Clinical involvement of visceral sites is relatively uncommon even in patients with widespread castration-resistant disease. Table 110–2 illustrates the distribution of metastatic sites reported in selected chemotherapy phase 2 and phase 3 trials. These figures suggest that clinical evidence of visceral metastasis is observed in less than 10% of patients, whereas about 20% have demonstrable soft tissue nodal disease. Because the majority of tumor burden in metastatic prostate cancer is found in bone, responses to treatment (e.g., tumor shrinkage) in soft tissue sites alone (e.g., nodal or visceral sites) may not reflect a major treatment benefit because it represents only a small proportion of the overall disease burden.

Patients with metastatic CRPC may present with a range of hematologic problems caused primarily by the disease or by its treatment. Anemia is the most common hematologic abnormality, which can be explained by a variety of factors, such as anemia of chronic disease, bone marrow invasion, blood loss, and rarely secondary to a microangiopathic hemolytic anemia usually associated with a consumption coagulopathy (disseminated intravascular coagulation). **A decrease in the red blood cell count of patients with advanced CRPC commonly results from a combination of factors, such as prior treatment with local irradiation of bone marrow, systemic use of radiopharmaceuticals, long-term androgen deprivation, and systemic chemotherapy, as well as from extensive bone marrow invasion by tumor resulting in substantial decrease in bone marrow reserves.** The use of erythropoietin can be effective, especially in patients with a history of long-term androgen suppression, and repeated administration may require the use of iron preparations. However, erythropoietin-stimulating agents should be used with caution, because evidence is now emerging that these agents may increase mortality in cancer patients (Bennett et al, 2008). **Granulocytopenia and thrombocytopenia are most commonly a complication of extensive radiation therapy or systemic chemotherapy.** Rarely, rapidly growing tumors with bone marrow involvement result in pancytopenia. Thrombocytosis is also a nonspecific manifestation associated with various neoplastic conditions, including prostate cancer. Clotting complications associated with thrombocytosis are rarely seen in patients with prostate cancer, and treatment is not usually necessary.

Among the most important urologic sequelae in patients with advanced prostate cancer is the

Table 110–2.

Typical Distribution of Metastatic Sites in Patients with Castration-Resistant Prostate Cancer Entered in Clinical Trials

STUDY	NO. PATIENTS	Metastatic Site			
		Bone	Lung	Liver	Soft Tissue–Nodal
Hudes et al, 1992	36	36 (100%)	0 (0%)	2 (6%)	7 (19%)
Pienta et al, 1994	42	42 (100%)	3 (7%)	5 (12%)	13 (31%)
Sella et al, 1994	39	36 (92%)	3 (8%)	3 (8%)	9 (23%)

development of obstructive uropathy. This complication, related to the primary disease, can be devastating in terms of quality of life and may even have major therapeutic implications. Besides an increased incidence of infection and pain, obstructed kidneys may critically impair renal function to a point where various chemotherapeutic agents (which depend largely on renal mechanisms for their clearance) cannot be safely employed. In general, patients who are otherwise candidates for treatment with cytotoxic drugs are best first managed by relief of obstruction either with placement of internal stents or by percutaneous nephrostomies.

One of the greatest emergencies in oncology is the development of epidural spinal cord compression (Sorensen et al, 1990). Because of the frequent involvement of vertebral bodies by metastatic prostate cancer, the incidence of cord compression is of particular concern (see later).

Key Points: Clinical Considerations

- Evaluate the extent and aggressiveness of the disease.
- Realize that the critical issues are presence or absence of metastases, clinical versus biochemical relapse, presence of symptoms (e.g., pain), and PSA kinetics (e.g., PSA doubling time, PSA velocity).
- Consider secondary hormonal manipulations before initiation of cytotoxic chemotherapy.

CYTOTOXIC CHEMOTHERAPY

Evaluation of Treatment Efficacy

The evaluation of chemotherapy based on uncontrolled clinical trials in patients with metastatic prostate cancer is usually confounded by significant methodologic challenges. The most common metastatic site is bone (nonmeasurable disease), manifested by diffuse osteoblastic lesions that cannot be measured reliably by current methods to allow assessments of therapeutic benefits. Soft tissue or visceral metastatic sites (measurable disease) that allow serial measurements are uncommon (see Table 110–2) and represent only a small fraction of the total burden of the disease. Selection of bi-dimensionally measurable disease sites to assess therapeutic efficacy with serial "tumor measurements" has been the subject of significant criticism. Patients with soft tissue metastasis (especially visceral disease) are considered by many a subgroup with biologic and clinical features distinct from those of the usual patient with prostate cancer who presents with bone metastasis only. A number of prognostic models evaluating baseline and post-treatment characteristics have been developed (Smaletz et al, 2002; Halabi et al, 2003; Armstrong et al, 2007). Among various clinical and laboratory parameters with consistent prognostic significance are baseline functional status (performance status), presence of pain, and pretreatment hemoglobin levels (cutoffs range from 10 to 12 g/dL). Other possible parameters are the baseline PSA level, extent of bone scintiscan involvement (number of lesions or pattern/distribution of bone involvement), and presence of visceral disease. Semi-quantitative methods to evaluate PSA mRNA expression in circulating cells (using reverse transcriptase/polymerase chain reaction) and various PSA constructs (e.g., PSADT and PSA velocity) are among the post-treatment parameters most likely to be of prognostic significance (Kantoff et al, 2001; Scher et al, 2004; Armstrong et al, 2007).

Preclinical observations have suggested that several drugs may reduce PSA secretion without affecting tumor growth (Larocca et al, 1991; Eisenberger and Nelson, 1996; Seckin et al, 1996). Whereas these laboratory observations are likely to be clinically relevant, assays used to evaluate a separate drug effect on PSA secretion still require careful validation. A PSA consensus meeting developed by several leading investigators in the field generated initial guidelines with regard to the use of the PSA test for clinical trials in patients with CRPC (Bubley et al, 1999). These guidelines were recently updated and now also provide a consensus on the use of radiologic end points as well as clinical end points (e.g., pain) for the evaluation of men with CRPC (Scher et al, 2008). The use of serum acid phosphatase and alkaline phosphatase has not been proven beneficial. Undoubtedly, new biomarkers are needed to enhance our ability to rapidly identify active treatments for CRPC. Evolving noncytotoxic and targeted therapies may require a new set of end points and identification of drug-specific intermediate biomarkers that reflect mechanism-specific biologic activity.

Clinical Trials

Most of the chemotherapeutic agents available in oncologic practice have been employed in patients with CRPC, either as single agents or in various combinations. Examples have included cyclophosphamide, 5-fluorouracil, estramustine, vinorelbine, etoposide, cisplatin, carboplatin, doxorubicin, mitoxantrone, paclitaxel, and docetaxel (Eisenberger, 1988). With the exception of docetaxel and perhaps mitoxantrone, most other cytotoxic agents are no longer being used with frequency because they have not been associated with either symptomatic improvements or extension of survival. Evolving data with selected chemotherapy during the new millennium suggest that the survival of patients with advanced CRPC is now somewhere between 16 and 18 months (Petrylak et al, 2004; Tannock et al, 2004) as opposed to 6 to 12 months as previously described (Eisenberger, 1988).

A first step forward in the chemotherapeutic management of CRPC came with mitoxantrone. This agent, a semi-synthetic anthracycline, had previously shown modest symptomatic benefits but with minimal evidence of objective antitumor activity (Osborne et al, 1983; Rearden et al, 1995). In addition, mitoxantrone appeared to have its maximal palliative effect in combination with low-dose corticosteroids (Moore et al, 1994). In two seminal prospective randomized trials of mitoxantrone plus prednisone versus prednisone alone (Tannock et al, 1996) or mitoxantrone plus hydrocortisone versus hydrocortisone alone (Kantoff et al, 1999), the combination resulted in significant improvements of various quality of life parameters, including pain, but survival was not significantly improved in either trial. These studies provided the justification for the approval in 1997 by the U.S. Food and Drug Administration (FDA) of the combination of mitoxantrone and prednisone for *symptomatic* metastatic prostate cancer.

The next significant advance in the use of chemotherapy for CRPC came with docetaxel, a member of the taxane family. This agent acts by inducing apoptosis in cancer cells through TP53-independent mechanisms that are thought to be due to inhibition of microtubule depolymerization and blockade of antiapoptotic signaling. The induction of microtubule stabilization intracellularly through β-tubulin interactions causes guanosine triphosphate (GTP)-independent polymerization and cell cycle arrest at G_2M. In addition, docetaxel has been found to induce BCL2 phosphorylation in vitro, a process

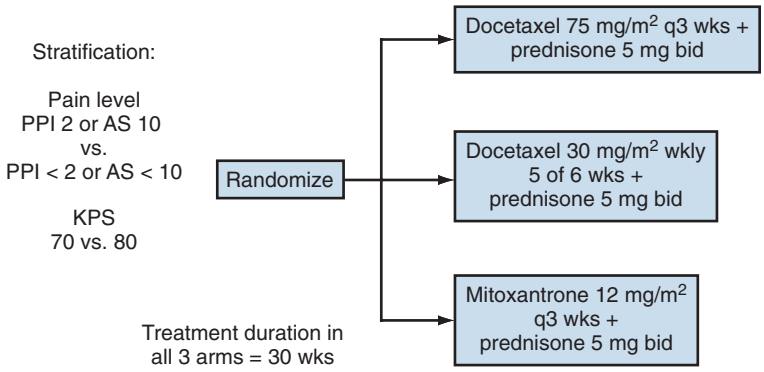

Figure 110–3. TAX 327 study design. AS, analgesic score; KPS, Karnofsky performance status score; PPI, present pain intensity score.

that has been correlated with caspase-3 activation and loss of its normal antiapoptotic activity. Unable to inhibit the pro-apoptotic molecule BAX, phosphorylated BCL2 may also induce apoptosis through this alternate pathway. However, additional mechanisms may also be important, such as CDKN1B (formerly p27) induction and repression of BCL-XL. Data with docetaxel monotherapy previously suggested that this compound has significant activity as a single agent (Friedland et al, 1999; Picus and Schultz, 1999; Beer, 2004).

As of 2004, docetaxel has become the agent of choice for treatment of metastatic CRPC on the basis of a large phase 3 randomized trial, TAX 327 (Figs. 110–3 to 110–5 and Tables 110–3 to 110–5), **which demonstrated superiority over the previous standard, mitoxantrone and prednisone** (Tannock et al, 2004). TAX 327 enrolled 1006 patients with no prior chemotherapy and stable pain scores to one of three study arms (all with concomitant prednisone at 5 mg orally twice daily): mitoxantrone, 12 mg/m^2 intravenously every 21 days; docetaxel, 75 mg/m^2 intravenously every 21 days; or docetaxel, 30 mg/m^2 intravenously every 7 days. Patients remained on

gonadal suppression (e.g., LH-RH agonists) but had all other hormonal agents discontinued. Treatment duration was 30 weeks in all study arms, or a maximum of 10 cycles in the every-3-week study arms, with more patients completing treatment in the every-3-week docetaxel group than in the mitoxantrone group, mostly because of differences in disease progression (46% vs. 25%). **After a median follow-up of 20.7 months, overall survival in the every-3-week docetaxel group was 18.9 months (with a pain response rate of 35% and a PSA response of 45%), contrasted to weekly docetaxel at 17.3 months (and 31% and 48%), respectively. This translated into a 24% relative reduction in the risk of death (95% confidence interval [CI], 6% to 48%; *P* = .0005) with 3-weekly docetaxel** (see Fig. 110–4). **Patients on the mitoxantrone arm had a median survival of 16.4 months, a pain response of 22%, and a PSA response of 32%.**

Toxicity in the 3-weekly versus weekly docetaxel groups was notable for more hematologic toxicity in the every-3-week group (3% neutropenic fever vs. 0%; 32% grade-3/4 neutropenia versus 1.5%) (see Table 110–5) **but slightly lower rates of nausea and vomiting, fatigue, nail changes, hyperlacrimation, and diarrhea. Neuropathy was slightly more common in the every-3-week group (grade 3/4 in 1.8% vs. 0.9% in the weekly treated group). Quality of life responses as measured by the FACT-P scores did not differ significantly among the docetaxel schedules but were more favorable than in the mitoxantrone group.**

The Southwest Oncology Group (SWOG) 9916 study was a second large phase 3 trial (Figs. 110–6 to 110–8) (Petrylak et al, 2004) **in which 770 patients with progressive CRPC were randomly assigned to oral estramustine (280 mg three times daily) plus docetaxel (60 mg/m²**

* Coumadin 2 mg PO daily + ASA 325 mg PO daily was added
Docetaxel and mitoxantrone doses could be increased to 70 mg/m² and 14 mg/m², respectively, if no grade 3 or 4 toxicities were seen in cycle 1

Figure 110–6. SWOG 9916 study design. D/E, docetaxel plus estramustine; M/P, mitoxantrone plus prednisone.

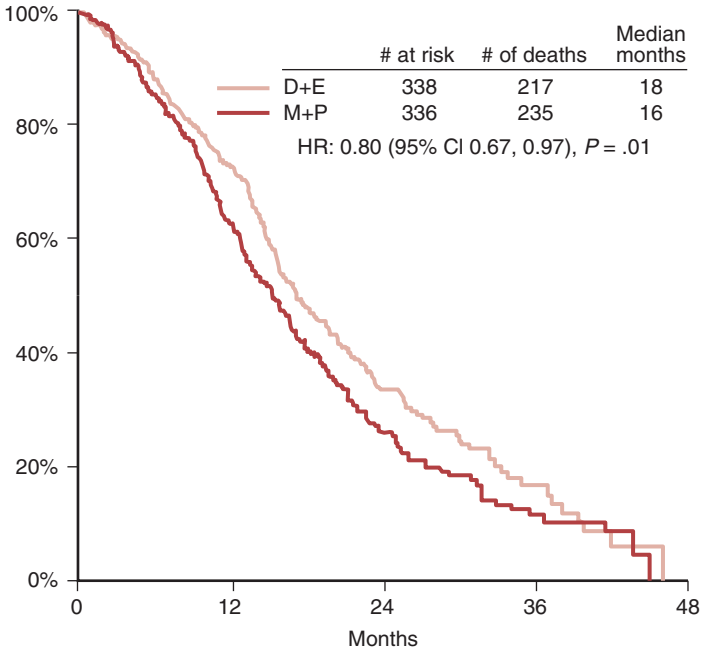

Figure 110–7. Overall survival, SWOG 9916. D+E, docetaxel plus estramustine; M+P, mitoxantrone plus prednisone.

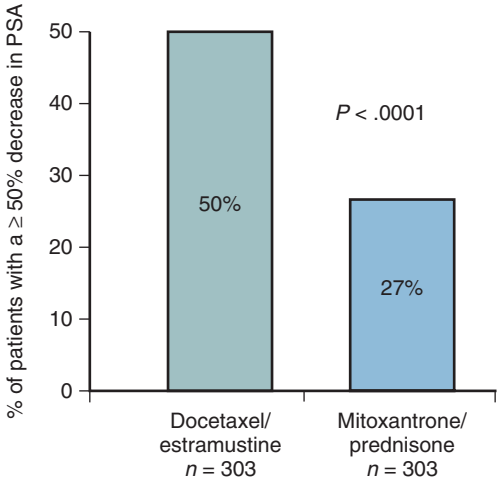

Figure 110–8. SWOG 9916 prostate-specific antigen (PSA) response rate.

every 21 days) versus mitoxantrone (12 mg/m² every 21 days) plus prednisone. In this study, median overall survival was longer in the docetaxel-estramustine group than in the mitoxantrone-prednisone group (17.5 vs. 15.6 months, $P = .02$), with a corresponding hazard ratio (HR) for death of 0.80 (95% CI, 0.67 to 0.97). Because of the high rate of thromboembolic events with estramustine, prophylactic low-dose warfarin and aspirin were added to that study arm, which did not reduce the incidence of thromboembolism. Similarly, 20% and 15%, respectively, of patients in the docetaxel-estramustine arm had grade 3/4 gastrointestinal and cardiovascular toxicities. **Although comparisons between the docetaxel arms across these two seminal trials may not be appropriate because of differences in schedule, patient populations, and docetaxel dosing (60 mg/m² in SWOG 9916 and 75 mg/m² in TAX 327), it may be concluded that estramustine is unlikely to add significantly to the activity of single-agent docetaxel.**

Until recently, effective life-prolonging therapies for men with docetaxel-refractory prostate cancer were lacking. This changed in 2010, when the FDA approved a second chemotherapy agent, cabazitaxel, for the treatment of metastatic CRPC. Cabazitaxel (Jevtana, Sanofi-aventis, Paris, France) is a novel tubulin-binding taxane that differs from docetaxel and paclitaxel due to its poor affinity for P-glycoprotein, the ATP-dependent drug efflux pump (Paller and Antonarakis, 2011). In preclinical studies using cancer cell lines and mouse xenograft models, cabazitaxel was shown to be active in both docetaxel-sensitive tumors as well as those with primary or acquired docetaxel resistance (Attard et al, 2006).

The first hint of cabazitaxel's safety and efficacy in men with prostate cancer came during phase I testing, where cabazitaxel was administered by intravenous infusion every 3 weeks at escalating doses of 10 to 25 mg/m² (Mita et al, 2009). In that study, the principal dose-limiting toxicity was neutropenia. Given the lack of cross-resistance to this agent with docetaxel, and early reports of responses in men with CRPC from this phase 1 trial, a phase 3 trial was launched to evaluate efficacy.

The safety and efficacy of cabazitaxel in patients with advanced prostate cancer was definitively evaluated in a pivotal randomized phase III trial (TROPIC) conducted in 146 institutions across 26 countries, and recruited 755 men with metastatic CRPC who had progressed during/after docetaxel-based chemotherapy (de Bono et al, 2010). Of these, 377 patients were randomized to receive mitoxantrone 12 mg/m² intravenously every 3 weeks (with oral prednisone 10 mg daily), and 378 patients were assigned to receive cabazitaxel 25 mg/m² intravenously every 3 weeks (plus prednisone). This study was the basis of the FDA's approval of cabazitaxel with prednisone for the second-line treatment of docetaxel-refractory metastatic CRPC in June 2010.

After a median follow-up of 12.8 months, overall survival in men receiving cabazitaxel was 15.1 months compared to 12.7 months in men receiving mitoxantrone (HR, 0.70; $P < .0001$) (de Bono et al, 2010). Compared to mitoxantrone, cabazitaxel also significantly lengthened progression-free survival (2.8 months vs. 1.4 months; $P < .0001$), extended time to PSA progression (6.4 months vs. 3.1 months; $P = .001$), increased radiographic tumor response rates (14.4% vs. 4.4%; $P = .0005$), and increased PSA response rates (39.2% vs. 17.8%; $P = .0002$). There were no differences between the two treatment arms with respect to pain responses, or time to pain progression.

In subset analyses, the survival advantage of cabazitaxel persisted regardless of whether patients had measurable disease or pain, or whether progression had occurred while receiving docetaxel or following a treatment holiday. In addition, cabazitaxel's survival benefit was most pronounced for men with ECOG performance status 0-1 (vs. 2), and for patients with disease progression within <3 months of docetaxel initiation (vs. ≥3 months of docetaxel initiation) (de Bono et al, 2010). The last observation implies that cabazitaxel may be effective even in men with truly docetaxel-refractory disease.

The most common serious adverse events related to cabazitaxel were hematological, including grade ≥3 neutropenia in 82% of patients (febrile neutropenia in 8%) (de Bono et al, 2010). This degree of myelosuppression begs the question of whether a lower dose of cabazitaxel (e.g., 20 mg/m²) may have been more appropriate, and a randomized trial comparing the safety and efficacy of these two doses (25 mg/m² vs. 20 mg/m²) is now being conducted. Use of growth factor support should be strongly considered, as reflected in several national guidelines (Mohler et al, 2010). Other nonhematologic toxicities included grade ≥3 diarrhea (6%) and grade ≥3 fatigue (5%). Encouragingly, although peripheral neuropathy (all grades) was observed in 14% of patients receiving cabazitaxel, only 1% developed grade 3 neuropathy.

Key Points: Cytotoxic Chemotherapy

- Docetaxel is the standard treatment for metastatic castration-resistant prostate cancer. It prolongs progression-free and overall survival, ameliorates pain, and improves quality of life.
- Toxicity of docetaxel includes myelosuppression, fatigue, edema, moderate to modest neurotoxicity, hyperlacrimation, and changes in liver function.
- No other chemotherapy regimen has shown a survival advantage in CRPC, but mitoxantrone has been approved to palliate symptoms associated with metastatic disease.
- Cabazitaxel has recently emerged as a treatment option for patients with metastatic CRPC who have experienced progressive disease during or after docetaxel treatment.

The Neuroendocrine/ Anaplastic Subtype

Laboratory and clinical evidence indicates that alterations in the differentiation pathway of prostate cancer can be seen in a small proportion of patients with advanced disease, giving rise to a neuroendocrine/anaplastic transformation (diSant'Agnese, 1995; Nelson et al, 2007). The therapeutic implications of this finding are of significance because tumors demonstrating this phenotype usually represent an inherently endocrine-resistant subtype and, in view of their different clinical and biologic properties compared with the usual adenocarcinoma of the prostate, these tumors usually require different treatment strategies.

Such tumors express a number of biologic characteristics unique to neuroendocrine tumors that can also arise from other organs, most commonly the lung. Among these are the expression of receptors to various neuroendocrine peptide growth factors, such as somatostatin, chromogranin A, and serotonin, as well as parathyroid hormone–related protein (PTHrP) and *TP53* mutations. These tumors have an uncharacteristic clinical behavior (compared with the usual metastatic prostate cancer), reflected by frequent visceral involvement and rapidly growing soft tissue metastases. Patients

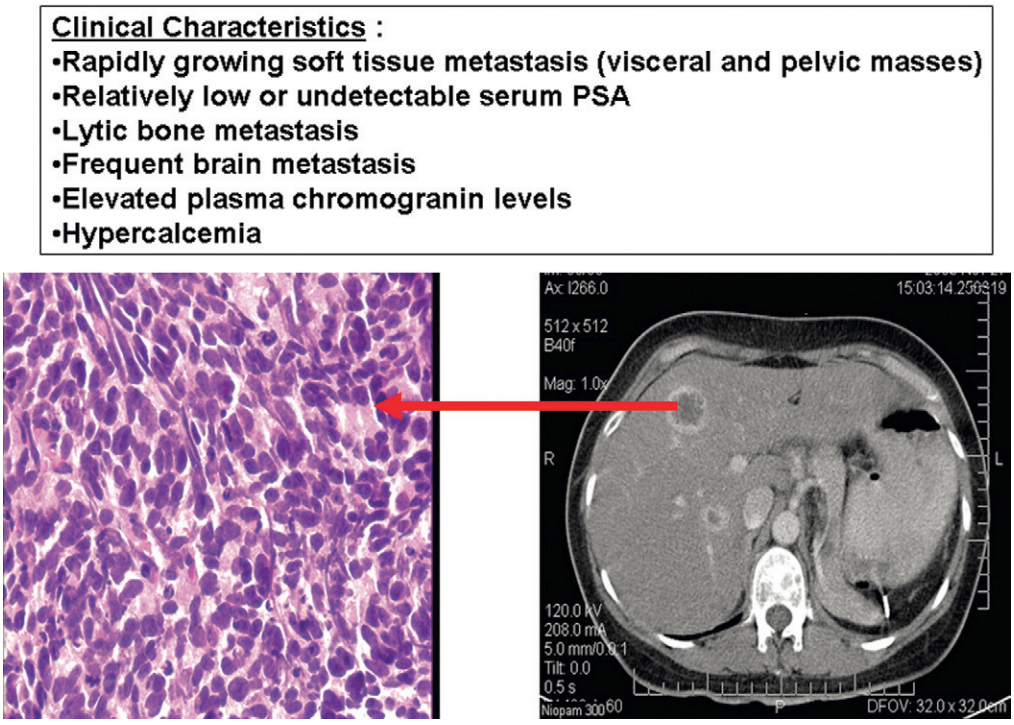

Figure 110–9. Neuroendocrine/anaplastic carcinoma of the prostate. PSA, prostate-specific antigen.

frequently present with subacute and often dramatic changes in their disease pattern characterized primarily by a rapidly growing soft tissue mass (frequently involving the primary site but also with retroperitoneal masses), rapid development of visceral (lung and liver) infiltration, osteolytic (as opposed to osteoblastic) bone metastasis, and a high incidence of parenchymal brain involvement (Fig. 110–9). **Histologic evaluation of areas demonstrating rapid growth is strongly encouraged. This frequently culminates with demonstration of a small cell variant or a poorly differentiated neoplasm on pathology and the presence of neuroendocrine markers on immunostaining** (diSant'Agnese, 1995; Nelson et al, 2007). **Interestingly, patients with this tumor phenotype either stop expressing PSA in the presence of major tumor progression or even have undetectable PSA levels at the time of this transformation.**

Treatment is usually similar to that of patients with other neuroendocrine tumors (e.g., small cell carcinoma of the lung) and includes combinations of cisplatin (or carboplatin) and etoposide (Frank, 1995), **paclitaxel, docetaxel, and topotecan. Doxorubicin-containing combinations have been reported to be moderately effective by one group** (Papandreou et al, 2002). **Radiation therapy is effective and should be considered in cases with bulky disease, with brain metastasis, or when local disease control in critical areas may have a positive impact on quality of life (pain, potential pathologic fractures, and bladder outlet obstruction). A combined chemotherapy and radiation therapy approach is frequently necessary to accomplish maximal disease control. Despite high initial response rates with chemotherapy and radiation treatment, the prognosis of these patients remains poor and is dependent on various factors, including extent and location of metastases.**

Key Points: The Neuroendocrine/Anaplastic Subtype

- Rapidly growing disease with the following clinical characteristics should prompt evaluation for the neuroendocrine/anaplastic phenotype: pelvic masses, visceral involvement, osteolytic metastasis with hypercalcemia (associated with high serum PTHrP), and brain metastasis.
- PSA is most commonly undetectable (or levels are low/declining) despite evidence of rapid disease progression. Serum chromogranin A and urine serotonin metabolites may be detected.
- These tumors are invariably unresponsive to hormonal manipulations but highly sensitive to radiation therapy and platinum-etoposide combinations.

PALLIATIVE MANAGEMENT

Pain and Epidural Cord Compression

As in other disseminated malignant neoplasms, palliation of symptoms and maintenance of adequate levels of quality of life represent the most important objectives in the management of advanced prostate cancer.

Cancer-related pain is undoubtedly the most debilitating symptom associated with metastatic prostatic carcinoma. **Prompt recognition of the various pain syndromes associated with this disease is critical to accomplish effective control of this devastating symptom.** The most common pain syndromes and their respective therapeutic considerations are described in Table 110–6.

Focal bone pain in patients with castration-refractory disease can be well controlled by external-beam localized radiation therapy. In general, it is also recommended that painful areas

Table 110–6.

Common Pain Syndromes in Metastatic Castration-Resistant Prostate Cancer

PAIN SYNDROME	INITIAL MANAGEMENT	OTHER THERAPEUTIC ALTERNATIVES
Localized bone pain	Pharmacologic pain management Localized radiotherapy (special attention to weight-bearing areas, lytic metastasis, and extremities)	Surgical stabilization of pathologic fractures or extensive bone erosions Epidural metastasis and cord compression should be evaluated in patients with focal back pain. Radiopharmaceuticals should be considered if local radiation therapy fails.
Diffuse bone pain	Pharmacologic pain management "Multi-spot" or widefield radiotherapy Radiopharmaceuticals	Corticosteroids Bisphosphonates Calcitonin Chemotherapy
Epidural metastasis and cord compression	High-dose corticosteroids Radiation therapy Surgical decompression and stabilization should be indicated in high-grade epidural blocks, extensive bone involvement, or recurrence after irradiation.	Pharmacologic pain management
Plexopathies caused by direct tumor extension or prior therapy (rare)	Pharmacologic pain management Radiation therapy (if not previously employed) Neurolytic procedures (nerve blocks)	Tricyclic antidepressants (amitriptyline) Anticonvulsants
Miscellaneous neurogenic causes: postherpetic neuralgia, peripheral neuropathies	Careful neurologic evaluation Pharmacologic pain management Discontinuation of neurotoxic drugs: paclitaxel, docetaxel, *Vinca* alkaloids, platinum compounds	Tricyclic antidepressants (amitriptyline) Anticonvulsants
Other uncommon pain syndromes: extensive skull metastasis with cranial nerve involvement, extensive painful liver metastasis or pelvic masses	Radiation therapy Pharmacologic pain management Corticosteroids (cranial nerve involvement)	Chemotherapy Intrathecal chemotherapy may ameliorate symptoms of meningeal involvement; regional infusions may be considered.

shown to be abnormal on bone scintigraphy should be evaluated with plain radiographs to exclude the presence of osteolytic lesions or pathologic fractures. Such considerations become even more important when the painful areas affect extremities and weight-bearing sites.

Epidural metastasis is a fairly common and potentially devastating complication of systemic cancer. In view of the propensity for prostate cancer to metastasize to the vertebrae and paravertebral region, the incidence of epidural cord compression is particularly high in this disease. Early diagnosis and treatment of epidural metastasis is critical in preserving ambulation and bowel and bladder function and aids in the management of back pain (Grossman and Lossignol, 1990; Gabriel and Schiff, 2004). Epidural cord compressions arising from vertebral bodies account for the majority of spinal cord compression; only less frequently is it associated with soft tissue masses involving the paravertebral region. Most patients have abnormalities on bone scintiscans and abnormal findings on radiography at the time of diagnosis. However, an abnormality on neurologic examination may be the only finding in patients who have soft tissue epidural metastasis in the paravertebral region.

Spinal magnetic resonance imaging (MRI) is routinely used to exclude the possibility of significant epidural disease, and it has almost entirely replaced other methods such as computed tomographic myelography and conventional myelography. The first therapeutic intervention should include the administration of high doses of intravenous glucocorticoids. **Dexamethasone at doses ranging from 16 to 100 mg daily is most commonly employed. Most frequently, patients are given an intravenous "loading dose" of 10 mg of dexamethasone followed by 4 to 10 mg every 6 hours; the optimal dose remains relatively undefined.** On improvement of symptoms, which can be accomplished promptly with corticosteroids, the corticosteroid dose may be tapered during a 2- to 3-week period.

Radiation therapy is often the main modality of definitive treatment. However, recent reports suggest that surgery followed by radiation therapy may be superior to radiation therapy alone (Patchell et al, 2005). **Surgery should be considered in patients who present with evidence of progressive signs and symptoms during radiation therapy, develop or present with unstable pathologic fractures, or have recurrence after radiotherapy. Clearly, the overall prognosis of the underlying disease should be taken into consideration during treatment selection. Chemotherapy is rarely used to treat epidural cord compressions.**

Bone-Targeted Approaches

The pathogenesis of bone metastases in prostate cancer remains a subject of major study (Galasko, 1986). Alterations in the normal process of bone absorption and formation, which usually follows an orderly and sequential basis, appear to be a key determining factor in the development of bone metastasis associated with most malignant neoplasms (Roodman, 2004). Under normal physiologic conditions the process of bone remodeling is initiated by an increase in osteoclastic activity followed by an increase in osteoblastic differentiation and maturation, which results in the

formation of new bone and repair of the initial absorption caused by osteoblasts. Bone loss associated with prostate cancer can result from an enhanced osteoclastic activity associated with long-term androgen suppression, which in turn will cause excessive resorption of bone mineral and organic matrix. Tumor cells may also cause mineral release and matrix resorption in the areas involved by metastatic disease (Galasko, 1986). In addition, various cytokines, growth factors, tumor necrosis factors, and bone morphogenic proteins have been shown in preclinical studies to play a major role in the induction of both osteoclastic and osteoblastic activity (Reddi and Cunningham, 1990). In prostate cancer, bone metastases are predominantly blastic, which reflects a predominance of osteoblastic activity in the process of bone remodeling (Roodman, 2004). This phenomenon may be due to specific growth factor secretion that is responsible for the induction of osteoblasts. Hypercalcemia is rare in metastatic prostate cancer. In fact, a significantly elevated serum calcium concentration is most frequently due to the neuroendocrine prostate cancer phenotype and is mediated through PTHrP, as discussed earlier (diSant'Agnese, 1995; Nelson et al, 2007).

Bisphosphonates

Bisphosphonates have become an integral part of the management of metastatic prostate cancer to the bones (Van den Wyngaert et al, 2009). These compounds reduce bone resorption by inhibiting osteoclastic activity and proliferation. Zoledronate is a potent intravenous bisphosphonate first approved for the treatment of hypercalcemia and decreased bone mineral density in postmenopausal women (Green and Rogers, 2002). In patients with progressive castration-refractory disease and bone metastases zoledronate was shown to reduce the incidence of skeletal-related events (e.g., pain, fractures) compared with placebo in a prospective randomized trial of 422 patients (Saad et al, 2004). In addition, zoledronate and pamidronate have also been shown to increase mineral bone density in patients with nonmetastatic prostate cancer receiving long-term androgen deprivation (Smith et al, 2001, 2003). At present, zoledronate is indicated for the treatment of patients with progressive prostate cancer with evidence of bone metastasis, and it is administered at a dose of 4 mg intravenously repeated at intervals of 3 to 4 weeks for several months. Side effects of this agent include fatigue, myalgias, fever, anemia, and mild elevation of the serum creatinine concentration. Hypocalcemia has been described, and concomitant use of oral calcium supplements (1500 mg/day) and vitamin D (400 units/day) is often recommended. **An unusual complication of zoledronate is the development of severe jaw pain associated with osteonecrosis of the mandibular bone.** The etiology of this effect is not well understood. However, it is most frequently seen in patients undergoing dental work or those with a history of poor dentition and chronic dental disease. Zoledronate should not be administered to patients with these problems. Other bisphosphonates have also been evaluated in prostate cancer, including alendronate, etidronate, ibandronate, and clodronate; however, their benefit has not been conclusively established in prospective randomized clinical trials (Berry et al, 2006; Van den Wyngaert et al, 2009).

RANKL Inhibitors

Interactions between tumor cells and the bone marrow microenvironment have been postulated as an additional important mechanism in the pathogenesis of bone metastasis. Tumor-associated cytokines have been shown to induce the expression of RANKL (the receptor activator of nuclear factor κB ligand), which binds and activates RANK, which is found in osteoclasts (Brown et al, 2001). Inhibition of the RANKL system has recently been the focus of much research and represents an evolving bone-targeted strategy. Among the approaches employed are monoclonal antibodies to RANKL and the use of recombinant osteoprotegerin (the natural decoy receptor of RANKL), both of which significantly inhibit osteoclastic function in vitro and in vivo (Schwarz and Ritchlin, 2007). Denosumab, a fully human monoclonal antibody against RANKL, has entered clinical trials in prostate and breast cancers. In a phase 2 randomized study evaluating 50 patients with metastatic prostate cancer, denosumab (180 mg subcutaneously every 4 weeks) produced a reduction in bone resorption over that of zoledronate, as indicated by a lowering of urinary *N*-telopeptide levels, and also resulted in less skeletal-related events (Fizazi et al, 2009). Following from these encouraging results, a pivotal multicenter phase III double-blind randomized study was conducted comparing denosumab against zoledronate for the prevention of skeletal-related events in patients with bisphosphonate-naïve metastatic CRPC. In that trial of 1904 patients, compared to men receiving zoledronate (n = 951), men receiving denosumab (n = 950) had an improved time to first skeletal-related events (20.7 vs. 17.1 months; P = .008) and longer time to first-and-subsequent skeletal-related events (HR, 0.82; P = .004) (Fizazi et al, 2011). Notably, there was no difference in overall survival or progression-free survival between study arms. Based partially on the results of this study (and partially on two other large randomized studies in metastatic breast cancer and other solid metastatic tumors), the FDA approved denosumab (Xgeva, Amgen, Thousand Oaks, CA) in November 2010 for the prevention of skeletal-related events in patients with bone metastases from solid tumors. Common toxicities of denosumab include fatigue, nausea, hypophosphatemia, hypocalcemia (5% grade ≥3), and osteonecrosis of the jaw (2%), and prophylactic calcium and vitamin D supplementation is strongly encouraged. Therefore denosumab is a reasonable alternative to zoledronate for the prevention of skeletal-related events in patients with metastatic CRPC, and also has the advantage that it does not require dose adjustment or monitoring for renal impairment. The recommended dose of denosumab is 120 mg given by subcutaneous injection every 4 weeks.

Radiopharmaceuticals

The introduction of "bone-seeking" radiopharmaceuticals has provided a useful resource for the management of diffuse bone pain from widespread prostate cancer metastases (Pandit-Taskar et al, 2004). Among the most commonly used compounds are strontium-89 (^{89}Sr) (Porter et al, 1993) and samarium-153 (^{153}Sm) (Sartor et al, 2004). Rhenium-186 has also been used (Kucuk et al, 2000). Initial studies with ^{89}Sr have shown palliation of bone pain in 25% to 65% of patients with castration-refractory disease and diffuse pain (Jager et al, 2000). The pharmacokinetics of ^{89}Sr vary considerably according to the extent of bone involvement, but the half-life is generally 4 to 5 days. The retention of the isotope is significantly longer in patients with diffuse osteoblastic metastases compared with those with relatively limited bone involvement. It is important to recognize this factor because it will undoubtedly affect the degree and duration of myelotoxicity associated with this radioactive compound (its most significant side effect). **The clinical experience with ^{153}Sm suggests that this isotope is associated with a lower incidence of severe myelotoxicity, probably because of**

its shorter half-life of 2 days. Encouraging results were reported by Sartor and colleagues (2004) in a phase 3 trial comparing radioactive ^{153}Sm and nonradioactive ^{152}Sm, indicating that a dose of ^{153}Sm of 1 mCi/kg is both safe and effective palliation for patients with castration-refractory disease and severe bone pain. One study reported encouraging synergism with ^{89}Sr and doxorubicin, a known and well-studied radiosensitizer (Tu et al, 2001). Randomized studies evaluating the synergism of various chemotherapeutic agents, including taxanes, and radiopharmaceuticals are being done.

Key Points: Palliative Management

- Patients with back pain and a history of bone metastasis should be aggressively evaluated for epidural cord compression. The clinical syndrome often has at least one of the following signs and symptoms: back pain, focal neurologic findings (leg weakness, sensory levels), or changes in bladder or bowel control.
- Initial management of suspected cord compression includes immediate magnetic resonance imaging of the spine and high-dose intravenous corticosteroid therapy.
- Definitive therapy should include surgical decompression, radiation therapy, or both.
- Zoledronic acid and denosumab are both reasonable treatment options for the prevention of skeletal-related events in patients with castration-resistant bone metastases.

NOVEL APPROACHES

Rational Target Overview

An understanding of the basic biology involved of pathogenesis of prostate cancer provides the opportunity to identify potential targets that predict the clinical outcome of the disease. The first opportunity is the demonstration of a mutation or functional dysregulation of the target. Simply targeting overexpressed proteins has been less efficient than the specific targeting of mutations that drive the bulk of the tumor growth. The second goal is identifying target causality, indicating the importance of the target alone or in combination with other mutations in reproducing the phenotypic findings of prostate cancer. Finally, there should be evidence from preclinical models that inhibition of the target leads to tumor regression or quiescence. In prostate cancer, the androgen receptor is one potential target although there are many others. Various molecular changes in the androgen receptor have been shown to parallel disease progression in castrate patients and in some situations may provide the explanation for the responses associated with some therapeutic maneuvers (antiandrogen withdrawal syndrome, responses to secondary endocrine manipulations with compounds designed to bind to the receptor). Despite this, a precise role of the androgen receptor in the pathogenesis of disease progression remains to be better elucidated. Given the molecular complexity of the prostate cancer cell pathways and relatively poor understanding of the role of individual pathways in the process of disease-specific progression, the simultaneous inhibition of multiple pathways remains a common strategy to induce sustained and clinically meaningful responses in prostate cancer.

The major biologic processes under therapeutic investigation in prostate cancer involve growth and survival, chemotherapy and hormone therapy resistance, extragonadal androgen production, modulation of the androgen receptor, angiogenesis, the bone interface, epigenetic regulation, immune surveillance and escape, and stem cell renewal. This section provides an overview of these pathways as they pertain to prostate cancer rational targets and the approaches that are currently being developed for therapeutic purposes (Table 110–7).

Targeted Treatments

Although a prostate cancer stem cell has yet to be conclusively demonstrated, prostate cancer clearly progresses from an androgen-dependent tumor with features similar to the luminal

Table 110–7.

Targeted Therapies for Castration-Resistant Prostate Cancer (CRPC): Selected Ongoing Clinical Trials

TARGET	AGENT	PHASE	SUMMARY OF TRIAL
PI3K/mTOR	Everolimus	2	Docetaxel + everolimus for first-line metastatic CRPC
EGFR/HER2	Lapatinib	2	Single-agent lapatinib for nonmetastatic CRPC
PDGFR	Imatinib	2	Docetaxel ± imatinib for first-line metastatic CRPC
Vitamin D	Calcitriol	3	Docetaxel ± calcitriol for first-line metastatic CRPC
HDAC	Vorinostat	2	Single-agent vorinostat for second-line metastatic CRPC
	Panobinostat	2	Single-agent panobinostat for second-line metastatic CRPC
Endothelin receptor	Atrasentan	3	Docetaxel ± atrasentan for first-line metastatic CRPC
	Zibotentan	3	Docetaxel ± zibotentan for first-line metastatic CRPC
RANK ligand	Denosumab	3	Denosumab vs. zoledronate for palliation in metastatic CRPC
VEGF	Bevacizumab	3	Docetaxel ± bevacizumab for first-line metastatic CRPC
VEGF receptor	Sorafenib	2	Docetaxel + sorafenib for first-line metastatic CRPC
	Sunitinib	2	Docetaxel + sunitinib for first-line metastatic CRPC
	Vatalinib	2	Single-agent vatalinib for nonmetastatic CRPC
CYP17	Abiraterone	3	Single-agent abiraterone for second-line metastatic CRPC
Androgen receptor	MDV3100	1/2	Single-agent MDV3100 for nonmetastatic/metastatic CRPC
Immunotherapy	Sipuleucel-T (Provenge)	3	Sipuleucel-T vs. placebo for first-line metastatic CRPC
	GVAX	3	GVAX vs. docetaxel for first-line metastatic CRPC
			Docetaxel ± GVAX for first-line metastatic CRPC
CTLA-4	Ipilimumab	3	Ipilimumab vs. placebo for second-line metastatic CRPC

differentiated glands of the prostate to a castration-refractory tumor that has features of adult stem cells, including antiapoptotic mechanisms, chemotherapy resistance, and reliance on nonhormonal signaling pathways. **Candidate pathways currently evaluated include hedgehog signaling, epidermal growth factor receptor (EGFR) signaling, phosphatidylinositol 3-kinase (PI3K)/Akt signaling, mitogen-activated protein kinase (MAPK) signaling, and others** (see Table 110–7). Activation of the hedgehog developmental pathway has been demonstrated in prostate cancer metastases and in preclinical models, and inhibition of this pathway has led to antitumor effects and significant inhibition of prostatic epithelial regeneration after androgen withdrawal. Inhibitors of this pathway, such as cyclopamine analogues and other agents, are in preclinical development.

PI3K/Akt/mTOR Pathway

In advanced prostate cancer, loss of the tumor suppressor *PTEN* (phosphatase and tensin homologue deleted on chromosome 10) occurs in more than 50% of metastatic lesions and in approximately 20% of locally advanced lesions (McMenamin et al, 1999; Graff, 2002). **Loss of *PTEN* correlates with advanced Gleason sum, stage, chemotherapy resistance, and other features of advanced prostate cancers** (McMenamin et al, 1999). ***PTEN* is a negative regulator of the PI3K/Akt survival pathway, and advanced prostate cancers frequently have elevated levels of phosphorylated (activated) Akt** (Gera et al, 2004). The Akt pathway is involved in signal transduction from multiple cell surface receptors, including the insulin receptor, epidermal growth factor receptor, insulin-like growth factor receptor, platelet-derived growth factor receptor, and interleukin-6 receptor, and it is likely to function as a cellular sensor for nutrient and growth signals (Vivanco and Sawyers, 2002). In addition to promoting cell survival through the inhibition of apoptosis, the Akt pathway regulates cell growth, proliferation, and angiogenesis through the mammalian target of rapamycin (mTOR) pathway and the facilitated translation of signals such as c-*MYC*, cyclin D, and vascular endothelial growth factor (Gera et al, 2004). Restoration of functional *PTEN* activity or inhibition of mTOR activity can block the growth of $PTEN^{-/-}$ prostate cancer xenografts and restore chemotherapy and possibly hormonal sensitivity (Neshat et al, 2001; Podsypanina et al, 2001; Grunwald et al, 2002).

Rapamycin is a natural compound derived from soil samples containing the bacterium *Streptomyces hygroscopicus*. It was initially discarded as an antifungal agent because of its immunosuppressive properties but later revived as a potent immunosuppressive agent for use in solid organ transplantation. Its antiproliferative properties and antitumor activity in cell lines led to its clinical development in cardiology as a means of preventing stent restenosis and in oncology, in which a wide variety of tumors were found to exhibit sensitivity to this agent and its analogue temsirolimus (Hidalgo and Rowinsky, 2000; Bjornsti and Houghton, 2004). Toxicities with rapamycin and its analogues have been predictable and often not dose related; they include maculopapular rash, hypertriglyceridemia, hyperglycemia, allergic reactions, pedal edema, mucositis, and thrombocytopenia (Hidalgo and Rowinsky, 2000; Atkins et al, 2004; Raymond et al, 2004). The combination of these agents with docetaxel is attractive, given their ability to induce apoptosis when they are given in combination with chemotherapy in patients who have demonstrable activation of the Akt pathway as a result of *PTEN* mutation or loss or other genetic alterations. For example, a new mTOR inhibitor, everolimus (RAD001), is being evaluated in combination with docetaxel as first-line treatment for metastatic CRPC in a phase 1/2 trial (Ross et al, 2008).

EGFR and PDGFR Pathways

The rapid development in the past several years of small molecules that inhibit tyrosine kinases has yielded encouraging results in a host of cancers. Demonstration of tumor response has usually correlated with mutation in the target tyrosine kinase, such as epidermal growth factor receptor (EGFR), BCR-ABL, and c-KIT. In these cases the target mutation has played a central role in the pathogenesis of these tumors. In prostate cancer, no such mutation has been identified, and early trials of tyrosine kinase inhibitors in prostate cancer have been disappointing.

EGFR is overexpressed in 40% to 80% of prostate cancer cells, and overexpression may be more common in African-American men with prostate cancer (Shuch et al, 2004). Furthermore, preclinical data suggested a correlation of EGFR expression with Gleason sum and androgen independence (Syed, 2003). In a phase 2 study of approximately 100 patients with castrate-resistant disease evaluating the EGFR tyrosine kinase inhibitor gefitinib, minimal activity and no PSA responses were reported (Moore et al, 2002; Schroder and Wildhagen, 2004). Gefitinib resistance may be related to overactivity of the PI3K/Akt pathway in prostate cancer, and thus combinations of agents that target multiple pathways may be more beneficial (She et al, 2003). Further trials of combination EGFR or dual kinase inhibitors with chemotherapy or other novel agents are in development.

Prostate cancer cells express high levels of platelet-derived growth factor receptor (PDGFR), and this signaling pathway uses the PI3K/Akt pathway, which has been implicated in prostate cancer progression. Single-agent activity with imatinib has been disappointing; however, encouraging results in combination with weekly docetaxel have been reported. A phase 2 randomized trial of this combination compared with docetaxel alone is in progress.

Another potential target in this family of receptors is the HER2/neu tyrosine kinase, whose expression has been shown to increase androgen receptor activation leading to prostate cancer growth and survival (Gregory et al, 2005). However, phase 2 studies using the anti-HER2 monoclonal antibody trastuzumab showed minimal efficacy in CRPC, perhaps owing to a low frequency of HER2 overexpression (Ziada et al 2004). Studies using the dual EGFR/HER2 small molecule inhibitor lapatinib for asymptomatic CRPC are now being conducted.

Vitamin D Analogues

Vitamin D analogues may have differentiation, antiproliferation, and chemosensitizing properties, and epidemiologic studies have shown an increased risk of prostate cancer in those with relative vitamin D deficiency. A phase 2 trial of weekly docetaxel and high-dose calcitriol demonstrated PSA responses in 30 of 37 patients (80%) and measurable responses in 8 of 15 (53%), with a median time to progression of 11.4 months and median survival of 19.4 months (Beer et al, 2005). **A randomized study with a total of 250 patients (125 per study arm) comparing the combination with docetaxel alone resulted in more than 50% decline of PSA level in 63% of the patients receiving the combination treatment compared with 52% with docetaxel alone (P = .07). However, interestingly, the authors reported a survival difference in favor of the**

combination (23.4 vs. 16.4 months; *P* = .03). These results led to the design of a large phase 3 placebo-controlled trial in metastatic CRPC evaluating docetaxel chemotherapy with or without calcitriol, with power to detect a survival benefit as the primary end point. However, early reports from this trial have shown that the primary end point was not met and that mortality was increased in the calcitriol groups, leading to premature closure of the study (Novacea, Inc., 2007).

Bone Interface

Preclinical studies suggest that endothelin A receptors are overexpressed in prostate cancer, and higher plasma endothelin levels in patients with prostate cancer have been shown to correlate with tumor stage, grade, and metastases. Endothelin-1 is a potent vasoconstrictor, and antagonists have been developed for the treatment of pulmonary hypertension. In oncology, endothelin is likely to be involved in the paracrine signals between osteoblasts and prostate cancer cells that regulate the development of bone metastases and have been shown to influence cell growth and proliferation, regulate osteoblast activity, and inhibit apoptosis. These preclinical observations suggest that this pathway may be a rational target for the interference of tumor-stromal interactions (Nelson JB et al, 2003; Carducci et al, 2002; Yin et al, 2003).

Atrasentan is a highly selective endothelin A receptor antagonist and has been extensively tested in prostate cancer. In preliminary phase 2 trials, a 10-mg dose of atrasentan was found to prolong time to progression compared with placebo in men with metastatic CRPC (196 vs. 129 days, respectively; *P* = .02) (Carducci et al, 2003). **Adverse events with atrasentan were mild and related to vasomotor reactions, including headache, rhinitis, flushing, and peripheral edema. In addition, favorable effects were seen in markers of bone deposition and resorption.** However, in a placebo-controlled double-blind phase 3 trial involving 809 patients with metastatic CRPC, oral atrasentan (10 mg/day) did not reduce the risk of disease progression (*P* = .14), despite evidence of biologic affects on PSA and bone alkaline phosphatase (Carducci et al, 2007). A second phase 3 trial in nonmetastatic CRPC that randomized 467 men to atrasentan and 474 to placebo also failed to improve time to metastatic progression (*P* = .29) or overall survival (Nelson et al, 2008). A large cooperative group phase 3 clinical trial evaluating docetaxel plus or minus atrasentan as first-line therapy for metastatic CRPC is in progress.

A novel small molecule endothelin receptor inhibitor, zibotentan (ZD4054), has shown initial promising results. In a phase 2 trial of zibotentan versus placebo in men with metastatic CRPC, this agent did not improve time to disease progression (the primary study end point; *P* = .55); however, overall survival was longer in the zibotentan group (*P* = .01) (James et al, 2009). Although survival was a secondary end point, this has led to the design of several ongoing placebo-controlled phase 3 clinical trials evaluating zibotentan either alone or in combination with docetaxel in patients with metastatic CRPC.

Angiogenesis Targets

Tumor angiogenesis is likely to be an important biologic component of prostate cancer metastasis, and elevated levels of the potent angiogenic molecule vascular endothelial growth factor (VEGF) have been shown to correlate with advanced clinical stage and survival (Duque et al, 1999; George et al, 2002).

In a retrospective study of archived serum samples, VEGF levels were independently associated with survival from prostate cancer (George et al, 2001). Similarly, antibodies to VEGF have slowed prostate xenograft growth rates, especially in combination with chemotherapy (Fox et al, 2002; Sweeney et al, 2002). These findings led to the phase 2 CALGB 90006 trial, which added bevacizumab to docetaxel and estramustine in men with metastatic CRPC. Among 79 treated patients in this study a decline of more than 50% in PSA level was seen in 65% of men, median time to progression was 9.7 months, and overall median survival was 21 months (Picus et al, 2003). Other phase 2 trials combining docetaxel and bevacizumab have also shown promising results (Ryan et al, 2006; Di Lorenzo et al, 2008). These favorable trials have led to the design of a phase 3 randomized study (CALGB 90401) evaluating docetaxel 75 mg/m^2 every 3 weeks and prednisone 10 mg daily plus either bevacizumab 15 mg/kg or placebo given every 3 weeks. The primary end point of this trial is overall survival, and accrual of 1020 patients with metastatic CRPC has been completed.

Thalidomide was originally developed in the 1960s for treatment of morning sickness and subsequently linked to teratogenic effects resulting in phocomelia and dysmelia. Whereas the exact mechanism of teratogenesis is unproven, the metabolites of thalidomide have been shown to inhibit angiogenesis through multiple potential mechanisms, including inhibition of proangiogenic signals such as VEGF, basic fibroblast growth factor (bFGF), interleukin-6, and tumor necrosis factor-α (Bartlett et al, 2004; Franks et al, 2004). Preclinical studies suggest that thalidomide has T-cell costimulatory activity and immunomodulatory properties as well. Phase 1/2 studies with high doses of thalidomide as a single agent have yielded low response rates on the order of 20% for PSA declines (Figg et al, 2001; Franks et al, 2004). However, in a randomized phase 2 trial of weekly docetaxel and low-dose thalidomide versus docetaxel alone, PSA responses, time to disease progression, and overall survival were greater in the combination therapy group (Dahut et al, 2004). Although this trial was underpowered to detect a difference from the standard study arm, the clinical activity and manageable toxicity of this agent have led to the development of more potent thalidomide analogues for combination therapy, and these are currently undergoing clinical evaluation. In a recent phase 2 trial using a three-drug combination of docetaxel, thalidomide, and bevacizumab, PSA responses were seen in approximately 80% of patients (Ning et al, 2008). However, neurotoxicity was a significant side effect with this regimen.

Toxicities with thalidomide include deep venous thrombosis, sedation, neuropathy, constipation, and fatigue. Newer thalidomide analogues with immunomodulatory features have been developed that lack the neurotoxicity of thalidomide but retain many of the T-cell modulatory functions, antiangiogenic properties, and even direct pro-apoptotic functions (Bartlett et al, 2004). Lenalidomide and CC-4047 are second-generation compounds with much more potent tumor necrosis factor-α inhibition than the parent compound, and clinical testing with these agents has begun. For example, several phase 1 and 2 studies have revealed PSA responses and partial radiologic responses with lenalidomide, both when used alone and when combined with ketoconazole or docetaxel (Dreicer et al, 2007; Moss et al, 2007; Garcia et al, 2008). Phase 3 trials using thalidomide or lenalidomide in CRPC have not yet been conducted.

There has been a recent interest in the evaluation of tyrosine kinase inhibitors (TKIs), agents that block angiogenic growth factor targets such as the VEGF and PDGF receptors. The drug

sorafenib is an oral inhibitor of RAF kinase, VEGFR, and PDGFR, which has been approved for use in metastatic renal cell carcinoma. In phase 2 studies using sorafenib in men with metastatic CRPC, this agent was shown to prevent radiologic progression and cause regression of bone metastases in some patients, but without affecting PSA levels (Dahut et al, 2006; Aragon-Ching et al, 2008).

To conclusively evaluate the efficacy and safety of abiraterone, a pivotal multicenter placebo-controlled blinded randomized phase III trial (COU-AA-301) was conducted in men with docetaxel-pretreated ketoconazole-naïve metastatic CRPC (de Bono et al, 2011). This trial randomized men (2:1) to receive either abiraterone 1000 mg daily plus prednisone 10 mg daily (n = 797) or placebo plus prednisone (n = 398). The trial met its primary endpoint, demonstrating a median overall survival of 14.8 months in the abiraterone arm and 10.9 months in the placebo arm (HR, 0.65; P < .0001). In addition, when compared to placebo, abiraterone prolonged radiographic progression-free survival (5.6 vs. 3.6 months; P < .0001), improved time to PSA progression (10.2 vs. 6.6 months; P < .0001), and produced more PSA responses (38% vs. 10%; P < .0001). Notably, the overall survival duration seen here (14.8 months) is similar to that of cabazitaxel/prednisone (15.1 months) in this second-line population with similar baseline characteristics, while the survival of men treated with prednisone alone was slightly inferior to that of mitoxantrone/prednisone in the TROPIC trial (10.9 vs. 12.7 months). Based on the results of the COU-AA-301 trial, the FDA approved abiraterone acetate (Zytiga, Janssen Biotech, Horsham, PA) in April 2010 for the treatment of patients with metastatic CRPC who have received prior docetaxel chemotherapy. The recommended dose of abiraterone is 1000 mg daily by mouth. A second randomized phase III trial (COU-AA-302) targeting men with docetaxel- and ketoconazole-naïve CRPC has completed accrual of over 1000 patients. Given the comfort level and safety of using this and other hormonal agents in prostate cancer patients prior to chemotherapy, it is very likely that abiraterone will be used clinically in both the predocetaxel and postdocetaxel settings.

CYP17 System

It has recently been recognized that the androgen receptor and ligand-dependent androgen receptor signaling commonly remain active and upregulated in men with castrate levels of testosterone (i.e., <50 ng/dL) (Debes and Tindall, 2004). Standard hormonal therapies inhibit gonadal androgenesis but do not affect androgen synthesis from adrenal or other extragonadal sources that may account for 5% to 10% of total androgen production. It has also been suggested that CRPC itself may produce intratumoral androgens autonomously (Mostaghel et al, 2007). In addition, overexpression of CYP17 has been demonstrated in tumors of men with CRPC (Stigliano et al, 2007). The novel agent abiraterone acetate is an oral selective inhibitor of the microsomal enzyme cytochrome P17 (17,20-lyase and 17α-hydroxylase) that is a key regulator of adrenal androgen synthesis. Phase 1/2 studies using abiraterone in men with CRPC (both before and after docetaxel) have shown a substantial number of PSA responses (PSA declines ≥ 50%) and also some partial radiologic responses in men with bony and visceral metastases (Attard et al, 2008; Danila et al, 2008). Common side effects of this agent include hypokalemia, hypertension, and pedal edema. These effects are explained by a syndrome of secondary mineralocorticoid excess, which improves with use of the mineralocorticoid receptor antagonist eplerenone. Phase 3 randomized studies of abiraterone plus docetaxel in first-line metastatic CRPC, and abiraterone used alone in the docetaxel-refractory setting, are being conducted.

Androgen Receptor Modulation

A slightly different androgen receptor (AR)-directed approach has focused on the development of second-generation antiandrogens that have advantages over the established agents in this class (bicalutamide, nilutamide, flutamide). One such drug is MDV3100, a potent oral nonsteroidal AR antagonist (Chen et al, 2009). Importantly, MDV3100 remains a potent antagonist of the AR in the castration-resistant state, even in the setting of overexpressed or constitutively activated AR (Watson et al, 2010). In addition, unlike other antiandrogens that may also function as partial AR agonists, MDV3100 does not exhibit any measurable agonistic activity and is able to prevent AR nuclear translocation with resultant tumoricidal (not cytostatic) activity (Tran et al, 2009). Notably, recent studies have demonstrated the emergence of ligand-independent AR splice variants in CRPC, some of which may also be inhibited by MDV3100.

A pivotal placebo-controlled double-blind phase III study (AFFIRM), randomizing 1170 patients with docetaxel-pretreated ketoconazole-naïve CRPC to MDV3100 160 mg daily (n = 780) or placebo (n = 390), has now completed accrual. A second randomized phase III trial (PREVAIL) investigating the same treatment arms in men with chemotherapy-naïve CRPC is currently underway. One advantage of MDV3100 over agents such as abiraterone is the lack of requirement for concurrent corticosteroid administration. However, the optimal sequencing of this agent, if approved, with immunotherapies and other emerging hormonal therapies will need to be defined through future clinical trials.

A phase I/II study of oral MDV3100 in men with chemotherapy-naïve (n = 65) or taxane-pretreated (n = 75) metastatic CRPC has recently been published (Scher et al, 2010). In that trial, ≥50% PSA declines were seen in 62% and 51% of chemotherapy-naïve and taxane-pretreated patients, respectively; objective tumor responses were observed in 36% and 12% of men, respectively. Radiographic progression-free survival was 6.7 months in the docetaxel-pretreated patients and >17 months in chemotherapy-naïve patients. Side effects of MDV3100 are generally mild and include fatigue (27%) and nausea (9%). Rare seizures (3/140 patients) have also been reported, perhaps mediated by a direct effect of AR antagonism on central nervous system GABA-A receptors.

Epigenetic Approaches

Histone deacetylases (HDACs) are key regulators of histone acetylation status, which is critical for AR-mediated transcriptional activation of genes implicated in the regulation of cell survival, proliferation, differentiation, and apoptosis. Vorinostat is a potent oral HDAC inhibitor that has shown antitumor activity in prostate cancer cell lines and animal models (Welsbie et al, 2009). This agent has previously been approved for the treatment of cutaneous T-cell lymphoma. However, a phase 2 study of vorinostat in the second-line treatment of men with CRPC that had progressed on docetaxel did not show significant PSA or radiologic responses and was associated with a high frequency of grade 3/4 adverse events, which included fatigue, nausea, anorexia, vomiting, diarrhea, and weight loss (Bradley et al, 2008). A novel oral HDAC inhibitor, panobinostat (LBH589), is currently in phase 1 development as an adjunct to docetaxel in first-line CRPC (Rathkopf et al, 2008).

Immunotherapy

Entraining the immune system to overcome tumor-induced tolerance is the goal of nearly every cancer vaccine program, and

active immunotherapy with vaccination against tumor antigens has been pursued in many different cancer models. A variety of approaches have been employed, including dendritic cell-based therapies; novel adjuvants such as bacille Calmette-Guérin (BCG), granulocyte-monocyte colony-stimulating factor (GM-CSF), and viral carriers; single-antigen or whole cell vaccines; and genetically modified tumors. More recently, combination therapies using costimulatory molecules, CTLA-4 blockade, Toll-like receptor agonism, and intracellular viral or bacterial mediators have been developed (Pardoll, 1992; Blattman et al, 2002; Mapara and Sykes, 2004; Harzstark and Small, 2009).

In prostate cancer, several immunologic strategies have been under clinical development. The most important of these include the sipuleucel-T (Provenge) autologous prostatic acid phosphatase (PAP)-loaded dendritic cell vaccine, the GVAX allogeneic recombinant whole cell vaccine, and CTLA-4 inhibitory approaches. Less successful strategies have included the Prostvac-VF recombinant pox viral PSA vaccine and the BLP25 MUC1 liposomal vaccine, among many others. Each of these vaccines is designed to stimulate the immune system to recognize a previously tolerance-inducing tumor in a cancer-specific way (Webster et al, 2005).

Sipuleucel-T

Sipuleucel-T (Provenge) is a vaccine derived from CD54+ dendritic cells, the major antigen-presenting cells, which are apheresed from individuals and processed with the recombinant fusion protein PAP and GM-CSF. PAP was chosen on the basis of its prostate cell membrane localization and the success of preclinical models using it to generate prostate-specific immune responses and autoimmune prostatitis. Modest activity was reported in phase 2 trials in patients with CRPC. In a randomized phase 2/3 trial comparing sipuleucel-T against placebo in 127 asymptomatic men with metastatic CRPC (PAP positive), the investigators reported no significant differences in time to disease and pain progression ($P = .052$), which corresponded to the main study end point (Small et al, 2006). Patients randomized to placebo were crossed over to receive the active vaccine at the time of progression, whereas those initially randomized to receive the active vaccine were treated at their physician's discretion at the time of progression. This postprogression management period was not part of the study and not prospectively controlled. Whereas the study as designed was negative, a 3-year update suggested a statistically significant improvement in survival for those randomly assigned to receive the active vaccine initially ($P = .01$). It is highly probable that survival differences were due to postvaccine treatments. Post hoc analyses also suggested that the benefits of sipuleucel-T may be limited to the subgroup of men with tumor Gleason sums of 7 or lower. Although preparation and production of large-scale quantities of individually tailored vaccine can be challenging, this vaccine was well tolerated with minimal infusion-related fevers and rigors being the predominant adverse events (Small et al, 2006).

A second phase 2/3 trial that randomized 98 men with asymptomatic CRPC to either sipuleucel-T or placebo also failed to show a statistically significant improvement in time to progression (the primary end point) but, unlike the previous study, did not demonstrate an overall survival advantage at 3 years ($P = .33$) (Dendreon, Inc., 2005). A post-hoc pooled analyses of these two trials ($n = 225$) did show an overall survival advantage, with median survival being 18.9 months in the placebo group and 23.2 months in the sipuleucel-T group (HR, 1.5; $P = .01$) (Dendreon, Inc., 2005). However, because overall survival was not the primary end point in either trial, the FDA did not grant approval of this treatment.

In an effort to satisfy FDA requirements, a pivotal multicenter double-blind placebo-controlled randomized phase III trial (IMPACT) was conducted in men with asymptomatic or minimally symptomatic metastatic CRPC (Kantoff et al, 2010), leading to the FDA-approval of this agent in April 2010. In this trial, 512 patients were randomized (2:1) to sipuleucel-T or placebo and the study was powered to detect an overall survival advantage. Notably, this study did not enroll men with visceral metastases or those taking narcotics for cancer pain, and most patients (85%) were chemotherapy-naïve. Impressively, median overall survival was 25.8 months in the sipuleucel-T group versus 21.7 months in the placebo group (HR, 0.78; $P = .03$), despite 64% of patients on placebo crossing over to receive salvage sipuleucel-T. In the subset of patients with prior chemotherapy exposure, overall survival trended in favor of sipuleucel-T, but this effect was not statistically significant. Therefore, although this immunotherapy is approved for all patients with asymptomatic or minimally symptomatic CRPC, it will likely have its largest impact in the prechemotherapy setting.

Similar to previous studies with sipuleucel-T, the IMPACT study found no difference in progression-free survival or PSA/radiographic response rates between the two treatment arms. Some investigators attribute the discordance between progression-free and overall survival to a possible class effect of immunotherapy agents, relating to their mechanism of action which is distinct from cytotoxic therapies. Problematic endpoints such as progression-free survival in CRPC (which may be confounded by bone scan flare or delayed-onset effects) may perhaps be better addressed by revised guidelines using outcomes that are tailored to immunologic agents (Hoos et al, 2010).

GVAX

Prostate GVAX is based on the demonstration in mouse melanoma models of improved tumor rejection when the irradiated tumor vaccine expressed the cytokine GM-CSF compared with other cytokine adjuvants (Dranoff et al, 1993; Dranoff, 2003). This form of immunotherapy uses inactivated allogeneic prostate cancer cell lines (PC3 and LNCaP) that have been modified through adenoviral transfer to secrete GM-CSF and irradiated to prevent further cell division (Ward and McNeel, 2007). The advantage with this approach is that the vaccine can be manufactured in large quantities and that multiple tumor antigens can be targeted simultaneously. However, because of the relative weakness of individual antigens, repeated intradermal dosing is necessary.

Two uncontrolled single-arm phase 2 studies in men with asymptomatic metastatic CRPC have shown antitumor effects of prostate GVAX, one demonstrating an overall survival of 26.2 months ($n = 34$) and the other showing an overall survival ranging from 20.0 to 29.1 months ($n = 80$) depending on dosing regimen (Small et al, 2007; Higano et al, 2008). In both studies the proportion of patients who generated an antibody response to one or both cell lines increased with the dose of vaccine given, and no dose-limiting or autoimmune toxicities were seen. The most common adverse events in both studies were injection-site erythema, fatigue, malaise, myalgias, and arthralgias.

Based on these promising findings, two large randomized phase 3 studies of GVAX immunotherapy (VITAL-1 and VITAL-2) were designed. VITAL-1 involved 626 men with asymptomatic chemotherapy-naive CRPC and randomized them to GVAX or docetaxel/prednisone, with the primary end point being overall survival. VITAL-2 was planned initially to enroll 600 patients with

symptomatic metastatic CRPC, randomizing them to docetaxel/prednisone or docetaxel/GVAX. Both trials were terminated early because of data observed at the time of interim analyses, suggesting that the survival improvements initially hypothesized were unlikely to be observed if the trials were to be continued (Higano et al, 2009). Moreover, in the VITAL-2 study, mortality was higher in patients on the experimental arm receiving docetaxel/GVAX (Small et al, 2009).

CTLA-4 Inhibition

Due to ongoing host immunologic pressures on evolving tumors, cancers have developed mechanisms to escape immune surveillance, effectively inducing a state of immune tolerance (Drake et al, 2006). One way to inhibit immunologic evasion by tumor cells is through blockade of the immune checkpoint molecule CTLA-4 (cytotoxic T lymphocyte-associated antigen-4), thus preventing the normal attenuation of antitumor T-cell responses (Hodi, 2007). In murine prostate cancer models, CTLA-4 inhibition has been shown to potentiate T-cell effects and induce tumor rejection.

Several clinical trials using the monoclonal anti-CTLA-4 antibody, ipilimumab, have been conducted in men with metastatic CRPC. These include phase I and II studies of ipilimumab monotherapy or in combination with radiation (Small et al, 2007), as well as a phase I study combining ipilimumab with GM-CSF (Fong et al, 2009). Encouragingly, ≥50% PSA reductions have been observed in about 20% of patients, and radiologic tumor responses were seen in about 5% of men, which is particularly noteworthy given that PSA and tumor responses were rarely reported in the immunotherapy trials with sipuleucel-T or other therapeutic vaccines. Common side effects of ipilimumab include fatigue (42%), nausea (35%), pruritus (24%), constipation (21%), and rash (19%). In addition, because CTLA-4 normally serves to attenuate autoimmunity, immunologic toxicities resulting from an unchecked immune response may occur. Such immune-related adverse events include colitis (8%), adrenal insufficiency (2%), hepatitis (1%), and even hypophysitis (1%) (Dillard et al, 2010). Ipilimumab is now in placebo-controlled phase 3 testing in the postdocetaxel setting in men with CRPC following a palliative and perhaps immune-stimulatory dose of radiation to a metastatic site, with the intent to demonstrate a survival advantage over radiation alone. A second predocetaxel placebo-controlled study is also underway.

Key Points: Novel Approaches

- Sipuleucel-T is the first therapeutic vaccine to be FDA-approved for the treatment of any cancer and is indicated for use in men with asymptomatic or minimally symptomatic metastatic CRPC.
- Abiraterone acetate is a novel androgen biosynthesis inhibitor that has gained FDA approval for the treatment of patients with metastatic CRPC who have previously received docetaxel chemotherapy.

CONCLUSIONS

With more drugs at our fingertips for the treatment of metastatic CRPC than ever before, and an increasing number of novel therapeutic targets being discovered every day, we are still left with several challenges and unanswered questions. First, we must determine how these approved and experimental therapies should ideally be sequenced in individual patients with CRPC. For example, should sipuleucel-T routinely be given prior to chemotherapy or abiraterone with prednisone? Should abiraterone be reserved only for docetaxel-resistant patients? How should we treat cabazitaxel-refractory patients? Second, we will need to develop strategies to optimally combine these drugs in a rational manner, taking advantage of our understanding of negative feedback loops and alternative pathway activation to overcome resistance to monotherapies. Ultimately, only prospective trials incorporating biomarker-driven hypotheses will be able to address these key clinical questions. Thus the collection of tumor specimens or correlative samples may be essential in identifying novel targets or developing enrichment strategies for future study of these agents. Third, we must design smarter trials with the goal of quickly yet reliably identifying agents that do not hold promise, while enabling those that do to move swiftly to registrational studies. For example, in the clinical development of MDV3100 and cabazitaxel, pivotal phase III trials were designed directly following the initial phase I/II studies that demonstrated significant drug activity in men with CRPC. Finally, we must select our patients more carefully based on clinical or molecular characteristics, in order to identify the subset most likely to benefit from a particular therapy. For example, in men with significant pain, perhaps sipuleucel-T is not appropriate systemic therapy given the prolonged onset of action and lack of palliative benefits; additionally, immune-based biomarkers may shed light on which men may obtain a greater degree of benefit from immunotherapies. Several active agents are currently in phase III development, and some of these therapies are also likely to further expand our therapeutic arsenal for men with metastatic CRPC in the near future.

Normal Development of the Genitourinary Tract

John M. Park, MD

Kidney Development

Bladder and Ureter Development

Genital and Reproductive Tract Development

The study of embryology provides a useful foundation for the understanding of definitive human anatomy and various congenital disease processes. During the past few decades, a torrent of molecular information and novel experimental techniques has revolutionized the field of embryology, and the knowledge base continues to expand at an exponential rate. From the urologic surgeon's perspective, however, the classic, descriptive aspects of anatomic embryology continue to serve as an important reference point from which various congenital problems are solved clinically. The aim of this chapter is to provide a concise presentation of the essential facts of normal genitourinary system development, clarifying the important anatomic features and supplementing them with updated molecular information. Deliberate efforts have been made to separate the ever-expanding molecular information from that of the descriptive, anatomic embryology to keep the main "story" of genitourinary system development clear and understandable from a surgical point of view (Fig. 111–1). To help with visualization of the key events, various schematic drawings are provided. The goal of this chapter is not to provide potential explanations for every congenital defect that might occur in the genitourinary system but to select pertinent examples highlighting the fundamental concepts and principles.

KIDNEY DEVELOPMENT

Early Events

Mammals develop three kidneys in the course of intrauterine life. The embryonic kidneys are, in order of their appearance, the *pronephros,* the *mesonephros,* and the *metanephros.* The first two kidneys regress *in utero,* and the third becomes the permanent kidney. **Embryologically, all three kidneys develop from the intermediate mesoderm.** As the notochord and neural tube develop, the mesoderm located on either side of the midline differentiates into three subdivisions: *paraxial (somite), intermediate,* and *lateral mesoderm* (Fig. 111–2). As the embryo undergoes transverse folding, the intermediate mesoderm separates away from the paraxial mesoderm and migrates toward the intraembryonic coelom (the future peritoneum). At this time there is a progressive craniocaudal development of the bilateral longitudinal mesodermal masses, called *nephrogenic cords.* Each cord is seen bulging from the posterior wall of the coelomic cavity, producing the *urogenital ridge.*

Pronephros and Mesonephros

The mammalian *pronephros* is a transitory, nonfunctional kidney, analogous to that of primitive fish. In humans, the first evidence of pronephros is seen late in the third week, and it completely degenerates by the start of the fifth week. The pronephros develops as five to seven paired segments in the region of the future neck and thorax (Fig. 111–3A). Development of the pronephric tubules starts at the cranial end of the nephrogenic cord and progresses caudally. As each tubule matures it immediately begins to degenerate along with the segment of the nephric duct to which the tubules are attached.

The second kidney, the *mesonephros,* is also transient, but in mammals it serves as an excretory organ for the embryo while the definitive kidney, the *metanephros,* begins its development (see Fig. 111–3B and C). There is a gradual transition from the pronephros to the mesonephros at about the 9th and 10th somite levels. Development of the *nephric ducts* (also called the wolffian ducts) precedes the development of the mesonephric tubules. The nephric ducts can be seen as a pair of solid longitudinal tissue condensations at about the 24th day, developing parallel to the nephrogenic cords in the dorsolateral aspect of the embryo. Its blind distal ends grow toward the primitive cloaca and soon fuse with it at about the 28th day. As the ducts fuse with the cloaca they begin to form a lumen at the caudal end. This process of canalization then progresses cranially in a reverse direction, transforming the solid tissue condensations into the definitive nephric ducts with excretory capability. Soon after the appearance of the nephric ducts during the 4th week, mesonephric vesicles begin to form. Initially, several spherical masses of cells are found along the medial side of the nephrogenic cords at the cranial end. This differentiation progresses caudally and results in the formation of 40 to 42 pairs of mesonephric tubules, but only about 30 pairs are seen at any one time because the cranially located tubules start to degenerate starting at about the 5th week. By the 4th month, the human mesonephros has almost completely disappeared, except for a few elements that persist into maturity as part of the reproductive tract. **In males, some of the cranially located mesonephric tubules**

C. Genital development

Figure 111–1, cont'd.

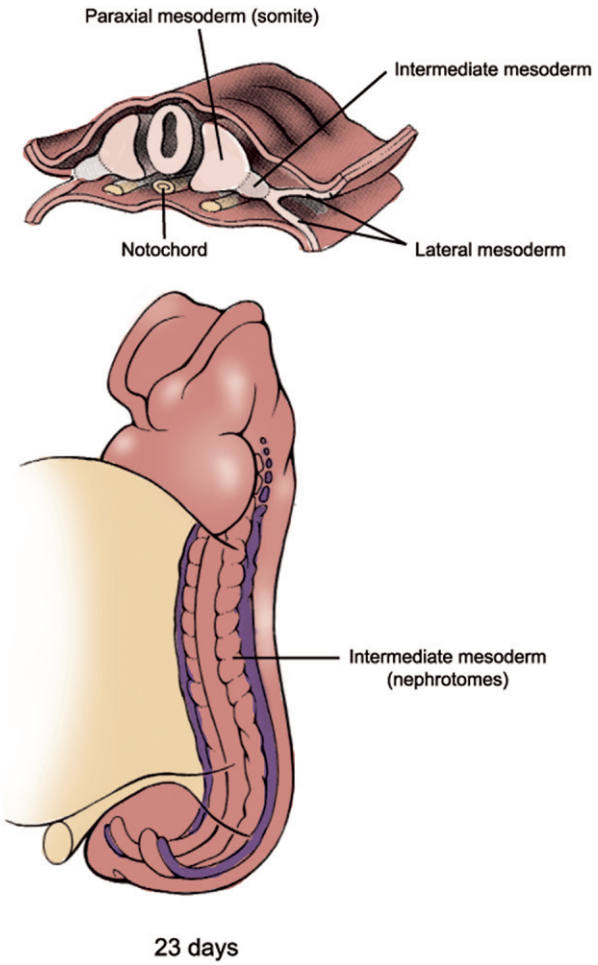

Figure 111–2. The intermediate mesoderm gives rise to paired, segmentally organized nephrotomes from cervical to sacral region. Cervical nephrotomes are formed early during the fourth week and are collectively referred to as the pronephros. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

become the efferent ductules of the testes. The epididymis and vas deferens are also formed from the nephric (wolffian) ducts. In females, remnants of cranial and caudal mesonephric tubules form small, nonfunctional mesosalpingeal structures termed the *epoöphoron* and *paroöphoron.*

The mesonephric tubules differentiate into excretory units that resemble an abbreviated version of an adult nephron. Shortly after the cell clusters are formed they develop lumens and take the shape of vesicles. As the vesicle elongates, each end curves in an opposite direction to form an S-shaped tubule. The lateral end forms a bud that connects with the nephric duct. The medial end lengthens and enlarges to form a cup-shaped sac, which eventually wraps around a knot of glomerular capillaries to form a renal corpuscle. The tuft of glomerular capillaries originating from a branch of the dorsal aorta invades the developing glomerulus while an efferent arteriole empties into a subcardinal sinus.

Metanephros

The definitive kidney, or the *metanephros,* forms in the sacral region as a pair of new structures, called the *ureteric buds,* sprout from the distal portion of the nephric duct and come in contact with the condensing blastema of *metanephric mesenchyme* at about the 28th day (Fig. 111–4). The ureteric bud penetrates the metanephric mesenchyme and begins to divide dichotomously. The tip of the dividing ureteric bud, called the *ampulla,* interacts with the metanephric mesenchyme to induce formation of future nephrons via mesenchymal-epithelial interaction. As the ureteric bud divides and branches, each new ampulla acquires a caplike condensation of metanephric mesenchyme, thereby giving the metanephros a lobulated appearance (Fig. 111–5).

The ureteric bud and metanephric mesenchyme exert reciprocal inductive effects toward each other, and the proper differentiation of these primordial structures depends on these inductive signals (see Molecular Mechanism of Kidney Development, later). The

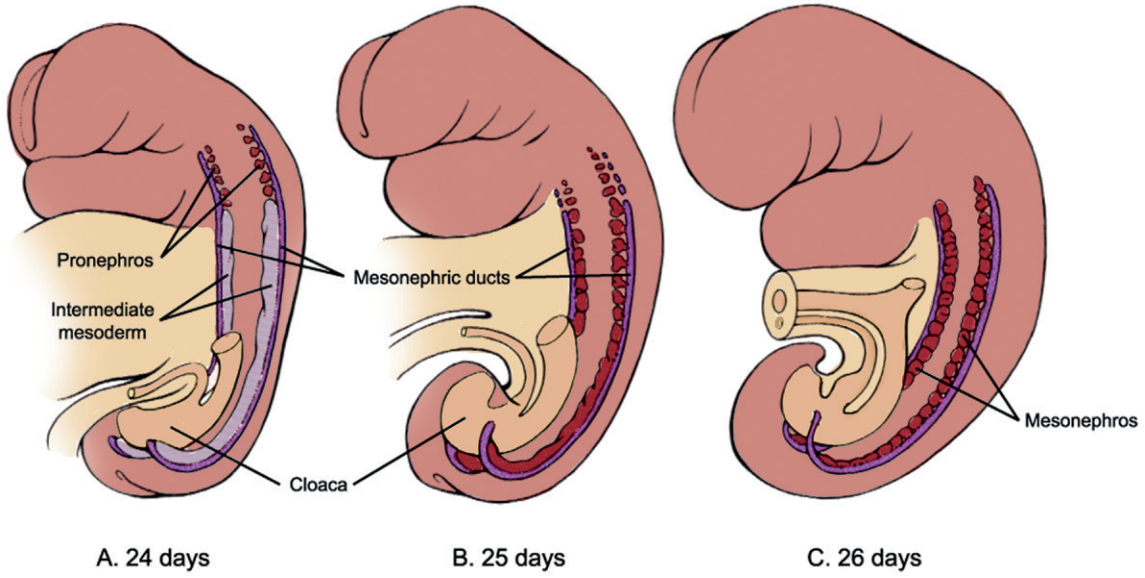

Figure 111–3. Development of pronephros and mesonephros. **A**, Pronephros develops in each of five to seven cervical segments, but this primitive renal structure degenerates quickly during the fourth week. The (meso)nephric ducts first appear on day 24. **B** and **C**, Mesonephric vesicles and tubules form in a craniocaudal direction throughout the thoracic and lumbar regions. The cranial pairs degenerate as caudal pairs develop, and the definitive mesonephros contains about 20 pairs confined to the first three lumbar segments. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

metanephric mesenchyme induces the ureteric bud to branch and divide, and, in turn, the ureteric bud induces the metanephric mesenchyme to condense and undergo mesenchymal-epithelial conversion. **The nephron, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, is thought to derive from the metanephric mesenchyme, while the collecting system, consisting of collecting ducts, calyces, pelvis and ureter, is formed from the ureteric bud** (Fig. 111–6).

In principle, all nephrons are formed in the same way and can be classified into fairly well-defined developmental stages (Larsson et al, 1983) (Fig. 111–7). The metanephric mesenchyme first condenses to form a four- to five-cell layer condensate around the ampulla of the advancing ureteric bud. Near the interface of the ampulla and its adjacent ureteric branch, a cluster of cells separates from the condensate and forms an oval mass, called a *pretubular aggregate*. An internal cavity forms within the pretubular aggregate, at which point the structure is called a *renal vesicle* (stage I). Cells of the stage I renal vesicle are tall and columnar and are stabilized by their attachments to the newly formed basement membrane. It has not yet established a contact with the ampulla of the ureteric bud, but it subsequently forms a luminal connection. Multipotential precursors residing in renal vesicles ultimately give rise to all the epithelial cell types of the nephron (Herzlinger et al, 1992). Nephron segmentation into glomerular and tubular domains is initiated by the sequential formation of two clefts in the renal vesicle (stage II). Creation of a lower cleft, termed the *vascular cleft,* precedes formation of a comma-shaped body. Generation of an upper cleft in the comma-shaped body precedes formation of an S-shaped body. At this stage, the cup-shaped glomerular capsule is recognized in the lowest limb of the S-shaped tubule. Epithelial cells lining the inner wall of this cup will comprise the visceral glomerular epithelium, or podocyte layer. Cells lining the outer wall of the cup will form parietal glomerular epithelium, which lines the Bowman capsule. The glomerular capillary tuft is formed via recruitment and proliferation of endothelial

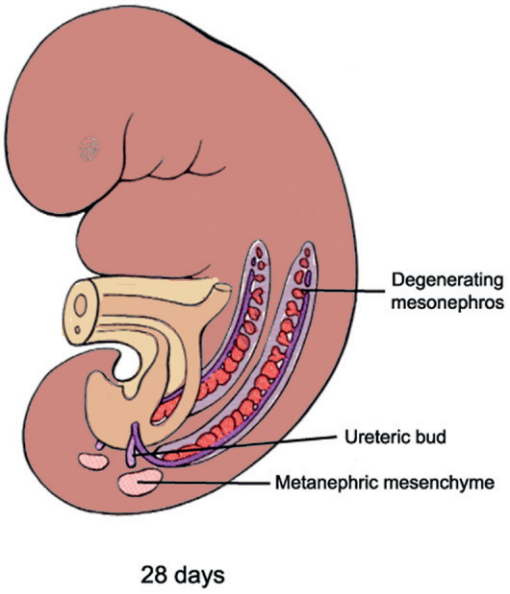

Figure 111–4. Metanephric mesenchyme condenses from the intermediate mesoderm during the early part of the fifth week and comes into contact with the ureteric bud, an outgrowth of the nephric duct, while the cranial mesonephros continues to degenerate. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

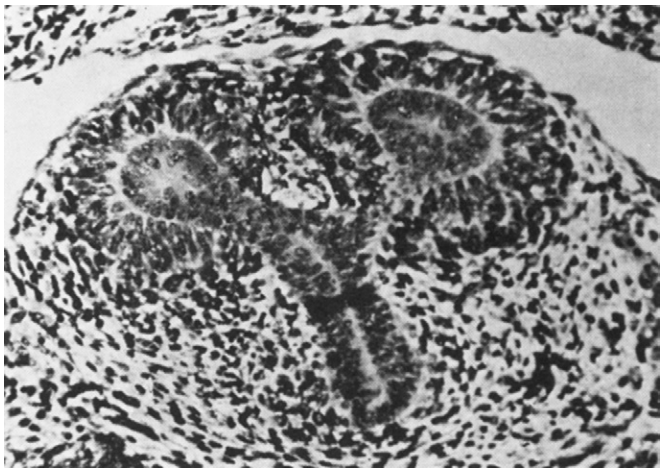

Figure 111–5. The ureteric bud divides to form enlarged tips, called ampullae, around which the metanephric mesenchyme condenses and begins nephron differentiation. The remaining mesenchymal cells remain stromal and continue to interact with tubular mesenchymal cells and dividing ureteric bud epithelial cells. (From Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

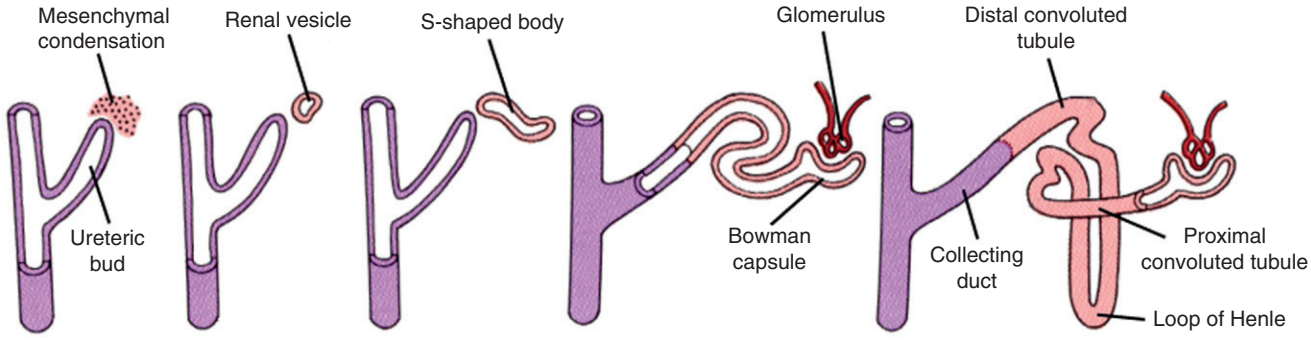

Figure 111–6. Development of the renal collecting ducts and nephrons. The tip of the dividing ureteric bud induces the metanephric mesenchyme *(in pink)* to condense, which then differentiates into a renal vesicle. This vesicle coils into an S-shaped tubule and ultimately forms a Bowman capsule as well as the proximal convoluted tubules, distal convoluted tubules, and loops of Henle. The ureteric bud *(in purple)* contributes to the formation of collecting ducts. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

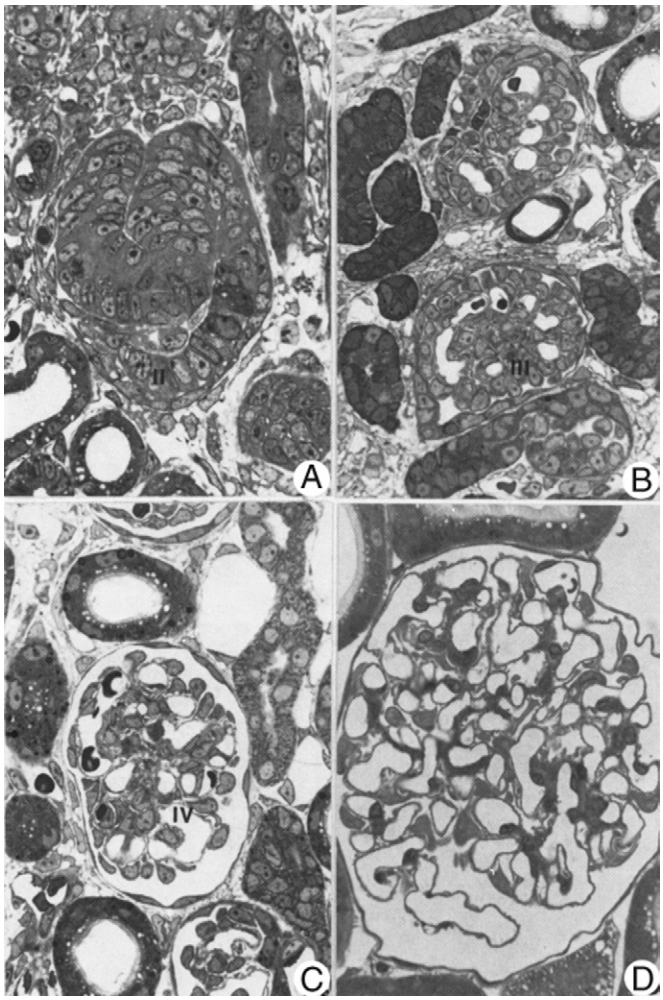

Figure 111–7. Nephron development as seen from a renal cortex of a 3-day-old rat. **A,** A developing nephron with S-shaped body (II). **B,** An oval glomeruli (III). **C,** Nephron now resembles that of mature tubules and glomeruli (IV). **D,** Mature superficial glomerulus from adult rat kidney. Figure 111–8. Schematic representation of progressive nephron differentiation. Older, more differentiated nephrons are located in the inner part of the kidney near the juxtamedullary region and newer, less differentiated nephrons are found at the periphery. (Reproduced from Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

and mesangial cell precursors. The rest of the S-shaped tubule develops into the proximal tubule, the loop of Henle, and the distal tubule. When the cup-shaped glomerular capsule matures into an oval structure the nephron has now passed into stage III of development. Now the nephron can be divided into identifiable proximal and distal tubules. The stage IV nephron is characterized by a round glomerulus that closely resembles the mature renal corpuscle. The morphology of the proximal tubule resembles that of a mature nephron, whereas the distal segments are still primitive. In some species, such as rodents, all stages of nephron development are present at birth, whereas in others, such as humans, all nephrons at birth are in varying steps of stage IV. Mesenchymal cells that do not become tubular epithelium give rise to interstitial stromal cells, which differentiate into a diverse population including fibroblasts, lymphocyte-like cells, and pericytes. **Overall, these events are reiterated throughout the growing kidney so that older, more differentiated nephrons are located in the inner part of the kidney near the juxtamedullary region and newer, less differentiated nephrons are found at the periphery** (Fig. 111–8). **In humans, although renal maturation continues to take place postnatally, nephrogenesis is completed before birth at around 32 to 34 weeks of gestation.**

Collecting System

The dichotomous branching of the ureteric bud determines the eventual pelvicalyceal patterns and their corresponding renal lobules (Cebrian et al, 2004) (Fig. 111–9). In humans, the first nine branch generations are formed by approximately 15 weeks' gestation. By 20 to 22 weeks, ureteric bud branching is completed. Thereafter, collecting duct development occurs by extension of peripheral branch segments. Between 22 and 24 weeks of human fetal gestation the peripheral (cortical) and central (medullary) domains of the developing kidney are established. The renal cortex, which represents 70% of total kidney volume at birth, becomes organized as a relatively compact, circumferential rim of tissue surrounding the periphery of the kidney. The renal medulla, which represents 30% of total kidney volume

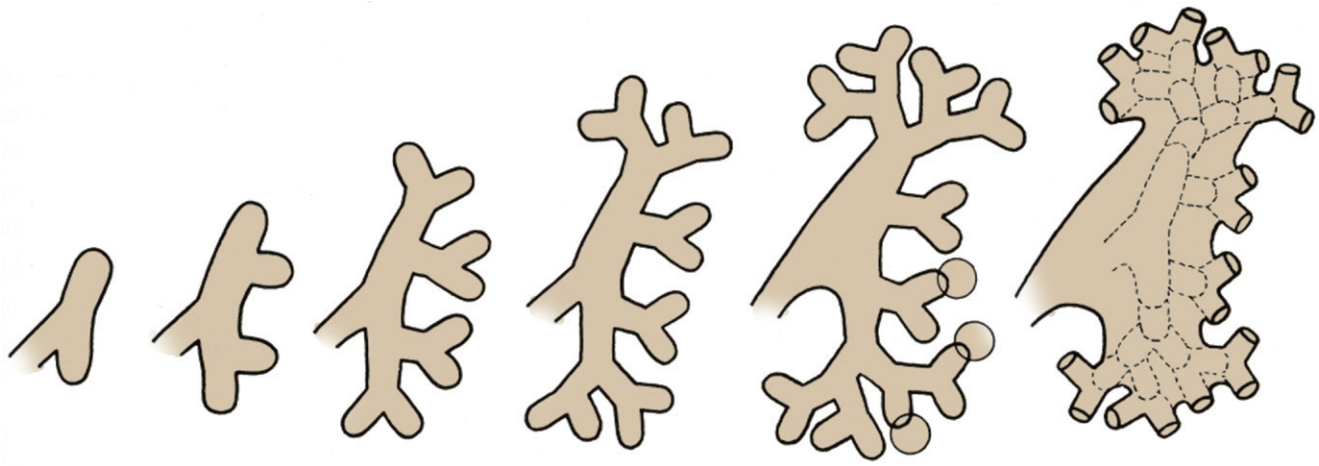

Figure 111–9. Dichotomous branching of the ureteric bud and subsequent fusion of the ampullae to form the renal pelvis and calyces. *Circles* indicate possible sites of infundibular development between the third, fourth, or fifth generations of branches and their subsequent expansions to give rise to the calyces. (Reproduced from Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

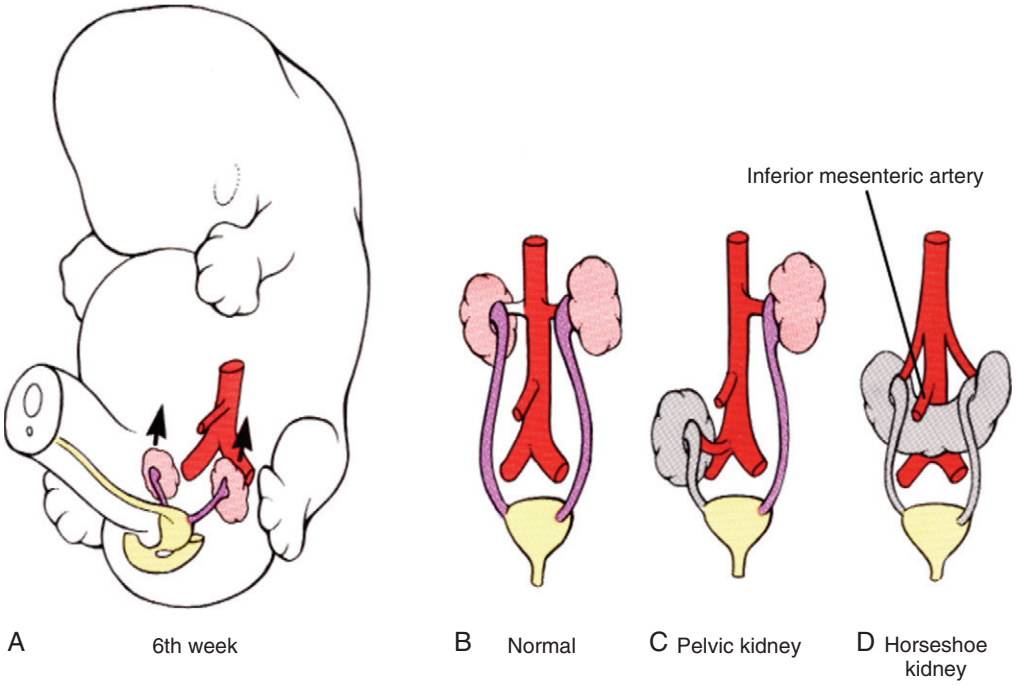

Figure 111–10. Normal and abnormal ascent of the kidneys. **A** and **B,** The metanephros normally ascends from the sacral region to its definitive lumbar location between the sixth and ninth weeks. **C,** Rarely, a kidney may fail to ascend, resulting in a pelvic kidney. **D,** If the inferior poles of the kidneys fuse before ascent, the resulting horseshoe kidney does not ascend to a normal position owing to entrapment by the inferior mesenteric artery. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

at birth, has a modified cone shape with a broad base contiguous with cortical tissue. The apex of the cone is formed by convergence of collecting ducts in the inner medulla and is termed the *papilla.* Distinct morphologic differences emerge between collecting ducts located in the medulla compared with those located in the renal cortex. Medullary collecting ducts are organized into elongated linear arrays that converge centrally in a region devoid of glomeruli. In contrast, collecting ducts located in the renal cortex continue to induce metanephric mesenchyme. The most central segments of the collecting system, formed from the first five generations of ureteric bud branching, undergo remodeling by increased growth and dilatation of these tubules to form the pelvis and calyces.

Renal Ascent

Between the sixth and ninth weeks the kidneys ascend to a lumbar site just below the adrenal glands (Fig. 111–10). The precise mechanism responsible for renal ascent is not known, but it is speculated that the differential growth of the lumbar and sacral regions of the embryo plays a major role. As the kidneys migrate they are vascularized by a succession of transient aortic sprouts that arise at progressively higher levels. These arteries do not elongate to follow the ascending kidneys but instead degenerate and are replaced by successive new arteries. The final pair of arteries forms in the upper lumbar region and becomes the definitive renal arteries. Occasionally, a more inferior pair of arteries persists as

accessory lower pole arteries. When the kidney fails to ascend properly its location becomes ectopic. If its ascent fails completely it remains as a pelvic kidney. **The inferior poles of the kidneys may also fuse, forming a horseshoe kidney that crosses over the ventral side of the aorta. During ascent the fused lower pole becomes trapped under the inferior mesenteric artery and thus does not reach its normal site.** Rarely, the kidney fuses to the contralateral one and ascends to the opposite side, resulting in a cross-fused ectopy.

Molecular Mechanism of Kidney Development

The details of inductive interactions among metanephric mesenchyme, ureteric bud epithelia, and, more recently, the stroma, are becoming clearer and provide insights into the complex regulatory mechanisms underlying renal development. **Formation of renal tubules and collecting system occurs sequentially and requires dynamic interactions among epithelial, mesenchymal, and stromal cells.** Many of the early events in embryonic kidney development were first elucidated by manipulating lower vertebrate embryos and by utilizing a mammalian in-vitro organ culture system. Clifford Grobstein's pioneering work in the 1950s led to an organ culture technique (Grobstein, 1956) whereby the metanephric mesenchyme is separated from the ureteric bud during the early part of kidney development and grown in vitro on a filter. An inducer tissue, such as ureter or spinal cord, cultured on the opposite side of the filter then provides the inductive signal (Fig. 111–11). This ingenious experimental approach has established the kidney as a model system for studying the role of epithelial-mesenchymal interaction in organ development. The development of many other organs, including lung, salivary glands, gonads, prostate, and bladder, also require epithelial-mesenchymal interaction for the controlled differentiation and proliferation of tissues.

Formation of Nephric Ducts

The first recognizable event in renal development may be the formation of nephric ducts within the region of the intermediate mesoderm. The molecular signals responsible for this early event, in which seemingly unorganized mesenchymal cells aggregate to become an epithelial duct, remain essentially unknown, but details are beginning to emerge. The early intermediate mesoderm destined to become nephric ducts is distinguished by expression of the transcription factors LIM1, PAX2, and SIM1, but only LIM1 appears to be absolutely essential for nephric duct formation (Shawlot and Behringer, 1995). PAX2 may be important for maintaining other marker gene expression in the nephric ducts (Torres et al, 1995). Available data suggest a model in which few opposing secreted factors from the surrounding tissues cumulatively restrict LIM1 expression to the intermediate mesoderm. LIM1 then

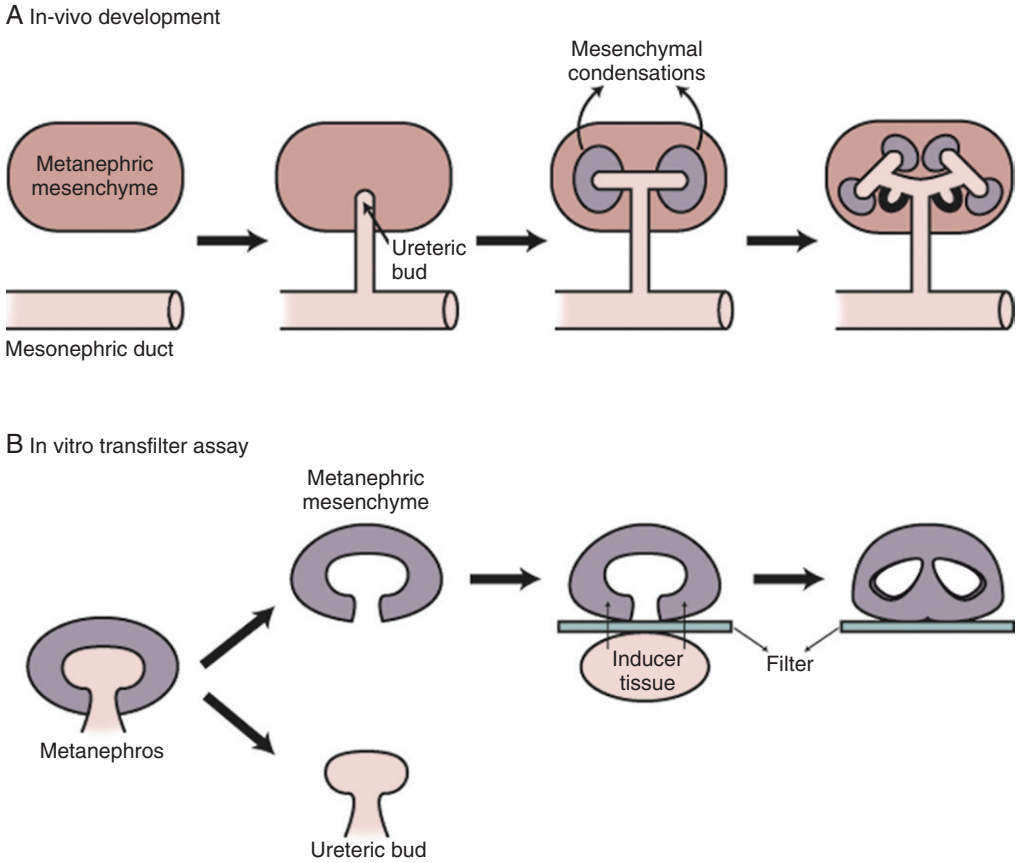

Figure 111–11. Schematic representation of in-vivo kidney development **(A)** and an in-vitro transfilter organ culture system of Grobstein **(B)**. At an early stage of renal development, the metanephric mesenchyme is separated from the ureteric bud and cultured on a filter. If there is an inducer tissue grown on the opposite side of the filter, such as ureter and spinal cord, the metanephric mesenchyme will continue to differentiate into nephron structures. In the absence of inducer tissue, the metanephric mesenchyme will degenerate via apoptosis. (Modified from Vainio S, Muller U. Inductive tissue interactions, cell signaling, and the control of kidney organogenesis. Cell 1997;90[6]:975.)

activates PAX2 expression to further orchestrate the formation of nephric ducts.

Ureteric Bud Outgrowth toward Metanephric Mesenchyme

The outgrowth of the ureteric bud from the nephric duct and its invasion into the condensing blastema of metanephric mesenchyme is a crucial initiating event in the development of the adult kidney *(metanephros).* Many candidate genes have been identified to play a critical role in this process (see http://golgi.ana.ed.ac.uk/kidhome.html). In particular, **several lines of experimental evidence have revealed a crucial role of the RET-GDNF-GFRα1 pathway in the ureteric bud outgrowth** (Fig. 111–12). Glial cell line–derived neurotrophic factor (GDNF) is a secreted peptide expressed in the metanephric mesenchyme that activates the RET receptor, which is expressed along the nephric duct. GDNF activation of RET requires the glycosylphosphatidylinositol (GPI)-linked protein GFRα1, which is expressed in both metanephric mesenchyme and nephric duct. Gene knockout mutations in *Ret, GDNF* (Moore et al, 1996; Pichel et al, 1996; Sanchez et al, 1996), and *GFRα1* (Cacalano et al, 1998) inhibit ureteric bud outgrowth. In organ culture systems, recombinant GDNF is sufficient to induce ectopic ureteric bud outgrowth (Sainio et al, 1997) (Fig. 111–13). However, the competence of the nephric duct to respond to GDNF is restricted along the anteroposterior axis. This anteroposterior restriction might be mediated by suppressors of RET signaling within the surrounding tissue, such as bone morphogenetic protein-4 (BMP4). Mice that are deficient for BMP4 show more broadened ureteric buds and/or secondary anterior buds, suggesting that full BMP4 activity is required to limit RET signaling to the caudal aspect adjacent to the developing metanephric mesenchyme (Miyazaki et al, 2000). Similarly, in organ culture, BMP4 can suppress the activity of GDNF to induce ectopic ureteric bud formation (Brophy et al, 2001). Proper positioning of the ureteric bud is also controlled by the localized expression of GDNF within the metanephric mesenchyme. Both positive and negative regulators have been described for GDNF localization. Homozygous mutation of a transcription factor Eya1 causes failure of ureteric bud outgrowth, and its metanephric mesenchyme lacks GDNF expression, suggesting that Eya1 regulates GDNF expression (Xu et al, 1999). In humans, haploinsufficiency of Eya1 results in a dominantly inherited disorder called branchio-oto-renal syndrome, which involves kidney and urinary tract anomalies (Abdelhak et al, 1997). Expression of PAX2 in the metanephric mesenchyme is also required for GDNF activation (Brophy et al, 2001). GDNF expression is also suppressed at the anterior boundary of the metanephric mesenchyme through the concerted action of the FoxC1 and FoxC2 transcription factors (Kume et al, 2000). Mutations in either Fox gene result in an expansion of GDNF expression and the formation of ectopic ureteric buds. Most FoxC1 homozygous mutants have duplex kidneys, in which the upper ureter is dilated and connects aberrantly to ectopic nephric duct derivatives in males such as seminal vesicles and vas deferens. In the developing kidneys, *Slit2* is primarily expressed in the nephric duct whereas *Robo2* is expressed in the metanephric mesenchyme (Piper et al, 2000). Mice deficient in *Slit2* or *Robo2* exhibit ectopic ureteric bud formation, multiple ureters and hydroureter, and anterior expansion of GDNF expression (Grieshammer et al,

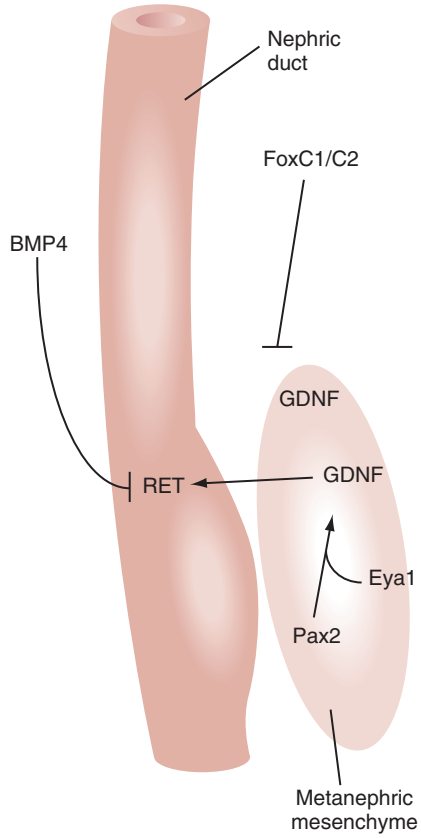

Figure 111–12. Inductive interactions during early kidney development. Glial cell line–derived neurotrophic factor (GDNF) is secreted from the metanephric mesenchyme and activates the RET receptor tyrosine kinase in the ureteric bud epithelium. The expression and localization of GDNF are positively regulated by Eya1 and Pax2 and negatively by FoxC transcription factors. The inducibility of nephric ducts to GDNF signaling is restricted by the action of BMP4. (Modified from Dressler GR. Tubulogenesis in the developing mammalian kidney. Trends Cell Biol 2002;12:390–5.)

