocytoma.** Onik and colleagues (2003) described their experience with two cases of hypertensive crisis in patients undergoing hepatic radiofrequency ablation. Both cases involved radiofrequency ablation of the posterior right lobe of the liver, close to the right adrenal. In one

patient in whom catecholamine levels were measured, the values were 10-fold greater than the upper limit of normal.

Cryoablation

The clinical experience with cryoablation is fairly limited (Munver and Sosa, 2004). Canine experiments have confirmed that cryotherapy can be delivered to the adrenal gland effectively (Schulsinger et al, 1999). Furthermore, the ability to observe the ice ball under ultrasound examination in a live dynamic fashion allows it to be applied in a controlled, reproducible fashion.

Key Points

- Laparoscopic adrenalectomy is the current standard of care for adrenal lesions with the exception of invasive adrenocortical carcinoma or adrenocortical carcinoma with caval thrombus.
- Preoperative computed tomography can help distinguish invasive from noninvasive adrenocortical carcinoma.
- Percutaneous ablative technologies are an increasingly attractive alternative to surgery for small incidental masses.
- If you suspect pheochromocytoma, avoid percutaneous ablation because of the risk for catecholamine release.
- Open adrenal surgery is reserved for lesions not amenable to minimally invasive techniques (i.e., invasive, large carcinomas, or carcinoma with caval involvement).
- When operating on patients for large invasive adrenocortical carcinoma, be sure to obtain consent for possible en bloc resection of adjacent organs.

Effect of Drugs on the Ureter

The function of the ureter is to transport urine from the kidney to the bladder. Under normal conditions, ureteral peristalsis originates with electric activity at pacemaker sites located in the proximal portion of the urinary collecting system (Bozler, 1942; Weiss et al, 1967; Constantinou, 1974; Gosling and Dixon, 1974; Tsuchida and Yamaguchi, 1977; Zhang and Lang, 1994; Lammers et al, 1996). The electric activity is then propagated distally and gives rise to the mechanical event of peristalsis, ureteral contraction, which propels the bolus of urine distally. Efficient propulsion of the urinary bolus depends on the ureter's ability to completely coapt its walls (Woodburne and Lapides, 1972). Urine passes into the bladder through the ureterovesical junction (UVJ), which, under normal conditions, permits urine to pass from the ureter into the bladder but not from the bladder into the ureter.

CELLULAR ANATOMY

The primary functional anatomic unit of the ureter is the ureteral smooth muscle cell. The cell is extremely small, approximately 250 to 400 μm in length and 5 to 7 μm in diameter. The **nucleus,** which is separated from the remainder of the cell by a nuclear membrane, is ellipsoidal and **contains a darkly staining body, the nucleolus, and the genetic material of the cell. Surrounding the nucleus is the cytoplasm or sarcoplasm, which contains the structures involved in cell function.** Frequently, in conjunction with the nucleus, **mitochondria** in the cytoplasm **perform many of the nutritive functions of the cell. Endoplasmic or sarcoplasmic reticulum dispersed in the cytoplasm serve as Ca^{2+} storage sites.**

Dispersed in the sarcoplasm are the **contractile proteins, actin, and myosin**. Depending on the local calcium ion (Ca^{2+}) concentration, they interact to produce contraction or relaxation. **Any process that leads to a significant increase in the Ca^{2+} concentration in the region of the contractile proteins results in contraction; conversely, any process that leads to a significant decrease in the Ca^{2+} concentration in the region of the contractile proteins results in relaxation.** Actin is dispersed throughout the sarcoplasm in hexagonal clumps and is interspersed among the less numerous clumps of more deeply staining myosin. Dark bands along the cell surface are referred to as *attachment plaques*. Along with dense bodies dispersed in the cytoplasm, they serve as attachment devices for the actin.

Around the periphery of the cell are numerous cavitary structures, some of which open to the outside of the cell and are referred to as ***caveolae.*** These **caveolae contain a cytoskeletal protein, caveolin, and a variety of signal transduction molecules and receptors for growth factors and cytokines** (William and Lisanti, 2004). **A double-layer cell membrane surrounds the cell. The inner plasma membrane surrounds the entire cell, but the outer basement membrane is absent at areas of close cell-to-cell contact, referred to as intermediate junctions.**

DEVELOPMENT OF THE URETER

The ureter, a 25- to 30-cm tube extending from the renal pelvis to the bladder, arises as an outpouching from the mesonephric duct. This begins on embryonic day (E) 10.5 in mice and E28 in humans. Signals from the metanephric mesenchyme, stroma, and angioblasts induce the ureteral bud to arise from the mesonephric duct, invade the mesenchyme, and undergo branching. Formation of the ureteric bud and its subsequent branching is induced by glial cell line–derived neurotrophic factor (GDNF), derived from adjacent metanephrogenic mesenchyme (Pepicelli et al, 1997; Sainio et al, 1997; Shakya et al, 2005). GDNF signals through the c-RET receptor tyrosine kinase (Vega et al, 1996), which results in increased phosphatidylinositol-3-kinase (P13-kinase) activity and AKT/PKB phosphorylation (Tang et al, 2002). Expression of *GDNF* or c-*RET* is activated by a transcription factor present in the metanephric mesenchyme, paired box 2 (from *PAX-2* gene) (Brophy

et al, 2001; Clarke et al, 2006). A number of other growth factors, including transforming growth factor–β (TGF-β); hepatocyte growth factor (HGF); fibroblast growth factors (FGF 1, 2, 7, and 10); transcription factors, from *Foxd1, Wnt11,* and *Spry1* genes; and matrix molecules, such as heparin sulphate proteoglycans, laminins, integrins, and matrix metalloproteinases (MMP9) are involved in stimulation or inhibition of growth and branching of the ureteral bud (Davies et al, 1995; Mendelsohn et al, 1999; Qiao et al, 1999; Pohl et al, 2000; Davies, 2001; Qiao et al, 2001; Takemura et al, 2002; Majumdar et al, 2003; Sakurai, 2003; Bush et al, 2004; Chen et al, 2004; Basson et al, 2006). Activin A, a member of the TGF-β family, is an endogenous inhibitor of ureteric bud outgrowth from the wolffian duct (Maeshima et al, 2006). Activin A inhibits GDNF-induced ureteral bud formation, and this is accompanied by inhibition of cell proliferation, reduced expression of *PAX-2*, and decreased phosphorylation of PI3-kinase and MAP kinase in the wolffian duct. The tip of each ureteral bud is capable of inducing adjacent metanephric mesenchyme to undergo a mesenchymal-to-epithelial transition (MET), with the formation of the nephron (Ekblom, 1989; Shah et al, 2004).

Programmed cell death, or apoptosis, is involved in branching of the ureteric bud and subsequent nephrogenesis. Inhibitors of caspases, which are involved in the apoptotic signaling pathway, inhibit ureteral bud branching (Araki et al, 1999). **During development, the ureteral lumen is obliterated, and then it recanalizes** (Russo-Gil et al, 1975; Alcaraz et al, 1991). **It appears that angiotensin, acting through the angiotensin II receptor, is involved in the recanalization process** (Yerkes et al, 1998) and in the inhibition of aberrant ureteral budding (Oshima et al, 2001). Knockout mice for the *ATR2* gene have congenital anomalies of the kidney and urinary tract, including duplicated collecting systems with a hydronephrotic upper pole moiety, multicystic dysplastic kidneys, megaureters, and ureteropelvic junction (UPJ) obstructions. Mutant mice lacking angiotensin II type I receptors fail to develop a renal pelvis and lack ureteral peristaltic activity (Miyazaki et al, 1998). Angiotensin II, acting through angiotensin II type I receptors, also is involved in ureteric bud cell branching, a process that depends on phosphorylation of the epidermal growth factor (EGF) receptor (Iosipiv and Schroeder, 2003; Yosypiv et al, 2006).

Calcineurin, a Ca^{2+}–dependent serine/threonine phosphatase also appears to be an essential signaling molecule in urinary tract development. Mutant mice in which calcineurin function is removed are noted to have reduced proliferation of smooth muscle and mesenchymal cells in the developing urinary tract, with abnormal development of the renal pelvis and ureter with resultant defective pyeloureteral peristalsis (Chang et al, 2004).

ELECTRIC ACTIVITY

The electric properties of all excitable tissues depend on the distribution of ions on both the inside and the outside of the cell membrane and on the relative permeability of the cell membrane to these ions (Hodgkin, 1958). The ionic basis for electric activity in ureteral smooth muscle has not been fully described; however, many of its properties resemble those in other excitable tissues.

Resting Potential

When a ureteral muscle cell is in a nonexcited or resting state, the electric potential difference across the cell membrane, transmembrane potential, is referred to as the resting membrane potential (RMP). The RMP is determined primarily by the distribution of potassium ions (K^+) across the cell membrane and by the permeability of the membrane to K^+ (Hendrickx et al, 1975). In the resting state, the K^+ concentration on the inside of the cell is greater than that on the outside of the cell, that is, $[K^+]_i > [K^+]_o$, and the membrane is preferentially permeable to K^+. Because of the tendency for the positively charged K^+ ions to diffuse from the inside of the cell, where they are more concentrated, to the outside of the cell, where they are less concentrated, an electric gradient is created, with the inside of the cell membrane being more negative than the outside (Fig. 59–1A). The electric gradient that is formed tends to oppose the further movement of K^+ outward across the cell membrane along its concentration gradient, and an equilibrium is reached.

If the membrane in the resting state were exclusively permeable to K^+, the measured RMP of the ureteral smooth muscle cell would

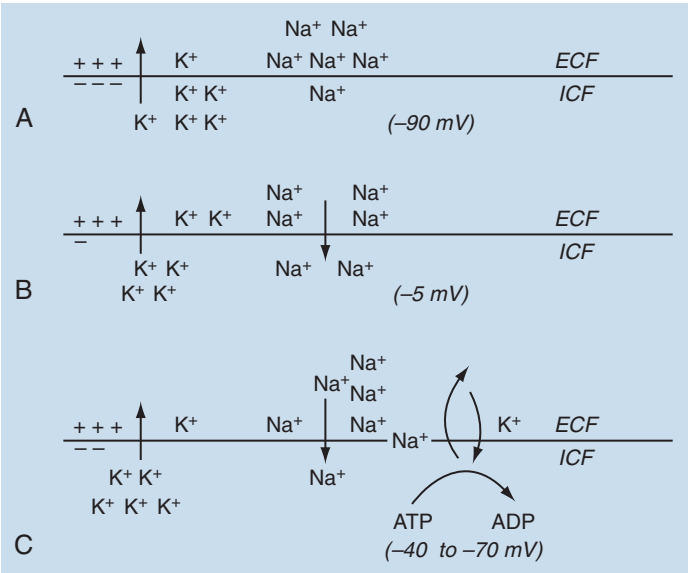

Figure 59–1. Ionic basis for the resting membrane potential (RMP) in smooth muscle. In the resting state, the K^+ concentration inside the cell is greater than the K^+ concentration outside the cell, and the Na^+ concentration outside the cell is greater than the Na^+ concentration inside the cell. **A,** Electrochemical changes that would occur if the membrane were solely permeable to potassium. Potassium would diffuse from the inside of the cell, where it is more concentrated, to the outside of the cell, where it is less concentrated. The outward movement of the positively charged K^+ ions would make the inside of the cell membrane negative with respect to the outside of the cell membrane. **B,** Electrochemical changes that would occur if the resting membrane were also permeable to sodium. An inward movement of Na^+ along its concentration gradient would make the inside of the cell membrane less negative with respect to the outside of the cell membrane than is depicted in **A**. **C,** Pump mechanism for extruding Na^+ from within the cell against concentration and electrochemical gradients. Inward movement of K^+ is coupled with outward movement of Na^+. This mechanism helps to maintain a steady state of ion distribution across the cell membrane and a stable RMP. ECF, extracellular fluid; ICF, intracellular fluid. (**A** to **C,** From Weiss RM. Ureteral function. Urology 1978;12:114.)

approximate –90 mV, the K^+ equilibrium potential, as predicted by the Nernst equation:

$$E_k = -RT/nF \ln[K^+]_i/[K^+]_o$$

where E_k is the potential difference attributable to the concentration difference of K^+ across the cell membrane, R is the molar gas constant, T is the absolute temperature, n is the number of moles of K^+, and F is the faraday constant (Nernst, 1908). However, in the ureter and in other smooth muscles, the RMP is considerably less than the K^+ equilibrium potential, with values of –33 to –70 mV, the inside of the cell being negative relative to the outside (Kuriyama et al, 1967). Studies from single isolated ureteral cells show spontaneous transient hyperpolarizations, with the RMP transiently becoming more negative (Imaizumi et al, 1989). This phenomenon appears to be due to spontaneous release of calcium ions (Ca^{2+}) from the sarcoplasmic reticulum, with activation of tetraethylammonium (TEA) and charbydotoxin-sensitive Ca^{2+}-dependent K^+ channels ($I_{K(Ca)}$). Although the low resting potential of ureteral cells may be explained in part by a relatively small resting K^+ conductance (Imaizumi et al, 1989), it also may be due to the contribution of other ions.

One such ion that could account for the relatively low RMP of the ureter and other smooth muscles is the sodium ion (Na^+) (Kuriyama, 1963). In the resting state, the Na^+ concentration on the outside of the cell membrane is greater than that on the inside, that is, $[Na^+]_o > [Na^+]_i$. If the resting membrane were somewhat permeable to Na^+, both the concentration and the electric gradient would support an inward movement of Na^+ across the cell membrane, with a resultant decrease in the electronegativity of the inner surface of the cell membrane (Fig. 59–1B).

If such an inward movement of Na^+ went unchecked, the RMP would be expected to decrease to a level lower than that actually observed, and the concentration gradient for Na^+ might become reversed. In order to maintain a steady-state ion distribution across the cell membrane with $[K^+]_o < [K^+]_i$ and $[Na^+]_o > [Na^+]_I$, and to prevent the transmembrane potential from becoming lower than the measured ureteral RMP, an active mechanism capable of extruding Na^+ from within the cell against a concentration and electrochemical gradient is required (Fig. 59–1C). Such an outward Na^+ pump that is coupled with an inward movement of K^+ derives its energy requirements from the dephosphorylation of ATP (Casteels, 1970). Na^+/Ca^{2+} exchange also may play a role in Na^+ extrusion, especially when the Na^+ pump is inhibited (Aickin, 1987; Aickin et al, 1987; Lamont et al, 1998).

The dynamic processes illustrated in Figure 59–1 enable the ureter in its resting state to maintain a relatively low RMP. In addition to the mechanisms described, the distribution of chloride ions (Cl^-) across the cell membrane and the relative permeability of the membrane to Cl^- may be factors in the maintenance of the RMP in the ureter and other smooth muscles (Kuriyama, 1963; Washizu, 1966).

Action Potential

The transmembrane potential of an inactive or resting ureteral cell remains stable until it is excited by an external stimulus—electric, mechanical (stretch), or chemical—or by conduction of electric activity (action potential) from an already excited adjacent cell. **When a ureteral cell is stimulated, depolarization occurs, with the inside of the cell membrane becoming less negative than it was before stimulation. If a sufficient area of the cell membrane is depolarized rapidly enough to reach a critical level of transmembrane potential, referred to as the threshold potential, a regenerative depolarization, or action potential, is initiated.**

The changes that occur are diagrammatically depicted in Figure 59–2. If a stimulus is very weak, as shown by *arrow a,* the transmembrane potential may remain unchanged. A slightly stronger, yet subthreshold, stimulus may result in an abortive displacement of the transmembrane potential, but not to such a degree that an action potential is generated *(arrow b).* If the stimulus is strong enough to decrease the transmembrane potential to the threshold potential, the cell becomes excited and develops an action potential *(arrow c).* The **action potential,** which **is the primary event in the conduction of the peristaltic impulse,** has the capability to act as the stimulus for excitation of adjacent quiescent cells **and, through a complicated chain of events, gives rise to the ureteral contraction.**

When the ureteral cell is excited, its membrane loses its preferential permeability to K^+ and becomes more permeable to Ca^{2+} ions that move inward across the cell membrane, primarily through fast L-type Ca^{2+} channels and give rise to the upstroke of the action potential (Fig. 59–3A) (Kobayashi, 1965; Kuriyama and Tomita, 1970; Imaizumi et al, 1989; Lang, 1989, 1990; Sui and Kao, 1997a, b; Smith et al, 2002). This channel is inhibited by the calcium channel blocker nifedipine and by cadmium ions (Cd^{2+}), and it is potentiated by barium ions (Ba^{2+}). As the positively charged Ca^{2+} ions move inward across the cell membrane, the inside of the membrane becomes less negative relative to the outside and may even become positive at the peak of the action potential, a state referred to as ***overshoot***. Na^+ ions also may play a role in the upstroke of the ureteral action potential (Kobayashi, 1964, 1965; Muraki et al, 1991). The rate of rise of the upstroke of the ureteral action potential is relatively slow, 1.2 ± 0.06 V/sec in the cat (Kobayashi, 1969). This compares with a 610 V/sec rate of rise in dog cardiac Purkinje fibers (Draper and Weidmann, 1951) and a 740 V/sec rate of rise in skeletal muscle (Ferroni and Blanchi, 1965). The slow rate of upstroke rise of the ureteral action potential accounts for the slow conduction velocity in the ureter.

After reaching the peak of its action potential, the ureter maintains its potential for a period of time

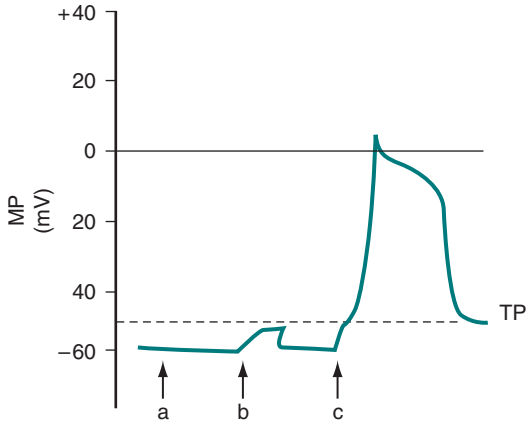

Figure 59–2. Response of ureteral transmembrane potential to stimuli. At *arrow a,* a weak stimulus is applied that does not alter the resting membrane potential (MP). At *arrow b,* a stimulus is applied that decreases the transmembrane potential but not to the level of the threshold potential TP (subthreshold stimulus). At *arrow c,* a stimulus is applied that decreases the transmembrane potential to TP, and an action potential is initiated (suprathreshold stimulus). (From Weiss RM. Ureteral function. Urology 1978;12:114.)

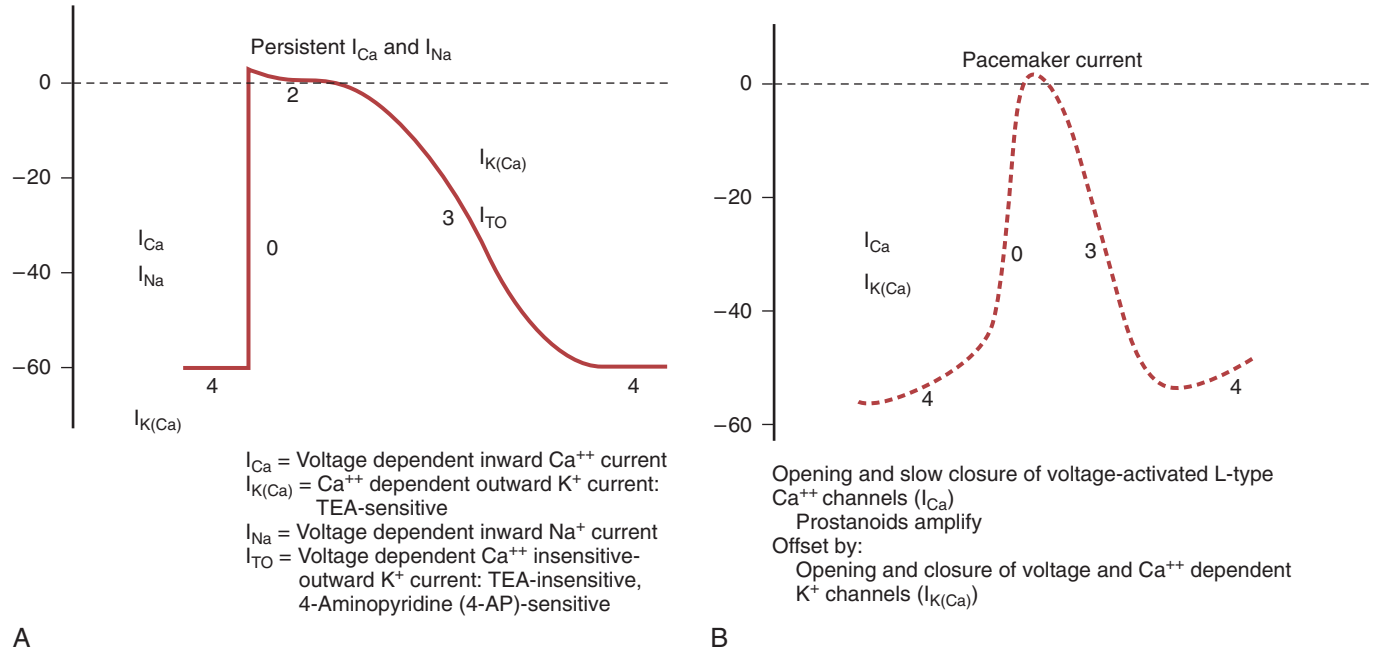

Figure 59–3. Schematic representation of ionic currents in **(A)** nonpacemaker *(solid line)* and **(B)** pacemaker *(dashed line)* action potentials: (0) upstroke or depolarization phase; (2) plateau phase; (3) repolarization phase; and (4) resting potential of the nonpacemaker cell and spontaneous depolarization phase of the pacemaker cell. A spontaneous decrease in the transmembrane potential of pacemaker cells accounts for their spontaneous activity.

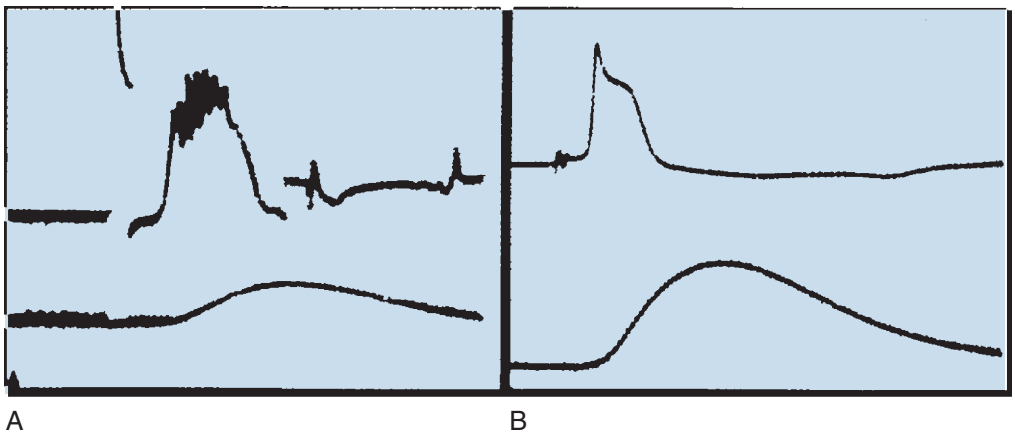

Figure 59–4. Intracellular recordings of ureteral action potentials *(upper tracings)* and isometric recordings of contractions (lower tracings) in response to electrical stimuli. Action potentials precede contractions. **A,** Guinea pig ureter; oscillations on the plateau of the action potential. **B,** Cat ureter; no oscillations on the plateau of the action potential. (**A** and **B,** From Weiss RM. Ureteral function. Urology 1978;12:114.)

(plateau of the action potential) before the transmembrane potential returns to its resting level (repolarization) (Kuriyama et al, 1967). The plateau phase of the guinea pig action potential is superimposed with multiple oscillations, a phenomenon not observed in the rat, rabbit, or cat (Fig. 59–4) (Bozler, 1938). The plateau phase appears to depend on the persistence of an inward Ca^{2+} current and on Na^+ influx through a voltage-dependent Na^+ channel (see Fig. 59–3A) (Kuriyama and Tomita, 1970; Imaizumi et al, 1989; Sui and Kao, 1997b). Also involved in the plateau formation is the maintenance of depolarization by an inward calcium-dependent chloride current ($I_{Cl(Ca)}$) which is countered by outward voltage-gated (I_{70}) and Ca^{2+}-activated K^+ currents ($I_{(KCa)}$) (Smith et al, 2002). There are species differences in the ionic currents involved in the formation of the action potential, with the Ca^{2+}-activated chloride current being present in the rat but not in the guinea pig ureter. The inward Cl^- current can be inhibited by niflumic acid and by Ba^{2+} (Smith et al, 2002). The oscillations on the plateau of the guinea pig action potential appear to depend on the repetitive activation of an inward Ca^{2+} current (Kuriyama and Tomita, 1970) and of a Ca^{2+}-dependent outward K^+ current (Imaizumi et al, 1989). Prolongation of the inward calcium current and the duration of the action potential correlate with an increased force of contraction (Burdyga and Wray, 1999b).

The activation of a Ca^{2+}-dependent K^+ current that is involved in repolarization is mainly due to Ca^{2+} release from the endoplasmic reticulum, which is triggered by the influx of extracellular Ca^{2+} through voltage-dependent Ca^{2+} channels. The increase in intracellular Ca^{2+} concentration during the upstroke and plateau of the

action potential finally may activate the outward Ca^{2+}-dependent K^+ current ($I_{K(Ca)}$) to such a degree that repolarization occurs with return of the transmembrane potential to its resting level (see Fig. 59–3A) (Imaizumi et al, 1989; Sui and Kao, 1997c). This $I_{K(Ca)}$ is sensitive to inhibition by tetraethylammonium (TEA). Based on this, TEA increases the amplitude and duration of in-vitro ureteral contractions (Floyd et al, 2008). A voltage-dependent, Ca^{2+} insensitive outward K^+ current (I_{TO}) also appears to be involved in the repolarization (Lang, 1989; Imaizumi et al, 1990). These currents are TEA-insensitive and 4-aminopyridine (4-AP)–sensitive. In the rat, but not the guinea pig, ureter there is a late TEA-, Cd^{2+}- and Ca^{2+}-insensitive outward K^+ current that also is involved in the repolarization process. The duration of the action potential in the cat ranges from 259 to 405 milliseconds (Kobayashi and Irisawa, 1964).

In summary, **the RMP of the ureteral cell is approximately –33 to –70 mV and is determined primarily by the distribution of K^+ ions across the cell membrane and the relatively selective permeability of the resting cell membrane to K^+. When excited by a suprathreshold stimulus, the membrane becomes less permeable to K^+ and more permeable to Ca^{2+}, which moves inward across the cell membrane and provides the ionic mechanism for the development of the upstroke of the action potential. After reaching the peak of its action potential, the membrane maintains a depolarized state—plateau of the action potential—for a period of time before the membrane potential of the activated cell returns to its resting level (repolarization). The plateau appears to be related to a persistent inward Ca^{2+} current and to an influx of Na^+. Repolarization of the membrane is related to a renewed increase in permeability to K^+.**

Pacemaker Potentials and Pacemaker Activity

Electric activity arises in a cell either spontaneously or in response to an external stimulus. If the activity arises spontaneously, the cell is referred to as a pacemaker cell. Pacemaker fibers differ from nonpacemaker fibers in that their transmembrane resting potential is lower (less negative) than that of nonpacemaker fibers (Lang and Zhang, 1996) and does not remain constant but, rather, undergoes a slow spontaneous depolarization (see Fig. 59–3B). If the spontaneously changing membrane potential reaches the threshold potential, the upstroke of an action potential occurs. The **ionic conduction underlying pacemaker activity in the upper urinary tract is due to the opening and slow closure of voltage-activated L-type Ca^{2+} channels that are amplified by prostanoids** (Santicioli et al, 1995a). This is opposed by the opening and closure of voltage and Ca^{2+}-dependent K^+ channels. It has been suggested that prostaglandins and excitatory tachykinins, released from sensory nerves, help maintain autorhythmicity in the upper urinary tract through maintenance of Ca^{2+} mobilization (Lang et al, 2002). **Tetrodotoxin and blockers of the autonomic nervous system, both parasympathetic and sympathetic, have little effect on peristalsis, suggesting that autonomic neurotransmitters have a small role in maintaining pyeloureteral motility** (Lang et al, 2001, 2002). Changes in the frequency of action potential development may result from a change in the level of the threshold potential, a change in the rate of slow spontaneous depolarization of the resting potential, or a change in the level of the resting potential.

Gosling and Dixon (1971, 1974) provided morphologic evidence of specialized pacemaker tissue in the proximal portion of the urinary collecting system and described species differences. **In species with a multicalyceal system, such as the pig, sheep, and human, the "pacemaker cells" are located near the pelvicalyceal border** (Dixon and Gosling, 1973). In species with a unicalyceal system, such as the dog, cat, rat, rabbit, and guinea pig, the "pacemaker cells" extend from the pelvicalyceal border to the ureteropelvic junction (UPJ). These **atypical smooth muscle cells that give rise to pacemaker activity** in the rat and guinea pig, in contrast to typical smooth muscle cells, have less than 40% of their cellular area occupied by contractile elements and demonstrate sparse immunoreactivity for smooth muscle and actin (Klemm et al, 1999; Lang et al 2001). These spindle-shaped cells are 90 to 230 μm in length, and their electrical activity consists of simple waveforms of alternating depolarizing and repolarizing phases that occur at a relatively rapid frequency of 8 to 15/min (Fig. 59–5A) (Tsuchida and Suzuki, 1992; Klemm et al, 1999). Pacemaker potentials have a lower resting membrane potential (RMP), a slower rate of rise, and a lower amplitude than action potentials recorded from nonpacemaker cells. In the guinea pig, these atypical, presumably pacemaker cells comprise greater than 80% of the cells at the pelvicalyceal junction, about 15% of the cells in the proximal renal pelvis, but are not present in the distal renal pelvis or ureter (Klemm et al, 1999). Electrical recordings correlate with histologic findings in that pacemaker potentials were not observed in the distal renal pelvis or ureter (Klemm et al, 1999).

Driven action potentials that fire at lower frequency (3 to 5/min) than pacemaker potentials are recorded from longer (150 to 400 μm) spindle-shaped typical smooth muscle cells (Fig. 59–5B) (Klemm et al, 1999). Most muscle cells of the ureter (100%), distal renal pelvis (97.5%), and proximal renal pelvis (83% are typical nonpacemaker smooth muscle cells with typical action potentials. Lang et al (1998) described fibroblast-like cells resembling the interstitial cells of Cajal (ICC), which serve as pacemaker cells in the intestine, in the proximal portion of the guinea pig renal pelvis. These "ICC-like" cells are irregularly shaped with oval nuclei and many branching interconnecting processes and contain numerous mitochondria, caveolae, and prominent endoplastic reticulum. The ICC-like cells in the guinea pig are not immunoreactive for α-smooth muscle actin, which is present in typical smooth muscle cells, or for c-KIT, a tyrosine kinase receptor that is expressed in intestinal ICC pacemaker cells (Klemm et al, 1999). The immunoreactivity to c-KIT appears to be species specific, because ICC-like cells that are immunoreactive to antibodies raised against the c-*KIT* proto-oncogene are present in the upper urinary tract of a number of mammals (Lang and Klemm, 2005; Metzger et al, 2005). Electrical recordings from these cells demonstrate action potentials with properties intermediate to the pacemaker and driven action potentials. These intermediate action potentials in the guinea pig have a single spike, a plateau without the superimposed spikes seen in driven action potentials and a rapid repolarization phase (Fig. 59–5C). Intermediate action potentials are noted in 11% to 17% of cells at the pelvicalyceal junction and the proximal and distal renal pelvis (Lang et al, 2002). These **ICC-like cells in the upper urinary tract do not appear to be primary pacemaker cells but, rather, may provide for preferential conduction of electrical signals from pacemaker cells to typical smooth muscle**

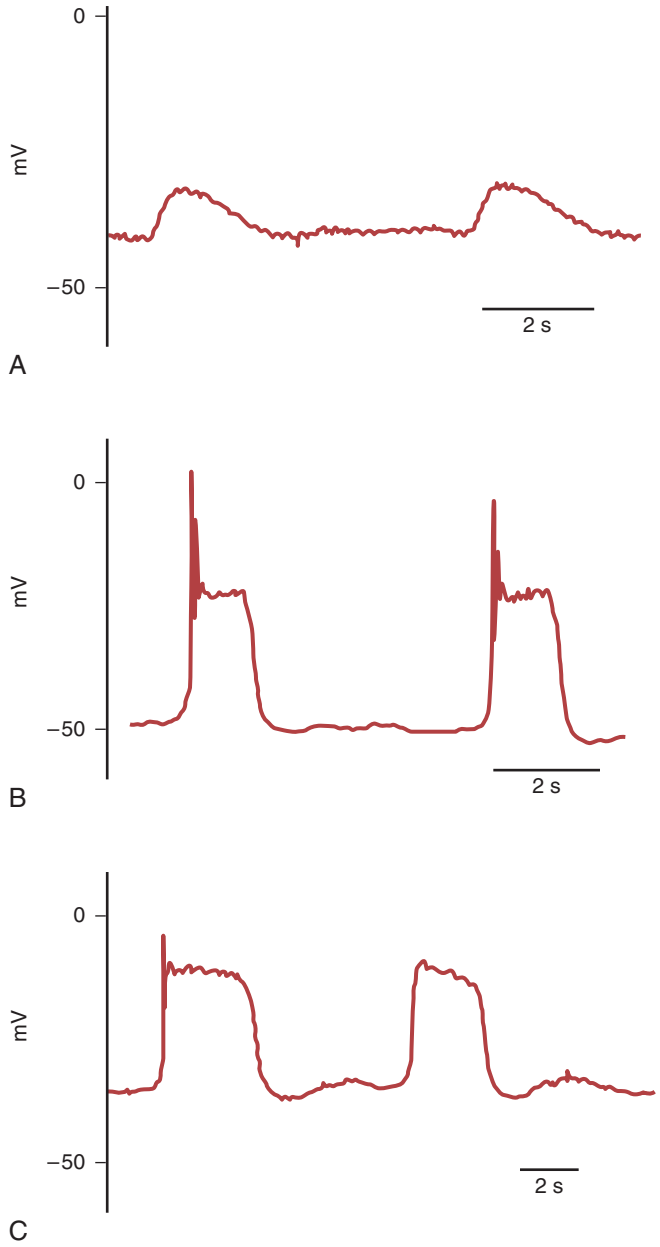

Figure 59–5. Action potentials in the upper urinary tract of the guinea pig. **A,** Pacemaker potentials. **B,** Driven action potentials. **C,** Intermediate action potentials. (Modified with permission from Klemm MF, Exintaris B, Lang RJ. Identification of the cells underlying pacemaker activity in the guinea pig upper urinary tract. J Physiol [Lond] 1999;519:867.)

cells of the renal pelvis and ureter (Klemm et al, 1999). **In the mouse ureteropelvic junction, c-KIT–positive ICC-like cells have been identified that showed high-frequency spontaneous transient inward currents that often occurred in bursts to sum and produce long-lasting large inward currents** (Lang et al, 2007b). **It is postulated that in the absence of a proximal pacemaker drive these ICC-like cells could act as pacemaker cells and trigger contractions in adjacent smooth muscle cells in the ureteropelvic junction. Thus both atypical smooth muscle cells and ICC-like cells both may play a pacemaker role in the initiation and propagation of pyeloureteric peristalsis** (Lang et al, 2006; Lang et al, 2007a).

c-KIT is a tyrosine kinase receptor that promotes cell migration and proliferation of melanoblasts, hematopoietic progenitors and primordial germ cells. Mice expressing mutant inactivating **c-*Kit*** alleles, lack intestinal interstitial cells of Cajal (ICC), have abnormal intestinal peristalsis, and develop bowel obstruction, showing that **c-*Kit* is important in the development of pacemaker activity and peristalsis of the gut** (Der-Silaphet et al, 1998). Pezzone et al (2003) identified c-Kit positive cells in the mouse ureter. They suggested that the difference from previous studies in the guinea pig upper urinary tract, in which c-Kit–positivity was not identified in ICC-like cells (Klemm et al, 1999), may be due to species differences, the c-Kit antibody used, and/or the fixation methods. **c-*Kit* gene expression** was noted to be **upregulated in the embryonic murine ureter prior to its development of unidirectional peristaltic contractions** (David et al, 2005). Incubation of isolated cultured embryonic murine ureters with antibodies that neutralize c-Kit activity altered ureteral morphology and inhibited unidirectional peristalsis. These data suggest that c-Kit–containing cells, which are probably ICC-like cells, have an important role in pyeloureteric peristalsis. c-Kit–positive cells have been identified in the human ureter (Metzger et al, 2004; van der Aa et al, 2004) and in the human UPJ (Solari et al, 2003). In the presence of obstruction, c-Kit–positive cells ICC-like cells at the UPJ were sparse or absent (Solari et al, 2003).

Bozler (1942), using small extracellular surface electrodes, demonstrated the characteristic slow spontaneous depolarization of pacemaker-type fibers in the proximal portion of the isolated ureter of a unicalyceal upper collecting system. In a multicalyceal kidney, Morita and associates (1981), using extracellular electrodes, recorded low-voltage potentials that appeared to be pacemaker potentials from the border of the pig minor calyces and the major calyx with the contraction rhythm varying between each calyx. Multiple pacemakers fire simultaneously as coupled oscillators, or individually, as pacemaker activity shifts from one site to another along the renal pelvis of the unicalyceal kidney or the pelvicalyceal border of the multicalyceal pig and sheep kidney (Golenhofen and Hannappel, 1973; Constantinou et al, 1977; Constantinou and Yamaguchi, 1981; Lammers et al, 1996).

Although the primary pacemaker for ureteral peristalsis is located in the proximal portion of the collecting system, other areas of the ureter may act as **latent pacemakers**. Under normal conditions, the latent pacemaker regions are dominated by activity arising at the primary pacemaker sites. When the latent pacemaker site is freed of its domination by the primary pacemaker, it, in turn, may act as a pacemaker. To demonstrate latent pacemaker sites, Shiratori and Kinoshita (1961) transected the in-vivo dog ureter at various levels. Before transection, peristaltic activity arose proximally from the primary pacemaker. When the ureter was transected at the UPJ, antiperistaltic waves of lower frequency than the previous normoperistaltic waves originated from the UVJ. Division of the ureter at the UVJ did not affect the normoperistaltic waves. After division of the midureter, the normoperistaltic waves in the upper segment remained unchanged, and the lower segment demonstrated antiperistaltic waves, which originated at the UVJ at a frequency less than that of the normoperistaltic waves in the upper segment. Thus cells at the UVJ of the dog may act as pacemaker cells when freed of control from the primary proximally located pacemaker. **Latent pacemaker cells are present in all regions of the ureter** (Imaizumi et al, 1989; Meini et al, 1995).

Propagation of Electric Activity

Excitable cells possess resistive and capacitative membrane properties similar to those of a cable or core conductor. The transverse resistance of the membrane is higher than the longitudinal resistance of the extracellular or intracellular fluid; this allows current resulting from a stimulus to propagate along the length of the fibers. The spread of current is referred to as *electrotonic spread* (Hoffman and Cranefield, 1960). The space constant (λ) determines the degree to which the electrotonic potential dissipates with increasing distance from an applied voltage. In a cable, this relation is expressed by

$$P = P_o\, e^{-X/\lambda}$$

where X is the distance from the applied voltage, P is the displacement of the membrane potential at X, P_o is the displacement of the membrane potential at the site of the applied voltage, e is the base of the natural logarithm, and λ is the space constant. Thus the electrotonic potential decreases by 1/e in one space constant. The space constant of the guinea pig ureter measured by extracellular stimulation is 2.5 to 3 mm (Kuriyama et al, 1967).

The time constant τ_m is expressed by

$$\tau_m = RC$$

where R is the membrane resistance and C is the membrane capacity. The time constant τ_m signifies that a small displacement of potential is decreased by 1/e of its value in one τ_m. The time constant of the guinea pig ureter measured by extracellular stimulation is 200 to 300 milliseconds (Kuriyama et al, 1967).

The ureter acts as a **functional syncytium**. Engelmann (1869, 1870) showed that stimulation of the ureter produces a contraction wave that propagates proximally and distally from the site of stimulation. Under normal conditions, **electric activity** arises proximally and is **conducted distally from one muscle cell to another across areas of close cellular apposition referred to as intermediate junctions** (Uehara and Burnstock, 1970; Libertino and Weiss, 1972). The similarity of these close cellular contacts to nexuses, which have been shown to be low-resistance pathways for cell-to-cell conduction in other smooth muscles (Barr et al, 1968), suggests that a similar mechanism for conduction may be present in the ureter. **Gap junctions, consisting of groups of channels in the plasma membrane of adjacent smooth muscle cells, enable exchange of ions and small molecules and play a role in electrical coupling between adjacent cells and electromechanical coupling** (Gabella, 1994; Santiciolli and Maggi, 2000). 18β-glycyrrhetinic acid, a gap junction inhibitor, inhibits cell-to-cell electrical coupling in the guinea pig renal pelvis and ureter and dissociates electrical and mechanical events (Santicioli and Maggi, 2000). **Conduction velocity in the ureter is 2 to 6 cm/sec** (Kobayashi, 1964; Kuriyama et al, 1967); it has been shown to vary with temperature, the time interval between stimuli (van Mastrigt et al, 1986), and the pressure within the ureter (Tsuchiya and Takei, 1990). This compares to conduction velocities ranging from 1.5 to 2 m/sec in cardiac Purkinje fibers (Rosen et al, 1981) and from 10 to 100 m/sec in the dorsal and ventral roots of the spinal cord (Biscoe et al, 1977). Conduction in the ureter is similar to that in cardiac tissue, even to the extent that the Wenckebach phenomenon (a partial conduction block) has been demonstrated in the ureter, as it has been in specialized cardiac fibers (Weiss et al, 1968).

CONTRACTILE ACTIVITY

The contractile event is dependent on the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins, actin and myosin. Any process that results in a significant increase in Ca^{2+} in the region of the contractile proteins favors the development of a contraction; any process that results in a significant decrease in Ca^{2+} in the region of the contractile proteins favors relaxation (Fig. 59–6).

Contractile Proteins

In skeletal muscle, Ca^{2+} appears to act as a derepressor. It is thought that in the relaxed state, a regulator system, consisting of the proteins troponin and tropomyosin, prevents the interaction of actin and myosin. In the relaxed state, troponin that is attached to tropomyosin is inactive, and tropomyosin prevents the interaction between actin and myosin. With activation, there is an increase in the sarcoplasmic Ca^{2+} concentration. The Ca^{2+} binds to troponin, producing a conformational change that results in the displacement of tropomyosin, thus allowing the interaction of actin and myosin and the development of a contraction.

In smooth muscle, on the other hand, Ca^{2+} appears to act as an activator. The most widely accepted theory suggests that **phosphorylation of myosin is involved in the contractile process** and that a troponin-like system does not constitute the

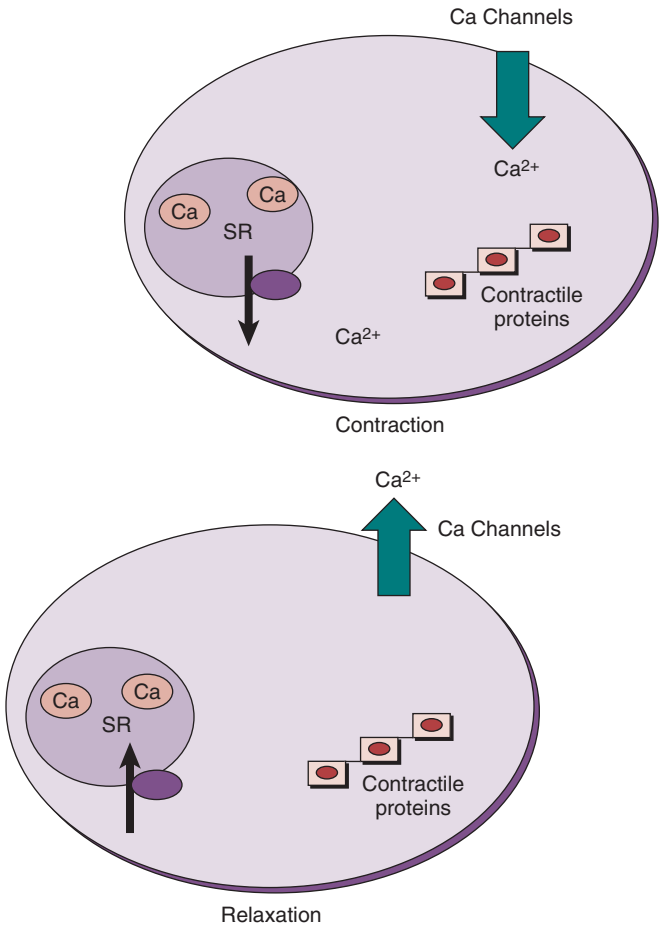

Figure 59–6. Schematic representation of calcium ion movements during contraction and relaxation. SR, sarcoplasmic reticulum.

primary regulatory mechanism, as it does in skeletal muscle. **With excitation, there is a transient increase in the sarcoplasmic Ca^{2+} concentration** from its steady-state concentration of 10^{-8} to 10^{-7} M to a concentration of 10^{-6} M or higher. At this higher concentration, **Ca^{2+} forms an active complex with the Ca^{2+}–binding protein calmodulin** (Watterson et al, 1976; Cho et al, 1988). Calmodulin without Ca^{2+} is inactive (Fig. 59–7). **The Ca^{2+}–calmodulin complex activates a calmodulin-dependent enzyme, myosin light-chain kinase** (see Fig. 59–7). **The activated myosin light-chain kinase, in turn, catalyzes the phosphorylation of the 20,000-D light chain of myosin** (Fig. 59–8). **Phosphorylation of the myosin light chain allows actin to activate myosin Mg^{2+}-ATPase activity, leading to hydrolysis of ATP and the development of smooth muscle tension or shortening** (Fig. 59–9). Actin cannot activate the ATPase activity of the dephosphorylated myosin light chain.

When the Ca^{2+} concentration in the region of the contractile proteins is low, the myosin light-chain kinase is not active, because calmodulin requires Ca^{2+} to activate the enzyme. This prevents activation of the contractile apparatus, because the myosin light chain cannot be phosphorylated, a process that must precede tension development. Furthermore, a phosphatase dephosphorylates the myosin light chain, thus preventing actin activation of myosin ATPase activity, and relaxation results.

Evidence indicates that phosphorylation of the enzyme myosin light-chain kinase by a cAMP-dependent protein kinase decreases myosin light-chain kinase activity by decreasing the affinity of this enzyme for calmodulin (Adelstein et al, 1981).

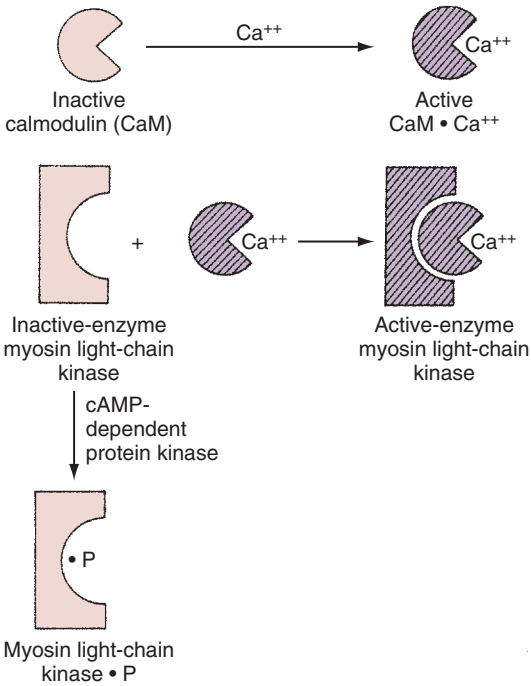

Figure 59–7. Schematic representation of the contractile process in smooth muscle. Calmodulin is activated by Ca^{2+}. The activated calcium-calmodulin complex activates the enzyme myosin light-chain kinase, which phosphorylates the light chain of myosin. Phosphorylation of myosin light-chain kinase decreases the rate of activation of the enzyme by the Ca^{2+}-calmodulin complex.

Although Ca^{2+} is required for most smooth muscle contractile events, there is evidence in some smooth muscles, including in the rabbit and human bladder, that Ca^{2+}-independent contractions can occur (Yoshimura and Yamaguchi, 1997). Carbachol, a muscarinic cholinergic agonist, and phorbol ester, which activate protein kinase C (PKC), can induce contraction in Ca^{2+}-depleted bladder strips that can be inhibited by a PKC inhibitor, H7. It is suggested that activation of PKC, coupled with agonist stimulation of the muscarinic receptor, can induce a Ca^{2+}-independent contraction.

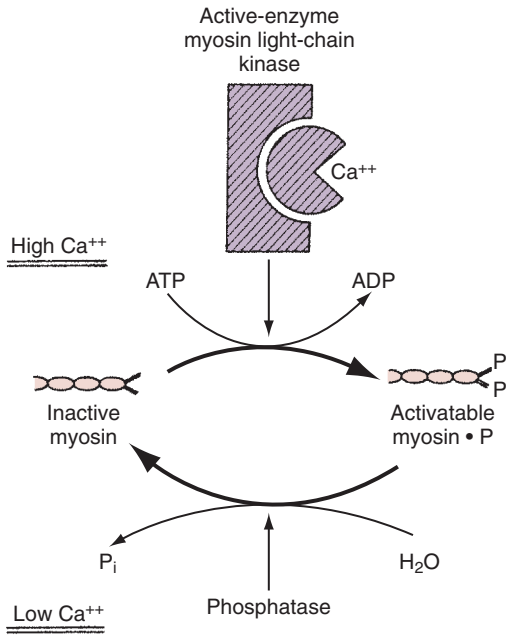

Figure 59–8. Schematic representation of the contractile process in smooth muscle. The activated enzyme myosin light-chain kinase catalyzes the phosphorylation of myosin. Myosin must be phosphorylated in order for actin to activate myosin ATPase. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

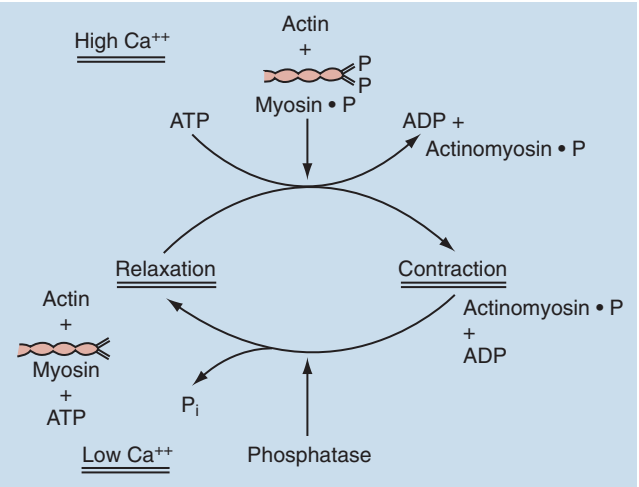

Figure 59–9. Schematic representation of the contractile process in smooth muscle. Actin activates ATPase activity of phosphorylated myosin. This allows interaction of actin and myosin with the development of a contraction. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Calcium and Excitation-Contraction Coupling

The mechanical event of ureteral peristalsis follows an electric event to which it is related. The Ca^{2+} involved in the ureteral contraction is derived from two main sources. Because smooth muscle cells have a very small diameter, the **inward movement of extracellular Ca^{2+} into the cell through L-type Ca^{2+} channels during the upstroke of the action potential provides a significant source of sarcoplasmic Ca^{2+}** (Brading et al, 1983; Hertle and Nawrath, 1989; Yoshida et al, 1992; Maggi et al, 1994a; Maggi and Giuliani, 1995; Floyd et al, 2008) (see Fig. 59–6). This inward movement across the cell membrane is the major source of calcium used for contraction in most smooth muscles. Na^+-Ca^{2+} exchange, with an outward movement of Na^+ and an inward movement of Ca^{2+}, also plays a role in the ureteral contraction (Lamont et al, 1998). Furthermore, in response to an excitatory impulse, Ca^{2+} release from tightly bound storage sites (i.e., the endoplasmic or sarcoplasmic reticulum) also increases the Ca^{2+} concentration in the sarcoplasm (Burdyga et al, 1998; Burdyga and Wray, 1999a; Lang et al, 2002). Calcium may be released from the sarcoplasmic reticulum (SR) of smooth muscle by an inositol 1,4,5-trisphosphate (IP_3)–induced release mechanism or by Ca^{2+}-induced Ca^{2+} release (CICR) (Somlyo and Somlyo, 1994). These processes appear to be species dependent. CICR, which involves ryanodine receptors, appears to be the sole mechanism for calcium release from the SR in the guinea pig ureter, whereas the SR stored in the rat ureter appears to be exclusively under the control of IP_3 receptors (Burdyga et al, 1995). IP_3 and ryanodine receptors are expressed in the human ureter (Floyd et al, 2008). The opening of caffeine-sensitive ryanodine receptors produces small local elevations of Ca^{2+} that are termed Ca^{2+} sparks (Nelson et al, 1995). In addition to providing a source of calcium for contraction, Ca^{2+} released from the SR activates Ca^{2+}–sensitive surface membrane channels and modulate membrane excitability (Imaizumi et al, 1989; Carl et al, 1996). Both calcium-activated outward potassium currents (K_{Ca}), or STOCS (spontaneous transient outward currents), and calcium-activated inward chloride currents (Cl_{Ca}), or STICS (spontaneous transient inward currents), have been identified in smooth muscles. These currents affect membrane potential and thus affect calcium entry through L-type Ca^{2+} channels in the membrane. The Ca^{2+}–activated chloride currents are present in rat but not guinea pig ureteral smooth muscle (Burdyga and Wray, 2002). Thus some Ca^{2+} released from SR results in contraction, but it has been shown that caffeine-induced release of SR Ca^{2+}, in the form of Ca^{2+} sparks, increases outward potassium currents (K_{Ca}), or STOCS, with an inhibitory effect on action potentials and contractility (Borisova et al, 2007). At least in the guinea pig ureter, this increase in the outward potassium current hyperpolarizes the membrane and determines the refractory period, which is important in determining the frequency of ureteral peristalsis and may have a protective effect on the kidney (Burdyga and Wray, 2005).

Support for use of a dual source of Ca^{2+} in the ureter has been provided by Vereecken and coworkers (1975), who noted that it took approximately 45 minutes for spontaneous contractions of isolated guinea pig ureters to cease when the tissue was placed in a Ca^{2+}-free medium. They interpreted this to indicate that some of the Ca^{2+} involved in the contractile process is derived from tightly bound intracellular stores. They also noted that recovery of the contractile response to electric stimuli was almost immediate when the tissue was returned to a physiologic solution containing a normal concentration of Ca^{2+}. This suggests that free extracellular Ca^{2+} entering the cell during excitation also provides a source of Ca^{2+} for the contractile machinery. A similar conclusion was reached by Hong and associates (1985). There is, however, some evidence that Ca^{2+} release from the sarcoplasmic reticulum may not play a significant role in ureteral contractions, at least in the guinea pig (Maggi et al, 1994a, 1995, 1996), and some perturbations of contractility may be related to movements of ions other than Ca^{2+}. The increase in developed force in the guinea pig ureter, with intracellular acidification and decrease with intracellular alkalinization, appear to result from modulation of outward K^+ currents rather than effects on inward Ca^{2+} currents (Smith et al, 1998). That is, alkalinization (increasing intracellular pH) enhances outward K^+ currents, and this reduces excitability; acidification has the opposite effect. Relaxation results from a decrease in the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins. The decrease in sarcoplasmic Ca^{2+} can result from the uptake of Ca^{2+} into intracellular storage sites (Maggi et al, 1994a, 1995) or from extrusion of Ca^{2+} from the cell (Burdyga and Magura, 1988).

In addition to the Ca^{2+}- signaling cascade that affects contractility, there is a Rho/Rho-kinase signaling pathway that affects contractility by altering the Ca^{2+}-sensitivity of the contractile system (Somlyo and Somlyo, 2003). The Rho-kinase pathway is involved in ureteral contractions in a number of species (Levent and Buyukafsar, 2004; Shabir et al, 2004; Hong et al, 2005). Rho-kinase inhibits myosin phosphatase by phosphorylation of its regulatory subunit, which prevents dephosphorylation of myosin light chain, which, in turn, leads to Ca^{2+} sensitization of the smooth muscle with a subsequent increase in contractility. Y-27632, an inhibitor of Rho-kinase, decreases both spontaneous and EFS-induced contractile responses of in vitro human ureteral segments (Hong et al, 2005). Y-27632 inhibits kinase activity by competing with ATP for binding to the Rho-kinases.

Urothelial Effects on Contractile Activity

Furchgott (1999) showed that **the endothelium produced a factor that had a relaxing action on the smooth muscle layer of blood vessels.** This factor was originally termed **endothelium-derived relaxing factor (EDRF)** and was subsequently shown to be **nitric oxide (NO).** Mastrangelo et al (2003) showed that the urothelium of rat ureter produced NO, which inhibited contractile responses of the rat ureter. Recently in the rat ureter, it was shown that the urothelium inhibited spontaneous contractions of isolated ureteral segments and that removal of the urothelium potentiated the stimulatory effects of neurokinin A, vasopressin, carbachol, bradykinin, and angiotensin II (Mastrangelo and Iselin, 2007). In intact ureteral segments, cyclooxygenase inhibitors potentiated the stimulatory effects of neurokinin A, vasopressin, carbachol, bradykinin, and angiotensin II. Cyclooxygenase inhibitors had no effect on the responses to these agents in urothelium-free ureters. These data suggest that the inhibitory effects of the urothelium on ureteral contractile events may involve the participation of a urothelial cyclooxygenase product such as prostacyclin.

Second Messengers

The functional response to a number of hormones, neurotransmitters, and other agents is mediated by means of *second messengers*. The agonist, or first messenger, interacts with a specific

membrane-bound receptor (Alquist, 1948; Furchgott, 1964); the agonist-receptor complex then activates or inactivates an enzyme, which leads to alteration of a second messenger within the cell. These **second messengers include cyclic AMP (cAMP), cyclic GMP (cGMP), Ca^{2+}, inositol 1,4,5-trisphosphate (IP_3), and diacylglycerol (DG).** They mediate the functional response to the agonist (first messenger) through a process that frequently involves protein phosphorylation.

Although relaxation of smooth muscle may occur independently of changes in cyclic nucleotides (Vesin and Harbon, 1974), cAMP is believed to mediate the relaxing effects of β-adrenergic agonists in a variety of smooth muscles (Triner et al, 1971; Andersson, 1972). According to this concept, a β-adrenergic agonist, such as isoproterenol, serves as the first messenger and combines with a receptor on the outer surface of the cell membrane (Fig. 59–10). Isoproterenol itself does not enter the cell. The **β-adrenergic agonist–receptor** complex activates the enzyme adenylyl cyclase on the inner surface of the cell membrane, in close morphologic relation to the receptor. **In the presence of magnesium ions (Mg^{2+}) and a guanine nucleotide (GTP), adenylyl cyclase catalyzes the conversion of ATP to cAMP within the cell.**

$$\text{ATP} \xrightarrow[Mg^{2+},\,GTP]{\text{adenylyl cyclase}} \text{cAMP}$$

A stimulatory guanine nucleotide–regulatory protein, or G protein (G_S), acts as a functional link between the agonist-receptor complex and the catalytic, or active unit, of the enzyme adenylyl cyclase. cAMP acts as a second, or "internal," messenger of the response elicited by the β-adrenergic agonist. It has been suggested that the increase in cAMP through activation of an enzyme, that is, a protein kinase, and phosphorylation of proteins leads to the uptake of Ca^{2+} into intracellular storage sites (i.e., the endoplasmic or sarcoplasmic reticulum) with the resultant decrease of free sarcoplasmic Ca^{2+} in the region of the contractile proteins (Andersson and Nilsson, 1972). The decrease in sarcoplasmic Ca^{2+} in the region of the contractile proteins leads to relaxation of the smooth muscle. β-Adrenoceptor–induced relaxation of smooth muscle also may be due to the opening of Ca^{2+}-activated K^+ channels (Uchida et al, 2005; Ferro, 2006).

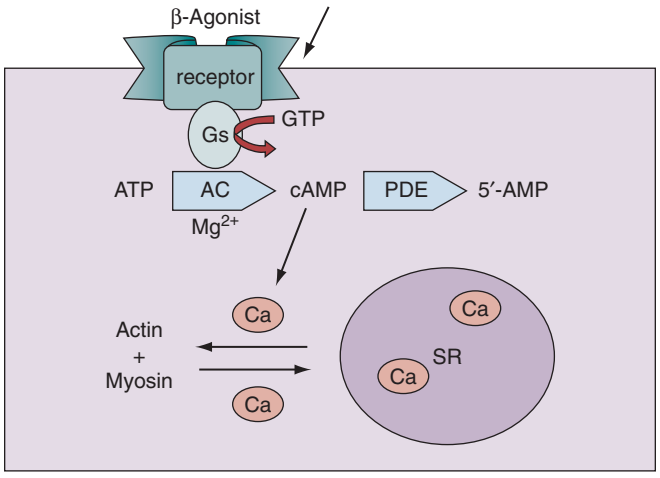

Figure 59–10. Schematic representation of the role of cAMP in β-adrenergic agonist–induced relaxation of smooth muscle. Agonist combines with receptor on the outer side of the cell membrane. The receptor-agonist complex, in turn, by a stimulatory G protein (G_s), activates the enzyme adenylyl cyclase (AC) on the inner surface of the cell membrane, which in the presence of Mg^{2+} and GTP results in the conversion of ATP to cAMP. cAMP is postulated to cause an increased uptake of Ca^{2+} into intracellular storage sites with a resultant decrease in Ca^{2+} in the region of the contractile proteins that results in relaxation. cAMP may also have other actions (not shown) that inhibit the contractile process. The enzyme phosphodiesterase (PDE) degrades cAMP to 5′-AMP. SR, sarcoplasmic reticulum.

cAMP levels may be increased within the cell in two ways. One is by increasing synthesis, which involves activation of the enzyme adenylyl cyclase; the other is by decreasing degradation. **The degradation of cAMP involves activation of an enzyme, a phosphodiesterase:**

$$\text{cAMP} \xrightarrow{\text{phosphodiesterase}} \text{5′-AMP}$$

Thus **agents that either increase adenylyl cyclase activity, such as the β-adrenergic agonist isoproterenol, or decrease phosphodiesterase activity, that is, phosphodiesterase inhibitors such as theophylline and papaverine, increase intracellular cAMP levels and cause smooth muscle relaxation.**

Weiss and associates (1977) demonstrated the presence of both adenylyl cyclase and phosphodiesterase activities in the ureter. They showed, in the ureter, that isoproterenol stimulates adenylyl cyclase activity and theophylline inhibits phosphodiesterase activity. These two agents that relax ureteral smooth muscle would be expected to increase cAMP levels—isoproterenol by increasing synthesis and theophylline by decreasing degradation. Further support of **a role for cAMP in smooth muscle relaxation** can be derived from the finding that dibutyryl cAMP, which more readily diffuses into the intact cell and is less likely to be broken down by phosphodiesterase than is cAMP, has been shown to relax a variety of smooth muscles, including the ureter (Takago et al, 1971; Wheeler et al, 1990), and forskolin, which activates the catalytic subunit of adenylyl cyclase, relaxes the ureter (Wheeler et al, 1986; Hernández et al, 2004).

In addition to receptors and G proteins that are involved in stimulation of adenylyl cyclase and the formation of cAMP, as in the actions of β-adrenergic agonists, other receptors and G proteins inhibit adenylyl cyclase activity (Londos et al, 1981). Some actions of α_2-adrenergic and muscarinic cholinergic agonists involve stimulation of these inhibitory G proteins (Gi) with subsequent inhibition of adenylyl cyclase activity.

Another cyclic nucleotide, **cGMP, can also cause smooth muscle relaxation**. The **cGMP is synthesized from GTP by the enzyme guanylyl cyclase and is degraded to 5′-GMP by a phosphodiesterase**. Phosphodiesterase activity that can degrade both cAMP and cGMP has been demonstrated in the canine ureter, and various inhibitors can preferentially inhibit the breakdown of one of the cyclic nucleotides (Weiss et al, 1981; Stief et al, 1995). Insulin has been shown to activate cAMP phosphodiesterase activity in the ureter (Weiss and Wheeler, 1988), and 8-bromo-cGMP has been shown to cause relaxation of a number of smooth muscles (Schultz et al, 1979), including the ureter (Cho et al, 1984).

Nitric oxide (NO) stimulates soluble guanylyl cyclase activity and causes smooth muscle relaxation (Dokita et al, 1991, 1994). **Nitric oxide synthase (NOS) converts L-arginine to NO and L-citrulline in a reaction that requires reduced nicotinamide adenine diphosphate (NADPH). There are three NOS isoforms. Neuronal NOS (nNOS) is present in neuronal tissues and is Ca^{2+} and NADPH dependent** (Bredt and Snyder, 1990). It is thought that neuronal excitation increases

Ca^{2+} concentration within nerves, which leads to the synthesis of NO from L-arginine. **NO** released from the nerve **activates** the enzyme **guanylyl cyclase in the smooth muscle cell, with the resultant conversion of GTP to cGMP and thus smooth muscle relaxation** (Fig. 59–11). It also is possible that a yet-to-be-determined neurotransmitter is released from the neuron, stimulating NO production in the smooth muscle cell, which, in turn, leads to cGMP formation and smooth muscle relaxation. **Endothelial NOS (eNOS), is also Ca^{2+} and NADPH dependent** (Sessa, 1994). Similar to neuronal NOS, eNOS produces small amounts of NO for prolonged periods of time. An **inducible NOS isoform, iNOS, is NADPH dependent but Ca^{2+} independent** and has been identified in ureteral smooth muscle (Smith et al, 1993). iNOS produces larger amounts of NO for short periods of time.

NOS-containing nerves have been demonstrated in the human ureter (Stief et al, 1993, 1996; Goessl et al, 1995; Iselin et al, 1998), and NOS has been demonstrated in the pig UVJ (Hernández et al, 1995; Phillips et al, 1995) and the upper ureter and calyces of pigs and humans (Iselin et al, 1998, 1999). NOS co-localizes with vasoactive polypeptide and neuropeptide Y (NPY) in nerves supplying the human ureter, including the intravesical segment (Smet et al, 1994; Iselin et al, 1997). NOS seems to localize in parasympathetic and sensory nerves but not in adrenergic neurons. In primary cultures of rat ureteral cells, NO production was detected in urothelial but not in smooth muscle cells (Mastrangelo et al, 2003). These cells contain both eNOS and iNOS.

There is evidence that the NO pathway is involved in human ureteral relaxation (Stief et al, 1996; Iselin et al, 1997). The NO donor, SIN-1, relaxes human ureteral segments, an action that is inhibited by the **guanylyl cyclase inhibitor methylene blue.** NO donors also inhibit agonist-induced contractions of isolated pig calyceal and rat, pig, and human intravesical ureteral segments, an action that is associated with an increase in cGMP. Furthermore, NO has been shown to be involved in nonadrenergic, noncholinergic–induced relaxation of the pig UVJ (Hernández et al, 1995). There is also evidence that adenosine relaxes the pig intravesical ureter through a process independent of NO (Hernández et al, 1999).

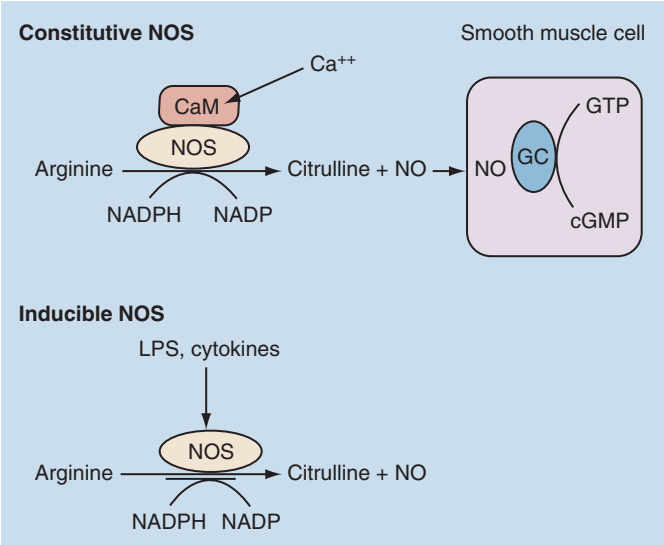

Figure 59–11. Schematic representation of inducible and constitutive nitric oxide synthase (NOS). CaM, calmodulin; GC; guanylyl cyclase; LPS, lipopolysaccharide.

Some actions of **α_1-adrenergic and muscarinic cholinergic agonists** and a number of other hormones, neurotransmitters, and biologic substances are associated with an increase in intracellular Ca^{2+} and are related to changes in inositol lipid metabolism. These agonists **combine with a receptor on the cell membrane, and the agonist-receptor complex, in turn, activates an enzyme, phospholipase C, that leads to the hydrolysis of polyphosphatidylinositol 4,5-bisphosphate, with the formation of two second messengers: inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DG)** (Berridge, 1984) (Fig. 59–12). The activation of phospholipase C involves a G protein. **IP_3 mobilizes Ca^{2+} from intracellular stores (i.e., endoplasmic or sarcoplasmic reticulum)** with an initiation of a cascade of events through the calmodulin branch of the Ca^{2+} messenger system. In smooth muscles, **IP_3 is thought to be involved in brief contractile responses or in the initial phase of sustained responses** (Park and Rasmussen, 1985).

The other second messenger, **DG, binds to an enzyme, protein kinase C (PKC),** translocates to the cell membrane, and, by reducing the concentration of Ca^{2+} required for PKC activation, results in an increase in this enzyme's activity. The **actions of PKC, and** thus **DG, involve the phosphorylation of proteins** (Nishizuka, 1984). The **PKC branch of the Ca^{2+} messenger system is thought to be responsible for the sustained phase of the contractile response in smooth muscle** (Park and Rasmussen, 1985) and is responsive to hormonally induced changes in intracellular Ca^{2+}. PKC has been implicated in Ca^{2+}-independent smooth muscle contractions (Yoshimura and Yamaguchi, 1997). Numerous PKC isoforms have been identified.

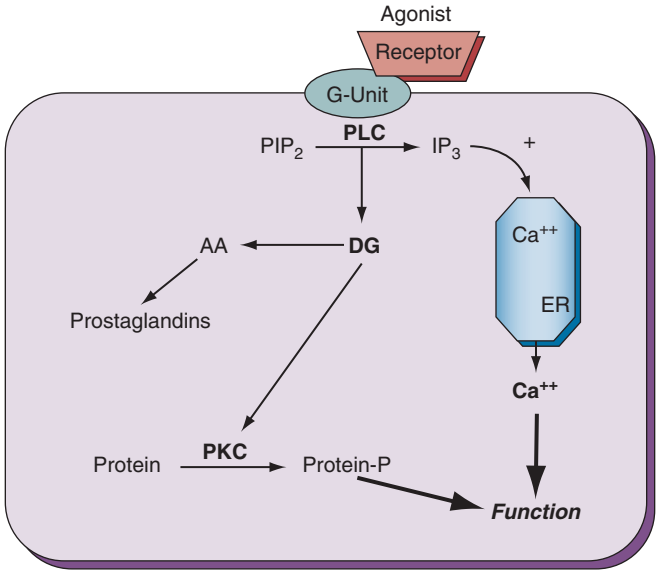

Figure 59–12. Schematic representation of the role of inositol lipid metabolism in smooth muscle function. The agonist combines with the receptor on the outer side of the cell membrane. The receptor-agonist complex in turn activates the enzyme phospholipase C (PLC), which leads to the hydrolysis of polyphosphatidylinositol 4,5-bisphosphate (PIP_2), with the formation of two second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DG). The activation of PLC involves a G protein. IP_3 mobilizes calcium from intracellular stores (i.e., endoplasmic reticulum), and this leads to a functional response. DG binds to an enzyme, protein kinase C (PKC), which results in phosphorylation of proteins and a subsequent functional response. AA, arachidonic acid; ER, endoplasmic reticulum.

The functional activity and specificity of function of these isoforms appear to be primarily determined by the state of phosphorylation of the isoenzyme and its subcellular localization (Dempsey et al, 2000).

DG also activates the enzyme phospholipase A, which serves as a source of arachidonic acid, the substrate for prostaglandin synthesis (Mahadevappa and Holub, 1983). Arachidonic acid, in turn, may stimulate guanylate cyclase activity with the subsequent formation of cGMP (Berridge, 1984), and this would explain the Ca^{2+}-dependent increase in cGMP levels associated with muscarinic cholinergic and α_1-adrenergic agonist–induced contractions in smooth muscle. The observed increases in cGMP levels follow, rather than precede, the onset of contractions induced by these agonists.

Thus a group of second messengers are involved in the transduction of the signal that is initiated when an agonist combines with a specific receptor on the cell membrane of the smooth muscle. This process of **signal transduction** ultimately results in the functional response to the agonist.

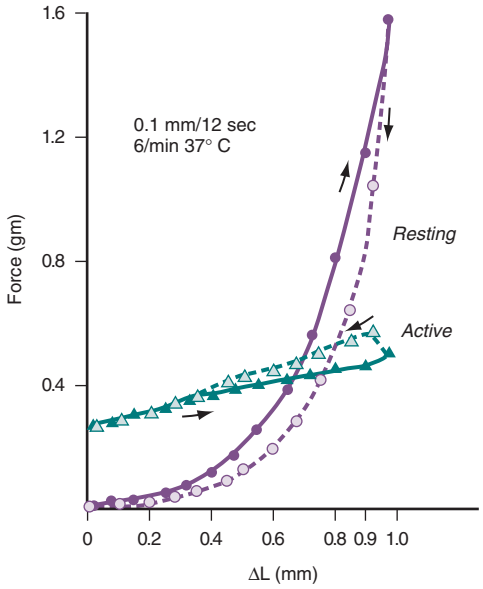

Figure 59–13. Hysteresis. Resting and contractile (active) force of cat ureter during muscle lengthening and shortening. Force is on the ordinate; change in length (ΔL) is on the abscissa. *Solid symbols* and *solid lines* show data obtained during muscle lengthening. *Open symbols* and *dashed lines* show data obtained during muscle shortening. *Circles* show resting force, and *triangles* show active or contractile force. Length and the direction of length change influence resting and contractile force. (From Weiss RM, Bassett AL, Hoffman BF. Dynamic length-tension curves of cat ureter. Am J Physiol 1972;222:388.)

MECHANICAL PROPERTIES

Mechanical characteristics of muscle are commonly assessed by defining force-length and force-velocity relations. Isometric force-length measurements depend on the number of linkages between the contractile proteins actin and myosin, which are brought into action during contraction. Force-velocity relations depend on the rate of formation and breakdown of linkages between the contractile proteins. Interventions may affect force-velocity relations, with or without affecting force-length relations. In addition to these methods of assessing mechanical properties of the ureter, the bidimensional nature of the ureter has lent itself to studies of pressure-length-diameter relations.

Force-Length Relations

Force-length relations express the relation between the force developed by muscle when it is stimulated under isometric conditions and the resting length of the muscle at the time of stimulation. With stretching of the ureter (muscle lengthening), the resting force (i.e., the tension present when the muscle is not excited) increases at a progressive rate (Weiss et al, 1972). The force developed during isometric contraction also increases with elongation until a length is reached at which the maximal contractile force is achieved. With further lengthening, the developed force decreases (Weiss et al, 1972; Thulesius et al, 1989). The ureter at this length is overstretched, or beyond the peak of its force-length curve. Ureteral resting tension is high at the length at which maximal contractile force is developed.

Because the ureter is a viscoelastic structure (Weiss et al, 1972), **the resting or contractile force developed at any given length depends on the direction in which the change in length is occurring and on the rate of length change** (Weiss et al, 1972; Vereecken et al, 1973). **This is referred to as hysteresis;** for the ureter, at any given length, the resting force is less, and the contractile force is greater when the ureter is allowed to shorten than when the ureter is being stretched (Fig. 59–13).

When the ureter is stretched, the resting force increases. If the length is kept constant at its new longer length after a stretch, changes occur that result in a decrease in the resting force, or stress relaxation (Fig. 59–14) (Weiss et al, 1972). Within certain limits, when the ureter is stretched to a length beyond the peak of the force-length curve—that is, when the ureter is stretched to a length at which the contractile force declines in the face of increasing muscle length—the degree of stress relaxation may be such that, within a period of time, the developed force no longer declines, even though the increased length is kept constant (Weiss et al, 1972). Stress relaxation can thus be considered a compensatory mechanism of a viscoelastic structure to stretch.

Force-Velocity Relations

Force-velocity curves depict the relation between the load and the velocity of shortening. A typical force-velocity curve, as predicted by Hill's equation for muscle shortening, has a hyperbolic configuration (Fig. 59–15) (Hill, 1938). From the force-velocity curve, one can extrapolate the **maximal velocity of shortening (V_{max}),** which **represents the velocity of shortening at zero load (i.e., at isotonic conditions).** V_{max} is determined by the level at which the force-velocity curve crosses the ordinate. V_{max} values in the ureter are in the range of 0.5 to 0.7 lengths per second (Biancani et al, 1984). The force-velocity curve intersects the abscissa at zero shortening, that is, at isometric conditions at which the load is great. Shortening depends on the total load lifted, with the ureter shortening to a lesser extent with heavier loads. At conditions near those of zero load, that is, conditions of free shortening (isotonic conditions), the in-vitro guinea pig ureter shortens by 25% to 30% of its initial length (Biancani et al, 1984).

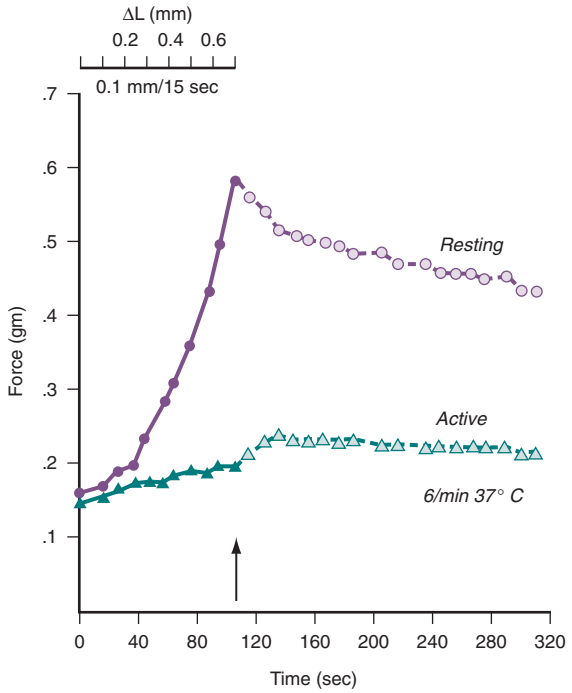

Figure 59–14. Stress relaxation. The resting and contractile (active) force of cat ureter is on the ordinate, the time from the onset of stretching is on the lower abscissa, and the change in length (ΔL) is on the left upper corner abscissa. Muscle is stretched by a given amount and then held at a fixed length. *Solid symbols* and *solid lines* show data obtained during muscle lengthening; *open symbols* and *dashed lines* show data obtained after stretching has ceased *(arrow)* and muscle is maintained at a constant length. Resting force decreases when muscle is held at a constant length after a stretch (stress relaxation). Contractile (active) force increases during this period of time. (From Weiss RM, Bassett AL, Hoffman BF. Dynamic length-tension curves of cat ureter. Am J Physiol 1972;222:388.)

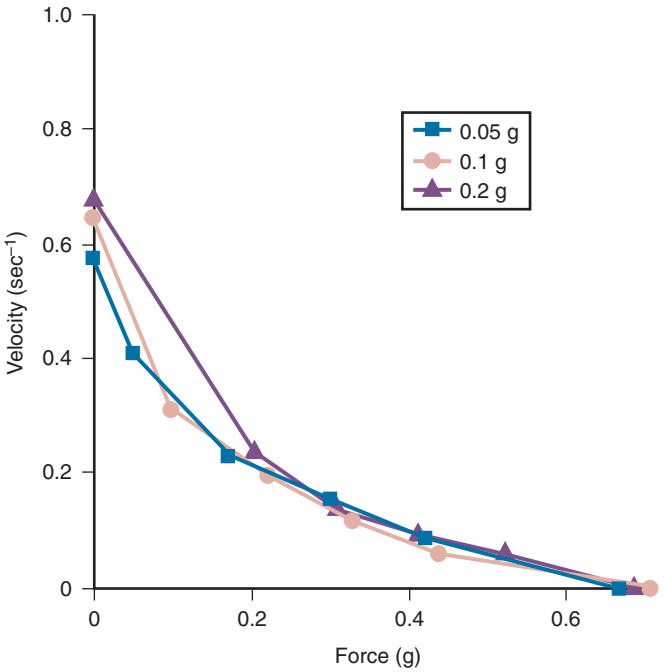

Figure 59–15. Force-velocity relation of guinea pig ureter. Specimens were stretched by three different preloads (0.05, 0.1, and 0.2 g). The velocity of shortening on the ordinate is plotted as a function of the total load lifted on the abscissa. V_{max} is obtained by extrapolating the experimental curves to intersect the ordinate. Isometric force is given by data points where velocity equals zero. (From Biancani P, Onyski JH, Zabinski MP, Weiss RM. Force-velocity relationships of the pig ureter. J Urol 1984;131:988. Copyright by Williams & Wilkins, 1984.)

Pressure-Length-Diameter Relations

Because ureteral muscle fibers are arranged in a longitudinal, circumferential, and spiral configuration (Tanagho, 1971), longitudinal and diametral deformation of the ureter are interrelated. Simultaneous studies of length and diameter changes in response to an intraluminal pressure load are another means of assessing the mechanical properties of a tubular structure. After application of an intraluminal pressure, the ureter increases in both length and diameter, a process known as *creep* (Biancani et al, 1973). Deformation in response to a given intraluminal pressure load is greater in vitro than in vivo; this difference is partially negated if the in-vivo preparation is pretreated with reserpine to suppress adrenergic influences (Fig. 59–16). Such data provide support for a role of the adrenergic nervous system in the control of ureteral function.

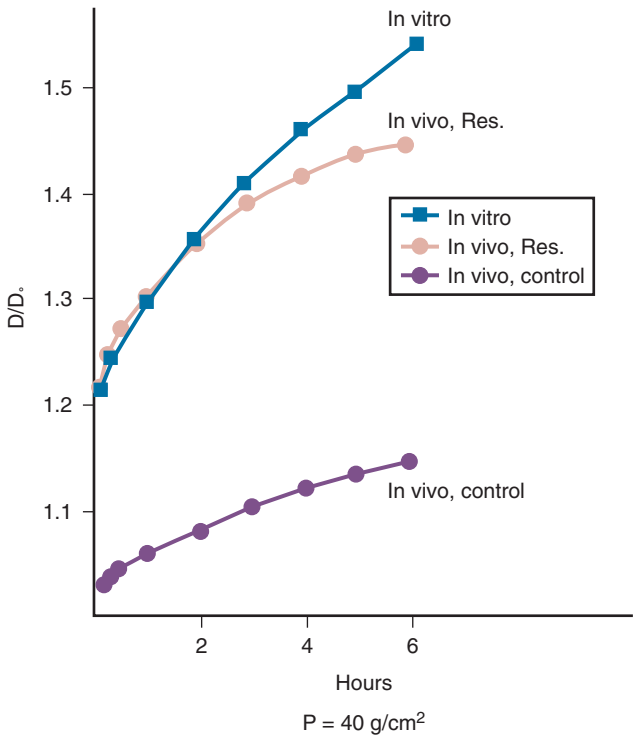

Figure 59–16. Pressure-diameter relations. An intraluminal pressure (P) load of 40 g/cm^2 is applied to rabbit ureters, and the change in diameter (D/D_0) is measured as a function of time. *Blue squares* show data obtained from in-vitro ureters. *Pink circles* show data obtained in vivo. *Purple circles* show data obtained in vivo from animals previously treated with reserpine. D_0, Initial diameter; D, diameter during deformation.

ROLE OF THE NERVOUS SYSTEM IN URETERAL FUNCTION

Some smooth muscles have a specific innervation of each smooth muscle fiber, whereas other, syncytial-type smooth muscles lack discrete neuromuscular junctions and depend on a diffuse release of transmitter from a bundle of nerves, with a subsequent spread

of excitation from one muscle cell to another. **The ureter is a syncytial type of smooth muscle without discrete neuromuscular junctions** (Burnstock, 1970).

Because peristalsis may persist after transplantation (O'Conor and Dawson-Edwards, 1959) or denervation (Wharton, 1932), because spontaneous activity may occur in isolated in-vitro ureteral segments (Finberg and Peart, 1970), and because normal antegrade peristalsis continues after reversal of a segment of ureter in situ (Melick et al, 1961), it is apparent that **ureteral peristalsis can occur without innervation**. However, analysis of the data in the literature clearly indicates that the **nervous system plays at least a modulating role in ureteral peristalsis**. Morita and colleagues (1987) have provided evidence that the autonomic nervous system may affect urine transport through the ureter by affecting both peristaltic frequency and bolus volume. Catecholamine fluorescence and acetylcholine (ACh) release studies indicate that the human ureter is supplied by sympathetic (noradrenaline-containing) and parasympathetic (ACh-containing) neurons (Duarte-Escalante et al, 1969; DelTacca, 1978).

Parasympathetic Nervous System

Although the role of the parasympathetic nervous system in the control of ureteral peristalsis has not been well defined, muscarinic cholinergic receptors have been demonstrated in the ureter of a number of species including the human (Latifpour et al, 1989, 1990; Hernández et al, 1993; Sakamoto et al, 2006), and acetylcholinesterase-positive nerve fibers have been demonstrated in the equine ureter (Prieto et al, 1994). The cholinergic innervation is especially rich in the distal and intravesical ureter (Hernández et al, 1993). Furthermore, ACh has been shown to be released from isolated guinea pig, rabbit, and human ureters in response to electric-field stimulation (DelTacca, 1978), and this release is inhibited by the neural poison tetrodotoxin. These data suggest but do not prove that the parasympathetic nervous system has at least a modulatory role in the control of ureteral activity.

The prototypic cholinergic agonist is acetylcholine (Ach), which serves as the neurotransmitter at (1) neuromuscular junctions of somatic motor nerves (nicotinic sites), (2) preganglionic parasympathetic and sympathetic neuroeffector junctions (nicotinic sites), and (3) postganglionic parasympathetic neuroeffector sites (muscarinic sites). ACh synthesis involves

$$\text{Acetyl CoA} + \text{Choline} \xrightarrow[\text{acetyltransferase}]{\text{choline}} \text{Ach}$$

where CoA is coenzyme A. The ACh is stored in vesicles within the synaptic terminal; its release depends on the influx of Ca^{2+} into the terminal, which presumably causes vesicle fusion with the presynaptic terminal membrane, thereby expelling ACh into the synaptic cleft. ACh subsequently is hydrolyzed by acetylcholinesterase. The muscarinic effects of cholinergic agonists can be blocked by atropine. The effects of nicotinic agonists can be blocked by nondepolarizing ganglionic blocking agents or by high concentrations of the nicotinic agonist itself, which may cause ganglionic blockade by desensitization of receptor sites after an initial period of ganglionic stimulation.