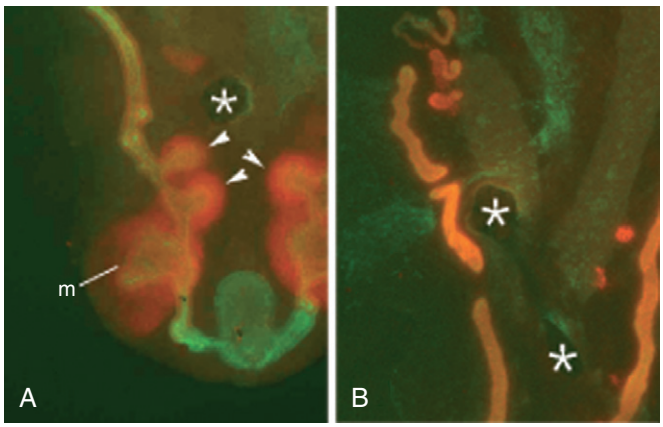

Figure 111–13. **A,** Stimulation of ectopic ureteric buds by GDNF. To determine whether GDNF is sufficient to promote outgrowth of nephric duct epithelial cells, heparin acrylamide beads preadsorbed with recombinant GDNF *(asterisks)* were placed between two nephric duct organ cultures. The native metanephros (m) is seen anteriorly. GDNF alone induces multiple ectopic ureteric buds in the posterior nephric ducts *(arrowheads).* **B,** However, the effect of GDNF is suppressed when Bmp4 is also added to the beads *(asterisks).* Cultures were stained with anti-cytokeratin *(green)* and anti-Pax2 *(red)* antibodies. (From Dressler GR. Tubulogenesis in the developing mammalian kidney. Trends Cell Biol 2002;12:390–5.)

2004). SPRY1 negatively regulates GDNF-RET signaling. Loss of SPRY1 function in mice results in renal malformations, including multiple ureters, duplex kidneys and hydroureter, and increased expression of GDNF in the metanephric mesenchyme (Basson et al, 2006). The data therefore suggest that multiple factors regulate, both positively and negatively, the precise timing and localization of GDNF, which then functions as a guidance cue to activate RET.

Ureteric Bud Branching

Once the ureteric bud has contacted the condensing metanephric mesenchyme it undergoes a dichotomous branching morphogenesis (Cebrian et al, 2004). **Many of the same factors that regulate the initial outgrowth of the ureteric bud also appear to be essential for the subsequent branching of the ureteric bud.** Ureteric bud branching is positively regulated by genetic and nutritional factors. PAX2, a paired-box type transcription factor that is mutated in humans with renal coloboma syndrome, is a positive regulator of ureteric bud branching. During renal development, *Pax2* is expressed in the nephric duct, ureteric bud, and metanephric blastema induced by ureteric bud branch tips. Mice with *Pax2* mutation exhibit decreased ureteric bud branching and renal hypoplasia (Porteous et al, 2000). Ureteric branching is also positively regulated by vitamin A and its retinoic acid receptor signaling, which promote Ret expression. Rarα and Rarβ2 are expressed in stromal cells surrounding Ret-expressing ureteric bud branch tips. Mice deficient in these receptors exhibit a decreased number of ureteric bud branches and diminished expression of Ret (Batourina et al, 2001). Certain markers such as Wnt11 might already be compartmentalized to opposing poles of the dilated bud tips, even before a morphologic branch point is evident (Pepicelli et al, 1997). In mice deficient for the homeobox gene *Emx2* (Miyamoto et al, 1997), ureteric bud outgrowth into the metanephric mesenchyme appears normal but the leading edge never dilates and branching is suppressed. Thus ureteric development is arrested before the first branching event, and the resulting metanephric mesenchyme does not express any markers for induction. Similarly, mice with mutation of *Sall1* exhibit developmental arrest just after ureteric bud outgrowth and before dilation of the leading edge (Nishinakamura et al, 2001). In normal murine embryos, *Sall1* is expressed in the metanephric mesenchyme. Thus *Sall1* might control mesenchyme-derived signals that are necessary for ureteric bud dilation and the early branch point determination. Clearly, the pattern of ureteric bud branching and the expression of ureteric bud–specific genes are influenced by the metanephric mesenchyme. Indeed, the heterologous mesenchyme derived from lung primordia can not only change the pattern of ureteric bud branching to that of lung epithelia but also induce the ureteric bud tissues to express lung-specific genes (Lin et al, 2001). Recent studies demonstrate that BMP/activin-like kinase-2 (ALK3) signaling negatively regulates early ureteric bud branching in vivo (Hartwig et al, 2008). The cell surface receptor ALK3 binds BMP2 and BMP4 with high affinity and is expressed in the nephric duct. Inactivation of ALK3 changes the pattern of primary ureteric bud branching from bifid to trifid and increases the number of first- and second-generation branches. These defects are associated with decreased formation of subsequent branch generations, resulting in a decreased complement of collecting ducts. These observations suggest that the pattern of early ureteric bud branching is a critical determinant of subsequent branching morphogenesis. **Thus ureteric bud epithelial branching morphogenesis is controlled by both intrinsic and extrinsic factors working in concert to generate a kidney-specific branching pattern.**

Tubulogenesis

Classic tissue recombination experiments focused almost exclusively on the relationship between metanephric mesenchymal cells and ureteric bud epithelial cells**. It is now clear that at least three cell types are involved in the control of renal development: the ureteric bud tip cells, the condensed mesenchymal cells, and the stromal or interstitial mesenchymal cells** (Fig. 111–14). It is not known whether the mesenchyme is a homogeneous cell population before its interaction with the ureteric bud. It is clear, however, that once induced by the ureteric bud the metanephric mesenchyme patterns itself into at least two different cell populations, a tubular one and a stromal one. The tubular cell population is thought to derive from mesenchymal cells in direct contact with the ureteric bud ampulla (Vainio et al, 1989; Stark et al, 1994; Torres et al, 1995), whereas the stromal cell population surrounds the tubular cells (Hatini et al, 1996). Once the mesenchyme has been patterned, the cells in the tubular zone undergo morphogenesis to become renal

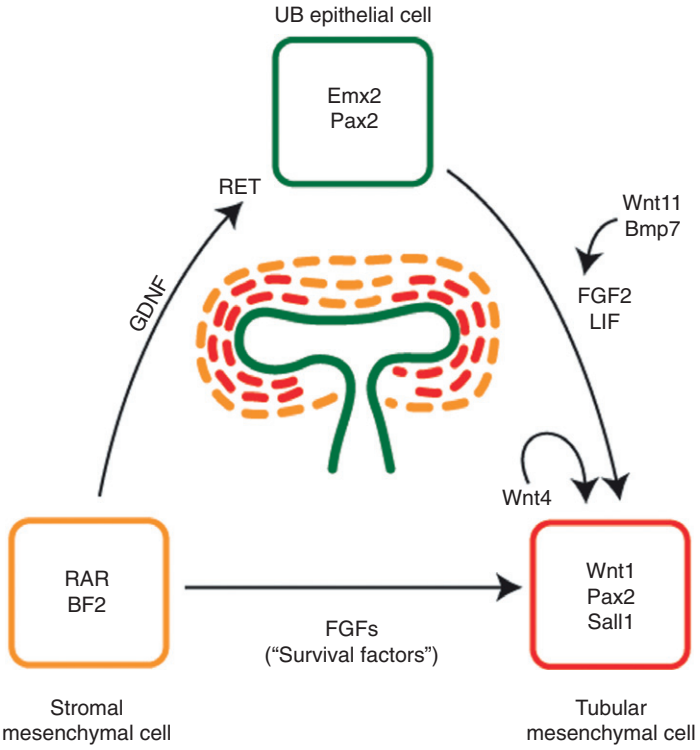

Figure 111–14. Cell-cell interactions promote nephrogenesis. Three major cell types—ureteric bud (UB) epithelial cells, condensing tubular mesenchymal cells, and stromal mesenchymal cells—are thought to play a critical role. At the UB tips, cells express unique markers such as Emx2 and Pax2. The stromal cell lineage is marked by expression of retinoic acid receptors (RAR) and BF2. Presence of Pax2, WT1, and Sall1 appear to be important for continued branching morphogenesis of the UB. Wnt4 is activated in the tubular mesenchymal cells by the invading UB and stimulates the development of polarized epithelium in an autocrine fashion. Finally, fibroblast growth factors (FGFs), such as FGF2, along with LIF, may be critical as survival factors for the developing renal tubular epithelial cells. (Modified from Dressler GR. Tubulogenesis in the developing mammalian kidney. Trends Cell Biol 2002;12:390–5.)

tubular epithelial cells. There is evidence that this process is dependent not only on signals from the ureteric bud but also on signals from the mesenchyme itself. One of these autocrine signals may be Wnt4, whose expression is induced in cells of the tubular zone on interaction with the ureteric bud. In *Wnt4* gene knockout mice the ureteric bud forms and invades the metanephric mesenchyme but subsequent development of epithelial tubules is abolished (Stark et al, 1994). This suggests that two signals are essential for renal tubule formation—initial ureteric bud derived signals activating Wnt4 expression in the metanephric mesenchyme and Wnt4 itself as a mesenchymal autocrine signal. Signals from the stromal cell population also contribute to tubule formation as well, because tubulogenesis is perturbed in *Bf2* gene knockout mice (Hatini et al, 1996). The discovery that Wnt4 acts as a downstream signal during the induction cascade leading to renal tubulogenesis leads to the question regarding the nature of the initial ureteric bud–derived signals. In-vitro data suggest a role for fibroblast growth factor-2 (FGF2) and other uncharacterized factors secreted by the ureteric bud (Karavanova et al, 1996). Candidate molecules that may cooperate with FGF2 are Wnt11 and BMP7 (Kispert et al, 1996; Vukicevic et al, 1996). Localization of RET protein to the ureteric bud tips is reinforced by both GDNF (Pepicelli et al, 1997) and signals emanating from surrounding stromal cells. For example, retinoic acid receptors are expressed in the stromal cells and are required for stromal cell–mediated signaling to maintain high levels of RET expression in the bud tips (Mendelsohn et al, 1999; Batourina et al, 2001). Consistent with the role of retinoic acid receptors in maintaining RET expression in the dividing ureteric bud, rats suffering from vitamin A deficiency have smaller kidneys and fewer nephrons (Lelievre-Pegorier et al, 1999). The cellular crosstalk among stromal, mesenchymal, and ureteric bud cells is further highlighted by gain- and loss-of-function experiments involving FGFs and BMPs. *Fgf7* null mutant mice have fewer branch points and correspondingly fewer nephrons, whereas ectopic FGF7 in organ culture can stimulate branching (Qiao et al, 1999). FGF1 and FGF10 affect elongation of the ureteric bud stalk before the branch-point decision is made (Qiao et al, 2001). Null mutations in *Bmp7* are associated with even more severe phenotypic anomalies, exhibiting limited branching morphogenesis and complete renal developmental arrest. Yet it is difficult to assess how FGFs and BMPs exert their collective effects on branching given the interplay among all the cell types present in the early kidney (Dudley et al, 1999). In addition to the proteins just mentioned, a growing list of growth factors, secreted peptides, and their receptors have been implicated in the control of branching morphogenesis, most by using a variety of in-vitro model systems (Pohl et al, 2000; Davies, 2001). For many of these factors, however, genetic studies have not proved conclusive in assigning specific functional roles during ureteric bud branching in vivo, either because of potential redundancies or embryonic lethalities before the onset of kidney development. Nevertheless, the role of these factors in the renal development must be considered.

Mesenchymal-Epithelial Conversion

The inductive signals emanating from the ureteric bud promote condensation of the metanephric mesenchymal cells around the ureteric bud tips and subsequent tubulogenesis. Mice with null mutations of *Pax2* or *Wt1* fail to exhibit ureteric bud outgrowth and, in both cases, the metanephric mesenchyme does not respond to induction even when recombined with strong inducers in vitro (Kreidberg et al, 1993; Brophy et al, 2001). The establishment of glomerular versus tubular cell fates is dependent on negative feedback between Wt1 and Pax2 (Ryan et al, 1995). During early kidney development, the expression domain of Pax2 is complementary to that of Wt1 in S-shaped bodies. Wt1 expression is restricted to glomerular epithelial precursors (Pelletier et al, 1991), whereas Pax2 expression is restricted to the portion that gives rise to tubular epithelial precursors of the proximal and distal nephron segments and later repressed in differentiated tubular epithelium (Dressler and Douglass, 1992). Evidence in support of Wnt proteins as mesenchyme inducers has been gained from in-vitro induction assays using Wnt-expressing cell lines (Herzlinger et al, 1994; Kispert et al, 1998). Of the *Wnt* mutants examined to date, only *Wnt4*, which is expressed in the mesenchyme and not the ureteric bud, is crucial for propagation of the inductive signals. Although *Wnt4* mutant mesenchyme is able to aggregate in response to ureteric bud contact, these mutant aggregates do not form polarized epithelia. Rat ureteric bud cells secrete tubulogenic factors, such as leukocyte-inhibitory factor (LIF), which, together with FGF2, appears to stimulate growth and tubulogenesis in vitro (Plisov et al, 2001). Once induced to form aggregates, metanephric mesenchyme becomes polarized into an early renal vesicle. This vesicle is closely associated with the branching ureteric bud and will eventually connect to the ureteric bud epithelium to form a continuous tubule. Profound changes take place in the expression of cell adhesion molecules such as cadherins. Shortly after induction, metanephric mesenchyme expresses R-cadherin, cadherin-6, and E-cadherin, along with suppression of the mesenchyme-specific cadherin-11. Both R-cadherin and cadherin-6 mutants show defects in the rate of mesenchymal condensation and polarization (Mah et al, 2000; Dahl et al, 2002). Some renal vesicles in cadherin-6 mutants also fail to fuse to the ureteric bud epithelia, resulting in "dead end" tubules and a subsequent loss of nephrons.

Renal Vascular Development

The origin of intrarenal vasculature is not completely understood. Until recently it was thought that renal vasculature derived exclusively from branches off the aorta and other pre-existing extrarenal vessels ("angiogenic" hypothesis). There is evidence, however, that the renal vessels may originate in situ, within the embryonic kidney from vascular progenitor cells ("vasculogenic" hypothesis) (Loughna et al, 1996; Tufro et al, 1999). Using antibodies to Flk-1, a vascular endothelial growth factor (VEGF) receptor present in angioblasts and mature endothelial cells, it was demonstrated that endothelial cell precursors were already present in the prevascular rodent kidneys before any vessels were discernible from a morphologic standpoint. When embryonic kidneys are cultured at the usual atmospheric oxygen concentration, vessels do not develop. However, if the explants are cultured in a hypoxic atmosphere containing 5% oxygen, capillary sprouts develop within and outside the glomeruli, an effect that is inhibited by anti-VEGF antibodies (Tufro-McReddie et al, 1997). Depending on the developmental potential of the cells involved, both angiogenesis and vasculogenesis may play a role in the development of renal vasculature (Abrahamson et al, 1998).

BLADDER AND URETER DEVELOPMENT

Formation of Urogenital Sinus

At the third week of gestation the cloacal membrane remains a bilaminar structure composed of endoderm and ectoderm. During the fourth week the neural tube and the tail of the embryo grow

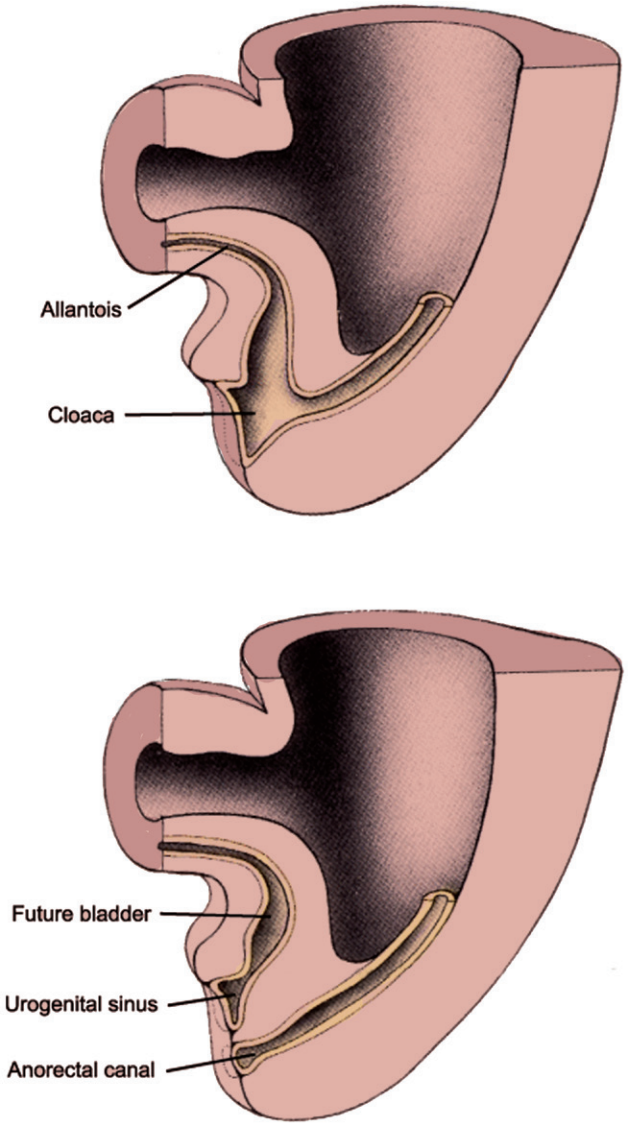

Figure 111–15. Development of the urogenital sinus. Between the fourth and sixth weeks the cloaca is divided into an anterior urogenital sinus and a posterior anorectal canal. The superior part of the urogenital sinus, continuous with the allantois, forms the bladder. The constricted narrowing at the base of the urogenital sinus forms the pelvic urethra. The distal expansion of the urogenital sinus forms the vestibule of the vagina in females and the penile urethra in males. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

dorsally and caudally, projecting itself over the cloacal membrane; and this differential growth of the body results in embryo folding. The cloacal membrane is now turned to the ventral aspect of the embryo, and the terminal portion of the endoderm-lined yolk sac dilates and becomes the *cloaca* (Fig. 111–15). According to the embryonic theories of Rathke and Tourneux, the partition of the cloaca into an anterior urogenital sinus and a posterior anorectal canal occurs by the midline fusion of two lateral ridges of the cloacal wall and by a descending urorectal septum. This process is thought to occur during the fifth and sixth weeks, and it is culminated by the fusion of this urorectal septum with the cloacal membrane. Recently, however, some investigators have challenged this classic view with evidence that there is neither a descending septum nor fusing lateral ridges of the cloacal wall (van der Putte, 1986; Kluth et al, 1995). There is further evidence that the urorectal septum never fuses with the cloacal membrane (Nievelstein et al, 1998). According to these observations the congenital cloacal and anorectal malformations, which were previously thought to occur due to a failure of septum formation and its fusion with the cloacal membrane, may in fact occur from an abnormal development of the cloacal membrane itself (Nievelstein et al, 1998) (Fig. 111–16).

The nephric (wolffian) duct fuses with the cloaca by the 24th day and remains with the urogenital sinus during the cloacal separation. **The entrance of the nephric duct into the primitive urogenital sinus serves as a landmark distinguishing the cephalad vesicourethral canal from the caudal urogenital sinus. The vesicourethral canal gives rise to the bladder and pelvic urethra, whereas the caudal urogenital sinus forms the phallic urethra for males and distal vaginal vestibule for females.**

Formation of Trigone

By day 33 of gestation, the *common excretory ducts* (the portion of nephric ducts distal to the origin of ureteric buds) dilate and connect to the urogenital sinus. The formation of these final connections involves apoptosis, which enables the ureters to disconnect from the nephric ducts, and fusion, in which the ureteral orifice inserts into the urogenital sinus epithelium at the level of the trigone (Batourina et al, 2005). **According to the classic view** (Weiss 1988), **the right and left common excretory ducts fuse in the midline as a triangular area, forming the primitive trigone, structurally different from bladder and urethra.** The ureteral orifice extrophies and evaginates into the bladder by day 37 and begins to migrate in a cranial and lateral direction within the floor of the bladder. During this process the nephric duct orifice diverges away from the ureteral orifice and migrates caudally, flanking the paramesonephric (müllerian) duct at the level of the urogenital sinus. This is the site of the future verumontanum in males and vaginal canal in females. Recent studies, however, have challenged this classic mechanism of trigone development. Using the cell lineage studies in mice, the trigone was found to form mostly from bladder smooth muscle cells with only a minor contribution from the ureters (Viana et al, 2007).

The embryonic pattern of ureteral orifice incorporation into the developing bladder is inferred primarily from clinical observations of duplex kidneys. The upper pole ureteral orifice rotates posteriorly relative to the lower pole orifice and assumes a more caudal and medial position. Weigert and Meyer recognized the regularity of this relationship between upper and lower pole ureteral orifices, which has come to be known as the *Weigert-Meyer rule*. **According to this concept, an abnormally lateral lower pole ureteral orifice may result from a ureteric bud arising too low on the nephric duct, therefore resulting in premature incorporation and migration within the developing bladder.** In such a ureteral orifice, vesicoureteral reflux is more likely to occur due to an inadequate intramural tunnel. **In contrast, an abnormally caudal upper pole ureteral orifice may result from a ureteric bud arising too high on the nephric duct.** It may drain at the bladder neck and verumontanum or remain connected to the nephric (wolffian) duct derivatives such as the vas deferens in males (Mackie and Stephens, 1977; Schwarz and Stephens, 1978). In females, the ectopic upper pole ureter may insert into the remnants of the nephric ducts (e.g., Gartner duct cyst) or vaginal vestibule (Fig. 111–17).

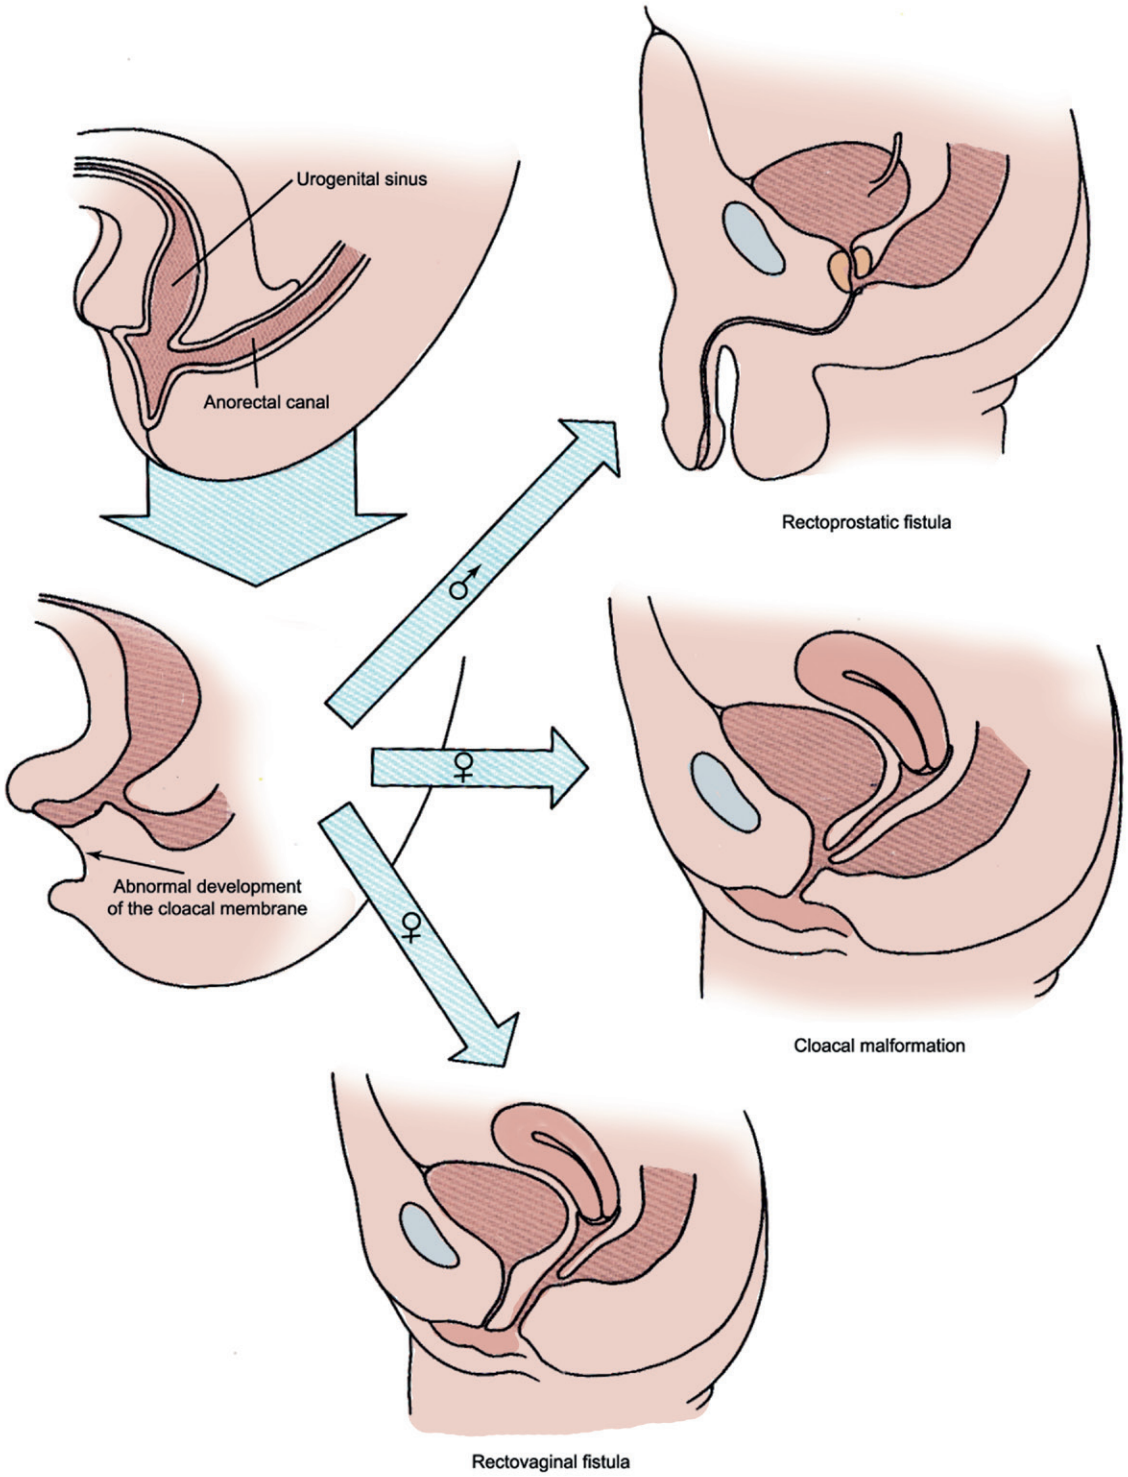

Figure 111–16. Abnormal development of cloacal membrane results in characteristic anomalies of the urogenital and lower gastrointestinal tract. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Anomalous development of the common excretory duct may lead to an ectopic vas deferens. In certain clinical situations the vas deferens is connected to the ureter rather than the verumontanum, so that both the ureter and vas drain into a common duct. This situation may occur when the ureteric bud arises too high on the nephric duct and the subsequent common excretory duct becomes too long, resulting in incomplete absorption into the developing bladder. This anomaly, although rare, should be kept in mind when evaluating males with recurrent epididymitis and ipsilateral hydronephrosis.

Development of the Ureter

In contrast to the previous discussion regarding the molecular aspects of renal development, little is understood at the molecular level concerning the events of ureteral development. There is only

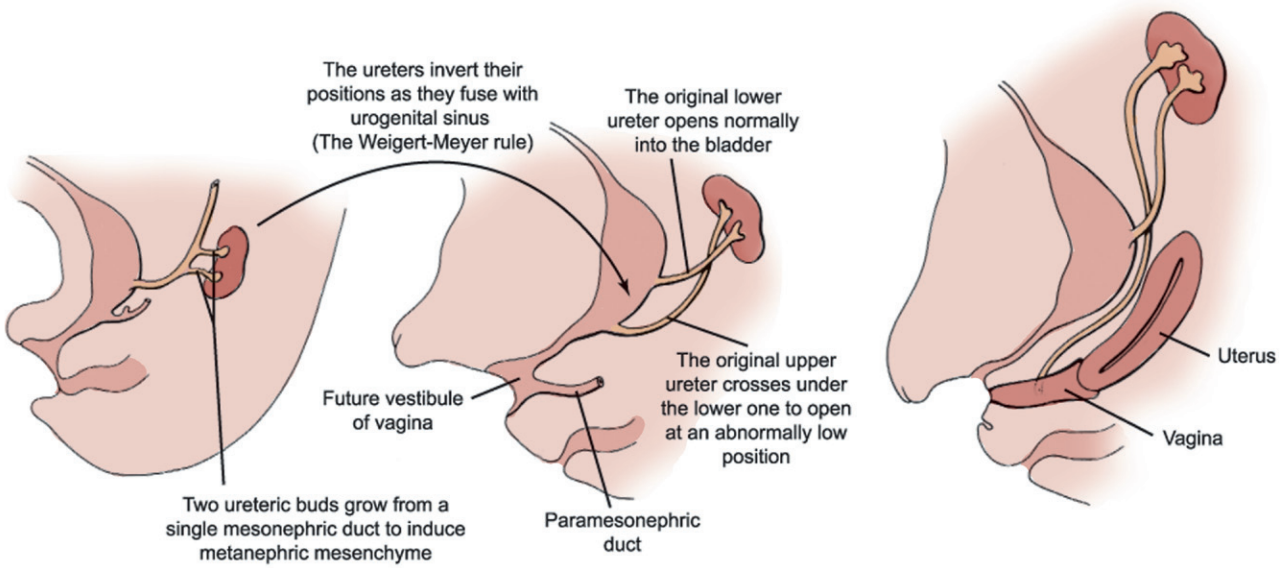

Figure 111–17. Development of an ectopic upper pole ureter draining into the vagina. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

a small amount of descriptive information and speculative theories regarding the molecular mechanism of smooth muscle cell and urothelial differentiation. Morphologically, the ureter begins as a simple cuboidal epithelial tube surrounded by loose mesenchymal cells that acquires a complete lumen at 28 days of gestation in human. It was suggested that the developing ureter undergoes a transient luminal obstruction between 37 and 40 days' gestation and subsequently recanalizes (Alcaraz et al, 1991). It appears that this recanalization process begins in the midureter and extends in a bidirectional manner both cranially and caudally. In addition, another source of physiologic ureteral obstruction may exist as the Chwalla membrane, a two-cell-thick layer over the ureteral orifice that is seen between 37 and 39 days' gestation. In humans, urine production is followed by proliferative changes in the ureteral epithelium (bilaminar by 10 weeks of gestation). The epithelium attains a transitional configuration by 14 weeks. The first signs of ureteral muscularization and development of elastic fibers are seen at 12 weeks of gestation. In both rat and human the ureteral smooth muscle phenotype appears later than that of the bladder. Smooth muscle differentiation is first detected in the subserosal region of the bladder dome and extends toward the bladder base and urethra, whereas smooth muscle differentiation of the ureter occurs later within the subepithelial region in the ureterovesical junction, ascending toward the intrarenal collecting system (Baker and Gomez, 1998). In the embryonic ureter and bladder it is likely that epithelial-mesenchymal interactions are important in the development of urothelium, lamina propria, and muscular compartments, but the exact nature of this induction process is unknown. Before 10 weeks of gestation elastic fibers are few in number, poorly developed, and randomly arranged. After 12 weeks these fibers become more numerous throughout the ureter and are seen with specific orientation (Escala et al, 1989).

Although more than 30 genes are found to be involved in the development of mammalian kidneys, only a few genes have been thus far demonstrated to concurrently cause both kidney and ureteral anomalies—*Agtr2, Bmp4, FoxC1, Pax2,* and *Eya1* (see Molecular Mechanism of Kidney Development, earlier). A mutation of *PAX2* gene has been identified in a human family carrying renal coloboma syndrome, a rare autosomal dominant syndrome characterized by optic nerve coloboma, renal anomalies, and vesicoureteral reflux (Sanyanusin et al, 1996). *EYA1* is mutated in patients with dominantly inherited disorder, branchio-oto-renal syndrome, which includes a duplex collecting system, renal hypoplasia/dysplasia, and renal agenesis (Abdelhak et al, 1997). Pax2 is required for the growth and elongation of nephric ducts prior to ureteric bud formation, whereas Eya1 appears to regulate the GDNF expression, which is a prerequisite for ureteric bud outgrowth. Bmp4 and FoxC1 appear to play a suppressive role in the ureteric bud outgrowth.

The renin-angiotensin system is present and active during fetal life. It is generally thought that the major role of this system in the fetus is to maintain fetal glomerular filtration and to ensure an adequate urine production (Lumbers, 1995). There is growing evidence, however, that the renin-angiotensin system is also important for normal growth and development of the kidney and ureter. The kidney is able to produce all components of this system, and thus the local (intrarenal) production of angiotensin II may play a critical role in this regard. Renin mRNA is detectable in the human mesonephros at about 30 days of gestation and in the metanephros at about 56 days of gestation (Schutz et al, 1996). A similar profile of expression is seen for angiotensinogen and angiotensin-converting enzyme (ACE). Mutant mice lacking ACE are found to have abnormal renal vasculature and tubules as well as increased renin synthesis in interstitial and perivascular cells (Hilgers et al, 1997). Pharmacologic inhibition of ACE in the neonatal rat produces irreversible abnormalities in renal function and morphology (Guron et al, 1997), supporting that an intact renin-angiotensin system is crucial for normal kidney development and maturation. In addition to the high rate of fetal loss, infants born to human mothers treated with ACE inhibitors during pregnancy have increased rates of oligohydramnios, hypotension, and anuria (Shotan et al, 1994; Sedman et al, 1995).

Both subtypes of angiotensin II receptors, AT1 and AT2, are expressed in the developing mesonephros and metanephros. AT2 expression predominates in the undifferentiated mesenchymal cells that surround the nephric duct at the time of ureteric bud outgrowth and declines with maturation, and this pattern of

expression suggests AT2's role in embryonic renal development. AT1 is expressed in more differentiated structures and may be involved in modulating later stages of renal vascular development and acquisition of classic angiotensin II–mediated effects of vasoconstriction and sodium reabsorption. The function of AT2 receptor is not defined completely, but when its gene, *Agtr2,* was inactivated genetically in mice these mutants demonstrated a significant incidence of anomalies in the kidney and urinary tract. Abnormal phenotype in these mice mimicked all the key features of human congenital anomalies of the kidney and urinary tract, such as ureteropelvic junction obstruction, hypoplastic kidney, vesicoureteral reflux, megaureter, and duplicated collecting system (Nishimura et al, 1999).

Because of its embryonic expression pattern, it was initially speculated that AT2 might play a role in regulating the initial outgrowth of the ureteric bud. Analysis of whole tissue sections showed that ectopic ureteric budding occurred in *Agtr2*-deficient mutant mice (Oshima et al, 2001). It was thus postulated that similar to Bmp4, AT2 might have a role in directing the site of ureteric bud outgrowth through its inhibitory effect. In other words, a defect in this process may lead to an abnormal timing and location of the ureteric bud outgrowth, resulting in congenital ureteral anomalies.

Recent evidence suggest that BMPs control formation of smooth muscle in the proximal ureter and pelvis. BMP4, expressed in the caudal mesenchyme cells, induces ureteral morphogenesis including smooth muscle differentiation and urothelial development (Brenner-Anantharam et al, 2007). Consistent with such a role, *Bmp4*- and *Bmp5*-mutant mice display hydronephrosis and hydroureter (Miyazaki et al, 2003).

Development of the Bladder and Continence Mechanism

By the 10th week of gestation the bladder is a cylindrical tube lined by a single layer of cuboidal cells surrounded by loose connective tissue. The apex tapers as the urachus, which is contiguous with the allantois. By the 12th week the urachus involutes to become a fibrous cord, which becomes the *median umbilical ligament.* The bladder epithelium consists of bilayered cuboidal cells between the 7th and 12th weeks, and it begins to acquire mature urothelial characteristics between the 13th and 17th weeks. By the 21st week it becomes four- to five-cell layers thick and demonstrates ultrastructural features similar to the fully differentiated urothelium. Between the 7th and 12th weeks the surrounding connective tissues condense and smooth muscle fibers begin to appear, first at the region of the bladder dome and later proceeding toward the bladder base. Collagen fibers first appear in the lamina propria and then later extend into the deeper wall between the muscle fibers (Newman and Antonakopoulos, 1989).

Bladder compliance is thought to change during development. When studied in whole organ preparation using fetal sheep bladders, bladder compliance is very low during early gestation and increases gradually thereafter (Coplen et al, 1994). The mechanism of these changes in bladder compliance is not known but may involve alterations in both smooth muscle tone and connective tissue composition. This phenomenon is also observed in developing human bladders (Kim et al, 1991). During gestation the bladder wall muscle thickness increases and the relative collagen content decreases. The ratio of thick-to-thin collagen fibers also decreases, whereas the amount of elastic fibers increases. These changes in compliance seem to coincide with the time of fetal urine production, suggesting a possible role for mechanical distention (Baskin et al, 1994). Using fetal mouse bladders as organ culture explants, bladder distention promoted a more orderly development of collagen fiber bundles within the lamina propria in comparison to decompressed bladder explants, suggesting that mechanical factors from accumulating urine may play a role during bladder development (Beauboeuf et al, 1998).

Similar to other organ development, the epithelial-mesenchymal inductive interactions appear to be necessary for orderly differentiation and proper development of the bladder. A modified Grobstein technique was applied to study the mechanism of bladder smooth muscle cell differentiation (Baskin et al, 1996). Undifferentiated rat bladder epithelial and mesenchymal rudiments were separated before bladder smooth muscle cell differentiation and then recombined to grow within the immunologically compromised host (athymic nude mouse). In the presence of epithelial cells, the mesenchymal cells differentiated into smooth muscle cells with sequential expression of appropriate smooth muscle markers, whereas in the absence of epithelial cells they involuted with evidence of apoptosis.

No functional study has been done to assess fetal continence mechanism. Only a handful of ontogenic descriptions are available using human fetal specimens, providing a basis for speculative theories. A mesenchymal condensation forms around the caudal end of the urogenital sinus after the division of the cloaca and the rupture of the cloacal membrane. Striated muscle fibers can be seen clearly by the 15th week. At this time the smooth muscle layer becomes thicker at the level of bladder neck and forms the inner part of the urethral musculature. The urethral sphincter, composed of central smooth muscle fibers and peripheral striated muscle fibers, develops in the anterior wall of the urethra (Bourdelat et al, 1992). Beyond this point, sexual dimorphism develops in conjunction with the formation of the prostate in males and the vagina in females (Tichy, 1989). The urethral sphincter muscle fibers extend to the posterior wall of the urethra. In males these fibers project to the lateral wall of the prostate, whereas in females the muscle fibers attach to the lateral wall of the vagina.

GENITAL AND REPRODUCTIVE TRACT DEVELOPMENT

Formation of Genital Ridges and Paramesonephric Ducts

During the fifth week, primordial germ cells migrate from the yolk sac along the dorsal mesentery to populate the mesenchyme of the posterior body wall near the 10th thoracic level (Fig. 111–18). **In both sexes the arrival of primordial germ cells in the area of future gonads serves as the signal for the existing cells of the mesonephros and the adjacent coelomic epithelium to proliferate and form a pair of *genital ridges* just medial to the developing mesonephros** (Fig. 111–19). During the sixth week the cells of the genital ridge invade the mesenchyme in the region of future gonads to form aggregates of supporting cells called the *primitive sex cords*. The primitive sex cords will subsequently invest the germ cells and support their development. The genital ridge mesenchyme containing the primitive sex cords is divided into the cortical and medullary regions. Both regions develop in all embryos, but after the sixth week they pursue different fates in the male and female.

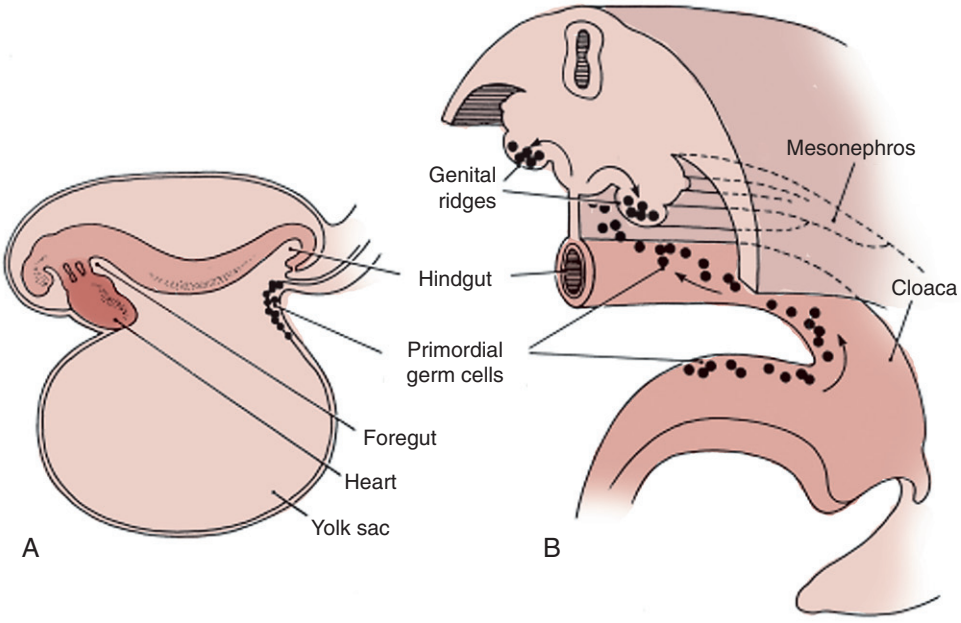

Figure 111–18. **A,** The site of the primordial germ cell origin in the wall of the yolk sac in a 3-week-old embryo. **B,** Migratory path of the primordial germ cells along the wall of the yolk sac and dorsal mesentery into the developing genital ridges. (Modified from Sadler TW. Langman's medical embryology. Baltimore: Williams & Wilkins; 1985.)

During this time a new pair of ducts, called the *paramesonephric (müllerian) ducts,* begins to form just lateral to the nephric ducts in both male and female embryos (Fig. 111–20). These ducts arise by the craniocaudal invagination of thickened coelomic epithelium, extending all the way from the third thoracic segment to the posterior wall of the developing urogenital sinus. The caudal tips of the paramesonephric ducts adhere to each other as they connect with the urogenital sinus between the openings of the right and left nephric ducts. The cranial ends of the paramesonephric ducts form funnel-shaped openings into the coelomic cavity, which is the future peritoneum.

Development of Male Genital Structures

Under the influence of *SRY* (the *S*ex-determining *R*egion of the *Y* chromosome), cells in the medullary region of the primitive sex cords begin to differentiate into *Sertoli cells,* while the cells of the cortical sex cords degenerate. Sex cord cells differentiate into Sertoli cells only if they contain the SRY protein; otherwise the sex cords differentiate into ovarian follicles. During the seventh week, the differentiating Sertoli cells organize to form the *testis cords*. At puberty these testis cords associated with germ cells undergo canalization and differentiate into seminiferous tubules. Direct cell-to-cell contact between developing Sertoli cells and primordial germ cells is thought to play a key role in the proper development of male gametes. This interaction occurs shortly after the arrival of the primordial germ cells in the presumptive genital ridge. The testis cords distal to the presumptive seminiferous tubules also develop lumen and differentiate into a set of thin-walled ducts called the *rete testis*. Just medial to the developing gonad the tubules of rete testis connect with 5 to 12 residual tubules of nephric ducts, called *efferent ductules*. The vas deferens also develops from the nephric duct. At this time the testis begins to become round, reducing its area of contact with the surrounding mesonephros. As the testis continues to develop the degenerating cortical sex cords become separated from the coelomic (peritoneal) epithelium by an intervening layer of connective tissue called the *tunica albuginea* (see Fig. 111–20).

As the developing Sertoli cells begin their differentiation in response to the SRY protein they also begin to secrete a glycoprotein hormone called *müllerian-inhibiting substance* (MIS). MIS causes the paramesonephric (müllerian) ducts to regress rapidly between the 8th and 10th weeks. **Small müllerian duct remnants can be detected in the developed male as a small tissue protrusion at the superior pole of the testis, called the *appendix testis,* and as a posterior expansion of the prostatic urethra, called the *prostatic utricle.*** In female embryos, MIS is absent; therefore the müllerian ducts do not regress. Occasionally, genetic males have persistent müllerian duct structures (uterus and fallopian tubes), a condition known as *hernia uteri inguinale*. In these individuals either MIS production by Sertoli cells is deficient or the müllerian ducts do not respond to normal MIS levels.

During the 9th and 10th weeks, Leydig cells differentiate from mesenchymal cells of the genital ridge in response to the SRY protein. These endocrine cells produce testosterone. At an early stage of development testosterone secretion is regulated by placental chorionic gonadotropin, but eventually the pituitary gonadotropins assume control of androgen production. Between the 8th and 12th weeks, testosterone secretion by Leydig cells stimulates the nephric (wolffian) ducts to transform into the vas deferens. The cranial portions of the nephric ducts degenerate, leaving a small remnant of tissue protrusion called the *appendix epididymis,* and the region of nephric ducts adjacent to the presumptive testis differentiate into the epididymis. During the 9th week, 5 to 12 nephric ducts in the region of the epididymis make contact with the sex cords of the future rete testis. It is not until the third month, however, that these tubules actually establish communication with the rete testis as the efferent ductules. Meanwhile, the nephric duct–derived tubules near the inferior pole of the developing testis degenerate, sometimes leaving a remnant of tissue protrusion called the *paradidymis*.

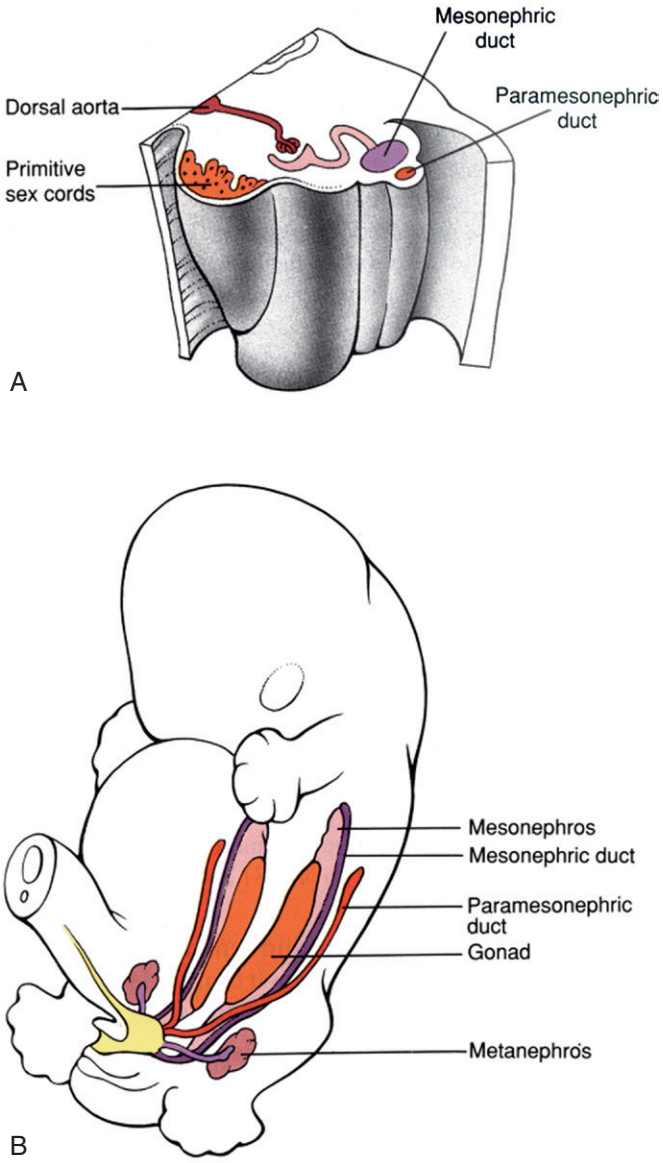

Figure 111–19. Formation of genital ridges and paramesonephric ducts. **A,** During the fifth and sixth weeks the genital ridges form in the posterior abdominal wall just medial to the developing mesonephros. The primordial germ cells induce the coelomic epithelial cells lining the peritoneal cavity and the cells of the mesonephros to proliferate and form the primitive sex cords. **B,** During the sixth week, the paramesonephric ducts develop lateral to the mesonephros. The caudal tips of the paramesonephric ducts fuse with each other as they connect with the urogenital sinus. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Prostate and Seminal Vesicle Development

The seminal vesicles sprout from the distal nephric ducts, whereas the prostate and bulbourethral glands develop from the urogenital sinus (Fig. 111–21). They therefore have different embryologic origins. **The initial event in prostatic development is an outgrowth of solid epithelial cords from the urogenital sinus epithelium into the surrounding mesenchyme during weeks 10 to 12 of gestation.** This prostatic bud growth and subsequent branching morphogenesis occur in a specific spatial pattern that eventually establishes the lobar subdivisions of the mature prostate gland (Sugimura et al, 1986; Timms et al, 1994). The solid prostatic ducts are subsequently canalized from their urethral connections, proceeding distally toward the ductal tips. As the solid epithelial cords canalize, the epithelium organizes itself into two distinct cell types—luminal and basal cells (Hayward et al, 1996). At this time the prostatic mesenchyme differentiates into a layer of smooth muscle cells that surround the prostatic ducts (Hayward et al, 1996). At puberty, corresponding to a rise in circulating testosterone, the prostate size increases rapidly, along with functional cytodifferentiation of luminal cells, as evidenced by the expression of prostate-specific secretory proteins (Hayward et al, 1996).

Circulating androgens produced by fetal testes play a critical role in the development of the prostate. Cellular responses to circulating androgens are mediated by nuclear androgen receptors that are activated by either testosterone or dihydrotestosterone (DHT). The evidence for the requirement of androgens in establishing the prostate specificity of the urogenital sinus comes primarily from the absence of prostate development in mice and humans that lack functional androgen receptors (Lubahn et al, 1989; He et al, 1991), as well as from the development of the prostate in the female urogenital sinus exposed to androgens (Takeda et al, 1986). In the urogenital sinus, testosterone could activate androgen receptors by directly binding to the receptor and also through a local conversion of circulating testosterone into the more potent DHT by the enzyme 5α-reductase (Russell and Wilson, 1994). DHT has a 10-fold greater affinity for the androgen receptor than testosterone (Deslypere et al, 1992). When 5α-reductase is deficient, the urogenital sinus is specified to become the prostate but the overall prostatic growth and development are severely compromised (Andersson et al, 1991). Tissue recombination and grafting experiments using testicular feminization mice that lack functional androgen receptor have shown that **the presence of androgen receptors in the urogenital sinus mesenchyme is required for prostate specification and differentiation** (Cunha and Lung, 1978). The fact that mesenchymal but not epithelial androgen receptors are required for prostate-specific ductal growth and branching suggests that paracrine signals from the urogenital sinus mesenchyme mediate the action of androgens on the epithelium. Prostate development appears to be affected by the levels of estrogenic compounds as well (vom Saal et al, 1997; Timms et al, 1999), but their specific role has not been fully elucidated.

Prostate development requires inductive and reciprocal interactions between the urogenital sinus epithelium and mesenchyme. In addition to mediating the effect of androgens to the developing prostatic epithelium, paracrine signals from the urogenital sinus mesenchyme also appear to direct lobe-specific patterning of juxtaposed epithelium (Timms et al, 1995). The urogenital sinus mesenchyme when combined with either embryonic or adult bladder epithelium (also a derivative of endodermal cloaca) will stimulate formation of prostatic ducts. In contrast, the urogenital sinus mesenchyme combined with epithelia of other anatomic origins, such as seminal vesicle (a mesodermal derivative), salivary gland, or esophagus, forms tissues with epithelial characteristics that resemble the anatomic origin of the partnering epithelium (Cunha et al, 1987). **These observations suggest that prostate development is spatially restricted by prostate-inducing paracrine signals from the urogenital sinus mesenchyme and that epithelial potential to respond to signals from the urogenital sinus mesenchyme is restricted to the endodermal epithelia of similar**

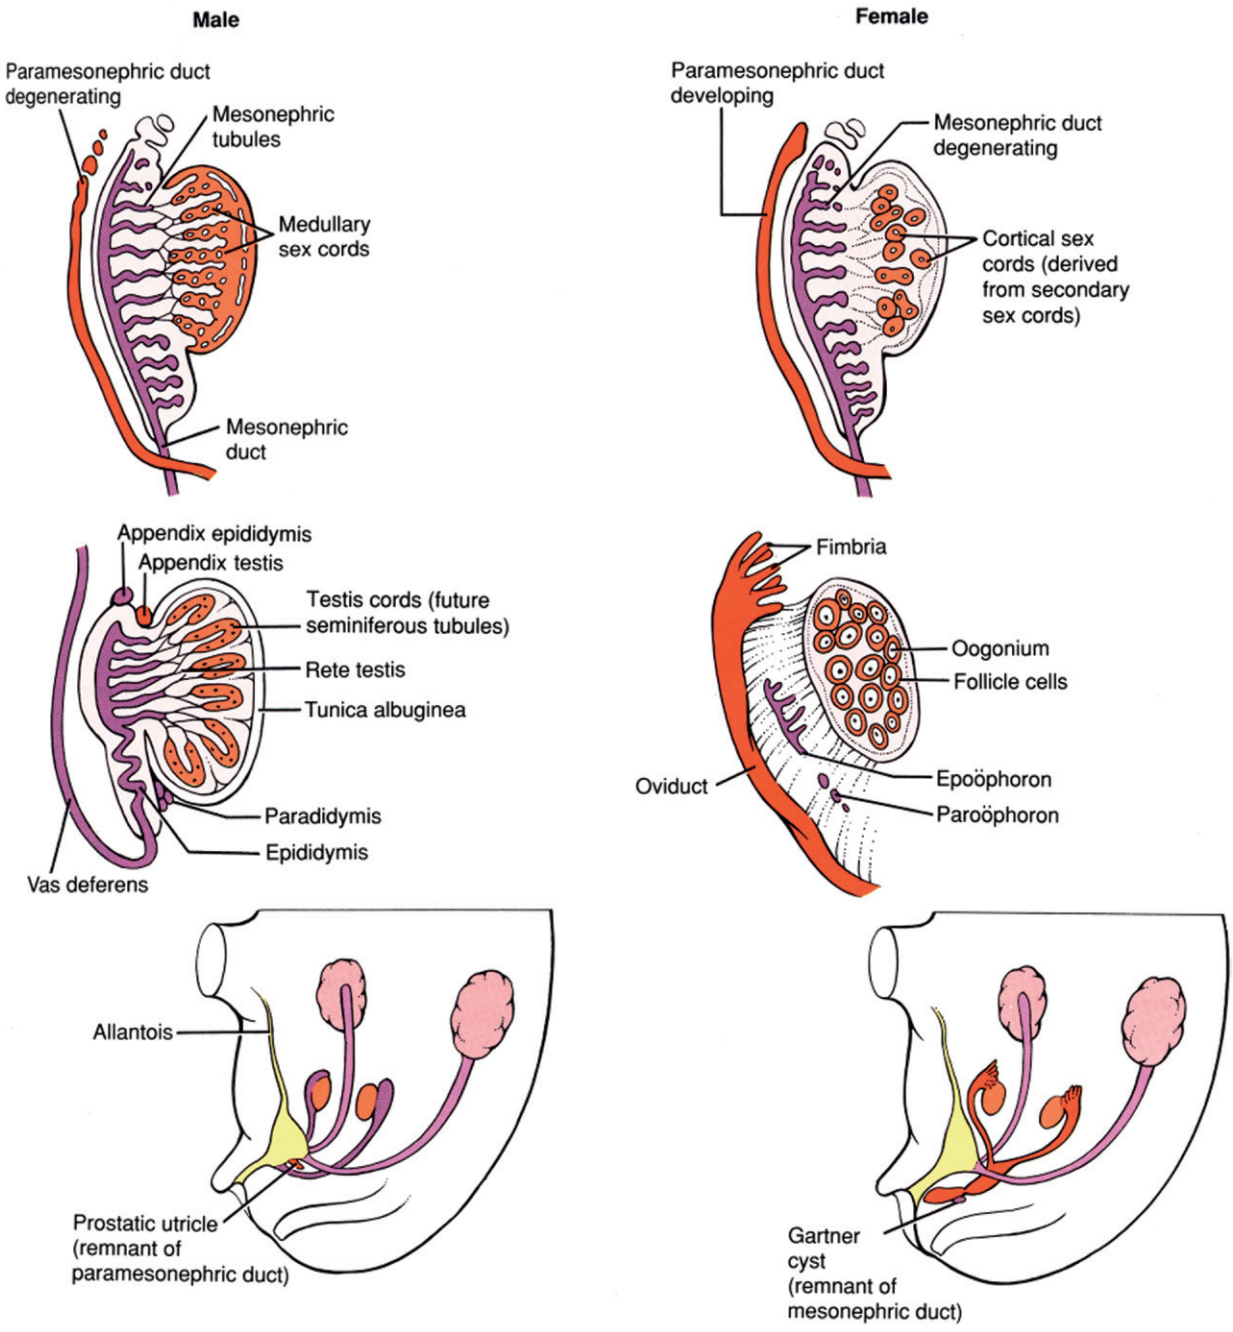

Figure 111–20. Male and female gonad and genital development. The male and female genital structures are virtually identical through the seventh week. In males, SRY protein produced by the Sertoli cells causes the medullary sex cords to become presumptive seminiferous tubules and causes the cortical sex cords to regress. Müllerian-inhibiting substance (MIS), a glycoprotein hormone produced by the Sertoli cells, then causes the paramesonephric ducts to regress, leaving behind appendix testis and prostatic utricle as remnants. Appendix epididymis and paradidymis arise from the mesonephric ducts. In females, cortical sex cords invest the primordial germ cells and become the ovarian follicles. In the absence of MIS, the mesonephric ducts degenerate and the paramesonephric ducts give rise to the fallopian tubes, uterus, and the upper vagina. The remnants of the mesonephric ducts are found in the ovarian mesentery as the epoöphoron and paroöphoron, and in the anterolateral vaginal wall as the Gartner's duct cysts. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

embryonic origin as the prostate. The interactions between epithelium and mesenchyme are reciprocal. The presence of prostate epithelium plays a critical role in the differentiation of mesenchymal cells into the periductal smooth muscle cells (Hayward et al, 1998).

Several candidate genes have been implicated in the prostate development, but the nature of paracrine mesenchymal factors that drive urogenital sinus epithelial transformation into prostatic ducts remains unknown. Furthermore, the precise relationship and the embryologic sequence of these candidate molecules have not been clearly defined. The *Hox* family of homeobox genes may be involved in the proper differentiation of male accessory sex glands, including the prostate (Podlasek et al, 1997, 1999b). In particular, Hoxa-13 and Hoxd-13 transcription factors are expressed in both urogenital sinus and nephric ducts, and the loss of function mutation of these genes in mice results in agenesis of

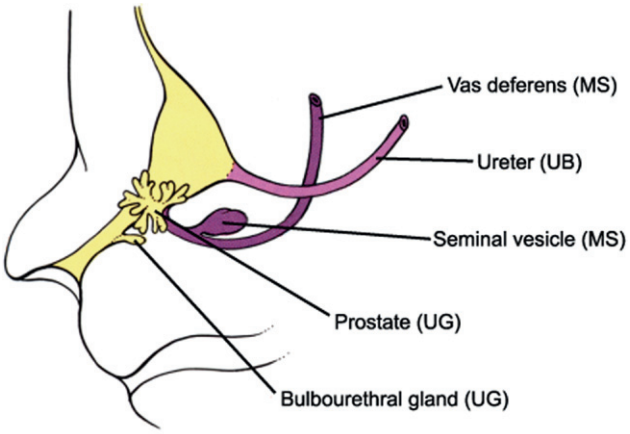

Figure 111–21. Development of male accessory sex glands. During the 10th week, the seminal vesicles sprout from the distal mesonephric ducts in response to testosterone whereas the prostate and bulbourethral glands develop from the urethra in response to dihydrotestosterone. Thus the vas deferens and seminal vesicle derive from the mesonephric ducts (MS) while prostate and bulbourethral glands develop from the urogenital sinus (UG). UB, ureteric bud. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

bulbourethral glands and defective morphogenesis of the prostate and seminal vesicles. Two members of the FGF family of secreted proteins, FGF7 and FGF10, are expressed in the urogenital sinus mesenchyme. In-vitro organ culture experiments have shown that exogenous FGF7 and FGF10 can stimulate proliferation and branching of developing prostate tissue, but these factors do not appear to be androgen responsive (Thomson and Cunha, 1999). There is also evidence that secreted factor activin-A and its antagonistic binding protein follistatin may be important in the regulation of prostate epithelial development (Cancilla et al, 2001). Activin-A is expressed in both urogenital sinus epithelium and mesenchyme, whereas its receptors are found in the epithelium. Follistatin, an activin-A antagonist, is expressed in the urogenital sinus epithelium. Prostatic ductal growth and branching might therefore be a result of balanced interplay between activin-A and follistatin. Other implicated molecules in prostate development include Bmp4 (Lamm et al, 2001), growth hormone receptor (Ruan et al, 1999), insulin-like growth factor-1 (Ruan et al, 1999), Nkx3.1 (Bhatia-Gaur et al, 1999), sonic hedgehog (Podlasek et al, 1999a), P63 (Signoretti et al, 2000), prolactin (Steger et al, 1998), hyaluronan (Gakunga et al, 1997), fucosyltransferase-1 (Marker et al, 2001), and urokinase plasminogen activator (Elfman et al, 2001).

Development of Female Genital Structures

In female embryos the primitive sex cords do not contain the Y chromosome, do not elaborate SRY protein, and therefore do not differentiate into Sertoli cells. In the absence of Sertoli cells and SRY protein, therefore, MIS synthesis, Leydig cell differentiation, and androgen production do not occur. Consequently, male development of the genital ducts and accessory glands is not stimulated and female development ensues. In females the primitive sex cords degenerate and the mesothelium of the genital ridge forms the secondary cortical sex cords. These secondary sex cords invest the primordial germ cells to form the ovarian follicles. The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes. The follicle cells then arrest further germ cell development until puberty, at which point individual oocytes resume gametogenesis in response to a monthly surge of gonadotropins.

In the absence of MIS and androgens, the nephric (wolffian) ducts degenerate, and the paramesonephric (müllerian) ducts give rise to the fallopian tubes, uterus, and upper two thirds of the vagina. The remnants of nephric ducts are found in the mesentery of the ovary as the *epoöphoron* and *paroöphoron* and near the vaginal introitus and anterolateral vaginal wall as *Gartner duct cysts*. The distal tips of the paramesonephric ducts adhere to each other just before they contact the posterior wall of the urogenital sinus. The wall of the urogenital sinus at this point forms a small thickening called the *sinusal tubercle*. As soon as the fused tips of the paramesonephric ducts connect with the sinusal tubercle the paramesonephric ducts begin to fuse in a caudal to cranial direction, forming a tube with a single lumen. This tube, called the *uterovaginal canal,* becomes the superior portion of the vagina and the uterus. The unfused, superior portions of the paramesonephric ducts become the fallopian tubes (oviducts), and the funnel-shaped superior openings of the paramesonephric ducts become the infundibula.

While the uterovaginal canal is forming during the third month, the endodermal tissue of the sinusal tubercle in the posterior urogenital sinus continues to thicken, forming a pair of swellings called the *sinovaginal bulbs*. These structures give rise to the lower third of the vagina. The most inferior portion of the uterovaginal canal becomes occluded transiently by a block of tissue called the *vaginal plate*. The origin of the vaginal plate is not clear; it may arise from the sinovaginal bulbs, from the walls of the paramesonephric ducts, from the nearby mesonephric ducts, or from a combination of these tissues. The vaginal plate elongates between the third to fifth month and subsequently becomes canalized to form the inferior vaginal lumen (Fig. 111–22).

As the vaginal plate forms, the lower end of the vagina lengthens, and its junction with the urogenital sinus migrates caudally until it comes to rest on the posterior wall of definitive urogenital sinus (future vestibule of the vagina) during the fourth month. An endodermal membrane temporarily separates the vaginal lumen from the cavity of the definitive urogenital sinus. This barrier degenerates partially after the fifth month, but its remnant persists as the vaginal *hymen*. The mucous membrane that lines the vagina and cervix may also derive from the endodermal epithelium of the definitive urogenital sinus.

Development of External Genitalia

Unlike the rest of the developing embryo the cloacal membrane, along with the oropharyngeal membrane (future oral cavity), is a bilayered structure, in which the outer ectoderm remains in close contact with the underlying endoderm without the intervening mesoderm. Initially, the cloacal membrane represents an elongated midline structure, which extends from the root of the umbilical cord to the future site of perineum distally. During the subsequent development **this bilayered cloacal membrane "retracts" into the perineum as a result of cranial and medial migration of mesodermal cells into the anterior body wall between the ectoderm and the endoderm layers of the cloacal membrane.** This mesenchymal migration brings about the closure of the inferior part of the anterior abdominal wall and causes the caudal portion of the cloacal

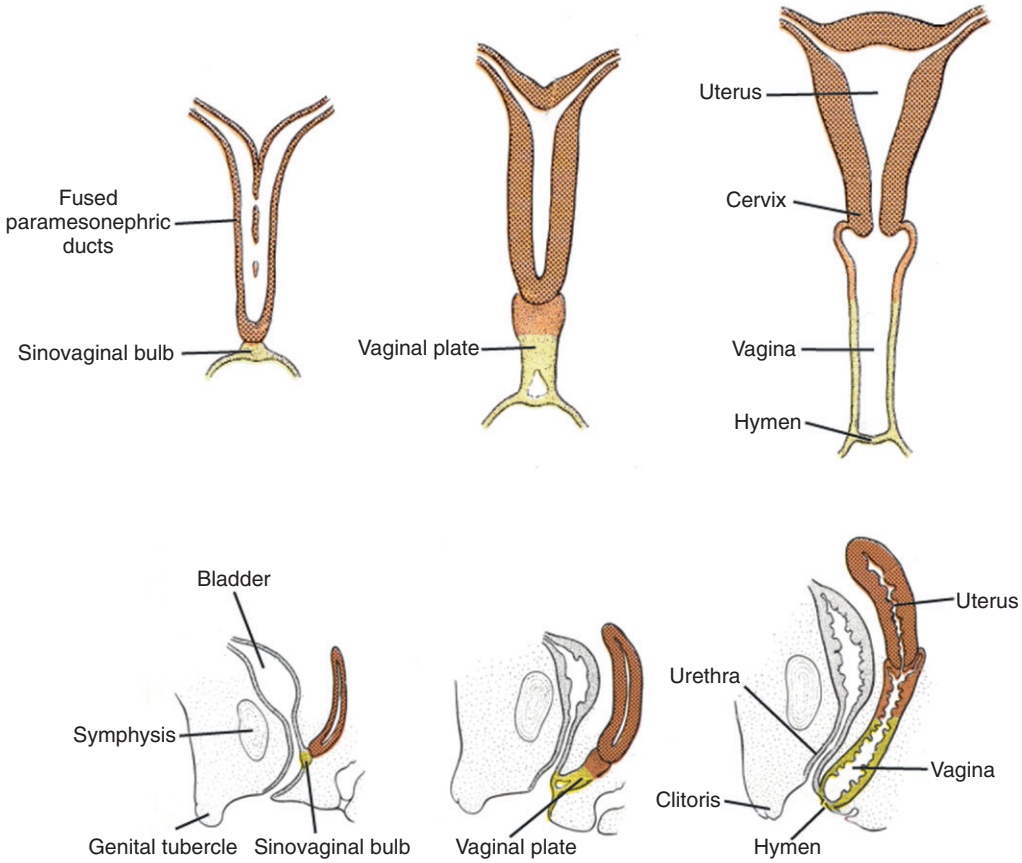

Figure 111–22. Development of uterus and vagina. During the 10th week the paramesonephric ducts fuse at their caudal ends to establish a common channel and come into contact with a thickened portion of the posterior urogenital sinus called the sinovaginal bulb. This is followed by development of the vaginal plate, which elongates between the third to fifth months and becomes canalized to form the inferior vaginal lumen. (Modified from Sadler TW. Langman's medical embryology. Baltimore: Williams & Wilkins, 1985.)

membrane to position itself in the perineal region. These migrating mesodermal cells give rise to the musculature of the medial portion of the anterior abdominal wall, the mesenchymal portion of the anterior bladder wall, the pubic symphysis, and the rudiments of the external genitalia (Vermeij-Keers et al, 1996). Failure of migration of these mesodermal cells into the midline results in bladder exstrophy and other associated genital defects (Langer, 1993; Vermeij-Keers et al, 1996).

The early development of the external genitalia is similar in both sexes. Migrating mesenchymal cells spread themselves around the cloacal membrane and pile up to form swellings. Early in the fifth week, a pair of swellings called *cloacal folds* develops on either side of the cloacal membrane. These folds meet just anterior to the cloacal membrane to form a midline swelling called the *genital tubercle* (Fig. 111–23). During the cloacal division into the anterior urogenital sinus and the posterior anorectal canal the portion of the cloacal folds flanking the opening of the urogenital sinus becomes the *urogenital folds* and the portion flanking the opening of the anorectal canal becomes the *anal folds*. A new pair of swellings, called the *labioscrotal folds,* appears on either side of the urogenital folds.

The most popular hypothesis of external genital and urethral development is based on work performed in the early part of the 20th century. Most embryology texts today quote the mechanism of urethral development proposed by Glenister (1954). As the genital tubercle elongates in males, a groove appears on its ventral aspect (called the *urethral groove*) during the sixth week. In both

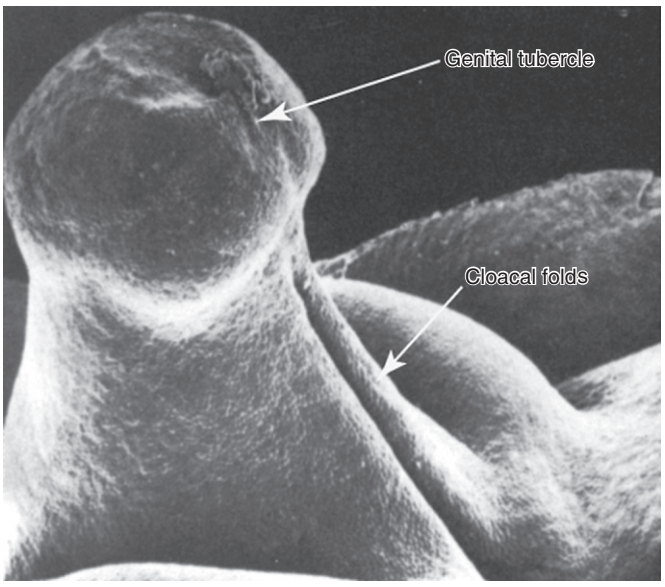

Figure 111–23. The early stages of cloacal fold development. (Reproduced from Hamilton WJ, Mossman HW. Human embryology prenatal development of form and function. New York: Macmillan; 1976; and from Waterman RE. Human embryo and fetus. In: Hafez ESE, Kenemans P, editors. Atlas of human reproduction. Hinghman [MA]: Kluwer Boston; 1982.)

sexes an ectodermal *epithelial tag* is present at the tip of the genital tubercle. The urethral groove is defined laterally by urethral folds, which are continuations of the previous urogenital folds surrounding the urogenital membrane. Initially, the urethral groove extends only part of the way distally along the shaft of the elongating genital tubercle. The distal portion of the urethral groove terminates in a solid epithelial plate called the *urethral plate* that extends into the glans penis. The solid urethral plate canalizes and thus extends the urethral groove distally toward the glans. The urethral groove is thought to be lined by endoderm. Likewise, the solid urethral plate, the distal precursor of the urethral groove, is also believed to derive from the endodermal source. **Clearly, fusion of the urethral folds is the key step in the formation of penile urethra.** A prerequisite of urethral fold fusion is the canalization of solid urethral plate and formation of the urethral groove bounded on each side by the urethral folds. If the urethral groove and urethral fold formations are abnormal, then the urethral fold fusion is likely to be impaired as well (Figs. 111–24 and 111–25).

The formation of the distal glanular urethra may occur by a combination of two separate processes—the fusion of urethral folds proximally and the ingrowth of ectodermal cells distally. It is generally thought that the stratified squamous epithelium of the fossa navicularis results from an ingrowth of surface ectoderm as far proximally as the valve of Guérin. The lacuna magna (also known as the sinus of Guérin), which can give symptoms of hematuria and dysuria in some boys, may form as a result of dorsal extension of this ectodermal ingrowth. It was suggested recently that the entire penile urethra might differentiate from the fusion of the endodermal urethral groove via the mechanism of epithelial-mesenchymal interactions (Kurzrock et al, 1999).

The molecular basis of the sexual dimorphism in genital development is based on the presence or absence of the signaling via the androgen receptor. As the fetal testis produces testosterone, cells within the fetal external genitalia express the enzyme 5α-reductase, which converts testosterone to DHT. Androgen receptors are present in cells of the developing external genitalia and prominently expressed in the genital tubercle mesenchymal cells. The action of DHT acting via androgen receptors masculinizes the developing external genitalia. The key role of androgen in sexually dimorphic development of the external genitalia has been corroborated through many experimental studies. In-utero exposure of rodents to antiandrogenic compounds reduces the size of the genital tubercle and prevents the development of the scrotum. Likewise, in-utero exposure of rats to 5α-reductase inhibitors leads to the development of hypospadias. Mice and humans with functional loss of androgen receptors via mutations demonstrate a complete feminization of the external genitalia.

The elongating phallus is covered externally by ectoderm that gives rise to the penile skin, whereas most of the substance of the penis is derived from mesodermal cells forming the corporeal bodies, connective tissue, and dermis. Corporeal tissue is first recognized as distinct dense mesenchymal condensations within the shaft of the developing penis. Little is known regarding the molecular regulatory mechanisms of the differentiation of penile mesenchyme into its various derivatives, but it is likely that this process is dependent on epithelial-mesenchymal interactions.

In the female, owing to absence of androgen receptor signaling via DHT, the primitive perineum does not lengthen and the labioscrotal and urethral folds do not fuse across the midline. The phallus bends inferiorly, becoming the clitoris, and the ostium of the urogenital membrane becomes the vestibule of the vagina. The urethral folds become the labia minora, and the labioscrotal folds become the labia majora. The external genitalia develop in a similar manner in genetic males who are deficient in 5α-reductase and therefore lack DHT.

Gonadal Descent

Morphologically, the human urogenital ridge is identical in both sexes at 7 to 8 weeks of gestation. **Before gonadal differentiation, the testis lies near the developing kidney, loosely held in place by two ligamentous structures. The dorsal ligament is referred to as the *cranial suspensory ligament* (CSL), whereas the ventral ligament later develops into the *gubernaculum*** (Fig. 111–26). Between 10 and 15 weeks, the testis remains close to the future inguinal region during the enlargement of the abdominal cavity while the ovary moves more cranially. **The testis is anchored near the inguinal region by enlargement of the gubernaculum and regression of the CSL.** As early as the 1700s, enlargement of the gubernaculum in males was observed to tether the testis near the groin while the kidney migrated cranially (Wyndham, 1943; van der Schoot, 1993). In females, the CSL continues to develop, keeping the ovary close to the kidney while the gubernaculum involutes. In males, androgen induces resorption of the CSL while the gubernaculum enlarges to become a plump ligamentous body, "holding" the testis close to the inguinal region. Starting in the seventh month, the gubernaculum begins to bulge beyond the external inguinal ring and descends to the scrotal location, while simultaneously it is hollowed out by the evaginating peritoneal diverticulum called the *processus vaginalis* (Heyns, 1987). The processus vaginalis allows the intra-abdominal testis to exit the abdominal cavity. The bulky distal end of the gubernaculum (known as the *bulb*) is resorbed in humans after completion of inguinoscrotal migration.

Caudal enlargement of the gubernaculum during the early relative transabdominal movement of the testis is known as the "swelling reaction" or "gubernacular outgrowth." The proximal gubernacular cord appears to shorten during this process, as it becomes incorporated into the enlarging bulb (Wensing, 1986). Shortening of the cord may be an important mechanism to position the testis over the inguinal ring to permit abdominal pressure to push the testis out of the abdomen (Quinlan et al, 1988; Attah and Hutson, 1993; Husmann and Levy, 1995). Transection of the gubernacular cord can lead to either accidental testicular descent into the contralateral inguinal canal or aberrant intra-abdominal location (Frey and Rajfer, 1984; Beasley and Hutson, 1988; Attah and Hutson, 1993).

Although intra-abdominal pressure may not be a factor during the initial transabdominal descent, it is thought to be important during transit through the inguinal canal and the subsequent scrotal migration. Inguinoscrotal descent requires migration of the gubernaculum over a considerable distance, along with an increase in the length of the processus vaginalis. The force for movement may come from the intra-abdominal pressure, transmitted directly and indirectly to the testis via the lumen of the processus vaginalis and the gubernacular cord, respectively.

Although patients with defective androgen production or metabolism show varied manifestations of cryptorchidism, the exact role of androgen in testicular descent still remains unclear. During intra-abdominal testicular descent, androgen appears to

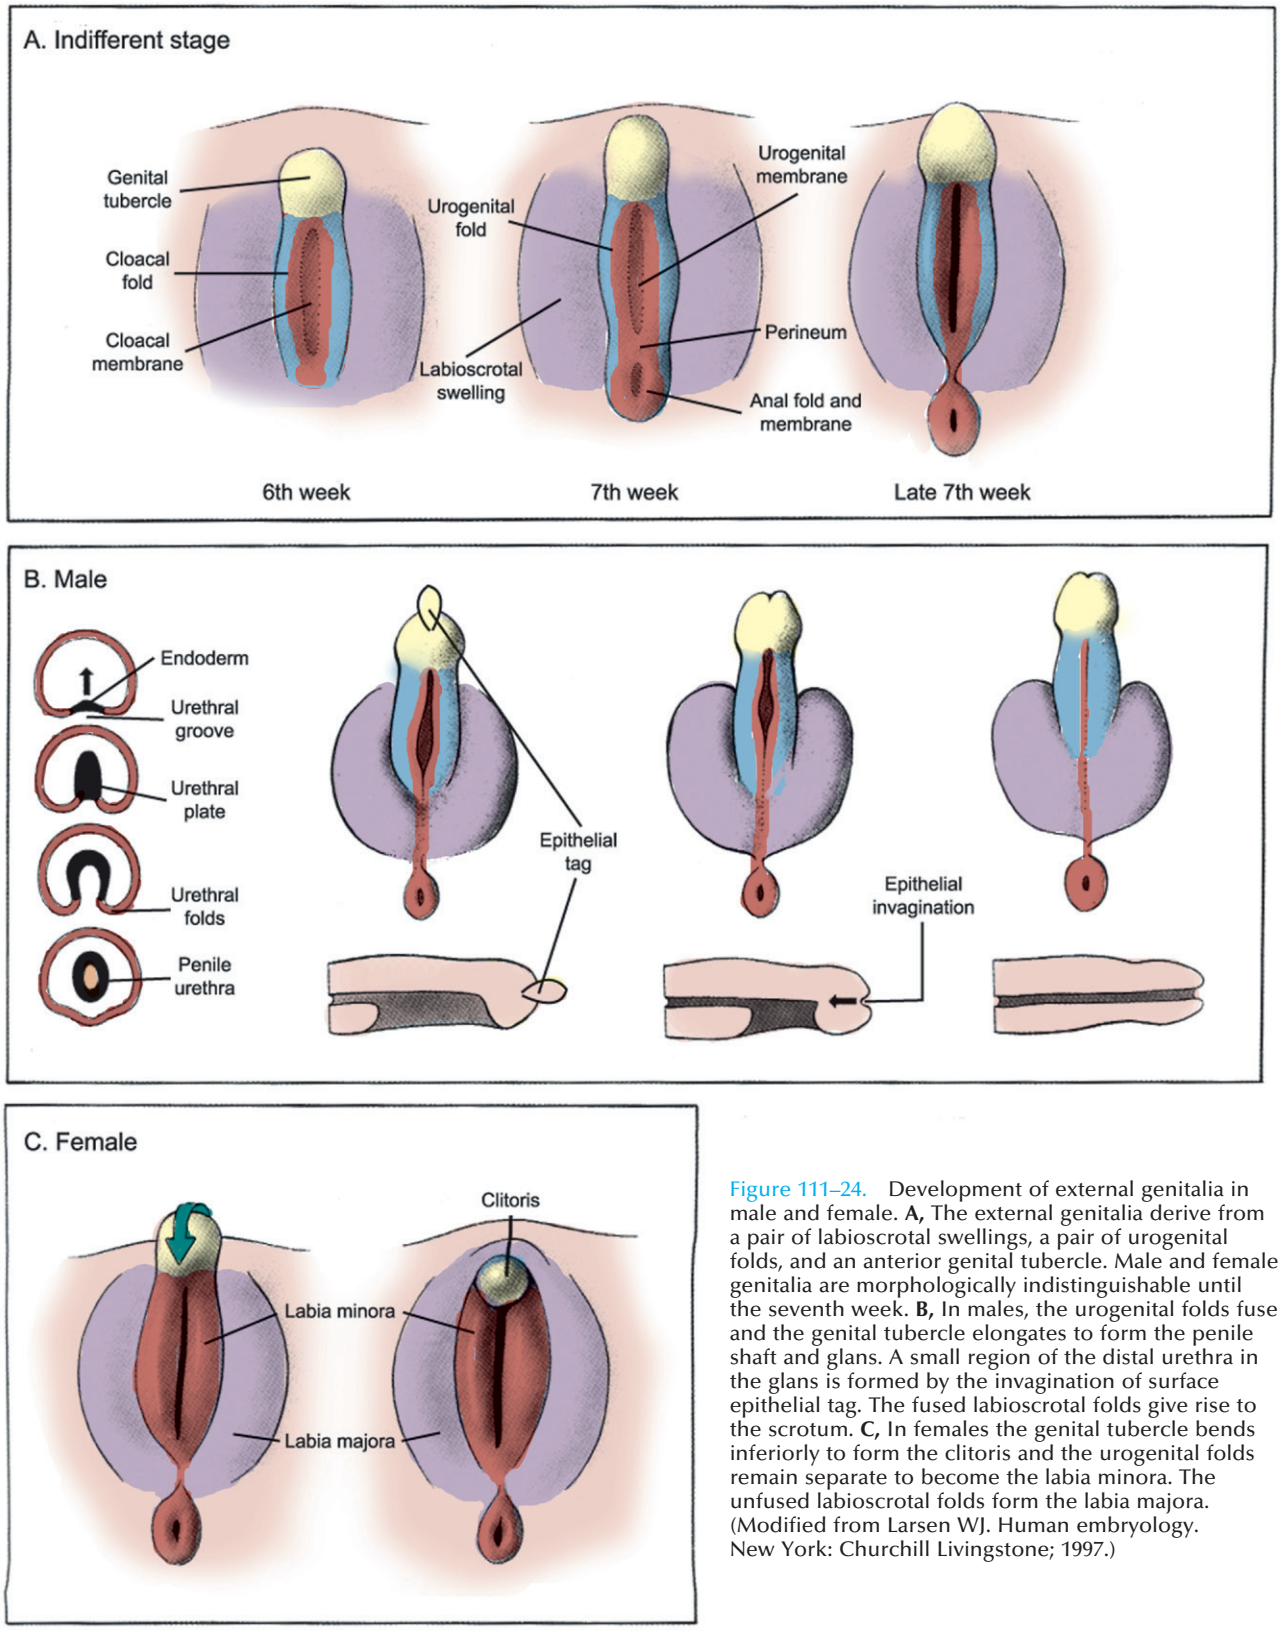

Figure 111–24. Development of external genitalia in male and female. **A,** The external genitalia derive from a pair of labioscrotal swellings, a pair of urogenital folds, and an anterior genital tubercle. Male and female genitalia are morphologically indistinguishable until the seventh week. **B,** In males, the urogenital folds fuse and the genital tubercle elongates to form the penile shaft and glans. A small region of the distal urethra in the glans is formed by the invagination of surface epithelial tag. The fused labioscrotal folds give rise to the scrotum. **C,** In females the genital tubercle bends inferiorly to form the clitoris and the urogenital folds remain separate to become the labia minora. The unfused labioscrotal folds form the labia majora. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

play a role in the regression of the CSL (van der Schoot, 1992). Gubernacular enlargement, in contrast, seems to occur independent of androgen activity, because it occurs in androgen-resistant mice and humans normally, being able to keep the testis close to the inguinal region (Hutson, 1985). The second migratory step—the inguinoscrotal phase—is thought to be more androgen dependent. Migration of the gubernaculum beyond the inguinal region is absent in gonadotropin-deficient mice (Grocock et al, 1988) and those with complete androgen resistance (Hutson, 1986). Regression of the gubernacular bulb after the completion

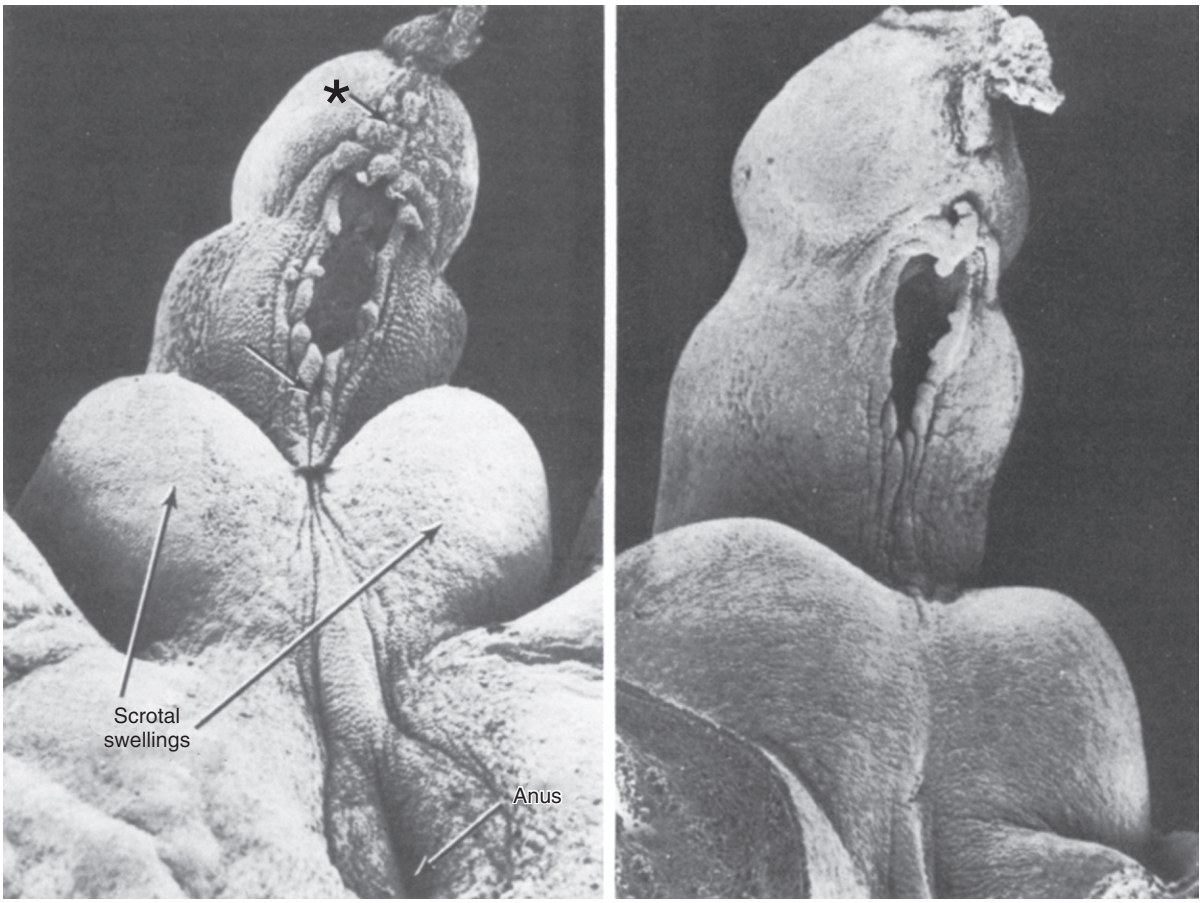

Figure 111–25. The epithelial tag *(asterisk)* and fusing urethral folds *(arrows)* in the developing male external genitalia. (Reproduced from Waterman RE. Human embryo and fetus. In: Hafez ESE, Kenemans P, editors. Atlas of human reproduction. Hinghman [MA]: Kluwer Boston; 1982.)

of scrotal descent also appears to be androgen dependent because in humans with androgen resistance the gubernaculum remains enlarged (Hutson, 1986).

Müllerian-inhibiting substance is a glycoprotein produced and secreted by Sertoli cells and is responsible for regression of the müllerian ducts (Josso et al, 1993; Lee and Donahoe, 1993). Evidence for the role of MIS in testicular descent is conflicting. Some clinical observations support the role of MIS, including patients with persistent müllerian duct syndrome caused by genetic defects of MIS or its receptor gene (Josso et al, 1983). In this clinical scenario the testes are undescended and the gubernaculum is thin and elongated. Transgenic mice with MIS deficiency show a variable testicular position depending on their androgenic status: those with normal androgen receptors have normally descended testes whereas those with androgen resistance have completely undescended testes (Behringer et al, 1994). A recent study on MIS-receptor knockout mice, however, failed to show any defect in gubernacular development and testicular positions (Bartlett et al, 2002).

INSL3 was identified as a novel gene product of the Leydig cells in 1993 (Adham et al, 1993). INSL3 is similar in structure to the peptide hormones relaxin or insulin and is expressed in both fetal and adult Leydig cells in a differentiation-dependent manner (Balvers et al, 1998). **Mice lacking a functional *Insl3* gene demonstrate intra-abdominal cryptorchidism but otherwise no obvious defects in other male reproductive organs. More importantly, early surgical correction of the cryptorchidism in these mice can restore normal fertility potential** (Nef and Parada, 1999; Zimmermann et al, 1999). These are important findings because they reflect the phenotype most commonly observed in classic cryptorchidism in humans. Recently, a G protein–coupled receptor—LGR8—has been cloned with binding and functional response to INSL3 in transfected cells (Hsu et al, 2002; Kumagai et al, 2002). Moreover, mutations in this receptor in mice can lead to the development of cryptorchidism and have been linked to a case of cryptorchidism in the human (Overbeek et al, 2001; Gorlov et al, 2002). Treatment of rat gubernacular explant with exogenous INSL3 leads to a rapid growth of the ligament, an effect that synergizes with androgen treatment (Kubota et al, 2002). It was also demonstrated that LGR8 was expressed in the rat gubernaculum (Kubota et al, 2002). Although INSL3 appears to be a good candidate for a responsible gene for cryptorchidism, to date no causative mutations have been identified in the human *INSL3* gene. Furthermore, because INSL3 is expressed in a differentiated testis, any factor that influences Leydig cell differentiation may also affect INSL3 expression and thereby cause cryptorchidism.

Treatment of pregnant mothers with diethylstilbestrol as a hormonal support during pregnancy was abandoned owing to a high rate of cryptorchidism and other genital defects (Stillman, 1982). The effect of environmental xenoestrogenic compounds has also been linked to the recent rise in cryptorchidism in humans (Toppari and Skakkebaek, 1998). In one study, mice were treated with diethylstilbestrol to induce cryptorchidism in male neonates

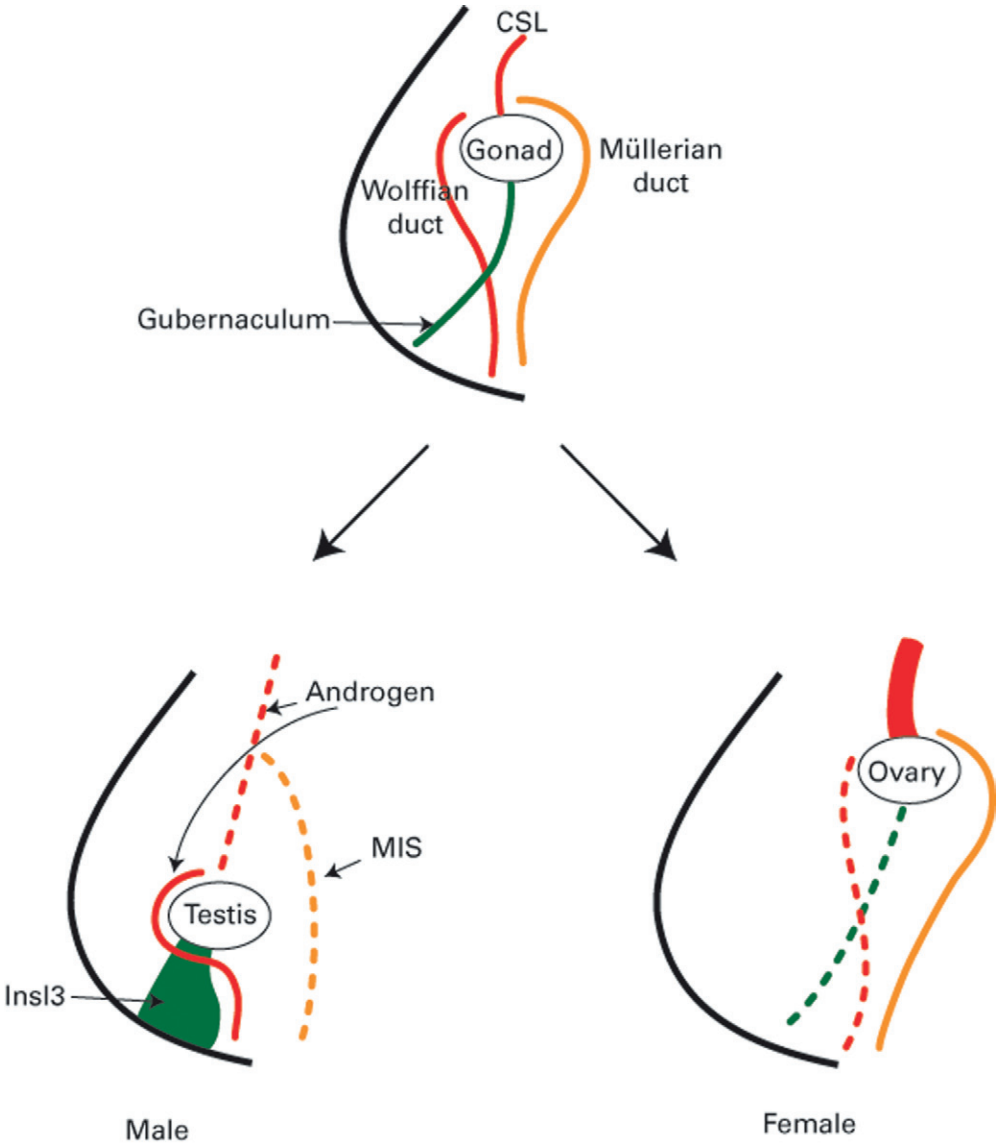

Figure 111–26. Mechanism of gonadal descent. The undifferentiated gonad is initially located high in the abdomen, anchored by the cranial suspensory ligament (CSL). In males, Insl3 will cause the swelling and enlargement of gubernaculum to pull the developing testis toward the inguinal region, whereas androgens will cause an involution of CSL. Owing to the action of müllerian-inhibiting substance (MIS), müllerian ducts will regress while androgens continue to stimulate the development of wolffian ducts into male genital ductal structures. In females, CSL persists due to the absence of androgens and the gubernaculum remains thin due to the absence of Insl3 activity, thereby keeping the ovary well within the pelvis.

(Emmen et al, 2000; Nef et al, 2000). Interestingly, the treated animals demonstrated a complete suppression of testicular *Insl3* expression on embryonic days 16 and 18.

The male knockout mice for the transcription factor *Hoxa-10* gene are viable but infertile. While they are normally virilized, they are bilaterally cryptorchid with severely underdeveloped gubernaculum. Fetal localization studies have shown that *Hoxa-10* is expressed in the gubernaculum, as well as in the kidneys, but not in other reproductive tissues. Although its function and role are not yet established, it appears to be another candidate regulatory gene for gubernacular development and testicular descent.

The spinal nucleus of the genitofemoral nerve (GFN) is located at L1-2 in the spinal cord and is sexually dimorphic (Goh et al, 1994). Transection of GFN produced cryptorchidism (Lewis, 1948), and the initial thought—now proven faulty—was that the cremasteric muscle paralysis caused by denervation led to an abnormal traction of the testis through the inguinal canal. When this observation was revisited many years later it was speculated that androgens may act via the GFN (Beasley and Hutson, 1987). The GFN innervates the gubernaculum from its posterior and caudal surface, so that distal transection would cause denervation of the gubernaculum (Tayakkanonta, 1963). Additional supporting evidence for the role of the GFN comes from the analysis of patients with spina bifida and animals with spinal cord transection (Hutson et al, 1988). In more than 300 boys with spina bifida, 23% had cryptorchidism, with a higher incidence found in those whose defect was higher than L4. In rats with neonatal spinal cord transection, approximately 40% had cryptorchidism when the lesions were midlumbar. Anatomic studies of the GFN identified calcitonin gene–related peptide (CGRP) as the primary neurotransmitter (Goh et al, 1994). The effect of CGRP on the rodent gubernaculum has been studied extensively. In male neonatal rats under

anesthesia the gubernaculum, which has not yet reached the scrotum, contracts rhythmically, and this is enhanced by increased intra-abdominal pressure and direct application of exogenous CGRP (Park and Hutson, 1991). In organ culture, neonatal rat gubernaculum responds to CGRP in a dose-dependent manner but not to other neuropeptides (Park and Hutson, 1991). Although these findings are raising a strong speculation for the role of CGRP, its significance in human testicular descent remains uncertain.

The ovaries also descend and become suspended within the broad ligaments of the uterus. As in males, the female embryos develop a gubernaculum-like structure extending initially from the inferior pole of the gonad to the subcutaneous fascia of the presumptive labioscrotal folds. This "female gubernaculum" later penetrates the abdominal wall as part of a fully formed inguinal canal and becomes the *round ligament*. In females, although the gubernaculum does not shorten like that in males, it still causes the ovaries to descend during the third gestational month (by anchoring the ovaries in the pelvis) and places them into a peritoneal fold (the *broad ligament* of the uterus). This translocation of ovaries appears to occur during the seventh week when the gubernaculum becomes attached to the developing paramesonephric (müllerian) ducts. As the paramesonephric ducts fuse together in their caudal ends they sweep out the broad ligaments and simultaneously pull the ovaries into these peritoneal folds. In the absence of androgens, the female gubernaculum remains intact and grows in step with the rest of the body. The inferior gubernaculum becomes the round ligament of the uterus and attaches the fascia of the labia majora to the uterus, while the superior gubernaculum becomes the ligament of the ovary, connecting the uterus to the ovary. As in males, the processus vaginalis of the inguinal canal is normally obliterated, but occasionally it remains patent to become an indirect inguinal hernia.

Molecular Mechanism of Sex Development

Mammalian sex development involves a complex interplay of multiple cell types, which occurs in a narrow window of time. Thus it is important to understand the temporal and spatial pattern of gene expression as well as the anatomic sequence of tissue movement and differentiation. In both sexes, before the expression of the male-determining gene *SRY,* a number of factors appear to play a role in urogenital ridge specification (Fig. 111–27). Because the urogenital ridge is the primordium for gonad, kidney, and reproductive tract, multiple organs are affected simultaneously by mutations of these genes.

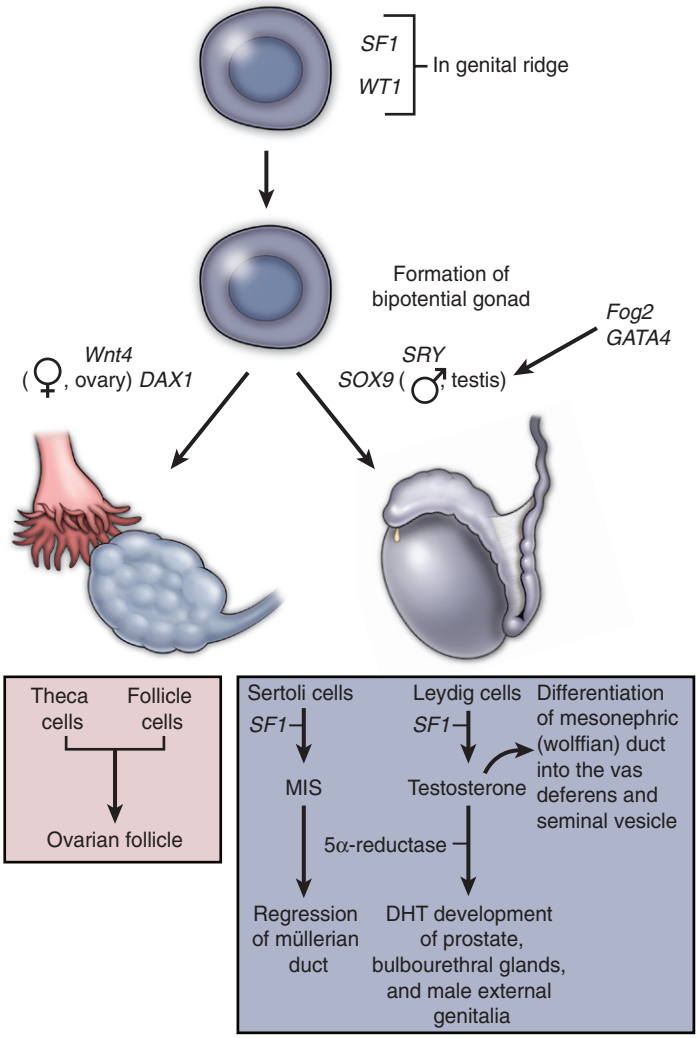

Figure 111–27. Molecular mechanism of male and female genital development. *SF1* and *WT1* expression is critical for genital ridge specification. *SRY* and *SOX9,* influenced by GATA4 and Fog2, are important factors for specifying the differentiation of Sertoli cells. *SF1* is also critical in the regulation of müllerian-inhibiting substance (MIS) and other genes involved in androgen synthesis. No specific female factors have been identified, but *Wnt4* and *DAX1* are expressed with unique female patterns. DNT, dihydrotestosterone.

In the mouse gonad, *Wt1* is expressed early, suggesting a role in specifying coelomic epithelial cells in the development of urogenital ridge. The *Wt1* homozygous knockout mice do not form kidney, adrenal, or gonad cells (Kreidberg et al, 1993). Humans heterozygous for mutations in *WT1* exhibit abnormalities of the genital system in addition to abnormalities in renal development, including WAGR syndrome, Denys-Drasch syndrome, and Frasier syndrome. *WT1* appears to function upstream of *SF1* (steroidogenic factor 1) and *DAX1* (*d*osage-sensitive sex reversal, *a*drenal hypoplasia congenita, *X* chromosome) (Wilhelm and Englert, 2002). *Wt1* and *Sf1* enhance transcription of mouse *MIS* gene, whereas *Dax1* appears to suppress this interaction (Nachtigal et al, 1998). *SF1* also regulates the expression of other genes involved in male differentiation, steroidogenesis, and reproduction (Achermann et al, 2001). Although *SF1* stimulates *DAX1* transcription (Ikeda et al, 1996), *DAX1* in turn acts as a transcriptional repressor of *SF1*-regulated genes (Ito et al, 1997). In *Sf1* knockout mice, neither XX nor XY animals form gonads, and cells in gonadal remnant undergo apoptosis, suggesting that *SF1* is a necessary survival factor for early progenitors of a developing gonad (Luo et al, 1994). Data suggest that *SF1* and *DAX1* are both independently important for normal male gonadal differentiation. Other candidate genes have also emerged based on mouse gene deletion models and embryonic expression studies, although their functional significance in gonadal development is not fully elucidated yet, and they include *M33, Lhx9, Pod1, Dmrt1, Mro, Pn1,* and *Vn1* (Park and Jameson, 2005).

Mammalian embryos remain sexually undifferentiated until the time of sex determination. When the Y-linked master regulatory gene, called *SRY* (the *s*ex-determining *r*egion of the *Y* chromosome), is expressed in the male, the epithelial cells of the primitive sex cords

differentiate into Sertoli cells, and this critical morphogenetic event triggers subsequent testicular development. Once the testes are established they produce androgens to give rise to the male phenotype. In the female gonads no morphologic change is observable at the time of *SRY* expression. It follows from this general picture that in mammals, sex determination is synonymous with testicular development, with the differentiation of Sertoli cells being the key event (McLaren, 1991). After 3 decades of search for the elusive mammalian testis-determining gene, the *SRY* gene was discovered in 1990 by Sinclair and colleagues. Since then, research has focused on identifying the putative regulatory mechanism operating downstream of *SRY* and the genetic control of *SRY* expression.

Although it has been known since 1921 that human males have an X and Y chromosome, the role of these "sex" chromosomes in human sex development was not elucidated until 1959. This question was answered by the examination of two individuals with unique chromosome abnormalities: one female with Turner syndrome (45,XO karyotype) and one male with Klinefelter syndrome (47,XXY karyotype). By 1966, analysis of many structurally aberrant Y chromosomes in humans led to the conclusion that the information necessary to initiate the male phenotypic development was present on the short arm of the Y chromosome. The identity of the protein encoded by the testis-determining region of the Y chromosome proved elusive. In the mid 1980s, the DNA of sex-reversed males with 46,XX karyotype was examined. The genome in these individuals was found to contain small amounts of Y chromosome that had been translocated onto the X chromosome. Analysis of this DNA narrowed the location of the *SRY* to a relatively small region within the short arm of the chromosome. The role of *SRY* in human sex development has been further supported by studies using mice (Greenfield and Koopman, 1996). The comparable genetic locus in mice *(Sry)* is activated and expressed in the genital ridge 11.5 days after coitus, just before the initiation of testicular development. Moreover, when the DNA of female XY mouse chromosomes was analyzed with specific DNA probes for *Sry*, this locus was absent. Most importantly, it has been demonstrated that insertion of *Sry* into one of the X chromosomes of genetically female mouse embryos converted these mice to phenotypic males (Koopman et al, 1991). These transgenic "female" mice exhibited testes, vas deferens, and an absence of the female reproductive tract. It was thought that identification of the SRY protein would rapidly lead to the identity of downstream elements regulating male sexual development. However, the binding of SRY protein to other genes or factors has not been demonstrated, and the molecular mechanism by which genes interact to determine sex remains speculative. Deletions of the *SRY* gene in humans cause XY male-to-female sex reversal, whereas *SRY* translocations to the X chromosome lead to XX female-to-male sex reversal (Harley et al, 2003). In the mouse, *Sry* expression occurs in a narrow temporal window in the developing Sertoli cells. The central region of the gonad demonstrates *Sry* expression first, followed by cephalad to caudal progression along the entire length of the gonad (Bullejos and Koopman, 2001). A closely related gene, *SOX9,* is the other definitive male-determining gene identified thus far. *SRY* and *SOX9* expression overlap in cells of the Sertoli lineage. As the *SRY* expression diminishes, *SOX9* expression increases in the male. *SOX9,* which is weakly expressed in the undifferentiated gonad, is downregulated in the female (Sekido et al, 2004). Transgenic expression of *Sox9* in XX mice is sufficient to induce female-to-male sex reversal and male differentiation (Vidal et al, 2001). Heterozygous human *SOX9* mutation leads to campomelic dysplasia, a severe skeletal disorder with defective cartilage development, and many of these patients have dysgenetic gonads (Foster et al, 1994). These individuals possess a normal *SRY* but may exhibit completely feminized genital structures. *Sox9* knockout mouse embryos have elevated levels of *Sry* expression, suggesting a possible negative feedback regulatory loop that downregulates *Sry* (Chaboissier et al, 2004). *GATA4* and *Fog2* are important in cardiac development but also appear to affect gonadal development as well. *GATA4* mutation eliminates expression of male differentiation markers *Sox9* and MIS. *Fog2* knockout mice have decreased expression of *Sry,* loss of *Sox9, MIS*, and *desert hedgehog,* but persistence of female gonad marker *Wnt4* (Tevosian et al, 2002). Similarly, triple mutants for insulin receptor, insulin-related receptor, and Igf-1 receptor have low *Sry* and *Sox9* expression and exhibit male-to-female sex reversal, implicating a role for an insulin signaling pathway (Nef et al, 2003).

Proliferation of Sertoli progenitor cells is an important event in male gonad development, a process driven by *SRY* expression (Schmahl et al, 2000). One paracrine factor linked to this proliferation is FGF9. *Fgf9* knockout mice demonstrate varying degrees of male-to-female sex reversal (Colvin et al, 2001). In addition, FGF9 is a candidate male gonad-specific chemoattractant paracrine signal that induces migration of cells from the mesonephros (endothelial and peritubular myoid cells) into the gonad (Martineau et al, 1997). Migration of these cells is critical for the development of testis cord formation (Buehr et al, 1993) as well as *SOX9* expression (Tilmann and Capel, 1999). Such migration is absent in females, presumably owing to absence of chemoattractants.

Once sex determination has occurred the subsequent phenotypic differentiation depends mostly on the production of androgens. As bipotential gonad differentiates into testis, Sf1 expression becomes restricted to Leydig cells and mediates expression of several gene-encoding enzymes that are required for testosterone biosynthesis, including StAR, Cyp11a1, Cyp17, and 3βHSD. Factors for Leydig cell determination are not known, and, moreover, Leydig cell origin, whether from immigrant mesonephric cells or progenitors within the gonad, remain speculative. There is evidence that Leydig cell fate is dependent on paracrine signals (Yao et al, 2002; Brennan et al, 2003).

Relatively few genes have been shown to exhibit a female-specific pattern of gene expression early in gonadal development. Thus far, no female-determining gene has been identified. The *DAX1* gene was initially suggested as a pro-ovarian (or antitestis) candidate gene because its duplication on an XY background was associated with impaired testicular development (Bardoni et al, 1994; Swain et al, 1998). However, loss of *DAX1* in XX background does not prevent ovary development (Yu et al, 1998). A growing list of genes demonstrates an ovary-specific expression patterns, including *Fst* and *Stra8* (Park and Jameson, 2005). There has been a postulate for a "Z-factor" that suppresses protesticular events in both XX and XY backgrounds (McElreavey et al, 1993). According to this hypothesis, the Z-factor, which normally suppresses testicular determination, is repressed by *SRY* in males, and in females, owing to absence of *SRY,* it will inhibit testicular development. Loss of Z-factor in XX background will result in female-to-male sex reversal, but gain-of-function in XY background may or may not result in male-to-female sex reversal, depending on whether the Z-factor can override the suppression effect of *SRY*-driven signaling. One candidate for such Z-factor is *Wnt4.* XX mice deficient for *Wnt4* develop testis-like differentiation and nephric (wolffian) duct derivative (Vainio et al, 1999). Curiously, their external genitalia remain female. Furthermore, *Wnt4* is downregulated in males whereas its expression remains strong in females (Yao et al, 2004).

Key Points

- The genitourinary system develops from three embryonic sources: intermediate mesoderm, mesothelium of coelomic (future peritoneum) cavity, and endoderm of the urogenital sinus.
- The urinary system begins its development before the genital system development becomes evident. With the formation of nephric ducts, embryonic kidneys develop sequentially in the order of pronephros, mesonephros, and metanephros.
- The permanent kidney, the metanephros, develops as a result of inductive interactions involving ureteric bud (an outgrowth of nephric duct), condensing blastema of metanephric mesenchyme, and stromal cells. The renal tubulogenesis occurs via mesenchymal-epithelial conversion, whereas dichotomous branching of the ureteric bud leads to the formation of the collecting system.
- The bladder and urethra develop from the endodermal urogenital sinus, which is an anterior portion of the cloaca after it becomes separated from the posterior anorectal canal.
- Morphologically, the genital development takes place about 3 weeks after the start of the urinary system development. Sexual dimorphism begins to take shape at about the seventh gestational week. Primordial germ cells migrate from the wall of the yolk sac to invade the posterior mesenchyme to establish the gonadal ridge.
- In males, driven by the *SRY* gene of the Y chromosome, mesenchymal cells of the developing testis differentiate to become the Sertoli cells. Sertoli cells produce müllerian-inhibiting substance (MIS) to cause degeneration of female müllerian ductal structures, while stimulating the development of testosterone-producing Leydig cells. Under the influence of testosterone, male external genitalia develop, as well as prostate and other male accessory sex glands.
- Both gonads descend to pelvic location by the third month, but the testis descends into the scrotum with the aid of the gubernaculum at about the seventh month.

Summary

Nephrology and urology are the two disciplines—one medical, the other surgical—devoted to the care of patients with kidney disease. This distinction between the two is often cast in sharp relief as if to imply that they are nonoverlapping fields. However, this misconception is exposed in pediatrics in which the close integration between nephrology and urology is displayed on a nearly daily basis in the wide spectrum of disorders resulting from congenital abnormalities of the genitourinary tract and the complicated impact of these malformations on all aspects of kidney function. The goal of this chapter is to review areas of shared focus with a primary emphasis on clinical aspects, rather than on the basic sciences, and on specific problems to facilitate a productive working collaboration between pediatric urologists and nephrologists.

TRANSITION FROM THE FETUS TO THE INFANT

All aspects of renal function are of limited capacity in the fetus compared with the adult. This is especially true in infants born before 34 weeks' gestation, in whom nephrogenesis is incomplete.

The glomerular filtration rate (GFR) at birth is 10% to 15% of the normal adult value. The decrease in function is caused by three factors: lower intraglomerular perfusion pressure, decreased ultrafiltration coefficient of the filtration barrier, and diminished filtration surface area. Of these three factors the final one is quantitatively the most important and is due to a combination of decreased number and perfusion of the cortical nephrons (Spitzer, 2003). Increased circulating levels of vasoactive hormones such as vasopressin and plasma renin activity and reduced synthesis of vasodilatory factors such as nitric oxide mediate the reduced glomerular blood flow. The reduction in filtration surface is exacerbated in very low–birth-weight infants delivered at 25 to 28 weeks' gestation because the premature delivery curtails the normal process of nephron development and glomerulogenesis (Ichikawa et al, 2002). **In utero obstruction interferes with normal glomerular development and triggers tubular atrophy and interstitial fibrosis.** This is associated with release of profibrotic cytokines such as transforming growth factor-β, macrophage infiltration, and epithelial-to-mesenchymal transformation (Bascands and Schanstra, 2005; Grande and Lopez-Novoa, 2009). Using experimental murine models, in which unilateral ureteral obstruction is created before completion of nephrogenesis, reversal of the obstruction leads to an increased tubular repair, reduced macrophage number, and less collagen accumulation (Cochrane et al, 2005). This suggests that correction of obstructive lesions prenatally could restore normal renal growth and preserve renal function.

Renal sodium handling is impaired in the fetus and infant. This is reflected in a higher fractional excretion of sodium (FE_{Na}) in low-birth-weight infants and even full-term neonates. In part this reflects increased permeability of the proximal and distal tubule. In addition, the response of the distal nephron to antinatriuretic hormones such as aldosterone is impaired. The urinary concentrating capacity is diminished in fetal life and in infants owing to reduced GFR and delivery of filtrate to the diluting segment of the nephron, shorter loops of Henle, and limited response of the collecting tubule to vasopressin. The renal acidification is limited in neonates because of lower sodium-hydrogen exchange in the proximal tubule, decreased bicarbonate reabsorption in the proximal tubule secondary to relative expansion of the extracellular fluid compartment, and reduced expression and activity of the Na^+,K^+-ATPase pump that drives hydrogen ion secretion. **The alterations in sodium and hydrogen balance result in compromised potassium secretion into the final urine.** The potassium retention in neonates is due to an absence of apical secretory potassium channels in the distal tubule and a predominance of the H^+,K^+-ATPase in the apical membrane that mediates potassium reabsorption (Gurkan et al, 2007). The inability to excrete potassium is also the

consequence of reduced number of renal outer medullary potassium (ROMK) channels and diminished potassium recycling in the loop of Henle.

In addition to the short-term impact of premature delivery and low birth weight, these two factors may have important long-term ramifications for kidney health. Beginning in the mid 1980s, reports appeared in the literature indicating that **low-birth-weight infants were at higher risk of developing hypertension and secondary renal diseases such as diabetic nephropathy in adulthood compared with infants of normal weight.** These epidemiologic linkages were strengthened by the detection of a lower number of nephrons in adults with hypertension who died in early adulthood after sudden unexpected accidents. The adverse outcomes have been attributed to the long-term consequences of being born with a diminished number of nephrons—sustained hyperfiltration and glomerular hypertrophy (Barker et al, 2006). The situation is analogous to the case of infants born with a solitary kidney who can develop proteinuria and focal segmental glomerulosclerosis (FSGS) at a relatively young age. The long-term implications of reduced nephron number at birth continue to be a subject of ongoing study (Vikse et al, 2008) and may represent a combined effect of both low birth weight and prematurity. There is uncertainty whether the consequences of low nephron number apply to both boys and girls and to all racial and ethnic groups. Finally, recent data suggest that impaired postnatal growth may exacerbate the maladaptive response to low birth weight (Bacchetta et al, 2009).

The evaluation of kidney function in infants is difficult because of technical problems collecting timed urine samples noninvasively or by bladder catheterization. Thus GFR is generally assessed based on changes in serum creatinine concentration, with the caveat that creatinine concentration in the first few days of life reflects maternal renal function. There are limited data about GFR based on infusion of clearance markers such as iothalamate or iohexol or measurements of serum cystatin C concentration. Tubular sodium handling can be assessed based on the following:

$$FE_{Na} = [\text{Urinary sodium/plasma sodium}] \div [\text{urinary creatinine/serum creatinine}]$$

This determination can be made using a spot urine sample collected at the time of collection of a blood sample. The normal value in neonates and infants is 1% to 3% and can be even higher in very low–birth-weight premature infants. The fractional excretion of potassium is also lower in infants compared with older children. Acid-base status is usually not evaluated with direct tests of function. Instead there is reliance on measurements of serum bicarbonate concentration and pH determinations in venous or arterial blood samples. Because of the physiologic limitations on acidification in infants, the normal serum bicarbonate concentration is lower, 15 to 18 mmol/L in infants.

The clinical manifestations of the reduced renal function in fetal life and the early transition to postnatal conditions include inability to excrete drugs that are cleared by the kidney. The ability of the infant to tolerate large infusions of isotonic fluids and blood products is also limited compared with older children. Similarly, the inability to maximally dilute the urine results in hyponatremia if infants are given excessive quantities of hypotonic fluids. The diminished capacity to reduce sodium excretion in response to dietary restrictions can lead to hyponatremia and impaired growth and hyperkalemia. The developmental defect in acidification can lead to mild renal tubular acidosis (RTA) and lower somatic growth rates.

Key Points: Transition from Fetus to Infant

- Nephrogenesis is complete by 34 weeks' gestational age in the fetus.
- GFR is dependent on gestational age and doubles in the first 2 weeks of life.
- GFR at birth is 15% to 20% of normal adult values.
- Sodium handling is impaired in the neonate with a higher FE_{Na}.
- Urine concentrating ability is reduced owing to the lower GFR.
- Renal acidification is reduced.
- Alterations in sodium and hydrogen balance as well as absence of potassium channels lead to potassium retention.
- Low-birth-weight infants are at increased risk of developing hypertension and secondary renal diseases in adulthood.

PRINCIPLES OF FLUIDS AND ELECTROLYTES

The key difference in body fluids between pediatric and adult patients is the larger percentage of body weight composed of water and the larger extracellular fluid (ECF) compartment size. **Thus, in infants and children, water makes up nearly 80% of body weight, with even higher values in premature infants of extremely low birth weight.** As children grow older and with increased adipose tissue in girls, the total amount of water falls to the normal value of 60% to 67%.

The composition of the two major body water compartments—ECF and intracellular fluid (ICF)—varies greatly. In the ECF the principal cation is sodium and the major anions are chloride and bicarbonate. In the ICF, in contrast, potassium is the major cation and proteins and phosphate comprise the bulk of the anions. However, in both compartments there is electroneutrality and an equal number of osmotically active solutes. The major factor leading to the differential distribution of solutes between the ECF and ICF is the Na^+,K^+-ATPase pump, which actively extrudes sodium from the cells. Because sodium is confined to the ECF, disturbances in the ECF volume reflect abnormalities in external sodium balance. Thus, if intake of sodium exceeds output, then the patient will have ECF volume expansion with clinical symptoms such as hypertension, pulmonary edema, and peripheral edema. If sodium losses are not counterbalanced by sufficient dietary intake, then the patient will develop intravascular volume contraction, manifesting as tachycardia, hypotension, and impaired peripheral perfusion. **Serum osmolality is the primary determinant of the normal distribution of water between the ECF and ICF in a 1:2 ratio.** Hyperosmolality causes ICF contraction, and hypo-osmolality causes ICF expansion. The major clinical consequences of changes in the ECF:ICF ratio occur because of altered cerebral volume and brain dysfunction, leading to irritability, lethargy, somnolence, and seizure (Trachtman, 1991).

From a clinical perspective, fluid and electrolyte management requires independent assessment of ECF volume status and tonicity. The former is a clinical judgment based on physical findings such as pulse rate, blood pressure, change in weight, skin turgor, urine output, and presence of peripheral edema. The degree of volume contraction is considered mild, moderate, or severe if the change in body weight is estimated as less than 3%, 3% to 6%, or

more than 6%. There is poor correlation between this clinical evaluation and most laboratory parameters such as blood urea nitrogen, serum creatinine, or bicarbonate concentration. In difficult cases, direct measurement of ECF status may be necessary, relying on invasive techniques such as insertion of a central venous or pulmonary artery catheter.

Intravenous fluid therapy should be considered a form of drug treatment and should be instituted only if there are appropriate clinical indications. These include inability to tolerate enteral fluids, severe ongoing losses, medical need to avoid oral intake, and acute kidney injury in which close monitoring of fluid intake may be necessary. Under these circumstances, maintenance fluids are provided to supply sufficient amounts of water, sodium, and potassium to account for normal urinary and gastrointestinal losses and insensible losses through the skin and respiratory tract. These quantities are best calculated based on surface area, although calculations based on body weight, a more accessible measurement, are generally reliable. Maintenance fluids need to be adjusted upward in children with fever, tachypnea, or dermatologic diseases that disrupt the skin barrier. For example, premature infants have increased insensible losses because of their thin skin and require increased free water intake to prevent hypernatremia. The maintenance fluid requirements are generally provided as a hypotonic solution of sodium chloride containing approximately 50 mmol/L. Recently, controversy has arisen about the appropriate composition of parenteral maintenance fluids. There are those who advocate routine administration of isotonic saline (0.9% or NaCl 154 mmol/L) to prevent hospital-acquired hyponatremia (Moritz and Ayus, 2003). Others suggest that the standard fluid should continue to be a hypotonic solution with recognition that modification may be necessary in seriously ill children who may be at risk of altered vasopressin release and hyponatremia (Holliday et al, 2004). Absent clinical trials, clinicians are advised to be aware of the risks of parenteral therapy in hospitalized children and to monitor the effects of prescribed fluid treatment.

Children with severe intravascular volume contraction should receive rapid infusion of isotonic saline to stabilize cardiovascular status, regardless of the serum sodium concentration. **In the majority, in which there is isotonic dehydration, the deficit can be repaired steadily over 24 hours. In patients with hyponatremia or hypernatremia the fluid deficit should be reversed more slowly over at least 48 hours to prevent adverse consequences** of cerebral cell swelling in patients with hypernatremia or cerebral cell shrinkage in patients with hyponatremia. In children with hypernatremia it is important to infuse hypotonic fluids but at a slow rate to enable gradual normalization of hyperosmolality (Banister et al, 1975). Children with nephrogenic diabetes (see later) are prone to excessive free water loss and hypernatremia (Adrogue and Madias, 2000). Similarly, patients with obstructive uropathy and pseudohypoaldosteronism are prone to develop hyponatremia, especially if they have a concurrent urinary tract infection. These disturbances need to be taken into account when formulating fluid regimens.

For patients with hyponatremia the sodium deficit can be calculated according to the following formula:

$$\text{Na deficit} = 0.6 \times \text{Body weight} \times [130 - \text{Serum Na concentration}]$$

For patients with hypernatremia the free water deficit can be calculated according to the following formula:

$$\text{Free water deficit} = 0.6 \times \text{Body weight} \times [\text{Serum sodium concentration}/140 - 1]$$

Patients with clinically manifest intravascular volume expansion require treatment with dietary sodium restriction and diuretics. In severe cases, dialysis may be required on an urgent basis to alleviate hypertension and/or pulmonary edema.

HEMATURIA

Isolated hematuria is a very common problem, the treatment of which is often shared by nephrologists and urologists. Studies done in a wide range of countries around the world indicate that the frequency of detecting blood in the urine in pediatric patients ranges from 0.5% to 3% (Hogg, 2009). **Most of the time the problem is self-limited, resolves spontaneously, and is not a sign of underlying disease.** Thus although mass screening of urine samples in pediatric patients is common in several Asian countries, there is a movement away from this practice. In 2007 the American Academy of Pediatrics revised its clinical recommendations and no longer suggests performing a urinalysis routinely at any age during childhood.

The majority of cases of hematuria are microscopic. The differential diagnosis (Table 112–1) in patients with gross hematuria is no different than in those with microscopic hematuria (Youn et al, 2006; Greenfield et al, 2007). The key difference is that patients with gross hematuria are more likely to be referred for urgent assessment and the likelihood of finding an underlying cause. **In studies of children with gross hematuria, nearly 60% have nonglomerular causes, 25% have a glomerular etiology, and the remainder have no established cause.**

Epidemiology

Studies of hematuria in children have been conducted by screening healthy children or by retrospective analyses of children with hematuria. Vehaskari (1979) estimated the prevalence of hematuria in children to be 1.1% (excluding those with transient hematuria): 74% of the 8954 children had hematuria in only one sample, 83 of the remaining 131 children with persistent hematuria had isolated hematuria most commonly due to urinary tract infection (7%), whereas 59 had associated proteinuria; this study was conducted before hypercalciuria was identified as a common cause of hematuria. Hisano (1991) found 251 of 160,000 screened

Table 112–1.

Causes of Hematuria in Children

GROSS	MICROSCOPIC
Hypercalciuria	Transient
Cystitis	Hypercalciuria
IgA nephropathy	Thin basement membrane nephropathy
Alport syndrome	Lupus
Poststreptococcal glomerulonephritis	Henoch-Schönlein purpura
Benign urethralgia	Idiopathic factors
Wilms tumor	Vasculitis
Bladder tumors	Exercise
Polycystic kidney disease	Nephrolithiasis
Exercise	Hematologic disorders
Coagulopathy	Drugs
Lupus	Trauma
Trauma	Interstitial nephritis
Renal vein thrombosis	Cystitis or pyelonephritis
Papillary necrosis	
Nutcracker syndrome	

junior high school students had isolated microscopic hematuria with an identifiable cause in 115: menses (35%), urinary tract infection (5.6%), hypercalciuria (2%), Henoch-Schönlein purpura (1.2%), and hydronephrosis (1.2%). Approximately 25% of children had resolution of hematuria, less than 1% had proteinuria, and none developed renal insufficiency. Turi (1989) reported a retrospective analysis of 341 children, ages 2 to 12 years with persistent, isolated hematuria of at least 6 months' duration followed for 2 to 17 years. Hematuria was isolated microscopic in 31%, macroscopic in 28%, or both in 41%. Persistent hematuria was documented monthly in 40%. Renal biopsy in 47 children for development of a nephritic urine sediment or proteinuria demonstrated mesangial proliferative glomerulonephritis and hereditary nephritis most commonly. Twenty percent of subjects had hypercalciuria and/or nephrolithiasis. The remaining 226 children had isolated hematuria, which resolved in 163 children. These studies support the concept that **isolated asymptomatic hematuria is a relatively benign condition after exclusion of children with easily identifiable causes by history and physical examination, family history, urine microscopy, renal imaging, urine culture, urinary calcium excretion, and renal biopsy, if indicated.**

Evaluation

Persistent microscopic hematuria lasting at least 6 months or gross hematuria warrants investigation. The evaluation of hematuria includes a proper history, physical examination, and laboratory and radiographic studies (Fig. 112–1). The history should include questions regarding the timing of the presence of the hematuria as an isolated or recurrent event; hematuria that occurs throughout voiding is more likely to be glomerular, whereas terminal hematuria is more likely to be nonglomerular. Benign **urethrorrhagia** presents as postvoid droplets of blood from the meatus after a grossly clear void (Kaplan and Brock, 1982). Glomerular hematuria is often described as urine that is tea or cola colored, whereas urine of nonglomerular hematuria is more likely to be red. Certain diagnoses may be suspected based on the presence of associated symptoms such as dysuria, urgency, frequency, abdominal pain, prior respiratory infection, lower

extremity swelling, or symptoms of hypertension (headaches, blurred vision), joint pain, fevers, weight loss, rash, or antecedent streptococcal infection. A patient or family history of sickle cell disease or trait, deafness, hematuria, or renal disease should be sought. The physical examination should assess for blood pressure with a proper-sized sphygmomanometer cuff, abdominal tenderness or masses, costovertebral angle tenderness, ecchymosis, rashes, periorbital or lower extremity swelling, and signs of trauma on the flank, pelvis, or genitalia.

A fresh urine sample should be collected for analysis and culture. Hematuria is defined as the presence of five or more red blood cells per high-power microscope field (Fitzwater and Wyatt, 1994). Hematuria is detected by dipstick via a reaction of a peroxidase with hemoglobin; however, the dipstick test may be falsely positive in the presence of hemoglobinuria or myoglobinuria. Fresh-spun urine should also be screened for protein, glucose, nitrates, leukoesterase, bilirubin, specific gravity, and pH. The key diagnostic test is a microscopic examination of the urine sediment. Patients with glomerular hematuria will have red blood cell casts and dysmorphic erythrocytes (irregular shape and size with distorted contours) in their sample, whereas children with nonglomerular hematuria have eumorphic red erythrocytes (uniform in size resembling circulating red blood cells) without red blood cell casts. This distinction can usually be made reliably by examining the urine directly (Trachtman, 2006). A 2- to 4-hour delay in urine inspection can cloud the distinction between nonglomerular and glomerular bleeding. If prompt examination of freshly voided urine samples is not feasible in a specific clinic setting, the addition of Cellfix, a formaldehyde-based fixative, allows preservation of red cell morphology for at least 24 hours and can enhance the diagnostic value of the microscopy portion of the urinalysis (Komarova et al, 2003). Phase contrast microscopy has been touted to enhance accuracy. In addition, some clinicians have recommended measurement of red cell size with Coulter counter devices used in hematology clinics. Patients with dysmorphic red cells in the urine will have smaller erythrocyte volume and greater scatter in cell size compared with patients with nonglomerular hematuria. Microscopic evaluation of the specimen should be performed to qualify and quantify the extent of the hematuria and the presence of crystals (uric acid, cystine) and casts (red or white cell).

Symptomatic children and those with persistent or recurrent microscopic or gross hematuria require additional evaluation. A second urinalysis devoid of red cells indicates transient microscopic hematuria. In the other children, urine should be cultured in the presence of symptoms of cystitis or pyelonephritis or if the urinalysis is indicative of infection. Urine calcium to creatinine ratio of greater than 0.21 suggests hypercalciuria, which needs confirmation by a 24-hour collection (>4 mg/kg/day). Serum studies should include electrolytes, blood urea nitrogen (BUN), creatinine, calcium, phosphorus, liver function tests, complete white cell count with differential, antinuclear antibodies, streptozyme and antistreptolysin O antibody titers, and C3, C4, and total complement only in patients who have other signs of renal disease in addition to hematuria, such as hypertension, proteinuria, or edema. Hematuria may occur with or without proteinuria. Large numbers of red blood cells may suggest proteinuria on the dipstick. Quantification of urinary protein aids in diagnosing isolated hematuria versus hematuria with proteinuria. Several contaminants can produce red urine without hematuria, including several drugs (rifampin and ibuprofen) and foods (beets and blackberries).

A renal and bladder ultrasound evaluation will screen for possible renal parenchymal or bladder causes of the hematuria. Computed tomography best defines renal masses, stones, and nutcracker syndrome, in which there is extrinsic compression on the aberrantly located renal vein. Additional information may be gleaned by magnetic resonance imaging (MRI). These modalities would be used to better characterize any abnormalities identified by ultrasonography. Voiding cystourethography is reserved for children with culture-positive infection or to further evaluate any abnormal ultrasound findings in the bladder. There is no role for cystoscopy in the evaluation of microscopic hematuria (Feld et al, 1998) if the sonogram is normal. Small tumors may be missed but are benign (Kaplan, 1985). Cystoscopy for gross hematuria can be useful if bleeding occurs at the time of the study. If bloody effluent is observed from both ureteral orifices, a glomerular source is more likely. If bloody urine is observed from only one ureteral orifice, unilateral urinary tract or vascular disease may be present and retrograde pyelography or ureteroscopy may be indicated.

Hypercalciuria

Hypercalciuria can present as isolated microscopic hematuria, dysuria, or recurrent gross hematuria. Gross hematuria secondary to hypercalciuria can be distinguished from that due to glomerular diseases by the potential presence of dysuria, clots in the urine, and rapid resolution of the hematuria within 24 hours. It should be noted that hypercalciuria can also cause dysuria and mimic a urinary tract infection in which the urine culture shows no bacterial growth. Finally, hypercalciuria can be the major factor leading to urolithiasis. Numerous dietary factors such as increased intake of sodium and magnesium influence tubular reabsorption of calcium and can cause hypercalciuria (Bonny et al, 2008). Hypercalciuria may have a genetic component, accounting for the clustering of kidney stones in family pedigrees. For example, specific polymorphisms in the calcium-sensing receptor gene are associated with a gain-of-function and increased susceptibility to idiopathic hypercalciuria (Vezzoli et al, 2007). The diagnosis of hypercalciuria is best made based on a 24-hour urine collection in which the calcium excretion exceeds 4 mg/kg/day. Because of logistic issues involved in collecting 24-hour collections, clinicians often rely on the calcium-to-creatinine ratio in a spot sample. **The normal calcium-to-creatinine ratio value declines with age, and in children older than 4 years old the ratio should be less than 0.2.** There are a number of secondary causes of hypercalciuria, including RTA, hyperparathyroidism, malignancies, immobilization, and sarcoidosis. However, in most cases it is idiopathic. In the past, effort was directed at discriminating between hyperabsorption of calcium from the gut versus renal leak of calcium as the basis for hypercalciuria. However, this distinction is no longer considered clinically relevant because it does not influence the diagnostic workup or patient management. In addition to these renal manifestations, idiopathic hypercalciuria predicts bone loss. Studies have demonstrated an association between the degree of hypercalciuria and bone density of the femoral neck in adult men and women (Asplin et al, 2006). The long-term implications of this finding require ongoing study. Treatment of hypercalciuria by increasing fluid intake should be started on all diagnosed children, with thiazide administration reserved for symptomatic children unresponsive to conservative measures or those with high urinary levels or active stone disease.

Key Points: Hematuria

- Isolated microhematuria (≥five red blood cells per high-powered field) in children is usually a benign self-limited condition whereas recurrent hematuria or microhematuria of 6 months' duration warrants investigation.
- Gross hematuria in children with normal urinary tract imaging rarely indicates cystoscopic examination unless it is persistent and nonglomerular in origin (60%).
- Hypercalciuria is a common cause of both macroscopic and microscopic hematuria in children and is defined as a calcium-to-creatinine ratio of greater than 0.2 in children older than age 4 years.
- Hematuria in the presence of significant proteinuria often indicates glomerular disease requiring percutaneous renal biopsy.
- A family history of renal disease or renal stones may help to guide the diagnostic evaluation of hematuria in children.

PROTEINURIA

The filtration mechanism of the glomerulus aims to limit the passage of macromolecules, such as protein, from the blood into the urine. The pores in the slit diaphragm between the foot processes have a 40-Å diameter, which allows passage of low-molecular-weight molecules (α_1 and β_1 microglobulins) that are reabsorbed by the proximal tubule and therefore not detected in the urine in the absence of tubular damage (Tomlinson, 1992). The negative charge of the glomerular capillary wall provided by heparin sulfate and proteoglycans repel other negatively charged molecules, such as albumin. The loss of the negative charge or breakdown of the size barrier can lead to proteinuria. A third factor involved in filtration is the presence of hydrostatic and oncotic forces as blood traverses the glomerulus. Proteinuria can arise from hyperfiltration when a reduction of functioning nephrons occurs (e.g., from nephrectomy). Recent studies have created controversy about the pathophysiologic basis of glomerular proteinuria—excessive leak due to a primary disturbance in glomerular barrier function or failure to reabsorb the filtered load in the proximal tubule (Russo et al, 2007).

Abnormal urinary protein excretion is defined as greater than 4 mg/m^2/hr (Nephrotic syndrome in children…, 1979) in an overnight urine collection or a protein-to-creatinine (mg/mg) ratio greater than 0.2 in a first morning urine sample. Proteinuria is prevalent in 5% to 15% of children (McKenzie et al, 1964) and is associated with increasing age with a peak incidence of 13 years in girls and 16 years in boys (Wagner et al, 1968). It is common to find isolated proteinuria, but persistent proteinuria indicates renal disease and warrants evaluation (Vehaskari and Rapola, 1982). Proteinuria is important because it may reflect progressive renal disease (Kannel et al, 1984; Williams and Coles, 1994) and lead to hypocholesterolemia and hypertriglyceridemia, which pose a higher cardiovascular risk (Sytkowski et al, 1990). Similarly, medications aimed at reducing proteinuria can delay progressive renal failure (Remuzzi et al, 2004).

Proteinuria is first detected by urinary dipstick testing, which primarily detects albumin (Fig. 112–2). The colorimetric reaction between albumin and tetrabromophenol blue results in variable shades of green, depending on the approximate concentration of protein in the urine: trace indicates approximately 15 mg/dL; 1+, 30 mg/dL; 2+, 100 mg/dL; 3+, 300 mg/dL; and 4+, 2000 mg/dL or

more. False-positive urine protein levels may be caused by alkaline urine, antiseptic cleanser, radiocontrast agents, or a highly concentrated sample. False-negative urine protein levels may be found in very dilute urine. Significant proteinuria is indicated by a urine sample with a dipstick reading of 1+ and a specific gravity of at least 1.015. Confirmation of the level of proteinuria may be performed using sulfosalicylic acid, which uses protein precipitation and turbidity to estimate the level of proteinuria (Hogg et al, 2000). In the absence of other signs or symptoms of renal or urinary tract disease, including systemic disease, the urinalysis may be repeated in several weeks on the first morning specimen to confirm proteinuria.

Quantification of the proteinuria is best performed from a 24-hour urine collection. Normal urine protein excretion in children is less than 4 mg/m^2/hr (<100 mg/m^2/24 hr). **Protein excretion rate greater than 4 mg/m^2/hr is abnormal, and greater than 40 mg/m^2/hr is nephrotic-range proteinuria.** Urinary creatinine value should be measured (normal is 15 to 20 mg/kg/day in girls and 20 to 25 mg/kg/day for boys) to confirm the adequacy of the collection. However, timed urine collection can be difficult to accomplish and therefore inaccurate, particularly in the incontinent child (Hogg et al, 2000). Moreover, it is not useful in establishing the diagnosis of orthostatic proteinuria, a variant of normal. A random urine protein-to-creatinine ratio correlates well with 24-hour quantification. The normal values are less than 0.5 for children 6 to 24 months of age and less than 0.2 for children older than 2 years; a ratio above 3.5 is considered in the nephrotic range. **In a first morning sample, protein-to-creatinine values greater than 2.0 indicate nephrotic range proteinuria.**

Children with 1+ or more protein by dipstick on more than one occasion have persistent proteinuria and deserve further evaluation. Inquiry should be made into the presence, severity, and duration of recent illnesses, rashes, arthralgias, edema, weight loss, fatigue, or changes in urine output or urine color; a family history of renal disease, vesicoureteral reflux, deafness, or hypertension should be sought. The complete physical examination should include weight, height (with comparisons made to standard growth charts), blood pressure measurements, then a search for the presence of edema and ascites. **Laboratory studies should include a first morning urine sample to measure the protein-to-creatinine ratio followed by a 24-hour urine collection to quantify the protein in the presence of an elevated ratio.** Serum studies including determination of electrolyte, BUN, and creatinine levels plus those of cholesterol, albumin, and triglycerides as well as serology aimed at detecting glomerular diseases (C3, C4, fluorescent antinuclear antibody, antistreptolysin O, and hepatitis B or C titers) should be done if there is persistent proteinuria for 76 months or if there are suggestive symptoms and signs. Renal ultrasonography should be performed and voiding cystourethrography should be ordered in the presence of ultrasound findings suggestive of vesicoureteral reflux.

Significant proteinuria can occur secondary to glomerular or tubulointerstitial diseases, but it is generally due to glomerulopathies. Proteinuria may be categorized as transient, orthostatic, or fixed/persistent. Transient proteinuria is present in 30% to 50% of children with proteinuria and may be associated with fever, stress, dehydration, and exercise. Transient proteinuria associated with a fever rarely exceeds 2+ on the dipstick and abates with the fever. Exercise-induced proteinuria increases with age (Poortmans et al, 1996), is related to the vigor of exercise and not duration, (Poortmans, 1985), rarely exceeds 2+ on dipstick, and resolves within 48 hours of rest. **Postural (or orthostatic) proteinuria is common (60% of asymptomatic children)** (Norman, 1987) **in which protein excretion is normal while supine but becomes abnormal when erect.** Children are asymptomatic, and the only abnormal laboratory finding is an elevated urine protein level after being upright. Postural proteinuria may be documented by collecting two timed urine samples and finding no proteinuria while the child is recumbent (sleeping) and proteinuria while the child is upright. The 24-hour urinary protein excretion in children with orthostatic proteinuria should not exceed 1000 mg/day. Persistent proteinuria (up to 6% of school-aged children (Vehaskari and Rapola, 1982; Yoshikawa et al, 1991) is diagnosed after confirming proteinuria on two dipstick tests with at least 1+ at least 1 week apart and excluding postural proteinuria. Its etiology can be divided as either glomerular where there is increased permeability of the glomerulus or as tubular from decreased protein reabsorption. The glomerular type is more common and can be selective (molecules smaller than albumin) or nonselective (molecules larger than albumin).

The differential diagnosis for isolated proteinuria includes rare cases of minimal change nephrotic syndrome, FSGS, membranous nephropathy, or IgA nephropathy. Although FSGS is more frequent in African-American children, IgA nephropathy is much more common in white children (Nair and Walker, 2006). Membranous nephropathy is a rare disease across the entire pediatric age range (Chen et al, 2007). Obstructive uropathy is thought to be a common cause of tubular proteinuria, but it usually presents as other signs and symptoms. The measurement of microalbuminuria is generally confined to the management of diabetic nephropathy. Tests to measure selectivity of proteinuria or to quantitate low-molecular-weight proteins are not routinely available and of uncertain value. Unlike the situation in adult patients, the long-term implications of microalbuminuria on general health and the incidence of cardiovascular disease is unknown in pediatric patients. In fact, because of the high prevalence of orthostatic proteinuria in adolescents, testing the early morning sample is both more appropriate and more feasible than measuring proteinuria in a 24-hour collection. The diagnosis of the cause of proteinuria usually requires performance of a kidney biopsy. In 70% of children with isolated proteinuria, the urinary abnormality spontaneously resolves within 12 months (Trachtman et al, 1994). **Therefore criteria for performing a kidney biopsy are (1) persistent subnephrotic proteinuria for at least 12 months or (2) nephrotic-range proteinuria that persists for 3 to 4 months or rising levels of proteinuria in patients who are being followed after the initial**

Key Points: Proteinuria

- Asymptomatic, isolated proteinuria is a common finding on urinalysis screening examinations in children.
- Quantification of urinary protein excretion is the most important diagnostic test with more than 4 mg/m^2/hr considered abnormal and more than 40 mg/m^2/hr considered nephrotic range.
- Children with 1+ proteinuria on more than one occasion without other associated symptoms are likely to have transient or postural proteinuria.
- Presence of hematuria, edema, hypertension, or systemic disease increases the suspicion of a glomerulopathy, making the diagnostic evaluation more urgent.

detection of isolated proteinuria. However, these standards are likely to vary from center to center reflecting the pattern of disease regional and at each institution. In general, renal biopsies done under ultrasonographic guidance are a safe and well-tolerated procedure (Gauthier et al, 1993). The presence of both hematuria and proteinuria suggests the need for a more comprehensive and urgent evaluation.

GLOMERULAR DISEASE

Nephrotic Syndrome

***Nephrotic syndrome* is defined as edema, hypoalbuminemia, hyperlipidemia, and heavy proteinuria.** The amount of proteinuria considered to be nephrotic is an excretion greater than 40 mg/m^2/hr or a random urine protein-to-creatinine ratio of greater than 2.0 to 3.0 (Hogg et al, 2000). Nephrotic syndrome may be subdivided into congenital, primary (from any type of glomerulonephritis), or secondary (systemic disease, malignancy, allergic reaction or nephrotoxin). The incidence of primary nephrotic syndrome is 2 to 4 cases per 100,000 children younger than 19 years old and is most commonly due to minimal change disease (65% to 80%). In general, nephrotic syndrome is a disease of the glomerular podocyte, with the identification of genetic disorders of podocyte proteins providing the basis for this understanding.

Hypoalbuminemia occurs from the urinary loss of albumin causing a reduced plasma colloid oncotic pressure and a fluid shift from the intravascular to the interstitial space. This translates clinically into the development of edema as the serum albumin level falls below 2.5 g/dL. The rapid intravascular volume loss leads to compensatory reabsorption of sodium and water by the kidney, which aggravates the edema. In addition to underfilling of the intravascular space, nephrotic edema occurs because of primary sodium retention and overfilling of the circulation (Schrier and Fassett, 1998). While albumin synthesis increases, it is insufficient to replace the ongoing albumin losses, poor dietary protein intake, and increased catabolism of albumin.

Serum cholesterol is high (usually exceeding 400 mg/dL), triglycerides levels are variable, and total lipids are elevated (low-density lipoproteins, very-low-density lipoproteins, and apoproteins). Lipids accumulate in renal tubular cells, especially in the proximal tubule; these cells can slough into the urine, appearing as "oval fat bodies" in the sediment and having a typical Maltese cross pattern under the polarizing microscope.

Nephrotic Syndrome in Infants

All infants with primary nephrotic syndrome have proteinuria, hypoalbuminemia, hyperlipidemia, hypogammaglobulinemia, and usually normal renal function. Edema is present at birth or develops over several weeks in concert with increasing proteinuria. Hematuria is uncommon. The leading causes of nephrotic syndrome in infants include congenital nephrotic syndrome–Finnish type (CNF), diffuse mesangial sclerosis (DMS), minimal change nephrotic syndrome (MCNS), and focal sclerosis glomerulonephritis (FSGS). Family history, outcome, and corticosteroid response may be the only ways to secure the diagnosis. MCNS is rare in early infancy, responds to corticosteroids, does not progress to end-state renal disease, shows minimal changes on biopsy, and has a negative family history. FSGS is rare and may respond to corticosteroids. The rarity of MCNS and FSGS and the increased risk of severe infection in infants with CNF preclude starting corticosteroids in the first 3 months of age in the absence of a definitive diagnosis. DMS is rare and clinically indistinguishable from CNF occurring in siblings, is resistant to corticosteroids, and progresses to end-stage renal disease (ESRD) before age 3 years. Early in the disease DMS can be distinguished from CNF on biopsy by its mesangial matrix expansion without hypercellularity, thickened glomerular basement membrane (GBM), crowding of the capillary lumens, and eventual glomerulosclerosis, leaving a contracted sclerotic mass in a dilated Bowman space. DMS is the lesion associated with the glomerulopathy of Denys-Drash syndrome and may occur secondary to mutations in the Wilms tumor-1 *(WT1)* gene (Chiang et al, 2008).

CNF, the most common form of nephrotic syndrome in infants, is an autosomal recessive disorder with a mutation of the gene coding for nephrin on chromosome 19q13.1. Nephrin is a transmembrane protein of the slit diaphragm of the glomerular podocyte. The incidence in Finland is 0.9 per 10,000 births, but most affected patients in North America lack Finnish ancestry. Two mutations, Fin-major and Fin-minor, account for the disease in nearly 90% of all affected Finnish patients. CNF may be suspected in utero by elevated amniotic fluid and maternal serum levels of α-fetoprotein and confirmed postnatally by specific genetic testing. Histopathologies of fetal kidney show foot process effacement and diffuse epithelial podocyte proliferation. Infants with CNF are small for gestational age and born prematurely. Edema is present at birth in more than 50% of patients and by 3 months in 100%. Proteins that are lost in the urine include immunoglobulins leading to hypoimmunoglobulinemia and a higher risk of bacterial infection, thyroxine causing hypothyroidism, transferrin and iron causing anemia, and protein-bound 25-hydroxyvitamin D causing vitamin D deficiency. Severe chronic nephrotic syndrome is associated with a hypercoagulable state that places these children at risk for thromboembolic events. Failure to thrive and malnutrition from excessive protein loss and anorexia occur in all affected infants. Renal function, initially normal, progresses to end-stage renal disease (ESRD) by age 3 to 8 years. Poor responders to aggressive medical management may require bilateral nephrectomy and dialysis even before ESRD. Early aggressive treatment including dialysis and renal transplantation offers good long-term survival (80%), whereas untreated infants die by age 4 years. Catch-up growth and development are common after transplantation, but CNF recurs in many (25%) patients owing to antinephrin antibody production.

Minimal Change Nephrotic Syndrome

MCNS is the most prevalent lesion throughout childhood, but the frequency declines from 85% to 90% in preschool-aged children to 50% in adolescents. **Most children with proteinuria between 1 and 10 years of age who respond to oral corticosteroids have minimal change disease.** Because most children who respond to corticosteroids with resolution of proteinuria do not undergo biopsy, the actual pathologic diagnosis is often unknown. However, the most important prognostic feature is remission of the disease with corticosteroid therapy.

Most children with MCNS present with edema, even ascites, but most children otherwise appear well. The diagnosis of MCNS is made by demonstrating nephrotic-range proteinuria, a serum albumin level below 2.5 g/dL, and elevated plasma cholesterol and/or triglyceride levels. Most children are normotensive and have normal BUN and creatinine concentrations. Microscopic evaluation of the urine demonstrates the presence of fatty casts and oval fat bodies but minimal hematuria and no cellular casts.

Once the presumptive diagnosis is made, high-dose (60 mg/m^2/day) daily treatment with oral prednisone is started (Mendoza and Tune, 1992). This regimen is continued for at least 4 weeks, followed by an additional 4 weeks of 40 mg/m^2/day on alternate days and then a gradual taper using alternate-day dosing. To simplify management, the daily dose can be 2 mg/kg and the alternate day dose 1.5 mg/kg (Gipson et al, 2009). Most children respond with remission of proteinuria within 4 weeks (negative or trace protein on dipstick for 3 consecutive days). Dietary salt restriction is another important component of treatment. Approximately two thirds of children will experience relapse, which is treated with high daily doses of corticosteroids until remission and then the dosage is tapered. Cytotoxic agents (cyclophosphamide or chlorambucil) or cyclosporine are used in some children if relapses are frequent or unsustainable without corticosteroids. In cases in which renal biopsy is performed, light microscopy demonstrates normal renal tissue or demonstrates a mild, focal increase in mesangial cellularity and matrix. On electron microscopy, effacement of epithelial cell foot processes, normal glomerular basement membrane thickness, and small paramesangial electron-dense deposits can be seen. These lesions fail to stain or stain slightly positive for IgM.

Children with MCNS are at heightened risk for infections owing to the urinary loss of opsonins, with particular risk for spontaneous bacterial peritonitis. The acute nephrotic syndrome is characterized by a relatively hypercoagulable state, and these children may develop venous thromboses during relapse. Therefore, placement of central venous catheters or femoral venipuncture is to be avoided. **Renal insufficiency rarely presents as an acute or late complication of MCNS.**

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is the second most common cause of primary nephrotic syndrome in children (Bonilla-Felix et al, 1999), accounting for 10% to 20% of cases. Its incidence may be increasing in all ethnic groups, perhaps related to the epidemic of obesity and the metabolic syndrome. **FSGS is more common among older children and African-American children and is much less likely to respond to corticosteroid therapy.** FSGS has many causes but no clear pathophysiology. Whereas 15% to 25% of children with primary nephrotic syndrome have biopsy-proven FSGS, 20% of patients with FSGS have asymptomatic proteinuria. Microscopic hematuria is present in over 50% of affected children, but gross hematuria is rare. Renal tubular dysfunction (glucosuria, aminoaciduria, RTA, Fanconi syndrome) and concentrating defects are risk factors for progression to chronic renal failure.

Early in the disease the renal lesions are focal and mainly located in the juxtamedullary glomeruli. The focal nature may lead to false-negative biopsies and delayed diagnosis. By light microscopy the glomeruli are enlarged, but affected glomeruli may have segmental sclerosis or segmental capillary loop collapse and increased mesangial matrix. Foam cells are associated with the segmental lesions. Tubulointerstitial disease is almost always present. IgM and C3 are detected by immunofluorescence in the mesangium or focally along the GBM of affected capillaries. Electron microscopy demonstrates endothelial cell swelling, effacement of epithelial podocytes, sclerosis, and scattered immune deposits.

Despite the suboptimal response to corticosteroids, evidence-based analyses still advocate their use as first-line therapy. Regardless of timing of the positive biopsy, only 20% of children initially have a complete response to prednisone. Twenty to 30 percent of nonresponders progress to ESRD within 5 years, and 60% do so by 10 years. Cyclosporine, tacrolimus, and mycophenolate mofetil have been used as single agents or in combination with corticosteroids with variable success. Pulse intravenous methylprednisolone for 8 to 12 weeks along with alternate-day oral prednisone with or without cyclophosphamide or chlorambucil has demonstrated sustained remission in 80% of patients. Disease progression is anticipated in the presence of persistent nephrotic syndrome and an increase in globally sclerotic glomeruli on follow-up biopsies. FSGS recurs in up to 30% after a first renal transplant and in 80% of subsequent transplants. The administration of high-dose cyclosporine, alone or in combination with plasmapheresis, has led to remission of nephrotic syndrome and allograft salvage.

Membranous Glomerulonephritis

Membranous nephropathy accounts for 1% to 3% of biopsies performed for the evaluation of nephrotic syndrome in childhood and for 10% to 20% of those performed in adolescents. Primary (idiopathic) membranous glomerulonephritis (MGN) occurs in two thirds of cases and secondary MGN from systemic diseases (systemic lupus erythematosus [SLE], chronic hepatitis B) in the others. **MGN may present months to years before the associated disorders.** Symptoms arise gradually, and MGN is commonly (two thirds) diagnosed during the evaluation for edema and nephrotic syndrome or after detecting proteinuria on screening urinalysis (one third). Hypertension (found in 30%) is not a prognostic indicator. Hematuria is nearly universal as microscopic (80%) or gross (20%). Renal function and serum C3 value are usually normal initially; the C3 may be low in SLE- and hepatitis B–associated MGN. Idiopathic MGN progresses slowly, with renal failure developing within 10 years in 10% of children younger than 10 years old and in 20% of adolescents. Spontaneous remission of proteinuria occurs in up to 30% of children.

The pathogenesis of MGN is not well known but may be due to (1) circulating antibodies that react with endogenous GBM antigens forming in-situ immune complexes or (2) deposition of circulating preformed immune complexes to the GBM induced by autoimmune reactions, infection, drugs, or toxins. Stages I to IV of MGN are classified by the progressive thickening of the GBM and larger coalescing subepithelial deposits of immune complexes (IgG and often C3) on light and electron microscopy. Stage V represents a regressive healing stage. Different stages may be observed on the same biopsy specimen. No clear correlation exists between the stage of MGN and the severity or duration of disease, and lesions may remain stable over several years.

Because of its rarity in children, controlled trials in children are lacking and management has been extrapolated from experience in adults. Angiotensin-converting enzyme I and/or angiotensin type II receptor antagonist administration is aimed at reducing proteinuria, intraglomerular hypertension, and progression to renal failure. Treatment of poorly controlled nephrotic syndrome includes use of corticosteroids possibly supplemented by chlorambucil, cyclophosphamide, or cyclosporine. Spontaneous remission is common in hepatitis B–associated MGN, allowing for initial observation. MGN associated with syphilis is effectively treated with penicillin. MGN associated with drugs or toxins may resolve after several months of withdrawal.

Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) accounts for only 2% to 10% of cases of primary nephrotic syndrome in childhood. Most children present between age 8 and 20 years without

a gender preference with persistent hypocomplementemia. MPGN is a chronic disease that may be idiopathic or due to other systemic diseases (SLE, malignancies) or infections (chronic hepatitis C). A hereditary component is suggested by its association with inherited deficiency of several complement components, haplotypes (HLA-B8, DR3, SC01, GL02) and predilection for siblings. Although many cases are identified after routine screening urinalysis, most children have microscopic or gross hematuria at onset and almost all have proteinuria: primary nephrotic syndrome in about 50%, asymptomatic proteinuria in 25%, and nephritis with hematuria and proteinuria in 25%. Three subtypes of MPGN can be identified by microscopy. Type I shows enlarged glomeruli, obliterated capillary lumina, marked mesangial proliferation, and positive immunofluorescent staining for IgG and C3 in the mesangium and subendothelial deposits. Type II is similar to type I with less mesangial proliferation, very dense material in the GBM, but with positive immunofluorescent staining for C3 only outlining the GBM and the dense deposits in the mesangium and only sparsely in the subendothelial and subepithelial spaces. Type III disease demonstrates extensive GBM disruption with mesangial, subendothelial, subepithelial, and transmembranous deposition of IgG and C3.

The natural history of MPGN is progression to ESRD (50% by 10 years), but a few patients have spontaneous durable remission. Poor prognostic indicators include a presenting serum creatinine concentration over 2 mg/dL, hypertension, gross hematuria, and unremitting nephrotic syndrome with edema. Corticosteroids are the mainstay of treatment. Renal transplantation is successful, but recurrence of type I (30%) and type II (60%) MPGN in the allograft is reported; the progression to graft loss is slow.

Diffuse Mesangial Proliferative Glomerulonephritis

Diffuse mesangial proliferative glomerulonephritis (DMPG) is uncommon (5%) among children with primary nephrotic syndrome. Children are likely to have microscopic hematuria (90%), hypertension (50%), and renal compromise (25%). Renal biopsy specimens demonstrate diffuse mesangial hypercellularity with or without mesangial electron-dense deposits (IgM). The significance of these IgM deposits is unknown. The prognosis is good despite initial corticosteroid resistance in 35% to 70% of patients. Some children undergo spontaneous remission of nephrotic syndrome, and progressive renal failure and ESRD occurs in fewer than 10%. DMPG recurs in up to 40% of patients after renal transplantation.

Postinfectious Glomerulonephritis

Children with resolving postinfectious glomerulonephritis will have had an upper respiratory infection with or without confirmed pharyngitis in the recent past, and this is the most common cause of acute glomerulonephritis in children. There is a latency period of 7 to 21 days after a group A β-hemolytic streptococcal infection and the acute phase of glomerulonephritis. At the time of presentation with cola-colored urine the children are well without hypertension, edema, or proteinuria. In these children, confirmation of the diagnosis is contingent on resolution of the hematuria, which may take up to 2 years after the acute episode. **The diagnostic studies include a positive antistreptolysin O or streptozyme titer and a decreased serum complement (C3) concentration.** However, there is an ongoing paradigm shift in obtaining serologic studies in suspected cases in that there may be no value in routinely measuring the C3 levels because the temporary fall in level during the acute phase of the illness has generally passed and an isolated elevation in antibody titers to streptococcal-related antigens has no diagnostic value (Srisawat et al, 2006). Provided the hematuria gradually resolves, it is thought that the long-term prognosis of the patients is no different than that of healthy controls (Blyth et al, 2007). Complete recovery of renal function can be expected in more than 90% of cases, even in those who have a protracted clinical course requiring dialysis.

The acute phase lasts approximately 2 weeks and is characterized by fluid retention, hypertension, significant hematuria (often macroscopic), and proteinuria. Varying degrees of acute renal insufficiency with oliguria, even anuria requiring intermittent dialysis, may be seen. **Control of hypertension, management of electrolyte and fluid balance, and treatment of renal functional impairment are necessary during the acute phase of the illness.** Microscopic hematuria and minimal proteinuria may persist for 3 to 6 months. C3 concentrations usually become normal within 2 months after disease onset. Proteinuria that persists for 12 months after disease onset may require a renal biopsy to assess the degree of renal histologic damage, otherwise biopsy is not required for diagnosis. The characteristic findings on biopsy are marked cellular proliferation within the glomerulus due to infiltration of polymorphonuclear leukocytes and monocytes and the associated stimulation and proliferation of endothelial and mesangial cells. Electron microscopy in classic cases demonstrates humplike dense deposits.

IgA Nephropathy

IgA nephropathy (Berger disease) is more prevalent in the second decade of life and is more common in boys compared with girls. It is usually heralded by recurrent episodes of painless gross hematuria without clots synchronous with upper respiratory tract infections (Davin and Weening, 1999). The gross hematuria takes 3 to 4 days to gradually return to normal; however, some children and adolescents have persistent isolated microscopic hematuria as the sole manifestation of IgA nephropathy. It is important to distinguish IgA nephropathy in which systemic manifestations are uncommon from Henoch-Schönlein purpura, which also can cause nephritis but, unlike IgA nephropathy, be associated with distinctive urologic problems such as acute scrotal swelling (Ha and Lee, 2007). Recent studies have suggested that IgA nephropathy may be the result of abnormal galactosylation of IgA1 molecules (Buck et al, 2008). This triggers the synthesis of autoantibodies, formation of immune complexes, and deposition in the glomerular mesangium (Suzuki et al, 2009). Serology will demonstrate elevated antistreptococcal titers and normal C3 levels. The decision on whether to perform a kidney biopsy to make the diagnosis is individualized in each case; however, in the absence of proteinuria and/or hypertension and in light of the lack of proven therapies for IgA nephropathy, biopsies are less likely to be performed in children with microscopic hematuria versus those with recurrent gross hematuria. The biopsy specimen will demonstrate variable degrees of mesangial cell proliferation and IgA deposits on immunofluorescent staining.

Wyatt (1995) reported that 15% of patients will reach ESRD after 10 years and 30% will do so after 20 years. Alternatively, nearly half of patients experience a disease-free state at some point, but the silent nature of the disease in adults warrants long-term follow-up. Treatment is based on the severity of disease at diagnosis and includes renoprotective agents such as angiotensin-converting enzyme (ACE) inhibitors, corticosteroids, and mycophenolate mofetil.

Hereditary Nephritis (Alport Syndrome)

Hereditary nephritis also manifests clinically in childhood with either persistent microscopic hematuria or recurrent episodes of gross hematuria during upper respiratory infections. **The key clinical step in distinguishing IgA nephropathy from hereditary nephritis is the absence of a family history of significant kidney disease in the former while there is a clear history of ESRD and hearing loss in first-order relatives of a child with potential hereditary nephritis.** Hereditary nephritis spans a spectrum of entities all of which are the result of genetic mutations in type IV collagen genes that are constituents of the GBM (Kashtan, 2004). In benign familial nephritis or familial thin basement nephropathy the genetic mutation is in the α3 or α4 chains of type IV collagen, which are on chromosome 2 (Kashtan, 2004). In the heterozygous state the renal involvement is mild and the sole manifestation of disease is persistent microscopic hematuria. The risk of progressive loss of kidney function is generally low in these cases. In contrast, Alport syndrome, the most severe variant of hereditary nephritis, is caused by mutations in the α5 chain of type IV collagen on the X chromosome. This accounts for the more severe disease in males. The phenotype is more variable in females because of the Lyon hypothesis and random inactivation of an X chromosome in each cell. There are autosomal dominant and recessive forms of Alport syndrome linked to mutations in the α3 and α4 chains of type IV collagen. There are extrarenal manifestations of Alport syndrome (eye, platelets, smooth muscle) that can facilitate the diagnosis but, in general, the diagnosis is made based on characteristic ultrastructural changes in the GBM—splitting and lamellation on electron microscopic examination. Immunohistochemical staining for the various α chains of type IV collagen at the dermal-epidermal junction in a skin biopsy specimen can show alterations that are diagnostic of the various categories of hereditary nephritis (Kashtan, 2004). The use of genetic testing for Alport syndrome is becoming more accessible but is still not considered a routine procedure that can replace a kidney biopsy because identification of the unique mutation in most families is a costly and time-consuming procedure.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a systemic vasculitis with a peak age for presentation of 4 to 6 years of age. The most common features include the characteristic palpable purpuric rash, abdominal pain with gastrointestinal bleeding, and arthritis with refusal to bear weight. Renal involvement, if present, is usually not evident until several weeks after the initial symptoms. Henoch-Schönlein purpura is an acute glomerulonephritis, and the renal biopsy specimen may demonstrate segmental necrosis of glomeruli or crescent formation. Children without renal involvement or only isolated hematuria or proteinuria can be managed with supportive care. Those children with more aggressive disease including nephrotic or nephritic syndromes are at higher risk for developing chronic renal disease, particularly girls, and should receive more aggressive therapy, including corticosteroids, renoprotective agents, and immunosuppressive drugs. There is the potential for affected members within the same family to have either Henoch-Schönlein purpura or IgA nephropathy and for an individual with Henoch-Schönlein purpura to have the disease evolve into IgA nephropathy.

Lupus Nephritis

The major renal manifestation of SLE is glomerular disease. **The primary symptoms leading to the diagnosis of renal disease in children with SLE are proteinuria, microscopic hematuria, hypertension, and mild renal insufficiency** (Cameron, 1994). SLE is an autoimmune disease with the potential to affect numerous organ systems. Children with SLE are more likely than adults to have renal involvement. The peak age at onset is 14 years, around the time of puberty, and females are more likely to be affected than males (M:F = 4.4:1). Half of children with lupus nephritis have nephrotic syndrome and/or renal insufficiency at diagnosis. SLE is divided into classes based on histopathology (the prevalence of each from several biopsy series in children is given in parentheses): class I, normal (6%); class II, mesangial proliferative (19%); class III, focal endocapillary proliferative (23%); class IV, diffuse endocapillary proliferative (43%); and class V, membranous (9%). Both C3 and C4 are commonly decreased during acute illness. Abnormalities common at presentation in children with lupus nephritis are fever (78%), arthralgia (75%), rash (68%), weight loss (40%), Coombs-positive anemia (48%), leukopenia (47%), thrombocytopenia (25%), coagulopathy (27%), and renal disease (82%).

Primary therapy for lupus nephritis is based on the class or severity at diagnosis and usually consists of corticosteroids plus additional cytotoxic drugs. Although no clinical trials have been performed in children, therapy is based on adult data, showing that the best long-term renal preservation for class IV nephritis is achieved with cyclophosphamide plus corticosteroids. Monthly pulses of cyclophosphamide are given during the 6-month induction phase followed by every-3-month doses up to 2 years. More recently, mycophenolate mofetil has been shown to have equal efficacy at 2 years compared with cyclophosphamide. Renoprotective therapy is a common adjunct in lupus nephritis, and many children require more than one antihypertensive medication during therapy. Long-term follow-up studies of childhood-onset lupus nephritis are lacking. From the case series at Guy's Hospital in London, of 78 children, 15% had progressed to ESRD, 6% were dead, 27% had remission of renal disease (some still on treatment), and 36% continued to have signs of renal disease on therapy (follow-up ranged from 1 to 26 years).

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome is defined by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal insufficiency. In children, hemolytic uremic syndrome may be the typical form, which is associated with diarrhea, or an atypical form (Pickering et al, 1994; Loirat and Taylor, 2004). This discussion will focus on the typical diarrhea-associated hemolytic uremic syndrome, which in North America is secondary to primary infection with enterotoxic *Escherichia coli*. The enteropathic *E. coli* infection is usually contracted through ingestion of food contaminated with bovine feces: ground beef, water supplies, or vegetables/fruits. Person-to-person spread is also possible. Specific serotypes of *E. coli* (O157:H7) produce a verotoxin that binds to enterocytes and gains access to the microcirculation. After endocytosis into vessels the toxin causes endothelial injury, particularly in the kidney, by inhibition of protein synthesis by the endothelial cell. Platelet-fibrin thrombi within glomeruli cause ischemia of glomerular capillaries associated with mesangiolysis. Severe forms are also characterized by cortical necrosis as larger arterioles may become involved.

The diagnosis of hemolytic uremic syndrome is based on clinical features at presentation, because renal biopsies are not usually performed in the classic, diarrhea-associated hemolytic uremic syndrome. **The prodrome consists of enterocolitis, typically bloody diarrhea (70% of cases) along with vomiting and fever, followed by transient improvement; 4 to 7 days later the onset of pallor (anemia), general malaise, oligoanuria, fluid overload, and hypertension occurs.** Serious neurologic sequelae (i.e., seizures, encephalopathy, and coma) may be present in 20% of cases. The severity of renal involvement is related to the severity of the gastrointestinal prodrome but not related to the severity of anemia. Efforts to isolate *E. coli* O157:H7 from stool of affected children should be made, and recovery is better when samples are obtained within 6 days from onset of diarrhea. Cases are reported to the state health department.

Treatment of diarrhea-associated hemolytic uremic syndrome is supportive. Antibiotic therapy for *E. coli*-associated enterocolitis is discouraged because there may be increased risk to develop hemolytic uremic syndrome possibly owing to release of the bacterial toxin. Antimotility agents may increase the risk of toxic megacolon. Plasma exchange seems to be an effective option for these patients, except when caused by *Streptococcus pneumoniae*. Careful attention must be paid to fluid balance and to electrolyte disturbances. Hyperkalemia, which occurs because of increased release of potassium during red blood cell lysis, is further complicated by acidosis and decreased GFR. Therapy with packed red blood cell transfusions is indicated when the hemoglobin drops to less than 7 g/dL, but platelet transfusions are discouraged. Dialysis may be required during the oliguric phase, but early dialysis does not appear to improve outcome. Mortality associated with hemolytic uremic syndrome is 1% to 2%, and irreversible renal failure occurs in 5%. Late sequelae of hemolytic uremic syndrome including proteinuria, hypertension, and renal insufficiency have been reported in as many as 30% of survivors. Late sequelae are more likely in individuals with anuria for more than 1 week or who require more than 2 weeks of dialysis.

Other, non–diarrhea-associated forms of hemolytic uremic syndrome that may occur in children but are not discussed in this brief review include *Streptococcus pneumoniae*-associated hemolytic uremic syndrome, complement factor H deficiency, abnormal von Willebrand protease inhibitor, abnormalities of vitamin B_{12} metabolism, calcineurin inhibitor–associated hemolytic uremic syndrome, and post–bone marrow transplant–associated hemolytic uremic syndrome.

Key Points: Glomerular Disease

- *Nephrotic syndrome* is defined as edema, hyperlipidemia, hypoalbuminemia, and heavy proteinuria (>40 mg/m^2/hr).
- Renal biopsy histology and immunohistochemistry, when indicated, allow for proper diagnosis and direct management and prognosis.
- Congenital nephrotic syndrome–Finnish type is the most common cause of nephrotic syndrome in infants and is due to a mutation of the gene coding for nephrin (slit diaphragm protein).
- Minimal change disease, the most common cause of nephrotic syndrome, is the presumptive diagnosis when proteinuria responds to a course of corticosteroids.
- FSGS is more common among African-American children and is often corticosteroid resistant.
- Acute glomerulonephritis most commonly occurs 7 to 21 days after an upper respiratory infection and presents as cola-colored urine in an otherwise well child. A full recovery occurs in 90%.
- Alport syndrome can be distinguished from IgA nephropathy by a family history of significant renal disease and hearing impairment in first-order relatives.
- Henoch-Schönlein purpura has variable effects on the kidneys several weeks after the onset of the typical syndrome symptoms.
- Hemolytic uremic syndrome consists of hemolytic anemia, thrombocytopenia, and acute renal insufficiency that typically occurs after enterocolitis from *E. coli* (O157:H7).

RENAL TUBULAR DISORDERS

The renal tubule is responsible for absorption or secretion of various substances after the process of glomerular filtration. Each portion of the tubule—proximal convoluted portion, loop of Henle, distal convoluted portion and collecting duct—has specific absorptive and/or secretive responsibilities. The proximal tubule transports sodium, chloride, glucose, phosphorus, ketoacids, low-molecular-weight proteins (<50 kD), and water. The loop of Henle is involved in sodium, chloride, calcium, and potassium movement. The distal tubule is limited to sodium and chloride transport, whereas the collecting ducts move sodium, chloride, potassium, and protons. Tubular disorders reflect disorders of active or passive transport mechanisms causing solute loss into the urine (Table 112–2). Active transport mechanisms require energy from adenosine triphosphate (ATP) hydrolysis and therefore a favorable sodium gradient created by the basolateral Na^+,K^+-ATPase. Disorders of tubular function may be genetic (or congenital) or acquired and specific for a solute or generalized. They are organized according to the portion of the renal tubule most affected (Gregory and Schwartz, 1998).

Proximal Tubular Disorders

Fanconi syndrome is not a specific disorder but a generalized dysfunction of the proximal tubule. The causes of Fanconi syndrome are usually primary inherited disorders

Table 112–2.

Molecular Basis of Common Pediatric Tubular Disorders

DISEASE	ABNORMAL PROTEIN
Renal tubular acidosis	Protein pump: H^+-ATPase
	WNK4
Nephrogenic diabetes insipidus	Vasopressin receptor: V2 receptor
	Aquaporin water channel: AQP2
Dent disease	Chloride channel: ClCN5
X-linked hypophosphatemia	Endopeptidase: PHEX
Gitelman syndrome	Na^+ transport: Na^+,Cl^- cotransporter
Bartter syndrome	Na^+ transport: Na^+,K^+,Cl^- cotransporter
	Chloride channel: ClCKb
	Potassium channel: ROMK
	Membrane channel: barttin

(Chesney, 2004; Jones and Chesney, 2004) (mutations of metabolic enzymes or mitochondrial DNA) but may be sporadic or due to intoxication of heavy metals and outdated tetracycline, gentamicin, cyclosporine, tacrolimus, and ifosfamide. The typical features include glucosuria, aminoaciduria, phosphaturia, proximal RTA, low-molecular-weight proteinuria, hypokalemia and hypomagnesemia, hypouricemia, and mild to moderate renal insufficiency (Chesney, 2003; Kaplan, 2004). Children usually present with polyuria, muscle weakness and pain (hypokalemia), signs of dehydration including constipation, bone pain and bowing from rickets (hypophosphatemia, calcitriol deficiency), or growth failure (acidosis). Treatment consists of electrolyte replacement (primarily sodium and phosphorus), correction of the acidosis, and active vitamin D (calcitriol) administration.

There are other rarer forms of proximal tubular dysfunction, including familial glucosuria (benign and confused with diabetes mellitus), bicarbonaturia (proximal RTA), phosphaturia (often X-linked causing rickets), and aminoaciduria (cystine).

Distal Tubular Disorders

Renal Tubular Acidosis

RTA represents the clinical syndrome that occurs when the renal acidification capacity is compromised. In general, the kidney serves two functions in maintaining acid-base homeostasis: reclamation of the filtered load of bicarbonate and regeneration of bicarbonate consumed in the titration of nonvolatile acid produced in daily metabolism. Reclamation is a large bulk process that occurs in the proximal tubule. It links H^+ secretion at the apical via the Na^+,H^+ antiporter to bicarbonate reabsorption across the basolateral membrane via the sodium bicarbonate symporter. The replacement of bicarbonate lost in normal metabolism, which amounts to 1 to 3 mmol/kg/day in a healthy adult, occurs in the distal tubule. Infants and growing children have a greater daily acid production because deposition of bone during skeletal growth is an acidogenic process. Net acid removal occurs via H^+-dislocating ATPase pumps.

RTA can occur in three basic varieties: type I or distal, type II or proximal, or type IV due to aldosterone deficiency. In proximal RTA the threshold for bicarbonate reabsorption is depressed and the serum bicarbonate is lowered to the threshold level. It can be an isolated problem or be a manifestation of broad proximal tubule dysfunction, termed *Fanconi syndrome*. In the latter case the RTA is accompanied by glycosuria, phosphaturia, hypokalemia, and aminoaciduria. The cause of proximal RTA can be idiopathic or secondary to a wide range of metabolic disorders that compromise the bioenergetic state in the proximal tubule. The most common cause is cystinosis; but other less frequent causes include galactosemia, hereditary fructose intolerance, tyrosinemia, and glycogen storage disease type I.

In distal RTA (type I), the defect in acidification reflects either a reduction in the activity of the H^+-ATPase pumps or an inability of the distal tubule to maintain a normal H^+ gradient. The cause of distal RTA can be idiopathic. Secondary causes include disorders that interfere with the structure and function of the distal tubule, including sickle cell anemia, SLE, transplant rejection, calcineurin nephrotoxicity, and reflux nephropathy.

In type IV RTA there is reduced biosynthesis of aldosterone or tubular hyporesponsiveness to the hormone. Aldosterone plays a pivotal role in acid-base balance by increasing the expression of Na^+,K^+-ATPase along the basolateral membrane and enhancing the activity of apical H^+ pumps. Aldosterone synthesis is compromised in a number of genetic disorders of corticosteroid synthesis. It can also be reduced as a consequence of hyporeninemia in patients with diabetes mellitus. Failure to respond to aldosterone is a characteristic feature of children and adults with obstructive uropathy.

Patients with RTA usually present with failure to thrive. Along with diabetes insipidus (see later) and chronic kidney disease, it represents one of the three "pure" renal causes of impaired growth. Other presentations include asymptomatic hypercalciuria, nephrocalcinosis, or kidney stones. Patients may also have episodes of diarrhea and dehydration. Rickets is present in some patients (Evan et al, 2007) and was initially thought to be more prevalent in distal RTA and be a consequence of bone buffering of retained H^+.

The diagnosis of RTA requires the presence of hyperchloremic metabolic acidosis. The bicarbonate level measured in a venous blood gas specimen is approximately 5 mmol/L higher than in a routine serum sample and provides a more accurate estimate of acid-base status (Adedoyin et al, 2003). The value of the urine pH is very limited in making the diagnosis. However, in a child with acute metabolic acidosis, urinary anion gap measurement can be a useful gauge of distal tubule acidification capacity. Under these circumstances, a normal child will enhance excretion of the cation ammonium (NH_4^+), and the urine anion gap ($[Na^+] + [K^+]) - [Cl^-]$ will be a negative number (Kim et al, 1996). The serum potassium concentration will be normal or low at presentation in type I and II RTA whereas it is high in type IV RTA. The classic method was to assess urinary acidification after infusion of ammonium chloride. However, it often is difficult to get access to this compound and it can cause gastrointestinal upset. A recent report described the efficacy of combined administration of furosemide and fludrocortisone simultaneously to stimulate acid secretion, with a positive test based on urine pH less than 5.5. This procedure was easier to perform, better tolerated, and as accurate as an ammonium chloride challenge in adult patients with RTA (Walsh et al, 2007).

The treatment of RTA involves primarily oral bicarbonate administration, and adequate therapy should result in growth normalization. The dose for type I RTA is usually in the range of 1 to 3 mmol/kg/day to neutralize nonvolatile acid production. The amount required may be higher among patients ingesting a high-protein diet or in younger children who are growing because bone growth utilizes bicarbonate in bone crystal formation. The daily bicarbonate dose is usually much higher in type II RTA because it is difficult to sustain a normal bicarbonate concentration in these children with a diminished reabsorptive threshold. In operational terms, the requirement for a large bicarbonate dose to sustain growth is indirect confirmation of a proximal RTA diagnosis. In these children, potassium supplementation may be required after the initiation of bicarbonate supplementation because the anion lowers the luminal voltage in the distal tubule and promotes a kaliuresis. There are a number of available bicarbonate preparations, including sodium bicarbonate, sodium citrate, and sodium/potassium citrate, that come in liquid or tablet formulations, allowing the choice of the one that is best tolerated by the child. In children with secondary RTA, treatment of underlying disease will lead to RTA resolution and obviate the need for bicarbonate supplementation.

Bartter Syndrome

Bartter syndrome is a group of transport disorders characterized by hypokalemia, metabolic alkalosis, polyuria, and growth failure

(Rodriguez-Soriano, 1998). The primary defect is potassium and chloride loss. Volume depletion stimulates the renin-angiotensin-aldosterone axis, which leads to further potassium and hydrogen ion loss, aggravating hypokalemia (often < 2 mEq/L) and acidosis. Hypercalciuria may lead to nephrocalcinosis. Treatment centers on correcting the volume depletion and hypokalemia, with indomethacin (prostaglandin synthetase inhibitor) being useful in some children.

Antenatal Bartter syndrome, or hyperprostaglandin E syndrome, is an autosomal recessive disorder with severe polyuria and salt wasting and is associated with polyhydramnios (Chesney, 2003; Kaplan, 2004), offspring of consanguineous progeny, sensorineural deafness, and chronic renal failure. Mutations have been identified in the loop $Na^+,K^+,2Cl^-$ cotransporter or in the luminal potassium channel (ROMK).

Classic Bartter syndrome is due to a mutation in the basolateral membrane chloride channel protein A or B (CLCKA, CKCKB) and presents within the first 2 years of life (not necessarily from birth). Features include polyuria, salt craving, constipation (dehydration), muscle weakness/cramping, and failure to thrive. Facial features include a drooping mouth, large batlike ears, and a triangular face. Serum studies demonstrate hypokalemia and hypochloremic and metabolic alkalosis whereas hypomagnesemia is found in 20% to 50% of patients; urine studies demonstrate loss of sodium and potassium. The associated volume depletion protects against developing hypertension.

Gitelman Syndrome

Gitelman syndrome, more common among adolescents and young adults, arises from mutations in the distal tubule Na^+,Cl^- cotransporter (Chesney, 2004; Jones and Chesney, 2004; Kaplan, 2004). The effect is a clinical syndrome that resembles the effects of thiazide-like diuretics. The clinical features of Gittelman syndrome include hypokalemia, metabolic acidosis, hypocalciuria (which distinguishes this from Bartter syndrome), and hypomagnesemia, leading to muscle weakness or tetany, vomiting with dehydration, abdominal pain, and fever. Treatment consists of potassium and magnesium repletion.

Collecting Tubule Disorders: Diabetes Insipidus

The ability to concentrate urine depends on (1) an intact concentration gradient in the renal medulla and (2) functioning water channels located in the collecting tubule. The binding of antidiuretic hormone (ADH) to the vasopressin receptor (V2) found on the basolateral membrane leads to the insertion of aquaporin-2 (water channel) into the apical membrane of the collecting tubule and subsequent movement of water.

Nephrogenic diabetes insipidus (NDI) results from resistance of the collecting tubules to ADH. NDI is divided into two major categories: primary or genetic and secondary or acquired (Deen et al, 2000; Sasaki, 2004). The most common causes of acquired NDI in children are obstructive uropathy, drugs, metabolic disturbances, and miscellaneous conditions. Patients with hydronephrosis have downregulation of the vasopressin receptor in the collecting duct and impaired concentrating capacity, which is reversed with obstruction relief (Shapiro et al, 1978). Genetic defects in the V2 receptor can present as congenital hydronephrosis and lead to occasional confusion in determining cause and effect in patients with NDI and hydronephrosis (McDill et al, 2006). Lithium and amphotericin are two commonly prescribed drugs leading to NDI in children. Lithium downregulates the AQP2 channel in the renal medulla. Hypercalcemia and hypokalemia are the most frequent metabolic causes of NDI. Finally, diseases that disrupt the tubulointerstitium such as sickle cell anemia and Sjögren syndrome can cause NDI (Ren et al, 2008).

In hereditary NDI, loss-of-function mutations in the V2 receptor gene on the X chromosome account for nearly 90% of cases (Sasaki, 2004). The functional consequences of the genetic alterations run the gamut from impaired membrane insertion to inability to activate adenyl cyclase (Rosenthal et al, 1993). Most female V2 mutations carriers are asymptomatic, but some may have mild polyuria and polydipsia. Contrary to expectation, the clinical spectrum of disease severity in female carriers does not correlate with the inactivation level of the normal X-chromosome (Satoh et al, 2008). Most of the remaining cases are due to changes in the gene for AQP2, which is present on chromosome 12. Both recessive and dominant forms of AQP2-related disease have been identified. Although most cases of autosomal recessive NDI occur in cases of consanguineous marriages, homozygous mutations have been documented in a child born to unrelated parents (Bircan et al, 2008). Other proteins such as AQP1 may also cause NDI.

The majority of cases of nephrogenic diabetes insipidus are diagnosed in the first year of life. **The characteristic features include massive polyuria, polydipsia, hypernatremia, and the inability to concentrate the urine due to a defect in the renal tubular response to vasopressin.** The most common signs and symptoms include vomiting, failure to thrive, fever, constipation, polydipsia that suppresses the appetite, dehydration, along with developmental delay and behavioral abnormalities. The water deprivation test secures the diagnosis by demonstrating urine osmolality (Uosm) (<200 mOsm/kg water) that remains below plasma osmolality (Posm) after dehydration *and* no change to either Uosm or Posm after ADH administration. When this test is inconclusive, the presence of normal plasma ADH levels after hypertonic saline administration distinguishes nephrogenic from central diabetes insipidus. The hypernatremia associated with NDI can cause failure to thrive and even intracranial calcifications (Bindu et al, 2007). However, the long-term neurocognitive outcome is surprisingly good (Hoekstra et al, 1996), probably because of parental diligence in ensuring adequate water intake.

Key Points: Renal Tubular Disorders

- Fanconi syndrome refers to a generalized dysfunction of the proximal tubule.
- Polyuria, polydipsia, and poor growth are common presenting complaints in children with tubular diseases.
- Type I (distal) RTA is due to disturbed management of H+ whereas type II RTA (proximal) is due to bicarbonate malabsorption.
- Type IV RTA is due to reduced aldosterone production or response and associated with hyperkalemia.
- Hypokalemia is common to both Bartter syndrome and types I and II RTA; however, Bartter syndrome is characterized by alkalosis.
- Nephrogenic diabetes insipidus presents as polyuria, polydipsia, hypernatremia, and an inability to concentrate urine and is managed by administration of free water.

The mainstay of treatment is provision of adequate free water with special attention to adjusting for fever and intercurrent illnesses. Second-line therapy is to modestly lower the solute load with avoidance of excessive protein and sodium intake. If these measures are ineffective at lowering the daily urine volume, then the use of diuretics such as hydrochlorothiazide alone or in combination with amiloride can improve quality of life (Knoers and Monnens, 1990; Kirchlechner et al, 1999). Nonspecific prostaglandin inhibitors such as ibuprofen or more selective cyclooxygenase-2 inhibitors also decrease solute free water excretion (Monn, 1981; Soylu et al, 2005). As children grow, management becomes a bit easier because their ability to express thirst and ensure access to free water becomes less problematic compared with infants. The urologic complications of hydroureteronephrosis, urinary retention, and nocturnal enuresis are related to the massive urinary flow rate.

UROLITHIASIS AND HYPERTENSION

Urolithiasis

Kidney stones (Fig. 112–3) have been considered primarily a health problem affecting middle-aged men between 20 to 50 years of age. In adults, kidney stones are not a cause of mortality but are associated with considerable morbidity and financial burden resulting from medical care costs and lost work productivity during peak employment years (Coe et al, 2005). In general there is consistent evidence of increasing prevalence of urolithiasis over the past 3 decades and the age at initial diagnosis has fallen (Sowers et al, 1998; Stamatelou et al, 2003; Lieske et al, 2006). This epidemiologic trend may vary by gender in certain geographic regions and has been attributed to dietary changes such as increased ingestion of fructose-containing beverages, increasing incidence of obesity, higher ambient temperatures due to global warming, and higher prevalence of urologic abnormalities (Taylor et al, 2005). For all of these reasons, urolithiasis often is seen as a rare childhood condition. However, recent single-center studies indicate **that the incidence of urolithiasis in children has nearly tripled in the past 10 years and that the problem can be manifest in the first decade of life** (VanDervoort et al, 2007).

The signs and symptoms of stone disease are less discrete in children compared with adults and include irritability, abdominal pain, vomiting, diarrhea, and hematuria. As children get older they are more likely to present with the classic picture of unilateral colicky pain and gross hematuria. The diagnosis of urolithiasis in children requires a high index of suspicion, especially in children with a positive family history.

The etiology of urolithiasis spans a spectrum from structural anomalies that interfere with regular drainage of the urinary tract and lead to urinary stasis to metabolic abnormalities that enhance the likelihood of crystal formation in the urine. Urologists play a more pivotal role in children with neuroanatomic defects such as posterior urethral valves or neurogenic bladder. **The most common factor leading to urolithiasis is hypercalciuria, which can be sporadic or familial.** Other factors that can cause stones due to excessive levels in the urine are oxalate, uric acid, and cystine. Hyperoxaluria can represent a rare genetic disorder in oxalate metabolism or be secondary to altered diet or gastrointestinal absorption of oxalate. Hyperuricosuria can be secondary to dietary factors, metabolic disease, or malignancy.

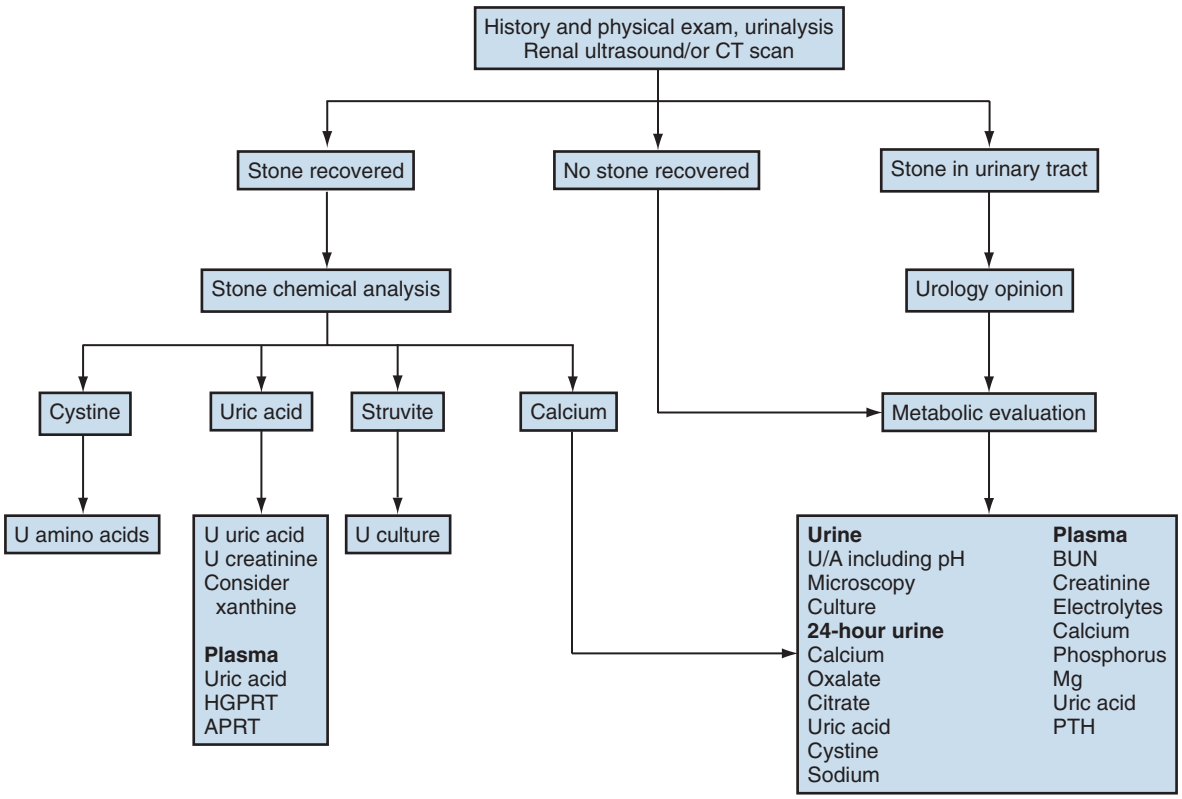

Figure 112–3. Algorithm for the evaluation of renal stones in children. APRT, adenine phosphoribosyl transferase; BUN, blood urea nitrogen; CT, computed tomography; HGPRT, hypoxanthine guanine phosphoribosyl transferase; PTH, parathyroid hormone; U/A, urinalysis.

Cystinuria is a genetic defect in dibasic amino acid transport. Among the factors that inhibit stone formation in the urine, the most prominent is citrate. Together with hypercalciuria, hypocitraturia is among two most common causes of urolithiasis in most studies of pediatric patients (VanDervoort et al, 2007). Recent studies suggest that these two factors are linked and that the urinary calcium-to-citrate ratio may be the most effect measurement to predict the occurrence of urolithiasis (Srivastava et al, 2009). Although some of the constituents of the urine can be quantitated based on spot urine with normalization to creatinine, most are best assessed based on 24-hour urine collections with reference to pediatric ranges for normal excretion of each solute.

The foundation of treatment is increased fluid intake, modest restriction in animal protein intake, and increased ingestion of fruits and vegetables. In patients with hypercalciuria, avoidance of extremes in calcium intake and use of thiazide diuretics can be implemented in patients with recurrent stone disease. Because patients with idiopathic calcium oxalate stones that may be linked to hypercalciuria demonstrate increased gastrointestinal absorption of oxalate, it may be beneficial to limit dietary intake of oxalate. Patients with hypocitraturia can be prescribed on citrate supplements. In certain high-risk populations, such as children with seizure disorders who are placed on a ketogenic diet, empirical treatment with potassium citrate without screening for hypercalciuria or hypocitraturia can achieve urinary alkalinization and reduce the incidence of kidney stones nearly sevenfold from 6.7% to 0.91% (McNally et al, 2009). Patients with hyperoxaluria can avoid excessive intake of high oxalate foods—chocolate, tea, rhubarb. However, there are data that these patients do not absorb oxalate excessively and only high oxalate-containing foods may need to be restricted (Sikora et al, 2008). A potentially exciting new development in the treatment of primary hyperoxaluria is the use of oxalate-utilizing bacteria *Oxalobacter formigenes* to diminish the gastrointestinal burden of oxalate (Kaufman et al, 2008). Long-term safety and efficacy studies are needed to validate the usefulness of this therapy. Those with cystinuria are placed on tiopronin and alkalinization of the urine to prevent recurrent stones. Extended follow-up is necessary for all children who have a kidney stone to monitor for recurrent stones that occur in 30% to 40% of patients and to assess the efficacy and need for any drug therapy. This is especially true in patients with an underlying genetic abnormality.

Hypertension

Blood pressure is influenced by a number of clinical factors, including age, gender, height, and patient posture. The range of normal values varies widely, and identification of hypertension requires consultation with reference tables of normative data collected in standardized pediatric cohorts (Feld and Corey, 2007). Based on the 2003 report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (Chobanian et al, 2003), which lowered the systolic and diastolic blood pressure levels required for a diagnosis of hypertension in adults, it became apparent that prevailing norms were unacceptable. Some blood pressure levels in pediatric patients that were considered normal for children adolescents were labeled prehypertensive or abnormal in adults. As a consequence, there was a reformulation of normal blood pressure readings to bring the definitions of hypertension in children and adolescents more in line with adult guidelines, as outlined in Table 112–3 (National High Blood Pressure Education Program…, 2004).

Table 112–3.
Pediatric Definitions of Hypertension

Normal	SBP or DBP < 90th percentile for age and gender
Prehypertensive	SBP or DBP from 90th to <95th percentile *or* BP > 120/80 even if <90th percentile up to 95th percentile
Stage 1 hypertension	SBP or DBP 95th to 99th percentile + 5 mm Hg
Stage 2 hypertension	SBP or DBP > 99th percentile + 5 mm Hg

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Measurement of blood pressure is not nearly as straightforward in infants and children as it is in adults. The child should be calm and sitting in a chair or a parent's lap with the arm in the right position. Older children should have their feet on the floor if possible. An appropriate size cuff that covers at least two thirds of the distance from the acromion to the olecranon should be applied to the right arm (Sala et al, 2005). Normative data for pediatric patients are based on auscultatory measurements. However, use of oscillometric devices is becoming more widespread in outpatient and emergency settings. In general, the two methods yield comparable values in children, with slightly lower systolic and slightly higher diastolic levels on oscillometric measurement.

The recommendation has been made to rely on 24-hour ambulatory blood pressure monitors (ABPMs) as the gold standard for the diagnosis of hypertension in children because the results of ABPM are more specific than home or clinic blood pressure measurements in hypertension diagnosis (Wuhl et al, 2004). There are normative data that facilitate the interpretation of 24-hour blood pressure monitoring for patients from ages 5 to 20 (Wuhl et al, 2002). In contrast to adults, for whom home blood pressure measurements are close to daytime ABPM, home measurements for pediatric patients are significantly lower than the results of 24-hour ABPM readings during waking hours (Stergiou et al, 2004). Additional benefits of ABPM include the ability to identify masked hypertension (high daytime ABPM but normal office blood pressure readings)—an entity that has the same prognosis as essential hypertension (Lurbe et al, 2005). In addition, ABPM in patients with secondary causes of hypertension including chronic kidney disease can be used to detect abnormalities in the circadian blood pressure rhythm with lack of a nocturnal dipping pattern (Seeman et al, 2005) and in blunting of ultradian rhythms that occur over intervals less than 24 hours (Wuhl et al, 2005).

There are data suggesting a trend toward rising blood pressure in children and adolescents during the past 2 decades related to an increased prevalence of childhood obesity (Munter et al, 2004; Robinson et al, 2004). A survey of blood pressure and lipid levels in 1717 eighth graders in Texas, California, and New York found that 24% had high blood pressure, a higher percentage than was seen in previous national surveys in which subjects were less overweight (Jago et al, 2006). However, a recent meta-analysis of 14 large population-based surveys of blood pressure conducted during the past few decades did not demonstrate an increase in blood pressure in children and adolescents despite the ongoing epidemic of pediatric obesity (Chiolero et al, 2007). Defining the epidemiology of hypertension in children is complicated by the observation that prehypertension and hypertension are frequently underdiagnosed in the pediatric population (Hansen et al, 2007). In a cohort study of 14,187 children and

adolescents aged 3 to 18 years who were observed at least three times for well-child care, only 26% of those with hypertension (n = 507) and 11% of those with prehypertension (n = 485) had the diagnosis documented in the electronic medical record. A large meta-analysis including data from diverse populations indicates that the strength of blood pressure tracking increases with baseline age, decreases with the duration of follow-up, and did not vary across ethnic groups (Chen and Wang, 2008). These findings indicate that although pediatric blood pressure levels do track into adulthood the correlation is not that high to preclude interventions designed to alter long-term outcomes. The role of low birth weight and reduced nephron number in the pathogenesis of essential hypertension is a contentious subject that is the focus of numerous conflicting studies (Huxley et al, 2002; Keller et al, 2003; Schreuder et al, 2007).

The secondary causes of hypertension can be divided into six categories:

1. Renal parenchymal diseases (e.g., reflux nephropathy, polycystic kidney disease, primary glomerulopathies, and obstructive uropathy)
2. Renal vascular diseases (e.g., fibromuscular dysplasia, neurofibromatosis)
3. Aortic coarctation
4. Endocrine disorders (e.g., hyperthyroidism, hyperaldosteronism)
5. Malignancy (e.g., Wilms tumor, neuroblastoma, pheochromocytoma)
6. Miscellaneous (e.g., drugs, immobilization, Guillain-Barré syndrome)

Although there are published reports that secondary disease is more common in pediatric patients, with more widespread measurement of blood pressure in routine clinical practice, most children and adolescents have primary or essential hypertension (National High Blood Pressure Education Program…, 2004).

The current recommended workup of a child with newly identified hypertension includes a complete serum biochemical panel, fasting lipid profile, urinalysis, renal ultrasonography, and an echocardiogram (National High Blood Pressure Education Program …, 2004, Nguyen et al, 2007). Use of a 24-hour ABPM is becoming more widespread and is likely to improve the accuracy and validity of hypertension assessment in children older than age 10. Additional testing including plasma renin activity, retinal examination, renal arteriography, serum cortisol, aldosterone, thyroid hormone levels, and urinary catecholamine excretion should be guided by the specific clinical circumstances in each case. A renal arteriogram is advised for patients with severe hypertension or in situations in which one drug cannot control the blood pressure because this test enables diagnosis and potential cure of the underlying renovascular cause for the hypertension (Shahdadpuri et al, 2000). However, the extensive list of tests outlined previously may not be cost effective. In a study of 200 children referred for outpatient evaluation of hypertension, only three tests yielded abnormal finding more than 10% of the time: ABPM, echocardiogram, and fasting lipid profile (Wiesen et al, 2008). This suggests that more extensive testing should be limited to those with more severe hypertension, clinical symptoms, or abnormalities in one of the three tests just listed.

The majority of pediatric patients in all ethnic groups, including whites and African-Americans, with an elevated blood pressure have essential hypertension. These patients are usually asymptomatic, have a positive family history of hypertension, tend to be obese, and are more prone to hypertensive responses to stressful events. In a study of 2816 young adults aged 20 to 35 who were not being treated with antihypertensive medications, every 10 mm Hg increment in blood pressure in response to video game and star tracing tasks was associated with a 24% increase risk of coronary artery calcification at follow-up (Matthews et al, 2006). Newly identified risk factors for essential hypertension in children and adolescents in addition to obesity (Munter et al, 2004; Robinson et al, 2004; Jago et al, 2006) include inactivity (Gidding et al, 2006), sleep apnea (Ievers-Landis and Redline, 2007), and neonatal nephrocalcinosis (Kist-van Holthe et al, 2007). Recent studies suggest that essential hypertension may not be a silent disease in pediatric patients. A survey of 409 children aged 7 to 18 with new-onset hypertension revealed that 64% of the patients reported various symptoms such as headaches, difficulty sleeping, and daytime tiredness compared with 26% of healthy normotensive controls (Croix and Feig, 2006). More serious target organ complications can also occur in this population. Children with uncontrolled essential hypertension experience cardiovascular load with resultant left ventricular hypertrophy in more than 40% of hypertensive children (Brady et al, 2008). The frequency of left ventricular hypertrophy is the justification for including echocardiograms as a standard part of the evaluation of a child with hypertension. Repeat imaging is advisable after 6 to 12 months to assess resolution of left ventricular hypertrophy with appropriate blood pressure management. Diastolic filling abnormalities were noted in 36% of patients (n = 55) with essential hypertension, changes that were more prominent in those with concentric hypertrophy (Border et al, 2007). Finally, subtle neurocognitive deficits such as reduced digit span, block design, and mathematics scores were documented in a cohort of 5077 children aged 6 to 16 who were included in the National Health and Nutrition Examination Survey III (Lande et al, 2003).

The treatment of acute severe hypertension usually requires parenteral therapy (Table 112–4). Current drug options include labetalol 0.25 to 0.5 mg/kg/dose or nicardipine 0.1 to 0.5 µg/kg/min. The goal of therapy is to lower the mean pressure by 20% (Calhoun and Oparil, 1990). Long-term management of severe hypertension can include drugs from various classes including diuretics, ACE inhibitors, angiotensin receptor blockers, calcium channel blockers, β-adrenergic blockers, and direct vasodilators. In response to the U.S. Food and Drug Administration Modernization Act of 1997 there are available data from controlled clinical trials involving children and adolescents for representative medications for most of the drug classes except diuretics and direct vasodilators (Flynn, 2003).

In patients with presumed essential hypertension, a trial of nonpharmacologic therapy including regular exercise, weight reduction, modest sodium restriction, smoking cessation, and relaxation/meditation techniques is warranted before resorting to drug treatment. The effectiveness of nonpharmacologic interventions should be reassessed after 3 to 6 months and

Table 112–4.

U.S. Food and Drug Administration–Approved Drugs for Use in Pediatric Patients

CLASS	DRUG
Angiotensin-converting enzyme inhibitors	Enalapril, lisinopril, ramipril
Angiotensin receptor blockers	Losartan, candesartan
Calcium channel blockers	Amlodipine
β-Adrenergic blockers	Metoprolol, bisoprolol

pharmacologic intervention should be instituted if normalization has not occurred by the end of the observation period (National High Blood Pressure Education Program …, 2004).

Key Points: Urolithiasis and Hypertension

- Renal stones may present in childhood as a manifestation of hypercalciuria or hypocitraturia but may be due to genetic disorders.
- Metabolic evaluation and treatment is warranted in children with nephrolithiasis.
- Proper technique, equipment, and patient cooperation are vital in measuring accurate blood pressure in children.
- Hypertension should be diagnosed using ambulatory blood pressure monitors and recently revised reference tables.
- Serum hormonal studies and angiography should be reserved for children with hypertension that is severe or fails to respond to medical therapy.
- Essential hypertension is most common and asymptomatic and related to obesity and inactivity.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is the new term that has been proposed to replace acute renal failure in patients with sudden decline in kidney function. It is preferred because it represents a less concrete nomenclature that allows coverage for the wide range in kidney damage and dysfunction that occur in clinical practice. In recognition of the numerous definitions that have employed in the past in studies of the epidemiology, cause, treatment, and outcome of AKI, new standards, called the RIFLE criteria (Risk, Injury, Failure, Loss, End-stage renal disease), have been adopted to classify AKI. These criteria incorporate changes in urine output and serum creatinine concentration over time in an integrated scheme to define risk, injury, and long-term damage in the spectrum of AKI.

AKI is characterized by a sudden reduction in GFR and the inability of the kidney to properly regulate fluids and electrolytes. Serum markers of renal function (BUN and creatinine) are elevated, although they may be insensitive measurements under several circumstances. **In children with normal renal function, GFR may fall by 50% before producing an increase in creatinine concentration; large changes in creatinine level are seen for small changes in GFR in children with chronic renal injury** (Doolan et al, 1962; Bennet and Porter, 1971). Creatinine levels also reflect the child's muscle mass whereas BUN is affected by hydration status and conditions that raise urea production (e.g., gastrointestinal bleeding, high protein intake) or lower urea production (e.g., severe liver disease, protein malnutrition).

The incidence of AKI ranges from 8% to 24% of neonates and is higher among hospitalized children, many with pre-existing kidney disease (Martin-Ancel et al, 1995; Mogal et al, 1998; Nolan and Anderson, 1998; Gouyon and Guignard, 2000). Genetic risks factors may predispose neonates to AKI such as polymorphisms of the ACE gene or the angiotensin receptor (Nobilis et al, 2001), tumor necrosis factor-α, interleukin (IL)-1β, IL-6, and IL-10 genes (Treszl et al, 2002). Certain causes of AKI have predilection for certain age groups, such as cortical necrosis and renal vein thrombosis in neonates, hemolytic uremic syndrome in young children, and rapidly progressive glomerulonephritis in older children.

Pathophysiology

The induction of and recovery from AKI is multifactorial, and some of the involved cellular and molecular mechanisms have been clarified. Early or mild hypoperfusion leads to activation of the adrenergic nerves causing diffuse vasoconstriction aimed at sustaining systemic blood pressure and perfusion. This compensatory response increases renal vascular resistance and decreases glomerular blood flow (Badr and Ichikawa, 1988; Tack and Perlman, 1988; Hricik and Dunn, 1990; van Bel, 1991; Schlondorff, 1993). When renal perfusion is compromised, renal vascular resistance decreases by afferent arteriolar vasodilation and the intrarenal production of prostaglandins (van Bel, 1991; Schlondorff, 1993). The renin-angiotensin-aldosterone axis is stimulated by hypovolemia and hypoperfusion: angiotensin II (AT2) production increases efferent arteriolar constriction, which in turn increases the glomerular filtration pressure (Steiner, 1979; Tucker and Blantz, 1983; Blantz, 1998) and also produces aldosterone, which stimulates salt and water reabsorption by the distal tubule. The cumulative affect is increased filtration fraction and maintenance of GFR. Administering ACE inhibitors under these conditions can precipitate AKI. Persistent or progressive hypoperfusion overwhelms the compensatory mechanisms, leading to excessive vasoconstriction, decreased glomerular blood flow, and decreased GFR (Badr and Ichikawa, 1988). The role of the renin-angiotensin system in AKI is uncertain because injury can be reduced by diuresis with mannitol or loop diuretics (neither affects intrarenal renin) or in animals immunized against renin-angiotensin, treated with ACE inhibitors, or infused with an AT2 antagonist.

ATP levels are depleted by ischemia in vivo (Karlowicz and Adelman, 1995), and inhibition of ATP production causes cellular injury in vitro. The medullary thick ascending limb (Brezis, 1984) and the straight segment of the proximal tubule (Donohoe et al, 1978) are susceptible to hypoxic injury. The marks of hypoxic injury can be averted or reversed by increasing oxygen delivery (Brezis and Rosen, 1995). Early ischemia leads to brush border sloughing; and further ischemia leads to either lethal (denuding of basement membrane epithelium) or sublethal injuries (swelling, cellular morphology disruption, mitochondrial condensation) with subsequent intratubular obstruction and tubular fluid backleak (Donohoe et al, 1978; Myers et al, 1979) largely by the loss of integrins (Gailit, 1993). Reactive oxygen molecules (hydroxyl radical, superoxide anion) play a role in local postischemia reperfusion injury (Andreoli, 1991) whereas hypochlorous acid and hydrogen peroxide can cause distant injury owing to their long half-lives and ability to cross cell membranes (McKelvey et al, 1988). These reactive molecules can cause functional protein loss by amino acid oxidation and membrane damage by lipid and lipoprotein peroxidation. Elevated intracellular calcium levels may be primary in cell injury or secondary to cell death (Weinberg, 1991). A role for apoptosis is unclear, although endonuclease activation has been identified in hypoxic and ischemic tubules (Liberthal and Levine, 1996). Cell membrane disruption occurs from the detergent affect of the degradative products, or endogenous phospholipase activation and ATP depletion may limit new phospholipids production (Humes et al, 1989; Chen et al, 1995). Redistribution of membrane lipids and proteins alters cell polarity and impairs certain cell functions (Molitoris, 1991).

Several factors influence recovery from AKI. In the first few minutes of reperfusion, ATP levels regain 50% to 70% of their loss depending on ischemia time and the pool of available adenine nucleotides (Weinberg, 1991). Over the next several hours ATP is produced from salvage pathways and from precursors provided

during reperfusion (also dependent on the ischemia time (Donohoe et al, 1978; Molitoris, 1991). ATP-$MgCl_2$ (stimulates purine synthesis) (Gaudio et al, 1982) and thyroxine (stabilizes mitochondrial adenine nucleotide transporter) (Boystun, 1995) hasten ATP recovery. Atrial natriuretic factors (Nakamoto et al, 1987) increase afferent arterial dilation and efferent arterial constriction, promoting salt and water excretion, renal blood flow, and GFR. Injured tubule cells regain polarity, perhaps through the 70-kD heat shock proteins (Emami et al, 1991). Postischemic infusion of several growth factors improves GFR, diminishes morphologic injury, increases thymidine incorporation into DNA, and increases survival (Fine et al, 1992).

Etiology

The classification of AKI into prerenal, renal, and postrenal causes with subsequent division of renal into glomerular and tubular causes is still broadly applicable to children (Table 112–5). Glomerular causes of kidney injury have key clinical signs and symptoms such as gross hematuria, hypertension, and edema that facilitate recognition and treatment.

Table 112–5.
Causes of Acute Renal Injury

Prerenal Injury
Decreased true intravascular volume
- Gastrointestinal losses
- Salt-wasting disease: renal or adrenal
- Diabetes insipidus: central or nephrogenic
- Third-space losses: sepsis, trauma, nephrotic syndrome

Decreased effective intravascular volume
- Congestive heart injury

Intrinsic Renal Disease
Acute tubular necrosis
- Ischemic-hypoxic insults
- Drugs: aminoglycosides, intravenous contrast, cisplatin, nonsteroidal anti-inflammatory drugs
- Exogenous toxins: ethylene glycol, methanol
- Endogenous toxins: myoglobin and hemoglobin

Uric acid nephropathy and tumor lysis syndrome
Interstitial nephritis
- Drug induced: antibiotics, anticonvulsants
- Idiopathic

Glomerulonephritis
- Postinfectious glomerulonephritis
- Membranoproliferative glomerulonephritis
- Systemic lupus erythematosus nephritis
- Chronic infection
- Henoch-Schönlein purpura
- Anti–glomerular basement membrane glomerulonephritis
- Idiopathic rapidly progressive glomerulonephritis

Vascular lesions
- Hemolytic uremic syndrome
- Cortical necrosis
- Renal artery thrombosis
- Renal venous thrombosis

Infectious causes
- Sepsis
- Pyelonephritis

Obstructive Uropathy
Obstruction in a solitary kidney
Bilateral ureteral obstruction
Urethral obstruction

Postrenal injury can generally be identified by history and physical examination, and the diagnosis is readily confirmed by ultrasonography in most cases. Urinary parameters are frequently used to help distinguish the category of AKI (Table 112–6).

Prerenal Injury

Prerenal causes are the most common etiology of AKI (60%). Hypoperfusion results from volume contraction after hemorrhage or dehydration from diabetes insipidus, gastrointestinal losses, salt-wasting diseases, increased insensible losses, or reduced effective blood volume (e.g., congestive heart injury, cardiac tamponade, hepatorenal syndrome). Because these kidneys are intrinsically normal, restoring renal perfusion restores renal function.

The tubules respond appropriately to renal hypoperfusion by conserving sodium and water. Thus urine osmolality is high (>400-500 mOsm/L), urine sodium is low (<10-20 mEq/L), and FE_{Na} is low (less than 1%). Infants are vulnerable to prerenal AKI because immature kidneys cannot maximally concentrate urine or conserve salt and water and their large body surface area increases insensible water loss. Neonates with immature tubules and children with pre-existing renal disease may have urinary indices suggestive of acute tubular necrosis (ATN). Nonoliguric AKI in children with concentrating defects make salt and water loss difficult to recognize. During polyuria, other indicators of free-water loss (e.g., weight loss, increased BUN, hypernatremia, increased hematocrit) should be used.

Intrinsic Renal Disease

The distinction between prerenal and true renal injury remains clinically challenging. Prerenal azotemia is a functional state in which there is reduced renal and glomerular hypoperfusion and which can be readily reversed by restoration of blood pressure and/or intravascular volume. As mentioned earlier, reliance on serum BUN and creatinine may be inaccurate and reliance on changes in serum creatinine may delay diagnosis and implementation of effective therapy. A number of new urinary biomarkers are

Table 112–6.
Urinary Values That Distinguish Categories of Acute Renal Injury

TEST	PRERENAL	INTRINSIC RENAL	POSTRENAL
BUN/Cr ratio	>20	10-20	10-20
Urine specific gravity	>1.020	~1.010	<1.010
Urine osmolality	>350	~300	~300
Urine sodium	<20	>30	>40
FE_{Na}	<1%	>2%	>3%
Urine microscopy	Normal	ATN: dark granular casts, renal epithelial cells/casts	Normal
	Hyaline casts	GN: RBCs, RBC casts, WBCs, proteinuria	Hyaline casts
		AIN: urine eosinophilia, WBCs, hyaline casts	

AIN, acute interstitial nephritis; ATN, acute tubular necrosis; BUN, blood urea nitrogen; Cr, creatinine; FE_{Na}, fractional excretion of sodium; GN, glomerulonephritis; RBCs, red blood cells; WBCs, white blood cells.

under investigation for early identification of AKI. These include neutrophil gelatinase-associated lipocalcin (NGAL), IL-18, and kidney injury molecule-1 (KIM-1). Of these three candidate biomarkers NGAL appears the most promising. A commercial kit is available to rapidly perform this measurement in urine samples, and it is being studied in clinical trials in wide variety of age groups and clinical settings to validate the diagnostic accuracy of the measurement. It is possible that optimal diagnosis of AKI will rely on dipstick testing with reagents to detect a panel of biomarkers.

Renal artery thrombosis is associated with use of an umbilical artery line and a patent ductus arteriosus. Infants present with hypertension, hematuria, and thrombocytopenia. AKI may occur in cases of a solitary kidney or massive thromboemboli (Bauer et al, 1975). The initial ultrasound image may appear normal or have minor abnormalities, whereas little or no blood flow is seen on a renal scan. Treatment aims at limiting clot extension by removing the umbilical catheter; anticoagulant or fibrinolytic therapy can be considered, particularly if the clot is large (Ellis et al, 1997).

Renal venous thrombosis (RVT) is more common and occurs after sepsis, perinatal asphyxia, hypovolemia, shock, maternal diabetes, or polycythemia in infants and from severe dehydration or hypercoagulable states in older children. RVT presents as gross hematuria, thrombocytopenia, hypertension, decreased urine output, and elevated BUN and creatinine levels. Ultrasonography reveals an enlarged kidney, and the renal scan shows reduced blood flow and function. Thrombectomy is rarely indicated or possible.

Acute glomerulonephritis is more common in schoolaged children who present with edema, hypertension, and hematuria. Postinfectious glomerulonephritis is most common and associated with mild to moderate AKI whereas other glomerulonephritides (Goodpasture syndrome) often present as AKI. Active lesions in biopsy specimens portend functional recovery. Immunosuppressive therapy might reverse renal injury (Michel and Kelly, 1998).

ATN can evolve from prerenal injury. The urinalysis may demonstrate low-grade proteinuria and granular casts, whereas urine indices of tubular function demonstrate an inability to conserve sodium and water. Serum creatinine concentration usually increases by 0.5 to 1.0 mg/dL/day. Ultrasonography reveals normal-sized kidneys with loss of corticomedullary differentiation, whereas the renal scan shows normal or slightly decreased renal blood flow with delayed tracer uptake in the parenchyma and absence of excretion in the collecting system. The prognosis of ATN is good except when the insult causes vasculature injury, microthrombi, and cortical necrosis. The mortality and morbidity is poorer in children with multiorgan injury (Stapleton et al, 1987; Bunchman et al, 2001). In those who recover, renal function returns to normal within days to weeks. There may be a diuretic phase when the recovering tubules cannot appropriately reabsorb solute and water. Fluid and electrolyte balance is important to promote recovery; however, a period of dialysis is often required. Children who do recover may later develop chronic renal disease and ESRD.

Several drugs are associated with AKI. Aminoglycoside nephrotoxicity, perhaps related to lysosomal dysfunction of proximal tubules, is related to drug dosing, therapy duration, and pretreatment renal function. Children present with nonoliguric AKI with minimal urinary abnormalities. Although the course is reversible, the serum creatinine level may rise for several days after drug discontinuation owing to ongoing tubular injury from high parenchymal levels. **Once-daily dosing of aminoglycosides decreases the incidence of nephrotoxicity without compromising efficacy** (Barza et al, 1996). Intravascular contrast media, particularly in patients with dehydration, diabetes, or preexisting renal disease may precipitate AKI. The risk can be reduced by using nonionic, low-osmolality (Rudnick et al, 1995) or isoosmolar, dimeric nonionic contrast media (Aspelin et al, 2003).

Nephrotoxic agents, exogenous or endogenous, may induce AKI. Ingestion of compounds (ethylene glycol, methanol) in their native state or after metabolism to breakdown products may be nephrotoxic. Hemolysis and rhabdomyolysis can induce tubular injury due to vasoconstriction, intra-tubular pigment precipitation, and/or heme protein–induced oxidant stress (Andreoli, 1991). Renal injury can be lessened by prompt fluid resuscitation followed by diuresis (mannitol or loop diuretics) to increase urine flow that prevents intratubular precipitation of heme proteins and by urine alkalization to increase hemoglobin and myoglobin solubility (Vanholder et al, 2000).

Malignancy or its treatment may induce AKI. Renal function can be affected by parenchymal infiltration of leukemic or lymphomatous cells or by uric acid crystal precipitation in the tubules, obstructing urine flow, or in the microvasculature, obstructing renal blood flow (Stapleton et al, 1988). More commonly, AKI results from tumor lysis syndrome associated with chemotherapy (Jones et al, 1995). Elevated levels of serum potassium, BUN, purine metabolite products, and phosphorus (with hypocalcemia) may require dialysis. Allopurinol limits uric acid excretion but increases xanthine (Andreoli et al, 1986) and other less soluble uric acid precursors. AKI is transient with expected full recovery of renal function.