Cholinergic Agonists

Cholinergic agonists, including ACh, methacholine (Mecholyl), carbamylcholine (carbachol), and bethanechol (Urecholine), in general have been observed to have an excitatory effect on ureteral and renal pelvic function, that is, to increase the frequency and force of contractions (Vereecken, 1973; Longrigg, 1974; Rose and Gillenwater, 1974; Morita et al, 1986, 1987; Maggi and Giuliani, 1992; Hernández et al, 1993; Prieto et al, 1994). The excitatory effect of carbachol on isolated canine ureter has been attributed to be mediated by the M3-receptor subtype, and carbachol-induced inhibition of KCl-induced contractions of longitudinal canine ureteral preparations appears to be mediated primarily by the M4-receptor subtype (Tomiyama et al, 2003). ACh also has been shown to increase the duration of the guinea pig and rat ureteral action potential (Prosser et al, 1955; Ichikawa and Ikeda, 1960) and the number of oscillations on the plateau of the guinea pig ureteral action potential (Ichikawa and Ikeda, 1960). **The excitatory effects of cholinergic agonists may be related to an indirect release of catecholamines**—supported by the findings that the excitatory effects of bethanechol can be blocked by the α-adrenergic blocking agent phentolamine (Rose and Gillenwater, 1974), and that the increased frequency of canine ureteral peristalsis induced by ACh can be blocked by adrenalectomy (Labay et al, 1968) or to a direct effect of the drug on muscarinic receptors (Vereecken, 1973; Hernández et al, 1993; Tomiyama et al, 2003).

Nicotinic agonists, such as nicotine, tetramethylammonium, and dimethylphenylpiperazin, cause an initial stimulation of nicotinic receptors followed by desensitization of the receptor sites; the receptors then become unresponsive to nicotinic agonists and also to endogenous ACh, with a resultant transmission blockade. Nicotine, as would be expected, has been shown to have excitatory (Boyarsky et al, 1968), biphasic (Satani, 1919; Labay and Boyarsky, 1967), or inhibitory (Prosser et al, 1955; Vereecken, 1973) actions on the ureter that may be dose dependent.

Anticholinesterases

Anticholinesterases prevent the hydrolysis of ACh by cholinesterases and thus increase the duration and intensity of ACh action at both muscarinic and nicotinic receptor sites. With prolonged administration in high doses, they can result in desensitization blockade at nicotinic sites. The effects of **anticholinesterases**, such as **physostigmine and neostigmine**, parallel the excitatory effects of ACh and other parasympathomimetics on the ureter (Satani, 1919; Vereecken, 1973).

Parasympathetic Blocking Agents

Atropine is a competitive antagonist of the muscarinic effects of ACh. The inhibitory effects of atropine may be preceded by a transitory stimulatory effect on muscarinic receptors. Although atropine has been shown to inhibit the excitatory effects of parasympathomimetic agents (Vereecken, 1973; Longrigg, 1974) and physostigmine (Macht, 1916a) on a variety of ureteral and calyceal preparations, the majority of studies have shown that **atropine itself has little direct effect on ureteral activity in a number of species** (Gibbs, 1929; Gould et al, 1955; Butcher et al, 1957; Washizu, 1967; Vereecken, 1973; Reid et al, 1976), including humans (Kiil, 1957). **Even when atropine has been observed to inhibit ureteral activity, its effects are frequently minimal and inconsistent** (Ross et al, 1967), **thus providing little rationale for its use in the treatment of ureteral colic.**

Reports of the direct effects on ureteral activity of two other parasympathetic blocking agents, methantheline (Banth[i-macron]ne) and propantheline (Pro-Banth[i-macron]ne), also have been

inconsistent (Draper and Zorgniotti, 1954; Kiil, 1957; Reid et al, 1976).

Sympathetic Nervous System

The sympathetic nervous system appears to modulate ureteral activity as evidenced by the demonstration of adrenergic receptors in the ureter (Latifpour et al, 1989, 1990; Morita et al, 1994), the identification of catecholaminergic neurons in the ureter as determined by labeling tyrosine hydroxylase as a marker (Edyvane et al, 1994), and the demonstration that catecholamines are released from the ureter (Weiss et al, 1978) and renal calyx (Longrigg, 1975) in response to electric-field stimulation.

The ureter contains excitatory α-adrenergic and inhibitory β-adrenergic receptors (McLeod et al, 1973; Rose and Gillenwater, 1974; Weiss et al, 1978) that have been demonstrated with receptor-binding techniques (Latifpour et al, 1989, 1990). In the human ureter, α_{1D} and α_{1A} adrenoceptor subtypes are more prevalent than the α_{1B} adrenoceptor subtype (Sigala et al, 2005; Itoh et al, 2007). The highest density of α_1 adrenoceptors is found in the distal ureter with the relative density being $\alpha_{1D} > \alpha_{1A} > \alpha_{1B}$. **Norepinephrine**, **primarily an α-adrenergic agonist** (although it also can stimulate β-adrenergic receptors), increases the force of electrically induced ureteral contractions (Weiss et al, 1978). When administered in the presence of **phentolamine** (Regitine), **an α-adrenergic blocking agent,** norepinephrine, decreases the force of ureteral contractions (Weiss et al, 1978). A similar reversal of action occurs in the in-vivo ureter (McLeod et al, 1973) and can be explained by norepinephrine's primary action on inhibitory β-adrenergic receptors when the excitatory α-adrenergic receptors are blocked. Propranolol (Inderal), a β-adrenergic antagonist, potentiates the increase in contractile force induced by norepinephrine (Weiss et al, 1978). This can be explained by norepinephrine acting more exclusively on excitatory α-adrenergic receptors when the inhibitory β-adrenergic receptors are blocked. Furthermore, **isoproterenol, a β-adrenergic agonist,** depresses contractility (Weiss et al, 1978). These data provide evidence for excitatory α-adrenergic and inhibitory β-adrenergic receptors in the ureter and are in accord with the observations of McLeod and associates (1973) and Rose and Gillenwater (1974) on in-vivo ureters.

Further support for the presence of excitatory α-adrenergic and inhibitory β-adrenergic receptors in the ureter includes the demonstration of adenylyl cyclase activity in the ureter (Weiss et al, 1977; Wheeler et al, 1986) and the finding that the ureters of rabbits depleted of catecholamines by the administration of reserpine undergo greater degrees of deformation when a given intraluminal pressure is applied than would result from the application of the same pressure load to the ureters of normal, non–reserpine-treated animals (see Fig. 59–16) (Weiss et al, 1974). Finally, electric stimulation with high-intensity, high-frequency, short-duration stimuli has been shown to release neurotransmitter, presumably from intrinsic neural tissue within the wall of the ureter (Weiss et al, 1978) and renal calyx (Longrigg, 1975).

Adrenergic Agonists

Norepinephrine, the chemical mediator responsible for adrenergic transmission, is synthesized in the neuron from tyrosine. After its release from the nerve terminal, some of the norepinephrine combines with receptors in the effector organ, leading to a physiologic response. The greatest percentage of the norepinephrine is actively taken up (reuptake or neuronal uptake) into the neuron. Neuronal reuptake regulates the duration that norepinephrine is in contact with the innervated tissue and thus regulates the magnitude and duration of the catecholamine-induced response. Agents such as cocaine and imipramine (Tofranil), which inhibit neuronal uptake, potentiate the physiologic response to norepinephrine. The enzymes monoamine oxidase and catechol-*O*-methyltransferase provide degradative pathways for norepinephrine.

According to the general consensus, **agents that primarily activate α-adrenergic receptors, such as norepinephrine and phenylephrine, tend to stimulate ureteral and renal pelvic activity** (McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Rose and Gillenwater, 1974; Hernández et al, 1992; Rivera et al, 1992; Danuser et al, 2001), and **agents that primarily activate β-adrenergic receptors, such as isoproterenol and orciprenaline, tend to inhibit ureteral and renal pelvic activity** (Finberg and Peart, 1970; Ancill et al, 1972; McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978; Hernández et al, 1992; Rivera et al, 1992; Danuser et al, 2001). The β-adrenergic subtypes involved in ureteral relaxation are species specific: β_1 adrenoceptors in rats, β_2 adrenoceptors in rabbits, mainly β_3 adrenoceptors in dogs, and β_2 and β_3 adrenoceptors in pigs and humans (Tomiyama et al, 1998; Park et al, 2000; Tomiyama et al, 2003; Wanajo et al, 2004). A synthesized β_2/β_3-adrenoceptor agonist, KUL-7211 was a more potent relaxant of isolated dog ureteral segments than the α-adrenergic antagonists tamsulosin and prazosin, the calcium channel blocker verapamil, and the phosphodiesterase inhibitor papaverine (Wanajo et al, 2005). Intraluminal isoproterenol has been shown to lower renal pelvic pressures during ureteroscopy, with the presumption that this would decrease intrarenal backflow that has potential harmful effects (Jung et al, 2008). In the rabbit renal pelvis, β_2-adrenergic agonists inhibit contractile activity of the distal renal pelvis, and β_1-adrenergic agonists potentiate contractile activity of the proximal renal pelvis (Kondo et al, 1989). Tyramine, whose adrenergic agonist effects are due primarily to the release of norepinephrine from adrenergic terminals, also has a stimulatory effect on the upper urinary tract (Boyarsky and Labay, 1969; Finberg and Peart, 1970; Longrigg, 1974). The reported stimulatory effects of cocaine on ureteral activity (Boyarsky and Labay, 1969) may be explained by blockage of norepinephrine reuptake into adrenergic nerve endings, with a resultant increase in the magnitude and duration of the effect of norepinephrine.

Adrenergic Antagonists

The α-adrenergic antagonists phentolamine and phenoxybenzamine (Dibenzyline) have been shown to inhibit the stimulatory effects of norepinephrine and other α-adrenergic agonists in a variety of preparations (Finberg and Peart, 1970; Gosling and Waas, 1971; McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Longrigg, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978; Hernández et al, 1992). The α-adrenergic antagonist doxazosin has been shown to slightly reduce spontaneous contractility of in-vitro pig ureter and to inhibit the contractile effects of epinephrine and phenylephrine (Nakada et al, 2007), and tamsulosin inhibited the contractility of human ureters in vitro (Rajpathy et al, 2008) and in vivo (Davenport et al, 2007). The β-adrenergic antagonist propranolol has been shown to block or attenuate the inhibitory effects of β-adrenergic agonists, such as isoproterenol, in a variety of preparations (McLeod et al, 1973; Vereecken, 1973; Longrigg, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978).

Sensory Innervation and Peptidergic Agents in the Control of Ureteral Function

Sensory nerves can play both a sensory afferent and motor efferent role in a given tissue. Tachykinins and calcitonin gene–related peptide (CGRP) are neurotransmitters released from peripheral endings of sensory nerves (Maggi, 1995). **Tachykinins stimulate and CGRP inhibit electrical and contractile activity. Capsaicin-sensitive sensory nerves are located in the ureter** (Maggi et al, 1986; Maggi and Meli, 1988; Dray et al, 1989; Ammons, 1992) and contain the tachykinins, substance P, neurokinin A, and neuropeptide K (Hua et al, 1985; Sann et al, 1992), as well as CGRP (Gibbins et al, 1985; Sann et al, 1992; Tamaki et al, 1992). Immunoreactivity for tachykinins and CGRP is less in the human than in the guinea pig ureter (Su et al, 1986; Hua et al, 1987; Edyvane et al, 1992, 1994). Capsaicin in low doses inhibits ureteral activity, presumably due to the release of CGRP, but in high doses it increases ureteral activity, presumably due to release of the tachykinins neurokinin A, neuropeptide K, and substance P (Hua and Lundberg, 1986). Neonatal capsaicin administration causes degeneration of CGRP-containing sensory nerves in the rat ureter, which is accompanied by an increase in sympathetic (noradrenergic) innervation (Sann et al, 1995). Because NGF (nerve growth factor) is responsible for both increased sensory and noradrenergic innervation, capsaicin-induced degeneration of sensory nerves decreases NGF uptake into sensory neurons with a resultant increase in the amount of NGF available for stimulating sympathetic innervation (Schicho et al, 1998). The excitatory effects of the tachykinins are more prominent in the renal pelvis than in the ureter, and the inhibitory effects of CGRP are more prominent in the ureter than in the renal pelvis (Maggi et al, 1992b). The excitatory effects of tachykinins involve excitation of neurokinin-2 (NK-2) receptors in the human, pig, and guinea pig ureter; pig intravesical ureter; and guinea pig renal pelvis (Patacchini et al, 1998; Jerde et al, 1999; Bustamante et al, 2001; Nakada et al, 2001). The inhibitory actions of the neurotransmitter CGRP appear to involve multiple mechanisms (Maggi and Giuliani, 1991; Maggi et al, 1994b). By opening ATP-sensitive K^+ channels, CGRP causes membrane hyperpolarization with a resultant blocking of voltage-sensitive Ca^{2+} channels that are involved in generation of the ureteral action potential and ureteral contraction (Maggi et al, 1994c; Santicioli and Maggi, 1994; Meini et al, 1995). CGRP-induced ureteral relaxation may also result from stimulation of adenylyl cyclase activity with a resultant increase in cAMP (Santicioli et al, 1995b). The action of CGRP on the ureter may be regulated by an endopeptidase that degrades the CGRP released from the sensory nerves (Maggi and Giuliani, 1994).

Histochemical studies show that the tachykinins and CGRP co-localize in the same nerves in the ureter (Hua et al, 1987). Peptidergic neurons containing neuropeptide Y (NPY) and vasoactive intestinal polypeptide (VIP) also are present in the ureter (Allen et al, 1990; Edyvane et al, 1992; Prieto et al, 1997). VIP and pituitary adenylate cyclase–activating polypeptide (PACAP) have been shown to relax pig intravesical ureteral segments through a cyclic AMP–dependent mechanism (Hernández et al, 2004). Edyvane and associates (1994) have provided evidence of at least four, and possibly six, different immunohistochemical populations of nerve fibers in the human ureter. The predominant types include noradrenergic nerves containing NPY, neurons containing NPY and vasoactive polypeptide, neurons containing substance P and CGRP, and neurons containing CGRP. NPY potentiates the excitatory effects of norepinephrine on the ureter (Prieto et al, 1997). Rare coexistences also were observed between CGRP and vasoactive polypeptide, CGRP and NPY, and CGRP and tyrosine hydroxylase, a marker of noradrenergic neurons. These investigators demonstrated regional differences in the innervation of the ureter, with a more extensive innervation noted in the lower than in the upper ureter.

Renal pelvic sensory nerves contain both substance P and CGRP. Increases in renal pelvic pressure result in the release of substance P and a subsequent increase in afferent renal nerve activity. CGRP potentiates the afferent renal nerve activity responses to substance P (SP) by retarding the metabolism of SP, thus resulting in increased amounts of SP available for potentiating afferent renal nerve activity (Gontijo et al, 1999). Prostaglandins also contribute to sensory receptor activation (Kopp et al, 2000).

Nonadrenergic, noncholinergic (NANC) excitatory neurotransmission is functional in the pig intravesical ureter (Bustamante et al, 2000, 2001). In the presence of agents that block adrenergic neurotransmission, muscarinic cholinergic receptors, NO synthase activity, prostaglandin synthesis, and A_1/A_2 adenosine receptors, electrical-field stimulation (EFS, 5 Hz) induced contractions that were potentiated by the tachykinins SP and NKA, and that were inhibited by a sensory neurotoxin, capsaicin, and by a NK_2 receptor antagonist, GR94800. The EFS-induced contractions were abolished by tetrodotoxin, providing evidence that the contractions were neurogenic in origin. It has been suggested that tachykinins, especially neurokinin A (NKA), released from capsaicin-sensitive afferent nerves and activating NK_2 receptors are involved in NANC excitatory neurotransmission.

Purinergic Nervous System

Burnstock and associates (1972) postulated that ATP could act as an excitatory transmitter in the bladder. It was subsequently shown that ATP is released along with acetylcholine in response to nerve stimulation (Kasakov and Burnstock, 1983) and that the excitatory response in the bladder is mediated through P2X receptors (Theobald, 1995). ATP activation of P2X purinoceptors promotes influx of extracellular Ca^{2+} into the muscle cells with resultant contraction. **Although there is no evidence for ATP mediating contractions in the ureter, there is evidence to suggest that ATP is involved in nociceptive processes.** P2X receptors are present in the ureter (Lee et al, 2000), and release of ATP from the urothelium, in response to ureteral distention (Knight et al, 2002), stimulates afferent terminals by interacting with multiple purinergic receptors (Rong and Burnstock, 2004).

Two classes of mechanosensitive afferent fibers have been identified in the guinea pig ureter (Cervero and Sann, 1989). It would appear that one group of fibers are tension receptors that respond to normal ureteral peristalsis, whereas the others are involved in the signaling of noxious events, such as kidney stones and increased intraluminal pressures. Both groups are chemosensitive, being excited by K^+, bradykinin, and capsaicin (Sann, 1998). Because both ureteral distention and exogenous ATP increase afferent nerve discharge (Rong and Burnstock, 2004), ATP may be involved in signaling visceral pain with ureteral dilatation (Burnstock, 2006). It has been proposed that ureteral distension causes release of ATP from the urothelium, which, in turn, activates purinoceptors on suburothelial nociceptive sensory nerves. Consistent with this postulation, ATP has been shown to be

released with distention of isolated human ureteral segments, and this was accompanied by staining of P2X(3) and capsaicin receptors (Calvert et al, 2008).

URINE TRANSPORT

Physiology of the Ureteropelvic Junction

At normal urine flows, the frequency of calyceal and renal pelvic contractions is greater than that in the upper ureter, and there is a relative block of electric activity at the UPJ (Morita et al, 1981). At these flows, the renal pelvis fills; as renal pelvic pressure rises, urine is extruded into the upper ureter, which is initially in a collapsed state (Griffiths and Notschaele, 1983). Ureteral contractile pressures that move the bolus of urine are higher than renal pelvic pressures, and a closed UPJ may be protective of the kidney in dissipating back-pressure from the ureter. As the flow rate increases, the block at the UPJ ceases and a 1:1 correspondence between pacemaker and ureteral contractions develops (Constantinou and Hrynczuk, 1976; Constantinou and Yamaguchi, 1981).

With UPJ obstruction, there may be areas of narrowing or valve-like processes (Maizels and Stephens, 1980) or mucosal folds (Takeyama and Sakai, 2007). In other instances, there is no gross narrowing at the UPJ, and abnormal propagation of the peristaltic impulse is a causative factor in the obstruction. In these instances, there appears to be a functional obstruction at the UPJ, because a large-caliber catheter can be passed readily through the UPJ, even though urine transport is inadequate. Murnaghan (1958) related the functional abnormality to an alteration in the configuration of the muscle bundles at the UPJ, and Foote and associates (1970) observed a decrease in musculature at the UPJ. Hanna (1978), in an electron microscopic study of severe UPJ obstructions, noted abnormalities in the musculature of the renal pelvis and disruption of intercellular relations at the UPJ itself. Increased accumulation of collagen has been described in the region of the UPJ with obstruction (Murakumo et al, 1997), and it has been suggested that differences in types I and III collagen in the region of the obstructed UPJ may be age dependent (Yoon et al, 1998). Increases in smooth muscle, myosin heavy-chain isoforms also have been described in congenital UPJ obstruction (Hosgor et al, 2005). Studies also have shown a decrease in nerves and in nerve growth factor mRNA expression in UPJ obstruction specimens compared with controls (Wang et al, 1995; Murakumo et al, 1997). An increase in apoptosis of smooth muscle cells in the region of congenital UPJ obstruction has been reported to accompany a decrease in smooth muscle and nerve terminals and an increase in collagen and elastin (Kajbafzadeh et al, 2006). Defective contractility of UPJ segments obtained at the time of pyeloplasty has been described (Pontincasa et al, 2006). A vessel or adhesive band crossing the UPJ may potentiate the degree of dilatation in any of the forms of UPJ obstruction.

The differences in the reported findings suggest a histopathologic spectrum in the group of cases referred to as *UPJ obstructions*. **It appears possible that, at least in some instances, disruption of cell-to-cell propagation of peristaltic activity results in impairment of urine transport across the UPJ.**

One must consider input and output when predicting whether or not dilatation will occur; the effects of diuresis and obstruction appear to be complementary and additive regarding the development of renal pelvic and calyceal dilatation. Some UPJs can handle urine flow regardless of the magnitude of diuresis; others cause dilatation at even the lowest flows, and still others can handle low flows but cause massive dilatation at high flows (Fig. 59–17).

Propulsion of Urinary Bolus

The theoretical aspects of the mechanics of urine transport within the ureter have been described in detail by Griffiths and Notschaele (1983); these are depicted in Figure 59–18.

At normal flow rates, as the renal pelvis fills, a rise in renal pelvic pressure occurs and urine is extruded into the upper ureter, which is initially in a collapsed state. The contraction wave originates in the most proximal portion of the ureter and moves the urine in front of it in a distal direction. The urine that had previously entered the ureter is formed into a bolus. To propel the bolus of urine efficiently, the contraction wave must completely coapt the ureteral walls (Woodburne and Lapides, 1972; Griffiths and Notschaele, 1983), and the pressure generated by this contraction wave provides the primary component of what is recorded by intraluminal pressure measurements. The bolus that is pushed in front of the contraction wave lies almost entirely in a passive, noncontracting part of the ureter (Fung, 1971; Weinberg, 1974).

Baseline, or resting, ureteral pressure is approximately 0 to 5 cm H_2O, and superimposed ureteral contractions ranging from 20 to 80 cm H_2O occur two to six times per minute (Kiil, 1957; Ross et al, 1972). The urine traverses the UVJ to enter the bladder; when functioning properly, the UVJ ensures one-way transport of urine. The bolus is forced into the bladder by the advancing contraction wave that then dissipates at the UVJ.

As with any tubular structure, the ureter can transport a set maximal amount of fluid per unit time. Under normal flows, in which bolus formation occurs, the amount of urine transported per unit time is significantly less than the maximal transport capacity of the ureter. **At extremely high flows, as are employed in the standard perfusion studies** (Whitaker, 1973), **the ureteral walls do not coapt, and a continuous column of fluid, rather than a series of boluses, is transported.**

When transport becomes inadequate, stasis of urine occurs with resultant ureteral dilatation. **Inadequate transport can result either from too much fluid entering the ureter per unit time or from too little fluid exiting the ureter per unit time**. Both input and output must be considered in predicting whether or not ureteral dilatation will occur. For example, a minor degree of obstruction to outflow will cause more dilatation at high flow rates than at low flow rates. Even a normal nonobstructed ureter will impede urine transport if the rate of flow is great enough.

Changes in ureteral dimensions that occur in pathologic states may, per se, result in inefficient urine transport, even if the contractile force of the individual fibers is unchanged. The Laplace equation expresses the relation between the variables that affect intraluminal pressure:

$$\text{Pressure} = \frac{\text{tension} \times \text{wall thickness}}{\text{radius}}$$

An increase in ureteral diameter, itself, can decrease intraluminal pressure and result in inefficient urine transport. Such dimensional changes may, at least theoretically, be deleterious (Griffiths, 1983). Another factor may be the histologic composition of the dilated ureter, as evidenced by the description of different amounts of type I and type III collagen in primary obstructed and refluxing megaureters (Lee et al, 1998).

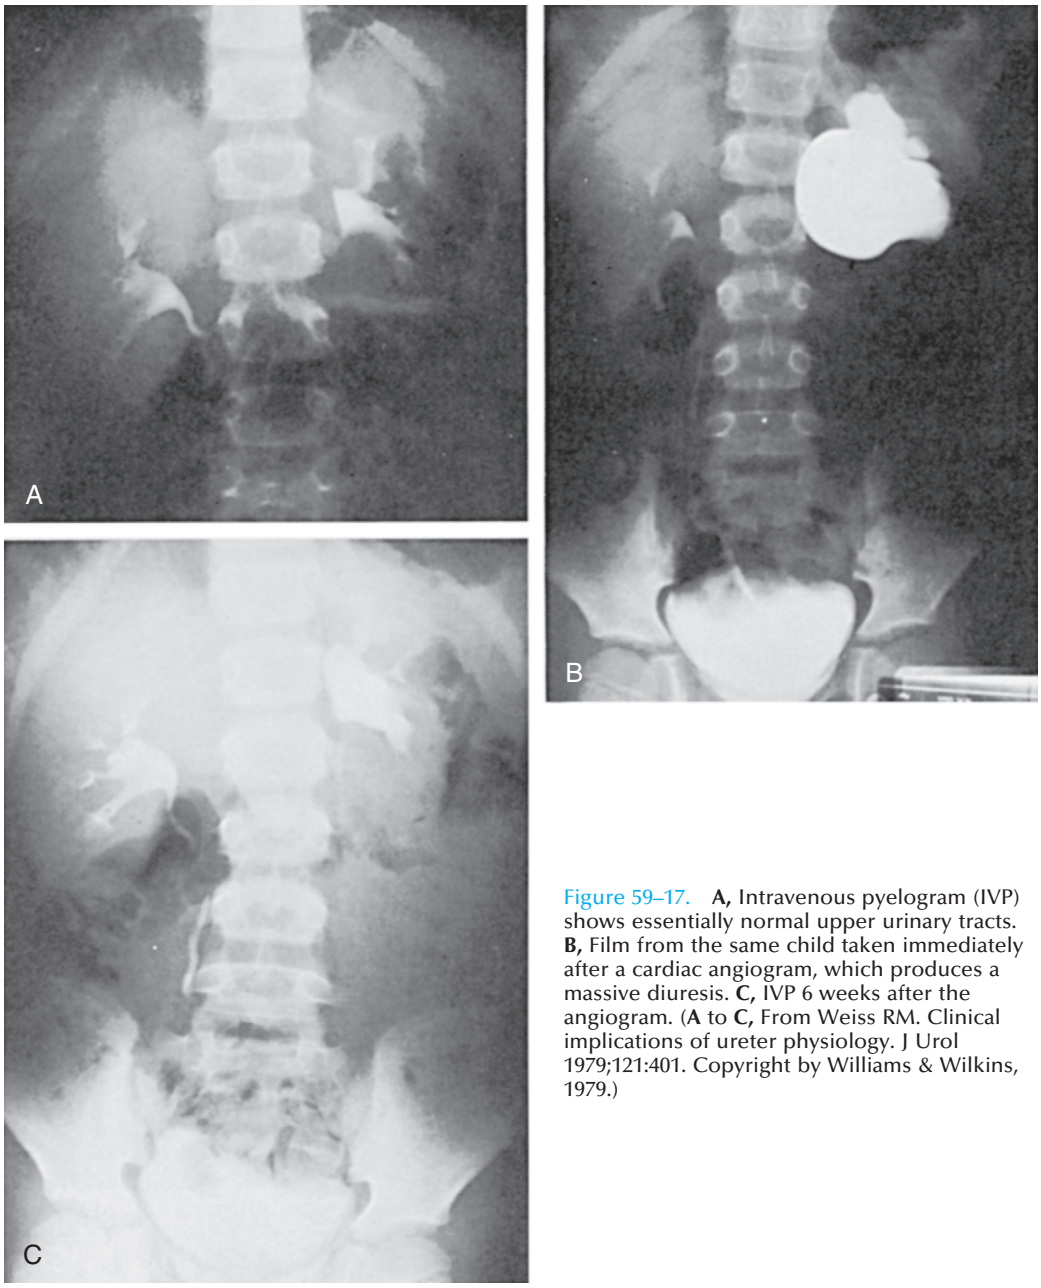

Figure 59–17. **A,** Intravenous pyelogram (IVP) shows essentially normal upper urinary tracts. **B,** Film from the same child taken immediately after a cardiac angiogram, which produces a massive diuresis. **C,** IVP 6 weeks after the angiogram. Effect of Diuresis on Ureteral Function

With increasing urine flow rates, the initial response of the ureter is to increase peristaltic frequency. After the maximal frequency is achieved, further increases in urine transport occur by means of increases in bolus volume (Morales et al, 1952; Constantinou et al, 1974). At relatively low flow rates, small increases in flow result in large increases in peristaltic frequency. At higher flow rates, relatively large increases in flow result in only small increases in peristaltic frequency. As the flow rate continues to increase, several of the boluses coalesce, and finally the ureter becomes filled with a column of fluid and dilates. At these high flow rates, urine transport is through an open tube.

Effects of Bladder Filling and Neurogenic Vesical Dysfunction on Ureteral Function

Ureteral dilatation can result either from an increase in fluid input or from a decrease in fluid output from the ureter. The relation between ureteral intraluminal pressure and intravesical pressure is important in determining the efficacy of urine passage across the UVJ into the bladder. In the case of the normal ureter under normal physiologic rates of flow, ureteral contractile pressure exceeds intravesical pressure, resulting in passage of urine into the bladder. In the dilated, poorly contracting ureter or in the normal ureter at extreme flow rates, the ureter does not coapt its walls to form boluses, and the baseline pressure in the column of urine

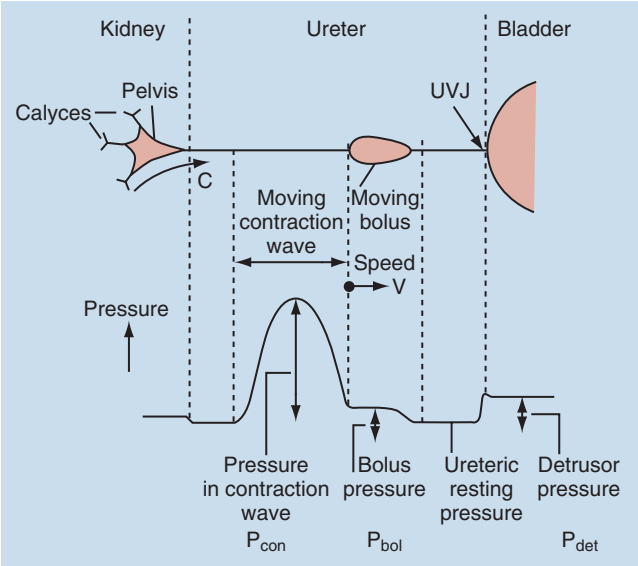

Figure 59–18. Schematic representation of a single bolus in the ureter moving away from the renal pelvis and toward the bladder. Arrow C indicates the direction of bolus transport. The corresponding distribution of pressure within the urinary tract is shown in the lower tracing. UVJ, ureterovesical junction. (From Griffiths DJ, Notschaele C. The mechanics of urine transport in the upper urinary tract. Neurourol Urodyn 1983;2:155.)

within the ureter must exceed intravesical pressure in order for urine to pass into the bladder.

The pressure within the bladder during the storage phase is of paramount importance in determining the efficacy of urine transport across the UVJ. This is the pressure that the ureter needs to work against for the longest period of time. During filling of the normal bladder, sympathetic impulses and the viscoelastic properties of the bladder wall inhibit the magnitude of the intravesical pressure rise, that is, the tonus limb. With filling, the normal bladder maintains a relatively low intravesical pressure (McGuire, 1983) that facilitates the transport of urine across the UVJ and prevents ureteral dilatation. In the noncompliant fibrotic bladder and in some forms of neurogenic vesical dysfunction, the bladder is autonomous, and relatively small increases in bladder volume result in large increases in intravesical pressure with resultant impairment of ureteral emptying. The ureter initially responds to its decreased ability to empty by increasing its peristaltic frequency (Zimskind et al, 1969; Rosen et al, 1971; Fredericks et al, 1972). Ultimately, stasis occurs with the development of ureteral dilatation. **The ureter has been shown to decompensate when intravesical pressure approaches 40 cm H_2O** (McGuire et al, 1981).

Physiology of the Ureterovesical Junction

Griffiths (1983) has analyzed the factors involved in urine transport across the UVJ. Under normal conditions and at normal flow rates, the contraction wave, which occludes the ureteral lumen, propagates distally with the urine bolus in front of it. When the bolus reaches the UVJ, the pressure within the bolus must exceed intravesical pressure so that the bolus of urine can pass across the UVJ into the bladder. Under these conditions, when the contraction wave can coapt the ureteral wall and move the urinary bolus distally, the pressure generated by the contraction wave exceeds the pressure within the urinary bolus. The contracted ureteral ring, just proximal to the ureteral orifice at the UVJ, is relevant in the antireflux mechanism (Roshani et al, 1996). As the bolus is ejected into the bladder, the distal ureter retracts within its sheaths; this telescoping of the ureter within its sheaths aids in decreasing UVJ resistance to flow and thus facilitates urine passage into the bladder (Blok et al, 1985). The UVJ does not relax (Weiss and Biancani, 1983). **Impediment of efficient bolus transfer across the UVJ into the bladder can occur when there is an obstruction at the UVJ, when intravesical pressure is excessive, or when flow rates are so high as to exceed the transport capacity of the normal UVJ. Under such conditions, when the bolus of urine cannot pass freely into the bladder, the pressure within the bolus increases and may exceed the pressure in the contraction wave. This results in an inability of the contraction wave to completely occlude the ureter; there is retrograde flow of urine from the bolus, and only a fraction of the urinary bolus passes across the UVJ into the bladder.** Griffiths (1983) has presented theoretical evidence to show that a similar situation of impaired bolus transport across the UVJ would be expected if the ureter was wide or weakly contracting, even if the UVJ was perfectly normal. The wider and more weakly contracting the ureter, the lower the UVJ resistance must be in order not to interfere with bolus transport. The resistance to flow at the UVJ has been variously attributed to forces in the trigone (Tanagho et al, 1968) and to detrusor pressure (Coolsaet et al, 1982).

The theoretical considerations outlined by Griffiths (1983) have direct clinical implications. **If the UVJ is obstructed (i.e., has an abnormally high resistance to flow) or if the detrusor pressure is excessive, large boluses occurring at high-flow conditions would not be completely discharged into the bladder, because the contraction wave pushing the bolus would be forced open and intraureteral reflux would occur.** Such obstruction at the UVJ would be detected by perfusion studies as popularized by Whitaker (1973) (i.e., the Whitaker test). On the other hand, Griffiths' (1983) theory suggests that a similar breakdown of bolus discharge into the bladder can occur in the wide or weakly contracting ureter at high flow rates even if the UVJ is normal, and that such a condition would go undetected by a Whitaker perfusion test.

There is evidence that gravity may assist urine transport and that the erect position may aid urine transport across the UVJ, especially in individuals with dilated upper tracts (Schick and Tanagho, 1973). From a practical standpoint, George and associates (1984) suggested that bed rest may be deleterious to renal function in individuals with urinary retention and wide upper urinary tracts.

PATHOLOGIC PROCESSES AFFECTING URETERAL FUNCTION

Effect of Obstruction on Ureteral Function

General

The effect of obstruction on ureteral function depends on the degree and duration of the obstruction, on the rate of urine flow, and on the presence or absence of infection. After the onset of obstruction, a backup of urine occurs within the urinary collecting system, along with an associated increase in baseline (resting) ureteral

intraluminal pressure and an increase in ureteral dimensions, that is, an increase in both length and diameter (Fig. 59–19) (Rose and Gillenwater, 1973; Biancani et al, 1976). **The increase in intraluminal pressure depends on the kidney's continued production of urine that cannot pass beyond the site of obstruction; the increase in ureteral dimensions results from the increased ureteral intraluminal pressure and the increased volume of urine retained within the ureter. A transient increase in the amplitude and frequency of the peristaltic contraction waves accompanies these initial dimensional and ureteral baseline (resting) pressure changes** (Rose and Gillenwater, 1978). **With time, as the ureter fills with urine, the peristaltic contraction waves become smaller and are unable to coapt the ureteral wall. Urine transport then becomes dependent on hydrostatic forces generated by the kidney** (Rose and Gillenwater, 1973). **Superimposed infection may result in a complete absence of contractions in the obstructed ureter and contributes to impairment of urine transport** (Rose and Gillenwater, 1973).

Within a few hours after the onset of obstruction, the intraluminal baseline ureteral pressure reaches a peak and then declines to a level only slightly higher than the normal baseline pressure. This occurs at a time when dimensional changes remain stable (Biancani et al, 1976). The decrease in ureteral pressure can be attributed to changes in intrarenal hemodynamics, such as a reduction in renal blood flow (Vaughan et al, 1971), with resultant decreases in the glomerular filtration rate and intratubular hydrostatic pressure (Gottschalk and Mylle, 1956). Fluid reabsorption into the venous and lymphatic systems and a decrease in wall tension also may play a role in the reduction in baseline ureteral pressure (Rose and Gillenwater, 1978). The persistence of dimensional changes in the face of a decrease in intraluminal pressure depends on the **hysteretic properties** of the viscoelastic ureteral structure (Fig. 59–20) (Weiss et al, 1972; Biancani et al, 1973, 1976; Vereecken et al, 1973).

As the obstruction persists, there is a gradual increase in ureteral length and diameter to considerable dimensions. This occurs even though ureteral pressure remains at a relatively low and constant level. This process, observed in viscoelastic structures, is referred to as creep (Biancani et al, 1973). Continued, albeit small, urine production is required for the continuing increase in intraureteral volume. Such changes account for the relatively low intrapelvic pressures clinically observed in the massively dilated, chronically obstructed upper urinary tract (Backlund et al, 1965; Struthers, 1969; Vela-Navarrete, 1971; Djurhuus and Stage, 1976); and in

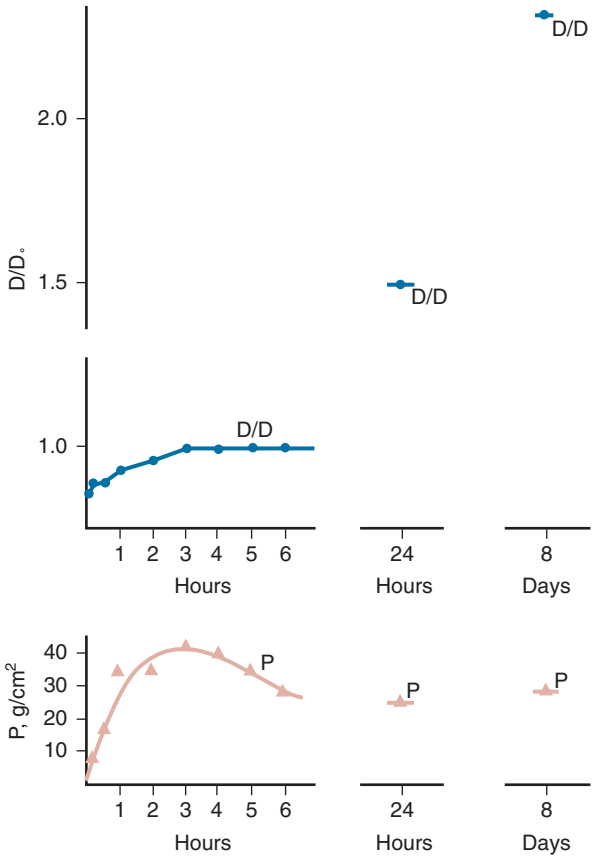

Figure 59–19. Intraluminal pressure and diameter changes after obstruction of rabbit ureter. The time from the onset of obstruction is on the abscissa. The change in diameter (D/D_0) is on the upper ordinate, and the intraluminal pressure is on the lower ordinate. During the initial 3 hours of obstruction, intraluminal pressure increased to reach a maximum and was associated with an increase in diameter. Between 3 and 6 hours after the onset of obstruction, pressure declined, although diametral deformation persisted. After 6 hours, pressure remained essentially unchanged, although the diameter continued to increase. Do, initial diameter; D, diameter during deformation; P, intraluminal pressure. (Adapted from Biancani P, Zabinski MP, Weiss RM. Time course of ureteral changes with acute and chronic obstruction. Am J Physiol 1976;231:393.)

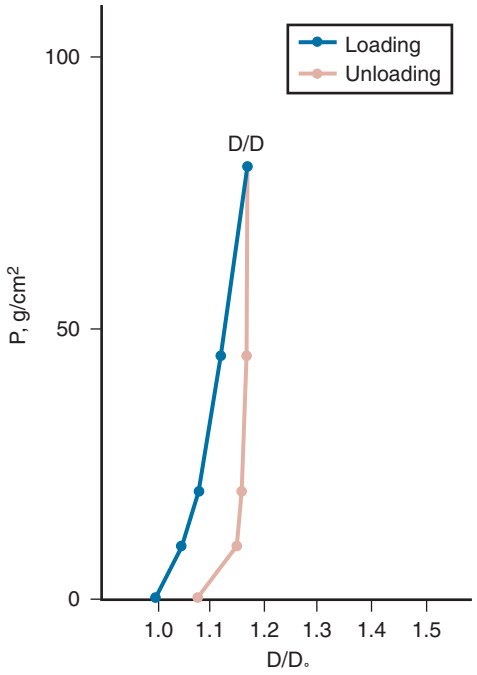

Figure 59–20. Demonstration of hysteretic properties of ureter show that dimensional changes depend on intraluminal pressure and on the direction of change of that pressure. At comparable pressures, deformations are greater during ureteral emptying than during ureteral filling. The *blue line* shows data obtained during loading; the *pink line,* data obtained during unloading. D_0, initial diameter; D, diameter during deformation; P, intraluminal pressure in grams per square centimeter. (Adapted from Biancani P, Zabinski MP, Weiss RM. Time course of ureteral changes with acute and chronic obstruction. Am J Physiol 1976;231:393.)

experimentally produced obstruction (Schweitzer, 1973; Koff and Thrall, 1981a). One could postulate that with prolonged complete obstruction, the total cessation of urine output ultimately occurs. A subsequent decrease in ureteral dimensions would depend on whether urine is reabsorbed and on the mechanical properties of the ureter at that time.

To determine the effect of obstruction on the contractile properties of the ureter, a rabbit model, in which the ureter is totally obstructed for 2 weeks, has been employed (Hausman et al, 1979; Biancani et al, 1982). After 2 weeks of obstruction, the cross-sectional muscle area increases by 250%, ureteral length by 24%, and ureteral outer diameter by 100%. In addition to undergoing **muscle hypertrophy**, in-vitro segments from obstructed ureters develop greater contractile forces, in both longitudinal and circumferential directions, than do segments from control ureters (Fig. 59–21). With experimental obstruction at the UPJ, there also is an increase in the frequency and amplitude of spontaneous mechanical contractions of the renal pelvis and an increase in the amplitude of phenylephrine and 5-hydroxytryptamine (5-HT)–induced contractions (Ekinci et al, 2004). Determinations of stress (force per unit area of muscle) provide a means of determining whether the observed increases in developed force result from an increase in contractility or from an increase in muscle mass alone. The increases in force were associated with an increase in maximal active circumferential stress but no change in maximal active longitudinal stress (Fig. 59–22). Because there is an increase in circumferential stress and no change in longitudinal stress, the sum of the stresses (total stress) or overall contractility increases after 2 weeks of obstruction. In order for these differences in longitudinal and circumferential stresses to occur after obstruction, rotation of muscle bundles must occur; otherwise, longitudinal and circumferential stresses would increase equally. The rotation could result from the greater increase in diameter than in length after obstruction, from remodeling of the muscle fibers, or from both. In addition to an increase in EFS-induced ureteral contractions with obstruction, carbachol, phenylephrine, and KCl also caused a greater increase in contractions in obstructed ureters, and the Rho-kinase inhibitor Y-27632 has a more pronounced effect in inhibiting these contractile events in the obstructed ureters (Turna et al, 2007). The expression of the two Rho kinase isoforms ROCK-1 and ROCK-2 is increased in the obstructed ureter (Turna et al, 2007).

Thus the ureter dilated after 2 weeks of obstruction is not mechanically decompensated but, rather, undergoes changes that result in an increase in contractility. **Despite both the muscle hypertrophy and the increase in contractility, it is clinically and experimentally evident that the obstructed, dilated ureter is less able than the normal ureter to generate the contractile pressures required for urine transport** (Rose and Gillenwater, 1973). The decrease in the ability to generate an intraluminal pressure, despite an increase in contractility, results from the increase in ureteral diameter that occurs after obstruction and can be explained by the **Laplace relation:**

$$\text{Pressure} = \frac{\text{stress} \times \text{wall thickness}}{\text{radius}}$$

Although contractility (stress) increases after 2 weeks of obstruction, the decrease in the wall's thickness-to-radius ratio, resulting from the marked increase in intraluminal diameter and thinning of the muscle layer, accounts for the decrease in pressure. It must be realized that a longer duration of obstruction or the presence of infection may alter these relations.

Estimates of intraluminal pressures as a function of diameter (pressure-diameter curves) can be calculated from in-vitro circumferential force-length data (Fig. 59–23) (Biancani et al, 1982; Weiss

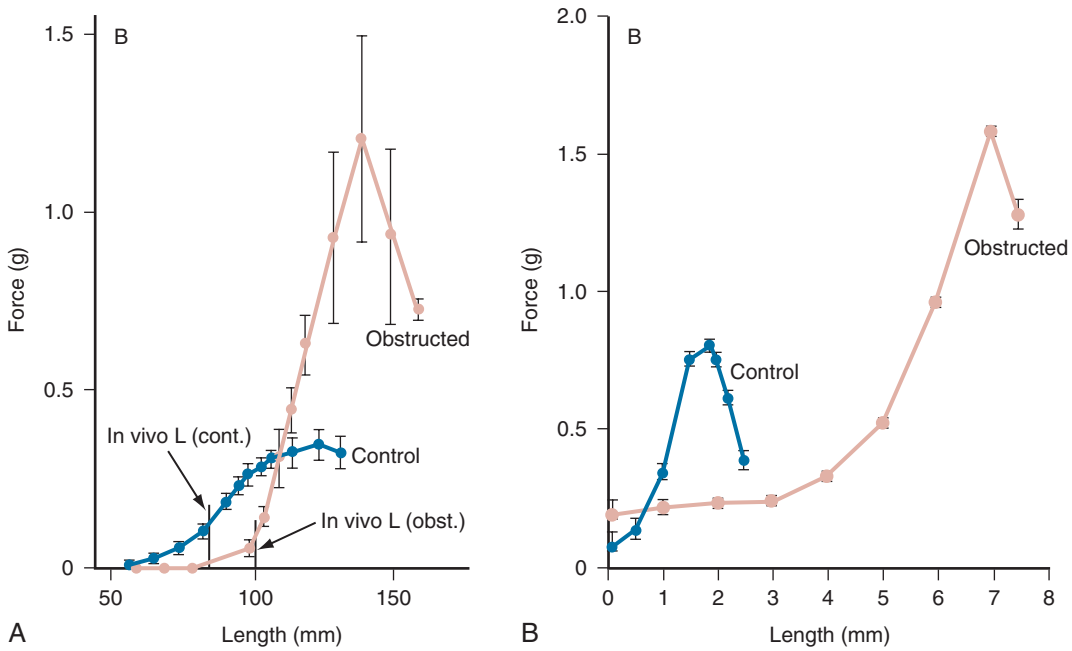

Figure 59–21. **A,** Active (contractile) longitudinal force-length relations of control *(blue circles)* and obstructed *(pink circles)* rabbit ureters. Each data point represents mean ± SEM. **B,** Active (contractile) circumferential force-length relations of obstructed *(pink)* and control *(blue)* ureteral rings. *Vertical bars* correspond to in-vivo lengths of control and obstructed segments. and Biancani, 1982) and provide insight as to how obstruction interferes with urine transport. The validity of such calculations is supported by their correspondence to actual in-vivo measurements (Rose and Gillenwater, 1973; Biancani et al, 1976). The obstructed ureter at in- vivo dimensions has a higher resting (baseline) pressure and a lower contractile (active) pressure than does a control ureter. In the control ureter, the total (active plus passive or resting) pressure developed at all diameters exceeds the passive pressure marked by the *horizontal dotted line,* and thus the generated active or contractile pressures are able to fully coapt the ureteral lumen and propel the urine bolus. In the obstructed ureter at diameters less than 3.3 mm, the passive pressure, as marked by the horizontal dotted line, exceeds the total pressure. The contraction ring therefore is incapable of contracting below this diameter, and the pressure in the whole ureter remains approximately uniform and equal to the passive pressure. The principal effect of the contraction wave in the obstructed dilated ureter is to slightly reduce the ureteral volume and thereby slightly raise the overall resting pressure. Thus although the obstructed ureter is able to develop greater circumferential contractile forces than the control ureter, the expected intraluminal pressure generated by the obstructed ureter would differ little from baseline (resting) pressure, and the contraction wave occurring during propagation of peristalsis would be incapable of coapting the ureteral lumen and propelling the urine bolus in an effective manner.

It should be noted that the calculated active pressure in the obstructed ureter estimates the pressure that would develop if the whole ureter contracted simultaneously and uniformly throughout its whole length, rather than the pressure measured in a peristaltic contraction wave, which involves contraction of only a small segment of ureter at a given time. The fact that the calculated pressures in the obstructed ureter are, if anything, a slight overestimate of expected pressures only further supports the conclusion that **the obstructed ureter is incapable of coapting its lumen and efficiently propelling the urine bolus. If, however, the urine were removed from the lumen of the ureter (e.g., by relieving the obstruction), the ureter obstructed for 2 weeks would be able to immediately coapt its lumen and produce pressures comparable with those of control ureters.** This can be appreciated from

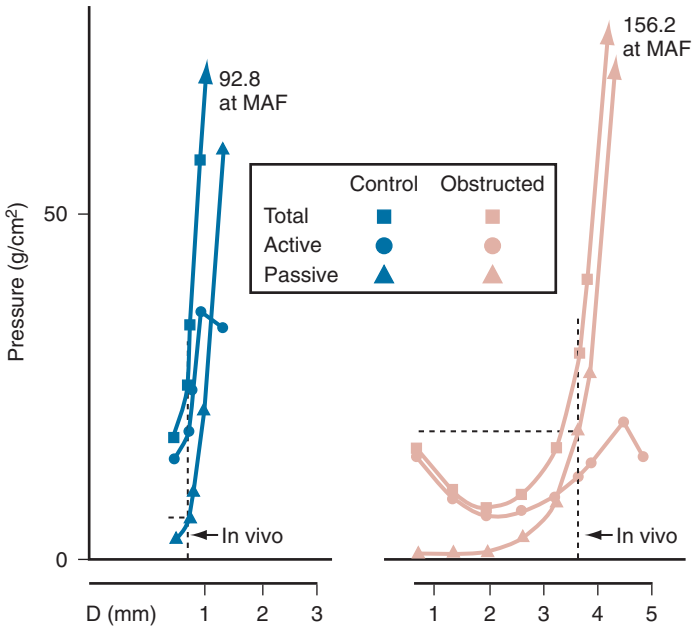

Figure 59–23. Pressure-diameter relationships of control and obstructed ureters. Calculated total, active, and passive pressures are shown as a function of intraluminal diameter (D). In-vivo passive pressures are indicated by *horizontal dashed lines* and in-vivo dimensions by *vertical dashed lines*. MAF, maximum active force. (Adapted from Biancani P, Hausman M, Weiss RM. Effect of obstruction on ureteral force-length relations. Am J Physiol 1982;243:F204.)

Figure 59–23, in which the total pressure in the obstructed ureter of near zero diameter is comparable to the total pressure in the control ureter of a similar diameter. Thus **2 weeks of obstruction results in an increase in ureteral contractility but a decrease in contractile intraluminal pressures.** This decrease in the ability to generate an active intraluminal pressure and to coapt the ureteral lumen impairs urine transport in the obstructed ureter.

Obstruction of the fetal ureter also is accompanied by an increase in ureteral weight, smooth muscle mass, extracellular

matrix, and the frequency and amplitude of spontaneous ureteral contractile activity (Santis et al, 2000). Obstructed and refluxing dilated ureters have an increase in type I and type III collagen and an increased ratio of collagen to smooth muscle (Gearhart et al, 1995; Lee et al, 1998). Hydrocortisone, verapamil (a calcium channel blocker), and D-penicillamine reduce collagen III production, which is increased in a variety of obstructed ureteral states and in ureteral cell cultures (Wolf et al, 1996). Obstruction also has been shown to alter the hierarchic organization of the multiple coupled pacemakers that normally coordinate peristaltic activity (Constantinou and Djurhuus, 1981; Djurhuus and Constantinou, 1982). Such disruption causes discoordination of pelvic contractility with resultant incomplete emptying of the renal pelvis that contributes to upper urinary tract dilatation.

Physiologic Methodologies for Assessing Clinical Obstruction

A variety of radiographic methodologies, the rationale for whose use is based on physiologic principles, are employed in the evaluation and differentiation of upper urinary tract dilatation and obstruction. Description of these examinations, which include diuretic urograms, diuretic MR urography, diuretic ultrasonography, diuretic radionuclide renograms, pulsed Doppler sonographic assessment of renal vascular resistance, and ultrasonographic evaluation of ureteral peristalsis are beyond the scope of this chapter. The best methods now available for differentiating obstructive from nonobstructive dilatation depend on assessing the efficacy of urine transport. When transport becomes inadequate, urine stagnates, and dilatation occurs. **Dilatation depends on the compliance of the system and can result either from too much fluid entering the system per unit time or from too little fluid exiting the system per unit time.** The properly functioning upper urinary tract should transport urine over the entire range of physiologically possible flow rates without undergoing marked deformational changes or increases in intraluminal pressure of a magnitude that would be deleterious to the function of the ureter, renal pelvis, or kidney.

Measurement of basal or resting intraluminal pressures does not help in differentiating obstructive from nonobstructive dilatation, because the pressures may be low even when obstruction is present (Backlund et al, 1965; Struthers, 1969; Vela-Navarrete, 1971). The values obtained vary with the state of hydration, the degree of renal function, the severity and duration of obstruction, and the compliance of the system. **Perfusion studies are used in an attempt to differentiate dilated systems that are obstructed from those that are not obstructed** (Backlund and Reuterskiöld, 1969a, b; Reuterskiöld, 1969, 1970; Whitaker, 1973, 1978). The technique involves cannulating the dilated upper urinary tract and perfusing the system at a rate of 10 mL/min. Pressures are measured after the achievement of steady-state conditions, which occur when an equilibrium is reached between the flow into and out of the system. Fluoroscopic monitoring aids in the interpretation of the data. **The basic hypothesis in perfusion studies is that if the dilated upper urinary tract can transport 10 mL/min (a fluid load greater than it would ever be expected to handle during usual physiologic states) without an inordinate increase in pressure, any degree of obstruction that is present is not clinically significant.** Whitaker (1978) and associates (1981) concluded from a large clinical experience that under these flow conditions, a pressure less than 15 cm H_2O correlates with a nonobstructive state, whereas pressures greater than 22 cm H_2O invariably correlate with clinically significant obstruction (Whitaker, 1978; Witherow and Whitaker, 1981). With this definition, minor degrees of obstruction could go undetected; however, **the presumption is that if at high flows the hydrostatic pressure in the system is not at a level that would produce renal deterioration, then lower and more physiologic flows surely will be tolerated.** The high flows are used to stress the system and thus to detect the slightest propensity to obstruction. The interpretation of data obtained by perfusion studies is schematically shown in Figure 59–24.

In order to obtain relevant information, strict adherence to detail is required in the performance of perfusion studies. Care must be taken to ensure that an equilibrium state has been reached before making pressure measurements. Extrinsic factors that affect the resistance to flow, such as the needle size, length and compliance of extrinsic tubing, viscosity of the perfusion fluid, temperature, and flow rate, must be considered when quantitative data are obtained (Toguri and Fournier, 1982). Furthermore, the bladder should be continuously drained to eliminate the bladder's effect on urine transport.

When performed and interpreted properly, perfusion studies may provide clinically relevant information in selected cases. The basic problem in the interpretation of data with this and other

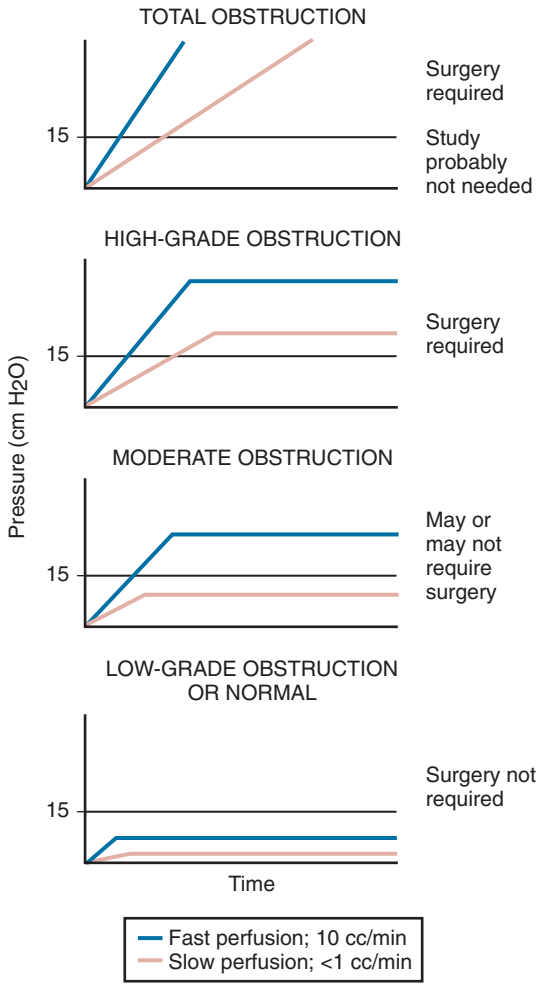

Figure 59–24. Schematic representation of data that can be obtained with perfusion studies. A fast perfusion rate, 10 mL/min, would be used in a standard Whitaker test. A slow perfusion rate, less than 1 mL/min, would be closer to more physiologic rates of flow. (From Weiss RM. Clinical implications of ureteral physiology. J Urol 1979;121:401. Copyright by Williams & Wilkins, 1979.)

diagnostic methods is the definition of "clinically relevant obstruction"—that is, just how much resistance to flow or increase in pressure is required to produce renal functional or anatomic deterioration as a function of time, taking into account the compliance of the system (Koff and Thrall, 1981b). Also, it is theoretically possible that the wide or weakly contracting ureter at high flow rates may interfere with bolus transport even if the UVJ is normal (Griffiths, 1983). Such an obstructive process would not be detected by perfusion studies.

These theoretical considerations provide a rationale for **ureteral tapering** (Hendren, 1970). The Laplace relation provides a possible explanation for anticipated improvement in function resulting from tapering. With ureteral tapering, muscle thickness and the ability of the ureteral fibers to contract (stress) are unchanged. The decrease in radius resulting from tapering itself, according to the Laplace relation, could account for higher intraluminal pressures, which could improve urine transport. Thus the tapered ureter may coapt its walls more readily and generate higher intraluminal pressures even though the material itself has not changed (Weiss and Biancani, 1982). Although the possibility of deleterious effects of the wide "nonobstructed" ureter remains controversial, one should consider such effects when interpreting data obtained with the present modalities for diagnosing obstruction and when determining management.

Relation between Vesicoureteral Reflux and Ureteral Function

Factors that have been implicated in the development of vesicoureteral reflux include (1) anatomic and functional abnormalities at the UVJ, (2) inordinately high intravesical pressures, and (3) impaired ureteral function. The normal intravesical ureter is approximately 1.5 cm in length and takes an oblique course through the bladder wall. It is composed of an intramural segment surrounded by detrusor muscle and a submucosal segment that lies directly under the bladder urothelium (Tanagho et al, 1968). The relation between the length and the diameter of this intravesical segment of ureter appears to be a factor in the prevention of vesicoureteral reflux (Paquin, 1959). Reflux may occur when the intravesical tunnel is destroyed. Trigonal function may also be a factor in the prevention of vesicoureteral reflux. Tanagho and associates (1965) created vesicoureteral reflux in the cat by disruption of the trigone or by sympathectomy and, conversely, increased the pressure within the intravesical ureter by electric stimulation of the trigone or by administration of IV epinephrine. The development of vesicoureteral reflux in individuals with bladder outlet obstruction and neurogenic vesical dysfunction provides evidence that increased intravesical pressures may also be a factor in certain instances of reflux.

A significant percentage of units with vesicoureteral reflux improve spontaneously with age. In a study by Jorgensen et al (1984), 35% of young pigs had vesicoureteral reflux that disappeared with age. In the pig, significant growth and organization of smooth muscle and increase in innervation occurs during the postnatal period, and this might be the anatomic correlate of maturation of the UVJ during infancy and the spontaneous functional disappearance of reflux (Pirker et al, 2007).

Although an abnormality of the UVJ is the primary etiologic factor in most cases of reflux, there is evidence to suggest that decreased ureteral peristaltic activity can be a contributory factor. This may explain why a normal ureter may not reflux even when reimplanted into a bladder without a submucosal tunnel (Debruyne et al, 1978), or why a defunctionalized refluxing ureter may cease to reflux when a proximal diversion is taken down (Teele et al, 1976; Weiss, 1979). The observation that vesicoureteral reflux may temporarily cease after ureteral electric stimulation (Melick et al, 1966) further supports this possibility.

Even the mildest forms of vesicoureteral reflux are associated with a decreased frequency of ureteral peristalsis (Kirkland et al, 1971; Weiss and Biancani, 1983). Although this may offer further evidence that decreased peristaltic activity is a possible etiologic factor in the development of reflux, an alternative interpretation is that the decreased peristaltic activity reflects changes in ureteral or renal function resulting from the reflux. Finally, the success rate of antireflux procedures is lower with poorly functioning dilated ureters, and, although this may be related to technical factors, decreased peristaltic activity may be another reason for failure in many instances.

Studies in normal and mildly refluxing systems have shown that there is a high-pressure zone in the distal ureter, with a resultant pressure gradient across the UVJ (Weiss and Biancani, 1983). Although the cause of the UVJ gradient is not known, the weight of the fluid within the bladder compressing the intravesical ureter may be a factor. Another causative factor may be bladder or trigonal tension involving myogenic or neurohumoral mechanisms. With bladder filling, there is an increase in the amplitude of the high-pressure zone that is greater in nonrefluxing than in refluxing systems. With bladder filling, the resultant UVJ–bladder pressure gradient increases in nonrefluxing systems, whereas it decreases and may disappear in refluxing systems (Fig. 59–25) (Weiss and Biancani, 1983). This decrease in pressure gradient may correspond to the time when reflux occurs and may be related to lateralization of the ureteral orifice and shortening of the intravesical tunnel. More recent studies have shown a decrease in basal and maximum pressures at the UVJ of refluxing ureters that correlated with histologic changes (Arena et al, 2007). The histologic changes included a degree of smooth muscle deterioration and atrophy, an increase in collagen deposition and fewer c-KIT–positive ICC-like cells at the UVJ in patients with vesico-ureteral reflux (Oswald et al, 2004; Schwentner et al, 2005; Arena et al, 2007). Contraction of the longitudinal muscles at the UVJ also may function as an active antireflux mechanism (Schwentner et al, 2005).

Effect of Infection on Ureteral Function

Infection within the upper urinary tract may impair urine transport. Pyelonephritis in the monkey has been associated with decreased peristaltic activity (Roberts, 1975). Furthermore, Rose and Gillenwater (1973) have shown that infection can potentiate the deleterious effects of obstruction on ureteral function. In 1913, Primbs showed that *Escherichia coli* and staphylococcal toxins inhibited contractions of in-vitro guinea pig ureteral segments. A number of studies have confirmed that bacteria and *E. coli* endotoxin can inhibit ureteral activity (Grana et al, 1965; King and Cox, 1972), although these findings have not been universal (Struthers, 1976). Thulesius and Araj (1987) also failed to suppress ureteral activity with *E. coli* endotoxin but noted that growth supernatants from *E. coli*, *Pseudomonas aeruginosa,* and *Klebsiella pneumoniae* inhibited ureteral contractility. These investigators suggested that the inhibition of peristaltic activity is due to an exotoxin.

In humans, irregular peristaltic contractions with often-decreased amplitude have been recorded with infection, and an absence of activity has been noted in the more severe cases (Ross

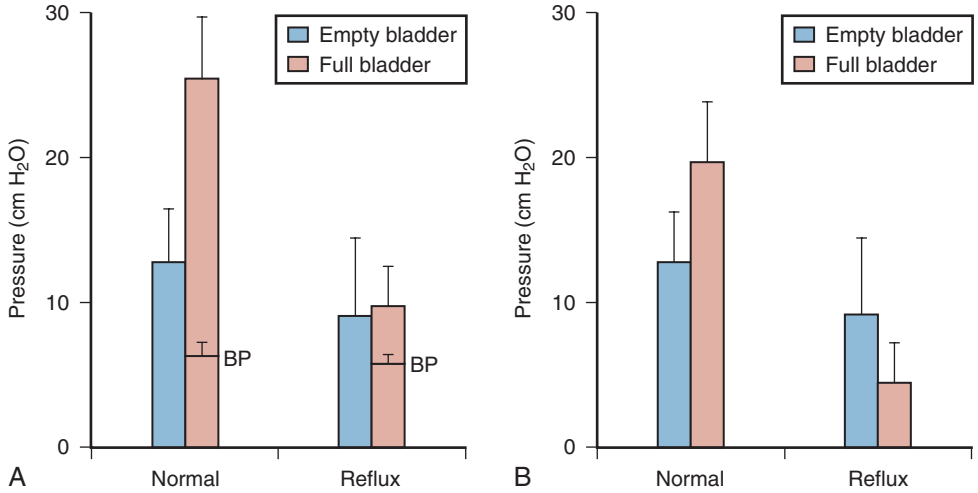

Figure 59–25. **A,** Ureterovesical junction pressures. Bladder pressure is approximately 0 cm H_2O with the bladder empty and is labeled BP with the bladder full. **B,** Pressure gradient across the ureterovesical junction, obtained by subtracting the bladder pressure from the ureterovesical junction pressure. (From Weiss RM, Biancani P. Characteristics of normal and refluxing ureterovesical junctions. J Urol 1983;129:858. Copyright by Williams & Wilkins, 1983.)

et al, 1972). Furthermore, ureteral dilatation has been reported to result from retroperitoneal inflammatory processes secondary to appendicitis, regional enteritis, ulcerative colitis, or peritonitis (Makker et al, 1972). Infection may also reduce the compliance of the intravesical ureter and permit reflux to occur in situations in which the UVJ is intrinsically of marginal competence (Cook and King, 1979).

Effect of Calculi on Ureteral Function

Factors that affect the spontaneous passage of calculi are (1) the size and shape of the stone (Ueno et al, 1977), **(2) intrinsic areas of narrowing within the ureter, (3) ureteral peristalsis, (4) hydrostatic pressure of the column of urine proximal to the calculus** (Sivula and Lehtonen, 1967), **and (5) edema, inflammation, and spasm of the ureter at the site at which the stone is lodged** (Holmlund and Hassler, 1965).

In an attempt to understand the physiologic processes that contribute to or hinder the passage of stones through the ureter, Crowley and associates (1990) created acute ureteral obstruction in the dog with an intraluminal balloon catheter and measured intraluminal ureteral pressures and peristaltic activity above and below the acutely obstructed site. The peristaltic rate and baseline, peak, and delta (peak minus baseline) pressures increased proximal to the site of obstruction. In contrast, the peristaltic rate remained unchanged distal to the obstruction, despite decreases in the baseline, peak, and delta pressures. It was suggested that failure of transmission of effective peristalsis across the site of obstruction may hinder stone passage; however, this remains to be proved. In a more recent study, implantation of an artificial calculus in a rat ureter resulted in an increase in the amplitude of contraction, a decrease in the rate of contractions, and a decrease in baseline pressure (Laird et al, 1997). These changes persisted for a period after spontaneous passage of the calculus. It was suggested that the increased motility caused by a stone contributes to the visceral pain associated with ureteral stone passage.

Two factors that appear to be most useful in facilitating stone passage are an increase in hydrostatic pressure proximal to a calculus and relaxation of the ureter in the region of the stone. In support of the theory that hydrostatic pressure facilitates stone passage, artificial concretions with holes were shown to move more slowly in the rabbit and dog ureter than those without holes (Sivula and Lehtonen, 1967). Furthermore, ureteral ligation proximal to a concretion, which decreases hydrostatic pressure by decreasing urine output and decreases peristaltic activity proximal to a stone, hampers stone passage (Sivula and Lehtonen, 1967).

With respect to the potential facilitative effect of ureteral relaxation on stone passage, the spasmolytic agents phentolamine (an α-adrenergic antagonist), and orciprenaline and isoproterenol (β-adrenergic agonists), have been shown to dilate the ureteral lumen or decrease ureteral wall tension at the level of an artificial concretion and thus permit increased fluid flow beyond the concretion (Peters and Eckstein, 1975; Miyatake et al, 2001). In a human study, renal colic was relieved by meperidine in 83% of patients, by phentolamine in 63%, and by propranolol, a β-adrenergic antagonist that presumably would interfere with the β-adrenergic inhibitory actions of catecholamines, in 0% (Kubacz and Catchpole, 1972). These data suggest that drugs with spasmolytic effects on the ureter may relieve renal colic, whereas those with spasmogenic actions do not.

Pharmacologic data can be interpreted to imply that ureteral relaxation in the region of a concretion could aid in stone passage. Agents such as theophylline (Weiss et al, 1977; Green et al, 1987), with strong relaxant effects on the ureter have potential value in facilitating stone passage. In a rabbit in-vivo model, rolipram, a cAMP-specific phosphodiesterase (PDE) inhibitor (PDE 4 inhibitor), caused a more marked ureteral relaxation than did the nonspecific PDE inhibitors papaverine and theophylline, and without the circulatory side effects seen with the nonspecific PDE inhibitors (Becker et al, 1998). Because the relaxant effect of rolipram was similar in human and rabbit in-vitro ureteral segments, it was suggested that rolipram could potentially be beneficial in the treatment of renal colic and in the facilitation of stone passage (Becker et al, 1998). Rolipram also has been shown to relax pig intravesical ureteral segments (Hernández et al, 2004). In addition to the PDE 4 inhibitor rolipram, PDE 5 inhibitors (cGMP-specific PDE inhibitor) relax in-vitro human ureteral segments (Kuhn et al, 2000). The relaxant effects of the PDE

4 and PDE 5 inhibitors were paralleled by an increase in cAMP and cGMP, respectively. Gratzke and coworkers (2007) showed that PDE 5 inhibitors reversed KCl-induced increases in tension of isolated human ureteral segments, with a rank order of efficacy of vardenafil (Levitra) > sildenafil (Viagra) > tadalafil (Cialis). Species differences in PDE subtypes may exist. Although the nonspecific PDE inhibitor papaverine decreased the frequency of ureteral peristalsis in the pig, the PDE 4 inhibitor rolipram had no effect (Danuser et al, 2001).

A combination of the calcium channel blocker nifedipine, which causes ureteral relaxation, and the corticosteroid deflazacort, which reduces edema, was shown to facilitate spontaneous passage of 1-cm or smaller distal ureteral stones (Borghi et al, 1994; Porpiglia et al, 2000). Spontaneous expulsion of 79% of stones (average size 5.8 ± 1.8 mm) occurred in an average of 7 days in patients treated with nifedipine and deflazacort, compared with spontaneous passage of 35% of stones (average size 5.5 ± 1.4 mm) within an average of 20 days in untreated patients (Porpiglia et al, 2000). In a subsequent study, this same group showed that both nifedipine and the α-adrenergic antagonist tamsulosin, when combined with deflazacort, increased the rate of spontaneous passage of lower ureteral calculi, and in addition, tamsulosin, a selective $\alpha_{1A/1D}$-adrenergic receptor antagonist, reduced the time to spontaneous expulsion (Porpiglia et al, 2004, 2006). They showed that tamsulosin alone was effective in facilitating expulsion of distal ureteral stones, and that this effect was potentiated by steroids. Steroids alone were ineffective. α_1-Adrenergic receptors are present throughout the human ureter, with the greatest quantity of α_1-adrenergic receptors being in the distal ureter (Sigala et al, 2004, 2005). α_{1D} mRNA was expressed throughout the human ureter, with significantly greater amounts than the α_{1A}- and α_{1B}-receptor subtypes in the proximal and distal ureter. $\alpha_{1A/1D}$-adrenergic receptors are present in the distal ureter. A number of other studies have noted an increased spontaneous stone expulsion rate and expulsion rate after extracorporeal shock wave lithotripsy (ESWL), a decrease in renal colic, and an improved tolerance of ureteral stents with the administration of tamsulosin and other α-adrenergic antagonists (Cervenakov et al, 2002; Dellabella et al, 2003; Kupeli et al, 2004; Autorino et al, 2005; Gravina et al, 2005; Resim et al, 2005; Yilmaz et al, 2005; De Sio et al, 2006; Gravas et al, 2007; Liatsikos et al, 2007; Damiano et al, 2008; Losek and Mauro, 2008). Although most of the studies address the efficacy of tamsulosin in facilitating stone passage, Yilmaz and associates (2005) reported that doxazosin and terazosin were equally effective in facilitating stone passage. Dellabella and colleagues (2005) reported that tamsulosin was more effective than the calcium channel blocker nifedipine in facilitating stone expulsion.

Effect of Diabetes on Ureteral Function

In cases of diabetes, changes in bladder function affect the ureter. Additionally, there is some evidence of a direct effect of diabetes on the ureter. The length and velocity of movement of the urinary bolus is decreased in the streptozotocin (STZ) diabetic rat (Watanabe and Miyagawa, 2002). Although the frequency of contractions of in-vitro segments of the renal pelvis and ureter of STZ-induced diabetic rats are unchanged, the amplitude of contractions are increased in comparison with renal pelvic and ureteral segments from control sucrose-induced diuretic rats (Davidson and Lang, 2007). Capsaicin is known to release tachykinins from sensory nerves, and it is postulated that a supersensitivity of the upper urinary tract of STZ-induced diabetic rats to the sensory neurotoxin capsaicin, and to the sensory excitatory neuropeptides substance P and neurokinin A, results from a sensory neuropathy (Davidson and Lang, 2007).

EFFECT OF AGE ON URETERAL FUNCTION

Clinically, the response of the ureter to pathologic conditions varies with age. **More marked degrees of ureteral dilatation are observed in the neonate and young child than in the adult.** Experimental data corroborating this clinical impression can be derived from observed age-dependent differences in the response of in-vitro ureteral segments to an intraluminal pressure load. The neonatal rabbit ureter undergoes a greater degree of deformation in response to an applied intraluminal pressure than does the adult rabbit ureter (Akimoto et al, 1977). Furthermore, norepinephrine decreases the diametral deformation of the neonatal rabbit ureter in response to an applied intraluminal pressure but has little effect on the deformation of the adult rabbit ureter (Fig. 59–26). Thus the in-vitro neonatal rabbit ureter appears to be more compliant and more sensitive to norepinephrine than the adult rabbit ureter.

Age also affects the response of the ureter to β-adrenergic agonists; with aging, there is a decrease in the relaxant response to the β-adrenergic agonist isoproterenol (Wheeler et al, 1990). The relaxant response to β-adrenergic agonists is related, in part, to cAMP levels. It has been shown that with aging there is a decrease in the enzymatic activities involved in the synthesis of cAMP (Wheeler et al, 1986) but no change in the enzymatic activities involved in cAMP degradation (Cho et al, 1988). These data suggest that the decrease in the ability of isoproterenol to relax the ureter with aging is due to a decrease in the ability of isoproterenol to activate adenylyl cyclase, the enzyme involved in cAMP synthesis. Developmental differences in the response of the ureter to metabolic inhibitors are evident, with cyanide causing a larger decrease in force in the adult than in the neonatal guinea pig ureter (Bullock and Wray, 1998a, 1998b).

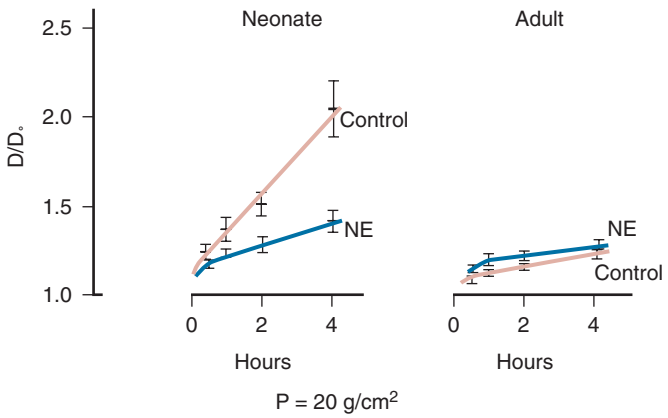

Figure 59–26. Changes in diameter of neonatal and adult rabbit ureteral segments as a function of time after the application of a constant intraluminal pressure (P) of 20 g/cm^2. Diametral deformation (D/D_0) of control neonatal ureters was significantly greater than that of control adult ureters. Norepinephrine (NE) (10^{-5} M) decreased the diametral deformation of the neonatal ureters but had no significant effect on the deformation of the adult ureteral segments. D_0, initial diameter; D, diameter during deformation; P, pressure. (From Akimoto M, Biancani P, Weiss RM. Comparative pressure = length – diameter relationships of neonatal and adult rabbit ureters. Invest Urol 1977;14:297.)

A progressive increase in ureteral cross-sectional muscle area is observed in the guinea pig between 3 weeks and 3 years of age. This is in accord with the findings of Cussen (1967), who noted in a human autopsy study (subjects ranging in age from 12 weeks of gestation to 12 years of age) that there is a progressive increase in the population of smooth muscle cells and a small increase in the overall size of the individual smooth muscle cells. In addition, an irregular increase in the number of elastic fibers was observed with increasing age.

The contractility of the ureter is also affected by age. The maximal active force of isolated guinea pig ureteral segments increases between 3 weeks and 3 years of age (Fig. 59–27) (Hong et al, 1980). The increase in force developed between 3 weeks and 3 months of age seems to be attributable to an increase in contractility, because there is an associated increase in active stress (force per unit area of muscle). The increase in force developed between 3 months and 3 years of age can be explained by an increase in muscle mass alone because there is no change in active stress between these two age groups (see Fig. 59–27).

Although changes in the force-length relations of guinea pig ureter occur with age, the force-velocity relations do not change with age (Biancani et al, 1984). Thus although ureteral contractility increases during early development, as shown by an increase in force per unit area of muscle, or stress, no significant change is apparent in the rate of the driving reactions that control the contractile process, that is, no change in shortening, velocity, work, or power.

EFFECT OF PREGNANCY ON URETERAL FUNCTION

Hydroureteronephrosis of pregnancy begins in the second trimester of gestation and subsides within the first month after parturition. It is more severe on the right side, and the ureteral dilatation does not occur below the pelvic brim. Roberts (1976) has presented a strong case in favor of obstruction as the etiologic factor in the development of hydroureteronephrosis of pregnancy, whereas other investigators have suggested a hormonal mechanism for the ureteral dilatation of pregnancy (van Wagenen and Jenkins, 1939).

Roberts (1976) emphasized the following: (1) Elevated baseline (resting) ureteral pressures consistent with obstructive changes have been recorded above the pelvic brim in pregnant women, and these pressures decrease when positional changes permit the uterus to fall away from the ureters (Sala and Rubi, 1967). (2) Normal ureteral contractile pressures recorded during pregnancy suggest that hormonally induced ureteral atony is not the prime factor in ureteral dilatation of pregnancy. (3) Women whose ureters do not cross the pelvic brim (i.e., those with pelvic kidneys or ileal conduits) do not develop hydronephrosis of pregnancy. (4) Hydronephrosis of pregnancy usually does not occur in quadrupeds, whose uterus hangs away from the ureters (Traut and Kuder, 1938). (5) Elevated ureteral pressures in the pregnant monkey return to normal when the uterus is elevated from the ureters at laparotomy or when the fetus and placenta are removed from the uterus.

Observed hormonal effects on ureteral function have been used to implicate a hormonal mechanism in the ureteral dilatation of pregnancy, although difficulties in interpretation arise from inconsistencies in the data. Several studies have shown an inhibitory effect of **progesterone** on ureteral function (Kumar, 1962). Progesterone has been noted to increase the degree of ureteral dilatation during pregnancy and to retard the rate of disappearance of hydroureter in postpartum women (Lubin et al, 1941). Other studies, however, have failed to demonstrate an effect of progesterone on ureteral activity in animals (McNellis and Sherline, 1967) or in humans (Lapides, 1948), and still others have failed to induce changes in ureteral activity in women through the

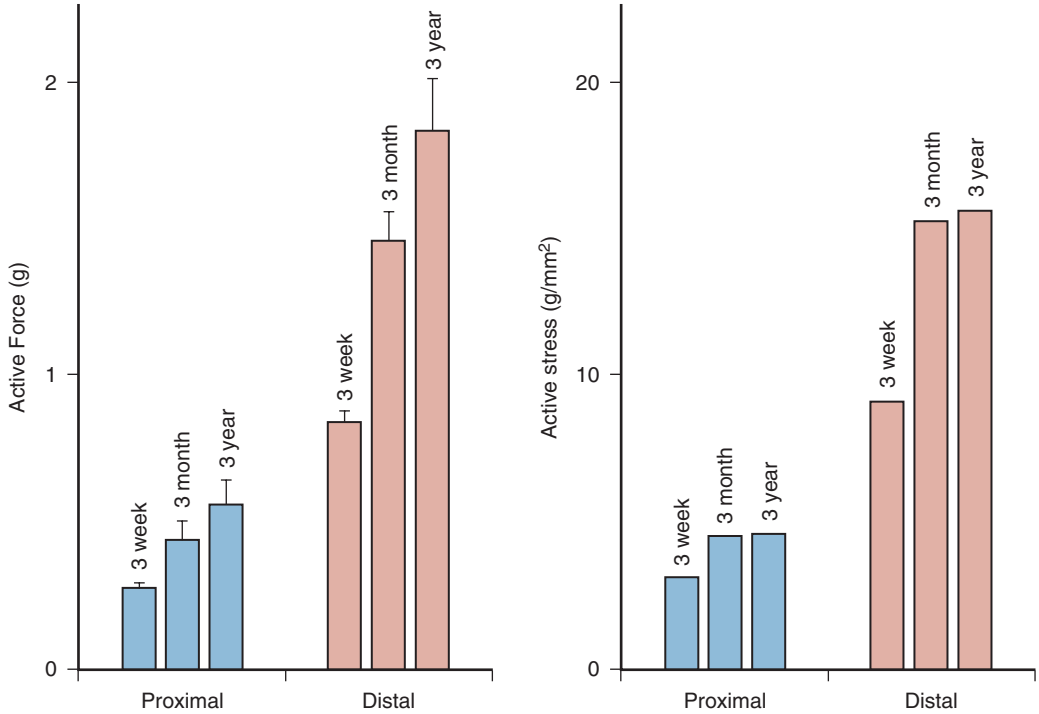

Figure 59–27. Maximal active (contractile) force and maximal active stress of proximal and distal guinea pig ureteral segments as a function of age.

administration of estrogens, progesterone, or a mixture of these drugs (Marchant, 1972; Clayton and Roberts, 1973). Although some workers have noted that estrogens increase ureteral activity (Hundley et al, 1942), the majority of investigators have failed to observe an effect of estrogens in animal models (Abramson et al, 1953) or in humans (Kumar, 1962). Thus **obstruction appears to be the primary factor in the development of hydronephrosis of pregnancy**, although some evidence suggests that a combination of hormonal and obstructive factors is involved (Fainstat, 1963).

EFFECT OF DRUGS ON THE URETER

This section provides an assessment of the effects of the major classes of drugs on ureteral function. Many of the studies referred to were performed in animal models, and extrapolation of the data to the intact human ureter is often difficult. In the clinical situation, the relatively sparse blood supply to the ureter limits the distribution of drugs to the ureter, and the pharmacokinetics is quite different in the laboratory than in the clinic. In addition, many drugs with potential usefulness in the management of ureteral abnormalities have potential untoward side effects when used in concentrations required to affect the ureter.

To assess the effect of drugs on the ureter, it is necessary to understand the anatomic, physiologic, and biochemical properties of the ureter, in addition to understanding the principles of drug action. For a drug to elicit a given response, it is necessary to achieve and maintain an appropriate concentration of that drug at its site of action. Factors that can influence the achievement of an effective concentration of drug at a site of action are (1) the route of administration and cellular distribution of the drug; (2) the dosage of the drug administered; (3) the biotransformation, including metabolism and excretion, of the drug; (4) the binding of the drug to plasma and tissue proteins; and (5) the effects of age and disease on the absorption, distribution, metabolism, and elimination of the drug.

The literature contains considerable confusing and conflicting information concerning the effects of drugs on the ureter. To some extent, the discrepancies in the available data are due to poorly controlled experimental procedures or to attempts to compare dissimilar functional responses of the ureter with a given drug. To simplify the present section, no attempt is made to analyze the validity of each pharmacologic study or to rationalize discrepancies in the literature; rather, an overview is presented with an attempt to provide a consensus that, at times, may be prejudiced by personal bias. Furthermore, discussion of drugs related to the nervous system, pregnancy, and a variety of pathologic states is included in earlier sections of this chapter.

Histamine and Its Antagonists

Histamine has a dual action on smooth muscle; it may (1) release catecholamines from sympathetic nerve endings or (2) act directly on receptors within the smooth muscle. In addition, **histamine may have excitatory or inhibitory effects on ureteral function**. The majority of studies have shown an excitatory effect of histamine on ureteral function (Borgstedt et al, 1962; Sharkey et al, 1965; Vereecken, 1973; Benedito et al, 1991; Smita et al, 2006), a finding that may be species dependent (Tindall, 1972). **Histamine's excitatory effect on the ureter and UVJ appears to be mediated by H_1 receptors** because they are inhibited by the H_1-receptor antagonists mepyramine, pheniramine, and dimethindene but not by the H_2-receptor antagonists cimetidine and ranitidine (Benedito et al, 1991; Dodel et al, 1996; Smita et al, 2006). An H_1 agonist, 2-(2-pyridyl)ethylamine, increases ureteral contractility (Dodel et al, 1996). The H_1 inhibitor pheniramine has no effect on spontaneous activity of isolated goat ureter (Smita et al, 2006). The excitatory effect of histamine on the sheep UVJ is partially blocked by scopolamine, suggesting an indirect stimulatory action of histamine on intramural parasympathetic nerves. H_1 histamine receptors are expressed in the smooth muscle and urothelium of the human ureter (Floyd et al, 2008). The antihistamines diphenhydramine (Benadryl) and tripelennamine have been shown to inhibit the effects of histamine on the ureter (Borgstedt et al, 1962; Sharkey et al, 1965). **The H_2 receptor mediates inhibitory effects of histamine**. Histamine and the H_2-receptor agonist impromidine relax precontracted ureteral segments, actions that are inhibited by the H_2-receptor antagonist cimetidine (Dodel et al, 1996).

Serotonin

Serotonin (5-hydroxytryptamine [5-HT]) has been reported to stimulate (Vereecken, 1973; Dodel et al, 1996; Hauser et al, 2002; Hernández et al, 2003), inhibit (Mazzella and Schroeder, 1960), or have no effect (Finberg and Peart, 1970) on a variety of ureteral preparations. In the pig ureter, the contractile effects appear to be mediated by 5-HT_2 receptors (Hauser et al, 2002; Hernández et al, 2003). Gidener et al (1999) showed that 5-hydroxytryptamine induces concentration-dependent contractions of isolated human ureteral segments. However, their studies suggested no involvement of 5-HT_2 receptors in the contractile effects of 5-hydroxytryptamine. Tetrodotoxin, guanethidine, and phentolamine had an inhibitory effect on 5-HT–induced contractions of pig isolated intravesical ureteral segments, suggesting that part of the contractile effects of 5-HT are indirectly mediated through release of norepinephrine from sympathetic nerves (Hernández et al, 2003).