Acute interstitial nephritis, perhaps from a hypersensitivity reaction to tubular basement membrane antigens, results from a drug reaction (e.g., methicillin, cimetidine, sulfonamides, rifampin, nonsteroidal anti-inflammatory drugs) or may be idiopathic. Children present with AKI, rash, fever, arthralgias, eosinophilia, and pyuria with or without eosinophiluria (Hawkins et al, 1989). The ultrasound image shows large echogenic kidneys, and the renal biopsy demonstrates an eosinophilic interstitial infiltrate. Treatment includes drug discontinuation and corticosteroids.

Postrenal Injury

Although urinary tract obstruction rarely causes AKI, children with chronic obstructive uropathies are vulnerable by either hypoxic-ischemic or nephrotoxic insults.

Management

Effective treatment of AKI, without dialysis, requires restoring adequate renal blood flow, avoiding agents that are nephrotoxic or interfere with renal compensatory mechanisms, and maximizing renal perfusion before using such agents. Increasing urine output makes fluid management easier, aids in maintaining electrolyte balance, and simplifies addressing nutritional needs.

Several vasodilatory agents have been used to maintain renal blood flow in AKI. "Renal-dose" dopamine (0.5 to 5.0 μg/kg/min) can increase renal blood flow and improve urine output by promoting natriuresis but may not decrease the need for dialysis or increase survival (Chertow et al, 1996; Denton et al, 1996). Fenoldopam mesylate (a selective dopamine-1 receptor agonist) may improve renal hemodynamics in animals and increase renal perfusion, urine flow, and sodium and potassium excretion in hypoxemic adults (Murphy et al, 2001). Atrial natriuretic peptide increases GFR by dilating afferent arterioles and constricting

efferent arterioles (Rahman et al, 1994) but failed to improve the overall dialysis-free survival rate in adults (Allgren et al, 1997).

Diuretic agents can stimulate urine output and allow safer administration of medications and nutrition; however, **converting oliguria to nonoliguria does not increase GFR or alter the course of AKI** (Shilliday et al, 1997; Kellum, 1998). Diuresis may exacerbate AKI in prerenal or contrast-induced azotemia. Mannitol (0.5 to 1.0 g/kg) may increase intratubular urine flow, limiting tubular obstruction. Furosemide (1 to 5 mg/kg/dose) acts similarly but also inhibits Na^+,K^+-ATPase to reduce oxygen consumption in damaged tubules. Loop diuretics do not alter the need for dialysis or mortality (Kellum, 1998), and high-dose furosemide can be ototoxic.

AKI may present as hypovolemia, euvolemia, or hypervolemia. Oliguria or anuria commonly presents as hypervolemia and requires fluid restriction and/or acute fluid removal. Euvolemia can be maintained by correcting insensible water losses (skin, respiratory and gastrointestinal tracts) and excess water loss from diarrhea or fever. Urine losses may be replaced milliliter for milliliter with the appropriate fluid (assessed by urine electrolytes). Nonoliguric renal injury is commonly associated with nephrotoxic insult and carries less morbidity and mortality than oliguric AKI (Mogal et al, 1998).

Hypertension is related to fluid overload and/or to increased vascular tone. Diuretic agents should be used first in cases of volume overload, but dialysis or hemofiltration may be necessary. Antihypertensive agents may be used in the form of intravenous sodium nitroprusside, labetalol, diazoxide, enalapril, and nicardipine for severe hypertension and intravenous hydralazine or sublingual nifedipine for less severe cases. Once the blood pressure is controlled, oral long-acting agents can be used.

Malnutrition associated with catabolism delays recovery, but studies in children supporting an improved outcome with nutritional supplementation are lacking. Dilute formula of increasing concentration is given to maintain calories. Hyperalimentation is used if enteral feeds are not possible. Children with oliguria/anuria may require dialysis because fluid balance may not be achievable while providing calories.

The purpose of acute renal replacement therapy is to remove endogenous and exogenous toxins and to maintain fluid, electrolyte, and acid-base balance until renal function returns. Renal replacement therapy may be provided by peritoneal dialysis, intermittent hemodialysis, or continuous renal replacement therapy

Sodium Disturbances

Mild hyponatremia may be due to dehydration, but fluid overload with dilutional hyponatremia is more common. If the serum sodium level exceeds 120 mEq/L, fluid restriction or dialytic water removal will increase the sodium level. When the serum sodium level is below 120 mEq/L, the infusion of hypertonic saline over several hours to raise the sodium level to 125 mEq/L reduces the risk of seizures.

Potassium Disturbances

Hyperkalemia is common and potentially life threatening by inducing arrhythmias. Serum potassium levels may increase owing to decreased filtration, impaired tubular secretion, acidosis-induced shifting to the extracellular compartment, and release of intracellular potassium during catabolic state. Each 0.1-unit reduction in arterial pH increases the serum potassium level by 0.3 mEq/L. The serum potassium level may be falsely elevated by hemolysis (during the blood draw) or an increased white blood cell (WBC) or platelet count (Rodriguez-Soriano, 1995). Hyperkalemia depolarizes the cardiac conduction pathway that is potentiated by hypocalcemia. The electrocardiographic findings include tall, peaked T waves followed by PR interval prolongation, flattening of P waves, and widening of the QRS complex with ventricular tachycardia and fibrillation possible. Symptoms include malaise, nausea, and progressive muscle weakness. Therapy options include intravenous calcium (stabilizes cell membranes reducing the arrhythmia risk without changing serum potassium levels), glucose and insulin or bicarbonate (shifts potassium into the intracellular space), or enteric exchange resins (sodium polystyrene sulfonate [Kayexalate]).

Acid-Base Disturbances

Acidosis is related to increased metabolic rate. Hyperventilation may partially correct the acidosis unless the child is obtunded, in which case the acidosis may become severe. Severe acidosis can be treated with intravenous or oral sodium bicarbonate or citrate solutions, but dialysis may be required. Balancing the acidosis may decrease ionized calcium levels, precipitating tetany and/or seizures; the total and ionized calcium levels must be known before starting therapy.

Calcium and Phosphate Disturbances

Kidneys excrete large amounts of ingested phosphorus, hence dietary restriction should be started and oral calcium compounds that bind phosphorus (preventing gastrointestinal absorption) may be added. Dialysis effectively removes phosphorus. Hypocalcemia may result from hyperphosphatemia, inadequate renal production of 1,25-dihydroxyvitamin D impairing adequate gastrointestinal calcium absorption, and skeletal resistance to parathyroid hormone. When severe, hypocalcemia should be treated with 10% calcium gluconate with continuous electrocardiographic monitoring. Less severe cases may be treated by oral calcium salts.

Outcome and Prognosis

Simple AKI without other underlying illness carries a 7% to 23% mortality rate, whereas children with AKI as a component of multisystemic injury have a much higher mortality rate (Goldstein, 2001) related to associated conditions. Recovery of renal function depends on the underlying cause. Children with acute interstitial nephritis and ATN typically recover normal renal function and are at low risk for any late complications. Children with substantial nephron loss or rapidly progressive glomerulonephritis are at risk for later developing renal injury. Hyperfiltration of the remnant nephrons may eventually lead to progressive glomerulosclerosis (Brenner et al, 1996). **Life-long renal function monitoring,**

Key Points: Acute Kidney Injury

- Serum BUN and creatinine may be insensitive markers of AKI.
- AKI reflects the kidneys' inability to regulate fluids and electrolytes in response to a sudden drop in GFR.
- Aminoglycoside nephrotoxicity can be reduced by once-daily dosing schemes.
- Effective treatment of AKI requires restoring renal blood flow, correcting fluid, electrolyte, and acid-base disturbances, and avoiding further insults. Dialysis is used as needed.
- Substantial nephron loss during AKI warrants life-long monitoring for progression to chronic renal disease.

blood pressure monitoring, and urinalysis in these patients is necessary to detect the harbingers of renal injury (i.e., hypertension, proteinuria, and eventually elevated BUN and creatinine levels).

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) refers to a state of irreversible kidney damage that may remain stable or progress to ESRD, at which point renal replacement (dialysis or transplantation) is required. Children account for about 1% of the total ESRD population in the United States (U.S. Renal Data System, 2008). The causes of CKD in pediatric patients are fairly evenly divided between congenital/hereditary and acquired causes. The exact percentages vary depending on the country of origin for the registry-based data of children with renal disease. In the very young child, congenital anomalies are the most common cause (North American Pediatric Renal Trials and Collaborative Studies, 2008; U.S. Renal Data System, 2008) whereas glomerulopathies are more common in older children (Foreman, 1988). Gender is a factor only in obstructive uropathy (more common in boys) and reflux nephropathy (more common in girls).

The classification system devised by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) has been widely used since 2002 (Table 112–7) (National Kidney Foundation, 2001). The system is based on renal function in children older than the age of 2 years and with at least 3 months of kidney disease. CKD is considered present when the GFR falls below 60 mL/min/1.73 m^2. Stages 1 and 2 require evidence of kidney damage to exclude children with reduced GFR due to nonrenal causes (e.g., solitary kidneys, malnutrition). Kidney damage is defined as structural (on biopsy) or functional (e.g., proteinuria, hypertension, or abnormal imaging).

GFR measurement requires quantification of creatinine from timed urine collection or can be estimated by the Schwartz formula. Timed urine collection from children can be unreliable and inaccurate, especially in incontinent children. Factors that affect GFR include age, gender, and body size. GFR matures over the first 2 years of life after correction for 1.73 m^2 body surface area (Heilbron et al, 1991). GFR may be reliably calculated by the Schwartz equation:

$$\text{GFR (mL/min/1.73 m}^2) = 0.413 \times \text{height (cm)/serum Cr (mg/dL)}.$$

This latest iteration of the Schwartz formula differs from the prior one in that a single constant value for all ages has been instituted rather than age-based constants (Schwartz et al, 2009).

Table 112–7.

Classification of Chronic Kidney Disease for Children Older than Age 2 Years

STAGE	DEFINITION	GFR (mL/min/1.73 m^2)
1	Normal or ↓ GFR (with kidney damage)	≥90
2	Mild ↓ GFR (with kidney damage)	60-89
3	Moderate ↓ GFR	30-59
4	Severe ↓ GFR	15-29
5	Kidney failure	<15 or dialysis

GFR, glomerular filtration rate.

The long-term outcome for preservation of kidney function is related to the extent of in-utero damage to the kidney. Urologic procedures are important to ensure regular voiding, adequate emptying of the urinary tract with as little manipulation as possible, and prevention of urinary tract infections. However, surgery does not materially influence the time when patients reach stage 5, that is, a GFR less than 15 mL/min/1.73 m^2.

Early detection of renal disease (with prenatal ultrasonography or determination of microalbuminuria) and treatment of the effects of CKD including proteinuria (with an ACE inhibitor or angiotensin type 1 receptor antagonist), hypertension, anemia, malnutrition, electrolyte and acid-base disturbances, and renal osteodystrophy may delay CKD progression (Wuhl and Schaefer, 2008). Practically, most patients present while in the throes of renal disease and treatment is aimed at staving off progression to glomerulosclerosis. Reversing renal injury requires shifting the balance of synthesis/degradation; however, new glomeruli cannot be generated after term in humans. High doses of an ACE inhibitor or angiotensin type 1 receptor antagonist regress existing glomerulosclerosis by decreased extracellular matrix synthesis with decreased transforming growth factor-β and increased extracellular matrix degradation with a decrease of plasminogen activator inhibitor type 1 (Fogo, 2001). A low-protein diet and ACE inhibitor attenuated glomerulosclerosis in rats (Marinides et al, 1990).

Sodium Disturbances

Children with congenital anomalies (e.g., cystic dysplasia, obstructive uropathy, cystinosis) tend to have dehydration and need to have sodium and water losses corrected (Rodriguez-Soriano et al, 1986; Parekh et al, 2001). In contrast, the sodium and fluid retention associated with acquired chronic glomerulonephritis or nephrotic syndrome is treated by restricting dietary sodium and fluid and administering loop diuretics (Rees et al, 2007).

Potassium Disturbances

Hypokalemia occurs in potassium-wasting tubular diseases (e.g., cystinosis, Fanconi syndrome, Bartter syndrome) or as a side effect of thiazide or loop diuretics and can be managed by providing oral potassium. Hyperkalemia may occur as the kidney inadequately excretes potassium; treatment starts with dietary potassium restriction, correction of acidosis, and discontinuation of ACE inhibitors or angiotensin receptor–blocking agents. Managing severe hyperkalemia is discussed in the section on acute renal failure.

Acid-Base Disturbances

Progressive metabolic acidosis is common among children with CKD because the kidneys cannot adequately excrete acid produced by cellular metabolism and growth and reabsorb bicarbonate by renal tubules. In CKD stages 3 and 4, an anion-gap acidosis results from reduced excretion of inorganic (e.g., sulfates, phosphates) and organic acids. A non–anion gap acidosis occurs with tubular bicarbonate loss from tubular injury or from RTA. Uncorrected metabolic acidosis retards linear growth (Wallia et al, 1986; Chiu et al, 2009) because bone is used to buffer the excess hydrogen ions (Salusky et al, 2004). The acidosis can often be managed with oral alkaline agents (e.g., sodium bicarbonate, citrate, or acetate) (National Kidney Foundation, 2000; Chiu et al, 2009).

Renal Osteodystrophy

Rickets, osteopenia, and secondary hyperparathyroidism are bone diseases related to CKD known as renal osteodystrophy, a disorder that can lead to linear growth failure, avascular necrosis, skeletal

fractures, and deformities. The pathophysiology starts with decreased renal synthesis of calcitriol (1,25-dihydroxyvitamin D), which reduces calcium absorption in the gut, causing hypocalcemia and secondary hyperparathyroidism aimed at replacing serum calcium. Vitamin D deficiency reduces available substrate for calcitriol synthesis (National Kidney Foundation, 2005). Hyperphosphatemia from poor renal clearance exacerbates hypocalcemia and secondary hyperparathyroidism, stimulating fibroblast growth factor production (Levin et al, 2007), which further suppresses renal calcitriol production (Gutierrez et al, 2005). The treatment of osteodystrophy includes raising serum parathyroid hormone levels with active vitamin D sterol administration (calcitriol or paracalcitol) and dietary phosphate restriction and administration of calcium-based or sevelamer-based phosphate binders (Coladonato, 2005; National Kidney Foundation, 2005) to reduce hyperphosphatemia. Aluminum salts are no longer used because of their toxicity (Andreoli et al, 1984).

Nutrition and Growth

Nutrition is often impaired (Martin, 1973) owing to poor appetite and limited food options (e.g., sodium, potassium, and phosphorus restrictions). The management of these children includes provision of adequate calories and protein to support growth without exacerbating azotemia. Caloric intake should provide at least the recommended daily recommended intake for age (Rees and Shaw, 2007). However, if insufficient caloric intake affects the child's height and weight, specially formulated supplements should be provided. Most children can be fed by mouth, and reliance on enteral tube feedings should be restricted to infants and children who cannot tolerate oral feeding. Nocturnal infusion of formula can supplement caloric intake when oral intake of nutrients during the day is insufficient. **Although accelerated progression of renal failure may occur with increased protein intake** (Meyer et al, 1987), **limiting dietary protein intake does not prevent CKD progression in children; proteinuria and hypertension are more reliable predictors of progression** (Uauy et al, 1994; Wingen et al, 1997). Peritoneal dialysis clears protein in the dialysate; these children require increased protein intake. Growth failure and short stature from acidosis, renal osteodystrophy, and growth hormone resistance (Kiepe et al, 2001; Tonshoff et al, 1997) may occur despite optimal nutrition. Those children who fail to grow despite provision of adequate calories will double their growth rate if placed on recombinant human growth hormone. The dosage needs to be higher than in children with normal kidney function who are being treated for short stature. This reflects relative resistance to recombinant human growth hormone in children with CKD (Fine et al, 1994).

Anemia

Anemia is nearly universal in children with CKD and largely results from reduced renal production of erythropoietin and/or iron deficiency (McGonigle et al, 1984; Koshy and Geary, 2008). The evaluation includes serum measurements of hemoglobin, hematocrit, reticulocyte count, and serum iron studies (e.g., serum iron, ferritin, transferrin or total iron-binding capacity, and percent transferrin saturation). Treatment includes the subcutaneous administration of erythrocyte-stimulating agents such as recombinant erythropoietin. The frequency of injections can be reduced by administering glycosylated forms of erythropoietin that have a prolonged half-life and an extended duration of action (Warady, 2006). A poor therapeutic response may reflect iron deficiency, which can be supplemented orally (National Kidney Foundation, 2006b).

Hypertension

Hypertension is an independent predictor for CKD progression (Wingen et al, 1997; Mitsnefes, 2003; Wuhl and Schaefer, 2008) and blood pressure should be maintained below the 90th percentile for age, gender, and height. Hypertension from fluid overload can be treated with dietary sodium and fluid restriction plus a loop diuretic or vasodilator such as a calcium channel blocker (e.g., nifedipine, amlodipine). Second-line agents include β-adrenergic blockers (e.g., propranolol, atenolol) and central-acting agents (e.g., clonidine). Renin-mediated hypertension is best treated with an ACE inhibitor (e.g., captopril, enalapril, lisinopril, ramipril) or angiotensin type 1 receptor antagonist (e.g., losartan, candesartan, valsartan). However, these agents may induce hyperkalemia and worsen renal function in CKD stages 4 and 5. Antihypertensive agents preserve glomerular function and structure by reducing systemic blood pressure and other nonhemodynamic effects (Dworkin, 1991; Fogo and Kon, 1996). ACE inhibitors reduce glomerular pressure, halting glomerular destruction in animals (Kasiske, 1993), and maintain normal GFR and decrease proteinuria in normotensive human diabetics (Marre et al, 1987; Mathiesen et al, 1991). Either ACE inhibitors or angiotensin type 1 receptor antagonists retard progression in patients with diabetic nephropathy and hypertension (Lewis et al, 1993, 2001; Brenner et al, 2001). Calcium antagonists are protective in animal models of diabetes, renal ablation, and hypertension (Dworkin, 1991) owing to afferent arteriole vasodilation, augmenting immunosuppression and antiproliferative effects (Cianciaruso, 1994). Combining ACE inhibitors and calcium channel blockers may be synergistic by decreasing both angiotensin II and calcium-mediated effector mechanisms linked to vascular injury (Lüscher et al, 1995).

Uremia

Uremic symptoms (e.g., bleeding, pericarditis, encephalopathy) are uncommon until CKD stage 4. Acquired platelet dysfunction

Key Points: Chronic Kidney Disease

- The staging system for CKD applies to children older than age 2 years and with reduced GFR from renal causes.
- Management principles includes electrolyte and acid-base balance, calcium homeostasis to avoid osteodystrophy, proper nutrition to foster growth, hemoglobin maintenance, and treatment of hypertension.
- Limiting proteinuria can be protective against CKD progression when induced by ACE inhibitors or angiotensin type 1 receptor antagonists but not by dietary protein restriction.
- Peritoneal dialysis is the preferred mode of renal replacement therapy in children because of its reliability, convenience, and efficacy.
- Peritonitis, the most common complication of peritoneal dialysis, is diagnosed by finding more than 100 WBCs/mm^3 and 50% neutrophils in the effluent and is treated by intraperitoneal administration of antibiotics.
- Omentectomy is performed by many to avoid occlusion and possible peritoneal dialysis catheter removal.

leads to prolonged bleeding (Boccardo, 2004). Pericarditis occurs only in undialyzed or insufficiently dialyzed stage 5 patients (Renfrew et al, 1980; Alpert and Ravenscraft, 2003). The signs and symptoms of uremic encephalopathy may be subtle (poor school performance) or present as obtundation and seizures (Lawry et al, 1994). All children, including infants and young children, should be assessed regularly.

RENAL REPLACEMENT THERAPY

In certain circumstances renal insufficiency is so severe that renal replacement is needed to sustain life processes or to clear accumulated electrolytes that pose a risk to the patient, such as acidosis and hyperkalemia. The options for these children include peritoneal dialysis, hemodialysis, and renal transplantation. Each modality has its indications and can be effective in meeting these goals. Of course, each modality similarly has its associated complications and impact on quality of life.

Peritoneal Dialysis

The options for managing ESRD are renal transplantation, peritoneal dialysis (PD), or hemodialysis (HD). In 1918, Blackfan and Maxcy described successful intraperitoneal injection of saline in dehydrated infants. Subsequently, PD evolved as the preferred mode of renal replacement therapy in children with the development of disposable nylon catheters (Maxwell et al, 1959), "permanent" catheters (Tenckhoff et al, 1966), and automated dialysate delivery systems (Boen et al, 1964). In the most recent report from the North American Pediatric Renal Trials and Collaborative Studies (2008), the first treatment among children with ESRD was home PD (50%), whereas 25% underwent pre-emptive transplantation 25% began chronic HD.

PD can be performed in any child with an intact peritoneal cavity allowing diffusion (e.g., movement of solutes down a concentration gradient) and convection (e.g., transport of a fluid flux largely determined by the ultrafiltration rate) to occur. PD is preferred over HD in the first few days of life (Neu et al, 2002) and may be done by manual fluid exchange or with an automatic cycler. In acute renal failure, PD effectively clears rapidly rising levels of potassium, phosphate, and other solutes. In children with ESRD, PD should be started when the creatinine clearance falls below 14 mL/min/1.73 m^2 regardless of serum BUN or creatinine levels. **The only absolute contraindication to PD is an inadequate peritoneal cavity** (e.g., omphalocele, diaphragmatic hernia, gastroschisis). PD can be performed after abdominal surgery in the absence of draining wounds, in children with vesicostomies, urinary diversions, or other stomas, (Alexander and Lubischer, 1982; Alexander, 1983; Flynn, 2002) and after renal transplantation if the graft is placed extraperitoneally.

A reliable catheter placed percutaneously or surgically is mandatory for successful PD. Bedside placement of a percutaneous catheter, using the Seldinger technique under local anesthesia, is reasonable in infants or children at high risk for general anesthesia (Borzotta et al, 1983). These catheters historically carried high rates of peritonitis (Day and White, 1977), but long periods of infection-free use are reported (Bunchman, 1996). Conversion to a surgically placed catheter can proceed when the child is stable and prolonged dialysis is confirmed.

The permanent Tenckhoff catheter is made of soft material, with intraperitoneal and extraperitoneal portions. The intraperitoneal portion, with holes to allow passage of peritoneal fluid, is either straight or curled; the curled design causes less pain and is less likely to suffer omental occlusion. The extraperitoneal portion has one or two Dacron cuffs (the first cuff positioned at the entrance to the peritoneum and the second cuff placed 1 cm from the skin tunnel exit site) that prevent fluid leaks and bacterial migration and fix the catheter's position to the abdominal wall. The catheter exit site is positioned as far from a stoma as possible (even to the chest) to prevent infection (Chadha et al, 2000). Omental occlusion of the catheter is the leading cause of revision (Warady et al, 1997); however, routine omentectomy is not universal (Neu et al, 1995).

The PD prescription specifies dialysate composition, exchange volume, inflow, dwell, and drain times of each exchange and the number of exchanges per 24 hours. Commercially available dialysate comes in dextrose concentrations of 1.5%, 2.5%, and 4.25% and electrolyte composition of sodium, 132 mEq/L; chloride, 102 mEq/L; lactate, 35 mEq/L; magnesium, 1.5 mEq/L; and calcium, 3.5 mEq/L. Warming the dialysate to body temperature before infusion prevents sudden hypotension. Continuous ambulatory peritoneal dialysis implies four to five daily exchanges with a long overnight dwell. Initially, exchange volumes are small but increased over the next 5 to 10 days. Initial stabilization often requires several days of 30- to 60-minute exchanges, but, once stabilized, PD can continue indefinitely.

Complications

Peritonitis is the most common complication of PD (Warady et al, 1984; Verrina et al, 2000), occurring once per 4.7 patient months (Neu et al, 2002) and more commonly in children younger than age 1 year. The most common organisms are gram positive (50%), gram negative (20%), and then fungal (2.3%). **Patients have cloudy dialysate with abdominal pain, fever, vomiting, or diarrhea, but the diagnosis is made by documenting greater than 100 WBCs/mm^3 with at least 50% neutrophils in the effluent.** Treatment relies on intraperitoneal administration of broad-spectrum antibiotics for 14 to 21 days and is changed according to sensitivity results. Gram-negative bacterial and fungal infections that require PD catheter removal are associated with peritoneal scarring and peritoneal membrane failure and may potentially require a change to hemodialysis (Warady et al, 2000).

Blood-tinged dialysate is common early in PD and clears after a few exchanges. Heparin can avert catheter obstruction by small clots. Detection of an injured organ or large vessel may be difficult based on dialysate color. Using ultrasound can minimize this risk during percutaneous catheter placement. Ultrasonography may also prevent bladder perforation, which may occur in an incompletely empty bladder, especially in infants and children with neuropathic or obstructed bladders. The injury may not be noted until there is a suprapubic mass, polyuria, gross hematuria, and glycosuria.

PD should be a painless procedure for children. Pain during inflow may reflect peritonitis, cold dialysate, local reaction to the low pH of the dialysate, local irritation from rapid inflow, omental or adhesion trapping of the catheter, and abdominal distention. Rectal or suprapubic pain occurs when the catheter tip is between the bladder and the rectum. Subdiaphragmatic air leads to shoulder pain.

Dialysate leakage is common in the first few days if initial exchange volumes are too large or the catheter is frequently manipulated or placed on traction. Leakage is less likely when use of a new catheter is delayed for 24 hours. When possible,

temporary suspension of PD may be needed or the catheter replaced with a larger one.

Adequate inflow but poor outflow leads to abdominal distention and fluid overload. Catheter occlusion by omentum is the most common cause; other causes include constipation, intraperitoneal adhesions, fibrin, blood clots, faulty position, and tube kinks. Drainage can occasionally improve by flushing with heparinized saline or instilling urokinase or tissue plasminogen activator (Shea et al, 2001; Stadermann, 2002). Surgical replacement and omentectomy may be necessary.

Respiratory distress may occur from increased intraperitoneal pressure from excessive or retained dialysate. Symptoms include dyspnea, hypoxemia, and respiratory failure, especially in small infants. Hydrothorax due to a diaphragmatic hernia or diaphragmatic eventration must be considered.

Sclerosing encapsulating peritonitis is a rare but serious problem after receiving PD for more than 5 years (Warady, 2000). It is characterized by continuous, intermittent, or recurrent bowel obstruction associated with gross thickening of the peritoneum (Warady et al, 2000). Peritoneal calcifications on CT in association with ultrafiltration failure suggests the diagnosis and may result in withdrawal of PD.

Hemodialysis

HD is best performed in specialized dialysis units equipped with appropriate pediatric dialysis equipment and personnel capable of providing adequate psychosocial, educational, and dietary support to children and their families. The child's vasculature is accessed and the blood travels to the dialyzer where accumulated toxins or solutes are extracted by perfusion across a semipermeable membrane driven by diffusion and convection, and the blood is then returned to the patient. Vascular access is gained by creating an arteriovenous fistula (AVF) or implanting an arteriovenous graft (AVG) in children who are larger than 20 kg and expected to require HD for longer than 12 months (National Kidney Foundation, 2006a). AVFs are created by anastomosis of an artery to a vein, most commonly in the wrist (radiocephalic) or the antecubital fossa (brachial artery to cephalic vein). The venous portion expands over time to a size large enough for safe needle placement—a minimum of 4 weeks but preferably 3 to 4 months (National Kidney Foundation, 2001) and may require 4 to 6 months in small children (Bourquelot et al, 1990). AVGs are made of polytetrafluoroethylene tubing connecting an artery to a vein that can be used after 4 weeks when the luminal portion endothelializes (National Kidney Foundation, 2001). One-, 3-, and 5-year AVF and AVG survival rates in children are similar (90%, 60%, and 40%, respectively). AVGs have higher thrombosis and surgical intervention rates (Sheth et al, 2002). Temporary HD catheters should be placed with the tip in the right atrium to allow adequate blood flow preferably through the internal jugular site, which has a lower incidence of venous thrombosis than the subclavian vein. The catheter should be placed on the side contralateral to a planned AVF or AVG (National Kidney Foundation, 2001). Acute HD is accomplished through a temporary, uncuffed dual-lumen catheter placed in the femoral, internal jugular, or subclavian vein. Two separate single-lumen venous catheters may be needed for infants. Besides for acute renal failure, acute HD may be needed in tumor lysis syndrome and in hyperammonemia in children with inborn errors of metabolism and drug ingestions.

AVF complications include development of venous collateral vessels, arterial inflow stenosis with poststenotic aneurysm formation, and thrombosis caused by stenosis of the venous outflow tract (Swedberg et al 1989; Kanterman et al, 1995). The most common complications of HD catheters include infection (tunnel or line), kinking of the catheter, and thrombosis. Despite heparin packing, catheter thrombosis is a significant problem that is treated by instilling tissue plasminogen activator into the catheter or by intraluminal clot extraction. Gram-positive organisms, especially *Staphylococcus* species, are the most common organisms. Because HD cannot be interrupted, catheter infections are treated with antibiotics alone. Catheters should be removed in the presence of repeated symptomatic bacteremia (high fever, rigors, chills, hypotension), intractable infections, or fungal infections. The median longevity of a dual-lumen HD catheter in children is 204 to 280 days (Goldstein et al, 1997, Sharma et al, 1997; Sheth et al, 2001).

Renal Transplantation

Preparation for transplant is key in the management of CKD stage 5 in pediatric patients. The ultimate goal in these children is to proceed directly to transplantation and avoid dialysis if at all possible. Patients with congenital uropathies represent ideal transplant candidates because there is no risk of recurrent disease. It is important to have the children undergo a full imaging and urodynamic evaluation and to perform any procedures before transplantation that will be needed to ensure that urine flow and drainage will be normal after transplantation. If dialysis is necessary, PD is preferred in younger children unless there is an anatomic contraindication to the procedure.

The sources of kidneys for pediatric transplantation are either living (related or unrelated) or deceased. Although transplants with living related kidneys historically carried the highest survival rates, **the 1-year graft survival of deceased donor kidneys (93.5%) currently approaches that of living related kidneys (95.4%)** owing to advances in immunotherapy (Wuhl and Schaefer, 2008). Contraindications to kidney transplantation include active malignancy or remitted disease for less than 2 years, human immunodeficiency virus infection, positive T-cell crossmatch, and history of poor compliance or noncompliance with medical management (Davis et al, 1998). Children undergoing transplantation for FSGS, hemolytic uremic syndrome, or primary oxalosis are at significant risk of disease recurrence that may place the graft at risk for failure (Cameron, 1993; First and Peddi, 1999; Hariharan et al, 1999).

The pretransplant urologic evaluation assesses the need for native nephrectomy and to assess the fittingness of the bladder to accept the transplanted kidney without placing its survival at risk. This evaluation includes a history for urologic disease and operations on the urinary tract as well as bladder function. The physical examination includes noting the location of scars and stomas that may interfere with transplantation. A urinalysis and urine culture as well as ultrasound evaluation of the kidneys and bladder (including a postvoid image) should be performed. Voiding cystourethrography is indicated if a recent status of vesicoureteral reflux is unknown. This can be included during the urodynamic evaluation in children with a history of posterior urethral valves, triad syndrome, bladder exstrophy, or neurogenic bladder. When the bladder is unacceptable for safely accepting the graft (poor compliance) despite maximal medical management, augmentation cystoplasty may be needed to improve the success of the renal transplant. Clean intermittent catheterization should be continued after transplantation. The indications for native nephrectomy before renal

transplantation include severe uncontrollable hypertension, uncontrolled significant proteinuria, recurrent pyelonephritis, grade 4 or 5 hydronephrosis, persistent severe vesicoureteral reflux, previously infected or symptomatic polycystic kidneys or those extending below the iliac vessels, and persistent anti–GBM antibody levels.

SUMMARY

The value of the collaboration between pediatric urologists and nephrologists cannot be overestimated. In this chapter many of the entities whose evaluation and management overlap between the two specialties were reviewed and several clinical problems primarily seen by pediatric nephrologists were discussed. Some of these latter clinical conditions may not always involve urologists, but an appreciation for their features broadens the scope of knowledge and interest and can only strengthen an already solid working relationship.

Prognosis and Management Strategies

CLINICAL CONTEXT

The spectrum of urinary obstruction in children is one of the most common conditions affecting the urinary tract and has substantial health consequences. Obstructive nephrouropathies constitute the single largest entity leading to renal insufficiency in male children younger than 1 year of age and are the largest single cause of renal failure requiring transplantation, occurring in about 23% of children who undergo renal transplantation (Seikaly et al, 2003). A large number of children are affected by lesser degrees of obstruction that induces concern, leading to ongoing imaging to monitor renal function and the status of the obstruction.

The wide spectrum of obstructive changes constitutes one of the major challenges in the clinical management of these conditions in that there is no definitive dividing line between obstruction that warrants intervention from that which does not (Peters, 1995). The presence of an obstructive lesion is readily determined with current imaging, but the criteria for intervention are highly controversial. This is largely because of a lack of information regarding the natural history of differing degrees of obstruction and the absence of effective markers of the pattern and progression of obstruction (Chevalier, 2004). We are left with few guideposts along the spectrum of obstruction by which clinical decisions may be made.

The current state of knowledge regarding the pathophysiology of congenital urinary obstruction, how it may be correlated with clinical scenarios, and its distinction from postnatal obstruction are reviewed here. It is anticipated that with increasing understanding of the mechanisms involved in congenital urinary obstruction we will become better able to discriminate between children requiring therapeutic interventions and those in whom this would be unnecessary.

Clinical Presentation of Obstruction

Prenatal ultrasonographic diagnosis has radically altered the clinical presentation of obstructive conditions, and today most of these conditions are detected before birth and many have no apparent clinical signs. Those that present as clinical manifestations are often severe obstructive conditions, such as posterior urethral valves or massive hydronephrosis. Children are still found with clinical signs of obstruction, usually infection or pain and, rarely, hypertension. In the child with obstruction of the entire urinary tract, even when the obstruction is relieved the functional abnormalities inform urologists of the effects of obstruction on developing kidneys. Reduced filtration function as manifest by a rising serum creatinine concentration is associated with glomerular injury, acidosis is due to tubular injury, and nephrogenic diabetes insipidus is secondary to collecting duct abnormalities. In extreme cases these may all be present, but on occasion they are noted in isolation and will often persist after correction of the obstruction (Hutcheon et al, 1976). Obstructive hypertension appears to be renin mediated (Riehle and Vaughan, 1981; Urata et al, 1985; Mizuiri et al, 1992) and may be reversible with surgical repair (de Waard et al, 2008).

The pathologic correlates of these functional alterations have been described in the congenitally obstructed kidney to varying degrees (Elder et al, 1995; Stock et al, 1995; Han et al, 1998; Poucell-Hatton et al, 2000; Zhang et al, 2000; Huang et al, 2006). The pathologic changes associated with lesser degrees of obstruction have been less thoroughly investigated, and a spectrum of qualitatively similar alterations have been described. In the absence of overt functional alterations and in unilateral conditions, determining the state of the affected kidney becomes a

clinical challenge. This challenge is often tied to the question of whether surgical intervention is appropriate, and much controversy has emerged from this question. Clinical imaging studies are currently the only widely used modality to make this assessment, and their interpretation is not uniform. The natural history of many conditions in the spectrum of obstruction is not well described yet is the essence of the question. It should be clearly seen that the spectrum of obstruction is wide, involves conditions that do not require intervention as well as others that produce profound renal injury, and may change with age and persistence of the condition.

Progressive Renal Dysfunction

A major concern regarding obstructive conditions in the urinary tract is the potential for a progressive situation leading to ever more loss of renal function. Progression may be seen in two forms, one with the uncorrected partially obstructive lesion (i.e., ureteropelvic [UPJ] obstruction) and the second with the previously obstructed but corrected obstruction that has produced some degree of renal damage (i.e., posterior urethral valves). In the first, renal function may initially appear intact on imaging tests yet in time there will be progressive loss of absolute and relative function of the kidney affected by the obstruction. If this were known prospectively, intervention would be appropriate and should be performed early. The challenge is in predicting this situation, and few markers are available to do this. The frequency of progressive deterioration in unilateral obstruction likely ranges from 20% to 40%, but duration of follow-up will significantly affect this rate. Every prospective study of obstructive conditions has documented the potential for progressive loss (Palmer et al, 1998; Parkhouse et al, 1988; Koff and Campbell, 1992; Koff, 2000).

The second situation reflects the fact that the damaged kidney does not have the functional reserve of a normal kidney by which it may maintain its absolute function over time. These kidneys will demonstrate a steady decline in function over time, and this is usually evident in bilateral obstruction. The mechanism may be hyperfiltration of remnant renal units, and clinically this is most often seen with posterior urethral valves (Parkhouse et al, 1988; Nguyen and Peters, 1999). These children may show very adequate renal function early in life yet demonstrate a delayed and inexorable progression into renal failure in adolescence (Fig. 113–1). Whether earlier intervention would have protected their renal function is uncertain, but that possibility cannot be neglected.

Predictors of ongoing progression of renal injury secondary to either ongoing or prior renal obstruction are of critical importance, yet there are few to rely on. The most evident one is altered absolute renal function, as clinically indicated by a creatinine clearance or serum creatinine value. This is relatively insensitive in early stages of progression. Radionuclide imaging may be helpful in some cases, but there is no gold standard as to the best interpretation of potentially progressive disease.

Definition of Obstruction

Although it may not be difficult to diagnose the potentially obstructed urinary tract, usually by ultrasonographic identification of hydronephrosis, the determination of whether this particular condition requires surgical intervention to protect renal function and development is much more difficult. The frequently quoted definition of congenital obstruction (Koff, 1987), which is "a condition producing a restriction of urinary flow that will lead to deterioration in renal function," is too limited. In the growing child, renal function is expected to increase markedly, initially in excess of body mass and subsequently in parallel to it. If this increase in function does not occur, renal functional potential is lost, which may be of greater consequence than losing absolute function. Therefore **the impairment of renal functional development should be considered as a determinant of obstruction that warrants intervention** (Peters, 1995).

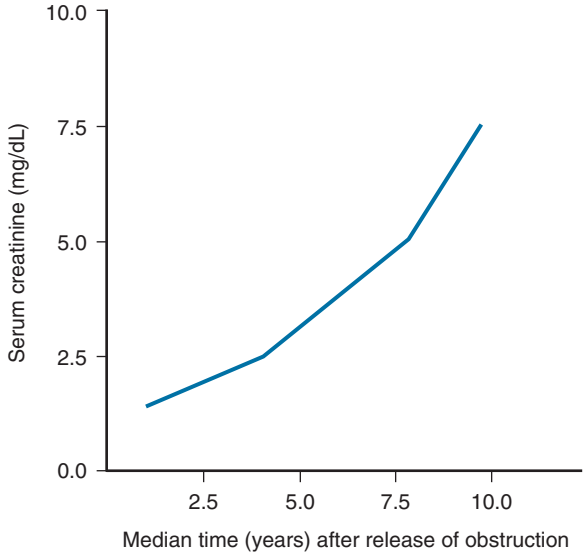

Figure 113–1. Graph depicting the progressive deterioration in renal function as indicated by a rising serum creatinine concentration in patients with posterior urethral valves despite surgical relief of obstruction. (From Roth KS, Carter WH Jr, Chan JCM. Obstructive nephropathy in children: long-term progression after relief of posterior urethral valve. Pediatrics 2001;107:1004–10.)

If this is the case, then an obstructive or hydronephrotic condition that has already resulted in less than normal function should be considered as obstructive and warranting intervention. The child with significant hydronephrosis with a kidney contributing significantly less than the anticipated 50% on a radionuclide renal scan has already suffered an impairment of functional potential and should perhaps be considered as having sufficient obstruction to warrant intervention to limit further impairment.

A critical element of congenital urinary obstruction is the recognition that it is distinct from acquired obstruction in the mature animal (or mature kidney). The fact that obstruction develops at the same time the kidney is in the process of formation creates an entirely different paradigm for congenital urinary obstruction as compared with obstruction of the mature kidney (Peters, 1997). The patterns of renal development are affected by obstruction, and this produces the ultimate functional effects. The mechanisms for these alterations are therefore wholly distinct from mature obstruction. Although there is likely to be some overlap in the critical mechanisms of change, many will be different. It cannot be assumed that the principles relevant to mature obstruction are applicable to congenital obstruction. This will clearly impact the interpretation of experimental data in the postnatal and mature animal, as well as the selection and application of experimental systems.

One of the frustrations in the management of clinical congenital obstruction is the dichotomy between therapeutic options, which are currently limited to either observation or surgery. Although the surgical options have expanded somewhat, the large

gap between these divergent options creates a great deal of tension in the minds of the patient and family as well as physicians. The absence of any medical or pharmacologic therapy to ameliorate or prevent the complications of obstruction has been a major factor in the controversy between those who choose to correct a problem and those who believe it is better to await spontaneous resolution or unambiguous evidence of obstructive injury. The horizon holds promise for medical therapies that might prevent renal injury in various ways, but it will be essential to more completely understand the nature of congenital urinary obstruction to permit such specific treatment.

Key Points: Clinical Context

- Obstruction is the single largest entity leading to renal insufficiency in boys younger than 1 year of age and the largest single cause of renal failure requiring transplantation.
- Progression of obstructive renal dysfunction may be seen in two forms, one with an uncorrected, partially obstructive lesion and the other with a previously obstructed, but corrected lesion that has produced some degree of renal damage.
- The second situation reflects the fact that the damaged kidney does not have the functional reserve of a normal kidney by which it may maintain its absolute function over time.
- Elevated creatinine concentration indicates altered absolute renal function but is relatively insensitive in the early stages of progression.

PATTERNS OF CONGENITAL OBSTRUCTIVE NEPHROPATHY

General Observations

In an attempt to understand the pathophysiology of congenital urinary obstruction, examination of obstructed renal tissues has shown disorganization of structure with primitive forms of renal tissues—dysplasia. Although the definition of *dysplasia* is not universally agreed on, evidence of altered renal development in association with obstruction is frequently reported (Bernstein, 1971; Matsell, 1998; Tarantal et al, 2001; Matsell et al, 2002; Matsell and Tarantal, 2002). Dysplasia is often considered to be an embryonic process and irreversible, yet this is not proven. It is clear that some dysplasias are due to very early abnormalities of renal development (Winyard and Chitty, 2008), unrelated to obstruction, but it is equally clear that obstructive processes can produce dysplasia. Whether there are subtle differences between these patterns is unclear, but it should not be difficult to understand that several underlying causes may produce similar outcomes when renal developmental patterns are disrupted.

In some cases, however, usually in lesser degrees of obstruction, there is no dysplasia (Bonsib, 1998; Zhang et al, 2000). In such cases the mechanisms of obstructive effect may be similar but to a lesser degree or they may be entirely different. It is important to recognize the variability of the patterns of response to obstruction.

If obstruction can produce dysplasia or abnormal developmental patterns, the particular mechanisms of obstructive effects may be identifiable. These include the fundamental processes of development, and by examining these specifically we may be able to understand the critical mechanisms of obstructive nephropathy. **Development is the controlled process of growth and differentiation of tissues in the formation of an organ or tissue. The forces that regulate these processes are likely targets of obstructive effects.**

Structural alterations with obstruction are obviously evident with hydronephrosis, but this is largely a distortion of normal architecture and relative alterations in the amounts of elements of renal tissues. There may be subtle changes, however, that are functionally important. Other alterations include fibrosis and increased interstitial tissues, as well as the presence of abnormal tubules and glomeruli. The normal layered organization of the kidney with the cortical and medullary areas with inner and outer stripes is often distorted or absent (Zhang et al, 2000). Less obvious will be changes in the differentiation of the individual renal cell types that make up the nephron (Huang et al, 2006). Cells are unlikely to perform their normal functions, including communicating with neighboring cells in an integrated fashion. Function will therefore be disrupted.

Closely tied with these altered patterns of structure are distortions of normal growth regulation with either increased or decreased growth of specific structures. In some cases, obstructed kidneys are markedly smaller than normal and in a developmental context this does not represent atrophy but hypoplasia. The distinction is important in that renal tissue mass has not been lost but has never been formed. This is growth failure not atrophy, and the mechanisms are likely distinct.

These observations are supported by both clinical and experimental work. Several biopsy studies have shown patterns indicative of altered differentiation and growth in various levels of obstruction, including both upper (UPJ obstruction) (Elder et al, 1995; Stock et al, 1995; Zhang et al, 2000; Huang et al, 2006) and lower (posterior urethral) valves (Poucell-Hatton et al, 2000; Haecker et al, 2002). These variations are not well explained, and correlation with clinical parameters is often imperfect. Experimental studies, however, have shown similarly that obstruction during development will produce changes in patterns of renal differentiation and in growth regulation (Beck, 1971; Steinhardt et al, 1988; Gonzalez et al, 1990; Peters et al, 1992; Wen et al, 2002; Cachat et al, 2003; Mure et al, 2006b). These can be seen to vary depending on the time of onset in experimental models, as well as the severity of obstruction (Fig. 113–2) (Chevalier et al, 1988, 1999c; Thornhill et al, 2005). The latter is difficult to measure accurately. The validity of any of these model systems must be challenged, however, until we have more definite correlations. Nonetheless it is clear that induced obstruction can produce such severe abnormalities of differentiation as to be considered dysplasia and to produce clear disruptions of growth regulation (Peters et al, 1992). It is therefore reasonable to examine the specific patterns observed and the potential mechanisms of those changes, all of which are likely contributing factors in the development of obstructive nephropathy.

Patterns of Effect

The effects of obstruction on the developing kidney may be summarized as producing alterations in the regulation of growth, tissue differentiation, extracellular matrix (ECM), and fibrosis and in altering the functional integration of the kidney (Fig. 113–3). The latter is largely a result of the first three major factors and refers to the mechanisms

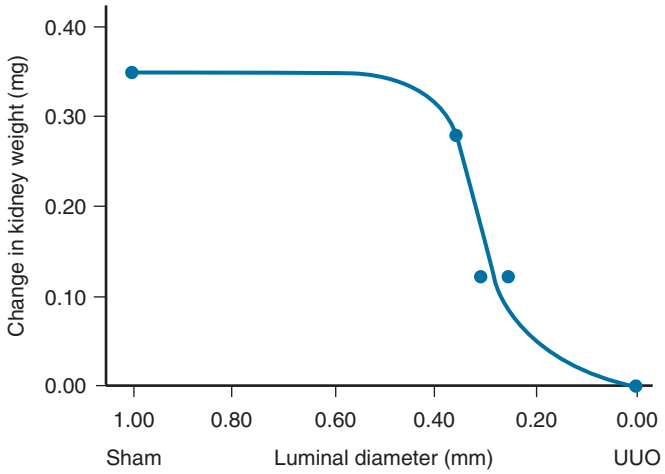

Figure 113–2. Interval change in kidney weight between 2 and 4 weeks of age in rats subjected to experimental unilateral ureteral obstruction (UUO) at birth. The sharp drop in weight with decreasing luminal diameter of the ureter suggests a threshold effect on the obstructive effects on renal growth regulation. (Modified from Thornhill BA, Burt LE, Chen C, et al. Variable chronic partial ureteral obstruction in the neonatal rat: a new model of ureteropelvic junction obstruction. Kidney Int 2005;67:42–52.)

Key Points: Patterns of Congenital Obstructive Nephropathy

- Impairment of renal functional development should be considered a determinant of obstruction that warrants intervention.
- Congenital urinary obstruction is distinct from acquired obstruction in a mature kidney.
- Obstructed renal tissues show disorganization of structure with primitive forms of renal tissues, called dysplasia.
- Structural alterations caused by obstruction are evident in hydronephrosis as a distortion in normal architecture and relative alterations in the amount of renal tissue elements. Subtle changes are functionally important and include fibrosis and increased interstitial tissue, as well as abnormal tubules and glomeruli.
- The effects of obstruction on the developing kidney vary with the time of onset, as well as the severity of obstruction.
- Obstruction of a developing kidney produces alterations in the regulation of growth, tissue differentiation, and ECM and fibrosis, as well as alterations in functional integration of the kidney.

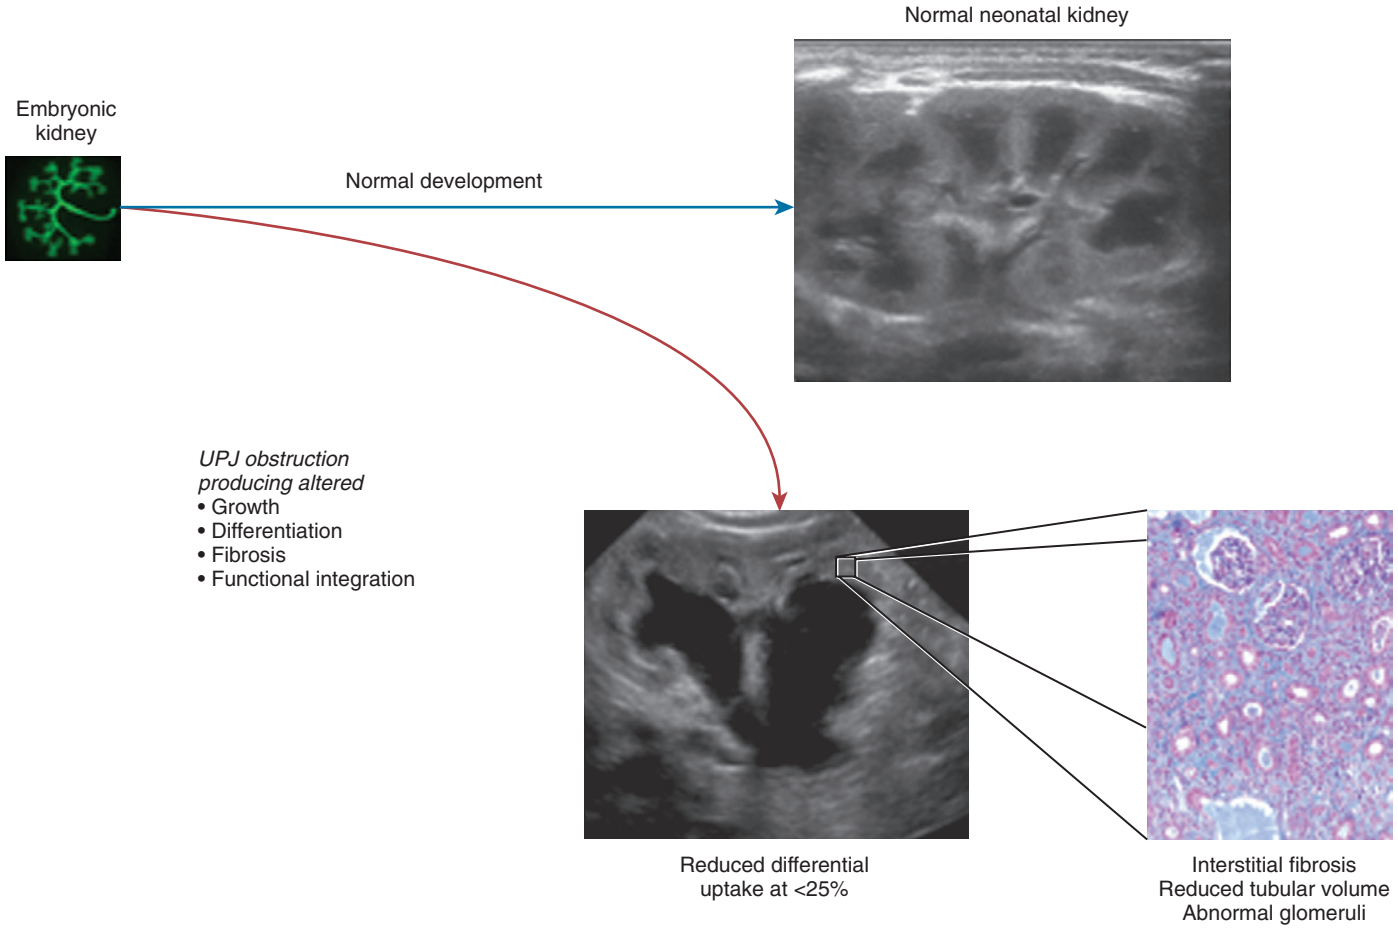

Figure 113–3. Diagram of the key patterns of effect due to obstruction during fetal life. UPJ, ureteropelvic junction.

producing vascular, neural, and humoral homeostasis and in the regulation of inflammatory cascades. Understanding the mechanisms by which these systems are dysregulated by obstruction will permit a better understanding of the outcomes of obstruction, which should improve our diagnostic, prognostic, and therapeutic abilities.

GROWTH AND DIFFERENTIATION

Growth

Growth regulation is a critical part of development, and the obstructed kidney may evidence impaired or accelerated growth. It is important to recognize that the small, obstructed kidney is not atrophic, as might be seen in the adult, but is hypoplastic. The growth it should have experienced never occurred. This can be readily seen on prenatal ultrasound evaluation and has been shown repeatedly experimentally (Peters et al, 1992; Mandell et al, 1994). This seems usually to be a generalized impairment of all parts of the kidney, with both reduced numbers of nephrons as well as smaller nephrons. Differential growth impairment within the nephron segments may be present as well (Cachat et al, 2003; Huang et al, 2006). The functional effects of significant growth impairment are obvious because there are fewer and smaller nephron units. There may be compensatory responses to these changes, and it is difficult to assess their long-term impact. Reduced renal mass can be associated with hypertension as well as reduced filtration function, and loss of tubular mass will affect electrolyte and acid-base homeostasis, as well as water balance.

Growth acceleration can be seen in the larger than normal hydronephrotic kidney, although this is difficult to prove in humans, because few of those kidneys are removed. In animal experiments, fetal partial obstruction can increase renal mass (Gobet et al, 1999a; Ayan et al, 2001). This is not seen with dysplastic changes and is not a product of edema, because the total protein and DNA are increased as well. The factors that predict altered growth appear to be the severity of obstruction and timing of the obstructive effect, although the latter is difficult to ascertain in human situations. The functional consequences of accelerated growth are not known, and this may correlate with the occasional hyperfunction measured on renal scans that is seen in some patients with hydronephrosis (Moon et al, 2003; Maenhout et al, 2005). Compensatory effects with obstruction may not be benign; growth enhancement of the glomeruli occurs in early diabetes and is later associated with glomerular sclerosis.

Growth Regulation

Regulation of renal growth is extremely complex and dynamic through development. A variety of growth factors are known to influence kidney growth at various stages of renal development and act at different loci of the nephron. Obstructive conditions have been shown to alter expression of growth-regulatory genes as well as the presence of the proteins coded by these genes (Chevalier, 1996). Some of the factors known to be altered in renal obstruction (not all in early or fetal models) are listed in Table 113–1. Epidermal growth factor (EGF) has been shown to reduce some of the growth effects of obstruction when administered exogenously (Kennedy et al, 1997; Chevalier et al, 1998, 1999a). Many studies have focused on specific growth factors, but it is evident from the complexity of renal development and growth regulation that the interactions of multiple factors and their signaling pathways will be of greater relevance.

Apoptosis Regulation

A critical component of growth in the developing kidney is apoptosis—regulated cell death. The early fetal kidney is extremely active in terms of new cell formation as well as turnover (Carr et al, 1995). **This permits remodeling during development, as well as providing a control system over unregulated growth.** Small increases in the rate of apoptosis, even with normal ongoing growth, would lead to significant reductions in renal mass over time. The role of apoptosis in congenital obstruction has become more firmly established in recent years, including cellular patterns characteristic of apoptosis and enhanced expression of apoptosis-regulating molecules (Yang et al, 2001; Yoo et al, 2006; Eskild-Jensen et al, 2007a; Campbell et al, 2008) (see Table 113–1). The changes may be seen heterogeneously, and the precise means by which these alterations occur remain incompletely defined, although apoptotic activity is regulated by cytokines (Cohen et al, 2007; Campbell et al, 2008) as well as mechanical factors (Nguyen et al, 2000; Hsieh and Nguyen, 2005). Inappropriate apoptosis may also be related to interstitial fibrosis as well (Docherty et al, 2006a). An important aspect of understanding the role of apoptosis in congenital obstruction is that the mediators may be measurable in the urine or blood, and they may permit therapeutic manipulation (Mizuguchi et al, 2008).

Differentiation

Differentiation is the process of cells attaining specific functional traits to permit specialized functions and organization into tissues. It is the basis for renal function, in its many aspects. Obstruction affects these finely tuned patterns, as can be seen histologically in a severely obstructed kidney with dysplasia. More subtle effects may require assessment of tubular or glomerular function, but all are a result of altered differentiation. Disruption of differentiation may begin as early as induction of the nephron or later in development with injury to renal collecting duct cells that regulate urinary concentrating ability. Some of these changes may be reversible, but it is usually presumed that many are not, in that some cells will undergo terminal differentiation, and if that does not occur at a particular time point in development there will not be another opportunity for it to occur. Disruption of normal differentiation of renal elements is unique to congenital obstruction and does not occur in a major way in adult obstruction. Abnormal epithelial-mesenchymal transformation (EMT) is one alteration in differentiation that does occur in the adult and can be reversible (Hay and Zuk, 1995; Yang et al, 2005; Docherty et al, 2006b; Forino et al, 2006; Higgins et al, 2007; Ivanova et al, 2008). A variety of mediators of EMT have been described, including transforming growth factor-β (TGF-β), plasminogen (Zhang et al, 2007), and leukocytes (Lange-Sperandio et al, 2007), as well as inhibitors, such as hepatocyte growth factor (HGF) (Yang et al, 2005) (Fig. 113–4). It is likely to be an important factor in fetal obstruction as well, although little is known about its role. Most adult cells may be injured and lose their differentiated capacity, but the cell types rarely change their behavior once differentiated. Understanding the patterns of altered differentiation and its regulators is critical to understanding congenital obstructive nephropathy.

Induction Process

Renal differentiation begins with induction and from then on is exquisitely sensitive to various outside effects that may disrupt the

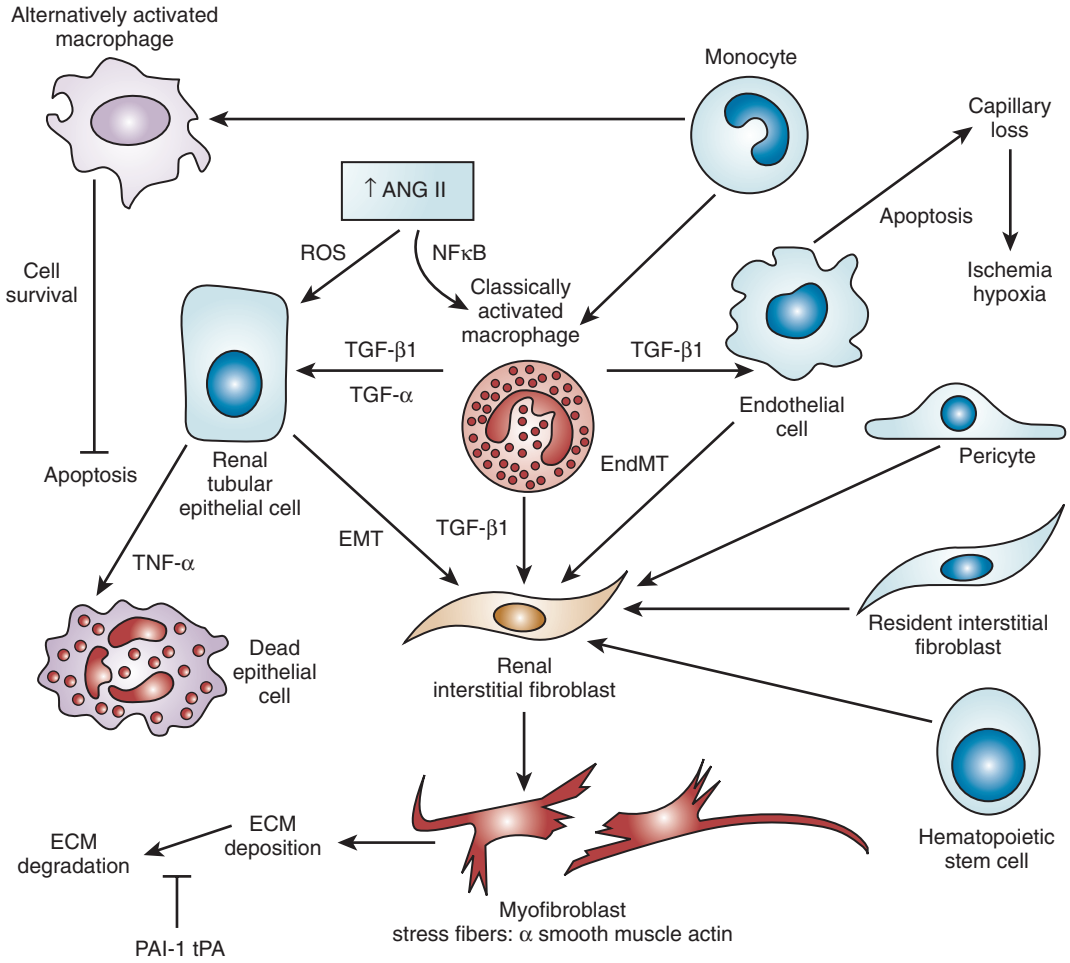

Figure 113–4. Renal cellular interactions in obstructive nephropathy. The interstitium is infiltrated by monocytes, which are "classically" activated to macrophages, which release cytokines such as transforming growth factor (TGF)-β1 and tumor necrosis factor (TNF)-α. In turn, TGF-β1 promotes a phenotypic response of tubular epithelial cells either to undergo apoptosis (leading to tubular atrophy) or to undergo epithelial-mesenchymal transition (EMT), becoming fibroblasts that migrate to the interstitium. Angiotensin II (ANG II), produced by the activation of monocytes, stimulates the production of nuclear factor kappa B (NFκB), which leads to the recruitment of more macrophages, as well as to the production of reactive oxygen species (ROS), which aggravates renal tubular injury. In contrast, alternatively activated macrophages can enhance tubular cell survival and proliferation. Endothelial cells can undergo endothelial-mesenchymal transition (EndMT) or apoptosis, which leads to capillary loss and secondary renal ischemia and hypoxia. Resident pericytes and infiltrating hematopoietic stem cells can also differentiate into fibroblasts. Under the stimulus of cytokines such as TGF-β1 produced by macrophages or other cells, fibroblasts synthesize stress fibers and undergo further differentiation to become myofibroblasts. The myofibroblasts are contractile and augment the deposition of extracellular matrix (ECM), leading to progressive interstitial fibrosis. This process is augmented by a decrease in ECM degradation, mediated by plasminogen activator inhibitor-1 (PAI-1) and tissue-type plasminogen activator (tPA). (From Chevalier RL, Forbes MS, Thornhill BA. Ureteral obstruction as a model of renal interstitial fibrosis and obstructive nephropathy. Kidney Int 2009;75:1145–52.)

normal sequence of cellular changes that results in a kidney. When these may be disturbed by obstruction is unclear, but it can be presumed that some of the variation in the spectrum of obstruction is due to different times of onset of the obstructive effect and to different degrees of severity. The pattern of effect is likely to reflect the time of onset and be reflected in the number of nephron generations and the degree of dysplastic transformation. Controversy remains as to whether obstruction can produce dysplasia, and it is often stated that if dysplasia is present, then it was due to abnormal induction and not obstruction. Abnormal induction and nephrogenesis may be produced by various factors, including genetic ones, or due to cellular disruption from mechanical forces with subsequent cellular responses. The study of Maizels and Berman is often cited to indicate that dysplasia in the chick kidney (a mesonephric kidney) was only produced with mechanical disruption of the mesenchyme and not hydronephrosis. The production of "obstruction" in that elegant study was by necessity rather crude, and several of the preparations were not obstructed. It is unclear whether they all were to a sufficient degree. It also suggests that mechanical forces can, in fact, disrupt nephronogenesis enough to produce dysplasia, and there is no inherent reason to believe that this cannot be from obstruction as well. Later mammalian studies in fetal sheep have shown dysplastic changes produced by obstruction (Steinhardt et al, 1988; Peters et al, 1992; Matsell et al, 1996), and this has also been shown in rodent studies (Thomasson et al, 1970).

The critical determinant of dysplasia in animal studies has been complete obstruction early in gestation. In the fetal sheep this was only seen when the obstruction was induced before 50% of gestation (70 days in most sheep species, which have a gestation from 140 to 145 days). Obstruction induced after that point only produces hydronephrotic changes, albeit severe ones (Beck, 1971).

Partial obstructions produced hydronephrosis only, without apparent disruption of the renal architecture. The reason for this is presumably altered sensitivity of the developing nephrons to obstructive effects at this point. Alternatively, the particular signaling systems that are active in the early phases of renal development begin to fade away with ongoing development. It is possible that the pathways sensitive to obstruction that would inherently alter the pattern of development have run their course of expression and activity by mid gestation. Expression of recognized mediators of renal development have been shown to be affected in models of fetal obstruction, including WT1 (Liapis, 2003), the *Wnt* gene family (Nguyen et al, 1999), and PAX2 (Attar et al, 1998; Mure et al, 2006b; Cohen et al, 2007).

One of the histologic hallmarks of renal dysplasia is fibromuscular collars surrounding tubular structures, so-called primitive ducts. These have a characteristic appearance, and the smooth muscle surrounding the tubules stains for α-smooth muscle actin (α-SMA) (Fig. 113–5). This pattern suggests an abnormality in the regulation of EMT (Butt et al, 2007; Baum et al, 2008). The mesenchymal structures of the primitive nephrogenic blastema and the epithelium of the ureteral bud processes interact, and there is differentiation from an epithelial to mesenchymal phenotypes and the reverse. It is uncertain whether the presence of the primitive tubules suggests persistence of mesenchyme that should have transformed to epithelium or inappropriate EMT. Understanding the signaling pathways involved in these processes will directly impact our understanding of obstructive processes (Roberts et al, 2006; Bani-Hani et al, 2008). Persistent expression of α-SMA can be seen in partial obstruction without dysplastic patterns and thus may be important at several levels of severity (Gobet et al, 1999; Mure et al, 2006a). α-SMA expression is regulated by TGF-β1, linking these two proteins to growth as well as to fibrotic changes.

Development of the glomerulus is a tightly regulated process that involves interaction of the mesenchyme and epithelium with a very specific pattern of growth and formation of intermediate structures such as the S-shaped body. In general, primitive glomeruli are not evident in obstructive changes but markedly abnormal glomeruli are seen as well as hypoplastic glomerular structures (Matsell et al, 2002). In some cases, glomeruli may be enlarged in obstruction, suggestive of the changes seen in hyperfiltration that lead to glomerulosclerosis. Dissociation of the glomerulus from the tubules can be seen in early neonatal rodent obstruction (Thornhill et al, 2007), suggesting severe disruption of the developmental program.

Key Points: Growth and Differentiation

- The effect of growth impairment includes fewer nephron units and delayed nephron maturation.
- Obstructive conditions have been shown to alter the expression of growth-regulating genes, as well as the presence of proteins coded by these genes.
- Congenital obstruction increases apoptosis and cellular patterns characteristic of apoptosis, with enhanced expression of apoptosis-regulating molecules.
- The ultimate cellular effects of such stimuli, however, depend on the summation of competing pro-apoptotic signals and antiapoptotic signals, as well as growth stimulation.
- Alteration in the differentiation of cells is unique to congenital obstruction and does not occur in a major way in adult obstruction.
- The critical determinant of dysplasia in animal studies has been complete obstruction early in gestation.

FIBROSIS

A universal characteristic of obstructive nephropathy appears to be renal fibrosis, although it is a nonspecific pattern seen in a variety of pathologic conditions

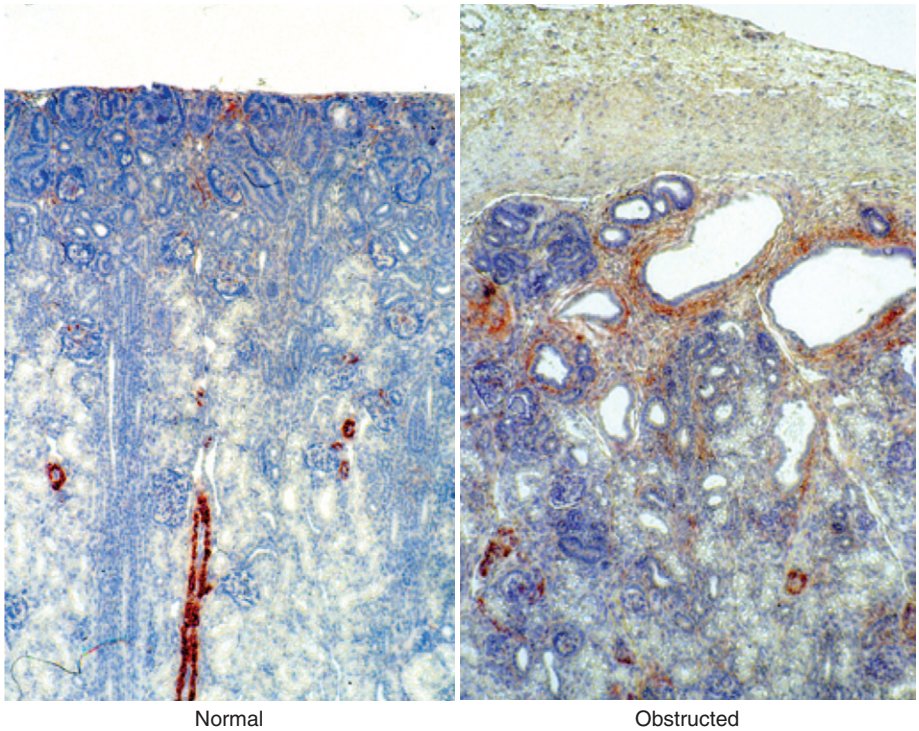

Figure 113–5. Histologic views of the kidneys of normal and obstructed full-term sheep showing the abnormal structural pattern, increased interstitial fibrosis and cells, as well as abnormally persistent α-smooth muscle actin *(brown stain)*. (From Gobet R, Bleakley J, Cisek L, et al. Fetal partial urethral obstruction causes renal fibrosis and is associated with proteolytic imbalance. J Urol 1999;162:854–60.)

affecting the kidney (Eddy, 2000). **It is seen as infiltration of the interstitium with abnormal amounts of ECM, including collagens, fibronectin, and other connective tissue proteins.** Their presence disrupts the normal interconnections between cells that permit functional integration of the renal tissues. Tubular cells may be disrupted and inadequately regulated. Cell–cell signaling by direct connection or paracrine messengers may be disrupted. Tissue oxygenation may be impaired. Fibrosis is a histopathologic hallmark of many renal diseases.

The ECM is essential to normal function of the kidney as well, in terms of providing structural integrity and contributing to normal signaling systems. When abnormally expressed, however, it becomes detrimental. ECM homeostasis is a complex balance of synthesis and breakdown. Synthetic regulation is controlled by various mechanisms, including growth factors and signaling systems that are just being discerned. Mechanical forces contribute to these signals in various conditions, including hypertension and hydronephrosis. ECM breakdown is tightly regulated and represents the product of degradative enzymes, the matrix metalloproteinases (MMPs), and their endogenous inhibitors, the tissue inhibitors of metalloproteinases (TIMPs). This product is the proteolytic balance and is regulated by various cytokines, hormones, and mechanical forces. This balance has been studied vigorously in renal disease and to a limited degree in congenital obstruction (Engelmyer et al, 1995; Ayan et al, 2001; Mure et al, 2006a). The interaction of these systems is complex, and various compensatory pathways are likely to be present (Kim et al, 2001).

Modulation of renal fibrosis may be a significant potential target for managing obstructive nephropathy, but the delicate balance of these factors needs to be understood to a greater degree than at present (Eddy, 2005).

Evidence and Patterns

Increased interstitial connective tissue is a hallmark of various renal pathologic processes (Eddy, 1996), **including obstruction. Although it is unclear if the mechanisms of fibrotic change are universal, they are believed to interfere with intercellular signaling and thus with functional integration** (Fig. 113–6). The most likely causes of excessive connective tissue include abnormal accumulation due to imbalance of synthesis and breakdown. It may also represent abnormal inductive signaling that produces excessive conversion of epithelium to mesenchymal tissue and connective tissues (Bascands and Schanstra, 2005; Burns et al, 2007; Zhang et al, 2007). These processes may be normal developmental sequences that persist due to the obstructive effect.

Abnormal accumulation may represent simply excessive synthesis with no change in ECM breakdown. Increased collagen synthesis has been shown by upregulation of collagen gene expression in obstructive models (Liapis et al, 1994; Fu et al, 2006). Collagen synthesis is regulated in part by various cytokines, including TGF-β and the renin-angiotensin system (RAS). Reduced fibrosis may be seen when angiotensinogen activity is downregulated in an obstructed system (Fern et al, 1999; Kellner et al, 2006). Similar approaches have been demonstrated in nonobstructive fibrosis as well.

The role of TGF-β is complex and context dependent, yet inhibition of activity will produce less fibrosis as well (Isaka et al, 2000; Miyajima et al, 2000; El Chaar et al, 2007). There is evidence that TGF-β interacts and regulates the activity of the RAS, as well as regulating cellular growth dynamics. Fetal obstruction induces

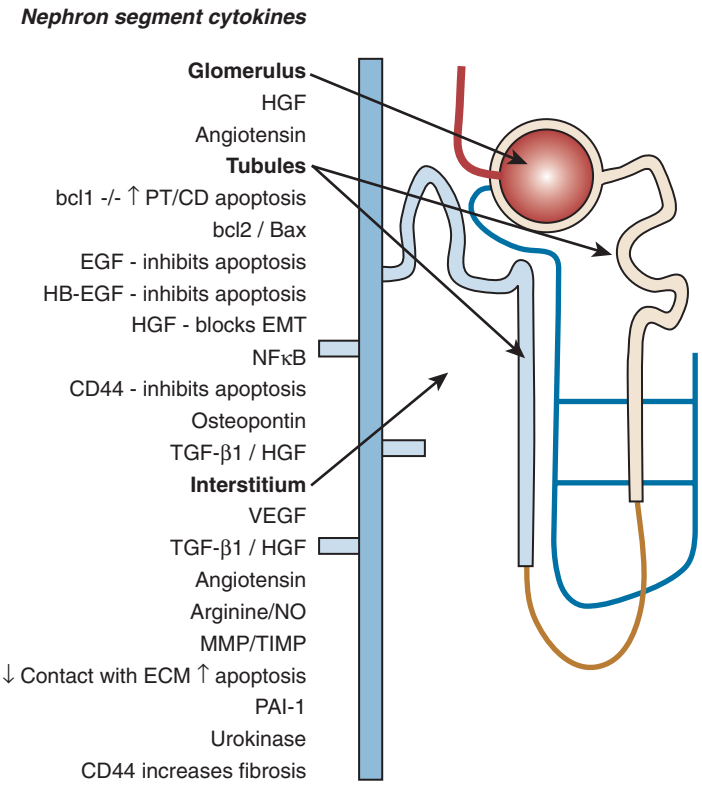

Figure 113–6. Diagram illustrating the various cytokines with reported effects on specific nephron segments. See text for details and references.

increased expression of TGF-β1 (Medjebeur et al, 1997; Ayan et al, 2001). As reviewed earlier, TGF-β1 regulates EMT, thereby contributing to renal dysplasia (Yang et al, 2000). There is considerable interest in the role of TGF-β1 in promoting EMT of differentiated renal tubular epithelial cells in response to chronic ureteral obstruction. As shown in Figure 113–4, renal interstitial fibroblasts, through transformation to myofibroblasts, play a pivotal role in the deposition of ECM in a hydronephrotic kidney. There is growing evidence that, in addition to proliferation of resident interstitial fibroblasts and transformation of hematopoietic stem cells, renal tubular epithelial cells can undergo EMT and migrate to the interstitium to contribute to the pool of fibroblasts (Iwano et al, 2002). Many of the steps involved in the transformation of tubular epithelial cells are regulated by TGF-β1; these steps include loss of cell adhesion, expression of α-SMA, disruption of tubular basement membrane, and cell migration to the interstitium (Liu, 2004). Signaling by TGF-β1 is mediated in part by Smads, which are both profibrotic (Smad2 and Smad3) and inhibitory (Smad7). Thus targeted deletion of Smad3 reduces apoptosis and fibrosis in mice with ureteral obstruction, whereas gene therapy with Smad7 also reduces fibrosis (Lan et al, 2003; Sato et al, 2003). TGF-β1 also acts through downregulation of transcriptional corepressors of the Smads: SnoN and Ski (Yang et al, 2003b). In contrast, HGF blocks EMT by blocking Smad2 and Smad3 and gene therapy with HGF reduces fibrosis in rats with ureteral obstruction (Gao et al, 2002; Yang and Liu, 2003). HGF also acts by upregulating the Smad corepressors SnoN and Ski, countering the action of TGF-β1 (Yang et al, 2005). These complex networks of counterbalancing factors provide many potential opportunities for therapeutic intervention to prevent the progression—or even promote the reversal—of interstitial fibrosis resulting from obstructive nephropathy (Fogo, 2003).

Nitric oxide has also been shown to regulate the development of obstructive fibrosis in postnatal animals and may play a similar role prenatally (Huang et al, 2000; Felsen et al, 2003). Increased nitric oxide generation reduces the degree of interstitial fibrosis (Ito et al, 2004), and in animals without the gene to produce nitric oxide synthase, unilateral obstruction produces a greater degree of fibrosis than in those animals with this enzyme intact (Hochberg et al, 2000). Data suggest a greater potential role for nitric oxide derived from endothelial nitric oxide synthase (eNOS) than inducible nitric oxide synthase (iNOS) (Huang et al, 2000; Chang et al, 2002).

Hypoxia may be a factor in the development of tissue fibrosis as well, in response to induction of hypoxia-inducible factors-1 and 2 (HIF-1, HIF-2) (Higgins et al, 2008). In-vitro stimulation of renal epithelia with HIF-1 increases EMT, known to induce fibrosis. Genetic models that do not express HIF-1α develop less fibrosis and inflammatory infiltration in response to ureteral obstruction in postnatal models (Higgins et al, 2007). The role in prenatal obstruction remains undefined but potentially relevant.

Altered regulation of ECM breakdown, the proteolytic balance, is a potential mechanism for interstitial fibrosis of obstruction as well, although less explored. Connective tissue breakdown is controlled by the MMPs, of which there are at least 15 having specific activity toward particular connective tissue proteins. MMP-1, for instance, is a collagenase (Pardo and Selman, 2005), whereas MMP-2 specifically degrades gelatin. Their expression and activity are both subject to close regulation, because it is crucial to appropriate ECM homeostasis. Too much activity will degrade the tissues, whereas too little permits accumulation of abnormal amounts of ECM. These pathologic alterations have been described in a variety of disease states, including arthritis and pulmonary fibrosis (Corbel et al, 2002; Vincenti and Brinckerhoff, 2002). One of the means by which their activity is regulated is through endogenous TIMPs. These are less varied and may have less specific activity over the MMPs in their environment and serve to check the degradative activity of the MMPs. Their expression and activity are closely regulated and their net activity is the proteolytic balance. The role of the proteolytic balance in a wide variety of disease states has been the subject of active research (Diamond et al, 1998; Vincenti, 2001).

Altered activity and regulation of the MMPs and TIMPs have been studied in the kidney (Eddy, 1996) in several conditions, and it is clear that they are important regulators of the state of the ECM. Their expression has been shown in the developing kidney as well, and in postnatal obstruction they are altered in activity. In prenatal obstruction increased expression (Ayan et al, 2001; Mure et al, 2006a) and activity (Gobet et al, 1999a) have been shown, as well as in congenital reflux-related fibrosis (Gobet et al, 1998). The precise regulators of the MMPs and TIMPs in development and obstruction are not well defined but are likely to be an important element in the development of pathologic fibrosis. There also is some evidence of regulation by the RAS and TGF-β, which opens therapeutic options for the treatment of fibrosis (Diamond et al, 1998; Ding et al, 2005; Bolbrinker et al, 2006; Yang et al, 2007).

Fibrosis is clearly a major component of the pathophysiology of congenital obstruction. Understanding the role and activities of the various components of this system may permit more specific diagnosis through urinary biomarkers reflecting the elements of the system. These elements may also be relevant targets of therapeutic intervention to modulate ECM homeostasis.

Key Points: Fibrosis

- One of the histologic hallmarks of renal dysplasia is the presence of fibromuscular collars around tubular structures, so-called primitive ducts.
- A universal characteristic of obstructive nephropathy appears to be renal fibrosis.
- Breakdown of ECM is tightly regulated and represents the product of degradative enzymes (matrix metalloproteinases [MMPs] and their endogenous inhibitors (tissue inhibitors of metalloproteinases [TIMPs]).

FUNCTIONAL INTEGRATION

Renal function is regulated at numerous levels, including vascular, neural, and hormonal factors, and this may be significantly affected by inflammatory processes. **Congenital obstruction alters both the ongoing functional integration of the kidney as well as the development of the mechanisms that are intrinsic to this regulation. It can change the regulatory mechanisms themselves.** For example, hypertension is well recognized as a potential consequence of obstruction and may have effects beyond the kidney. More subtle effects on the normal regulatory systems of the kidney may be more difficult to detect.

Inflammation appears to be a common consequence of obstruction in the postnatal human or animal model. Much attention has been paid to this in acquired obstruction, but it is surprisingly absent in congenital obstruction. Biopsies of human kidneys with obstruction but no history of infection have sparse inflammatory infiltrates (Huang et al, 2006). Models of fetal obstruction have little evidence of inflammation (Peters et al, 1992). The reason for this marked difference is unclear but suggests fundamentally distinct mechanisms. It is another indication that congenital obstruction is distinct in many ways from postnatal acquired obstruction.

Vascular Development

The developing vascular tree plays a critical role in renal development, and any disruption could be associated with a wide variety of abnormalities, ranging from lack of development of the glomerulus to aberrant regulation of renal blood flow. Sensitivity to humoral and neural regulation of blood flow may be altered as well, which may be a permanent effect.

Expression of renal renin is increased in the obstructed kidney (el-Dahr et al, 1993; Gobet et al, 1999b; Ayan et al, 2001) and decreased in the contralateral kidney. Renin-secreting renal cortical cells appear to be recruited with obstruction as well (Norwood et al, 1994). Expression of receptors for the RAS is altered in specific patterns in neonatal obstruction. Angiotensin I, which mediates vasoconstriction (as well as growth alterations) (Chung et al, 1995; Yoo et al, 1998) increases whereas the levels of angiotensin II, which acts in a contrary manner, are decreased. These alterations suggest a role for a local renal RAS in obstruction-mediated vasoconstriction and that are independent of the systemic RAS.

Altered sensitivity of both kidneys to renin-mediated vasoconstriction has been shown to occur with unilateral obstruction. Interaction with nitric oxide has been seen to be important in regulation of both glomerular and tubular function in early obstruction (Eskild-Jensen et al, 2007b). After release of obstruction, sensitivity to angiotensin II–mediated vasoconstriction was

reduced in the obstructed kidney but increased in the contralateral kidney (Chevalier and Gomez, 1988). These observations indicate the sensitivity of renal vascular regulation to obstruction as well as the importance of recognizing the interaction of the two developing kidneys. The role of renal counterbalance in obstruction has been recognized but only investigated to a limited degree. A possible mechanism for these observations is through neural regulation of renin expression (Chevalier and Thornhill, 1995a).

Neural Development

Renal innervation is an important regulator of vascularity and perfusion and is associated with expression of renin in the kidney (el-Dahr et al, 1991). Sympathetic denervation, both mechanical and chemical, has been shown to reduce the expected increase in renin expression in the setting of obstruction (Chevalier and Thornhill, 1995b). A more primitive pattern of renin gene expression appears to persist with congenital obstruction and may cause a persistence of fetal patterns of neural and vascular regulation.

Hormonal Development

The major hormones regulating renal functional development are in the RAS, and these are significantly affected by congenital urinary obstruction. This has a variety of effects, including growth alterations and fibrosis, as well as altered blood flow. The sensitivity of the kidney to elements of the RAS changes during development, presumably to permit transition from a fetal state with reduced oxygen tension and limited need for renal perfusion, to the postnatal environment. Postnatally, all filtration must be through the kidneys rather than the placenta as it is prenatally. This is thought to be related to the shift in expression of the angiotensin receptors as one aspect of this system. In fetal life, angiotensin receptor type 2 (AT2) is predominant in expression and has a vasodilating effect and may promote growth whereas type 1 (AT1) is less active until postnatally to permit regulation of renal perfusion in the postnatal environment (Robillard et al, 1995). Altered developmental regulation of these receptors has been induced with fetal obstruction as well (Gobet et al, 1999a). Activity of the RAS is balanced in the developing kidney by nitric oxide, and alterations in this balance have been demonstrated in the developing kidney subjected to obstruction (Bogaert et al, 1996), perhaps explaining the observed preservation of renal blood flow despite ongoing fetal bladder obstruction (Bogaert et al, 1995; Nguyen and Kogan, 1998). In contrast, with complete fetal unilateral ureteral obstruction, renal blood flow was not maintained, indicating thresholds of obstructive severity for certain renal responses (Mure et al, 2006a). Targeting these specific alterations may provide information as to the impact of obstruction as well as having possible therapeutic value (Topcu et al, 2007). Improved diagnostics may be developed if imaging can be linked to hormonal activity that has distinct patterns in obstruction. For example, if congenital urinary obstruction induces a balance of the RAS that favors the more fetal pattern of receptor subtypes, perfusion renography or imaging coupled with pharmacologic inhibition or stimulation of this system, as in a captopril renogram, may permit identification of this pattern (Bajpai et al, 2002). It is essential to recognize that the integrity of the RAS is critical to normal renal development and inhibition may produce negative effects on normal renal function or even exacerbate obstructive effects (Coleman et al, 2007).

Aldosterone may be a potentially useful target for therapy, because it has been shown to contribute to cardiac and renal fibrosis in various pathologic situations (Xu et al, 2008; Ku and Campese, 2009; Lea et al, 2009). Inhibition using spironolactone, a receptor antagonist, has been shown experimentally to limit the amount of interstitial fibrosis in a juvenile rodent model of complete obstruction (Trachtman et al, 2004). This raises the potential for therapeutic interventions using familiar pharmacologic tools yet also indicates the complexity of interaction in the kidney's responses to obstruction.

Tubular Function

Although glomerular filtration and renal plasma flow are the most commonly measured elements of renal function, renal tubular function is equally important yet often ignored in urinary obstruction. Tubular function regulates acid-base homeostasis, electrolyte balance, and urinary concentration as well as vitamin D homeostasis. When obstruction is bilateral, defects in these various functions are major clinical problems; when obstruction is unilateral, they are often compensated by the contralateral kidney and are therefore difficult to measure accurately and noninvasively. There are reports of persisting tubular dysfunction in various congenital obstructions (Hutcheon et al, 1976), but it is uncommon for this to be a clinical problem.

Congenital obstruction can be shown experimentally to produce several functional effects on the renal tubules, including acid-base, sodium, and water homeostasis. Specific downregulation of sodium transporters (Norregaard et al, 2005) in the tubules as well as reduction in the expression and protein levels of the aquaporins has been demonstrated in neonatal obstruction in rats and juvenile piglets (Frokiaer et al, 1997, 2003; Eskild-Jensen et al, 2006; Jensen et al, 2006). Downregulation of acid-base transporters in tubular epithelium has been demonstrated in juvenile rats (Wang et al, 2009). Although these defects may be compensated for by a normal contralateral kidney, limiting their clinical impact, alterations in urinary levels of these protein may serve as markers for significant obstructive effects.

The mechanisms of injury are likely to be a combination of the previous described effects, and therapeutic interventions targeted to those mechanisms may limit tubular dysfunction. Measuring abnormal tubular function may be possible using more sensitive measures and imaging technology.

Inflammatory Mediators

Although inflammatory changes do not appear to be a major factor in early postnatal congenital urinary obstruction (Misseri et al, 2004), it is likely that they begin to play a greater role with age. It will be necessary to confirm the pattern and role of these factors in congenital urinary obstruction in humans, because many animal systems demonstrate significant inflammation postnatally, although fetal systems do not (Peters et al, 1992). Human pathologic material has not shown large amounts of inflammation (Huang et al, 2006), except when complicated by infection (Bartoli et al, 2000; Kiratli et al, 2008). If there is a subset of patients with inflammatory changes in the presence of obstruction, it would seem an important target for investigation to improve both diagnostic and therapeutic capability (Meldrum et al, 2006, 2007). The various inflammatory cascades that have been investigated postnatally can be manipulated pharmacologically, and this may permit important therapeutic regulation of renal injury (Cale et al, 2000). Inflammatory mediators such as monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor-α (TNF-α), regulated on activation normal T-cell expressed and secreted (RANTES), and

others may be measurable in the urine as well, as has been shown in experimental systems (Crisman et al, 2001; Silverstein et al, 2003).

Key Points: Functional Integration

- Angiotensin is a key modulator of many of the inflammatory responses to ureteral obstruction.
- Expression of renal renin is increased in the obstructed kidney and decreased in the contralateral one. Renin-secreting renal cortical cells appear to be recruited with obstruction as well.
- The activity of the renin-angiotensin system is altered with obstruction, which affects renal functional development by a variety of changes, including growth, fibrosis, and blood flow.

REVERSAL OF CONGENITAL RENAL OBSTRUCTION

An important element in the understanding of congenital obstruction is the potential for reversal of renal functional and developmental impairment with correction of the obstructive lesion. This is clinically relevant when making decisions regarding the utility of intervention either postnatally or prenatally. In the latter, the potential for reversal has great significance in determining whether the risks associated with fetal intervention are warranted. Improvement in function is also important in the expectation of response to relief of obstruction.

In the fetal obstructed kidney, Glick and colleagues (1984) **showed that the functional salvageability of a unilaterally obstructed kidney was dependent on the duration of obstruction and gestational age.** A direct relationship between progression of nephronogenesis and reversibility can be demonstrated (Edouga et al, 2001). Similar observations have been made in early postnatal models, with the recognition that complete reversal of the damage is seldom achieved (Claesson et al, 1987; Chevalier et al, 1988, 1999a, 1999b, 2002; Eskild-Jensen et al, 2003; Shi et al, 2004; Dissing et al, 2008). Mediators of improvement have not been explored. The severity of obstruction is also a critical determinant (Bussieres et al, 1993), but it is challenging to measure in any meaningful way. Biomarkers of salvageability have been developed and were first used clinically in accordance with the work of Glick and Adzick in obstructed fetal sheep (Adzick et al, 1985). From these basic parameters emerged the clinical prognostic factors currently used, with modification, in fetal obstruction (Harrison et al, 1982; Glick et al, 1985). **Measures of urinary sodium, chloride, osmolarity, and calcium have correlated with fetal renal functional potential** (Muller et al, 1993; Johnson et al, 1995; Dommergues et al, 2000; Biard et al, 2005). **When fetal urine approaches the character of serum, irreversible damage appears to have been done to the developing kidney.** Other markers have been explored in the fetus, including α_1-microglobulin in amniotic fluid and β_2-microglobulin in urine and serum (Burghard et al, 1987; Freedman et al, 1997; Nicolini and Spelzini, 2001; Craparo et al, 2007).

The mechanisms of functional recovery may be similar to the mechanisms of injury, but they may also be unique and the potential may exist for enhancing recovery if these mechanisms can be understood and used. In part, the pathway of recovery includes normal developmental pathways that had been impaired because of obstruction (Chevalier et al, 1988). **As a consequence of urinary tract obstruction, nephron injury is heterogeneous, with some nephrons undergoing adaptive growth and hyperfiltration and others being destroyed. Thus, 1 month after relief of 5 days of unilateral ureteral obstruction in the neonatal rat, the glomerular filtration rate (GFR) of the postobstructed kidney was normal despite a 40% reduction in the number of glomeruli** (Chevalier et al, 1999c). **However, 1 year after relief of the obstruction the GFR of the postobstructed kidney had decreased by 80%** (Chevalier et al, 2000). Even though there had been no further loss of nephrons during this interval the remaining glomeruli had undergone progressive sclerosis (Chevalier et al, 2000). Although relief of temporary unilateral ureteral obstruction did not lead to nephron loss in the adult rat, there was a reduction in glomeruli after this relief in the period immediately after nephrogenesis, as well as during nephrogenesis (Chevalier et al, 2002). This underscores the susceptibility of the developing kidney to obstructive injury not only during nephrogenesis but also during subsequent nephron maturation.

Key Points: Reversal of Congenital Renal Obstruction

- The functional salvageability of a unilateral obstructed fetal kidney is dependent on the duration of obstruction and gestational age.
- Measures of urinary sodium, chloride, osmolarity, and calcium have been correlated with fetal renal functional potential.
- When fetal urine approaches the character of serum, irreversible damage appears to have been done to the developing kidney.

APPROACH TO CLINICAL CASES

General Approach

The clinical challenge of congenital urinary obstruction reflects the clinical spectrum of the condition itself. A determination must be made as to which patients need intervention to protect renal functional development. Some will clearly need such intervention, whereas many others will do well without. Given the wide spectrum it is extremely difficult to determine a clinically practical dividing line between those in whom intervention is appropriate and those in whom it is not needed. This question is relevant to the largest number of patients with some form of congenital urinary obstruction. The ultimate determination of the need for intervention may come as a single diagnostic test or be based on a pattern of change or lack thereof over time. In this situation we wish to be sensitive but will accept being less specific. We would rather not miss a large number of patients with congenital urinary obstruction needing intervention, recognizing that some patients may undergo further evaluation or intervention when they might not have needed it.

The second challenge is with the patients at the extreme end of the spectrum in whom renal functional impairment has already occurred and poses the threat of permanent and progressive renal insufficiency. In the presence of obstruction, what is our best approach to preserve the maximal amount of renal function? Even with successful surgical intervention, we are often confronted with

an inexorable progression to renal failure in these children, yet it would seem reasonable to ask if we can prevent renal demise. As yet there has been no clinically applicable approach, but as our understanding of the pathophysiologic mechanisms of congenital urinary obstruction improve, we may be able to specifically alter critical components of the system to better regulate the mechanisms affecting renal response to obstruction.

Diagnosis

The challenge to be able to diagnose "obstruction" has been made more difficult owing to disagreement as to the definition of *obstruction*. Although the concept that obstruction is an "impairment of urine flow that will produce a reduction in function if left uncorrected" is logical, it misses several important elements in the context of congenital obstruction. One is that the developing kidney should be increasing its function, not remaining static. It also does not provide any insight into the interpretation of a kidney that has reduced function when diagnosed. Strictly interpreted, this kidney is already affected by having had its normal potential function limited, and, by definition, is "obstructed." This interpretation has not been widely used, however, and it is only on prospective follow-up that a decrease from normal is thought to be indicative of "obstruction." A more useful definition might be any condition that has or will limit ultimate functional potential should be considered clinically significant obstruction. It should also be recognized that obstruction does not mean surgical therapy is required. Obstruction may be mild and clinically insignificant. The exclusion of these patients from the diagnosis of obstruction has tended to force people to create convoluted descriptions of hydronephrotic kidneys.

Ultimately, a determination of the potential risk to a kidney will have to be made clinically and a judgment made as to whether a particular child would benefit from intervention. It would seem reasonable and cautious to assume that any hydronephrotic kidney is obstructed until proven otherwise and to assess the degree of risk. Understanding the pathologic mechanisms of obstructive nephropathy will permit more specific examination of the kidney to determine its response. It should be the renal response primarily that is used to make the determination of obstructive effect. The fluid dynamics of the upper urinary tract, while obviously relevant to the renal effect, should not be the primary focus. This may be why many drainage studies, including diuretic renography and pressure-perfusion tests, are imperfect predictors of the renal response. We have seen that the obstructed kidney is undergoing altered growth regulation, abnormal differentiation and increased fibrosis, all mediated through a variety of molecular, cellular and renal homeostatic mechanisms. These patterns of change are likely to be reflected in altered expression of proteins and chemicals, which may be assayed in the urine. There may be systemic alterations that are detectable in the blood as well. The search for these biomarkers has been active, yet few have been firmly linked to the pathologic progression of obstructive nephropathy (Chevalier, 2006).

Biomarkers of renal obstruction may reflect the response of the kidney in a direct manner, such as expression of growth factors that contribute to fibrosis or are associated with increased apoptosis in renal epithelium. They may also be downstream effects reflecting specific alterations mediated by other cytokines and in themselves not directly relevant but more indicative of the level and pattern of the obstructive effect. A broad approach that is emerging uses assessment of changes in overall protein expression in the urine—proteomics. Normal developing kidneys have an evolving protein fingerprint, which can be defined (Lee et al, 2008) and which is altered with obstruction. If particular elements of the alteration can be identified and associated with clinical outcomes, these patterns may be diagnostic of functionally significant obstruction. Such patterns may reflect a single protein, which may be an element of a response pattern, or a downstream consequence. It may be that a particular pattern of protein expression involving several factors will be the best indicator of obstruction (Decramer et al, 2006, 2008). Such studies will require development in animal systems and validation in humans. It will be necessary to set limits for what is and is not clinically significant "obstruction" and correlate this with clinical and functional outcomes of relevance. These changes also will need to be correlated with histopathologic changes in the developing kidney because our ability to measure some functional alterations remains imperfect.

An alternative approach to diagnosis may be to assess response to stimulus. This is the basis of the captopril renogram, in which radionuclide uptake in the presence of obstruction is reduced when the RAS is inhibited by the angiotensin-converting enzyme inhibitor captopril but not in the dilated, nonobstructed system (Bajpai et al, 2002). The underlying rationale for this test is that, in the obstructed kidney, function is dependent on increased activity of the RAS, as suggested earlier. By reducing the capacity of this system to support function by administration of captopril, a decrease is detected in the post-captopril study. The concept is reasonable, but problems with definitions of true "obstruction" continue to thwart its broad applicability. Alternative pharmacologic manipulations are needed to more specifically address one or more functional factors in the potentially obstructed kidney. The production of various cytokines in the presence of a stimulus may be able to distinguish the kidney at risk for injury from the kidney not at risk.

At present we are limited to the conventional imaging modalities of ultrasonography, diuretic renography, and, increasingly, magnetic resonance imaging (MRI).

Key Points: Approach to Clinical Cases

- Congenital urinary obstruction may best be defined as urinary flow impairment that has limited or may potentially limit normal renal development.
- Not all hydronephrosis represents obstruction that requires surgical correction.
- Biomarkers for renal obstruction should reflect changes in normal development, as well as specific alterations due to obstruction.
- Although most clinical cases of congenital obstruction are asymptomatic, cases in children are still detected due to pain, a mass, hematuria, and hypertension.

CLINICAL EVALUATION

The mode of presentation of obstructive uropathy will often determine the clinical management. Those presenting with symptoms will require a careful anatomic and functional assessment and, likely, surgical intervention. Those in the less discrete category, including ureteropelvic junction (UPJ) obstruction and ureterovesical

junction (UVJ) obstruction, presenting without symptoms are more challenging. If posterior urethral valves, ureterocele, or ectopic ureter is detected, even if asymptomatically, intervention is almost always appropriate. Patients with very mild versions might be considered candidates for an observational approach if no evidence of bladder or renal dysfunction is present.

Symptomatic presentation of UPJ and UVJ obstruction almost always can be managed with surgical intervention. Although it is unknown when such a symptom episode might recur, the likelihood is high, although it has never truly been determined. Infection is uncommon with UPJ obstruction but not with UVJ obstruction, and these children can become very ill due to the combination of infection and obstruction. It seems as if the severity of the obstruction may be exacerbated by the reaction to the infection. Marked increases in hydronephrosis have been reported in association with an acute infectious episode, likely owing to the effect of bacterial toxins (Pais and Retik, 1975). Subsequent resolution should not falsely suggest an insignificant process.

Stone development is another form of clinical presentation, often presenting as hematuria or pain. Although the two conditions are linked, it cannot be assumed that a treatable metabolic disorder is not possible (Husmann et al, 1996). Appropriate evaluation is warranted. Conversely, a stone impacted in the UPJ can create the appearance of a congenital UPJ obstruction on routine imaging.

The classic presentation of acute episodes of flank pain and nausea due to UPJ obstruction is termed a *Dietl crisis* when bilateral (Dietl, 1864). **It can occur more often unilaterally and is often thought to be a gastrointestinal disorder with subsequent misdirected evaluation** (Alagiri and Polepalle, 2006). These children can present at any age, although it is rarely recognized in early childhood. The pattern is often one of increasingly frequent and severe episodes of acute-onset abdominal or flank pain with nausea and vomiting. These episodes may last for minutes to several hours and often occur in the evening. Only occasionally is the episode obviously triggered by fluid intake. Some children will report that leaning over a chair can help reduce the discomfort. Little can reduce their discomfort otherwise, yet when the episode has passed they seem fully recovered. The repetitive and consistent nature of the episodes, particularly with a nonrevealing gastrointestinal workup, should prompt consideration of a renal cause and performance of an ultrasound evaluation. Diagnoses given to these episodes before being accurately identified have included abdominal migraines, food allergies, musculoskeletal problems, and emotional disturbances. In a most extreme example a girl had ongoing diagnoses of more and more food allergies while her kidney became progressively nonfunctional as a result of having had an early evaluation that was misinterpreted.

IMAGING

To define both the nature and extent of any potentially obstructive condition it is necessary to obtain an anatomic and functional assessment of the kidneys, ureters, bladder, and urethra. Performing this in a logical sequence will usually permit an appropriately selective workup.

Anatomic Assessment

Ultrasonography

The most widely useful initial imaging study for many obstructive conditions is renal and bladder ultrasonography. Although essentially a structural evaluation, functional information can also be gained. The characterization of hydronephrosis is straightforward with ultrasonography, and seldom is there a real need for any other imaging to define the degree of hydronephrosis. **Any indication of hydronephrosis on ultrasonography must be qualified by a description of the laterality, severity, and associated alterations in the renal parenchyma.**

Some consider hydronephrosis to be present only with calyceal dilation, so it is best to use the terms *pelviectasis* and *caliectasis* to describe these entities, along with a qualifier as to severity. Because the degree of pelvic and calyceal dilation is not always the same, distinct description is important. Indeed, the situation in which the renal pelvis is not markedly dilated yet there is marked caliectasis may even suggest a process distinct from UPJ obstruction, such as infundibulopelvic stenosis. A very dilated pelvis, with minimal to no caliectasis, suggests a functionally milder obstruction than the degree of dilation might indicate. The most widely used grading system is the Society for Fetal Urology scale (Fig. 113–7), which divides hydronephrosis into four grades (Fernbach et al, 1993). This is a useful communication tool but is limited in its description of the more severe degrees of dilation, which are combined into one grade with very wide inclusion. It still provides more information than a report simply stating "hydronephrosis."

The condition of the renal parenchyma is reflected to some degree in its ultrasound appearance. With increasingly abnormal development, kidneys are more echogenic. This may be due to more tissue-urine interfaces to reflect the sound waves; and although it is not proof of "dysplasia," which is a pathologic diagnosis, it is suggestive. The thickness of the renal parenchyma is often described, and the effect of hydronephrosis may be referred to as cortical thinning or cortical atrophy, although some of these kidneys have intact uptake on nuclear scans (Erickson et al, 2007). The kidney can undergo a significant amount of stretching without being markedly affected functionally, probably as a compensatory mechanism. This should not be used as an indicator of a nonsalvageable kidney in the absence of functional testing.

Direct Imaging

In some cases, specific imaging of the anatomy of the urinary collecting system may be important in determining management. This is usually when the ultrasound appearance is atypical or with a duplicated system. The intravenous pyelogram was often able to provide these anatomic insights and on occasion may still be useful. Magnetic resonance imaging (MRI) can often provide this level of detail even in small children. Retrograde pyelography performed during cystoscopy can demonstrate ureteral and pelvic anatomy very clearly and can ensure the localization of the obstructive area. This is often in preparation for operative intervention. It is important to recognize the risk of infection if the kidney is not going to be decompressed after the study, whether by stent or definitive surgery.

Antegrade imaging can be useful if a percutaneous nephrostomy has been placed. This is usually in the setting of an ill infant with bilateral obstruction or a solitary obstructed kidney or for severe pain.

In the initial evaluation of most infants with hydronephrosis, voiding cystourethrography is performed to determine whether reflux may be present. The occurrence of both reflux and obstruction can be a very challenging clinical situation. In particular this is difficult when

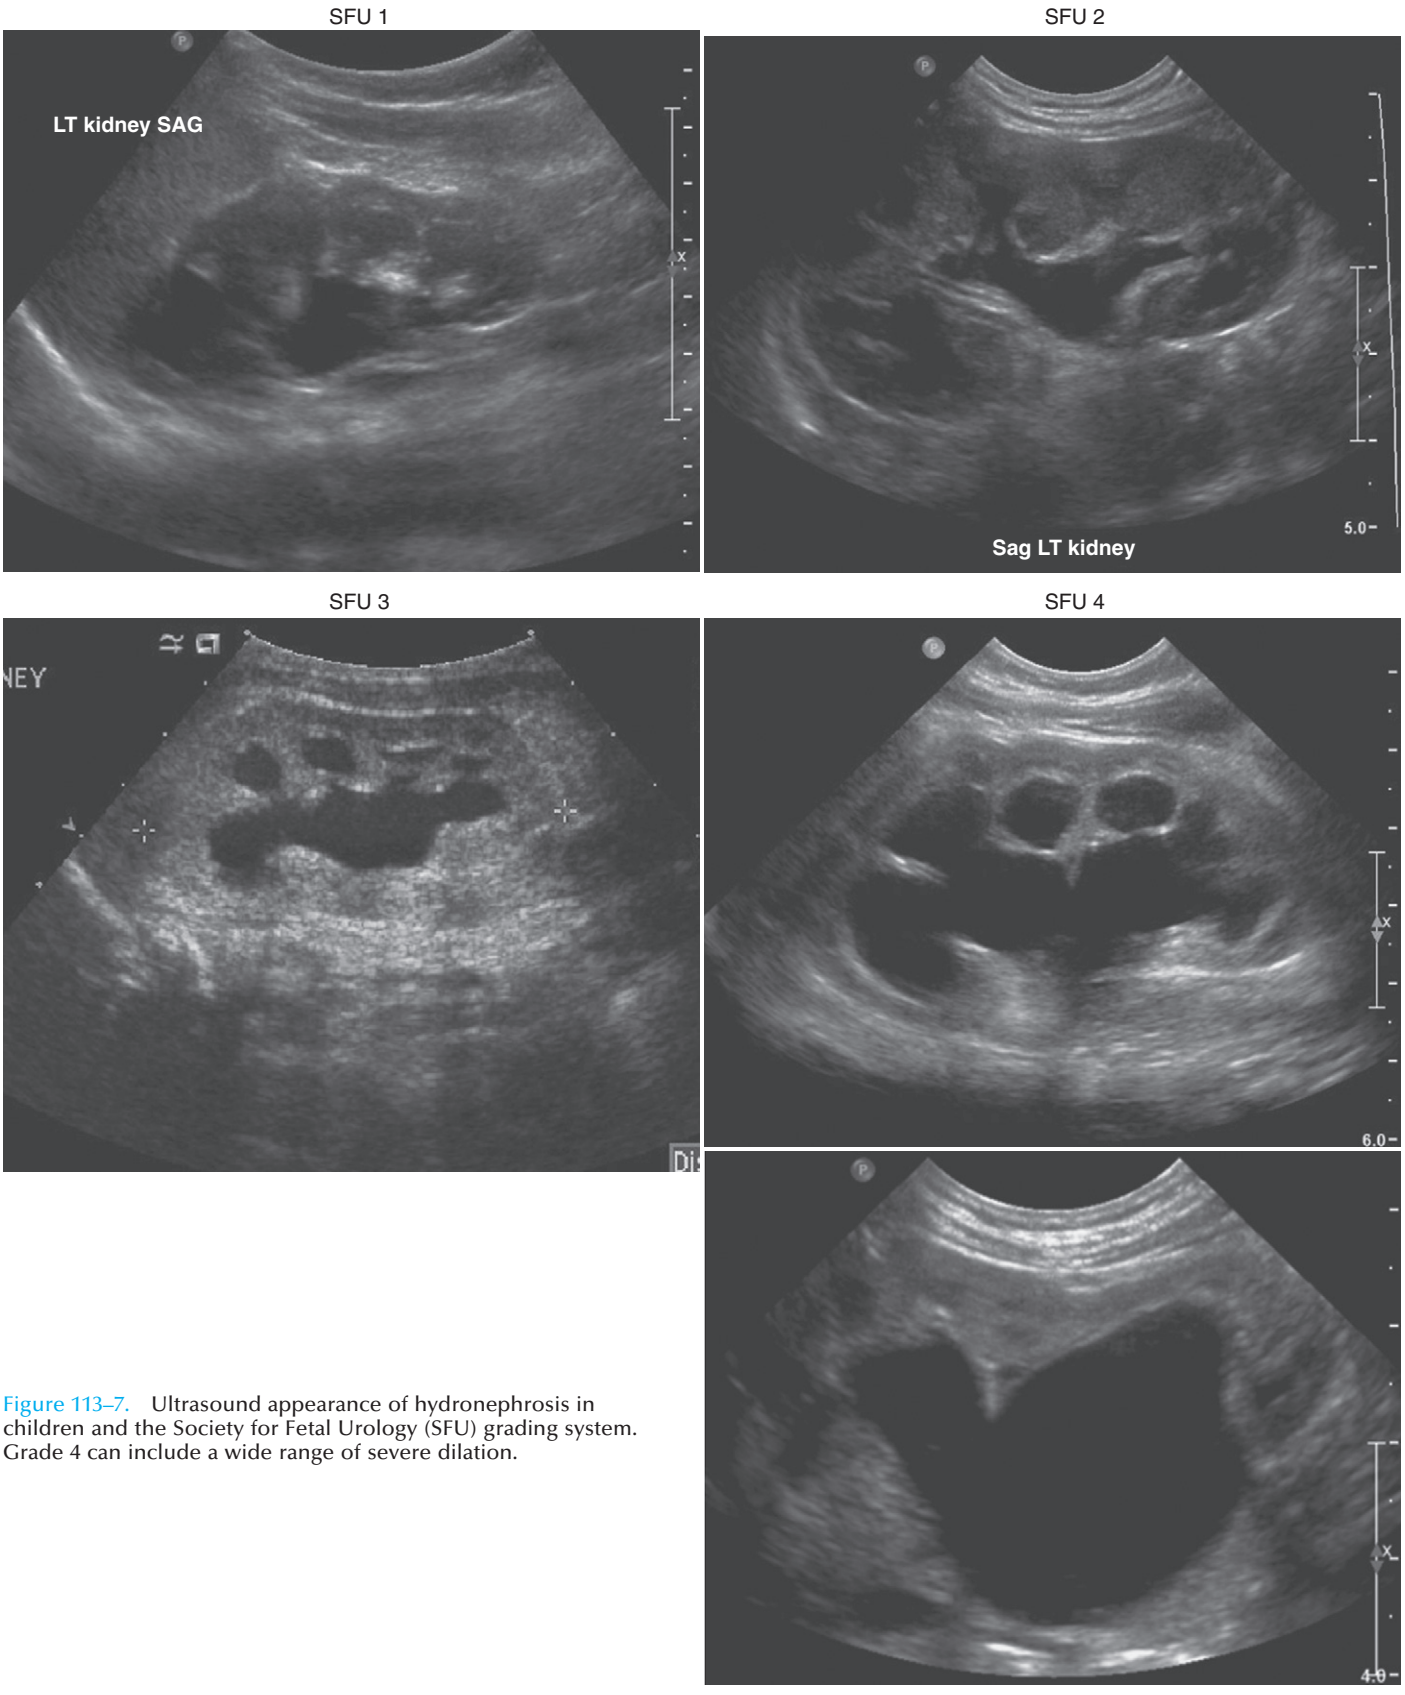

Figure 113–7. Ultrasound appearance of hydronephrosis in children and the Society for Fetal Urology (SFU) grading system. Grade 4 can include a wide range of severe dilation.

high-grade reflux may produce a very dilated pelvis, and this may create impaired drainage due to ureteral tortuosity. Whether there is a true UPJ obstruction in addition to the reflux is unclear. The decision as to which process to correct, if surgical intervention is appropriate, is difficult (Stauss et al, 2003). If there is significant ureteral tortuosity, correction of the reflux first can allow for improvement of the UPJ obstruction, but close monitoring is required (Hollowell et al, 1989).