Kinins

The kininskallidin, eledoisin, and bradykinin increase the frequency of contraction and baseline intraluminal pressure of the dog ureter (Boyarsky et al, 1966a, b; Labay and Boyarsky, 1966), and bradykinin decreases the contractile force of the sheep ureter (Kaygisiz et al, 1995).

Angiotensin

Angiotensin has a stimulatory effect on the ureter. Angiotensin II (ANG II) and mRNA for angiotensinogen, a principal precursor of ANG II, renin, angiotensin-converting enzyme (ACE), and type I angiotensin receptor are expressed in the human ureter (Santis et al, 2003). Losartin, an ANG II-receptor antagonist, decreases the amplitude and frequency of spontaneous contractions of human ureteral segments. ANG II induces phasic contractions of rat ureteral segments, an effect that is inhibited by losartin (Fujinaka et al, 2000). The ANG II type I receptor also is expressed in the rat ureter (Paxton et al, 1993).

Narcotic Analgesics

Morphine has been reported to increase ureteral tone or the frequency and amplitude of ureteral contractions or both in a variety of experimental preparations and in humans (Macht, 1916b; Gruber, 1928; Ockerblad et al, 1935; Vereecken, 1973). Others,

however, have failed to observe an effect of morphine on ureteral function (Gould et al, 1955; Kiil, 1957; Weinberg and Maletta, 1961; Ross et al, 1967).

Meperidine (Demerol) appears to have a similar excitatory effect on the activity of the intact dog ureter (Sharkey et al, 1968). Kiil (1957), however, failed to observe an effect of meperidine on ureteral peristalsis in humans. **If one considers only the effects on ureteral activity, there is no basis to preferentially favor morphine or meperidine in the treatment of renal colic. Both agents may have ureteral spasmogenic effects that theoretically would detract from their value in the management of ureteral colic. They certainly do not have potentially valuable spasmolytic actions. Their efficacy in treating colic depends on their central nervous system (CNS) actions, which decrease the perception of pain.**

Prostaglandins

Prostaglandins are derived from fatty acids and have a variety of biologic actions in various systems of the body. Their effects vary with the species, type of prostaglandin, endocrine status of the tissue, experimental conditions, and origin of the smooth muscle. **The "primary" prostaglandins (PGs), PGE_1, PGE_2, and $PGF_{2\alpha}$, are synthesized from the fatty acid arachidonic acid by enzymatic reactions involving two cyclooxygenase (COX) isoforms, COX-1 and COX-2** (Vane, 1998). In most tissues, COX-1 is constitutively expressed and is involved in the regulation of normal physiologic processes, whereas COX-2 is induced in response to processes such as inflammation and mitogenesis (Mitchell and Warner, 1999). **These enzymatic reactions can be inhibited by indomethacin and aspirin, and by a number of COX-1 and COX-2 inhibitors.** COX-1 and COX-2 receptors have been identified in the human ureter (Chaignat et al, 2008).

Indomethacin has been employed in the management of ureteral colic (Holmlund and Sjöden, 1978; Flannigan et al, 1983; Jönsson et al, 1987). The beneficial effects probably are due to indomethacin's inhibition of the prostaglandin-mediated vasodilatation that occurs subsequent to obstruction (Allen et al, 1978; Sjöden et al, 1982). The vasodilatation theoretically would result in an increase in glomerular capillary pressure and a subsequent increase in pelviureteral pressure. Indomethacin, by reducing pelviureteral pressure and thus pelviureteral wall tension, might eliminate some of the pain of renal colic that is dependent on distention of the upper urinary tract. An upregulation of COX-2 mRNA and protein with obstruction supports the potential use of selective COX-2 inhibitors in the treatment of obstructive ureteral disease (Nakada et al, 2002). **A potential problem with the use of indomethacin for the treatment of renal colic is that prostaglandin-mediated vasodilatation aids in preserving renal function; thus, indomethacin may provide pain relief, but it may be potentially deleterious to renal function** (Perlmutter et al, 1993; Kristova et al, 2000).

PGE_1 inhibits the activity of the dog (Boyarsky et al, 1966b; Wooster, 1971; Abrams and Feneley, 1976) and guinea pig ureter (Vermue and Den Hertog, 1987). PGE_1 inhibition of ureteral activity in the guinea pig is associated with an increase in cAMP levels (Vermue and Den Hertog, 1987). In the ureter, PGE_1 activates adenylyl cyclase, and this may account for the increase in cAMP (Wheeler et al, 1986). Johns and Wooster (1975) suggested that the inhibitory effects of PGE_1 on ureteral activity depended on the sequestration of Ca^{2+} at the inner surface of the cell membrane, with a resultant increase in outward K^+ conductance and hyperpolarization of the membrane. Although reports have indicated that PGE_2 relaxes the ureter (Vermue and Den Hertog, 1987), other reports describe an excitatory action of PGE_2 on sheep (Thulesius and Angelo-Khattar, 1985) and human (Angelo-Khattar et al, 1985; Cole et al, 1988) ureters and on renal pelvic smooth muscle (Lundstam et al, 1985). PGE_2 increases the contractility of chronically obstructed human ureters, and although it relaxed normal porcine ureter, it increased the contractility of acutely obstructed porcine ureters (Ankem et al, 2005; Lowry et al, 2005). In contrast to the inhibitory effects of PGE_1, PGE_2 increases the frequency of ureteral peristalsis in the dog (Boyarsky and Labay, 1969). In human ureteral preparations PGE_1 and PGE_2 have been shown to decrease spontaneous contractions, whereas PGF_{2a} increased ureteral contractility (Abrams and Feneley, 1976). In human renal pelvis and ureter there is a higher concentration of $PGF_{2\alpha}$ than PGE_2 (Zwergel et al, 1991). $PGF_{2\alpha}$ increased contractility of porcine ureteral segments (Ankem et al, 2005). The prostanoid PGI_2 is synthesized in the urothelium of the ureter (Ali et al, 1998). COX inhibitors such as indomethacin have been shown to inhibit the activity of rat (Davidson and Lang, 2000), guinea pig (Davidson and Lang, 2000), sheep (Thulesius and Angelo-Khattar, 1985), and human ureters (Angelo-Khattar et al, 1985; Cole et al, 1988) and renal pelvic smooth muscle (Lundstam et al, 1985; Zhang and Lang, 1994; Santicioli et al, 1995a; Davidson and Lang, 2000). The nonspecific COX inhibitor diclofenac and the selective COX-2 inhibitors NS-398 and celecoxib have been shown to be equipotent in inhibiting agonist-induced contractions of isolated pig and human ureter (Mastrangelo et al, 2000; Nakada et al, 2000), and diclofenac also has been shown to relax human ureteral segments that were precontracted with KCl (Sivrikaya et al, 2003). The COX-2 selective inhibitor celecoxib, and indomethacin, inhibited porcine ureteral contractility and TNF-α–induced prostanoid release (Jerde et al, 2005). Diclofenac, but not the COX-2 selective inhibitor valdecoxib, decreased the contractile amplitude of electrically stimulated in-vitro human ureteral segments and valdecoxib decreased the contractility of nonobstructed, but not obstructed, ureters of the pig in vivo (Chaignat et al, 2008). Species differences may exist, with COX-2 being the primary enzyme involved in synthesizing PGs in the guinea pig upper urinary tract, and COX-1 being the primary enzyme involved in PG synthesis in the rat upper urinary tract (Davidson and Lang, 2000).

Chronic obstruction upregulates COX-2 activity in the human ureter (Nakada et al, 2002). Upon stretching of the porcine ureter, there is COX-2 induction in both the urothelial and smooth muscle layers of the porcine ureter, with a more significant induction in the urothelium (Jerde et al, 2006). In the normal rat ureter COX-1, but not COX-2, mRNA was detected, and following obstruction, there was an increase in COX-2 mRNA and protein expression but no change in COX-1 expression (Norregaard et al, 2006). In addition to an increased synthesis of prostanoids with obstruction, there is a decrease in prostanoid degradation contributing to the increase in prostanoids with obstruction. 15-Hydroxyprostaglandin dehydrogenase (PGDH), the enzyme responsible for prostaglandin degradation is suppressed in the human ureter with obstruction (Jerde et al, 2004). The dilated ureter following obstruction has an increase expression of COX-2, PGE_2, $TGF\beta_1$, α-smooth muscle actin (α-SMA), fibrosis, apoptotic cells, and proliferation cell nuclear antigen (PCNA) (Chuang et al, 2007). The administration of the COX-2 selective inhibitor celecoxib abolished the expression of COX-2 and PGE_2, decreased the expression of TGF-β_1 and α-SMA, and decreased apoptotic cells

and fibrosis but increased the expression of PCNA in the smooth muscle in the dilated obstructed ureter (Chuang et al, 2007). These investigators concluded that the COX-2 inhibitor might ameliorate, in part by inhibition of COX-2 and TGF-β_1 expression, ureteral damage resulting from obstruction.

Cardiac Glycosides

Ouabain, a cardiac glycoside, has an effect on ureteral activity that appears to be species dependent. In the isolated cat ureter, ouabain produces a marked increase in contractility, which usually is followed by a late decrease in excitability (Weiss et al, 1970). In the guinea pig ureter, ouabain inhibits activity without a preliminary potentiation of contractility (Washizu, 1968; Hendrickx et al, 1975). The inhibitory effects of ouabain are accompanied by a shortening of the action potential duration, a decrease of the number of oscillations on the plateau of the guinea pig action potential, and a decrease in the RMP.

Calcium Antagonists

Because Ca^{2+} is necessary for the development of the action potential and contraction of the ureter, agents that block the movement of Ca^{2+} into the cell would be expected to depress ureteral function. Voltage-dependent Ca^{2+} channel antagonist binding sites (receptors) have been demonstrated in the ureter, and their density decreases with age (Yoshida et al, 1992). These dihydropyridine-sensitive, **L-type, voltage-dependent Ca^{2+} channels appear to provide the main inward current for generation of the ureteral action potential and the phasic contractile response** (Shuba, 1977; Brading et al, 1983; Aickin et al, 1984; Imaizumi et al, 1989; Lang, 1989). Potassium-induced ureteral contractions depend on the inward movement of Ca^{2+} through L-type voltage-dependent Ca^{2+} channels (Maggi and Giuliani, 1995). The dihydropyridine Ca^{2+} channel agonist Bay K 8644 has an excitatory effect on ureteral activity (Maggi et al, 1994a; Floyd et al, 2008) and potentiates K^+-induced contractions. The Ca^{2+} channel blockers verapamil, D-600 (a methoxy derivative of verapamil), diltiazem, and nifedipine have been shown to inhibit ureteral activity (Golenhofen and Lammel, 1972; Vereecken et al, 1975; Hertle and Nawrath, 1984; Hong et al, 1985; Sakanashi et al, 1985, 1986; Maggi et al, 1994a; Davenport et al, 2006). These inhibitory effects are accompanied by decreases in the duration of the action potential, the number of oscillations on the plateau of the guinea pig action potential, excitability, and the rate of rise and amplitude of the action potential. High concentrations of verapamil and D-600 cause a complete cessation of electric and mechanical activity.

Potassium Channel Openers

Potassium channel openers such as cromakalim, nicorandil, BRL 38227, and PFK217-744b hyperpolarize smooth muscle membranes and **inhibit renal pelvic and ureteral activity** (Kontani et al, 1993; Maggi et al, 1994c; Weiss et al, 2002; Smita et al, 2006; Floyd et al, 2008). Glibenclamide, a blocker of K^+/ATP channels had no effect on contractility (De Moura and De Lemos Neto, 1996). The inhibitory effects of cromakalim and nicorandil are prevented by glibenclamide, providing evidence that ATP-sensitive K^+ channels are involved in these processes (Maggi et al, 1994c; Smita et al, 2006). Activation of these K^+ channels may reduce the probability of the opening of voltage-sensitive Ca^{2+} channels, inhibit agonist-induced increases in inositol 1,4,5-trisphosphate, or reduce Ca^{2+} sensitivity of contractile elements processes that are important in the generation of the ureteral action potential and the contractile response (Cook and Quast, 1990; Quayle et al, 1997).

The tricyclic antidepressant amitriptyline (Elavil) has been shown to relax isolated pig and human ureteral strips by opening potassium channels (Achar et al, 2003). This relaxation response is inhibited by 4-aminopyridine (4-AP), a voltage-dependent K^+ channel blocker. Nicorandil, a K^+ channel opener and nitric oxide (NO) donor, stimulates guanylyl cyclase activity with formation of cyclic GMP and hyperpolarizes the smooth muscle with resultant relaxation of rabbit, guinea pig, and human ureter (Klaus et al, 1989, 1990; Weiss et al, 2002). The relaxant effects of nicorandil can be inhibited by both the K_{ATP} antagonist glibenclamide and the guanylyl cyclase inhibitor methylene blue (Weiss et al, 2002).

Endothelins

Endothelins are potent vasoconstrictor peptides that exist in three isoforms: ET-1, ET-2, and ET-3. These peptides interact with their specific receptors: ET_A, ET_B, and ET_C. Endothelin binding sites (receptors) have been identified in the ureter and renal pelvis (Eguchi et al, 1991; Latifpour et al, 1995; Wada et al, 2001), where they are primarily of the ET_A subtype (Latifpour et al, 1995; Wada et al, 2001). Diabetes results in upregulation of the expression of ureteral endothelin receptors (Nakamura et al, 1997). Endothelins have been shown to initiate contractions in isolated guinea pig and porcine ureters (Eguchi et al, 1991; Maggi et al, 1992a) and increase the contractile force of renal pelvis smooth muscle (Wada et al, 2001).

Antibiotics

Ampicillin causes relaxation of the ureter and antagonizes the stimulatory effects of barium chloride ($BaCl_2$), histamine, serotonin, and carbachol on the ureter, thus suggesting that its action is directly on the smooth muscle (Benzi et al, 1970b). Chloramphenicol, the isoxazolyl penicillins, and gentamicin also have spasmolytic effects on the ureter (Benzi et al, 1970a, 1971, 1973). The tetracyclines, on the other hand, potentiate the contractile effects of $BaCl_2$ on the ureter (Benzi et al, 1973).

Mechanisms of Detrusor Overactivity
Summary
Future Research

The medical, social, and economical impact of urinary incontinence, overactive bladder, and voiding dysfunction is staggering (Yoshimura and Chancellor, 2002). In the United States, there are an estimated 34 million community-dwelling men and women with an overactive bladder (Hu et al, 2004). It costs an estimated $19.5 billion and $12.6 billion a year in the United States to manage urinary incontinence and the overactive bladder, respectively (Hu et al, 2003; Hu et al, 2004). With the continued aging of the populations in all developed countries, the problems associated with bladder control will certainly continue to increase. In this chapter, we review the neuromuscular physiology and pathophysiology of the bladder and urethra. We will discuss what is new in pharmacology that may better help our patients with voiding dysfunction. Finally, we will speculate about future treatment methods to conquer urinary incontinence.

The micturition process can be visualized as a complex of neural circuits in the brain and spinal cord that coordinate the activity of smooth muscle in the bladder and urethra (Torrens and Morrison, 1987; de Groat et al, 1993a; Yoshimura and de Groat, 1997). **These circuits act as on-off switches to alternate the lower urinary tract between two modes of operation: storage and elimination.**

Injuries or diseases of the nervous system in adults can disrupt the voluntary control of micturition, causing the reemergence of reflex micturition and resulting in detrusor overactivity and urgency incontinence (Fig. 60–1) (Torrens and Morrison, 1987; Wein, 1992; de Groat et al, 1993a; Yoshimura and de Groat, 1997). Because of the complexity of the central nervous control of the lower urinary tract, urgency incontinence can result from a variety of neurologic disorders. In addition, urgency incontinence may be due to intrinsic detrusor myogenic abnormalities, resulting in detrusor overactivity (Brading, 1997b). The morphology and function of the detrusor wall are reviewed, including new insights into the urothelium.

Urethral dysfunction can also be an important cause of urinary incontinence in both women and men. Many health care professionals who are not trained in urology erroneously believe that urethral dysfunction can cause only genuine stress urinary incontinence. This is not true. Urethral dysfunction can also cause urgency incontinence. Increased bladder outlet urethral resistance in men with benign prostatic hyperplasia and in younger men and women with detrusor-sphincter dyssynergia (e.g., spinal cord injury, multiple sclerosis) causes secondary bladder changes. Increased bladder outlet resistance causes secondary bladder remodeling and can result in urgency incontinence. In addition, it can be speculated that in patients with mixed stress and urgency incontinence, stress incontinence can cause urgency incontinence. Leakage of urine into the urethra (stress incontinence) may stimulate urethral afferents that induce an involuntary voiding reflex (urgency incontinence).

This chapter reviews studies in humans and animals that provide insights into

- organization of neural pathways controlling the lower urinary tract;
- neurotransmitters involved in storage and voiding reflexes;
- function of the detrusor wall, including urothelium and smooth muscle;
- contribution of the smooth and skeletal muscle urethral function and interaction of urethra with bladder function;
- action of drugs on the bladder; and
- mechanisms that contribute to overactive bladder.

Speculation about what the future holds in terms of research and treatment of lower urinary tract dysfunction ends the chapter. With the mapping of the human genome now completed, we believe that we are on the verge of a paradigm shift in clinical medicine. The future will bring molecular medicine into the hands of the practicing urologists.

RELEVANT ANATOMY AND BIOMECHANICS

General Concepts

The bladder can be divided into two parts: a **body** lying above the ureteral orifices and a **base** consisting of the trigone and bladder neck, because the two areas are different but homogeneous within themselves regarding neuromorphology and

neuropharmacology (Elbadawi and Schenk, 1966). Histologic examination of the bladder body reveals that myofibrils are arranged into fascicles in random directions (Donker et al, 1982). This architecture differs from the discrete circular and longitudinal smooth muscle layers in the ureter or gastrointestinal tract.

The bladder outlet is composed of the bladder base, urethra, and external urethral sphincter (Fig. 60–2). The bladder base has a laminar architecture with a superficial longitudinal layer lying beneath the trigone. A muscle layer deep to the superficial layer is continuous with the detrusor (Tanagho, 1982; Dixon and Gosling, 1987; Zderic et al, 1996). The smaller muscle bundles of the deep muscle layer in the bladder base exhibit a predominantly circular orientation.

The urethra begins at the internal meatus of the bladder and extends to the external meatus. In the male, four segments are readily identified. The first is the preprostatic portion, or the bladder neck. The prostatic urethra then extends throughout the length of the gland, terminating at its apex. The membranous urethra extends from the prostatic apex through the pelvic floor musculature until it becomes the bulbous and penile urethra (fourth segment) at the base of the penis. In women, the urethra extends throughout the distal third of the anterior vaginal wall from the bladder neck to the meatus. **The urethra is composed of tissues that aid continence rather than a single discrete and visible "sphincter." A network of vascular subepithelial tissue in women contributes to a urethral seal effect.**

It is debatable whether the detrusor or trigone muscles project into the proximal urethra (see Fig. 60–2). Embryologic data support the concept of a separate origin for muscles of the bladder and urethra (Dixon and Gosling, 1987; Zderic et al, 1996). Histologic studies show that the longitudinal muscle of the bladder base extends distally into the urethra to form an inner longitudinal layer (Hutch and Rambo, 1967; Tanagho, 1982). Examination of adult and fetal specimens shows that striated and smooth muscles coalesce in the urethra and interdigitate with the fibrous prostatic capsule (Oelrich, 1980). Conversely, a complete and competent ring of smooth muscle at the male bladder neck has been described (Gosling, 1999). No such collar of muscle is identified in the female. The maintenance of continence in men and some women with destruction or opening of the bladder neck argues that the bladder neck may not be the principal site of urinary continence (Chapple et al, 1989). **The importance of the bladder neck as the principal zone of maintaining continence remains controversial.**

The bladder neck serves an important function in reproduction. **In men, closure of the bladder neck facilitates antegrade ejaculation. This is accompanied through a rich noradrenergic innervation by sympathetic nerves that actively contract the bladder neck during ejaculation**. However, **in women, the density of adrenergic innervation in the**

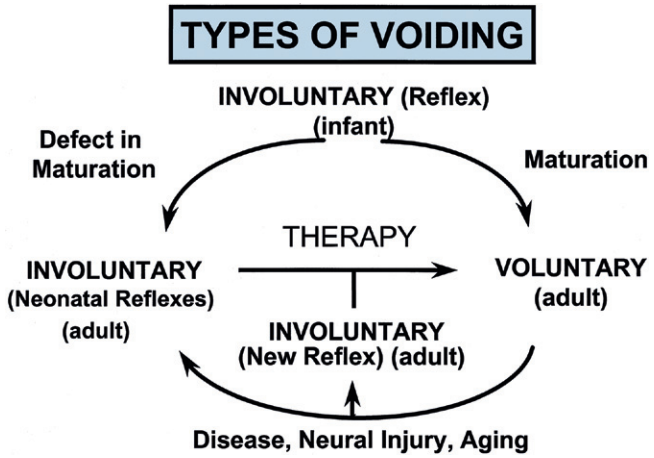

Figure 60–1. Bladder's "circle of life" by influence of maturation, pathologic processes, and aging. In infants, voiding is initiated and coordinated by reflex circuits. After maturation of central neural pathways, voiding is controlled voluntarily by neural circuitry in higher centers in the brain. A defect in neural maturation allows involuntary voiding to persist in adults. Aging, neural injury, or diseases, such as benign prostatic hyperplasia, can disrupt the central voluntary micturition neural pathways. Pathologic processes can lead to the formation of new reflex circuitry by reemergence of primitive reflex mechanisms that were present in the infant or that appear as the result of synaptic remodeling. The goal of therapy is to reverse the pathologic process and to reestablish normal voluntary control of voiding.

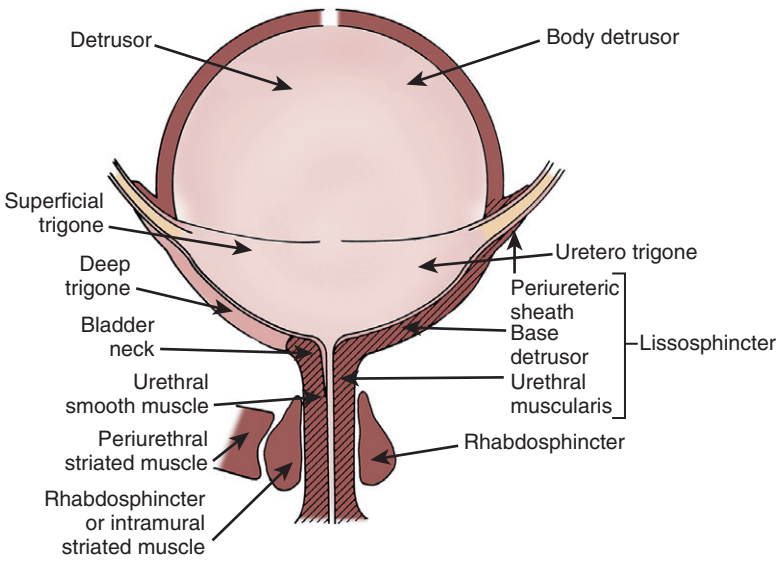

Figure 60–2. Anatomy of the bladder and its outlet, as defined by Gosling and Dixon *(left)* versus Elbadawi and coworkers *(right)*. (From Torrens M, Morrison JFB. The physiology of the urinary bladder. Berlin: Springer-Verlag; 1987. p. 1.)

bladder neck is reportedly less than that in men (de Groat and Booth, 1993).

Understanding voiding and continence requires some working knowledge of the contractile properties of smooth and striated muscle. The contractile properties of bladder smooth muscle cells are well suited for either urine storage or release. Filling the bladder at a slow physiologic rate maintains an intravesical pressure of less than 10 cm H_2O (Klevmark, 1974). Acute denervation of the bladder does not appreciably alter this low filling pressure (Langley and Whiteside, 1951). This concept has been used to support the hypothesis that the **intrinsic myogenic or viscoelastic properties of cellular and extracellular components are major contributors to low-pressure bladder filling and compliance** (see the section Mechanisms of Detrusor Overactivity). Conversely, neural input is required for the rapid and sustained smooth muscle contraction accompanying voiding.

Bladder Biomechanics

What basic bladder hydrodynamics and biomechanical properties should practicing urologists know, and why should they know them? These are some of the questions we attempt to answer in this section. We lay the foundation of the relationship between bladder shape, size, pressure, and tension as expressed by the Laplace law (Chancellor et al, 1996). Marquis Pierre-Simon de Laplace (1779 to 1827) has been called the Newton of France. **Laplace** made the keen observation that the **tension in the wall of a container necessary to contain a given pressure is directly proportional to the radius of curvature at any point**. This is the Laplace law.

It is intuitive to urologists that there is a relationship between intravesical pressure and the size of the bladder and that this affects the tension in the bladder wall. Increased wall tension activates bladder afferent nerves that evoke the sensation of bladder filling and also can evoke involuntary bladder contractions. Large increases in intravesical pressure, especially in a hypertrophic, small-capacity bladder, can dramatically elevate bladder wall tension, producing ischemia, vesicoureteral reflux, and bacterial emptying into the venous or lymphatic systems. Elevated wall tension and intravesical pressure may be the cause of bladder rupture sometimes seen after enterocystoplasty.

The Laplace equation states that there is a direct relationship between wall tension and intravesical pressure and bladder size. In this equation, T is tension, P is intravesical pressure, R is bladder radius, and d is wall thickness. During bladder filling, Pves is relatively constant. With a fully distended bladder, d, because of its relative thinness, is ignored relative to the other parameters unless a hypertrophied wall exists. Thus, T = P • R/2 approximates tension in the full normal bladder (Fig. 60–3).

Filling Mechanics

The viscoelastic behavior of the bladder and urethra depends on both neuromuscular and mechanical properties. Mechanical properties vary with the magnitude of stretch (distention), even in tissue deprived of adenosine triphosphate (ATP) (e.g., postmortem). Mechanical properties are extremely sensitive to tissue structure and composition. In the bladder and urethra, collagen and elastin content have a profound influence on the viscoelastic properties when these tissues are subjected to stress (force per area). **Besides smooth muscle, the human bladder is composed of roughly 50% collagen and 2% elastin. With injury, obstruction, or denervation, collagen content increases** (Macarak and Howard, 1999). When contractile protein content exceeds collagen, greater distensibility is achieved (compliance). **Conversely, when collagen levels increase, compliance falls.** Bladder compliance (C) is defined as the change in volume (V) relative to the corresponding change in intravesical pressure (P):

$$C = \Delta V / \Delta P$$

A decrease in compliance or efferent neural input can alter wall tension, cause afferent firing, and thereby change bladder sensations and the volume threshold for micturition. With increasing bladder volume, wall stress or tension (T) increases, as defined by the Laplace equation (see Fig. 60–3).

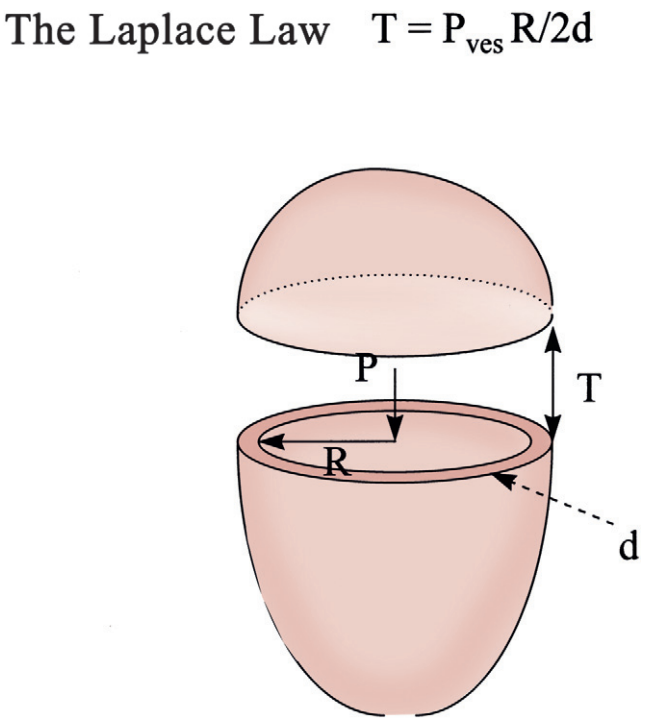

Figure 60–3. The Laplace equation describing wall tension (T) as a function of the bladder radius (R), intravesical pressure (Pves), and wall thickness (d).

Bladder Accommodation

The bladder surface undergoes incredible change in size going from empty to full. The percentage change is truly unmatched by any other organ in the body. The change is accommodated by both the urothelium and the bladder wall smooth muscle and connective tissue.

The changes in the thickness of the lamina propria and the detrusor are mechanical requirements for the bladder to accommodate increasing urine volume. During filling, the lamina propria thins at a faster rate than the muscle wall. It has been proposed that bladder wall thinning during filling is the result of a rearrangement of the muscle bundles and also alteration of collagen coil structure (Macarak and Howard, 1999). A combination of muscle and connective tissue spatial changes is required to accommodate urine at low intravesical pressures (Chang et al, 1999).

During filling, the detrusor reorganizes and muscle bundles shift position from a top-to-bottom to a side-to-side configuration. During reorganization, the coiled type III collagen fibers connecting the muscle bundles orthogonally become extended, longer, and taut and assume an orientation such that the fibers become oriented parallel to the lumen.

Voiding Mechanics

Intravesical pressure reflects the combined factors of abdominal (Pabd) and detrusor (Pdet) pressures. Therefore,

$$Pdet = Pves - Pabd$$

Micturition relies on a neurally mediated detrusor contraction, causing Pdet to rise without a significant change in Pabd. To assess the strength of a detrusor contraction, Pdet alone is an insufficient measure. A muscle can use energy either to generate force or to shorten its length. Because the bladder is a hollow viscus, the force developed contributes to Pdet, whereas the velocity of shortening relates to urine flow (Q). There is a trade-off between generating Pdet and urine flow. This has been nicely reviewed by Griffiths (1988). **If urethral resistance is low, as in women with sphincter insufficiency and even in normal continent women, Pdet may be almost undetectable; yet, these women with modest Pdet would have normal flow rates. The trade-off between Pdet and Q resembles a curve for constant mechanical power (W) in which**

$$W = Pdet \times Q$$

The equation explains why a woman could have normal detrusor contractility and normal detrusor power despite low voiding pressure. During micturition, Pdet reflects outlet resistance. When the urethra opens widely with a high flow (Q), little Pdet is needed to achieve the work necessary to empty the bladder. The key message is that low voiding pressure in a woman does not equate with impaired detrusor contractility; she may simply be able to open her urethra widely. Moreover, pressure-flow nomograms developed for men for diagnosis of obstruction should not be applied to women without validation.

Tissue Biomechanics and Bladder Function

In addition to important molecular and cellular parameters, tissue- and organ-level bladder properties are important to the function of the bladder during filling (Damaser, 1999). Fundamental mechanical properties include the stress-strain relationship, viscoelasticity, and deformation of bladder tissue. Whole-bladder properties include bladder shape, mass, and distention. Organ-level pressure-volume assessment is usually achieved by the cystometrogram. Although it is an essential tool for the urologist, the cystometrogram *alone* cannot rigorously distinguish between the effects of changes in tissue compliance, and the shape and wall stress distribution of the whole organ. For example, changes in the cystometrogram in spinal cord injury could be a result of alterations in both bladder shape (Ogawa et al, 1988) and tissue properties. Thus to assess intrinsic changes in bladder wall properties, proper assessment of the changes in bladder function requires an understanding of bladder wall biomechanical properties. The biomechanical components contributing to tissue mechanical responses have been studied in isolated detrusor tissue (Wagg and Fry, 1999). However, an ongoing problem is to determine whether clinically observed alterations in detrusor function are due to changes in the contractile apparatus or in the surrounding extracellular matrix.

The complexity of the bladder shape raises similar questions. The bladder can be mechanically idealized as a thin-walled shell. In the theory of thin shells, surface geometry is an integral part of how wall tensions are spatially distributed (Flügge, 1973). That is, a change in surface geometry can alter the stress distributions independent of changes in the mechanical properties. Thus focal points of high curvature on the bladder surface (Fig. 60–4) can potentially induce regions of localized stress concentrations and may be related to bladder deformity, for example, during the spinal cord injury disease process. These phenomena have been underscored by the bladder shape modeling work of Damaser and Lehman (1995), who demonstrated the sensitivity of bladder wall stress distribution on bladder shape.

Although it is typically modeled as a spheroid, the bladder is probably one of the more irregularly shaped anatomic structures.

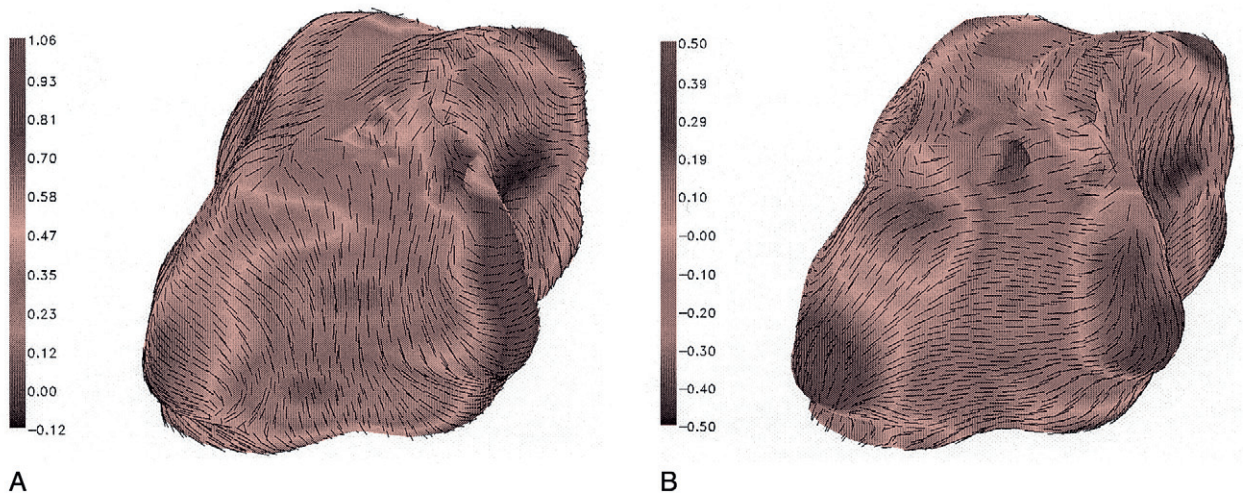

Figure 60–4. Major principal curvature **(A)** and minor principal curvature **(B)** for the bladder. Curvature magnitudes are indicated by gray scale and directions by vectors. When the bladder is full, as in this case, wide variations in curvature exist because of contact with the surrounding pelvic structures.

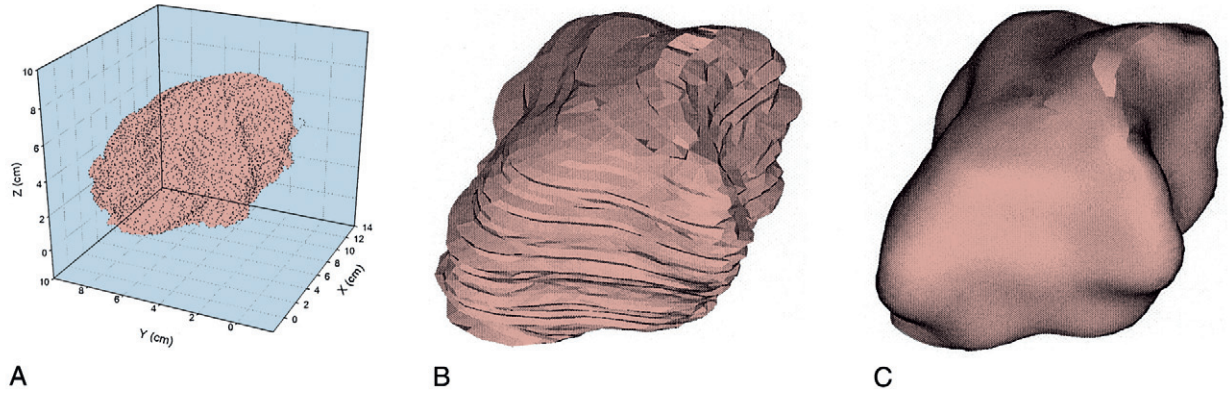

Figure 60–5. Three-dimensional reconstruction of the bladder. **A,** "Point cloud" of 3146 digitized surface points from a normal human bladder from computed tomographic images. **B,** The resulting reconstructed bladder surface, revealing a complex, nonspheroidal surface. **C,** Same surface as in **B** but with the surface roughness from imaging noise removed.

Irregularity in bladder shape, especially when it is full, is due to contact with surrounding pelvic structures. Note in particular the complex spatial distribution of surface curvatures, including pointed regions of high curvature and rapid transitions between elliptical (both principal curvatures are positive) and hyperbolic (or saddle-shaped, where one principal curvature component is negative) regions (see Fig. 60–4). By use of the techniques developed by Sacks and colleagues (1993, 1999), this roughness can be removed and the original smooth in-vivo surface recovered (Fig. 60–5).

THE URINARY BLADDER

The bladder performs several important functions. First, it must store a socially adequate volume of urine. The bladder wall must be able to stretch and rearrange itself to allow an increase in bladder volume without significant rise in pressure. In other words, the bladder wall must be highly compliant. Second, the smooth muscle and intrinsic nerves have to be protected from exposure to urine by the urothelium, which itself must also expand readily during filling. Third, bladder emptying requires synchronous activation of all the smooth muscle of the bladder body, because if only part of the wall contracted, the uncontracted compliant areas would stretch and prevent the increase in pressure necessary for urine to be expelled through the urethra. This is the problem often seen in an elderly man with benign prostatic hyperplasia who develops urinary retention and a bladder diverticulum.

In this section, we review the various components of the bladder, including smooth muscle, stroma, and blood vessels. First, we focus on the detrusor smooth muscle by contrasting the characteristics of smooth and striated muscle, the activation of smooth muscle contractility, the maintenance of bladder tone, and its neural regulation. In addition, we concentrate on the urothelium, because there is now a resurgence of research interest in this thin but complex membrane. Some exciting studies are presented that discuss the barrier, transport, and neurocommunication properties of the urothelium that are just beginning to be understood. Last, we briefly discuss ion channels and how they might contribute to detrusor dysfunction.

Smooth Muscle

There are several universal characteristics of smooth muscle:

Smooth muscle consists of a sheet containing many small, spindle-shaped cells linked together at specific junctions. Smooth muscle cells contain actin and myosin, but these proteins are not arranged in a regular sarcomere pattern. Instead, each smooth muscle cell consists of a more variable matrix of contractile proteins that is attached to the plasma membrane at the junctional complexes between neighboring cells. Smooth muscle maintains a steady level of tension that can be modulated by circulating hormones, by local factors such as nitric oxide, or by activity in the autonomic nerves. Smooth muscle is more adaptable than skeletal muscle and is able to adjust its length over a much wider range than skeletal muscle.

Based on the assumption of a spherical bladder, the circumference of a 400-mL capacity bladder is approximately 30 cm. If the bladder empties to a residual urine volume of 10 mL, the circumference would be only 8 cm. To accomplish this feat, the detrusor would have a change in muscle length of 75%. If the bladder were to be made of skeletal muscle instead, the maximum length change would be only about 30%. The maximum "skeletal muscle bladder" emptying would be only 70% of its contents, leaving a residual urine of 120 mL. Thus the bladder requires the unique property of smooth muscle to accomplish its job. What is assumed to be the stronger skeletal muscle is not up to the job of bladder emptying (Gabella, 1995; Brading et al, 1996; Brading, 1999).

Morphology

The individual smooth muscle cells in the bladder wall are small spindle-shaped cells with a central nucleus; fully relaxed, they are several hundred micrometers long with a 5- to 6-μm maximum diameter. Skeletal muscle fibers are some 20 times wider and thousands of times longer (Smet et al, 1996).

Smooth muscle has a unique range of physiologic properties and consists of sheets containing many small spindle-shaped cells linked together at specific junctions. Each cell has a single nucleus. No cross striations are visible under the microscope, but like skeletal and cardiac muscle, smooth muscle cells contain actin and myosin. In addition, they contain cytoskeletal intermediate

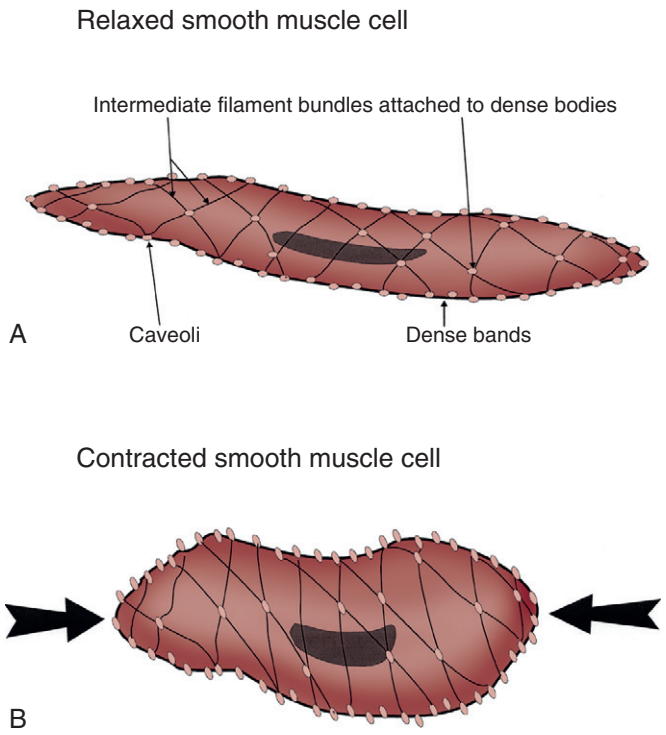

Figure 60–6. The organization of the contractile elements of smooth muscle fibers by a simple model of the contraction of smooth muscle. **A,** Relaxed smooth muscle cell. **B,** Contracted smooth muscle cell. Intermediate filaments, dense bodies, and dense bands of smooth muscle fibers harness the pull generated during myosin cross-bridge activity. Intermediate filaments attach to dense bodies scattered throughout the sarcoplasm and occasionally anchor to the dense bands situated between caveolae (invaginations of the sarcolemma). As the obliquely running contractile elements contract, the muscle shortens.

Table 60–1.

Comparison of the Properties of Skeletal and Smooth Muscle

PROPERTY	SKELETAL MUSCLE	SMOOTH MUSCLE
Cell characteristics	Long cylindrical cells with many nuclei	Spindle-shaped cells with a single nucleus
Maximum cell size (length × diameter)	30 cm × 100 μm	200 μm × 5 μm
Visible striations	Yes	No
Ultrastructure	Sarcomere pattern No immediate filaments	No sarcomere pattern Intermediate filaments Dense bodies
Motor innervation	Somatic	Autonomic
Type of contracture	Phasic	Mostly tonic, some phasic
Contractile activity	Disinhibition of tropomyosin Sliding filaments Rapid contraction	Active myosin phosphorylation ? Sliding filaments Formation of "latch state"
Calcium regulation	Rapid Ca^{2+} influx via T tubule	Voltage- and receptor-operated Ca^{2+} channels Release from internal stores
Basic muscle tone	Neural activity	Intrinsic, extrinsic factors
Force of contraction regulated by hormone	No	Yes

filaments that assist in transmission of the force generated during contraction to the neighboring smooth muscle cells and connective tissue. Although there are no Z lines in smooth muscle, they have a functional counterpart in dense bodies that are distributed throughout the cytoplasm and that serve as attachments for both the thin and the intermediate filaments. The thin and thick filaments of smooth muscle fibers are arranged as myofibrils that cross the fibers obliquely in a lattice-like arrangement. The filaments of contractile proteins are attached to the plasma membrane at the junctional complexes between neighboring cells (Fig. 60–6). A comparison of some of the properties of smooth and skeletal muscle is listed in Table 60–1 (Chacko et al, 1999).

Smooth Muscle Cellular Mechanics

Detrusor smooth muscle contracts and shortens by interaction between thin and thick filaments. The thin actin filaments are anchored at the membranes on the dense bands, or in the cytoplasm on the dense bodies, and interact with the thick filaments through cross bridges formed from the heads of myosin molecules. In both cases, the contractile mechanism is a myosin-activated system. **Cross-bridge cycling is initiated when the ATPase activity of the myosin heads is switched on. This is achieved by phosphorylation of two light chains on the cross bridge, through a specific enzyme, myosin light-chain kinase, that is activated by a rise in the intracellular calcium concentration** (Hai and Murphy, 1989; Gunst et al, 1993; Andersson and Arner, 2004). Changes in the contractile proteins occur in developing bladders and also during bladder hypertrophy (Wang et al, 1995; Wu et al, 1995; Sjuve et al, 1996).

The bladder muscle has a broad length-tension relationship, allowing tension to be developed over a large range of resting muscle lengths (Uvelius and Gabella, 1980). The tissue shows viscoelasticity that influences muscle tension and is manifested as total bladder wall tension (Venegas, 1991). Isolated detrusor strips show spontaneous mechanical activity to a variable extent. It is more frequently seen in bladders from small mammals (Sibley, 1984) but can also be seen in muscle strips from human detrusor. However, spontaneous fused tetanic contractions, such as those commonly seen in smooth muscles from the gastrointestinal tract and uterus, are almost never seen in normal bladders.

Membrane Electrical Properties and Ion Channels. The smooth muscle of the detrusor is able to support a regenerative action potential from a resting potential of –50 to –60 mV (Montgomery and Fry, 1992; Fry et al, 2002). The action potentials have marked after-hyperpolarizations, and several different K^+ channels, such as delayed rectifier and transient outward channels and both small and large calcium-activated K^+ channels (SKCa and BKCa, respectively), appear to be involved in determining their shape (Fujii et al, 1990; Brading and Turner, 1996; Heppner et al, 1997; Andersson and Arner, 2004). The upstroke is supported by calcium influx through L-type Ca^{2+} channels (Rivera, 1998). In addition, a K^+ channel opened by reduced intracellular ATP has been

demonstrated (Bonev and Nelson, 1993), which, on activation, is profoundly inhibitory to the spontaneous activity (Foster et al, 1989). Several other conductances, which include a nonspecific cation channel linked to the P2X receptor (Inoue and Brading, 1990) and stretch-activated cation channels (Wellner and Isenberg, 1993), have been demonstrated in detrusor smooth muscle.

In response to acetylcholine released from parasympathetic nerve terminals, muscarinic M_3 receptors are thought to induce detrusor muscle contractions by calcium entry through nifedipine-sensitive L-type Ca^{2+} channels (Andersson and Arner, 2004; Andersson and Wein, 2004; Schneider et al, 2004a, 2004b), **in addition to increased polyphosphoinositide hydrolysis resulting in inositol 1,4,5-trisphosphate (IP_3) production and release of intracellular calcium stores** (Iacovou et al, 1990; Eglen et al, 1994; Harriss et al, 1995; Hashitani, Bramich et al, 2000; Fry et al, 2002; Braverman et al, 2006a), although the importance of L-type channel activation in muscarinic M_3 receptor–mediated detrusor bladder contractions is still a matter of debate (Fry et al, 2002; Hashitani et al, 2000; Schneider et al, 2004a, 2004b; Braverman et al, 2006a, 2006b; Frazier et al, 2008). **The calcium influx through L-type Ca^{2+} channels also triggers calcium-induced calcium release through ryanodine receptors and activates BKCa channels to generate the membrane after-hyperpolarization** (Hashitani and Brading, 2003). **The opening of the K^+ channel repolarizes the membrane potential by the efflux of positively charged potassium ions from the cell** (Mostwin, 1986). In addition, increased polyphosphoinositide hydrolysis after M_3 receptor activation can also generate diacylglycerol in the membrane; diacylglycerol can activate protein kinase C, which may be involved in generating the tonic element of the response through modulation of Ca^{2+} and K^+ channels (Zhao et al, 1993).

Calcium also activates a variety of cellular responses when it enters the cytoplasm of a cell by means of transmembrane channels. To be effective as a signal, its concentration must be returned to submicromolar levels, driven by ATP pumps. The Ca^{2+} pump is a membrane-bound, Ca^{2+}-activated ATPase, similar to the Na^+–K^+ pump that controls ion balance and membrane potential in all animal cells. These pumps belong to a superfamily of ATPases known as P type, because they depend on the autophosphorylation of a conserved aspartic acid residue using ATP.

Excitation-Contraction Coupling in Smooth Muscle. Like skeletal and cardiac muscle, smooth muscle contracts when intracellular calcium concentration rises. Because smooth muscle does not possess the tubules of the "T system," the rise in calcium concentration occurs through calcium influx through voltage-gated Ca^{2+} channels in the plasma membrane or release from the sarcoplasmic reticulum after activation of receptors that increase the formation of IP_3. Although calcium serves the same triggering role in all muscle types, the mechanism of activation is different in smooth muscle. The contractile response is slower and longer lasting than that of skeletal and cardiac muscle. This can be explained by the slowness with which smooth muscle is able to hydrolyze ATP during the contractile process. A calcium-binding protein called calmodulin regulates the interaction between actin and myosin. The thin filaments lack troponin and are always ready for contraction. The slow and relatively steady generation of tension enables smooth muscle to generate and to maintain tension with relatively little expenditure of energy (Fig. 60–7 and Table 60–2).

The rise in cytoplasmic calcium concentration brought on by the action potential results in binding of calcium to calmodulin. Calcium-bound calmodulin is then capable of activating myosin light-chain kinase, permitting it to phosphorylate the myosin type II light chain. Phosphorylation of the light chain allows the myosin to interact with actin, leading to force generation (White et al, 1993; Chacko et al, 1994; Andersson and Arner, 2004). The actual geometric arrangement of the actin-myosin complex that permits force generation is unclear. Different isoforms of the myosin heavy chain have been defined by Chacko and associates (1994), as well as the components of the regulatory system linking cytoplasmic calcium levels to contraction (White et al, 1993). The smooth muscle myosin heavy chain is encoded by a single gene, and two heavy-chain variants formed by alternative splicing are identified (SM1 and SM2). Two additional myosin heavy-chain

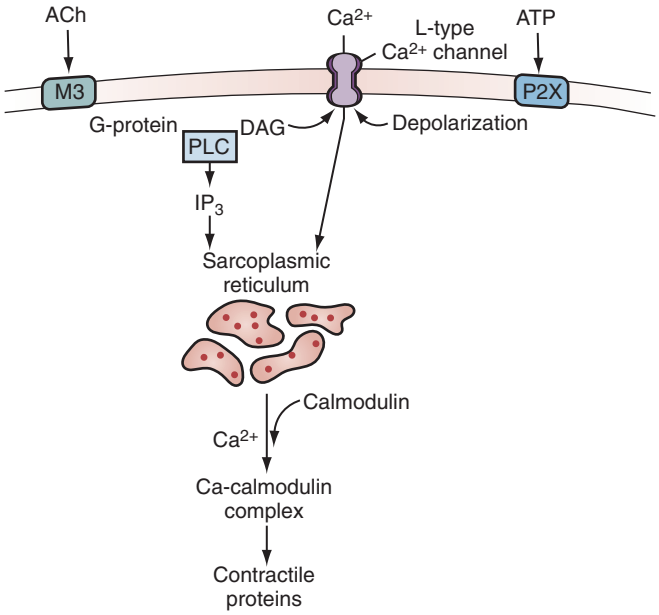

Figure 60–7. Acetylcholine (ACh) and adenosine triphosphate (ATP) pathway in the bladder. Acetylcholine interacts with M_3 muscarinic receptors and activates phospholipase C (PLC) through a G protein. Phospholipase activation leads to the production of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 elicits release of calcium from the sarcoplasmic reticulum through IP_3 receptors, and DAG may modulate voltage-sensitive Ca^{2+} channels in the plasma membrane. ATP acting through P2X purinergic receptors opens nonselective cation channels in the membrane, leading to depolarization that opens voltage-sensitive Ca^{2+} channels. Both lead to entry of calcium. This triggers release of more calcium from the stores through ryanodine receptors. The rise in intracellular free calcium concentration triggers contraction and may also open calcium-activated channels in the membrane, such as calcium-activated K^+ channels, that can modulate the response. (Redrawn from Brading A. Cellular biology. In: Abrams P, Khoury S, Wein A, editors. Incontinence. Plymouth [UK]: Health Publications; 1999. p. 73.)

Table 60–2.

Detrusor Smooth Muscle Contraction Sequence

Ca^{2+} binds to calmodulin, activating it.
Calmodulin activates the kinase enzyme.
Kinase enzyme catalyzes phosphate transfer from adenosine triphosphate to myosin, allowing myosin to interact with actin of the thin filaments.
Smooth muscle relaxes to widen intracellular decrease in Ca^{2+} levels.

isoforms, SM-A and SM-B, are then formed by alternative splicing in the amino-terminal region, enabling four possible isoforms: SM1-A, SM1-B, SM2-A, and SM2-B (Babu et al, 2000). Because the SM-B isoform is shown to propel actin at a faster velocity (Lauzon et al, 1998), the relatively high expression of SM-B isoform in the bladder shown at the mRNA level (Arafat et al, 2001) would contribute to a comparatively fast smooth muscle type of the bladder (Andersson and Arner, 2004).

Propagation of Electrical Responses. The lack of fused tetanic contractions in normal detrusor smooth muscle strips suggests that there is poor electrical coupling between smooth muscle cells (Uvelius and Mattiasson, 1986). **Measurements of tissue impedance support the observation that the detrusor is less well coupled electrically than other smooth muscles** (Brading and Mostwin, 1989; Parekh et al, 1990)**. Poor coupling could be a feature of a normal detrusor that prevents synchronous activation of the smooth muscle cells during bladder filling.** Nevertheless, some degree of coupling within a muscle bundle clearly does exist, because it is possible to measure the length constant of a bundle (Seki et al, 1992). There is also evidence for gap-junction coupling between detrusor cells in humans and guinea pigs, detected by whole-cell patch clamp recordings (Wang et al, 2006) and Ca^{2+} imaging (Neuhaus et al, 2002), respectively. Significant expression of connexins 43 and 45, gap-junction proteins, is found in human detrusor muscles (John et al, 2003; Wang et al, 2006). However, electrical couplings between detrusor cells seem to be reduced during postnatal development because coordinated, large-amplitude, low-frequency contractile activity is seen in the neonate rat bladder declines and is replaced by low-amplitude, high-frequency, more irregular activity in older rats, which appears to depend on the disruption of the intercellular smooth muscle communication (Szell et al, 2003). It has also been suggested that a change in the properties of the cell coupling may underlie the generation of the uninhibited detrusor contractions occurring in overactive and aging bladders (Seki et al, 1992; Brading, 1997b; Brading, 2006).

Smooth Muscle during Filling. As the bladder fills, the myocytes are stretched, leading to activation of nonselective cation channels that permit rapid entry of sodium and of some calcium (Wellner and Isenberg, 1993). Entry of cations depolarizes the smooth muscle membrane potential. If the extent of stretch is mild, there is low activation, and the membrane potential rests at a more depolarized level, predisposing the cell to activation by lower levels of muscarinic agonists. If the extent of the stretch is more significant, the activation of cation channels may be sufficient to depolarize the cell sufficiently for initiation of an action potential. **Although individual cells may contract spontaneously, contraction of the bladder as a whole generally requires stimulation by parasympathetic nerves** (Andersson, 1993). **When the membrane is sufficiently depolarized, L-type Ca^{2+} channels open and Ca^{2+} channels in the sarcoplasmic reticulum open, flooding the cell with calcium and resulting in an action potential, thereby leading to spontaneous phasic activity in the bladder** (Mostwin, 1986; Kumar et al, 2005).

Between contractions, the sarcoplasmic reticulum accumulates calcium to levels far above those of the cytosol by means of a calcium ATPase (Wall et al, 1990). Calcium stores in the sarcoplasmic reticulum can be released in the absence of action potentials by exposure to caffeine, which renders the Ca^{2+} channels sensitive to normal ambient cytoplasmic calcium levels.

Interstitial Cells. Recent evidence suggests that the "normal" bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of detrusor overactivity. In a rat model for detrusor overactivity, local areas of spontaneous contractions are increased and more coordinated in partial outlet-obstructed rat bladders (Drake et al, 2003). However, it is still not clear which cells generate spontaneous activity in the bladder. As mentioned before, detrusor myocytes could be spontaneously active, and electrical coupling through gap junctions could trigger spontaneous contractions (Brading, 1997b, 2006). Alternatively, **another population of cells in the bladder known as interstitial cells, or myofibroblasts, has been proposed for a pacemaking role in spontaneous activity of the bladder** (Andersson and Arner, 2004; Kumar et al, 2005). Interstitial cells have been identified in the human and guinea pig ureter, urethra, and bladder body (Kumar et al, 2005; Hashitani, 2006; Fry et al, 2007).

Suburothelial Interstitial Cells. In the human bladder, subepithelial interstitial cells, which are also called myofibroblasts, stain for vimentin and α–smooth muscle actin but not for desmin (Fry et al, 2004). These cells are linked by gap junctions consisting of connexin 43 proteins and make close appositions with C-fiber nerve endings in the submucosal layer of the bladder, suggesting that there is a network of functionally connected interstitial cells immediately below the urothelium that may be modulated by other nerve fibers (Fry et al, 2004) (Fig. 60–8). ATP can induce inward currents associated with elevated intracellular Ca^{2+} in isolated suburothelial interstitial cells (Fry et al, 2007). Immunohistochemical studies show the expression of P2Y receptors, most notably $P2Y_6$ receptors, and M_3 muscarinic receptors in suburothelial interstitial cells from guinea pigs (Fry et al, 2007; Grol et al, 2009). In the human bladder, increased expression of muscarinic M_2 and M_3 receptors in vimentin-stained suburothelial interstitial cells is found and correlates with the urgency score in humans with idiopathic detrusor overactivity (Mukerji et al, 2006). Because

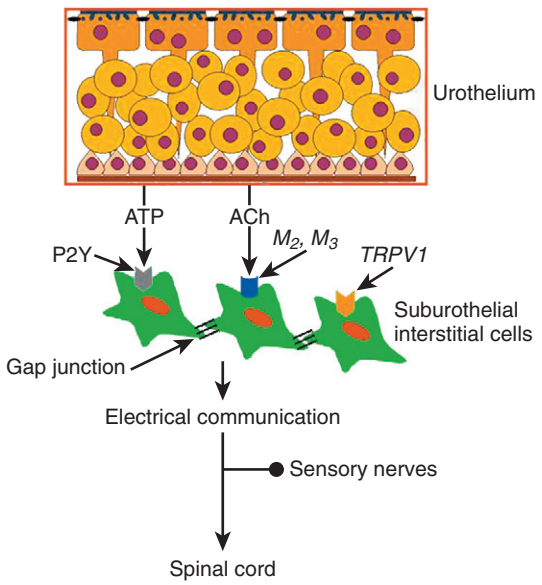

Figure 60–8. Schematic representation of suburothelial interstitial cells (IC), which are also called myofibroblasts. Substances released from the basolateral surface during stretch, such as adenosine triphosphate (ATP) and acetylcholine (ACh), activate afferents in the suburothelial layer through the intermediation of suburothelially located interstitial cells, which express purinergic P2Y receptors, muscarinic M_2 and M_3 receptors, or capsaicin TRPV1 receptors, and are connected to each other by gap-junction proteins.

ATP or acetyl choline (ACh) is known to be released from the urothelium during bladder stretch, suburothelial interstitial cells are in an ideal position between the urothelium and nerve endings to modify a sensory feedback mechanism. Application of a nitric oxide donor sodium nitroprusside (SNP) also attenuates an increase in intracellular Ca^{2+} and current responses to ATP in guinea pig interstitial cells, suggesting the cGMP-dependent inhibition of cell activity (Sui et al, 2008).

Intradetrusor Interstitial Cells. Interstitial cells are also found in the detrusor layer and shown to be spontaneously active (Kumar et al, 2005). These cells are stained for c-Kit and located along both boundaries of muscle bundles in the guinea pig bladder (McCloskey and Gurney, 2002; Hashitani et al, 2004; Hashitani, 2006). These cells can fire Ca^{2+} waves in response to cholinergic stimulation by M_3 muscarinic receptor activation and can be spontaneously active, suggesting that they could act as pacemakers or intermediaries in transmission of nerve signals to smooth muscle cells (McCloskey and Gurney, 2002; Johnston et al, 2008) (Fig. 60–9). However, Hashitani and colleagues (2004) have also suggested that interstitial cells in the detrusor may be more important for modulating the transmission of Ca^{2+} transients originating from smooth muscle cells rather than being the pacemaker of spontaneous activity because spontaneous Ca^{2+} transients occur independently in smooth muscles and interstitial cells. It has also been demonstrated that the c-Kit tyrosine kinase inhibitor Glivec decreased the amplitude of spontaneous contractions in the guinea pig bladder (Kubota et al, 2004, 2006) and in muscle strips from the overactive human bladder, in which c-KIT–positive cells were increased compared with normal subjects (Biers et al, 2006), suggesting that targeting these receptors expressed in intradetrusor interstitial cells may provide a new approach for treating overactive bladder. In addition, following application of SNP (a nitric oxide [NO] donor), interstitial cells throughout the bladder, but not detrusor muscle cells, demonstrate cyclic guanosine monophosphate (cGMP) immunoreactivity (Smet et al, 1996; Gillespie et al, 2004). Thus increased levels of cGMP found in interstitial cells by using phosphodiesterase-5 inhibitors, for example, may diminish synchronicity between detrusor muscle bundles (Hashitani, 2006). These cells are also a source of prostaglandin E_2 (PGE_2) because of their expression of cyclooxygenase and a reduction in spontaneous activity of bladder muscle strips by use of prostaglandin E_2 receptor (EP) antagonists in rabbits (Collins et al, 2009).

Further research is definitely required to fully understand the role of suburothelial/intradetrusor interstitial cells and their contribution to spontaneous contractions or detrusor overactivity.

Smooth Muscle Tone. The bladder smooth muscle maintains a steady level of contracture and tone. Tone is important in maintaining the capacity of the bladder. Smooth muscle tone depends on many factors, some intrinsic and some extrinsic. Extrinsic factors include activity in the autonomic nerves and circulating hormones; intrinsic factors include the response to stretch, local metabolites, and locally secreted agents such as nitric oxide, and temperature. Consequently, smooth muscle tone does not depend solely on activity in the autonomic nerves or on circulating hormones.

The contraction of smooth muscle is slow, sustained, and resistant to fatigue. Smooth muscle takes 30 times longer to contract and relax than does skeletal muscle and can maintain the same contractile tension for prolonged periods at less than 1% of the energy cost.

Length-Tension Relationship. If a smooth muscle is stretched, there is a corresponding increase in tension immediately after the stretch. This is followed by a progressive relaxation of the tension toward its initial value. This property is unique to smooth muscle and is called stress relaxation (Chancellor et al, 1996).

Compared with skeletal or cardiac muscle, smooth muscle can shorten to a far greater degree. A stretched striated muscle can shorten by perhaps as much as a third of its resting length, whereas a normal resting muscle would shorten by perhaps a fifth. This is perfectly adequate for it to perform its normal physiologic role. In contrast, a smooth muscle may be able to shorten by more than two thirds of its initial length. This unusual property is conferred by the loose arrangement of the thick and thin myofilaments in smooth muscle cells. It is a crucial adaptation because the volume contained by the bladder depends on the cube of the length of the individual muscle fibers. The ability of the detrusor smooth muscle to change its length to such a large degree permits the bladder to adjust to a much wider variation in volume than would be possible for skeletal muscle.

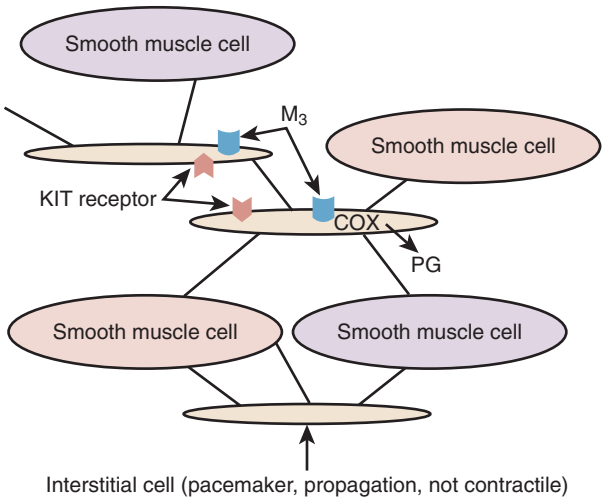

Figure 60–9. Schematic representation of interstitial cells in the detrusor muscle layers. These cells are not contractile but may be pacemakers with spontaneous activity and propagate signals between detrusor muscles. They also express KIT receptors and muscarinic M_3 receptors, and can produce prostaglandins (PG), such as PGE_2, through activation of cyclooxygenase (COX).

Key Points: Smooth Muscle Mechanics

- Muscarinic receptors induce detrusor contraction, in response to acetylcholine released from parasympathetic nerve terminals, by calcium entry through Ca^{2+} channels
- Although calcium serves the same triggering role in all muscle types, the mechanism of activation is different in smooth muscle. The contractile response is slower and longer lasting than that of skeletal and cardiac muscle.
- Recent evidence suggests that the "normal" bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of an overactive bladder. A population of cells in the bladder known as interstitial cells or myofibroblasts has been proposed for a pacemaking role in spontaneous activity of the bladder.

Stroma

The main constituents of bladder wall stroma are collagen and elastin in a matrix composed of proteoglycans. The main cells are fibroblasts. **The passive mechanical properties of the bladder wall depend on the viscoelastic properties of the stroma and of the relaxed detrusor muscle** (Cortivo et al, 1981). The stroma has commonly been considered a passive low-metabolic tissue that fills out the space between muscle bundles, vessels, and nerves. In recent years, the important role of the stroma in the adaptation of the bladder to pathophysiologic conditions has been more appreciated (Macarak and Howard, 1999). Bladder hypertrophy is likely to involve an interaction of stroma and smooth muscle. In arteries, disruption of elastin in the stroma can stimulate proliferation of smooth muscle (Li et al, 1998). Although no such mechanisms are yet known in the bladder, it is possible that there could be a more intimate relationship between changes in the composition of the stroma and muscle function and growth than is appreciated at present.

Bladder Wall Collagen

Most of the bladder wall collagen is found in the connective tissue outside the muscle bundles. Changes in the relative amounts of muscle and nonmuscle tissue in the bladder wall would therefore influence collagen concentration. A number of different collagen types have been identified. In the bladder, **types I, III, and IV are the most common** (Macarak et al, 1995; Andersson and Arner, 2004). Landau and coworkers (1994) developed morphometric and histochemical techniques to determine the percentage volume of connective tissue in the bladder wall and to measure the two major types (I and III) of collagen. These methods quantitate three parameters of bladder ultrastructure: percentage volume of connective tissue, ratio of connective tissue to smooth muscle, and ratio of type III to type I collagen. These parameters have been shown to be abnormally elevated in patients with bladder disease compared with normal patients. They further studied the ultrastructural changes that occur in the wall of dysfunctional bladders to determine the ability of new urodynamic techniques to reliably detect the clinical effect of these histologic changes. The study included 29 consecutive patients undergoing bladder augmentation. Preoperative urodynamic evaluation included measurement of the total bladder capacity, pressure-specific bladder volume, and dynamic analysis of bladder compliance. Full-thickness bladder biopsy specimens were obtained from the dome of the bladders during augmentation. The percentage of connective tissue and the ratio of connective tissue to smooth muscle were determined for all patients. These histologic results were compared with previously established normal values. All 29 patients had decreased bladder compliance, even though 9 had a normal bladder capacity. **The ratio of connective tissue to smooth muscle was significantly increased in poorly compliant versus normal bladders. The ratio of type III to type I collagen was also significantly elevated. One can conclude that the poor storage function of poorly compliant bladders is secondary to an alteration in the connective tissue content of the bladder wall, especially increased collagen type III.**

In the rat, infravesical obstruction or bladder denervation induces hypertrophy of the detrusor smooth muscle and, in turn, a decrease in the collagen concentration (Uvelius and Mattiasson, 1984, 1986). Aging is associated with a relative decrease in smooth muscle, in both men and women, relative to collagen content (Susset et al, 1978; Lepor et al, 1992). This could perhaps be related to the decreased packing density of submucosal collagen during aging (Levy and Wight, 1990).

Perhaps the most comprehensive work on bladder collagen has been performed by Macarak and Howard (1999), who have speculated that connections must exist between the tension-generating elements (i.e., the smooth muscle cells) and the other components of the bladder. In bladders that become noncompliant (e.g., from spinal cord injury), it is likely that there is some interference with the ability of the collagen fibers to alter their tortuosity. This, predictably, would reduce total bladder capacity. Further studies are required to establish the relationship between compliance changes and the passive mechanical elements of the bladder wall that make up its structural protein matrix.

Bladder Wall Elastin and Matrix

Elastic fibers are amorphous structures composed of elastin and a microfibrillar component located mainly around the periphery of the amorphous component (Rosenbloom et al, 1995). In the mature fiber, the amorphous component composes about 90%. The microfibrils contain a number of glycoproteins. Elastin fibers are sparse in the bladder, compared with collagen, but are found in all layers of the bladder wall (Murakumo et al, 1995). In spinal cord–injured rats, the elastin/collagen ratio first increased and is well correlated with increased bladder compliance due to bladder overdistention up to 6 weeks after injury, including a bladder areflexia phase. Then the ratio is reduced as bladder compliance is decreased due to the emergence of detrusor overactivity 10 weeks after injury, suggesting a potential role for elastin in the modulation of bladder compliance (Nagatomi et al, 2005; Toosi et al, 2008).

The nonfibrillar matrix in the stroma is largely composed of a gel of proteoglycans and water. Proteoglycans are glycoproteins with glycosaminoglycans covalently attached. The arrangement of the proteoglycans in the matrix creates a compartment of tissue water that has a viscous behavior when it is subjected to deformation.

Blood Vessels

The bladder has a multilayer vascular plexus, and this fact has morphologic as well as functional implications. When it is carefully examined, the underside of the epithelium is depressed by numerous grooves that are occupied by a dense network of blood capillaries. These vascular grooves allow a large number of capillaries to run at a distance of only a few tenths of a micron from the epithelium (Inoue and Gabella, 1991). The subepithelial capillary plexus may be associated with maintenance of the barrier function of the urothelium, reducing any exposure of the detrusor smooth muscle to substances diffusing from the urine (Hossler and Monson, 1995). It may also play a role in epithelial transport function and be necessary for urothelial metabolism.

Because of the large increase in surface area of the bladder wall during filling, the blood vessels must be able to lengthen considerably. To maintain good blood flow, mechanisms may be needed to ensure that the overall resistance of the vessels, as they lengthen, does not increase sufficiently to reduce the effective perfusion of the tissue. Several groups have investigated the effects of bladder filling on the blood flow. The majority of reports have shown that the blood flow is reduced by distention (Batista et al, 1996; Greenland and Brading, 1996). In patients with a low compliant bladder, there is a marked increase in the intravesicular pressure and a more pronounced decrease in bladder blood flow compared with normal controls (Ohnishi et al, 1994). **The principal determinant of**

blood flow in the bladder wall seems to be intramural tension. During normal filling, the blood flow is able to adapt to the large increase in surface area until the pressure increases in the bladder (Greenland and Brading, 1996).

When the detrusor is deprived of oxygen or a metabolic substrate, as would occur in ischemia, its contractile ability rapidly declines (Levin, 1983; Zhao et al, 1991; Pessina et al, 1997; Levin et al, 2003). **It has been suggested that ischemia and reperfusion might lead to damage to intramural neurons and result in the patchy denervation and altered smooth muscle function seen in bladders of patients with detrusor overactivity** (Brading, 1997a).

Urothelium

The basic functions of the bladder are storage of urine, maintenance of urine composition, and facilitation of voiding at appropriate time intervals. The urothelium has physiologic functions in relation to all parts of these basic functions and, as such, can no longer be thought of as an inert barrier between urine and plasma.

Structure

The urothelium consists of a variable number of cell layers, depending on the species (Fawcett, 1984). There are generally three distinct layers. A layer of basal cells are germinal in nature and 5 to 10 μm in diameter. Intermediate cells are superficial to these and approximately 20 μm in diameter, and a layer of umbrella cells forms the luminal surface of the urothelium (Lewis, 2000; Apodaca, 2004). These umbrella cells are the largest epithelial cells in the body, measuring 100 to 200 μm in diameter; they are polyhedral, are generally hexagonal, and can flatten and have more surface area with stretching. They may also be multinucleate (Kelly, 1984). The surface of the umbrella cells is covered with a glycosaminoglycan layer (Fig. 60–10).

Glycosaminoglycan Layer. The glycosaminoglycan (GAG) layer has been a controversial subject of research into urothelial barrier function. Parsons and associates (Parsons et al, 1990) reported that intravesical treatment of the rabbit bladder with protamine sulfate increased urothelial permeability, to water, urea, and calcium both in vivo and in vitro. This effect was reversed with pentosan polysulfate. They concluded that the protamine sulfate affected the GAG layer and that this was repaired by pentosan polysulfate. However, no microscopic evidence of the anatomic changes was presented in this paper. This study was confirmed by Nickel and coworkers (1998), who compared pentosan polysulfate, heparin, and hyaluronic acid as treatments. The authors concluded that heparin was the best of the three agents in efficacy but pointed out that this may be due to its anti-inflammatory properties. Indeed, the role of the GAG layer may be more in line with an antibacterial adherence function as outlined by Hanno and coworkers (1981). The GAG layer may also be important for the formation and attachment of particulates to the urothelium and stone formation (Hurst, 1994; Grases et al, 1996). However, there are a number of problems with the theory that the GAG layer is the urothelial plasma barrier:

- The GAG layer does not prevent small molecules, such as amiloride, from reaching the Na^+ channels expressed on the surface of the umbrella cells and interfering with them (Niku et al, 1994).
- The polyene antibiotic nystatin can reach the urothelium, as evidenced by increases in the short-circuit currents and reduction of transepithelial resistance to insignificant values, as it generates nonspecific cation pores in the cholesterol-containing luminal membrane of the umbrella cells.
- With the use of microelectrodes, the first resistive barrier is found on entry into the cell. Addition of monomeric arginine or polyvalent cations does not alter transepithelial ion permeability based on electrical measurements.
- Use of hydrolytic agents, such as neuraminidase, hyaluronidase, and chondroitinase, or of proteolytic agents, such as trypsin and kallikrein (to deliberately strip the urothelium of the GAG layer), does not alter the ability of protamine to increase the urothelial permeability (Lewis et al, 1995). This implies that the protamine acts not at the level of the GAG layer but rather at the surface of the luminal cells.

Protamine sulfate increases the apical membrane (luminal surface of umbrella cells) permeability to both

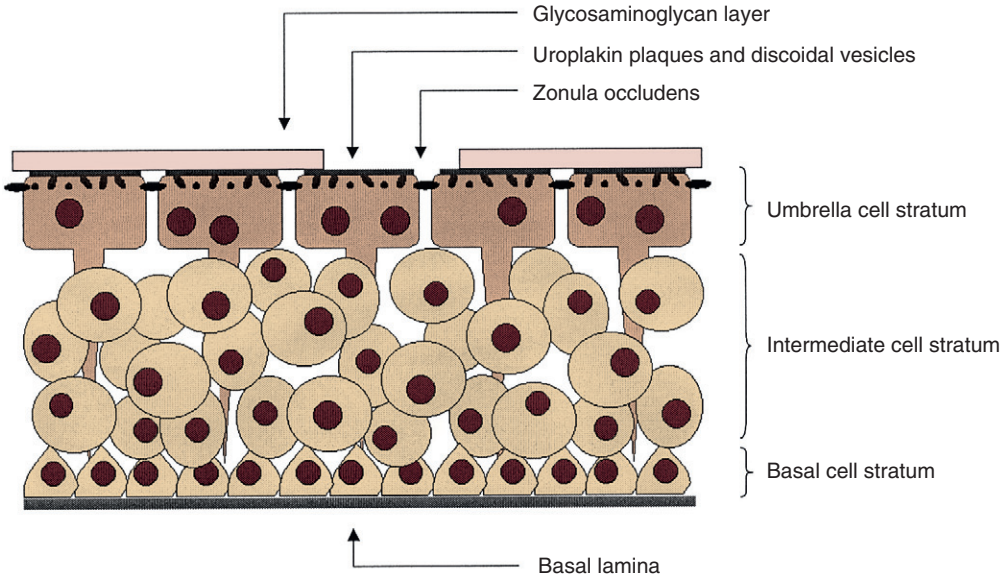

Figure 60–10. Diagrammatic representation of the bladder urothelium. The lumen of the bladder is on top and the lamina propria is below. The glycosaminoglycan layer is shown as discontinuous for illustrative purposes, enabling labeling of deeper structures.

monovalent cations and anions. This may be reversed on the basis of the concentration of the protamine, the composition of the bathing solution, and the exposure time of the urothelium to protamine. Prolonged exposure to protamine (>15 minutes) is poorly reversible and is thought to be caused by a decrease in paracellular resistance from cell lysis (Tzan et al, 1993, 1994).

In an indirect method of examining the GAG layer, Madin-Darby canine kidney (MDCK) cells were transfected with MUC-1, the major GAG of the bladder, with different tandem repeat units to vary the length of the glycosylated chain outside the cell. After this treatment, no difference in the transcellular water and urea permeability was found (Lavelle et al, 1997). **In summary, the GAG layer may have importance in bacterial antiadherence and in prevention of urothelial damage by large macromolecules. However, there is no definite evidence that the GAG layer acts as the primary epithelial barrier between urine and plasma.**

The Umbrella Cells. **The large umbrella cells that form the primary urine-plasma barrier are unique in several ways. First, they have the ability to increase and to decrease considerably their surface area primarily at the apical (luminal) surface. Second, they may be multinucleate. Third, they have an unusual apical surface membrane, which is described as an asymmetrical unit membrane, with the outer leaflet consisting of protein plaques and lipid and with a lipid inner leaflet. Fourth, these cells maintain an extremely high gradient between the plasma and the urine in terms of water concentration, urea concentration, potassium concentration, osmolality, and pH.**

Umbrella cells are so called for their shape, in that they look like umbrellas over the intermediate cell layer. They may cover several intermediate cells and have a stem that may extend to the lamina propria of the urothelium. They are capable of changing shape and can increase their surface area as the bladder fills and, conversely, decrease their surface area as the bladder empties. How this phenomenon occurs is still under debate. The primary theory is that there are a large number of subapical discoid vesicles with an asymmetrical membrane structure just under the apical membrane. These vesicles decrease in number with bladder stretch and increase the electrical capacitance of the luminal surface of the umbrella cells. This is consistent with the exocytosis of these vesicles to increase the cell surface area (Porter et al, 1967). Conversely, the discoid vesicles may be infoldings of membrane that stretch out and disappear with the requirement for increased surface area (Staehelin et al, 1972). These discoid vesicles are associated with a dense network of filaments (Hicks, 1965), which may be connected to the uroplakin plaques (Minsky and Chlapowski, 1978). The insertion of these vesicles into the apical membrane is a microfilament-dependent system, requiring ATP for insertion but not collapse, (Sarikas and Chlapowski, 1986) that does not require an intact microtubule system (Lewis and de Moura, 1982).

In membrane physiology, the primary determinant of the permeability of the lipid bilayer is the permeability of the individual leaflets. The leaflet that is least permeable will determine the overall permeability of the membrane (Negrete et al, 1996). In the umbrella cell luminal membrane, there is a unique structure where the membrane has most (70% to 90%) of the apical surface covered with protein plaque, with the remaining area consisting of hinge-like regions. The composition of the hinge regions is unclear but may be a protein or lipid. The large plaque units are 0.5 μm to 12 nm thick, with subunits approximately 16 nm from center to center (Walz et al, 1995). They are composed of a class of proteins called uroplakins, which are highly conserved across several species (human, monkey, sheep, pig, dog, rabbit, rat, and mouse). There are four uroplakin proteins: UP Ia (27 kD), UP Ib (28 kD), UP II (15 kD), and UP III (47 kD). Antibodies raised against UP I proteins have shown them to be present only in the umbrella cells of the urothelium, and therefore they may act as specific markers of terminally differentiated umbrella cells (Yu et al, 1994; Sun et al, 1999).

The primary function of the uroplakin proteins is hypothesized to be part of the primary plasma-urine barrier. Uroplakins have also been shown to act as the primary attachment site of type 1 piliated uropathogenic *Escherichia coli* in mice, leading to apoptosis of the umbrella cells that were inhibited by the caspase inhibitor Boc-aspartyl(OMe)-fluoromethylketone (BAF) (Mulvey et al, 1998). Given the highly conserved nature of uroplakins, the same is likely to happen in humans.

Coupled with the theory that the apical asymmetrical membrane of the umbrella cells is the primary barrier of the bladder to urine is the observation that cells are joined by tight junctions consisting of four to six interconnecting strands (Peter, 1978). It is the combination of the umbrella cells and tight junction connections that creates the physical barrier to the movement of substances between urine and blood. Once the umbrella cell layer of the urothelium is breached, there is little morphologic (Peter, 1978) or electrophysiologic (Lewis et al, 1976) diffusive permeability evidence (Negrete et al, 1996; Lavelle et al, 1998, 2000) for a barrier to the movement of water and urea.

Urothelial Permeability

Epithelial permeability, including that of the urothelium, depends on a number of factors. These are passive diffusion, osmotically driven diffusion, active transport, and inertness of the membrane to the solutes to which it is exposed.

Descriptions of finite passage of substances across the urothelium are well known. In 1856, Kaupp reported that the composition and volume of urine were altered with 12-hour voiding patterns instead of hourly voiding. These changes in volume have also been noted in rats during isovolumetric cystometrograms during 3-hour periods (Sugaya et al, 1997), and the rate of water loss has also been estimated by direct measurement of passive water diffusion in vitro in the rabbit (Negrete et al, 1996). There is a passive permeability to most substances in the blood or urine (Hicks, 1975).

The diffusive permeability of the mammalian bladder to water and urea has been directly measured in several species (Lavelle et al, 2000). The permeability of water in the bladder remains remarkably constant, ranging from 4.01 to 5.74×10^{-5} cm/sec, and that of urea, 1.5 to 4.51×10^{-6} cm/sec. Water permeability value in humans is similar at 6.5×10^{-5} cm/sec (Fellows and Marshall, 1972). This value was obtained by estimating the absorption of tritiated water into the plasma after instillation of the tritiated water into the bladder of volunteers. A direct measurement of urothelial diffusive permeability in the human has not yet been made.

Breakdown of the umbrella cells in animal models of cystitis has shown increased water and urea permeability. Presumably, leakage of urine into the detrusor is also responsible for the symptoms of cystitis (Lavelle et al, 1998, 2000). This increase in urothelial permeability with cystitis is increased further by distention of the bladder. The hypothesis is that with distention of the bladder, the weakened urothelium with denuded apical umbrella

cells and no real barrier in the intermediate or basal cells is further disrupted, thus allowing further egress of urine constituents into the detrusor. Similar breakdown of the apical cells is thought to occur in most forms of infectious cystitis and also in radiation cystitis.

Direct measurements of the osmotic effect on permeability have not been performed on urothelium. However, the urothelium maintains an osmotic gradient between plasma (300 mOsm/kg approximately) and urine (100 to 1500 mOsm/kg), depending on the level of water balance and diuresis of the individual. In the normal bladder, the osmotic effects of the urine appear to go unnoticed, and the patients have few or no symptoms. However, once the bladder is inflamed, such as in bladder pain syndrome/interstitial cystitis (BPS/IC), the effects of osmotic gradients become important (Gao et al, 1994).

Patients with spinal cord injury or with myelodysplasia tend to have chronic cystitis with bacteriuria and inflamed urothelium. When detrusor activity was increased in the rat by instillation of hyperosmolar compounds, this was accompanied by neurogenic inflammation, including plasma extravasation of Evans blue that could be decreased by pretreatment with the C-fiber afferent neurotoxin capsaicin (Maggi et al, 1990) indicating that hyperosmolar solutions excite afferent nerves. With increased osmolality, detrusor contractions were much stronger and accompanied by blood pressure elevations. These effects were enhanced when the bladder was pretreated with dimethyl sulfoxide to simulate cystitis conditions (Hohlbrugger and Lentsch, 1985; Hohlbrugger, 1987).

Increased permeability of the urothelium in inflammatory conditions has become the basis of the potassium sensitivity test, during which the bladder is distended with 400 mM of potassium chloride solution. Potassium penetrates the urothelium in the inflamed bladder and causes pain by activation of bladder afferent nerves (Parsons, 1996). This does not occur in normal bladders. The validity and accuracy of the intravesical potassium chloride test has not yet been proven clinically by multicenter randomized double-blind studies.

The fact that changes in the osmolality, pH, and ionic composition of the urine can influence the activity of the detrusor is important in the performance of cystometry. The nature of the infusate could alter the outcome of the test, particularly in the neurogenic bladder, where there are usually some changes in the urothelium because of the chronic bacteriuria (Hohlbrugger, 1995).

Ionic Transport

The apical membrane of the urothelium has a high electrical resistance (Lavelle et al, 1998, 2000), whereas the basolateral membrane resistance is approximately 10-fold lower (Clausen et al, 1979). Active sodium transport across the urothelium has been demonstrated (Wickham, 1964; Lewis and Diamond, 1976). Na^+ channels that exist on the apical surface of the umbrella cells and in the cytoplasmic vesicles below the apical surface are primarily amiloride sensitive (inhibition) and aldosterone responsive. However, amiloride-insensitive, cation-selective, as well as amiloride-insensitive, unstable cation channels have also been identified. Both of these channels were found to be degradation products of the amiloride-sensitive Na^+ channel. The amiloride-sensitive Na^+ channel is hydrolyzed by serine proteases such as kallikrein and urokinase and plasmin (normally found in the urine but produced by the kidney) (Lewis et al, 1995).

Sodium that is transported into the cell is removed at the basolateral membrane by a Na^+–K^+ exchanger. This leaves the cell with a negative intracellular charge. The basolateral membrane contains K^+ and Cl^- channels, Na^+–H^+ exchangers, and Cl^-–HCO_3^- exchangers. These channels and exchangers are important in recovery of cell volume during an increase in serosal osmolality (Donaldson and Lewis, 1990). Unfortunately, the precise role of the Na^+ channel in the apical membrane of the umbrella cell is unknown. It is possible that the degradation of the channel might follow the filling of the bladder and that the changes in conductance of sodium may be a signaling factor for the bladder and micturition when it reaches capacity. Alternatively, it may be involved in the signaling pathway that allows insertion or removal of apical membrane on expansion of the bladder.

Key Points: Urothelium

- Uroplakin proteins may be a key part of the primary plasma-urine barrier. Uroplakins have also been shown to act as the primary attachment site of type 1 piliated uropathogenic *Escherichia coli*.
- Protamine sulfate increases the luminal surface of umbrella cells permeability to cations and anions.
- The GAG layer may have importance in bacterial antiadherence and in prevention of urothelial damage, but there is no definite evidence that the GAG layer acts as the primary epithelial barrier between urine and plasma because the GAG layer does not prevent small molecules such as amiloride from reaching the cationic channels on the surface of the umbrella cells.

THE URETHRA

The urethra is composed of striated and smooth muscles. Contraction of the longitudinal smooth muscle could play a role in stabilizing the urethra and allowing force generated by the circular muscle elements to occlude the lumen or in aiding in the opening of the bladder neck during micturition. There is controversy about the relative roles of the urethral smooth and striated circular muscles and the lamina propria in generating the urethral pressure profile, but it seems likely that both contribute (Thind, 1995). **Blocking striated sphincter activity with nicotinic neuromuscular blocking agents has variable effects and may reduce urethral tone, but rarely by more than 40%, suggesting that the smooth muscles are important. Blocking sympathetic tone with α-adrenoceptor blockers may also reduce urethral pressure by about a third** (Torrens and Morrison, 1987). There is little evidence for the involvement of the cholinergic innervation in generating urethral pressure.

Urethral Muscle

The smooth muscle cells in the urethra are gathered into small bundles and linked to each other by many adherens-type junctions but no gap junctions. The smooth muscle bundles in the urethral wall are thinner than in the detrusor and arranged in obvious layers. **In humans and larger mammals, there is a relatively thick inner layer that is predominantly longitudinally arranged, and outside this, there is a thinner circular muscle layer.** In the lamina propria of the urethra, scattered small bundles of only a few cells are often found.

Striated muscle occurs in the walls of the male and female urethra, where it forms a rhabdosphincter that is separate from the periurethral skeletal muscle of the

pelvic floor. In the male, the striated muscle extends from the base of the bladder and the anterior aspect of the prostate to the full length of the membranous urethra. In the female, the striated muscle extends from the proximal urethra distally. The striated sphincter is horseshoe shaped, and the muscle cells are smaller than ordinary skeletal muscle, being 15 to 20 μm in diameter.

Morphology

The urethral stroma has been less extensively studied than the bladder stroma, but it is known to contain primarily longitudinally arranged collagen fibers and elastin fibers (Hickey et al, 1982; Huisman, 1983). The vascular filling of the urethral lamina propria is known to be of importance for urinary continence, although the magnitude of its contribution to continence is still not understood (Rud et al, 1980). Estrogen is known to increase the urethral blood flow, resulting in an increased distention of the lamina propria blood vessels (Brading, 1997a).

Impaired arterial blood supply to the urethra decreases the intraluminal pressure (Rud et al, 1980), but at present, it is not known whether it is the decrease in vascular filling or the urethral hypoxia that mediates the decrease in urethral pressure. It has been suggested that both these mechanisms may be involved because it was shown that the initial drop in urethral pressure was mediated through decreased vascular filling, whereas the later phase was due to a hypoxic effect on the urethral smooth muscle (Greenland and Brading, 1996).

Sphincter Configuration

An issue of continuing confusion is what composes the external sphincter and what the distinction is between the rhabdosphincter and the external striated sphincter proper. **In the membranous urethra, a thin smooth muscle layer extends along the entire urethra in the female and throughout the prostate and its capsule in the male** (Tanagho, 1982; Dixon and Gosling, 1987). **On the anterior surface of the male urethra, an outer layer of circularly oriented striated muscle forms a horseshoe configuration in the adult near the prostatic apex.** This striated muscle develops as a complete ring in the fetus and neonate and forms the external urethral sphincter or rhabdosphincter. **The periurethral striated muscles of the pelvic floor lie external to the rhabdosphincter** (see Fig. 60–2).

Despite the horseshoe configuration with the open end in the posterior direction, urethral pressure recording at the external sphincter during bladder filling increases uniformly along the entire circumference like an iris (Morita, 1989). Norepinephrine or hypogastric nerve stimulation augments this pressure, suggesting a role for adrenergic receptors and sympathetic nerves in the function of the external urethral sphincter (Kakizaki et al, 1991).

The arrangement of muscle forming the distal sphincter of the female differs from that in the male. **The female has an attenuated striated sphincter mechanism, as well as additional muscle structures termed the compressor urethrae and urethrovaginal sphincter** (DeLancey, 1989). The posterior wall remains rigid if there is adequate pelvic support from muscle and connective tissues. **As in the male, the striated components are deficient posteriorly.** This relative deficiency of periurethral striated musculature contributes to the difficulty in obtaining reliable external sphincter electromyography results during urodynamic studies in women. This attenuation of distal sphincteric muscles may contribute to urinary incontinence in females after resection of the bladder neck.

In women, urinary continence is maintained during elevations in intra-abdominal pressure by three processes. First, there is passive transmission of abdominal pressure to the proximal urethra. A guarding reflex involving an active contraction of striated muscle of the external urethral sphincter can transiently help continence (Enhorning, 1961; Tanagho, 1982). **However, mere transmission of abdominal pressure to proximal urethra does not account for the entire increase in urethral pressure** (Constantinou and Govan, 1982). **Urethral pressure rises before cough transmission** (Fig. 60–11). **These findings implicate an active urethral continence (neural) mechanism in women** (Constantinou and Govan, 1982). **DeLancey proposes the "hammock hypothesis" that abdominal pressure transmitted through the proximal urethra presses the anterior wall against the posterior wall. The posterior wall remains rigid if there is adequate pelvic support from muscle and connective tissues. More distally, based on morphologic data, DeLancey and colleagues** (DeLancey 1989, 1997; Sampselle and DeLancey, 1998) **have postulated that the urethral attachments to the pubis (pubourethral) and vaginal connections to pelvic muscles and fascia actively change the position of the bladder neck and proximal urethra with voiding. This**

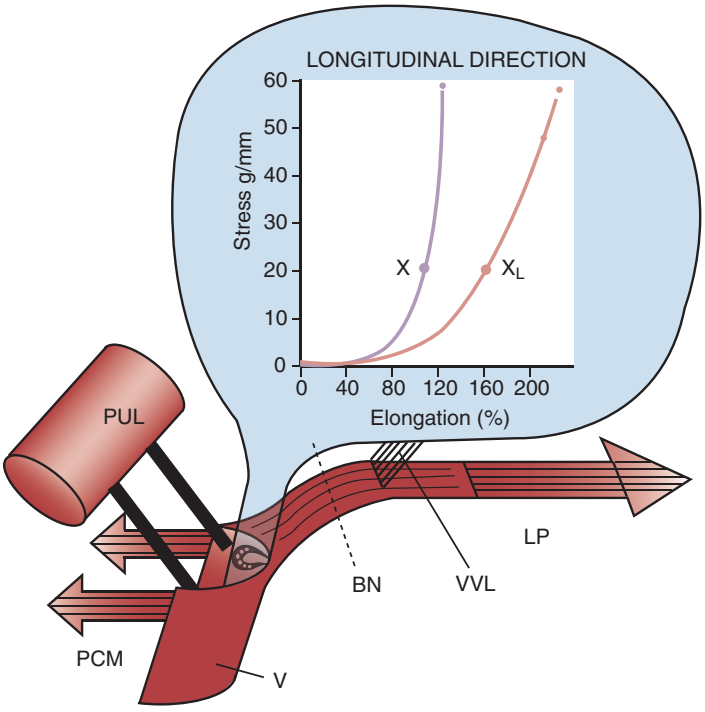

Figure 60–11. Influence of vaginal laxity on muscle force transmission and urinary continence. *Inset,* Stress extension curve of vagina. BN, bladder neck; LP, levator plate; PCM, pubococcygeus muscle; PUL, pubourethral ligament; V, vaginal hammock; VVL, vaginal attachment to the bladder base; X, normal elasticity; X_L, vaginal laxity. The authors propose that an increase in urethral pressure before cough transmission proves that an active continence mechanism is involved in preventing stress urinary incontinence. (From Petros PE, Ulmsten U. An integral theory and its method for the diagnosis and management of female urinary incontinence. Scand J Urol Nephrol 1993;27[Suppl. 153]:1–93.Copyright 1993, Scandinavian University Press, Stockholm, Sweden.)

arrangement compresses the urethra against the pubis during bladder filling and straining. These attachments contain both fascia and smooth muscle (Oelrich, 1983; DeLancey, 1988, 1989). **Thus urinary continence results from the combination of active muscle tone and passive anatomic coaptation.**

Fiber Types of Urethral Striated Muscle

Striated muscles are characterized as **slow type** and **twitch type**. **Twitch-type myofibrils can be further classified as slow and fast on the basis of functional and metabolic characteristics** (Padykula, 1967). Slow-twitch fibers seem ideally suited to maintaining sphincter tone for prolonged periods, whereas fast-twitch fibers may be needed to add to sphincter tone rapidly to maintain continence when intra-abdominal pressure is abruptly increased. Similar to smooth muscle, contraction of striated muscle fibers is governed by intracellular calcium, through interactions with troponin.

The fast-twitch fibers can be recruited rapidly but also fatigue rapidly, and perform predominantly anaerobic metabolism (Markwardt and Isenberg, 1992). Fast-twitch fibers exhibit rapid bursts of contractile force and are rich in myosin ATPase that catalyzes the actin–myosin interaction. The speed of contraction may be correlated with the histochemical reaction of this ATPase and alkaline pH. In addition, fast-twitch muscles are supplied with a fast isoform of the Ca^{2+}-ATPase, which translocates the cytosolic calcium into the abundant sarcoplasmic reticulum to allow rapid relaxation.

In contrast, slow-twitch fibers are found in greater percentage in muscles that require sustained tension, such as the pelvic levators and urethral sphincter. These muscle fibers are recruited and fatigue slowly and can perform high rates of oxidative metabolism because they possess less of the myosin ATPase activity and contain an increased expression of a slow isoform of the Ca^{2+}-ATPase (Markwardt and Isenberg, 1992). These fibers give rise to the background electromyographic activity seen during a urodynamic evaluation.

The external urethral sphincter is composed of two parts. The periurethral striated muscle of the pelvic floor contains both fast-twitch and slow-twitch fibers. The striated muscle of the distal sphincter mechanism contains predominantly slow-twitch fibers (Elbadawi, 1984) **and provides more than 50% of the static resistance** (Tanagho et al, 1989). **Gosling and colleagues** (2000) **presented histochemical evidence in humans that striated muscle within the distal urethra is composed primarily of slow-twitch myofibrils in contrast to the periurethral striated muscles of the pelvic floor, which contain fast-twitch and slow-twitch fibers. In the male, the rhabdosphincter consists of 35% fast-twitch and 65% slow-twitch fibers** (Padykula and Gauthier, 1970). **In the female, the ratio of slow-twitch to fast-twitch fibers is 87% slow-twitch and 13% fast-twitch.**

The majority of the fast-twitch fibers and about a fourth of the slow-twitch fibers in the intramural striated muscle of the human membranous urethral sphincter show positive staining for nitric oxide synthase in the sarcolemma (Ho et al, 1998). Moreover, the striated periurethral muscles of the pelvic floor are adapted for the rapid recruitment of motor units required during increases in abdominal pressure. **It has been speculated that the successful treatment of stress incontinence by pelvic floor exercises or electrostimulation is caused by the conversion of fast-twitch to slow-twitch striated muscle fibers** (Bazeed et al, 1982).

In addition to striated muscle, the external sphincter appears to contain smooth muscle, which receives noradrenergic innervation. Investigators have shown that stimulation of the hypogastric nerve elicits myogenic potentials in the external urethral sphincter (Kakizaki et al, 1991). Whether this activity is the result of smooth or striated muscle is unclear. Because these potentials persist after α-adrenergic blockade, investigators postulate that it arises from striated muscle.

Lamina Propria and Paraurethral Tissue

Results are divergent regarding the clinical significance of connective tissue outside the urethra. Paraurethral tissue biopsy specimens from premenopausal women with stress incontinence contain 30% more collagen, and the diameter of the fibrils is 30% larger than in controls (Falconer et al, 1998a). Postmenopausal stress-incontinent women, on the other hand, have no difference in collagen concentration compared with their age-matched controls (Falconer et al, 1998b). Others, however, have found a decreased periurethral collagen concentration (Rechberger et al, 1993) and a decreased collagen I to collagen III ratio (Keane et al, 1997) in patients with stress incontinence.

NEURAL CONTROL OF THE LOWER URINARY TRACT

Peripheral Nervous System

The lower urinary tract is innervated by three sets of peripheral nerves involving the parasympathetic, sympathetic, and somatic nervous systems (Fig. 60–12). **Pelvic parasympathetic nerves arise at the sacral level of the spinal cord, excite the bladder, and relax the urethra. Lumbar sympathetic nerves inhibit the bladder body and excite the bladder base and urethra. Pudendal nerves excite the external urethral sphincter.** These nerves contain afferent (sensory) as well as efferent axons (Wein, 1992; de Groat et al, 1993a; Sugaya et al, 1997; Yoshimura et al, 2008).

Parasympathetic Pathways

Parasympathetic preganglionic neurons innervating the lower urinary tract are located in the lateral part of the sacral intermediate gray matter in a region termed the sacral parasympathetic nucleus (Nadelhaft et al, 1980; Morgan et al, 1981; de Groat et al, 1993a; Morgan et al, 1993; de Groat et al, 1996). Parasympathetic preganglionic neurons send axons through the ventral roots to peripheral ganglia, where they release the excitatory transmitter acetylcholine (de Groat and Booth, 1993). **Parasympathetic postganglionic neurons in humans are located in the detrusor wall layer as well as in the pelvic plexus. This is an important fact to remember because patients with cauda equina or pelvic plexus injury are neurologically decentralized but may not be completely denervated. Cauda equina injury allows possible afferent and efferent neuron interconnection at the level of the intramural ganglia** (de Groat et al, 1993a; de Groat et al, 1996).

Sympathetic Pathways

Sympathetic outflow from the rostral lumbar spinal cord provides a noradrenergic excitatory and inhibitory input to the bladder and

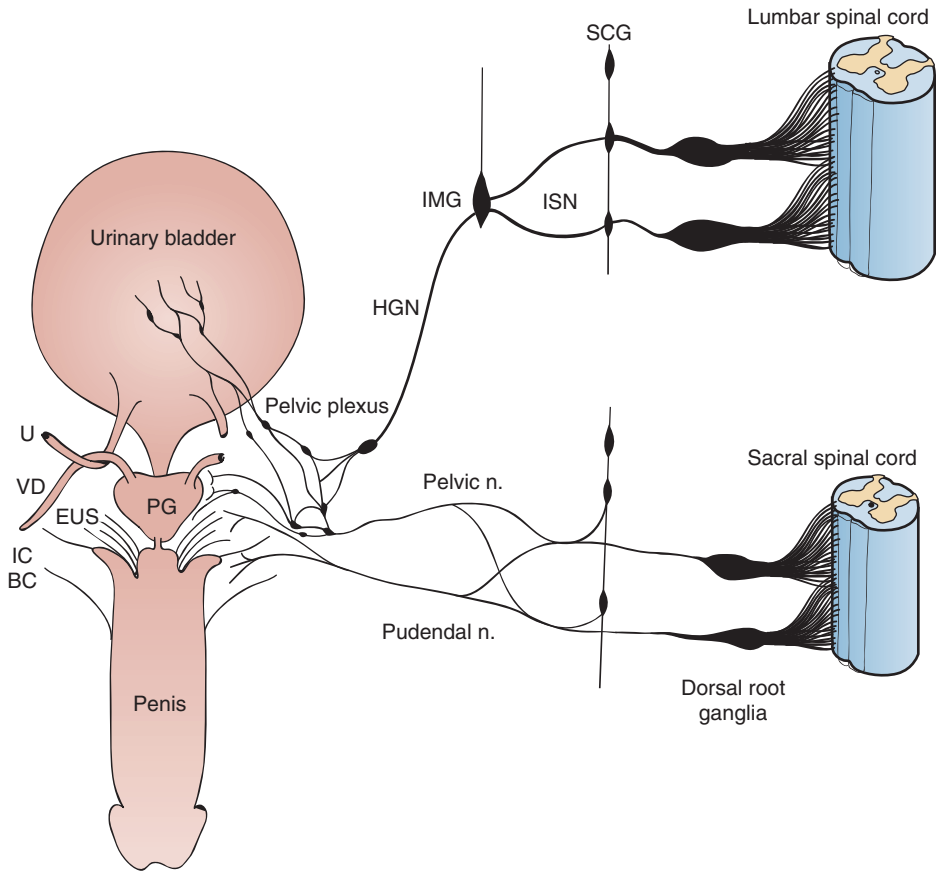

Figure 60–12. Diagram showing the sympathetic, parasympathetic, and somatic innervation of the urogenital tract of the male cat. Sympathetic preganglionic pathways emerge from the lumbar spinal cord and pass to the sympathetic chain ganglia (SCG) and then through the inferior splanchnic nerves (ISN) to the inferior mesenteric ganglia (IMG). Preganglionic and postganglionic sympathetic axons then travel in the hypogastric nerve (HGN) to the pelvic plexus and the urogenital organs. Parasympathetic preganglionic axons that originate in the sacral spinal cord pass in the pelvic nerve to ganglion cells in the pelvic plexus and to distal ganglia in the organs. Sacral somatic pathways are contained in the pudendal nerve, which provides an innervation to the penis and the ischiocavernosus (IC), bulbocavernosus (BC), and external urethral sphincter (EUS) muscles. The pudendal and pelvic nerves also receive postganglionic axons from the caudal sympathetic chain ganglia. These three sets of nerves contain afferent axons from the lumbosacral dorsal root ganglia. PG, prostate gland; U, ureter; VD, vas deferens.

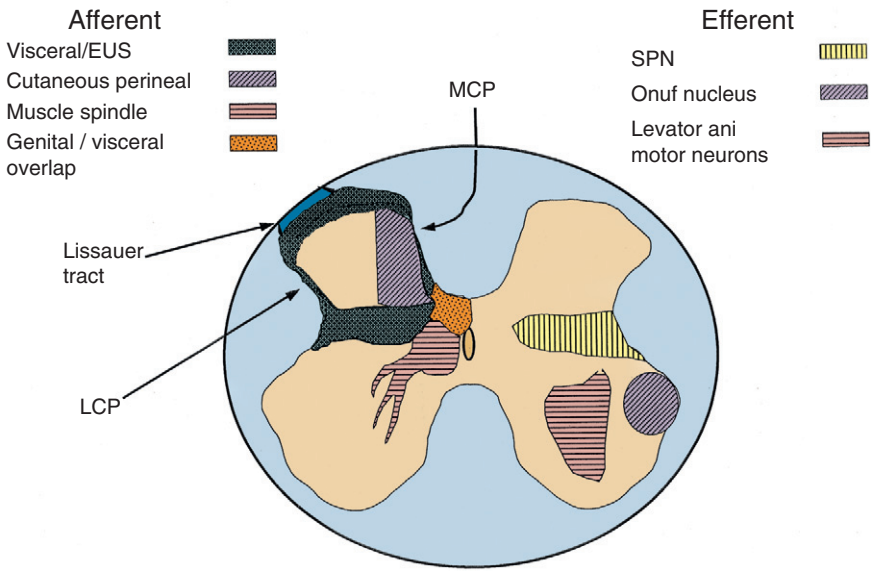

Figure 60–13. Cross section of sacral spinal cord; neuroanatomic distribution of primary afferent and efferent components of storage and micturition reflexes. For purposes of clarity, afferent components are shown only on the *left*, and efferent components are shown only on the *right*. Both components are, of course, distributed bilaterally and thus overlap extensively. Visceral afferent components represent bladder, urethral, and genital (glans penis or clitoris) afferent fibers contained in the pelvic and pudendal nerves. Cutaneous perineal afferent components represent afferent fibers that innervate the perineal skin contained in the pudendal nerve. Muscle spindle afferent components represent Ia/b afferent fibers contained in the levator ani nerve that innervate muscle spindles in the levator ani muscle. EUS, external urethral sphincter; LCP, lateral collateral projection; MCP, medial collateral projection; SPN, sacral parasympathetic nucleus.

urethra (Andersson, 1993). Activation of sympathetic nerves induces relaxation of the bladder body and contraction of the bladder outlet and urethra, which contribute to urine storage in the bladder. **The peripheral sympathetic pathways follow a complex route that passes through the sympathetic chain ganglia to the inferior mesenteric ganglia and then through the hypogastric nerves to the pelvic ganglia.**

Somatic Pathways

The external urethral sphincter motoneurons are located along the lateral border of the ventral horn, commonly referred to as the Onuf nucleus (Fig. 60–13) (Thor et al, 1989). Sphincter motoneurons also exhibit transversely oriented dendritic bundles that project laterally into the lateral funiculus, dorsally into the intermediate gray matter, and dorsomedially toward the central canal.

Afferent Pathways

Afferent axons in the pelvic, hypogastric, and pudendal nerves transmit information from the lower urinary tract to the lumbosacral spinal cord (de Groat, 1986; Janig and Morrison, 1986; Yoshimura et al, 2008). **The primary afferent neurons of the pelvic and pudendal nerves are contained in sacral dorsal root ganglia (DRG), whereas afferent innervation in the hypogastric nerves arises in the rostral lumbar DRG.** The central axons of the DRG neurons carry the sensory information from the lower urinary tract to second-order neurons in the spinal cord (Morgan et al, 1981; de Groat, 1986; Thor et al, 1989; de Groat et al, 1996) (see Fig. 60–13). Visceral afferent fibers of the pelvic (Morgan et al, 1981) and pudendal (Thor et al, 1989) nerves enter the cord and travel rostrocaudally within the Lissauer tract.

Pelvic nerve afferents, which monitor the volume of the bladder and the amplitude of the bladder contraction, consist of myelinated (Aδ) and unmyelinated (C) axons (Table 60–3). **During neuropathic conditions and possibly inflammatory conditions, there is recruitment of C fibers that form a new functional afferent pathway that can cause urgency incontinence and possibly bladder pain.**

Sensing bladder volume is of particular relevance during urine storage. On the other hand, afferent discharges that occur during a bladder contraction have an important reflex function and appear to reinforce the central drive that maintains the detrusor contraction. Afferent nerves that respond to both distention and contraction, that is, "in-series tension receptors," have been identified in the pelvic and hypogastric nerves of cats and rats (see Table 60–3) (Iggo, 1955; Floyd et al, 1976; Morrison, 1997). Afferents that respond only to bladder filling have been identified in the rat bladder (Morrison, 1998) and appear to be volume receptors, possibly sensitive to stretch of the mucosa. In the cat bladder, some in-series tension receptors may also respond to bladder stretch (Downie and Armour, 1992). In the rat, there is evidence that many C bladder afferents are volume receptors that do not respond to bladder contractions, a property that distinguishes them from in-series tension receptors (Morrison, 1998).

In the mouse pelvic nerve, four classes of bladder afferents (serosal, muscular, muscular/urothelial, and urothelial) have been identified based on responses to receptive field stimulation with different mechanical stimuli, including probing, stretch, and stroking the urothelium. Both low-threshold, representing 65% to 80% of the total population, and high-threshold stretch-sensitive muscular afferents are present (Daly et al, 2007; Xu and Gebhart, 2008). The muscular afferents can be sensitized by application of a combination of inflammatory mediators (bradykinin, serotonin, prostaglandin, and histamine at pH 6.0) (Xu and Gebhart, 2008).

In the guinea pig bladder, four classes of C-fiber afferents have also been detected (Zagorodnyuk et al, 2006, 2007). The first class, muscle mechanoreceptors, are activated by stretch but not by mucosal stroking with light (0.05 to 0.1 mN) von Frey hairs or by hypertonic saline, α,β-methylene ATP or capsaicin. Removal of the urothelium did not affect their stretch-induced firing. The second class, muscle-mucosal mechanoreceptors, are activated by both stretch and mucosal stroking, by hypertonic solution, α,β-methylene-ATP but not by capsaicin. Stroking- and stretch-induced firing is significantly reduced by removal of the urothelium. The third class of afferents, mucosal high-responding mechanoreceptors, are stretch insensitive but can be activated by mucosal stroking, hypertonic solution, α,β-methylene-ATP, and capsaicin. Stroking-induced activity is reduced by removal of the urothelium. The fourth class of afferents, mucosal low-responding mechanoreceptors, are stretch insensitive but can be weakly activated by mucosal stroking but not by hypertonic solution, α,β-methylene-ATP, or capsaicin. Removal of the urothelium reduces stroking-induced firing. A recent study by Zagorodnyuk and colleagues (2009) also showed that mechanotransduction during stretch or mucosal stroking in the second and third classes of afferents, stretch-sensitive muscle-mucosal mechanoreceptors, and stretch-insensitive, mucosal high-responding afferents, are not dependent upon Ca^{2+}-dependent exocytotic release of mediators or ATP, but are likely to be induced by benzamil-sensitive, stretch-activated ion channels on nerve endings. This is because stretch- or stroking-induced firing of these afferents are not affected by the nonselective P2 purinoreceptor antagonist or Ca^{2+}-free solution, but are inhibited by benzamil, a mechanogated channel blocker. These results suggest that substances released from the urothelium during mechanical stimulation, such as ATP, may not be involved in the modulation of the activity of bladder afferents located in the vicinity of the urothelium, at least in the normal condition, which is against the current theory of the urothelium–afferent interaction by urothelially released substances during bladder stretch.

Species differences, as well as differences of nomenclature, might account for some of the variations in reported properties of bladder afferents. For example, the conduction velocity that differentiates Aδ and C fibers is 2 m/sec in the cat, whereas it is 1.3 m/sec in the rat (Waddell et al, 1989). In the cat, Aδ bladder afferents appear to be low-threshold mechanoreceptors (Häbler et al, 1993), whereas C-bladder afferents (Häbler et al, 1990) are generally mechanoinsensitive ("silent C fibers") (see Table 60–3). Some of the latter may be nociceptive and have been found to be sensitized by intravesical administration of chemicals (such as high potassium), low pH, high osmolality, and irritants such as capsaicin (Fig. 60–14) (Maggi et al, 1987; McMahon and Abel, 1987; Häbler et al, 1990; Wen et al, 1994; Wen and Morrison, 1994, 1996; Zagorodnyuk et al, 2009). After exposure to these

Table 60–3.

Bladder Afferent Properties

FIBER TYPE	LOCATION	NORMAL FUNCTION	INFLAMMATION EFFECT
Aδ (finely myelinated axons)	Smooth muscle	Sense bladder fullness (wall tension)	Increase discharge at lower pressure threshold
C fiber (unmyelinated axons)	Mucosa	Respond to stretch (bladder volume sensors)	Increase discharge at lower threshold
C fiber (unmyelinated axons)	Mucosa muscle	Nociception to overdistention	Sensitive to irritants
		Silent afferent	Becomes mechanosensitive and unmasks new afferent pathway during inflammation

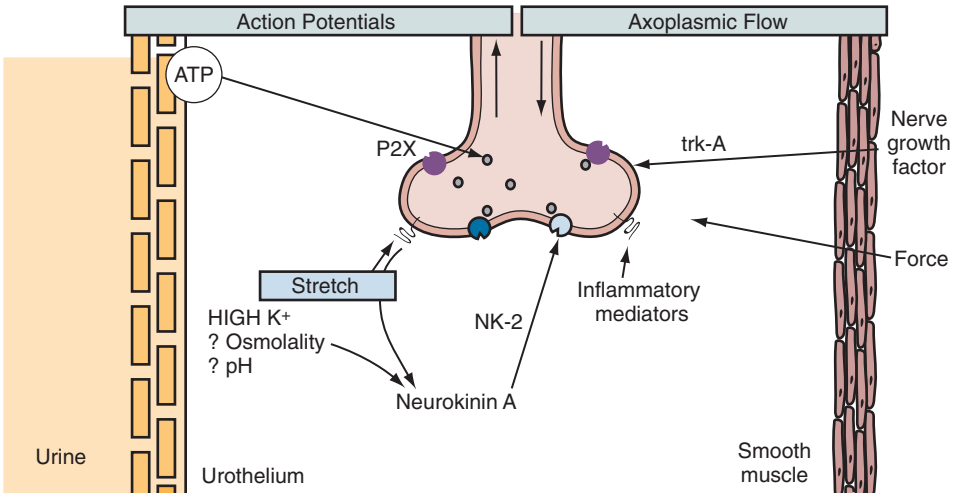

Figure 60–14. Actions of chemical mediators that may sensitize mechanosensory nerve endings in the bladder mucosa. Adenosine triphosphate (ATP) can be released from the urothelium and may sensitize the mechanoreceptors, which respond to stretch of the mucosa during bladder distention. Neuropeptides transported to the sensory ending by axoplasmic transport may be released during distention and chemical stimulation, and neurokinin A can act on NK_2 autoreceptors, which sensitize the mechanosensitive endings. This mechanism can be induced by high urinary potassium concentrations and possibly by other sensitizing solutions within the bladder lumen, such as those with high osmolality or low pH; the presence in the tissues of inflammatory mediators may also sensitize the endings. The smooth muscle can generate force that may influence some mucosal endings, and the production of nerve growth factor is another mechanism that can influence the mechanosensitivity of the sensory ending through the TrkA receptor.

substances, the sensitivity of bladder mechanoreceptors to distention increases, and some "silent" afferents become mechanoreceptive.

In the urethra, afferent nerves are distributed between the muscle fibers, around blood vessels, in the urothelium, and in a dense suburothelial plexus (Crowe et al, 1986; Tainio, 1993; Fahrenkrug and Hannibal, 1998). In some species, afferent nerves extend to the luminal surface of the urothelium. The striated sphincter muscle that surrounds the urethra receives a very sparse afferent innervation that is localized primarily to nerve bundles passing between the muscle bundles. Specialized tension receptors (muscle spindles) that are innervated by large-diameter myelinated group IA afferents and that are prominent in most striated muscles are absent (Gosling et al, 1981) or are present in low density (Lassmann, 1984) in striated sphincter muscles.

Afferent Nerves and Interorgan Cross Sensitization. Axonal tracing studies revealed that a subpopulation (6% to 21%) of afferent neurons in dorsal root ganglia of the rat and mouse can innervate multiple pelvic organs (Keast and de Groat, 1992; Christianson et al, 2007). In the rat, the largest percentage of these neurons is present in the thoracolumbar DRG; whereas in the mouse the larger percentage is in the lumbosacral DRG. Subsequent studies provided evidence that **chemical irritation of one organ (either the urinary bladder or the colon) can facilitate/sensitize the activity of the other organ** (Pezzone et al, 2005). Electrophysiologic experiments showed that acute colonic irritation can sensitize bladder C-fiber afferents to mechanical and chemical stimuli (Ustinova et al, 2006, 2007) and enhance the firing of lumbosacral spinal interneurons receiving afferent input from the bladder (Qin et al, 2005). Lumbosacral afferent neurons in the L6-S2 DRG innervating both the colon and bladder ("convergent neurons") exhibited decreased voltage and current thresholds for action potential firing three days after colonic irritation with trinitrobenzene sulfonic acid (TNBS) in rats (Malykhina et al, 2006). The effect persisted for 30 days in the absence of overt colonic inflammation. Colitis also enhanced the responses to capsaicin and increased the peak amplitude of tetrodotoxin-resistant Na^+ currents in bladder afferent neurons isolated from the L6-S2 DRG (Malykhina et al, 2004).

Changes in bladder function after colonic inflammation also appear to be mediated by a change in the cholinergic efferent pathway to the bladder (Noronha et al, 2007). During the active colonic inflammation, three days after TNBS instillation into the colon, the bladder was not inflamed, but the contractions of bladder strips induced by electrical field stimulation or carbachol, a muscarinic receptor agonist, were reduced, while the contractions induced by potassium (KCl) were not changed. During and after recovery of the colonic inflammation (15 to 30 days), the contractile responses of the bladder returned to normal. It was suggested that bladder dysfunction was mediated by visceral organ cross talk induced by sensitization of a subpopulation of afferents innervating both the bladder and colon.

Key Points: Afferent Pathways

- Studies of the properties of bladder afferents in the pelvic nerve, particularly in the rat, indicate that in series tension receptors, volume receptors and silent afferents (including nociceptors) are present.
- Intravesical irritant chemicals reduce the pressure thresholds of most of these endings, including the high-threshold receptors.
- A substantial proportion of the C-fiber afferent population is silent (i.e., insensitive to normal distention). However, these fibers become mechanosensitive after the action of various chemical mediators.
- During inflammation and possibly other pathologic conditions, there is recruitment of mechanosensitive C fibers that form a new functional afferent pathway. This is the rationale for intravesical C-fiber neurotoxin capsaicin and resiniferatoxin (RTX) therapy (Chancellor and de Groat, 1999).

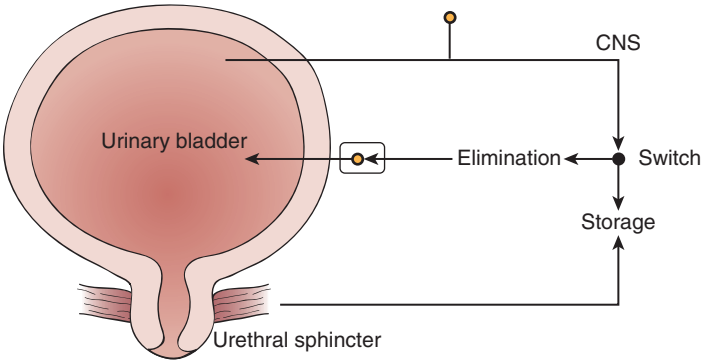

Figure 60–15. Diagram illustrating the anatomy of the lower urinary tract and the "switchlike" function of the micturition reflex pathway. During urine storage, a low level of afferent activity activates efferent input to the urethral sphincter. A high level of afferent activity induced by bladder distention activates the switching circuit in the central nervous system (CNS), producing firing in the efferent pathways to the bladder, inhibition of the efferent outflow to the sphincter, and urine elimination.

Table 60–4.

Reflexes to the Lower Urinary Tract

AFFERENT PATHWAY	EFFERENT PATHWAYS	CENTRAL PATHWAY
Urine Storage		
Low-level vesical afferent activity (pelvic nerve)	External sphincter contraction (somatic nerves) Internal sphincter contraction (sympathetic nerves) Detrusor inhibition (sympathetic nerves) Ganglionic inhibition (sympathetic nerves) Sacral parasympathetic outflow inactive	Spinal reflexes
Micturition		
High-level vesical afferent activity (pelvic nerve)	Inhibition of external sphincter activity Inhibition of sympathetic outflow Activation of parasympathetic outflow to the bladder Activation of parasympathetic outflow to the urethra	Spinobulbospinal reflex

Reflex Circuitry Controlling Micturition

Multiple reflex pathways organized in the brain and spinal cord mediate coordination between the urinary bladder and the urethra. The central pathways controlling lower urinary tract function are organized as simple on-off switching circuits (Fig. 60–15) that maintain a reciprocal relationship between the urinary bladder and the urethral outlet (de Groat, 1975; de Groat et al, 1993a). The principal reflex components of these switching circuits are listed in Table 60–4 and illustrated in Figure 60–16. Some reflexes promote urine storage, whereas others facilitate voiding. It is also possible that individual reflexes might be linked together in a serial manner to create complex feedback mechanisms. For example, **the bladder to external urethral sphincter guarding reflex that triggers sphincter contractions during bladder filling could, in turn, activate sphincter muscle afferents that initiate an inhibition of the parasympathetic excitatory pathway to the bladder. Thus a bladder to sphincter to bladder reflex pathway could, in theory, contribute to the suppression of bladder activity during urine storage. Alterations in these primitive reflex mechanisms may contribute to neurogenic bladder dysfunction.** Direct activation of these reflexes by electrical stimulation of the sacral spinal roots very likely contributes to therapeutic effects of sacral nerve root neuromodulation (Dijkema et al, 1993; Chancellor and Chartier-Kastler, 2000).

The Storage Phase of the Bladder

Intravesical pressure measurements during bladder filling in both humans and animals reveal low and relatively constant bladder pressures when bladder volume is below the threshold for inducing voiding (Fig. 60–17). **The accommodation of the bladder to increasing volumes of urine is primarily a passive phenomenon dependent on the intrinsic properties of the vesical smooth muscle and stroma, as well as the quiescence of the parasympathetic efferent pathway** (Torrens and Morrison, 1987; de Groat et al, 1993a; Yoshimura et al, 2008). **The bladder to sympathetic reflex also contributes as a negative feedback or urine storage mechanism that promotes closure of the urethral outlet and inhibits neurally mediated contractions of the bladder during bladder filling** (de Groat and Theobald, 1976) (see Table 60–4). Reflex activation of the sympathetic outflow to the lower urinary tract can be triggered by afferent activity induced by distention of the urinary bladder (de Groat and Theobald, 1976; de Groat et al, 1993a). This reflex response is organized in the lumbosacral spinal cord and persists after transection of the spinal cord at the thoracic levels (Fig. 60–18). **However, this bladder to sympathetic mechanism to suppress bladder contractions during urine storage may be weak in humans**, given that bilateral retroperitoneal lymph node dissection, in which the sympathetic chains are destroyed, has no discernible alteration of filling or storage function in humans.

During bladder filling, the activity of the sphincter electromyogram also increases (see Fig. 60–17), **reflecting an increase in efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of urinary continence. Pudendal motoneurons are activated by bladder afferent input (the guarding reflex)** (Park et al, 1997), **whereas during micturition the motoneurons are reciprocally inhibited** (de Groat et al, 1993a). External urethral sphincter motoneurons are also activated by urethral or perineal afferents in the pudendal nerve (Fedirchuk et al, 1992). This reflex may represent, in part, a continence mechanism that is activated by proprioceptive afferent input from the urethra or pelvic floor and that induces closure of the urethral outlet. These excitatory sphincter reflexes are organized in the spinal cord. **Inhibition of external urethral sphincter reflex activity during micturition is dependent, in part, on supraspinal mechanisms, because it is weak or absent in chronic spinal animals and humans, resulting in simultaneous contractions of bladder and**

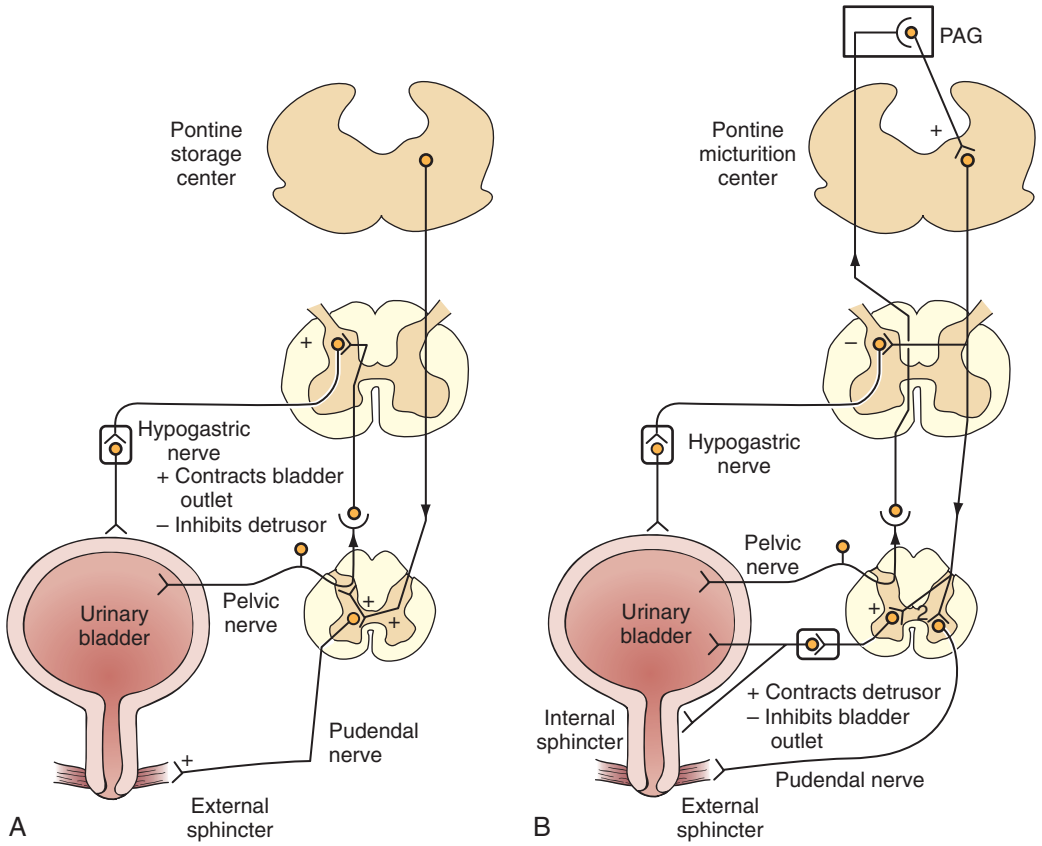

Figure 60–16. Mechanism of storage and voiding reflexes. **A,** Storage reflexes. During the storage of urine, distention of the bladder produces low-level bladder afferent firing. Afferent firing, in turn, stimulates the sympathetic outflow to the bladder outlet (base and urethra) and pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways and represent "guarding reflexes," which promote continence. Sympathetic firing also inhibits detrusor muscle and transmission in bladder ganglia. **B,** Voiding reflexes. At the initiation of micturition, intense vesical afferent activity activates the brainstem micturition center, which inhibits the spinal guarding reflexes (sympathetic and pudendal outflow to the urethra). The pontine micturition center also stimulates the parasympathetic outflow to the bladder and internal sphincter smooth muscle. Maintenance of the voiding reflex is through ascending afferent input from the spinal cord, which may pass through the periaqueductal gray matter (PAG) before reaching the pontine micturition center.

sphincter (i.e., detrusor-sphincter dyssynergia) (Rossier and Ott, 1976; Blaivas, 1982).

Sphincter to Bladder Reflexes. It is well known that **stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding function. The inhibition can be induced by activation of afferent input from various sites, including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter** (de Groat et al, 1979, 1993a, 2001). Electrophysiologic studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons (de Groat et al, 1982).

On the basis of experiments in our laboratory and the review of medical literature, we believe that contractions of the external urethral sphincter, and possibly other pelvic floor striated muscles, stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (Fig. 60–19). A similar inhibitory mechanism has been identified in monkeys by directly stimulating the anal sphincter muscle (McGuire et al, 1983). In monkeys, at least part of the inhibitory mechanism must be localized in the spinal cord, because it persisted in T4 chronic paraplegic animals.

The Emptying Phase of the Bladder

The storage phase of the bladder can be switched to the voiding phase either involuntarily (reflexively) or voluntarily. The former is readily demonstrated in the human infant or in patients with neuropathic bladder when the bladder wall tension due to increased volume of urine exceeds the micturition threshold. At this point, increased afferent firing from tension receptors in the bladder reverses the pattern of efferent outflow, producing firing in the sacral parasympathetic pathways and inhibition of sympathetic and somatic pathways. The expulsion phase consists of an initial relaxation of the urethral sphincter (see Fig. 60–17) **followed in a few seconds by a contraction of the bladder, an increase in bladder pressure, and the flow of urine. Relaxation of the urethral smooth muscle during micturition is mediated by activation of a parasympathetic pathway to the urethra that triggers the release of nitric oxide, an inhibitory transmitter** (Andersson, 1993; Bennett et al, 1995), **and by removal of excitatory inputs to the urethra. Secondary reflexes elicited by flow of urine through the urethra facilitate bladder emptying** (Torrens and Morrison, 1987; de Groat et al, 1993a; Jung et al, 1999). These reflexes

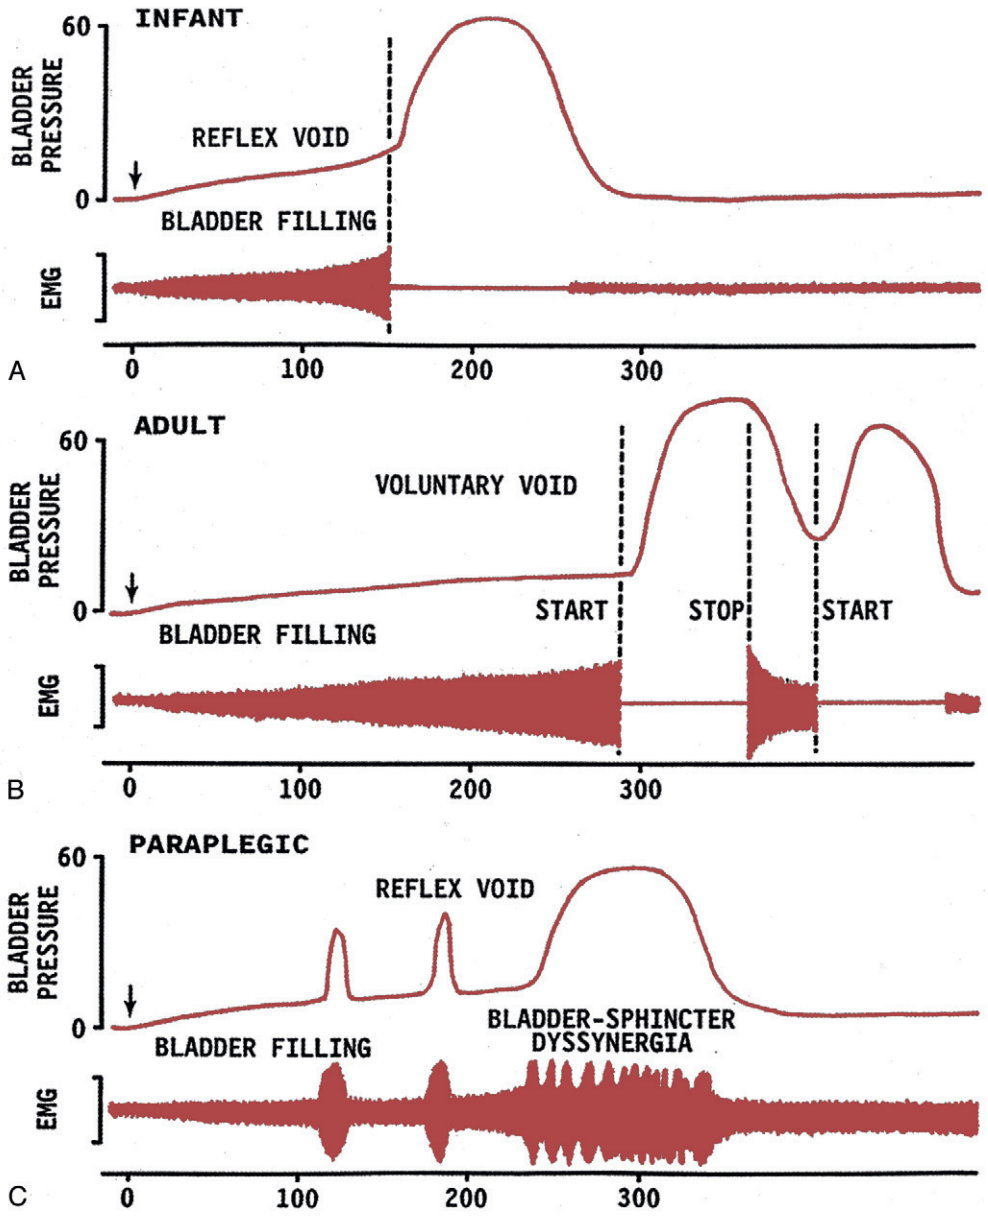

Figure 60–17. Combined cystometrogram and sphincter electromyogram (EMG) comparing reflex voiding responses in an infant **(A)** and in a paraplegic patient **(C)** with a voluntary voiding response in an adult **(B).** The x-axis in all records represents bladder volume in milliliters, and the y-axis represents bladder pressure in centimeters of water and electrical activity of the electromyographic recording. On the *left* side of each trace, the arrows indicate the start of a slow infusion of fluid into the bladder (bladder filling). Vertical *dashed lines* indicate the start of sphincter relaxation that precedes by a few seconds the bladder contraction in **A** and **B.** In **B,** note that a voluntary cessation of voiding (stop) is associated with an initial increase in sphincter electromyographic activity followed by a reciprocal relaxation of the bladder. A resumption of voiding is again associated with sphincter relaxation and a delayed increase in bladder pressure. On the other hand, in the paraplegic patient **(C),** the reciprocal relationship between bladder and sphincter is abolished. During bladder filling, transient uninhibited bladder contractions occur in association with sphincter activity. Further filling leads to more prolonged and simultaneous contractions of the bladder and sphincter (bladder-sphincter dyssynergia). Loss of the reciprocal relationship between bladder and sphincter in paraplegic patients interferes with bladder emptying. (From de Groat WC. Basic neurophysiology and neuropharmacology. In: Abrams P, Khoury S, Wein A, editors. Incontinence. Plymouth [UK]: Health Publications; 1999. p. 112.)

require the integrative action of neuronal populations at various levels of the neuraxis (see Fig. 60–16A). **The parasympathetic outflow to the detrusor and urethra has a more complicated central organization involving spinal and spinobulbospinal pathways passing through a micturition center in the pons (pontine micturition center)** (see Fig. 60–16B).

Urethra to Bladder Reflexes. A landmark in the historical progress of neurourology is the contribution of Barrington. Using his keen observational skills, Barrington (1931, 1941) reported that urine flow or mechanical stimulation of the urethra with a catheter could excite afferent nerves that, in turn, facilitated reflex bladder contractions in the anesthetized cat (see Fig. 60–19). **He proposed that this facilitatory urethra to bladder reflex could promote complete bladder emptying.** Barrington identified two components of this reflex. One component was activated by a somatic afferent pathway in the pudendal nerve and produced facilitation by a supraspinal mechanism involving

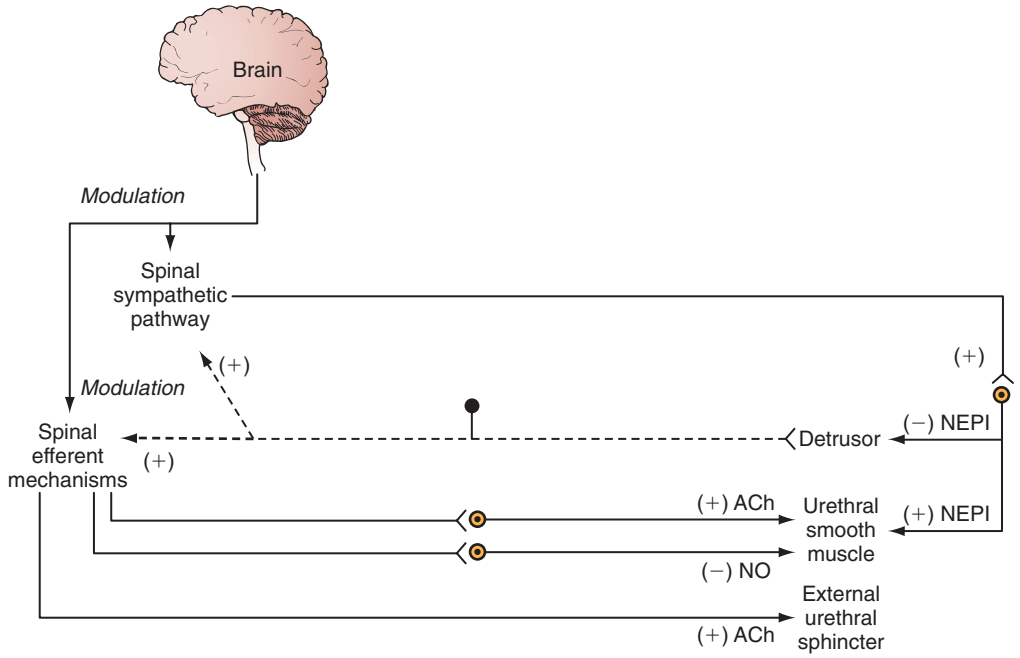

Figure 60–18. Diagram showing bladder to urethra reflex pathways. Afferent pathway *(dashed line)* from the detrusor activates spinal reflex mechanisms that induce firing in somatic cholinergic nerves to the external urethral sphincter, sympathetic adrenergic nerves to the urethral smooth muscle, and cholinergic and nitrergic nerves to the urethral smooth muscle. Bulbospinal pathways from the brain can modulate these spinal reflex mechanisms. ACh, acetylcholine; NEPI, norepinephrine; NO, nitric oxide; excitatory (+) and inhibitory (–) mechanisms.

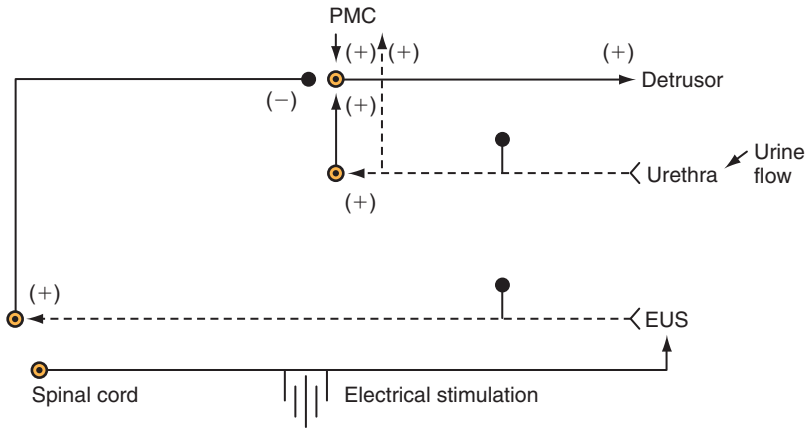

Figure 60–19. Urethra to bladder reflexes. Activity in afferent nerves *(dashed lines)* from the urethra can facilitate parasympathetic efferent outflow to the detrusor by means of a supraspinal pathway passing through the pontine micturition center (PMC), as well as a spinal reflex pathway. Afferent input from the external urethral sphincter (EUS) can inhibit parasympathetic outflow to the detrusor through a spinal reflex circuit. Electrical stimulation of motor axons in the S1 ventral root elicits an EUS contraction and EUS afferent firing that, in turn, inhibits reflex bladder activity, excitatory (+) and inhibitory (–) mechanisms.

the pontine micturition center (Barrington, 1931) (see Fig. 60–19). Studies have confirmed the existence of this type of reflex by the pudendal nerve because low-frequency electrical stimulation of afferent axons in the pudendal nerve in humans, or the deep perineal nerve (a caudal branch of the pudendal nerve) in cats, can initiate reflex bladder contractions and voiding (Shefchyk and Buss, 1998; Boggs et al, 2005). The other component was activated by a visceral afferent pathway in the pelvic nerve and produced facilitation by a spinal reflex mechanism (Barrington, 1941).

Studies (Jung et al, 1999) in the anesthetized rat have also provided additional support for Barrington's findings (Dokita et al, 1991). Measurements of reflex bladder contractions, under isovolumetric conditions during continuous urethral perfusion (0.075 mL/min), revealed that the frequency of micturition reflexes was significantly reduced when urethral perfusion was stopped or after infusion of lidocaine (1%) into the urethra. Intraurethral infusion of nitric oxide donors (*S*-nitroso-*N*-acetylpenicillamine [SNAP], or nitroprusside, 1 to 2 mM) markedly decreased urethral perfusion pressure (approximately 30%) and decreased the frequency of reflex bladder contractions (45% to 75%) but did not change the amplitude of bladder contractions (Fig. 60–20). Desensitization of the urethral afferent with intraurethral capsaicin also dramatically altered the micturition reflex (Fig. 60–21). It was concluded that activation of urethral afferents during urethral perfusion could modulate the micturition reflex in the rat. This may be an explanation of why stress incontinence and urgency incontinence often occur together in women. Jung and colleagues (1999) speculated that **in women with mixed incontinence, leakage of urine into the urethra can stimulate afferents and induce or increase detrusor overactivity. The theory is that stress incontinence can induce urgency incontinence** (Lavelle et al, 2000). Surgical cure of the stress incontinence of women with mixed incontinence has resolved the urgency incontinence in up to half of the patients.

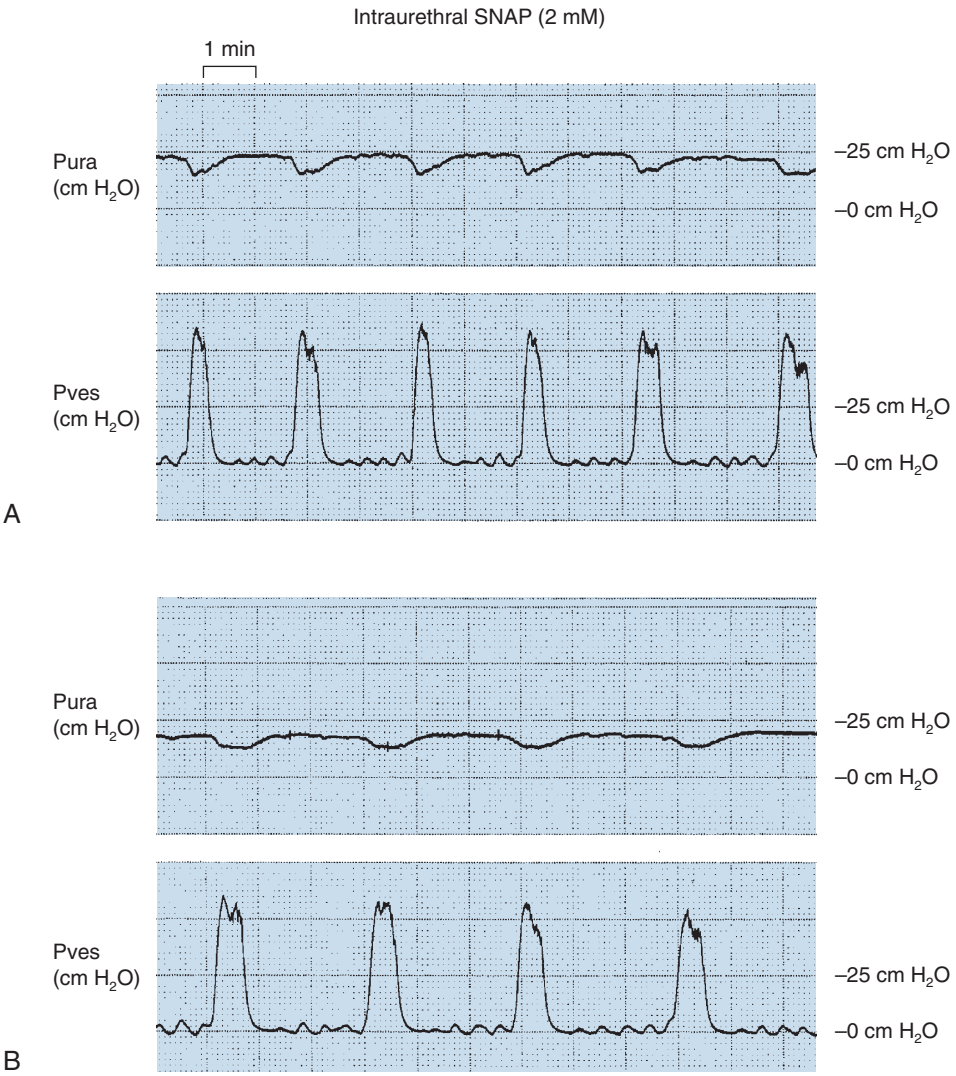

Figure 60–20. Effects of intraurethral *S*-nitroso-*N*-acetylpenicillamine (SNAP) on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. **A,** Before treatment. **B,** After intraurethral administration of SNAP (2 mM). Urethral perfusion pressure immediately decreased. In addition, bladder contraction frequency was significantly decreased. The duration of reflex urethral relaxation was increased. (From Jung SY, Fraser MO, Ozawa H, et al. Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. J Urol 1999;162:204–12.)

Spinal and Supraspinal Pathways Involved in the Micturition Reflex

Spinal Cord

In the spinal cord, afferent pathways terminate on second-order interneurons that relay information to the brain or to other regions of the spinal cord, including the preganglionic and motor nuclei. Because disynaptic or polysynaptic pathways, but not monosynaptic pathways, mediate bladder, urethral, and sphincter reflex, interneuronal mechanisms must play an essential role in the regulation of lower urinary tract function. Electrophysiologic (de Groat et al, 1981; Araki and de Groat, 1997) and neuroanatomic (Birder and de Groat, 1993; Vizzard et al, 1995; Nadelhaft and Vera, 1996; Sugaya et al, 1997) techniques have identified lower urinary tract interneurons in the same regions of the cord that receive afferent input from the bladder.

As shown in Figure 60–13, horseradish peroxidase labeling techniques in the cat revealed that afferent projections from the external urethral sphincter and levator ani muscles (i.e., pelvic floor) project into different regions of the sacral spinal cord. The external urethral sphincter afferent terminals are located in the superficial layers of the dorsal horn and at the base of the dorsal horn (laminae V to VII and lamina X), whereas the levator ani afferents project into a region just lateral to the central canal and extend into the medial ventral horn. The external urethral sphincter afferents overlap closely with the central projections of visceral afferents in pelvic nerve that innervate the bladder and urethra (Morgan et al, 1981). Intracellular labeling experiments also showed that the dendritic patterns of external urethral sphincter motoneurons (Sasaki, 1994) and parasympathetic preganglionic neurons (Morgan et al, 1993) are similar. **Pharmacologic experiments revealed that glutamic acid is the excitatory transmitter in these pathways.** In addition, approximately 15% of interneurons medial to the sacral parasympathetic nucleus in laminae V through VII make inhibitory synaptic connections with the preganglionic neurons (de Groat et al, 1996). **These inhibitory neurons release γ-aminobutyric acid (GABA) and glycine. Reflex pathways that control the external sphincter muscles also use glutamatergic excitatory and GABAergic and glycinergic inhibitory interneuronal mechanisms.**

Tracing with neurotropic viruses, such as pseudorabies virus, has been particularly useful. Pseudorabies virus can be injected into a target organ and then move intra-axonally from the periphery to the central nervous system. In the nervous system, the virus can

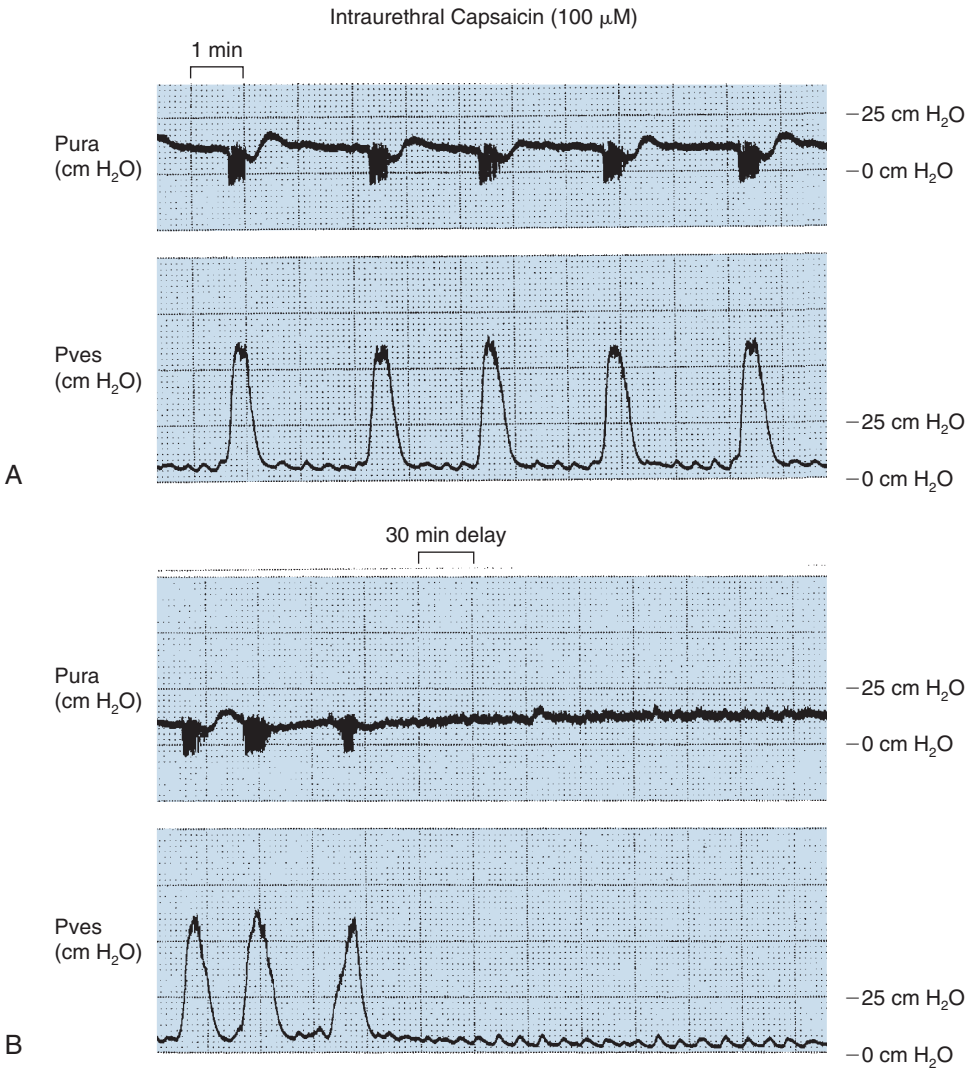

Figure 60–21. Effects of intraurethral capsaicin on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. **A,** Before treatment. **B,** After intraurethral administration of capsaicin (100 μM). Initially, intraurethral capsaicin instillation increased the bladder contraction frequency, but 30 minutes after continuous infusion, the activity was blocked. (From Jung SY, Fraser MO, Ozawa H, et al: Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. J Urol 1999;162:204–12.)

replicate and then pass retrogradely across synapses to infect second- and third-order neurons in the neural pathways (Vizzard et al, 1995; Nadelhaft and Vera, 1996; Sugaya et al, 1997). Because pseudorabies virus can be transported across many synapses, it could sequentially infect all the neurons that connect directly or indirectly to the lower urinary tract. Interneurons identified by retrograde transport of pseudorabies virus injected into the urinary bladder are located in the region of the sacral parasympathetic nucleus, the dorsal commissure, and the superficial laminae of the dorsal horn (de Groat et al, 1996; Nadelhaft and Vera, 1996; Sugaya et al, 1997). A similar distribution of labeled interneurons has been noted after injection of virus into the urethra (Vizzard et al, 1995) or the external urethral sphincter (Nadelhaft and Vera, 1996), indicating a prominent overlap of the interneuronal pathways controlling the various target organs of the lower urinary tract.

The micturition reflex can be modulated at the level of the spinal cord by interneuronal mechanisms activated by afferent input from cutaneous and striated muscle targets. Micturition reflex can also be modulated by inputs from visceral organs (de Groat et al, 1975; McGuire, 1977; de Groat, 1978; de Groat et al, 1981; McMahon and Morrison, 1982; Torrens and Morrison, 1987; de Groat et al, 1993a; Morrison et al, 1995; Yoshimura et al, 2008). Stimulation of afferent fibers from various regions (anus, colon-rectum, vagina, uterine cervix, penis, perineum, pudendal nerve) can inhibit the firing of sacral interneurons evoked by bladder distention (de Groat et al, 1981). This inhibition may be a result of presynaptic inhibition at primary afferent terminals or be due to direct postsynaptic inhibition of the second-order neurons. Direct postsynaptic inhibition of bladder preganglionic neurons can also be elicited by stimulation of somatic afferent axons in the pudendal nerve or visceral afferents from the distal bowel (de Groat and Ryall, 1969; de Groat, 1978). **Suppression of detrusor overactivity in patients by sacral root stimulation may reflect, in part, activation of the afferent limb of these visceral-bladder and somatic-bladder inhibitory reflexes** (Wheeler et al, 1992; Bosch and Groen, 1995; Chancellor and Chartier-Kastler, 2000).

Pontine Micturition Center and Brainstem Modulatory Mechanisms

Various studies indicate that the micturition reflex is normally mediated by a spinobulbospinal reflex pathway passing through relay centers in the brain (see Fig. 60–16B) (de Groat, 1975; Torrens and Morrison, 1987; de Groat et al, 1993a; Yoshimura et al, 2008). Studies in animals by use of brain-lesioning techniques revealed that neurons in the brainstem at the level of the inferior colliculus have an essential role in the control of the parasympathetic component of micturition (Torrens and Morrison, 1987; de Groat et al, 1993a; Yoshimura and de Groat, 1997; Yoshimura et al, 2008). **Removal of areas of brain above the colliculus by intercollicular decerebration usually facilitates micturition by elimination of inhibitory inputs from more rostral centers. However, transections at any point below the colliculi abolish micturition.**

The dorsal pontine tegmentum has been firmly established as an essential control center for micturition in normal subjects. First described by Barrington (1921), it has subsequently been called the **Barrington nucleus,** the **pontine micturition center** (Blok and Holstege, 1997), or the **M region** (Blok and Holstege, 1996; Holstege et al, 1996) because of its medial location.

In addition to providing axonal inputs to the locus ceruleus and the sacral spinal cord (Ding et al, 1995; Otake and Nakamura, 1996; Valentino et al, 1996), neurons in the pontine micturition center (PMC) also send axon collaterals to the paraventricular thalamic nucleus, which is thought to be involved in the limbic system modulation of visceral behavior (Otake and Nakamura, 1996). Some neurons in the PMC also project to the periaqueductal gray region (PAG) (Blok et al, 1998), which regulates many visceral activities as well as pain pathways (Valentino et al, 1995). Thus neurons in the PMC communicate with multiple supraspinal neuronal populations that may coordinate micturition with other functions of the organism. Although the circuitry in humans is uncertain, brain imaging studies have revealed increases in blood flow in this region of the pons during micturition (Blok et al, 1997b). This change presumably reflects increases in neuronal activity. Thus the PMC appears critical for micturition across species.

Neurons in the PMC provide direct synaptic inputs to sacral preganglionic neurons (Blok and Holstege, 1997) **as well as to GABAergic neurons in the sacral dorsal commissure region** (Blok et al, 1997a). **The former neurons carry the excitatory outflow to the bladder, whereas the latter neurons are thought to be important in mediating an inhibitory influence on external urethral sphincter motoneurons** (Blok et al, 1998). Because of these reciprocal connections, the PMC can promote bladder–sphincter synergy. Studies in rats indicate that activation of bladder preganglionic neurons by input from the PMC can be blocked by inotropic glutamate receptor antagonists, suggesting that neurons in the PMC use glutamate as a neurotransmitter (Matsumoto et al, 1995a).

Besides the PMC region, transneuronal virus tracing methods have identified many populations of neurons in the brainstem that are involved in the control of bladder, urethra, and the urethral sphincter, including medullary raphe nuclei, which contain serotonergic neurons; the locus coeruleus, which contains noradrenergic neurons; PAG; and the A5 noradrenergic cell group (Nadelhaft and Vera, 1992; Vizzard et al, 1995; Sugaya et al, 1997). Other anatomical studies in which anterograde tracer substances were injected into brain areas and then identified in terminals in the spinal cord are consistent with the virus tracing data. **Projections from neurons in the lateral pons (L-region or nucleus locus subcoeruleus) terminate rather selectively in the sphincter motor nucleus to enhance the contraction of pelvic floor muscle and increased urethral pressure during the storage phase in cats, providing evidence that this area in the lateral pons functions as "the pontine continence center"** (Blok, 2002; Sugaya et al, 2003). The parabrachial nuclei (PBN) at the dorsolateral pons, which send projections to the sacral spinal cord neurons, are also known to be involved in the control of micturition (Lumb and Morrison, 1987; de Groat et al, 1993b). A recent study in rats has shown that firing of PBN neurons corresponds to bladder contraction during cystometry and that the medial subnuclei of PBN plays an important role in the mediation of normal bladder contractions (Liu et al, 2007).

In the midbrain, there is increasing evidence that the mesencephalic PAG, which directly receives information of bladder fullness by ascending spinal tract neurons and sends projections to the PMC, seems to play an important role in the integration of the micturition reflex (Blok, 2002; Holstege, 2005). Stimulation of the pelvic nerve results in short latency potentials in the caudal periaqueductal gray (Noto et al, 1991). Electrical and chemical stimulation of the ventrolateral PAG induces micturition in rats and cats (Matsuura et al, 2000; Taniguchi et al, 2002), and this PAG-mediated micturition reflex seems to be induced by subsequent activation of the PMC following PAG stimulation (Matsuura et al, 2000). In cats, there are different patterns of neuronal firing in response to storage/micturition cycles in the PAG, and stimulation of the rostral PAG can inhibit the micturition reflex (Liu et al, 2004; Numata et al, 2008). **Thus the PAG appears to function as a relay center between the PMC and spinal cord neurons that are critically involved in the excitatory and inhibitory control of the micturition reflex.**

Central Pathways That Modulate the Micturition Reflex

Transneuronal virus tracing methods have identified virus-infected cells in several regions of the hypothalamus and the cerebral cortex after injection of pseudorabies virus into the lower urinary tract in animals (Nadelhaft and Vera, 1992; Vizzard et al, 1995; Sugaya et al, 1997). Neurons in the cortex were located primarily in the medial frontal cortex. Tracers injected into the paraventricular nucleus of the hypothalamus labeled terminals in the sacral parasympathetic nucleus as well as the sphincter motor nucleus (Holstege and Mouton, 2003). The influence of the cortex on voiding function could be mediated by a number of pathways, including direct cortical projections from the prefrontal cortex and insular cortex to the PMC or projections through the hypothalamus and the extrapyramidal system (de Groat et al, 1993a). **Studies in humans indicate that voluntary control of voiding is dependent on connections between the frontal cortex and the septal-preoptic region of the hypothalamus, as well as on connections between the paracentral lobule and the brainstem. Lesions to these areas of cortex appear to directly increase bladder activity by removing cortical inhibitory control** (de Groat et al, 1993a).

Human Brain Imaging Studies

In the last decade, **the areas of the brain involved in the control of micturition have been examined in human brain imaging studies using single photon emission–computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI)** (DasGupta et al, 2007; Griffiths and Tadic, 2008) (Fig. 60–22). Some studies evaluated the brain areas responsible for the perception of bladder fullness and the sensation of the desire to void during bladder filling, whereas others examined brain activity during micturition, voluntary contractions of the pelvic floor during urine withholding, or during cold stimulation of the bladder. **PET scan studies in normal men and women revealed that during voiding two cortical areas (the dorsolateral prefrontal cortex and anterior cingulate gyrus) were active** (i.e., exhibited increased blood flow). **The hypothalamus, including the preoptic area, as well as the pons and the PAG, also showed activity in concert with voluntary micturition** (Blok et al, 1997c, 1998). Another PET study during voiding also confirmed that micturition was associated with increased activity in the pons, inferior frontal gyrus, hypothalamus, and PAG, while also showing activity in several other cortical areas (postcentral gyrus, superior frontal gyrus, thalamus, insula, and globus pallidus) and the cerebellar vermis (Nour et al, 2000).

Other PET studies that examined the changes in brain activity during filling of the bladder revealed that increased activity occurred in the PAG, the midline pons, the anterior and midcingulate gyrus, anterior insula, and bilaterally in the frontal lobes (Athwal et al, 1999; Athwal et al, 2001; Matsuura et al, 2002). The results were consistent with the notion that the PAG receives information about bladder fullness and then relays this information to other brain areas involved in the control of bladder storage**. In fMRI studies in men and women, activation during urinary storage is found in the supplementary motor area, midcingulate cortex, insula, and right prefrontal cortex,** and the right anterior insula and midbrain PAG were more active at higher than at lower bladder volumes (Kuhtz-Buschbeck et al, 2005, 2009). Other fMRI studies also addressed the effect of pelvic floor contraction with a full bladder, and reported activation of the parietal cortex, cerebellum, putamen and supplementary motor area (Zhang et al, 2005), or the frontal cortex, basal ganglia, and cerebellum (Seseke et al, 2006).

Brain imaging studies have also been performed to identify changes in cerebral perception of detrusor overactivity. A PET study in patients with Parkinson disease reported activation of the PAG, supplementary motor area, basal ganglia, and cerebellum during detrusor overactivity, (Kitta et al, 2006). When comparing healthy control subjects and those with confirmed overactivity using fMRI, infusion into the bladder is associated with activity in the PAG, thalamus, insula, and anterior cingulated gyrus; however, weak responses or deactivation in the prefrontal cortex or the limbic system, as well as exaggerated responses in the anterior cingulate gyrus at large bladder volumes, are observed in urgency-incontinent patients (Griffiths et al, 2005, 2007). Based on the results in human imaging studies, **Griffiths proposes that (1) during urine storage in healthy subjects, bladder and urethral afferents received in the PAG and mapped in**

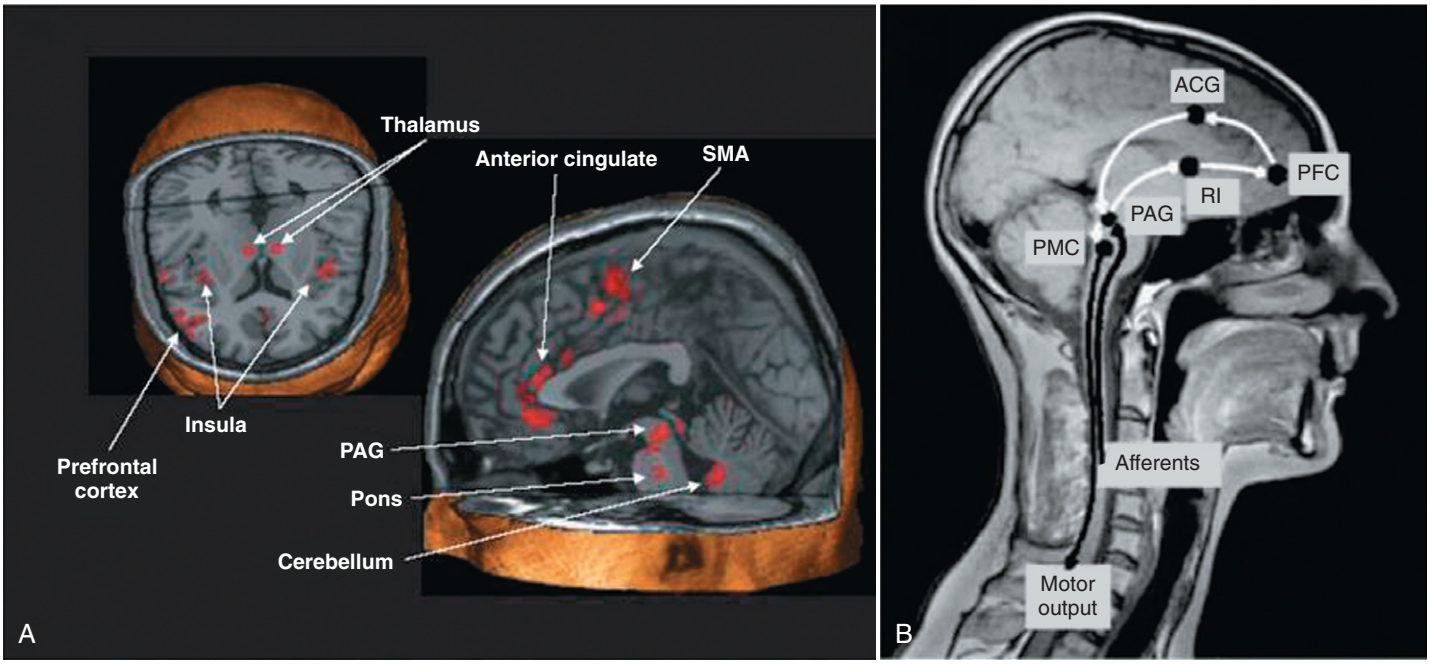

Figure 60–22. **A,** Areas of brain activation during the urinary storage phase based on human imaging studies using PET and fMRI. SMA, supplementary motor area. PAG, periaqueductal gray. **B,** Simplified model of supraspinal control system. Ascending afferent fibers (afferents) carrying the information from the bladder synapse in the PAG and are relayed to the right insula (RI), forming the substrate for sensation. The anterior cingulate gyrus (ACG) is responsible for monitoring, arousal, and efferent output to the PAG and pontine micturition center (PMC). The prefrontal cortex (PFC) is involved in voluntary decision about voiding and generates efferent signals to control ACG and ultimately PMC. The PMC then provides motor output to cause voiding. (**A,** Modified from Fowler A, Griffiths CJD, et al. The neural control of micturition. Nat Rev Neurosci 2008;9:453–66; **B,** modified from Griffiths D, Tadic SD. Bladder control, urgency, and urge incontinence: evidence from functional brain imaging. Neurourol Urodyn 2008; 27:466–74.)

the insula form normal sensations of desire to void, which is monitored by the anterior cingulate gyrus, and the voiding reflex is continuously inhibited until the decision to void is made in the prefrontal cortex; and (2) urgency-incontinent patients have weak responses or deactivation observed in the prefrontal cortex or the limbic system, leading to a defect of supraspinal bladder control, which may cause urgency incontinence, and enhanced responses in the anterior cingulate gyrus, which may be due to abnormal bladder afferents or related to a loss of control in other brain areas, and could be correlated with the urgency sensation (Griffiths and Tadic, 2008) (see Fig. 60–22). Radiographic imaging of the central nervous system (CNS), with control and dysregulation of the lower urinary tract, is an exciting area of research, but the results are preliminary. Subjects are conscious and thinking about their bladder during the test and may have an indwelling catheter that may alter what parts of the brain are activated naturally or artificially.

Hypothesis of Mechanism of Action of Sacral Neuromodulation

Neuromodulation of the sacral nerves and, more recently, pudendal nerves is now commonly used for the treatment of refractory overactive bladder and urinary retention relating to pelvic floor dysfunction (Das et al, 2004; Leng and Chancellor, 2005). Some have criticized the inconsistency that electrical stimulation of the sacral nerve can paradoxically inhibit incontinence in the overactive bladder (OAB) group of patients and yet aid the retentive patients to void. But neuromodulation has worked for both these groups of patients. **The effects of sacral neuromodulation may depend on electrical stimulation of afferent axons in the spinal roots that, in turn, modulate voiding and continence reflex pathways in the central nervous system.** The afferent system is the most likely target, because beneficial effects can be elicited at intensities of stimulation that do not activate movements of striated muscles (Vadusek et al, 1986; Thon et al, 1991; de Groat et al, 1997). Sacral neuromodulation activates somatic afferent axons that modulate sensory processing and micturition reflex pathways in the spinal cord. Urinary retention and dysfunctional voiding can be resolved by inhibition of the guarding reflexes. Detrusor overactivity can be suppressed by direct inhibition of bladder preganglionic neurons. Inhibition of interneuronal transmission in the afferent limb of the micturition reflex can also block detrusor overactivity. **Thus the principle behind sacral neuromodulation can be summarized as somatic afferent inhibition of sensory processing in the spinal cord**.

Rational for Neuromodulation to Facilitate Voiding. In adults, brain pathways are necessary to turn off sphincter and urethral guarding reflexes to allow efficient bladder emptying. Thus spinal cord injury produces bladder-sphincter dyssynergia and inefficient bladder emptying by eliminating the brain mechanisms involved (Fig. 60–23). This may also occur after more subtle neurologic lesions in patients with idiopathic urinary retention, such as after a bout of prostatitis or urinary tract infection. Before the development of brain control of micturition, at least in animals, the stimulation of somatic afferent pathways passing through the pudendal nerve from the perineum can initiate efficient voiding by activating bladder efferent pathways and turning off the excitatory pathways to the urethral outlet (de Groat et al, 1993a; Kruse and de Groat, 1993). Tactile stimulation of the perineum in the cat also inhibits the bladder–sympathetic reflex component of the guarding reflex mechanism. The sacral nerve stimulation may elicit similar responses in patients with urinary retention, and it may turn off excitatory outflow to the urethral outlet and promote bladder emptying. Because sphincter activity can generate afferent input to the spinal cord that can, in turn, inhibit reflex bladder activity, an indirect benefit of suppressing sphincter reflexes would be a facilitation of bladder activity.

Rationale for Neuromodulation to Inhibit the Overactive Bladder. Several reflex mechanisms may be involved in the sacral neuromodulation suppression of detrusor overactivity. Afferent pathways projecting to the sacral cord can inhibit bladder reflexes in animals and humans. The source of afferent input may be from sphincter muscles, distal colon, rectum, anal canal, vagina, uterine cervix, and cutaneous afferents from the perineum (Fig. 60–24). As mentioned previously, two mechanisms have been identified in animals for somatic and visceral afferent inhibition of bladder reflexes. The most common mechanism is suppression of interneuronal transmission in the bladder reflex pathway (de Groat and Theobald, 1976; Kruse et al, 1990; Kruse and de Groat, 1993). It is assumed that this inhibition occurs, in part, on the ascending limb of the micturition reflex and therefore blocks the transfer of information from the bladder to the PMC. This action would prevent

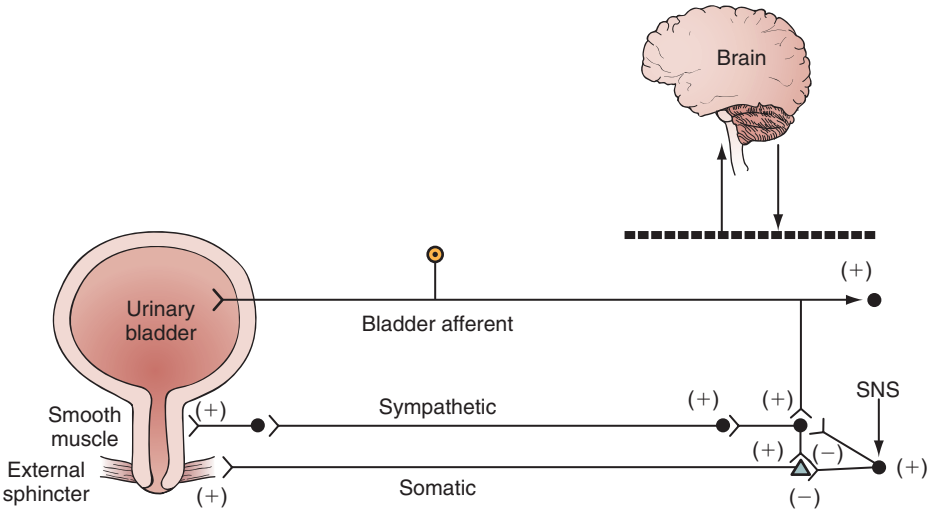

Figure 60–23. When there is a sudden increase in intravesical pressure, such as during a cough, the urinary sphincter contracts by means of the spinal guarding reflex to prevent urinary incontinence (guarding reflex). The spinal guarding reflexes can be turned off by the brain for urination. In cases of neurologic diseases, the brain cannot turn off the guarding reflex and retention can occur. The sacral nerve stimulation (SNS) restores voluntary micturition in cases of voiding dysfunction and urinary retention but inhibits the guarding reflex.

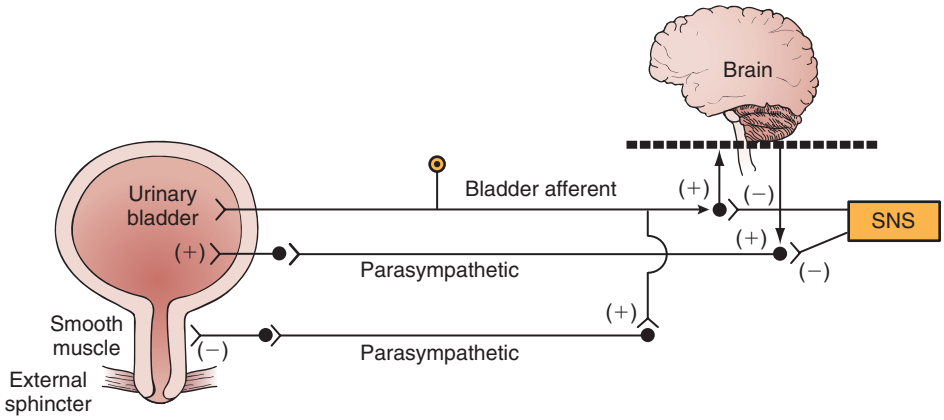

Figure 60–24. The voiding reflex involves afferent neurons from the bladder that project on spinal tract neurons that ascend to the brain. Descending pathways connect to parasympathetic efferent nerves to contract the bladder (bladder-bladder reflex). A spinal bladder-urethra reflex is activated by a similar bladder afferent innervation. In cases of supraspinal dysfunction, overactive micturition reflexes occur. The sacral nerve stimulation (SNS) inhibits urinary urgency, frequency, and urge incontinence by inhibiting the bladder-bladder and bladder-urethra reflexes.

involuntary (reflex) micturition but not necessarily suppress voluntary voiding that would be mediated by descending excitatory efferent pathways from the brain to the sacral parasympathetic preganglionic neurons. A second inhibitory mechanism is mediated by a direct inhibitory input to the bladder preganglionic neurons. This can be induced by electrical stimulation of the pudendal nerve or by mechanical stimulation of the anal canal and distal bowel. It is not elicited by tactile stimulation of penile or perineal afferents; this mechanism would be much more effective in turning off bladder reflexes, because it would directly suppress firing in the motor outflow from the spinal cord.