Functional Assessment

Although anatomic assessment is a critical element of clinical diagnosis of obstruction, so, too, is a functional assessment; yet we remain limited by technology in the accuracy and utility of these methods. **At present, diuretic renography is the "gold standard" for functional imaging of congenital obstruction; yet questions must be raised as to its prognostic value and true role in clinical management.** These uncertainties are based on a poor correlation with renal pathology, variability in interpretation, and lack of reproducibility in individual patients. Attempts have been made to standardize testing protocols (the well-tempered renogram) (Conway and Maizels, 1992), but none has been validated with any method other than diuretic renography. There is still utility to the diuretic renogram when interpreted judiciously, and the emergence of MR technology for obstructive uropathy holds great, yet unfulfilled, promise. An integral part of any utility will be studies that validate imaging observations with both functional assessment by other means, pathologic correlations, and clinical outcomes.

Diuretic Renography

Diuretic renography is based on the ability to measure the rate and location of uptake of a radiolabeled organic molecule that is handled by the kidney in a specific way. The most commonly used tracer is ^{99m}Tc-mercaptoacetyltriglycine (MAG3). This tracer is taken up by the renal tubules and is largely excreted by the tubules into the tubular lumen. There is relatively little glomerular filtration. The early pattern of uptake is roughly equivalent to renal plasma flow and is parallel to GFR. Unlike dimercaptosuccinic acid (DMSA), it is not bound to the tubules and is rapidly cleared, permitting assessment of drainage from the collecting system. Another agent, diethylenetriaminepentaacetic acid (DPTA), was less avidly taken up, resulting in higher levels of background tracer, making initial functional assessment less precise. MAG3 has a very high signal-to-noise ratio during the first 1 to 2 minutes, during which time relative uptake is assessed.

Function. **What is often referred to as "function" from a diuretic renogram is relative uptake of tracer during the first 1 to 2 minutes after injection and, again, is roughly equivalent to GFR. It is expressed as differential function between the two kidneys and always adds up to 100%. It should always be borne in mind that if both kidneys are abnormal a 50% measurement is not "normal" function.** With one healthy kidney, the relative uptake of the affected unit reflects current GFR and is a reasonably good overall assessment of function. The estimated differential uptake is generally believed to be accurate to plus or minus five percentage points. It is not a direct reflection of tubular function, acid-base handling, concentrating ability, or hormonal function, but it is useful. Changes over time are a valuable clinical parameter, again with the caveat that one kidney must be normal. Attempts have been made to assess absolute function by determining an extraction factor that reflects true renal clearance (Heyman and Duckett, 1988; Cartwright et al, 1992). This may be useful in some extreme cases but has limitations on utility and is not often used clinically.

In the assessment of hydronephrosis, several aspects may affect interpretation of relative uptake. In very young infants, relative uptake is not as avid and the signal-to-noise ratio is decreased with higher background levels. Subtracting these levels can be operator dependent yet will be critical in determining uptake. For the right kidney the overlap with the liver may further confound an accurate assessment. The dilation of the parenchyma of the kidney moves it further away from the camera and the retained urine may quench some of the radioactivity, further reducing accuracy. It remains unclear how the immature obstructed kidney responds to the obstruction as noted earlier, and the compensating kidney may show relatively normal uptake yet still be abnormal. This was demonstrated in the observation of normal relative uptake in kidneys with significant histologic abnormalities in unilateral UPJ obstruction (Huang et al, 2006). Relative hyperfunction may also be seen, and it remains controversial what this actually represents (Steckler et al, 1994; Capolicchio et al, 1999; Moon et al, 2003, Maenhout et al, 2005). It may be a healthy kidney that is actually hypertrophied from the obstruction, or it may be a compensatory response that ultimately will be detrimental over time (Capolicchio et al, 1999, Oh et al, 2001). This is not a common occurrence and has not been carefully studied (Ozcan et al, 2006).

Despite these limitations a well-performed diuretic renogram provides a reasonable measure of relative uptake and "function" of the hydronephrotic kidney. It is best used as a serial marker to be followed to determine deterioration or improvement (Fig. 113–8) (Eskild-Jensen et al, 2005). When relative uptake is reduced, it is rarely recoverable despite successful surgery. Reports of spontaneous increases in uptake are difficult to interpret, because they seem rare in experience and may equally represent systematic underassessment of uptake in younger children, owing to background assessment differences (Ulman et al, 2000; Onen et al, 2002).

Drainage. The ability to assess drainage from a hydronephrotic kidney differentiates the MAG3 renogram from the DMSA. As a measure of the degree of obstruction, the time required to clear half of the accumulated tracer from the renal pelvis after reaching its peak and being stimulated by administration of furosemide, the washout half-life has become a measure of obstructive severity. **When it is over 20 minutes it is generally considered "obstructed"; less than 10 minutes is considered normal, and in between is considered uncertain** (O'Reilly et al, 1978; Koff, 1982; Abramson et al, 1983). **These parameters have been broadly used, although the clinical validation is lacking. There has been no truly effective assessment of their predictive utility in children** (Eskild-Jensen et al, 2005). Several studies have shown that the washout time did not predict functional changes over time, nor the development of symptoms (Ulman et al, 2000; Thorup et al, 2003, Koff, 2008). Washout time correlated poorly with renal histology in a biopsy study (Huang et al, 2006). Again, the value of the washout time, until better indicators become available, is in serial follow-up. There can be variability of uncertain etiology, but if a consistent trend can be demonstrated, either improving or worsening drainage, clinical decisions may be aided.

Several factors can contribute to the variability and interpretation of the washout time (Eskild-Jensen et al, 2004). Most centers will use a bladder catheter to make the assessment of washout times to eliminate bladder filling as a factor in upper tract drainage (Conway and Maizels, 1992). Although some have criticized this

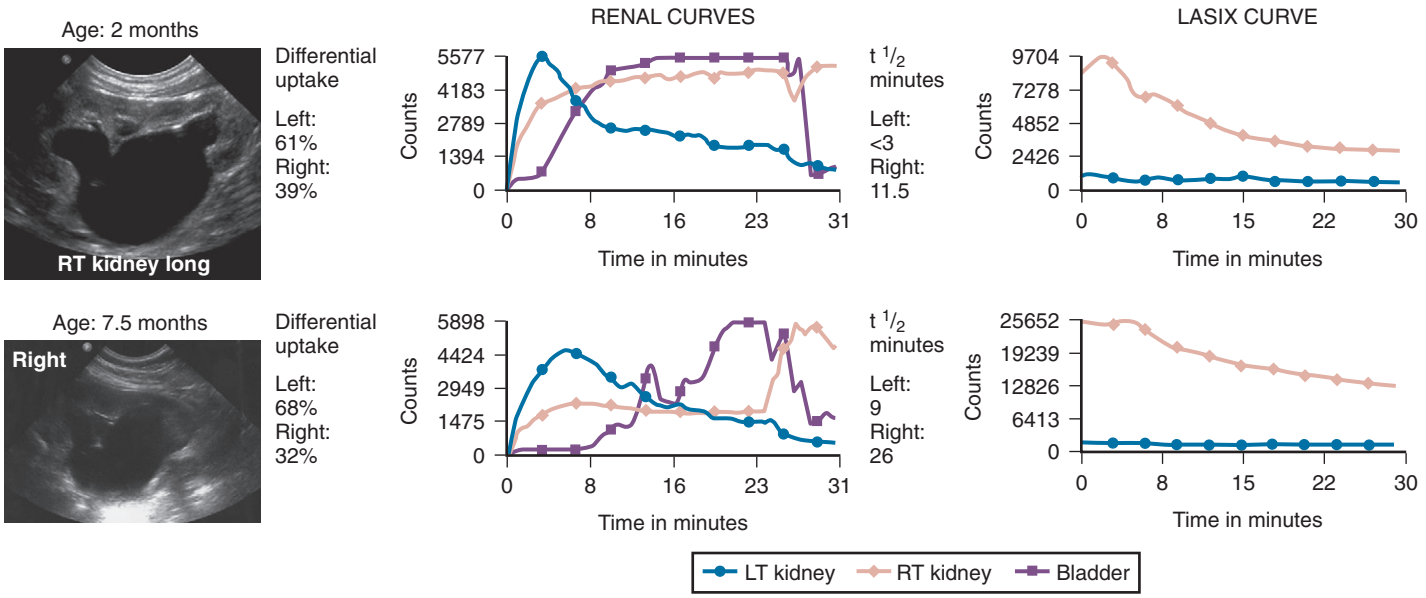

Figure 113–8. Example of the use of diuretic renography using 99mTc-mercaptoacetyltriglycine in the clinical follow-up of an infant with right ureteropelvic junction obstruction. Severe hydronephrosis (grade 4) was present and did not significantly change. Initial renography showed relative uptake of the right kidney at 39% and at ½ washout time of 11.5 minutes, which increased to 26 minutes associated with a decrease in relative uptake to 31% by age 7½ months.

as nonphysiologic, it permits standardization and in the pre–toilet-trained child is preferable. The means by which the washout time is calculated can be variable and dependent on the curve of tracer drainage. Some systems will have a brief and limited drainage, and if that initial phase of the curve is used to extrapolate the washout time it will be falsely normal. Some curves appear to be slow in initial drainage, then rapidly draining, perhaps due to delayed effect of the diuretic agent.

Some authors have attempted to modify the technique and to make it more efficient by administering the diuretic before or simultaneous with the tracer. These are termed the *F–15* or *F zero diuretic renograms* (Upsdell et al, 1992; Donoso et al, 2003; Liu et al, 2005). Although they may be equally effective, they have not been validated against a uniform standard of clinical outcome.

The time required for the tracer to move through the renal parenchyma into the collecting system is the cortical transit time and is analogous to the delay for calyceal filling in the intravenous pyelogram showing a persisting nephrogram. With severe obstruction cortical transit is prolonged, although it is uncommonly used for clinical assessment (Schlotmann et al, 2008, 2009). It is not very useful for subtle distinctions; but if it is elevated well above the normal 2 to 3 minutes, consideration for significant obstructive effect should be given.

For the present, diuretic renography is the most robust means to assess congenital obstruction, particularly of the upper tracts. Its interpretation requires judgment, and simply "going by the numbers" without inspecting the appearance of the kidneys and the uptake and washout curves is inadequate.

Magnetic Resonance Imaging

MRI holds the promise of integrating both anatomic detail with functional assessment of the kidney and urinary tract. In pediatric obstruction it has not yet been fully validated in this regard, but progress is being made and it is likely that MRI will be the modality of choice for evaluating hydronephrosis in the near future. The benefits of MRI include absence of ionizing radiation, detailed anatomic definition of the entire urinary tract, functional assessment comparable to current diuretic renography, and the potential for more specific functional assessment based on tissue characteristics and metabolic factors. Current limitations include cost, limited availability of experienced imaging professionals, need for sedation, and limited validation with clinically relevant outcomes. All of these issues are potentially solvable.

The current status of MRI in hydronephrosis in children is well outlined in several recent review articles (Cerwinka et al, 2008; Grattan-Smith and Jones, 2008) and demonstrates the ability to accurately provide data comparable to diuretic renography with the detailed imaging well known for MRI. Protocols for imaging are being established and validated with diuretic renography, the de facto gold standard. Validation against renal developmental patterns, based on histology or long-term clinical outcomes, remains to be done. At present, MRI in children can provide an accurate assessment of differential renal function, comparable to differential uptake on radionuclide imaging, and a more precise measure of obstruction, including renal transit time, cortical to medullary crossover time, ureteral filling time, and several subjective indicators of obstruction.

Relative function is expressed both as the fraction of total renal function (differential uptake), as well as an estimate of GFR. This is based on one of two methods. The first is relative volume determination (vGFR), in which the functional volume of the kidney is measured and compared with the opposite kidney. These measurements have been correlated with differential uptake on diuretic renography (Perez-Brayfield et al, 2003; Martin et al, 2008). It remains to be seen how well this method will correlate with uptake in the severely hydronephrotic kidney. It is somewhat counterintuitive that function is directly proportional to renal volume, because there are many kidneys with large volume that do not function well. The second method uses Patlak curves of tracer extraction to estimate an index of individual kidney GFR (pGFR), which has also been correlated with radionuclide methods. This can permit more accurate estimates in bilateral diseases or

with scarring. As with radionuclide imaging, the limitations of these studies include the fact that this measures GFR, an important indicator but not the only indicator of renal "function," and cannot estimate other aspects of renal function, such as acid-base, sodium, and water handling. These measures cannot accommodate for renal functional compensation as discussed earlier, and they have not been correlated with renal histology.

The second aspect of MRI is to assess the drainage function of the individual renal unit. This is performed using several parameters reflecting the passage of tracer (gadolinium) through the kidney. In some ways these differing measures probably reflect similar processes, and they do correlate with conventional diuretic renography washout times (Jones et al, 2004). Renal transit time (RTT) is the time required from first visualization in the renal parenchyma of the tracer until it is first seen in the collecting system. Normal values are reported to be up to 245 seconds, intermediate values are from 245 to 490 seconds, and "obstructed" values are over 490 seconds (Jones et al, 2004; Grattan-Smith et al, 2008). These numbers are largely based on conventional diuretic renography, and it has been recognized that this may not be accurate or reflective of relevant clinical outcomes. Calyceal transit time (CTT) has also been used, particularly when the contralateral kidney is normal, permitting comparison of symmetry (Grattan-Smith et al, 2008). Similar to RTT is the corticomedullary crossover point, which is the time required to develop sufficient signal intensity in the medulla to equal that in the cortex (Jones et al, 2005). This is comparable to RTT in that it measures rate of passage of tracer through the renal vasculature and tubules, presumably responding to increased tubular pressures from obstruction. The time until tracer is seen in the ureter is also a reflection of obstructive effect but is probably much less sensitive in the moderately severe degrees of hydronephrosis, which are the ones of most clinical uncertainty. Clinical studies of MR urography in children with hydronephrosis have been limited and have largely been attempts to correlate with diuretic renography. These indicate adequate correlation, and it has been recognized that further assessment with more clinically important parameters is required (Grattan-Smith et al, 2003; Perez-Brayfield et al, 2003; Teh et al, 2003; McDaniel et al, 2005; Martin et al, 2008). A lack of standardized protocols has been suggested as a potential basis for the limited accuracy and reproducibility of clinical reports, and a recent review indicates that routine clinical usage is not yet justified (Grenier et al, 2008).

A further potential benefit from MRI that has been utilized in other areas, and suggested in pediatric urinary imaging, is to use the exquisite sensitivity of MRI to alterations in the metabolic context of tissues. Oxygen tension (Textor et al, 2008; Edlund et al, 2009), sodium levels (Maril et al, 2006), and energy consumption (von Elverfeldt et al, 2007) in the kidney are all potentially measurable by MRI and, coupled with anatomic detail, may provide the critical information to indicate patterns of cellular response that may lead to functional impairment or loss as described earlier. These studies are yet to be conducted in the developing kidney.

There has been recent concern regarding the safety of gadolinium with regard to renal function. A pattern of systemic fibrosis associated specifically with gadolinium has been reported (Wiginton et al, 2008; Graziani et al, 2009; Perazella, 2009). This has been largely restricted to patients with impaired renal function, but it is unlikely that this is a risk to an individual kidney with reduced function due to obstruction. Continued caution is appropriate.

Clinically, MR urography is particularly useful in situations with complex anatomy that cannot be resolved with ultrasonography (Fig. 113–9) and has been used to evaluate chronic hydronephrosis when diuretic renography is ambiguous. It is not yet validated as a "gold standard" but ultimately will become this.

Intravenous Pyelography

It is rare in current usage to require a conventional intravenous pyelogram, but the simplicity of the test is occasionally of benefit. Because it can convey both anatomic and functional information,

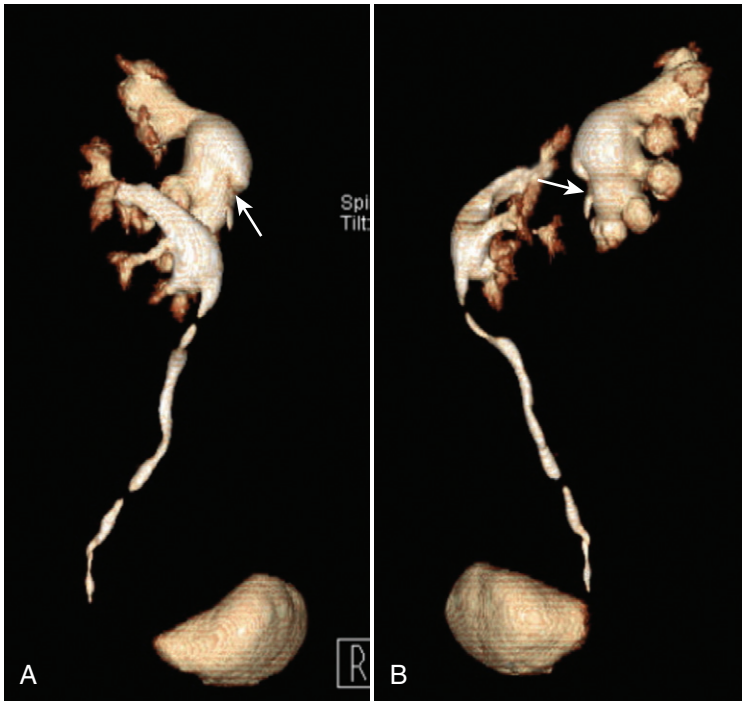

Figure 113–9. Example of the use of MR urography with three-dimensional reconstruction, with two views (**A** and **B**) demonstrating the presence of a crossing vessel causing intermittent pain and obstruction in a boy with a horseshoe kidney. The *arrows* indicate the impression of the vessel on the proximal ureter. Hydronephrosis is mild to moderate, but pain was relieved with surgical repair.

it provides a less precise and nonquantitative version of what MRI promises. Its use has become limited, and some centers no longer perform the test. The authors have found it useful in complex anatomic cases, particularly with duplication anomalies combined with hydronephrosis in which it may provide preoperative data to indicate the appropriate surgical approach. It is also useful in the postoperative situation with persisting hydronephrosis when it is uncertain if there is high-grade obstruction and a renal scan may not be needed. The intravenous pyelogram can show that the kidney is functioning and, although draining slowly, is safe for further observation to demonstrate improvement. In these cases a simple three-image study can be perfectly adequate. As MRI evolves further, and shorter scan times become routine, the intravenous pyelogram will become obsolete, but it can still play a role in selected situations.

Key Points: Imaging for Congenital Obstruction

- To define both the nature and extent of any potentially obstructive condition it is necessary to obtain an anatomic and functional assessment of the kidneys, ureters, bladder, and urethra.
- The most widely useful initial imaging study for many obstructive conditions is renal and bladder ultrasonography.
- Any indication of hydronephrosis on ultrasonography must be qualified by a description of the laterality, severity, and associated alterations in the renal parenchyma.
- In the initial evaluation of most infants with hydronephrosis, voiding cystourethrography is performed to determine whether reflux may be present. The occurrence of both reflux and obstruction can be a very challenging clinical situation.
- What is often referred to as "function" from a diuretic renogram is relative uptake of tracer during the first 1 to 2 minutes after injection and is roughly equivalent to GFR.
- Differential function on a radionuclide study represents the relative contribution of each kidney to total uptake and always adds up to 100%. If both kidneys are abnormal, a 50% measurement is not "normal" function.
- When the diuretic washout time is more than 20 minutes, it is generally considered "obstructed"; less than 10 minutes is normal, and in between that time frame it is considered uncertain.
- MRI holds the promise of integrating both anatomic detail with functional assessment of the kidney and urinary tract. In pediatric obstruction it has not yet been fully validated in this regard.

PROGNOSIS AND MANAGEMENT STRATEGIES

The assessment of possible outcome for an obstructed kidney is important in terms of determining the value of an intervention and in providing clinical prediction of possible failure of the kidney. These predictions will serve to guide therapy and assess the risk-benefit balance in treatment. As yet there are few studies to suggest any accuracy either in unilateral obstruction or bilateral obstruction. Use of renal biopsies in obstruction has shown some loose correlations but none that is clinically practical. It is likely that this ability will follow from more accurate diagnostic ability.

Can any of our current incomplete understanding of congenital urinary obstruction be used in developing a clinical management strategy for these patients? Several factors seem to emerge from the many conflicting and incomplete studies of congenital obstruction. Obstruction can be very harmful to the developing kidney, to an extent far beyond that seen in the mature kidney. The effects of obstruction may not be reversible, owing to alteration of the actual structure and functional characteristics of the kidney, which does not occur in the mature kidney. There seems to be a limited time window to permit reversal of obstruction and anticipate clinically relevant recovery of functional potential. It is clear that the developing kidney, as with the mature kidney, is able to compensate in the presence of obstruction and appear to be healthy. Yet most biologic compensation mechanisms are ultimately limited in the ability to maintain homeostasis and may mask eventual significant functional derangements. The clinical threshold for intervention may therefore be better set lower than in the mature patient.

The response to obstruction in the developing kidney is extremely complex, and multiple factors are involved in various aspects of this response. Although this may seem to be a significant impediment to understanding and clinically managing these problems, it should be seen as providing multiple opportunities to develop biomarkers of these responses that may eventually facilitate decision making.

It is clear that not all children with dilated kidneys will suffer ill effects from this condition; it is equally evident that the potential for obstructive nephropathy is significant and has severe clinical implications. As the understanding of these conditions and the mechanisms of renal response to obstruction in development improves, determination of those kidneys at risk for developmental impairment will become more accurate.

Postnatal Management of Antenatally Detected Urologic Renal Abnormalities
Summary

FETAL IMAGING

The increased use of maternal-fetal ultrasound has led to the development of the field of perinatal urology. **Antenatal hydronephrosis** (ANH) is identified in 1% to 3% of all pregnancies and is one of the most common birth defects detected (Livera et al, 1989; Blyth et al, 1993; Gunn et al, 1995; Sairam et al, 2001). In addition to hydronephrosis, renal cystic disease, renal agenesis, stones, and tumors have been diagnosed prenatally as well. For the urologist, these prenatal findings have created numerous challenging clinical and scientific dilemmas.

Ultasonography continues to be the mainstay of fetal imaging. With experience, this modality provides intricate detail and diagnostic capability that is similar to that of ultrasonography in the neonate. Ultrasound evaluation facilitates screening large numbers of fetuses with no radiation exposure and is near universally available. The potential advantages of three-dimensional ultrasonography in imaging of urologic diagnoses are unclear.

Fetal magnetic resonance imaging (MRI) is a valuable adjunct in those instances in which further delineation of anatomic detail is believed to be necessary to optimize diagnosis and/or management strategy (Estroff, 2009). As with ultrasonography there is no radiation exposure. Utilization of complementary computed tomography is controversial, because the additive information may not outweigh the added risk of fetal and maternal radiation exposure.

The discussion here centers on the diagnosis of prenatal urologic abnormalities and the postnatal implications, the rationale behind prenatal intervention, and clinical experience in managing children with prenatal urologic abnormalities. Further detailed discussion regarding evaluation and management of many of these entities when they occur beyond the perinatal period is presented in other chapters in this textbook.

FETAL DIAGNOSIS

Previously, a large prospective study of 11,986 Swedish women done between 1978 and 1983 identified renal anomalies in 0.28% of fetuses, of which over two thirds of the anomalies were hydronephrosis (0.18%) (Helin and Persson, 1986). Similarly, a British prospective screening study of 6292 pregnant women at 28 weeks' gestation demonstrated hydronephrosis in 1.40% of cases, with postnatal confirmation in 0.65% (Livera et al, 1989). These authors defined ANH as an **anteroposterior diameter** (APD) of the renal pelvis greater than 5 mm but noted the lack of consensus on the definition of ANH (Scott and Renwick, 1993, 1999; Scott et al, 1995). **With the rapid improvement of ultrasound technology the incidence of detection of renal anomalies may be changing.** In a more recent prospective cohort study (1999-2003), a 0.76% incidence of urinary tract abnormalities was detected that was increased as compared with an earlier cohort from the same institution (0.3%, 1989-1993) (Mallik and Watson, 2008). However, many variations in the definition and management of ANH exist in the literature and clinical practice, including method and frequency of in-utero testing, radiographic documentation, classification, or postnatal management (Benacerraf et al, 1990; Corteville et al, 1992; Fernbach et al, 1993; Adra et al, 1995; Thompson and Thilaganathan, 1998; Chudleigh et al, 2001; Lee et al, 2006). This variability may significantly alter the incidence reported within the literature.

Regardless, when an abnormality of the urinary tract is determined by antenatal ultrasonography several questions should be raised by the ultrasonographer and consulting urologist. Combinations of specific findings direct the differential diagnosis and permit a more accurate prognosis and tailoring of postnatal evaluation. The principal findings and their implications are listed in Table 114–1.

Diagnostic Findings

Kidney

There are critical elements to an antenatal ultrasound examination that may help identify urologic pathology. A constellation of aberrations may indicate pathology, particularly when placed in context with other clinical findings. Specific details of the examination need to be reported to assist antenatal counseling. **The ultrasound evalution of the kidney should comment on number, location, size, duplication, renal parenchyma (echogenicity), pelvic dilation, calyceal dilation, urothelial thickening, and cystic disease.**

Kidneys should be appropriate size for gestational age and relatively symmetrical (Chitty and Altman, 2003). Large differences in size may indicate contralateral compensatory growth. Absence of the kidney in the normal location may represent ectopia or agenesis/dysplasia. **The normal kidney should be elliptical**

Table 114–1.

Elements of Prenatal Urologic Ultrasonographic Diagnosis

PARAMETER	COMMENT	POSSIBLE CAUSES
Hydronephrosis	Variable severity; may include pelviectasis and/or caliectasis	Obstruction, reflux
Caliectasis	Intrarenal dilation; more indicative of significant pathologic process	Obstruction, reflux
Pelvic anteroposterior diameter	Measured in the coronal plane, variable; in extremes may predict clinical outcome; caution should be exercised in overreliance on these measurements	Increased in obstruction, reflux
Renal parenchyma	Echogenicity should be less than that of liver or spleen; lucent medullary pyramids should be seen	Increased echogenicity in dysplasia, obstruction, ARPKD
Urothelial thickening	Increased thickness of pelvic lining	Variable dilation as with reflux or occasionally obstruction
Duplication	Separation of renal pelvic sinus echoes when no hydronephrosis seen	Possible associated reflux or obstruction; look for dilated ureter and ureterocele
Cystic structures, renal	Simple cysts rare	MCDK, ADPKD
Cystic structures, intravesical	May be very large and fill bladder; thin walled	Ureterocele
Urinoma	Fluid collection around kidney; perinephric or subcapsular	Obstruction
Bladder filling	Fill and void cycles may be demonstrated over time	Urine production
Bladder wall thickness	Must be interpreted in context of bladder filling	Obstruction, neurogenic dysfunction
Keyhole sign	Dilated posterior urethral; difficult to image	Posterior urethral valves
Oligohydramnios	Markedly reduced amniotic fluid; usually considered as no pocket of fluid > 2 cm	Poor urine output because of obstruction and/or renal failure

ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; MCDK, multicystic dysplastic kidney.

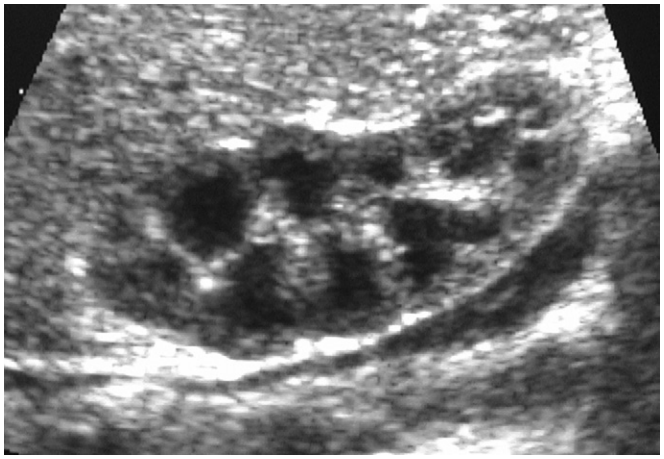

Figure 114–1. Ultrasound appearance of normal fetal kidney with echolucent medullary pyramids distinguishable from the more echogenic cortical parenchyma. The cortical parenchyma should be of lower echogenicity than adjacent liver or spleen.

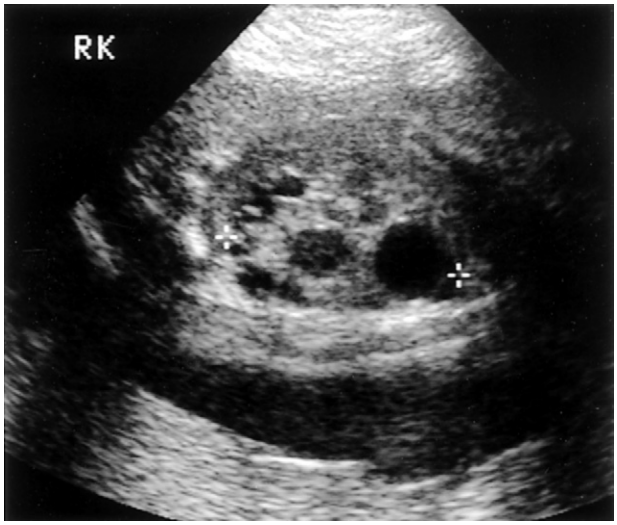

Figure 114–2. Multicystic dysplastic kidney with large, multiple, variable-sized cysts without a central large cystic area. As here, most cases show virtually no parenchyma.

and have distinctive internal echolucency, representative of normal medullary pyramids (Fig. 114–1). **The appearance of the medullary pyramids should not be confused with renal calyceal dilation.** The echogenicity of the kidney should be slightly less than the corresponding spleen or liver. Abnormalities of echogenicity with or without hydronephrosis may indicate renal disease. Isolated increased echogenicity has been associated with renal parenchymal disorders, but it has also been shown to be of no clinical significance (Carr et al, 1995). When seen with hydronephrosis it may indicate renal dysplasia, particularly if there is accompanying decreased amniotic fluid (Kaefer et al, 1997b).

Renal cystic disease can be seen in utero. Autosomal-recessive polycystic kidney disease (ARKPD) may appear as large, bright or echogenic kidneys, because the numerous small renal cysts cannot be resolved by ultrasonography. In contrast, a multicystic dysplastic kidney (MCDK) typically presents as a large noncommunicating macrocyst (Fig. 114–2). A single cyst may represent a dilated renal calyx or diverticulum, an atypical MCDK, severe hydronephrosis, or a nonrenal structure.

Ureter, Bladder, and Urinoma

In addition to kidney-specific findings, ureteral dilation, bladder filling and emptying, bladder wall thickness, intravesical cystic structures, dilation of the posterior urethra (keyhole sign), urinoma, amount of amniotic fluid, intra-abdominal/pelvic mass, and external genitalia should be noted. **Hydroureter is best**

Figure 114–3. Fetal ultrasonography showing a dilated, tortuous ureter *(arrow)*. These may be associated with reflux, valves, ectopic ureters, ureteroceles, and ureterovesical junction obstruction. In this case the ureter is associated with a dilated upper pole indicating an ectopic ureter or ureterocele.

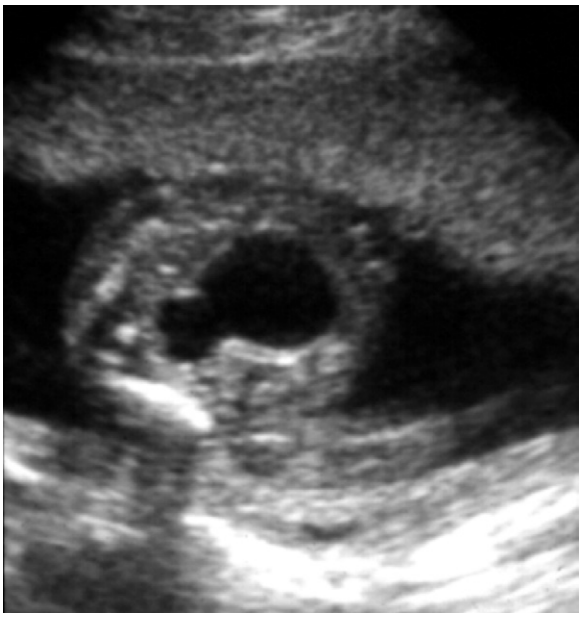

Figure 114–4. Fetal ultrasonography at 22 weeks' gestation of a male with posterior urethral valves. The bladder is thick walled and has a dilated posterior urethra (keyhole sign). There was also bilateral hydronephrosis, echogenic renal parenchyma, and a perinephric urinoma.

Figure 114–5. Appearance of a fetal perinephric urinoma associated with posterior urethral valves.

seen in cross section of a full bladder but is often difficult to detect (Fig. 114–3). Duplication and ureteral ectopia may also make this a difficult diagnosis.

Although the bladder is sometimes difficult to image well, visualization of the bladder can be very informative, because a full bladder implies renal function. **Inability to identify the bladder on repeat studies should raise the question of bladder exstrophy. Increased bladder wall thickness may indicate outlet obstruction, and dilation of the posterior urethra (keyhole sign) is strongly suggestive of posterior urethral valves** (Fig. 114–4). In duplex systems, ureteroceles may present as an intravesical cystic structure and a dilated upper pole.

Perirenal urinoma may indicate an obstructive condition (Yerkes et al, 2001) (Fig. 114–5). Typically it will have the appearance of an anechoic structure around the kidney or be in a subcapsular location. **When identified, a urinoma or urinary ascites is often associated with cases of severe bladder obstruction, or posterior urethral valves, in which the urinoma may indicate a popoff mechanism.** The popoff mechanism may be renal protective (Adzick et al, 1985). A urinoma also may be associated with a unilateral hydronephrotic/obstructed kidney (Mandell et al, 1994).

Amniotic Fluid

Critical to the evaluation of the urinary tract is the assessment of the amniotic fluid level and changes during pregnancy. **After 16 weeks, amniotic fluid production shifts from placental transudate to fetal urine; and by 20 to 22 weeks the vast majority of amniotic fluid is fetal urine** (Takeuchi et al, 1994). Consequently, **reduced amniotic fluid or oligohydramnios identified after 18 to 20 weeks' gestation may be a result of urinary tract obstruction or poor renal development** (Stiller et al, 1988).

External Genitalia

Proper identification of the external genitalia also can be very valuable in cases of gender-specific diagnoses, such as posterior urethral valves. **In cases of virilization (e.g., congenital**

adrenal hyperplasia), a clitoris may appear as a small phallus; therefore the presence of scrotal testes is critical for male gender assignment (Benacerraf et al, 1989; Bromley et al, 1994; Mandell et al, 1995). Megalourethra, or a dilated, elongated penile urethra, may be an isolated anomaly or associated with prune-belly syndrome (Dillon et al, 1994) (Fig. 114–6). **A female fetus with bilateral renal obstruction and bladder outlet obstruction would suggest a cloacal anomaly** (Cilento et al, 1994; Ohno et al, 2000; Taipale et al, 2004) (Fig. 114–7).

Hydronephrosis

Hydronephrosis, or dilation of the renal pelvis, is the most common urologic abnormality found on ultrasound evaluation. Numerous grading systems have been developed; however, there is no consensus on the best and most consistent method of reporting ANH (Fig. 114–8) (Fernbach et al, 1993). Measurement of the APD has been used widely, but there have been no formal studies to determine the interobserver and intraobserver reproducibility of ANH measurement. **One of the disadvantages of the APD can be the failure to describe pelvic configuration, calyceal dilation, and the laterality of findings, which should be included.** The APD can be affected by gestational age, hydration status of the mother, bladder hypertonicity, and degree of bladder distention. Because the dimensions of the renal pelvis may normally increase with gestational age, most investigators have adjusted threshold APD values for early and later gestational age. Unfortunately, a simple threshold APD value that separates normal from abnormal does not exist, because even severe cases of ANH have the potential to resolve without incident, whereas mild degrees of ANH have the potential to progress (Pates and Dashe, 2006).

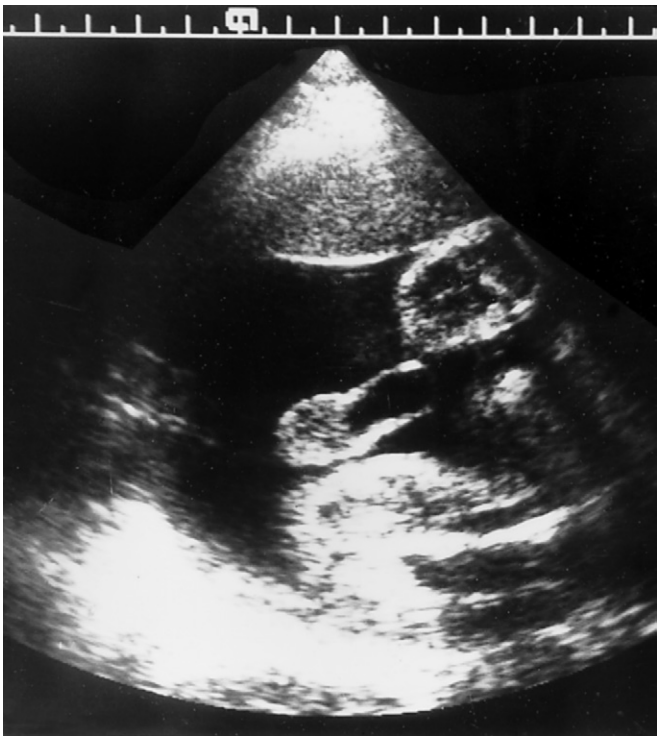

Figure 114–6. Fetal ultrasound appearance of a male with a dilated and patulous urethra typical of a megalourethra. This may be seen in prune-belly syndrome as well as in isolation. This child also had marked vesicoureteral reflux.

Varying the minimal APD threshold can significantly alter the specificity and sensitivity of APD as a measure of ANH and postnatal pathology. To date there is no consensus on the optimal APD threshold for determining the need for postnatal follow-up. An APD cutoff of 15 mm for determining obstruction yielded a

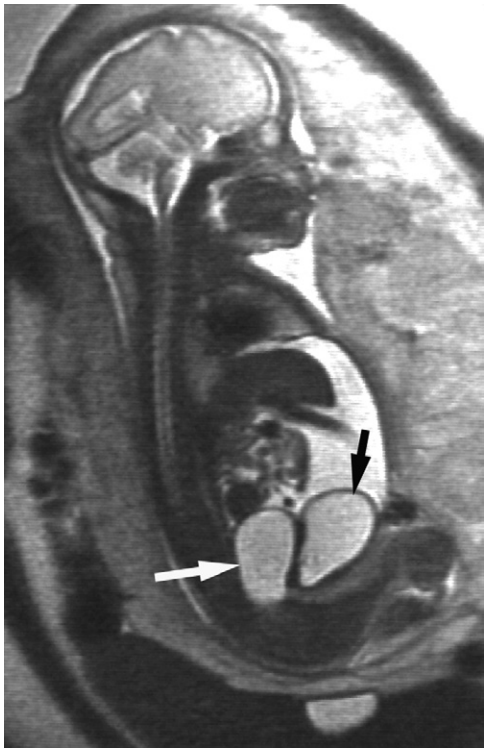

Figure 114–7. Fetal MR image illustrating severe bladder dilation *(black arrow)* and a separate dilated pelvic structure behind the bladder *(white arrow)* in a female fetus at 22 weeks' gestation. The kidneys were bilaterally and symmetrically dilated with ureteral distention. This pattern can be seen with oligohydramnios and represents a urogenital sinus malformation with bladder outlet obstruction caused by vaginal distention from urine flowing into the urogenital sinus.

Figure 114–8. Severe fetal hydronephrosis with diffuse calyceal dilation arrayed around the markedly dilated renal pelvis. The renal parenchyma is stretched over the dilated collecting system, but this does not mean loss of functional potential. Corticomedullary differentiation is difficult to see in this configuration.

postnatal sensitivity of 73% and specificity of 82% (Coplen et al, 2006). A late gestational age APD cutoff of 10 mm would detect aproximately 23% of abnormal kidneys, whereas a cutoff of 7 mm detected 68% (Ismaili et al, 2003). One large systematic review estimated that only 11.9% of total pathology presented with late gestational age APD less than 9 mm, whereas 39% of total pathology was noted at APD levels less than 15 mm (Lee et al, 2006). Nearly identical results have been demonstrated by other investigators (Wollenberg et al, 2005). What appears certain is that lower cutoffs will be more sensitive in detecting postnatal pathology but will incur a higher false-positive rate.

Categorizing ANH by APD. There is near agreement that APD greater than 15 mm represents severe or significant hydronephrosis, and some would also agree that a lower threshold of 4 to 5 mm is an appropriate value for considering APD to be abnormal (Feldman et al, 2001; Ahmad and Green, 2005; Wollenberg et al, 2005; Lee et al, 2006; Coelho et al, 2007, 2008). Taking these limitations into consideration, we define ANH in the second and third trimesters using APD thresholds for which the best available evidence provides prognostic information; along with these definitions the estimated distribution of the ANH based on the previous defined definition of APD is outlined in Table 114–2.

Diagnostic Accuracy

As both ultrasound and MRI technology improve, more accurate radiographic information is obtainable (Laifer-Narin et al, 2007). However, determining accurate postnatal diagnosis and prognosis remains challenging. Regardless of the diagnosis, early intervention is uncommon except in the potential case of severe obstruction or posterior urethral valves. In the vast majority of other cases, early detection of ANH may be an impetus for future postnatal evaluation.

The ability to determine definitive postnatal pathology based on antenatal findings is difficult. As an example, a recent systematic review of the ANH literature attempted to determine the risk of a pathologic diagnosis for patients with varying severity of ANH (Lee et al, 2006). The review included 1308 patients who were identified with ANH and sufficient postnatal radiographic follow-up. The degree of ANH was defined by APD identified in a particular trimester. Approximately 36% of the patients had a postnatal pathologic diagnosis, and the overall risk for any pathologic process increased with increasing degree of ANH (Table 114–3). **However, the risk of vesicoureteral reflux (VUR) remained consistent regardless of the degree of ANH, thereby implying that ANH is not an appropriate indicator for VUR.**

Similarly, previous literature suggests that obstruction location can be determined prenatally in 88% of the cases; many others have reported a high false-positive rate (9% to 22%) (Hobbins et al, 1984; Scott and Renwick, 1993). The majority of false-positive findings in these studies were nonobstructive causes of hydronephrosis, such as high-grade reflux, large, nonobstructed extrarenal pelves, or transient hydronephrosis.

Early and accurate diagnosis of posterior urethral valves is critical; however, it can be difficult. The hallmark signs of an in-utero diagnosis of posterior urethral valves have been described (e.g., oligohydramnios, dilated posterior urethra, thickened bladder, and hydroureteronephrosis). Other findings such as increased renal echogenicity and decreased amniotic fluid have also been suggested to be indicative of obstructive conditions (Kaefer et al, 1997b). Regardless, there are very few studies that have prospectively examined the clinical urologic implications of these findings alone or in combination (Lee et al, 2006). In one series of 22 fetuses, the false-positive rate was as high as 58% (Abbott et al, 1998), and in a population-based series the sensitivity in detecting valves was as low as 23% (Scott and Renwick, 1993).

Regardless of the degree or severity of the finding, with any antenatal detection of a urinary tract anomaly

Table 114-2.

Definition of Antenatal Hydronephrosis by Anterior Posterior Diameter and Estimated Severity Percentage Range

	Anteroposterior Diameter		
DEGREE	Second Trimester	Third Trimester	SEVERITY
Mild	4 to <7 mm	4 to <9 mm	56.7%-88%
Moderate	7 to ≤10 mm	9 to ≤15 mm	10.2%-29.8%
Severe	>10 mm	>15 mm	1.5%-13.4%

Data from Feldman et al, 2001; Ahmad and Green, 2005; Wollenberg et al, 2005; Lee et al, 2006; and Coelho et al, 2007, 2008.

Table 114-3.

Risk of Pathology by Degree of Antenatal Hydronephrosis

	Degree of Antenatal Hydronephrosis [% (95% CI)*]					
POSTNATAL PATHOLOGY	Mild (*N* = 587)	Mild-Moderate (*N* = 213)	Moderate (*N* = 235)	Moderate-Severe (*N* = 179)	Severe (*N* = 94)	TREND *P* VALUE†
Any pathology	11.9 (4.5, 28.0)	39.0 (32.6, 45.7)	45.1 (25.3, 66.6)	72.1 (47.6, 88.0)	88.3 (53.7, 98.0)	<.001
Ureteropelvic junction obstruction	4.9 (2.0, 11.9)	13.6 (9.6, 18.9)	17.0 (7.6, 33.9)	36.9 (17.9, 61.0)	54.3 (21.7, 83.6)	<.001
Vesicourethral reflux	4.4 (1.5, 12.1)	10.8 (7.3, 15.7)	14.0 (7.1, 25.9)	12.3 (8.4, 17.7)	8.5 (4.7, 15.0)	.10
Posterior urethral valves	0.2 (0.0, 1.4)	0.9 (0.2, 3.7)	0.9 (0.2, 2.9)	6.7 (2.5, 16.6)	5.3 (1.2, 21.0)	<.001

Modified from Lee RS, Cendron M, et al. Antenatal hydronephrosis as a predictor of postnatal outcome: a meta-analysis. Pediatrics 2006;118(2):590.

*Pointwise 95% confidence intervals were estimated by logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure to adjust for clustering by study for all degrees of antenatal hydronephrosis except mild to moderate. Because only one study had subjects with mild-to-moderate antenatal hydronephrosis, the pointwise 95% confidence intervals had to be estimated using logistic regression with unadjusted standard errors.

†Testing for trend in risks with increasing degree of antenatal hydronephrosis using logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure.

‡Includes prune-belly syndrome, VATER syndrome, solitary kidney, renal mass, and unclassified causes.

a thorough fetal survey must be conducted. Amniocentesis and karyotype should be considered if intervention or a major anomaly is suspected, because the incidence of concurrent chromosomal anomalies is relatively high in fetuses with concomitant urologic anomalies (Callan et al, 1990; Nicolaides et al, 1992a, 1992b; Snijders et al, 1995).

Key Points: Prenatal Diagnostic Findings

- Ultrasonography is the mainstay of prenatal imaging. Selective use of fetal MRI may further delineate anatomic details and help with diagnosis and management.
- The normal kidney should be elliptical and have distinctive internal echolucency, representative of normal medullary pyramids.
- The appearance of the medullary pyramids should not be confused with renal calyceal dilation.
- Inability to identify the bladder on repeat studies should raise the question of bladder exstrophy.
- Dilation of the posterior urethra (keyhole sign) is strongly suggestive of posterior urethral valves.
- Reduced amniotic fluid or oligohydramnios identified after 18 to 20 weeks' gestation may be a result of urinary tract obstruction or poor renal development.
- Hydronephrosis, or dilation of the renal pelvis, is the most common urologic abnormality found on ultrasonography and is typically measured by the anteroposterior diameter (APD) of the renal pelvis.
- The APD fails to describe pelvic configuration, calyceal dilation, and the laterality of findings.
- A threshold APD value that separates normal from abnormal does not exist.
- The risk of VUR per degree of ANH is similar, implying that ANH is not an appropriate indicator of VUR.
- Antenatal detection of any urinary tract anomaly should prompt a thorough fetal survey.

SPECIFIC DIAGNOSES

Ureteropelvic Junction Obstruction

The basic features of ureteropelvic junction (UPJ) obstruction in the fetus include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation. Lee and associates (2006) demonstrated that increasing severity of ANH increased the likelihood of identifying postnatal UPJ obstruction. However, the threshold for recommending postnatal follow-up is largely arbitrary and currently there are no long-term prospective studies to determine the degree of postnatal evaluation, particularly for mild and moderate cases of ANH. Nevertheless, **in the case of significant unilateral hydronephrosis there is little rationale for in-utero intervention or early delivery.** In a few cases with massive dilation, therapeutic aspiration has been recommended for prevention of dystocia. In the case of bilateral UPJ obstruction the efficacy of in-utero intervention is difficult to assess. Severe forms of UPJ obstruction may be associated with urinary ascites or perinephric urinomas, which may be a predictor of nonfunction of the kidney (Mandell et al, 1994).

Ureterovesical Junction Obstruction

Less common than UPJ obstruction, ureterovesical junction (UVJ) obstruction is characterized by ureteral dilation along with varying degrees of renal pelvic and calyceal dilation. The best way to detect ureteral dilation is at the level of the bladder, preferably in the transverse view. It is not uncommon for the distal ureter to be more dilated as compared proximally. **The causes of this appearance may be primary obstruction of the UVJ, ectopic ureter inserting into the bladder neck, or high-grade VUR.** Typically, the differentiation is made postnatally.

Cystic Kidneys

The distinction between severe unilateral hydronephrosis and MCDK occasionally may be unclear. **The findings of multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst are diagnostic of MCDK** (Bearman et al, 1976; Sanders and Hartman, 1984). **The appearance of noncommunicating cysts is essential to the diagnosis and should be distinguished from severe hydronephrosis** (see Fig. 114–2). Real-time examination of the kidneys to help determine the communication of the calyces is essential. Doppler ultrasonography of the renal vasculature pulse pattern has also been reported to help make the distinction (Kaminopetros et al, 1991).

An MCDK may be present in any ectopic location but typically is in the normal position. In addition, **MCDK can be present in a duplex kidney, typically the upper pole.** If detected early in the pregnancy, the MCDK will involute over a period of time either prenatally or postnatally (Mandell et al, 1994).

Bilaterally enlarged echogenic kidneys without renal cystic disease, particularly if associated with hepatobiliary dilatation or oligohydramnios, suggest ARPKD (Smedley and Bailey, 1987; Townsend et al, 1988) (Fig. 114–9). Typically this is identified before 20 weeks' gestation, but later development has been reported (Zerres et al, 1988; Edwards and Baldinger, 1989; Mandell et al, 1991). Genetic testing is possible in some cases, thereby allowing for early diagnosis and the option for early termination because postnatal mortality and morbidity is high (Wilson, 2004; Zerres et al, 2004). A more challenging finding are normal-sized, diffusely echogenic kidneys that are not associated with other urologic lesions. A series of 19 cases (14 bilateral) included 10 patients with normal function who survived and 4 with ARPKD who died (Carr et al, 1995).

Macrocystic disorders include the rare congential multilocular cystic nephroma, which is characterized by segmental involvement of the kidney with variable macrocysts (Eble and Bonsib, 1998); cystic Wilms tumor, which typically has larger amounts of functioning parenchyma; and ADPKD, which has heterogeneous cysts in size, location, and number (Reeders et al, 1986; McHugo et al, 1988; Ceccherini et al, 1989; Edwards and Baldinger, 1989; Novelli et al, 1989).

Nonrenal cystic diseases are confused for MCDK; however, these cystic anomalies are typically not in the renal fossa and unlikely to be confused in the presence of two normal kidneys. These include mesenteric duplication cysts (Barr et al, 1990), neurenteric cysts (Uludag et al, 2001), bronchogenic cysts (Bagolan et al, 2000), extrathoracic pulmonary sequestration (Carpentieri et al, 2000), and cystic neuroblastoma (Granata et al, 2000).

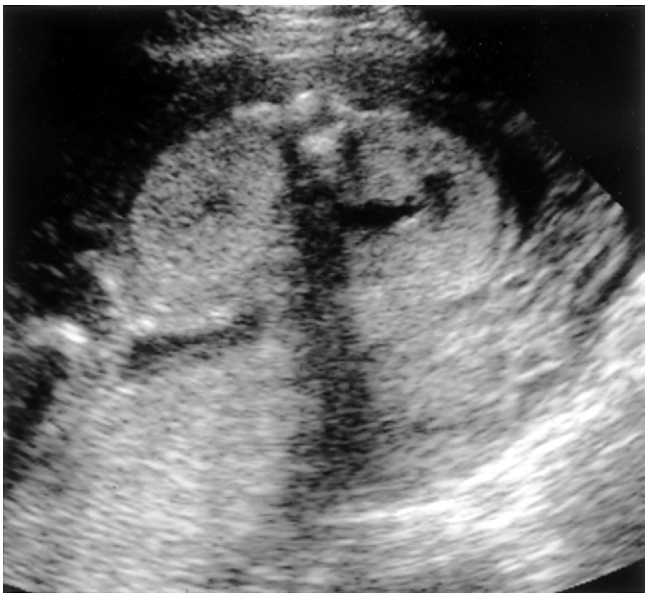

Figure 114–9. Bilaterally enlarged, echogenic kidneys without grossly apparent cysts are typical of autosomal recessive polycystic kidneys. This appearance usually, but not always, becomes apparent by 22 weeks of gestation. In early-onset cases, oligohydramnios is seen.

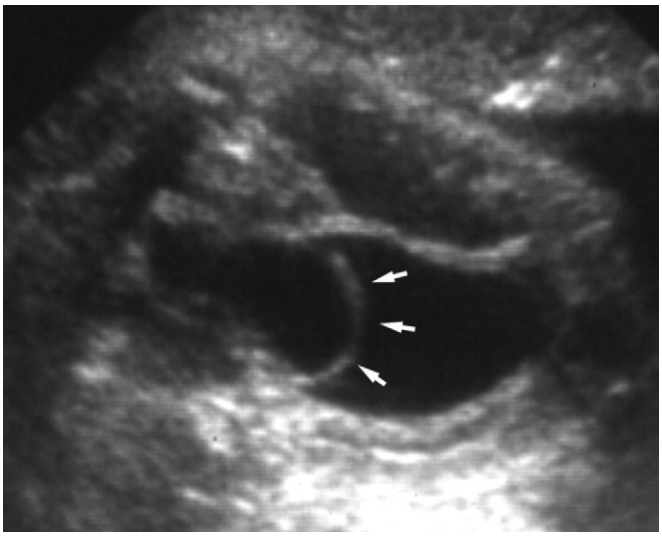

Figure 114–10. Fetal ultrasonography showing an intravesical ureterocele. The ureterocele is indicated by the *arrows* and partially fills the bladder. With this finding the ultrasonographer should examine the upper tracts to determine whether there is hydronephrosis in the entire affected kidney or only the upper pole, as shown in Figure 114–3.

Duplication Anomalies and Ureteroceles

Duplication anomalies are often recognized on the basis of upper pole hydroureteronephrosis, associated with either an obstructing ureterocele within the bladder or ectopic ureter inserting outside the bladder (Vergani et al, 1999). Ureteroceles are identified as an intravesical, thin-walled cystic structure near the base of the bladder (Fig. 114–10). **In cases of a very large ureterocele the ureterocele may be mistaken for the bladder.** Alternatively, in the setting of an ureterocele the upper pole may not always present with hydronephrosis. **The upper pole may appear as a cystic dysplastic unit without hydronephrosis and a concomitant ureterocele. This is often termed *ureterocele disproportion*** (Share and Lebowitz, 1989). Additionally, single-system ureteroceles are more likely to occur in boys and have variable degrees of hydronephrosis of the entire kidney.

Lower pole hydronephrosis may be present as a result of VUR (Fig. 114–11) or more rarely a lower pole UPJ obstruction. Occasionally, lower pole dilation is due to obstruction of both the upper and lower pole ureter by a large ureterocele. Similarly, bilateral hydronephrosis may be secondary to an element of bladder outlet obstruction from prolapse of the ureterocele into the bladder neck (Sozubir et al, 2003).

In the absence of a ureterocele, upper pole hydroureteronephrosis suggests an obstructed ectopic ureter (Abuhamad et al, 1996). The dilated ectopic ureter can be mistaken for an ureterocele because of the impression that it creates on the back wall of the bladder. However, typically the ectopic ureter is much thicker than an ureterocele. **Bilateral single-system ectopic ureters are uncommon but typically present as echogenic renal parenchyma, cystic disease, minimal bladder volume, and low amniotic fluid levels.**

Vesicoureteral Reflux

Vesicoureteral reflux cannot be definitively diagnosed on prenatal ultrasonography, although intermittent or varying degrees of hydronephrosis or hydroureter are suggestive of the diagnosis. Several studies have demonstrated that a high incidence of VUR is associated with prenatally detected hydronephrosis; however, the true incidence of VUR in children with a history of ANH is difficult to determine based on the variability of postnatal diagnostic management in the literature (Lee et al, 2006). **In two systemic reviews of the ANH literature a 10% to 15% incidence of VUR was identified regardless of the degree of ANH** (Lee et al, 2006; van Eerde et al, 2007), **indicating that the severity of ANH is not indicative of VUR and may not be the appropriate trigger for postnatal evaluation.** In a neonate with prenatally detected hydronephrosis, the importance of diagnosing VUR remains controversial, because VUR diagnosed on postnatal evaluation for ANH is associated with earlier resolution of VUR (Estrada et al, 2009a).

Posterior Urethral Valves

Perhaps the most important diagnosis to be made prenatally is that of posterior urethral valves in the male fetus. The finding of posterior urethral valves, at the very least, mandates prompt postnatal intervention, and, in some cases, prenatal intervention may be warranted. **Fetal ultrasound findings include bilateral hydroureteronephrosis, a thick-walled bladder with dilated posterior urethra, and, in more severe cases, dysplastic renal parenchymal changes with perinephric urinomas and urinary ascites** (see Fig. 114–5) (Bellinger et al, 1983; Reuter and Lebowitz, 1985; Barakat et al, 1991; Dinneen et al, 1993; Hutton et al, 1994; Gunn et al, 1995; Kaefer et al, 1997b; Abbott et al, 1998; Peters, 1998). Massive bladder dilation

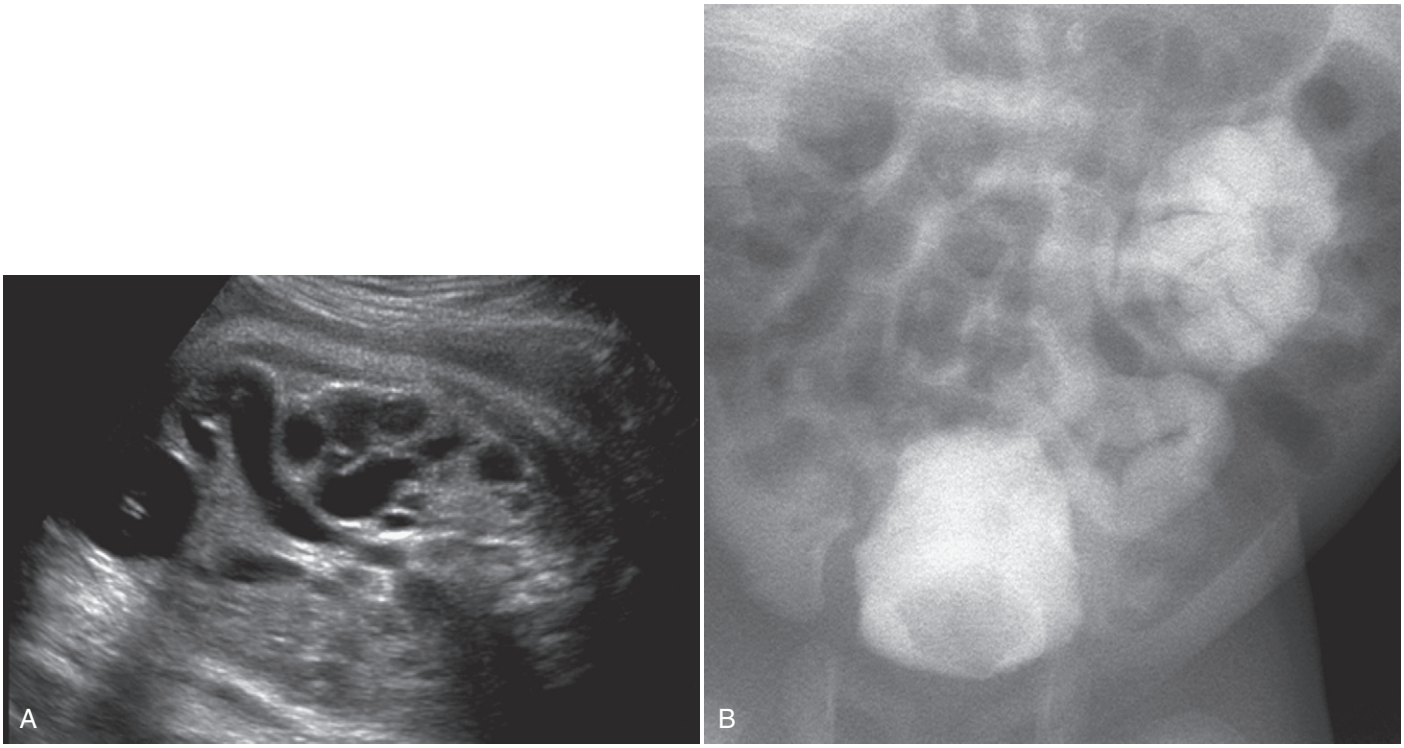

Figure 114–11. **A,** Image of a 28-week gestational age fetus with left lower pole hydronephrosis, hydroureter, and an ureterocele. **B,** Postnatal voiding cystourethrogram demonstrating lower pole vesicourethral reflux and the ureterocele.

can be seen to occupy a good proportion of the abdomen (Fig. 114–12). With progression of the pregnancy, the bladder may become more thick walled with increasing posterior urethral dilation (see Fig. 114–4). **When characteristic ultrasound findings are present the differential diagnosis includes prune-belly syndrome (with or without urethral atresia), massive VUR, and certain cloacal anomalies (in genetic females)** (Kaefer et al, 1997a; Oliveira et al, 2000).

Bladder Exstrophy

Bladder exstrophy is a congenital abnormality affecting development of the lower abdominal wall, lower urinary and reproductive tracts, and musculoskeletal system. Prenatal diagnosis can be made with reasonable certainty using ultrasonography. **Common observations in the fetus with bladder exstrophy include nonvisualization of the fetal bladder, a lower abdominal wall mass immediately inferior to a low-lying umbilicus, and diminutive genitalia** (Gearhart et al, 1995). Patience and expertise in the ultrasonographer are important for recognition of the consistent negative finding on fetal imaging—absence of bladder filling—that is critical in making the diagnosis of bladder exstrophy. **Other findings that may be evident to the experienced observer include normal kidneys in orthotopic position, normal vertebrae and spinal cord, abnormal symphyseal diastasis, and anteriorly displaced anus** (Fig. 114–13).

Prenatal diagnosis of bladder exstrophy provides an opportunity for discussion of bladder exstrophy, complex reconstruction as a neonate, follow-up care and outcomes, other organ system normality, and options of termination versus continuation of the

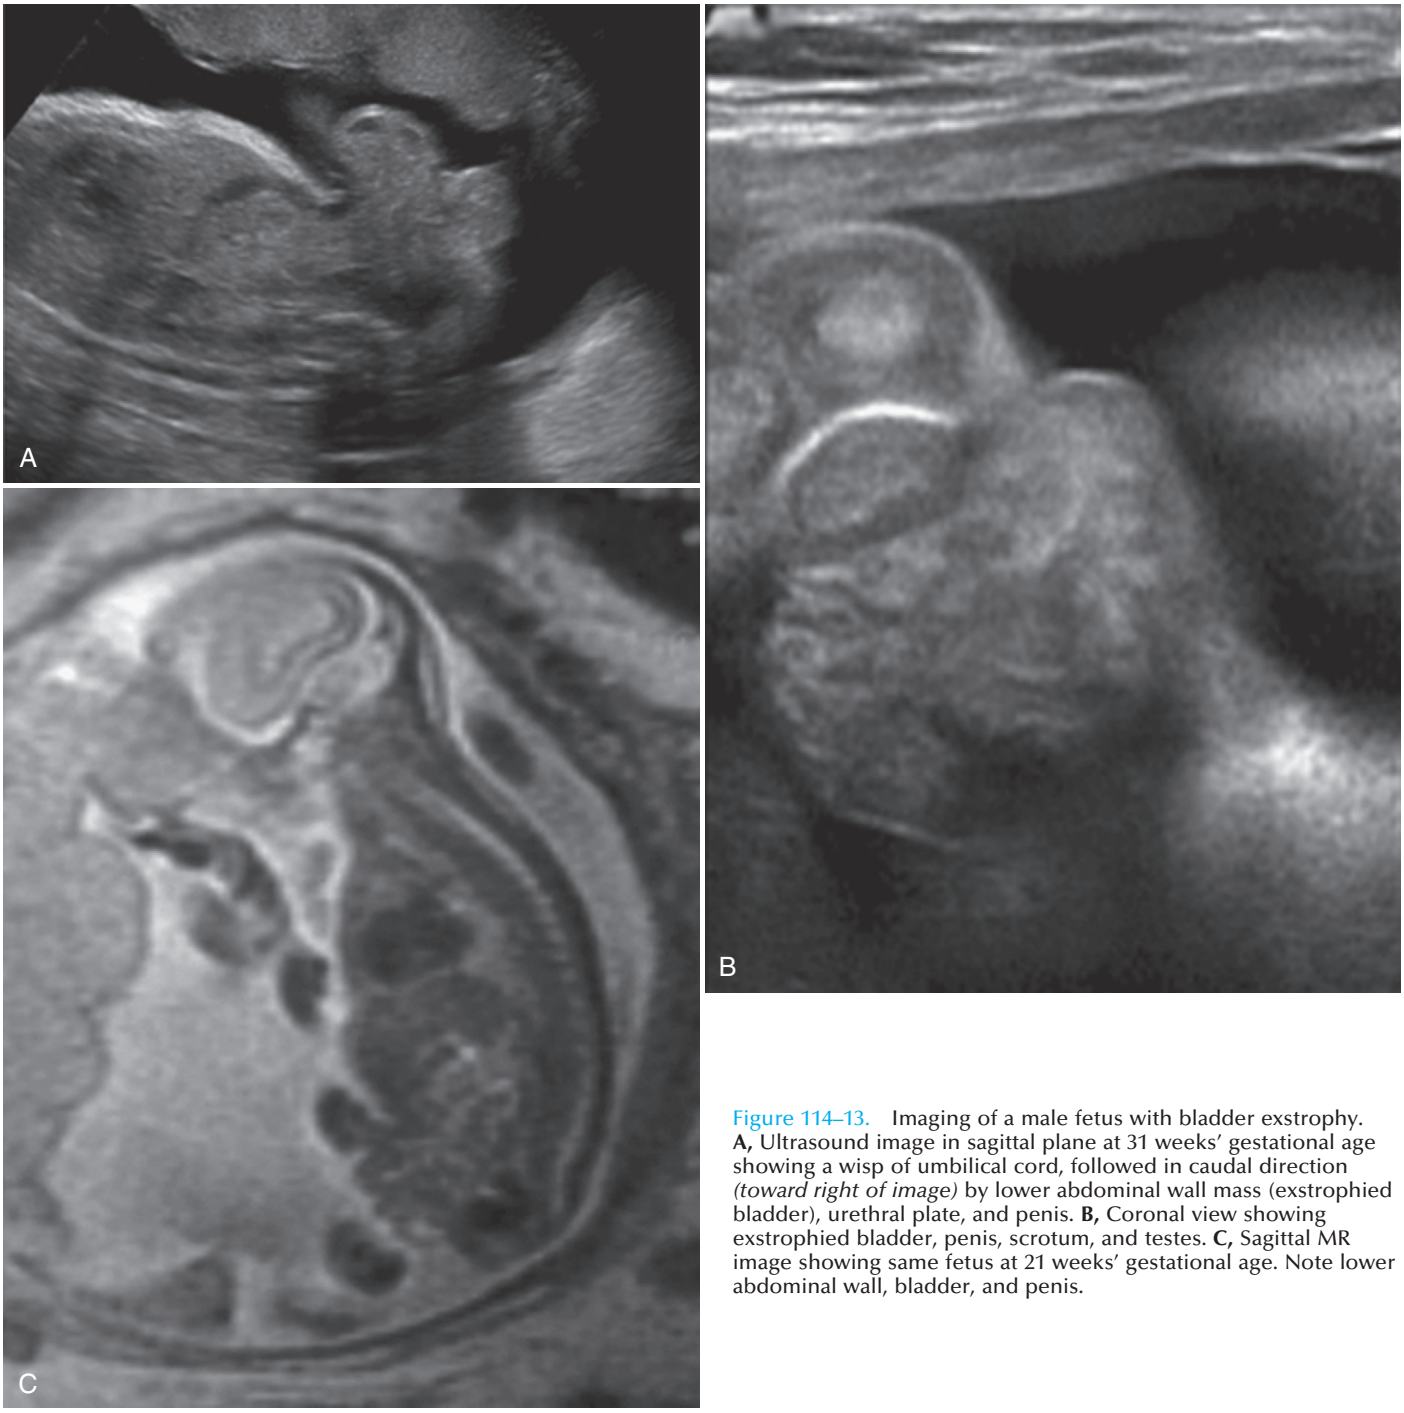

Figure 114–13. Imaging of a male fetus with bladder exstrophy. **A,** Ultrasound image in sagittal plane at 31 weeks' gestational age showing a wisp of umbilical cord, followed in caudal direction *(toward right of image)* by lower abdominal wall mass (exstrophied bladder), urethral plate, and penis. **B,** Coronal view showing exstrophied bladder, penis, scrotum, and testes. **C,** Sagittal MR image showing same fetus at 21 weeks' gestational age. Note lower abdominal wall, bladder, and penis.

pregnancy (Cacciari et al, 1999). The increasing ability to accurately diagnosis this and other complex diagnoses may have led to an increase in termination (Cromie et al, 2001).

Increasingly, the initial management of the newborn with bladder exstrophy is, perhaps, believed not to present an emergency state, and prenatal diagnosis may be helpful for several reasons. For example, at a center of excellence, expectant parent(s) who are interested may be offered advanced obstetric care, interaction with the pediatric urologic team, introduction to the pediatric hospital's support services, familiarity with the pediatric hospital itself, and interaction with parents of a child with bladder exstrophy.

Cloacal Exstrophy

Cloacal exstrophy (OEIS: Omphalocele, Exstrophy, Imperforate anus, Spinal abnormality) **is the most severe manifestation of the exstrophy-epispadias complex spectrum, carrying all of the findings associated with bladder exstrophy and renal, spinal, and bowel involvement in the form of a lateral enterovesical fistula.** Cloacal exstrophy describes a rare grouping of component malformations. The etiology is unknown but likely heterogeneous. Although postnatal identification of its associated gastrointestinal, spinal, and genitourinary systems delineates the extent and natural history of OEIS complex,

prenatal findings may provide additional information regarding early detection, possible causative factors, and outcome. The association of twinning and OEIS complex suggests that abnormal developmental step(s) may occur as early as blastogenesis (Keppler-Noreuil, 2001; Keppler-Noreuil et al, 2007). Based on fetal ultrasound findings Casale and colleagues (2004) raised a possible role of blighted conjoined twinning as a cause of cloacal exstrophy variants.

The prenatal diagnosis of cloacal exstrophy should be suspected with findings of nonvisualization of the bladder in association with a low-lying umbilicus, lower abdominal wall mass—typically omphalocele—and kidney (number, location, and/or appearance) and lumbosacral spine abnormalities (Fig. 114–14). Austin and colleagues (1988) reviewed 22 patients with prenatal ultrasound studies and cloacal exstrophy and identified relatively common "major" criteria for prenatal diagnosis of cloacal exstrophy of nonvisualization of the bladder, a large midline infraumbilical anterior wall defect, omphalocele, and lumbosacral anomalies and less frequently observed "minor" criteria including lower extremity defects, renal anomalies, ascites, widened pubic arches, hydrocephalus, and one umbilical artery. Additional ultrasound findings suggestive of cloacal exstrophy in the fetus include an elephant trunk–like image of the protruding bowel (Hamada et al, 1999) and/or hemivertebrae (Wax et al, 2008).

The differential diagnosis in the setting of a fetus with an abdominal wall mass includes omphalocele, gastroschisis, bladder exstrophy, and cloacal exstrophy. The latter two diagnoses would be entertained when nonvisualization of the urinary bladder is also noted. A study of 41 cases involving fetal abdominal wall mass from the database of the Centre of Fetal Care at Queen Charlotte's and Chelsea Hospital in London from 2000 to 2005 revealed that 25 cases were omphalocele (61%), 9 were gastroschisis (22%), 6 were body stalk anomaly (15%), and 1 case was cloacal exstrophy (2%). Seventeen cases (41%) were associated with other major malformations (Arnaoutoglou et al, 2008).

Cloacal Malformation

Abnormal early development in the fetus may result in lack of separation of the urinary, reproductive, and intestinal tracts resulting in persistent cloaca (also known as cloaca or cloacal malformation) in the female. Direct communication of these three tracts deep to the skin surface results in single perineal opening. **Persistent cloaca should be considered in any female fetus presenting as hydronephrosis and a large cystic mass arising from the pelvis as assessed by ultrasonography and/or MRI** (Cilento et al, 1994; Suzumori et al, 2009). Chaubal and colleagues (2003) have found calcified meconium to be an important sign in the prenatal sonographic diagnosis of cloacal malformation. Other authors have found that the prenatal ultrasound and MRI findings of fetal ascites, multicystic pelvic mass, bilateral hydronephrosis, and oligohydramnios are highly suggestive of the cloacal malformations associated with meconium peritonitis (Shono et al, 2007).

Similar to the fetus shown in Figure 114–15, Liu and colleagues reported MRI findings of hydrocolpos with septate vagina and massive urinary ascites due to cloacal malformation (Liu and Chen, 2009), and prenatal diagnosis of cloaca associated with esophageal atresia and tracheoesophageal fistula has also been reported (Mori et al, 2007). When present in the fetus with cloaca, urinary ascites develops from retrograde flow of urine from bladder into vagina(s), passing through cervix, uterus, and finally fallopian tube(s). The clinician should be suspicious of associated esophageal atresia and tracheoesophageal fistula with the finding of polyhydramnios in the fetus with suspected cloaca.

As with fetal diagnosis of other complex malformations, prenatal diagnosis of cloaca allows for parental counseling and planning of the delivery at a tertiary center that is well equipped with a neonatal intensive care unit and pediatric surgical and urologic expertise (Warne et al, 2002; Suzumori et al, 2009).

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) due to deficiency of 21-hydroxylase is a disorder of the adrenal cortex characterized by cortisol deficiency, with or without aldosterone deficiency, and androgen excess. The severe classic form occurs in one in 15,000 births worldwide, and the mild nonclassic form is a common cause of hyperandrogenism. **Neonatal screening for CAH and gene-specific prenatal diagnosis are now possible** (Merke and Bornstein, 2005). Clinical management of patients with CAH involves treating hormonal deficiencies, addressing issues related to genital ambiguity, avoiding morbidities, and communicating with the family about risk of CAH in other members. Screening for CAH can reduce adrenal crises, avoid incorrect sex assignments, lower mortality (especially in males), and avoid inappropriate somatic growth and precocious puberty (Speiser, 2007).

The most common form of CAH is 21-hydroxylase deficiency (21-OHD). In its severe form, 21-OHD causes prenatal virilization of external female genitalia. Through molecular genetic analysis of fetal DNA, defects in 21-OH synthesis can be diagnosed in utero. **Genital ambiguity in females can be reduced or eliminated with prenatal dexamethasone treatment, which successfully suppresses fetal androgen production.** Current data from large human studies show that prenatal diagnosis and treatment are safe in the short term for both the fetus and the mother. Preliminary data from long-term studies support these results (Nimkarn and New, 2007). Nimkarn and New (2009) also reported safety over the long term, but recommend that all subjects exposed to dexamethasone treatment during fetal life have all aspects of their development followed closely.

Megalourethra/Prune-Belly Syndrome Association

Congenital megalourethra is a rare genital anomaly characterized by dilatation of the penile urethra with or without evidence of proximal or distal urethral obstruction (Fig. 114–16). Reports of the prenatal diagnosis of this condition in the literature are limited. However, there are reports of spontaneous resolution (Nijagal et al, 2004) and also reports of associated bilateral echogenic kidneys and pregnancy termination and universal poor perinatal outcome secondary to pulmonary hypoplasia in those fetuses carried through pregnancy (Sepulveda et al, 2005). Some authors have reported cases with prune-belly syndrome–like features (Fisk et al, 1990; Wu et al, 1995). The clinician must also consider an anterior urethral valve in the differential diagnosis when a dilated penile urethra is identified in a male fetus.

Myelomeningocele

Prenatal screening with α-fetoprotein and ultrasonography have allowed the prenatal diagnosis of neural tube

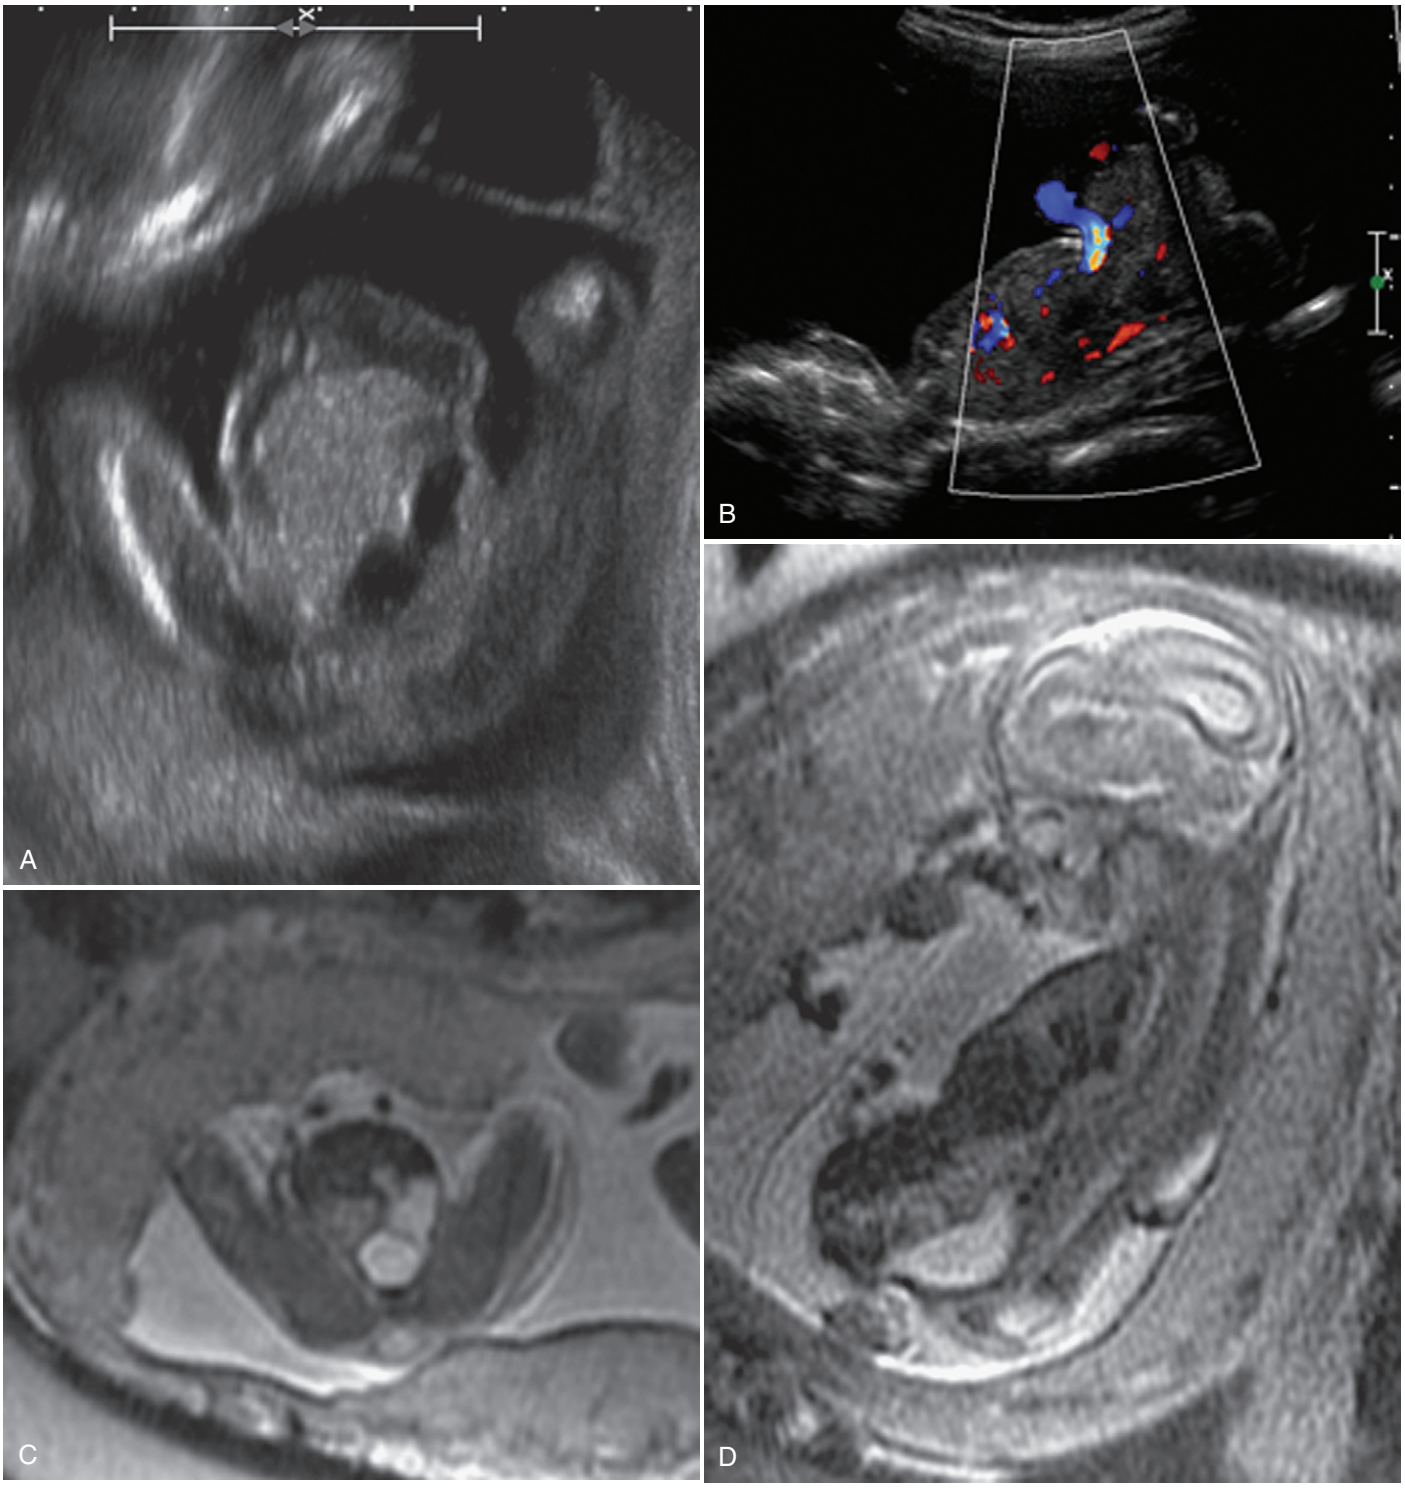

Figure 114–14. Appearance of cloacal exstrophy on imaging of a 19-week gestational age male fetus. **A,** Transverse ultrasound image through lower abdomen showing abdominal wall mass and consistent nonvisualization of the urinary bladder. **B,** Sagittal ultrasound view showing umbilical blood flow and lower abdominal wall mass immediately caudal to the umbilicus. **C,** Transverse MR image showing omphalocele with liver and dilated distal left ureter. **D,** Sagittal MR image with omphalocele, ureter, and terminal myelocystocele evident.

defects in current obstetric care, and the finding of open spina bifida in a fetus has been considered an indication for potential in-utero surgical treatment. D'Addario and colleagues (2008) evaluated the diagnostic accuracy of ultrasonographic signs that may be looked for in fetuses with spina bifida. They confirmed the usefulness of evaluation of the posterior fossa in the diagnosis of spina bifida, particularly in cases of small spinal defects that may be missed at ultrasound evaluation, noting that in 49 fetuses reviewed a small cerebellum was found in 96%, an effaced cisterna magna in 93%, and a small posterior fossa in 96%. Ventriculomegaly was present in 40 of 49 (81%) cases. With the finding of these associated features the spinal defect was identified in all but

one fetus. Miller and colleagues (2006) studied the impact of prenatal MRI on diagnosis and neurosurgical treatment. Between 1999 and 2003 they reviewed 320 fetal MRI studies that were performed at a single institution. Twenty-four fetuses were found to have central nervous system abnormalities. The diagnoses included spinal anomalies (e.g., scoliosis, myelomeningocele, and closed spinal dysraphism) and brain anomalies (e.g., ventriculomegaly with or without hemorrhage, intracranial cyst, craniosynostosis, and encephalocele). Fourteen of the 24 fetuses underwent surgery based on findings of prenatal MRI, and in 7 cases the pregnancy was terminated.

Fetal intervention for myelomeningocele (MMC) may improve hydrocephalus and hindbrain herniation associated with the Arnold-Chiari type II malformation and may reduce the need for ventriculoperitoneal shunting. As of now there is little evidence that prenatal repair of MMC improves neurologic function. MMC is the first nonlethal disease under consideration and study for fetal surgery. As a result, potential improvements in outcome must be balanced with maternal safety and well-being, in addition to that of the unborn patient (Hirose and Farmer, 2009).

Renal Mass

Although congenital mesoblastic nephroma (CMN) is a rare benign congenital renal tumor it is the most common solid renal tumor in the neonatal period. Prenatal diagnosis of CMN previously has been made on the basis of the findings of ultrasonography in the third trimester, and MRI-based diagnosis has also been reported. Chen and colleagues (2003) reported a case of prenatally diagnosed classic-type CMN diagnosed at 22 weeks of gestation based on the findings of ultrasonography and MRI. A vascular "ring" sign—an anechoic ring surrounding the tumor—has been described for CMN (Kelner et al, 2003).

Rhabdoid tumor of the kidney is relatively rare but a highly lethal malignancy of infancy. Prenatal detection of a renal rhabdoid tumor with mesoblastic components has been diagnosed in a 27-week fetus (Fuchs et al, 2004). The tumor presented as a large mass in the left renal area, and there was concomitant massive polyhydramnios. Ultrasound features alone did not distinguish the tumor from a benign lesion, but aggressive growth of the tumor indicated malignancy. Amniotic fluid cytology was performed but failed to confirm the diagnosis.

Leclair and colleagues (2005) reviewed outcome in 28 patients from 20 institutions with prenatally diagnosed renal tumors. The diagnosis was congenital mesoblastic nephroma in 26 patients and Wilms tumor in 2 patients. One or more complications were identified in 20 of the 28 cases (71%) during the perinatal period. Polyhydramnios was observed in 11 fetuses (39%), 2 presented with hydrops fetalis, and 7 presented in acute fetal distress requiring emergency cesarean section, of which 1 died in utero before delivery. Median gestational age of the 27 neonates born alive was 35 weeks (range 29 to 39), including 13 (46%) who were born before term. Complications at birth included hemodynamic instability in 3 neonates, respiratory distress syndrome in 8 (30%), and hypertension in 6 (22%). Surgical complications occurred in 7 patients (26%), including tumor rupture in 1 and intraoperative bleeding with postoperative death in 1. At median follow-up of 42 months, 26 of the 27 children were in complete remission. Leclair and colleagues concluded that prenatally diagnosed renal tumors have an excellent oncologic outcome but a high risk of perinatal complications. Prenatal diagnosis should allow planning the delivery at a pediatric tertiary care center to avoid a potentially life-threatening condition in early neonatal life.

Renal Vein Thrombosis

Renal vein thrombosis (RVT) is a rare event. The incidence varies from 0.5 per thousand of admissions in neonatal intensive care units to 0.5% in autopsy findings. Clinical presentation in infants includes a flank mass, hematuria, and thrombocytopenia. Antenatal ultrasound findings include an enlarged kidney, loss of corticomedullary differentiation, and branching hyperechoic vessels (Fig. 114–17). Often, an inferior vena cava thrombus can be seen with decreased or no flow in the affected renal vein (Fig. 114–18). Diallo and colleagues (1998) reported a case of RVT that was diagnosed at 34 weeks of gestation by ultrasonography in a fetus showing signs of fetal distress. The typical pattern of renal enlargement, loss of the corticomedullary differentiation, echogenic streaks, lack of definition of renal sinus echoes, and loss of venous flow in the effected kidney by Doppler imaging was observed.

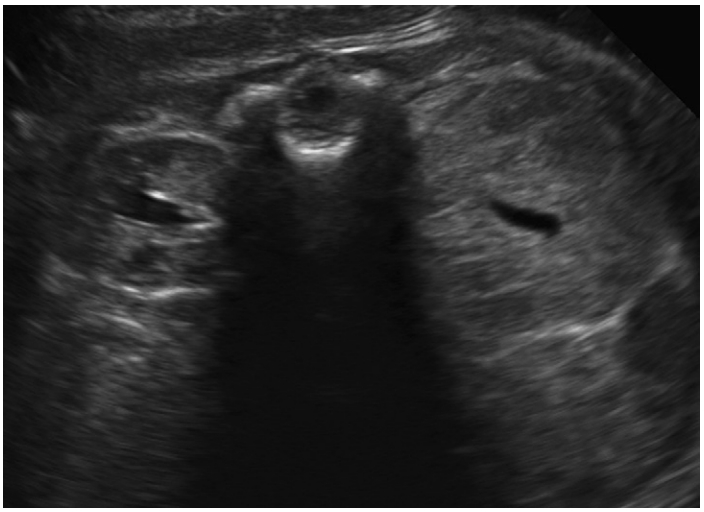

Figure 114–17. Antenatal ultrasound image at 38 weeks' gestation demonstrates an enlarged left hyperechoic kidney with loss of corticomedullary differentiation.

Figure 114–18. Antenatal ultrasound image at 36 weeks' gestation shows a left renal vein thrombosis extending into the inferior vena cava. Note the mural calcification of the inferior vena cava.

After cesarean section, full recovery at 1 week and a normal evolution at 1 month of life was reported.

Adrenal Mass

The differential diagnosis of prenatally diagnosed adrenal masses includes neuroblastoma, adrenal hemorrhage, adrenal and cortical renal cysts, adrenal adenoma and carcinoma, subdiaphragmatic pulmonary sequestration, Beckwith-Wiedemann syndrome, duplication of the renal system, Wilms tumors, congenital mesoblastic nephroma, and mesenteric and enteric duplication cysts. According to Sherer and colleagues the worldwide annual incidence of childhood adrenal cortical neoplasms ranges between 0.3 and 0.38 per 1 million children younger than 15 years. These neoplasms are even more unusual among infants, suggesting spontaneous resolution in some lesions, with only 23 cases reported in the literature (Sherer et al, 2008).

Curtis and colleagues (1997) developed an algorithm that facilitates the correct diagnosis of the suprarenal masses subdiaphragmatic extralobar pulmonary sequestration and neuroblastoma, making the correct diagnosis prenatally in 95% of patients. Based on literature review, the authors identified distinguishing features of the two lesions and created an algorithm on the basis of these distinctions. Typical findings on prenatal ultrasonography for subdiaphragmatic extralobar pulmonary sequestration include an echogenic mass that is left sided and can often be identified during the second trimester. Neuroblastoma is most often cystic, right sided, and identified in the third trimester.

Fang and colleagues (1999) reported adrenal hemorrhage confirmed in a neonate after first detection by ultrasonography at 21 weeks' gestational age. The echogenic right suprarenal mass became larger and hypoechoic on follow-up postnatal ultrasonography. With difficulty differentiating the lesion from cystic neuroblastoma, the authors performed a surgical exploration when the patient was 2 months old, and adrenal hemorrhage was confirmed, thus suggesting that adrenal hemorrhage can occur as early as the second trimester. Characteristic imaging features on ultrasonography, color Doppler imaging, and MRI help differentiate adrenal hemorrhage from neuroblastoma (Gocmen et al, 2005).

Adrenal Hemorrhage

Adrenal hemorrhage is a relatively common condition and is estimated to occur in 1% to 2% of healthy infants. More small adrenal hemorrhages are being detected with routine perinatal ultrasonography with unclear long-term significance. **Predisposing factors include prolonged labor, birth trauma, and large birth weight. RVT may be associated** (Suga et al, 2000). An association with the Beckwith-Weidemann syndrome has been reported in several cases (Anoop and Anjay, 2004; Merrot et al, 2004; Gocmen et al, 2005). Clinically, the neonate with adrenal hemorrhage may have anemia, shock, and an abdominal mass. Gross hematuria is unusual. Ultrasonography is the most efficient diagnostic measure and usually reveals an echogenic suprarenal mass (Rubenstein et al, 1995; Schwarzler et al, 1999; Lee and Lin, 2000; Velaphi and Perlman, 2001). This may appear similar to a neuroblastoma, and further evaluation, particularly with MRI, may be necessary. Scrotal hemorrhage may also be a presenting sign of adrenal hemorrhage (Avolio et al, 2002; Duman et al, 2004). The imaging characteristics of an adrenal hemorrhage evolve with time, often providing a definitive diagnosis as the mass involutes. Calcifications may later develop, reportedly as soon as 1 week (Smith and Middleton, 1979). **The late appearance of an adrenal hemorrhage is that of peripheral eggshell calcifications in contrast to stippled calcifications of neuroblastoma.** Management is almost always supportive and expectant, with a rare need for intervention.

Renal Artery Thrombosis

Hypertension and hematuria in a neonate should suggest the possibility of renal artery thrombosis (Roth et al, 2003). The clinical setting is usually suggestive in that umbilical artery catheterization is the most common cause of this condition. Renal insufficiency may be a clinical feature of this condition, as well as proteinuria and congestive heart failure (Andreoli, 2004; Cachat et al, 2004). Thrombotic involvement of the aorta may be present as well. Ultrasound examination usually reveals the diagnosis and the

extent of the thrombus. Management is dependent on the clinical setting, and unilateral involvement is best managed expectantly, although thrombolytic therapy may be appropriate (Ellis et al, 1997; Kavaler and Hensle, 1997). Control of hypertension is the most important aspect of management and occasionally requires removal of a nonfunctional kidney.

Key Points: Specific Diagnoses

- Antenatal ultrasound findings suggestive of UPJ obstruction include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation.
- The findings of MCDK include multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst.
- Antenatal detection of ARPKD often presents as bilaterally enlarged echogenic kidneys without obvious renal cystic disease. Concomitant hepatobiliary dilatation or oligohydramnios further suggests the disease.
- Duplication anomalies are often recognized on the basis of upper pole hydroureteronephrosis in association with either an obstructing ureterocele or an ectopic ureter.
- Very large ureteroceles can be mistaken for the bladder.
- VUR cannot be definitively diagnosed on antenatal ultrasonography, although intermittent or varying degrees of hydronephrosis or a hydroureter is suggestive of the diagnosis.
- Antenatal findings of posterior urethral valves include bilateral hydroureteronephrosis, a thick-walled bladder with dilated posterior urethra, renal dysplasia, and/or perinephric urinomas and urinary ascites.
- Fetal characteristics of bladder exstrophy include nonvisualization of the fetal bladder, lower abdominal wall mass immediately inferior to a low-lying umbilicus, and diminutive genitalia.
- Antenatal findings of exstrophy in combination with omphalocele and with kidney and lumbosacral spine abnormalities suggest cloacal exstrophy.
- A female fetus presenting with hydronephrosis and a large cystic mass arising from the pelvis suggests a persistent cloaca.

ANTENATAL MANAGEMENT OF FETAL UROPATHIES

Up to 3% of all pregnancies have fetal urinary tract anomalies. The vast majority of anomalies are associated with hydronephrosis. Severe obstruction that might warrant antenatal intervention is less than 5% of all detected anomalies.

The primary role for the perinatal urologist is to provide education and counseling for prospective parents in an objective manner. Often the patient is referred to the urologist after much information has been provided to the family. **The counseling urologist should provide (1) reassurance and dispel misconceptions, (2) a reasonable differential diagnoses, (3) information of the natural history of the disease, (4) antenatal recommendations, and (5) a postnatal management plan,** which will be discussed further. The need for continued antenatal evaluation is debatable and unclear, particularly in the cases of mid and late trimester mild and moderate hydronephrosis. In the setting of severe unilateral or bilateral hydronephrosis more regular follow-up is reasonable. **If there is a suspicion of bladder outlet obstruction, regular follow-up is needed.** In addition to normal fetal growth parameters, amniotic fluid volume, renal appearance (echogenicity, degree of hydronephrosis, cystic changes), and extrarenal fluid collections should be monitored closely.

Rationale for Fetal Intervention

Overall, the need to consider in-utero intervention for obstruction is uncommon. However, in the specific cases in which it should be considered, the rationale for antenatal treatment of hydronephrosis is to maximize normal development of renal and pulmonary function. These two aspects of fetal development are closely linked because urine comprises greater than 90% of amniotic fluid volume by the 16th week of gestation and oligohydramnios during the second trimester is usually associated with a lethal postnatal outcome secondary to pulmonary hypoplasia.

Before prenatal surgical intervention for obstructive uropathy it is critical to assess the risk-benefit ratio. The time of onset of oligohydramnios has been shown to be an important determinant of outcome (Mahony et al, 1985; Mandell et al, 1992). In fetuses in which adequate amniotic fluid was documented at up to 30 weeks' gestation in association with a urologic abnormality, pulmonary outcomes were satisfactory and postnatal clinical problems were related to renal disease. Therefore **in the setting of late-onset oligohydramnios there appears to be limited utility of urinary tract decompression or early delivery for pulmonary reasons.** It is also unclear whether early delivery, to permit earlier postnatal urinary decompression, is beneficial. If early delivery is considered, maternal corticosteroid administration for pulmonary development should be considered. Neonatology colleagues should also be involved in any early delivery decision process.

The most widely accepted indicator of salvageable renal function is analysis of fetal urine. When the urinary sodium value is less than 100 mg/dL, urine chloride value is less than 110 mmol/L, and urine osmolarity is less than 200 mOsm/dL, renal function appears to be salvageable with in-utero intervention (Table 114–4) (Glick et al, 1985). The accuracy of these predictors has been challenged (Wilkins et al, 1987; Elder et al, 1990) and, more recently, **serial aspirations of fetal urine have been reported to yield more valuable results** (Johnson et al, 1995). Guez and coworkers (1996) reported 10 fetuses who underwent multiple urine samplings and in whom severe obstruction reduced sodium and calcium reabsorption. They concluded that fetal urinary chemistries were reasonably predictive of severe but not moderate postnatal renal impairment. Other investigators have suggested the use of fetal urinary β_2-microglobulin as an indicator of tubular damage. Including this parameter, poor renal outcome has been predicted with a specificity of 83% and sensitivity of 80% (Tassis et al, 1996).

Clinical Experience

The ability to diagnose severe prenatal hydronephrosis and advances in fetal intervention has helped develop prenatal surgery for obstructive uropathy. In 1982, Harrison and colleagues (1982b) described the initial report of fetal surgery in a 21-week-old fetus with bilateral hydroureteronephrosis secondary to posterior urethral valves. After the 1986 report of the International Fetal

Table 114–4.

Indications and Conditions for In-Utero Urinary Decompression

INDICES	COMMENT
Evidence of bladder outlet obstruction	Dilated bladder, hydroureteronephrosis
Normal karyotype	By amniocentesis
No systemic anomalies	For example, central nervous system, cardiovascular
Male fetus	
Singleton	
Oligohydramnios	Early onset: <25 weeks
Noncystic kidneys	Degree of echogenicity is subjective; cysts are poor prognostic sign
Favorable urinary indices	Na < 100 mg/dL, Cl < 110 mg/dL, Osm < 210 mOsm/dL; or serial samplings trending toward normal; β_2-microglobulin in < 10 to 20
Informed consent	Risks of partial treatment must be included

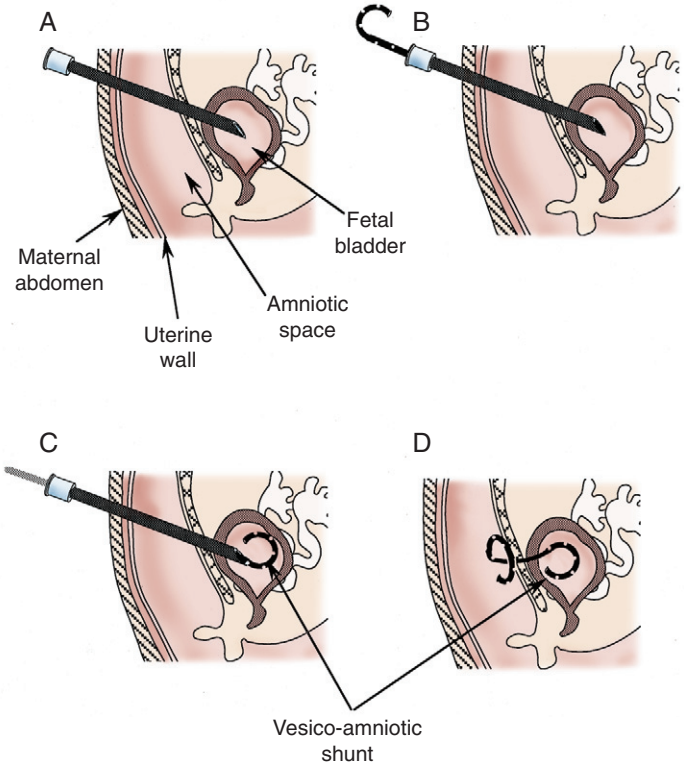

Figure 114–19. Diagram showing technique of fetal vesicoamniotic shunt placement. The fetal bladder is initially reached by needle, and a large-bore introducing sheath is passed into the bladder **(A).** Within this sheath, the shunt is passed **(B** and **C).** It is a double pigtail shunt with holes at each end allowing free drainage between the bladder and amniotic space **(D).** (From Peters CA. Surgical management of fetal uropathies. In: Marshall FF, editor. Textbook of operative urology. Philadelphia: WB Saunders; 1996. p. 1063.)

Surgery Registry in which outcomes did not seem to justify risk, a de facto moratorium on in-utero urinary tract shunting evolved (Manning et al, 1986).

More recently, with improved technology and renewed interest in fetal shunting, most cases have been referred to a small number of highly specialized centers actively engaged in prenatal surgery. **The initial method of decompression with open surgery has largely been replaced by in-utero shunt placement.** The technique of shunt placement emerged from the University of California, San Francisco (UCSF) group (Harrison et al, 1982a). **The shunt is placed under ultrasound guidance using a Seldinger technique through a trochar** (Fig. 114–19). Current practice uses the Rodeck shunt, which lies flat against the abdomen to minimize shunt dislodgment. This method has been complicated by technical problems of shunt dislodgment and, in the case of the double-J shunt, bowel herniation (Robichaux et al, 1991). Amnioinfusion may be needed to improve visualization for shunt placement; however, this may lead to excessive fetal movement. Occasionally the fetus needs to be paralyzed for accurate placement. Very large bladders may cause the shunt to be placed too high in the abdomen, resulting in dislodgment from the bladder after it decompresses.

Because of these complications some investigators have explored the use of fetoscopic methods for direct intervention to provide prolonged bladder drainage; others have attempted direct endoscopic valve ablation (Estes et al, 1992; Luks et al, 1994; Kohl et al, 1997; Luks et al, 1997; Quintero et al, 2000). **Experience with fetoscopic/endoscopic valve ablation is currently at the case report and experimental level, and long-term outcomes are unknown.** There are no studies to determine if this method of decompression is adequate in the presence of significant bladder dysfunction.

The indications and contraindications for intervention in prenatal obstructive uropathy are outlined in Table 114–4. Currently, **serial bladder sampling over 3 days has been used to help determine if the fetus is a viable candidate.** The serial nature of the procedure allows one to see the subsequent trend of urine osmolality and electrolyte composition as a reflection of fetal kidney response (Johnson et al, 1995). The principal reason for considering vesicoamniotic shunting is to prevent early neonatal pulmonary insufficiency and death. The risks that one accepts with intervention include induction of premature labor, perforation of fetal bowel and bladder, fetal loss, and fetal and/or maternal hemorrhage and infection.

More recently, the ability to influence renal outcome in male patients with posterior urethral valves but without oligohydramnios has been suggested as a possible indication for in-utero intervention. In this setting the principal goal of intervention is not to prevent pulmonary hypoplasia and deaths but to prevent or delay end-stage renal failure. Although some reports have shown promise in the ability to distinguish those fetuses with likely early renal failure from those with later-onset failure, the specificity and accuracy of methods using a combination of ultrasound and urinary chemistries (sodium, β_2-microglobin, and calcium) has not been well defined (Muller et al, 1993; Clautice-Engle et al, 1995; Dommergues et al, 2000). **In summary, precise identification of those situations in which intervention may benefit the fetus with obstructive uropathy remains unclear.**

Clinical Outcomes

To date, the reported long-term outcomes of antenatal intervention for severe obstructive uropathy (e.g., posterior urethral valves, prune-belly syndrome, urethral atresia) are mixed (Crombleholme et al, 1990; Johnson et al, 1994; Coplen et al, 1996; Freedman et al, 1999; Holmes et al,

2001; McLorie et al, 2001; Clark et al, 2003; Biard et al, 2005; Salam, 2006). Significant variability in patient selection and assessment of outcome within these studies has limited the ability to determine if prenatal intervention has altered the postnatal course. A large systematic review of the prenatal intervention for obstructive uropathy showed a statistically significant perinatal survival advantage with shunting (Clark et al, 2003). Of the studies that have reported long-term outcomes of in-utero vesicoamniotic shunting, many of the children have renal insufficiency (57%) and growth impairment (86%) (Freedman et al, 1999; Holmes et al, 2001; Biard et al, 2005). Biard and associates (2005) reported on long-term follow-up (5.8 years) of patients who have survived in-utero shunting. They noted acceptable renal function in 44%, mild impairment in 22%, and renal failure in 33%. Patients with prune-belly syndrome had the best renal outcome (57%), followed by those with posterior urethral valves (43%), and then urethral atresia (25%).

Overall, it appears that in-utero intervention for the appropriate patient may reduce the risk of neonatal mortality and may potentially improve renal function. Currently, a European-based multicenter randomized clinical trial (PLUTO: Percutaneous Shunting for Lower Urinary Tract Obstruction) is being conducted to help answer these questions. The trial is attempting to enroll 150 singleton pregnancies with ultrasound evidence of lower urinary tract obstruction to evaluate the safety and effectiveness of in-utero shunting compared with conservative management. In addition to this trial, **more sensitive and specific markers to better identify which fetus will benefit from in-utero shunting need to be defined.**

Key Points: Antenatal Management of Fetal Uropathies

- Up to 3% of all pregnancies have a urinary tract anomaly.
- The primary role for the perinatal urologist is to provide education and counseling for prospective parents in an objective manner.
- The need to consider in-utero intervention for obstruction is uncommon.

POSTNATAL MANAGEMENT OF ANTENATALLY DETECTED UROLOGIC RENAL ABNORMALITIES

A child with a prenatal diagnosis of a urologic renal abnormality such as ANH should be carefully evaluated and followed by a pediatric urologist from birth. The vast majorities of these children appear entirely healthy and in the absence of prenatal ultrasound findings would not have any indications for regular urologic follow-up. **Parental anxiety is common and should be addressed directly with prenatal counseling and education.**

Unilateral Hydronephrosis

The presence of prenatally detected unilateral dilation of the kidney warrants postnatal evaluation in a timely but nonurgent fashion (3 to 8 weeks of life) with an ultrasound evaluation (Clautice-Engle et al, 1995). The most common diagnoses associated with this finding are UPJ obstruction, VUR, and UVJ obstruction/megaureter. Early ultrasound evaluation is unlikely to miss a significant abnormality. A normal postnatal ultrasound examination indicates that obstructive uropathy is not present; however, it does not determine whether the child has VUR (Tibballs and De Bruyn, 1996). **It is important to keep in mind that a postnatal ultrasound evaluation performed within the first 48 hours of life may not yet demonstrate hydronephrosis or may underestimate the degree of hydronephrosis secondary to physiologic oliguria in the newborn.**

The decision to perform voiding cystourethrography (VCUG) or initiate prophylactic antibiotics in the neonatal period is unclear. Although some groups advocate postnatal VCUG in any child with a history of antenatal hydronephrosis, others have questioned the value of this approach (Yerkes et al, 1999). Infants with severe ANH should be placed on a prophylactic antibiotic (amoxicillin, 10 to 25 mg/kg/day) and undergo VCUG. Severe ANH may be associated with an increased risk of febrile urinary tract infection (Song et al, 2007). As for mild ANH, a recent prospective study of 192 infants with ANH noted that the majority of patients with mild ANH had no significant events during infancy (Coelho et al, 2007). Conversely, it is suggested that female infants with a history of ANH and postnatal uropathy had a higher risk of febrile urinary tract infection (Coelho et al, 2008). In a much larger study of 1514 patients with a history of ANH and persistent postnatal Society of Fetal Urology grade II hydronephrosis, of the patients who were screened (76%, 1150), VUR was identified in 28% and urinary tract infection in 1.6% (Estrada et al, 2009b). Of those not screened, the number who developed a febrile urinary tract infection and VUR was significantly higher than expected (febrile urinary tract infection: 4.4%, odds ratio 8.9) as compared with the screened group. These two studies suggest that infants with a history of ANH and persistent postnatal hydronephrosis may warrant further investigation by VCUG in the early postnatal period. However, to date, no appropriate prospective studies with coordinated and comprehensive postnatal follow-up have examined this question in a rigorous fashion to provide consensus guidelines (Lee et al, 2006; van Eerde et al, 2007).