Pudendal Nerve Stimulation. The pudendal nerve is a peripheral branch of the sacral nerve roots, and stimulating the pudendal allows afferent stimulation to all three of the sacral nerve roots (S2, S3, S4), and that may raise the stimulation threshold needed for micturition and inhibit detrusor activity. Because this is a more peripheral nerve, it is less likely that stimulation of the sciatic and sural nerves will occur, thus decreasing the potential risk for discomfort in the thighs, calves, and feet as seen on occasion with sacral stimulation at the S3 nerve root. The pudendal nerve arises from the sacral plexus within the pelvis; it must go around the pelvic floor to reach the ischioanal fossa. In the pelvis, it runs on the piriformis and then passes laterally through the greater sciatic foramen to enter the gluteal region. Here it lies inferior to the piriformis as does the sciatic nerve, the inferior gluteal neurovascular bundle, and the nerve to the quadratus femoris. The pudendal nerve curls around the spine of the ischium, lying superficial to the sacrospinous ligament, and then passes into the lesser sciatic notch to enter the ischioanal fossa. The nerve then divides into the inferior rectal, the perineal, and the dorsal nerve of the penis or clitoris.

Afferent pudendal nerve stimulation has been demonstrated to inhibit the micturition reflex, abolish uninhibited detrusor contractions, and increase bladder capacity in animals and humans (Fall and Lindstrom, 1991). Peters and colleagues (2005) compared the effectiveness of sacral and pudendal nerve stimulation for voiding dysfunction in a prospective, single-blinded, randomized crossover trial of 30 subjects (22 with urgency/frequency, 5 with urgency incontinence, and 3 with urinary retention) scheduled for sacral implantation a tined quadripolar lead consented to the placement of a second pudendal lead. Twenty-four of the 30 subjects demonstrated a significant clinical response and had an implantable pulse generator placed. Sacral nerve stimulation resulted in 46% improvement in symptoms, while pudendal nerve stimulation demonstrated 63% improvement in symptoms. Urgency-incontinence episodes were reduced by approximately 47%; however, this did not reach statistical significance because of small sample size ($n = 5$).

Inhibitory and Excitatory Stimulation Frequencies of the Pudendal-Bladder Reflexes. The exact mechanism of action of neuromodulation is unknown. In addition, there are no studies involving neuromodulation that look at programming parameters (pulse width, intensity, or frequency) and their impact on voiding function. The pudendal nerve may have a dual mechanism depending on the frequency and continuity of stimulation. A recent study by Tai et al (2007) in anesthetized spinal cord–injured cats demonstrated that at 3 Hz, stimulation of the pudendal nerve inhibited bladder function and decreased bladder pressures, whereas intermittent stimulation at 20 Hz improved the efficiency of the bladder to empty (Tai et al, 2007). Furthermore, the clinical outcomes of continuous (which potentially can fatigue the urethral sphincter and accommodate the nerve) and intermittent stimulation have not been explored. It would directly suppress firing in the motor outflow from the spinal cord.

Developmental Changes of Bladder Reflexes

The neonatal bladder is a conduit of urine more than a storage organ. Without cerebral control, the bladder will reflexively empty into a diaper when it reaches functional capacity. Therefore by definition, a normal toddler has detrusor overactivity. Neonatal animal bladder strips have repetitive spontaneous contraction, which can be initiated by pacemaker cells within the bladder and propagated by gap junctions between cells (see Fig. 60–1) (Pezzone et al, 1999; Szell et al, 2003) and/or directly induced by enhanced smooth muscle activity due to the low level expression of Ca^{2+}-activated K^+ channels (Ng et al, 2007).

The neonatal pathways responsible for bladder overactivity do not disappear with growth and development; rather, increasing cerebral maturation actively inhibits them. Inhibition rather than resolution of neonatal reflexes may be difficult to grasp initially, but this concept holds true across most concepts of neuroscience. **With disease processes such as neurologic diseases and aging, the neonatal reflexes are released and involuntary detrusor contractions recur** (de Groat, 1975).

One of the most interesting clinical demonstrations of the reemergence of the primitive neonatal micturition reflex is the bladder ice-water test. The bladder ice-water cooling test is performed by quickly instilling up to

100 mL of 4° C sterile saline solution. The normal adult will sense cold but maintain a stable bladder. However, infants and neuropathic patients will develop involuntary detrusor contractions with this test (Chancellor and de Groat, 1999).

The bladder cooling response is triggered by activation of cold receptors within the bladder wall. The receptors are supplied by unmyelinated C-fiber afferent neurons (Chancellor and de Groat, 1999). The cooling response represents a neonatal reflex that may be unmasked by central neuropathologic processes, analogous to the appearance of the Babinski reflex in pyramidal tract lesions. The cooling response is present (development of involuntary detrusor contraction) in neurologically normal infants and children until about the age of 4 years. **The reflex becomes absent with further maturation of the nervous system, but the response may be unmasked by pathologic processes that disturb the descending neuronal control of normal voiding** (Geirsson et al, 1999). It has also been suggested that men with prostatic bladder outlet obstruction also have an ice-water test response. Chai and colleagues (1998) reported an ice-water test response in 12 of 17 patients (71%) with bladder outlet obstruction, but their method of ice-water infusion has been criticized (Geirsson et al, 1999). Hirayama and colleagues (2003) have also reported that an ice-water test response was found in 35 (27%) of 127 patients with benign prostatic hyperplasia and that the patients with the ice-water test response had detrusor overactivity and higher bladder outlet obstruction index than the nonresponders on the pressure flow study.

PHARMACOLOGY

Peripheral Pharmacology

Traditional teaching in uropharmacology is that if a drug works on the bladder or urethra, it is working on the postjunctional receptors. In this section, we present evidence for prejunctional as well as postjunctional actions of drugs.

Muscarinic Mechanisms

Detrusor strips from normal human bladders are contracted by cholinergic muscarinic receptor agonists and by electrical stimulation of intrinsic cholinergic nerves. Contractile responses can be completely abolished by atropine (Sibley, 1984). **There are at least five receptor subtypes based on molecular cloning and four different receptor subtypes based on pharmacology (M_1 to M_5)** (Somogyi et al, 1994; Wang et al, 1995; Eglen et al, 1996; Yamaguchi, 1996; Hegde et al, 1997).

Pharmacologically, M_1, M_2, and M_3 receptor subtypes have been found in the human bladder by receptor binding assays (Kondo et al, 1995); **all M_1 to M_5 receptor mRNAs are detected by reverse transcription–polymerase chain reaction assays** (Andersson and Wein, 2004; Mansfield et al, 2005). **Although ligand receptor binding studies revealed that M_2 receptors predominate, M_3 receptors mediate cholinergic contractions** (Eglen et al, 1994; Harriss et al, 1995; Yamaguchi, 1996; Hegde et al, 1997; Lai et al, 1998). **Stimulation of M_3 receptors by acetylcholine leads to IP_3 hydrolysis due to phospholipase C activation and then to the release of intracellular calcium and a smooth muscle contraction** (Harriss et al, 1995; Fry et al, 2002) (Fig. 60–25). **The involvement of transmembrane flux of calcium ions through nifedipine-sensitive L-type Ca^{2+} channels has also been indicated in M_3 receptor–mediated detrusor muscle contractions** because the L-type Ca^{2+} channel inhibitor nifedipine strongly suppressed carbachol-induced detrusor contractions, whereas the phospholipase C inhibitor or the store-operated Ca^{2+} channel inhibitor caused little inhibition in rats and humans (Andersson and Arner, 2004; Andersson and Wein 2004; Schneider et al, 2004a, 2004b; Frazier et al, 2008) (see Fig. 60–25). However, other studies have indicated the major contribution of the phospholipase C–mediated mechanism to M_3 receptor–induced detrusor contractions, because phospholipase C inhibitors significantly suppressed carbachol-induced detrusor contractions in rats (Braverman et al, 2006a, 2006b), and intracellular calcium elevation after carbachol application was observed without membrane depolarization in human bladders, which is required for the opening of L-type Ca^{2+} channels (Fry et al, 2002). Hashitani and colleagues (2000) have reported that the stimulation of muscarinic receptors activates both calcium influx through L-type Ca^{2+} channels and calcium release from intracellular calcium stores in guinea pig bladders.

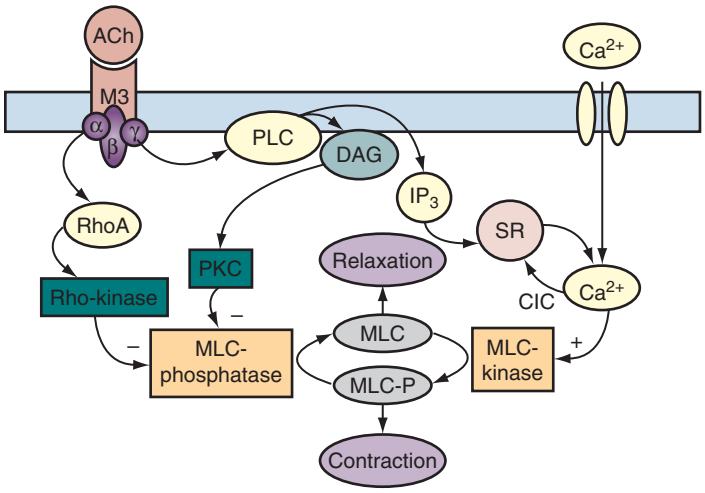

Figure 60–25. Transmitter signal pathways involved in activation of detrusor contractions through muscarinic M_3 receptors. There seem to be differences between species in the contribution of the different pathways in contractile activation. ACh, acetylcholine; CIC, calcium-induced calcium release; DAG, diacylglycerol; IP_3, inositol 1.4.5-trisphosphate; MLC, myosin light chain; PKC, protein kinase C; PLC, phospholipase C; SR, sarcoplasmic reticulum. (From Andersson KE, Wein AJ. Pharmacology of the lower urinary tract: basis for current and future treatments of urinary incontinence. Pharmacol Rev 2004;56:581–631.)

It has also been proposed (Hegde et al, 1997; Ehler et al, 2005) that **coactivation of M_2 receptors could enhance the response to M_3 stimulation by (1) inhibition of adenylate cyclase, thereby suppressing sympathetically mediated depression of detrusor muscle; (2) inactivation of K^+ channels; or (3) activation of nonspecific cation channels.** In addition, because the specific Rho-kinase inhibitor Y-27632 reportedly suppresses carbachol-induced detrusor contractions in rats and humans, **muscarinic receptor activation in detrusor smooth muscles is likely to stimulate the Rho-kinase pathway, leading to a direct inhibition of myosin phosphatase that induces calcium sensitization to enhance the ability of the muscle to generate the same contractile force with lower levels of intracellular calcium** (Andersson and Wein, 2004; Schneider et al, 2004a, 2004b; Frazier et al, 2008). Although the involvement of M_3 receptors for the Rho-kinase activation has been suggested (Andersson

Table 60–5.

Drugs with Bladder Action

CLASSIFICATION	EXAMPLES	PHARMACOLOGIC ACTION
Anticholinergic agents	Atropine Glycopyrrolate Oxybutynin Propantheline Tolterodine	Inhibit muscarinic receptors, thus reducing the response to cholinergic stimulation; used to reduce pressure during bladder filling and for the treatment of unstable bladder contractions
Smooth muscle relaxants	Dicyclomine Flavoxate	Direct smooth muscle relaxation reduces intravesical pressure during filling and reduces severity and presence of unstable bladder contractions; most of these agents have some degree of anticholinergic action
Calcium antagonists	Diltiazem Nifedipine Verapamil	Used in the treatment of unstable bladder contractions to reduce the magnitude of the spikes by reducing the entrance of calcium during an action potential
Potassium channel openers	Cromakalim Pinacidil	Act to increase the membrane potential and thus reduce the myogenic initiation of unstable bladder contractions
Prostaglandin synthesis inhibitors	Flurbiprofen	Prostaglandins have been implicated in increased smooth muscle tone and in the induction of spontaneous activity. Inhibition of prostaglandin synthesis could promote relaxation of the bladder during filling and decrease spontaneous activity of the bladder.
β-Adrenergic agonists	Isoproterenol Terbutaline	Stimulation of β receptors induces relaxation of the bladder body, resulting in a decrease in intravesical pressure during filling.
Tricyclic antidepressants	Amitriptyline Imipramine	These agents have anticholinergic, direct smooth muscle relaxant, and norepinephrine reuptake inhibition properties.
α-Adrenergic agonists	Ephedrine Phenylpropanolamine Midodrine Pseudoephedrine	Increase urethral tone and closure pressure by direct stimulation of α-adrenergic receptors
Afferent nerve inhibitors	DMSO Capsaicin Resiniferatoxin	Reduce the sensory input from bladder and thereby increase bladder capacity and reduce detrusor overactivity
Estrogen	Estradiol	Direct application to the vagina or oral therapy may increase the thickness of the urothelial mucosa, making a better seal and reducing the incidence of incontinence. Other actions may include increasing adrenergic effects on the urethra and increasing blood flow.

DMSO, dimethyl sulfoxide.

and Arner, 2004; Andersson and Wein, 2004; Schneider et al, 2004a) (see Fig. 60–25), a study has also suggested the participation of M_2 receptors in this mechanism because Y-27632 not only suppressed carbachol-induced muscle contractions but also increased the affinity of darifenacin, an M_3 receptor antagonist with approximately a 30-fold selectivity for M_3 over M_2 receptors, for inhibiting carbachol-induced contractions of rat bladders (Braverman et al, 2006a, 2006b). It has also been reported that the muscarinic receptor subtype–mediated detrusor contractions shift from M_3 to M_2 receptor subtype in certain pathologic conditions, such as obstructed or denervated hypertrophied bladders in rats (Braverman and Ruggieri, 2003; Braverman et al, 2006a, 2006b), as well as in bladder muscle specimens from patients with neurogenic bladder dysfunction (Pontari et al, 2004).

Studies using constructed mutant mice lacking the M_3 receptor or the M_2 and M_3 receptors have demonstrated that this subtype plays key roles in salivary secretion, pupillary constriction, and detrusor contractions (Matsui et al, 2000, 2002; Igawa et al, 2004). However, M_3-mediated signals in digestive and reproductive organs are dispensable, probably because of redundant mechanisms through other muscarinic acetylcholine receptor subtypes or other mediators (Matsui et al, 2000). In addition, it has also been found that male M_3 knockout mice had a distended bladder and larger bladder capacity compared with females, indicating a considerable sex difference in the micturition mechanism (Matsui et al, 2002; Igawa et al, 2004). Thus M_3 or M_2 and M_3 double-knockout mice should provide a useful animal model for the detrusor overactivity pathophysiology and pharmacology.

Muscarinic receptor antagonists tolterodine and oxybutynin (Table 60–5) are the most widely prescribed drugs for urinary incontinence. Oxybutynin is a nonspecific muscarinic antagonist with additional smooth muscle relaxant properties. The smooth muscle relaxation properties of oxybutynin may be clinically relevant only with intravesical instillation of the drug. Because new antimuscarinic drugs are such a hot topic for pharmaceutical development, all urologists should be aware of the existence of muscarinic receptor subtypes and their distribution in the lower urinary tract and other organs.

We will briefly present two additional issues regarding the effect of antimuscarinic drugs on the bladder and salivary glands that have clinical relevancy. First, antimuscarinic drugs are metabolized, and their metabolites have pharmacologic effects. It has been shown that oxybutynin has less of a dry mouth effect than does its metabolite desethyoxybutynin (Gupta and Sathyan, 1999). Therefore the controlled-release formulation of oxybutynin maintains the efficacy of immediate-release oxybutynin but with significantly fewer side effects. Tolterodine and solifenacin have been shown in cats and rats, respectively, to have less activity on the salivary gland muscarinic receptors than on the bladder muscarinic receptors (Nilvebrant et al, 1997; Ohtake et al, 2004).

Second, the site and speed of antimuscarinic metabolism appear to have profound effects in terms of clinical efficacy and side effects.

Muscarinic receptors are also located prejunctionally on cholinergic nerve terminals in the bladder (D'Agostino et al, 1986; Somogyi and de Groat, 1992; Somogyi et al, 1996; D'Agostino et al, 1997; Braverman et al, 1998; D'Agostino et al, 2000). Activation of M_1 prejunctional receptors facilitates acetylcholine release (Somogyi and de Groat, 1992; Somogyi et al, 1996), whereas activation of M_2 to M_4 receptors inhibits the release (D'Agostino et al, 1997; Braverman et al, 1998). It has been proposed that inhibitory M_2 to M_4 receptors are preferentially activated by autofeedback mechanisms during short periods of low-frequency nerve activity and thereby suppress cholinergic transmission during urine storage (Somogyi and de Groat, 1992). Conversely, M_1 receptors are activated during more prolonged, high-frequency nerve firing that would occur during voiding and thus participate in an amplification mechanism to promote complete bladder emptying. M_1-mediated facilitation of transmitter release involves the activation of a phospholipase C–protein kinase C signaling cascade that appears to facilitate the opening of L-type Ca^{2+} channels that are necessary for prejunctional facilitation of acetylcholine release from parasympathetic nerve terminals (Somogyi et al, 1996, 1997). Inhibitory and facilitatory muscarinic receptors are also present in the central nervous system (de Groat et al, 1993a; Yoshimura and de Groat, 1997; Ishiura et al, 2001) and in bladder parasympathetic ganglia, where they modulate nicotinic transmission (de Groat and Booth, 1993). The ability to modulate neurotransmission in the bladder through the selective activation and inhibition of specific presynaptic receptors may lead, in the future, to novel forms of pharmacologic therapy for specific forms of lower urinary tract dysfunction.

Muscarinic Selectivity. Pharmacologically defined subtype-selective drugs have been developed. Darifenacin and vamicamide have been demonstrated to be relatively selective for the M_3 subtype (Yamamoto et al, 1995; Andersson, 1997; Steers, 2006). However, they are not necessarily tissue selective, because salivary glands and other tissues also contain M_3 muscarinic receptors. Currently, several drugs are being tested for their tissue selectivity. Tolterodine appears to be a muscarinic antagonist that has selectivity for the bladder compared with the salivary gland, even though it may not be an M_3 subtype–selective antagonist (Nilvebrant et al, 1997; Andersson, 1998). More recently, solifenacin has also shown selectivity to the bladder over the salivary gland; the receptor selectivity of solifenacin to M_3 receptors over M_2 receptors (10-fold) is similar to that of oxybutynin (Ikeda et al, 2002; Ohtake et al, 2004). Thus, therapeutically, it is more important to be tissue selective than subtype selective (Nilvebrant, et al. 1997; Andersson, 1998). A truly bladder-selective antimuscarinic drug with *no* side effects is the "holy grail" of overactive bladder drug therapy.

Key Points: Muscarinic Mechanisms

- There are at least five muscarinic receptor subtypes. Pharmacologically, M_1, M_2, and M_3 receptor subtypes have been found in the human bladder.
- Stimulation of M_3 receptors by acetylcholine induces calcium influx through L-type Ca^{2+} channels, as well as IP_3 hydrolysis due to phospholipase C activation, resulting in the release of intracellular calcium, both of which contribute to a smooth muscle contraction.
- Muscarinic receptor subtype–mediated detrusor contractions shift from M_3 to M_2 receptor subtype has been reported in bladder muscle specimens from neurogenic bladder dysfunction patients.

Purinergic Mechanisms

Purinergic contribution to parasympathetic stimulation in vivo, or field stimulation in vitro, has been proved to exist in a variety of species including rat, rabbit, and guinea pig (Burnstock et al, 1972; Chancellor et al, 1992; Burnstock, 1996). **However, there is less evidence that purinergic neurotransmission exists in humans, at least regarding normal responses to stimulation, but it may play a role in pathologic conditions such as detrusor overactivity or bladder outlet obstruction** (Palea et al, 1993; Burnstock, 2000; O'Reilly et al, 2001a).

ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G protein–coupled receptor family (P2Y) (Inoue and Brading, 1990; Inoue and Gabella, 1991; McMurray et al, 1997). Seven P2X subtypes and eight P2Y subtypes have been identified. Analysis of the structure-activity relationships of a series of excitatory purinergic agonists on the guinea pig bladder revealed an order of potency consistent with $P2X_1$ or $P2X_2$ receptors (Burnstock, 2001; Zhong et al, 2001). In other species (rabbit, cat, and rat), various studies suggested that multiple purinergic excitatory receptors are present in the bladder (Burnstock, 2000). Immunohistochemical experiments with specific antibodies for different P2X receptors showed that $P2X_1$ receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder (Lee et al, 2000). Clusters of $P2X_1$ receptors were detected on rat bladder smooth muscle cells, some of which were closely related to nerve varicosities. Northern blotting and in-situ hybridization revealed the presence of $P2X_1$ and $P2X_4$ mRNA in the bladder (Valera et al, 1995). **The predominant expression of $P2X_1$ receptors has also been confirmed in the human bladder** (O'Reilly et al, 2001a, 2001b). **Investigators also found that the amount of $P2X_1$ receptors was increased in the obstructed bladder compared with the control bladder, suggesting upregulated purinergic mechanisms in the overactive bladder due to bladder outlet obstruction** (O'Reilly et al, 2001a). In addition, ATP also seems to act through P2Y receptors in the smooth muscle to suppress cholinergic and purinergic contractions (Lee et al, 2000; Burnstock, 2001).

Purinergic nerves are likely to have other functions in the lower urinary tract, because excitatory receptors for ATP are present in parasympathetic ganglia (Theobald and de Groat, 1989; Nishimura and Tokimasa, 1996; Zhong et al, 1998, 2001), afferent nerve terminals (Dmitrieva et al, 1998; Namasivayam et al, 1999; Lee et al, 2000; Burnstock, 2001), and urothelial cells (Buffington et al, 1999; Vlaskovska et al, 2001). Excitatory purinergic receptors in pelvic ganglia have been demonstrated in the cat (Theobald and de Groat, 1989), rabbit (Nishimura and Tokimasa, 1996), and rat (Zhong et al, 1998, 2001).

$P2X_3$ receptors that have been identified in small-diameter afferent neurons in DRG have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves (Lee et al, 2000). Studies using patch clamp recordings in rats have also demonstrated that the majority (90%) of bladder afferent neurons projecting by pelvic nerves responded to ATP and α,β-methylene ATP with persistent currents, suggesting that bladder afferent pathways in the pelvic nerve express

predominantly $P2X_{2/3}$ heteromeric receptors rather than $P2X_3$ homomeric receptors (Zhong et al, 2003; Dang et al, 2005). Intravesical or intra-arterial administration of ATP- or 2-methylthio-ATP–activated bladder afferent fibers and enhanced reflex bladder activity (Dmitrieva et al, 1998; Namasivayam et al, 1999; Pandita and Andersson, 2002; Zhang et al, 2003; Nishiguchi et al, 2005). On the other hand, desensitization of purinergic receptors by intravesical administration of α,β-methylene ATP, a purinergic receptor agonist, or administration of a receptor antagonist, suramin, depressed bladder afferent activity (Dmitrieva et al, 1998; Namasivayam et al, 1999). **In $P2X_3$ knockout mice, afferent activity induced by bladder distention was significantly reduced** (Burnstock, 2000; Cockayne et al, 2000; Cook and McCleskey, 2000; Souslova et al, 2000). Furthermore, deletion of the gene encoding $P2X_2$ and loss of heteromeric $P2X_{2/3}$ receptors also result in a marked urinary bladder hyporeflexia, as evidenced by increased thresholds for bladder contractions during bladder filling (Cockayne et al, 2005). These data indicate that **purinergic receptors are involved in mechanosensory as well as nociceptive signaling in the bladder.**

ATP is also released by afferent nerves and might act in an autofeedback manner to regulate afferent excitability. Two studies (Dmitrieva et al, 1998; Morrison, 1998) presented evidence for purinergic sensitization of bladder afferent nerve endings. Intra-arterial injection of ATP can activate bladder afferent nerves (Dmitrieva et al, 1998), whereas suramin, an antagonist of certain types of ATP receptors (P2X purinergic receptors), given intravesically reduced by 50% the firing of bladder mechanoreceptors induced by bladder distention (Morrison, 1998). Intravesical administration of α,β-methylene ATP also reduced the firing of mechanosensitive afferents, presumably by desensitizing purinergic receptors on the afferent terminals.

In addition, adenosine, which can be formed by the metabolism of ATP, can depress parasympathetic nerve-evoked bladder contractions by activating P1 inhibitory receptors in parasympathetic ganglia (Akasu et al, 1984), in postganglionic nerve terminals, and in the bladder muscle (Cockayne et al, 2000; Burnstock, 2001). Adenosine P1 receptors have been further classified into a number of subtypes (i.e., A_1, A_{2A}, A_{2B}, and A_3) (Olah et al, 1995). A study has demonstrated that adenosine reduces the force of nerve-mediated contractions by acting predominantly at presynaptic sites at the nerve-muscle junction through a subtype of an adenosine receptor (the A_1 receptor in guinea pigs), although these actions of adenosine are less evident in human detrusor muscles (Fry et al, 2004).

Key Points: Purinergic Mechanisms

- $P2X_3$ receptors that have been identified in small-diameter afferent neurons in dorsal root ganglion have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves.
- Deletion of the gene encoding $P2X_2$ and loss of heteromeric $P2X_{2/3}$ receptors also result in a marked urinary bladder hyporeflexia, as evidenced by increased thresholds for bladder contractions during bladder filling.

Adrenergic Mechanisms

β-Adrenergic. Stimulation of β_2- and β_3-adrenergic receptors that exist in the human detrusor results in the direct relaxation of the detrusor smooth muscle (Andersson, 1993; Morita et al, 1993; Nishimoto et al, 1995; Levin and Wein, 1995). In addition, β-adrenergic–stimulated relaxation is mediated through the stimulation of adenylate cyclase and the accumulation of cyclic AMP (cAMP) (Levin et al, 1986; Andersson, 1993; Andersson and Arner, 2004). Because β-adrenoceptor–mediated relaxation of the human detrusor was not blocked by selective β_{1-} or β_2-adrenoceptor antagonists, such as dobutamine and procaterol, but was blocked by selective β_3-adrenoceptor antagonists, **the relaxation induced by adrenergic stimulation of the human detrusor is mediated mainly through β_3-adrenoceptor activation** (Igawa et al, 1999; Yamaguchi, 2002; Andersson and Arner, 2004). A quantitative analysis by reverse transcription–polymerase chain reaction has also confirmed that the β_3-adrenergic receptor is the most highly expressed subtype among α– and β-adrenoceptor subtypes at the mRNA level in human bladders (Nomiya and Yamaguchi, 2003). Therefore β_3-receptor agonists have been proposed to be effective for treatment of detrusor overactivity, and this is an exciting area of research for overactive bladder (Andersson and Arner, 2004; Tyagi et al, 2009). β-Adrenergic blockers have also been advocated for urinary incontinence due to inappropriate reflex urethral relaxation, because propranolol prevents the reduction in urethral pressure after sacral root stimulation (McGuire, 1978). However, β-adrenergic antagonists are not particularly useful in treating bladder or urethral disorders (Castleden and Morgan, 1980; Naglo et al, 1981; Takeda et al, 1997).

A second pharmacologic method of increasing cAMP levels is with phosphodiesterase (PDE) inhibitors. PDE is the enzyme that catalyzes the degradation of cAMP to AMP and thus limits the action of cAMP (Andersson, 1997; Longhurst, et al, 1997). There are several classes of PDEs that have individual substrate affinities, specific species and tissue distributions, and pharmacologic selectivities (Truss et al, 1996; Longhurst et al, 1997). **Currently, there is considerable research trying to identify the specific isoform of PDE present in the bladder as opposed to that in the penis** (Truss et al, 1996). **Selective inhibition of bladder PDE would result in both an increase in the basal levels of cAMP (and possibly relaxation of the detrusor) and enhancement of the sensitivity and efficacy of β-adrenergic agonists. In the isolated guinea pig bladder, the frequency of agonist-induced phasic activity is slowed by cAMP, and degradation of intracellular cAMP in the cells responsible for phasic activity appears to involve primarily PDE4** (Gillespie 2004). PDE4 inhibitors are shown to suppress detrusor overactivity in a rat model of bladder outlet obstruction induced by partial urethral ligation (Kaiho et al, 2008). Thus a selective β agonist and a selective PDE inhibitor might be an effective combination for the relaxation of the detrusor in the future.

α-Adrenergic. Although α-adrenergic stimulation is not prominent in the normal bladder, recent evidence indicates that **under pathologic conditions, such as detrusor overactivity associated with bladder outlet obstruction, the α-adrenergic receptor density, especially the α_{1D}-receptor subtype, can increase to such an extent that the norepinephrine-induced responses in the bladder are converted from relaxation to contraction** (Andersson and Arner, 2004). In rats with outflow obstruction, the proportion of α_{1D}-receptor subtype in the total α_1-receptor mRNA in the bladder is increased to 70% from 25% in normal rat bladders (Hampel et al, 2002), and urinary frequency is suppressed by an inhibition of α_{1D} and α_{1A} receptors by tamsulosin, whereas α_{1A}-receptor suppression by 5-methyl-urapidil has no effect. Moreover, α_{1D}-receptor knockout mice have larger bladder capacity and voided volumes

than do their wild-type controls, which supports an important role of α_{1D} receptors in the control of bladder function (Chen et al, 2005). **However, in humans, there is the predominant expression of α_{1D} receptors already in the normal bladder** (Malloy et al, 1998), **and the level of expression of α-adrenoceptor mRNA, which is considerably low compared with β_3 adrenoceptors in normal bladders, was not increased in the bladder with outflow obstruction** (Nomiya and Yamaguchi, 2003). Thus the contribution of α_{1D} receptors to detrusor overactivity observed in a variety of pathologic conditions, including obstructive uropathy and incontinence, still needs to be established (Andersson and Arner, 2004).

α-Adrenergic mechanisms are more important in urethral function. Substantial pharmacologic and physiologic evidence indicates that **urethral tone and intraurethral pressure are influenced by α-adrenergic receptors.** The presence of α_1 and α_2 adrenoceptors has been shown in the urethra of various species including humans. Among α_1 adrenoceptors, **the α_{1A} adrenoceptor is the major subtype expressed in urethral smooth muscle** at the mRNA and protein levels (Yono et al, 2004; Michel and Vrydag, 2006). Isolated human urethral smooth muscle contracts in response to α-adrenergic agonists (Yalla et al, 1977; Awad et al, 1978; Nordling, 1983; Mattiasson et al, 1984). It is also reported in the rabbit that the urethral contraction is mediated by the α_{1A}-adrenoceptor subtype (Testa et al, 1993; Michel and Vrydag, 2006). Likewise, **hypogastric nerve stimulation and α-adrenergic agonists raise intraurethral pressure, which is blocked by α_1-adrenergic antagonists** (Awad et al, 1976; Yalla et al, 1977). These findings provide the rationale for use of α-adrenergic agonists to promote urine storage by increasing urethral resistance.

Conversely, α-adrenergic receptor antagonists facilitate urine release in conditions of functionally increased urethral resistance, such as benign prostatic hyperplasia. Although the α_{1A} adrenoceptor is the major subtype in the prostate and urethra, highly selective α_{1A}- adrenoceptor antagonists (e.g., RS-17053) do not alter lower urinary tract symptom (LUTS) scores in men with BPH, but these agents are effective at relaxing prostate smooth muscle and increasing urine flow in men (Schwinn and Roehrborn, 2008). In contrast, α_1-adrenoceptor antagonists that contain α_{1D}-adrenoceptor blocking activity improve bladder-based symptoms in humans (Nishino et al, 2006), suggesting the important role of the α_{1D} adrenoceptors for storage symptoms associated with bladder outlet obstruction, receptors potentially located at the bladder or the spinal cord (Schwinn and Roehrborn, 2008).

α_2-Adrenergic antagonists increase the release of norepinephrine from urethral tissues through a presynaptic mechanism, but this does not affect the contractility of urethral smooth muscle in vitro (Mattiasson et al, 1984; Willette et al, 1990; Michel and Vrydag, 2006). The human urethra lacks postjunctional α_2-adrenergic receptors, although in-vitro prejunctional activation of these receptors produces a feedback inhibition of norepinephrine release. Pharmacologic and electrophysiologic data suggest that adrenergic nerves influence excitatory cholinergic transmission in pelvic ganglia. de Groat and Booth (1993) have shown, in the cat, that hypogastric nerves inhibit excitatory cholinergic transmission in vesical ganglia by activation of α_2-adrenergic receptors (Fig. 60–26). Conversely, β-adrenergic agonists facilitate transmission in vesical ganglia.

Urethral Tone in Women. Taki and associates (1999) separated the entire length of the human female urethra into several parts and studied regional contractile effect to norepinephrine, clonidine, acetylcholine, and potassium chloride. Their findings suggest that sympathetic innervation helps maintain resting urethral tonus, mainly through α_1 adrenoceptors. With the recent identification of at least three distinct subtypes of α_1 adrenoceptors with distinct pharmacologic profiles, it may be possible to develop urethra-specific adrenergic agonists for the treatment of stress urinary incontinence. A small-scale, placebo-controlled clinical study has demonstrated that activation of the $\alpha_{1A/1L}$-adrenoceptor subtype, which is a pharmacologic isoform of the α_{1A}-adrenoceptor gene product, was effective in reducing the number of incontinence episodes in women with mild to moderate stress urinary incontinence (Musselman et al, 2004), suggesting an important role of α_1 adrenoceptors in the urethral continence mechanism, although the data are still preliminary.

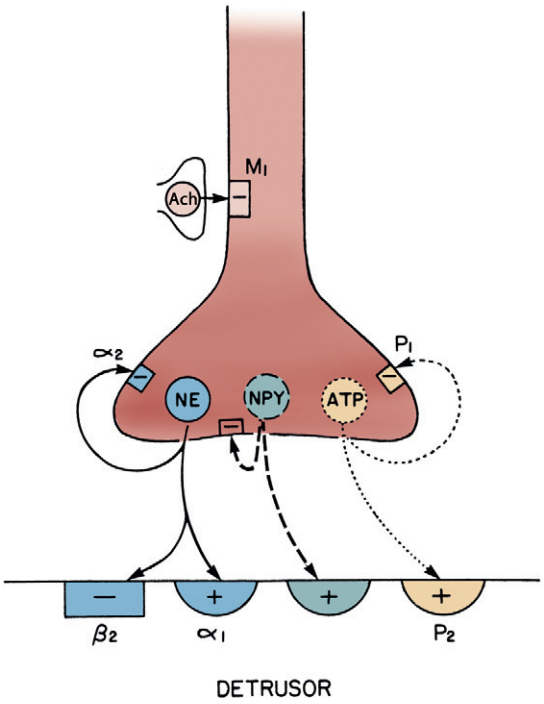

Figure 60–26. Diagram of possible transmitters in an adrenergic terminal supplying the bladder or urethra. Norepinephrine (NE) release can activate α_1-adrenergic receptors and produce contraction (+) or β receptors and cause relaxation (–) of the detrusor. Feedback inhibition of NE release through α_2 receptors can also occur. Neuropeptide Y (NPY) can produce smooth muscle contraction (+) or inhibit acetylcholine (ACh) release (not shown), or feedback can inhibit NE release. Adenosine triphosphate (ATP) can activate P2 receptors in the detrusor, which elicit contraction (+) or inhibit (–) further ATP release through P1 prejunctional receptors. ACh release from terminals in synaptic contact with an adrenergic varicosity can inhibit firing of adrenergic axons by activation of M_1 receptors.

Nitric Oxide

Nitric oxide (NO) has been identified as a major inhibitory transmitter mediating relaxation of the urethral smooth muscle during micturition (Andersson et al, 1992; Andersson, 1993; Andersson and Persson, 1995; Bennett et al, 1995). In 1931, Barrington hypothesized that stimulation of the pelvic nerve, in addition to evoking a bladder contraction, produces urethral relaxation. Indeed, urodynamic studies document a reduction in urethral pressure just before a bladder contraction (Scott et al, 1964; van Waalwijk van Doorn et al, 1991). In support of the contention that parasympathetic nerves mediate

Key Points: Adrenergic Mechanisms

- β-Adrenergic–stimulated relaxation is mediated through the activation of adenylate cyclase and the accumulation of cyclic AMP (cAMP).
- The β_3-adrenergic receptor is the most highly expressed subtype among α- and β-adrenoceptor subtypes, and β_3-receptor agonists are in clinical trial for treatment of detrusor overactivity.
- In the human, there is a predominant expression of α_{1D} receptors present in the normal bladder, and the level of expression of α-adrenoceptor mRNA, which is considerably low compared with β_3 adrenoceptors in normal bladders, was not increased in the bladder with outflow obstruction.
- Urethral tone and intraurethral pressure are influenced by α-adrenergic receptors. The α_{1A} adrenoceptor is the major subtype in the prostate and urethra, and all three α_1 adrenoceptor subtypes (α_{1A}, α_{1B}, α_{1D}) are present in blood vessels.

this urethral relaxation, sacral root stimulation reduces urethral pressure (McGuire, 1978; Torrens, 1978). Cholinergic innervation to the urethra has been supported by histochemical identification of acetylcholinesterase-staining fibers and ultrastructural data showing varicosities containing small clear vesicles in the human urethra (Ek, 1977; Gosling et al, 1977). Exogenous cholinergic agonists do not relax but rather contract urethral smooth muscle in vivo (Nergardh and Boreus, 1972; Ek et al, 1978) and in vitro (Ek et al, 1978). Therefore parasympathetic pathways mediating urethral relaxation must rely on a noncholinergic transmitter.

In the rat, NO is released by postganglionic nerves arising from neurons in the major pelvic ganglia (Fraser et al, 1995) (see Fig. 60–18). These neurons contain nitric oxide synthase (NOS), the enzyme that synthesizes NO, as well as nicotinamide adenine dinucleotide phosphate diaphorase, a marker for NOS (Vizzard et al, 1994). Electrophysiologic studies in female rats showed that electrical stimulation of the lumbosacral (L6-S1) spinal roots elicits simultaneous bladder contractions and urethral relaxation (Fraser et al, 1995). The urethral relaxation was inhibited by NOS inhibitors, which did not alter the bladder responses. The inhibition was reversed by administration of L-arginine, a precursor of NO. The electrically evoked urethral relaxation was abolished by ganglionic blocking agents, indicating that it was mediated by stimulation of preganglionic parasympathetic axons in the lumbosacral roots.

NO is also involved in controlling bladder afferent nerve activity. Inhibitors of NOS, given systemically or intrathecally, do not affect normal micturition in conscious or anesthetized rats. However, detrusor overactivity that accompanies irritation with turpentine, acetic acid, or cyclophosphamide is ameliorated by spinal application of NOS inhibitors (Rice, 1995; Kakizaki and de Groat, 1996; Lagos and Ballejo, 2004). However, intravesically administered capsaicin induces detrusor overactivity that is not influenced by an intrathecally applied NOS inhibitor, although the behavioral effects of the irritation are reduced (Pandita et al, 1997). It is believed that NO is involved in mediating *N*-methyl-D-aspartate (NMDA) receptor–dependent effects but not those involving neurokinin 2 (NK_2) receptors. **Overall, the NO mechanism at the spinal level has an excitatory effect on the micturition reflex.**

However, NO seems to have an inhibitory effect in the bladder. Intravesical application of NO can suppress bladder overactivity due to cyclophosphamide-induced bladder irritation in rats (Ozawa et al, 1999)**.** Intravesical oxyhemoglobin, an NO scavenger, also induces bladder overactivity as evidenced by reductions in bladder capacity and micturition volume, which is prevented by L-arginine or enhanced by the guanylate cyclase inhibitor in rats (Pandita et al, 2000). Masuda and colleagues (2007) also showed that bladder overactivity induced by intravesical capsaicin instillation was enhanced by a NOS inhibitor (L-NAME) administered intravenously or intravesically, and that these L-NAME–induced excitatory effects were significantly suppressed by desensitization of C-fiber afferent pathways by capsaicin pretreatment. **Thus NO released locally in the bladder can mediate inhibitory effects by modulation of bladder afferent activity** (Yoshimura et al, 2001).

Possible Gender Difference in Cholinergic and Nitrergic Innervation in the Urethra. A parasympathetic cholinergic excitatory input to the urethra (see Fig. 60–18) has been identified in male but not in female rats (Flood et al, 1995; Kakizaki et al, 1997). This was demonstrated by measuring intraurethral pressure during voiding after blockade of striated external urethral sphincter activity with a neuromuscular blocking agent. Under these conditions, urethral pressure increased during micturition in male rats. This urethral reflex was blocked by hexamethonium (a ganglionic blocking agent), markedly reduced by atropine, and increased by an NOS inhibitor. However, it was not changed by transection of sympathetic nerves or administration of an α_1-adrenergic blocking agent (prazosin). These results indicate that in male rats, parasympathetic nerve activity induces a predominant cholinergic muscarinic contraction of the urethra and a subordinate NO-mediated relaxation. These studies implicate possible gender differences in parasympathetic and especially nitrergic pathways in the human urethra.

Smooth Muscle Tone and Nitric Oxide. NO-mediated smooth muscle relaxation is due to increased production of intracellular cyclic guanosine monophosphate (cGMP). The second messengers cAMP and cGMP are synthesized from the corresponding nucleoside triphosphates by their respective membrane-bound or soluble adenylate or guanylate cyclases. cAMP and cGMP are inactivated by PDEs by hydrolytic cleavage of the 3′-ribose phosphate bond. Therefore the level of intracellular second messengers can be regulated by PDE isoenzymes (Truss et al, 1999, 2001).

Because of their central role in regulating smooth muscle tone and the considerable variation of PDE isoenzymes among species and tissues, PDEs have become an attractive target for drug development. So far, 7 PDE families, 16 genes, and 33 individual enzyme proteins have been defined. The hope is that bladder-specific PDEs can be developed.

Studies have reported that **PDEs 1 to 5 exist in human detrusor smooth muscle** (Truss et al, 1996). The PDE1-selective inhibitor vinpocetine has been tested, with encouraging but preliminary results, in patients with detrusor overactivity who did not respond to conventional anticholinergic drugs (Truss et al, 1997, 2001).

Afferent Neuropeptides

Afferent neurons innervating the lower urinary tract exhibit immunoreactivity for various neuropeptides, such as substance P (SP), calcitonin gene–related peptide (CGRP), pituitary adenylate cyclase–activating polypeptide (PACAP), leucine enkephalin, corticotropin-releasing factor, and vasoactive intestinal polypeptide (VIP) (de Groat, 1986; de Groat, 1989; Keast and de Groat, 1992; Maggi,

1993; Vizzard, 2001, 2006), as well as growth-associated protein-43 (GAP43), nitric oxide synthase (NOS) (Vizzard et al, 1996), glutamic acid, and aspartic acid (Keast and Stephensen, 2000). These substances have been identified in many species and at one or more locations in the afferent pathways including (1) afferent neurons in lumbosacral dorsal root ganglia, (2) afferent nerves in the peripheral organs, and (3) afferent axons and terminals in the lumbosacral spinal cord (Kawatani et al, 1985, 1986, 1996; Morrison et al, 2005). The majority (>70%) of bladder DRG neurons in rats appear to contain multiple neuropeptides—CGRP, substance P, or PACAP being the most common. In cats, VIP is also contained in a large percentage of bladder DRG neurons (de Groat, 1989).

Many of these peptides, which are contained in capsaicin-sensitive, C-fiber bladder afferents, are released in the bladder by noxious stimulation and contribute to inflammatory responses by triggering plasma extravasation, vasodilation, and alterations in bladder smooth muscle activity (Maggi, 1993; Ishizuka et al, 1994, 1995b). **These agents also function as transmitters at afferent terminals in the spinal cord.**

Tachykinins. The tachykinins are a family of small peptides sharing a common C-terminal sequence, Phe-Xaa-Gly-Leu-Met-NH_2, whose main members are **substance P**, **neurokinin A, and neurokinin B**. Tachykinins are found in both central and peripheral nervous systems. In the peripheral nerves, tachykinins are predominantly located in the terminals of nonmyelinated, sensory C fibers. **The diverse biologic effects of the tachykinins are mediated through three receptors, designated NK_1, NK_2, and NK_3**, which belong to the superfamily of seven transmembrane-spanning G protein–coupled receptors (Khawaja and Rogers, 1996). Substance P is the most potent tachykinin for the NK_1 receptor, whereas neurokinin A exhibits the highest affinity for the tachykinin NK_2 receptor, and neurokinin B for the tachykinin NK_3 receptor (Table 60–6). All receptor subtypes have been identified in the bladder of humans and animals such as rats, mice, and dogs (Lecci and Maggi, 2001; Andersson and Arner, 2004).

Tachykinins released from capsaicin-sensitive sensory C fibers in response to irritation in the bladder can act on (1) NK_1 receptors in blood vessels to induce plasma extravasation and vasodilation, (2) NK_2 receptors to stimulate bladder contractions, and (3) NK_2 receptors on primary afferent terminals to increase the excitability during bladder filling or during bladder inflammation (de Groat, 1989; Andersson, 1993; Morrison et al, 1995; Lecci and Maggi, 2001). A study by Kamo and associates (2005) also demonstrated that **activation of NK_3 receptors on capsaicin-sensitive C-fiber afferents in the rat bladder can increase the excitability during bladder filling**.

Intrathecal administration of NK_1 antagonists (RP 67580 and CP 96345) or systemic application of centrally acting NK_1 antagonists (GR 205171 and CP 99994) increased bladder capacity in normal rats and guinea pigs, respectively, without changing voiding pressure, whereas NK_2, NK_3, or peripherally acting NK_1 antagonists were ineffective (Lecci et al, 1993; Yamamoto et al, 2003). Detrusor overactivity in rats induced by chemical cystitis, intravesical administration of capsaicin, or intravenous injection of L-dopa was also suppressed by intrathecal injection of NK_1 antagonists (Ishizuka et al, 1994, 1995b; Lecci et al, 1994). Detrusor overactivity induced by capsaicin was reduced by an NK_2 antagonist (SR 48965) that did not influence normal voiding (Lecci et al, 1997). In the anesthetized guinea pigs, TAK-637, an NK_1 receptor antagonist, administered orally or intravenously, also increased the volume threshold for inducing micturition and inhibited the micturition reflex induced by capsaicin applied topically to the bladder (Doi et al, 1999). In a clinical study, an NK_1 receptor antagonist, aprepitant, is also shown to effectively decrease the average daily number of micturitions and urgency episodes compared with placebo at 8 weeks in women with idiopathic overactive bladder (Green et al, 2006). These results indicate that **sensory input to the spinal cord from nonnociceptive bladder afferents is mediated by tachykinins acting on NK_1 receptors, whereas input from nociceptive afferents in the bladder can be mediated by NK_1, NK_2, and NK_3 receptors.** In addition, tachykinin NK_3 receptor activation in the spinal cord can inhibit the micturition reflex through an activation of the spinal opioid mechanism (Kamo et al, 2005).

Autofeedback mechanisms may also be important at afferent nerve terminals (see Fig. 60–14). As mentioned earlier, some stimuli are known to release neuropeptides from afferent nerves, and these neuropeptides may, in turn, sensitize the afferents. NK_2 agonists were found (Wen and Morrison, 1996) to sensitize bladder mechanoreceptors by acting on NK_2 autoreceptors in the sensory endings in the bladder mucosa to produce the combination of effects found previously for other sensitizing agents (Morrison, 1998). The NK_2 receptor blocker SR 48968 decreases the sensitivity of bladder mechanoreceptors and also blocks the sensitization produced by NK_2 agonists and high urinary potassium levels. This suggests that the sensitization produced by intravesical chemical stimuli may be due to a mechanism using the NK_2 receptor. On the basis of these findings, it could be hypothesized that high urinary potassium concentration or higher levels of bladder distention release neurokinin A from sensory endings, and that the sensitization is due to the action of the peptide on local NK_2 autoreceptors on the sensory endings. It has also been shown that sensory neurons obtained from rat DRG can be excited by NK_2 agonists and inhibited by NK_3 agonists through modulation of Ca^{2+} channel activity mediated by protein kinase C activation (Sculptoreanu and de Groat, 2003). NK_2 receptor activation also leads to PKC-induced phosphorylation of TRPV1 channels, resulting in an increase in capsaicin-evoked currents in rat DRG neurons (Sculptoreanu and de Groat, 2007; Sculptoreanu et al, 2008).

Other Neuropeptides. Other afferent neuropeptides have effects on the peripheral organs or the central reflex pathways controlling the lower urinary tract. However, the effects can vary in different species and at different sites in the lower urinary tract. **CGRP** applied exogenously or released from primary afferents relaxes smooth muscle and produces vasodilation. The effect of CGRP on bladder is prominent in the guinea pig and dog but is absent in the rat and human bladder (Andersson 1993). **VIP**, which is contained in C-fiber afferents, as well as in postganglionic neurons (de Groat and Booth, 1993), inhibits spontaneous contractile activity in isolated bladder muscle from several species, including humans. However, VIP usually has little effect on bladder

Table 60–6.

Tachykinins and Tachykinin Receptors

TACHYKININ	RECEPTOR
Substance P	NK_1
Neurokinin A	NK_2
Neurokinin B	NK_3

contractions induced by muscarinic receptor agonists or by nerve stimulation (Andersson, 1993). In-vivo studies in the cat revealed that VIP facilitates muscarinic, but not nicotinic transmission, in bladder parasympathetic ganglia and also depresses neurally evoked contractions of the bladder (de Groat and Booth, 1993).

In the spinal cord, VIP-containing afferent pathways have been implicated in the recovery of bladder reflexes after spinal injury. In cats with chronic spinal injury, VIP immunoreactivity, which is a marker for C-fiber afferent terminals, is distributed over a wider area of the lateral dorsal horn, suggestive of afferent axonal sprouting after spinal injury (Yoshimura and de Groat, 1997; Doi et al, 1999). In addition, the effects of intrathecal administration of VIP are changed. In normal cats, VIP inhibits the micturition reflex; whereas in paraplegic cats, VIP facilitates the micturition reflex. These findings suggest that the action of a putative C-fiber afferent transmitter may underlie the emergence of C-fiber bladder reflexes in the paraplegic cat. In the normal rat, VIP and **PACAP**, another member of the secretin-glucagon-VIP peptide family, also facilitate the micturition reflex by actions on the spinal cord (Ishizuka et al, 1995a; Yoshiyama and de Groat, 2008). In rats with spinal cord injury, an increase in expression of PACAP-immunoreactivity in bladder DRG neurons and expansion of PACAP-IR afferent axons in the lumbosacral spinal cord are observed, and intrathecal administration of PACAP6-38, a PAC1 PACAP–receptor antagonist, reduces premicturition contractions during bladder filling and reduces maximal voiding pressure, suggesting that activation of PAC1 receptors by endogenous PACAP contributes to the micturition reflex and bladder overactivity in spinalized rats (Zvarova et al, 2005; Zvara et al, 2006).

Patch clamp studies in neonatal rat spinal-slice preparations revealed that PACAP has a direct excitatory action on parasympathetic preganglionic neurons due in part to blockade of K^+ channels (Miura et al, 2001). In addition, PACAP has an indirect action by activating excitatory interneurons.

Prostanoids, Endothelins, and Hormones

Prostanoids. Prostanoids (prostaglandins and thromboxanes), which comprise a family of oxygenated metabolites of arachidonic acid, by the enzymatic activity of cyclooxygenases 1 and 2, are manufactured throughout the lower urinary tract and have been implicated in bladder contractility, inflammatory responses, and neurotransmission. Biopsy specimens of human bladder mucosa contain prostaglandin (PG) I_2, PGE_2, $PGE_{2\alpha}$, and thromboxane A. **In decreasing order of potency, $PGF_{2\alpha}$, PGE, and PGE_2 contract the human detrusor** (Andersson, 1993; Andersson and Arner, 2004). The actions of prostanoids are mediated by specific receptors on cell membranes. The receptors include the DP, EP, FP, IP, and TP receptors that preferentially respond to PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, and thromboxane A_2, respectively. Furthermore, EP is subdivided into four subtypes: EP_1, EP_2, EP_3, and EP_4 (Breyer et al, 2001, 2003). **The slow onset of action for these substances suggests a modulatory role for prostaglandins. Some prostaglandins may affect neural release of transmitters, whereas others inhibit acetylcholinesterase activity.** These actions provide mechanisms whereby prostaglandins could potentially augment the amplitude of cholinergic-induced detrusor contractions (Borda et al, 1982).

Attempts to use prostaglandins to facilitate voiding have had mixed results. Intravesical PGE_2 has been shown to enhance bladder emptying in women with urinary retention and patients with neurogenic voiding dysfunction (Bultitude et al, 1976; Vadyanaathan et al, 1981; Tammela et al, 1987). Others have failed to find PGE_2 useful to facilitate complete evacuation of the bladder ((Delaere et al, 1981; Wagner et al, 1985). Intravesical PGE_2 does produce urgency and involuntary bladder contractions (Schussler, 1990). Consistent with this finding, inhibition of prostaglandin synthesis with indomethacin reduces detrusor overactivity (Cardozo and Stanton, 1980).

Endothelins. Endothelins (ETs), a family of 21–amino acid peptides (originally isolated from bovine aortic endothelial cells), include ET-1, ET-2, and ET-3, which are encoded by separate genes and mediate a variety of biologic actions through two distinct G protein–coupled receptor subtypes, the endothelin-A (ETA) and the endothelin-B (ETB) receptor (Yanagisawa et al, 1988; Masaki, 2004). The ETA receptor subtype has a higher affinity for ET-1 and ET-2 than for ET-3; the ETB receptor subtype binds all ETs with equal affinity (Rubanyi and Polokoff, 1994). ET-1, which is known to be primarily produced by human endothelial cells, can induce prolonged contractile responses in isolated urinary bladder muscle strips in various species (Maggi et al, 1990; Khan et al, 1999). In humans and rabbits, ET-like immunoreactivity is identified in almost all cell types in the bladder, including bladder epithelium, vascular endothelium, detrusor, and vascular smooth muscles, and fibroblasts; **it plays a role in control of bladder smooth muscle tone, regulation of local blood flow, and bladder wall remodeling in pathologic conditions** (Saenz de Tejada et al, 1992). In a rabbit model of bladder outlet obstruction, ET-1 and ETA receptor binding sites in detrusor smooth muscle and urothelium, as well as ETB receptor binding sites in detrusor smooth muscle, were significantly increased (Khan et al, 1999). In addition, the endothelin-converting enzyme inhibitor WO-03028719, which suppresses ET-1 production, can improve voiding efficiency and suppress detrusor overactivity in a rat model of bladder outlet obstruction (Schroder et al, 2004). YM598, a selective ETA receptor antagonist, also reduces detrusor overactivity in urethral obstructed rats (Ukai et al, 2006). These results suggest that **the increase in ET-1 expression and ET receptors could be involved in detrusor hyperplasia and overactivity seen in patients with bladder outlet obstruction resulting from benign prostatic hyperplasia.**

There is also evidence that ETs have a role in modulation of sensory function in the peripheral and central nervous system. The activation of ET_A receptors in capsaicin-sensitive C-fiber afferents in the bladder induces detrusor overactivity, whereas ET_A receptor activation in the spinal cord can inhibit the micturition reflex through activation of a spinal opioid mechanism in rats (Ogawa et al, 2004). In spinal cord–injured rats, the bladder ET-1 level was increased, and the application of ABT-627, an ET_A antagonist, suppresses C-fiber–mediated detrusor overactivity. Taken together, modulation of ET_A receptor activity in bladder afferent pathways or the spinal cord could be effective in treating bladder overactivity or painful conditions (Ogawa et al, 2008).

Parathyroid Hormone–Related Peptide. Some locally released substances cause **detrusor relaxation**. Parathyroid hormone–related peptide is **manufactured by bladder smooth muscle**. **Stretch** in vivo (Yamamoto et al, 1992) and in vitro (Steers et al, 1998) **increases parathyroid hormone–related peptide**. Slow or gradual distention could release local relaxants, thereby maintaining low filling pressures.

Sex Steroids. Differences in responses of human and animal bladders to the effect of drugs suggest that sex steroids play a role in detrusor contractility. It is not unusual for women to note changes in voiding, bladder pain, or continence at different times of their menstrual cycle. **Sex steroids do not directly affect bladder contractility, but they modulate receptors and**

influence growth of bladder tissues. Estrogen receptors are expressed by the trigone in women (Iosif et al, 1981). Levin and associates (1980) noted that bladder body muscle from young female rabbits treated with estrogens exhibits increased responsiveness to α-adrenergic, cholinergic, and purinergic agonists. Others have seen a decreased density of adrenergic and muscarinic receptors in the bladder after estrogen administration (Shapiro, 1986; Batra and Andersson, 1989). In contrast to the study by Levin and coworkers (1980), Elliot and associates (1992) showed that bladder smooth muscle from estrogen-treated rats exhibited decreased contractions.

Estrogens also increase adrenergic receptors in the urethra (Callahan and Creed, 1985). Ekstrom and associates (1993) reported that estrogen administration to ovariectomized rabbits unmasked contractile responses to α-adrenergic agonists, whereas contracted and normal rabbit bladders demonstrated no response to these agents. Some clinicians have combined these agents to elevate urethral pressure in patients with stress incontinence (Wilson et al, 1987). However, the clinical efficacy of the combined use of estrogen with α agonists has been questioned (Walter et al, 1978). **The effect of estrogens on urinary continence in females probably reflects the multiple actions of this hormone on adrenergic receptors, vasculature, and urethral morphology. In addition, progesterone increases electrical and cholinergic contractions of the bladder.** Exogenous estrogens and progesterones also induce NOS activity in bladders of female guinea pigs (Ehren et al, 1995). This effect is postulated to contribute to relief of detrusor overactivity with hormonal treatment. However, the use of estrogens alone to treat either stress urinary incontinence or urgency incontinence has given disappointing results (Abrams et al, 2005), and studies have suggested that estrogen may be associated with an increase in urinary incontinence in postmenopausal women (Hendrix et al, 2005).

Androgen treatment in the male rat has been reported to have similar effects on synaptic connections, as well as effects on motoneuronal somatic and dendritic size in the androgen-sensitive motoneurons innervating the bulbocavernosus and levator ani muscles of the rat (Jordan, 1997; Matsumoto, 1997). Testosterone treatment can also influence the size of postganglionic neurons in the major pelvic ganglion of the male rat (Keast and Saunders, 1998). Thus further studies are needed to evaluate the influence of changes in hormonal environment on the neural pathways controlling the lower urinary tract.

"Transducer" Function of the Urothelium

Whereas the urothelium has historically been viewed primarily as a "barrier," **there is increasing evidence that urothelial cells display a number of properties similar to sensory neurons (nociceptors and mechanoreceptors) and that both types of cells use diverse signal-transduction mechanisms to detect physiologic stimuli.** Examples of "sensor molecules" (i.e., receptors and ion channels) associated with neurons that have been identified in urothelium include receptors for bradykinin (Chopra et al, 2005), neurotrophins (TrkA and p75) (Murray et al, 2004), purines (P2X and P2Y) (Lee et al, 2000; Hu et al, 2002; Birder et al, 2004; Tempest et al, 2004; Chopra et al, 2008), norepinephrine (α and β) (Birder et al, 1998; Birder et al, 2002), acetylcholine (nicotinic and muscarinic) (Chess-Williams, 2002; Beckel et al, 2006; Kullmann et al, 2008a), protease-activated receptors, amiloride-/mechanosensitive Na^+ channels such as ENaC (Smith et al, 1998; Wang et al, 2003; Araki et al, 2004), and a number of TRP channels (TRPV1, TRPV2, TRPV4, TRPM8) (Birder and de Groat, 1998; Birder et al, 2001, 2002, 2007; Stein et al, 2004; Gevaert et al, 2007).

When urothelial cells are activated through these receptors and ion channels in response to mechanical as well as chemical stimuli, they can, in turn, release chemical mediators such as NO, ATP, acetylcholine, and substance P (Ferguson et al, 1997; Birder et al, 1998; Burnstock, 2001; Birder et al, 2003; Chess-Williams, 2004). **These agents are known to have excitatory and inhibitory actions on afferent nerves that are close to or in the urothelium** (Bean et al, 1990; Dmitrieva et al, 1998; Birder et al, 2001; Yoshimura et al, 2008). **Chemicals released from urothelial cells may act directly on afferent nerves or indirectly through an action on suburothelial interstitial cells** (also referred to as myofibroblasts) that lie in close proximity to afferent nerves. Myofibroblasts are extensively linked by gap junctions and can respond to chemicals that in turn modulate afferent nerves (Fowler et al, 2008). **Thus it is believed that urothelial cells and myofibroblasts can participate in sensory mechanisms in the urinary tract by chemical coupling to the adjacent sensory nerves.**

NO can be released by the urothelium, particularly during inflammation (Birder et al, 1998). The release of NO may be evoked by the calcium ionophore A-23187, norepinephrine, and capsaicin. Substance P also acts on receptors on urothelial cells to release NO. The adrenergic release of NO from bladder strips was reduced by 85% after removal of the urothelium. Denervation of the bladder did not completely block the release of capsaicin-induced NO production, suggesting other sites of production. This is consistent with the observations that capsaicin released NO from cultured rat, cat, rabbit, and human urothelial cells and that the TRPV1 capsaicin receptor is expressed in cultured urothelial cells. NOS expression in afferent neurons is also increased in chronic bladder inflammation. Given that NO does not have much effect on the detrusor muscle but does inhibit Ca^{2+} channels in rat bladder afferent neurons (Yoshimura et al, 2001), **the role of NO in the urothelium has still to be clarified**. However, **NO released locally in the bladder appears to have an inhibitory effect on afferent activity in the bladder** because suppression of endogenous NO by intravesical oxyhemoglobin, an NO scavenger, or L-NAME, a NOS inhibitor, enhances bladder activity in rats (Pandita et al, 2000; Masuda et al, 2007).

ATP released from urothelial cells during stretch can activate a population of suburothelial bladder afferents expressing $P2X_3$ receptors, signaling changes in bladder fullness and pain (Ferguson et al, 1997; Burnstock, 2001). Accordingly, **$P2X_3$ null mice exhibit a urinary bladder hyporeflexia, suggesting that this receptor, as well as neural–epithelial interactions, are essential for normal bladder function** (Cockayne et al, 2000). This type of regulation may be similar to epithelium-dependent secretion of mediators in airway epithelial cells, which are thought to modulate submucosal nerves and bronchial smooth muscle tone and may play an important role in inflammation (Homolya et al, 2000; Jallat-Daloz et al, 2001). Thus it is possible that activation of bladder nerves and urothelial cells can modulate bladder function directly or indirectly by the release of chemical factors in the urothelial layer. ATP released from the urothelium or surrounding tissues may also play a role in the regulation of membrane trafficking. This is supported by studies in the urinary bladder in which urothelium-derived ATP release purportedly acts as a trigger for exocytosis, in part by autocrine activation of urothelial purinergic (P2X, P2Y) receptors (Wang et al, 2005).

These findings suggest a mechanism whereby urothelial cells sense or respond to ATP and thereby translate extracellular stimuli into functional processes.

Prostaglandins are also released from the urothelium. These are assigned two possible functions: regulation of detrusor muscle activity and cytoprotection of the urothelium, based on effective treatment of hemorrhagic cystitis by prostaglandins (Jeremy et al, 1987). The predominant forms found in human urothelium from biopsy specimens are 6-oxo-$PGF_{2\alpha}$ > PFE_2 > $PGF_{2\alpha}$ > thromboxane B_2. PGI_2 (prostacyclin) is also produced. These findings were confirmed and further developed in the guinea pig, in which it was found that the major production of prostaglandins occurred in the urothelium. The production of prostaglandins also increased greatly with inflammation (Saban et al, 1994). Prostaglandin synthesis also occurs in the ureter, where it is speculated to be important in the regulation of ureteral peristalsis and also in reducing the development of blood clots in the lumen of the ureter (Ali et al, 1998).

Evidence also suggests that the involvement of the muscarinic receptor in bladder function extends beyond detrusor contractility and into afferent sensory functioning. Muscarinic receptors are found on the urothelium at high density (Hawthorn et al, 2000), **and there is a basal release of acetylcholine from the urothelium that is increased by stretch and aging** (Yoshida et al, 2006). **Thus activation of the muscarinic receptors in the urothelium releases substances that modulate afferent nerves and smooth muscle activity** (Hawthorn et al, 2000; de Groat, 2004; Kullmann et al, 2008b).

The urothelium also releases substances called urothelium-derived inhibitory factors, which decrease the force of detrusor muscle contraction in response to muscarinic stimulation (Hawthorn et al, 2000; Kumar et al, 2005). The molecular identity of this factor is not known; however, pharmacologic studies suggest that it is not NO, a prostaglandin, prostacyclin, adenosine, catecholamine, GABA, or one that acts through apamine-sensitive, small-conductance K^+ channels. It has been shown that an inhibitory response through this factor is attenuated in a fetal model of bladder outlet obstruction (Thiruchelvam et al, 2003). Further studies are required to clarify the identity of this substance and its role in bladder function.

Serotonin

Serotonin (5-HT) has been found in neuroendocrine cells along the urethra and in the prostate ((Hanyu et al, 1987). In animals, 5-HT_2 and, possibly, 5-HT_3 agonists contract the urethra. If inflammatory conditions promote release of serotonin from paraurethral cells, irritative symptoms, such as the urethral syndrome, may arise because of serotonergic mechanisms. The 5-HT_2 antagonist ketanserin has been shown to reduce urethral pressure in humans (Horby-Petersen et al, 1985). However, the reduction in urethral pressure after ketanserin administration can also be the result of blockade of α-adrenergic receptors (Thor and Katofiasc, 1995).

5-HT also has several pharmacologic effects on mammalian urinary bladders, both in vitro and in vivo. Human and pig isolated detrusor muscles are known to contract in a concentration-dependent manner in response to 5-HT (Klarskov and Horby-Petersen, 1986). In human isolated urinary bladder, there was potentiation of the contractions induced by electrical field stimulation, mediated by the 5-HT_4 receptor subtype (Candura et al, 1996; Darblade et al, 2005). A similar response is present on guinea pig detrusor muscle through 5-HT_{2A} and 5-HT_4 receptors, whereas in the rabbit and the rat, the receptors involved are the 5-HT_3 and 5-HT_7 subtypes, respectively (Palea et al, 2004).

TRP Channels and C-Fiber Pharmacotherapy

The superfamily of TRP **(transient receptor potential)** channels expressed in mammals are subdivided into six subfamilies: TRPC (canonical), TRPV (vanilloid), TRPM (melastatin), TRPP (polycystin), TRPML (mucolipin), and TRPA (ankyrin) groups, which are **Ca^{2+}-permeable cation channels and activated by physical (depolarization, hot/cold temperature, mechanical stress) or chemical (pH, osmolality) stimuli and binding to specific ligands** (vanilloids, menthol) (Krause et al, 2005; Everaerts et al, 2008). The available evidence suggests that TRP channels have a four-subunit combination, in either a homotetrameric or heterotetrameric complex, to form functional ion-permeation complexes (Krause et al, 2005).

TRPV1

TRPV1, the most extensively studied TRP channel, is expressed on capsaicin-sensitive afferent pathways, predominantly C-fiber nociceptors, and responds to increases in temperature to the noxious range (>43° C) and to protons, suggesting that it functions as a **transducer of painful thermal stimuli and acidity in vivo**. When it is activated, the channel opens, allowing an influx of Ca^{2+} and Na^+ ions that depolarizes the nociceptive afferent terminals, initiating a nerve impulse that travels through afferent nerves into the central nervous system. Noxious temperature uses the same elements, which explains why the mouth feels hot when eating chili peppers (Clapham, 1997). **In the lower urinary tract, TRPV1 is expressed in suburothelial afferent fibers, urothelium, detrusor smooth muscle, and other non-neuronal cells such as suburothelial interstitial cells** (see Fig. 60–8). Studies using TRPV1 knockout mice showed that TRPV1 receptors are not essentially involved in conscious voiding but have a role in afferent sensitization due to cystitis because bladder overactivity induced by chemical cystitis, using cyclophosphamide or acrolein, was not observed in TRPV1 knockout mice (Birder et al, 2002; Charrua et al, 2007; Wang et al, 2008). In addition, TRPV1 expressed in the bladder urothelium may function as a stretch sensor because the release of ATP and NO from cultured urothelial cells during hypotonic stretch is reduced in TRPV1 knockout mice compared with the wild type (Birder et al, 2002).

Activation of TRPV1 by vanilloids, such as capsaicin and its ultrapotent analog resiniferatoxin (RTX), results in spikelike currents (Liu and Simon, 1996) **and selectively excites and subsequently desensitizes TRPV1-expressing C fibers.** Desensitization induced by capsaicin is defined as a long-lasting, reversible suppression of sensory neuron activity (Craft et al, 1995). Thus because **of the unique ability to desensitize TRPV1-expressing C fibers, the vanilloids have been used for treatment of pain/overactivity of the bladder** (Cheng et al, 1995; Chancellor and de Groat, 1999). The normal sensations of bladder filling appear to be mediated by small myelinated Aδ fibers. In the cat, Aδ fibers have pressure thresholds in the range of those at which humans report the first sensation of bladder filling (Janig and Morrison, 1986). **C-fiber afferents, which are small and unmyelinated, have high mechanical thresholds and do not normally respond to**

even high levels of intravesical pressure in the cat (Häbler et al, 1990). **C-fiber afferents are activated by noxious chemical irritation** (Häbler et al, 1990) **or by cold** (Fall et al, 1990). **In the irritated state, C-fiber afferents become responsive to low-pressure bladder distention such as mechanoreceptive Aδ fibers. C fibers, therefore, are normally "silent." C-fibers have the specific function of signaling of inflammatory or noxious events in the bladder** (Chancellor and de Groat, 1999) (Figs. 60–27 and 60–28).

RTX is the principal active ingredient in the drug euphorbium that is derived from the air-dried latex (resin) of the cactus-like plant *Euphorbia resinifera*. *E. resinifera* belongs to the Euphorbiaceae, commonly known as the spurge family, one of the most important families of medicinal plants. In 1975, the principal active ingredient in euphorbium was isolated and named **resiniferatoxin** (Hergenhahn et al, 1975). In 1989, **RTX was recognized as an ultrapotent analog of capsaicin; however, it has unique pharmacologic effects as well** (Szallasi and Blumberg, 1990), **such as desensitization without prior excitation of the pulmonary chemoreflex pathway** (Szolcsanyi, 1990). In patients with spinal cord injury–induced detrusor overactivity, clinical response to intravesical therapy with RTX led to a marked decrease of nerve fibers positively stained for PGP9.5, a neuronal marker, and TRPV1. Six of 17 patients in this investigation showed a satisfactory clinical response to RTX treatment, with marked improvements on cystometry and other parameters (Brady et al, 2004). Spinal-injury patients who did not respond to RTX showed no decrease in nerve fiber population, similar to controls. In addition, intravesical RTX administered to patients with idiopathic detrusor overactivity delayed or suppressed involuntary detrusor contractions during filling cystometry. The mean interval to the first involuntary contraction more than doubled versus baseline at 30 and 90 days; mean maximal cystometric capacity increased; the mean number of episodes of urinary incontinence daily fell to fewer than one; and mean daily frequency also decreased significantly (Silva et al 2002). It has also been reported that C-fiber desensitization induced by intravesical application of high-dose capsaicin and resiniferatoxin (RTX) is effective for treating painful symptoms in IC patients (Lazzeri et al, 1996, 2000) although a prospective, randomized clinical trial using intravesical RTX application showed no effect in patients with IC (Payne et al, 2005).

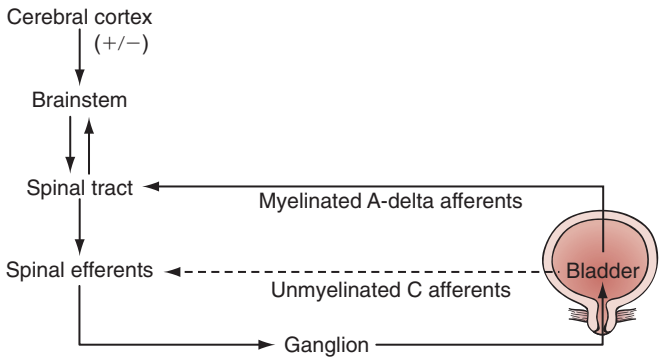

Figure 60–27. Illustration depicting the predominant Aδ afferent contribution to the normal micturition reflex.

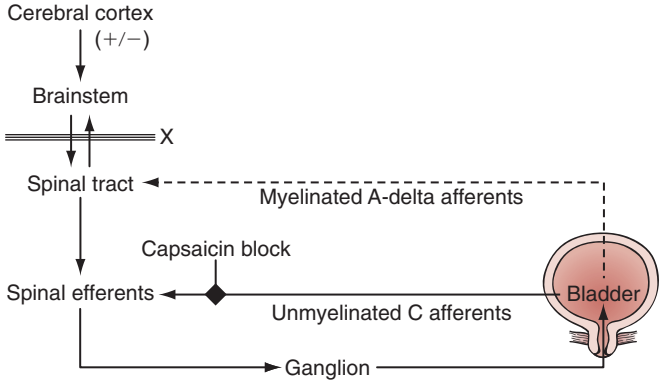

Figure 60–28. Illustration depicting the switch in afferent contribution to the micturition reflex from Aδ-fiber predominant to C-fiber predominant with neurologic diseases, aging, and possibly inflammatory disease. Note that capsaicin (and other vanilloids) can block the C-fiber contribution under these conditions.

More recently, selective antagonists of TRPV1 channels are being evaluated as potential analgesics in clinical trials (Everaerts et al, 2008). GRC-6211, a new oral TRPV1 antagonist, has been shown to decrease bladder overactivity and noxious bladder input in cystitis animal models (Charrua et al, 2009), suggesting the **possibility of TRPV1 antagonists for the treatment of bladder pain/overactivity.**

TRPM8 and TRPA1

TRPM8 is a member of the temperature-sensitive TRP channels that responds to cold temperature of less than 23° C. Pharmacologic agents that evoke cool sensation, such as menthol and ilicin, can activate TRPM8. In sensory pathways, TRPM8 is expressed in DRG and trigeminal ganglion neurons that do not express TRPV1, isolectin-B4, or CGRP, which are usually markers of C-fiber afferents. Thus TRPM8 is considered to be **expressed in a subpopulation of thermoceptive and nociceptive afferents that are different from the TRPV1-expressing subpopulation.** In the human lower urinary tract, TRPM8 expression is found in the prostate, the testes, scrotal skin, and bladder (Stein et al, 2004). In addition, although the study by Stein and colleagues showed that expression in the human bladder was limited to the urothelium, Mukerji and colleagues (2006) showed TRPM8 immunoreactivity in the bladder urothelium, as well as in fine nerve fibers in the suburothelial layer, and that the number of TRPM8-positive C-fibers in the bladder suburothelium is increased in patients with idiopathic detrusor overactivity. In animal studies, activation of TRPM8 channels in the guinea pig bladder by intravesical application of menthol reduces volume threshold for micturition and increases sensitivity to bladder cooling (Tsukimi et al, 2005), while a TRPM8 antagonist, ammonium/methyl ammonium transport B (AMTB), decreases bladder contraction frequency without affecting contraction amplitude in cystometry, as well as the visceromotor reflex of abdominal muscle in response to noxious urinary bladder distention in rats (Lashinger et al, 2008). Therefore **TRPM8 in bladder afferent pathways and urothelium could be involved in modulation of sensory function of the lower urinary tract.**

TRPA1 is the only member of the ankyrin TRP channel and a receptor for several pungent chemicals that evoke pain, such as allyl-isothiocyanate (the pungent compound in mustard oil), allicin (garlic), cinnamaldehyde (in cinnamon), and acrolein (a metabolite of cyclophosphamide). TRPA1 also functions as a receptor-operated channel that can be activated by growth factors or proinflammatory peptides such as bradykinin, which increases intracellular Ca^{2+} levels using G protein–coupled receptors. TRPA1 is expressed in sensory neurons, in which it is coexpressed with TRPV1, but not with TRPM8. Although TRPA1 can be activated by

cold (<17° C) by an increase in intracellular Ca^{2+} concentration when expressed in heterologous systems, its role as a cold sensor in native peripheral sensory neurons, including DRG cells, remains uncertain. In mice, cooling does not evoke unspecific rises in Ca^{2+} concentration in DRG neurons, while visceral sensory neurons in nodose ganglia exhibit a strong correlation between cold sensitivity and TRPA1 expression (Fajardo et al, 2008), suggesting that TRPA1 may contribute to cold transduction in visceral sensory neurons rather than somatic neurons (Caspani and Heppenstall, 2009). In the bladder, TRPA1 is expressed in the urothelium, TRPV1 and CGRP-positive suburothelial afferent nerves, and detrusor muscles in mice, rats, and humans (Nagata et al, 2005; Du et al, 2007, 2008; Streng et al, 2008). TRPA1 receptor activation by intravesical application of hydrogen sulfide, allyl isothiocyanate, and cinnamaldehyde induces frequent voiding as evidenced by a reduction in intercontraction intervals, which is suppressed by capsaicin-induced C-fiber desensitization in rats (Du et al, 2007; Streng et al, 2008). In addition, TRPA1 mRNA expression in the bladder mucosa from male patients with lower urinary tract symptoms due to bladder outlet obstruction is significantly increased compared with control subjects (Du et al, 2008). Thus TRPA1 expressed in the bladder urothelium and sensory pathways **may have a role in sensory transduction in pathologic conditions, including overactive bladder.**

In patients with various types of overactive bladder, the ice-water test, in which infusion of ice cold water in the bladder causes reflex detrusor contraction, has been used as a diagnostic tool to detect hyperexcitability of C-fiber bladder afferent pathways (Chancellor and de Groat, 1999). TRPM8 and TRPA1, both of which can be activated by cooling, may be responsible for activation of the bladder cooling reflex in the ice-water test, although the involvement of TRPA1 in cold transduction is still equivocal.

TRPV4

TRPV4 is a member of vanilloid TRPV channels and a nonselective cation channel **activated by mechanical pressure, osmolality (hypotonicity), moderate warmth (>27° C), and chemical stimuli** such as phorbol derivates. Its expression **has been detected in urothelial cells and detrusor muscle**, but not in the suburothelial layer, in the bladder of mice, rats, and guinea pigs (Birder, 2007; Gevaert et al, 2007; Thorneloe et al, 2008; Xu et al, 2009; Yamada et al, 2009). The TRPV4 agonist, 4α-phorbol 12,13-didecanoate, and hypotonic cell swelling promote Ca^{2+} influx and evoke ATP release in cultured urothelial cells from mice (Gevaert et al, 2007) or rats (Birder, 2007). In cultured urothelial cells from TRPV4 knockout mice, the intracellular Ca^{2+} increase and ATP release in response to stretch stimulation were significantly attenuated compared to the wild-type mice (Mochizuki et al, 2009). Cystometric experiments revealed that TRPV4 knockout mice exhibit a lower frequency of voiding contractions, as well as a higher frequency of nonvoiding contractions (Gevaert et al, 2007), and that intravesical application of TRPV4 agonists induces bladder overactivity as evidenced by increased micturition pressure in rats (Birder, 2007) or reduced contraction frequency in mice (Thorneloe et al, 2008). These results suggest that **urothelial TRPV4 channels act as a pressure sensor to enhance bladder activity, predominantly through activation of bladder afferent pathways by urothelially released ATP**.

Botulinum Toxin

In recent years, there has been increasing evidence for the therapeutic efficacy of botulinum neurotoxin (BoNT) for the treatment of various urethral and bladder dysfunctions (Smith and Chancellor, 2004; Apostolidis and Fowler, 2008).

Botulinum toxins act by **inhibiting acetylcholine release at the presynaptic cholinergic nerve terminal, thereby inhibiting striated and smooth muscle contractions**. The toxins are synthesized as single-chain polypeptides with a molecular weight of about 150 kD (DasGupta, 1994). Initially, the parent chain is cleaved into its active dichain polypeptide form, consisting of a heavy chain (approximately 100 kD) connected by a disulfide bond to a light chain (approximately 50 kD) with an associated zinc atom (Schiavo et al, 1992). Four steps are required for toxin-induced paralysis: binding of the toxin heavy chain to an as yet unidentified nerve terminal receptor, internalization of the toxin within the nerve terminal, translocation of the light chain into the cytosol, and inhibition of neurotransmitter release. Neurotransmitter release involves the ATP-dependent transport of the vesicle from the cytosol to the plasma membrane (Barinaga, 1993). Vesicle docking requires the interaction of various cytoplasm, vesicle, and target membrane proteins (i.e., synaptosome-associated membrane receptor [SNARE] proteins), some of which are specifically targeted with clostridial neurotoxins (Fig. 60–29). For example, BoNT-A cleaves the cytosolic translocation protein SNAP-25, thus preventing vesicle fusion with the plasma membrane (Fig. 60–30) (Schiavo et al, 1993).

Seven immunologically distinct neurotoxins are designated types A, B, C, D, E, F, and G. Clinically, the urologic community has used commercial preparations of BTX-A to treat patients with neurogenic and idiopathic detrusor overactivity (Dykstra et al, 1988; Dykstra and Sidi, 1990; Schurch et al, 1996; Petit et al, 1998; Schurch et al, 2000; Apostolidis et al, 2009). **Although acetyl choline (ACh) release from bladder parasympathetic efferent terminals is the primary target of BoNT treatment, suppression of bladder afferent activity with BoNT treatment is also evident** because the reduction of urgency symptom in patients with neurogenic and idiopathic detrusor overactivity is associated with reduced expression of the capsaicin receptor (TRPV1) and the ATP receptor ($P2X_3$) in C-fibers (Apostolidis et al, 2005). In addition, **in basic research, botulinum toxins are shown to suppress not only efferent nerve activity by inhibition of the release of acetylcholine but also afferent nerve activity by release of inhibition of neurotransmitters, such as substance P and CGRP, from sensory terminals** (Chuang et al, 2004; Dressler et al, 2005). There is also evidence that the toxin can reduce the release of ATP from urothelial cells in spinalized rats (Khera et al, 2004; Smith et al, 2005; Smith et al, 2008). Thus the use of the toxins has been expanded to treat women with pelvic floor spasticity, as well as patients with non-neurogenic overactive bladder and even bladder pain syndrome (Smith et al, 2003; Smith and Chancellor, 2004; Smith et al, 2005; Apostolidis and Fowler, 2008). The efficacy of botulinum toxins was also recently identified in patients with benign prostatic hyperplasia, in whom BoNT-A injection into the prostate induced an atrophy of the prostate by inducing apoptosis, inhibiting proliferation, and downregulating α_{1A}-adrenergic receptors (Chuang et al, 2006).

Actions of Drugs on Bladder Smooth Muscle

Two major classes of pharmacologic agents that are used clinically to inhibit spontaneous activity of the bladder are calcium channel

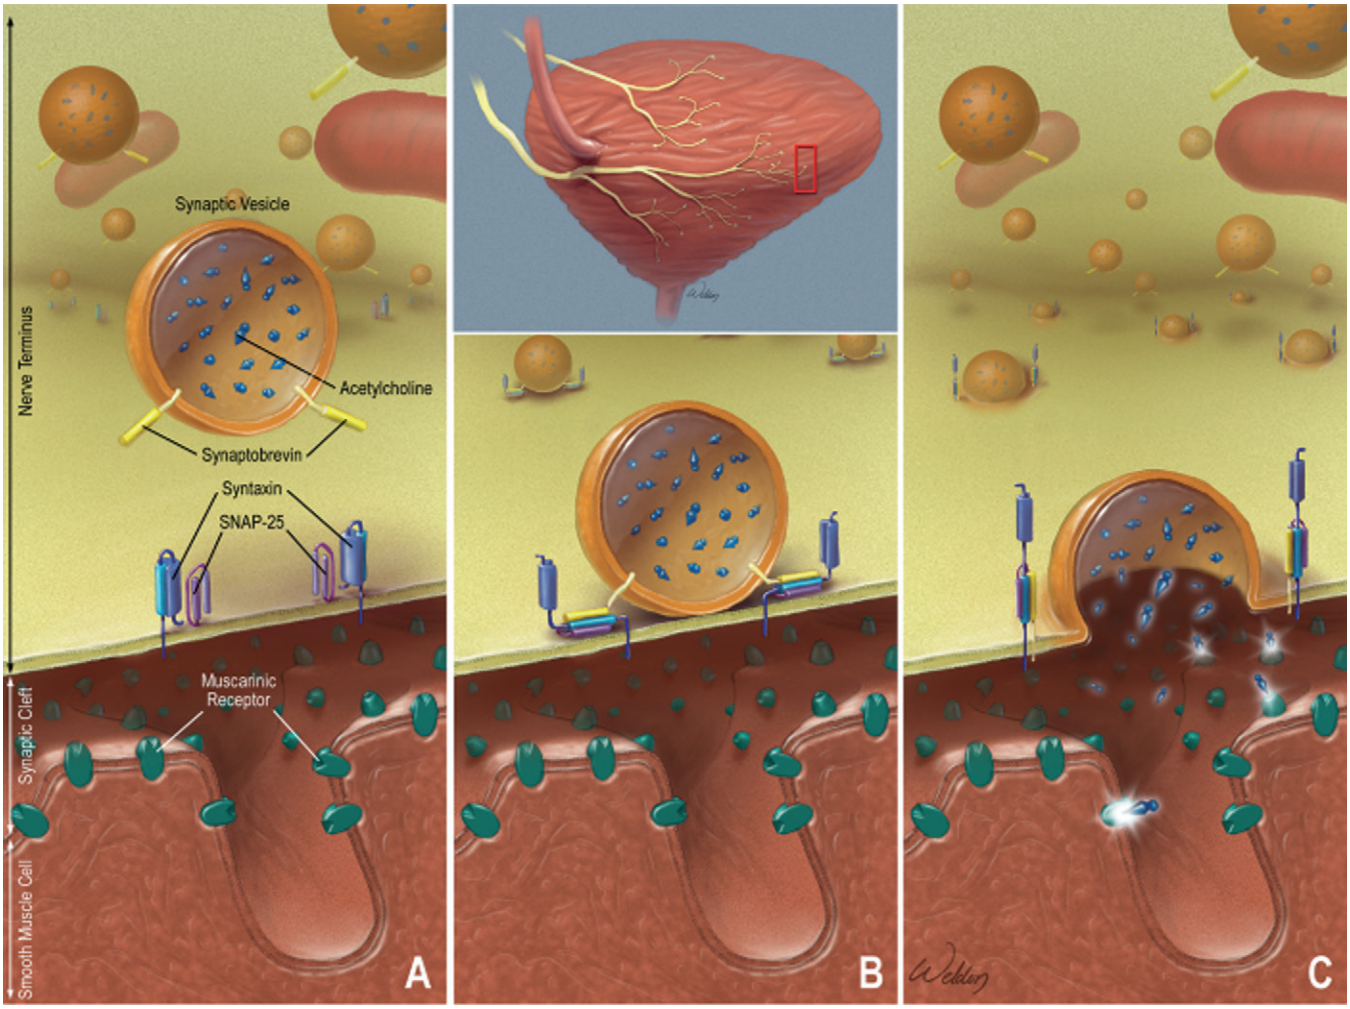

Figure 60–29. Schematic diagram demonstrating normal fusion and release of acetylcholine from nerve terminals through interaction of vesicle and membrane-bound (SNARE) proteins. Parasympathetic nerves innervate the urinary bladder *(inset)* with **(A)** nerve terminal in an unactivated state displaying numerous vesicles containing the neurotransmitter acetylcholine. **B,** After nerve activation, assembly of the SNARE protein complex (e.g., synaptobrevin, SNAP-25, and syntaxin) leads to **(C)** release of acetylcholine and activation of postjunctional muscarinic receptors, resulting in bladder contraction.

blockers, such as diltiazem and verapamil, and potassium channel openers, such as cromakalim and pinacidil (see Table 60–5) (Andersson, 1993, 1997; Andersson et al, 1999). Also, the direct effect of tricyclic antidepressants on the bladder is briefly discussed.