At the authors' institution, children with moderate or severe ANH are placed on a prophylactic antibiotic at birth. These children undergo renal bladder ultrasonography and VCUG postnatally. Diuretic renography is reserved for those with persistent moderate or severe postnatal hydronephrosis not related to VUR. Infants with persistent mild hydronephrosis on serial ultrasound evaluation or no postnatal hydronephrosis are observed and followed clinically. Infants with any degree of antenatal or postnatal ureteral dilation undergo ultrasonography, VCUG, and possibly diuretic renography (with ^{99m}Tc-mercaptoacetyltriglycine) if clinically indicated.

Perhaps the most challenging aspect of managing ANH is determining if and when postnatal surgical correction for obstruction is appropriate (Ransley et al, 1990). Some have suggested that regardless of the degree of ANH, moderate or severe postnatal hydronephrosis with evidence of decreased renal function should be an indication for surgical intervention (Chertin et al, 2006). Despite the improved anatomic detail afforded by real-time ultrasonography and the increasing experience with functional nuclear medicine studies, no radiographic or clinical gold standard for physiologically significant obstruction exists. Over time, hydronephrosis has been seen to improve whereas other kidneys appear to lose function. The natural history of ANH is not clearly defined.

The debate over the appropriate management of infants with unilateral ANH continues and may ultimately be determined by a combination of epidemiologic, radiographic, and new innovative biomarker discoveries. More accurate and reproducible prenatal and postnatal radiographic documentation of the degree of hydronephrosis and function combined with appropriate natural history data are needed to better categorize these infants. Finally, new serum or urine biomarkers indicative of ongoing renal damage will be critical in helping to further define which infants are truly at risk.

Bilateral Hydronephrosis

Infants with bilateral hydroureteronephrosis may have posterior urethral valves, bilateral VUR, bilateral UPJ or UVJ obstruction, or a combination of these findings. **For the child with bilateral hydroureteronephrosis suggestive of bladder outlet obstruction, an ultrasound evaluation and VCUG should be performed promptly.** In boys, posterior urethral valves is the most important diagnosis to be ruled out. In girls, an obstructing ectopic ureterocele would be the most likely cause for bladder outlet obstruction. In the event that an obstructive lesion is discovered, it should be corrected promptly. For children with suspected lower urinary tract obstruction (e.g., posterior urethral valves), prompt bladder decompression and antibiotic prophylaxis (amoxicillin 10 to 25 mg/kg/day) should be initiated before radiographic intervention.

Renal Agenesis, Renal Ectopia, and Unilateral Multicystic Dysplastic Kidney

Infants born with solitary kidneys (renal agenesis), renal ectopia, or unilateral multicystic dysplasia should be evaluated postnatally by ultrasonography and VCUG. Functional studies such as with dimercaptosuccinic acid (DMSA) are occasionally needed to confirm the diagnosis. The need for further screening with VCUG is controversial. It has been reported that of infants with a solitary kidney, 30% have VUR, 11% UPJ obstruction, and 7% UVJ obstruction (Atiyeh et al, 1993; Cascio et al, 1999). Similarly, those with renal ectopia (simple or crossed fused ectopia) may also be at risk for VUR in the ectopic or contralateral kidney (30%) (Gleason et al, 1994; Guarino et al, 2004; Arena et al, 2007). However, there are others that report a very low incidence of associated urologic anomalies and do not recommend screening (Calisti et al, 2008).

An MCDK is primarily unilateral, isolated, and associated with a good prognosis. **If at birth the ultrasound findings are not absolutely diagnostic of a classic MCDK, a DMSA study can be used to confirm the diagnosis with the absence of uptake.** Patients with MCDK are often thought to be similar to those born with a solitary kidney. Additionally, patients with MCDK have an increased frequency of VUR and UPJ obstruction in the contralateral normal kidney (Kaneko et al, 1995; Miller et al, 2004).

Key Points: Postnatal Management of Antenatally Detected Urologic Renal Abnormalities

- Infants with antenatal unilateral hydronephrosis should undergo an ultrasound evaluation in 3 to 8 weeks after birth.
- Postnatal ultrasonography performed with 48 hours of life may underestimate the degree of hydronephrosis.
- An infant with bilateral hydroureteronephrosis consistent with bladder outlet obstruction should undergo ultrasound evaluation and VCUG promptly.

SUMMARY

With the increased use of maternal-fetal ultrasound, more genitourinary abnormalities are being detected prenatally. Although advances in imaging have increased the detection and characterization of these abnormalities, further work is needed to identify which abnormalities are clinically significant. Research directives should focus on identifying which infants require postnatal diagnostic imaging and intervention. Developments in the fields of imaging, proteomics, and genomics may provide the necessary information to not only detect the abnormality but also prognosticate which ones require further testing and medical intervention.

Acknowledgment

The authors acknowledge the assistance of Drs. Beryl R. Benacerraf, Bryann Bromley, Carol E. Barnewolt, Susan A. Connolly, and Judy A. Estroff for providing many of the fetal ultrasound images.

Medications and Allergies in the Pediatric Patient
Pediatric Urologic Examination
Pediatric Laboratory Evaluation
Pediatric Radiographic Evaluation
Pediatric Urodynamic and Biofeedback Evaluation
Office Surgical Procedures
Summary

Pediatric urology encompasses a spectrum of disorders from complex congenital anomalies, such as bladder or cloacal exstrophy, to more routine but nevertheless important problems such as daytime wetting in a school-aged child. This chapter focuses on the history and physical examination of the pediatric urology patient. We have placed particular emphasis upon clinical entities, examination techniques, and adjunct investigations that are unique to the pediatric population. The evaluation and treatment of pediatric urologic patients are often complex. The reader may find further details about specific conditions in other chapters within this text. The following information is an introduction to the nuances of the pediatric urologic evaluation.

CHIEF COMPLAINT AND HISTORY OF PRESENT ILLNESS

In most cases, the initial contact with the child and family will be through a referring phone call from the parent, pediatrician, family practitioner, or, if prenatal evaluation is desired, the obstetrician. In many cases, the child's family is calling from a distance and the urologist will need to decide with the referring clinician whether the child is healthy enough to be transferred or must first have his or her condition stabilized. Usually, even in remote areas, skilled general pediatric support is available. With coaching from the accepting team, most clinicians will be able to manage even complex problems in the stabilization phase of the triage process. A thorough understanding of the chief complaint, history of the present illness, and past medical history is essential to appropriate management of all pediatric urologic patients.

An important first question when beginning the history in the pediatric patient with a urologic problem is **"why is the child here?" In some cases, the child can begin to answer these questions, and it is worthwhile early in the interview to ask the child a few questions directly. This shows respect for the child, who may be an excellent historian despite young age.** As soon as the child realizes that the interview is directed to him or her, rather than to the parent, he or she will concentrate on the examination. If future therapy requires behavioral training that involves cooperation from the child, he or she may be more receptive. Additionally, it is often helpful to interview adolescents separately from their parents when asking sensitive questions.

Abdominal Complaints

Children with acute abdominal pain should be seen immediately. An accurate history of the character of the pain may be the best indicator of the source of the pain. Details about the character of the pain, timing, acuteness of onset, radiation, and migration are important and should, if possible, be elicited directly from the child. Associated loss of appetite, nausea, vomiting, or a change in bowel pattern may help to distinguish gastrointestinal from genitourinary sources. Causes of abdominal pain in children vary widely and are often unique to the pediatric population. As urologists, we suspect pyelonephritis, renal colic, or cystitis, but the differential diagnosis includes many nonurologic etiologies. Intra-abdominal causes in children include pyloric stenosis, midgut volvulus, appendicitis, and intussusception. Non-abdominal sources, such as sickle cell crisis, streptococcal pharyngitis, or pneumonia, should also be considered. In addition to a thorough abdominal examination designed to rule out surgical abdominal disease, these children should be evaluated for urinary tract infection (UTI), constipation, and spermatic cord torsion. Usually an acute abdominal series is ordered, which will show considerable amounts of stool throughout the colon if constipation is the problem. Occasionally, some children with spermatic cord torsion complain of abdominal pain and have surprisingly few complaints referring to the scrotum. **Most abdominal masses originate in genitourinary organs and should be evaluated immediately** (Chandler et al, 2004) (Table 115–1). The most common malignant abdominal tumor in infants is neuroblastoma, followed by Wilms tumor (Golden and Feusner, 2002). Children with neuroblastoma typically relate a history of more constitutional symptoms than children with Wilms tumor. If an abdominal mass is suspected, an abdominal ultrasound evaluation

Table 115–1

Distribution of Abdominal Masses of 280 Patients in the Neonatal Period*

TYPE	NO.
Kidney (65%)	
Hydronephrosis (UPJ obstruction, UVJ obstruction, ureterocele, etc.)	80 (28%)

*Distended bladder, hepatomegaly, and splenomegaly were excluded in most series.

UPJ, ureteropelvic junction; UVJ, ureterovesical junction.

Data from Griscom, 1965; Emanuel and White, 1968; Raffensperger and Abousleiman, 1968; Wedge et al, 1971; Wilson, 1982.

should be ordered. If the mass is solid, computed tomography (CT) is almost always required.

Scrotal Symptoms

A child with acute scrotal pain must be presumed to have spermatic cord torsion regardless of age until proven otherwise. However, in some cases, an accurate history may save the child an unnecessary surgical exploration. It is particularly important to interview the child as well as the parent. The differential diagnosis of the acute scrotum includes testicular torsion, torsion of the appendix testis or epididymis, epididymitis/orchitis, hernia/hydrocele, trauma, sexual abuse, tumor, idiopathic scrotal edema, dermatitis, cellulitis, and vasculitis, such as Henoch-Schönlein purpura (Gatti and Murphy, 2007). Gradual onset of the pain is more consistent with epididymitis, whereas abrupt pain suggests spermatic cord torsion or torsion of one of the testicular appendices. Associated scrotal wall swelling, erythema, or superior displacement of the testis with an absent cremasteric reflex is suggestive of spermatic cord torsion. Yet, the absence of edema or erythema or the presence of a cremasteric reflex does not rule out the possibility of acute testicular torsion, especially if the onset of pain was recent. The classic presentation of testicular torsion is the sudden onset of severe, unilateral pain that is often associated with nausea and emesis. A history of similar intermittent episodes may suggest intermittent testicular torsion. Traditionally, significant ischemic damage is believed to occur after 4 to 8 hours. Therefore testicular torsion represents a true surgical emergency. Patients presenting after 8 hours should still be explored, because the viability of the testis is difficult to predict (Beard et al, 1977; Bartsch et al, 1980).

If there is history of inguinal or scrotal pain, infants and children with an inguinal hernia or a hydrocele that changes in volume should be seen within 24 hours or sooner. Not all of these children will need emergency surgery, but a few will require surgical intervention within a short period. If there is a history of scrotal or inguinal pain, the child's parents should be taught to recognize the signs of an incarcerated inguinal hernia and instructed to go to the emergency department if symptoms occur before the planned surgical correction. **Infants with asymptomatic hydrocele rarely require surgery initially.** In most cases, the hydrocele will resolve in the first year of life. The authors make an exception if the hydrocele is particularly large or palpable in the inguinal region. A large hydrocele with a palpable inguinal component or one that is enlarging may indicate the presence of an abdominoscrotal hydrocele. These do not spontaneously resolve and usually enlarge. These should be corrected, usually at 6 to 12 months through an initial scrotal incision that will decompress the hydrocele (Luks et al, 1993; Belman, 2001).

Boys with undescended testes are one of the most common referrals to the pediatric urologist. Undescended testes are present in 30% of preterm neonates and are present in 3% of full-term male infants at birth (Ghirri et al, 2002; Boisen et al, 2004). Undescended testes do not represent a surgical emergency. **We operate on patients with undescended or absent testes at about 6 months of age. Very few of these testes will descend after 3 months of age** (Berkowitz et al, 1993). Some infants with impalpable testes may require laparoscopic evaluation, and this examination may be done at 6 months as well. In prepubertal boys, concerns of an undescended testis often reflect a retractile testis that results from a brisk cremasteric reflex and does not require surgical intervention. A retractile testis must be differentiated from an ascending testis, which may require an orchidopexy.

Varicoceles are uncommon in prepubertal boys and increase in incidence to around 15% by 15 years of age (Schiff et al, 2005). We normally try to document the size of the testis with an ultrasound examination. From the three-dimensional measurements on ultrasonography, the relative testicular volumes may be calculated and used to guide further treatment (Diamond et al, 2000). Varicoceles are 90% left-sided and 10% right-sided (MacLellan and Diamond, 2006). A right-sided varicocele in the absence of a left-sided varicocele should prompt an evaluation for a retroperitoneal process.

Testicular masses should be evaluated immediately. Prepubertal testicular and paratesticular tumors should

be considered in the differential diagnosis of a scrotal mass. Although much less common than epididymal cysts or spermatoceles, a complaint of a painless testicular or paratesticular mass should be addressed urgently. A physical examination and scrotal ultrasonography should determine if the mass is concerning for neoplasia. In a contemporary series from a tertiary center, the most common prepubertal testis tumor was a teratoma, followed by rhabdomyosarcoma, epidermoid cyst, yolk sac tumor, and germ cell tumor, respectively (Metcalfe et al, 2003). This histologic distribution was corroborated by a multicenter review, including four tertiary pediatric hospitals, demonstrating that 74% of tumors were benign, with 48% being teratomas (Pohl et al, 2004). Testicular tumors occur in the newborn and in early childhood as well as after adolescence. It is important to recognize that the peak incidence of testicular tumors in young children and infants occurs at age 2. In this population, yolk sac tumors are most common, and approximately 75% of tumors are malignant (Levy et al, 1994; Ciftci, 2001). Tumors of nontesticular origin, such as leukemia and lymphoma, must also be considered in the pediatric population.

Male Penile or Urethral Symptoms

Boys with painful priapism must be evaluated immediately. Pain may suggest ischemia of the corporeal bodies, which may progress to corporeal fibrosis if untreated. **Children with sickle cell anemia are especially at risk for priapism,** with 75% of patients experiencing their first episode by the age of 20 years (Mantadakis et al, 1999; Adeyoju et al, 2002). Outpatient treatment with penile aspiration and epinephrine irrigation has successfully been used in the treatment of this condition (Mantadakis et al, 2000).

Paraphimosis also requires immediate attention and manual reduction. In children, this procedure may require some level of sedation. Conversely, phimosis is physiologic in young infants and attempts to manually retract the foreskin in boys less than 2 years of age should be avoided. Phimosis in older children is typically treated with one or two courses of low-dose steroid cream and circumcision if necessary (Ashfield et al, 2003).

Boys with hypospadias are seen routinely. Normally, we initiate the evaluation as a newborn because most parents of with a child with a birth defect, even a relatively minor one such as hypospadias, desire an early opportunity to speak with a specialist.

We evaluate children who have developed a complication after circumcision at the convenience of the family as long as there is no active bleeding, the child is voiding normally, and there is no injury to the penile shaft or shaft skin. Narrowing of the preputial ring after circumcision may result in a trapped penis (Casale et al, 1999; Gillett et al, 2005). These infants can usually be managed with application of petroleum jelly to the penis for 4 to 6 weeks as healing continues. As long as voiding remains normal during this period, the revision of the circumcision may be postponed until age 4 to 6 months when an outpatient surgical procedure can be performed. A more common complication, urethral meatal stenosis, may be present as early as 6 months of age in circumcised infants (Upadhyay et al, 1998; Ahmed et al, 1999). This problem may be easily corrected in the office (Smith and Smith, 2000).

Female Genital Symptoms

Infant girls with introital masses commonly present to the pediatric urologist's outpatient office. Vaginal masses may be palpable or may protrude from the introitus. The differential diagnosis of these masses includes benign periurethral cysts, skin tags, urethral prolapse, imperforate hymen, prolapsed ureterocele, or, rarely, malignancies such as a rhabdomyosarcoma. **Bladder outlet obstruction may result from a prolapsed ureterocele.** The majority of these lesions are differentiated by physical examination, but historical information, such as pain, bleeding, or voiding difficulties, help solidify the diagnosis.

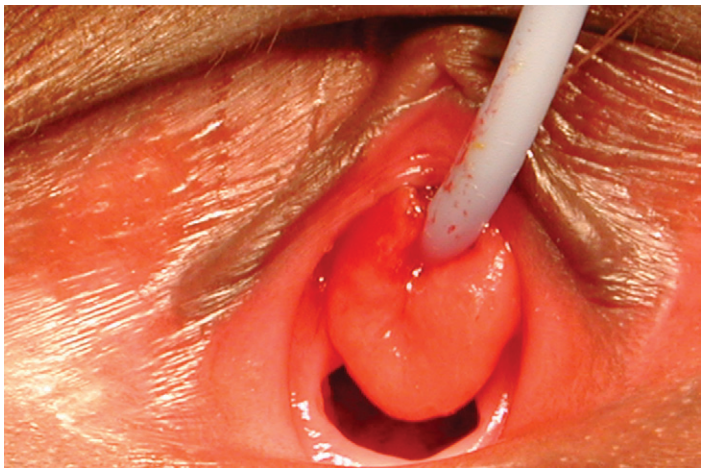

Figure 115–1. Urethral prolapse. (Courtesy of Pasquale Casale, MD.)

Urethral prolapse is relatively common, particularly in young African-American girls. Figure 115–1 demonstrates urethral prolapse in a young girl. A urethral catheter demonstrates the circumferential prolapsed urethral tissue. The prolapse is through the meatus, forming a hemorrhagic, often sensitive mass that bleeds with palpation or when in contact with the undergarments. Girls may have difficulty with urination depending on the size of the prolapse and whether it compromises the urethral meatus. Urethral prolapse may respond to topical application of estrogen and may be managed expectantly as long as voiding is normal (Redman, 1982).

Benign and malignant tumors of the vagina should be considered when vaginal bleeding occurs in young girls. A broad spectrum of entities ranging from capillary hemangioma, rhabdomyosarcoma, or carcinoma may be associated with vaginal bleeding. Labial masses may be associated with hernia or hydrocele of the canal of Nuck (Kizer et al, 1995). **Adhesions of the labia minora are common.** In most cases, they are not symptomatic. Occasionally, a girl with labial adhesions will complain of vaginal irritation from pooled urine. In this case, if the labial adhesions are not separated, the irritation may progress to irregular voiding that may exacerbate the problem of frequency and urgency. In some girls, a short course of estrogen cream applied to the labia may be effective. In many, however, separation of the adhesions in the office with local anesthetic cream may be required. Labial fusion may be associated with congenital adrenal hyperplasia (CAH), gonadal dysgenesis, or cloaca (Powell et al, 1995). A genitosinogram may be indicated in cases where the urethra cannot be distinguished from the vaginal orifice and a urogenital sinus is suspected.

The authors evaluate adolescent girls who have not menstruated and in whom there is concern about a ureteral or vaginal anomaly within 3 days. Patients with complete androgen insensitivity (CAIS) can also present with primary amenorrhea. Many of these girls have an imperforate hymen or uterine anomaly that results in poor uterine drainage that may be uncomfortable. If left

untreated, retrograde drainage of the uterus may place these patients at risk of endometriosis and infertility (Rock et al, 1982). Pelvic ultrasonography or magnetic resonance imaging (MRI) can further delineate the anatomy and guide intervention if necessary.

Voiding Symptoms

Like most teams, we see a large number of children of both sexes with voiding complaints and incontinence. Incontinence is classified as diurnal (daytime), nocturnal (nighttime) or both. If a child has never been dry, the incontinence is primary. If the child is wet after a dry interval greater than 6 months, the incontinence is secondary. **The ability to place children in categories based on the voiding history will help to focus the rest of the evaluation and guide further therapy.** The time and duration of the voiding disorder must be identified early in the interview. A thorough history obtained from both the parents and the child is important to determine the actual pattern of voiding, which may differ from parental perceptions. Did symptoms begin before or after potty training? Is wetting associated with pain, urgency, or frequency? What is the character of the voiding? Is the urinary stream steady from beginning to end or is it a "staccato" or stop and start pattern suggestive of dysfunctional voiding? Are the symptoms worse at a particular time of the day? Does the child void frequently during the day yet sleep through the night without wetting? Is wetting confined to the night, suggestive of primary nocturnal enuresis? Additionally, behavioral signs can be used to further understand the etiology of functional incontinence. Episodes of urgency in children are often suggested by holding maneuvers, such as squatting, crossing legs, and sitting on heels (Ellsworth et al, 2008). Poor potty habits may result in incomplete voiding or vaginal voiding. Giggle incontinence is encountered in young girls and describes large-volume incontinence that occurs only with laughter. In this situation, the incontinence is associated with a complete emptying of the bladder and should be distinguished from stress urinary incontinence in adults because the treatment differs significantly (Berry et al, 2009).

The voiding history is incomplete without a record of the child's eating and drinking pattern. Does the child consume small amounts of water during the day and large amounts of alternative liquids, such as soft drinks and juices, which tend to be laden with salt and sugar and low in free water? What is the stooling pattern? Does the child have firm, chunky, or pebble-like bowel movements suggestive of a retentive pattern of stooling, or does the child have soft, well-formed bowel movements more suggestive of a normal stooling pattern? Very few children hold the urine and not the stool. Conversely, children who retain stool nearly always retain urine. All of these are indicators of a dysfunctional voiding pattern, which may lead to UTI. Referencing a standardized stool chart, such as the Bristol stool form scale (http://en.wikipedia.org/wiki/Bristol_Stool_Scale; Lewis and Heaton, 1997) may be helpful to further clarify the stooling pattern (Koh et al, 2010).

Children with day or nighttime wetting are evaluated routinely in the absence of other complicating problems. The care of children with nocturnal enuresis is individualized. Although some recommend treatment in children after age 5, the authors often wait to treat until the child seems bothered by the problem. If the child does not perceive nighttime wetting as a problem, there is usually little advantage to treatment with medications or alarms. In our experience, only a few children younger than age 6 or 7 are bothered emotionally by nocturnal enuresis. Wetting during the day causes more concern and may indicate incomplete or infrequent voiding. Incomplete or infrequent voiding may lead to UTI, which may exacerbate wetting.

Although the majority of voiding symptoms are secondary to voiding habits, it is important to remember that more serious pathophysiology may present with similar complaints. After a careful history, any concerns regarding a structural etiology for voiding dysfunction should be investigated. Continuous leakage in between normal voiding patterns in a girl should raise concerns of an ectopic ureter. Symptoms suggestive of detrusor-sphincter dyssynergia may represent occult spinal dysraphism. Urinary retention and stranguria may be caused by posterior urethral valves in a boy or a bladder mass, such as a polyp, ureterocele, or rhabdomyosarcoma, in either sex. Uroflow, postvoid residual urine, and ultrasound studies are usually appropriate first steps in the evaluation of voiding dysfunction and investigation of potential structural anomalies. Additional testing may include a voiding cystourethrogram (VCUG), retrograde urethrogram, spinal MRI or ultrasound (USG), and an urodynamic evaluation.

Sexual Abuse

Although genital injuries may be accidental, the possibility of physical or sexual abuse must be considered in all cases of genital trauma in females or males. **Sexual abuse is surprisingly common and includes any activity with a child before the age of legal consent that is for sexual gratification of an adult or a significantly older child.** Sexual intercourse includes vaginal, oral, or rectal penetration, which is defined as entry into an orifice with or without tissue damage. Sex acts perpetrated by young children are learned behaviors and are associated with experiencing sexual abuse or exposure to adult sex or pornography. In 2007, there were more than 740,000 reported cases of child maltreatment. Included in this number were 56,460 victims of sexual abuse in the United States. Of these children, 18% were less than 4 years of age, 23% were 4 to 7 years of age, 24% were 8 to 11 years of age, and 35% were 12 to 15 years of age. The perpetrators of the sexual abuse are most commonly a friend or neighbor, followed by a relative or daycare worker (U.S. Department of Health and Human Services, 2009). In a recent review, the peak incidence of sexually transmitted diseases was seen in the 10- to 14-year age group (Pandhi et al, 2003). In one study of women presenting to an urban sexual assault clinic, 43% were adolescents (Jones et al, 2003). Pelvic inflammatory disease rates are highest in females age 15 to 25 with 33% of those infections in females younger than age 19 (Jenkins, 2000). Any pediatric patient with a sexually transmitted infection should be evaluated for sexual abuse. Although the mode of transmission of human papillomavirus (HPV) and herpes simplex virus (HSV) is often unclear, *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infections in a prepubertal child should be reported to child protective services (Bechtel, 2010).

The possibility of sexual abuse should be considered a result of associated physical symptoms, including (1) vaginal, penile, or rectal pain, discharge, or bleeding or (2) chronic dysuria, enuresis, constipation, or encopresis. In one study, 74% of pediatric patients with documented sexually transmitted diseases had histories or signs of abuse (Pandhi et al, 2003). Sexual abuse should be considered when the vaginal mucosa is bruised or injected, the vaginal opening is dilated, or the hymen is damaged, showing a V-shaped notch or cleft (Walker, 1998). Despite these guidelines, the diagnosis of sexual abuse is

often made by the history and not by the physical examination. In a review of 506 girls with a history of penetrative abuse referred to a sexual abuse clinic, only 11% had examination findings suggestive of sexual abuse (Anderst et al, 2009). Investigating the possibility of sexual abuse requires supportive, sensitive, and detailed history taking. Many hospitals have a sexual abuse team that can be consulted if sexual abuse is suspected. The key is to be aware of the possibilities when they might exist and to invite the team in early. The pediatric urologist will likely be asked to evaluate the abdomen and perineum (Johnson, 2000). If abuse is suspected, it must be reported to the police. Furthermore, if the perpetrator is a caregiver of the child, or a parent, the state child welfare team must be contacted.

Urinary Tract Infection

Febrile UTIs in the newborn are treated emergently, because newborns are particularly susceptible to significant renal damage if the infection is not treated promptly. A urine culture should be obtained, and these infants require intravenous antibiotics as early as possible after a urine culture has been obtained, because they have a higher prevalence of concomitant bacteremia (10% to 22%) (Pitteti and Choi, 2002). Appropriate antibiotic therapy administered without delay has been shown to reduce the incidence of scarring (Ransley and Risdon, 1981; Hiraoka et al, 2003). Some authors suggest this decreased incidence of scarring reflects a decreased likelihood of renal involvement rather than a true prevention of scar formation (Doganis et al, 2007).

Febrile UTIs in children older than newborns should be treated acutely. Children of all ages with a severe urinary tract infection may be subject to renal scarring (Ransley and Risdon, 1981; van der Voort et al, 1997) and should be seen within 24 hours or sooner. **Children older than newborns with nonfebrile UTI should be seen semiurgently.** In practice, many of these patients are seen by their pediatrician and are seen in follow-up by the pediatric urologist. Nearly all children with culture-proven UTI should be evaluated with ultrasonography and VCUG, although some groups are re-evaluating the role of renal nuclear scans in these children.

The evaluation for UTI is completed at the parent's convenience after the initial infection has been treated. In most cases, radiologic studies after UTI in a child include VCUG to detect vesicoureteral reflux. However, a substantial number of cortical defects on dimercaptosuccinic acid scintigraphy (DMSA) scan occur in the absence of identifiable reflux (62% to 82%) (Majd and Rushton, 1992; Benador et al, 1997; Ditchfield and Nadel, 1998; Biggi et al, 2001; Ditchfield et al, 2002). This has led to a re-evaluation of the role of VCUG as the initial investigation in a child with a UTI. It is important to recognize that infants less than 6 months of age and uncircumcised male infants are at increased risk for recurrent UTI (Wiswell and Roscelli, 1986).

Hematuria

A practical approach to the evaluation of hematuria in children is presented in Chapter 112. The authors' recommendation for patients with microscopic hematuria with unrelated clinical symptoms is to treat the affiliated illness (e.g., pulmonary or immunologic conditions, glomerular and interstitial disease, lower urinary tract disease, stones, tumors, vascular disease, or acute abdominal conditions) and ignore hematuria until the treatment for the underlying illness is underway. Transient microhematuria is also common in healthy children (Vehaskari et al, 1979). **The large majority of children with microscopic hematuria are evaluated, and the source of the hematuria is never identified** (Diven and Travis, 2000). Notably, the most commonly identified etiology of asymptomatic microhematuria and gross hematuria in children is hypercalciuria (Parekh et al, 2002; Bergstein et al, 2005). Microscopic hematuria in the absence of other symptoms is not an emergency in children.

Gross hematuria in children is less common than microscopic hematuria, with an estimated prevalence of 1.3 per 1000 (Ingelfinger et al, 1977). The most common diagnoses are UTI (26%), perineal irritation (11%), trauma (7%), meatal stenosis with ulceration (7%), coagulation abnormalities (3%), and urinary tract stones (2%). The most common glomerular causes of gross hematuria in children are poststreptococcal glomerulonephritis and IgA nephropathy. An antecedent sore throat, pyoderma, edema, or red blood cell casts suggest glomerulonephritis. IgA nephropathy can cause recurrent gross hematuria with flank or abdominal pain and may be preceded by an upper respiratory tract infection (Meyers, 2004). Adenoviral infection, hypercalciuria, and hyperuricosuria are other sources to consider. In peripubertal boys, benign urethrorrhagia can present with terminal gross hematuria. The authors perform ultrasonography of the kidneys, ureters, and bladder in children with gross hematuria, although the yield is low (Fernbach, 1992). In contrast with the adult patient, cystoscopic examination in children rarely reveals a cause for hematuria but should be performed when bladder pathology is a consideration.

Gross hematuria in the newborn is an emergency because it may indicate renal venous thrombosis or renal arterial thrombosis. Both may be life-threatening. Renal venous thrombosis affects boys twice as often as girls, with a left-sided predominance. These infants require resuscitation and, occasionally, anticoagulant or operative therapy (Kuhle et al, 2004). **Gross hematuria outside the newborn period, although not life-threatening, should be evaluated without delay.** Many children have an easy-to-recognize source such as UTI, urethral prolapse, trauma, and meatal stenosis with ulceration, coagulation abnormalities, or urinary tract stones. Less obvious sources include acute nephritis, ureteropelvic junction obstruction, cystitis cystica, epididymitis, or tumor (Diven and Travis, 2000; Meyers, 2004). As with adult patients, a thorough history including a specific description of the color of the urine, the presence of clots, and timing of hematuria, such as terminal hematuria or hematuria upon initiation of micturition, should facilitate the diagnostic process. A directed history should include medications, exercise habits, propensity for bleeding diathesis, and a travel history to rule out exposure to infectious diseases such as schistosomiasis or tuberculosis.

Renal Trauma

The pediatric trauma patient usually presents to the emergency department and is evaluated by the emergency medicine and trauma teams, often with the assistance of the urology service. Blunt force trauma is the primary mechanism for major renal trauma (Mohamed et al, 2010). The pediatric kidney is particularly susceptible to trauma due to the limited visceral adipose tissue, limited chest wall protection, relatively increased renal size, and increased mobility of the kidney (Brown, 1998). The mechanism of injury should be determined and a thorough history obtained from the patient and caregivers or observers. **Epidemiologic data demonstrate that the majority of renal injuries**

result from motor vehicle accidents, falls, or high-velocity activities, such as sledding, skiing, all-terrain vehicle accidents, and skateboarding (Margenthaler et al, 2002; Rogers, 2004). Therefore injuries of this nature should alert the clinician to potential renal damage. The history should include any congenital renal anomalies, such as an ureteropelvic junction obstruction, a solitary kidney, or renal ectopia. Finally, evaluation of associated injuries must be undertaken. Any abdominal injury in a toddler or young child without an antecedent history of blunt force trauma should be evaluated for physical abuse (Barnes et al, 2005).

Blunt force renal trauma represents a urologic emergency that requires immediate attention but does not necessarily require operative intervention. It is well accepted that low-grade blunt renal injuries are managed conservatively. More recently, the conservative treatment of high-grade blunt renal injuries have been successfully described in children. A consecutive series of 101 patients from The Children's Hospital of Philadelphia (CHOP) with blunt renal injury demonstrated that a nonoperative management strategy was advantageous and successful in 94.7% of pediatric blunt renal injuries (Nance et al, 2004). The children with high-grade injuries at risk for failure of conservative management include those with major vascular avulsion or extensive urinary extravasation, especially in the setting of ureteropelvic junction disruptions (Henderson et al, 2007). These patients deserve close urologic observation and repeated examinations. The authors recommend conservative management and recognize that a complete evaluation is necessary to accurately determine which patients require further intervention.

Ambiguous Genitalia

Infants with ambiguous genitalia also require immediate evaluation. Many will require direct transfer from a referring hospital. **Because CAH may result in salt wasting, which may be life threatening, infants with ambiguous genitalia must be evaluated quickly and stabilized** (Forest, 2004). **If CAH is suspected, the infant should not be discharged home from the nursery before appropriate testing is complete.** In some cases, a genotypic female neonate with CAH may be incorrectly identified as a male neonate. The correct diagnosis should be made as quickly as possible to establish the appropriate sex of rearing. Infants with ambiguous genitalia may also have other syndromes and may require further evaluation (Tables 115–2 and 115–3). A history of a discordant karyotype from an amniocentesis and infant phenotype should prompt an evaluation. The parents should be asked about a family history of infertility, amenorrhea, and infant mortality. The complete evaluation of infants with ambiguous genitalia should include urology, neonatology, endocrinology, genetics, and radiology.

Antenatal Hydronephrosis

In neonates with prenatally detected hydronephrosis and a normal bladder, the authors begin the postnatal evaluation of the hydronephrosis within the first few days of life. Families are usually concerned about the diagnosis and anxious to establish a management plan. The postnatal evaluation can be scheduled at the family's convenience for most infants. This classification includes infants with a history of prenatal hydronephrosis who are not suspected of having bladder outlet obstruction on the postnatal ultrasonography. Additionally, the ultrasonogram must not demonstrate bilateral hydronephrosis, a solitary kidney, or a thickened bladder wall. The infant must be thriving and have normal electrolytes and normal blood urea nitrogen (BUN) and creatinine levels.

The postnatal history should also include the sex of the infant, laterality of the hydronephrosis, the level of obstruction (i.e., ureteropelvic junction [UPJ], ureterovesical junction [UVJ], urethra), the presence or absence of oligohydramnios, and any other associated anomalies. The additional tests to be scheduled can include a repeat ultrasonogram, a renal scan, or a voiding cystourethrogram to evaluate the relative drainage and percentage of function of the kidneys, as well as to evaluate for vesicoureteral reflux. Until this postnatal evaluation is completed, most infants are maintained on amoxicillin prophylaxis. The utility of specific testing remains controversial. The differential diagnosis for antenatal hydronephrosis most commonly includes UPJ obstruction, vesicoureteral reflux, ectopic ureter, ureterocele, megaureter (UVJ obstruction), multicystic dysplastic kidney, posterior urethral valves, prune-belly syndrome, and megacystis microcolon syndrome.

Certain conditions require more immediate intervention, especially when bladder outlet obstruction is present. If posterior urethral valves are considered, the bladder should be drained with a feeding tube and a VCUG performed at an appropriate interval. Conversely, if prune-belly syndrome is considered, urethral catheterization should be avoided, if possible, to minimize the risk of urinary tract infection. Additionally, a ureterocele may obstruct the bladder outlet and result in bilateral upper tract dilatation. This situation can be ameliorated by placement of a urinary catheter.

An increasing number of **pregnant mothers carrying a fetus with hydronephrosis seek prenatal evaluation with the urologist. These visits are scheduled within the week unless the following conditions exist: (1) there is bilateral hydronephrosis or hydronephrosis in a single system kidney, (2) there is oligohydramnios, and (3) there is evidence of significant cystic renal disease in a fetus younger than 22 weeks' gestation.** In certain circumstances, termination of pregnancy may be considered. Conversely, fetal intervention may be indicated. These difficult decisions are often precipitated by oligohydramnios and the risk of severe pulmonary and renal insufficiency. The decision for discontinuation of the pregnancy is dependent on the gestational age of the fetus; thus prompt evaluation may be required.

Congenital Anomalies in the Neonate

Patients with major abdominal defects, such as bladder or cloacal exstrophy, require direct admission to the neonatal nursery for stabilization and surgical planning. In many cases, a team is assembled and provides orthopedic, general surgical, and urologic care during the surgery (Jeffs, 1978; Lattimer et al, 1979; Gearhart, 1999). Patients with imperforate anus and variants, such as a cloacal anomaly, require decompression of the intestinal tract, usually within the first 24 to 48 hours (Chen, 1999). At the time of the colostomy, the urologist may evaluate the perineum and perform endoscopy to further assess the urinary anomalies. Procedures to correct these major defects must be planned by surgeons who are familiar with the potential risks and complications associated with the reconstruction of the urethra, vagina, and colon. The anesthesia team must be skillful in the management of the complex metabolic changes that may occur in infants who are under anesthesia for long periods. The neonatologists must be expert in the management of infants who have undergone major surgical procedures.

Table 115–2

Syndromes Associated with Multisystemic Disease

SYNDROME	INHERITANCE	RENAL ANOMALIES	GENITAL ANOMALIES	ANOMALIES IN OTHER SYSTEMS
Aarskog-Scott			Shawl scrotum, cryptorchidism	Broad facies, short stature
Beckwith-Wiedemann		Wilms tumor		Macroglossia, gigantism, hepatoblastoma
Carpenter	AR		Small genitalia	Acrocephaly, polydactyly
Caudal regression		Hydronephrosis, renal agenesis	Vaginal and uterine agenesis	Imperforate anus, LS spine abnormality
Cerebro-oculofacial	AR	Renal agenesis	Cryptorchidism	Arthrogryposis, microcephaly, cataracts
CHARGE			Small genitalia	Coloboma, heart defects, ear anomalies
Cornelia de Lange			Small genitalia, cryptorchidism	Micromelia, bushy eyebrows
Curran		Renal agenesis		Acral anomalies
Donohue			Enlarged penis or clitoris	Hirsutism, elfin face, thick lips, low-set ears
Drash		Wilms tumor, glomerulonephritis	Mixed gonadal dysgenesis	
Dubowitz	AR		Hypospadias, cryptorchidism	Eczema, small stature, peculiar facies
Ehlers-Danlos	AR	Hydroureter		Skin hyperextensibility, poor wound healing
Fraser			Hypospadias, cryptorchidism	Cryptophthalmos
G			Hypospadias	Esophageal defect, low-set ears, abnormal facies
Holt-Oram		Renal anomalies		Defects of upper limb
Laurence-Moon-Biedl			Small genitalia	Obesity, retinal pigmentation, polydactyly
Marfan	AD	Renal duplication, hydroureter	Cryptorchidism	Aortic aneurysm, arachnodactyly
Mayer-Rokitansky		Renal agenesis	Duplex uterus, vaginal atresia	
Meckel-Gruber	AR	Renal cysts	Ambiguous genitalia, cryptorchidism	Microcephaly, polydactyly
Menkes		Hydronephrosis, reflux	Cryptorchidism	Kinky hair, CNS abnormality
Ochoa		Neurogenic bladder, hydronephrosis	Cryptorchidism	Aortic aneurysm, arachnodactyly
Opitz	AR		Hypospadias, cryptorchidism	Hypertelorism, mental retardation
Prader-Willi			Cryptorchidism	Hypotonia, obesity, mental retardation
Prune-belly		Hydronephrosis	Cryptorchidism	Hypoplastic abdominal muscle
Robert	AR	Hydroureter	Hypospadias, large penis, cryptorchidism	Hypomelia, growth retardation
Robinow	AD		Small genitalia, cryptorchidism	Flat face, short forearms
Rubenstein-Taybi	AR		Chordee	Hypoplastic maxilla, broad thumbs and toes
Rudiger	AR	Hydroureter	Small penis	Bicornuate uterus, coarse facies, stub nose
Russell-Silver	AR	Nonspecific renal anomalies	Small penis, hypospadias, cryptorchidism	Short stature, café-au-lait spots, skeletal asymmetry
Seckel	AR		Small genitalia, cryptorchidism	Small head, beak nose
Smith-Lemli-Opitz	AR		Hypospadias, cryptorchidism	Pernicious anemia, mental retardatic syndactyly, microcephaly
VATER		Hydronephrosis, renal dysplasia	Hypospadias	Vertebral anomalies, anal atresia, VSD, TE fistula, radial dysplasia
von Hippel-Lindau		Renal cyst, renal tumor		Pancreatic cyst, cerebral tumor, ichthyosis
Wolfram	AR	Hydroureter		Optic atrophy, deafness, diabetes
Zellweger	AR	Hydroureter	Hypospadias, cryptorchidism	Hypotonia, hepatomegaly

AD, autosomal dominant; AR, autosomal recessive; CHARGE, coloboma, heart anomaly, choanal atresia, retardation, and genetic and ear anomalies; CNS, central nervous system; LS, lumbosacral; TE, tracheoesophageal; VATER, vertebral, anal atresia, tracheoesophageal, renal; VSD, ventriculospetal defect.

Table 115–3

Chromosomal Syndromes Associated with Genitourinary Anomalies

CHROMOSOME NUMBER	CLINICAL FEATURES	RENAL ANOMALIES	GENITAL ANOMALIES
4 Autosome	Microcephaly	Hydronephrosis	Hypospadias
Wolf-Hirschhorn syndrome	Hemangiomas		Undescended testis
4p Trisomy	Hypertelorism		
4q	Cleft lip/palate		
	Low-set ears		
8 Autosome	Large, square head	Hydronephrosis	Hypospadias
Trisomy 8	Prominent forehead	Horseshoe kidney	Undescended testis
	Widely spaced eyes	Reflux	
	Slender body and limbs		
9 Autosome	Small cranium	Renal hypoplasia	Hypospadias
9p Trisomy, 9p tetrasomy	Strabismus	Pancake kidney	Undescended testis
9p Monosomy	Large nose		Infantile male genitalia
	Webbed neck		
10 Autosome	Microcephaly	Cystic kidney	Undescended testis
10q Syndrome	Oval, flat face	Hydronephrosis	Small penis
10p Syndrome	Microphthalmia		
	Short neck		
11 Autosome		High forehead	
		Micropenis	
11q Syndrome	Flat nose		
	Wide glabella		
	Cleft lip/palate		
13 Autosome	Microcephaly	Horseshoe kidney	Undescended testis
Patau syndrome	Hypertelorism	Hydronephrosis	
Trisomy 13	Polydactyly	Cystic kidney	
	Congenital heart disease		
15 Autosome	Obesity		Hypogonadism
Monosomy 15q	Hypotonia		Cryptorchidism
Prader-Willi syndrome	Retardation		
18 Autosome	Micrognathia	Horseshoe kidney	Undescended testis
Trisomy 18	Hypertonia	Hydronephrosis	Small penis
Edwards' syndrome	Congenital heart disease		
20 Autosome	Round face	Hydronephrosis	Hypospadias
20p Syndrome	Short nose	Polycystic kidney	
	Dental abnormalities		
	Vertebral abnormalities		
21 Autosome	Brachycephalic skull		Undescended testis
Trisomy 21	Congenital heart disease		Small penis
Down syndrome	Nasal hypoplasia		
	Broad, short hands		
22 Autosome	Microcephaly		Undescended testis
Trisomy 22	Preauricular skin tags		Small penis
	Low-set ears		
	Beaked nose		
	Cleft palate		
Cat's eye syndrome	Coloboma	Renal agenesis	
Possibly from both 13 and 22 autosomes	Anal atresia	Horseshoe kidney	
	Low-set ears	Reflux	
	Hemivertebrae		
	Congenital heart disease		
Sex chromosome Y	Elongated legs		Small penis
Klinefelter syndrome	Gynecomastia		Small testes
XXY, XXXY	Eunuchoid body build		
XXXXY	Sparse body hair		
Sex chromosome	Short stature	Horseshoe kidney	Infantile genitalia
X Turner syndrome	Primary amenorrhea		
XO	Webbed neck		
	Broad chest		
	Coarctation of aorta

Table 115–4

Developmental Milestones

AGE (mo)	GROSS MOTOR	FINE MOTOR	SOCIAL SKILLS	LANGUAGE
3	Supports weight on forearms	Opens hands spontaneously	Smiles appropriately	Coos, laughs
6	Sits momentarily	Transfers objects	Shows likes and dislikes	Babbles
9	Pulls to stand	Pincer grasp	Plays pat-a-cake, peek-a-boo	Imitates sounds
12	Walks with one hand held	Releases an object on command	Comes when called	1-2 meaningful words
18	Walks upstairs with assistance	Feeds from a spoon	Mimics actions of others	At least 6 words
24	Runs	Builds a tower of six blocks	Plays with others	2-3 word sentences

From Haslam RHA. Neurological examination. In: Behrman R, Kliegman R, Jenson H, editors. Nelson textbook of pediatrics. 16th ed. Philadelphia: Elsevier; 2000.

Today, **many newborns with spinal dysraphisms are diagnosed in utero** (Babcook et al, 1995). These infants are referred by direct admission to the neonatal intensive care nursery. Most of these children are not in urinary retention initially, but many develop spinal shock after neurosurgery in the newborn period and have a transient period of overflow urinary drainage. As soon as possible after closure of the spinal defect, a baseline renal and bladder ultrasonogram is performed to evaluate for evidence of bladder or upper tract abnormalities. Initial urodynamics investigation is performed after resolution of the spinal shock to ensure that bladder storage pressures are not excessive (McGuire et al, 1977, 1983; Bauer, 1998; Tarcan et al, 2001). High-risk infants (those with a detrusor leak-point pressure greater than 40 cm H_2O or detrusor-sphincter dyssynergia) are started on anticholinergic therapy and intermittent catheterization (Snodgrass and Adams, 2004). Even those infants with normal urodynamic findings require close follow-up due to the risk for subsequent neurourologic deterioration resulting from spinal cord tethering (Tarcan et al, 2001).

Key Points: Chief Complaint and History of Present Illness

- Pediatric diagnoses should be triaged into categories: emergent, urgent, semiurgent, and routine.
- Acute scrotal pain must be evaluated emergently due to the risk of spermatic cord torsion, regardless of age.
- Neonates with bilateral hydronephroses or hydronephrosis in a solitary kidney should be evaluated immediately after birth while in the newborn nursery.
- If congenital adrenal hyperplasia is suspected, evaluation should be completed prior to hospital discharge.
- If sexual abuse is suspected the sexual abuse team should be immediately consulted and appropriate interventions initiated.

PAST MEDICAL AND SURGICAL HISTORY

A patient's past medical and surgical history are always germane to the patient history and often provide insight into the current condition. Many pediatric congenital syndromes include urologic anomalies (see Tables 115–2 and 115–3), and the pediatric urologist should be aware of these associations. Additionally, an assessment of the child's developmental progress may impact their urologic development, especially in the context of potty training and enuresis. A brief description of developmental milestones is provided in Table 115–4.

Other pediatric conditions impact the timing of surgical intervention and affect the level of risk from anesthesia. In healthy children, a recent history of a respiratory illness or asthma increases the risk of reactive airway disease and therefore the risk of general anesthesia (Schreiner et al, 1996; Parnis et al, 2001). Preterm infants are also at increased risk of anesthetic complications and postoperative apnea. As a result, many of these infants require postoperative cardiopulmonary monitoring. Neonates with a history of apnea are at highest risk (Murphy et al, 2008). A history of recent upper or lower respiratory tract infection increases the risk of reactive airway disease and anesthetic-related complications (Stasic, 2004). Infants with significant cardiac anomalies may benefit from a pediatric anesthesiologist with cardiac experience. Although the pediatric anesthesiology team will assess the child for anesthetic risk, the pediatric urologist should be aware of these conditions as well. Finally, all bleeding dyscrasias, such as von Willebrand disease, should be evaluated by pediatric hematology prior to operative intervention.

MEDICATIONS AND ALLERGIES IN THE PEDIATRIC PATIENT

Medications are typically dosed based upon weight, such as milligrams per kilogram. Therefore an accurate weight must be obtained prior to prescribing most medications to pediatric patients. Additionally, many adult medications are contraindicated in children, and pediatric guidelines should be consulted. For example, **aspirin has been associated with Reye syndrome in children and adolescents and is not recommended for the treatment of fever in children.** Acetaminophen (10 to 15 mg/kg every 4 hr) and ibuprofen (5 to 10 mg/kg every 6 hr) are not associated with significant adverse effects. However, overdoses of acetaminophen can lead to hepatic failure. Trimethoprim-sulfamethoxazole is contraindicated in preterm infants and full-term infants less than 2 to 3 months of age due to the risk of hyperbilirubinemia and kernicterus. Sulfonamide medications can be initiated after 2 to 3 months of age (Fefer and Ellsworth, 2006).

Allergies should be recorded for all patients and be clearly documented. In the pediatric urology population, children with myelomeningoceles are at increased risk for latex allergies, and latex precautions should be instituted in these patients. Children with an increased number of operations and operative intervention in the neonatal period are associated with an increased risk of latex sensitivity in this population (Pires et al, 2002).

Key Points: Past Medical and Surgical History, Medications, and Allergies in the Pediatric Patient

- Congenital urologic anomalies are often associated with known syndromes, and the pediatric urologist should be aware of concurrent conditions.
- Pediatric pulmonary conditions directly impact the anesthesia risk and should be evaluated prior to surgical intervention.
- Aspirin is associated with Reye syndrome and should be avoided in children.
- Patients with myelomeningoceles are at greater risk for latex sensitivity and latex precautions should be used.

PEDIATRIC UROLOGIC EXAMINATION

General Examination

In most cases, the primary care provider has identified a problem that requires review by the pediatric urologist. However, because other processes may coexist, the urologist must be alert for evidence of disease in other organ systems. Although few children are severely ill when evaluated in the urologist's office, it is important to develop the skills to recognize an infant or child who requires hospitalization. The ability to determine when an infant requires an inpatient admission is particularly important, because the metabolic reserve is less abundant in the newborn (Park, 2000). **Observation of the child and a careful history from the parent may be more important than the vital signs or the physical examination when attempting to determine the severity of illness, particularly in the infant or small child.** The child's color (pale or cyanotic), level of alertness, response to the parent's comforting, quality of interaction with the examiner, and the quantity of tearing while crying may provide considerable information about mental status and level of hydration. If the child's response in any of these areas suggests severe illness, the child should be transferred to the emergency department, where appropriate resuscitation can be delivered while the diagnostic evaluation continues. In the acute emergency department setting, a full general and urologic examination must be performed by the evaluating medical team. Patients with hemodynamic instability must be emergently addressed.

In the office, the authors record vital signs on every new patient, and in children with history of renal anomalies or vesicoureteral reflux, on all subsequent visits. Because **the blood pressure and heart rate change as a function of age,** reference ranges for blood pressure and pulse rates for boys and girls should be posted in the clinic near where the vital signs are taken (Bernstein, 2000). Assistants taking the blood pressure should all be aware of the variation with age and should notify the team of blood pressure readings greater than the 90th percentile. Upon entering the room, a clinician can address both the child and parent to encourage the child to participate in the examination process. Physical examination in young children can prove challenging and the clinician must attempt to create a favorable environment. Examining a child on his or her mother's lap can be useful in comforting a frightened child. Additionally, sitting or kneeling near a young child facilitates interaction at the child's level.

Abdominal Examination

When examining the abdomen, the examiner's hand should be placed behind the flank to help palpate the kidney on either side. If the abdomen is supple, the approximate size and location of each kidney may be determined with deep palpation. An attempt should be made to feel the liver edge and spleen as well as the colon, particularly the descending colon. In the newborn, the liver may be palpable, sometimes as much as 2 cm below the ribs on the left. When examining the left lower quadrant, an estimate should be made of the volume of stool in the descending colon. In infants, a large amount of gas may be present within the gastrointestinal tract. The abdominal wall is normally weak, especially in premature infants. An abdominal examination can be performed on a crying infant during inspiration when the anterior abdominal muscles are relaxed. Separation of the rectus muscles and umbilical hernias are common in the newborn. The abdominal wall is lax and protuberant in boys with prune-belly syndrome. Occasionally, children with other types of bladder outlet obstruction or profound antenatal hydronephrosis will also have considerable laxity of the abdominal muscles. The abdomen should be inspected for other abnormalities, such as ventral hernia, flaring of the rib cage, umbilical leakage, mass, or hernia. Unusual masses should be investigated immediately with ultrasonography.

Renal pathology is the source of up to two thirds of neonatal abdominal masses (Pinto and Guignard, 1995). **Cystic abdominal masses include hydronephrosis, multicystic dysplastic kidneys, adrenal hemorrhage, hydrometrocolpos, intestinal duplication, and choledochal ovarian omental or pancreatic cysts. Solid masses include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma.** A solid flank mass may be due to renal venous thrombosis, which becomes apparent with signs of hematuria, hypertension, and thrombocytopenia. Renal venous thrombosis in infants is associated with polycythemia, dehydration, diabetic mothers, asphyxia, sepsis, and coagulopathies such as antithrombin-3 or protein C deficiencies. In neonates, transillumination of the abdomen may assist in distinguishing between solid and cystic lesions.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract, often due to meconium ileus. Later distention suggests bowel obstruction, sepsis, or peritonitis. Abdominal wall defects may be present either through the umbilicus (omphalocele) or lateral wall (gastroschisis). Omphaloceles are associated with other anomalies and syndromes, such as Beckwith-Wiedemann syndrome, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus (Hassink et al, 1996; Chen et al, 1997; Kallen et al, 2000). In bladder exstrophy, the posterior bladder wall is visible through a midline defect in the abdominal wall and a pubic diastasis is appreciated. In addition, a bifid clitoris or epispadias is present. In cloacal exstrophy, an omphalocele is superior to the cecal plate and lateral bladder halves with prolapsed ileum typically in the midline. Additionally, a bifid clitoris or penis, imperforate anus, and spinal abnormalities are present.

Many patients presenting with blunt force renal trauma will have associated extrarenal injuries, such as other solid organ injuries, a pneumothorax, pelvic fractures, and bladder or urethral injuries. Therefore complete physical examination in trauma patients is essential (Margenthaler et al, 2002; Mohamed et al, 2009). During examination for renal trauma, the urine should be

assessed for gross hematuria. A urethral catheter should be postponed in the setting of gross hematuria until the lower urinary tract is assessed by the urology team.

Genital Examination

Scrotal Examination

To begin the scrotal examination, the inguinal canal should be inspected on each side for signs of asymmetry or mass. To begin the examination, the examiner's left hand closes the internal inguinal ring (Fig. 115–2). This maneuver prevents an intracanalicular testis from migrating into the abdomen. The inguinal canal is then palpated to identify a fullness or mass suggestive of a hernia or hydrocele of the spermatic cord. The examiner may feel a "silk glove" sign suggestive of a thickened patent processus vaginalis that may be present if a hernia is intermittent. The examiner's right hand is then brought down to the scrotal area, and the testis is then palpated. The testis should be examined with consideration of the anatomy of the testis, the epididymis, and the vas deferens, which can be palpated even in some newborns. Particular attention to the symmetry of the examination is important, if intersex conditions are thought to exist. **In the infant with a possible disorder of sexual differentiation, a symmetrical gonadal examination (gonads palpable on each side or impalpable on both sides) suggests a global disorder, such as CAH or androgen insensitivity. Asymmetry in the gonadal examination suggests a localized problem, such as mixed gonadal dysgenesis or ovotesticular disorder of sexual differentiation.**

The acute scrotum should be examined carefully to determine the true etiology. Testicular torsion may present with varied clinical findings, but the involved testis often demonstrates signs, such as riding higher in the hemiscrotum, a transverse orientation, an anterior epididymis, absent cremasteric reflex, and tenderness of the testis and epipdidymis. In addition, the testis with torsion is often very hard to palpation if significant time has elapsed prior to presentation. In contrast, torsion of the appendix testis or epididymis often results in localized tenderness at the superior pole of the testis or caput epididymis and is often associated with a reactive hydrocele. Additionally, in boys with thin scrotal skin, the "blue dot" sign can be seen reflective of a necrotic appendix. Epididymitis classically has a gradual onset and is not associated with nausea or emesis (Gatti and Murphy, 2007).

Figure 115–2. Clinical examination of male groin.

The normal newborn scrotum is relatively large. Its size may be increased with the trauma of breech delivery or by a newborn hydrocele that can be distinguished from hernia by palpation and transillumination as well as from the absence of a mass in the inguinal canal. In the absence of volume changes within the hydrocele, the processus vaginalis is usually not patent, and the newborn hydrocele resolves by 1 year of age without surgery. Persistence of a hydrocele beyond 12 to 18 months, even in the absence of volume changes, usually indicates a patent processus vaginalis and is an indication for surgical ligation of the processus vaginalis and incision of the scrotal component of the hydrocele. Neonatal extravaginal testicular torsion can also occur prenatally, resulting in a firm, enlarged, nontender mass in the hemiscrotum that is usually associated with dark discoloration of the overlying skin. A normal scrotal examination at birth and subsequent development of erythematous, tender, edematous hemiscrotum suggests postnatal extravaginal testicular torsion and should be addressed immediately with surgical intervention if the neonate is clinically stable.

Undescended testes can be palpated if they are in the scrotum or outside the external inguinal ring. Occasionally, the testis in a newborn can be palpated if it is in the inguinal canal, but, in many cases, the testis will move in and out of the canal into the abdomen, which makes palpation of the testis inconsistent. Retractile testes may in some cases be difficult to distinguish from a low, undescended testis. Pressure on the femoral artery may sometimes help to relax the cremasteric reflex in boys older than 2 years of age. Placing the child in a squatting or legs-crossed position will sometimes relax the reflex and facilitate palpation of the testis. A testis is descended if it can be manipulated to the base of the scrotum and remains there after release, at least for a moment. Testes that feel tethered during manipulation and cannot be manipulated to the base of the scrotum are at risk for becoming ascending testes. If doubt exists, a second examination 6 to 18 months later may be helpful to distinguish a retractile testis from a tethered testis. As the child ages, an ascending or tethered testis (both cryptorchid testes) will be more and more difficult to manipulate into the bottom of the scrotum (Eardley et al, 1994; Clarnette and Hutson, 1997; Davey, 1997).

Scrotal masses can be transilluminated to determine if the component is primarily fluid, such as a tense hydrocele, or solid, such as a testicular tumor. If a firm intratesticular mass is palpated, a thorough examination of the lymph nodes should be performed to evaluate for lymphoma, leukemia, or metastatic disease. Patients with a nontender testicular mass and signs of precocious puberty should be evaluated for a Leydig cell tumor or, less commonly, a Sertoli cell tumor (Agarwal and Palmer, 2006). Epididymal cysts and spermatoceles can present as extratesticular masses but are characteristically smooth, round, and located within the epididymis. A scrotal ultrasonogram can further differentiate these physical examination findings.

Varicoceles (varicosities of the internal spermatic vein) almost always occur on the left side and are bilateral in about 10%. Varicoceles are palpable when the boy is standing but drain when supine. If only the right side is involved or if the varicocele does not decompress when the boy is supine, there exists a possibility that a retroperitoneal tumor is present and compressing the vein.

Penile Examination

In the newborn, the foreskin is adherent to the glans. These glanular adhesions should not be separated, and the glans need not be inspected if the parents do not desire a circumcision. Glanular preputial adhesions usually separate before the age of 4 but may persist in some boys for longer periods. **In the absence of balanitis or UTI, the prepuce should not be retracted but allowed to separate naturally** (Imamura, 1997). If symptoms do develop, topical corticosteroids have successfully been used as an alternative to circumcision in some boys with adherent foreskin (Chu et al, 1999; Monsour et al, 1999; Orsola et al, 2000; Elmore et al, 2002).

The position of the urethral meatus is almost never abnormal in the uncircumcised penis with a circumferential foreskin. If the ventral foreskin is short, or absent, or if there is a ventral or dorsal curvature, the boy should not be circumcised in the nursery by the obstetrician or the pediatrician and should be re-examined as soon as possible by the specialist if hypospadias or epispadias correction may need to be performed. The presence of a midline dimple on the ventral penile shaft should lead one to suspect a diagnosis of hypospadias, despite a normal-appearing foreskin. The severity of hypospadias is based on the position of the urethral meatus, the presence or absence of penile curvature, and the degree of ventral penile shaft skin coverage. Occasionally, when the foreskin is pulled back before a circumcision, the distal urethra and urethral meatus are enlarged. If a megameatus is identified before a newborn circumcision, the circumcision should be canceled. The foreskin may be removed at the time of the urethral repair. However, because normal spongiosum is present on the ventral surface of the penis, repair of the urethra is not usually difficult even after a circumcision has been performed (Duckett and Keating, 1989).

Stretched penile length and girth should be measured. If the penis in a term infant is less than 1.9 cm, micropenis should be suspected and a karyotype should be performed and the hypothalamic-pituitary-testicular axis should be assayed. **The penis should be examined in relation to the scrotum for evidence of penile concealment, buried penis, or webbed penis.** In these conditions, the penis is of normal size but buried or concealed beneath a prominent pubic fat pad; trapped by a narrowed, more proximal preputial ring; or tethered to the scrotum. If the penile shaft skin is shortened, correction may require a rotational flap of inner preputial skin to provide additional coverage for the ventrum of the penis after release of the narrowed preputial ring. If a newborn clamp circumcision is performed, more penile shaft than indicated is often removed, resulting in a scar and sometimes a secondary trapped penis. If there is encroachment of the scrotum onto the penile shaft, circumcision should be deferred until it can be done freehand under a general anesthesia, usually at 4 to 6 months (Casale et al, 1999; Williams et al, 2000).

Female Perineal Examination

Examination of the perineum in female infants and young children should include examination of the urethral meatus, vaginal introitus, and anus. An easy way of examining the perineum is to gently grasp the labia majora and pull inferiorly (Fig. 115–3).

This maneuver tends to better define the various perineal folds and provide for a consistent examination in nearly all cases (Redman, 1982). The female genital examination video (available on the Expert Consult website) demonstrates this efficient maneuver. The clitoris is examined for evidence of hypertrophy that may be suggestive of a disorder of sexual differentiation. Additionally, any introital masses should be examined for site of origin, laterality, symmetry, and signs of infection or irritation. Placing a small feeding tube into the urethral meatus can help distinguish between an asymmetrical prolapsed ureterocele or the circular edema and congestion associated with urethral prolapse. Skene duct cysts are paraurethral in location, with a bulging whitish mass superior to the vagina, and may present with signs of maternal estrogen effects, such as breast enlargement and edema of the vaginal introitus (Soyer et al, 2007). An imperforate hymen in infancy generally appears as a midline, bulging, pearly white membrane.

Figure 115–3. Female perineal examination. (Courtesy of Pasquale Casale, MD.)

In an adolescent girl, the examination may be performed with the mother present if the adolescent is in agreement. In general, bimanual examination in an adolescent girl is best performed in the operating room in the dorsolithotomy position. In the office, the girl can be examined in a frog-leg position. Gently spreading the labia majora in an inferior direction will allow inspection of the clitoral area and usually of the introitus. The vestibule is assessed for any evidence of discharge. The hymen should be inspected as well as the introitus. **An imperforate hymen may result in hydrometrocolpos and a lower abdominal mass.** In older girls, a small speculum may be used to evaluate the cervix and vaginal canal. Palpation of the vaginal walls and cervix and bimanual examination of the uterus completes the examination. A Valsalva maneuver may allow adequate assessment of the introital vaginal area. Vaginal discharge can be associated with vaginal voiding and is particularly common in children who hold urine and subsequently dribble urine into the vagina. Treatment of dysfunctional voiding results in reduced vaginal drainage. Vaginal bleeding in the preadolescent may result from foreign bodies, such as wadded toilet paper trapped in the vagina. Occasionally, other foreign bodies may have been inserted intentionally or accidentally.

Additional Physical Examination

In addition to the abdominal and perineal examination, an examination of the back should be performed. The lower back should be examined for any evidence of presacral dimpling or other cutaneous markers of occult spinal dysraphisms. **An "atypical"**

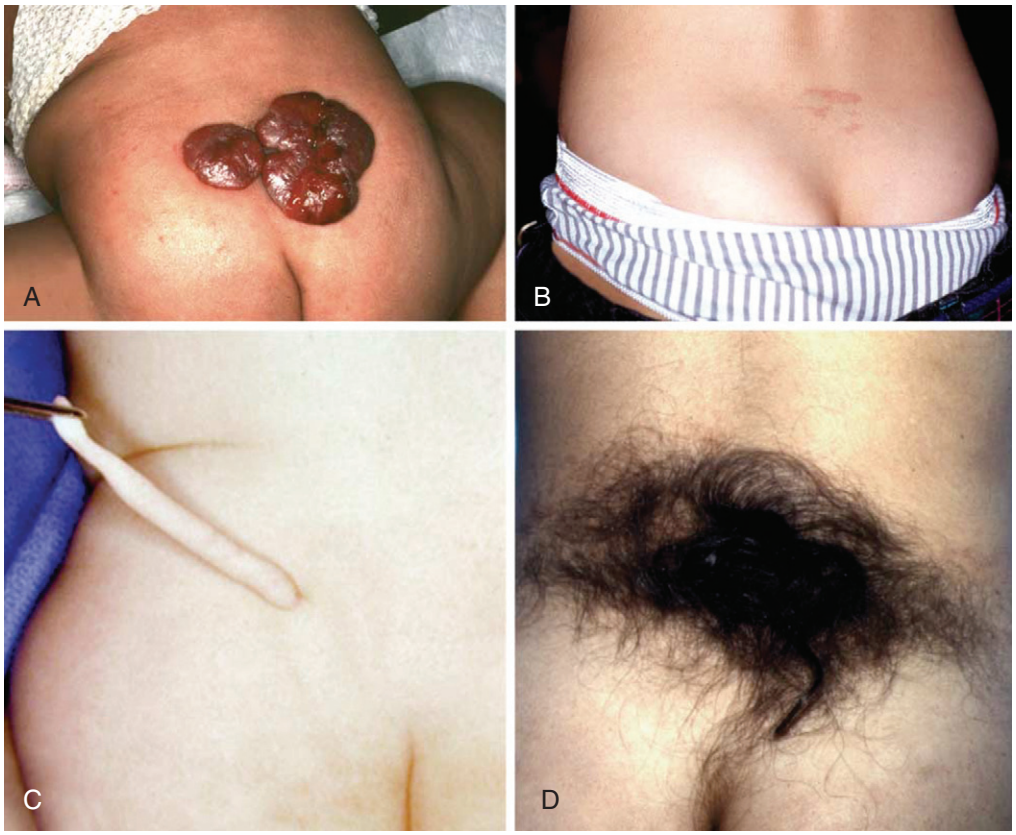

Figure 115–4. Clinical aspects of congenital median lumbosacral cutaneous lesions. **A,** Ulcerated hemangioma centered on a dermal sinus and deviation of the gluteal furrow. **B,** Isolated port-wine stain. **C,** Human tail. **D,** Faun tail. (From Guggisberg D, Hadj-Rabia S, Viney C, et al: Skin markers in occult spinal dysraphism: a review of 54 cases. Arch Dermatol 2004;140:1109–15.)

presacral dimple may indicate spina bifida or cord tethering if the dimple is off center, more than 2.5 cm from the anal verge at birth, or deeper than 0.5 cm (Soonawala et al, 1999). In a series of 207 neonates with sacral and presacral cutaneous stigmata, 40% of patients with atypical dimples were found to have occult spinal dysraphism (Kriss and Desai, 1998). Other skin markers to suggest occult spinal abnormalities include subcutaneous lipomas, dermal sinuses, tails, and localized hypertrichosis (Fig. 115–4). A combination of two or more of these congenital midline skin lesions is the strongest marker of occult spinal dysraphism (Guggisberg et al, 2004). We recommend an ultrasonogram of the lumbosacral spine in the newborn if any of these conditions exists (Unsinn et al, 2000; Hughes et al, 2003). For equivocal ultrasound studies and in older children, the authors order MRI for a complete evaluation. A brief evaluation of the upper and lower extremities and of the back is performed for any evidence of asymmetry, length discrepancy, or misalignment of the spine.

If a neurologic examination is indicated, the examination should begin with observation of the child at the outset of the visit. Often, delays in development (see Table 115–4) are identified by simple observation. A note is made of the level of alertness of the pediatric patient. Factors affecting the alertness of a newborn include the time of the last feeding, room temperature, and the gestational age. One should suspect an underlying metabolic or infectious cause in cases of decreased alertness. Identification of a sensory level in association with a spinal cord lesion can be very difficult in the infant. Differences in color or temperature can sometimes be observed, with the skin drier and cooler below the level of the cord lesion. Children older than 4 to 5 years of age are often capable of detailed sensory testing; however, success depends on the ingenuity and patience of the examiner. A child with a low spinal cord lesion may have a patulous anus and absence of contraction of the anal sphincter when stimulated in the anal region by a sharp object (anal wink). Changes in bladder function, such as new-onset urinary incontinence, may indicate a spinal cord lesion.

Often, the urologist may encounter signs of nonurologic or systemic illnesses during physical examination. In the infant, generalized edema may occur with prematurity or hypoproteinemia. Localized edema suggests a congenital malformation of the lymphatic system. **When confined to one or more extremities, edema may be a presenting sign of coarctation of the aorta in association with Turner syndrome.** Vasomotor instability and decreased peripheral circulation are revealed by red or purple color in a crying infant. Scattered **petechiae** in the infant may be present in the scalp and face after a difficult delivery. **Café-au-lait spots** are uniformly hyperpigmented, sharply demarcated macular lesions, the hues of which vary within the normal degree of pigmentation of the individual. These may be dark brown in African-American children. They may vary in size and may be large, covering a significant proportion of the trunk or limb. One to three lesions are common in normal children. Approximately 10% of normal children have café-au-lait macules. They may be present at birth or develop during childhood. **If there are five or more spots, each more than 5 mm in diameter, in prepubertal patients or six or more spots, more than 15 mm, in postpubertal children, neurofibromatosis type 1 (von Recklinghausen disease) should be suspected.**

An exceptionally large head suggests hydrocephaly, a storage disease, achondroplasia, cerebral gigantism, neurocutaneous syndromes, or inborn errors of metabolism, or it may be a familial condition. Dysmorphic features, such as **broadened epicanthal folds, widely spaced eyes, micrognathia, and low-set ears are often associated with congenital syndromes that may suggest a genitourinary problem.** Preauricular sinuses and pits may be the result of imperfect fusion of the tubercles of the first and second branchial arches. These anomalies may be unilateral or bilateral, may be a familial condition, are more common in females and African-Americans, and at times are associated with other anomalies of the ears and face. Preauricular pits are present in bronchio-oto-renal dysplasia, an autosomal-dominant disorder that consists of external ear malformations, bronchial fistulas, hearing loss, and renal anomalies. **Macroglossia can be associated with Beckwith-Wiedemann syndrome, which also includes hepatosplenomegaly, nephromegaly, and hypoglycemia secondary to pancreatic β-cell hyperplasia in a large gestational age infant.** These children are predisposed to a specific subset of childhood neoplasms, including Wilms tumor and adrenocortical carcinoma. Webbing of the neck in a female infant suggests intrauterine lymphedema in Turner syndrome, as do the widely spaced nipples with a shield-shaped chest (Stoll and Kliegman, 2000).

The skin, hair, and nails should be evaluated with special focus on congenital or metabolic problems that may be associated with brittle or abnormal hair and nails or abnormal skin dryness (see Tables 115–2 and 115–3). Supernumerary nipples may occur in a unilateral or bilateral distribution along a line from the anterior axillary fold to the inguinal area. They are more common in African-American infants (3.5%) than white (0.6%) children. Accessory nipples may not have an associated areola and may be mistaken for congenital nevi. They may be excised if desired to improve appearance. Associated renal or urinary tract anomalies may be present.

Key Points: Pediatric Urologic Examination

- Renal pathology is the source of up to two thirds of neonatal abdominal masses.
- Performing a scrotal examination in the legs-crossed position facilitates palpation of the testes.
- The inner preputial skin is adherent to the glans in infants and should not be forcibly retracted in the absence of balanitis or UTI.
- The lower back should be examined for evidence of cutaneous markers suggestive of occult spinal dysraphisms.

PEDIATRIC LABORATORY EVALUATION

The urine specimen may be obtained in a number of different ways. In the child who is not potty trained, a bagged specimen, although the most susceptible to contamination, is the easiest and least invasive to obtain. To minimize contamination with fecal or skin flora, a hole is cut in the diaper and the perineal bag is brought through the hole in the diaper. A parent is instructed to watch the bag, and as soon as urine is noted (which can be easily seen because the bag is visible coming through a hole in the diaper), the bag should then be removed. If the specimen is collected in the office, the bag is immediately drained and the urine plated and sent to the laboratory for culture. Using this method, the skin contamination of the urine specimen is minimized, and the trauma of catheterization is avoided (Falcao et al, 1999). However to be reliable, positive cultures must still be confirmed with catheterized specimens. In most cases, we push for catheterized specimens for the diagnostic reliability they provide.

Older children generally provide a clean midstream urine specimen. Most studies have failed to show any benefit to formally cleansing the introitus before obtaining the specimen. Once a midstream urine specimen is collected, it is sent to the laboratory for urinalysis and culture. **Pyuria is defined as more than 5 white blood cells per high-powered field for girls and more than 3 white blood cells per high-powered field for boys.** Infection can occur without pyuria and, conversely, pyuria may be present without UTI. Consequently, pyuria as an isolated finding is more confirmatory than diagnostic for UTI. Nitrate and leukocyte esterase assays are usually positive in infected urine. However, if the urine has not remained in the bladder for more than 1 hour, the conversion of nitrates to nitrites may not be complete, and the chemical strip may read negative despite the presence of nitrogen-splitting bacteria in the bladder.

If the culture grows greater than 100,000 colonies of a single pathogen or if there are 10,000 colonies and the child is symptomatic, we consider a UTI to be present. **White blood cell casts and urinary sediment suggest renal involvement,** but these are rarely identified. If the child is not symptomatic and the urinalysis is normal, it is unlikely that the urine is infected. However, if the child is symptomatic, a UTI is possible regardless of the results of the urinalysis (Bonadio, 1987). Microscopic hematuria is common in acute bacterial as well as viral cystitis. Gross hematuria may be present in viral cystitis but is less common in acute bacterial cystitis. If the child is symptomatic, the urinalysis is suggestive of UTI, and the culture grows more than one organism or fewer than 100,000 colonies, the clinician has the option of treating with an antibiotic that is effective based on the sensitivities or repeating the culture. The authors repeat the culture but start the child on a treatment dose of antibiotic at that time. If a second catheterized culture is negative, then the antibiotics are discontinued and close follow-up is provided. This is particularly important in infants who may not demonstrate the usual signs and symptoms of infection that would be present in an older child.

Microscopic hematuria is common in children. Routine office screening with urinalysis for urinary abnormalities is no longer recommended. Thus the actual time of onset for microscopic hematuria is often unknown. Normally, the first indicator is a positive urine strip test for blood. Most strips can detect concentrations of 5 to 10 intact red blood cells/mL. This concentration corresponds to 2 to 5 red blood cells per high-powered field. Improper interpretation of the dipstick, such as delayed reading or cross-contamination of urine from other chemically impregnated pads, may result in false-positive results. The urine should be dipped, the excess urine tapped off, and the strips should be read immediately at the recommended time. **Confirmation of microscopic hematuria after a positive dipstick examination requires a microscopic examination of the urine for the presence of red blood cells.** Microscopic hematuria may be defined as more than 5 red blood cells per high-powered field in at least two of three urinalyses over 2 to 3 weeks. An absence of red blood cells in the urine with a positive dipstick result suggests hemoglobinuria or myoglobinuria. A positive dipstick on a single specimen with microscopic confirmation should be viewed as an indication for further urine testing rather than as diagnostic until persistence is confirmed on subsequent studies.

PEDIATRIC RADIOGRAPHIC EVALUATION

Ultrasonography

Ultrasonography of the kidneys, ureters, and bladder is an extension of the physical examination. Ultrasonography provides a noninvasive evaluation that does not require sedation, ionizing radiation, or contrast injection and can be performed at the bedside in critically ill children. Additionally, the body habitus of young children allow for accurate imaging. Older children or children with significant skeletal abnormalities, such as severe scoliosis or kyphosis, often require other imaging modalities to accurately assess the kidneys and collection system. Palpable masses within the abdomen can be localized and even diagnosed with the aid of ultrasonography performed by a uroradiologist with an interest in pediatrics. The examination should evaluate not only the genitourinary system but also adjacent organs, such as the adrenal gland, liver, and spleen. The image of the parenchyma of the liver and spleen should be used for comparison when assessing the parenchyma of the right and left kidney, respectively. The density of the kidney and of the renal medullary pyramids, as well as the wall thickness and configuration of the collecting system, the presence or absence of caliectasis, pelviectasis, or ureterectasis are all important indicators of renal and ureteral pathophysiology (Hulbert et al, 1992). The luminal diameter of the ureters, thickness of the bladder wall, and the volume of the bladder both before and after voiding should be recorded (Palmer, 2006). If hydronephrosis or ureterectasis is present before voiding, the kidneys and ureters should be rescanned after voiding. A skillful ultrasonographer can provide anatomic detail about the insertion of the ureters and the degree of dilation of the ureter and can identify the jet of urine as it enters the bladder (Kirby and Rosenberg, 1992; Cvitkovic et al, 2001). Ultrasonography is the first radiographic test used in the evaluation of suspected urolithiasis. Ultrasonography may also be used to accurately measure postvoid residual urine (Coombes and Millard, 1994). Increased thickness of the bladder wall may be suggestive of bladder outlet obstruction from posterior urethral valves or urethral atresia. Trabeculation within the bladder, bladder diverticulum, and ureteral duplication or ureterocele are all easily identified with ultrasonography. Children presenting with a febrile UTI are evaluated with ultrasonography to determine if a structural anomaly is present (Giorgi et al, 2005). **Ultrasonography in the absence of comparison studies or appropriate history cannot by itself distinguish obstructive from nonobstructive hydronephrosis.** Therefore a functional study such as a renal scan is usually required for diagnosis. Ultrasonography is also sensitive in detecting solid renal masses, particularly those that measure at least 1.5 cm in the largest dimension. For smaller renal masses, the ultrasound findings should be considered preliminary and should be confirmed with CT or MRI (Jamis-Dow et al, 1996).

Ultrasonography is also frequently used to examine the scrotum, such as in cases of boys with varicoceles (Diamond et al, 2000). It may also be used to assess blood flow if spermatic cord torsion is suspected, as well as to distinguish between epididymitis and torsion of the appendix testis in cases in which tenderness is localized to the upper pole of the testis. In the setting of acute scrotal pain, ultrasonography has been reported to have a sensitivity of 78.6% and specificity of 96.9% in diagnosing surgical and nonsurgical scrotal conditions (Blask et al, 2002) Therefore it is important to remember that false-negative ultrasonograms can occur and must be confirmed by a careful physical examination. The authors have also found it useful in distinguishing a hernia from a hydrocele or identifying abdominoscrotal hydroceles (Finkelstein et al, 1986). Additionally, scrotal masses are evaluated by ultrasonography.

When used as a first-line test in suspected occult spinal dysraphism, optimal timing of the spinal ultrasonography is earlier than 6 months of age. Ossification of the posterior elements after 6 months of age prevents an acoustic window. Agreement between ultrasonography and MRI is good, particularly for the detection of the low-lying cord (90%) (Hughes et al, 2003).

Ultrasonography is also performed during routine prenatal care. The kidneys and bladder can be visualized at 15 weeks of gestation. Further details, including the renal pelvis and corticomedullary differentiation, are detectable after 20 weeks of gestation (Sty and Pan, 2006). Hydronephrosis remains one of the most common abnormalities detected by prenatal sonography. After delivery, repeat renal and bladder ultrasonography is performed to further assess the collecting system and determine the appropriate evaluation and treatment if necessary.

Voiding Cystourethrography

VCUG is used to identify vesicoureteral reflux (VUR), to evaluate the anatomy of the bladder outlet (bladder neck and posterior urethra) during bladder filling and voiding, and to assess the presence of residual urine after micturition. Additional information regarding trabeculation of the bladder, bladder diverticula, and presence or absence of urachal abnormalities may be identified with a fluoroscopic VCUG (Fernbach, 2000; Goldman et al, 2000; McDonald et al, 2000). The VCUG begins with a plain film, followed by placement of a feeding tube rather than a Foley catheter. The balloon on a Foley catheter may obscure the anatomy of the bladder neck and trigone, particularly at the beginning of the study. The percentage of bladder filling when the reflux is first identified may also be an indicator of potential resolution of VUR. On subsequent examinations, improvement in VUR may be assumed if a smaller percentage of total bladder volume is refluxing into the ureter or if the reflux occurs at a greater percentage of total bladder filling (Mozley et al, 1994). On the plain film, abnormalities of the spine, ribs, and pelvis and the presence or absence of stones within the kidney, ureter, or bladder should be noted. The gas pattern and volume of stool is particularly important in infants and in children with dysfunctional voiding in whom constipation may be an important part of the clinical pattern. Gas should normally be present in the rectum on plain film by 24 hours of age. The bladder should be drained, and contrast medium should be gently infused. In children in whom an ureterocele is suspected, the first few images during filling of the bladder best demonstrate the ureterocele. The bladder is then filled slowly, and the child voids.

Voiding views must be obtained in all cases, but particularly if bladder outlet obstruction such as a posterior urethral valve is suspected. In children in whom VUR is suspected or in patients with an ectopic ureter, cyclic VCUG must be performed in which at least two voiding cycles are completed. In some cases, the ectopic ureter that is draining to the bladder neck must empty for additional contrast material to reflux. If a second voiding cycle is not performed, one might miss reflux into the ectopic system (Hellstrom and Jacobsson, 1999; Polito et al, 2000). It is important to image the bladder neck during voiding in the female as well as the male. The presence of a "spinning top urethra" in a

school-aged girl may be an important indicator of dysfunctional voiding (Saxton et al, 1988; Soygur et al, 2004). Vaginal voiding and subsequent emptying (or failure to empty) of the vagina should also be noted, which may be seen on the postvoid views.

In patients with a urogenital sinus, contrast VCUG may be modified to image the urethra and vagina simultaneously. In this study, the urogenital sinus is intubated with a blunt-tipped catheter (which can be made by trimming the cone-shaped end of a feeding tube) and placed against the perineal opening. Contrast medium is injected retrograde to identify the point where the vaginal introitus meets the urethra to form the urogenital sinus. The study will also aid in differentiating a cervical dimple from a prostatic utricle. If a cloaca is present, the sinogram will provide detail about the position of the rectum, vagina, and urethra and about the point of confluence and the distance to the perineum (Shaul and Harrison, 1997; De Filippo et al, 1999). The distances of these structures will help determine the approach required during surgery (Pena et al, 2004).

Nuclear Medicine Renal Scan

A radionuclide renal scan is measured in two phases: the cortical imaging and tubular imaging phase. Most radionuclide agents will demonstrate renal tubular as well as renal cortical binding. Radionuclide studies are best suited to demonstrate changes in tubular or cortical transit that result from abnormalities of renal perfusion, secretion, and filtration. In most cases, the radionuclide study is inferior to CT, MRI, or ultrasonography for demonstration of anatomic alterations. **Technetium-99m mercaptoacetyltriglycine (MAG-3)** is secreted, in part, by renal tubular function and may also be used to approximate relative renal plasma flow. The MAG-3 renal scan assists in differentiating obstructive versus nonobstructive dilatation of the urinary tract. Proper interpretation of the information obtained from this study requires detailed knowledge of the factors affecting drainage of the upper urinary tract (Shulkin et al, 2008). If detailed imaging of the renal cortex is required to identify renal scarring, **technetium-99m dimercaptosuccinic acid (DMSA)** may be given and the kidneys imaged 3 to 4 hours after the injection (Piepsz et al, 1999).

Renal scintigraphy scans using gallium-67– or indium-111–labeled leukocytes may be helpful to diagnose and localize the site of urinary tract infections (Yen et al, 1999; Velasco et al, 2004). These techniques may be used to identify and guide therapy for children with focal segmental bacterial pyelonephritis in whom the duration of therapy is uncertain. In a prospective study by Yen and associates (1999), gallium-67 renal scans were more sensitive than DMSA scans in the diagnosis of acute pyelonephritis, especially in differentiating new lesions from old ones. These are particularly useful in patients with abnormal renal anatomy or in patients with diminished renal function in whom the DMSA scan may be less specific.

Computed Tomography

Computed tomography (CT) is used judiciously in specific pediatric clinical settings due to the ionizing radiation required. CT is rarely used in neonates or infants, with the exception of evaluation of a retroperitoneal or pelvic mass. Conversely, CT with intravenous (IV) contrast is the current imaging modality of choice for evaluation of pediatric abdominal trauma. **Ultrasonography provides effective evaluation for most suspected cases of pediatric stone disease and should be used as a first-line test due to the absence of ionizing radiation. Spiral CT has in most cases replaced the intravenous pyelogram (IVP) as a confirmatory study in children with complex stone disease. A recent study documented 76% sensitivity and 100% specificity of ultrasonography in comparison with CT in the diagnosis of pediatric urolithiasis** (Passerotti et al, 2009). In addition, CT with or without contrast medium enhancement is particularly important as an adjunct in children with suspected focal segmental bacterial pyelonephritis. CT is also particularly important in the diagnosis and staging of solid tumors of the chest and abdomen. Contrast medium–enhanced CT is particularly useful in cases of nephroblastomatosis, in which ultrasonography shows little displacement of the renal capsule. One must be reminded that radiation doses from CT are cumulative over the life of an individual (Frush et al, 2003). With sufficient clinical information, the radiologist may be able to recommend other imaging modalities (e.g., ultrasonography, MRI) that do not use ionizing radiation.

Magnetic Resonance Imaging

Although still expensive as an individual radiologic study, **magnetic resonance urography (MRU) may provide the best information of the anatomy and function of the genitourinary tract from a single study.** Advantages of MRU include the avoidance of ionizing radiation, its use in patients with impaired renal function, and higher-quality contrast and spatial resolution in any plane relative to other imaging modalities (Fig. 115–5) (Wille et al, 2003; Grattan-Smith, 2008). If obstruction of the urinary tract is suspected, gadolinium followed by furosemide can be administered. Notably, MRI with gadolinium should not be performed earlier than 2 months of age in a full-term infant. Antenatal MRI is used to diagnose ureteropelvic junction

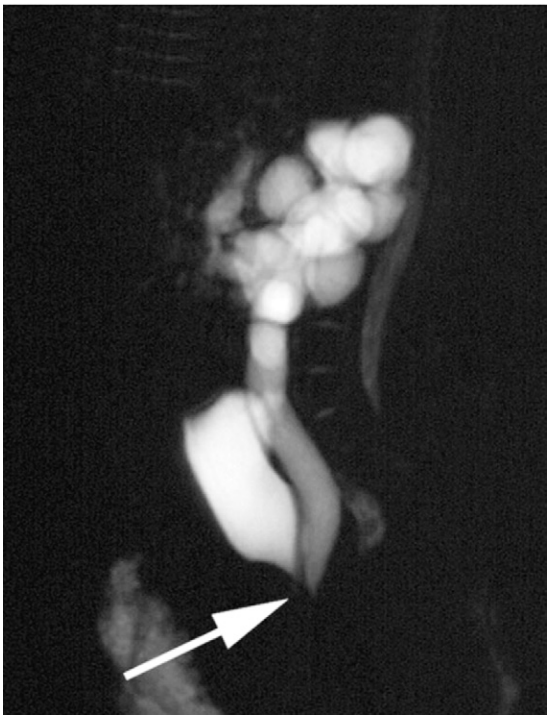

Figure 115–5. Magnetic resonance urogram of a megaureter on the left side in the sagittal plane with narrowing of the distal ureter *(arrow)*. (From Wille S, Knobloch R, Klose KJ, et al. Magnetic resonance urography in pediatric urology. Scand J Urol Nephrol 2003;37:16–21.)

obstructions, ectopic ureters, abnormal ureteral buds associated with renal agenesis, and cloacal exstrophy in the fetus (Maas et al, 1997; Matsuki et al, 1998; Wille et al, 2003). When antenatal ultrasonography is equivocal, antenatal MRU provides additional anatomic detail, especially in the diagnosis of ureteral pathology (Kajbafzadeh et al, 2008). The limitations of MRU, at this time, include its high costs and the requirement for sedation/anesthesia in most young patients. Although not routine, MRI is used more frequently now in the evaluation and identification of the impalpable testis (Yeung et al, 1999; Lam et al, 2001). In the workup of suspected renovascular hypertension, gadolinium-enhanced MR angiography (MRA) is a noninvasive modality with comparable accuracy to digital subtraction angiography (Hacklander et al, 2004). In the presence of renal insufficiency, however, caution must be exercised in the use of gadolinium contrast due to the risk of nephrogenic systemic fibrosis (Penfield, 2008).

Intravenous Pyelography

Despite the newer imaging techniques that are now available, the intravenous pyelogram (IVP) is useful in selected cases. The plain film of the abdomen should be inspected for calculi, spinal abnormalities, and an abnormal intestinal gas pattern. The nephrogram phase of the IVP identifies mass effects within the kidney and the presence or absence of scarring after pyelonephritis. Subsequent views can sequentially assess the anatomy of the renal cortex, calyces, fornices, renal pelvis, ureters, bladder, and urethra (Smellie, 1995). Subtle anatomic variations in normal anatomy of the renal calyces or of the ureteropelvic junction that may be confusing on ultrasonography or CT may be clarified with the IVP.

Key Points: Pediatric Laboratory and Radiographic Evaluation

- Microscopic hematuria diagnosed on dipstick evaluation should be confirmed with microscopic examination of the urine.
- Ultrasonography cannot definitively distinguish obstructive for nonobstructive upper tract urinary dilatation.
- A VCUG should include multiple voiding cycles with images of voiding views.
- Nuclear medicine evaluation is increasingly used in the evaluation of patients with vesicoureteral reflux.
- CT should be used judiciously in children due to the risks of ionized radiation.
- MR urography provides functional and anatomic information about the entire urinary tract.

PEDIATRIC URODYNAMIC AND BIOFEEDBACK EVALUATION

The well-equipped urology office will have a urodynamic suite as part of the overall complex. Modern urodynamic systems allow accurate measurements of the intravesical pressures before, during, and after bladder contraction. From these measurements, estimates of bladder compliance, as well as the bladder outlet resistance, may be made. With this information, the pediatric urologist may assess whether the bladder stores at pressures low enough to prevent renal damage and empties well enough to prevent UTI. The addition of fluoroscopic monitoring of the bladder and upper tracts during urodynamics greatly adds to the information garnered from the urodynamic study. However, videourodynamic suites must be located within a lead-lined room, which may preclude placement in every office.

Biofeedback training designed to help the child to improve bladder emptying may also be performed in the office. Biofeedback sessions should be done in a room that is separate from the urodynamic suite, because, in most cases, a different population of patients requires biofeedback training than will undergo urodynamic study (Yamanishi et al, 2000; Schulman, 2004). Biofeedback, if done properly, is time consuming. The child must be relaxed and motivated for the session to be effective. Awareness of the pelvic floor muscle and urinary sphincter is a key factor to achieve successful biofeedback treatment. Biofeedback incorporating interactive computer games is available, with success rates approaching 90% after a mean of 4.9 sessions (Herndon et al, 2001).

OFFICE SURGICAL PROCEDURES

Successful outpatient surgery with a local anesthetic depends on cooperation from the parent as well as the child. Parents must believe that the convenience of having the procedure in the office outweighs the advantages of a general anesthetic in the main operating room. We believe many infants weighing less than 10 pounds may easily undergo an office circumcision with an anesthetic cream combined with an injected local anesthetic (Hoebeke et al, 1997). However, in a recent meta-analysis by Brady-Fryer and colleagues (2004), dorsal penile nerve block was the most effective at reducing circumcision pain compared with a eutectic mixture of local anesthetics (EMLA) and placebo. The authors rarely provide for office circumcision in older children. Infants older than 3 months are too big to be easily restrained, and the risk of bleeding postoperatively, if the skin edges are not sutured, is considerable.

A number of techniques may be used in the clinic for circumcision, including a Plastibell, Mogen, and Gomco clamp. We use the Gomco clamp, which is a three-component device that includes a bell that fits over the glans of the penis and separates the glans from the inner preputial skin (Guazzo, 1999; Amir et al, 2000; Wan, 2002). The clamp is applied, and the foreskin is trimmed away from the clamp. If the clamp is left in place for a considerable amount of time (usually about 10 minutes), then there is very little separation of the skin postoperatively. If desired, a small nonstick bandage is placed beneath a transparent adhesive dressing. The bandage is removed the next day. The boy's parents are instructed to apply petroleum jelly to the incision during the healing period.

Complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, and secondary phimosis resulting from removal of insufficient foreskin or removal of insufficient inner preputial skin. Potentially serious complications include death, sepsis, amputation of distal part of the glans, removal of excessive foreskin, and urethrocutaneous fistula (Baskin et al, 1997; Hutcheson, 2004). After a circumcision, the cut edge of the preputial surface may occasionally graft to the inflamed glans tissue forming a preputial-glanular bridge that may be incised in the office with application of local anesthetic cream and subsequent injection of local anesthetic. After injection, the skin bridge is clamped, the clamp is removed, and the skin bridge is sharply incised. No suturing is required in most cases. This procedure is easy and virtually

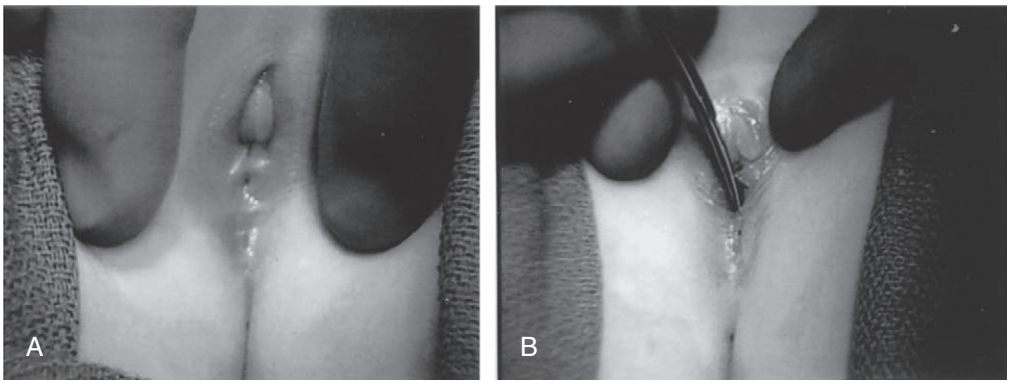

Figure 115–6. Outpatient lysis of labial adhesions. **A,** Dense labial adhesions. **B,** Adhesions clamped and incised. (From Nurzia MJ, Eickhorst KM, Ankem MK, Barone JG. The surgical treatment of labial adhesions in prepubertal girls. J Pediatr Adolesc Gynecol 2003;16:21–3.)

painless. After the procedure, the parents apply petroleum jelly to the incised edges to prevent them from readhering.

Meatal stenosis is common after circumcision. It may result from contraction of the meatus after healing of the inflamed, denuded glans tissue that occurs after retraction of the foreskin or from damage to the frenular artery at the time of circumcision (Persad et al, 1995; Upadhyay et al, 1998). If the narrowing is pronounced enough to cause deflection of the urinary stream or dysuria, a meatotomy is indicated.

To perform a meatotomy in the office, an anesthetic cream is applied. After 45 minutes, lidocaine with 1% epinephrine is injected with a 26-gauge needle to provide a small wheal at the ventrum of the urethral meatus. The ventral edge of the urethral meatus is clamped, and a small wedge of the scarred tissue is crushed with a straight hemostat and sharply excised. After the procedure, the parents are advised to apply a fine petrolatum ointment to the cut edges of the urethral meatus. A small meatal dilator is used twice a day for 4 to 6 weeks. Postoperatively, these children are seen 2 to 3 months later to assess the result.

If a VCUG is required, or if dysuria associated with vaginal pooling of urine contributes to a dysfunctional voiding pattern, we have occasionally separated labial adhesions in the office. These membranous adhesions are easy to separate on the midline with a probe or the tip of a curved hemostat (Fig. 115–6). A local anesthetic cream is applied to the labia in hope of easing the discomfort, which is minimal. After lysis of the adhesions, the child's parent must separate the labia and apply a barrier cream, such as petroleum jelly, at least twice a day for 4 to 6 weeks while the labial tissue matures. With diligent postoperative care, recurrence is rare.

Key Points: Pediatric Urodynamic Evaluation, Biofeedback Evaluation, and Office Surgical Procedures

- A well-equipped urology office will have a urodynamics and biofeedback training suite.
- Most infants weighing less than 10 pounds may easily undergo an office circumcision with an anesthetic cream combined with injected local anesthesia.
- Petroleum jelly is applied after circumcision, urethral meatotomy, or lysis of labial adhesions to prevent complications.

SUMMARY

The final goal of the surgical care of children is to assure as normal an adult life as possible. The pediatric urologist should continue to act as consultant, even after the child enters adulthood, for boys with prune-belly syndrome or posterior urethral valves and for children of either sex born with bladder or cloacal exstrophy. **As children grow into adults, the pediatric team must develop a liaison with a skilled, interested adult team. Using this method, a lifetime plan of care may be designed and carried out to ensure well-coordinated urologic therapy that is capable of addressing the complicated problems unique to this special group of boys and girls.**

Considerations in Treating Children with Urinary Tract Infection

Bacterial urinary tract infection (UTI) is the most common cause of childhood urinary tract inflammation. Beginning with bacterial adherence to host epithelial cells at the portal of entry, bacterial clonal studies now clearly support the fecal-perineal-urethral route and subsequent retrograde ascent of bacteria that cause UTI (Tullus et al, 1986; Mitsumori et al, 1997; Yamamoto et al, 1997). In UTI, both bacterial virulence factors and the human immune system (innate and adaptive) interact, and both are critical in understanding UTI pathogenesis. The practitioner must consider the human microbiome, moreover, as a community when managing difficult and recurrent UTI. We need to understand issues of (1) prenatal fetal anatomy, (2) issues of infection prevention versus treatment, and (3) medical globalism.

Recognition that bacteriuria can cause renal parenchymal and functional loss has prompted recommendations for rapid diagnosis and evaluation of UTI with genitourinary imaging techniques and tests. In infants, UTI is a common cause of fever and may be the most common cause of renal parenchymal damage and loss. For this reason, the goal of managing childhood UTI is based upon identifying and modifying, if possible, factors that increase risk of renal damage from the time of the index infection forward. With improved diagnosis based upon imaging and improved antimicrobial agents, some of these risks may have shifted. This chapter focuses upon host and bacterial mechanisms by which bacteria gain access to the bladder and kidney, management and evaluation of first and recurrent urinary tract infections, possible short- and long-term complications of urinary tract infection, and potential factors that identify a child who may risk bacteriuria or its potential complications.

EPIDEMIOLOGY OF PEDIATRIC URINARY TRACT INFECTIONS

Only during the first year of life do males get more UTIs than females (Asscher et al, 1973; Winberg et al, 1974), and during that year, the risk of UTI in **uncircumcised boys is about ten times that of circumcised boys** (Rushton and Majd, 1992a; Wiswell and Hachey, 1993). By age 1 year, 2.7% of boys and 0.7% of girls have had bacteriuria (Wettergren et al, 1980). Although this incidence declines to less than 1% in school-age boys (ranging from 0.03% to 1.2%), it rises to 1% to 3% in school-age girls (Asscher, 1975; Savage, 1975; Bailey, 1979), with sexually active females having more UTIs than sexually inactive ones (Kunin and McCormack, 1968).

Data from the U.S. Healthcare Cost and Utilization Project (HCUP) show that UTI causes about 51 per 100,000 children per year to be hospitalized and 174 per 100,000 infants (children younger than 3 months); about 18 to 20 per 100,000 of these cases are coded as pyelonephritis (Freedman, 2004). Overall, girls were hospitalized 2.5 times more than boys. UTI accounts for 2.4% to 2.8% of physician visits for children with commercial insurance or Medicaid; the National Ambulatory Medical Care Survey shows that UTIs are 0.7% of all pediatric office visits, thus documenting a heavy burden of childhood ambulatory UTI visits (Freedman, 2004). Given an average of 40,000 admissions for UTI per year (HCUP data) and a mean cost of $4500 per child for each UTI admission (Freedman, 2004), the financial cost for hospitalization of children with UTI alone is $180 million per year, without

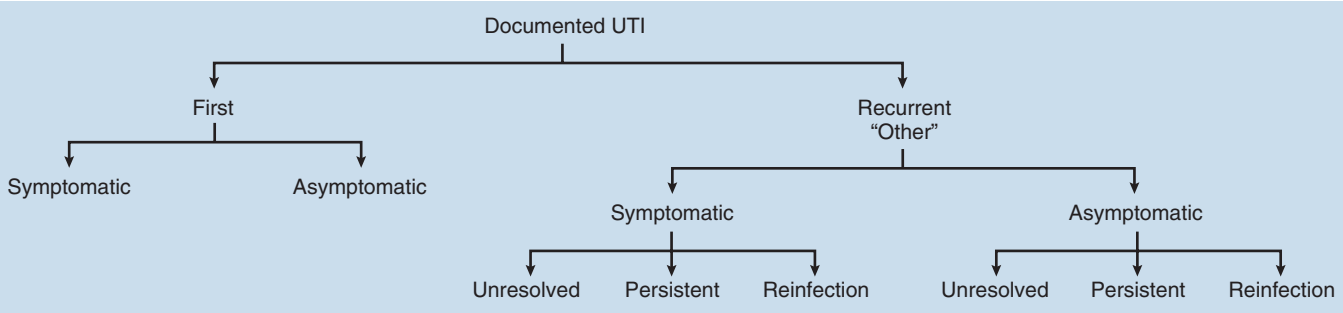

Figure 116–1. Functional classification of urinary tract infections (UTI) in children.

including ambulatory visits that account for much of UTI treatment in this country (Freedman, 2004).

Definition of Infection

What constitutes a "significant" clinical UTI is controversial. The urinary tract is normally sterile. Whether "colonization" of the urinary tract occurs (benign bacteriuria) or whether colonization is true infection is debatable. Specimen contamination can occur, and specimens are often difficult to interpret.

Urinary collection is important for the reliability of UTI diagnosis (Fig. 116–1).

Classification of Urinary Infections

UTI is classified in many ways: complicated versus uncomplicated, upper versus lower tract, persistent infection versus reinfection, and symptomatic versus asymptomatic. For practical purposes pediatric UTI can be divided into two categories: first infections and recurrent or other infections.

Recurrent infections may be (1) unresolved during initial therapy, (2) persistent (from an anatomic site) and/or (3) reinfection from a separate microorganism (Stamey, 1975). As will be discussed, first childhood UTIs are complicated because of evaluation and management implications and considerations.

A UTI may not resolve because it is treated with a drug to which the bacterium is resistant, the antimicrobial levels are too low for physiologic reasons of poor renal concentrating ability or gastrointestinal malabsorption, or the infection is polymicrobial. When proper culture and antimicrobial sensitivity results are available, usually unresolved UTIs are treated successfully.

UTI imaging evaluation reveals most sources of bacterial persistence early in childhood. The discovery of surgically correctable sources of bacterial persistence is obviously important so that these sites can be removed (Table 116–1). The majority of recurrent UTIs are not surgically correctable, because they result from reinfection from the same or a different gut microorganism. Screening urinary culture when a child is being examined for reasons unrelated to urinary symptoms, may diagnose an asymptomatic or covert UTI (Savage, 1975); these UTIs will be discussed.

Table 116–1.

Surgically Correctable Causes of Bacterial Persistence in Children

Infection stones
Infected nonfunctioning or poorly functioning kidneys or renal segments
Infected ureteral stumps after nephrectomy
Vesicointestinal or urethrorectal fistula
Vesicovaginal fistula
Infected necrotic papillae in papillary necrosis
Unilateral medullary sponge kidney
Infected urachal cyst
Infected urethral diverticulum or periurethral gland

Bacteria

Some bacteria appear to have a special affinity for causing UTI. The most common bacteria infecting the urinary tract are the gram-negative Enterobacteriaceae, usually *Escherichia coli*. Specific cell wall O-antigens that are identified by serotyping, such as *E. coli* serotypes 01, 02, 04, 06, 07, and 075, commonly cause pediatric UTI (Kunin et al, 1964; Bergström et al, 1972; Winberg et al, 1974), and many of these are now called UPEC (uropathogenic *E. coli*) or are included among ExPEC (extraintestinal *E. coli*) (Russo and Johnson, 2000). Experimental findings suggest that current *Enterococcus faecalis* with multidrug resistance may have a specific affinity for the kidney (Kau et al, 2005).

Bacterial surface structures, pili or fimbriae, may increase uropathogenicity. The bacterial fimbriae mediate bacterial adherence to uroepithelial cells and agglutinate red blood cells. Red blood cell agglutinating characteristics of *E. coli,* called hemagglutination, are blocked by different sugars (Duguid et al, 1978; Svanborg Edén and Hanson, 1978). Using this characteristic, Källenius and associates (1981) discovered that pyelonephritic *E. coli* cause mannose-resistant hemagglutination (MRHA) of human red blood cells. The terminal glycolipid of the human red cell P blood group antigen is a receptor that binds the P fimbriae on these *E. coli*. Therefore **two important markers for *E. coli* virulence are MRHA characteristics and P blood group–specific adhesins** (P fimbriae or P pili) (Källenius et al, 1981; Väisänen et al, 1981).

Most *E. coli* strains causing pediatric clinical pyelonephritis have both MRHA and P fimbriae (MRHA 91% [29/32], P fimbriae 81%) (Väisänen et al, 1981). P fimbriae are absent on less virulent strains. Källenius and associates (1981) found P fimbriae on 94% (33/35) of *E. coli* causing acute pyelonephritis, 19% (5/26) of *E. coli* causing acute cystitis, 14% (5/36) of *E. coli* causing asymptomatic bacteriuria, and on 7% (6/82) of *E. coli* from the feces of healthy children.

Two virulence factors appear to subvert the urinary tract immune system: one found in UPEC strains that acts by inhibiting Toll-like receptor (TLR) signaling (Cirl et al, 2008) and another that is a secreted autotransporter toxin (serine protease

autotransporter) that damages tight junctions in epithelial cells (Guignot et al, 2007).

Other less well-characterized virulence factors are hydrophobic *E. coli* properties and the iron-binding capability of the bacteria associated with aerobactin production (Jacobson et al, 1988, 1989b). Genes with three specific uropathogenic proteins (USP, a *Vibrio cholerae* zot gene homologue; IrgA homologue adhesin Iha, a nonhemagglutinating adhesin; IroN(*E. coli*), a catechole siderophore receptor homologue) are associated with factors that cause UTI and pyelonephritis (Bauer et al, 2002).

Organisms that cause covert or asymptomatic UTI may lack such virulence characteristics, be self-agglutinating, and lack fimbriae.

PATHOGENESIS OF URINARY TRACT INFECTION IN CHILDREN

The natural course of UTI in children is unpredictable. Although risk factors and bacterial virulence influence this course, these factors alone are unhelpful in predicting who gets pyelonephritis, renal scarring, or parenchymal and functional loss from a single or recurrent UTI. Of the 3% of girls and 1% of boys who get a prepubertal UTI (Winberg et al, 1974), 17% or more will get infection-related renal scarring. Of those with scarring, 10% to 20% may become hypertensive, and only a rare child acquires progressive renal dysfunction culminating in end-stage renal disease. The course of UTI in adults and children differs, and studies on UTI in children are reported without regard for age and other child-specific factors (Shortliffe and McCue, 2002). For this reason, much of the course of pediatric UTI remains elusive.

Cystitis and Pyelonephritis

The bladder's normal lack of susceptibility to bacteria is a complex interplay between bacterial virulence factors and the innate immune responses at the level of the uroepithelial cell. Because adaptive immune systems are incapable of immediate response to continual bacterial challenge at the urethral portal of entry, the initial response must be innate and reflexive for the host who is at times sitting in fecal microbiota (i.e., diapers). For this reason, the role of the fecal flora and human microbiome transitions—for reasons of diet, geography, pharmacotherapy, or epidemic and endemic contacts—must not be underestimated (Hällgren et al, 2005; Manges et al, 2008; Moreno et al, 2008; Smith et al, 2008) (Fig. 116–2).

Bacterial genetic clonal studies confirm that entry into the urinary tract occurs through the suspected fecal-perineal-urethral route with subsequent retrograde ascent of periurethral bacteria (Kaijser and Larsson, 1982; Tullus et al, 1984; Mitsumori et al, 1997; Yamamoto et al, 1997). Bacteria overcome urethral defenses of urethral washout, epithelial shedding, and paraurethral glandular secretion, all of which vary by gender, age, and individual, causing variable likelihood for bacterial ascent and establishment of UTI (Kunin, 2002). At the molecular level, **microbial polysaccharides may**

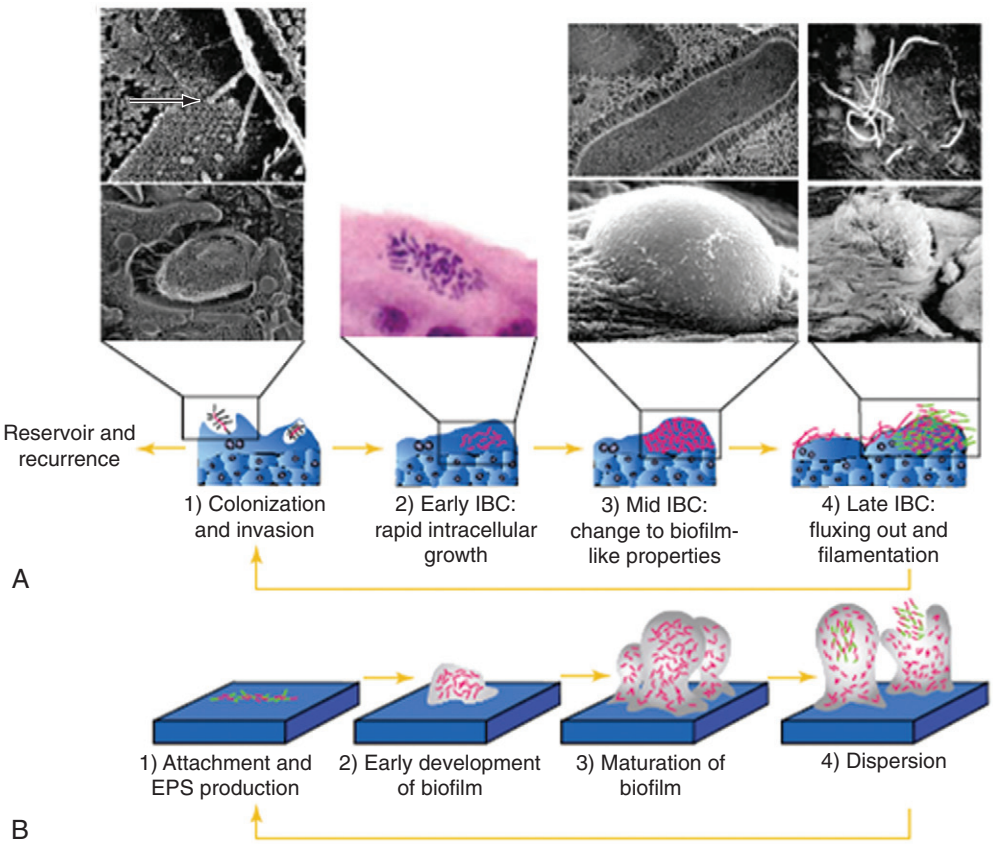

Figure 116–2. **A,** The stages of bacterial invasion of uropathogenic *Escherichia coli* attaching to uroepithelial cell and subsequent formation of pod and dispersion. **B,** The similar stages compared with previously known biofilm formation on inert surfaces such as urethral catheters. EPS, extracellular polymeric substances; IBC, intracellular bacterial communities. (From Kau A, Hunstad D, Hultgren SJ. Interaction of uropathogenic *Escherichia coli* with host uroepithelium. Curr Opin Microbiol 2005;8:54; Fig. 2.)

trigger urothelial receptors (Toll-like receptors) that activate the local immune system (Akira and Takeda, 2004). Tamm-Horsfall protein (THP) a common urinary protein, moreover, adheres specifically to type 1 fimbriated uropathogenic *E. coli* to participate in the host defense by helping to wash out bacteria during voiding (Bates et al, 2004; Raffi et al, 2005; Säemann et al, 2005) and may decrease inflammation during injury (El-Achkar et al, 2008).

Rodent and murine models have revealed the potential bacterial and uroepithelial interactions through which UTI occurs, and the models explain a new paradigm for acute and recurrent UTI. Superficial bladder umbrella cells are unique slow-cycling cells that renew only every few months. These cells contain special two-dimensional hexagonal crystals of 16-nm uroplakin particles that normally allow these superficial cells to flatten, expand, and allow normal bladder surface activity (Kong et al, 2004). A genetically altered uroplakin-deficient mouse has major urinary tract abnormalities.

Although the **initial event in infection is attachment between the uroepithelial cell and bacteria through factors such as type 1 pili and P fimbriae, this attachment initiates a molecular interaction in which the adhesin-receptor complexes trigger a series of events that causes uptake of the bacteria into the bladder surface umbrella cells** (Kau et al, 2005). In response, the host response rapidly sheds the uroepithelial cells (Mulvey et al, 1998). The bacteria then enter the bladder epithelial cells, interacting with lipid rafts and uroplakins and forming intracellular bacterial communities. These bacterial communities develop, and the organisms transform into an organized biofilm and have a more coccoid form. As these communities enlarge, they form cellular "pods" that protrude from the surface and may detach. These may then retransform into their rodlike motile form and disseminate through the urinary tract (Anderson et al, 2003). The intracellular bacterial "pod" may defend bacteria from normal host cellular immune and antimicrobial effects (Justice et al, 2004). **These biofilms appear to allow microbial adaption to variable environments and then allow aggregate detachment that will cause systemic infection, antimicrobial resistance through plasmid exchange, endotoxin production, and overall increased resistance to host immune systems** (Donlan, 2002). Simultaneously, however, the bacteria also attach to uroepithelial cell receptors (Toll-like receptors) and initiate a dramatic immune response with release and activation of proinflammatory cytokines and chemokines (IL-1, IL-6, IL-8) that signal and direct neutrophil transmigration across the epithelial barrier and into the urinary tract lumen, creating the clinical symptoms and signs of bladder and urinary tract infection. The balance between these processes determines whether UTI occurs.

Once bacteria are in the bladder, host immunity, impaired ureteral peristalsis, vesicoureteral reflux, and the specific organism uropathogenicity affect possible retrograde ascent. Under normal circumstances, nonspecific mechanisms, such as cytokine release, may play a role (Davidoff et al, 1997).

Although hematogenous dissemination of bacteria may occur, this appears to be relatively uncommon and may primarily involve infants with incompletely developed immunity, staphylococcal skin or systemic infections with organism dissemination, or systemic infection, such as tuberculosis. In these situations, renal, perirenal, or epididymal abscesses can occur.

Pyelonephritis is important because of the clinical severity of the illness and the potential renal damage that may occur. Bacterial infection of the urinary tract also causes bladder and ureteral inflammation with tissue changes that alter dynamics of the entire urinary tract (Hinman, 1971; Boyarsky and Labay, 1972; Issa and Shortliffe, 1992; Johnson et al, 1992). Animal studies have shown that UTI causes abnormally elevated renal pelvic pressures even if (or especially if) vesicoureteral reflux is absent (Issa and Shortliffe, 1992; Angell et al, 1998), thus giving increased pressure and poor smooth muscle compliance as a further explanation for ureteral dilation observed in patients with acute pyelonephritis and otherwise normal upper collecting systems (Mårild et al, 1989).

Determining the point of clinical progression from cystitis to pyelonephritis or differentiating between these entities is impossible, because simple techniques with which to localize the level and extent of urinary tract bacteria are lacking. Although ureteral catheterization with sequential cultures is the gold standard for localizing upper and lower tract bacteria, this requires cystoscopy and is an impractical invasive way of following the course of infection (Stamey, 1980). Moreover, localizing the site of bacteria does not show the extent of renal inflammation. The Fairley bladder washout localization technique requires urethral catheterization during acute infection and subsequent bladder irrigation and washing with sterile water to localize bacteria to bladder (found in the first bladder culture) or above the bladder (found in cultures taken after the washing). **Clinical symptoms correlate poorly with the results of localization studies using the Fairley or ureteral catheterization techniques. In one study comparing clinical symptoms with Fairley results, fewer than half the patients (mainly children) with fever and flank pain had upper tract bacteria (34/73) on Fairley test, and almost 20% (83/473) who were asymptomatic had upper tract bacteria** (Busch and Huland, 1984).

Key Points: Urinary Tract Infection Pathogenesis

- The first year of life is the only year during which males have more UTIs than females.
- Each year about 50 per 100,000 children are hospitalized for UTI; the rate is greater than 3 times this number in infants (children younger than 3 months).
- In children, discovering surgically correctable sources of bacterial persistence is important.
- Bacterial pili or fimbriae increase uropathogenicity.
- Approximately 17% or more of children who have pyelonephritis acquire renal scarring.
- Clinical symptoms correlate poorly with bacterial localization within the urinary tract.
- Bacterial clonal studies confirm the fecal-perineal-urethral retrograde ascent of periurethral bacteria causing UTI.
- Microbial lipopolysaccharides may trigger urothelial receptors (Toll-like receptors) to activate the innate local immune system—cytokines, chemokines, and neutrophils.
- Intracellular bacterial biofilms allow microbial adaption to variable environments and allow aggregate detachment causing systemic infection in a way that increases bacterial resistance to the host immune system.

Risk Factors for Bacteriuria and Renal Damage

Although we are unable to alter bacterial pathogenicity at this time, it is worth reviewing characteristics that alter risk of UTI

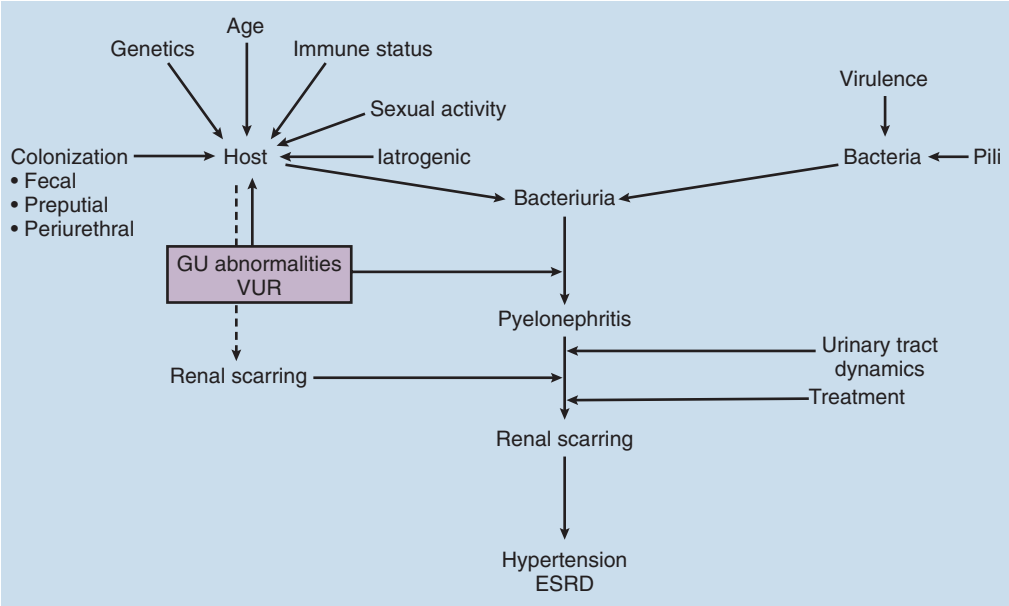

Figure 116–3. Factors that affect the development of bacteriuria and subsequent pyelonephritis, renal scarring, hypertension, and end-stage renal disease (ESRD). Urinary tract urodynamics reflect urinary tract pressures and related factors. GU, genitourinary; VUR, vesicoureteral reflux.

and renal damage and that may be therapeutically altered (Fig. 116–3).

Age

The prevalence of UTI is age dependent. **Bacteriuria is more common at the extremes of life—in neonates and the elderly** (Shortliffe and McCue, 2002). As already discussed, the prevalence of UTI for both males and females younger than 1 year is higher than at other times during childhood. There may be many factors causing this age-dependent relationship, some of which involve interactions with other host factors, such as periurethral colonization, breast-feeding, or immature immune status. Although none of these factors appears to be independent, the importance of the various factors may be age related. Others have discussed major factors creating risk for UTI in females, for instance, sexual intercourse, contraceptive usage (diaphragm/spermicidal), antimicrobial usage, previous history of UTI, estrogen status, and postvoid residual (Stamm and Raz, 1999). The degree to which these factors contribute is more or less dependent upon the subject's age and previous history.

Genetics

Multiple host genetic factors that affect risk have been identified. Individuals who have childhood UTI continue to be at risk for adult UTI whether or not they have vesicoureteral reflux (Beetz et al, 2002). Obviously, issues related to gender, race, or ethnicity have specific genetic links and will be discussed separately.

Both alteration of bacterial–uroepithelial attachment related to bacterial virulence, which depends upon microorganism specificity, and alteration of the host immune response affect periurethral colonization. Children who originally had primary vesicoureteral reflux that resolved are commonly still susceptible to recurrent UTI, although symptoms are confined to the lower tract (Mansfield et al, 1995; Beetz et al, 2002). Clinical histories support a familial risk for UTI. On screening, sisters of girls who have recurrent UTI have a higher incidence of significant bacteriuria cultures than expected for the normal population (Fennell et al, 1977; Stauffer et al, 2004). **Notably, two distinct risks for recurrent UTI in young women (age 18 to 30 years) are age at first UTI (less than age 15 years; odds ratio [OR] = 3.9) and UTI in the mother (OR = 2.3)** (Scholes et al, 2000). The possible genetic relationship of renal scarring and UTI is discussed in the section Renal Scarring.

In the early 1980s, when bacterial P fimbriae were identified as a virulence factor, glycolipids characterizing the P blood group antigens were found on host uroepithelial cells and found to act as bacterial receptors. Because hosts with these receptors (i.e., P blood group phenotype) were suspected to have increased susceptibility for infection, children with recurrent infections were tested for this P blood group phenotype. **The P1 blood group phenotype was found in 97% (35/36) of girls with recurrent pyelonephritis with minimal (grade I) or no reflux** and was found in 75% (63/84) of controls without UTI (Lomberg et al, 1983). They found, moreover, that bacteria binding to glycolipid receptors (bacteria with P fimbriae) were more likely to be found in the girls with the P1 blood group without reflux than in those with the P1 blood group having reflux, suggesting that vesicoureteral reflux is more likely to contribute to ascent of the bacteria once UTI occurs than would the UTI itself.

Other blood group antigens on the urothelial surface (ABO, Lewis, and secretor phenotypes) influence UTI susceptibility. Adult women with Le (a–b–) and Le (a+b–) blood phenotypes are 3 times more likely to have a recurrent UTI than Le (a–b+) women, and epithelial cells from nonsecretors have more bacterial receptors than cells from secretors (Sheinfeld et al, 1989). Similarly, in children with UTI, the frequency of Le (a–b–) phenotype is higher, and the relative risk of infection in these children is 3.2 (Jantausch et al, 1994). Analysis of children with various anatomic abnormalities (e.g., ureteropelvic junction obstruction, vesicoureteral reflux, ureteroceles, and primary obstructive lesions) suggests that children with these abnormalities and a presumed nonsecretor phenotype (minimal or undetectable ABO and Le^b immunoreactivity) are more likely to have had a history of UTI (16/17, 94.1%) (Sheinfeld et al, 1989, 1990). More

recently, the nonsecretor status of ABH blood type antigens (ABH Ag) was found to be associated with ^{99m}Tc-dimercaptosuccinic acid (DMSA)–defined focal renal scarring in children with vesicoureteral reflux (Kanematsu et al, 2005).

Predisposition for pyelonephritis correlates with decreased expression of IL-8 receptors (CXCR1) on peripheral neutrophils (Frendéus et al, 2001; Lundstedt et al, 2007; Ragnarsdóttir et al, 2008) **and polymorphisms of cytokine interleukin-8 (IL-8) regardless of vesicoureteral reflux status** (Artifoni et al, 2007). Genetic polymorphisms, such as of intercellular adhesion molecule-1 (ICAM-1), which modulates the inflammatory infiltration into the surrounding tissues (Gbadegesin et al, 2006), and of transforming growth factor-β1 (TGF-β1) (Yim et al, 2007), which may affect other parts of the inflammatory and scarring process, are also associated with children who develop UTI-associated renal scarring. Other, separate gene polymorphisms of TLR correlate with UTI (TLR2 with both symptomatic and asymptomatic UTI [Tabel et al, 2007]; TLR4 with UTI and asymptomatic UTI [Karoly et al, 2007; Ragnarsdöttir et al, 2007] and vascular endothelial growth factor [VEGF] [Yim et al, 2007]).

In summary, it appears that **host genes separate from those associated with vesicoureteral reflux increase urinary tract susceptibility to infection and/or to pyelonephritis and renal scarring**. Further investigation should improve our identification of these individuals.

Gender

As discussed earlier, the ratio of UTI by sex in the white population shows a preponderance of UTI in boys during the first year of life, but, thereafter, more girls than boys have UTI. Although many factors, including urethral length, prostate, hormones, and foreskin, are hypothesized to account for this finding, the complete explanation is unclear.

Race and Ethnicity

Although UTIs occur in all races, epidemiologic studies show varying prevalence and complications of UTIs in different races. These factors are incompletely studied. In one comparative study of children less than 2 years old, including white, Hispanic, and African-American children, UTIs were most prevalent in white, then Hispanic, and finally African-American girls, but, in boys, UTIs were most common in Hispanic, white, and African-American boys, in that order. Circumcision status confounds these data (Bachur and Harper, 2001a, 2001b). **Several studies show that African-Americans have fewer UTIs, lower incidence of vesicoureteral reflux, and perhaps less likelihood of reflux nephropathy than Hispanics or whites** (Kunin and McCormack, 1968; Kunin, 1970; Lohr et al, 1994; Hoberman and Wald, 1997; Pinto, 2004). Interestingly, it has been reported that in Chinese children, UTI, vesicoureteral reflux (VUR), and renal scarring are more common in boys than girls; however, the ages are unreported, and these findings could be confounded by age and circumcision status (Howard et al, 2001; Williams et al, 2001a).

Renal Scarring

Renal scarring correlates with later UTI complications, such as hypertension, renal insufficiency, progressive renal scarring, and renal functional deterioration (Berg, 1992). **Clinical studies that examine the association of recurrent bacteriuria and new renal scarring or progressive renal scarring** support the notion that **renal scarring begets renal scarring** (Newcastle Asymptomatic Bacteriuria Research Group, 1975; Savage, 1975; Cardiff-Oxford Bacteriuria Study Group, 1978; Newcastle Covert Bacteriuria Research Group, 1981). Long-term follow-up has also shown that kidneys that were initially normal after UTI tend to remain normal, while those that were initially scarred appear to be more likely to suffer subsequent damage (Smellie, 1991; Smellie et al, 1998).

Angiotensin-converting enzyme (ACE) gene polymorphisms that are associated with increased renin-angiotensin activity are implicated in renal scarring. Increased DD genotype polymorphism is associated with increased risk of progressive renal failure in IgA nephropathy, diabetic nephropathy, autosomal-dominant polycystic kidney disease, focal glomerulosclerosis, and in children with congenital urologic abnormalities who have evidence of renal parenchymal damage and reflux nephropathy (Brock et al, 1997, 1998; Ozen et al, 1999). Genetic polymorphisms that relate to the immune response, such as those of ICAM-1, which modulates the inflammatory infiltration into the surrounding tissues (Gbadegesin et al, 2006), and of TGF-β1, which may affect other parts of the inflammatory and scarring process (Yim et al, 2007), are associated with children who develop UTI-associated renal scarring.

A systematic review and meta-analysis concluded that **primary vesicoureteral reflux is a weak predictor of renal scarring in children *hospitalized* with UTI** (Gordon et al, 2003). Using a definition of UTI as fever, positive urinary culture, and a DMSA scan showing photopenia during acute illness, another meta-analysis concluded that the rate of renal scarring after acute pyelonephritis is 36% to 41.6%, and those children with VUR have a 2.8 times greater risk of renal scarring (Faust et al, 2009). Although both meta-analyses found that children with VUR were more likely to have scarring than those without, the severity of illness differed and might account for the differing conclusions.

Colonization

Periurethral Colonization

The incidence of UTI in infants is higher during their first few weeks to months of life than at any subsequent time in the next few years. During this time, the periurethral area of healthy girls and boys is colonized massively with aerobic bacteria (especially *E. coli,* enterococci, and staphylococci) (Bollgren and Winberg, 1976b). This colonization decreases during the first year and is unusual in children who do not get recurrent infections after age 5 years. After this period, only those women and children who suffer repeated UTI remain more colonized by periurethral gram-negative bacteria than those who do not get infections (Stamey and Sexton, 1975; Bollgren and Winberg, 1976a, 1976b). Times and conditions of increased periurethral colonization are therefore associated with increased risk of UTI.

Preputial Skin

During the first few months of life, foreskin, periurethral, and preputial bacterial colonization and UTI appear to correlate. This association between the foreskin and neonatal UTI has caused controversy regarding the advantages and disadvantages of circumcision (Hallett et al, 1976). This has resulted in numerous editorials and recommendations by the American Academy of Pediatrics (King, 1982; Cunningham, 1986; Roberts, 1986; Lohr, 1989; Schoen et al, 1989; Winberg et al, 1989; Poland, 1990; Schoen, 1990; American Academy of Pediatrics [Task Force on Circumcision], 1999b), and more recently, the controversy has expanded to include sexually transmitted infection.

In a group of mainly uncircumcised normal boys, Bollgren and Winberg (1976b) documented that preputial aerobic bacterial colonization is highest during the first months after birth, decreases after 6 months, and is uncommon after age 5 years. Subsequently, Wiswell and associates (1988) **compared the periurethral bacterial flora (using intraurethral and glanular cultures) during the first year of life in circumcised and uncircumcised boys and found that, for the first 6 months, periurethral uropathogenic organisms were cultured more frequently from the uncircumcised than circumcised boys.** They and others concluded that the foreskin is responsible for this finding (Hallett et al, 1976; Glennon et al, 1988; Wiswell et al, 1988).

Although the reasons for neonatal bacterial colonization of the foreskin are multifactorial, including immature immune status, unusual nosocomial colonization, breast-feeding (Winberg et al, 1989), and other characteristics mediating bacterial adherence (Fussell et al, 1988), this high colonization is associated with a greater number of neonatal UTIs. In a series of retrospective reviews of 55 worldwide U.S. Army hospitals, Wiswell and Roscelli (1986) examined the incidence of UTI diagnosed by catheterization or suprapubic aspirate in male infants hospitalized during 1974 to 1983. **They found that the incidence of infections in circumcised male infants was 0.11% (193/175,317); that in uncircumcised infants was 1.12% (468/41,799); and that in female infants was 0.57%** (1164/205,212). Because these numbers are from hospitalized children in Hawaii, they may underestimate UTI; others report higher overall incidence of UTI in infant boys of 2.2% to 4.1%, with the majority (70% to 86%) occurring in uncircumcised infants (Wiswell et al, 1985; Schoen et al, 2000; Wiswell, 2000).

Uncircumcised male infants, moreover, have an increased relative risk of UTI of 3.12 when compared with circumcised boys, but this risk decreases from 3.7 at age 1 year to 3.0 at age 3 years (Wiswell and Hachey, 1993; To et al, 1998; Wiswell, 2000). The majority of infections occurred during the first 3 months of life. When the UTI incidence of the first and the final years of the study are compared, the total number of UTIs increased as the circumcision rate decreased, leading Wiswell to conclude that UTIs are more frequent in uncircumcised boys (Wiswell and Roscelli, 1986; Wiswell et al, 1987).

Using case-control methodology, circumcised boys in a population with a high rate of uncircumcised boys (Australia) were compared with a population of circumcised boys. Craig and associates (1996) concluded that circumcision was still associated with a lower rate of UTI before and past the first year of life. Although there may be difficulties with these data related to retrospective analysis and selection bias, periurethral colonization is associated with increased risk of UTI in girls and women also.

Others found no difference in pre- and postoperative rates of UTI **whether or not circumcision is performed at the time of ureteroneocystotomies** (Kwak et al, 2004). At this time, there is no way of predicting whether a male infant with a normal urinary tract who gets a UTI has a genetic or familial predisposition for infection. Because few infant boys who suffer a neonatal UTI risk a recurrent UTI after 1 year if they remain UTI free in the interim, prophylactic antibiotics for 6 months may be helpful in these boys.

There is some evidence that circumcision in hospitalized (neonatal intensive care) premature boys may decrease risk of recurrent UTI during the neonatal period (Cason et al, 2000). UTI treatment in uncircumcised infant boys also tends to be more expensive to treat, because these children are more likely to be hospitalized, especially during the first 3 months of life (Schoen et al, 2000). The cause for this is unknown, but it is reported that the organisms involved in these uncircumcised boys are more virulent and appear more similar to the strains causing pyelonephritis and urosepsis in adults (Bonacorsi et al, 2005). After meta-analysis, one group has calculated that circumcision decreases risk of UTI with an odds ratio of 0.13, yet UTI is rare enough in boys and common circumcision complications high enough so that only boys having recurrent UTI or high risk for recurrent UTI may benefit from circumcision (Singh-Grewal et al, 2005).

Although a full discussion of sexually transmitted infections (STI) are beyond the scope of this chapter, recent literature focuses upon a relationship between STI and circumcision status. A systematic meta-analysis of literature evaluating studies that examine sexually transmitted urethritis and genitourinary ulcerative diseases concluded that circumcised males may be more likely to acquire urethral STI (primarily *Chlamydia*), whereas uncircumcised males may be more likely to acquire ulcerative diseases (primarily chancroid) without a difference between rates of gonococcal infection (Van Howe, 2007). As might be expected, however, interstudy diversity makes definitive conclusions difficult. Other recent studies suggest that specific groups of circumcised males have lower rates of human papilloma viral penile and urethral infection and reduced HIV prevalence, but again, the conclusions relate to special populations and may not be generalizable (Auvert et al, 2009; Nielson et al, 2009; Sobngwi-Tambekou et al, 2009; Warner et al, 2009).

Current data do not support routine neonatal circumcision for UTI prevention in neonates or children, although some evidence exists that boys with recurrent UTI may benefit (American Academy of Pediatrics [Task Force on Circumcision], 1999b; Singh-Grewal et al, 2005). Although there appears to be evidence that specific STI may be increased in specific populations, STI (e.g., *Chlamydia,* gonorrhea, syphilis, nonspecific urethritis, genital herpes or warts) rates, when adjusted for socioeconomic status and sexual behavior, show no significant difference based on neonatal circumcision status in developed countries (Dickson et al, 2008). Opinions on this differ (Thiruchelvam and Cuckow, 2005). Some reports document slightly higher UTI incidence following ritual circumcision, which may reflect surgical technique (Liora et al, 2002).

Fecal Colonization

Because most UTIs result from fecal-perineal-urethral ascent of bacteria, fecal colonization is an important consideration. The human fecal flora is dependent upon the surrounding microbial ecology, native immunity, and microbial-altering drugs and foods. Studies showing that fecal colonization with specific pyelonephritic bacteria may occur in a neonatal nursery or hospital, with subsequent bacteriuria or pyelonephritis occurring several months later, emphasizing the importance of abnormal fecal colonization (Tullus et al, 1986). **Bacterial clonal studies also associate fecal and urinary bacteria with community outbreaks** (Manges et al, 2006, 2008; Smith et al, 2008) and show household members may share rectal flora (Johnson et al, 2008a).

The creation and selection of resistant organisms in the gut by antimicrobial usage is well recognized. **Because the fecal flora is commonly responsible for perineal and periurethral colonization, the importance of responsible antimicrobial usage should not be underestimated.** In one study, antibiotic treatment of school girls with phenoxymethylpenicillin

for intercurrent nonbladder infections, usually otitis media, caused colonization and bacteriuria with strains more likely to be symptomatic (Hansson et al, 1989b).

Immune Status and Infancy

Compromised native immunity is associated with increased risk of infection. In children, the immune status varies with normal development, with transmission either natural or acquired (e.g., vaccination, breast-feeding, illness), and with congenital or acquired immunodeficiencies. UTIs are common in infants and children with immature immune systems. For instance, serum IgG is lowest from age 1 to 3 months (Robbins, 1972) when periurethral colonization is high in normal children. Secretory IgA is an important human immunoglobulin at the secretory and mucosal surface, and it is transferred to the newborn in colostrum if the child is breast-fed. Serum IgA is found in diminished concentrations for the first several months and is either absent or almost absent at the secretory surfaces of the nasopharynx, gut, and urothelium during this period (Svanborg Edén et al, 1985; Fliedner et al, 1986; Yoder and Polin, 1986) and undetectable in the urine at birth. Urinary secretory IgA and total IgA increase during the first year and are higher in children who are breast-fed (James-Ellison et al, 1997). The role that urinary IgA plays in childhood UTI has not been investigated extensively. In children with acute UTI or pyelonephritis, urinary excretion of IgA is higher than in those without UTI, yet levels are exceeded in normal adults (Svanborg Edén et al, 1985; James-Ellison et al, 1997).

Urinary IgA in infants, moreover, is in the monomeric rather than the secretory form normally found in adults, suggesting that urinary IgA in infants may be systemic immunoglobulin excreted as a result of infection-related tubular dysfunction rather than secretory. Children with recurrent UTI have lower urinary secretory IgA concentrations than those without (Fliedner et al, 1986). The benefits of breast milk are unclear (Hanson, 1998; Committee on Breast Feeding, 2005). **Case-control studies suggest that breast-feeding confers a protective effect against UTI during the first 6 months of life.** These studies show the duration of breast-feeding is shorter in children who have UTI (9 vs. 16 weeks in children who had exclusive breast-feeding) (Mårild et al, 1989), but that full or partial breast-feeding may confer a protective effect against UTI for the first 6 months of life (Pisacane et al, 1990, 1992). Although the mechanism of the protection is unknown, the oligosaccharide content of the mother's breast milk and urine are the same as in the breast-fed infant. Some hypothesize that the oligosaccharides inhibit the adherence of pathogenic *E. coli* to the uroepithelium (Coppa et al, 1990). Other **studies show that exclusive breast-feeding for 4 or more months protects against single or recurrent otitis media in children** or infants with cleft palate (Duncan et al, 1993; Paradise et al, 1994).

As expected, children with specific immune deficiency syndromes have altered immunity and commonly have an increased risk of infection and its dissemination. About 20% of human immunodeficiency virus (HIV)-infected children have bacterial UTI with both common and opportunistic organisms (Grattan-Smith et al, 1992), and others have associated UTI and HIV; specifically, in HIV-seropositive women, UTI was associated with high viral load (OR = 1.82) (Park et al, 2002). Specific deficiencies of the immune response associated with genetic polymorphisms that involve the TLR and cytokine-associated responses are discussed in the section Genetics.

Sexual Activity

Epidemiologic studies show that sexual activity is a risk factor for UTI. Sexually active females have more UTIs than inactive females (e.g., nuns) (Kunin and McCormack, 1968). This association has caused some to suggest that **UTI is a marker for teenage sexual activity** (Nguyen and Weir, 2002). Whether this relationship stems from colonization or other factors is unclear.

Genitourinary Anatomic Abnormalities

UTI has been a marker for pediatric genitourinary tract anatomic abnormalities; hence, the reason UTI evaluation consists of imaging. This maxim was reaffirmed when investigators followed children with prenatally detected renal pelvic dilation of 5 mm or greater at 28 weeks' gestation, and found the children had increased risk of UTI (Coelho et al, 2008). Genitourinary abnormalities, in particular, nonfunctioning segments can serve as niduses of infection causing bacterial persistence because of renal inability to achieve urinary antimicrobial concentrations adequate to eradicate bacteria in these segments. Similarly, genitourinary partial obstruction or renal functional impairment may create increased risk of renal damage because of poor or inadequate antimicrobial penetration. A sequela of chronic UTI and inflammation, xanthogranulomatous pyelonephritis, may also occur in children with obstruction and UTI in renal segments (Stamey et al, 1977; Zafaranloo et al, 1990; Cousins et al, 1994; Hammadeh et al, 1994).

Vesicoureteral Reflux

Vesicoureteral reflux is discussed in Chapter 122. Reflux is common in children with UTI, but no correlation between reflux and susceptibility to UTI is evident (Winberg et al, 1974). At least one group has shown no difference in occurrence of recurrent UTI between children who have reflux and those who do not (Garin et al, 2006). Surveys show that 21% to 57% of children who have bacteriuria have vesicoureteral reflux when evaluated (Kunin et al, 1964; Abbott, 1972; Asscher et al, 1973; Newcastle Asymptomatic Bacteriuria Research Group, 1975). Although vesicoureteral reflux raises risk of pyelonephritis associated with bacteriuria, it correlates poorly with UTI-induced renal scarring (Gordon et al, 2003).

Peripubertal Girls with Persistent Vesicoureteral Reflux (Pregnancy)

The question of whether girls approaching puberty who have persistent vesicoureteral reflux should have their reflux corrected because of the potential for future pregnancy is problematic. If primary vesicoureteral reflux persists as a girl approaches puberty, it becomes statistically less likely each year to resolve spontaneously. For this reason, some advocate that all girls approaching puberty undergo correction of reflux to avoid the risks of pyelonephritis during future pregnancies. Whether a female with persistent vesicoureteral reflux who has never had a UTI and demonstrates no increased susceptibility for UTI should undergo routine correction of reflux is controversial; moreover, whether a female with persistent vesicoureteral reflux who has demonstrated increased susceptibility for UTI should undergo correction is also controversial. Although the prevalence of bacteriuria in pregnant women is the same as in nonpregnant women (Shortliffe and Stamey, 1986b; Shortliffe, 1991), **the likelihood that bacteriuria may progress to pyelonephritis is greatly increased. Thirteen and a half to 65 percent of pregnant women who are bacteriuric on a screening urinary culture will develop subsequent pyelonephritis during pregnancy if**

untreated (Sweet, 1977), **whereas pyelonephritis is rarely the consequence of uncomplicated cystitis in a nonpregnant woman.**

The reasons for this increased likelihood of pyelonephritis during pregnancy are unknown, but they may relate to hormonal and hydrodynamic changes of pregnancy. There is increased bladder and urinary tract compliance and bladder enlargement, and an enlarging uterus may cause anatomic displacement of the bladder and ureters (Hsia and Shortliffe, 1995). There are no data to suggest that pregnancy causes vesicoureteral reflux (Shortliffe and Stamey, 1986b). When 321 women had a single-film voiding cystourethrogram during the third trimester of pregnancy or immediately postpartum, only 9 (2.8%) had vesicoureteral reflux (Heidrick et al, 1967). Although 6.2% (20/321) of these women had asymptomatic bacteriuria, only 1 of these 20 women had vesicoureteral reflux. Therefore in contrast to the pediatric situation, few pregnant women who develop pyelonephritis have reflux. Of the 9 women who had reflux, 3 developed pyelonephritis during a pregnancy.

In another series, 21 of 100 pregnant women (27 refluxing renal units in 21 patients) with asymptomatic bacteriuria evaluated postpartum had vesicoureteral reflux, mostly of low grade (67% into the ureter only), and 17% of these women had renal scarring (Williams et al, 1968). Although some use these data to justify correction of all pubertal reflux in girls, this renal scarring is unlikely to be the result of UTI during pregnancy. This rate of scarring is similar to that found in children with screening bacteriuria and renal scarring (Asscher et al, 1973; Newcastle Asymptomatic Bacteriuria Research Group, 1975; Savage, 1975). Because these women had no imaging before pregnancy, it is most likely that any renal scarring found post partum was present beforehand and occurred in childhood.

These data suggest that postpubertal females who have vesicoureteral reflux and a predisposition for frequent urinary tract infections will continue to have this predisposition for infections into adulthood and pregnancy. Moreover, those women who were susceptible to UTI before pregnancy will continue to be more likely to develop UTI during and after pregnancy, whether or not they have vesicoureteral reflux (Mansfield et al, 1995; Bukowski et al, 1998; Beetz et al, 2002).

Even though correction of vesicoureteral reflux, spontaneously or by intervention, may decrease the likelihood of developing ascending pyelonephritis from bladder bacteriuria under normal circumstances, during pregnancy the nonrefluxing orifice does not appear to offer the expected protection from pyelonephritis. Unless a surgically corrected ureterovesical junction better protects the kidney against the pyelonephritis of pregnancy than nature's normal nonrefluxing ureteral junction does, intervention cannot be justified. Therefore both persistent reflux and a patient's susceptibility to UTI should be assessed before surgical correction of reflux. **If vesicoureteral reflux is corrected in a girl with recurrent UTI, these females should be told that pyelonephritis during pregnancy is still possible. When these females become pregnant, bacteriuria screening is essential.**

Pregnant Women with Renal Insufficiency

When a practitioner counsels a woman with known reflux nephropathy and renal insufficiency about pregnancy, renal function needs evaluation. With physiologic pregnancy—renal hyperperfusion and resulting hyperfiltration—a blood urea nitrogen (BUN) greater than 14 mg/dL and serum creatinine greater than 0.9/dL may indicate pre-existing renal insufficiency (Vidaeff et al, 2008). **Though outcomes data for pregnancy are sparse, when there is moderate or severe renal insufficiency (moderate, initial serum creatinine, 1.4 to 2.4 mg/dL; severe, 2.5 mg/dL or greater), even though infant survival may be greater than 90%, maternal and obstetrical complications are high** (Bear, 1976; Davison and Lindheimer, 1978; Jones and Hayslett, 1996). In these high-risk women, 43% had a pregnancy-related deterioration in creatinine clearance of at least 25% that occurred during pregnancy (20%) or immediately postpartum (23%). In the majority, this pregnancy-related deterioration in renal function was irreversible (Epstein, 1996; Jones and Hayslett, 1996). This accelerated renal insufficiency was associated with increased hypertension and high-grade proteinuria. Almost 60% of these pregnancies ended in preterm delivery with cesarian section, and the majority of infants were below the 50th percentile in birth weight (Jones and Hayslett, 1996). **These data have been interpreted to indicate that when the serum creatinine exceeds 2.0 mg/dL in a pregnant woman, she has a 1 in 3 risk of progressing to end-stage renal disease either during or just after delivery** (Epstein, 1996).

The effect of a maternal UTI on the fetus has been controversial. Analyses of National Collaborative Perinatal Project (NCCP) data from the 1970s and Medicaid data from the 1990s (both representative of women of low socioeconomic status) show an association between third-trimester maternal UTI and fetal mental retardation or developmental delay; and NCPP data, furthermore, associates third-trimester UTI with increased chance of fetal death (McDermott et al, 2001). Others have documented infant low birth weight and prematurity (Naeye, 1979). **With mild to moderate renal insufficiency, fetal survival is only slightly diminished** (Vidaeff et al, 2008).

Neurogenic and Bowel-Augmented Bladders

Children who have neurogenic bladders with abnormally elevated bladder pressures risk increased renal damage. Risk of UTI is also increased secondary to increased instrumentation common with the neurogenic bladder (intermittent catheterization). Increased pressure within the neurogenic system combined with the physiologic effects of UTI that create increased pressure creates a greater likelihood for subsequent renal parenchymal damage (Hansen et al, 2003). Chronically or intermittently elevated bladder pressures may cause secondary vesicoureteral reflux from decompensation of the ureterovesical junction from the elevated pressure (Hutch, 1952). If this does not occur, the elevated bladder pressures associated with a neurogenic bladder may also cause effective ureterovesical obstruction. This obstruction increases the risk of renal damage associated with urinary tract infections (Cowan and Shortliffe, 1998), and as discussed earlier in this chapter, intermittent elevations in bladder pressure associated with physiologic bladder dynamics in the immature bladder may exacerbate the effects of vesicoureteral reflux and UTI.

When untreated, children with neurogenic bladders that empty or fill at abnormally high pressures will be more likely to risk the effects of UTI and renal damage, because of inability to spontaneously clear bacteria. Clean intermittent catheterization programs are useful for emptying the neurogenic bladder, but these

catheterizations introduce bacteria. **Although conclusions from previous studies involving clean intermittent catheterization in children are limited because they combined sexes, wide age ranges, different types of neurogenic bladders, short follow-up, different prophylactic regimens, and differing definitions of bacteriuria, they all agree that bacteriuria and even pyuria occurs in most children.**

Forty to 80 percent of the urinary specimens sampled had bacteriuria and/or pyuria (Taylor et al, 1985; de la Hunt et al, 1989; Joseph et al, 1989; Gribble and Puterman, 1993; Johnson et al, 1994; Schlager et al, 1995, 1998), and most were asymptomatic (Geraniotis et al, 1988; Joseph et al, 1989; Schlager et al, 1995). However, this catheter-associated asymptomatic bacteriuria appears to lack morbidity much of the time. Notably, even though a majority of these children have asymptomatic bacteriuria, most may undergo urodynamic studies without complications (Shekarriz et al, 1999).

Even though prophylactic antibiotics administered during clean intermittent catheterization may delay and possibly decrease bacteriuria in the short term (Johnson et al, 1994), long term there appears to be no proven efficacy and may cause increased microorganism resistance (Clarke et al, 2005). **Meta-analysis of data on the use of sterile versus nonsterile, single versus multiple use, and lubricated versus nonlubricated catheters document no benefits among the alternatives in reducing UTI** (Schlager et al 2001; Moore et al, 2007). **Thus neither sterile, single-use lubricated catheters nor antimicrobial prophylaxis is recommended for long-term bladder management.** The natural history of clean intermittent catheterization programs deserves further study.

Novel management for those with neurogenic bladders who acquire frequent symptomatic recurrent UTI is to induce asymptomatic UTI using previously identified strains from individuals with asymptomatic UTI (Trautner et al, 2008; Prasad et al, 2009). These studies are preliminary at this time.

Little investigation of the bacteriuria of bowel-augmented bladders exists. In a prospective study, those who have bladder substitution were found to have greater bacteriuria than those without, and there was a substantial local IgA antibody response to the resident bacteria and increased IgG response from the bladder or upper tracts (Iwakiri et al, 2002). Whether this local response contributes to asymptomatic UTI or is protective is unknown.

Iatrogenic Factors

The urinary tract is the most common site of nosocomial infection. Although there are no good data on risk of catheter-induced infections in children, in adult women the incidence of catheter-induced UTI ranges from 1% to 20% depending upon the circumstances of catheterization (Stamey, 1980). It has been documented that nosocomial UTI frequently complicates hospitalization in children, especially when urethral catheterization is performed (Dele Davies et al, 1992; Lohr et al, 1994), and this may be a reason to consider giving antimicrobial prophylaxis. On this basis, children who have hospital-acquired UTI, have urinary tract abnormalities, have recently been instrumented, or have had recent antimicrobial treatment are more likely to have infections caused by unusual and more antibiotic-resistant organisms (Ashkenazi et al, 1991).

When urethral catheters remain indwelling for longer than 4 days, bacteriuria is almost inevitable, because bacteria attach to the device surface and form biofilms of extracellular polymers, making these bound organisms resistant to routine antimicrobial treatment (Donlan, 2001). **Because the urinary tract is second only to the mouth as the source of bacterial endocarditis, the American Heart Association recommends bacterial endocarditis antimicrobial prophylaxis before urethral catheterization in individuals with a known urinary infection.** Cost-outcome analysis for bacterial endocarditis prophylaxis of febrile children with moderate cardiac lesions in an emergency room being evaluated for UTI shows no cost-benefit value (Caviness et al, 2004).

Endocarditis antimicrobial prophylaxis is not recommended, however, when urine is sterile. It is noteworthy that the British Society for Antimicrobial Chemotherapy revised their guidelines in 2006 and continue to recommend prophylaxis for prevention of enterococcal endocarditis for cystoscopy, urethral dilation, and transurethral procedures, whereas the American Heart Association in 2007 no longer recommended routine prophylaxis for gastrointestinal or urologic procedures with "uninfected tissues" (Pediatric Care Online, 2007; Wilson et al, 2007; Shanson, 2008).

In school-age boys, urethral self-manipulation with water injection or self-instrumentation can cause UTI (Labbé, 1990). About 25% of children who are victims of sexual abuse may complain of dysuria and urinary frequency, but these children rarely have UTI (Klevan and DeJong, 1990).

Key Points: Urinary Tract Infection Pathogenesis and Risk Factors

- Risk factors for bacteriuria and subsequent renal damage are distinct for individual hosts.
- Bacteriuria is most common at the extremes of life—infancy and old age.
- Blood group phenotypes found on the urothelial surface influence risk of UTI.
- Two risks for recurrent UTI in young women are age at first UTI of less than 15 years and UTI in the mother.
- Renal scarring is a risk factor for future renal scarring.
- Host genetic polymorphisms affect both UTI and scarring susceptibility.

DIAGNOSIS OF URINARY TRACT INFECTION

Rapid diagnosis of UTI is essential to initiating rapid antimicrobial treatment and preventing renal damage. In children who have no alternative fever source from history or physical findings, UTI accounts for greater than 5% of fevers (American Academy of Pediatrics, 1999a). In febrile infants (younger than 8 weeks), UTIs account for 13.6% of these fevers with the majority occurring in males (Lin et al, 2000). Young children may show only signs of generalized illness—fever, irritability, poor feeding, vomiting, and diarrhea. In a busy children's hospital emergency room, the **overall prevalence of UTI in febrile infants younger than 12 months and girls younger than 2 years with fever greater than 38.5° C and without other cause was 3.3%,** with higher prevalence in whites, girls, and uncircumcised boys; white girls had a UTI prevalence of 16.1% (Shaw et al, 1998a, 1998b).

Symptoms

UTI is a common cause of pediatric bacterial infection (Crain and Gershel, 1990; Bonadio et al, 1993; Hoberman et al, 1993). Fever accounts for about 20% of pediatric office visits (Eggli and Tulchinsky, 1993), and UTI causes 4.1% to 7.5% of these febrile episodes (American Academy of Pediatrics, 1999a).

Infants

In seriously ill infants and young children, one must suspect UTI and obtain a urinary specimen, even if signs may point elsewhere. Especially in febrile infants, from birth to 8 to 10 weeks, neither clinical symptoms nor laboratory tests will predict a presumptive UTI. Even if clinical symptoms suggest other sites of infection, this does not eliminate the likelihood of a UTI (Crain and Gershel, 1990).

The prevalence of UTI in febrile infants (younger than 8 weeks) is about 13.6%, with the majority occurring in males (Lin et al, 2000). **It is important to note that febrile infants not suspected of having a urinary source of infection are as likely of having a urinary source as those who are suspected of having a urinary source (5.1% vs. 5.9%). In infants with another possible fever source, such as otitis media, 3.5% also had a UTI** (Hoberman et al, 1993).

Young Children

As in infants, children less than 2 years old have UTI symptoms that are vague and generalized—fever, irritability, poor feeding, vomiting, diarrhea, and ill appearance (Ginsburg and McCracken, 1982) (Tables 116–2 and 116–3). **If one uses a clinical decision rule to decide which febrile young girls should be cultured for UTI, the presence of two of the following five variables may be useful: (1) age less than 12 months, (2) white race, (3) absence of other fever source, (4) fever greater than 39° C, and (5) fever of 2 days or more. Using these parameters, one can predict UTI with a sensitivity of 95% and specificity of 0.31 while avoiding 30% of unnecessary cultures** (Gorelick and Shaw, 2000).

Older Children

The older toilet-trained, talking child may indicate signs that better localize to the urinary tract, such as dysuria, suprapubic pain, voiding dysfunction, incontinence, or flank and/or abdominal pain. Many of these children still do not describe urinary tract symptoms, however. In children without localizing signs or with symptoms only vaguely referable to the urinary tract, suspicion must still be high to avoid missing the diagnosis.

Adolescents

Adolescents with lower urinary tract symptoms should not be treated as large children or young adults. Although *E. coli* is still the most common UTI in female adolescents, the second most common is *Staphylococcus saprophyticus,* and it may be associated with sexual activity and recurrent UTI (Huppert et al, 2007). In adolescent males, UTI may be associated with structural abnormalities and lower urinary tract symptoms with voiding dysfunction (unfortunately labeled prostatitis IIIb—noninflammatory, nonbacterial) (Li et al, 2006). Adolescent females with dysuria and frequency should be evaluated for both UTI and sexually transmitted infection (STI). **There are estimates that 50% of high school students have had at least one sexual encounter. The prevalence of *Chlamydia* is 13% to 26% and *Neisseria gonorrhea* is about 2% to 10% in this population.** For this reason, considering STI in this group (age 16 to 24 years) may be just as important, or more important, in considering UTI for the differential diagnosis (Claudius, 2000; Pimenta et al, 2000). A suggested marker for teenage sexual activity is UTI (Nguyen and Weir, 2002).

Sexually active adolescent females with urinary symptoms need evaluation for both UTI and STI with clean catch urinalysis, culture, and *Chlamydia* and *N. gonorrhea* testing (vaginal swab), because they can occur together. The U.S. Preventive Services recommends screening for chlamydial infection using urinary or vaginal swab nucleic acid amplification testing in sexually active young women age 24 years and younger, whether pregnant or nonpregnant. Individuals who have had previous chlamydial infection, other sexually transmitted infections, sex work, and inconsistent condom usage are at increased risk (U.S. Preventive Services Task Force, 2007). *N. gonorrhea* and *Trichomonas* (wet mount for *Trichomonas,* urinary nucleic acid amplification testing for *N. gonorrhea*) tests should be performed upon symptoms and the presence of urinary leukocytes, because these infections cause sterile pyuria that will not be discovered until cultures are negative days later. Although wet-mount microscopic examination for *Trichomonas* was available in the past, many practitioners have lost laboratory access due to regulation; so, *Trichomonas* culture or antigen tests may need to be ordered (Huppert et al, 2007). Rescreening in 3 months is recommended for patients in whom

Symptoms of Urinary Tract Infection in 100 Infants with Acute Urinary Tract Infections

SYMPTOM	PERCENTAGE
Fever	67
≥38° C	100
≥39° C	57
Irritable	55
Poor feeding	38
Vomiting	36
Diarrhea	36
Abdominal distention	8
Jaundice	7

Modified from Ginsburg CM, McCracken GHJ. Urinary tract infections in young infants. Pediatrics 1982;69:409–12.

testing is positive for *Chlamydia* or *Trichomonas* due to high risk for asymptomatic reinfection (Peterman et al, 2006). There are insufficient data to recommend screening in adolescent males (U.S. Preventive Services Task Force, 2007).

In this group of teenage females, untreated STI can progress to pelvic inflammatory disease in 10% to 40% with 12% infertility and an even greater possibility of chronic pelvic pain. One study documents that differentiating between females with culture UTI and those with STI on the basis of symptoms is not possible (Claudius, 2000); moreover, some had both infections (Huppert et al, 2007).

Physical Examination

There are no specific symptoms or signs for UTI in the infant. If there is a gross genitourinary anatomic abnormality, a renal mass may be palpable, as in children with xanthogranulomatous pyelonephritis or infected severe hydronephrosis. Palpation in the suprapubic and flank areas may cause pain in the older child, but generalized abdominal or upper quadrant pain may also be present. Perineal examination will rarely show an ectopic ureteral opening, ureterocele, or urethral discharge in girls. Signs such as back scars, sacral fat pads, or sacral dimples or pits may suggest a neurogenic bladder and may require further investigation. In boys, the testes are abnormal if affected by epididymitis or epididymo-orchitis.

Diagnostic Tests

Urinary Specimens

Good urinary specimens with which to make the diagnosis of UTI are hard to obtain in children, and diagnostic reliability depends upon the quality of the specimen. Routinely, four types of urinary specimens are obtained from children. **In order of least to most reliable for UTI diagnosis** (Hardy et al, 1976), **the specimen types are (1) a plastic bag attached to the perineum—a bagged specimen, (2) midstream void, (3) catheterized specimen, or (4) suprapubic bladder aspirate.**

Even after extensive skin cleansing, a plastic bag specimen usually reflects perineal and rectal flora and often leads to indeterminate results. Although an individual midstream-voided specimen in a circumcised boy, older girl, or older uncircumcised boy who can retract his foreskin can be reliable, such specimens obtained in young girls and uncircumcised boys usually reflect periurethral and preputial organisms and cells. A catheterized specimen is reliable if the first portion of urine, which may contain urethral organisms, is discarded, and the specimen is taken from later flow through the catheter. Catheterization has the disadvantages of being traumatic and potentially introducing urethral organisms into a sterile bladder (Dele Davies et al, 1992; Lohr et al, 1994).

Suprapubic bladder aspiration is the most reliable method. This procedure is performed safely in children and even premature infants with a full bladder. After cleaning the skin, a 21- or 22-gauge needle is introduced 1 to 2 cm above the pubic symphysis until urine is obtained by aspirating into a sterile syringe (Barkemeyer, 1994). Although unnecessary in most instances, in infants and young children, ultrasound guidance of suprapubic aspiration may aid the procedure (Buys et al, 1994), and also the use of topical and local anesthesia.

Because urine does not cross the urethra in the aspirated specimen, urethral or periurethral organisms are absent; skin contamination should be nil. **Organisms present in a suprapubic aspirate are pathognomonic of bacteriuria, and low bacterial counts are routine** (Buys et al, 1994). The main drawback of suprapubic aspiration is that needle aspiration may be distasteful and/or inconvenient to the older child, parent, or even physician, and these considerations are important (Kramer et al, 1994).

Generally, if a UTI is suspected in a child who is not yet toilet-trained, only a catheterized or needle-aspirated specimen is acceptable for diagnosis, because bagged urinary specimens have an unacceptably high false-positive rate. Under special collection circumstances, when the perineum is cleaned well and the bag removed and processed promptly after voiding, a bagged specimen, or even a diaper specimen, that shows no growth is useful in eliminating bacteriuria as a diagnosis (Ahmad et al, 1991; Whiting et al, 2005). **Plastic bag specimens are unreliable and unacceptable for *diagnosis* of UTI in high-risk populations and infants younger than 2 months** (Crain and Gershel, 1990).

Urinalysis

Four determinations from the urinalysis are advocated to support a UTI diagnosis: (1) microscopic urinary examination for white blood cells (WBCs)—pyuria, usually defined as greater than 5 white blood cells/high-power field (WBC/HPF) in a centrifuged specimen, (2) microscopic urinary examination for bacteria, defined as any bacteria per HPF in the unstained centrifuged urinary sediment, (3) urinary leukocyte esterase, and (4) urinary nitrite. The finding of red and white cell casts in the urinary sediment is unreliable.

Sensitivity of routine urinalysis for UTI is calculated to be 82% and is independent of age in children less than 2 years old, and the probability of a UTI with a negative urinalysis is based upon the patient-specific prevalence of UTI (Shaw et al, 1998b; Bachur and Harper, 2001b). The prevalence depends upon the child's age, race, sex, and temperature. Urinalysis findings that do not support a UTI, however, decrease the likelihood of a UTI fivefold (Bachur and Harper, 2001b).

Microscopic Examination

Although there are many confounding factors, the microscopic identification of bacteria in the urine is more sensitive and specific for diagnosing UTI than identification of pyuria (Hallender et al, 1986; Lohr, 1991). **Identification of bacteria under high dry magnification (450 to 570× magnification) represents about 30,000 bacteria per mL.** In a meta-analysis of screening tests, microscopic identification of any bacteria on Gram stain of uncentrifuged urine had the best combination of sensitivity and false-positive rates (Gorelick and Shaw, 1999). However, each of these tests separately has such low sensitivity in this high-risk population that neither is reliable.

In febrile children younger than 2 years, Hoberman and associates (1997) found that catheter-collected specimens had a positive predictive value for UTI diagnosis of 84.6% when microscopic examination showed bacteria (any bacteria on 10 oil-immersion fields in a Gram-stained specimen) and greater than or equal to 10 WBC/mm^3 (on enhanced urinalysis—not per HPF) (Hoberman and Wald, 1997). Although these two parameters offer predictive value, the office practitioner cannot perform either of these tests easily and rapidly without further instruction (enhanced

quantitative WBC count and Gram-stained bacteria on unspun specimen). **These investigators emphasize that UTI in these children is still best defined by a urinary leukocyte count of greater than or equal to 10/mm^3 and greater than or equal to 50,000 colony-forming units (CFU)/mL on culture** (Hoberman et al, 1994; Hoberman and Wald, 1997).

Urinary Leukocyte Esterase, Nitrite, and Other Chemical Tests

Several other "quick" tests that may be performed on urinalysis have been popular for trying to predict UTI. Urinary leukocyte esterase detects urinary enzymes produced by the breakdown of white cells in the urine and, as such, is dependent upon the presence of white cells that may or may not be present with the infection. The test may be less reliable in infants (Hoberman et al, 1994). **Dietary nitrates that are reduced to nitrite by many gram-negative urinary bacteria are measured by the urinary nitrite test. The fact that first morning-voided urinary specimens should be used for this test, because bacterial reduction of nitrate can take several hours and many gram-positive bacteria do not perform this reduction, are serious drawbacks.** Urinary catalase, an enzyme commonly produced by bacteria infecting the urinary tract, although sensitive, has too high a false-positive rate to be reliable (Waisman et al, 1999). Although these tests are rapid and efficient, they are even less reliable when the bacterial count is less than 100,000 CFU/mL. In a general pediatric population, when urinary specimens are properly collected and promptly processed, **the combination of positive leukocyte esterase and nitrite testing, and microscopic confirmation of bacteria, has almost 100% sensitivity for detection of UTI. When all (or leukocyte esterase and nitrite tests) are negative, the negative predictive value approaches 100%** (Wiggelinkhuizen et al, 1988; Lohr et al, 1993; Whiting et al, 2005). The arguments for and against relying upon urinalysis characteristics for presumptive diagnosis of a UTI are well summarized (Lohr, 1991; American Academy of Pediatrics, 1999a; Gorelick and Shaw, 1999; Whiting et al, 2005). Moreover, presumptive treatment when the dipstick shows at least 2+ leukocyte esterase or positive nitrite while the culture is obtained appears to be most cost effective as well (Shaw et al, 1998b). Although there is no test or combination of urinary tests that meets gold standard of culture, combinations of these tests may help suggest patients in whom culture will be positive and in whom presumptive treatment can be started.

Urinalysis cannot replace urinary culture. A risk-benefit analysis, based on the current literature about febrile children 3 to 24 months old, shows that one needs both urinalysis and culture to optimize prevention of end-stage renal disease and hypertension, (Kramer et al, 1994). A negative microscopic examination of urinary sediment for bacteria and white cells, negative leukocyte esterase, and negative nitrite are probably sufficient evidence to avoid culture (Whiting et al, 2005).

Serum Tests Indicating Urinary Tract Severity

Complete blood counts (Kramer et al, 1993), erythrocyte sedimentation rates (ESR), C-reactive protein (CRP), urinary concentrating ability (Åbyholm and Monn, 1979), urinary tubular enzymes (Johnson et al, 1990; Tomlinson et al, 1994), antibody-coated bacteria, urinary antibodies, and interleukins 6 and 8 (IL-6, IL-8) (Benson et al, 1994; Sheu et al, 2008; Zaki, 2008) have been examined as possible simple and noninvasive markers of renal infection (Buyan et al, 1993), but none are in widespread use.

C-reactive protein greater than 7 mg/dL has been associated with serious bacterial infection in febrile children age 1 to 36 months (Pulliam et al, 2001). Although the host urinary tract responds to bacterial infection with the production of cytokines, and IL-6 and IL-8 are secreted in response to *E. coli* attachment to the Toll-like receptors, it appears that this local response is then followed by a systemic increase in CRP and fibrinogen, temperature, and ESR (de Man et al, 1991). Some recommend that children who have UTI and fever longer than 2 days and CRP greater than 66.4 mg/L, or fever less than 2 days and CRP greater than 27.3 mg/L, should be treated for presumptive acute pyelonephritis if no DMSA scan is available (Huang et al, 2007). Recent examination of children diagnosed to have acute pyelonephritis has shown that both serum and urinary IL-6 and IL-8 are elevated when there is "upper tract" involvement and that elevated urinary IL-8 may be useful as a marker for pyelonephritis (Tullus et al, 1994; Sheu et al, 2006; Artifoni et al, 2007; Zaki, 2008).

Serum procalcitonin, a hormonally inactive precursor of calcitonin produced in the thyroid, is elevated in sepsis and appears to be in the systemic circulation only during severe inflammation. **Elevation of serum procalcitonin is reported to correlate better than ESR or CRP with pyelonephritis and to predict risk of renal scarring** and may be particularly useful in infants (Pecile and Romanello, 2007; Bressan et al, 2009; Kotoula et al, 2009). Still, this is a nonspecific systemic marker for severe infection.

Reduced urinary concentrating ability is associated with pyelonephritis, but this appears to be unassociated with the acute febrile response in pyelonephritis and is probably not a reliable sign for early detection of pyelonephritis (de Man et al, 1991). Unfortunately, none of these tests is reliable enough for early UTI detection or to differentiate between upper and lower tract infections or severity of infection for routine use.

Urinary Culture

The gold standard for the diagnosis of UTI is quantitative urinary culture. This requires that a known quantity of urine is plated onto a culture plate, and the number of bacterial colony-forming units that grow is counted and determined as CFU/mL. The interpretation of the culture results defining a UTI diagnosis, however, is debatable and dependent upon specimen quality. Because it may take 24 or more hours before bacterial colony-forming units grow and the culture is complete, indirect urinary tests that may be performed with routine urinalysis to detect the presence of bacteria or byproducts have been sought for a more rapid diagnosis.

Although greater than or equal to 100,000 CFU/mL of voided urine is the traditional definition for a clinically significant UTI (Kass and Finland, 1956), other studies have shown that less than or equal to 10,000 or fewer organisms on a voided specimen may indicate a significant UTI (Stamm et al, 1982; Bollgren et al, 1984). In febrile children younger than 2 years, Hoberman and associates (1994) showed that greater than or equal to 50,000 CFU/mL in catheterized specimens constitutes a significant UTI. Occasionally, even lower numbers of bacteria may justify diagnosis of a significant UTI, especially when the specimen is obtained by suprapubic needle aspiration, circumstances under which any number of organisms might be significant. Cultured colony-forming units per milliliter may be low because of hydrational dilution, frequent

voiding that prevents bacterial multiplication in the bladder, and bacterial growth characteristics.

Acute and Focal Pyelonephritis (Lobar Nephronia or Focal Bacterial Nephritis)

Symptoms and Signs

Children with pyelonephritis may have classic symptoms of fever, chills, and unilateral or bilateral flank pain with or without accompanying lower tract symptoms of dysuria, frequency, and urgency. They may complain of nonspecific abdominal discomfort and not complain of flank pain. Physical examination reveals fever usually accompanied by abdominal discomfort and pain over the costovertebral area.

The urine is usually cloudy and malodorous. Urinary sediment usually shows pyuria, white blood cell casts, and red blood cells. Bacterial rods are often present. Bacterial infection of the urinary tract causes bladder, ureteral, renal pelvic, and renal inflammation that alter urinary tract urodynamics and causes ureterectasis, elevated renal pelvic pressures, and renal inflammatory changes that may be associated with renal swelling (Hinman, 1971; Boyarsky and Labay, 1972; Issa and Shortliffe, 1992; Johnson et al, 1992).

Radiologic Findings

The discoveries that early renal cortical lesions from pyelonephritis can be detected by ^{99m}Tc-dimercaptosuccinic acid (DMSA) nuclear scan, and that these lesions correlate with histopathologic areas of acute renal inflammation in animal models, have advanced knowledge of the natural history of urinary tract bacteriuria (Wikstad et al, 1990; Rushton and Majd, 1992b; Giblin et al, 1993). Radiologic findings in acute pyelonephritis depend upon the imaging modality used. When intravenous urography was the main urinary tract imaging modality, the majority of patients had normal studies. Other modalities show renal enlargement related to inflammation and edema, focal renal enlargement (acute lobar nephronia or focal bacterial pyelonephritis), impaired or delayed excretion, and dilation of the urinary collecting system, findings that are commonly associated with acute infection. These acute changes affect renal and collecting system dilation and size, making the interval between the UTI and imaging evaluation an important consideration when a clinician evaluates renal size or shape. What appears to be a kidney of normal, or even enlarged, size and shape may be a scarred small one later (Hansen and Shortliffe, 1998).

Focal or general renal enlargement or swollen kidneys may be found in acute pyelonephritis. Renal ultrasonography, nuclear scans, and computed tomography (CT) may show generalized renal enlargement or focal hypo- or hyperechoic areas representing focal pyelonephritis (lobar nephronia). The latter represents a localized, severe nonliquefactive infection of one or more renal lobules (Greenfield and Montgomery, 1987; Klar et al, 1996; Wallin et al, 1997; Uehling et al, 2000). Other findings on ultrasonography include thickening of the renal pelvis, hypoechogenicity and focal or diffuse hyperechogenicity, and ureteral dilation (Mårild et al, 1989; Morin et al, 1999). **CT or power Doppler may show areas of decreased perfusion** (Dacher et al, 1996). High-resolution renal ultrasonography has been suggested to be almost as sensitive as DMSA scanning for diagnosing renal involvement in pyelonephritis (Dacher et al, 1996; Morin et al, 1999).

When DMSA-defined lesions are the standard for diagnosing acute pyelonephritis, about 50% to 86% of children (about 60% of kidneys) with febrile UTI and other clinical signs have renal involvement or pyelonephritis (Verber and Meller, 1989; Rushton and Majd, 1992b; Benador et al, 1994; Jakobsson et al, 1994). About half (38% to 75%) of these lesions persist on DMSA scans performed 2 months to 2 years later (Rushton and Majd, 1992b; Benador et al, 1994; Stokland et al, 1996), with fewer lesions persisting at longer intervals of follow-up. This suggests that as many as 40% to 50% of young children who have febrile UTI suffer renal scarring. In children older than age 1 year with first-time symptomatic UTI, 38% have DMSA-defined evidence of renal damage after 1 year, and almost half of these (47%) have reflux. **Children who have elevated CRP, fever, and dilating reflux have a 10-fold higher risk of renal damage than children with UTI who have a normal or slightly elevated CRP, no or mild fever, and no vesicoureteral reflux** (Stokland et al, 1996; Yen et al, 1999).

Pyonephrosis

Pyonephrosis is characterized by accumulation of purulent debris and sediment in the renal pelvis and urinary collecting system. Children with pyonephrosis have symptoms similar to acute pyelonephritis but have additional structural obstructive hydronephrosis. This situation usually implies bacterial infection and obstruction; so, rapid diagnosis and treatment is essential to avoid sepsis and parenchymal loss. Renal ultrasonography is usually diagnostic. The majority of obstructed pyonephrotic kidneys are either nonfunctioning or poorly functioning. **The renal sonogram may show shifting fluid-debris levels with changes in the patient's position, persistent echoes from the lower collecting system, air in the collecting system, or weak echoes secondary to pus in a dilated poorly transonic renal collecting system** (Coleman, 1985). If performed, retrograde pyelography shows ureteral obstruction and irregular renal pelvic filling defects caused by purulent sediment. When it is possible to pass a ureteral catheter past the obstruction, drainage becomes both diagnostic and therapeutic. The treatment for pyonephrosis is administration of appropriate antimicrobial drugs and prompt drainage of the infected pelvis by either retrograde catheterization or nephrostomy placement. When the acute infection is treated and the patient is on appropriate antimicrobial agents, further evaluation to identify and treat the obstruction may be necessary.

Perinephric or Renal Abscess

Improvements in imaging of the genitourinary tract and widespread use of powerful antimicrobial agents have changed the evaluation and natural history of perinephric and renal abscesses (Shortliffe and Stamey, 1986a). In the past, the high mortality rate from perinephric abscesses related, in part, to diagnostic delay. Perinephric and renal abscesses are uncommon in children. These abscesses arise from either hematogenous seeding from extragenital sites of infection or renal extension of ascending urinary infections. **Since the introduction of broad-spectrum and powerful antimicrobial agents in the 1940s, the percentage of perirenal abscesses caused by staphylococci decreased from 45% before 1940 to 6% after 1940, and those attributed to *E. coli* and *Proteus* rose from 8% to 30% and 4% to 44%, respectively** (Thorley et al, 1974). This large decrease in perirenal and renal abscesses caused by staphylococci may relate to the advent of antimicrobial agents discovered to treat skin and wound abscesses (Thorley et al, 1974;

Shortliffe and Stamey, 1986a). Children with renal and perirenal abscesses have severe pyelonephritis—fever, flank pain, leukocytosis, and occasionally sepsis. With the frequent use of renal ultrasonography for evaluation of such symptoms and characteristic findings, diagnosis is now easier and earlier. Because most abscesses have a fluid component, perinephric collections usually appear sonolucent, and diagnostic aspiration of this area usually carries minimal morbidity. Computed tomography will assess the extent and may show perirenal fluid or gas, renal distortion, and involvement of the retroperitoneum (Hoddick et al, 1983). **Although *Staphylococcus aureus* with antecedent skin lesions may have been the most common cause of renal abscesses in children and adults more than 2 decades ago** (Rote et al, 1978), **gram-negative organisms (*E. coli*) are now the most common cause.** These are more likely associated with retrograde extension of ascending infection in relation to severe pyelonephritis and genitourinary anomalies (Rote et al, 1978; Steele et al, 1990; Barker and Ahmed, 1991; Vachvanichsanong et al, 1992). Anaerobic bacteria may cause perinephric or renal abscesses in association with previous abdominal surgery, renal transplant, malignancy, and oral or dental infection (Brook, 1994).

Current systemic antimicrobial agents allow successful treatment of some abscesses with antimicrobial therapy alone without surgical intervention. In many cases, however, percutaneous or surgical drainage combined with appropriate antibiotic therapy is required (Rote et al, 1978; Steele et al, 1990; Vachvanichsanong et al, 1992).

Key Points: Urinary Tract Infection Diagnosis

- Febrile infants unsuspected of having a UTI are as likely of having a UTI as those who are suspected to have a UTI.
- In adolescents, UTI is a possible marker for teenage sexual activity, and they should be evaluated for STI.
- Any organisms present in a suprapubic urine aspirate are pathognomonic of bacteriuria; low bacterial counts are routine.
- Plastic bag specimens are unreliable and unacceptable for UTI diagnosis in high-risk populations and infants.
- Identification of bacteria under high dry microscope field represents about 30,000 bacteria/mL.
- C-reactive protein greater than 7 mg/dL is likely to be associated with serious bacterial infection in febrile children to age 3 years.
- In acute pyelonephritis, focal or general renal swelling may be found in imaging tests.
- Children with elevated CRP, fever, and dilating reflux have 10 times the risk of renal damage than those with these elements absent.
- Gram-negative organisms are now the most common cause of renal abscesses, in contrast to *S. aureus* being the most common 3 decades ago.

MANAGEMENT OF PEDIATRIC URINARY TRACT INFECTIONS

The therapeutic strategy in managing pediatric UTI is first to minimize renal damage during the acutely diagnosed UTI and second to minimize risk of future renal damage from subsequent infections. Rapid recognition of a UTI and rapid, appropriate antimicrobial treatment are crucial to preventing renal damage. As discussed earlier, clinical and experimental data show that early antimicrobial treatment appears to be the most effective means of preventing renal scarring and subsequent complications.

Treatment of Acute Urinary Tract Infections

Infants (Children Younger Than 90 Days)

In UTI treatment, infants and children younger than 90 days are treated differently than older children. Children younger than 90 days are more likely to have their course of disease change rapidly because of their physiology and incompletely developed immune system. There have been documented studies that emphasize immune deficiencies or alterations in neonatal T, B, and antigen-presenting cells compared with adult cell behavior (Adkins et al, 2004). Moreover, infants have vague and nonspecific symptoms of illness that are difficult to interpret. Most commonly, children are seen with growth failure, diarrhea, irritability, lethargy, malodorous urine, fever, oliguria, or polyuria.

Because UTIs are a common cause of fever in infants, with a prevalence of 5% to 11%, consideration of UTI diagnosis and management is important. In these children with "occult" serious bacterial infection, C-reactive protein (Pulliam et al, 2001), absolute neutrophil count greater than 10.6×10^9/L (Isaacman and Burke, 2002), and asymptomatic jaundice (Garcia and Nager, 2002) may be present. **It is recommended that testing for UTI be part of the evaluation of asymptomatic jaundice that occurs in an infant younger than 8 weeks, especially with onset after 8 days of life** (Garcia and Nager, 2002). Other risks for infantile UTI are lack of circumcision, female sex, and fever lasting longer than 24 hours (Newman et al, 2002). For febrile infants younger than 90 days, UTI (67%) is one of the common causes of serious bacterial infection (Byington et al, 2003). Although those younger than 1 month are commonly hospitalized for treatment, those between age 30 to 90 days have been managed as outpatients. Although antibiotic prophylaxis against group B *Streptococcus* during pregnancy has decreased serious neonatal infections with this organism, in many communities increasing numbers of pathogens are ampicillin resistant. In one study from Utah Children's Hospital, **ampicillin-resistant gram-negative bacteria are the most common cause of serious bacterial infection in infants younger than 3 months** (Byington et al, 2003). This resistance must be taken into consideration for judicious and effective treatment.

Treatment depends upon the child's age and severity of illness. In the child younger than 2 to 3 months, particularly 30 days or younger with a presumptive serious bacterial infection and possibly a UTI, consideration must be given to antimicrobial coverage of *Listeria monocytogenes* (perinatally acquired) and *Enterococcus* (usually postnatally acquired) in which ampicillin gives coverage, thus making ampicillin and gentamicin recommended in this age group (Brown et al, 2002).

Others recommend that, for children younger than 60 days, a third-generation cephalosporin may replace ampicillin with or without gentamicin unless meningitis or gram-positive UTI is suspected, because of the unlikelihood of *Listeria* and the high resistance rate of other gram-negative organisms. **However, because *Enterococcus* UTI still occurs in this group, this is not appropriate when UTI is suspected** (Sadow et al, 1999). Other young children who are suspected to have UTI and are severely systemically ill (or have a fever and flank or abdominal

Table 116–4.

Potentially Useful Antibacterial Drugs for Urinary Tract Infection (UTI)

UTI SEVERITY	ADULT DOSAGE*	PEDIATRIC DOSAGE†	MODE
Urinary Tract Sepsis			
THIRD-GENERATION CEPHALOSPORIN ± AMINOGLYCOSIDE			
Cefotaxime (Claforan)		50-180 mg/kg/day (q4-6h)	
Ceftriaxone (Rocephin)		50-75 mg/kg/day (q12-24h)	
Ceftazidime (Fortaz, Tazicef, Tazidime)		90-150 mg/kg/day (q8-12h)	
PENICILLIN GROUP (E.G., ENTEROCOCCUS SUSPECTED) ± AMINOGLYCOSIDE		50-100 mg/kg/day (q4-8h)	
Ticarcillin/clavulanate (Timentin)	200-300 mg/kg/day	50-200 mg/kg/day (q4-8h)	
Aminoglycosides			
Gentamicin		7.5 mg/kg/day (q8h)	
Tobramycin			
Amikacin		7.5 mg/kg/day (q8h)	
Aztreonam (Azactam)		90-120 mg/kg/day (q6-8h)	
Vancomycin *(if penicillin allergy)*	2 g/day (q6h)	10 mg/kg/dose (q6h)	
Acute Uncomplicated Pyelonephritis			
Fluoroquinolones			
Ciprofloxacin (Cipro)	500-1500 mg/day (q12h)	20-40 mg/kg/day (q12h)‡	PO
Amoxicillin/clavulanate (Augmentin)		20-40 mg/kg/day (q8h)	PO
Third-generation cephalosporin			PO
Uncomplicated UTI			
Trimethoprim (TMP)-sulfamethoxazole			
Generic (400 mg/80 mg)	4 tablets/day (q12h)	8 mg/kg/day (TMP) (q12h)	PO
Double strength (DS) (800 mg/160 mg)	2 DS tablets/day (q12h)		PO
Amoxicillin/clavulanate (Augmentin)		20-40 mg/kg/day (q8h)	PO
Cephalosporin			
Cephalexin (Keflex)	1-4 g daily (q6-12h)	25-50 mg/kg day (q6-12h)	PO
Cefixime (Suprax)	400 mg/day	8 mg/kg/day (q12-24h)	PO
Nalidixic acid	4 g/day (qid)	55 mg/kg/day (qid)	PO
Fluoroquinolones			
Ciprofloxacin (Cipro)	500-1500 mg/day (q12h)	20-40 mg/kg/day (q12h)‡	PO
Nitrofurantoin			
Nitrofurantoin (generic, Macrodantin)	200-400 mg/day (q6h)	5-7 mg/kg/day (q6h)	PO
Macrobid	200 mg/day (q12h)	>12 yr 200 mg/day (q12h)	PO

*Dosage may need to be adjusted for renal or hepatic insufficiency.
†Safety indications and dosage should be checked for children younger than 3 months, and dosage may need adjustment for renal or hepatic insufficiency.
‡Not to exceed 750 mg/dose even in children weighing >51 kg.
Adapted from Abramowicz M. Drugs for bacterial infection. Med Lett 2010;8:43–55; and Lindert KA, Shortliffe LMD. Evaluation and management of pediatric urinary tract infections. Urol Clin North Am 1999;26:719–28.

pain), are unable to take fluids, and are immune compromised, should be treated with parenteral broad-spectrum antimicrobial agents (e.g., aminoglycoside and ampicillin, third-generation cephalosporin, aminoglycoside, and cephalosporin) (Table 116–4), with aminopenicillin/clavulonic acid used because of widespread ampicillin resistance (Prelog et al, 2008). Whether this child requires hospitalization or outpatient parenteral or oral treatment depends upon the clinical status.

Children and Outpatient Therapy

In appropriate infants and young children with presumptive febrile UTI who are taking fluids, who have cooperative and reliable parents, and with whom daily contact is possible, some of the newer third-generation cephalosporins, such as **ceftriaxone, allow once-daily outpatient parenteral therapy** (Baskin et al, 1992; Gordon, 1991). Most of these third-generation cephalosporins have a broad spectrum, treat *Enterobacter* species and some *Pseudomonas aeruginosa,* and conveniently require only once- or twice-daily dosing. It must be emphasized that ***Enterococcus is still resistant to most third-generation cephalosporins.*** **Meta-analysis of available randomized evidence recommends adoption of a once-daily dosing of aminoglycosides in children; this minimizes cost, may improve efficacy and safety, and allows day or potentially outpatient treatment** (Contopoulos-Ioannidis et al, 2004). It may be that efficacy of once-daily dosing for treatment of urinary tract infections stems from the fact that serum aminoglycoside drug levels so often targeted in treatment of bacteremia are unnecessary in the treatment of urinary tract infections without associated sepsis. As the drugs are concentrated during excretion in the kidney and urine to levels many times those achieved in the serum, lower serum levels may be achieved with treatment efficacy. There is little evidence that gentamicin is likely to permanently affect those with reduced residual renal function (Baker et al, 2003).

Because the antimicrobial spectrum varies slightly for each of these drugs, the environment and local ecology (e.g., community-acquired outpatient versus hospital-acquired UTI)

should determine drug selection. National and local antimicrobial resistance to common organisms that commonly infect the urinary tract must be considered in the selection of both the agent for initial treatment and that for prophylaxis. Generally, parenteral treatment continues for 2 to 4 days until fever is gone, the child is able to take adequate fluids, and bacterial sensitivities are available to allow treatment with an oral drug with a narrow spectrum.

The clinical response to treatment also depends upon the severity and rapidity of treatment. In children age 2 years or younger (median 5.6 months) who were hospitalized with a diagnosis of febrile UTI, **89% (of 288 children) were afebrile 48 hours after parenteral antimicrobial agents were started even if bacteremia or significant genitourinary abnormality was found** (Bachur, 2000). **The median time to attain a normal temperature was 13 to 16 hours.**

Although the duration of treatment is debatable, in most studies involving treatment of febrile UTI in young children, total duration of therapy has extended from 7 to 10 days. When culture and sensitivity information are available, the antimicrobial agent should be re-evaluated and changed if necessary, and treatment continued for 7 to 10 days. In most cases, an oral drug with a narrower spectrum, but to which the organism is sensitive, can be selected. **Analysis has shown that no follow-up urinary culture after 48 hours is required, if organisms are sensitive to the antibiotic selected** (Currie et al, 2003)**.**

Less-ill older infants and young children who have presumptive febrile UTI and are capable of taking fluids and oral medicines may be treated with an antimicrobial agent that has a broad spectrum for genitourinary pathogens. Although the newer oral cephalosporins have good gram-positive and gram-negative treatment spectra and need only once- or twice-daily dosing, many *Enterococcus, Pseudomonas,* and *Enterobacter* species may be resistant to treatment (Fennell et al, 1980; Ginsburg et al, 1982; Ginsburg and McCracken, 1982; Dagan et al, 1992; Stutman, 1993). **In a recent multicenter randomized clinical trial, oral cefixime appeared as effective as initial intravenous cefotaxime in children with febrile UTI at age 1 to 24 months** (Hoberman et al, 1999).

In adults, the quinolones are useful because of their broader antimicrobial spectrum and special activity against *Pseudomonas aeruginosa,* but in children, usage of this drug has been limited because of studies showing quinolone-induced cartilage toxicity in young animals. With careful monitoring, limited quinolone usage has shown no cartilage-related toxicities. In situations such as an abnormal urinary tract with upper tract *Pseudomonas aeruginosa*, there may be good indication for usage (Schaad, 1991). In 2005, the quinolones were not yet approved for the treatment of pediatric UTI, but clinical trials are examining pediatric safety and efficacy issues, and they are more widely used in children. In adult women, amoxicillin-clavulanate is less effective than ciprofloxacin for treatment of uncomplicated cystitis for the possible reason that ciprofloxacin is more likely to eradicate vaginal *E. coli* (Hooten et al, 2005). Because young children are less likely to be sexually active, vaginal colonization may be less important in the pathogenesis.

As with other effective antimicrobial agents, resistance to quinolones is rising. In one report from Spain in 1995, 6.4% of *E. coli* UTIs were resistant to ciprofloxacin (Ena et al, 1995). Risk for resistance was related to urinary tract abnormalities, previous quinolone treatment, urinary catheterization, and being age 65 years or older. In Colorado, 9% quinolone resistance was reported with risks for resistance being hospitalization and previous levofloxacin exposure (Johnson et al, 2008b). Quinolone resistance in other organisms unrelated to UTIs has led to the U.S. withdrawal of approval for addition of these drugs in animal feed in 2005.

School-Age Children

In school-age children who do not appear systemically ill and have a "clinically uncomplicated bladder infection," many oral broad-spectrum antimicrobial agents that are well tolerated will cure the "uncomplicated" UTI in a course of 3 to 5 days; there are no clinical advantages to longer therapy (Lohr et al, 1981; Copenhagen Study Group of Urinary Tract Infections in Children, 1991; Jójárt, 1991; Gaudreault et al, 1992). In some of these children, single-dose treatment, particularly with intramuscular aminoglycoside, may be curative and cause less fecal antimicrobial resistance (Grimwood, 1988; Khan, 1994), but, **in unselected children, single doses may not be quite as effective as 3 to 5 days of treatment** (Madrigal et al, 1988; Khan, 1994). Although these trials appear to show that shorter therapy of 3 to 5 days may be as effective as 7 to 14 days, a **meta-analysis of trials involving 3- to 5- versus 7- to 10-day therapy shows that longer therapy is more effective. They attribute their findings to the fact that in children, unlike adults, urinary tract abnormalities or vesicoureteral reflux may require longer treatment** (Keren and Chan, 2002).

"Switch Therapy"

"Switch therapy," intravenous therapy followed by oral therapy, is commonplace in adults and becoming common in children. **A large series of children age 3 months to 5 years had successful treatment of febrile UTI with intravenous gentamicin 5 mg/kg/day once-daily until afebrile (2 to 4 days) given in a day treatment center of a tertiary-care hospital, followed by oral antibiotic for a total of 10 days** (Gauthier et al, 2004). Similar findings were reported in a randomized trial between once-daily intravenous treatment with ceftriaxone for 3 days versus 10 days followed by oral cefixime for 15 days (Benador et al, 2001).

Antimicrobial Agent Selection

Common uropathogens are increasingly resistant to trimethoprim-sulfamethoxazole and ampicillin. This should be considered when prescribing initial antimicrobial therapy for UTI. The prevalence of uropathogen resistance to trimethoprim-sulfamethoxazole has increased from 8% in 1992 to greater than 16% in 1996 (Gupta et al, 1999), with *E. coli* resistance as high as 32% (range of 0% to 46%) in the western United States (Talan et al, 2000). Resistance to ampicillin is reported to range from 25% to 45% in recent years (Dyer et al, 1998; Gupta et al, 1999, 2001). **Predictors of situations in which uropathogens will be more likely resistant to commonly used agents are diabetes, recent hospitalization, recent use of antibiotics (especially trimethoprim-sulfamethoxazole)** (Wright et al, 1999), **and presence of urinary malformations, urethral catheters, and antimicrobial prophylaxis** (Ashkenazi et al, 1991).

Nitrofurantoin attains high urinary concentrations and low serum concentrations, and, as such, is a poor choice to treat any severe systemic or renal infection but is ideal for treating a bladder UTI when there is a normal urinary tract. **Resistance rates to nitrofurantoin have changed little over the past decade** (Kashanian et al, 2008). **After the therapeutic regimen for acute UTI, the child may be started on a daily prophylactic antimicrobial agent until radiologic evaluation of**

the urinary tract can be performed in the next days to weeks.

PROPHYLACTIC ANTIMICROBIAL AGENTS

Giving daily antimicrobial agents to prevent recurrent urinary tract infections in children who have a 30% to 40% chance of recurrence within a year is rational if this prevents significant morbidity and renal damage; however, no definitive trials to examine efficacy of UTI prevention using this management for vesicoureteral reflux and hydronephrosis have been performed. Antimicrobial prophylaxis to prevent UTI was originally suggested for women and girls who had a history of recurrent (two or more UTIs within 6 to 12 months); it was not intended for individuals who had never had UTI (e.g., prenatally diagnosed vesicoureteral reflux or hydronephrosis) or for those with a single UTI. Nonetheless, retrospective data show that reflux nephropathy is less likely in children with high-grade vesicoureteral reflux who present without UTI (Sweeney et al, 2001). Review of the few trials of randomized studies of children involving prophylactic antibiotics offer inadequate data to definitively support prophylaxis (Le Saux et al, 2000; Thompson et al, 2001; Williams et al, 2001a, 2001b; Wheeler et al, 2003; Fanos and Cataldi, 2004; Conway et al, 2007). **A systematic review and meta-analysis of studies in 2006, concludes, moreover, that data are of low quality and do not give definitive evidence that prophylaxis prevents recurrent symptomatic UTI** (Williams et al, 2006). **Two randomized prospective studies published since the meta-analysis, including one of children with and without vesicoureteral reflux, also found no preventive benefit from prophylactic antimicrobial agents** (Garin et al, 2006; Roussey-Kesler et al, 2008). In children, antimicrobial prophylaxis is most commonly used to prevent UTI in the situations listed in Table 116–5. Although urinary tract prophylaxis has been used and shown to decrease infections over a limited period in select groups of children with vesicoureteral reflux (Hansson et al, 1989d), long-term efficacy compared with adequate patient supervision, (Cascio et al, 2001) surveillance, and education has not been studied with randomization and proper patient stratification (Bollgren, 1999; Thompson et al, 2001). In some situations, such as partially obstructive hydronephrosis, the efficacy of prophylaxis is not established.

The use of antimicrobial prophylaxis with clean intermittent catheterization is controversial, and some of the considerations are discussed in the section Neurogenic and Bowel-Augmented Bladders. The use of nightly urinary tract antibiotic prophylaxis in children without known urinary tract abnormalities who suffer recurrent UTI is often successful in decreasing symptomatic UTI, and so is postintercourse prophylaxis in teens who suffer apparent postcoital "induced" UTI (Pfau and Sacks, 1994; Vosti, 2002).

It has been suggested that circumcision be performed to remove bacterial colonization of the prepuce (uncircumcised penis) in infant boys with vesicoureteral reflux and severe hydronephrosis, because one report states antibiotic prophylaxis is ineffective: Periurethral swabs grew uropathogens in 37% of boys (mean 2.5 years) taking prophylaxis (Cascio et al, 2001). Although periurethral colonization is a risk factor for UTI, it is unclear how prophylaxis was managed and unlikely that the only role of prophylaxis is in clearing the periurethral area of organisms (Cascio et al, 2001). Moreover, benefits of prophylactic circumcision are controversial.

Once urinary tract antimicrobial prophylaxis is initiated, duration is unclear. Prophylaxis may be stopped when resolution of the urinary tract abnormality occurs (e.g., spontaneous or surgical resolution of vesicoureteral reflux or obstruction).

When resolution does not occur within a few months to years, however, the time for stopping prophylaxis becomes indeterminate. Because evidence exists that renal scarring in girls with pyelonephritis may be less likely after 5 to 6 years of age, and may occur less frequently until age 15 to 16 years (see Renal Scarring), it is reasonable to try stopping prophylaxis when a patient reaches age 5 to 8 years or older, especially when he or she has no history of UTI and no renal scarring. Although select groups of children have been followed for a few years after stopping prophylaxis, and they have generally done well without evidence of urinary tract infections or new scars, these studies are limited by lack of randomization, short follow-up, and/or small numbers (Cooper et al, 2000). Although many antimicrobial agents treat UTI, the efficacy, microbiology, and pharmacology of few antimicrobial agents used for prophylactic effect have been examined in children.

The ideal prophylactic agent should have low serum and high urinary concentrations, minimal effect on the normal fecal flora, be easily administered and tolerated, and be cost effective. The potency of these antimicrobial agents is based upon the general susceptibility of most fecal Enterobacteriaceae to these agents at urinary levels. Because these agents are generally concentrated in the urine, the urinary drug levels should be much higher than the drug levels found simultaneously in serum, gut, or tissue, and, if sufficiently low, antimicrobial resistance patterns should not develop in the gut. In some instances, this characteristic of the prophylactic antimicrobial agents may be dose related, so that inappropriately high dosing for prophylaxis is less effective rather than more effective, because bacterial resistance is created (Martinez et al, 1985).

A difficulty in determining prophylaxis efficacy is dose selection. Although adequate urinary levels are required for bactericidal activity, how many hours per day these levels must persist is unknown. In an unusual urinary bioassay study of pediatric prophylaxis, after a single prophylactic evening dose, cotrimoxazole and cefixime sustained bactericidal effect for about 60% of a 24-hour day, with much shorter effects for nalidixic acid and cephalexin (Pomeranz et al, 2000). It is unclear, however, whether a shorter-lived, lower urinary concentration would achieve better prophylaxis with less likelihood of creating bacterial resistance. There is also evidence that commonly selected antibiotics may have different absorption and metabolism patterns in children than in adults (Rylance et al, 1985; Hoppu, 1987; Pomeranz et al, 2000).

Table 116–5.

Indications for Urinary Tract Antimicrobial Prophylaxis

Vesicoureteral reflux
Unstable urinary tract abnormality (e.g., partial urinary tract obstruction)
Normal urinary tract but frequent reinfections
After acute UTI awaiting radiologic evaluation
Urethral instrumentation
Immunosuppressed or immunocompromised status
Infants with first UTI before 8-12 weeks of age
Clean intermittent catheterization and vesicoureteral reflux (?)

UTI, urinary tract infection.

In any case, the parent who doubles or triples the dose of prophylactic antimicrobial agent each time their child develops the slightest symptom or cold may be destroying the prophylactic value of the agent and creating greater bacterial resistance with a higher likelihood of a break-through infection with a resistant organism. Another consideration is that long-term patient compliance with daily prophylaxis may be difficult (Smyth and Judd, 1993).

Because urinary prophylaxis is usually initiated following treatment of an infection for which long-term (10 days) high-dose treatment was given, the fecal flora is usually resistant to the treatment drug and many of the prophylactic agents. The child who is very susceptible to urinary infections is likely to become reinfected with an organism resistant to the prophylactic agent before the gut is repopulated with more normal flora. This accounts for frustrating "break-through" infections that occur when the child is on prophylactic antimicrobial agents or after treatment of other frequent infections such as otitis media. **The period of greatest risk of recurrent infection is usually the first few weeks after any full-dose treatment. This is the reason why the therapeutic antimicrobial agent should not be the prophylactic agent.** In children with normal urinary function, useful agents for urinary prophylaxis are nitrofurantoin, cephalexin, and trimethoprim-sulfamethoxazole (Brendstrup et al, 1990). In toilet-trained children, urinary tract prophylactic antimicrobial drugs may be best given once nightly, when they will be excreted into and remain in the urine overnight.

The long-term effects of prophylactic agents on the child and their microbial ecology are incompletely examined. A literature review of nitrofurantoin and trimethoprim-sulfamethoxazole prophylaxis in children supports long-term safety (Karpman and Kurzrock, 2004). A question relating antibiotic usage and breast cancer in women was raised following an epidemiologic study of the two entities; however, data relating the two entities are equivocal, and further exploration of this information is needed before a clear conclusion can be drawn (Sørensen et al, 2004; Velicer et al, 2004). Although there is some evidence that antibiotics that lack systemic absorption and are excreted only in the urine may result in less overall bacterial resistance and change to human microbial ecology than systemic agents, long-term studies are lacking (Gribble and Puterman, 1993; Johnson et al, 1994; Sandock et al, 1995; Schlager et al, 1998).

Nitrofurantoin

Nitrofurantoin is an effective urinary prophylactic agent because its serum levels are low, urinary levels high, and it produces minimal effect upon the fecal flora (Winberg et al, 1973). Its effect is based upon urinary excretion of the antimicrobial once daily and is found to be effective in girls at doses of 1.2 to 2.4 mg/kg given each evening (Lohr et al, 1977). When renal function is less than half of normal, the efficacy of nitrofurantoin may also be reduced.

The majority of nitrofurantoin drug reactions occur in adults; it has caused acute allergic pneumonitis, neuropathy, and liver damage (Holmberg et al, 1980). Long-term treatment has been associated with rare cases of pulmonary fibrosis. **Children with glucose-6-phosphate dehydrogenase deficiencies should not take nitrofurantoin, because it is an oxidizing agent that can cause hemolysis.** About 10% of African-Americans, Sardinians, non-Ashkenazi Jews, Greeks, Eti-Turks, and Thais may have a glucose-6-phosphate deficiency, and in these persons, regeneration of glutathione, which is partially responsible for maintaining red blood cell integrity, is impaired by the enzyme deficiency. When nitrofurantoin is given, it oxidizes the hemoglobin to methemoglobin, which is degraded (Thompson, 1969).

E. coli resistance to nitrofurantoin at one institution was 2.3%, whereas resistance to the quinolones was about 24% (Kashanian et al, 2008).

Cephalexin

Cephalexin was studied in adults as a prophylactic agent (Martinez et al, 1985). **Although fecal Enterobacteriaceae resistance has developed in many patients taking full-dose cephalexin (500 mg 4 times daily), patients taking low-dose (one quarter to one eighth the adult daily dose, 250 to 125 mg/day) do not appear to develop resistance.** Cephalexin at one quarter or less of the treatment dose per weight may be a useful pediatric prophylactic agent.

Trimethoprim-Sulfamethoxazole

Trimethoprim-sulfamethoxazole has been a successful combination drug in the treatment of UTI and useful for prophylaxis at a dose of approximately 2 mg/kg of trimethoprim (Grüneberg et al, 1976; Stamey et al, 1977). The trimethoprim has the unusual characteristic of diffusing into the vaginal fluid and therefore decreasing vaginal bacterial colonization in the female (Stamey and Sexton, 1975). **Because the trimethoprim-sulfamethoxazole combination contains a sulfonamide, it probably should not be used in the first few months of life; sulfonamides may compete for bilirubin binding sites on albumin and cause neonatal hyperbilirubinemia and kernicterus.** As previously mentioned, there has been a significant increase in the bacterial resistance rate seen for this drug over the past decade, making it less useful than previously.

Trimethoprim

Initial studies performed in adult women found trimethoprim (dose approximately 2 mg/kg once nightly) to be as effective as trimethoprim-sulfamethoxazole and nitrofurantoin in preventing recurrent UTI (Stamm et al, 1980). In contrast, other studies show rapid emergence of significant trimethoprim-resistant *E. coli* during either treatment or prophylaxis (Huovinen and Toivanen, 1980; Brogden et al, 1982; Murray et al, 1982; Murray and Rensimer, 1983; Brumfitt et al, 1985; Brendstrup et al, 1990).

Studies examining emergence of resistance are controversial. In one study after 14 days of trimethoprim 200 mg daily, 96% of the trimethoprim-resistant *E. coli* isolated from the fecal flora were resistant to at least four other antimicrobial agents (Murray et al, 1982), emphasizing the need for concern regarding resistance and spread of multidrug resistance. **A clinical trial in children examined the efficacy of nitrofurantoin and trimethoprim prophylaxis in preventing recurrent UTI and showed nitrofurantoin to be more effective as prophylaxis when used in association with urinary tract abnormalities or vesicoureteral reflux** (Brendstrup et al, 1990). Nitrofurantoin prophylaxis did not change the resistance pattern in uropathogens causing subsequent UTI, whereas those on trimethoprim prophylaxis developed a breakthrough UTI with an organism resistant to the drug in 76%.

With the recent distribution of liquid trimethoprim approved for treatment of acute otitis media in children and possible wider

usage, judicious use may prevent a repetition of previous antimicrobial resistance.

Nalidixic Acid

Nalidixic acid was used to treat children before the advent of more powerful quinolones; however, testing of the newer quinolones (e.g., norfloxacin, cinoxacin, ciprofloxacin) showed these drugs to cause cartilage erosion in weight-bearing joints and arthropathy in immature animals. In limited groups of children treated with quinolones, there have not been these problems (Schaad, 1991). A study examining quinolones in children was performed, but the results are unknown at this time.

Probiotic and Naturopathic Treatments

Study of human infectious disease requires understanding of the normal human microbiota—the microorganisms living on and within the human body. The combination and interplay between these microorganism genomes and the human genome (together called the microbiome) requires a complex interchange and balance in which the "normal" microbiota forms part of normal bodily function. Microbial imbalance or invasion with abnormal organisms creates infection or disease (Turnbaugh et al, 2007).

Concerns about the growing rate of bacterial resistance and possible antimicrobial therapy–associated conditions, such as childhood allergy, has stemmed interest in dietary, probiotic, and alternative therapies to routine antimicrobial agents for UTI treatment and potential prevention. Because the rectal bacterial flora is the bacterial reservoir for UTI, investigators have attempted to manipulate the organisms. As such, **probiotic therapy refers to a concept in which live organisms are given to patients for therapeutic benefit, often as food or dietary supplements**.

Although the entire mechanisms of action of most probiotic organisms are undiscovered, they are generally nonpathogenic and nontoxigenic organisms. They are characterized by their ability to survive transit through the gastrointestinal system by adherence to gut epithelium or mucus. These microorganisms protect against pathogenic organisms by competitive exclusion, secretion of adhesion or growth-inhibitory products that have antimicrobial effects, alteration of the host immune status, or contribution to host nutritional status (Vanderhoof and Young, 2002; Macfarlane and Cummings, 2002; Kontiokari et al, 2004; Servin, 2004; Jones and Versalovic, 2009; Lim et al, 2009). Yeast, bacilli, *E. coli*, enterococci, bifidobacteria, and *Lactobacillus* trials have had variable success.

Investigation has shown that certain undigested portions of food, usually nondigestible carbohydrates (oligosaccharides), may be consumed by certain gut microbiota, especially probiotic organisms, and encourage their growth. These molecules are **prebiotics** (Chen and Walker, 2005; Hord, 2008).

Both prebiotic and probiotic agents have been used to alter allergic reactions, infectious or postantibiotic diarrhea, infant necrotizing enterocolitis (Lin et al, 2005), urinary tract infections (Czaja et al, 2007), and adult female vaginosis (Reid, 2008). In the area of UTI, probiotic lactobacilli have been used to prevent necrotizing enterocolitis in infants, catheter-related infections in spinal cord–injured patients or in children with a neurogenic bladder, and to prevent recurrent UTI in women. There are studies showing that probiotics may have a place in decreasing recurrent UTI, and also ongoing studies. At this time, results are variable and appear to be dependent upon bacterial strain, preparation, dosage and regimen, and administrative route. A randomized trial in premature infants using *Lactobacillus* GG showed no protective probiotic effect for UTI or necrotizing enterocolitis (Dani et al, 2002; Lin et al, 2008). A combination vaginal suppository of *L. rhamnosus* and *L. reuteri* has treated bacterial vaginosis in adult women (Reid, 2008), and others have shown that *L. crispatus* vaginal suppositories can establish vaginal colonization, particularly when the vaginal microbiota is abnormal (Czaja et al, 2007). **Because there are no evidence-based data related to UTI treatment or prevention with *Lactobacillus* or specific regimens and dosing, and variable drug formulation and activity are found** (Michail et al, 2006), **a recommendation cannot be made at this time.**

It is notable that risks of probiotic *Lactobacillus* usage are recognized in premature neonates or individuals with immune deficiency, chronic disease, or extreme debilitation in whom probiotic usage–associated instances of bacterial sepsis and death have occurred (Land et al, 2005; Boyle et al, 2006).

Microorganisms have also been used to create a "protective" interference bacteriuria using organisms with nonvirulent features. The theory is that these strains will competitively inhibit more virulent or pathogenic organisms. Trautner and associates have introduced genetically engineered *E. coli* that caused asymptomatic bacteriuria in another patient into neurogenic bladders of patients on intermittent catheterization (Trautner et al, 2007, 2008; Prasad et al, 2009). Although bacteriuria occurred and symptomatic UTI decreased in this population, the study sample size was too small for conclusions. This approach offers a novel form of intervening in recurrent UTI.

There is public interest in alternative dietary or food supplements that may decrease the likelihood of UTI. There is evidence that cranberry products inhibit fimbriated *E. coli* adherence and seem to decrease bacterial biofilms, perhaps thus decreasing recurrent UTI (Kontiokari et al, 2005). Reviews of randomized control studies in adult women show that cranberry products reduced the incidence of UTI during a period of a year; however, side effects and subsequent study-patient dropout was high. Because controls regarding formulation and dosing were variable, the optimal methods of administration, dosage, and timing are unclear from these studies (Jepson and Craig, 2007a, 2007b).

Studies on cranberry-product usage in children has focused upon use in children with a neurogenic bladder, and benefit in these groups is not supported at this time (Schlager et al, 1999; Jepson and Craig, 2007a, 2007b).

Future Treatments

At this time, the most powerful therapies for acute UTI are antimicrobial agents. Vaccine trials to prevent mucosal adherence of uropathogenic *E. coli* in animals by using common bacterial antigens or the FimH subunit of type 1 pili (Langermann et al, 1997; Thankavel et al, 1997; Uehling et al, 1999), and use of preventive *Lactobacillus* variants are ongoing, but there are no acceptable long-term preventive interventions at this time.

IMAGING EVALUATION

Imaging studies are basic to urinary tract evaluation for infection. Guidelines for optimal imaging are changing as data emerge. Some imaging evaluation data are mixed with data related to imaging for potential risk of UTI, so interpretation is complex. With multiple imaging modalities available, however, the most efficient and

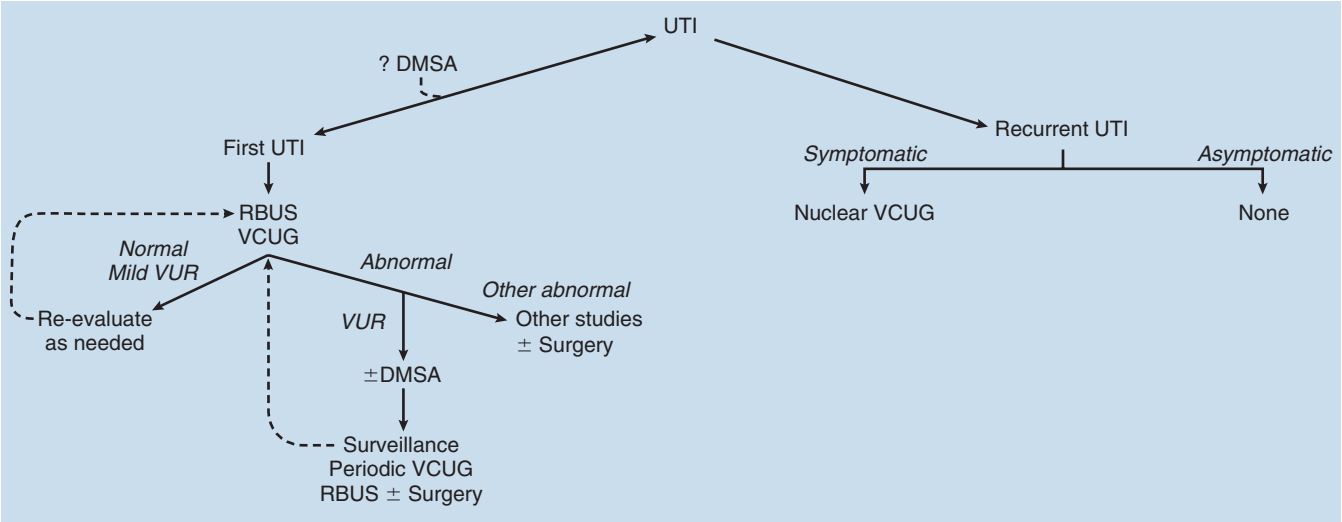

Figure 116–4. Flow diagram of imaging studies used to evaluate and manage urinary tract infections (UTI) in infants and children using the functional classification of UTI from Figure 116–1. DMSA, technetium-99m dimercaptosuccinic acid renal scanning; RBUS, renal and bladder ultrasonography; VCUG, voiding cystourethrogram; VUR, vesicoureteral reflux.

rational order and selection of studies must be made with a goal of minimizing damage from the acute and future UTI. **Radiologic imaging can be used to (1) evaluate and localize the acute urinary infection, (2) detect renal damage from the acute infection, (3) identify genitourinary anatomy that increases risk of future renal damage from infection, and (4) evaluate change in the urinary tract over time.** Deciding which studies are necessary in a child with a presumptive or diagnosed UTI should depend on whether potential radiologic findings would change a child's clinical management (Fig. 116–4).

Acute Imaging

Early urinary tract imaging is important in a seriously ill and/or febrile child in whom the site of infection is unclear or who has unusual circumstances. Circumstances such as newly diagnosed azotemia; a poor response to appropriate antimicrobial drugs after 2 to 3 days; an unusual infecting organism (e.g., tuberculosis or urea-splitting organism such as *Proteus*); known partial obstruction, such as a ureterocele, ureteropelvic junction obstruction, and megaureters; nonfunctioning or poorly functioning renal units; or history of diabetes, papillary necrosis, or a neuropathic bladder, warrant acute or early upper and lower tract urinary tract imaging. If treatment depends upon localizing the infection to the kidney, an acute imaging study can be performed. This is particularly important in the severely ill hospitalized child who improves on initial parenteral treatment, but urinary cultures are inadequate or indeterminate for bacterial infection. An acute DMSA scan may show if acute renal inflammation is present and justifies treatment. If, on the other hand, UTI appears highly likely, and antimicrobial treatment will be started regardless of radiologic findings, early DMSA scintigraphy is probably unnecessary. This has been confirmed recently by Hoberman and associates (Gorelick et al, 2003; Hoberman et al, 2003).

Acute imaging (ultrasonography) is recommended by the United Kingdom National Institute for Health and Clinical Excellence Guidelines when a child does not respond to antimicrobial treatment within 48 hours or if the UTI is "atypical" (defined as a child being seriously ill), has poor urinary flow, an abdominal mass, elevated creatinine, or has an infection with a non–*E. coli* organism (Baumer and Jones, 2007).

Definition of Renal Morphology and Identification of Urinary Tract Abnormalities

Because UTI in infants and young children may serve as a marker for anatomic abnormalities, after the initial UTI has been adequately treated, the child may be maintained on antimicrobial prophylaxis, and radiologic studies may be performed to delineate the urinary tract. Although there is controversy whether studies should be performed after the first or recurrent episode, if obstructive lesions are found in 5% to 10% of children and reflux occurs in 21% to 57% (Kunin et al, 1964; Abbott, 1972; Asscher et al, 1973; Newcastle Asymptomatic Bacteriuria Research Group, 1975), early detection of these abnormalities merits imaging attention.

It is of interest that VUR is diagnosed more frequently in children than in neonates. One study of the first UTI in neonates shows that VUR occurred at a rate of 20% in both girls and boys, yet the rate of UTI occurrence was sixfold greater in infant boys versus girls (Cleper et al, 2004). **Urinary tract imaging evaluation consists of some form of renal and upper collecting system evaluation (usually renal and bladder ultrasonography [RBUS]) and at times voiding cystourethrogram (VCUG).** As prenatal ultrasonography reveals many genitourinary abnormalities, the need for performing postnatal UTI imaging evaluation has been questioned. In one multicenter study examining children after their first UTI, however, no cases of grade V vesicoureteral reflux, obstructive lesions, and few cases of grade IV reflux were detected, although 39% of children scanned had mild to moderate vesicoureteral reflux (Hoberman et al, 2003). Another study demonstrated that in their population RBUS may be disregarded with a normal prenatal ultrasonography

(US) (Miron et al, 2007). Because this study occurred under circumstances of universal health care with a high physician to patient ratio, this recommendation may not apply to all populations.

Need for the VCUG in children less than 2 years old who have a UTI, a renal ultrasonography without evidence of urinary tract dilation, and a DMSA scan without scarring 3 months later has also been questioned (Hansson et al, 2004). In a retrospective study of children with UTI who are less than 2 years old, in which children who had suspected obstruction were eliminated, VUR grade III or higher correlated with presence of renal lesions, and 26% of children had evidence of renal scarring on DMSA scan. Although a normal DMSA scan and dilating grade III VUR were present in seven children, after 2 years, VUR resolved spontaneously in five children, one improved, and one developed a scarred kidney. Forty-six percent of infants without VUR had DMSA-defined scarring and 20 of 44 (45%) of children with grade I to II VUR had scarring (Hansson et al, 2004). Had the children with a normal DMSA scan and grade I to III VUR been undetected and untreated with prophylaxis, as suggested by these authors, the outcome would be unclear.

The United Kingdom National Institute of Clinical Excellence guidelines have limited imaging recommendations. Although they recommend RBUS for children during acute atypical UTI, as noted earlier, RBUS is ultimately performed only when UTI is recurrent or the child is less than 6 months old. VCUG is recommended only for children younger than 6 months or those from 6 months to 3 years with non–*E. coli* UTI, if there is poor urinary flow, if ultrasonography shows urinary tract dilation, or there is a family history of vesicoureteral reflux. It must be emphasized, however, although the guidelines restrict earlier imaging, they recommend a DMSA nuclear scan 4 to 6 months after the UTI, whenever the UTI is recurrent, and after an atypical UTI if the child is less than 3 years old (Baumer and Jones, 2007). Others recommend performing a VCUG only when an acute DMSA scan is positive (Preda et al, 2007).