Calcium Channel Blockers

In the bladder smooth muscle, both spontaneous and evoked contractile activities are mediated by membrane depolarization and the movement of calcium into the smooth muscle cell through L-type Ca^{2+} channels (Brading, 1997b; Fry and Wu, 1997; Brading, 2006). In addition, Ca^{2+} channels and nonselective stretch-activated divalent ion channels have been demonstrated in detrusor smooth muscle (Brading, 1997b; Fry and Wu, 1997; Martin et al, 1997). The one thing in common is that **all contractile activity involves the entrance of extracellular calcium. Some forms of contractile responses are mediated by both the entrance of extracellular calcium and the release of intracellular calcium from the sarcoplasmic reticulum** (Levin and Wein, 1995; Zderic et al, 1996; Brading, 1997b; Fry and Wu, 1997; Martin et al, 1997).

The relationship between various forms of contractile response and calcium translocation and release has been the subject of a large number of studies. Inhibition of the entrance of calcium can inhibit spontaneous and evoked contractile activity (Levin et al, 1991). L-type Ca^{2+}-blocking agents, such as nifedipine, can reduce the level and severity of spontaneous myogenic contractile activity, which depends primarily on the entrance of extracellular calcium through L-type Ca^{2+} channels. Ca^{2+} channel blockers are less effective in suppressing nerve-mediated contractions, which are dependent on both the entrance of extracellular calcium and the stimulated release of intracellular calcium from the sarcoplasmic reticulum through IP_3-mediated mechanisms (Levin and Wein, 1995; Zderic et al, 1996; Brading, 1997b; Andersson and Arner, 2004). This leads to the possibility of developing selective Ca^{2+}-channel blocking agents that eliminate spontaneous contractions without affecting micturition contractions.

Potassium Channel Openers

K^+ channel openers, such as cromakalim and pinacidil (see Table 60–5), **stimulate the movement of potassium out of the cell, resulting in membrane hyperpolarization and a**

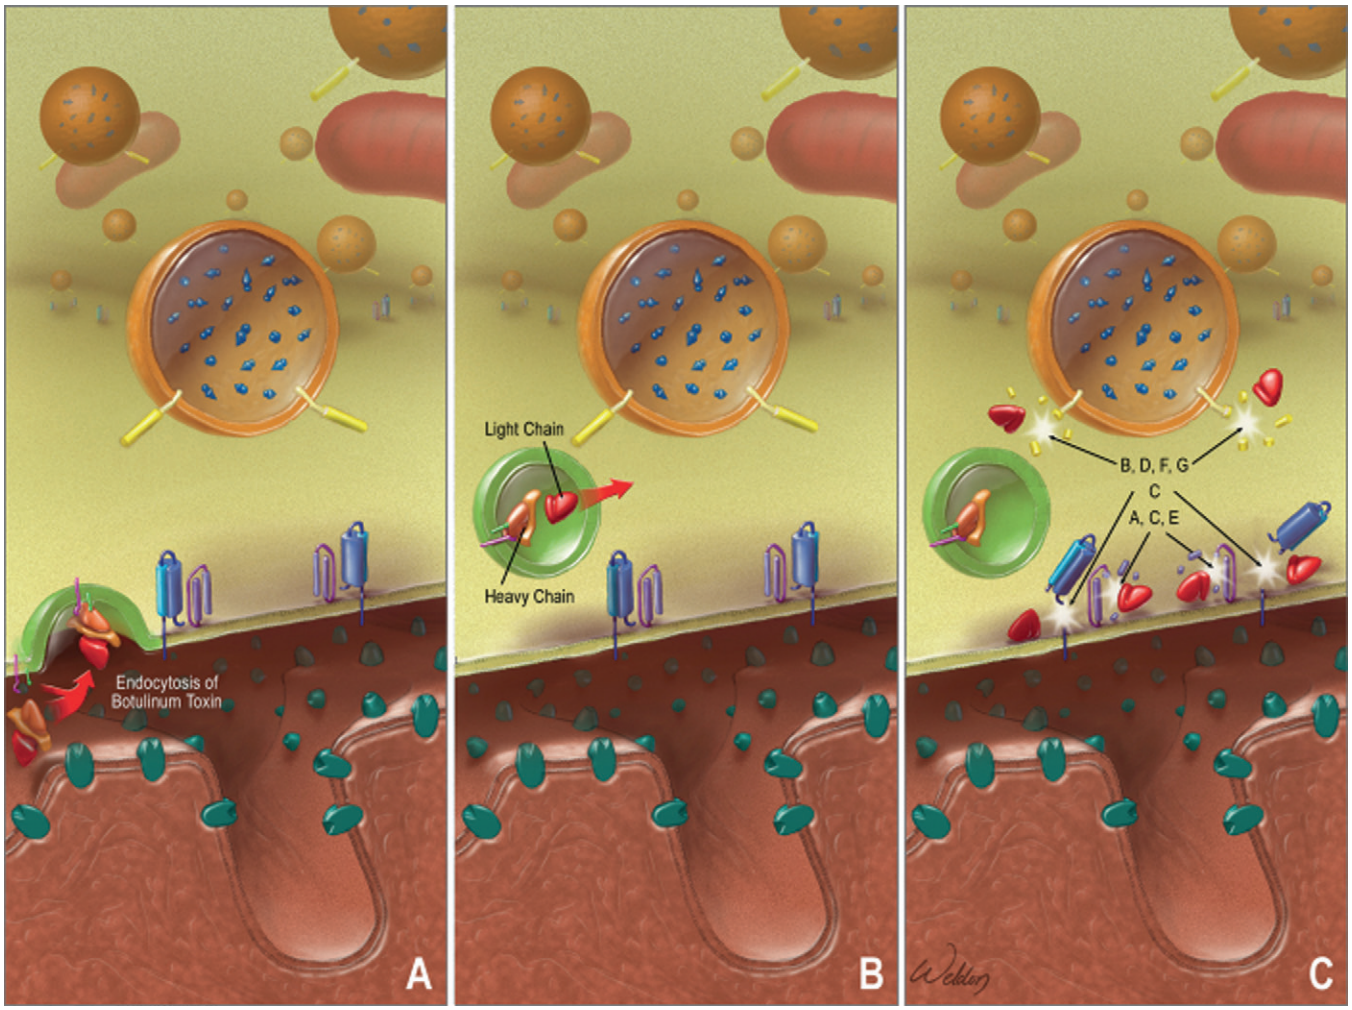

Figure 60–30. Diagram of parasympathetic nerve terminal demonstrating **(A)** binding of the toxin heavy chain to an as yet unidentified receptor and internalization of the toxin within the nerve terminal; **(B)** translocation of the light chain into the cytosol; and **(C)** inhibition of neurotransmitter release by cleavage of specific SNARE proteins. reduction in spontaneous contractile activity (Andersson, 1993; Andersson, 1997; Andersson et al, 1999). In the detrusor, various types of K^+ channels have been identified, including ATP-sensitive (K_{ATP}), calcium-dependent small conductance (SKCa), and calcium-dependent large conductance (BKCa) channels (Andersson, 1992; Trivedi et al, 1995; Andersson and Arner, 2004; Gopalakrishnan and Shieh, 2004). It is currently still under investigation what the relationship is between each of these K^+ channels and the different forms of contractile activity (myogenic contractions, neurogenic contractions, and micturition contractions). However, **it is apparent that pharmacologic manipulation of both Ca^{2+} and K^+ channels can result in reduced spontaneous contractile activity** (Levin et al, 1991; Andersson, 1992; Trivedi et al, 1995; Brading, 1997b; Fry and Wu, 1997; Martin et al, 1997; Andersson and Arner, 2004). It has been documented that **intravesical instillation of the bladder-selective K_{ATP} channel opener ZD6169 significantly reduced detrusor overactivity in bladder outlet–obstructed rats** (Pandita and Andersson, 1999). **The mechanisms of action may be both direct smooth muscle action and action on the afferent nerve endings near the urothelium** (Hu and Kim, 1997; de Groat et al, 1999). Another K_{ATP} channel opener ZD0947 caused detrusor muscle relaxation through activation of glibenclamide-sensitive K_{ATP} channels in human and guinea pig urinary bladders (Aishima et al, 2006; Yunoki et al, 2008). Moreover, mice with the gene deletion of *mSlo1* for the pore-forming subunit of the BKCa channel exhibit increased urinary bladder spontaneous and nerve-evoked contractions, as well as a marked elevation in urination frequency (Meredith et al, 2004). It has also been demonstrated that local injection of *hSlo* cDNA into the bladder lumen to increase BKCa channel activity eliminated detrusor overactivity in rats with bladder outlet obstruction (Christ et al, 2001), suggesting an important role of BKCa channels in urinary bladder function and overactive bladder. Thus **there is considerable interest in the development of specific K^+ channel openers for therapeutic use in the treatment of bladder overactivity** (Pandita and Andersson, 1999; Andersson and Arner, 2004).

Tricyclic Antidepressants

Tricyclic antidepressants, such as imipramine and amitriptyline, have been shown to be clinically effective in reducing the level of detrusor overactivity under specific conditions (Wein, 1998). Their effectiveness has been linked to antimuscarinic activity, inhibition of calcium translocation, and direct smooth muscle relaxant properties, and possibly to an action on the central nervous system (Maggi et al, 1989). Each of these actions would relax the bladder and reduce the level of spontaneous activity. Because these are

nonselective agents with multiple mechanisms of action, there is little research in the development of more bladder-selective tricyclic agents.

Spinal Ascending and Descending Pathways

It is possible to conjecture about the sites of action of drugs in the spinal cord on the basis of certain experimental designs. For example, alterations in the volume threshold for inducing micturition (in the absence of other changes of bladder activity) are interpreted as indicating an effect on the ascending limb of the micturition reflex. Alterations in the magnitude of bladder contractions (or pelvic nerve discharge) produced by PMC stimulation (Matsumoto et al, 1995b) may be taken to indicate an action on the descending limb of the micturition reflex.

Glutamatergic Mechanisms

Intrathecal or intravenous administration of glutamatergic NMDA or α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) antagonists in urethane-anesthetized rats depressed reflex bladder contractions and electromyographic activity of the external urethral sphincter in animals with an intact spinal cord, as well as in animals with chronic spinal injury (Yoshiyama et al, 1994, 1997). These results indicate that **spinal reflex pathways controlling bladder and sphincter functions use NMDA and AMPA glutamatergic transmitter mechanisms**. In spinal cord–injured rats, external sphincter muscle activity was more sensitive than bladder reflexes to glutamatergic antagonists, raising the possibility that the two reflex pathways might have different glutamatergic receptors (Yoshiyama et al, 1994). This was confirmed with in-situ hybridization techniques, which revealed that sacral parasympathetic preganglionic neurons in the rat express high mRNA levels of GluR-A and GluR-B AMPA receptor subunits and NR1, but not NR2 NMDA receptor subunits (Shibata et al, 1999). Conversely, motoneurons in the urethral sphincter nucleus express all four AMPA receptor subunits (GluR-A, GluR-B, GluR-C, and GluR-D) in conjunction with moderate amounts of NR2A and NR2B, as well as high levels of NR1 receptor subunits. It seems likely that this difference in expression accounts for the different sensitivity of bladder and sphincter reflexes to glutamatergic antagonists. In addition, intrathecal application of an mGluR agonist inhibits isovolumetric bladder contractions (Tanaka et al, 2003), although intrathecal application of an mGluR antagonist has no effects on bladder activity in rats (Yoshiyama and de Groat, 2007), suggesting that spinal mGluR are not tonically active, but can inhibit the micturition reflex when stimulated.

Glutamate also plays a role as an excitatory transmitter in the afferent limb of the micturition reflex. The c-*FOS* expression induced in spinal interneurons by activation of bladder afferents is suppressed by the administration of both NMDA and non-NMDA glutamatergic receptor antagonists (Birder and de Groat, 1992; Kakizaki et al, 1996).

Inhibitory Amino Acids

Intrathecal injection of either $GABA_A$ or $GABA_B$ agonists increases bladder capacity and decreases voiding pressure and efficiency in rats (Igawa et al, 1993). **Glycine and GABA inhibitory mechanisms have also been identified in the neonatal rat spinal cord** in local interneuronal inhibitory pathways projecting directly to the preganglionic neurons (Araki, 1994). Clinical studies have revealed that intrathecal administration of a $GABA_B$ receptor agonist (baclofen) increased the volume threshold for inducing the micturition reflex (Bushman et al, 1993). Intrathecally administered baclofen also produced a phaclofen-sensitive inhibition of distention-evoked micturition in conscious rats that appears to be resistant to capsaicin (substance P depletion) or parachlorophenylalanine (5-HT depletion) pretreatment. Because baclofen also inhibits field stimulation–evoked release of CGRP from primary afferent terminals in dorsal horn slices, one possible site for this action is suppression of transmitter release from primary afferent terminals in the spinal cord. In addition, studies by Miyazato and colleagues (2003, 2005) have revealed that the level of glycine in the spinal cord is decreased by approximately 50% in rats with detrusor overactivity induced by chronic spinal cord injury compared with spinal intact rats, and that dietary supplement with glycine can restore bladder function, along with an increase in the serum level of glycine in spinal cord–injured rats. The level of glutamic acid decarboxylase, a GABA synthesis enzyme, is also reduced in lumbosacral DRG and the spinal cord in spinal cord–injured rats, and intrathecal application of $GABA_A$ or $GABA_B$ receptor agonists suppresses detrusor overactivity and sphincter-detrusor dyssynergia (Miyazato et al, 2008). These results suggest that downregulation of the spinal glycinergic and GABAergic mechanisms may contribute to the emergence of neurogenic detrusor overactivity associated with spinal cord injury.

Adrenergic Mechanisms

In the spinal cord, α adrenoceptors can mediate excitatory and inhibitory influences on the lower urinary tract. In anesthetized cats, α_1 adrenoceptors were implicated in a bulbospinal noradrenergic excitatory pathway from the locus ceruleus to the sacral parasympathetic outflow to bladder (Yoshimura et al, 1988, 1990), although subsequent studies could not confirm these findings in conscious cats (Espey et al, 1992).

Experiments in conscious or anesthetized rats (Ishizuka et al, 1996; de Groat et al, 1999) revealed that intrathecal administration of an α_1-adrenergic antagonist (doxazosin) decreased the amplitude of bladder contractions (Ishizuka et al, 1996, 1997). The bladder inhibitory effect of the intrathecal α_1-adrenergic antagonist was more prominent in animals with chronic outlet obstruction (Ishizuka et al, 1996). Also, intrathecal administration of doxazosin suppressed detrusor overactivity (unstable bladder contractions) in spontaneously hypertensive rats (Persson et al, 1997). Although intrathecal injection of doxazosin suppressed the amplitude of reflex bladder contractions in anesthetized rats, it increased the frequency of isovolumetric contractions, indicating the presence of a tonic adrenergic inhibitory mechanism (de Groat et al, 1999). This was supported by the finding that phenylephrine, an α_1-adrenergic agonist, applied intrathecally, decreased the frequency of bladder contractions without changing contraction amplitude (de Groat et al, 1999). Thus it appears that **efferent and afferent limbs of the micturition reflex receive excitatory and inhibitory input, respectively, from spinal noradrenergic systems.**

Evidence for a modulatory role of α_2 adrenoceptors in micturition is conflicting because both facilitatory and inhibitory roles of α_2 adrenoceptors have been documented (Ishizuka et al, 1996; de Groat et al, 1999). Atipamezole, an α_2-adrenergic antagonist given intrathecally, can increase micturition pressure in the conscious rat, implying that there is a tonic inhibitory adrenergic control (Ishizuka et al, 1996). However, yohimbine, an α_2-adrenergic

antagonist, inhibits micturition in rats anesthetized with chloralose-urethane (Kontani et al, 1992). In paraplegic patients, intrathecal injection of clonidine suppressed detrusor overactivity (Denys et al, 1998). Conversely, in conscious spinal cats, clonidine, an α_2-adrenergic agonist, increased bladder pressures and facilitated voiding (Galeano et al, 1986).

Pharmacologic experiments showed that the bladder-sympathetic reflex pathway is modulated by central noradrenergic mechanisms (Danuser and Thor, 1995; de Groat et al, 1999; de Groat and Yoshimura, 2001). In the chloralose-anesthetized cat, prazosin or doxazosin, α_1- adrenoceptor antagonists, suppressed spontaneous firing (Ramage and Wyllie, 1995) or the reflex discharge recorded on the hypogastric nerve in response to pelvic nerve afferent stimulation (Danuser and Thor, 1995). Administration of α_2-adrenergic agonists also suppresses reflex sympathetic activity (Danuser and Thor, 1995). These observations suggest that bulbospinal noradrenergic pathways provide a tonic α_1-excitatory control of the bladder-sympathetic reflex in the spinal cord. α_2-Adrenergic inhibitory mechanisms are not active under control conditions in anesthetized animals but can be upregulated by elevating endogenous norepinephrine levels with an inhibitor (tomoxetine) of norepinephrine reuptake (Danuser and Thor, 1995). These results suggest that the lumbar sympathetic outflow is controlled by α_1-excitatory and α_2-inhibitory mechanisms.

The activation of urethral sphincter motoneurons by stimulation of bladder (pelvic nerve) or urethral or perineal (pudendal nerve) afferents is part of a continence-maintaining mechanism. These reflexes, recorded as efferent discharges on the pudendal nerve in chloralose-anesthetized cats, were suppressed by the α_1-adrenoceptor antagonist prazosin (Gajewski et al, 1984; Danuser and Thor, 1995; Downie, 1999), but not by the α_2 blocker idazoxan (Danuser and Thor, 1995). Conversely, clonidine, an α_2-adrenoceptor agonist, suppressed the reflex in anesthetized cats (Downie and Bialik, 1988). The norepinephrine uptake blocker tomoxetine produced a slight inhibition alone and only a slightly greater inhibition after prazosin. However, it greatly facilitated the reflex when given after idazoxan (Danuser et al, 1995). These data indicate the existence of α_2 adrenoceptor–mediated inhibition and α_1 adrenoceptor–mediated tonic facilitation of sphincter function, and that the α_2 adrenoceptor–dependent inhibitory mechanism is the dominant adrenergic modulator of the pudendal nerve reflex (Thor and Donatucci, 2004). These excitatory α_1 and inhibitory α_2 adrenoceptor–mediated modulations of external sphincter function are also involved in the urethral continence reflexes during passive intravesical pressure rises and sneezing. Nisoxetine, a norepinephrine uptake blocker, induces an increase in pressure responses at the middle urethra measured by a microtransducer-tipped catheter during sneezing, which is antagonized by prazosin, an α_1 adrenoceptor antagonist, in normal rats and rats with simulated birth trauma induced by vaginal distention (Kaiho et al, 2007). On the contrary, external urethral sphincter–electromyographic (EUS-EMG) activity that increased during lower abdominal wall compression was reduced by medetomidine, an α_2-adrenoceptor antagonist, in rats (Furuta et al, 2009).

Serotonergic Mechanisms

Neurons containing 5-HT in the raphe nucleus of the caudal brainstem send projections to the dorsal horn, as well as to the autonomic and sphincter motor nuclei in the lumbosacral spinal cord. In cats, activation of raphe neurons or 5-HT receptors in the spinal cord inhibits reflex bladder contractions and firing of the sacral efferent pathways to the bladder (McMahon and Spillane, 1982; Chen et al, 1993; de Groat et al, 1993a; de Groat, 2002) and also inhibits firing of spinal dorsal horn neurons elicited by stimulation of pelvic nerve afferents (Fukuda and Koga, 1991). In rats, administration of 5-HT_{2C} receptors agonists, such as *m*-chlorophenylpiperazine, Ro 60-0175, and WAY 161503, suppresses efferent activity on bladder nerves and/or the micturition reflex (Steers and de Groat, 1989; Mbaki and Ramage, 2008). These effects are blocked by mesulergine, a 5-HT_2 receptor antagonist (Steers and de Groat, 1989; Guarneri et al, 1996), or by SB 242084, a 5-HT_{2C} antagonist (Mbaki and Ramage, 2008). Intrathecal administration of methysergide, a 5-$HT_{1/2}$ antagonist, or zatosetron, a 5-HT_3 antagonist, decreases the micturition volume threshold in cats (Espey et al, 1998), implying that **descending serotonergic pathways tonically depress the afferent limb of the micturition reflex.**

8-OH-DPAT, a 5-HT_{1A} agonist, administered intrathecally, facilitated bladder activity in both normal and spinal cord–injured rats but not in rats in which bladder afferents were damaged by treatment with capsaicin at birth (Lecci et al, 1992). Conversely, administration of the 5-HT_{1A} receptor antagonist WAY 100635, which increases the firing rate of raphe neurons by blocking 5-HT_{1A} inhibitory autoreceptors, inhibits reflex bladder contractions (Testa et al, 1999). The inhibition is antagonized by pretreatment with mesulergine, a 5-HT_2 receptor antagonist, indicating that 5-HT_2 receptors are involved in descending raphe and spinal inhibitory mechanisms (Testa et al, 1999). When the effects of intrathecal administration of WAY 100635 on the ascending and descending limbs of the micturition reflex pathway were examined in anesthetized rats, WAY 100635 depressed bladder contractions evoked by electrical stimulation of the PMC but did not alter the evoked field potentials in the region during electrical stimulation of afferent axons in the pelvic nerve, indicating that the drug suppresses the pathway from the brainstem to the spinal cord but does not alter the afferent pathway from the bladder to the PMC (Kakizaki et al, 2001; de Groat, 2002). However, in contrast to 5-HT_{1A} receptor-mediated facilitatory effects on bladder activity in rats, 5-HT_{1A} receptor activation exerts inhibitory effects in cats, especially when C-fiber afferent function is unregulated because 8-OH-DPAT induces dose-dependent increases in threshold volume and bladder capacity in cats with acetic acid–induced cystitis (Thor et al, 2002) or spinal cord injury (Gu et al, 2004; Gu et al, 2007). Thus micturition in the rat is facilitated by stimulation of 5HT_{1A} inhibitory autoreceptors, whereas in the cat 5HT_{1A} receptor activation appears to act primarily through postsynaptic mechanisms to suppress bladder activity.

The sympathetic autonomic nuclei, as well as the sphincter motor nuclei, also receive a serotonergic input from the raphe nucleus (de Groat et al, 1979; Downie, 1999; Thor and Donatucci, 2004). Serotonergic activity mediated by 5-HT_2 and 5-HT_3 receptors enhances urine storage by facilitating sphincter reflexes in acts and rats (Danuser and Thor, 1996; Espey et al, 1998; Mbaki and Ramage, 2008). The role of 5-HT_{1A} receptors in the control of EUS activity may be different depending on animal species or experimental conditions. Activation of 5-HT_{1A} receptors with 8-OH-DPAT increased external sphincter activity during stimulation of the pelvic nerve in normal and spinalized rats, and this effect was reversed by WAY-100635 (Chang et al, 2006, 2007). In cats, both 8-OH-DPAT and 5-methoxy-*N,N*-dimethyltryptamine (5-MeODMT), 5-HT_{1A} receptor agonists, cause dose-dependent decreases in bladder activity and increases in EUS-EMG activity especially when acetic acid was infused into the bladder to induce bladder irritation (Thor et al, 2002). However, another study in

urethane-anesthetized chronic spinal cord injured rats has shown that 8-OH-DPAT induces periodic external urethral sphincter relaxation during voiding, suggesting the 5-HT_{1A}-mediated suppression of sphincter activity (Dolber et al, 2007).

Duloxetine, a combined norepinephrine and 5-HT reuptake inhibitor (Sharma et al, 2000), **has been shown, in a bladder-irritated model, to increase the neural activity of both the urethral sphincter and the bladder** (Thor and Katofiasc, 1995; Thor and Donatucci, 2004). Duloxetine appears to have effects on both the bladder and the sphincter and has been proposed for treatment of both stress incontinence and urgency incontinence (Cannon et al, 2003; Thor and Donatucci, 2004). Duloxetine increases the neural activity to the external urethral sphincter and decreases bladder activity through effects on the central nervous system in cats (Thor and Donatucci, 2004). In a rat study, duloxetine also enhances the urethral continence reflex during sneezing as evidenced by an increase in sneeze-induced pressure responses at the middle urethra, although the effect appears to be mainly mediated by α_1 adrenoceptors (Miyazato et al, 2008). Clinical trials have also shown the efficacy of duloxetine for the treatment of stress urinary incontinence; the drug has been approved in Europe and is already available in several countries (Castro-Diaz and Amoros, 2005), although it has been withdrawn from the Food and Drug Administration approval process in the United States by the manufacturer.

Opioid Peptides

Opioid peptides have an inhibitory action on reflex pathways in the spinal cord. In the cat spinal cord, inhibition of reflex bladder activity is mediated by δ receptors, whereas inhibition of sphincter activity is mediated by κ receptors (de Groat et al, 1993a; Yoshimura and de Groat, 1997; de Groat and Yoshimura, 2001; Gu et al, 2004). In the rat, both μ and δ receptors mediate bladder inhibition (Dray and Metsch, 1984b). Enkephalin gene transfer to bladder afferent pathways using herpes simplex virus vectors reduces pain behavior and bladder overactivity induced by capsaicin injection into the bladder by activation of spinal opioid receptors in rats (Yokoyama et al, 2008).

Purinergic Mechanisms

Adenosine A_1 (and perhaps A_2) receptor activation by intrathecal agonist administration has produced a caffeine-sensitive increase in volume threshold in conscious rats. Based on the known distribution of adenosine receptors in the spinal cord, excitatory interneurons are the presumed site of inhibitory action of adenosine A_1 agonist (Sosnowski et al, 1989).

Key Points: Spinal Circuitry Neurotransmitters

- Glutamate plays an important role in the spinal efferent circuitry supporting micturition.
- The spinal noradrenergic system, mediated by α_1 adrenoceptors, has a modulatory role in controlling micturition by inhibiting afferent inputs from the bladder and facilitating the descending limb of the spinal micturition reflex to increase bladder contractility.
- Transmitters such as 5-HT, purines, glycine, and GABA appear to selectively modulate the volume threshold by actions in the sacral spinal cord.
- These mechanisms seem to be favorable for development of novel drug therapies.

Pontine Micturition Center and Supraspinal Mechanisms

Glutamatergic Mechanisms

Glutamic acid also has a role in excitatory transmission at supraspinal sites in the micturition reflex pathway (See Fig. 60–31 on the Expert Consult website). Exogenous L-glutamate, or its analog, were injected at sites (locus ceruleus or parabrachial nucleus) in the brainstem of supracollicular decerebrate cats, where electrical stimulation–evoked bladder contractions elicited voiding or increased frequency and amplitude of rhythmic bladder contractions (Kruse et al, 1990; Mallory et al, 1991).

Administration of glutamatergic agonists into the region of the PMC in cats and rats elicits voiding or increases frequency and amplitude of bladder contractions (Mallory et al, 1991; de Groat et al, 1999), whereas injection of agonists at other brainstem nuclei known to have inhibitory functions in micturition elicits inhibitory effects (Chen et al, 1993). Intracerebroventricular injection of AMPA or NMDA receptor antagonists blocks reflex bladder contractions in anesthetized rats, indicating that glutamatergic transmission in the brain is essential for voiding function (Yoshiyama and De Groat, 1996; Yoshiyama and de Groat, 2005). Similarly, Yokoyama and colleagues (1999) have shown that glutamate plays an important role, especially through NMDA receptors, in the rat middle cerebral artery occlusion model of detrusor overactivity.

Cholinergic Mechanisms

Excitatory and inhibitory cholinergic influences on the micturition pathway have been identified at the supraspinal level. A decreased volume threshold and increased micturition pressure were detected after administration of bethanechol, a muscarinic agonist, into the central circulation of the cross-perfused dog (O'Donnell, 1990). One site of action can be localized to the midbrain-pons region, because cholinergic agonists are effective after supracollicular decerebration in rats (Sillen et al, 1982). In the rat brain, muscarinic receptor–mediated cholinergic mechanisms may be involved in both inhibitory and facilitatory modulation of the micturition reflex (Ishiura et al, 2001; Yokoyama et al, 2001; Ishizuka et al, 2002), and the muscarinic inhibitory mechanism seems to involve an activation of M_1 muscarinic receptors (Yokoyama et al, 2001; Masuda et al, 2009) and protein kinase C (Nakamura et al, 2003). In the brainstem, microinjection of acetylcholine to the PMC in cats increased or decreased the threshold volume for inducing a reflex contraction of the bladder (Sugaya et al, 1987; Yoshimura and de Groat, 1997). These effects were blocked by atropine, indicating a role for muscarinic receptors. Nicotinic receptors are also involved in the control of voiding function because a nicotinic receptor agonist, epibatidine, injected into the lateral ventricle suppressed the micturition reflex in the rat (Lee et al, 2003).

GABAergic Mechanisms

GABA has been implicated as an inhibitory transmitter at supraspinal sites where it can act on both $GABA_A$ and $GABA_B$ receptors (de Groat and Booth, 1993; Yoshimura and de Groat, 1997; de Groat et al, 1999; Kanie et al, 2000; de Groat and Yoshimura, 2001). Injection of GABA or muscimol, a $GABA_A$ receptor agonist, into the PMC of decerebrate cats suppressed reflex bladder activity and increased the volume threshold for inducing micturition (Mallory et al, 1991). These effects were reversed by

bicuculline, a $GABA_A$ receptor antagonist. Because bicuculline alone stimulated bladder activity and lowered the volume threshold for micturition, the micturition reflex pathway in the PMC must be tonically inhibited by a GABAergic mechanism. Intracerebroventricular baclofen, a $GABA_B$ agonist, suppressed distention-evoked micturition in urethane-anesthetized rats, but the effect was not blocked by phaclofen, a $GABA_B$ receptor antagonist (de Groat and Yoshimura, 2001; de Groat et al, 1993a).

Dopaminergic Mechanisms

In the central nervous system, dopaminergic pathways exert inhibitory and facilitatory effects, respectively, on the micturition reflex through D_1-like (D_1 or D_5 subtype) and D_2-like (D_2, D_3, or D_4 subtype) dopaminergic receptors (Albanese et al, 1988; Kontani et al, 1990; Yoshimura et al, 1992; Yoshimura et al, 1993, 1998, 2003; Yokoyama et al, 1999; Seki et al, 2001; Hashimoto et al, 2003) (see Fig. 60–31 on the Expert Consult website). In anesthetized cats, activation of dopaminergic neurons in the substantia nigra inhibits reflex bladder contractions through D_1-like receptors (Yoshimura et al, 1992). A study also revealed that a D_1 dopaminergic antagonist (SCH 23390) facilitated the micturition reflex, whereas a D_1 agonist (SKF 38393) had no effect on the reflex bladder contractions in awake rats, suggesting that D_1 receptor–mediated suppression of bladder activity is tonically active in the normal awake state (Seki et al, 2001). Disruption of this tonic dopaminergic inhibition by destroying the nigrostriatal pathway with the neurotoxin methyphenyltetrahydropyridine (MPTP) produces Parkinson-like motor symptoms in monkeys accompanied by detrusor overactivity (Albanese et al, 1988), as reported in patients with Parkinson disease (Albanese et al, 1988; Yoshimura et al, 1993; Steers et al, 1996). Similarly, a rat model of Parkinson disease induced by a unilateral 6-hydroxydopamine lesion of the nigrostriatal pathway also exhibits detrusor overactivity. In these parkinsonian animals, detrusor overactivity was suppressed by stimulation of D_1-like receptors with SKF 38393 or pergolide (Yoshimura et al, 1993, 1998, 2003).

Conversely, activation of central D_2-like dopaminergic receptors with quinpirole or bromocriptine facilitates the micturition reflex pathway in rats, cats, and monkeys (Kontani et al, 1990; Yoshimura et al, 1993, 1998, 2003; Yokoyama et al, 1999). D_2-like receptor-mediated facilitation of the micturition reflex may involve actions on brainstem because microinjection of dopamine to the PMC reduced bladder capacity and facilitated the micturition reflex in cats (de Groat et al, 1993a) D_2-like receptors are also involved in detrusor overactivity induced by middle cerebral artery occlusion in rats (Yokoyama et al, 1999). Thus **central dopaminergic pathways exhibit different effects on micturition through actions on multiple receptors at different sites in the brain.**

It is also known in cats that neurons in the substantia nigra pars compacta and the ventral tegmental area, which are the major dopamine-containing nuclei in the midbrain, respond to the storage/micturition cycles of isovolumetric cystometry (Sakakibara et al, 2002), and that the dopamine level in the striatum, where nigrostriatal dopaminergic nerves terminals are found, is shown to increase during the urine storage phase (Yamamoto et al, 2005). For the control of urethral function, activation of D_2-like receptors at a supraspinal site suppresses the activity of the striated sphincter muscle to reduce urethral pressure. Inhibition of dopamine D_1- or D_2-like receptors has a minimal effect on urethral function in anesthetized rats, suggesting the dopaminergic control of urethral function is minimally active in the normal condition (Ogawa et al, 2006).

Opioid Peptides

Intracerebroventricularly administered morphine suppressed isovolumic bladder contractions, and this effect was blocked by naloxone (Dray and Metsch 1984a). Naloxone administered intracerebroventricularly also reversed the effects of systemically administered morphine. **Naloxone administered alone intracerebroventricularly or injected directly into the PMC facilitates the micturition reflex** (Hisamitsu and de Groat, 1984). Both μ and δ opioid receptors mediate inhibitory effects that are blocked by naloxone (Hisamitsu and de Groat, 1984; Mallory et al, 1991; Downie, 1999). In a recent study, activation of μ and δ_1, but not δ_2, opioid receptors in the brain increases bladder capacity in both normal rats and rats with cerebral infarction that exhibit frequent voiding; however, κ receptor activation increases bladder capacity only in cerebral infarct rats (Nagasaka et al, 2007).

Key Points: Supraspinal Circuitry Neurotransmitters

- Glutamate appears to be involved as an excitatory transmitter in the supraspinal circuitry controlling micturition.
- Glutamate may also be a mediator of detrusor overactivity after neural injury.
- Transmitters such as 5-HT, purines, glycine, and GABA appear to selectively modulate the volume threshold by actions in the sacral spinal cord. The role of other potential excitatory transmitters remains to be examined.
- Several substances can exert significant modulatory influences on the supraspinal circuits (see Fig. 60–31 on the Expert Consult website) and can have dramatic influences on micturition.
- The receptors for these substances represent potential sites for therapeutic intervention.

MECHANISMS OF DETRUSOR OVERACTIVITY

A variety of models have been used to explore the pathogenesis of detrusor overactivity and to formulate treatments for overactive bladder and urgency incontinence. Models for detrusor overactivity in several species have been developed that are relevant to spinal cord injury, obstruction, denervation, Parkinson disease, interstitial cystitis, diabetes, multiple sclerosis, and aging (de Groat et al, 1993a; Dupont et al, 1994). In addition, the spontaneously hypertensive rat has provided a useful genetic model for detrusor overactivity (Steers et al, 1999). A common feature of many of these models is that changes in smooth muscle function can elicit long-term changes in nerves. Investigators are accustomed to examining short-term effects. However, there is now a greater appreciation that long-term events involving growth factors lead to plasticity in neural pathways with implications for disorders of micturition.

Neurotransmitters, prostaglandins, and neurotrophic factors, such as nerve growth factor (NGF), are substances that provide mechanisms for communication between muscle and nerve. Disturbances in these mechanisms can cause detrusor overactivity by alterations in autonomic reflex pathways. This detrusor overactivity can, in turn, lead to urgency incontinence. Cystometry and

urinary frequency are commonly used to define detrusor overactivity and can be used to monitor responses to drugs or other therapies. A multidisciplinary approach incorporating biochemical, molecular, pharmacologic, physiologic, and behavioral methods can provide insight into the pathogenesis of detrusor overactivity. In addition, recent advances in constructing mutant mice lacking specific genes provide a useful tool to study the contribution of specific molecules to the lower urinary tract function or the emergence of detrusor overactivity. For example, bladder function has been investigated in knockout mice lacking muscarinic receptors (M_1 to M_5) (Matsui et al, 2002; Igawa et al, 2004), purinergic receptors ($P2X_2$, $P2X_3$) (Cockayne et al, 2000, 2005), TRPV1 (Birder et al, 2002), *hSlo* for BKCa channels (Meredith et al, 2004), serotonin reuptake transporter (Cornelissen et al, 2005), or TRP channels (Birder et al, 2002; Mochizuki et al, 2009).

SUMMARY

This chapter began with the premise that the lower urinary tract has two main functions: storage and periodic elimination of urine. These functions are regulated by the unique biomechanics of bladder and urethral muscles, as well as by a complex neural control system located in the brain and spinal cord. The neural control system performs like a simple switching circuit to maintain a reciprocal relationship between the reservoir (urinary bladder) and the outlet components (urethra and urethral sphincter) of the urinary tract. The switching circuit is modulated by various neurotransmitters and is sensitive to a variety of drugs. In infants, the switching circuits function in a purely reflex manner to produce involuntary voiding; however, in adults urine storage and release are subject to voluntary control (see Fig. 60–1).

Injuries or diseases of the nervous system in adults can disrupt the voluntary control of micturition, causing the reemergence of reflex micturition, resulting in detrusor overactivity and incontinence. Because of the complexity of the central nervous control of the lower urinary tract, incontinence can result from a variety of neurologic disorders. Experimental studies indicate that detrusor overactivity occurs after a wide range of neurologic diseases, including interruption of cortical inhibitory circuits, disruption of basal ganglia function in models of Parkinson disease, damage to pathways from the brain to the spinal cord (multiple sclerosis, spinal cord injury), and sensitization of bladder afferents. Various mechanisms contribute to the emergence of bladder dysfunction, including reorganization of synaptic connections in the spinal cord, changes in the expression of neurotransmitters and receptors, alterations in neural target organ interactions mediated by neurotrophic factors, and changes in smooth muscle function. **An understanding of the physiologic events mediating micturition and continence provides a rational basis for the management of lower urinary tract dysfunction.**

FUTURE RESEARCH

During the past few years, research in neurourology and female urology has led to the development of new concepts regarding the etiology of unstable bladder dysfunction and urinary incontinence. The breakthroughs outlined in this chapter have stimulated the development of new therapeutic approaches for incontinence, including the local administration of botulinum toxin and afferent neurotoxins, such as capsaicin and RTX. What are the research priorities for the future? It will be important to focus on the development of neuropharmacologic agents that can suppress the unique components of abnormal bladder reflex mechanisms and thereby act selectively to diminish symptoms without altering normal voiding function.

Neurourologic research with a clinical application is intensifying at major medical centers and also in the pharmaceutical industry. With the aging population across all the developed nations and public education that is demystifying the stigma of bladder control problems and urinary incontinence, more patients are seeking help. The dramatically expanding commercial markets and need for improved medications for the lower urinary tract have been recognized and publicized. We need better drugs and approaches to help the 85% of people with detrusor overactivity and urinary incontinence who have not yet sought medical help.

To end this chapter, we would like to look into our crystal ball and speculate about a few areas of research that we think may pay off within the next 5 years with new and better treatments of urinary incontinence.

1. NGF has been implicated as one of the key factors inducing bladder overactivity and pain conditions. Can the tissue or urinary level of NGF be a biomarker for the diagnosis and/or evaluation of therapeutic efficacy of bladder dysfunction?
2. Can the drug companies develop a truly bladder-specific and effective anticholinergic drug with *no* dry mouth? β_3-Agonists are currently in phase 3 studies internationally.
3. Tachykinin or TRP channel antagonists are appealing, because they may be effective for unstable and painful bladder conditions without increasing residual urine volumes. Can clinically useful and safe oral antagonists be developed?
4. We need an effective drug for stress incontinence, such as one based on urethral smooth muscle– or skeletal muscle–specific agonists/antagonists or norepinephrine/5-HT reuptake inhibitors.
5. Although not as clinically obvious as the ideas just listed, we believe that drugs that can affect urothelial trafficking and permeability may be tremendously helpful. These types of drugs not only can aid the overactive and painful bladder but may have indications for bladder cancer and even urinary tract infection.
6. In addition, given that spontaneous activity in the detrusor muscle and interstitial cells in the urothelium and bladder wall has an important role in the regulation of bladder activity, targeting detrusor muscles or interstitial cells could be effective for treating detrusor overactivity, especially that of myogenic origin.

Beyond the horizon of near-term advances, we predict a brave new paradigm in neurourology. What has already started is the evolution of unstoppable forces of change in medicine that include pharmacogenomics, tissue engineering, and gene therapy. These will change how we practice urology.

Drug by Design (Pharmacogenomics). Medicine will be tailored to the genetic makeup of each individual. Through microarray gene chip technology, we will know how a patient metabolizes medications, or a patient's receptor profile and allergy risks. These factors can be used to screen against a list of medications before therapy. A urologist will then be able to always prescribe the best drug for each patient without the risk of side effects.

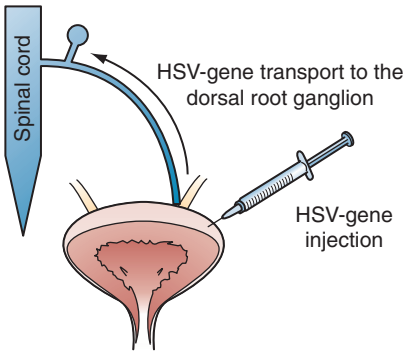

Figure 60–33. Illustration depicting the concept of gene therapy for neurogenic bladder, voiding dysfunction, and pain. Herpes simplex virus (HSV) is used as a vector for directed transfection of nerves that innervate the urinary bladder. Such an approach has interesting potential for the treatment of bladder dysfunction.

Stem Cells and Tissue Engineering. Rapid advances are being made in tissue engineering (Atala, 2004) and organ reconstruction with autologous tissue and stem cells (Chancellor et al, 2000). We envision a day, in the not too distant future, when stress incontinence is cured not with a cadaver ligament and metal screws into the bones but rather with minimally invasive injection of muscle stem cells that will not only bulk up the deficient sphincter but actually improve the deficient sphincter's contractility.

Gene Therapy. Benign prostatic hyperplasia (Marcelli et al, 2000), diabetic neurogenic bladder (Phelan et al, 2000; Goins et al, 2001; Sasaki et al, 2004), neurogenic detrusor overactivity (Miyazato et al, 2009), and even BPS/IC (Yokoyama et al, 2008) may be cured with one or more treatments with a gene vector that the urologist will inject into the bladder or prostate. The injection of a viral vector expression apoptotic factor can direct the hypertrophied prostate to shrink. Injection of NGF through a herpes simplex virus vector into the bladder of a diabetic person may promote the recovery of bladder sensation and innervation (Fig. 60–33). Finally, what about the single condition most troubling to just about every urologist, BPS/IC? Can the introduction of a viral vector that is targeted to nerves, and that carries a gene for an endogenous opioid peptide that blocks pain pathways, be used to help alleviate pain, regardless of the cause of BPS/IC?

Acknowledgments

We want to thank Dr. William C. (Chet) de Groat for reviewing this chapter. Around the world, Dr. de Groat is warmly regarded as the godfather of neurourology, but to the two of us, Dr. de Groat is much more. Chet is the father of our laboratory and our research. His intellectual brilliance is matched only by his decency of heart. Chet is always there to help us in developing research ideas and writing papers and grants. Chet is there when we run into trouble and need guidance. We dedicate our research in honor of our teacher, Dr. Chet de Groat. We would also like to thank Dr. John Lavelle at the University of North Carolina for his assistance with the section on bladder urothelium and Dr. Michael Sacks at the University of Pittsburgh for helping us with the bladder biomechanics section.

Pathophysiology and Classification of Lower Urinary Tract Dysfunction: Overview

Alan J. Wein, MD, PhD (Hon), FACS

Normal Lower Urinary Tract Function: Overview

Mechanisms Underlying the Two Phases of Function: Overview

Micturition Cycle: Simplification and Overview

Abnormalities of Filling/Storage and Emptying/Voiding: Overview of Pathophysiology

Classification Systems

The lower urinary tract functions as a group of interrelated structures whose joint function in the adult is to bring about efficient and low-pressure bladder filling, low-pressure urine storage with perfect continence, and periodic complete voluntary urine expulsion, again at low pressure. This should occur with appropriate sensation, meaning that a sense of deferrable bladder fullness should gradually occur between voluntary voids up to a volume that is sufficient to prevent urinary frequency and without any pain or sudden compelling desires to void, which are difficult to defer (urgency). Because in the adult the lower urinary tract is normally under voluntary neural control, it is clearly different from other visceral organs innervated by the autonomic nervous system whose regulation is solely by involuntary mechanisms.

For the purposes of description and teaching, the micturition cycle is best divided into two relatively discrete phases: bladder filling/urine storage and bladder emptying/voiding. The micturition cycle normally displays these two modes of operation in a simple on-off fashion. The cycle involves switching from inhibition of the voiding reflex and activation of storage reflexes to inhibition of the storage reflexes and activation of the voiding reflex—and back again. This chapter begins with a functional, physiologic, and pharmacologic overview of normal and abnormal lower urinary tract function. A simple way of looking at the pathophysiology of all types of voiding dysfunction is then presented, followed by a discussion of various systems of classification and categorization. Consistent with the author's philosophy and prior attempts to make the understanding, evaluation, and management of voiding dysfunction as logical and simple as possible (Wein and Barrett, 1988; Wein, 2002), a functional and practical approach is favored.

As an apology and explanation to significant contributors to the field whose works have not been specifically referenced by name as frequently as they could have been, citations have been chosen primarily because of their comprehensive review or informational content and not because of originality or initial publication on a particular subject, except where noted.

NORMAL LOWER URINARY TRACT FUNCTION: OVERVIEW

Two-Phase Concept of Function: Filling/Storage and Emptying/Voiding

Whatever disagreements exist regarding the anatomic, morphologic, physiologic, pharmacologic, and mechanical details involved in both the storage and the expulsion of urine by the lower urinary tract, the author has always taken the rather simple-minded view that the "experts" would agree on certain general points (Wein, 1981; Wein and Barrett, 1988; Wein, 2007; Wein and Moy, 2007). The first is that **the micturition cycle involves two relatively discrete processes: (1) bladder filling and urine storage and (2) bladder emptying or voiding.** The second is that, whatever the details involved, **one can succinctly summarize these processes from a conceptual point of view as follows:**

Bladder filling and urine storage require:

Accommodation of increasing volumes of urine at a low intravesical pressure (normal compliance) and with appropriate sensation.

A bladder outlet that is closed at rest and remains so during increases in intra-abdominal pressure.

Absence of involuntary bladder contractions (detrusor overactivity).

Bladder emptying/voiding requires:

A coordinated contraction of the bladder smooth musculature of adequate magnitude and duration.

A concomitant lowering of resistance at the level of the smooth and striated sphincter (no functional obstruction).

Absence of anatomic (as opposed to functional) obstruction.

The **smooth sphincter** refers to the smooth musculature of the bladder neck and proximal urethra. This is a physiologic but not an anatomic sphincter and one that is not under voluntary control. The **striated sphincter** refers to the striated musculature that is a part of the outer wall of the proximal urethra in both the male and the female (this portion is often referred to as the **intrinsic or intramural striated sphincter or rhabdosphincter)** and the bulky skeletal muscle group that closely surrounds the urethra at the level of the membranous portion in the male and primarily the middle segment in the female (often referred to as the **extrinsic or extramural striated sphincter**). The extramural portion is the classically described **external urethral sphincter** and is under voluntary control (for a detailed discussion see Chapter 60; DeLancey et al, 2002; Zderic et al, 2002).

MECHANISMS UNDERLYING THE TWO PHASES OF FUNCTION: OVERVIEW

This section briefly summarizes pertinent points regarding the physiology and pharmacology of the various mechanisms underlying normal bladder filling/storage and emptying/voiding abnormalities, which constitute the pathophysiologic mechanisms seen in the various types of dysfunction of the lower urinary tract. The general information is consistent with that detailed in Chapter 60 and in previous source materials and their supporting references: Wein and Barrett, 1988; deGroat et al, 1993, 1999, 2001; Zderic et al, 2002; Andersson and Arner, 2004; Andersson and Wein, 2004; Morrison et al, 2005; Mostwin et al, 2005; Yoshimura and Chancellor, 2007; Fowler et al, 2008; Birder et al, 2009; and Koelbl et al, 2009. Other specific references are provided only when particularly unique or applicable.

Bladder Response during Filling

The normal adult bladder response to filling at a physiologic rate is an almost imperceptible change in intravesical and detrusor pressure. During at least the initial stages of bladder filling, after unfolding of the bladder wall from its collapsed state, **this high compliance (Δ volume/Δ pressure) of the bladder is due primarily to its elastic and viscoelastic properties. Elasticity** allows the constituents of the bladder wall to stretch to a certain degree without any increase in tension. **Viscoelasticity** allows stretch to induce a rise in tension followed by a decay ("stress relaxation") when the filling (stretch stimulus) slows or stops. The viscoelastic properties are considered to be primarily due to the characteristics of the extracellular matrix in the bladder wall. Andersson and Arner (2004) cite references demonstrating that the main extracellular components are elastic fibers and collagen fibrils present in the serosa, between muscle bundles, and between the smooth muscle cells in the muscle bundles. Brading and colleagues (1999) add that they believe that there is continuous contractile activity in the smooth muscle cells to adjust their length during filling but without the type of synchronous activity that would increase intravesical pressure, impede filling, and could cause urinary leakage. Clinically and urodynamically, therefore, the bladder seems "relaxed." The urothelium also expands but must preserve its barrier function while doing so.

There may also be a non-neurogenic active component to the storage properties of the bladder. Hawthorn and colleagues (2000) have suggested that an as yet unidentifiable relaxing factor is released from the urothelium during filling and storage, and Andersson and Wein (2004) have suggested that urothelium-released nitric oxide may have an inhibitory effect on afferent mechanisms as well.

The viscoelastic properties of the stroma (bladder wall less smooth muscle and epithelium) and the urodynamically relaxed detrusor muscle thus account for the passive mechanical properties and normal bladder compliance seen during filling. The main components of the stroma are collagen and elastin. In the usual clinical setting, filling cystometry seems to show a slight increase in intravesical pressure, but Klevmark (1974, 1999) elegantly showed that **this pressure rise is a function of the fact that cystometric filling is carried out at a greater than physiologic rate and that, at physiologic filling rates, there is essentially no rise in bladder pressure until bladder capacity is reached.**

When the collagen component of the bladder wall increases, compliance decreases. This can occur with chronic inflammation, bladder outlet obstruction, neurologic decentralization, and various other types of injury. Bladder muscle hypertrophy, which can result from outlet obstruction, can also result in decreased compliance because it is said to be less elastic than normal detrusor; it also can synthesize increased amounts of collagen (Mostwin, 2006). **Once decreased compliance has occurred because of a replacement by collagen of other components of the stroma, it is generally unresponsive to pharmacologic manipulation, hydraulic distention, or nerve section.** Most often, under those circumstances, augmentation cystoplasty is required to achieve satisfactory reservoir function.

Does the nervous system affect the normal bladder response to filling? At a certain level of bladder filling, **spinal sympathetic reflexes** facilitatory to bladder filling/storage are clearly evoked in animals, a concept developed over the years by deGroat and others (deGroat et al, 1993; deGroat and Yoshimura, 2001; Chancellor and Yoshimura, 2002; Zderic et al, 2002; Yoshimura and Chancellor, 2007; see Chapter 60), who have also cited indirect evidence to support such a role in humans. **This inhibitory effect is thought to be mediated primarily by sympathetic modulation of cholinergic ganglionic transmission.** Through this reflex mechanism, **two other possibilities exist for promoting filling/storage.** One is neurally mediated stimulation of the predominantly α-adrenergic receptors (α_1) in the area of the smooth sphincter, the net result of which would be to cause an increase in resistance in that area. The second is neurally mediated stimulation of the predominantly β-adrenergic receptors (β_3 inhibitory) in the bladder body smooth musculature, which would cause a decrease in bladder wall tension. McGuire and colleagues (1983) have also proposed a direct inhibition of detrusor motor neurons in the sacral spinal cord during bladder filling related to increased afferent pudendal nerve activity generated by receptors in the striated sphincter. **Good evidence also seems to exist to support an inhibitory effect of other neurotransmitters (e.g., glycine, gamma amino butyric acid [GABA], opioids, purines, the noradrenergic system) on the micturition reflex at various levels of the neural axis.** Bladder filling and consequent wall distention may also result in the release of factors from the urothelium that may influence contractility (e.g., acetylcholine [Ach], adenosine triphosphate [ATP], nitric oxide, prostaglandins, other peptides, as yet unidentified inhibitory factors).

Outlet Response during Filling

There is a gradual increase in urethral pressure during bladder filling, contributed to at least by the striated sphincteric element and perhaps by the smooth sphincteric element as well. The rise in urethral pressure seen during the filling/storage phase of micturition can be correlated with an increase in efferent pudendal nerve impulse frequency and in electromyographic activity of the striated sphincter. This constitutes the efferent limb of a spinal somatic reflex, the so-called **guarding reflex,** which results in a gradual increase in striated sphincter activity during normal bladder filling and storage. Although it seems logical and certainly compatible with neuropharmacologic, neurophysiologic, and neuromorphologic data to assume that the muscular component of the smooth sphincter also contributes to the change in urethral response during bladder filling, probably through sympathetically induced contraction, it is extremely difficult to prove this either experimentally or clinically. The direct and circumstantial evidence in favor of such a hypothesis has been summarized by Wein and Barrett (1988), Brading (1999), and Andersson and Wein (2004).

The passive properties of the urethral wall certainly deserve mention because these undoubtedly play a role in the maintenance of continence (Zinner et al, 1983; Brading, 1999). Urethral wall tension develops within the outer layers of the urethra; however, urethral pressure is a product not only of the active characteristics of smooth and striated muscle but also of the passive characteristics of the elastic, collagenous, and vascular components of the urethral wall because this tension must be exerted on a soft or plastic inner layer capable of being compressed to a closed configuration—the **"filler material"** representing the submucosal portion of the urethra. The softer and more pliable this area is, the less pressure required by the tension-producing area to produce continence. Finally, whatever the compressive forces, the lumen of the urethra must be capable of being obliterated by a watertight seal. This **"mucosal seal mechanism"** explains why a thin-walled rubber tube requires less pressure to close an open end when the inner layer is coated with a fine layer of grease than when it is not, the latter case being much like scarred or atrophic urethral mucosa.

Voiding with a Normal Bladder Contraction

Although many factors are involved in the initiation of micturition, in adults it is **intravesical pressure producing the sensation of distention that is primarily responsible for the initiation of normal voluntarily induced emptying of the lower urinary tract. Although the origin of the parasympathetic neural outflow to the bladder, the pelvic nerve, is in the sacral spinal cord, the actual coordinating center for the micturition reflex in an intact neural axis is in the rostral brainstem.** The complete neural circuit for normal micturition includes the ascending and descending spinal cord pathways to and from this area and the facilitatory and inhibitory influences from other parts of the brain, particularly the cerebral cortex. **The final step in voluntarily induced micturition involves inhibition of the somatic neural efferent activity to the striated sphincter and an inhibition of all aspects of any spinal sympathetic reflexes evoked during filling. Efferent parasympathetic pelvic nerve activity is ultimately what is responsible for a highly coordinated contraction of the bulk of the bladder smooth musculature.**

A decrease in outlet resistance occurs with adaptive shaping or funneling of the relaxed bladder outlet. Besides the inhibition of any continence-promoting reflexes that have occurred during bladder filling, the change in outlet resistance may also involve an active relaxation of the smooth sphincter area through a noradrenergic noncholinergic (NANC) mechanism, proposed to be mediated by nitric oxide (Andersson and Arner, 2004; Andersson and Wein, 2004). **The adaptive changes that occur in the outlet are probably also due at least in part to the anatomic interrelationships of the smooth muscle of the bladder base and proximal urethra.** Longitudinal smooth muscle continuity (Mostwin, 2006; see Chapter 60) would promote shortening and widening of the proximal urethra during a coordinated emptying bladder contraction. Other reflexes that are elicited by bladder contraction and by the passage of urine through the urethra may reinforce and facilitate complete bladder emptying. Superimposed on these autonomic and somatic reflexes are complex, modifying supraspinal inputs from other central neuronal networks. These facilitatory and inhibitory impulses, which originate from several areas of the nervous system, allow the full conscious control of micturition in the adult.

Urinary Continence during Abdominal Pressure Increases

During voluntarily initiated micturition, the bladder pressure becomes higher than the outlet pressure and certain adaptive changes occur in the shape of the bladder outlet with consequent passage of urine into and through the proximal urethra. One could reasonably ask, **why do such changes not occur with increases in intravesical pressure that are similar in magnitude but that are produced only by changes in intra-abdominal pressure such as straining or coughing?** First, a coordinated bladder contraction does not occur in response to such stimuli, clearly emphasizing the fact that increases in total intravesical pressure are by no means equivalent to emptying ability. Secondly, for urine to flow into and through the proximal urethra in an individual who does not have sphincteric incontinence, there must be (1) an increase in intravesical pressure that is primarily a product of a coordinated, neurally mediated bladder contraction and that is (2) associated with characteristic tension and conformational changes in the bladder neck and proximal urethral areas.

Assuming that the bladder outlet is competent at rest, a major factor required for the prevention of urinary leakage during increases in intra-abdominal pressure is that there is **at least equal pressure transmission to the proximal urethra (the midurethra, as well as in the female) during such activity.** This phenomenon was first described by Enhorning (1961) and has been confirmed in virtually every urodynamic laboratory since that time. **Failure of this mechanism is an invariable correlate of effort-related urinary incontinence in the female and male. The urethral closure pressure increases with increments in intra-abdominal pressure, indicating that active muscular function related to a reflex increase in striated sphincter activity or other factors that increase urethral resistance is also involved in preventing such leakage.** Tanagho (1978) was the first to provide direct evidence of this. A more complete description of the factors

involved in sphincteric incontinence can be found later in this chapter and in Chapters 60 and 63.

Sensory Aspects

Most of the afferent input from the bladder and urethra reaches the spinal cord through the pelvic nerve and dorsal root ganglia and some through the hypogastric nerve.

Afferent input from the striated muscle of the sphincter and pelvic floor travels in the pudendal nerve. The most important afferents for initiating and maintaining normal micturition are those in the pelvic nerve, relaying to the sacral spinal cord. These convey impulses from tension, volume, and nociceptive receptors located in the serosal, muscle, and urothelial and suburothelial layers of the bladder and urethra. In a neurologically normal adult the sensation of filling and distention, but not urgency or pain, is what develops during normal filling/storage and initiates the reflexes responsible for emptying/voiding (deGroat and Yoshimura, 2001; Chancellor and Yoshimura, 2002; Morrison et al, 2005; Birder et al, 2009; see Chapter 60). Alterations in this finely tuned pathway can be responsible for significant alterations in lower urinary tract function.

MICTURITION CYCLE: SIMPLIFICATION AND OVERVIEW

Filling/Storage

Bladder accommodation during filling is a primarily passive phenomenon dependent on the elastic and viscoelastic properties of the bladder wall and the lack of parasympathetic excitatory input. An increase in outlet resistance occurs by means of the striated sphincter somatic guarding reflex. In at least some species, a sympathetic reflex also contributes to storage by (1) increasing outlet resistance by increasing tension in the smooth sphincter, (2) inhibiting bladder contractility through an inhibitory effect on parasympathetic ganglia, and (3) causing a decrease in tension of bladder body smooth muscle. Continence is maintained during increases in intra-abdominal pressure by the intrinsic competence of the bladder outlet (bladder neck and proximal/middle urethra) and the pressure transmission ratio to this area with respect to the intravesical contents. A further increase in striated sphincter activity, on a reflex basis, is also contributory.

Emptying/Voiding

Emptying (voiding) can be voluntary or involuntary and involves an inhibition of the spinal somatic and sympathetic reflexes and activation of the vesical parasympathetic pathways, the organizational center for which is in the rostral brainstem. Initially, there is a decrease in outlet resistance, mediated not only by the cessation of the somatic and sympathetic spinal reflexes but possibly also by a relaxing factor released by parasympathetic stimulation or by some effect of bladder smooth muscle contraction itself. A highly coordinated parasympathetically induced contraction of the bulk of the bladder smooth musculature occurs, with shaping or funneling of the relaxed outlet, owing at least in part to smooth muscle continuity between the bladder base and the proximal urethra. With amplification and facilitation of the bladder contraction from other peripheral reflexes and from spinal cord supraspinal sources, and in the absence of anatomic obstruction between the bladder and urethral meatus, complete emptying occurs.

ABNORMALITIES OF FILLING/STORAGE AND EMPTYING/VOIDING: OVERVIEW OF PATHOPHYSIOLOGY

Excluding psychologic reasons, the pathophysiology of failure of the lower urinary tract in the adult to fill with or store urine adequately or to empty adequately must logically be secondary to reasons related to the bladder, the outlet, or a combination (Wein, 1981; Wein and Barrett, 1988).

Filling/Storage Failure

Absolute or relative failure of the bladder to fill with and store urine adequately results from bladder overactivity (involuntary contraction or decreased compliance), decreased outlet resistance, heightened or altered sensation, or a combination.

Bladder Overactivity

Overactivity of the bladder during filling/storage can be expressed as phasic involuntary contractions, as low compliance, or as a combination. Involuntary contractions are most commonly seen in association with **neurologic disease or injury, bladder outlet obstruction, stress urinary incontinence** (perhaps because of sudden entry of urine into the proximal urethra, eliciting a reflex contraction), **aging** (probably related to neural degeneration), or may be truly **idiopathic.** However, they may also be associated with **increased afferent input** related to inflammation or irritation of the bladder or urethral wall. Excitatory neurotransmitters may be released from the urothelium during filling/storage and activate afferent receptors/nerves, ultimately resulting, in some individuals, in involuntary contractions or altered (heightened) sensation, either a premature sensation of distention or fullness, true urgency (a sudden compelling desire to void, which is difficult to defer), or pain. If an individual has urgency urinary incontinence, it can be assumed that an involuntary contraction (DO) has occurred. The symptom of urgency without incontinence suggests DO, but this is often not demonstrable on urodynamic study. Conversely, urodynamically demonstrable DO may not be associated with clinically troublesome filling/storage symptomatology.

The possible pathophysiologies of the symptom syndrome "overactive bladder" (defined by the ICS as urgency with or without urge incontinence, usually with frequency and nocturia) can be summarized as (1) reduced suprapontine inhibition, (2) damaged axonal paths in the spinal cord, (3) damaged axonal paths in the periphery, (4) loss of peripheral inhibition, (5) enhancement of excitatory neurotransmission in the micturition reflex pathway, (6) increased lower urinary tract afferent

input, and (7) idiopathic. Staskin (2001) and Mostwin and colleagues (2005) also hypothesized that decreased stimulation from the pelvic floor can contribute to phasic bladder overactivity. **Decreased compliance** during filling/storage may be secondary to neurologic injury or disease, usually at a sacral or infrasacral level, but may result from any process that impairs or destroys the viscoelastic or elastic properties of the bladder wall.

Filling/Storage Failure due to Altered Sensation

Bladder-related storage failure may also occur in the absence of overactivity because of increased afferent input from inflammation, irritation, other causes of hypersensitivity, and pain. The causes may be chemical, psychologic, or idiopathic. One classic example is *painful bladder syndrome,* a term that is replacing *interstitial cystitis* (see Chapter 12). Increased afferent activity can then be responsible for true detrusor overactivity (an involuntary contraction), true urgency without DO, a premature feeling of fullness or distention without urgency or DO, or the sensation of pain during filling.

Outlet Underactivity

Decreased outlet resistance may result from any process that damages the innervation of structural elements of the smooth or striated sphincter, or both, or damages or impairs the support of the bladder outlet in the female. This may occur with **neurologic disease or injury, surgical or other mechanical trauma, or aging. Classically, sphincteric incontinence in the female was categorized into relatively discrete entities:** (1) so-called **genuine stress incontinence** and (2) **intrinsic sphincter deficiency,** originally described as type III stress incontinence (DeLancey et al, 1994; Mostwin et al, 2005; Koelbl et al, 2009; see Chapters 60, 63, 71, and 73). **Genuine stress incontinence in the female** was described as associated with hypermobility of the bladder outlet because of poor pelvic support and with an outlet that was competent at rest but lost its competence only during increases in intra-abdominal pressure. **Intrinsic sphincter deficiency** (ISD) described a nonfunctional or poorly functional bladder neck and proximal urethra at rest. **The implication of classic ISD was that a surgical procedure designed to correct only urethral hypermobility would have a relatively high failure rate, as opposed to one designed to improve urethral coaptation and compression. The contemporary view is that the majority of cases of effort-related incontinence in the female involve varying proportions of support-related factors and ISD.** It is possible to have outlet-related incontinence that is due only to ISD but not due solely to hypermobility or poor support—some ISD must exist.

Stress or effort-related urinary incontinence is a symptom that arises primarily from **damage to muscles, nerves, or connective tissue, or a combination, within the pelvic floor** (DeLancey et al, 2002; Mostwin et al, 2005; Koelbl et al, 2009). Urethral support is important in the female, the urethra normally being supported by the action of the levator ani muscles through their connection to the endopelvic fascia of the anterior vaginal wall. Damage to the connection between this fascia and this muscle, damage to the nerve supply, or direct muscle damage can therefore influence continence. Bladder neck function is likewise important, and loss of normal bladder neck closure can result in incontinence despite normal urethral support. In older writings, the urethra was sometimes ignored as a factor contributing to continence in the female, and the site of continence was thought to be exclusively the bladder neck. However, in approximately 50% of continent women, urine enters the urethra during increases in abdominal pressure. The continence point in these women (highest point of pressure transmission) is at the midurethra.

Urethral hypermobility implies weakness of the pelvic floor support structures. During increases in intra-abdominal pressure, there is descent of the bladder neck and proximal urethra. If the outlet opens concomitantly, stress urinary incontinence ensues. In the classic form of urethral hypermobility, there is rotational descent of the bladder neck and urethra. However, the urethra may also descend without rotation (it shortens and widens), or the posterior wall of the urethra may be pulled (sheared) open while the anterior wall remains fixed. However, urethral hypermobility is often present in women who are not incontinent, and thus the mere presence of urethral hypermobility is not sufficient to make a diagnosis of a sphincter abnormality unless urinary incontinence is also demonstrated. The **"hammock hypothesis"** of John DeLancey (1994) proposes that for stress incontinence to occur within hypermobility, there must be a lack of stability of the suburethral supportive layer. This theory proposes that the effect of abdominal pressure increases on the normal bladder outlet, if the suburethral supportive layer is firm, is to compress the urethra rapidly and effectively. If the supportive suburethral layer is lax or movable, or both, compression is not as effective. **Intrinsic sphincter dysfunction** denotes an intrinsic malfunction of the urethral sphincter mechanism itself. In its most overt form, it is characterized by a bladder neck that is open at rest and a low abdominal leak point pressure and urethral closure pressure (see Chapter 62) and is usually the result of prior surgery, trauma with scarring, or a neurologic lesion.

Urethral instability refers to the rare phenomenon of episodic decreases in outlet pressure unrelated to increases in bladder or abdominal pressure. The term urethral instability is probably a misnomer because many believe that the drop in urethral pressure represents simply the urethral component of what would otherwise be a bladder contraction/urethral relaxation in an individual whose bladder does not measurably contract, for either myogenic or neurogenic reasons. Little has appeared in the literature about this entity since the last edition of this text.

In theory at least, categories of outlet-related incontinence in the male are similar to those in the female. Sphincteric incontinence in the male is not, however, associated with hypermobility of the bladder neck and proximal urethra but is similar to what is termed *intrinsic sphincter dysfunction* in the female. There is essentially no information regarding the topic of urethral instability in the male.

The treatment of filling/storage abnormalities is directed toward inhibiting bladder contractility, decreasing sensory output, or mechanically increasing bladder capacity; and/or toward increasing outlet resistance, the latter either continuously or just during increases in intra-abdominal pressure.

Emptying/Voiding Failure

Absolute or relative failure to empty the bladder results from decreased bladder contractility (a decrease in magnitude or duration), increased outlet resistance, or a combination.

Bladder Underactivity

Absolute or relative failure of bladder contractility may result from temporary or permanent failure or impairment in one of the neuromuscular mechanisms necessary for initiating and maintaining a normal detrusor contraction. Inhibition of the voiding reflex in a neurologically normal individual may also occur; it may be by a reflex mechanism secondary to increased afferent input, especially from the pelvic and perineal areas, or may be psychogenic. **Non-neurogenic causes** also include impairment of bladder smooth muscle function, which may result from overdistention, various centrally or peripherally acting drugs, severe infection, or fibrosis.

Outlet Overactivity or Obstruction

Pathologically increased outlet resistance is much more common in men than in women. Although it is most often secondary to anatomic obstruction, it may be secondary to a failure of relaxation or active contraction of the striated or smooth sphincter during bladder contraction (see Chapter 65). **Striated sphincter dyssynergia** is a common cause of functional or nonanatomic (as opposed to fixed anatomic) obstruction in patients with neurologic disease or injury. Except for the true smooth sphincter contraction, which occurs in conjunction with autonomic hyperreflexia (see Chapter 65), true dyssynergia at the level of the bladder neck–proximal urethra is unusual at best. Incomplete opening of an anatomically normal bladder neck during voluntary or involuntary voiding is termed *bladder neck dysfunction,* an uncommon entity found almost exclusively in young and middle-aged men, and also sometimes known as *primary bladder neck obstruction, smooth sphincter dyssynergia,* and *dysfunctional bladder neck* (see Chapter 65). The common causes of anatomic outlet obstruction include prostatic enlargement, bladder neck contracture, and urethral stricture. A common cause of outlet obstruction in the female is compression or fibrosis following surgery for sphincteric incontinence.

The treatment of emptying failure generally consists of maneuvers to increase intravesical/detrusor pressure, facilitate the micturition reflex, decrease outlet resistance, or a combination. If other means fail or are impractical, intermittent (or continuous) catheterization is an effective way to circumvent emptying failure.

CLASSIFICATION SYSTEMS

On the basis of the data obtained from the neurourologic evaluation, a given voiding dysfunction can be categorized in an ever-increasing number of descriptive systems. The purpose of any classification system should be to facilitate understanding and management and to avoid confusion among those who are concerned with the problem for which the system was designed. A good classification should serve as **intellectual shorthand** and should convey, in a few key words or phrases, the essence of a clinical situation. An ideal system for all types of voiding dysfunction would include or imply a number of factors: (1) the conclusions reached from urodynamic testing, (2) expected clinical symptoms, and (3) approximate site and type of a neurologic lesion or lack of one. If the various categories accurately portray pathophysiology, treatment options should then be obvious, and a treatment "menu" should be evident. **Most systems of classification for voiding dysfunction were formulated primarily to describe dysfunction secondary to neurologic disease or injury. The ideal system should be applicable to all types of voiding dysfunction.** On the basis of the data obtained from the neurourologic evaluation, a given voiding dysfunction can be categorized in a number of descriptive systems. **No one system is perfect.** Most major systems or types of systems in use are reviewed, along with their advantages and applicability. Understanding the rationale and shortcomings of each system significantly improves one's knowledge of voiding function and dysfunction.

Functional System

Classification of voiding dysfunction can be formulated on a simple functional basis, describing the dysfunction in terms of whether the deficit produced is primarily one of the filling/storage or the emptying/voiding phase of micturition (Table 61–1) (Wein, 1981; Wein and Barrett, 1988). The genesis of such a system was proposed initially by F. Brantley Scott's group (Quesada et al, 1968). This simple-minded scheme assumes only that, whatever their differences, all "experts" would agree on the two-phase concept of micturition (filling/storage and emptying/voiding), on the simple overall mechanisms underlying the normality of each phase (see previous discussion), and on the possibilities for dysfunction.

Storage failure results from either **bladder or outlet abnormalities or a combination.** The proven **bladder abnormalities** simply include only involuntary bladder contractions, low compliance, and heightened or altered sensation. The **outlet abnormalities** can include only an intermittent or continuous decrease in outlet resistance.

Emptying failure, likewise, can occur because of **bladder or outlet abnormalities or a combination.** The bladder side includes only inadequate or unsustained bladder contractility, and the outlet side includes only anatomic obstruction and sphincter dyssynergia or dysfunction.

There are indeed some types of voiding dysfunction that represent combinations of filling/storage and emptying voiding abnormalities. Within this scheme, however, these become readily understandable and their detection and treatment can be logically described. Various aspects of physiology and pathophysiology are always related more to one phase of micturition than another. **All aspects of urodynamic and videourodynamic evaluation can be conceptualized in this functional manner as to exactly what they evaluate in terms of either bladder or outlet activity during filling/storage and emptying/voiding** (Table 61–2)**. In addition, one can easily classify all known treatments for voiding dysfunction under the broad categories of whether they facilitate filling/storage and emptying/**

Table 61–1.

Functional Classification

Failure to Store
Because of the bladder
Because of the outlet
Failure to Empty
Because of the bladder
Because of the outlet

Table 61–2.

Urodynamics Simplified

	BLADDER	OUTLET
Filling/storage phase	Pves[1] Pdet[2] (FCMG[3]) DLPP[4]	UPP[5] VLPP[6] FLUORO[7]
Emptying phase	Pves[8] Pdet[9] (VCMG)[10]	MUPP[11] FLUORO[12] EMG[13]
	(_____ _____) _____FLOW[14]_____ _____RU[15]_____	

This functional conceptualization of urodynamics categorizes each study as to whether it examines bladder or outlet activity during the filling/storage or emptying phase of micturition. In this scheme, uroflow and residual urine integrate the activity of the bladder and the outlet during the emptying phase.
[1,2]Total bladder (Pves) and detrusor (Pdet) pressures during a filling cystometrogram (FCMG).
[3]Filling cystometrogram.
[4]Detrusor leak point pressure.
[5]Urethral pressure profilometry.
[6]Valsalva leak point pressure.
[7]Fluoroscopy of outlet during filling/storage.
[8,9]Total bladder and detrusor pressures during a voiding cystometrogram (VCMG).
[10]Voiding cystometrogram.

[13]Electromyography of periurethral striated musculature.
[14]Flowmetry.
[15]Residual urine.

voiding and whether they do so by an action primarily on the bladder or on one or more of the components of the bladder outlet (Tables 61–3 and 61–4).

Failure in either category generally is not absolute but more often is relative. Such a functional system can easily be "expanded" and made more complicated to include etiologic or specific urodynamic connotations (Table 61–5). However, the simplified system is perfectly workable and avoids argument in the complex situations in which the exact etiology or urodynamic mechanism for a voiding dysfunction cannot be agreed on.

Proper use of the functional system for a given voiding dysfunction obviously requires a reasonably accurate notion of what the urodynamic data show. However, **an exact diagnosis is not required for treatment.** It should be recognized that **some patients do not have only a discrete storage or emptying failure, and the existence of combination deficits must be recognized to use this system classification properly.** For an example, the "classic" T10 paraplegic patient after spinal shock generally exhibits a relative failure to store because of involuntary bladder contraction and a relative failure to empty the bladder because of striated sphincter dyssynergia. With such a combination deficit, to use this classification system as a guide to treatment, one must assume that one of the deficits is primary and that significant improvement will result from its treatment alone or that the voiding dysfunction can be converted primarily to a disorder of either storage or emptying by means of nonsurgical or surgical therapy. The resultant deficit can then be treated or circumvented. Using this example, the combined deficit in a T10 paraplegic patient can be converted primarily to a storage failure by procedures directed at the dyssynergic striated sphincter; the resultant incontinence (secondary to involuntary contraction) can be circumvented (in a male) with an external collecting device. Alternatively, the deficit can be converted primarily to an emptying failure by pharmacologic or surgical measures designed to abolish or reduce the involuntary contraction, and the resultant emptying failure can then be circumvented with clean intermittent catheterization. Other examples of combination deficits include impaired bladder contractility or overactivity with sphincter dysfunction, bladder outlet obstruction with detrusor overactivity, bladder outlet obstruction with sphincter malfunction, and detrusor overactivity with impaired contractility.

One of the advantages of this functional classification is that it allows the clinician the liberty of "playing" with the system to suit his or her own preferences without an alteration in the basic concept of "keep it simple but accurate and informative." For instance, one could easily substitute the terms overactive or oversensitive bladder and underactive outlet for because of the bladder and because of the outlet under "Failure to Store" in Table 61–1. One could choose to categorize the bladder reasons for overactivity (see Table 61–5) further in terms of neurogenic, myogenic, or anatomic causes and further subcategorize neurogenic in terms of decreased inhibitory control, increased afferent activity, increased sensitivity to efferent activity, and so on. The system is flexible.

The classification system proposed by the International Continence Society (ICS) (Table 61–6) is **in essence an extension of a urodynamic classification system.** The storage and voiding phases of micturition are described separately, and, within each, various designations are applied to describe bladder and urethral function (Abrams et al, 1988, 1992). Some of the definitions were changed by the standardization subcommittee of the International Continence Society in 2002, and the relevant changes are indicated here (Abrams et al, 2002, 2003). **Normal bladder function during filling/storage implies no significant rises in detrusor pressure (stability). Overactive detrusor function indicates the presence of "involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked."** If the condition is caused by neurologic disease, the term ***neurogenic detrusor overactivity*** (previously, *detrusor hyperreflexia*) is applied. If not, the term ***idiopathic detrusor overactivity*** (previously, *detrusor instability*) is applied. **Bladder sensation** can be categorized only in qualitative terms as indicated. **Bladder capacity and compliance** (Δ volume/Δ pressure) are cystometric measurements. Bladder capacity can refer to cystometric capacity, maximum cystometric capacity, or maximum anesthetic cystometric capacity (Abrams et al, 2002). **Normal urethral function during filling/storage indicates a positive urethral closure pressure (urethral pressure minus bladder pressure) even with increases in intra-abdominal pressure, although it may be overcome by detrusor overactivity. Incompetent urethral function during filling/storage** implies urine leakage in the absence of a detrusor contraction. This may be secondary to genuine stress incontinence, intrinsic sphincter dysfunction, a combination, or an involuntary fall in urethral pressure in the absence of detrusor contraction.

During the voiding/emptying phase of micturition, normal detrusor activity implies voiding by a voluntarily initiated sustained contraction that leads to complete bladder emptying within a normal time span. An **underactive detrusor** defines a contraction of inadequate magnitude or duration, or both, to empty the bladder within a normal time span. An **acontractile detrusor** is one that cannot be demonstrated to contract during urodynamic testing. **Areflexia** is defined as acontractility due to an abnormality of neural control, implying

Table 61–3.

Therapy to Facilitate Urine Storage/Bladder Filling

Bladder Related (Inhibiting Bladder Contractility, Decreasing Sensory Input, and/or Increasing Bladder Capacity)

Behavioral therapy including any or all of the following:
- Education
- Bladder training
- Timed bladder emptying or prompted voiding
- Fluid restriction
- Pelvic floor physiotherapy ± biofeedback

Pharmacologic therapy (oral, intravesical, intradetrusor)
- Anticholinergic agents
- Drugs with mixed actions
- Calcium antagonists
- Potassium channel openers
- Prostaglandin inhibitors
- β-Adrenergic agonists
- α-Adrenergic antagonists
- Tricyclic antidepressants; serotonin and norepinephrine reuptake inhibitors
- Dimethyl sulfoxide (DMSO)
- Polysynaptic inhibitors
- Capsaicin, resiniferatoxin, and like agents
- Botulinum toxin

Bladder overdistention

Electrical stimulation and neuromodulation

Acupuncture and electroacupuncture

Interruption of innervation
- Very central (subarachnoid block)
- Less central (sacral rhizotomy, selective sacral rhizotomy)
- Peripheral motor and/or sensory

Augmentation cystoplasty (auto, bowel, tissue engineering)

Outlet Related (Increasing Outlet Resistance)

Behavioral therapy
- Education
- Bladder training
- Timed bladder emptying or prompted voiding
- Fluid restriction
- Pelvic floor physiotherapy ± biofeedback

Electrical stimulation

Pharmacologic therapy
- α-Adrenergic agonists
- Tricyclic antidepressants; serotonin and norepinephrine reuptake inhibitors
- β-Adrenergic antagonists, agonists

Vaginal and perineal occlusive and/or supportive devices; urethral plugs

Nonsurgical periurethral bulking
- Collagen, synthetics, cell transfer (tissue engineering)

Vesicourethral suspension ± prolapse repair (female)

Sling procedures ± prolapse repair (female)

Closure or compression of the bladder outlet (balloons, surgical closure)

"Sling/Tape" procedure (male)

Artificial urinary sphincter

Bladder outlet reconstruction

Myoplasty (muscle transposition)

Circumventing the Problem

Absorbent products

External collecting devices

Antidiuretic hormone-like agents

Short acting diuretics

Intermittent catheterization

Continuous catheterization

Urinary diversion

the complete absence of centrally coordinated contraction. **Normal urethral function** during voiding indicates a urethra that opens and is continuously relaxed to allow bladder emptying at a normal pressure. **Abnormal urethral function during voiding** may be due to either mechanical obstruction or urethral overactivity. **Dysfunctional voiding** describes an intermittent or fluctuating flow rate due to involuntary intermittent contractions of the periurethral striated muscle in neurologically normal individuals. **Detrusor sphincter dyssynergia** defines a detrusor contraction concurrent with an involuntary contraction of the urethral or periurethral striated muscle, or both. **Nonrelaxing urethral sphincter obstruction** usually occurs in individuals with a neurologic lesion and is characterized by a nonrelaxing obstructing urethra resulting in reduced urine flow.

Lower urinary tract dysfunction in a classic T10-level paraplegic patient after spinal shock has passed would be classified in the ICS system as follows:

- Storage phase—overactive neurogenic detrusor function, absent sensation, low capacity, normal compliance, normal urethral closure function.
- Voiding phase—overactive obstructive urethral function, overactive detrusor function.

The micturition dysfunction of a stroke patient with urgency incontinence would most likely be classified during storage as overactive neurogenic detrusor function, normal sensation, low capacity, normal compliance, and normal urethral closure function. During voiding, the dysfunction would be classified as normal detrusor activity and normal urethral function, assuming that no anatomic obstruction existed.

Urodynamic Classification

As urodynamic techniques have become more accepted and sophisticated, systems of classification have evolved solely on the basis of objective urodynamic data (Table 61–7). Among the first to popularize this concept were Krane and Siroky (1984). When exact urodynamic classification is possible, such a system can provide a truly exact description of the voiding dysfunction that occurs. If a normal or hyperreflexic (overactive) detrusor exists with coordinated smooth and striated sphincter function and without anatomic obstruction, normal bladder emptying should occur. **Detrusor hyperreflexia** (now termed ***neurogenic detrusor overactivity*** in ICS parlance) is most commonly associated with neurologic lesions above the sacral spinal cord.

Table 61–4.

Therapy to Facilitate Bladder Emptying/Voiding

Bladder Related (Increasing Intravesical Pressure or Facilitating Bladder Contractility)

- External compression, Valsalva
- Promotion or initiating of reflex contraction
  - Trigger zones or maneuvers
  - Bladder "training"; tidal drainage
- Pharmacologic therapy (oral, intravesical)
  - Parasympathomimetic agents
  - Prostaglandins
  - Blockers of inhibition
    - α-Adrenergic antagonists
    - Opioid antagonists
- Electrical stimulation
  - Directly to the bladder or spinal cord
  - Directly to the nerve roots
  - Intravesical (transurethral)
  - Neuromodulation
- Reduction cystoplasty
- Bladder myoplasty (muscle wrap)
- Tissue engineering

Outlet Related (Decreasing Outlet Resistance)

- At a site of anatomic obstruction
  - Pharmacologic therapy—decrease prostate size or tone
    - α-Adrenergic antagonists
    - 5 α-reductase inhibitors
    - Luteinizing hormone releasing hormone-agonists/antagonists
    - Antiandrogens
  - Prostatectomy, prostatotomy (diathermy, heat, laser)
  - Bladder neck incision or resection
  - Urethral stricture repair or dilation
  - Intraurethral stent
  - Balloon dilatation of stricture/contracture
- At level of smooth sphincter
  - Pharmacologic therapy
    - α-Adrenergic antagonists
    - β-Adrenergic agonists
    - Botulinum toxin (injection)
  - Transurethral resection or incision
  - Y-V plasty
- At level of striated sphincter
  - Behavioral therapy ± biofeedback
  - Pharmacologic therapy
    - Benzodiazepines
    - Baclofen
    - Dantrolene
    - α-Adrenergic antagonists
    - Botulinum toxin (injection)
  - Urethral overdilation
  - Surgical sphincterotomy
  - Urethral stent
  - Pudendal nerve interruption

Circumventing the Problem

- Intermittent catheterization
- Continuous catheterization
- Urinary diversion (conduit)

Striated sphincter dyssynergia is most commonly seen after complete suprasacral spinal cord injury, following the period of spinal shock. **Smooth sphincter dyssynergia** is seen most classically in autonomic hyperreflexia (see Chapter 65) when it is characteristically associated with detrusor overactivity and striated sphincter dyssynergia. **Detrusor areflexia** (actually this category includes acontractile and areflexic bladder) may be secondary to bladder muscle decompensation or to various other conditions that produce inhibition at the level of the brainstem micturition center, the sacral spinal cord, bladder ganglia, or bladder smooth muscle. Patients with a voiding dysfunction secondary to detrusor areflexia generally attempt bladder emptying by abdominal straining, and their continence status and the efficiency of their emptying efforts are determined by the status of their smooth and striated sphincter mechanisms.

This classification system is easiest to use when detrusor hyperreflexia (overactivity) or normoreflexia exists. Thus a typical T10-level paraplegic patient after spinal shock exhibits detrusor hyperreflexia, smooth sphincter synergia, and striated sphincter dyssynergia. When a voluntary or a hyperreflexic contraction cannot be elicited, the system is more difficult to use because it is not appropriate to speak of true sphincter dyssynergia in the absence of an opposing bladder contraction. There are obviously many variations and extensions of such a system. **Such systems can work well only when total urodynamic agreement exists among classifiers. Unfortunately, there are many voiding dysfunctions that do not fit neatly into a urodynamic classification system that is agreed on by all experts. Compliance is not mentioned in this particular version, nor is sensation or the concept of deficient but not absent detrusor contractile function.** As sophisticated urodynamic technology and understanding improve, this type of classification system may become more commonly used. The ICS system (see previous discussion) is in reality a logical and more complete extension of such a system.

Lapides Classification

Lapides (1970) contributed significantly to the classification and care of the patient with neuropathic voiding dysfunction by slightly modifying and popularizing a system originally proposed by McLellan in 1939 (Table 61–8). Lapides' classification differs from that of McLellan in only one respect, and that is the division of the group of "atonic neurogenic bladder" into sensory neurogenic and motor neurogenic bladder. This remains a familiar system to urologists and nonurologists because it describes in recognizable shorthand the clinical and cystometric conditions of many types of neurogenic voiding dysfunction.

A sensory neurogenic bladder results from disease that selectively interrupts the sensory fibers between the bladder and the spinal cord or the afferent tracts to the brain. **Diabetes mellitus, tabes dorsalis, and pernicious anemia** are the most responsible. The first clinical changes are described as those of impaired sensation of bladder distention. Unless voiding is

Expanded Functional Classification

I. Failure to store
- A. Because of the bladder
  - 1. Overactivity
    - a. Involuntary contractions
      - Neurologic disease, injury, or degeneration
      - Bladder outlet obstruction
      - Stress urinary incontinence
      - Increased afferent input
        - Inflammation
        - Increased neurotransmitter release
      - Idiopathic
    - b. Decreased compliance
      - Neurologic disease or injury
      - Fibrosis
      - Bladder muscle hypertrophy
      - Idiopathic
    - c. Combination
  - 2. Hypersensitivity
    - a. Inflammatory/infectious
    - b. Neurologic
    - c. Increased neurotransmitter release
    - d. Psychologic
    - e. Idiopathic
  - 3. Decreased pelvic floor activity (?)
  - 4. Combination
- B. Because of the outlet
  - 1. Combination (GSI and ISD)
  - 2. Genuine stress urinary incontinence (GSI)
    - a. Lack of suburethral support
    - b. Pelvic floor laxity, hypermobility
  - 3. Intrinsic sphincter deficiency (ISD)
    - a. Neurologic disease or injury
    - b. Fibrosis
- C. Combination

II. Failure to empty
- A. Because of the bladder
  - 1. Neurogenic
  - 2. Myogenic
  - 3. Psychogenic
  - 4. Idiopathic
- B. Because of the outlet
  - 1. Anatomic
    - a. Prostatic obstruction
    - b. Bladder neck contracture
    - c. Urethral stricture
    - d. Urethral compression, fibrosis
  - 2. Functional
    - a. Striated sphincter dyssynergia
    - b. Smooth sphincter dyssynergia or dysfunction
    - c. Dysfunctional voiding
- C. Combination

Lapides Classification

Sensory neurogenic bladder
Motor paralytic bladder (motor neurogenic bladder)
Uninhibited neurogenic bladder
Reflex neurogenic bladder
Autonomous neurogenic bladder

initiated on a timed basis, varying degrees of bladder overdistention can result with resultant hypotonicity. If bladder decompensation occurs, significant amounts of residual urine result, and at that time the cystometric curve generally demonstrates a large capacity bladder with a flat, high-compliance, low-pressure filling curve.

A **motor paralytic bladder** results from disease processes that destroy the parasympathetic motor innervation of the bladder. **Extensive pelvic surgery or trauma** may produce this. **Herpes zoster** has been listed as a cause as well, but recent evidence suggests that the voiding dysfunction seen with herpes may be more related to a problem with afferent input (see Chapter 65). The early symptoms of a motor paralytic bladder may vary from painful urinary retention to only a relative inability to initiate and maintain normal micturition. Early cystometric filling is normal but without a voluntary bladder contraction at capacity. Chronic overdistention and decompensation may occur, resulting in a large-capacity bladder with a flat, low-pressure filling curve; a large residual urine may result.

An **uninhibited neurogenic bladder** was described originally as resulting from injury or disease to the "corticoregulatory tract." The sacral spinal cord was presumed to be the micturition reflex center, and this corticoregulatory tract was believed normally to exert an inhibitory influence on the sacral micturition reflex center. A destructive lesion in this tract would then result in overfacilitation of the micturition reflex. **Cerebrovascular accident, brain or spinal cord tumor, Parkinson disease, and demyelinating disease** were listed as the most common causes in this category. The voiding dysfunction is most often characterized symptomatically by frequency, urgency, and urge incontinence and urodynamically by normal sensation with involuntary contraction at low filling volumes. Residual urine is characteristically low unless anatomic outlet obstruction or true smooth or striated sphincter dyssynergia occurs. The patient generally can initiate a bladder contraction voluntarily but is often unable to do so during cystometry because sufficient urine storage cannot occur before involuntary contraction is stimulated.

Reflex neurogenic bladder describes the post–spinal shock condition that exists after complete interruption of the sensory and motor pathways between the sacral spinal cord and the brainstem. Most commonly, this occurs in **traumatic spinal cord injury and transverse myelitis,** but it may occur with **extensive demyelinating disease or any process that produces significant suprasacral (cord) spinal cord destruction.** Typically, there is no bladder sensation, and there is inability to initiate voluntary micturition. Incontinence without sensation generally results from low-volume involuntary contraction. Striated sphincter dyssynergia is the rule. This type of lesion is essentially equivalent to a complete upper motor neuron (UMN) lesion in the Bors-Comarr system (see later).

An autonomous neurogenic bladder results from complete motor and sensory separation of the bladder from the sacral spinal cord. This may be caused by **any disease that destroys the sacral cord or causes extensive damage to the sacral roots or pelvic nerves.** There is inability to initiate micturition voluntarily, no bladder reflex activity, and no specific bladder sensation. This type of bladder is equivalent to a complete lower motor neuron (LMN) lesion in the Bors-Comarr system and is also the type of dysfunction seen in patients with spinal shock. The characteristic cystometric pattern is initially similar to the late stages of the motor or sensory paralytic bladder, with a marked shift to the right of the cystometric filling curve and a large bladder capacity at low intravesical pressure. However, decreased compliance may develop, secondary either to chronic inflammatory change or to the effects of denervation/decentralization with secondary neuromorphologic and neuropharmacologic reorganizational changes. Emptying capacity may vary widely, depending on the ability of the patient to increase intravesical pressure and on the resistance offered during this increase by the smooth and striated sphincters.

These classic categories in their usual settings are generally understood and remembered, and this is why this system provides an excellent framework for teaching some fundamentals of neurogenic voiding dysfunction to students and nonurologists. Unfortunately, **many patients do not exactly fit into one or another category.** Gradations of sensory, motor, and mixed lesions occur, and the patterns produced after different types of peripheral denervation/defunctionalization may vary widely from those that are classically described. **The system is applicable only to neuropathic dysfunction.**

Bors and Comarr (1971) made a remarkable contribution by logically deducing a classification system from clinical observation of their patients with traumatic spinal cord injury (Table 61–9). **This system, primarily of historical interest at present, applies only to patients with neurologic dysfunction and considers three factors: (1) the anatomic localization of the lesion, (2) the neurologic completeness or incompleteness of the lesion, and (3) whether lower urinary tract function is *balanced* or *unbalanced*.** The last terms are based solely on the percentage of residual urine relative to bladder capacity. **Unbalanced** signifies the presence of greater than 20% residual urine in a patient with a UMN lesion or 10% in a patient with an LMN lesion. This relative residual urine volume was ideally meant to imply coordination (synergy) or dyssynergia between the smooth and the striated sphincters of the outlet and the bladder during bladder contraction or during attempted micturition by abdominal straining or the Credé maneuver. The determination of the completeness of the lesion is made on the basis of a thorough neurologic examination.

Upper somatomotor neuron, lower visceromotor neuron
Lower somatomotor neuron, upper visceromotor neuron
Normal somatomotor neuron, lower visceromotor neuron

The system erroneously assumes that the sacral spinal cord is the primary reflex center for micturition. LMN implies collectively the preganglionic and postganglionic parasympathetic autonomic fibers that innervate the bladder and outlet and originate as preganglionic fibers in the sacral spinal cord. The term is used in an analogy to efferent somatic nerve fibers such as those of the pudendal nerve, which originate in the same sacral cord segment but terminate directly on pelvic floor striated musculature without the interposition of ganglia. **UMN** is used in a similar analogy to the somatic nervous system to describe the descending autonomic pathways above the sacral spinal cord (the origin of the motor efferent supply to the bladder).

In this system, **UMN bladder** refers to the pattern of micturition that results from an injury to the suprasacral spinal cord after the period of spinal shock has passed, assuming that the sacral spinal cord and the sacral nerve roots are intact and that the pelvic and pudendal nerve reflexes are intact. **LMN bladder** refers to the pattern resulting if the sacral spinal cord or sacral roots are damaged and the reflex pattern through the autonomic and somatic nerves that emanate from these segments is absent. This system implies that if skeletal muscle spasticity exists below the level of the lesion, the lesion is above the sacral spinal cord and is by definition a UMN lesion. This type of lesion is characterized by involuntary bladder contraction during filling. If flaccidity of the skeletal musculature below the level of a lesion exists, an LMN lesion is assumed to be present, implying that detrusor areflexia is present. Exceptions occur and are classified in a **"mixed lesion group"** characterized either by involuntary bladder contraction with a flaccid paralysis below the level of the lesion or by detrusor areflexia with spasticity or normal skeletal muscle tone neurologically below the lesion level.

The use of this system is illustrated as follows. A **"UMN lesion, complete, imbalanced"** implies a neurologically complete lesion above the level of the sacral spinal cord that results in skeletal muscle spasticity below the level of the injury. Involuntary bladder contraction occurs during filling, but a residual urine volume of greater than 20% of the bladder capacity is left after bladder contraction, implying obstruction in the area of the bladder outlet during the involuntary detrusor contraction. This obstruction is generally due to striated sphincter dyssynergia, typically occurring in patients who are paraplegic or quadriplegic with lesions between the cervical and the sacral spinal cord. Smooth sphincter dyssynergia may be seen as well in patients with lesions above the level of T6, usually associated with autonomic hyperreflexia (see Chapter 65). An **"LMN lesion, complete, imbalanced"** implies a neurologically complete lesion at the level of the sacral spinal cord or of the sacral roots, resulting in skeletal muscle flaccidity below that level. Detrusor areflexia results, and whatever measures the patient may use to increase intravesical pressure during attempted voiding are not sufficient to decrease residual urine to less than 10% of bladder capacity.

This classification system applies best to spinal cord injury patients with complete neurologic lesions after spinal shock has passed. It is difficult to apply to patients with multicentric neurologic disease and cannot be used at all for patients with non-neurologic disease. The system fails to reconcile the clinical and urodynamic variability exhibited by patients who, by neurologic examination alone, seem to have similar lesions. The period of spinal shock that immediately follows severe cord injury is generally associated with bladder areflexia, whatever the status of the sacral somatic reflexes. Temporary or permanent changes in bladder or outlet activity during filling/storage and emptying/voiding may occur secondary to a number of factors such as chronic overdistention, infection, and reinnervation or reorganization of neural pathways following injury or disease; such changes make it **impossible to always accurately predict lower urinary tract activity solely on the basis of the level of the neurologic lesion.** Finally, although the terms *balanced* and *imbalanced* are helpful, in that they describe the presence or absence of a certain relative percentage of residual urine, they do not necessarily imply the true functional significance of a lesion, which depends on the potential for damage to the lower or upper urinary tracts and also on the social and vocational disability that results.

Suprasacral lesion
Suprasacral spinal lesion
Infrasacral lesion
Peripheral autonomic neuropathy
Muscular lesion

Hald-Bradley Classification

Hald and Bradley (1982) described what they termed a simple neurotopographic classification (Table 61–10). The system is of historical interest only. A **supraspinal lesion** is characterized by synergy between detrusor contraction and the smooth and striated sphincters, but defective inhibition of the voiding reflex exists. Involuntary bladder contraction generally occurs, and sensation is usually preserved. However, depending on the site of the lesion, detrusor areflexia and defective sensation may be seen. A **suprasacral spinal lesion** is roughly equivalent to what is described as a UMN lesion in the Bors-Comarr classification. An **infrasacral lesion** is roughly equivalent to an LMN lesion. **Peripheral autonomic neuropathy** is most frequently encountered in the diabetic patient and is characterized by deficient bladder sensation, gradually increasing residual urine, and ultimate decompensation, with loss of detrusor contractility. A **muscular lesion** can involve the detrusor itself, the smooth sphincter, or any portion, or all, of the striated sphincter. The resultant dysfunction is dependent on which structure is affected. Detrusor dysfunction is the most common and generally results from decompensation, following long-standing bladder outlet obstruction. In my opinion, this system is as confusing as the word neurotopographic and adds little to the understanding of lower urinary tract dysfunction.

Bradley Classification

Bradley's "loop system" of classification is a primarily neurologic system based on his conceptualization of central nervous system control of the lower urinary tract that identifies four neurologic "loops" (Hald and Bradley, 1982). Dysfunctions are classified according to the loop affected. Occasional reference is made to this system, primarily by nonurologists.

Loop 1 consists of neuronal connections between the cerebral cortex and the pontine mesencephalic micturition center; this coordinates voluntary control of the detrusor reflex. **Loop 1 lesions** are seen in conditions such as **brain tumor, cerebrovascular accident or disease, and cerebral atrophy with dementia.** The final result is characteristically **involuntary bladder contractions.**

Loop 2 includes the intraspinal pathway of detrusor muscle afferents to the brainstem micturition center and the motor impulses from this center to the sacral spinal cord. Loop 2 is thought to coordinate and provide for a detrusor reflex of adequate temporal duration to allow complete voiding. Partial interruption by spinal cord injury results in a detrusor reflex of low threshold and in poor emptying with residual urine. **Spinal cord transection of loop 2 acutely produces detrusor areflexia and urinary retention—spinal shock. After this has passed, involuntary bladder contractions result.**

Loop 3 consists of the peripheral detrusor afferent axons and their pathways in the spinal cord; these terminate by synapsing on pudendal motor neurons that ultimately innervate periurethral striated muscle. Loop 3 was thought to provide a neurologic substrate for coordinated reciprocal action of the bladder and striated sphincter. **Loop 3 dysfunction could be responsible for detrusor striated dyssynergia or involuntary sphincter relaxation.**

Loop 4 consists of two components. Loop 4A is the suprasacral afferent and efferent innervation of the pudendal motor neurons to the periurethral striated musculature. Loop 4B consists of afferent fibers from the periurethral striated musculature that synapse on pudendal motor neurons in Onuf nucleus—the segmental innervation of the periurethral striated muscle. Bradley conceptualized that, in contrast to the stimulation of detrusor afferent fibers, which produced inhibitory postsynaptic potentials in pudendal motor neurons through loop 3, pudendal nerve afferents produced excitatory postsynaptic potentials in those motor neurons through loop 4B. These provided for contraction of the periurethral striated muscle during bladder filling and urine storage. The related sensory impulses arise from muscle spindles and tendon organs in the pelvic floor musculature. **Loop 4 provides for volitional control of the striated sphincter.** Abnormalities of the suprasacral portion result in abnormal responses of the pudendal motor neurons to bladder filling and emptying, manifested as detrusor striated sphincter dyssynergia or loss of the ability to contract the striated sphincter voluntarily, or both.

The Bradley system is sophisticated and reflects the ingenuity and neurophysiologic expertise of its originator, himself a neurologist. For neurologists, this method may be an excellent way to conceptualize the neurophysiology involved, assuming that there is, in fact, agreement on the existence and significance of all four loops—a big assumption. Most urologists find this system difficult to use for many types of neurogenic voiding dysfunction and not at all applicable to non-neurogenic voiding dysfunction. Urodynamically, it may be extremely difficult to test the intactness of each loop system, and multicentric and partial lesions are difficult to describe.

Urodynamics (UDS) is the term used to describe testing and measurements of the function of the lower urinary tract. The lower urinary tract has two essential functions: the storage of urine at low pressure and the voluntary evacuation of urine. Low-pressure storage is essential to protect kidneys and ensure continence, whereas voluntary evacuation allows for the elimination of urine in socially acceptable situations without fear of leakage or overdistention. It is clear that a number of conditions and diseases affect the lower urinary tract and disrupt the storage and/or evacuation of urine. This can lead to bothersome symptoms (e.g., urinary incontinence or pain from failure to empty) or, in some cases, potentially harmful sequela. In many cases, a precise assessment of storage and emptying is necessary to optimally treat patients. **UDS is the dynamic study of the transport, storage, and evacuation of urine. It is composed of a number of tests that individually or collectively can be used to gain information about urine storage and evacuation.** UDS involves the assessment of the function and dysfunction of the urinary tract and includes the actual tests that are performed (UDS studies) and the observations during the testing (UDS observations) (Abrams et al, 1988, 2002). In this chapter we discuss the use of urodynamics to help in the assessment and treatment of voiding dysfunction. We keep that discussion in practical terms and supplement it with evidence for the technical performance and clinical utility of UDS.

ROLE OF URODYNAMIC TESTING IN CLINICAL PRACTICE

UDS has been used for decades, yet clear-cut, level 1, evidenced-based "indications" for its use are surprisingly lacking. There are a number of reasons for this. It is difficult to conduct proper randomized controlled trials on UDS for conditions in which lesser levels of evidence and expert opinion strongly suggest clinical utility and in which "empiric treatment" is potentially harmful or even life threatening (e.g., neurogenic voiding dysfunction). Additionally, symptoms can be caused by a number of different conditions and it is difficult to study pure or homogeneous patient populations. **Given the current state of evidence for UDS studies, what is most important is that the clinician has clear-cut reasons for performing the study and that the information obtained will be used to guide treatment of**

the patient. Therefore it is probably more useful to describe the role of UDS in clinical practice rather than precise "indications" for its use.

In practical terms, UDS is most useful when history, physical examination, and simple tests are not sufficient to make an accurate diagnosis and/or institute treatment. This has clinical applicability in two general scenarios:

1. To obtain information needed to make an accurate diagnosis for what condition(s) is causing symptoms (e.g., lower urinary tract symptoms or incontinence).
2. To determine the impact of a disease that has the potential to cause serious and irreversible damage to the upper and lower urinary tract (e.g., neurologic diseases like spinal cord injury and multiple sclerosis, radiation cystitis). Sometimes profound abnormalities can be found in the relative absence of symptoms.

Rather than refer to a list of "indications for UDS" that often are not evidence based at all, it is more useful for clinicians to think of how UDS should be used in a broader clinical perspective. In keeping with that theme, the role of UDS in clinical practice has been nicely summarized by Hosker and colleagues (2009) **for the following situations:**

1. **To identify or rule out factors contributing to lower urinary tract dysfunction (e.g., urinary incontinence) and assess their relative importance**
2. **To obtain information about other aspects of lower urinary tract function or dysfunction**
3. **To predict the consequences of lower urinary tract dysfunction on the upper urinary tract**
4. **To predict the outcome including undesirable side effects of a contemplated treatment**
5. **To confirm the effects of intervention or understand the mode of action of a particular type of treatment (especially a new one)**
6. **To understand the reasons for failure of previous treatments for symptoms (e.g., urinary incontinence) or for lower urinary tract function in general**

In order to use UDS in a practical and effective way, it is important that the clinician has the proper expertise to know when and why to perform a UDS study. Despite many technical advances in the recording, processing, and printing of UDS studies, careful attention to technical details to ensure accurate collection of data remains the cornerstone of a good study. Because not all patients undergo UDS for the same reasons, the clinician should "customize" UDS to the patients' symptoms and condition. **That means deciding on the questions to be answered before starting each study and designing that study to obtain the answers to those questions.** It is important to remember that UDS is performed in an "unnatural setting" and therefore does not always duplicate real life. A UDS study that does not duplicate complaints or symptoms when an abnormality is recorded is not necessarily diagnostic. In addition, failure to record an abnormality does not always rule out its existence (e.g., failure to demonstrate detrusor overactivity in a patient with urge incontinence). Finally, not all UDS observations are clinically significant. **Therefore it is important to interpret UDS studies in the context of the patient's history including symptoms and concomitant diseases/conditions, as well as other information like postvoid residual volumes and frequency volume charts (voiding and intake diaries) when clinically applicable.**

FUNCTIONAL CLASSIFICATION OF VOIDING DYSFUNCTION: APPLICABILITY TO URODYNAMIC TESTING

In order to formulate a set of questions to be answered by a urodynamic test, an understanding of the possible causes of symptoms and the possible urodynamic manifestations of a preexisting condition is necessary. In order to accomplish this, a practical classification of voiding dysfunction is invaluable. The system proposed and popularized by Wein (1981) is simple and allows one to classify voiding dysfunction according to urodynamic findings. **Functional abnormalities of the lower urinary tract can be divided into the following:**

1. **Storage dysfunction (failure to properly store urine)**
2. **Emptying dysfunction (failure to empty the bladder normally)**
3. **Combined dysfunction (failure to store and empty)**

In addition, functional abnormalities can be subclassified to the anatomic region of the lower urinary tract that is affected and how it is affected. Thus storage and emptying abnormalities can be caused by the following:

1. **Bladder dysfunction: overactive (causing failure to store) or underactive (causing failure to empty)**
2. **Bladder outlet dysfunction: overactive (causing failure to empty) or underactive (causing failure to store)**
3. **Combined bladder and bladder outlet dysfunction**

The beauty of a functional classification system is that it helps to clarify treatment options for a given patient. Thus in practical terms, the UDS evaluation should help to determine if there is bladder or bladder outlet dysfunction (or both) and whether there is a storage and/or emptying problem. By providing answers to these simple questions, the urodynamic test can lead to a correct diagnosis and, equally as important, institution of appropriate treatment. Obviously, an understanding of the physiology of urine storage and voiding and the pathophysiology of voiding dysfunction (see Chapter 61) is required to formulate appropriate questions to be answered by a urodynamic study. However, all too often clinicians get caught up in the intricate neurophysiologic aspects of voiding and storage dysfunction and fail to think in practical terms. One should always focus on the possible urodynamic findings in a given case and how each of the findings may ultimately affect the patient and his or her treatment. Obviously, these potential findings will be determined by symptoms and/or underlying conditions or diseases.

CONDUCTING A URODYNAMIC STUDY: PATIENT AND TECHNICAL FACTORS

Preparing for Urodynamic Study: Clinician, Patient, and Facility

Once the decision has been made to perform UDS on a particular patient, it is important to consider what information is expected from the test. The simple fact that a patient has symptoms or a disorder that may affect the lower urinary tract is not sufficient to

start the UDS evaluation. **A list of problems or questions that should be solved or answered by UDS should be made before any testing is performed.** All patients are not alike, so each urodynamic evaluation may be different depending on the information needed to answer the questions relevant to a particular patient. **We follow three important rules before starting the UDS evaluation** (Nitti and Combs, 1998):

1. **Decide on questions to be answered before starting a study.**
2. **Design the study to answer these questions.**
3. **Customize the study as needed.**

By following these simple rules, one can maximize the chance of obtaining useful information from a study. If a particular question is not answered, the study can be repeated in the same session. Most people who do urodynamics regularly would concur that a urodynamic test is not always perfect in answering all important questions, but by defining the information needed before starting the study, "unanswered questions" can be kept to a minimum. As mentioned earlier, one of the most important parts of UDS is its proper performance with careful attention to technical details so that accurate interpretation is possible. It is beyond the scope of this chapter to describe the proper performance of UDS in detail; however, the reader is referred to Schafer and colleagues (2002) for good urodynamic practices and Abrams and colleagues (2002) for terminology. The International Continence Society (ICS) has now defined the term "urodynamic observations" to denote those observations that occur during and are measured by the UDS test itself. In order to be consistent, it is recommended that all clinicians performing and interpreting UDS use the current ICS terminology (Abrams et al, 2002). A list of common UDS terms is provided in Table 62–1.

Ideally a room of suitable size should be dedicated to urodynamics (Nitti and Combs, 1998). This area does not have to be exclusively for urodynamics, but when a study is being performed, there should not be distractions from people walking into and out of the area for other reasons. A quiet, private area is the best. It is difficult enough to recreate a natural environment during testing without outside distractions. The room should be large enough to allow for the patient to lie down to have catheters placed and also to be able to stand and sit on a commode as needed. Many patients

Table 62–1.

Terminology for Common Urodynamic Terms and Observations According to the International Continence Society Standardization Subcommittee

The ICS has now defined the term urodynamic observations to denote observations that occur during and are measured by the urodynamics (UDS) test itself. In order to be consistent, it is recommended that all clinicians performing and interpreting UDS use the current ICS terminology (Abrams et al, 2002).

Two principal methods of urodynamic investigation exist:
- Conventional urodynamic studies: normally take place in the urodynamic laboratory involving artificial bladder filling.
- Ambulatory urodynamic studies: a functional test of the lower urinary tract using natural filling and reproducing the subject's everyday activities.

The following are required of both types of studies:
- Intravesical pressure: the pressure within the bladder.
- Abdominal pressure: the pressure surrounding the bladder; currently it is estimated from rectal, vaginal, or extraperitoneal pressure or a bowel stoma.
- Detrusor pressure: the component of intravesical pressure created by forces on the bladder wall that are both passive and active.
- Filling cystometry: the method by which the pressure and volume relationship of the bladder is measured during bladder filling.
- Physiologic filling rate: a filling rate less than the predicted maximum. Predicted maximum is the body weight in kilograms divided by 4 and expressed as milliliters per minute.
- Nonphysiologic filling rate: a filling rate greater than the predicted maximum.

Bladder sensation during filling cystometry:
- Normal bladder sensation, defined by three points noted during filling cystometry and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints.
- First sensation of bladder filling: the volume at which the patient first becomes aware of the bladder filling.
- First desire to void: the feeling during filling cystometry that would lead the patient to pass urine at the next convenient moment.
- Strong desire to void: a persistent desire to void without the fear of leakage.
- Increase that occurs at low bladder volumes and persists.
- Reduced bladder sensation: diminished sensation throughout bladder filling.
- Absent bladder sensation: the individual has no bladder sensation.
- Nonspecific bladder sensation: the individual is aware of bladder filling because of other sensations such as abdominal fullness or vegetative symptoms.
- Bladder pain: a self-explanatory term that is abnormal.
- Urgency: a sudden compelling desire to void.
- Normal detrusor function: allows bladder filling with little or no change in pressure, no involuntary contractions despite provocative maneuvers.
- Detrusor overactivity: involuntary detrusor contractions during the filling phase, spontaneous or provoked.
- Phasic detrusor overactivity: a characteristic waveform that may or may not lead to urinary incontinence.
- Terminal detrusor overactivity: a single involuntary detrusor contraction occurring at cystometric capacity that cannot be suppressed, resulting in incontinence with bladder emptying.
- Detrusor overactivity incontinence: incontinence related to involuntary detrusor contractions. This may be qualified according to cause.
- Neurogenic detrusor overactivity: overactivity accompanied by a neurologic condition; this term replaces the term *detrusor hyperreflexia*.
- Idiopathic detrusor overactivity: detrusor overactivity without concurrent neurologic etiology. This term replaces the term *detrusor instability*.

Continued

Table 62–1.

Terminology for Common Urodynamic Terms and Observations According to the International Continence Society Standardization Subcommittee—cont'd

Provocative maneuvers: techniques used during urodynamic border to provoke detrusor overactivity.
Cystometric capacity: the bladder volume at the end of the filling cystogram when permission to void is given.
Maximum cystometric capacity: the volume at which the patient feels he or she can no longer delay micturition and has a strong desire to void.
Maximum anesthetic bladder capacity: the volume to which the bladder can be filled under deep general or spinal anesthesia. This should be qualified as to what type of anesthesia is used, the rate of filling, the length of time of filling, and the pressure to which the bladder is filled.
Normal urethral closure mechanism: this maintains a positive urethral closure pressure during bladder filling even in the presence of increased abdominal pressure.
Incompetent urethral closer mechanism: this is defined as one allowing leakage of urine in the absence of detrusor contraction.
Urethral relaxation incontinence: leakage related to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity.
Urodynamic stress incontinence: noted during filling cystometry and defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction. This currently replaces genuine stress incontinence.
Urethral pressure measurements:
- Urethral pressure: the fluid pressure needed to just open a closed urethra.
- Urethral pressure profile: a graph indicating the intraluminal pressure along the length of the urethra.
- Urethral closure pressure profile: the subtraction of intravesical pressure from urethral pressure.
- Maximum urethral pressure: the maximum pressure of the measured profile.
- Maximum urethral closure pressure (MUCP): the maximum difference between the urethral pressure and the intravesical pressure.
- Functional profile length: the length of the urethra along which the urethral pressure exceeds intravesical pressure in women.
- Pressure transmission ratio: the increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in intravesical pressure.

Abdominal leak point pressure: the intravesical pressure at which urine leakage occurs because of increased abdominal pressure in the absence of a detrusor contraction.
Detrusor leak point pressure: the lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure.
Pressure-flow studies: the method by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying.
Pressure measurements during pressure-flow studies:
- Premicturition pressure: the pressure recorded immediately before the initial isovolumetric contraction.
- Opening pressure: the pressure recorded at the onset of urine flow.
- Opening time: the elapsed time from original rise in detrusor pressure to onset of flow.
- Maximum pressure: the maximum value of the measured pressure.
- Pressure at maximum flow: the lowest pressure recorded at maximum measured flow rate.
- Closing pressure: the pressure measured at the end of measured flow.
- Minimum voiding pressure: the minimum pressure during measurable flow.
- Flow delay: the time delay between a change in bladder pressure and the corresponding change in measured flow rate.

From Abrams P, Cardozo L, Fall M, et al. The standardisation of terminology of lower urinary tract function: report from the Standardisation Subcommittee of the International Continence Society. Neurourol Urodyn 2002;21:167–78; and Schafer W, Abrams P, Liao L, et al. Good urodynamic practices: uroflowmetry, filling, cystometry, and pressure-flow studies. Neurourol Urodyn 2002;21:261–74.

undergoing urodynamic testing will have neurologic problems that limit mobility and will require assistance with positioning. This includes patients in wheelchairs. This must be considered when determining the size of the room. Centers that perform video-urodynamics (VUDS) will require a larger area to allow for x-ray equipment.

The importance of a well-trained, attentive, and supportive staff involved with the UDS study cannot be overemphasized. With that said, in general, UDS is well tolerated. **However, patients should be properly prepared and told why the test is being done, how the results may affect treatment, and what to expect during the actual UDS test.** Scarpero and colleagues (2005) used a questionnaire-based study to assess patient expectations of anxiety, pain, embarrassment, and apprehension before UDS and compared it with the patient's actual experience. They found that UDS was associated with minimal to moderate degrees of anxiety, discomfort, and embarrassment. After testing, most respondents (>90% per question) thought that the test was the same or better than expected and had an expected or less than expected level of pain and embarrassment. This did not vary between the sexes, but a higher number of younger individuals found that the test experience was worse than expected, whereas a higher number of older individuals found that it was better than expected. Therefore younger patients may require more reassurance and attention in preparation for the procedure.

Many patients undergoing urodynamic testing will have been placed on medications that affect bladder function (e.g., antimuscarinics). For such patients the clinician should decide in advance what information is desired and whether or not the study should be done on or off medication. For example, if the goal of the study is to determine the therapeutic effect of a medication, obviously the UDS should be done with the patient on a regular dosing schedule for that medication. On the other hand, if medication was started empirically to treat symptoms and the goal of the urodynamic test is to uncover the etiology of those symptoms, then consideration can be given to discontinuing the medication before testing because this may give the highest yield.

COMPONENTS OF THE URODYNAMIC STUDY

Before discussing the details of the UDS test itself, it is useful to be familiar with its different components. These tests within the test can be used individually or in combination depending on the information desired. For the purposes of this chapter we discuss each component as part of the entire multichannel UDS or video UDS study. Uroflow and postvoid residual (PVR) determination are two simple, noninvasive tests that can be used to evaluate voiding function and perhaps prompt further testing. In addition, both are part of a multichannel UDS study.

PVR is an excellent assessment of bladder emptying. It can be performed by ultrasound (bladder scan) or catheterization. Elevation of PVR indicates a problem with emptying but does not tell why. An elevated PVR may prompt further testing.

Uroflowmetry is measurement of the rate of urine flow over time. It is also an assessment of bladder emptying. Normal uroflow is a bell-shaped curve. When the flow rate is reduced or the pattern is altered, this could indicate bladder (underactive) or bladder outlet (obstruction) dysfunction (Fig. 62–1).

Cystometrogram (CMG): Cystometry or, more appropriately, "filling cystometry" is the method by which the pressure/volume relationship of the bladder is measured during bladder filling. The filling phase starts when filling commences and ends when the patient and urodynamicist decide that "permission to void" has been given. CMG can be performed by the single measurement of bladder pressure via a bladder catheter (urethral or suprapubic); however, changes in bladder pressure can represent a change in detrusor pressure (Pdet) or a change in abdominal pressure (Pabd) (see later). Therefore it is recommended that CMG be performed by measuring both the total vesical pressure (Pves) and Pabd (measured by a catheter placed in the rectum or vagina). To calculate Pdet, the following equation is used: **Pdet = Pves – Pabd** (Fig. 62–2).

Electromyography (EMG) is the study of the electronic potentials produced by the depolarization of muscle membranes. In the case of UDS, EMG measurement of the striated sphincteric muscles of the perineum is done to evaluate possible abnormalities of perineal muscle function, which are often associated with lower urinary tract symptoms and dysfunction. EMG activity is measured during both filling and emptying. EMG is obtained via electrodes placed in or near the muscle to be measured.

Urethral pressure profile (UPP) is a graph indicating the intraluminal pressure along the length of the urethra. Urethral pressure is defined as the fluid pressure needed to just open a closed urethra. UPP is obtained by the withdrawal of a pressure sensor (catheter) along the length of the urethra.

Pressure-flow studies (PFS) of voiding are the method by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying. Detrusor pressure is measured as explained earlier with the simultaneous measurement of flow rate by a uroflowmeter. The voiding phase starts when "permission to void" is given, or when uncontrollable voiding begins, and ends when the patient considers voiding has finished.

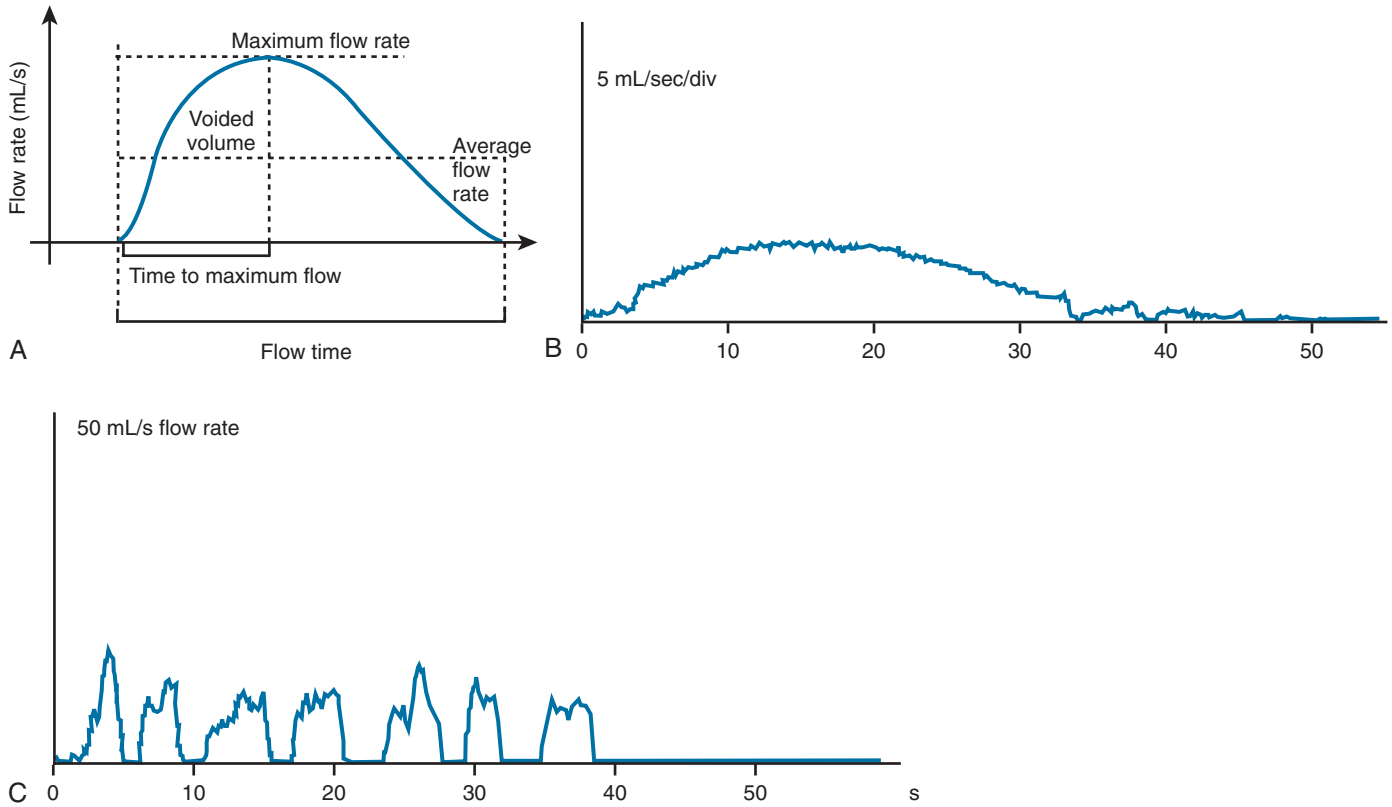

Figure 62–1. Examples of uroflow curves. **A,** Normal bell-shaped flow curve of flow rate versus time. **B,** A flattened pattern is usually indicative of obstruction. **C,** An interrupted or straining pattern, which can be seen with impaired bladder contractility, obstruction, or voiding with or by abdominal straining. (**A** from Wein AJ, English WS, Whitemore KE. Office urodynamics. Urol Clin North Am 1988;15:609; **B** and **C** from Boone TB, Kim YH. Uroflowmetry. In: Nitti VW, editor. Practical urodynamics. Philadelphia: WB Saunders; 1998. p. 28–51.)

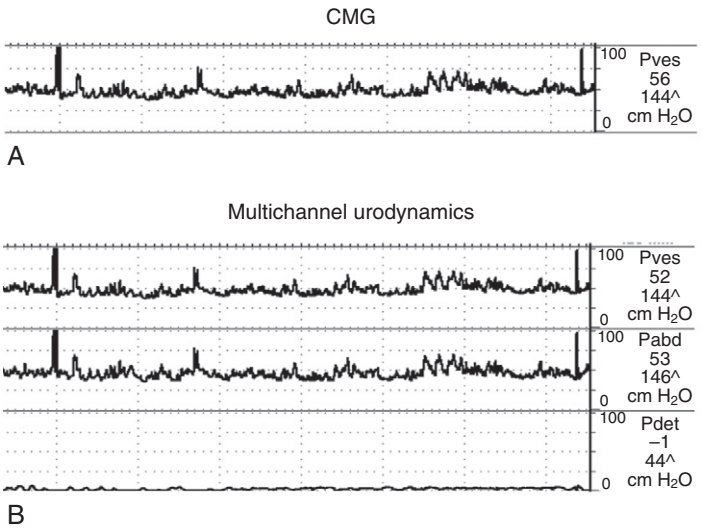

Figure 62–2. Cystometrogram (CMG) measures the pressure in the bladder as the bladder fills over time. Standard fill rates in adults are 30 to 100 cm/H_2O per minute. Adding intra-abdominal pressure monitoring gives a better representation of the true detrusor pressure. **A,** Single-channel CMG where only the total vesical pressure (Pves) is measured. Note the multiple spikes and rises in pressure. Without having simultaneous monitoring of intra-abdominal pressure, it is impossible if these pressure spikes are due to a rise in detrusor or abdominal pressure. **B,** This same tracing with intra-abdominal pressure (Pabd) monitoring added (Multichannel UDS). This allows for the determination of (subtracted) detrusor pressure (Pdet). Now it can be clearly seen that changes in Pves were due to the changes in Pabd (e.g., movement, coughing). The Pdet curve is noted to be flat and without any rises in pressure. (From Nitti VW. Cystometry and abdominal pressure monitoring. In Nitti VW, editor. Practical urodynamics. Philadelphia: WB Saunders; 1998. p. 38–51.)

URODYNAMIC EQUIPMENT

Urodynamic Systems

Various urodynamic systems are available today. They range in price from several thousand dollars to more than 100,000 dollars depending on their complexity and the features they contain. Most high-end systems are computer-based digital systems that allow for easy data storage and postprocessing of the study. In addition, they allow for hardware and software upgrades as needed. It is beyond the scope of this chapter to describe in detail the options available for UDS systems. However, it is recommended that, when choosing a system, one must consider the patient population and spectrum of diseases frequently encountered, space, convenience of operation (if a factor), and the need for data storage and processing. In addition, it is recommended that a multichannel system in which channels are available to measure vesical pressure, abdominal pressure (and subtracted detrusor pressure), and flow rate is used. Some clinicians may also desire channels for electromyography and urethral pressure measurement. The UDS system and software market is constantly changing, so what is state-of-the-art today may seem "outdated" tomorrow. However, despite all the advances, the clinician performing the study remains the most important constant in data collection and interpretation. For the most realistic assessment, the infusant should be a liquid (e.g., normal saline or radiographic contrast) that will most approximate urine. The use of gas such as carbon dioxide is no longer recommended. Many advanced urodynamic centers now perform VUDS. Adding this capability is expensive but allows one to perform the most comprehensive study possible. There are certain clinical settings in which VUDS is the test of choice (see later). In addition to the necessary urodynamic hardware and software, a fluoroscopy unit and room of adequate size are required. Obviously, this is not practical or necessary in every setting. Video-urodynamic studies also require a greater time commitment on the part of the clinician to ensure accurate data collection.

Signal Transmission and Transducers

Transducers are the hardware that allows pressure in the patient to be measured and transferred to the UDS system. External strain-gauge transducers located "between" the patient and the urodynamic machine have been popular for years. Pressurized tubing (to avoid dampening or dissipation of the pressure) extends from the pressure transducer to the catheters placed in the patient. An electronic cable or "wireless transmission" brings the signal from the transducer to the urodynamic machine. Traditionally a water-filled system in which the entire system from transducer to patient is filled with water has been used. Since this system depends on the transmission of pressure through fluid (water), it is crucial that there are no air bubbles in the transducer or tubing. The pressurized tubing transmission lines should be lucent to allow for easy recognition of air in the line. The transducers are usually set at the level of the patient's bladder (symphysis pubis) at the start of the study. This is important because if the patient changes position during the test (e.g., standing to sitting), the height of the transducer can be adjusted so that it remains at the level of the bladder.

More recently, **air-charged catheters** have become popular for pressure measurement (T-Doc, Wenonah, NJ). This catheter uses a miniature, air-filled balloon placed circumferentially around a polyethylene catheter. External forces on the balloon of the catheter are transmitted to the air-filled catheter lumen and communicated to an external semiconductor transducer. The technology of the balloon system allows circumferential measurement readings. The catheters are disposable and single use. Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no fluid connection between the patient and the urodynamic equipment—just air. This means there is no hydrostatic pressure effect to account for so that there is no need to position anything at the level of the symphysis pubis and there is no need to flush the system through to exclude air (essential when using a fluid-filled system). Also, there are no artifactual fluctuations in pressure produced when the patients move. It must also be remembered that **many UDS nomograms and other "standards of measurement" were determined using fluid-filled systems. Although there is comparative evidence for the use of air-charged catheters to measure urethral pressure** (Pollak et al, 2004), **no studies have shown definitively that air-charged catheters provide an acceptable alternative to fluid-filled lines for measuring intravesical and intra-abdominal pressure in UDS.** Thus it is recommended that investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure monitoring check for themselves that they have an equivalent performance to their current system for measuring pressure (Hosker et al, 2009).

Finally a microtip or fiberoptic system can be used to process pressure transmission. Here the transducer is contained within the catheter. This in turn is connected directly into the urodynamic machine via a cable. These catheters are quite expensive but reusable. They must be sterilized before each use.

Uroflowmeters

Urine flow rate or uroflow can be determined by a number of different types of devices or uroflowmeters. Modern uroflowmeters use weight, electrical capacitance, or a rotating disc to determine urinary flow rates. The two most common techniques used today are the weight transducer or load cell method and the rotating disc method. With the load cell the voided "weight" is measured and is then differentiated with respect to time to determine the flow rate. In the rotating disc method the urine stream is directed onto a rotating disc, and the power necessary to keep a disc rotating at a constant rate is measured. This power is proportional to the flow rate. The electronic dipstick flowmeter measures the electrical capacitance of a dipstick mounted in a collecting chamber. The output of the signal is proportional to the accumulated volume, and the volumetric flow rate is determined by differentiation. Each of these methods has advantages and disadvantages. The weight transducer method is simple, reliable, and accurate regardless of the site of stream impact but requires that the density of urine must be set. The rotating disc method is also reliable and accurate, and it provides a direct measurement without need for differentiation of volume with respect to time. Electronic flowmeters provide a range of electronically read flow parameters with graphical depiction of the uroflow and have sufficient precision for clinical use with error rates of 1% to 8% in voided volume and 4% to 15% in flow rate (Susset, 1983). Variations in specific gravity of the fluid voided (infusant when doing UDS studies) can affect the calculated flow rate. Most systems allow for calibrations for various fluids such as radiographic contract.

Electromyography

Muscle depolarization must be detected by an electrode placed in or near the muscle. Several different methods are available to do this including surface electrodes and needle electrodes (the two most common methods), as well as anal plug or urethral catheter–mounted electrodes (O'Donnell, 1998). Surface electrodes are self-adhesive skin patch electrodes that are applied over the skin of the anal sphincter. Except in some neurologic diseases, the external anal sphincter EMG will be the same as the external urethral sphincter EMG. Surface electrodes have a significant advantage compared with the needle electrode regarding patient convenience and comfort. However, the surface electrodes provide an inferior signal source and must be precisely placed to provide an adequate signal source. Most clinicians feel that the concentric needle electrode is the superior technique for obtaining a signal source of EMG activity of the striated external sphincter muscles. Compared with the surface electrode, placement of the needle electrode has the disadvantage of being uncomfortable for the patient, especially if more than one attempt at placement of the electrode is required to obtain an adequate signal. Also, the needle electrode is easily dislodged and may require replacement during the study. Patients typically have a low tolerance for replacement of the needle electrode during urodynamic studies. The performance of an EMG and the selection of the type of electrode to be used depend on the UDS question to be answered.

URODYNAMIC STUDY: ANALYSIS AND INTERPETATION

The author has found it useful to divide the UDS test into filling/storage and voiding phases. This allows for ease of classification of voiding dysfunction according to the functional classification system mentioned previously. The filling/storage phase consists primarily of the CMG, provocative testing (e.g., measurement of abdominal leak point pressure), and urethral pressure measurement during storage. The voiding phase evaluates bladder contractility, bladder outlet resistance, and sphincter coordination by pressure-flow analysis and EMG.

FILLING AND STORAGE PHASE

The CMG assesses the bladder's response to filling. The CMG can measure filling pressure, sensation, involuntary contractions, compliance, and capacity. Sensation is the part of cystometry that is truly subjective and therefore requires an alert and attentive patient and clinician. Several subjective parameters that can be recorded during filling are recognized by the ICS (see Table 62–1).

Normal Filling and Storage

Normally, the bladder should store urine at low pressure and not contract involuntarily. Once capacity is reached or voluntary voiding is desired, intravesical pressure will increase (voluntary detrusor contraction). In actuality this is preceded by a relaxation of the external sphincter. A normalized adult CMG is shown in Figure 62–3. **Normally detrusor pressure should remain near zero during the entire filling cycle until voluntary voiding is initiated. That means baseline pressure stays constant (and low) and there are no involuntary contractions.**

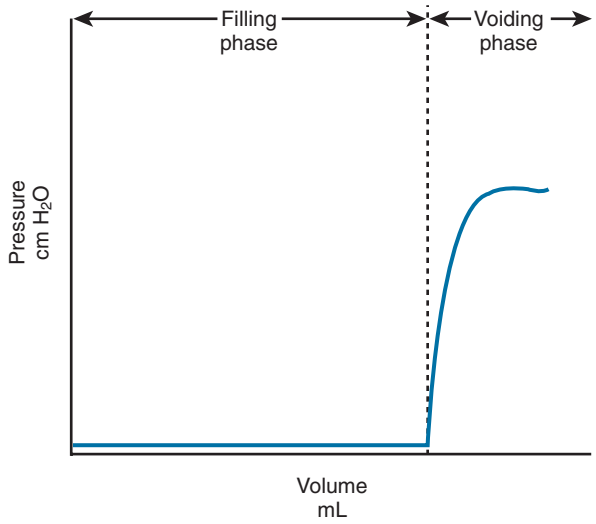

Figure 62–3. Normal, idealized adult cystometrogram with low pressure storage until the patient is given the command to void and the voiding phase starts. Note that the baseline bladder pressure is near zero (compliant) and there are no involuntary contractions.

As mentioned previously, the simultaneous measurement of Pabd, usually by a rectal or vaginal catheter, and Pves during urodynamics provides a means of calculating the true Pdet. **The ability to calculate subtracted Pdet allows one to distinguish between a true rise in detrusor pressure (either via a contraction or loss of compliance) and the effect of increased abdominal pressure** (e.g., straining, Valsalva). This is especially important when rises in detrusor pressure are small or when they are accompanied by changes in abdominal pressure.

Abnormalities of Bladder Filling—Detrusor Overactivity and Impaired Compliance

During filling, involuntary detrusor contractions (IDCs) can occur. These are often associated with urgency and even urgency incontinence. **Detrusor overactivity (DO) is a *urodynamic observation* characterized by IDCs during the filling phase, which may be spontaneous or provoked** (Fig. 62–4)**. DO may be further characterized as *neurogenic DO,* which means it is associated with a relevant neurologic condition (e.g., spinal cord injury, multiple sclerosis) or *idiopathic DO,* which means there is "no defined cause" (non-neurogenic)** (Abrams et al, 2002). The term *idiopathic* is a bit of a misnomer in that the cause of DO in a non-neurogenic patient may be readily apparent (e.g., bladder outlet obstruction, inflammatory process) or may be truly "unknown." Thus from a practical standpoint, the terms neurogenic and non-neurogenic DO make sense but do not fit the ICS definitions. (It should be noted that the term *neurogenic DO* replaced the term *detrusor hyperreflexia,* and the term *idiopathic DO* replaced the term *detrusor instability* in previous ICS terminology). Neurogenic and idiopathic DO may look identical on CMG. These terms are strictly defined by the patient's neurologic status and not the CMG appearance of the IDCs.

The presence of DO during UDS must be interpreted in the context of the patient's symptoms and condition. Ideally, a patient's symptoms should be reproduced during UDS, so we would expect DO to be accompanied by urgency or urgency incontinence, although it can occur and be significant without being symptomatic, particularly in neurogenic DO. However, DO can also be "test induced" or clinically insignificant. It has been reported in 14% to 18% of healthy asymptomatic volunteers undergoing UDS (van Waalwijk van Doorn et al, 1992; Robertson, 1999; Wyndaele et al, 2002). This is even more dramatic in ambulatory UDS studies where DO has been found in up to 69% of asymptomatic females (van Waalwijk van Doorn, et al, 1996). Conversely, failure to demonstrate DO on UDS does not rule out its existence. It is well known that up to 50% of women with urgency incontinence do not demonstrate DO on UDS. However, the ability to suppress DO during UDS test may in and of itself be significant. For example, Osman (2003) showed that patients with mixed incontinence and a normal CMG (no DO) not only had excellent cure rates for stress incontinence but also had an 87% cure rate for urgency incontinence (compared with only 43% cure for urgency incontinence for women randomized to receive antimuscarinic medication instead of stress incontinence surgery).

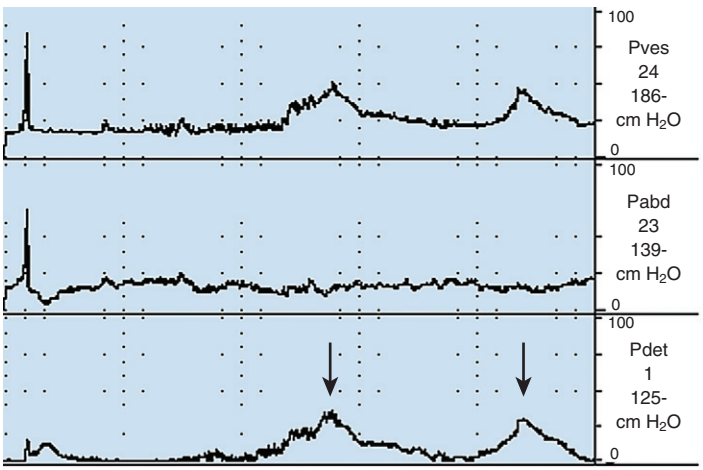

Figure 62–4. Detrusor overactivity. In this tracing there are two involuntary detrusor contractions *(arrows)*. There is a rise in Pves with no associated rise in Pabd, and therefore the subtracted Pdet looks identical to the Pves.

It is important that the person performing the UDS study be absolutely sure that the contraction is indeed involuntary. Sometimes a patient may become confused during the study and actually void as soon as the desire is felt. The volume at which contractions occur and the pressure of the contractions should be recorded. It is often worthwhile to repeat the CMG at a slower filling rate if the patient experiences uncharacteristic symptoms associated with DO. If the patient experiences incontinence during an involuntary contraction (DO incontinence), this should be noted.

In addition to the presence of DO, its characteristics can be noted. DO can be observed as a single event or as multiple IDCs. It can be phasic (continuous), sporadic, or terminal (occurring at the end of filling near capacity). It can also be suppressed or nonabortable and may lead to leakage or precipitant micturition. Classifying DO in such a way can be valuable in certain circumstances. For example, overactivity bladder symptoms associated with obstruction have been shown to have a higher likelihood of resolving with intervention (e.g., transurethral resection of the prostate [TURP]) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al, 2000).

The viscoelastic properties of the bladder, on the basis of its composition of smooth muscle, collagen, and elastin, normally produce a highly compliant structure. Therefore as the bladder fills there is little change in pressure (**see normalized CMG** Fig. 62–3). **Compliance** is the relationship between change in bladder volume and change in detrusor pressure (Δ volume/Δ pressure) and is measured in mL/cm H_2O. The ICS recommends two standard points, the Pdet at the start of bladder filling (usually zero) and the Pdet at cystometric capacity or before the start of any detrusor contraction that results in significant leakage (Abrams et al, 2002). Both points are measured excluding any detrusor contractions. **It is difficult to define what "normal compliance" is in terms of mL/cm H_2O.** Several authors have shown that mean values for compliance in healthy subjects range from 46 to 124 mL/cm H_2O (Sorensen et al, 1988; van Waalwijk van Doorn et al, 1992; Hosker, 2004). However, there is great variation. For example, van Waalwijk van Doorn and colleagues (1992) showed a variation of compliance from 11 to 150 mL/cm H_2O (mean 46) in 17 healthy subjects. Some of the variation in "normal" is likely due to the fact that compliance per se is dependent on bladder capacity. Furthermore, various definitions of impaired compliance have been used (e.g., between 10 and 20 mL/cm H_2O); however, there is no consistent definition based on mL/cm H_2O. Stohrer and colleagues (1999) suggest that a value of less than 20 mL/cm H_2O is consistent with impaired compliance and implies a poorly

accommodating bladder. However, examples in which this may not be the case can be cited (e.g., small cystometric capacity). Therefore **in practical terms, absolute pressure is probably more useful than a "compliance number" or value.** For example, it has been shown that storage greater than 40 cm H_2O is associated with harmful effects on the upper tracts (McGuire et al, 1981) (Fig. 62–5). Also, depending on the clinical scenario, a particular compliance in terms of mL/cm H_2O can mean different things (Fig. 62–6). As a general rule, **prolonged storage at high pressures can lead to upper tract deterioration.** Elevated storage pressures and impaired compliance should be interpreted in the context of the clinical scenario. It appears that **conventional cystometry may provoke filling pressures higher than natural filling in some cases.** Robertson (1999) showed that for six patients with neuropathic bladder and severely impaired compliance on conventional cystometry, compliance was actually normal on ambulatory monitoring with natural filling.

Impaired compliance is seen in a variety of neurologic conditions (spinal cord injury/lesion, spina bifida) and usually results from increased outlet resistance (e.g., detrusor-external sphincter dyssynergia [DESD]) or decentralization in the case of lower motor neuron lesions. It can also result from long-term bladder outlet obstruction (e.g., BPH) (Leng and McGuire, 2003) or structural changes like radiation cystitis or tuberculosis.

The measurement of compliance can be affected by a number of factors. Sometimes an increase in Pdet during cystometry is seen as a result of rapid filling (filling during cystometry is almost always faster than physiologic filling). This is more of an accommodation problem rather than a true decrease in compliance. When Pdet is seen to be rising, filling may be stopped or reduced to see if the effect is real. An IDC, particularly if it is of sustained and low amplitude, can be confused with impaired compliance. If filling is stopped and the pressure returns to baseline, then the compliance is not impaired. Finally, a number of "pop-off" mechanisms can make compliance seem better than it actually is. Vesicoureteral reflux and bladder diverticulum are two examples. With reflux, pressure is actually transferred to the refluxing renal unit and may be harmful. The author has seen instances where the upper tract holds more urine than the bladder. VUDS (see later) is useful in these cases. Because a bladder diverticulum is actually part of the bladder, it may provide a protective effect for the upper tracts. Finally, an incompetent outlet may be a pop-off mechanism. This may only become apparent when outlet resistance is increased, which can be done during cystometry by occluding the outlet but may not be seen until the outlet resistance is surgically increased (e.g., with an artificial urinary sphincter or sling procedure).

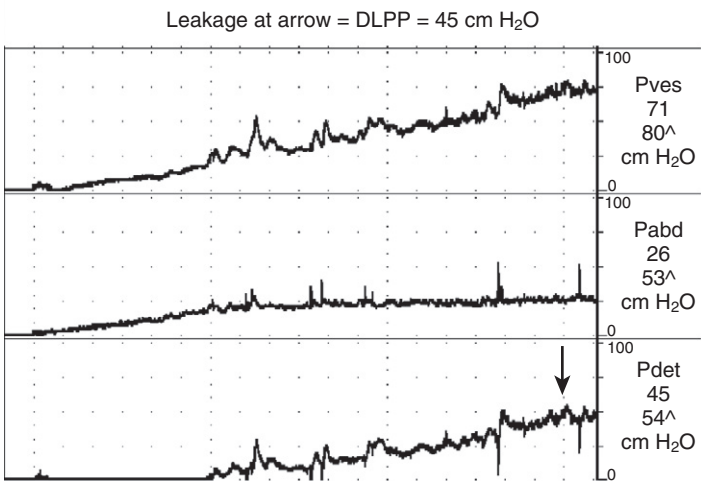

Figure 62–5. Impaired compliance. Note the rise in Pves (and Pdet) with bladder filling. The Pdet at the end of filling is approximately 45 cm H_2O, which is a potentially dangerous situation. In this case the bladder was filled to a volume of 300 mL, so the compliance is 6.67 mL/cm H_2O. The *arrow* is the point at which incontinence was demonstrated, which is the detrusor leak point pressure (DLPP).

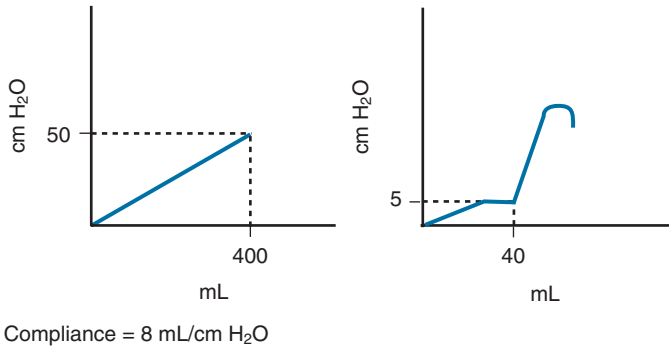

Figure 62–6. A problem with measuring compliance. Shown are two theoretical cystometrograms. The one on the left demonstrates impaired compliance with a constant rise in Pdet throughout filling. At 400 mL the Pdet is 50 cm H_2O (8 mL/cm H_2O), a dangerous situation. There is significant storage time where the det is greater than 40 cm H_2O. The CMG on the right could represent a small-capacity bladder with DO and precipitant micturition. At a volume of only 40 mL, an IDC occurs. The Pdet just before this was only 5 cm H_2O. The calculated compliance would be 6 mL/cm H_2O, the same as the one on the left. Yet the CMG on the right does not demonstrate a dangerous situation, just a highly symptomatic (incontinent) patient.

Key Points: Abnormalities of Bladder Filling

- DO is often a significant UDS finding and may explain a number of storage symptoms.
- In addition to its presence, the characteristics of DO should be noted.
- It is also important that clinicians recognize normal test-retest variation and also that "usual lower urinary tract behavior" is not always replicated in the test setting.
- Impaired compliance with prolonged elevated storage pressures is a urodynamic risk factor and usually needs to be treated to prevent renal damage.

Leak Point Pressures

Two distinct types of leak point pressures can be measured in the incontinent patient: abdominal leak point pressure (ALPP) and detrusor leak point pressure (DLPP). The two are independent of each other and conceptually measure completely different things.

ALPP is a measure of sphincteric strength or the ability of the sphincter to resist changes in abdominal pressure (McGuire et al, 1993). **ALPP is defined as the intravesical pressure at which urine leakage occurs due to increased**

abdominal pressure in the absence of a detrusor contraction (Abrams et al, 2002). **This measure of intrinsic urethral function is applicable to patients with stress incontinence. An ALPP can only be demonstrated in a patient with stress urinary incontinence (SUI). Conceptually, the lower the ALPP, the weaker the sphincter. There is no normal ALPP because patients without stress incontinence will not leak any physiologic abdominal pressure. ALPP should be measured as the total abdominal pressure required to cause leakage, not the change in pressure** (McGuire et al, 1993). Therefore if ALPP is measured in the standing position, it should include the baseline Pabd (or Pves), which is usually about 20 to 40 cm H_2O. Classically, **the reading is taken from the Pves channel as long as there is no involuntary contraction** (Fig. 62–7). In cases where patients do not leak with a urethral catheter in place, the ALPP can be measured from the abdominal pressure channel either rectally or vaginally (Stohrer et al, 1999). The original description of ALPP was done at an arbitrary bladder volume of 150 milliliters; however, in some cases it is necessary to fill the bladder more. The volume at which ALPP is determined should be noted as some investigators have found that it decreases at higher volumes (Faerber and Vashi, 1998). As a general rule, one should start testing at 150 mL and then every 50 mL thereafter until SUI is demonstrated. If there is no SUI demonstrated at capacity, the urethral catheter is removed and ALPP is measured via the rectal catheter (provided there is no increase in Pdet from DO or impaired compliance).

Attempts have been made to quantify intrinsic sphincter deficiency (ISD) in women using ALPP. In 1993 McGuire and colleagues measured ALPP in 125 women with SUI. When the ALPP was less than 60 cm H_2O, all patients had high-grade incontinence with 81% having continuous leakage and 75% having a fixed urethra (no urethral hypermobility). When ALPP was between 61 and 89 cm H_2O, 80% had pronounced urethral hypermobility and moderate to high-grade incontinence. When ALPP was greater than 90 cm H_2O, patients had lesser grades of incontinence and minimal to gross urethral hypermobility. The inferences are that:

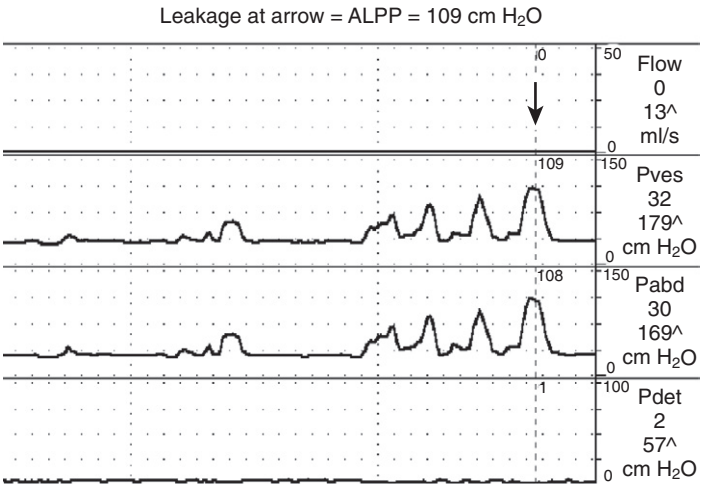

Figure 62–7. Abdominal leak point pressure measurement. After progressive Valsalva maneuvers, leakage is demonstrated on the last one at 109 cm H_2O *(arrow)*. There is no rise in Pdet.

ALPP less than 60 cm H_2O signifies ISD.
ALPP between 60 and 90 cm H_2O is equivocal (there is a component of ISD).
ALPP greater than 90 cm H_2O indicates little or no ISD.

Current technology does not permit a method to distinguish between ISD in the face of urethral hypermobility in women. Therefore although these ALPP values are often used as guidelines, **they should be interpreted with caution.** For example, **if there is no urethral hypermobility, SUI must be caused by ISD, regardless of the ALPP**. Furthermore, Fleischmann and colleagues (2003) found that urethral hypermobility was equally common in women with lower versus higher ALPP. ISD and urethral hypermobility may coexist, and they do not define discrete classes of patients with stress urinary incontinence. Thus an isolated measure of ALPP without considering other factors such as cystometry and urethral mobility is of limited utility in predicting success for commonly performed female SUI procedures (Hosker et al, 2009).

The term *ALPP* has been used interchangeably with "Valsalva" leak point pressure (VLPP); however, this is not entirely correct. An ALPP can be measured during UDS testing by a voluntary Valsalva maneuver (VLPP) or by a cough (cough leak point pressure or CLPP). In the same person, **VLPP tends to be significantly lower than CLPP.** Therefore exact terminology and methods should be used when describing an ALPP. ALPP can also be influenced by the presence or the size of a urethral catheter (Bump et al, 1995; Huckabay et al, 2005; Türker et al, 2010). It has been shown in women with SUI that the larger the catheter, the lower the ALPP. ALPP can also be measured without a urethral catheter by assessing the abdominal pressure via a rectal (or vaginal) catheter. It has been shown that 15% of women with SUI (Türker et al, 2010) and 35% of men with postprostatectomy SUI (Huckabay et al, 2005) will demonstrate an ALPP only with the urethral catheter removed.

The second type of leak point pressure is the detrusor leak point pressure (DLPP), which is a measure of detrusor pressure in patients with decreased bladder compliance. It is defined as the lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure (Abrams et al, 2002) (see Fig. 62–5). The higher the urethral resistance, the higher the DLPP. One can imagine that in a poorly compliant bladder, if outlet resistance is low, incontinence will occur at a relatively low or "safe" pressure. However, if outlet resistance is high, the pressure in the bladder will continue to increase as the bladder fills. There is potentially less incontinence, but eventually the pressure is transmitted to the upper tracts (Fig. 62–8).

From a clinical perspective, DLPP is most useful in patients with lower motor neuron disease causing "decentralization" and in non-neurogenic patients with low bladder compliance (after multiple bladder surgeries, radiation, and tuberculous cystitis). The higher the DLPP, the more likely is upper tract damage because intravesical pressure is transferred to the kidneys. McGuire (1981) documented the deleterious effects that a detrusor high-leak point pressure has on the upper urinary tracts; **detrusor leak point pressures greater than 40 cm H_2O result in hydronephrosis or vesicoureteral reflux in 85% of myelodysplastic patients.**

The significance of an elevated DLPP is that bladder pressures are getting too high before the "pop-off" mechanism of urethral leakage occurs. In most cases treatment is aimed at lowering bladder pressures, so the DLPP is never reached. In some cases

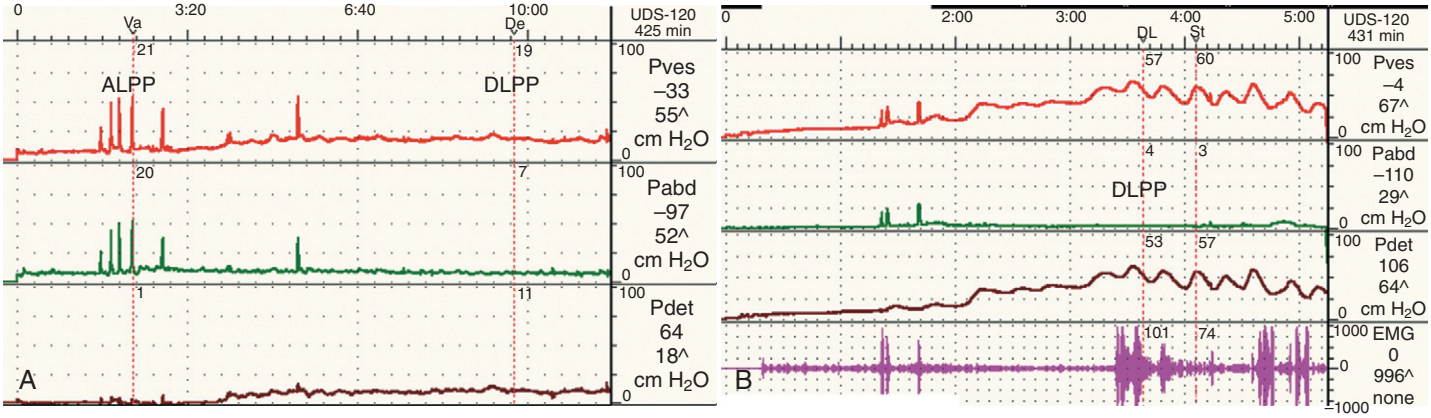

Figure 62–8. Outlet resistance causes impaired compliance. Urodynamic (UDS) studies of two children with the same neurologic problem and symptoms but dramatically different findings. **A**, UDS tracing of a young boy with spina bifida who is incontinent in between catheterizations. The study shows a low-pressure system with poor outlet resistance and stress incontinence (ALPP demonstrated) and a low DLPP. His upper tracts are protected. **B**, UDS tracing of a young girl with spina bifida who is incontinent in between catheterizations. The study shows a high-pressure system with strong outlet resistance and a high DLPP. There was no stress incontinence. Her upper tracts are at risk. The difference in these two cases is difference in storage pressures caused by the difference in outlet resistance.

DLPP can be lowered by decreasing outlet resistance, for example, with a sphincterotomy in a patient with DESD.

Key Point: Leak Point Pressures

- ALPP and DLPP, although both called "leak point pressure," are completely different. The ALPP measures the sphincter response to increased abdominal pressure. The lower the ALPP, the "weaker" the sphincter. The DLPP measures the injured bladder response to increased outlet resistance. The higher the resistance (e.g., detrusor-external sphincter dyssynergia), the higher the DLPP, which is potentially dangerous to the upper tracts.

Stress-Induced Detrusor Overactivity

Sometimes detrusor overactivity can be triggered by a rise in abdominal pressure (Fig. 62–9). Thus the symptom may appear to be stress incontinence, but the condition causing the symptom is actually an involuntary contraction, not sphincteric weakness. In a patient with stress-induced detrusor overactivity (SIDO), it is important to note if there is also urodynamic SUI and/or DO independent of the SIDO.

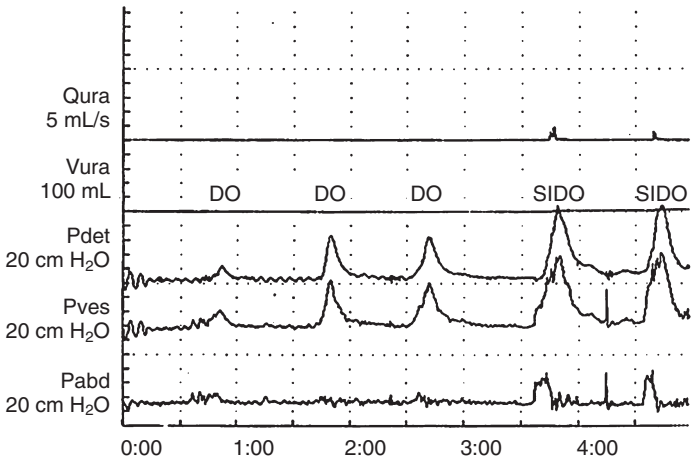

Figure 62–9. Stress-induced detrusor overactivity. In this case, there are three episodes of detrusor overreactivity (DO) preceding two episodes of stress-induced DO (SIDO). In the case of SIDO, note that as Pabd increases, so does Pves. Shortly *after* this, Pdet rises and continues long after Pabd returns to baseline. With both episodes of stress-induced instability, incontinence occurred, as can be seen on the flow (Qura) curve. (From Nitti VW: Cystometry and abdominal pressure monitoring. In Nitti VW, editor. Practical urodynamics. Philadelphia: WB Saunders; 1998. p. 38–51.)

Occult Stress Incontinence

Stress incontinence that is demonstrated in a clinically continent woman with pelvic prolapse, only when the prolapse is reduced, is referred to as *occult incontinence* (Ballert et al, 2009). Prolapse reduction can be done with a pessary, a packing, a forceps, or manually. Technically, if this is demonstrated during urodynamic testing, it may be referred to as *urodynamic occult SUI.*

Urethral Pressure Profilometry

The method of urethral pressure profilometry (UPP) was popularized by Brown and Wickman in 1969 using a small catheter with lateral apertures. Fluid is continuously infused through this type of catheter. Simultaneous bladder and urethral pressure is measured as the catheter is slowly withdrawn along the course of the urethra. The urethral pressure transducer measures the fluid pressure required to lift the urethral wall off the catheter side holes and thus elevates the circumferential and radial stresses induced by the presence of the catheter in the urethra and the slow urethral profusion. **Thus urethral pressure is defined as the fluid pressure needed to just open a closed urethra** (Abrams et al, 2002). Accurate measurements are recorded only in those cases in which the urethra is distensible and therefore able to create a perfect seal.

Despite an abundant literature on urethral profilometry, **its clinical relevance is controversial.** Many urologists do not routinely perform urethral profilometry. The urethral pressure profile (UPP) represents the intraluminal pressure along the length of the urethra in graphic form (Fig. 62–10). Several parameters can be obtained from the UPP:

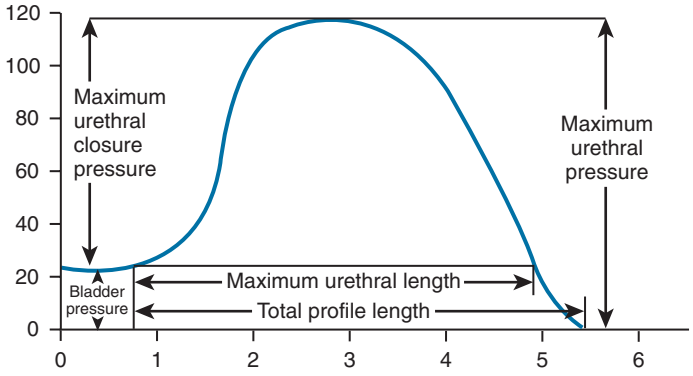

Figure 62–10. Urethral pressure profile with appropriate parameters identified.

The urethral closure pressure profile (UCP) is given by the subtraction of intravesical pressure from urethral pressure.

Maximum urethral pressure (MUP) is the highest pressure measured along the UPP.

Maximum urethral closure pressure (MUCP) is the maximum difference between the urethral pressure and the intravesical pressure.

Functional profile length is the length of the urethra along which the urethral pressure exceeds intravesical pressure in women.

In most continent women, the functional urethral length is approximately 3 cm and the MUCP is 40 to 60 cm H_2O, but normal values vary widely. MUCP has also been used to define ISD. McGuire (1981) performed a retrospective evaluation of women who failed SUI surgery and found that a preoperative MUCP less than 20 cm H_2O resulted in higher surgical failure rates. These patients represented a specific subtype of SUI caused by a fixed, open urethra (type III SUI). In 1992 the term was redefined as *ISD*. **Many authors have used the definition of MUCP less than 20 to define ISD; however, this definition has many of the same problems as ISD definitions for ALPP.** Another caveat of UPP is that its measurement does not diagnose stress incontinence and SUI is not required to measure it (contrary to ALPP). MUCP in incontinent women has been shown to be lower than in continent women, but there is certainly overlap (Schick et al, 2004). In addition, MUCP is not always indicative of the severity of incontinence. For example, there is a difference between the urethra of an incontinent patient whose MUCP equals 38 cm H_2O and that of a continent woman with the same MUCP.

In 2002 the ICS standardization subcommittee concluded that the clinical utility of urethral pressure measurement is unclear (Lose et al, 2002). **Furthermore, there are no urethral pressure measurements that (1) discriminate urethral incompetence from other disorders; (2) provide a measure of the severity of the condition; and (3) provide a reliable indicator to surgical success and return to normal after surgical intervention** (Lose et al, 2002).

VOIDING AND EMPTYING PHASE

Normal Voiding and Emptying

Evaluation of the voiding phase provides an assessment of both detrusor contractility and bladder outlet resistance, the two parameters that are critical for normal bladder emptying. In simple terms, abnormalities of bladder emptying are caused by too much outlet resistance, inadequate (strength or duration) bladder contractility, or a combination of both. The simultaneous measurement of detrusor pressure and urinary flow rate during voluntary voiding, known as a PFS, is the most accurate way to access these two critical parameters (Fig. 62–11).

In order to understand the relationship between bladder contractility and outlet resistance, one must start with an understanding of the normal micturition process. Normal voiding is accomplished by activation of the micturition reflex, which involves the following (Fig. 62–12):

1. Relaxation of striated urethral sphincter
2. Contraction of detrusor muscle
3. Opening of vesical neck and urethra
4. Onset of urine flow

This occurs as a result of coordination between pontine and sacral micturition centers with suprapontine input, which allows for voluntary control of the micturition reflex.

UDS can evaluate the critical parameters during the voiding phase: detrusor contractility, relaxation of the bladder outlet, and coordination of sphincters (Fig. 62–13).

According to the ICS, *normal detrusor function* is characterized by a voluntarily initiated continuous contraction that leads to complete bladder emptying within a normal time span, and in the absence of obstruction. *Detrusor underactivity* is defined as a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span. Finally, an *acontractile detrusor* is when there is no demonstrable contraction during UDS (Abrams et al, 2002). Normal detrusor function and detrusor underactivity are "nebulously defined" in terms of absolute pressure because that will depend on outlet resistance. When evaluating detrusor function urodynamically, UDS must be correlated with clinical findings. For example, if a patient who normally voids is unable to void during a UDS study, one cannot make a definitive diagnosis of "acontractile detrusor."

Urinary flow rate in combination with PVR is a useful clinical tool to assess emptying. When flow rate is reduced or PVR is elevated, it tells us that emptying is not complete but does not tell us why (e.g., obstruction vs. impaired contractility). Flow rate also depends on voided volume because there is a linear relationship between Q_{max} and voided volume with a voided volume above and a hyperbolic relationship below a voided volume of 150 mL (Drach et al, 1979). Therefore many authors have recommended a minimum voided volume of 150 mL to accurately assess uroflow. However, establishing a minimum voided volume puts major limitations on uroflowmetry because many patients with voiding dysfunction do not routinely void large enough volumes to be evaluable. The corrected form of Q_{max}, Q_{max} divided by the square root of voided volume, may provide useful information in such patients (Boone and Kim, 1998). Over the years several nomograms have been developed to define normal flow rates for a specified population and correct for voided volume. These include the Siroky nomogram (Siroky et al, 1979, 1980) for men and the Liverpool nomogram (Haylen et al, 1989) for men and women.

The bethanechol supersensitivity test has been used to help distinguish the cause of detrusor underactivity as neurogenic or myogenic. It is based on the Cannon theory of denervation, which states that denervated structures develop increased sensitivity to chemical stimulation. This concept was applied to the bladder by Lapides and colleagues (1962). The original

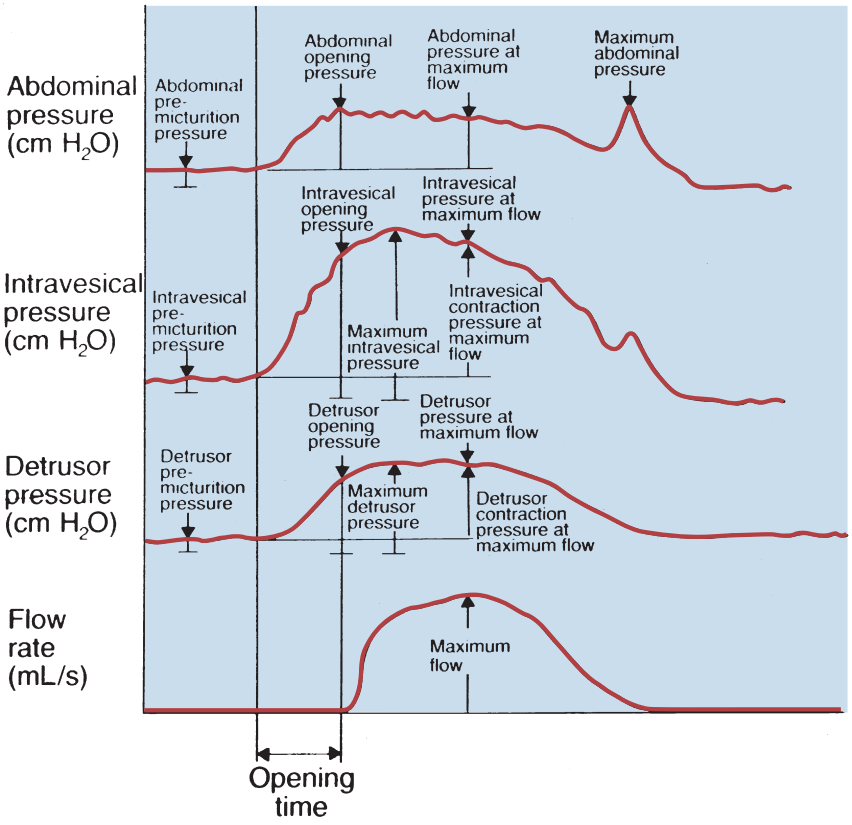

Figure 62–11. Schematic pressure-flow study labeled with recommended terminology.

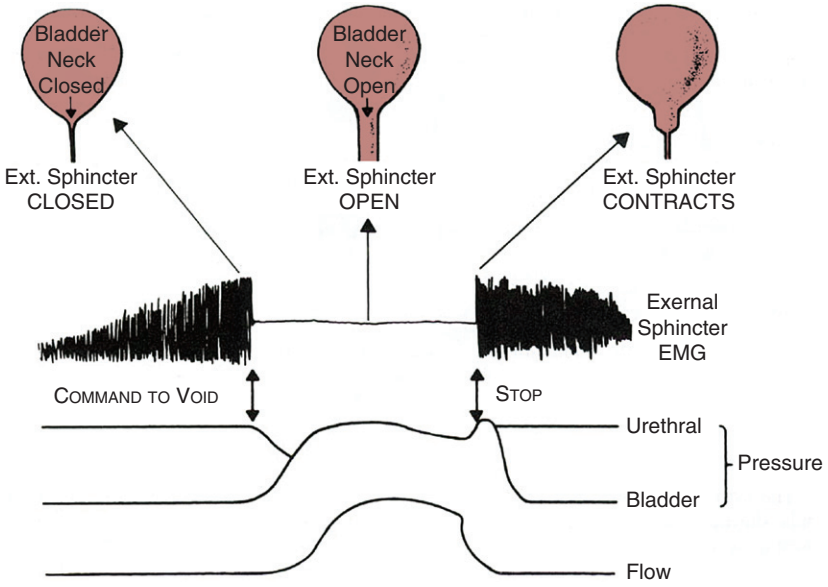

Figure 62–12. Physiology of micturition. See text for details. (From Blaivas JG. Pathophysiology of lower urinary tract dysfunction. Clin Obstet Gynecol 1885;12:295–309.)

bethanechol supersensitivity test described by these authors was performed by infusing liquid at a rate of 1 mL/sec to a volume of 100 mL, where the pressure is measured. This can be done up to three times, and the pressure values averaged. The patient is then given 2.5 mg of bethanechol chloride (later revised to 0.035 mg/kg) subcutaneously, and the study is repeated at 10, 20, and 30 minutes. A normal bladder (or myogenically impaired bladder) should show an increase of less than 15 cm H_2O above control value at 100 mL at 30 minutes. This is considered a negative study. A positive study, indicating a sensory or motor paralytic bladder, is a response of at least 15 cm H_2O above the control value. More recent studies have indicated that the bethanechol supersensitivity test is rather unreliable in predicting "neurogenic bladder." Blaivas and colleagues (1980) reported only 76% sensitivity and 50% specificity in doing this. Another problem is that even if the test is able to differentiate between neurogenic and myogenic dysfunction, treatment is often the same (e.g., clean intermittent catheterization). Bethanechol chloride, whether administered subcutaneously or orally, has not proved to be a consistently effective treatment for the underactive detrusor (Wein et al, 1978, 1980). In addition, a positive test does not predict improved voiding when it is used therapeutically**. Therefore we feel that there is a limited role for the use of the bethanechol supersensitivity test**.

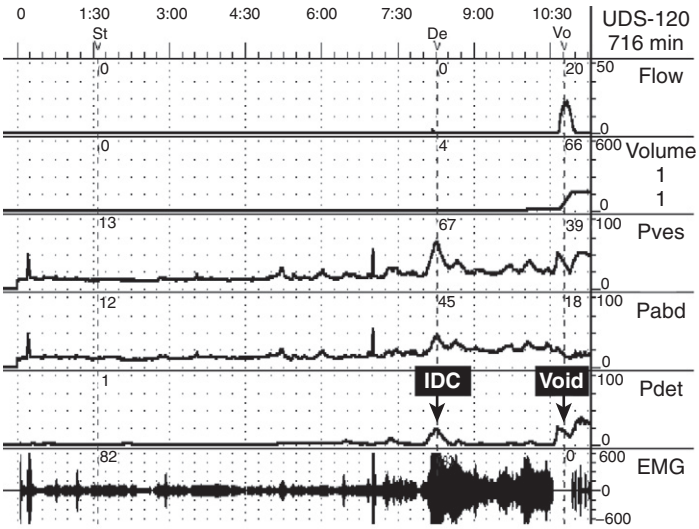

Figure 62–13. Multichannel urodynamics study showing filling and voiding phases with pressure and electromyography (EMG) readings. In this case, the patient experienced an involuntary detrusor contraction (IDC) that led to increased external sphincter contraction and an increase in EMG activity (guarding reflex). However, shortly after that the patient is given permission to void. First there is quieting of the EMG (sphincter relaxation) followed by an increase in Pdet and volitional voiding with a normal-appearing uroflow curve.

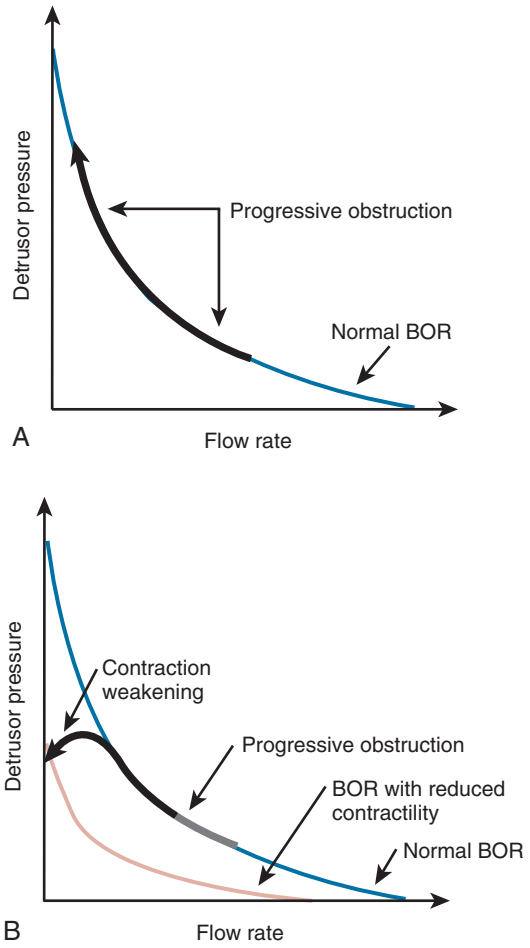

Figure 62–14. **A** and **B**, Relationship between detrusor pressure and flow in a given person—the bladder outlet relation (BOR). See text for details. (From Griffiths DJ. The mechanics of the urethra and of micturition. Br J Urol 1973;45:497–507.)

Pressure-Flow Relation

As mentioned previously, detrusor pressure during voiding is a function of outlet resistance. For a normal detrusor, the greater the outlet resistance is, the higher the detrusor pressure during voiding will be. This is accompanied by a reduced flow rate. A healthy bladder is able to overcome obstruction by contracting more forcefully. Although the flow may be slower, the bladder can empty itself. Over time, the detrusor may decompensate and no longer be able to generate the necessary pressure to overcome obstruction. When this occurs, the result will be incomplete bladder emptying or retention of urine. **Thus the urodynamic manifestation of bladder outlet obstruction (BOO) is high-pressure and low-flow voiding** (or more practically speaking, increased pressure and reduced flow). Over time, if bladder decompensation results, detrusor underactivity or impaired contractility can result.

In order to use the common measures of obstruction and impaired contractility that are used today, it is important to understand basic bladder output and urethral resistance relations. Attempts to mathematically define urethral resistance date back to 1962 (Gleason and Lattimer). Early equations calculating urethral resistance followed standard hydrodynamic formulas calculating outlet resistance. These concepts failed to consider that the urethra is not a rigid tube but rather has an active and a distensible nature. They also failed to consider the importance of bladder volume. Rigid tube hydrodynamics were abandoned in favor of more dynamic ways to analyze micturition. In 1972 Griffiths introduced Bladder Output Relation (BOR), which depicts the interrelations between bladder pressure and uroflow at a given volume and essentially measures the function of the bladder independent of the function of the urethra. Griffiths further defined a method to evaluate urethral resistance independent of bladder function, the urethral resistance relation (URR). According to this relation, as bladder pressure rises the flow rate will be zero until the intrinsic bladder pressure equals the intrinsic urethral pressure. At this point flow will start and the flow rate will rise rapidly with further increases in the intrinsic bladder pressure. If pairs of simultaneously measured values of detrusor pressure and flow rate are plotted against one another throughout the course of a micturition event, a curve is obtained. The curve shows the resistance to flow independent of detrusor function, representing the urethral resistance relation. If the urethra were relaxed or tightened during voiding, the URR would move toward the left or right, respectively. Because the BOR represents the function of the bladder independent of the urethra and the URR depicts urethral function independent of bladder function, the actual detrusor pressure and flow rate are determined by the intersection of the bladder output relation and the urethral resistance relation, which is the point at which intrinsic bladder pressure equals urethral pressure (Fig. 62–14). A change in one of these relations during micturition would not affect the curve representing the other relation but would result in the point of intersection to moving along that curve.

Bladder Outlet Obstruction in Men

The value of making a precise diagnosis of obstruction in men comes from the assumption that the outcomes of surgery to treat

benign prostatic hyperplasia (BPH) and its consequent lower urinary tract symptoms (LUTS) are improved when obstruction can be documented. Because BPH and benign prostatic obstruction (BPO) are highly prevalent conditions, it was intuitive to use them as a model for defining obstruction. Most of the analytic work has focused on defining obstruction-based PFS. Three well-known nomograms based on PFS have been described to diagnose men as obstructed, equivocal, or unobstructed. These are the Abrams Griffiths nomogram (Abrams and Griffiths, 1979); the Urethra Resistance Factor (URF) (Griffiths et al, 1989); and the Linear Passive Urethral Resistance Relation or Schafer nomogram (Schafer, 1990). The categories of obstruction described in these nomograms are based on observations of men who underwent surgery for LUTS (mainly transurethral resection of the prostate, TURP). After surgery, the detrusor pressure at maximum flow ($PdetQ_{max}$) was reduced in the obstructed group, reduced unpredictably in the equivocal group, and unchanged in the unobstructed group. Subsequently, Lim and Abrams (1995) showed that patients were similarly classified by all three methods. **They described a number, the AG number (now known as the bladder outlet obstruction index [BOOI]), derived from the equation for the slope of the line dividing obstructed from equivocal in the Abrams Griffiths nomogram, which is the same line dividing obstructed from slightly obstructed in the Schafer nomogram: BOOI = $PdetQ_{max} - 2(Q_{max})$. Subsequently, Griffiths and colleagues** (1997) (Fig. 62–15) **described the ICS provisional nomogram, which is now suggested for use in diagnosing obstruction in men with LUTS suggestive of BPH** (Abrams, 1999). **Men are considered obstructed if BOOI is greater than 40, unobstructed if BOO is less than 20, and equivocal if BOOI is 20 to 40.**

Voiding PFS show consistent reproducibility in the diagnosis of BOO in men. In a review of the topic, Abrams and colleagues (2001) concluded that random variations of about 9 to 14 cm H_2O in pressure measurement and about 0.4 to 2 mL/sec in maximum flow rate occur. In repeated studies during the same session there is usually a systematic decrease of up to 4 cm H_2O in detrusor pressure and 0.4 mL/sec in maximum flow rate. These variations have little clinical importance because they cause only 10% to 16% of patients to change classification on the ICS nomogram, and in all but about 1% that change is only by one class (e.g., from equivocal to unobstructed or from obstructed to equivocal).

Although much effort has focused on defining outlet resistance (i.e., obstruction), an index for bladder contractility can also be derived from the contractility groups Schafer (1995) described (strong, normal, weak, very weak). The **slope of Schafer's lines, now known as the bladder contractility index (BCI), is given by the formula: $PdetQ_{max} + 5(Q_{max})$** (Abrams, 1999). **Strong contractility is a BCI greater than 150, normal contractility a BCI of 100 to 150, and weak contractility a BCI of less than 100** (Fig. 62–16).

Although contractility and obstruction can be independently measured, it is sometimes difficult to diagnosis obstruction in the face of impaired contractility using the ICS or other nomograms. For example, in order to make a diagnosis of unequivocal obstruction, BOOI must be at least 40 cm H_2O. That means that a Pdet of at least 40 cm H_2O must be generated and that assumes flow is zero. If the Q_{max} is 5 mL/sec, then $PdetQ_{max}$ must be at least 50 cm H_2O. Thus the ICS nomogram can exclude obstructed patients whose impaired contractility is the result of long term obstruction. In such cases, clinical judgment becomes important.

BOO is associated with abnormalities of storage as well. This is presumably due to changes in ultrastructure that occur with obstruction. Detrusor overactivity and impaired compliance occur in conjunction with obstruction. For example, about two thirds of men with symptomatic BPO have DO that resolves 50% to 67% of the time with treatment of obstruction (Abrams et al, 1979). Reduced compliance is also associated with obstruction and has been shown to improve with treatment of obstruction (TURP) (Leng and McGuire, 2003).

An alternative to voiding PFS as a way of measuring outlet resistance is the **micturitional urethral pressure profile** (MUPP), or voiding profilometry. This technique, popularized by Yalla, can both diagnose and localize obstruction (Yalla et al, 1980, 1981). The MUPP is performed with a triple-lumen catheter under fluoroscopic guidance similar to the static UPP described earlier. During voiding the catheter is slowly withdrawn and the pressure is measured from the bladder neck through the anterior urethra (Steele et al, 1998). Normally during voiding, the pressure in the bladder is isobaric with the prostatic urethra and then pressure decreases across the membranous urethra and gradually decays along the rest of the anterior urethra. The membranous urethra is the narrowest segment of the bladder outlet during voiding, which accounts for the expected pressure drop of 20 to 30 cm H_2O. In patients with obstruction secondary to BPH, the MUPP is quite different. One will typically see a pressure disparity somewhere along the prostatic urethra. When this pressure disparity is greater than 5 cm H_2O, obstruction at the point of pressure drop is present. MUPP has been shown to be as effective in diagnosing bladder outlet obstruction as standard pressure-flow studies (DuBeau et al, 1995). An analysis of symptomatic BPH patients has shown that

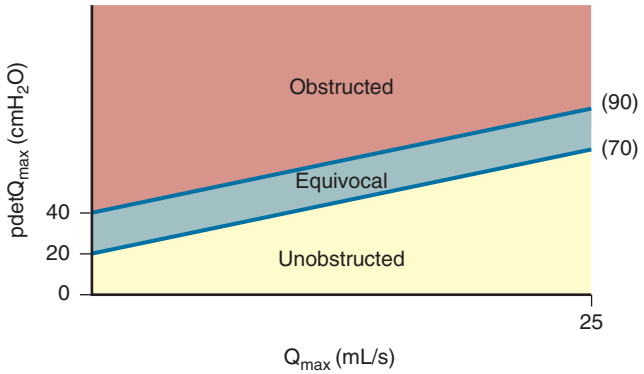

Figure 62–15. Provisional International Continence Society nomogram. See text for details.

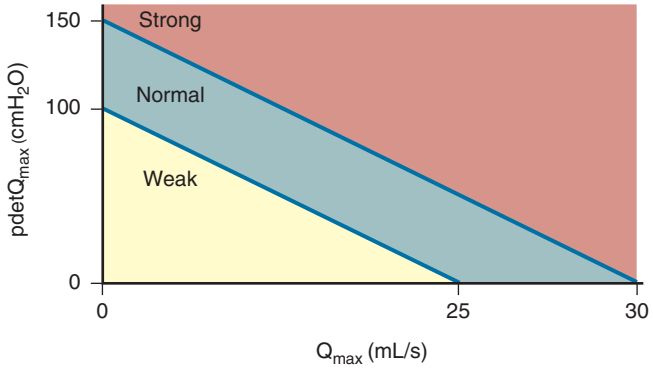

Figure 62–16. The Bladder Contractility Nomogram. See text for details.

successful treatment outcomes have been achieved with treatment based on MUPP results (Lecanwasam et al, 1994).

Bladder Outlet Obstruction in Women

Bladder outlet obstruction in women can present more of a diagnostic dilemma than in men. Because there is no highly prevalent condition (like BPH) that causes female obstruction, it is difficult to establish nomograms. Furthermore, nomograms derived for men cannot be applied to women because voiding dynamics differ. In addition, anatomic differences allow many women to empty their bladders by simply relaxing the pelvic floor, and some will augment voiding by abdominal straining. Minor elevations in detrusor pressure or decreases in flow rate, which might be considered insignificant in the male population, might signify BOO in women. Accordingly, clinicians must have a high index of suspicion on the basis of the presence of lower urinary tract symptoms, incomplete emptying, persistent urinary tract infections, and a history of anti-incontinence surgery, prolapse, or other conditions.

In an effort to develop cut-off values for pressure and flow for the diagnosis of obstruction in women, Chassagne and colleagues (1998) studied a group of "clinically obstructed women" (after incontinence surgery; secondary to cystocele; or "other etiologies") and compared them with a group of controls (women with stress incontinence). Using receiver operator (ROC) curve analysis, they found the optimum sensitivity and specificity for predicting obstruction was obtained with a Q_{max} less than 15 mL/sec and a $PdetQ_{max}$ of greater than 20 cm H_2O (74.3% sensitivity and 91.1% specificity). In 2000 with an expanded population, the authors (Lemack and Zimmern, 2000) revised this to Q_{max} = 11 mL/sec and $PdetQ_{max}$ = 21 cm H_2O as optimal for the selection of patients with BOO. In the most recent publication (Defreitas et al, 2004), these authors used normal asymptomatic women as the control group and found the highest sensitivity and specificity for predicting obstruction was obtained with **Q_{max} less than 12 mL/sec and $PdetQ_{max}$ greater than 25 cm H_2O**. These cut point studies have some limitations, namely that obstruction was predefined clinically and only patients with anatomic obstruction were included. Women with functional obstruction (e.g., from primary bladder neck obstruction or dysfunctional voiding) were not included in any of the cut point analyses. This would be a difficult group of women to define "clinically" without any testing.

In 1999 Nitti and colleagues showed that the addition of fluoroscopic imaging to urodynamics was helpful in diagnosing female BOO (see section on VUDS). In this study, patients were classified as obstructed if there was radiographic evidence of obstruction between the bladder neck and distal urethral in the presence of a sustained detrusor contraction of any magnitude. In addition to diagnosing BOO, it also localizes the site of obstruction and allows for the diagnosis of obstruction in the face of impaired contractility if indeed the site can be localized. **With both the video-urodynamic and cut point criteria there is a significant difference in mean Q_{max} and $PdetQ_{max}$ in the group of obstructed versus the group of unobstructed women, but there is a large overlap of values between obstructed and unobstructed patients. This demonstrates that absolute pressure and flow values are imprecise and that another parameter (e.g., radiographic or clinical evidence of obstruction) is necessary for diagnosis**.

Blaivas and Groutz (2000) presented a nomogram for defining female BOO. Citing the fact that in their series there was a significantly higher flow rate in the same woman without a catheter, they chose to use noninvasive flow rate in their nomogram. Also, because they found no statistical difference between $PdetQ_{max}$ and $Pdet_{max}$ in obstructed or unobstructed patients, they chose $Pdet_{max}$ as the pressure parameter. Using cluster analysis to classify patients with low- and moderate-grade obstruction, they formulated the nomogram. The nomogram places women into four zones: no, mild, moderate, and severe obstruction. An obvious criticism of the nomogram is that it is based on two separate voids (invasive and noninvasive), and one must assume that the pressure characteristics of the void are the same. Akikwala and colleagues (2006) compared the three methods of diagnosing BOO in women and found good concordance between the video-urodynamic and cut point criteria. They also noted that the Blaivas Groutz nomogram over diagnosed obstruction compared with the other two methods.

Obstruction in women cannot be defined by the ICS nomogram or the BOOI because these will grossly underestimate female BOO. This is because normally women void at much lower pressures than men, and therefore the obstructed female bladder outlet may not respond as dramatically (or at least with the same pressures) as in the male. Unfortunately there is no condition in women that causes BOO as commonly as BPO in men, and therefore creating a consistent standard is difficult. Thus concepts are the same (higher pressure and lower flow), but the values are different and less well defined. Those who are interested are referred to suggested readings (Nitti et al, 1999; Blaivas and Groutz, 2000; Defreitas et al, 2004; Akikwala et al, 2006).

Sphincter Coordination

External Sphincter. Normal voiding requires external sphincter relaxation followed by contraction of the detrusor. The external sphincter (and internal sphincter) should remain relaxed until voiding is complete. In normal voluntary voiding, a rise in detrusor pressure is preceded by a fall in urethral pressure and relaxation of the external sphincter as measured by electromyography (EMG). The sphincter and urethral pressure remain low during voiding and then increase when voiding is completed (Fig. 62–17). **Failure of the sphincter to relax or stay completely relaxed during micturition is abnormal** (Abrams et al, 2002). **Thus normally EMG activity decreases before a voluntary bladder contraction; however, it is not abnormal for EMG activity to increase with an involuntary contraction as part of a guarding reflex to inhibit the IDC** (see Fig. 62–11).

Several abnormalities are related to external sphincter relaxation (or lack thereof). **DESD occurs when there is an involuntary increase external sphincter associated with DO and also with voiding** (see Fig. 62–17). **It is caused by a neurologic lesion in the suprasacral spinal cord. DESD can produce profound changes as the detrusor involuntarily contracts against a relatively closed sphincter. This will result in high pressures and can even cause impaired bladder compliance over time. Because long periods of elevated detrusor pressure during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk** (McGuire et al, 1996; Kurzrock and Polse, 1998; Tanaka et al, 1999). **DESD may be considered a urodynamic risk factor for upper tract deterioration. True DESD only occurs when there is a known neurologic lesion above the sacral micturition center.** The higher the lesion, the more likely DESD will occur (Blaivas, 1982). If there is no neurologic lesion, then the "dyssynergia" is considered to be

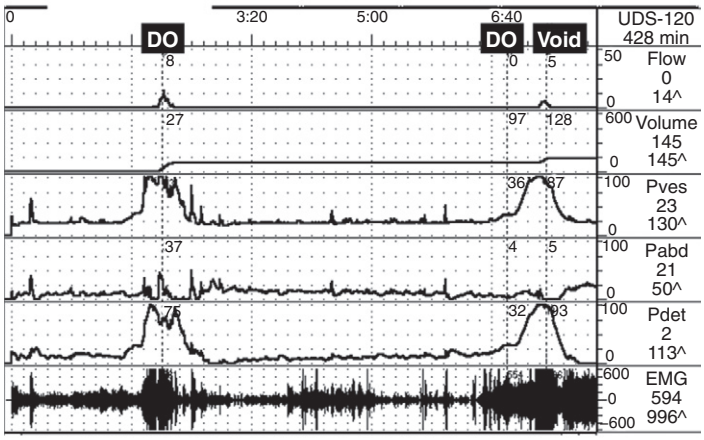

Figure 62–17. Urodynamic tracing of a patient with myelodysplasia and neurogenic detrusor overactivity (DO) and detrusor-external sphincter dyssynergia (DESD). Note the initial involuntary detrusor contraction associated with DESD and incontinence (measured on the flow channel). With refilling there is again DO with DESD. Then the patient is told to voluntarily void, and there is persistent increased electromyographic activity. As a result there is high-pressure, low-flow voiding (obstruction from the dyssynergic sphincter).

a learned behavior and is known as *dysfunctional voiding*. The term *dysfunctional* describes malfunction (failure to relax or involuntarily contraction of the external sphincter) during the voiding phase only and says nothing about the storage phase (Nevéus et al, 2006). However, it is entirely possible and quite common for a patient to experience storage symptoms (and UDS abnormalities) associated with dysfunctional voiding. Although the condition has been extensively described in children, it has also been described in adult men (Kaplan et al, 1997; Nitti et al, 2001; He et al, 2009) and women (Carlson et al, 2001) and can be a major cause of LUTS. It is recommended that when dysfunctional voiding is diagnosed by UDS, the flow pattern (reduced and/or intermittent) is confirmed by noninvasive uroflowmetry to rule out a test-induced phenomenon (Barrett and Wein, 1981; Carlson et al, 2001). He and colleagues (2010) used the following diagnostic criteria in men: nothing abnormal detected in the history and no symptoms on an examination for neurologic diseases; transient and intermittent closure of the external sphincter during voiding detected by EMG and fluoroscopic cystourethrography; a higher external sphincter EMG activity with no abdominal pressure increase in the voiding phase. Uroflowmetry was assessed individually to show any discontinuity in a diagram of urinary flow, in conditions with as little external interference as possible.

Internal Sphincter. Just as there can be a lack of coordination of the detrusor and external sphincter, so too can there be dyscoordination of the internal sphincter or bladder neck. In the case of neurologic disease, if a suprasacral spinal cord lesion is above the level of the sympathetic ganglia (T10-L1), detrusor-internal sphincter-dyssynergia may occur in conjunction with external sphincter dyssynergia (Pan et al, 2009). In non-neuropathic men, women, and children the phenomenon of bladder neck dyssynergia or primary bladder neck obstruction is a well-known cause of LUTS, although its exact etiology is not known (Diokno et al, 1984; Norlen and Blaivas, 1986; Combs et al, 2005). Conditions of internal sphincter dysfunction require VUDS for an exact diagnosis and are described later in the next section.

Key Points: Urodynamic Risk Factors

- The following urodynamics findings are potentially dangerous and usually require intervention to prevent upper and lower urinary tract decompensation:
  - Detrusor-external sphincter dyssynergia
  - Detrusor-internal sphincter dyssynergia
  - High-pressure detrusor overactivity present throughout filling
  - Elevated detrusor leak point pressure (>40 cm H_2O)
  - Poor emptying with high storage pressures
  - Impaired compliance

VIDEO-URODYNAMICS

VUDS consists of the simultaneous measurement of UDS parameters and imaging of the lower urinary tract. It provides the most precise evaluation of voiding function and dysfunction and is particularly useful when anatomic structure and function are important (Keane at al, 1993; McGuire et al, 1996). Examples of where VUDS are useful include the localization of obstruction, detecting incontinence not seen on physical examination, and evaluating vesicoureteral reflux during storage and/or voiding. It can be particularly useful in cases of neuropathic voiding dysfunction. VUDS is the only way to evaluate bladder neck dysfunction and can confirm sphincteric dysfunction diagnosed by EMG. Also, there are instances where a known anatomic abnormality exists and simultaneous imaging can determine if that abnormality is playing a role in voiding dysfunction (e.g., bladder or urethral diverticulum, vesicoureteral reflux).

VUDS can be performed using various different methods. Most commonly fluoroscopy is employed using a C-arm. This gives the most flexibility in allowing patient positioning. However, a fixed unit with a fluoroscopy table that can move from 90 to 180 degrees may also be used. It is important that the patient can be positioned properly to evaluate the desired function and anatomy. For example, SUI in men and women is best evaluated in the standing position. Voiding is best evaluated in the position that the patient characteristically voids (usually sitting for women and standing for men). It is always recommended that fluoroscopy time be limited and focus on situations of high yield such as during provocative maneuvers to demonstrate SUI, during rises in pressure associated with impaired compliance or involuntary contractions, and during voiding.

VUDS can be extremely useful for the diagnosis of bladder outlet obstruction in women (Nitti el al, 1999; Blaivas and Groutz, 2000). In fact, Nitti and colleagues (1999) described the VUDS criteria for the diagnosis obstruction in which radiographic evidence of obstruction between the bladder neck and urethral meatus during voluntary voiding defines and localizes obstruction. Primary bladder neck obstruction can only be diagnosed on VUDS. Figures 62–18 and 62–19 distinguish between the two most common causes of functional obstruction in women, primary bladder neck obstruction, and dysfunctional voiding.

Similarly, VUDS can be used to evaluate LUTS in young men and in particular make a diagnosis of primary bladder neck obstruction (Norlen and Blaivas, 1986; Kaplan et al, 1996). Although obstruction can be diagnosed by PFS alone, many surgeons would not feel comfortable performing surgical intervention on a young man without localizing that obstruction. In addition, sometime bladder neck obstruction can present without

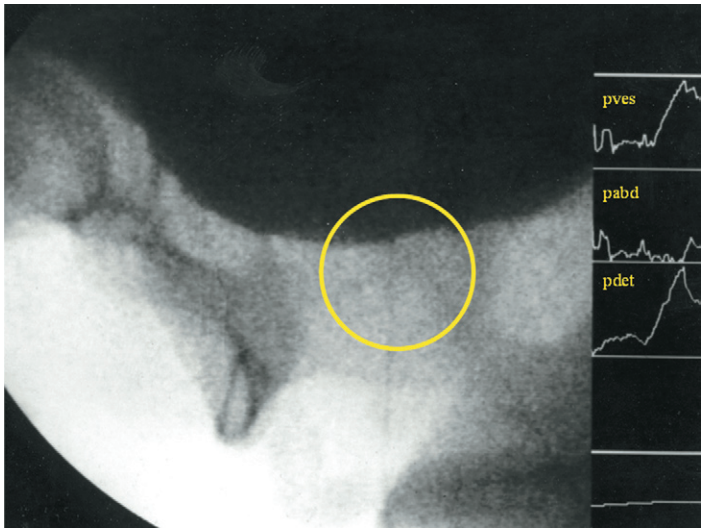

Figure 62–18. Primary bladder neck obstruction in a 35-year-old woman with obstructive voiding symptoms and intermittent urinary retention. Note the failure of the bladder neck to open at all, despite a detrusor contraction of greater than 60 cm H_2O. (From Nitti VW. Primary bladder neck obstruction in men and women. Rev Urol 2005;7[Suppl 8]:S12–7.)

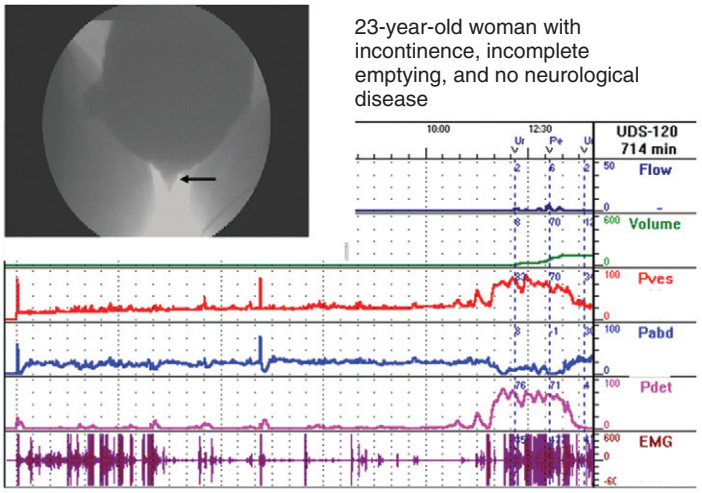

Figure 62–19. Dysfunctional voiding—a urodynamics study of a 23-year-old woman with urgency incontinence, incomplete emptying, and no neurologic disease. Just before voiding there is an involuntary detrusor contraction. With voiding there is increased EMG activity. The fluoroscopic picture taken during voiding shows a characteristic "spinning top urethra" with the level of obstruction at the external sphincter. The high-pressure–low-flow voiding is also characteristic of obstruction.

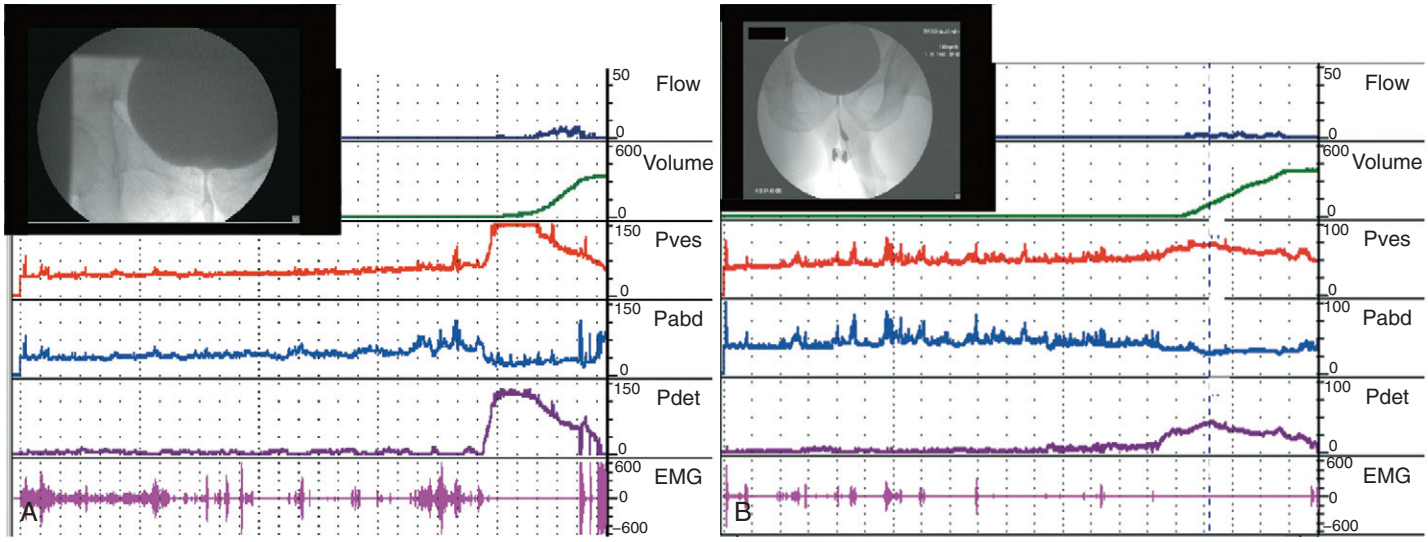

Figure 62–20. Primary bladder neck obstruction (dysfunction). **A**, Type 1—high-pressure, low-flow voiding in a 45-year-old male with severe lower urinary tract symptoms (LUTS) including frequency, urgency, and decreased force of stream. Image is taken during voiding—note the incompletely opened bladder neck. **B**, Type 2—normal-pressure, low-flow voiding in a 35-year-old male with similar LUTS as **A**. There is also an incompletely open bladder neck during voiding. The much lower voiding pressures compared with **A** should still be enough to empty normally, though there may be a component of impaired contractility because the bladder is unable to compensate for the increased resistance at the bladder neck. (From Nitti VW. Primary bladder neck obstruction in men and women. Rev Urol 2005;7[Suppl 8]:S12–7.)

classical findings of high pressure and low flow. Three distinct types have been described (Nitti et al, 2001): classic high pressure—low flow (type I); normal pressure—low flow with narrowing at the bladder neck (type II); and delayed opening of the bladder neck (type III). Figure 62–20 shows types I and II male primary bladder neck obstruction. Fluoroscopy is critical to the diagnosis, especially in types II and III.

VUDS is an important aid in diagnosing neuropathic voiding dysfunction, as well as other conditions that may cause elevated storage pressures. In cases where vesicoureteral reflux occurs, the volume and pressure at which it starts can be documented. In fact, in cases of impaired compliance, in which there is compensation by the "pop-off" mechanism of vesicoureteral reflux, the impaired compliance might not be identified unless the reflux is also recognized by fluoroscopy. In addition, an accurate DLPP can be obtained in cases where it would otherwise be impossible to position a patient to observe leakage (e.g., some tetraplegics). Furthermore, in cases of possible internal sphincter dyssynergia (often found in conjunction with external sphincter dyssynergia), VUDS is the only way to make the diagnosis and can dramatically change treatment (Fig. 62–21). The latest ICI recommendations (Hosker et al, 2009) include that VUDS be used, if possible, to evaluate patients with suspected neuropathic lower urinary tract dysfunction to "establish the state and function of the lower urinary

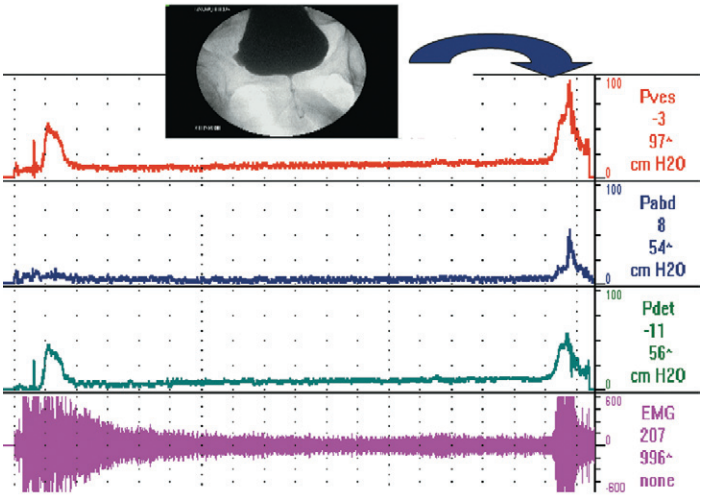

Figure 62–21. Video-urodynamics evaluation of a cervical spine–injured man with neuropathic voiding dysfunction with incontinence and incomplete emptying. The urodynamic tracing clearly shows detrusor overactivity with detrusor-external sphincter dyssynergia (increased electromyographic activity with involuntary contraction). However, it is only with the fluoroscopic view of the bladder outlet during an involuntary contraction that detrusor-internal sphincter dyssynergia is diagnosed (the bladder neck remains relatively closed).

tract." Although VUDS can be helpful in many cases, it is not readily available to all physicians.

Key Points: Video-Urodynamics

- VUDS is the procedure of choice for documenting bladder neck dysfunction in men and women.
- Patients at high risk for complicated voiding dysfunction such as those with known or suspected neuropathic voiding dysfunction, unexplained urinary retention in women, prior radical pelvic surgery, urinary diversion, prerenal or postrenal transplant, or prior pelvic radiation should be considered for referral to a center with VUDS capabilities if a complete and accurate diagnosis cannot otherwise be obtained (Scarpero, 2009).

AMBULATORY URODYNAMICS

Ambulatory urodynamic studies are defined as a functional test of the lower urinary tract, using natural filling and reproducing the subject's everyday activities (Abrams et al, 2002). The development of natural and slow-filling urodynamic studies was initially undertaken in the investigation of neuropathic patients by Comarr (1957) using diuresis-induced natural filling. He demonstrated an increase in bladder capacity and decreases in bladder pressures during filling when compared with CMG. Similar investigations of spinal injury patients by Tsiju and colleagues (1960) demonstrated increased phasic activity associated with incontinence during natural filling. Today it is a well-established method for investigating lower urinary tract function under the conditions of normal daily activities. Ambulatory UDS has its greatest value in patients in whom conventional UDS is not suitable or is unable to reproduce symptoms in question.

In 2000 the ICS published guidelines for the performance of ambulatory UDS (van Waalwijk van Doorn et al, 2000). Before the investigation, patients receive detailed information describing the test and the necessary preparation. Patients are instructed on how to accurately record symptoms and how to identify catheter displacement and hardware failure. A sample diary is given to record all relevant events so that UDS findings can be correlated with symptoms. Most systems employ microtip transducer catheters, which allow the most mobility. These are placed transurethrally to record bladder pressure and transrectally to record abdominal pressure. These catheters are firmly secured to the patient and are connected to a portable recording device. Some systems contain a third channel, which can be used for measuring urinary leakage objectively using an absorbent electronic (capacitance change) nappy pad (Robertson and Neil, 1998). This allows accurate data on the relationship of urinary leakage to detrusor activity to be obtained. Home uroflowmetry units are also available. After the completion of testing, ambulatory UDS tracings are analyzed, and this can be a time-consuming process depending on the length of the study. This must be done with great care and frequent quality checks to make sure that urethral and abdominal catheters are properly transducing pressure (e.g., using cough tests). In addition, the reader must be able to identify physiologic artifacts (after contractions and aberrant rectal pressures) and technical artifacts (movement or variation in pressure and lack of balance in the transducer lines), which could affect the interpretation of the study. The ambulatory study should be designed to reproduce symptoms. For example, if the patient complains of stress incontinence, a standard protocol of exercises can be performed and recorded (e.g., jumping up and down, squatting, coughing).

CLINICAL UTILITY OF AMBULATORY URODYNAMICS

Ambulatory UDS is performed in an effort to capture more realistic or more physiologic observations, especially of incontinence episodes (Hosker et al, 2009). It attempts to increase sensitivity by providing a longer time for DO (and other abnormalities) to manifest itself. Practically speaking, ambulatory UDS is most useful when standard UDS is inconclusive and diagnosis and, more importantly, treatment are uncertain. Ambulatory UDS has been most commonly used to diagnose the cause of urinary incontinence, but it has also been applied to the diagnosis of male bladder outlet obstruction and neuropathic voiding dysfunction.

It has been shown that ambulatory monitoring detects more actual incontinence than conventional cystometry (Cassidenti and Ostergard, 1999). Several studies have shown ambulatory UDS to be more sensitive than conventional CMG for the diagnosis of DO (Robertson et al, 1994; Heslington and Hilton, 1996). Radley and colleagues (2001) found that ambulatory monitoring revealed DO in 70 of 106 women with symptoms suggestive of DO (twice as many as conventional cystometry with provocation by hand washing) and it detected DO incontinence (DOI) in 40 of the 70. The observation of DOI was correlated with symptom severity, but it is not clear how many women complaining of urgency incontinence showed DOI. Thus the sensitivity is unknown. The finding of higher rates (and sensitivity) of DO found on ambulatory monitoring must be weighed against the fact that ambulatory UDS has found rates of DO asymptomatic volunteers. DO has been found in asymptomatic females as often as 69% versus 18% for conventional CMG (vanWaalwijk van Doorn et al, 1996) and in 38% versus 17% in asymptomatic men and women (Robertson et al, 1994). Thus some degree of detrusor overactivity may be normal

in the setting of a urethral catheter for a prolonged period of time, making some sort of standardization important.

In a review of 422 female ambulatory UDS studies over a 12-year period, Patravali (2007) argued for the value of the study. It was seen that 85% of patients complaining of urinary incontinence showed detectable leakage with a diagnosable mechanism on ambulatory study, and in 77% of 74 women with a normal CMG ambulatory UDS diagnosed the cause of incontinence and provided "clear added value." DO was a component in 42 of these 57 patients (76%). What is unknown is exactly what was meant by "clear added value" and how treatment was affected. In a smaller study of 25 patients, Pannek and Pieper (2008) had similar findings but a more useful interpretation of those findings. They found that ambulatory UDS was helpful (versus standard UDS) in diagnosing lower urinary tract dysfunction in 72% of the evaluable examinations. However, 24% of the studies done were not evaluable owing to technical problems or catheter dislocation. Thus ambulatory UDS was clinically useful in only 48% of the patients who underwent this examination. When a diagnosis was made on ambulatory UDS, successful treatment was established in 42% of the patients. However, when ambulatory UDS was not helpful and patients were treated on the basis of clinical symptoms, 33.3% were treated successfully. Gorton and Stanton (2000) also looked at the effect of ambulatory UDS on clinical management. In a retrospective review of 71 women there were technical difficulties in 42% of the studies with 2 being uninterpretable. DO was found in 45% of the women, and nearly all were treated with medication. Among the remainder without DO, fewer received medication. However, less than half of those who received medication improved. The authors concluded that ambulatory UDS was not helpful in deciding on management.

Ambulatory UDS has been used for the diagnosis of obstruction in men with LUTS and inconclusive (borderline or nondiagnostic) conventional PFS. Rosario and colleagues (1999) reclassified 24% of such patients as either obstructed or nonobstructed. However, Robertson and colleagues (1996) found no difference in the classification of patients with ambulatory versus conventional PFS. It has been demonstrated that storage pressures in patients with chronic obstruction and neuropathic voiding dysfunction are lower on ambulatory, natural-fill UDS than on conventional CMG (Webb et al, 1989, 1992). Patients with poor compliance (high filling pressures) and hydronephrosis on conventional CMG were found to have normal compliance but significant phasic DO on ambulatory monitoring. It has been suggested that phasic DO and not impaired compliance may lead to upper tract deterioration in these patients. Although this may be true, it needs to be proven in a series of patients followed over time, and for now, on the basis of the available evidence, one must still conclude that significantly impaired compliance on conventional CMG is a risk factor for upper tract damage.

Key Points: Ambulatory Urodynamics

- Ambulatory UDS may be useful in a select group of patients where conventional UDS is nondiagnostic and the information provided will affect treatment, counseling, or follow-up.
- Ambulatory UDS and its interpretation are time consuming and technically challenging.
- The data obtained for ambulatory UDS studies must be weighed against the fact that for many findings, both normal and abnormal standards have not been established.

CLINICAL APPLICATIONS OF URODYNAMIC STUDIES: EVIDENCE-BASED REVIEW

Thus far this chapter has described the technical aspects of UDS and general indications for its use. This final section provides an evidence-based review of UDS for different common clinical applications. In many situations there is not enough evidence in the literature to conclude how useful UDS is for a particular case, and as such, its use should be based on a clinical impression. Nevertheless, there are some instances and indications where the evidence is strong enough to provide guidance as to how useful UDS will be. In cases where recommendations are made, these are based on the Oxford system: Grade A recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. Grade B recommendation usually depends on consistent level 2 and/or 3 evidence studies or "majority evidence" from randomized controlled trials. Grade C recommendation usually depends on level 4 evidence studies or "majority evidence" from level 2/3 studies or from "expert opinion." Four areas in which UDS is commonly used for evaluation are addressed. Enough evidence exists to make valid conclusions or recommendations for women with SUI, men with LUTS, neuropathic voiding dysfunction, and pediatric urologic conditions.

EVALUATION OF WOMEN WITH STRESS INCONTINENCE

Several studies have shown that **for women with pure SUI without urge symptoms who empty normally and demonstrated SUI on physical examination, UDS will not provide much useful information.** For example, in a randomized trial comparing the efficacy of Burch procedure versus pubovaginal sling in 655 *selected* women with pure or predominate SUI who had fewer than 12 micturitions/day, a positive standardized stress test (volume < 300 mL), a maximum cystometric capacity of at least 200 mL, a PVR of less than 150 mL and unobstructed voiding (Q_{max} > 12 mL/sec, $PdetQ_{max}$ < 50 cm H_2O), UDS including ALPP, and presence of DO added little to help determine surgical outcomes with respect to efficacy (Nager et al, 2008) or postoperative voiding dysfunction (Lemack et al, 2008). In 2006, in the United Kingdom, the National Institute for Health and Clinical Excellence issued guidelines that UDS was recommended before surgery for urinary incontinence only if (1) there is a clinical suspicion of DO, (2) there has been previous surgery for stress incontinence or anterior compartment prolapse, or (3) there are symptoms suggestive of voiding dysfunction. In other words, urodynamics is not routinely recommended for women before surgery for a "clearly defined clinical diagnosis of stress urinary incontinence."

However, many women with SUI who are considering surgical correction have mixed symptoms or emptying difficulties and it is here that UDS probably has its most significant role for female SUI. In addition, previous studies have found significant variation of the predictive value of symptoms in identifying the three UDS observations of urodynamic SUI, DOI, and mixed urinary incontinence (Harvey and Versi, 2001; Homma, 2002; Agur et al, 2009). This variation is probably explained by the nonhomogeneous patient populations and an

inconsistency in the clinical and the UDS diagnosis between the studies.

UDS does seem to have a valuable role in the preoperative evaluation of patients with mixed symptoms. In fact, several studies have shown excellent cure rates for both stress and urge symptoms in women with urodynamic SUI and a normal CMG (no DO) for pubovaginal sling (Chou, 2003; Osman, 2003); Burch procedure (Osman, 2003); and tension-free vaginal tape (Rezapour and Ulmstem, 2001).

In view of these discrepancies between symptoms and urodynamic findings, the soundest basis for the clinical diagnosis and evaluation of stress urinary incontinence and urgency urinary incontinence remains to be established, as does the significance of the corresponding urodynamic observations such as USI, DOI, and DO (Hosker et al, 2009). In cases of straightforward SUI with no significant urgency symptoms and with normal bladder emptying, it seems reasonable to forego UDS evaluation if the clinician and patient are comfortable with the limitations of symptoms as a predictor of all possible lower urinary tract abnormalities. These considerations are best reflected in the following grade A recommendation from the Fourth ICI Committee on Dynamic Testing (Hosker, 2009):

> "the cost effectiveness of urodynamic testing is kept in mind when discussing 'cost and gain' of the various methods of diagnosis for urinary incontinence, in relation to the method of treatment."

Many attempts to measure and quantify the severity of SUI urodynamically have been made using urethral pressure profilometry and leak point pressure measurements. In a review of static urethral pressure profilometry parameters such as MUCP or cough profile parameters such as pressure transmission ratio, Weber (2001a) concluded that these measures cannot be used to characterize the severity of incontinence. Another review by the same author (Weber, 2001b) suggested that ALPP might be a useful tool to quantify urethral dysfunction associated with SUI. However, other studies have found no correlation between leak point pressures and the severity of urinary incontinence as measured by bladder diaries and quality of life instruments (Theofrastous et al, 1995; Nager et al; 2001; Fleischmann et al, 2003; Albo et al, 2007; Chen et al, 2008). Leak point pressures have also been criticized as a diagnostic tool because of a lack of standardization of the technique (Rodrigues et al, 2006). Furthermore, leak point pressure and urethral pressure profilometry have not been shown to consistently predict outcomes for surgical treatment of SUI. In a review of this topic, Lemack (2004) found little evidence to suggest that women with "more severe forms" of SUI as measured urodynamically fare more poorly after commonly performed surgical procedures than those with "less severe forms." Recently it has been suggested that lower urethral pressure cut points are predictive of failure for transobturator versus retropubic midurethral slings (Miller et al, 2006; O'Connor et al, 2006; Guerette et al, 2008). However, this has not been confirmed by randomized studies to date. Other investigators have shown that MUCP is not a predictor or surgical failure (Homma, 2002; Bai et al, 2007). Finally, in the prospective, randomized Stress Incontinence Surgical Treatment Efficacy (SISTEr) trial comparing Burch colposuspension and pubovaginal sling, leak point pressures were not found to be predictive of surgical outcome for either procedure (Nager et al, 2008).

In 2009 the Fourth ICI Committee on Dynamic Testing made the following grade B/C recommendations on the basis of available evidence-based literature (Hosker et al, 2009):

1. **Urethral function measurements of leak point pressures and urethral closure pressures are not used as a single factor to grade the severity of incontinence.**
2. **Use caution with the prediction of the outcome of any surgical treatment on the basis of contemporary urethral function tests.**

EVALUATION OF MEN WITH LOWER URINARY TRACT SYMPTOMS

LUTS are common among men of 50 years and older. The cause of male LUTS is multifactorial, comprising at least four conditions: (1) BOO, (2) impaired contractility, (3) detrusor overactivity, and (4) sensory urgency (Blaivas, 1988). Often storage symptoms of frequency and urgency accompany voiding symptoms of decreased force of stream and hesitancy. Urgency incontinence can also occur as a result of DO with or without BOO. It has been established that coexistence of BOO and DO increases with age and with the degree of BOO (Vesely et al, 2003; Oelke et al, 2008). In such cases UDS can be helpful to establish the underlying bladder and/or bladder outlet abnormality.

The question of how much help UDS is in the evaluation and treatment of male LUTS has been debated for years. How necessary is a diagnosis of BOO before transurethral prostate resection, for example? The answer depends on how comfortable the clinician is making a diagnosis and treating with less invasive and less definitive testing. Few would argue that in order to institute an α blocker for the treatment of LUTS in a man with relatively normal bladder emptying, UDS is not required. However, as the scenario becomes more complex and the treatment more invasive and potentially morbid, a precise diagnosis will be helpful in many cases. Often it is ultimately up to the clinician to decide how much information is useful or necessary to make a treatment decision and properly counsel patients.

It is well documented that in men with BOO, surgery such as transurethral prostate resection (by any means) reduces obstruction and relieves symptoms. However, storage symptoms like urgency frequency and urgency incontinence will persist in about one third of cases. It has been shown that when storage symptoms are associated with DO and BOO, UDS can help predict resolution of those symptoms. In such a scenario, storage symptoms have a higher likelihood of resolving with intervention (e.g., TURP) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al, 2000). Such information can be quite valuable when counseling patients. For example, given the same UDS presentation of BOO plus continuous IDCs, a patient primarily concerned with his inability to empty may opt for surgery, whereas a patient who is primarily concerned about OAB symptoms may not.

As for the utility of UDS before surgical treatment or no treatment of LUTS thought to be secondary to BPH, the literature is mixed. Several studies support its necessity (Javle et al, 1998; Rodrigues et al, 2001; Porru et al, 2002; Thomas et al, 2004), whereas others have concluded that UDS is not necessary (Pannek et al, 1998; Kanik et al, 2004) or necessary only in inconclusive cases (Ignjatovic, 1997). Three reviews (Abrams et al, 2001; Homma, 2001; Clemens, 2003) have suggested that UDS has some but not strong predictive value for the outcome of treatment. Another review by Bhargava and colleagues (2004) concluded that conventional urodynamic studies are useful in providing preoperative information about detrusor function and to exclude

patients less likely to benefit from prostate surgery. Despite this, some regard the need for performing urodynamic evaluation routinely, before transurethral resection of the prostate, as still controversial. **This led the experts at the Sixth International Consultation on New Developments in Prostate cancer and Diseases to conclude that although almost all evidence for the advantages of UDS before invasive therapy for BPO is level 3 (good-quality retrospective "case-control studies" or "case series"), the quantity of evidence allows a grade B recommendation** (Abrams et al, 2006).

Most of the time when BOO is treated, it is done so because of symptoms. However, "symptomatic" BOO, if not relieved in time, may lead to progression of the disease and affect organ function. For many years attention was paid only to the backpressure effects of obstruction on the kidneys (from high voiding pressures and/or impaired compliance). However, it is now known that BOO affects bladder function, leading to structural changes. Because the changes may eventually become irreversible, some would argue that management should be directed toward early relief of significant obstruction (Flanigan et al, 1998; Lu et al, 2000; Brierly et al, 2003). **However, at this time, a critical level of obstruction (e.g., based on the BOOI) has not been defined. No evidence-based studies suggest when surgical relief is indicated to prevent bladder decompensation. However, many papers have shown that if there is no evidence of obstruction on PFS, the results of surgical relief are not as good** (Porru et al, 2002; Thomas, 2004). **Significantly impaired compliance remains the only "absolute urodynamic indication" for treating BOO.**

EVALUATION OF NEUROPATHIC LOWER URINARY TRACT DYSFUNCTION

Neuropathic lower urinary tract dysfunction usually presents clinically as incontinence and/or inability to empty the bladder. Incontinence may be of bladder origin (detrusor overactivity or impaired compliance) or sphincter origin. Poor emptying can also be of bladder origin (impaired detrusor contractility) of sphincter origin (dyssynergia). In addition to symptomatic presentation, neuropathic lower urinary tract dysfunction can present as upper urinary tract decompensation with hydroureteronephrosis and renal insufficiency without bothersome symptoms. The goal of management in these patients is to prevent upper tract decompensation and relieve symptoms. A specific understanding of the pathophysiology of the condition in each individual is essential for the correct choice of therapy (Stohrer, 1990; Stohrer et al, 1994; Rivas and Chancellor, 1995). **UDS probably has its most important role in the diagnosis and management of patients with neuropathic voiding dysfunction.**

The aims of therapy for neuropathic lower urinary tract dysfunction are to achieve physiologic filling (and if possible voiding) conditions, as well as to control symptoms and create a management situation acceptable to the patient in daily life. Much of the evidence base for management of the lower urinary tract in the neuropathic patient consists of level 3 evidence. This is primarily because of the potential negative consequences of untreated neuropathic dysfunction. As such, randomized, controlled trials are thought by many to be dangerous and unethical. Because prolonged periods of elevated detrusor pressure during bladder filling or abnormally prolonged elevated pressures during voiding have been found to put the upper urinary tract at risk (McGuire et al, 1996; Kurzrock and Polse, 1998; Tanaka et al, 1999), primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling even if this leads to incomplete emptying and the need to supplement emptying with catheterization. Adequate therapy depends on whether the detrusor is overactive or has reduced compliance, and only urodynamics can answer those questions unequivocally. Timely and adequate diagnosis of DO and impaired compliance is thought to be of paramount importance for the patient's quality of life (Stohrer, 1990; Stohrer et al, 1994; Bomalaski et al, 1995; Cardenas et al, 1995). UDS is also essential for assessing the response to treatment and following any sequelae of the disease and its management (Hosker et al, 2009).

In 2009 the Fourth Consultation on Incontinence committee on dynamic testing made the following grade B/C recommendation on the basis of the available evidence-based literature (Hosker et al, 2009): **Patients with suspected neurogenic dysfunction of the LUT should receive comprehensive UDS evaluation including VUDS, if possible, to establish the state and function of the lower tract. In addition, UDS testing in this group of patients should be done in a specialized environment with trained personnel.**

EVALUATION OF CHILDREN

Many of the conditions for which UDS is used in children involve anatomic and neurologic abnormalities in which lower urinary tract function is variable and unpredictable. UDS is used to establish as clearly as possible the baseline situation so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment even if the result of UDS testing is not necessarily the deciding factor (Hosker et al, 2009). In the pediatric population, the aim of UDS is not only to provide precise knowledge of lower urinary tract function but also to provide an understanding of the current and future condition to the caregiver and to the patient (and his or her parents). Of course, it is still imperative that the testing should be relevant, reliable, and reproducible. We briefly describe the evidence base for several commonly studied pediatric conditions. The reader is referred to the relevant chapters on pediatric urology for a more detailed discussion.

Pediatric Neurologic Conditions: Myelodysplasia, Occult Spinal Dysraphism, and Sacral Agenesis

When evaluating children with myelodysplasia, a number of effects on the lower urinary tract can be seen. Detrusor overactivity (on filling) or underactivity (on voiding), DESD, impaired compliance, and elevated DLPP are the key parameters evaluated on UDS testing in this population (McGuire et al, 1981; Bauer et al, 1984). Retrospective and prospective studies have shown that the urodynamic diagnosis of DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs, symptoms, or level of lesion (Dator et al, 1992; Landau et al, 1994; Pontari et al, 1995; Kaefer et al, 1997; Palmer et al, 1997), making UDS an important tool in assessing the lower urinary tract. Furthermore, these studies reveal clinically relevant results with regard to detrusor storage function. In a retrospective study of 64 children, Rendeli and

colleagues (2007) showed that UDS evaluation and the presence of neurologic impairment have crucial roles in determining the optimal timing of surgery in patients with lipomeningocele and in diagnosing the onset of tethered cord. Finally, it has been demonstrated that lower urinary tract function may change over time (McGuire et al, 1981; Bauer et al, 1984; Sidi et al, 1986; Wang et al, 2006) and repeat evaluation may be necessary. However, no studies have helped to determine the optimum timing and frequency of UDS follow-up.

Sacral agenesis is often missed in infancy because of its subtle clinical manifestations and no obvious loss of lower extremity motor and sensory function. Similar to myelodysplasia, patients can present with a variety of lower urinary tract dysfunctions. Several studies have shown that 30% to 40% of patients present with DO and an intact but dyssynergic sphincter (upper motor neuron lesion), 25% to 50% will have an acontractile detrusor with a denervated sphincter (lower motor neuron lesion), and 15% to 20% have normal lower urinary tract function (Koff et al, 1977; Guzman et al, 1983, Jabokson et al, 1985). In eight reports that provide adequate data, UDS has been 90% accurate in delineating the neurologic deficit and in managing incontinence and upper urinary tract abnormalities (Koff et al, 1977, 1983; Jabokson et al, 1985; Gotoh et al, 1991; Saito et al, 1991; Boemers et al, 1994, 1996; Wilmshurst et al, 1999; Torre et al, 2002).

In 2009 the Fourth Consultation on Incontinence committee on dynamic testing made the following recommendations for children with myelodysplasia or occult spinal dysraphism and sacral agenesis on the basis of the available evidence-based literature (Hosker et al, 2009):

1. **Comprehensive UDS testing is advised in all patients with myelodysplasia or occult spinal dysraphism (grade B/C).**
2. **Video-urodynamic testing should be considered in all children with myelodysplasia or occult spinal dysraphism (grade C).**
3. **Timing and technique of UDS testing in children with myelodysplasia or occult spinal dysraphism should be selected on an individual basis (grade C).**
4. **To help identify children at risk for subsequent urinary tract deterioration or a changing neurologic picture, initial UDS studies early in the neonatal period are recommended for children with myelodysplasia or occult spinal dysraphism (grade C).**
5. **Clinicians should consider UDS testing in children with sacral agenesis when clinical signs of lower urinary tract dysfunction or relevant neurologic abnormalities exist (grade C).**

Pediatric Anatomic Abnormalities: Posterior Urethral Valves, Bladder Extrophy, Vesicoureteral Reflux

A number of congenital and acquired anatomic abnormalities can affect lower urinary tract function. Because of a lack of prospective data, it is recommended that for each of the abnormalities presented, clinicians should consider UDS, depending on the clinical scenario (Hosker et al, 2009). Studies on posterior urethral valves have shown that some boys will have significant lower urinary tract dysfunction, namely DO and impaired compliance (Kim et al, 1997; Kajbafzadeh et al, 2007). When storage pressures are considered to be dangerously elevated, improvements in DO and compliance after valve ablation have been documented (De Gennaro et al, 1996, 2000; Holmdahl et al, 1996; Kim et al, 1997; Donohoe et al, 2004). Myogenic failure and poor emptying are late sequela of posterior urethral valves, and persistence of upper tract changes is related to high storage pressure and/or incomplete emptying. Several studies have shown the predictability of developing upper tract decompensation on the basis of UDS parameters of persistent poor compliance, high detrusor pressures, and impaired contractility during voiding (Bauer et al, 1979; Peters et al, 1990; Holmdahl et al, 1995, 1996; Lopez Pereira et al, 2002).

Bladder extrophy is another condition in which UDS may be helpful. A few studies have shown that after bladder neck reconstruction, the prevalence of DO increases and compliance worsens in up to 50% of cases (Hollowell et al 1992, 1993; Diamond et al, 1999; Caione et al, 2005; Burki, 2006). Although there is no prospective information regarding long-term outcomes based on UDS finding, this information may be helpful in management.

There is increasing evidence that a significant number of vesicoureteral reflux cases are due to bladder dysfunction (DO) and not necessarily an anatomic abnormality at the ureterovesical junction (Koff et al, 1979; Griffiths and Scholtmeijer, 1987; Sillen et al, 1996; Capitanucci, 2000; Greenfield and Wan, 2000; Podesta, 2004). DO may be a result of high voiding pressures, particularly in boys, or dysfunctional voiding. Four separate studies have shown that treating DO and/or voiding with antimuscarinics leads to a rapid rate of reflux resolution (63% to 92%) within 1 year (Homsy et al, 1985; Scholtmeijer and Nijmanl, 1994; Batista Miranda et al, 1997). This is higher than the 25% to 54% rate of reflux resolution seen with treatment using antibiotics alone to prevent recurrent infection (Seruca, 1989). Treating dysfunctional voiding with biofeedback has also been shown to reduce the grade of reflux (Kuo and Liu, 2006). Because of these findings, many clinicians advocate UDS for children with high-grade vesicoureteral reflux, especially those with incontinence, renal damage, or pending surgery to correct reflux (Scholtmeijer and Nijman, 1994; Moran Penco et al, 2004; Musquera et al, 2004; Fotter and Riccabona, 2005). **On the basis of the available literature, the Fourth ICI Committee had the following grade C recommendation regarding UDS testing of children with anatomic abnormalities discussed earlier: Clinicians should consider complete urodynamic testing, at least once, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesicoureteral reflux, and bladder extrophy. Clinicians should consider regular uroflowmetry and PVR in the management and follow-up of children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesicoureteral reflux, and bladder extrophy.**

Epidemiology of Pelvic Organ Prolapse

DEFINITION AND CLASSIFICATION OF URINARY INCONTINENCE

Urinary incontinence (UI) has a considerable social and economic impact. Indeed, it has been estimated that UI in women was the primary cause for more than 1.1 million office visits in 2000 in the United States (Litwin et al, 2005). Hu and colleagues (2004) estimated the total direct and indirect cost of incontinence in the United States in the year 2000 to be approximately $19.5 billion. Incontinence has a larger economic impact than many chronic conditions and diseases.

The lower urinary tract comprises the bladder and urethra and should be considered as a single functioning vesicourethral unit required to store urine and empty efficiently. Most of the bladder's functional time is spent in storing urine. Dysfunction occurs when there is a breakdown of these fundamental tasks, resulting in storage and/or voiding symptoms, urinary retention, or incontinence. The bladder tends to be an "unreliable witness," its symptoms often being nonspecific and neither diagnosing the underlying dysfunction nor paralleling the severity of the underlying functional disorder. The customary evaluation of patients with both storage and voiding dysfunction includes an in-depth history and physical examination, as well as appropriate laboratory studies. Endoscopy and radiography provide useful structural information and are used when clinically indicated. Urodynamic studies provide the only objective functional tests of bladder and urethral function and are a valuable adjunct to the investigation of patients with lower urinary tract dysfunction (LUTD). Urodynamics, when properly selected and accurately interpreted, provides health care professionals with an improved diagnostic capability useful in formulating treatment strategies, educating patients, and ultimately improving therapeutic outcome. The results of urodynamics should not be interpreted as a free-standing study but in conjunction with the clinical presentation. Although the interpretation of urodynamics can be complex on occasion, in the majority of cases the indications for urodynamic investigation are evident and its application provides an essential complement to the modern practice of urology, gynecology, and associated specialties.

The "storage" component of **lower urinary tract symptoms (LUTS),** of which incontinence is unarguably the most troublesome, is a common and important cause of morbidity and impairment of quality of life, in both men and women (Chapple et al, 2008). In order to effectively consider the subject of incontinence, it is important to think in terms of symptoms, signs, urodynamic observations, and conditions, as defined by the International Continence Society (ICS) and summarized in their published standardization report (Abrams, 2002; Abrams et al, 2002).

When a condition cannot be documented by urodynamic observation, it may be "presumed" by clinical documentation.

In this chapter we widely quote the ICS standardization documents, which underpin all clinical and academic evaluation of patients and should form the basis for all therapy. The authors of this chapter want to acknowledge the hard work of all of the authors and contributors to these documents. **Signs** are observed by the physician by simple means (e.g., observation of the loss of urine with a cough) or by the use of diaries, pad **tests, symptoms scores, and validated quality of life instruments. Urodynamic observations** are made during urodynamic studies and reflect the definitive pathophysiologic condition that is causing the incontinence (e.g., detrusor overactivity or sphincteric weakness).

Lower Urinary Tract Symptoms

Symptoms are the subjective indicator of a disease or change in condition as perceived by the patient, caregiver, or partner and may lead him or her to seek help from health care professionals. They may be volunteered or described during the patient interview. They are usually qualitative. In general, LUTS cannot be used

to make a definitive diagnosis. LUTS can also indicate pathologies other than LUTD such as urinary infection.

Signs Suggestive of Lower Urinary Tract Dysfunction

Signs are observed by the physician including simple means to verify symptoms and quantify them. For example, a classical sign is the observation of leakage on coughing. Observations from frequency volume charts, pad tests, and validated symptom and quality-of-life questionnaires are examples of other instruments that can be used to verify and quantify symptoms.

Urodynamic Observations

Urodynamic observations are observations made during urodynamic studies. For example, an involuntary detrusor contraction (detrusor overactivity) is a urodynamic observation. In general, a urodynamic observation may have a number of possible underlying causes and does not represent a definitive diagnosis of a disease or condition and may occur with a variety of symptoms and signs or in the absence of any symptoms or signs.

Conditions

Conditions are defined by the presence of urodynamic observations associated with characteristic symptoms or signs and/or nonurodynamic evidence of relevant pathologic processes.

LUTS are best considered as three groups of symptoms: **storage, voiding,** and **postmicturition.** Storage symptoms will be considered in detail later, and the reader is directed to other chapters for a consideration of the other categories of LUTS.

Storage symptoms are experienced during the storage phase of the bladder and include daytime frequency and nocturia.

- **Increased daytime frequency** is the complaint by the patient who considers that he or she voids too often by day (equivalent to the term *pollakisuria* used in many countries).
- **Nocturia** is the complaint that the individual has to wake at night one or more times to void. **This is sleep-disturbing voiding.**

  Night-time frequency differs from nocturia because it includes voids that occur after the individual has gone to bed but before he or she has gone to sleep and voids that occur in the early morning, which prevent the individual from getting back to sleep as he or she desires.
- **Urgency** is the complaint of a sudden, compelling desire to pass urine, which is difficult to defer.
- **UI** is the complaint of any involuntary leakage of urine.

The International Continence Society (ICS) has defined the symptom of UI as "the **complaint of any involuntary loss of urine that is a social or hygienic problem."** When considering incontinence, it is important to particularly consider relevant factors such as **type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage, and whether or not the individual seeks or desires help** because of UI. Urinary leakage may need to be distinguished from sweating or vaginal discharge.

- Stress UI is the:

  symptomatic complaint of involuntary leakage on effort or exertion, or on sneezing or coughing.

  sign of involuntary urinary loss from the urethra synchronous with exertion, sneezing, or coughing.

  urodynamic diagnosis of the involuntary leakage of urine during increases in abdominal pressure in the absence of a detrusor contraction—so-called **urodynamic stress incontinence.**

  The term "stress," although unsatisfactory in the English language because of its mental connotations, has been retained because although the terms "effort or exertion incontinence" are preferable, they do not capture some of the common precipitating factors for stress incontinence such as coughing or sneezing.
- Urgency UI is the:

  symptomatic complaint of involuntary leakage accompanied by or immediately preceded by urgency as *contrasted* to urge, which is a normal sensation (Abrams et al, 2009). The current term *urge* has therefore been replaced by **urgency UI.**

  sign of involuntary urinary loss from the urethra that is accompanied by or immediately preceded by urgency.

  urodynamic diagnosis of incontinence related to an involuntary detrusor contraction during urodynamics—so-called **detrusor overactivity associated incontinence.**

Urgency incontinence can present in different symptomatic forms (e.g., as frequent small losses between micturitions or as a catastrophic leak with complete bladder emptying).

- Mixed UI is the:

  symptomatic complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing.

  sign of involuntary urinary loss from the urethra synchronous with exertion, sneezing, or coughing and of involuntary urinary loss from the urethra that is accompanied by or immediately preceded by urgency.

  urodynamic diagnosis of both involuntary leakage of urine during increases in abdominal pressure. It is related to an involuntary detrusor contraction during urodynamics and is present in approximately 40% of women with stress incontinence.

Overactive bladder (OAB), or the urgency frequency symptom syndrome, comprises urgency, with or without **urgency incontinence,** usually with frequency and nocturia. Urgency is widely held to be a key symptom driving the clinical sequence as demonstrated by Figure 63–1.

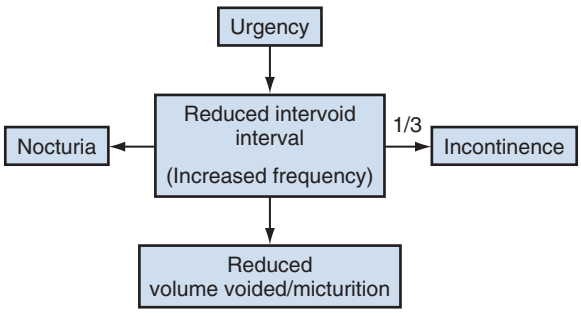

Figure 63–1. The overactive bladder symptom complex. (From Chapple CR, Artibani W, Cardozo LD, et al. The role of urinary urgency and its measurement in the overactive bladder symptom syndrome: current concepts and future prospects. BJU Int 2005;95:335–40.)

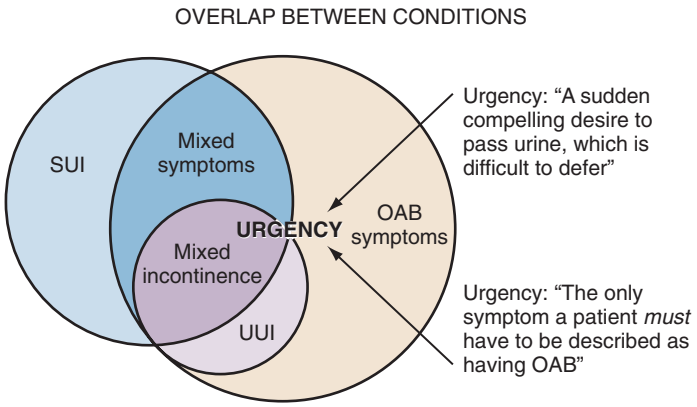

Figure 63–2. Overlap between conditions. OAB, overactive bladder; SUI, stress urinary incontinence; UUI, urgency urinary incontinence. (From Wein AJ, Rackley RR. Overactive bladder: a better understanding of pathophysiology, diagnosis and management. J Urol 2006;175:S5–10.)

- **Mixed urinary symptoms** is a term applied to the presentation of a patient with a combination of OAB dry (without urgency incontinence) and stress incontinence (Fig. 63–2).
- **Enuresis** means any involuntary loss of urine. If it is used to denote incontinence during sleep, it should always be qualified with the adjective "nocturnal."
- **Nocturnal enuresis** is the complaint of loss of urine occurring during sleep.
- **Continuous UI** is the complaint of continuous leakage.
- **Other types of UI** may be situational (e.g., the report of incontinence during sexual intercourse, giggle incontinence).

  Overflow incontinence is not a symptom or condition but rather a term used to describe leakage of urine associated with urinary retention.

  Postmicturition dribble is the complaint of an involuntary loss of urine. Both are voiding symptoms.

  Extraurethral incontinence is the observation of urine leakage through channels other than the urethra (e.g., fistula or ectopic ureter) immediately after passing urine.

  Bladder sensation is an important factor to take into account when interpreting storage disorders affecting the lower urinary tract and can be categorized during history taking into five broad categories:

  1. **Normal:** The individual is aware of bladder filling and increasing sensation up to a strong desire to void.
  2. **Increased:** The individual feels an early and persistent desire to void.
  3. **Reduced:** The individual is aware of bladder filling but does not feel a definite desire to void.
  4. **Absent:** The individual reports no sensation of bladder filling or desire to void.
  5. **Nonspecific:** The individual reports no specific bladder sensation but may perceive bladder filling as abdominal fullness, vegetative symptoms, or spasticity. These nonspecific symptoms are most frequently seen in neurologic patients, particularly those with spinal cord trauma and in children and adults with malformations of the spinal cord.

  Physical examination is essential in the assessment of all patients with LUTD. It should include abdominal, pelvic, perineal, and a focused neurologic examination. For patients with possible neurogenic lower urinary tract dysfunction, a more extensive neurologic examination is necessary. Clinical assessment of pelvic floor anatomy is determined by physical examination of the external genitalia and vaginal canal.

  Abdominal: The bladder may be felt by abdominal palpation or by suprapubic percussion. Pressure suprapubically or during bimanual vaginal examination may induce a desire to pass urine.

  Perineal/Genital Inspection allows the description of the skin (e.g., the presence of atrophy or excoriation, any abnormal anatomic features, observation of incontinence).
- **UI (the sign)** is defined as urine leakage seen during examination: This may be urethral or extraurethral. **Extraurethral incontinence** is defined as the observation of urine leakage through channels other than the urethra.
- **Stress UI** is the observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing. Stress leakage is presumed to be due to raised abdominal pressure.

Coughing may induce a detrusor contraction—hence the sign of stress incontinence is only a reliable indication of urodynamic stress incontinence when leakage occurs synchronously with the first proper cough and stops at the end of that cough.

- **Uncategorized incontinence** is the observation of involuntary leakage that cannot be classified into one of the above categories on the basis of signs and symptoms.

DEFINITION AND CLASSIFICATION OF PELVIC ORGAN PROLAPSE

More than 40% of women with urethral sphincter incompetence will have a significant cystocele (Cardozo and Stanton, 1980). Conversely, a history of stress incontinence associated with a mild or moderate cystocele is not specific for diagnosing genuine stress incontinence (Summitt et al, 1992). **"Occult or latent" incontinence is urethral sphincteric incompetence masked by the presence of pelvic prolapse** (Rosenzweig et al, 1992a, 1992b). Not infrequently, incontinent women may note the decrease or disappearance of stress incontinence episodes as the degree of prolapse worsens. The sign of occult stress incontinence is facilitated by the use of a speculum or pessary to reduce the prolapse while a stress maneuver is performed. The method to reduce vaginal prolapse to evaluate latent incontinence is not universally agreed on or standardized at this time.

A large rectocele may cause incomplete bowel evacuation and tenesmus. Sexual function consists of a complex interaction of biologic, psychologic, and social factors that affect both patient and partner. A complex relationship exists between anatomic descent of pelvic organs and physiologic function, and often these components do not correlate well with each other.

Vaginal examination allows the description of observed and palpable anatomic abnormalities and the assessment of pelvic floor muscle function. Segments of the lower reproductive tract should be considered as a substitute for terms as "cystocoele, rectocoele, enterocoele, or urethrovesical junction" because these terms convey an unrealistic certainty relating to the structures associated with the vaginal bulge, especially following previous prolapse surgery. This section draws heavily on the ICS standardization report, which commented on the evaluation of pelvic organ prolapse (Bump et al, 1996) as modified by the ICS standardization report 2002.

- **Pelvic organ prolapse** is defined as the descent of one or more of the following: anterior vaginal wall, posterior vaginal wall, and apex of the vagina (cervix/uterus) or vault (cuff) after hysterectomy. Absence of prolapse is defined as stage 0 support; prolapse can be staged from stage I to stage IV.

Pelvic organ prolapse can occur in association with UI and other lower urinary tract dysfunction and may on occasion mask incontinence.

- **Anterior vaginal wall prolapse** is defined as descent of the anterior vagina so that the urethrovesical junction (a point 3 cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3 cm above the plane of the hymen.
- **Prolapse of the apical segment of the vagina** is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point that is 2 cm less than the total vaginal length above the plane of the hymen.
- **Posterior vaginal wall prolapse** is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3 cm above the level of the hymen or any posterior point proximal to this is less than 3 cm above the plane of the hymen.

Pelvic floor muscle function can be qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, weak, or absent or by a validated grading system (e.g., Oxford 1 to 5). A pelvic muscle contraction may be assessed by **visual inspection, palpation**, **electromyography,** or **perineometry**. Factors that must be assessed are **strength, duration, displacement, and repeatability. Rectal examination** allows the description of observed and palpable anatomic abnormalities and is the easiest method of assessing pelvic floor muscle function in children and men. In addition, rectal examination is essential in children with UI to rule out fecal impaction.

RELATIONSHIP BETWEEN INCONTINENCE AND PROLAPSE

Patients with severe prolapse may develop voiding symptoms as a result of urethral kinking, leading to obstruction that is worsened during straining effort (Richardson et al, 1983). For instance, a moderate or severe cystocele may promote urethral compression and kinking, pressure dissipation, and an increase in maximum urethral closure pressures (Bergman et al, 1988; Versi et al, 1998). Clearly, a number of storage urinary symptoms may occur in combination with prolapse. Risk factors contributing to the symptoms of urgency and frequency include age and urogenital atrophy. One study found that women with mild cystoceles had a 20% incidence of detrusor overactivity, and the incidence increased to 52% in those with moderate to severe cystoceles (Enhorning, 1961).

More than 40% of women with urethral sphincter incompetence will have a significant cystocele (Cardozo and Stanton, 1980). A complaint of stress incontinence associated with the appearance of a mild or moderate cystocele, however, is not specific for diagnosing genuine stress incontinence (Walters and Shields, 1988; Summitt et al, 1992).

Occult or latent incontinence is urethral sphincteric incompetence masked by the presence of pelvic prolapse (Rosenzweig et al, 1992). Not infrequently, incontinent women may note the decrease or disappearance of stress incontinence episodes as the degree of prolapse worsens. The office demonstration of the sign of occult stress incontinence is facilitated by the use of a speculum or pessary to reduce the prolapse while a stress maneuver is performed. Its presence may influence management options given to the patient. However, the method to reduce vaginal prolapse to evaluate latent incontinence is not universally agreed on or standardized at this time.

A large rectocele may cause incomplete bowel evacuation and tenesmus, leading some to splint or manually reduce the posterior vaginal segment or perineum to assist in defecation. Patients may describe stool becoming trapped in the rectocele pocket itself. Constipation and straining may worsen the symptoms and lead to left lower quadrant abdominal pain if impaction occurs.

The prevalence of fecal incontinence increases to 17% in populations with pelvic organ prolapse and UI (Jackson et al, 1997) compared with 2% to 3% in the general population (Leigh and Turnberg, 1982; Thomas et al, 1984). The most common mechanisms are an incompetent sphincteric mechanism (secondary to a structural defect or pudendal nerve damage) and overflow incontinence.

Sexual function consists of a complex interaction of biologic, psychologic, and social factors that affect both patient and partner. Various studies have described the presence of sexual problems in patients who present with pelvic organ prolapse and UI (Haase and Skibsted, 1988; Field and Hilton, 1993).

Key Points: Conditions Associated with Pelvic Organ Prolapse

- Patients with severe prolapse may develop voiding symptoms as a result of urethral kinking leading to obstruction.
- More than 40% of women with urethral sphincter incompetence will have a significant cystocele.
- Occult or latent incontinence is urethral sphincteric incompetence masked by the presence of pelvic prolapse.
- A large rectocele may cause incomplete bowel evacuation and tenesmus.
- The prevalence of fecal incontinence increases in populations with pelvic organ prolapse and UI.
- Sexual problems are an important issue in patients who present with pelvic organ prolapse and urinary incontinence.

PATHOPHYSIOLOGY OF INCONTINENCE AND PROLAPSE

Continence

To understand the pathophysiology of urinary incontinence, it is important to be familiar with the micturition cycle and the physiology of normal storage and emptying of urine. The details of the physiology of micturition are provided in Chapter 60. The **function of the lower urinary tract is to temporarily store a continuously increasing amount of urine at low pressure and expel it under appropriate circumstances.** This is dependent on the coordinated activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. The bladder and urethra constitute a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors (Andersson and Wein, 2004).

Bladder emptying and, conversely, urine storage rely on a complex series of finely tuned and integrated neuromuscular events that involve anatomic and neurologic mechanisms. It is a complex pattern of efferent and afferent signaling in parasympathetic, sympathetic, somatic, and sensory nerves. Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in overflow incontinence. A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance.

During bladder filling at physiologic rates, detrusor pressure remains nearly constant because of this property of **accommodation** (Klevmark, 1974), otherwise known as "tonus" or receptive relaxation. Accommodation accounts for the nearly flat cystometric curve that is seen during normal bladder filling. **The viscoelastic properties of the bladder, based on its composition of smooth muscle, collagen, and elastin, normally produce a highly compliant structure. When accommodation is impaired, low bladder compliance ensues. This is manifest as a steep rise in detrusor pressure during bladder filling.** In addition to the viscoelastic properties of the bladder, the neural control of the lower urinary tract and the anatomy and support of the sphincteric unit are important factors in the maintenance of urinary continence. **The micturition reflex is normally under voluntary control** and is organized in the rostral brainstem (the pontine micturition center [PMC]). Micturition results from a release from the negative inhibitor effect of the higher centers on the PMC. It requires integration and modulation by the parasympathetic and somatic components of the sacral spinal cord (the sacral micturition center) and the thoracolumbar sympathetic components (Fowler et al, 2008).

The reservoir function of the bladder requires a permanently low intravesical pressure over a wide volume range and a bladder outlet that remains firmly closed, even under conditions of abdominal pressure rises, during the filling phase of the bladder, which represents the majority of its activity cycle. Conversely, during voiding the bladder should be able to develop a sustained contraction of sufficient strength with opening of the bladder outlet offering a low resistance to urinary flow to assure adequate emptying of the bladder. During micturition, the first recorded event is sudden and complete relaxation of the striated sphincteric muscles, characterized by complete electrical silence of the sphincter electromyogram (Tanagho and Miller, 1970). This is followed almost immediately by a rise in detrusor pressure and concomitant fall in urethral pressure as the bladder and proximal urethra become isobaric (Yalla et al, 1980). The bladder neck and urethra open, and voiding ensues. Voluntary interruption of the stream is accomplished by a sudden contraction of the striated periurethral musculature, which, through a reflex mechanism, shuts off the detrusor contraction, aborting micturition. The sphincteric system is also designed to resist physiologic increases in abdominal pressure and thereby prevent the development of incontinence.

Normal storage of urine is therefore dependent on the following:

1. **An intact normally functioning innervated lower urinary tract (bladder, urethra, sphincters, and pelvic floor)**
2. **Spinal reflex mechanisms that allow centripetal afferent nerve traffic to activate sympathetic and somatic pathways to the bladder outlet**
3. **Tonic inhibitory systems in the brain that suppress parasympathetic excitatory outflow to the bladder** (Morrison et al, 2005)

It is important to identify the underlying bladder abnormality in a reproducible manner. Bladder abnormalities that cause UI include detrusor overactivity and low bladder compliance.

Disordered lower urinary tract function can result from the following:

- **Disruption of the normal peripheral or central nervous system (CNS) control mechanisms**
- **Disordered bladder muscle function, either primary (of unknown etiology) or secondary to an identifiable pathology such as prostatic-mediated bladder outflow obstruction**

Patients who have disordered lower urinary tract function in routine clinical practice represent a heterogeneous collection for most of whom there is no identifiable neurologic abnormality. Some of these patients will have a primary neural or muscular disorder (e.g., primary idiopathic detrusor overactivity) in contrast to postobstructive secondary detrusor overactivity, in which the major etiologic factor is likely to be peripheral disruption of local neuromuscular function.

Detrusor overactivity is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked. Detrusor overactivity may be phasic, terminal, or both (Abrams et al, 2002). There are certain patterns of detrusor overactivity:

- **Phasic detrusor overactivity** is defined by a characteristic wave form and may or may not lead to urinary incontinence. Phasic detrusor contractions are not always accompanied by any sensation or may be interpreted as a first sensation of bladder filling or as a normal desire to void.
- **Terminal detrusor overactivity** is defined as a single, involuntary detrusor contraction, occurring at cystometric capacity, which cannot be suppressed and results in incontinence usually resulting in bladder emptying (voiding). *Terminal detrusor overactivity* is a new ICS term: It is typically associated with reduced bladder sensation (e.g., in the elderly stroke patient when urgency may be felt as the voiding contraction occurs). However, in complete spinal cord injury patients there may be no sensation whatsoever.
- **Detrusor overactivity incontinence** is incontinence due to an involuntary detrusor contraction. In a patient with normal sensation, urgency is likely to be experienced just before the leakage episode.
- **Other patterns of detrusor overactivity** are seen (e.g., the combination of phasic and terminal detrusor overactivity, the sustained high pressure detrusor contractions seen in spinal cord injury patients when attempted voiding occurs against a dyssynergic sphincter).

Provocative maneuvers are used during urodynamics in an effort to provoke detrusor overactivity (e.g., rapid filling, use of cooled or acid medium, postural changes, hand washing).

Detrusor overactivity may also be qualified, when possible, according to cause. Examples follow:

- **Neurogenic detrusor overactivity,** when there is a relevant neurologic condition. This term replaces the term *detrusor hyperreflexia*.

Table 63–1.

Causes of Detrusor Overactivity

Neurogenic Detrusor Overactivity
Supraspinal neurologic lesions
Stroke
Parkinson disease
Hydrocephalus
Brain tumor
Traumatic brain injury
Multiple sclerosis
Suprasacral spinal lesions
Spinal cord injury
Spinal cord tumor
Multiple sclerosis
Myelodysplasia
Transverse myelitis
Diabetes mellitus
Idiopathic Detrusor Overactivity
No neurologic abnormality is evident, but associated abnormalities include the following:
Bladder infection
Bladder outlet obstruction
Men—prostatic and bladder neck, strictures
Women—pelvic organ prolapse, postsurgical, urethral diverticulum, primary bladder neck, strictures
Bladder tumor
Bladder stones
Foreign body
Aging

- **Idiopathic detrusor overactivity** when there is no defined cause. This term replaces *detrusor instability.*

In clinical and research practice, the extent of neurologic examination/investigation varies. It is likely that the proportion of neurogenic-to-idiopathic detrusor overactivity will increase if a more complete neurologic assessment is carried out (Table 63–1).

Interpretation of Vesicourethral Dysfunction

Because so many different aspects of vesicourethral function can be impaired in neurologic conditions, interpretation may be difficult. The most important points to clarify in clinical practice are **the presence or absence of neurogenic detrusor overactivity** and **the behavior of the distal urethral sphincter mechanism during voiding.**

High-pressure bladders with detrusor–sphincter dyssynergia are prone to develop vesicoureteral reflux, which may ultimately lead to renal impairment. This can be clearly demonstrated by videocystometrography (VCMG). Preservation of renal function is of utmost importance in the management of patients who have chronic neurologic conditions. As a rule of thumb, those patients with a competent bladder outflow and an end filling pressure of 40 cm H_2O or higher before leakage occurs—(the **detrusor leak point pressure**) are at particular risk of developing upper urinary tract problems due to back pressure (McGuire et al, 1996).

Neurogenic detrusor overactivity can be defined as abnormal function of the bladder and urethra due to lesions affecting their innervation, either within the central nervous system or in the peripheral nerves of the lower urinary tract.

Urodynamic investigations are essential to characterize the nature of the detrusor and sphincteric abnormality to do the following:

- **Identify patients who are at risk of deteriorating renal function as a result of the abnormally high bladder pressures**
- **Formulate the best treatment strategies to achieve efficient bladder emptying and continence and reduce the incidence of urinary tract infections and autonomic dysreflexia**

The interpretation of urodynamics in such complex cases is often difficult and is best performed in specialist centers using VCMG.

Neurologic conditions can alter vesicourethral function by impairing the following:

- Detrusor activity
- Striated sphincter activity
- Bladder and urethral sensation
- Urethral smooth muscle activity

These alterations may occur in isolation or in combination. Identical abnormalities may also occur without clinical evidence of a neurologic deficit.

Classification of Neuropathic Bladder Dysfunction

Neuropathic bladder dysfunction may be classified into supraspinal, suprasacral, and infrasacral, according to the level of the lesion in relation to the pontine and sacral micturition centers:

- Supraspinal lesions include all cerebral diseases such as cerebral hemorrhage and thrombosis, dementia, tumors, arteriosclerosis, and Parkinson disease.
- Suprasacral lesions are all spinal cord lesions above the conus.
- Infrasacral lesions involve the conus or sacral roots and may be further subdivided into cauda equina lesions (within the spinal canal) and peripheral lesions (outside the spinal canal).

Neurologic lesions generally affect bladder and urethral function in a relatively consistent fashion, depending on the area affected and the completeness of the lesion. A basic understanding of the bladder dysfunction associated with each level of injury is necessary to interpret the results of urodynamics properly.

Supraspinal Lesions

Patients who have supraspinal lesions generally empty their bladders efficiently unless they have associated bladder outlet obstruction. Preexisting bladder dysfunction is not uncommon, and urodynamics plays a major role in defining the abnormality and formulating treatment strategies.

Suprasacral Lesions

Patients who have cord lesions above the sacral micturition center initially go through a period of spinal shock in which there is loss of neurologic activity below the level of the injury. Detrusor areflexia (the inability to generate a detrusor contraction due to neurologic causes) and maintenance of some residual sphincteric competence usually results in urinary retention requiring either indwelling or intermittent catheterization.

Recovery is characterized by the gradual return of reflex bladder activity or neurogenic detrusor overactivity mediated through the sacral micturition center, which is intact but separated from higher centers. It usually occurs within 2 to 3 months, but in a small number of patients it may take up to 2 years for reflex activity to return. As reflex bladder activity increases during the recovery phase, the bladder may empty well at the expense of incontinence

or high detrusor voiding pressures may develop, resulting in hydronephrosis.

Infrasacral Lesions

Detrusor activity may be absent or diminished if there are lesions of the cell bodies or parasympathetic efferents to the bladder from the sacral roots (S2 to S4). This may be due to trauma to the spinal cord or pelvic nerves or destruction of the cord segment by lesions such as a plaque of multiple sclerosis.

Injury to the conus or sacral roots results in the following:

- Detrusor areflexia
- A denervated open bladder neck
- A paralyzed closed external sphincter
- In most patients, urinary retention

The weakened urethral sphincter mechanism and paralyzed pelvic floor make patients prone to stress incontinence, especially women.

Some patients empty their bladders by abdominal straining or suprapubic compression (Credé's maneuver), but the majority need clean intermittent self-catheterization to empty efficiently. For poorly understood reasons, a minority of patients are at risk of developing poorly compliant high-pressure bladders that can lead to renal damage.

Partial infrasacral lesions may result in a mixed pattern of weak or absent detrusor activity, poor compliance, and considerable reflex activity in the pelvic floor muscles.

Idiopathic Detrusor Overactivity