Although the American Academy of Pediatrics practice parameters limited the original recommendations for first UTI imaging evaluation of the upper and lower urinary tract to children between 2 months and 2 years old (American Academy of Pediatrics, 1999a), others support such evaluation in even younger infants (Goldman et al, 2000). These recommendations are under revision and are likely to reflect more selective imaging, except in children with recurrent UTI.

Acute studies of the kidney may cause overestimation of renal size resulting from initial edema or lack of appreciation of renal scarring, because mature renal scars may take up to 2 years to be seen by certain imaging techniques (Filly et al, 1974; Troell et al, 1984; Gordon, 1986; Conway, 1988; Johansson et al, 1988a, 1988b; Conway and Cohn, 1994). As a result, later studies may show smaller or scarred kidneys that may be misinterpreted and cause inappropriate changes in patient management. **It is reported that the risks of missing renal scars by performing ultrasonography alone ranges from 0.4% (school-age children) to 11.1% (infants with recurrent upper tract UTI)** (Christian et al, 2000), but it should be emphasized that this is age dependent so that further evidence associated with the risk is needed. Obviously, obstruction and other anatomic abnormalities demonstrated by radiologic evaluation may require other evaluation(s) specific to their diagnosis before definitive management is decided. These situations need to be evaluated and treated individually.

Follow-up Imaging Evaluation

When a child who has a UTI has no abnormality found after urinary tract radiologic evaluation, they need no further studies. If the collecting systems are normal, but one or both kidneys show massive generalized or focal edema with areas of possible hypoperfusion during the acute infection, a subsequent study may be performed to examine the kidney for signs of renal scarring or shrinkage. The situations under which the United Kingdom National Institute for Clinical Excellence recommends a DMSA scan at 4 to 6 months after recurrent UTI are described in greater detail in the section Acute Imaging (Baumer and Jones, 2007). A DMSA scan will identify children who need monitoring for recurrent infections, hypertension, and renal dysfunction. **If a child has recurrent symptomatic pyelonephritis and no reflux found on previous fluoroscopic voiding cystourethrogram (VCUG), a nuclear VCUG may be more sensitive at revealing reflux, although less likely to define it** (Kogan et al, 1986; Macpherson and Gordon, 1986).

SPECIFIC IMAGING TECHNIQUES

Imaging techniques that are useful for evaluating children with UTI consist of an upper tract modality and limited use of a lower tract one that evaluates for vesicoureteral reflux. The radiologic follow-up of children diagnosed to have vesicoureteral reflux is discussed elsewhere. Details related to the use of each of these modalities are discussed in relation to each specific study.

Voiding Cystourethrography (VCUG, Fluoroscopic versus Nuclear)

The VCUG is the most important examination in assessing for vesicoureteral reflux in children, and, as such, is important when one wants to diagnose reflux. The VCUG may be performed either with fluoroscopy and iodinated contrast medium or with nuclear imaging agents (usually technetium-99m pertechnetate) using similar techniques (direct radionuclide cystography), but these studies give different information. The traditional fluoroscopic VCUG can show urethral and bladder abnormalities and vesicoureteral reflux.

The radionuclide VCUG may be more sensitive for reflux detection, but offers poorer spatial resolution so that details of the urethra and collecting system and degree of reflux may not be seen. **Vesicoureteral reflux detection by either fluoroscopic or radionuclide VCUG is dependent upon the child voiding** and the technical performance (e.g., bladder filling volume) of the study (Fairley and Roysmith, 1977; Lebowitz, 1986; Macpherson and Gordon, 1986). When a single nuclear VCUG shows no vesicoureteral reflux if performed for reflux follow-up, a year later 30% of patients may show reflux. Whether this discrepancy relates to previously missed reflux, recurrent reflux, or technical variation is unclear (Neel and Shillinger, 2000).

The main advantage of radionuclide VCUG has been the lower radiation exposure of 1 to 5 mrad or 1 mSv (ovarian dose) compared with 27 to 1000 mrad or 0.8 to 1.6 mSv from VCUG (reported ovarian exposure depends upon equipment) (Cleveland et al, 1992; Lebowitz, 1992). With modern imaging technology and a tailored examination, however, the fluoroscopic VCUG has been done with 1.7 to 5.2 mrad (Kleinman et al, 1994) and, if available, may offer advantages of anatomic resolution compared

with the radionuclide VCUG. Fluoroscopic radiation from modern equipment claiming low-dose radiation at four different children's hospitals may produce a wide exposure range—from 34 to 2230 mrads/minute—and pulsed fluoroscopy with optimization for pediatric image produces the best image quality per exposure (Brown et al, 2000).

The radionuclide VCUG may be most useful for periodic reflux re-evaluation (Lebowitz, 1992) or for screening siblings who have low risk of reflux. **In first infections, in infants or young boys in whom risk of genitourinary abnormality is high and urethral visualization important, or in any child in whom high-resolution imaging of the lower urinary tract is important, the radionuclide VCUG should not be used.**

Indirect radionuclide VCUG is performed as part of a renal imaging study. The radionuclide is injected intravenously and the study performed when the kidneys and upper collecting systems are cleared of the radiopharmaceutical agent and the bladder is filled maximally with it. The child then voids. Although this method avoids catheterization, when compared with the direct radionuclide VCUG, there is increased radiation exposure and decreased resolution because of body radionuclide background. Because it detects only about 60% of the reflux compared with the direct VCUG, there are few reasons to perform this test (Eggli and Tulchinsky, 1993).

VCUG may be performed as soon as the urine is sterile and voiding is normal; patient compliance may be greater when performed within a week of the diagnosis. Studies have shown that UTI does not cause reflux, and there is no reason to wait 3 to 6 weeks to perform the study as long as voiding and bladder volumes have returned to normal (Lebowitz, 1986; McDonald et al, 2000). Whether the VCUG is done during antimicrobial therapy, immediately after, or a few weeks afterward is not important so long as the child has normal renal function, has normal voiding, responds rapidly to antimicrobial treatment with urinary sterilization, and/or is maintained on prophylactic antimicrobial treatment to keep urine sterile in the interval between the herald infection and the radiologic evaluation.

If the VCUG is the initial radiologic study, subsequent imaging may be directed by VCUG results (Hellström et al, 1989). If the VCUG is normal, shows a ureterocele, or vesicoureteral reflux, an ultrasound examination of the kidney and bladder will usually demonstrate other urinary tract structural abnormalities or anomalies, such as dysplasia or obstruction, should they exist. In general and commonly, renal and bladder ultrasonography may be the initial study and will detect children who may need urgent urologic intervention (Alon et al, 1986, 1989; Honkinen et al, 1986; Lindsell and Moncrieff, 1986; Macpherson and Gordon, 1986). If, however, vesicoureteral reflux appears to be the primary diagnosis, DMSA scintigraphy with single-photon emission computed tomography (SPECT) or three-dimensional renal magnetic resonance imaging (MRI) may be the most useful studies with which to detect renal scars when desired (Fig. 116–5).

Renal and Bladder Ultrasonography (RBUS)

Renal ultrasonography has replaced intravenous pyelography as the standard for evaluating the pediatric urinary tract after UTI. Because this modality is not dependent upon renal function, ultrasonography will detect both gross and subtle abnormalities of the urinary tract, including those that involve poorly functioning or nonfunctioning renal units. **Routine renal ultrasonography is not as sensitive as CT, MRI, or DMSA scintigraphy at detecting changes associated with acute UTI** (Verboven et al, 1990, Björgvinsson et al, 1991; Eggli and Tulchinsky, 1993; MacKenzie et al, 1994; Mucci and Maguire, 1994)**.**

When performed at the time of acute inflammation, ultrasonography may show enlarged swollen kidneys, focal enlargement from edema and inflammation that may create a masslike effect (focal pyelonephritis or lobar nephronia), and ureteral widening (Silver et al, 1976; Hellström et al, 1987; Conway, 1988; Johansson

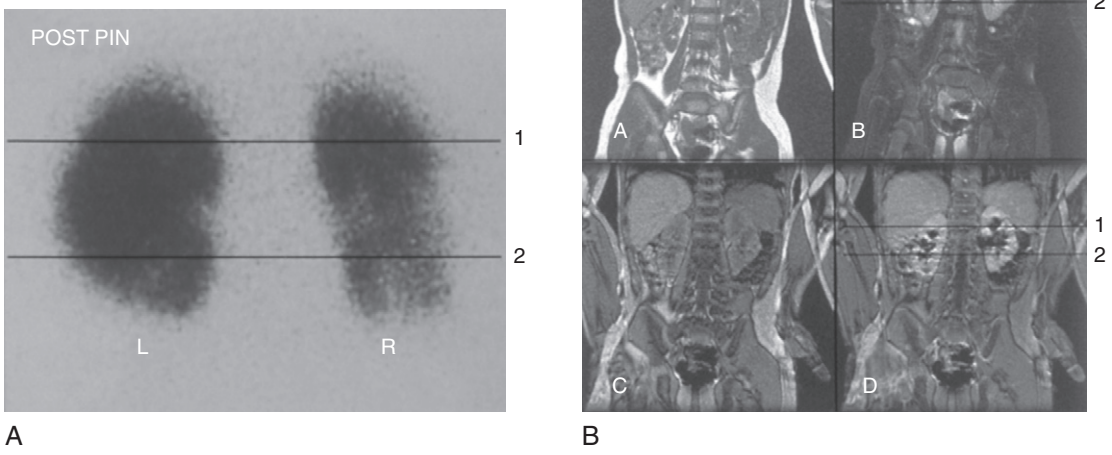

Figure 116–5. Dimercaptosuccinic acid (DMSA) renogram with single-photon emission computed tomography (SPECT) **(A)** and magnetic resonance imaging (MRI) **(B),** showing renal scars in a 3-year-old girl with reflux nephropathy. Comparative coronal levels of DMSA **(A)** and MRI **(B)** are shown. (From Rodriguez L, Spielman D, Herfkens R, Shortliffe L. Magnetic resonance imaging [MRI] for the evaluation of hydronephrosis, reflux, and renal scarring in children. J Urol 2001;166:1023–27.)

et al, 1988a, 1988b). High-resolution power and color Doppler ultrasonography may also detect small areas of inflammation and hypoperfusion detected by DMSA scintigraphy (Dacher et al, 1996; Morin et al, 1999). As noted previously, renal pelvic debris and sediment levels are diagnostic of pyonephrosis. Although renal inflammatory masses are usually easily differentiated from other masses based on symptom context, sometimes imaging with CT or MRI is needed (Cheng et al, 2004).

RBUS is, moreover, more likely to detect perinephric fluid collections or anatomic abnormalities, especially those involving urinary tract dilation, than either DMSA scanning or intravenous urography (MacKenzie et al, 1994). Pediatric RBUS is probably more dependent upon the skill and experience of the ultrasonographer with children than is DMSA scintigraphy (Patel et al, 1993). **Even with careful examination for vesicoureteral reflux, however, RBUS is notoriously poor at detecting or predicting vesicoureteral reflux** (Mahant et al, 2002).

Nuclear Renography

Because nuclear scintigraphy can detect areas of acute renal inflammation and chronic scarring, this test has improved detection of renal inflammation in pediatric UTI over the past 10 years. **Because approximately 60% of injected ^{99m}Tc-DMSA is bound to the proximal renal tubular cells and is excreted slowly in the urine, it is a good cortical imaging agent** (Jakobsson et al, 1992).

Radionuclide technology using pinhole images and high-resolution computed tomography (single-photon emission computed tomography [SPECT]) gives greater renal anatomic detail, resolution, and scar detection (Eggli and Tulchinsky, 1993). DMSA scintigraphy with SPECT is the benchmark for renal scars, and is the study used when cortical definition alone is needed (Björgvinsson et al, 1991; Eggli and Tulchinsky, 1993).

Because ^{99m}Tc-glucoheptonate, on the other hand, is partially concentrated, excreted, and partially bound to the renal tubule, both collecting system visualization and cortical definition is observed. Similarly, ^{99m}Tc-mertiatide (MAG3), a tubular renal imaging agent primarily used to assess renal parenchymal flow, function, and drainage, also has renal cortical imaging characteristics (planar or SPECT). MAG3 or ^{99m}Tc-glucoheptonate is almost as effective as DMSA in detecting changes of acute pyelonephritis (Traisman et al, 1986; Sreenarasimhaiah and Alon, 1995; Sfakianakis and Georgiou, 1997; Laguna et al, 1998). MAG3 has advantages over DMSA, because it is more rapid, gives a lower radiation dose to most organs, including the urinary bladder and gonads, and evaluates urinary tract drainage (Sfakianakis and Georgiou, 1997).

The findings of pyelonephritis detected by renal nuclear scintigraphy (i.e., DMSA with SPECT) differ depending upon the timing of the scan. Acutely, the renal studies will usually show either uptake defects or renal swelling (Wallin and Bajc, 1993; Wallin et al, 1997). The uptake defects may appear as wedge-shaped polar or lateral renal defects or as scattered uptake defects within the kidney. For this reason, DMSA may differentiate focal pyelonephritis, lobar nephronia, the column of Bertin, and neoplasm, although CT and MRI are generally more detailed. **After the acute episode heals, scans may show (1) a normal pattern, (2) generally diminished uptake and small kidney volume, (3) diminished uptake in the medial kidney, or (4) polar defects with diminished uptake in the renal poles** (Wallin and Bajc, 1994).

DMSA scintigraphy is clearly more sensitive than routine renal ultrasonography, or even intravenous urography, at detecting renal scarring, but newer high-resolution ultrasonography is nearly as sensitive as DMSA scintigraphy in diagnosing acute renal involvement (Morin et al, 1999). Because recurrent pyelonephritis appears to occur in the same areas as scarring, however, it may be difficult to differentiate between new and old or progressive renal scarring unless serial studies are performed (Björgvinsson et al, 1991; Rushton and Majd, 1992b). **Attempts to distinguish between congenital and acquired reflux nephropathy cite generalized decreased renal uptake relating to congenital and dysplastic changes, whereas focal defects are usually acquired** (Polito et al, 2000). These distinctions are important if one believes acquired lesions are preventable. In children in whom severe renal scarring has occurred and the glomerular filtration rate (GFR) may need to be estimated, the radionuclide renogram gives an accurate estimate of GFR even in young children (Gates, 1982; Shore et al, 1984; Rehling et al, 1989).

Intravenous Urography (IVU)

Although the traditional means of evaluating the upper urinary tract and documenting renal scarring was intravenous urography with renal tomography, in most situations DMSA scintigraphy has replaced the role of intravenous urography. DMSA scintigraphy is more sensitive for detecting renal scars but shows less resolution in defining the scars. An IVU still defines collecting system abnormalities in more detail than either DMSA scintigraphy or ultrasonography. It is probably most useful in defining the collecting system in patients with confusing situations or in whom calyceal detail may be important.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

Although seldom used to evaluate acute renal inflammatory processes unless unusual or complicating anatomic configurations occur on ultrasonography, CT or MRI reveal detailed and sensitive signs of acute renal inflammation. These modalities are often able to differentiate and distinguish between inflammatory, neoplastic, and other renal masses seen on other imaging techniques.

For CT and MR evaluation all four stages of renal enhancement following contrast delivery—renal vascular (10 to 15 seconds), corticomedullary nephrographic (20 to 45 seconds), parenchymal nephrographic (45 seconds to 2 minutes), and excretory phase when the contrast appears in the collecting system (2 to 3 minutes)—should be examined for changes related to inflammation.

Acute inflammatory changes of the kidney may be described as (1) unilateral or bilateral, (2) focal or diffuse, (3) with or without focal swelling, and (4) with or without renal enlargement. Other features that may be seen during the various phases are cortical hypoattenuation, wedge defects, and poor corticomedullary differentiation during the cortical and parenchymal nephrographic phases, and linear bands of alternating hyper- and hypoattenuation parallel to the tubules and collecting ducts, creating a striated effect during the excretory phase. Scans delayed 3 or more hours may help to differentiate renal abscess from hypofunctioning parenchyma in severe pyelonephritis (Kawashima et al, 1997). It should be noted that acute focal pyelonephritis (or lobar nephronia) on CT has been misinterpreted as renal abscess, because of an appearance of acute decreased perfusion, and, at times, MRI- or

CT-guided needle aspiration may be needed to clarify the clinical situation. As the mass effect of focal pyelonephritis may take months to resolve, more remotely these may need to be differentiated from neoplasm.

In direct comparison studies of MRI, DMSA planar, and SPECT for detection of renal scars, single-series coronal fat-saturated T1W MRI is judged as able to replace DMSA, avoiding the need for injection and ionizing radiation (Kavanagh et al, 2005). For routine evaluation of UTI, neither CT nor MRI is cost effective, but in children with complicated anatomy and UTI, either CT or MRI can be highly useful for defining renal abnormalities and extent of disease, when other modalities are inconclusive. Because MRI may determine function, anatomy, and vesicoureteral reflux while avoiding the significant ionizing radiation of CT, MRI becomes a preferable imaging modality (Rodriguez et al, 2001).

RISKS OF IONIZING RADIATION AND RESPONSIBLE IMAGING

Recommendations for imaging evaluation after UTI have changed, in part, from greater knowledge of the epidemiology of UTI and, in part, from developing imaging technologies. Although technology has wrought newer imaging modalities with improved tissue and organ resolution, some progress occurs at the cost of significant increased patient radiation exposure. **Use of CT imaging is the main cause in one country for increased exposure to medical ionizing radiation by almost 25% (1.59 to 1.98 mSv per capita) from 1994 to 2002** (Shannoun et al, 2006). Others have noted that a few procedures, such as CT, angiography, and gastrointestinal and genitourinary contrast studies with fluoroscopy, account for almost 80% of total collective ionizing radiation dosage given to the public (Wall, 2004). With the growing ease and rapidity of CT scanning, moreover, abdominal-pelvic CT usage in children increased 92% at one U.S. institution from 1996 to 1999 (Brenner et al, 2001).

Increased recognition of the increased risks of lifetime cancer from relatively low-dosage radiation to children and fetuses has emerged from studies of children and fetuses who survived the atomic bomb in Nagasaki and Hiroshima, Japan. **These studies give evidence for a linear increase in excess lifetime solid cancer and leukemia risk for radiation exposure of 1 to 150 mSv and is highest for those exposed as children** (Preston et al, 2003, 2008).

Concern specifically relates to childhood radiation exposure because (1) childhood radiation has a longer time span during which effects may become manifest, (2) developing cells have greater potential of developing direct damage from radiation exposure, and (3) medical and diagnostic procedure radiation appropriate for adults is often unadjusted for children, causing disproportionately high-radiation exposure.

The measure of effective radiation dose is the millisievert (mSv), which is used to refer to a radiation dosage averaged over the entire body, accounting for the relative differences in the exposed tissues in a way that is comparative to natural background radiation (ICRP [International Commission on Radiological Protection], 1998). Most common background radiation is from cosmic rays at ground level, primordial radionuclides, or ingested potassium. Average background radiation is estimated to be 3 mSv per year (American College of Radiology and Radiological Society of North America, 2009), and estimated procedural radiation exposure of common pediatric urologic procedures is shown in Table 116–6. **A CT scan with and without contrast in a child, using pediatric parameters, will give an effective radiation dose of 6 to 10 mSv—almost 3.5 years of equivalent background radiation** (Gaca, 2008), **and the estimated lifetime cancer mortality from an abdominal pediatric CT in a 1-year-old child is 0.18%** (Brenner et al, 2001).

Radiation exposure risks to young developing infants and children must be considered carefully as practitioners consider individualized evaluation of UTI. Radiation risk to children may be limited in two ways: (1) decreased exposure through technologic imaging advance and (2) practitioner decision analysis in which imaging studies with risk of ionizing radiation exposure are selected only when information that may give advantage to treatment or management is obtained. Radiologists have adopted the concept of radiation exposure termed "as low as reasonably achievable" (ALARA) (Strauss and Kaste, 2006), and technical adjustments and improvements allow decreased exposure through such changes as pediatric-specific settings and pulsed and digital fluoroscopy.

Table 116–6.

Relative Radiation Exposure

EXAMINATION	AVERAGE EFFECTIVE DOSE (mSv)	EQUIVALENT CHEST RADIOGRAPHS	EQUIVALENT BACKGROUND RADIATION
Background radiation in a year	3	150	1 year
U.S. coast to coast airline flight	0.03	1.5	3.6 days
Chest radiograph	0.1	1	10 days
Abdomen radiograph	1.0	50	125 days
VCUG infant	0.8	40	90 days
VCUG (5-10 years)	1.6	80	180 days
Intravenous urogram (IVU)	1.6	80	180 days
Abdomen/pelvis CT (pediatric parameters)	3-5	250	1 year 260 days
Abdomen/pelvis CT with and without contrast (pediatric parameters)	6-10	500	3 years 155 days
Abdomen/pelvis CT (adult parameters)	15-20	750-100	5-6 years
Renal scan ^{99m}Tc-DMSA	1	50	125 days

CT, computed tomography; 99mTc-DMSA, technetium-99m dimercaptosuccinic acid; VCUG, voiding cystourethrogram.

Data from Gaca AM. Radiation protection and safety in pediatric imaging. Pediatr Ann 2008;37:383–7; American College of Radiology and Radiological Society of North America. Radiation exposure in x-ray examinations. Oak Brook (IL): RSNA; 2009. Smith T, Gordon I, Kelly J. Comparison of radiation dose from intravenous urography and 99Tcm DMSA scintigraphy in children. Br J Radiol 1998;71:314–9.

Ionizing radiation exposure in imaging studies for UTI evaluation occurs with CT, IVU, VCUG, and DMSA scintigraphy (1 mSv) (Smith et al, 1998). High-quality ultrasonography has generally replaced IVU, and digital and pulsed fluoroscopy limit exposure from performance of VCUG to low or negligible (in the opinion of some) (Perisinakis et al, 2006; Sulieman et al, 2007). In complex situations in which greater clarity or detail of the urinary tract is needed, MRI is increasingly useful, even though it may require sedation.

These changes, however, do not mitigate the urologist's role in choosing whether a child requires radiation exposure. Because we have advanced past using IVU and VCUG with fluoroscopy as primary imaging technologies with which we evaluate the urinary tract, and we have alternatives limiting or eliminating ionizing radiation, such as renal and bladder ultrasonography, nuclear VCUG, and magnetic resonance imaging, it is incumbent on the practitioner to make judicious and knowledgeable selection for imaging evaluation and use of fluoroscopy. Further limitations to ionizing radiation exposure need to be considered in vesicoureteral reflux evaluations.

SEQUELAE OF URINARY TRACT INFECTION

Chronic Pyelonephritis—Renal Scarring and Dysfunction

Coarse renal scarring seen radiologically as calyceal deformity and renal parenchymal thinning over localized or multiple calyces is known as "reflux nephropathy." Because it is now clear that such scarring occurs with or without reflux, the phenomenon would be better termed "pyelonephritic scarring." **The pediatric kidney appears to be at greater risk of scarring from bacterial pyelonephritis than the mature kidney.** Many factors, such as intrarenal reflux, urinary tract pressures, host immunity, age, genetic polymorphisms, and treatment appear to contribute to this.

Rolleston and associates (1974) found that areas of renal scar were associated with intrarenal foci of reflux (pyelotubular backflow) observed on voiding cystourethrography in children less than age 4 years who had vesicoureteral reflux. Calyces allowing reflux contained papillae fused with adjacent papillae, which caused the papillary ducts to open at right angles rather than at oblique angles that are more resistant to reflux (Ransley and Risdon, 1974). **These compound papillae are at the renal poles, the areas in which clinical renal scarring is observed most commonly clinically** (Hannerz et al, 1987)**.** Common patterns of scarring are seen (Fig. 116–6).

In pigs with vesicoureteral reflux and even intrarenal reflux, however, renal scarring occurs only when both vesicoureteral reflux and bacteriuria are present (Ransley and Risdon, 1978). Reflux without bacteriuria resulted in renal scarring only when the urethra was partially obstructed, causing abnormally high voiding pressures (Hodson et al, 1975; Ransley et al, 1984). Experimentally, therefore, the "water hammer" (back pressure) effect of vesicoureteral and intrarenal reflux alone causes renal scarring only when associated with abnormally high bladder and renal pressures.

In the neonate, however, the kidney may respond to urinary back pressure, or the "water-hammer" effect at different thresholds and in different ways than the adult kidney. Autopsy studies on normal neonates (younger than 1 month) reveal that intrarenal reflux into compound calyces occurs at low pressures of 2 mm Hg, whereas the same reflux in a child 1 year old occurs at 20 mm Hg. At autopsy, furthermore, at 50 mm Hg pressure, intrarenal reflux occurs in all calyces, even simple ones, in children less than 12 years old (Funston and Cremin, 1978).

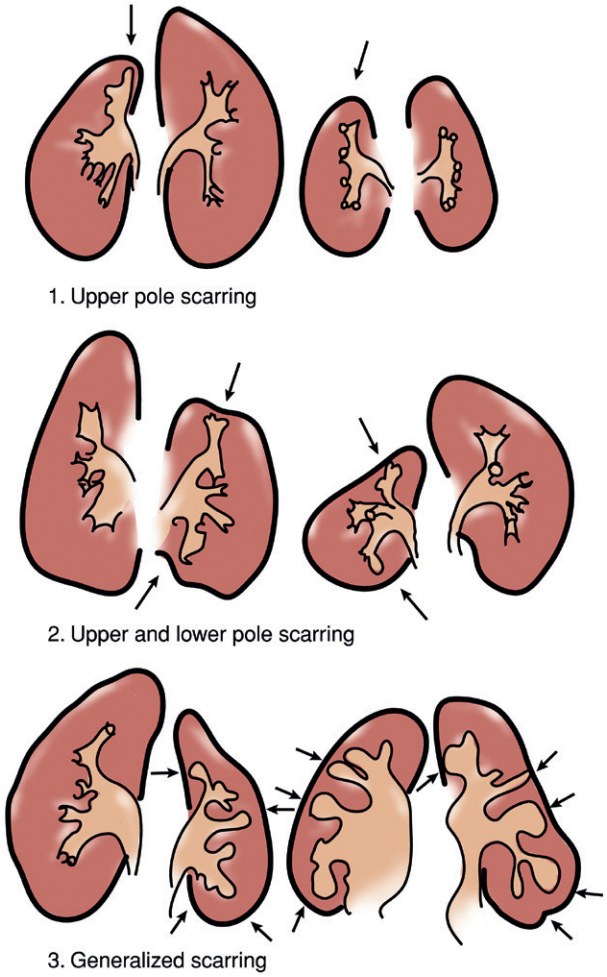

Figure 116–6. The common areas of renal scarring, characterized by parenchymal thinning over a deformed calyx, as examined from intravenous pyelograms. The extent of scarring was related to single polar scars; multiple areas of upper, lower, and medial scars; or generalized scarring, as depicted. (From Hodson CJ. Natural history of chronic pyelonephritic scarring. Br Med J 1965;2:191–4.)

This suggests that physiologically normal urinary intrapelvic pressures in adults or older children could have a different response in neonates. This effect could be augmented by increases in renal pelvic pressures that may result from ureteral and pelvic smooth muscle dysfunction in infection. Animal models with bacterial urinary infection show that infection elevates renal pelvic pressures whether or not reflux is present, and, in fact, renal pelvic pressures may even be higher when reflux is absent. This may also account for further parenchymal damage with severe infection (Issa and Shortliffe, 1992; Angell et al, 1998). Young children have incompletely developed immune and neurologic systems. A depressed or incompletely mature immune system may allow easier bacterial colonization of the bladder and kidney because of decreased local and systemic defenses, and it may eliminate bacteria even less efficiently once bacteriuria occurs. Immature

bladder activity associated with increased contractions may also contribute to dynamic change in the upper tracts, even in the apparently normal child (Koff and Murtagh, 1984). As a result, bacteriuria combined with reflux may result in greater susceptibility to renal damage.

Neonatal symptoms of urinary infection and pyelonephritis are often vague and nonspecific, resulting in delayed or inadequate treatment. During this period of delay, bacterial invasion of the kidney creates an inflammatory response characterized by vascular granulocytic aggregation and hypoperfusion with subsequent scarring and loss of renal parenchyma (Winberg et al, 1974). Finally, genetic polymorphisms associated with the immune system and renin angiotensin system may make some individuals more susceptible to renal scarring from pyelonephritis, as previously discussed.

One must not confuse small, scarred kidneys with congenitally small, dysplastic, poor, or nonfunctioning kidneys, however. This distinction, one that is difficult and sometimes impossible to make radiologically, is important because dysplastic kidneys are histologically abnormal. Dysplastic kidneys and atrophic, scarred kidneys are histologically distinct. Although gross renal changes may be detected radiologically, lesser lesions associated with vesicoureteral reflux and infection insult, such as cortical pitting, global renal shrinkage, or hypoplasia, may not be detected by routine imaging tests and yet may affect renal histology and function (Chang et al, 2007; Wong et al, 2009).

Using pyelographic techniques before DMSA scintigraphy, about 17% of school-age children with screening bacteriuria (cultures performed for screening rather than for symptoms) are diagnosed with renal scarring (Asscher et al, 1973; Newcastle Asymptomatic Bacteriuria Research Group, 1975; Savage, 1975). This correlates with the observation of Winberg and associates (1974) that 4.5% of children had radiologic renal scars after their first symptomatic UTI, and 17% had scars after the second symptomatic UTI. Although the percentage of scars using these earlier techniques may underestimate scarring, because some studies using DMSA scintigraphy suggest the incidence of scarring after symptomatic UTI could be almost twice this rate, these data emphasize that a child with both covert and symptomatic UTI has significant risk for renal scarring. Although by definition, the natural history and pathogenesis of scarring in covert or asymptomatic bacteriuria is unknown, these scars probably reflect injury from previous undiagnosed bacteriuric episodes.

In most children with UTI in whom renal scars are found (and who have normal voiding) on the first set of imaging studies, the scarring does not improve or worsen irrespective of the child's future clinical course (Verber and Meller, 1989). It has been hypothesized that the young kidney may be more prone to damage, and, as such, the initial UTI in the neonate or young child less than 4 or 5 years old causes whatever renal damage that will occur, and this initial response determines the kidney's future course ("big bang theory"). This theory is supported by the higher prevalence of early cortical DMSA-defined defects observed in children less than 2 years old who have UTI, compared with those greater than 2 years old (Ditchfield et al, 1994). One retrospective study links individuals with scars found on DMSA scanning with a greater likelihood of breakthrough UTI and less likely spontaneous resolution of their vesicoureteral reflux (Mingin et al, 2004). Although older children appear to have less risk of scarring from UTI than children less than 5 years old, vulnerability for scarring persists until puberty (10 to 15 years old). Studies link new or progressive renal scarring after early childhood diagnosis to uncontrolled recurrent UTI and persistent vesicoureteral reflux (Filly et al, 1974; Smellie et al, 1985; Shimada et al, 1989). Filly and associates (1974) found that in girls less than 10 years old who had recurrent UTI and vesicoureteral reflux, renal scars progressed (i.e., developed clubbing or scarring in previously normal areas) in 43% of kidneys (17/40), and 2 of 16 normal kidneys developed new scars. Some of these scars took up to 2 years from the episode of pyelonephritis to maximally evolve.

Investigators who have used DMSA scanning routinely to detect renal scars have also found that new or progressive renal scarring is more common than previously thought. Up to 7.3% of children with recurrent or persistent bacteriuria and reflux have progressive scarring, and almost all young children with recurrent pyelonephritis suffer renal scarring (Shimada et al, 1989; Verber and Meller, 1989; Jakobsson et al, 1994).

Conversely, imaging evaluation of girls with reflux grades II to IV/V (International Reflux Grading) without further UTI show no progressive renal damage when followed up to 10 years (Holland et al, 1990). This supports earlier animal and clinical data that given normal urinary tract urodynamics, vesicoureteral reflux alone (sterile reflux) does not cause renal damage or impair renal growth (Ransley and Risdon, 1978; Smellie et al, 1981; Ransley et al, 1984). If no infections occur, no association between the severity of vesicoureteral reflux and impaired renal growth has been demonstrated in an otherwise normal urinary tract.

Furthermore, adults who have acute nonobstructive pyelonephritis and normal urinary tracts rarely develop focal renal cortical scarring, papillary and/or calyceal distortion, or measurable generalized renal shrinkage (Davidson and Talner, 1978). In all these studies, however, wedge-shaped polar renal scars or grossly small kidneys were the markers, rather than renal mass or size. Others have examined renal mass and found that children with UTI and VUR have smaller kidneys (not grossly small) without signs of gross cortical scars (Chang et al, 2007). This implies that renal scarring is not the most sensitive measure of renal UTI damage.

Renal infection stimulates both innate (immediate) and more specific (delayed) immune responses. In rat models of pyelonephritis, maximal renal suppuration and exudation with an inflammatory infiltration occurs 3 to 5 days after the infection starts, and collagen infiltration and scarring follows (Glauser et al, 1978; Miller et al, 1979; Miller and Phillips, 1981; Shimamura, 1981; Slotki and Asscher, 1982). During the acute inflammatory cell infiltrate, granulocytic aggregation may cause vascular occlusion and ischemia with renin elevation (Kaack et al, 1986; Ivanyi and Thoenes, 1987). Bactericidal activity of the neutrophils and release of enzymes, superoxide, and oxygen radicals may cause the renal tubular damage observed in pyelonephritis (Roberts et al, 1981, 1982).

Advanced understanding of the innate "reflex" and specific immune responses to bacterial infection at a molecular and cellular level has increased knowledge of this process in UTI. UTI susceptibility is a complex interplay between factors of bacterial virulence and the immune response at the level of the uroepithelial cell. The uroepithelial cells have receptors (Toll-like receptors [TLRs]) that recognize structural molecules from microbes. When triggered by the microbial molecules, these TLRs activate proinflammatory cytokines and chemokines (IL-1, IL-6, IL-8) that signal and direct neutrophil transmigration across the epithelial barrier and into the urinary tract lumen, creating the clinical symptoms and signs of bladder and urinary tract infection. TLR4 is present on bladder uroepithelial cells; TLR5 is primarily in the bladder, with some expression in the kidney; and TLR11 is primarily in the kidney (Zhang et al, 2004).

Type 1 fimbriated bacterial attachment to bladder TLR initiates this cascade. Uroepithelial TLR4 appears to signal cytokine and chemokine production by either a NF-kβ pathway or a faster pathway involving 3′,5′-cyclic adenosine monophosphate (cAMP), both of which create an inflammatory response with the goal of shedding the infecting microbes and inhibiting bacterial invasion (Song et al, 2007; Ragnarsdóttir et al, 2008; Song and Abraham, 2008).

Discovery of genetic immune system deficiencies that cause more frequent UTI and pyelonephritis in mouse knockout models has given investigators clues to discovering human genetic polymorphisms associated with increased effects of UTI. Investigators have predicted and found groups of individuals with increased susceptibility for pyelonephritis associated with cytokine abnormalities, suggesting that aberrant immune response pathways may be associated with increased UTI susceptibility (Frendéus et al, 2001; Godaly et al, 2001; Artifoni et al, 2007; Ragnarsdóttir et al, 2008; Svensson et al, 2008). Measurement of the proinflammatory cytokines in serum or urine (e.g., IL-6, IL-8) also offer means of detecting or monitoring renal inflammation in acute pyelonephritis, and, as such, detection of elevated IL-6 and IL-8 has been proposed to diagnose acute pyelonephritis and renal scarring (Gürgöze et al, 2005; Sharifian et al, 2008; Sheu et al, 2008).

This inflammatory response causes proximal and distal tubular dysfunction and abnormal reduction in urinary concentrating ability (Berg, 1981), increased fractional sodium excretion, decreased phosphate reabsorption, and increased low-molecular-weight protein excretion (Tulassy et al, 1986). More recently, animal models examining bacterial attachment to renal collecting duct cells have shown that this process causes deregulation in vasopressin hormonal release and may affect TLR4 and innate immune activity (Chassin et al, 2007).

Decreased renal concentrating capacity correlates with evidence of severity of renal scarring (bilateral worse than unilateral) (Åbyholm and Monn, 1979). Other investigators correlate elevated urinary retinol binding protein (RBP, a tubular protein giving evidence of tubular dysfunction) excretion with the type and severity of renal scarring, and they link elevated *N*-acetyl-β-D-glucosaminidase (NAG, an excretory protein indicating tubular damage) and albumin excretion to children with bilateral scarring. These data suggest that tubular dysfunction occurs before glomerular dysfunction and commonly occurs in children with bilateral renal scarring (Tomlinson et al, 1994).

If antimicrobial treatment starts within the first days of infection, the acute suppurative response to the bacteria may be minimized, and renal scarring may be decreased or prevented (Glauser et al, 1978; Miller and Phillips, 1981; Shimamura, 1981; Slotki and Asscher, 1982). Inhibition of superoxide production may decrease renal inflammation and tubular damage (Roberts et al, 1982). Other animal studies suggest that supplementing antimicrobial treatment with anti-inflammatory agents, such as ibuprofen, decreases neutrophil chemotaxis and blocks the cyclooxygenase pathways, or that any other glucocorticoid anti-inflammatory agent may decrease renal scarring (Huang et al, 1999; Pohl et al, 1999).

Clinically, larger cortical defects correlate with longer delay in treatment and longer length of illness (Jakobsson et al, 1992). The likelihood of renal scarring directly correlates, moreover, with the number of UTI occurrences (Jodal, 1987; American Academy of Pediatrics, 1999a) (Fig. 116–7).

Certain recent studies have questioned these premises, however. In one study, hospitalized children less than 12 months old who were treated with intravenous antibiotics 1 to 8 days from the time of fever onset had more limited renal involvement when treated within the first 24 hours. No difference in scarring occurred when treated early or late though (Doganis et al, 2007). Another study examined children less than 7 years old with first episodes of pyelonephritis and concluded that early treatment had no effect on later renal scarring, but this study excluded children who were found to have "renal and/or urologic abnormalities" (Hewitt et al, 2008). Because the typical child with a first febrile UTI may not be hospitalized for intravenous antimicrobial drugs or have knowledge of their urologic abnormalties prior to diagnosis, the clinical implications of these kinds of studies are unclear.

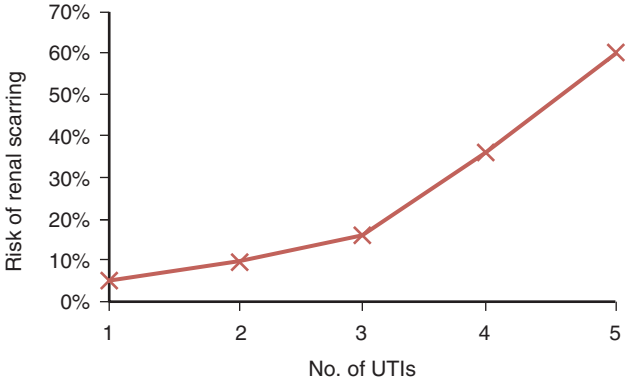

Figure 116–7. The relationship between risk of renal scarring and number of urinary tract infections (UTIs). (From American Academy of Pediatrics. Committee on Quality Improvement. Subcommittee on Urinary Tract Infection. Practice parameter: the diagnosis, treatment, and evaluation of the initial urinary tract infection in febrile infants and young children. Pediatrics 1999a;103:845.)

Xanthogranulomatous Pyelonephritis (XGP)

Under certain circumstances, chronic bacterial pyelonephritis and obstruction are associated with a distinct severe inflammatory process known as xanthogranulomatous pyelonephritis (XGP). Although this occurs in only about 1% of cases and recently is diagnosed more frequently with imaging (Malek and Elder, 1978; Zugor et al, 2007), it is important because the entity has been confused with childhood renal tumors (e.g., Wilms tumor, multilocular cystic nephroma, congenital mesoblastic nephroma, malignant rhabdoid tumors, and clear cell sarcoma). Although the ***cause is unknown,*** the process is usually associated with both infection and obstruction. XGP affects mainly adults, but children also have the entity. Symptoms in children are similar to those in adults with flank pain, fever, chills, and chronic bacteriuria (*E. coli* and *Proteus* are most common) and associated with more vague symptoms of malaise, malnutrition, weight loss, and failure to thrive. Lower tract irritative symptoms are uncommon. Symptoms are often chronic with the majority, with XGP being symptomatic for greater than a month (Brown et al, 1996; Zugor et al, 2007). **The most common infecting organisms are *Proteus* and *E. coli*.** Urinalysis usually shows pus and protein, and blood counts often show anemia, reflecting the chronic nature of the disease. The process is usually unilateral and may involve pericalyceal tissue alone (focal) or the kidney diffusely (diffuse), with extension into the perinephric fat, and even the retroperitoneum with encasement of the great vessels (Malek and Elder, 1978; Eastham et al, 1994). The clinical presentation in children differs

from adults**. In children XGP often affects those less than 8 years old and is of the focal renal rather than diffuse renal form (17% to 25% of cases in children). Boys are affected more frequently** (Brown et al, 1996), **and contralateral renal hypertrophy may occur** (Quinn et al, 1999). Although obstructive calculi occur in both children and adults, obstruction may involve congenital genitourinary abnormalities in children. On the other hand, focal XGP seldom occurs with obstruction.

Radiologic findings include renal calculi in 38% to 70% of patients, nonfunctioning renal segments in 27% to 80%, and a mass in as many as 62% (Anhalt et al, 1971; Malek and Elder, 1978). Ultrasonography may show an enlarged kidney with hypoechoic areas that represent areas of necrosis and pus-filled calyces. Computed tomography with contrast shows areas of low attenuation that do not enhance and may show extension of the mass into the perinephric fat. The "bear paw" sign with areas of low-attenuation nonenhancing dilated calyces and abscesses within areas of high-attenuation enhancing renal parenchyma may be present (Cousins et al, 1994; Goodman et al, 1998). No radiologic feature of XGP is diagnostic, but in recent reports, magnetic resonance imaging (MRI) or computed tomography (CT) has allowed correct preoperative diagnosis and planning in some patients.

Grossly, the kidney shows yellow-white nodules and evidence of pyonephrosis. **The histologic diagnostic feature is the xanthoma cell, a foamy lipid-laden histiocyte that may simulate the renal carcinoma cell.** These xanthoma cells may also appear in other conditions of chronic inflammation and obstruction, such as obstructive pneumonia (Moller and Kristensen, 1980). If one makes a preoperative diagnosis of XGP, partial nephrectomy will treat localized disease, but diffuse and extensive disease associated with a nonfunctioning kidney usually requires removal of the involved kidney and perinephric fat. Medical treatment of focal XGP is successful, and rare instances and some instances of remote amyloidosis occurring in the remaining kidney are reported (Brown et al, 1996; Quinn et al, 1999).

Pyelonephritic Hypertension

The childhood incidence of hypertension is between 1% to 11%, depending upon age and sex. Renal-related hypertension is most common (Dillon, 1979). **Children with gross pyelonephritic nephropathy (reflux nephropathy) have at least a 10% to 20% risk of future hypertension** (Holland et al, 1975; Wallace et al, 1978; Smellie and Normand, 1979; Jacobson et al, 1989a), with risks of later progressive deterioration in renal function and other complications of hypertension. Wallace and associates (1978) found that 12.8% of 141 patients with urinary infections and surgically corrected vesicoureteral reflux developed hypertension during the first 10 years of follow-up. Of those with renal scarring, 17% became hypertensive during follow-up. In another series, Smellie and Normand (1979) followed 83 children with scars, of whom 11(13%) had initial hypertension, 6 (7%) had malignant hypertension, and another 14 (17%) became hypertensive during the next 4 to 20 years, making a total of 37% who developed infection-related hypertension. In Sweden, Jacobson and associates (1989a) found that 7 of 30 (23%) children with focal renal scarring developed hypertension after 27 years, and of these, 10% developed end-stage renal disease. Eleven of the children followed by Smellie and Normand had hypertension initially, and none of Wallace's or Jacobson's did, probably indicating that the group followed by Smellie and Normand had more severe initial renal damage. In both series, however, **hypertension occurred whether renal scarring was segmental, focal, unilateral, or bilateral, and it was therefore independent of the degree of scarring.** An examination of ambulatory blood pressure measurements (24-hour ambulatory blood pressure measurement) suggests that hypertension measured in this way correlates directly with degree of reflux nephropathy. Nocturnal hypertension was the most sensitive indicator, but whether this is predictive of daytime hypertension is not confirmed (Patzer et al, 2003).

The etiology of pyelonephritic hypertension is poorly understood. It is likely that the renin-angiotensin system is involved. In 1978 at Great Ormond Street in London, the plasma renin activity was measured in children with reflux nephropathy who had been corrected surgically 1 to 10 years earlier (Savage et al, 1978). In all 15 children who were hypertensive when studied, plasma renin activities were above the normal mean, with 9 having levels above normal for their age, whereas in 8 of 100 children who were normotensive after the surgery, the plasma renin levels were elevated above the normal range for their age. When 85 of these 100 children were traced 5 years later, 4 had developed serious hypertension, and 4 others had borderline hypertension. A single elevated plasma renin activity level in 1978 did not, however, predict hypertension 5 years later, and by 1987 19% (16 of 85) of the children had elevated plasma renin activity. In this study, moreover, the normal tendency for the plasma renin activity to decrease with increasing age was not seen, and instead the opposite was observed; plasma renin activity increased with age, and the standard deviation increased. Almost 10 years later, the percentage of children with elevated peripheral plasma renin activity continued to increase in teenagers older than age 15 years, but elevation appeared to plateau by age 25 years, and blood pressure had leveled by age 15 years (Goonasekera et al, 1996). Peripheral plasma renin elevation did not predict future hypertension during the 15 years of follow-up. The value of selective renal vein renin measurements in the management of children with hypertension from reflux nephropathy is controversial (Holland et al, 1975; Stecker et al, 1977; Bailey et al, 1978; Bailey et al, 1984a, 1984b; Dillon et al, 1984), even though segmental renal vein renin has been useful in some for localizing sources of renin production (Dillon et al, 1984). Further indirect evidence for the role of renin in pyelonephritic nephropathy has been the successful treatment of hypertension with agents specifically aimed at blocking the renin-angiotensin system. In those children who have been examined with renal arteriography, normal main renal arteries are found to progress to scarred kidneys with vascular changes limited to small interlobular arterial branches (Holland et al, 1975; Stecker et al, 1977).

Progressive Renal Dysfunction

Although renal failure associated with acute pyelonephritis occurs rarely after recurrent pyelonephritis, especially that associated with pyelonephritic nephropathy, some children develop delayed hypertension and progressive renal dysfunction without further known UTI. **Generally, when measured years after UTI, overall renal function is well preserved, but individual GFR of scarred kidneys is decreased; this decrease correlates inversely with the original degree of vesicoureteral reflux when associated with reflux (higher-grade reflux, lower GFR)** (Jacobson et al, 1989a; Wennerström et al, 2000). As might be expected with long-term follow-up, those with small kidneys, whether scarred or not, had a lower GFR than those

with normal kidneys, and those with bilaterally small or scarred kidneys had the lowest GFR (Berg, 1992). **Most long-term studies emphasize that early detection of complications of renal scarring, such as hypertension, renal insufficiency, and proteinuria, is useful in minimizing progressive deterioration in renal function** (Jacobson et al, 1989a; Berg, 1992; Martinell et al, 1996; Smellie et al, 1998; Wennerström et al, 2000).

When renal scarring is found in children or bilateral renal scarring is found in adults with a history of UTI, it seems to be a risk factor for further decreasing renal function. As confirmed by Smellie and associates (1998), on long-term follow-up (mean, 27 years) of children with reflux and recurrent UTI (who were carefully managed to prevent UTI), those who had complications as adults had extensive renal scarring in childhood, while those who had no scarring in childhood did well as adults.

For over a decade, glomerular lesions and progressive proteinuria have been observed in patients who have renal scarring (Kincaid-Smith, 1975; Torres et al, 1980). Significant proteinuria (greater than 1 g/24 hr) has been a routine finding in patients with vesicoureteral reflux and progressive deterioration in renal function (Torres et al, 1980). Certain investigators, moreover, have found glomerular sclerosis in the nonscarred, radiologically normal kidney in cases of unilateral reflux nephropathy (Kincaid-Smith, 1975, 1984; Bailey et al, 1984a, 1984b). Two theories, one involving progressive renal damage from hyperfiltration of remaining nephrons, and the other involving progressive immunologic damage to the kidney, have been postulated to cause this. Micropuncture studies of rat renal tubules have allowed measurement of single-nephron glomerular filtration rates. These investigations have shown that removal of a kidney or loss of a majority of functioning nephrons results in hyperfiltration in the remaining nephrons and increased glomerular plasma flow. From rat studies in which one kidney and two thirds of the other kidney were removed (a five-sixths nephrectomy model), increases in glomerular plasma flow, mean net glomerular transcapillary hydraulic pressure, and single-nephron glomerular filtration rates were measured in the remnant nephrons. Later, as an apparent consequence, these rats developed focal segmental glomerulosclerosis (FSGS) (Hostetter et al, 1981, 1982). The glomerulosclerosis was felt to result from vascular injury caused by renal hyperfiltration. Rats maintained on a low-protein diet failed to show the pressure or pathologic changes, and indeed, rats maintained on a high-protein diet had greater degrees of glomerular sclerosis and more rapid renal death than those on normal diets (Brenner et al, 1982). **FSGS has been found in children with reflux nephropathy and proteinuria, even when renal function (measured by glomerular filtration rate) is relatively preserved.** In these children, glomerular involvement correlates with degree of proteinuria. Because most children who suffer renal scarring and loss of parenchyma have adequate renal function, the glomerular and vascular changes may be an evolving response to hyperfiltration injury (Morita et al, 1990).

Another explanation for the progressive renal dysfunction involves a chronic inflammatory response that develops into an autoimmune phenomenon. Tamm-Horsfall protein (THP) is produced in the renal tubular cells of the loop of Henle and distal convoluted tubules and is secreted into the urine. Whether it has any specific physiologic role is unknown, but it does appear to affect bacterial adherence to the mucosa and may serve some protective role (Duncan, 1988; El-Achkar et al, 2008) (see section on Cystitis and Pyelonephritis).

Although Tamm-Horsfall protein is usually found only in the urine and on the luminal side of the tubules, both clinically and experimentally, the protein has been detected in interstitial deposits in kidneys that have been subject to infection or reflux and has been associated with mononuclear cell infiltrates and renal scarring (Andriole, 1985). Also, even though antibodies (autoantibodies) to Tamm-Horsfall protein are widespread, the immunologic response to Tamm-Horsfall protein after a UTI may be disturbed in children with renal scarring (Fasth et al, 1980). This protein may account for findings of renal dysfunction or scarring associated with urinary vesicoureteral reflux without known infections, and the autoimmune response related to it may also provide a reason why chronic or progressive renal damage occurs long after cessation of reflux or active infections (Andriole, 1985).

End-Stage Renal Disease (ESRD)

Although end-stage renal disease caused by UTI alone is rare, end-stage renal disease related to reflux nephropathy is commonly associated with UTI and is estimated to account for 7% to 17% of ESRD worldwide, but it is only about 2% in the United States (Craig et al, 2000). This retrospective analysis of reflux nephropathy–associated ESRD does not show that treatment of vesicoureteral reflux with long-term antimicrobial prophylaxis or surgery has improved the natural history of reflux nephropathy. However, the proportion and incidence of children with ESRD with diagnosis of reflux nephropathy has decreased from 32.5% (1967 to 1971) to 7.2% (2002 to 2006) (Orr et al, 2009). The extent to which this finding is confounded by diagnoses of congenital renal dysplasia or hypoplasia associated with antenatal vesicoureteral reflux, rather than postnatal pyelonephritic scarring, is unclear. Notably, in Sweden in the 1990s, no child was recorded to have ESRD related to pyelonephritic scarring, and according to the Swedish Registry of Uremia, the incidence of pyelonephritic scarring–related ESRD is now only 6% to 7% (Wennerström et al, 2000).

MANAGEMENT OF SPECIAL URINARY TRACT INFECTIONS AND COMMON ASSOCIATED PROBLEMS

Urinary Tract Abnormalities

A reason for imaging to be part of the UTI evaluation in children comes from historical information of the close association of UTI and genitourinary malformations. These data appear two ways: (1) data examining the imaging findings after first UTI and (2) data examining genitourinary malformations and citing the proportion diagnosed by UTI evaluation. Earlier data have shown that imaging evaluation of children with UTI reveal that 5% to 10% of children have obstructive urinary tract lesions, and an additional 21% to 57% have vesicoureteral reflux (Kunin et al, 1964; Abbott, 1972; Asscher et al, 1973; Winberg et al, 1974; Newcastle Asymptomatic Bacteriuria Research Group, 1975). Because these data were collected prior to the widespread usage of both routine and prenatal ultrasonography and prophylactic antimicrobial usage in infants identified to have many genitourinary abnormalities, current practice confounds these associations in more recent reports. Although many countries now use prenatal screening and discover many genitourinary abnormalities for special management, thus removing children who may otherwise have had UTI, recent statistics

using imaging evaluation triggered by febrile UTI still reveal significant numbers of genitourinary abnormalities. A more recent retrospective examination of imaging results obtained from children in Taiwan after a first febrile UTI showed 56.1% to have abnormalities (all vesicoureteral reflux, 29.5%; grades III to V vesicoureteral reflux, 17%; renal hypodysplasia, 2%; hydronephrosis, 34% [grades I to II, 32%; grades III to IV, 2%]; hydroureter, 3%) (Lee et al, 2009).

From the side of the genitourinary abnormality, at one institution in Nigeria in which 28 boys were diagnosed to have posterior urethral valves (the majority of whom had prenatal ultrasonography), 50% of 28 boys were diagnosed only after UTI with urosepsis (Ikuerowo et al, 2008). Although renal scarring and hypoplasia are not considered correctable urinary tract abnormalities, they are abnormalities found after evaluation of UTI. In febrile UTI in children less than 5 years old (excluding those with obstructive lesions), 45% had acute DMSA-defined lesions (29% of kidneys). Two years later, 27% of these children (24% of kidneys) still had kidney scars independent of the presence of vesicoureteral reflux (Ditchfield et al, 2004).

Recurrent Urinary Tract Infection with a Normal Genitourinary System

Children who have no anatomic genitourinary problems but have recurrent UTI are common, and the condition is frustrating to parents and physician. Because host uroepithelial characteristics are independent of gross urinary tract abnormalities or reflux, **recurrent UTI will occur in about 20% of patients, the majority being girls, regardless of whether the urinary tract is normal** (Bratslavsky et al, 2004). Recurrent UTIs are common, and Winberg and associates (1974) have nicely documented the natural history. **Of boys who are infected before they are 1 year old, 18% develop a recurrent infection, but recurrences more than a year after the initial infection are rare. In contrast, if the initial infection occurs in an older boy, 32% become reinfected, suggesting that risk for neonatal UTI differs from that in older children.**

About 26% of girls who have an initial neonatal infection have a recurrence, and similar to infant boys, recurrences 1 year after the neonatal infection are less frequent. Girls who have their first infection after the neonatal period have a 40% recurrence rate, with the majority of recurrences occurring within the first 3 months after the hallmark UTI and two thirds occurring within the first year. Although the risk of recurrent infection in these girls drops with each subsequent infection-free year, 8% had their first recurrence more than 4 years after their original UTI; so, the risk never totally disappears.

For a girl who has a UTI, Winberg and associates (1974) calculated the risk of another UTI occurring within a year of the previous UTI to be proportional to the number of previous infections (i.e., the more UTIs a girl has, the more likely she is to get another). His data showed that this risk is greater than 25% with one previous UTI, greater than 50% with two previous UTIs, and almost 75% after three previous UTIs (Bergström et al, 1967; Winberg et al, 1974). This rate did not change whether the initial infection was symptomatic or asymptomatic, or if there was pyelonephritis or cystitis; in fact, about a third of the recurrences were asymptomatic. Data using polymerase chain reaction analysis of UTI *E. coli* isolates suggest that more recurrent UTIs in infants may be endogenous relapses (i.e., reinfection with same organism from the bowel) rather than new organism reinfections (Jantunen et al, 2002).

The lower rate of recurrent UTI in neonates and young boys and higher rate for older girls supports the importance of variable host and bacterial factors that create risk for bacteriuria in any individual. Unfortunately, there are no routinely available tests that can predict which children with a normal urinary tract have a biologic predisposition for UTI; polymorphisms discovered so far are part of research studies. Routine bacterial biotyping and sensitivity data obtained from cultures, moreover, do not give data relating to bacterial virulence. For this reason, management of the possibility of recurrences in these patients depends upon the child's age and severity of symptoms.

In the majority of children with normal urinary tracts who have mainly bladder irritative symptoms with their UTI (so-called uncomplicated infections), there is evidence that 3 to 5 days' treatment with an appropriate antimicrobial agent to which the organism is sensitive (Lohr et al, 1981; Madrigal et al, 1988; Copenhagen Study Group of Urinary Tract Infections in Children, 1991; Jójárt, 1991), or even a single dose of a parenteral antimicrobial agent (e.g., an aminoglycoside), is an effective treatment (Principi et al, 1977; Vigano et al, 1985; Grimwood, 1988). Longer antimicrobial courses of 10 to 14 days have not been proven to be more effective in these cases and may cause increased side effects and antimicrobial resistance in the fecal bacteria (Hansson et al, 1989a, 1989b, 1989c; Copenhagen Study Group of Urinary Tract Infections in Children, 1991). If the child has frequent recurrent infections (two or more during a 6-month period), a urinary prophylactic antimicrobial treatment during a limited period may be worthwhile, because the child has then established herself or himself to have susceptibility for infections. Antimicrobial agents taken at a prophylactic dosage will usually successfully decrease the rate of infections during the period of prophylaxis. When the antimicrobial agent is stopped, however, the child may extend into a period of remission from infection, but often eventually returns to an increased basic susceptibility for urinary infections (Winberg et al, 1974; Kraft and Stamey, 1977). Results from a questionnaire given to women with urinary frequency and painful bladder syndromes (e.g., interstitial cystitis) have associated childhood recurrent urinary infections and dysfunctional voiding symptoms in these individuals (Peters et al, 2009); however, there are no prospective or biologic studies confirming this.

Voiding Dysfunction and Constipation

Symptoms of nocturnal and diurnal incontinence are common in children with recurrent UTI. Epidemiologic investigations showed that monosymptomatic nocturnal enuresis is not associated with UTI, but diurnal enuresis or a combination of diurnal and nocturnal enuresis, even if as infrequent as once a week, may be associated with pediatric UTI (Hansson, 1992). Interestingly, **this study also revealed that 7-year-old girls who were greater than 3 years old when they had their first UTI were more likely to have symptoms of voiding dysfunction than those who were less than 3 years old at the time of the first UTI;** this may indicate an age-related phenomenon of this syndrome. Others, who compared children with UTI who were less than 2 years old to children without UTI, were unable to associate dysfunctional elimination syndrome with either UTI or VUR if the children were assessed again when they were 7 years

old (Shaikh et al, 2003). **Of note, almost 20% of children who had a recurrent UTI developed new diurnal enuresis that, starting with the onset of the UTI, persisted as long as 12 months, even when they remained free of UTI during the follow-up interval** (Sørensen et al, 1988).

Urodynamic testing in neurologically normal children with recurrent urinary infections and incontinence has shown abnormal cystometry and voiding patterns (Kass et al, 1979; Koff et al, 1979; Bauer et al, 1980; Koff, 1982; Kondo et al, 1983; Qvist et al, 1986; Hansson, 1992; Passerini-Glazel et al, 1992; vanGool et al, 1992). In 35 such children, Bauer and associates (1980) found 12 (34%) had normal filling cystometry, 9 (26%) had large hypotonic bladders, 9 (26%) had small capacity hypertonic bladders with increased intravesical filling pressure and sustained uncontrolled detrusor contraction at a low volume, and 5 (14%) had hyper-reflexic bladders showing uninhibited detrusor contractions during filling (Bauer et al, 1980). Voiding dysfunction has also been described with staccato (interrupted) urinary flows during voiding, showing increased pelvic floor activity during voiding with resulting incomplete bladder emptying (Bauer et al, 1980; Hansson, 1992; Passerini-Glazel et al, 1992; vanGool et al, 1992; Kjølseth et al, 1993). One group has shown that paradoxic pelvic floor activity may respond to biofeedback (de Jong et al, 2007). Notably, voiding dysfunction defined as increased pelvic floor activity causing elevated voiding pressures that lead to renal damage is probably unusual, whereas voiding patterns of extraordinary frequency, urgency with detrusor instability, infrequency, and incontinence are common (Hellerstein and Linebarger, 2003).

In addition to voiding dysfunction, children with recurrent UTI have frequent constipation. When 47 girls with normal urinary tracts, but who had recurrent UTI (with or without incontinence) and cystometry-proven bladder instability, were studied by digital rectal examination and rectal manometry, all had signs of functional constipation (O'Regan et al, 1985). Diurnal and nocturnal urinary incontinence (29% and 34%, respectively) and UTI (11%) were found in children greater than 5 years old who had chronic constipation (as defined by stool retention on rectal examination) and encopresis at least once a week (Loening-Baucke, 1997). Importantly, these findings were present even when constipation or encopresis was denied.

Others have not found constipation or daytime incontinence to be predictive of recurrent UTI (Bratslavsky et al, 2004). Although these findings do not establish causality between UTI, constipation, and voiding dysfunction, it can be seen that UTI may initiate symptoms of bladder and sphincter (urethral and rectal) dysfunction with variable persistence (Chase et al, 2004). **Girls with recurrent UTI are more likely to have a family history of UTI, infrequent voiding, poor fluid intake, and stool retention** (Stauffer et al, 2004). In some situations, treatment of constipation and/or voiding abnormalities has resulted in decreased UTI, and this possible relationship should be considered in the management of vesicoureteral reflux as well (Koff et al, 1998; Upadhyay et al, 2003), even though the association is unclear (Chen et al, 2004). These data suggest that bacteriuria or constipation may provoke abnormal detrusor-sphincter activity, or vice versa.

Covert or Asymptomatic Urinary Tract Infection

When covert or asymptomatic infections are diagnosed on screening urinary cultures, children often have symptoms related to the lower urinary tract upon careful interviews. They may have nocturnal and/or diurnal enuresis, squatting, and urgency, and at least 20% have a history of previous urinary tract infection (Kunin et al, 1962; Savage, 1975); however, these symptoms were not the reason they had the urinalysis or culture. About 50% of these children have normal urinary tracts defined by intravenous urography and voiding cystourethrogram.

Jodal (1987) found that a majority of infants who have covert bacteriuria may clear their bacteriuria without treatment; others state that only about 30% of asymptomatic school-age girls with asymptomatic UTI clear their bacteriuria spontaneously (without treatment) (Verrier-Jones et al, 1975; Lindberg et al, 1978). Whether treated or not, the majority of these girls will acquire persistent infection or reinfection. Whether the UTI is symptomatic or asymptomatic may not be important for the first UTI; the UTI marks host susceptibility. Thus this first UTI should be treated similar to any other first UTI. However, once the urinary tract has been evaluated and found to be normal or abnormal, treatment or screening for subsequent asymptomatic or covert UTI is debatable and probably unnecessary; obtaining routine cultures or urinary screening cultures are not supported (Shortliffe, 1995; Narchi, 2004).

Because covert bacteriuria may not be totally asymptomatic in school-age children, if symptoms such as incontinence are elicited by history, they should be treated. Treatment of the infection alone, however, may not obviate symptoms of voiding dysfunction. **Controlled studies involving older children with treated and untreated covert bacteriuria show that treatment makes little difference in the rate of future reinfection; over half will have recurrent infection whether treated or not, and the risk of any renal damage in these older children is very low** (Lindberg et al, 1975; Savage, 1975; Verrier-Jones et al, 1975; Jodal, 1987).

Furthermore, women with type 2 diabetes mellitus and asymptomatic bacteriuria have increased risk of getting a symptomatic UTI (Geerlings et al, 2001a, 2001b). Therefore there is little evidence that the natural history of asymptomatic UTI is changed by therapy, and the UTI event, symptomatic or asymptomatic, marks a susceptible host. This is now supported by long-term follow-up of women with symptomatic bacteriuria and prospective studies of those with asymptomatic bacteriuria (Hooten et al, 2000; Vosti, 2002). However, not all share this conclusion and the management implications (Bensman, 2002).

In several series in which girls with urinary tract infections were randomized between antimicrobial treatment and no treatment, subsequent renal scars rarely occurred when the kidney was free of scars at first imaging; conversely, new or increased scarring usually occurred in previously scarred kidneys in which vesicoureteral reflux was present. This was independent of antimicrobial therapy (Newcastle Asymptomatic Bacteriuria Research Group, 1975; Savage et al, 1975; Cardiff-Oxford Bacteriuria Study Group, 1978; Newcastle Covert Bacteriuria Research Group, 1981).

There is evidence that *E. coli* causing covert bacteriuria may be strains of *E. coli* that show self-agglutination, loss of surface antigens, inability to develop an epithelial cell IL-6 response, and less overall pathogenicity (Lindberg et al, 1975, 1978; Hansson et al, 1989a; Mabbett et al, 2009). Some studies have suggested that urinary tract colonization with a strain of *E. coli* causing asymptomatic bacteriuria may prevent colonization with an *E. coli* causing symptoms, and that treatment may actually lead to later acute symptomatic pyelonephritis (Hansson et al, 1989a, 1989b, 1989c). Other evidence points to a host deficit, with an impaired

mucosal TLR4 inflammatory response causing decreased symptoms (Ragnarsdöttir et al, 2007). For this reason, in difficult cases of recurrent asymptomatic infection without other urinary tract abnormalities or pregnancy, follow-up without further antimicrobial treatment should be considered seriously.

Incontinence Associated with Urinary Tract Infection and Normal Urinary Tracts

When symptoms of voiding dysfunction accompany recurrent UTI, it is probably worth observing the child on prophylactic antimicrobial agents to observe any change in voiding pattern while the urine is sterile. If symptoms of incontinence persist, addition of an anticholinergic agent, such as oxybutynin, and/or bladder rehabilitation that includes timed voiding and biofeedback techniques may help to improve incontinence and decrease the frequency of UTI.

In addition, **if constipation is found or even suspected, there may be an improvement in voiding and reduction in UTI if this is treated.** With the acute onset of bowel and bladder dysfunction in a child, the possibility of a tethered cord or other neurologic abnormalities must be eliminated.

OTHER GENITOURINARY TRACT INFECTIONS AND SYNDROMES

Bacteria and other organisms that grow under fastidious conditions and cannot be cultured without special growth media may cause UTI and pyelonephritis, especially in association with abnormal urinary tracts and renal insufficiency. Organisms such as *Haemophilus* associated with UTI in abnormal urinary tracts (Hansson et al, 2007) and *Trichomonas, Chlamydia,* microaerophilic microorganisms, and viruses will not grow in ordinary cultures; so, one must be suspicious of organisms other than those causing tuberculosis if evaluating sterile pyuria.

Inflammatory Acute Hemorrhagic Cystitis (Viral Cystitis)

Acute hemorrhagic cystitis accompanied by frequency, urgency, and dysuria in children has been associated with UTI caused by adenovirus 11 (Manolo et al, 1971; Mufson et al, 1973; Numazaki et al, 1968, 1973) and, occasionally, *E. coli* (Loghman-Adham et al, 1988-1989). **Adenovirus is the most common cause of viral acute hemorrhagic cystitis in children.** In a series of 69 infants and children with acute hemorrhagic cystitis, adenovirus 11 was recovered from the urine of 10 (14.5%), adenovirus 21 was in the urine of 2 (2.9%), and *E. coli* was present in 12 (17.4%), but the remainder (greater than 60%) had no infectious agents isolated from the urine (Mufson et al, 1973). Polyomaviruses have caused both hemorrhagic and nonhemorrhagic cystitis in children.

Viral cystitis has been commonly associated with bone marrow transplantation and other immunosuppressed conditions. Severe adenovirus in these children has caused fatalities as high as 50% to 80% without successful treatment, although recent ribavirin usage has been reported (Gavin and Katz, 2002). **BK, a DNA virus of the polyomavirus genus, has been found in the urine of bone marrow transplantation and other immunosuppressed patients having hemorrhagic cystitis (0.5 to 5 months after transplantation), causing both symptomatic (hematuria and dysuria), and asymptomatic infections** (Apperley et al, 1987; Bedi et al, 1995). It is hypothesized that immunosuppression may relate to reactivation of BK virus. In several series, hemorrhagic cystitis was associated with persistent BK viruria the majority of the time, and shedding of BK virus was usually correlated with onset of hemorrhagic cystitis.

Because routine viral cultures are infrequently done, children with symptoms of acute hemorrhagic cystitis most often have no growth on routine urinary culture. Although no antimicrobial treatment is indicated in healthy individuals with viral cystitis, renal and bladder ultrasonography or other imaging should still be performed to eliminate other causes for hematuria. It has been suggested that ribavirin may be useful for adenovirus cystitis after bone marrow transplantation (Cassano, 1991). Chemically induced hemorrhagic cystitis is not discussed in this section.

Interstitial Cystitis

Although individuals with interstitial cystitis often have a history of possible UTI, and some patients recall childhood symptoms (Peters et al, 2009), there is no evidence that it results from infection. Initial symptoms of frequency—suprapubic pain, nocturia, and urgency—may be confused with UTI but must be differentiated in children with either voiding dysfunction or urinary frequency syndrome. When strict diagnostic criteria of interstitial cystitis, such as Hunner ulcers, pain on bladder filling relieved with emptying, suprapubic pain, and urinary urgency or frequency are applied, this is a rare condition in children (Farkas et al, 1977; Close et al, 1996). This is primarily a diagnosis of exclusion, but the diagnosis is usually based upon finding bladder glomerulations on cystoscopy and decreased compliance on cystometrogram. Urodynamic findings of instability and involuntary bladder contractions are incompatible with this diagnosis (Close et al, 1996). When culture and sensitivity information are available, the antimicrobial agent should be re-evaluated and changed, if necessary, with treatment continuing for 7 to 10 days.

Epididymitis, Epididymo-orchitis, and Orchitis

Epididymitis is an important clinical syndrome because of its differential diagnosis and management. Although prepubertal epididymitis was diagnosed rarely in earlier series (Anderson and Giacomantonio, 1985), more **recent series using newer imaging modalities have diagnosed epididymitis almost as frequently as acute testicular torsion.** In 2000, according to the HCUP data, children were rarely hospitalized with orchitis—1.6 hospitalizations per 100,000 (Freedman, 2004). **Epididymitis is often difficult to distinguish from other pediatric acute scrotal processes, especially acute testicular torsion, and occurs almost as frequently (15% to 45%)** (Caldamone et al, 1984; Knight and Vassy, 1984; Mendel et al, 1985; Yazbeck and Patriquin, 1994). Although the differential diagnosis and evaluation of the acute scrotum is discussed in Chapter 132, the etiology and evaluation of epididymitis is related to UTI in some of these cases.

Although there is overlap, pediatric epididymitis occurs in a somewhat bimodal age distribution. **It usually occurs in very young and postpubertal boys** (Gierup et al, 1975; Knight and

Vassy, 1984; Anderson and Giacomantonio, 1985; Likitnukul et al, 1987; Siegel et al, 1987; Melekos et al, 1988; Anderson et al, 1989). This is a useful distinction clinically, because the etiologies and management differ.

Symptoms and Signs

The symptoms and signs of acute epididymitis cannot be differentiated from those of any acute scrotal condition and may also be the reactive result of early torsion of the testes or appendix testes. Characteristics that may be useful for comparison with acute torsion of the testes are history of more gradual onset, dysuria, urethral discharge, and history of urethral manipulation; recent urinary tract surgery (hypospadias, ureteral reimplantation); catheterization; neurogenic bladder; imperforate anus; or known lower tract genitourinary anatomic abnormalities (ureteral or vasal ectopia, bladder exstrophy) (Mandell et al, 1981; Knight and Vassy, 1984; Umeyama et al, 1985; Siegel et al, 1987; de la Hunt et al, 1989; Stein et al, 1994). The scrotum is usually inflamed and swollen (Doolittle et al, 1966); there may be localized epididymal pain; 18% to 33% of boys have fever (Doolittle et al, 1966; Gierup et al, 1975; Knight and Vassy, 1984; Siegel et al, 1987); and 24% to 73% have pyuria (Doolittle et al, 1966; Gislason et al, 1980; Knight and Vassy, 1984; Anderson and Giacomantonio, 1985; Siegel et al, 1987; Anderson et al, 1989). Although these symptoms are more likely to be associated with epididymitis than acute testicular torsion or torsion of the appendix testes, none is diagnostic. Pyuria and bacteriuria are rarely found in torsion.

When a boy has an acute scrotum, scrotal color flow Doppler ultrasonography and testes scintigraphy help confirm or follow epididymitis, and may at times confirm torsion of the appendix testes (Mendel et al, 1985; Mueller et al, 1988; McAlistar and Sisler, 1990; Atkinson et al, 1992; Yazbeck and Patriquin, 1994). Ultrasonography may show an enlarged epididymis of mixed echogenicity surrounded by reactive fluid. Color flow Doppler sonography usually shows increased testicular flow, except when there is such extensive swelling that ischemia may occur. However, most changes, including those from viral or mumps orchitis or epididymo-orchitis, are nonspecific (Tarantino et al, 2001). Nuclear scintigraphy, similarly, will usually show increased perfusion and increased radiotracer deposition in the affected side of the scrotum. Although nuclear scintigraphy may be more sensitive in detecting flow, especially in prepubertal boys, sonography has better anatomic resolution and may reveal epididymal or testicular abscesses (McAlistar and Sisler, 1990; Atkinson et al, 1992).

Pathogenesis

In young boys and infants, epididymitis is more likely to be related to genitourinary abnormalities (abnormal connections) or systemic hematogenous dissemination than in older males (Williams et al, 1979). **Urethral and urinary cultures from the prepubertal male are likely to show either nothing or gram-negative organisms and thus are referred to as "nonspecific epididymitis," whereas, in postpubertal sexually active boys, the cause may involve sexually transmitted organisms (*N. gonorrhea, Chlamydia trachomatis*).** Similar to the pathogenesis of renal abscess, data support two means of bacterial access to the epididymitis and testes: hematogenous dissemination and urinary tract–related infection. In young boys and infants, hematogenous pathogenesis is supported by reports in which *Haemophilus influenzae* type b have been cultured from epididymal abscesses concurrent with other sites of infection, such as otitis media, while the urinalysis remains normal, and associated positive viral titers may be found in others with acute inflammation (Weber, 1985; Greenfield, 1986; Lin et al, 1988; Somekh et al, 2004). Because organisms such as *Haemophilus influenzae* may require special culture techniques that may not ordinarily be used for urinary cultures, this may also account for the 40% to 84% of cultures from boys diagnosed to have epididymitis without an identifiable organism (Knight and Vassy, 1984; Cabral et al, 1985; Likitnukul et al, 1987). The fact that ascending UTI or bacteria sometimes causes epididymitis and epididymo-orchitis is supported by the observation that these boys who have pyuria and bacteriuria are more likely to have a urinary tract abnormality and may be diagnosed at a young age (Siegel et al, 1987).

Management

Epididymitis should be treated for the presumptive causative organism. Specifically, in the young child who has pyuria and possible bacterial epididymitis, initial broad-spectrum antimicrobial coverage similar to that used to treat a UTI in an ill child should be used. Once the culture results and antimicrobial sensitivities are available, the most specific and cost-effective agent (with few side effects) that achieves good tissue and urinary levels should be selected. Clearly, those children who are thought to have epididymitis on the basis of viral infection, reaction to torsion of the appendix testes, trauma, or other nonbacterial etiology should not be given antimicrobial agents; treatment with analgesics and nonsteroidal anti-inflammatory agents is more appropriate.

During or after treatment of the acute bacterial urinary and epididymal infections, radiologic evaluation of the urinary tract should be performed as with any UTI. Two studies report a high probability of genitourinary anatomic abnormalities, in particular abnormal connections between the urinary tract and bowel or genital duct system when a child has bacterial epididymitis and a UTI (Siegel et al, 1987; Anderson et al, 1989). In both studies, boys with negative urinary cultures had normal urinary tracts. Whether all boys with epididymitis, including those with negative urethral and urinary cultures, need a full radiologic evaluation of the urinary tract is unclear from current data. It does appear prudent, however, to perform a voiding cystourethrogram and renal and bladder ultrasonography on prepubertal boys with documented urinary infections, and perhaps those in whom epididymal abscesses are found, although the latter may be related to hematogenous spread.

Epididymitis Associated with Unusual Organisms

Whenever scrotal masses are considered, tuberculous epididymitis must also be considered as the most common form of urogenital tuberculosis (Cabral et al, 1985). Whereas this form of epididymitis is more likely to be confused with a malignancy rather than a cause of an acute scrotal mass, because it usually involves painless swelling, this can be an important cause of epididymitis when dealing with patients from areas in which tuberculosis may be endemic. Although there is evidence for both local urinary spread and hematogenous spread of tuberculosis to the epididymis, in the reported pediatric cases of tuberculous epididymitis, there are usually other signs of hematogenous involvement, and the urine may or may not be positive for the organism (Cabral et al, 1985).

Funguria

Fungal UTI is an increasing health care–associated infection, especially in individuals who have received antimicrobial agents and have urinary drainage catheters (Kauffman et al, 2000). **Candidemia in one neonatal intensive care unit increased more than 11-fold between 1985 and 1995** (Kossoff et al, 1998). In children, predisposing factors may include antimicrobial therapy, prematurity, and intravenous or umbilical artery catheterization, parenteral nutrition, and immunocompromised status (Keller et al, 1977). The urinary tract may serve both as a primary portal of entry and as a site of disseminated infection. **Prophylactic usage of oral nystatin or fluconazole in very low–birth-weight babies (<1000 to 1500 g) has been reported to be useful in preventing colonization and invasive fungal infection** (Sims et al, 1988; Kaufman et al, 2001; Kicklighter et al, 2001). In children and adults with disseminated candidiasis, the kidney is the most commonly involved organ (Keller et al, 1977). ***Candida* species are the most common cause of fungal UTI, with *Candida albicans* being the most common of these and responsible for about half of these. The second most common is *Torulopsis glabrata* (also known as *Candida glabrata*), an important species to recognize because of its common resistance to fluconazole** (van't Wout, 1996; Kauffman et al, 2000). Fungal bezoars may form in the renal pelvis, causing obstruction and anuria in infants with bilateral involvement (Keller et al, 1977; Eckstein and Kass, 1982; Robinson et al, 1987; Bartone et al, 1988; Rehan and Davidson, 1992; Hitchcock et al, 1995). For this reason, renal ultrasonography may be helpful in evaluating the extent of fungal infection when funguria is persistent. Although urinary alkalinization and oral or intravenous antifungal chemotherapy may dissolve some of these fungal balls, in infants these balls may totally obstruct the small urinary tract, requiring percutaneous or surgical removal of the bezoars or drainage so that both local irrigation and systemic therapy can be given. Streptokinase was reported to rapidly dissolve a fungal ball in one infant (Kabaalioglu et al, 2001). **Deciding when asymptomatic funguria related to an indwelling urethral catheter should be treated remains controversial, and a surveillance study involving 861 patients has shown that progression to disseminated candidemia is relatively uncommon** (Kauffman et al, 2000). When repeated cultures grow to concentrations greater than 10,000 to 15,000 CFU/mL, treatment is usually recommended (Wise, 1998). Although stopping unnecessary antimicrobial agents, changing or removing the indwelling catheter, and urinary alkalinization may be helpful, these means do not clear many cases of funguria. Recent prospective studies with intravesical amphotericin B bladder irrigation and oral fluconazole appear to show that both may clear funguria, although fungal recurrences are common (Gubbins et al, 1994, 1999). Optimal dosages, length of treatment, and delivery (intermittent vs. continuous) for amphotericin are indeterminate and controversial, but amphotericin B (50 mg/L) infused continuously at 42 mL/hr for 72 hours is effective (Trinh et al, 1995; Nesbit et al, 1999). Fluconazole has been used successfully in children, although unapproved for those less than 6 months old (Hitchcock et al, 1995; Zia-ul-Miraj and Mirza, 1997). Fungal bezoars in the collecting system require treating obstruction, when present, with a percutaneous nephrostomy tube for drainage and potential local irrigation. In these situations, both local and systemic therapy with amphotericin B and/or oral fluconazole may be useful for management. Should the fungal balls persist, surgical removal is necessary.

GENITOURINARY TRACT AND NOSOCOMIAL INFECTIONS

Surgical-Site Infections and Surgical Prophylaxis

There is scant literature on surgical-site infection for the urinary tract in children (Grabe et al, 2001). In 1992, the Centers for Disease Control and Prevention (CDC) changed the term for surgical procedure–associated infections to surgical-site infections: incisional superficial (skin and subcutaneous tissue) and deep (deep soft tissue, muscle, fascia), organ, and spaces manipulated during an operation. The organisms associated with such infections relate to the organs and orifices entered. When the gastrointestinal, genitourinary, or respiratory tracts have not been entered, the most common pathogen is *Staphylococcus aureus*.

Data from the U.S. National Nosocomial Infections Surveillance System show the **incidence of surgical-site infections are higher in infants younger than 2 months than in older children** (Richards et al, 1999). Other data support the view that prepubertal children, except neonates, have lower incidence of surgical-site infections than older children and adults, but these data are difficult to compare. One report on genitourinary infections in children and adolescents reports that shaving the surgical site in the operating room, rather than the night before, is associated with decreased wound infections (McCray et al, 1986).

The most recent published CDC guidelines related to surgical-site infections were published in 1999 and summarized by Nichols and associates (Nichols, 2001; Nichols and Florman, 2001). None are specific for children or include genitourinary operations (Bratzler et al, 2005). **These guidelines recommend (1) not removing hair unless it will interfere with the operation and, if removed, clipping immediately before the operation; (2) identifying and treating all remote infections; (3) maintaining as short a hospitalization as possible; (4) administering antimicrobial agents only when indicated, based upon published recommendations for a specific operation; (5) administering antimicrobial agents intravenously to ensure bactericidal serum and tissue levels when the incision is made (60 minutes before incision with most agents and 120 minutes before incision with vancomycin) and maintaining these levels for a few hours after closure, with discontinuation no later than 24 hours after surgery, even if drainage catheters are left in place** (Botto et al, 2001); **(6) preparing the bowel for elective operations with mechanical bowel preparation, including enemas and cathartic agents and nonabsorbable oral antimicrobial agents the day before surgery, in addition to the intravenous drugs; and (7) withholding routine vancomycin usage** (Zanetti et al, 2005). In situations in which the value of antibiotic prophylaxis is unproven, a single-dose systemic-appropriate cephalosporin given during the immediate preoperative period may be indicated. Although the CDC website lists the preceding guidelines as of 2009, augmentation cystoplasty in children and ileal conduit urinary diversion has been performed without mechanical and antibiotic preparation,

and without increased morbidity (Gundeti et al, 2006; Tabibi et al, 2007). Others perform small and large bowel surgery without bowel preparation.

Nosocomial Urinary Tract Infections

Catheter-associated UTIs are the most common hospital-acquired infections, usually associated with urethral instrumentation or chronic indwelling catheterization (Shortliffe, 1997). The risk of UTI increases with the duration of catheterization, and the acute nosocomial UTI is usually asymptomatic. **In one study, 20% of childhood bacteremia was caused by UTI or prior urinary tract manipulation with introduction of pathogens** (Dupont and Spink, 1969). Other infectious complications associated with catheterization and UTI are acute epididymitis-orchitis, pyelonephritis, periurethral abscesses, and struvite and renal calculi. Cultures taken from urethral catheter tips show little correlation with urine cultures (Gross et al, 1974a, 1974b).

When urethral catheters are placed, the patient risks urethral injury and bacteremia from catheter manipulation. As a result, **any individual with a cardiac problem who risks endocarditis must receive antimicrobial prophylaxis before catheter manipulation.** The incidence of UTI directly relates to the duration of the indwelling catheterization. There are no studies examining the rate of bacteriuria in children, but adult studies show that **in 95% of open drainage systems, bacteriuria occurs within 4 days** (Kass and Finland, 1956), **and with closed drainage systems, 5% to 10% become bacteriuric each day** (Warren et al, 1978).

Catheter-associated UTI originates from (1) periurethral organisms, (2) organisms infecting the collecting bag or device, and (3) organisms entering the system with breaks in the closed drainage system or lack of a closed system. **Recommendations for indwelling catheter care are (1) genital washing once or twice daily with water and soap without antiseptics or antimicrobial agents, (2) regular emptying of the collection bag, and (3) ongoing prophylactic antimicrobial drug therapy to prevent infection during insertion or while indwelling, but it is not recommended unless the patient is at risk for endocarditis or is neutropenic** (Daschner et al, 2001; Warren, 2001). There is no need for irrigation with antibacterial substances, antimicrobial agent instillation into the collecting bag, special antibacterial-coated catheters, or routine change of the catheter. None of these procedures can prevent catheter-associated UTI permanently.

Asymptomatic bacteriuria associated with catheter drainage need only be treated before any urinary tract manipulation or when the drainage tube is removed; the resident organisms should then be treated and the urine sterilized prior to removal (Botto et al, 2001; Warren, 2001). **If the catheter has been left in for 4 or more days, the practitioner should assume that the urine is infected. (See earlier section [Neurogenic and Bowel-Augmented Bladder] on management of the neurogenic bladder for information on clean intermittent catheterization programs.)**

BACTERIOLOGIC ECOLOGY AND ANTIMICROBIAL RESISTANCE

The development of more powerful antimicrobial agents allows improved and less morbid treatment of UTI, specifically pyelonephritis. At the same time, however, infecting organisms are becoming more and more resistant to routine antimicrobial agents and more problematic to treat, with fewer agents from which to select. In 1993, Calvin Kunin referred to this problem as a "worldwide calamity" resulting from bacterial genetic change causing resistance and population mobility (Kunin, 1993). The situation has not improved in the last 15 years.

The widespread usage of antimicrobial agents was thought to create the pressure that creates and selects for most resistant organisms. However, using techniques of DNA fingerprinting, electrophoretic pattern characterization, serotyping, and virulence identification, **certain clones of multidrug–resistant *E. coli* have been shown to behave with characteristics of an "epidemic outbreak."** For instance, an outbreak of *E. coli* 015:K52:H1 caused a community-acquired cystitis, pyelonephritis, and sepsis in London from 1987 to 1988 with epidemic-like spread, and the outbreak caused endemic *E. coli* urinary infections in Spain. In another instance, a single, previously unidentified multidrug–resistant *E. coli* clonal group A isolate (with resistance to trimethoprim-sulfamethoxazole) was discovered to cause 11% of community-acquired UTI in women seen in a California university health service during a 4-month period and to account for about 50% of the resistant isolates. The same clonal group appeared to cause almost 40% of resistant infections in cohort groups in Michigan and Minnesota (Manges et al, 2001). In another evaluation of this resistant *E. coli* clonal group A organism in a large public health system in Denver, Colorado, the **risk of having UTI with the resistant organism was associated with those younger than age 3 years, Hispanic ethnicity, recent travel outside the United States, and prior UTI.** Almost 15% of groups had trimethoprim-sulfamethoxazole–resistant organisms (Burman et al, 2003). The source of these clonal epidemic-like occurrences is unclear, but some evidence implicates food and or contact with food sources that may have had antimicrobial agent contact (Drexler, 2002).

This resistance is global; in 1999 in Israel, community-acquired UTI organisms were resistant to trimethoprim-sulfamethoxazole (31%), to cephalexin (37%), and to ampicillin (70%) (Prais et al, 2003). In Canada, from 1992 to 1994, examination of 1636 consecutive isolates of *E. coli* causing UTI found antimicrobial resistance occurrence was 45% for ampicillin, 31.4% for trimethoprim-sulfamethoxazole, with combined resistance to both at 22.2%; 1.7% of organisms were resistant to both ampicillin and gentamicin. Case-control examination of those with trimethoprim-sulfamethoxazole–resistant organisms showed that children who were given antimicrobials for more than 4 weeks in the previous 6 months were 23 times more likely to have resistance; children with genitourinary abnormalities (e.g., genitourinary tract abnormalities, spina bifida, vesicoureteral reflux) were 2.4 times more likely to have resistance; and children with previous hospital admissions had an OR of 2.3 if one admission and an OR of 3.2 if there was more than one admission. Also the OR was 0.3 in those less than 2 years old compared with those 2 to 6 years old (Allen et al, 1999) (Table 116–7).

To attempt any control of this global problem, we must prescribe antimicrobial agents in a socially conscious manner. Recommendations by the Infectious Disease Society of America (IDSA) include **(1) optimal use of antimicrobial agents, (2) restriction of classes or specific agents, (3) rotational or cyclic usage, and (4) use of combination antimicrobial therapy to decrease resistance** (Shlaes et al, 1997).

Table 116–7.

Factors Associated with Trimethoprim-Sulfamethoxazole Resistance

FACTOR	ODDS RATIO
Antibiotics taken for >4 weeks in past 6 months	23.4
Genitourinary tract abnormality	2.4
Number of hospital admissions in past year	
0 (reference)	1.0
1	2.3
≥2	3.2
Age in years	
<2	0.3
2-6 (reference)	1.0
>6	0.5

CONSIDERATIONS IN TREATING CHILDREN WITH URINARY TRACT INFECTION

Rational treatment of infants and children with UTI is based upon an understanding of bacterial and host risk factors with rapid detection of UTI and evaluation of potential risks to modify them when possible. Moreover, judicious use of antimicrobial agents allows effective treatment and limits organism selection and bacterial resistance. We should consider the inevitable emergence of antimicrobial resistance with widespread usage of any antimicrobial agent and that future virulence targets for drugs are limited (Lee et al, 2003).

Antimicrobial usage should be limited to the shortest effective duration and narrowest spectrum. When a child with UTI and renal scarring has been identified, their management should minimize their chances of future bacteriuria and assess potential risk factors to prevent further infection-related renal damage. In some instances, knowledge of predisposing risk factors may help select children for urinary tract antimicrobial prophylaxis or further evaluation. In others, anatomic knowledge may allow consideration of lack of antimicrobial treatment. When renal scarring is identified, the child and parents should be educated about potential future hypertension, proteinuria, and progressive nephropathy. In moderate to severe renal scarring with renal insufficiency, early nephrologic consultation for evaluation and surveillance for hypertension, proteinuria, acid-base imbalance, and counseling and management may improve or stabilize renal function and improve growth. In particular, the young female with renal insufficiency from "pyelonephritic nephropathy" and recurrent UTI may desire pregnancy counseling related to future renal insufficiency.

Although full genetic screening for UTI, renal scarring, and vesicoureteral reflux susceptibility is not yet available, or perhaps practical, families in whom a member has vesicoureteral reflux, renal insufficiency, and/or renal scarring should be made aware of potential risk for vesicoureteral reflux, UTI, and consequences of UTI, as appropriate, and the need for early diagnosis, treatment, and evaluation of UTI in family members. Future research should help direct more selective identification of those children at high risk of renal damage from UTI.

Key Points: Urinary Tract Management

- No follow-up urinary culture after 48 hours of treatment is required if organisms are sensitive to the antibiotic selected.
- Risk factors for acquiring antimicrobial-resistant uropathogens are diabetes, recent hospitalization, recent antibiotic usage (especially trimethoprim-sulfamethoxazole), urinary malformations, urethral catheters, and antimicrobial prophylaxis.
- Radionuclide VCUG should not be used to evaluate first infections in infants, young boys, or those in whom risk of genitourinary abnormality is high and urethral visualization is important.
- VCUG performed for purposes of UTI evaluation may be performed when the urine is sterile, bladder volume is normal, and bladder irritability is no longer present.
- The pediatric kidney is more likely to scar than the mature adult kidney.
- Focal segmental glomerulosclerosis is found in children with reflux nephropathy and proteinuria, even when renal function is relatively preserved.
- Epididymitis in children is difficult to distinguish from testicular torsion and occurs almost as frequently.
- Antimicrobial agents must be prescribed in a responsible way to avoid and decrease antimicrobial agent resistance.
- Benefits of antimicrobial prophylaxis for children with general vesicoureteral reflux and hydronephrosis are unclear.
- Benefits of probiotic microorganisms are unclear.

Anomalies of the Upper Urinary Tract

Ellen Shapiro, MD ● Stuart B. Bauer, MD ● Jeanne S. Chow, MD

Anomalies of Number
Anomalies of Ascent
Anomalies of Form and Fusion
Anomalies of Rotation
Anomalies of Renal Vasculature
Anomalies of the Collecting System

Congenital anomalies of the upper urinary tract comprise a group of abnormalities, ranging from complete absence to aberrant location, orientation, and shape of the kidney as well as aberrations of the collecting system and blood supply. These diverse entities are among the most common malformations in newborns. Historically, developmental biology of the urinary tract was based on observations in animal models and human fetuses. The mechanism and timing of various congenital anomalies were extrapolated from the normal process of organogenesis. Technical advances in molecular genetics have provided the opportunity to hypothesize complex mechanisms of normal and abnormal development.

ANOMALIES OF NUMBER

Bilateral Renal Agenesis

Of all the anomalies of the upper urinary tract, bilateral renal agenesis (BRA) has the most profound effect on the fetus. Fortunately, it occurs infrequently when compared with other renal abnormalities. Although BRA was first recognized in 1671 by Wolfstrigel, it was not until Potter's extensive description of the constellation of associated defects that the full extent of the syndrome could be appreciated and easily recognized (Potter, 1946a, 1946b, 1952). Subsequently, many investigators have attempted to explain the syndrome by employing a single unifying etiology (Fitch and Lachance, 1972). However, we are learning that there is probably no single etiology as we begin to unravel the myriad of complex molecular events that are required for normal renal development.

The incidence of BRA is rare, with only about 500 cases reported in the literature. Potter (1965) estimated that BRA occurs once in 4800 births, but in British Columbia the incidence is 1 in 10,000 births (Wilson and Baird, 1985). Davidson and Ross (1954) noted a 0.28% incidence in autopsies of infants and children, whereas Stroup and colleagues (1990) detected an incidence of 3.5 per 100,000 in the Centers for Disease Control Birth Defects Monitoring Program. A recent study using prenatal ultrasonography in 8500 pregnancies in Poland reported an incidence of 0.25% (Forys et al, 2003). There is significant male predominance, with almost 75% of individuals being male. Increasing maternal age appears to be a risk factor (Bianca et al, 2003), but specific complications of pregnancy or any maternal disease do not appear to consistently influence the incidence of BRA (Davidson and Ross, 1954; Ruhland et al, 1998). The anomaly was reported in three infants of an insulin-dependent diabetic mother (Novak and Robinson, 1994). It has been observed in several sets of siblings (Rizza and Downing, 1971; Dicker et al, 1984) and in monozygotic twins (Thomas and Smith, 1974; Cilento et al, 1994). In four pairs of monozygotic twins, one sibling was anephric while the other had normal kidneys (Kohler, 1972; Mauer et al, 1974; Cilento et al, 1994; Klinger et al, 1997). It has been suggested that an autosomal-recessive inheritance pattern exists (Dicker et al, 1984). There is a genetic predisposition to this syndrome with a high level of penetrance (Stella, 1998). **When siblings and parents of an index child with BRA were screened, 4.5% had unilateral renal agenesis** (Roodhooft et al, 1984) and 3.5% had BRA (McPherson et al, 1987). This is 1000 times higher than in the general population (Stroup et al, 1990). Other investigators have suggested that this is an autosomal-dominant trait with variable penetrance (Kovacs et al, 1991; Murugasu et al, 1991; Moerman et al, 1994; Stella, 1998). Recently, McPherson (2007) evaluated renal anomalies in families of individuals with congenital solitary kidneys that included renal agenesis or a very poorly functioning kidney due to dysplasia/hypoplasia. The empiric risk of 7% for offspring, 4% for parents, and 2.5% for siblings may be an underestimation, because not all relatives underwent ultrasound screening. The incidence of BRA in offspring of congenital solitary kidney probands was ≈1%, which is significantly greater than the risk found in the general population but less than that for families with a history of BRA. Ultrasound screening has been recommended for parents and siblings of infants born with either unilateral or bilateral renal agenesis or dysgenesis (Roodhooft, 1984). McPherson (2007) has recommended prenatal ultrasound examination when either parent has a congenital solitary kidney. Ultrasound screening is also recommended for first-degree relatives of persons with congenital solitary kidney.

Syndromic Associations. BRA has been detected in higher-than-expected proportions in esophageal atresia (Saing et al, 1998) and several syndromes, including cryptophthalmos or Frazer syndrome (Fryns et al, 1997), Klinefelter syndrome (Barroeta et al, 2004), and Kallmann syndrome (Colquhoun-Kerr et al, 1999).

Renal Embryology. The **intermediate kidney, or mesonephros, develops and then regresses except for the mesonephric tubules** (Constantini and Shakya, 2006; Schedl, 2007; Uetani and Bouchard, 2009). In the male, these are the efferent ductules that serve as a link between the gonad and the mesonephric or wolffian duct (WD) structures (the body and tail of the epididymis and vas deferens). In the female, the mesonephric tubules link the ovary through the fimbriated end of the fallopian tube to the reproductive tract. The WD elongates caudally and fuses with the anterior cloaca. **The definitive kidney differentiates from the metanephric blastema, which is a specialized region of the intermediate mesoderm termed the metanephric mesenchyme (MM).**

This process requires the reciprocal induction between the metanephric blastema and the ureteral bud (UB). The metanephric blastema sends signals to the WD to initiate UB formation between the fifth and seventh weeks of gestation. As a result, the ureter is induced from the caudal end of the WD. The UB evaginates and invades the metanephric blastema and branches repeatedly in a characteristic pattern to form the collecting duct system. The ureteral tips induce nephron differentiation in the adjacent mesenchyme, forming the mature metanephros (Airik, 2007; Uetani and Bouchard, 2009). The absence of a nephrogenic ridge on the dorsolateral aspect of the coelomic cavity or the failure of a UB to develop from the WD will result in renal agenesis. Therefore in order for BRA to occur, there must be an alteration in normal molecular development or a mutation that causes renal or ureteral maldevelopment on both sides of the midline (see Molecular Mechanisms of Mammalian Kidney Organogenesis).

Relationship of the Wolffian Duct to Müllerian Duct Formation. **A review of the relationship of the WD to müllerian duct (MD) development is necessary to understand the genitourinary phenotype of individuals with renal anomalies or more specifically, renal agenesis** (Kobayashi and Behringer, 2003). The cellular mechanisms involved in MD formation have been partially unraveled only recently. Gene fate mapping and lineage tracing experiments show that the WD does not contribute cells to the MD, and the MDs are derived from the coelomic epithelium (Guioli et al, 2007; Orvis and Behringer, 2007). **A three-phase model of MD development has recently been proposed** (Guioli et al, 2007; Orvis and Behringer, 2007). In the first phase, cells of the coelomic epithelium in the cervical region of the intermediate mesoderm are specified to become MD cells and have been noted to express *Lim1* (Kobayashi et al, 2005; Orvis and Behringer, 2007; Masse et al, 2009) (Fig. 117–1). After the process of specification is complete, the second phase is heralded by *Wnt4* expression from the mesonephros or coelomic epithelium, which induces these cells that are destined to become the MDs to invaginate (Kobayashi et al, 2004, 2005; Orvis and Behringer, 2007). The second phase of MD development is WD independent and ends when the MD extends caudally and contacts the WD (Carroll, 2005; Kobayashi et al, 2005; Orvis and Behringer, 2007). The third phase involves elongation of the MDs posteriorly until they are joined at the urogenital sinus. This process is WD dependent, requiring the MD epithelium at its posterior end to be in close physical contact with the WD epithelium, while the MDs are separated from the coelomic epithelium by only a basement membrane (Orvis and Behringer, 2007). This intimate relationship between the WD and MD is emphasized in experiments that interrupt the formation of the WD at a specific point and show that the MD could not grow beyond that point to complete its formation (Gruenwald, 1941).

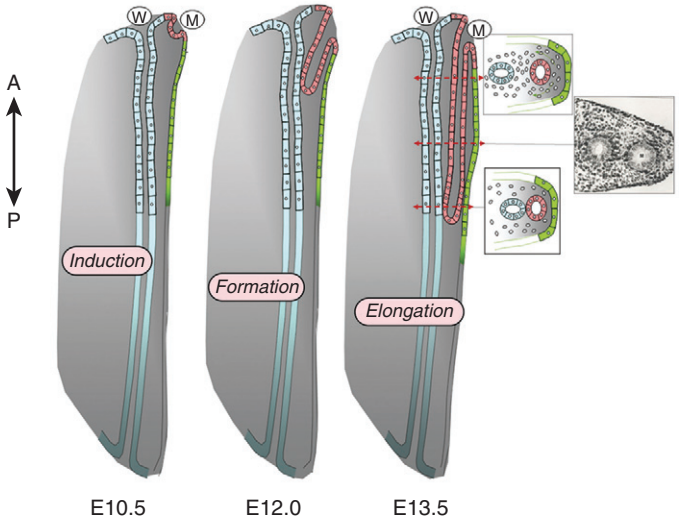

Figure 117–1. Model for müllerian duct development. At E11.75, after a subset of coelomic epithelium cells (represented in green) are specified, they invaginate in the intermediate mesoderm. Then, the invaginating cells form the müllerian duct (*M*, represented in pink). Anteriorly, the funnel is opened in the abdominal cavity, and caudally, the growing tip extends to and contacts the wolffian ducts (*W*, represented in blue) at E12.0. A phase of elongation allows the müllerian duct to elongate posteriorly in very close contact with the wolffian duct. As soon as the müllerian duct growing tip has deposited cells and elongated caudally, the physical contact between the ducts is lost by the appearance of mesenchymal cells around the müllerian duct epithelium. At E13.5, the two müllerian ducts reach the urogenital sinus and fuse together. Developmental stages indicated in this figure correspond to mouse stages. (From Masse J, Watrin T, Laurent A, et al. The developing female genital tract: from genetics to epigenetics. Int J Dev Biol 2009;53:411–24.)

Lim1 in the WD is critical for WD maintainance. Loss of *Lim1* in the WD by inactivation leads to WD loss. Because the MD is dependent upon the WD in this third phase, the MDs are again incompletely formed (Kobayashi et al, 2005). This third phase is also dependent upon the *Pax2* gene; mice mutants for this gene show cellular invagination but no elongation because the WDs have degenerated (Torres et al, 1995; Miyamoto et al, 1997). Studies have also shown that the WD not only acts as a physical guide but also plays a role in MD elongation through paracrine signaling. More specifically, *Wnt9b* is expressed by the WD epithelium, and gene inactivation results in incomplete formation of the MDs (Carroll et al, 2005). Loss of *Wnt9b* expression did not affect the WD, per se, or the first two phases of MD development but did affect the caudal extension and elongation of the MDs, suggesting that WD signaling by *Wnt9b* is one of the critical factors in directing MD formation (Carroll et al, 2005). For a clinical correlation, see Anomalies in the Female (Unilateral Renal Agenesis section).

Molecular Mechanisms of Mammalian Kidney Organogenesis. **Several genes play a critical role in WD development, including *Pax2/8, Gata3, and Lim1*.** Many of the same genes affecting renal development will also affect internal duct development. If there is gene inactivation of *Pax2/8, Gata3,* or *Lim1,* there will be no formation of the kidneys (BRA), ureters, or genital tract (Uetani and Bouchard, 2009). The pathway for mammalian kidney development is regulated by reciprocal epithelial-mesenchymal inductive signaling between the UB epithelium and the MM (Yu et al, 2004). Ureteral bud formation and the induction of its branching require glial cell line–derived neurotrophic factor

(GDNF), a secreted growth factor expressed in the MM (Michos et al, 2007). The GDNF ligand activates the RET receptor, which is expressed in the WD epithelium and then around the UB tips as branching proceeds. *Gdnf* expression and localization are positively regulated by *Eya1* and *Pax2* (Michos, 2009). GDNF activation of RET requires the glial cell line–derived neurotrophic factor family receptor α1 (GFRα1) and is essential for induction of UB formation and initiation of outgrowth and branching (Chi, 2009). Most genes that are thought to be essential for UB formation are also regulators of *Gdnf* or *Ret* expression. Studies of murine kidney development show that *Gdnf* –/– mice have renal agenesis, while *Ret*–/– mice have renal agenesis or dysplastic kidneys (Pichel et al, 1996; Schuchardi et al, 1996, Glassberg, 2002).

Skinner and colleagues (2008) examined the association between abnormal kidney development and mutations of *RET, GDNF,* and *GFRα1* in 29 stillborn fetuses with BRA or unilateral renal agenesis (URA). Mutations in *RET* were found in 7 of 19 fetuses with BRA and 2 of 10 fetuses with URA. A mutation in *GDNF* was found in 1 fetus with URA who also had mutations in *RET*. No *GFRα1* mutations were observed. These data suggest that congenital renal agenesis results from *RET* mutations that prevent or impede the embryonic development of *RET*-dependent structures.

After the GDNF/GFRα1 complex binds to RET, the *Wnt11* gene is activated in the epithelial tips of the UB and is associated with UB branching (Majumdar et al, 2003). *Wnt11* is a member of the *Wnt* gene family, which is composed of structurally related genes encoding secreted signaling proteins. These proteins are likely involved in several processes, including regulation of cell fate and patterning during embryogenesis. WNT11 signaling is required for the propagation of mesenchymal GDNF signaling, which establishes the autoregulatory epithelial-mesenchymal GDNF/WNT11 feedback signaling loop that controls the progression of metanephric branching morphogenesis after initiation of UB outgrowth (Majumdar et al, 2003; Michos et al, 2007).

Bone morphogenetic protein-4 (BMP4), a member of the transforming growth factor-α family, is expressed in the periureteral mesenchyme and is essential for morphogenesis (Glassberg, 2002; Miyazaki et al, 2000, 2003; Michos et al, 2007). In wild-type mouse embryos, BMP4 is expressed by the mesenchyme surrounding the WD and UB. Mesenchymal cells that express BMP4 inhibit UB formation, in part by inhibiting *Wnt11* expression. BMP4 migrates to ectopic sites, thereby preventing ectopic UB formation. The BMP4 mesenchymal cells act in a similar fashion during UB branching by inhibiting side branching and permitting stems to lengthen. Mesenchymal cells that are devoid of BMP4 surround the tip, where further branching proceeds. Mice heterozygous for a null mutation in BMP4 (+/–) manifest anomalies, including hypoplastic/dysplastic kidney, hydroureter, ectopic ureter, ureteral duplication, megaureter, ureterovesical junction obstruction, and reflux (Miyazaki et al, 2000, 2003).

Mammalian Kidney Organogenesis: New Advances. Gremlin 1 (GREM1) is an extracellular BMP antagonist that is expressed in the meso- and metanephric mesenchyme (Michos et al, 2004) (Fig. 117–2). GREM1 is upregulated in the mesenchyme around the origin of the UB prior to initiation of its outgrowth. BMP activity, at this time, is reduced locally. In the *Grem1*-deficient mouse embryo, metanephric development is disrupted at the stage of UB outgrowth initiation, resulting in bilateral renal agenesis. This inhibition of UB outgrowth causes progressive loss of *Gdnf* expression, resulting in apoptosis of the MM.

To further examine the relationship of these various ligands and their effects on epithelial-mesenchymal interactions, Michos and colleagues (2007) cultured early *Grem1*-deficient mutant mouse kidney rudiments in medium supplemented with recombinant GREM1. The addition of GREM1 restored UB outgrowth and induced supernumerary epithelial buds that invaded the MM and initiated branching morphogenesis. At the molecular level, GREM1 replacement activated *Wnt11* expression in the epithelial buds and upregulated *Gdnf* expression in the mesenchyme. Because genetic suppression of BMP4 activity in a *Grem1*-deficient mouse model completely restored kidney development, the local reduction of BMP4 activity by GREM1 was presumed to be critical to the initiation of UB outgrowth and kidney organogenesis.

Because BMP4 signaling by the mesenchyme surrounding the WD prevents formation of supernumerary epithelial buds, successful initiation of UB outgrowth most likely requires both antagonism of BMP4 by GREM1 in mesenchyme and signaling by GDNF from the MM to RET in the ureteric epithelium (Michos et al, 2007). In addition, autoregulatory feedback signaling between GDNF in the mesenchyme and WNT11 in the epithelial tips regulates branching morphogenesis. *Grem1* is essential for both upregulation of *Wnt11* in the ureteric epithelium and *Gdnf* expression in the mesenchyme and the establishment of epithelial-mesenchymal feedback signaling.

Gross Pathologic Description of Retroperitoneal Findings

In an extensive autopsy analysis by Ashley and Mostofi (1960), **the kidneys were completely absent on gross inspection of the entire retroperitoneum.** Occasionally, there was a small mass of poorly organized mesenchymal tissue containing primitive glomerular elements with only minute vascular branches from the aorta. Complete absence of the renal vessels was observed in about 25% of specimens with BRA in this series. **Complete ureteral atresia was observed in 39 of the 42 cases of BRA, and partial ureteral absence was noted in 3.** Only small projections with no demonstrable lumen alongside the bladder were noted. With complete absence of the ureter, a rudimentary kidney was discovered in only a few instances, supporting the concept of reciprocal induction.

The adrenal gland may appear flattened on ultrasonography but is rarely malpositioned or absent (Davidson and Ross, 1954; Hoffman et al, 1992). A normally located adrenal gland is expected, because the adrenal cortex develops from primitive mesoderm medial to the urogenital ridge and the medulla develops from ectodermal neural crest cells, while the metanephros is derived from the intermediate mesoderm.

Fused and/or horseshoe-shaped glands have been noted on prenatal ultrasound screening (Strouse et al, 2002). Potter (1965) noted that fused glands were often found in the presence of spinal anomalies. In a small number of autopsies, the gonads were

Key Points: Bilateral Renal Agenesis

- Forty percent of the affected infants are stillborn.
- Most of the children who are born alive do not survive beyond 48 hours due to respiratory distress associated with pulmonary hypoplasia.
- The characteristic Potter facies and the presence of oligohydramnios are pathognomonic.
- The ureters are almost always absent, and the bladder is either absent or hypoplastic.
- The adrenal glands are usually positioned normally.
- Müllerian duct anomalies are commonly observed.

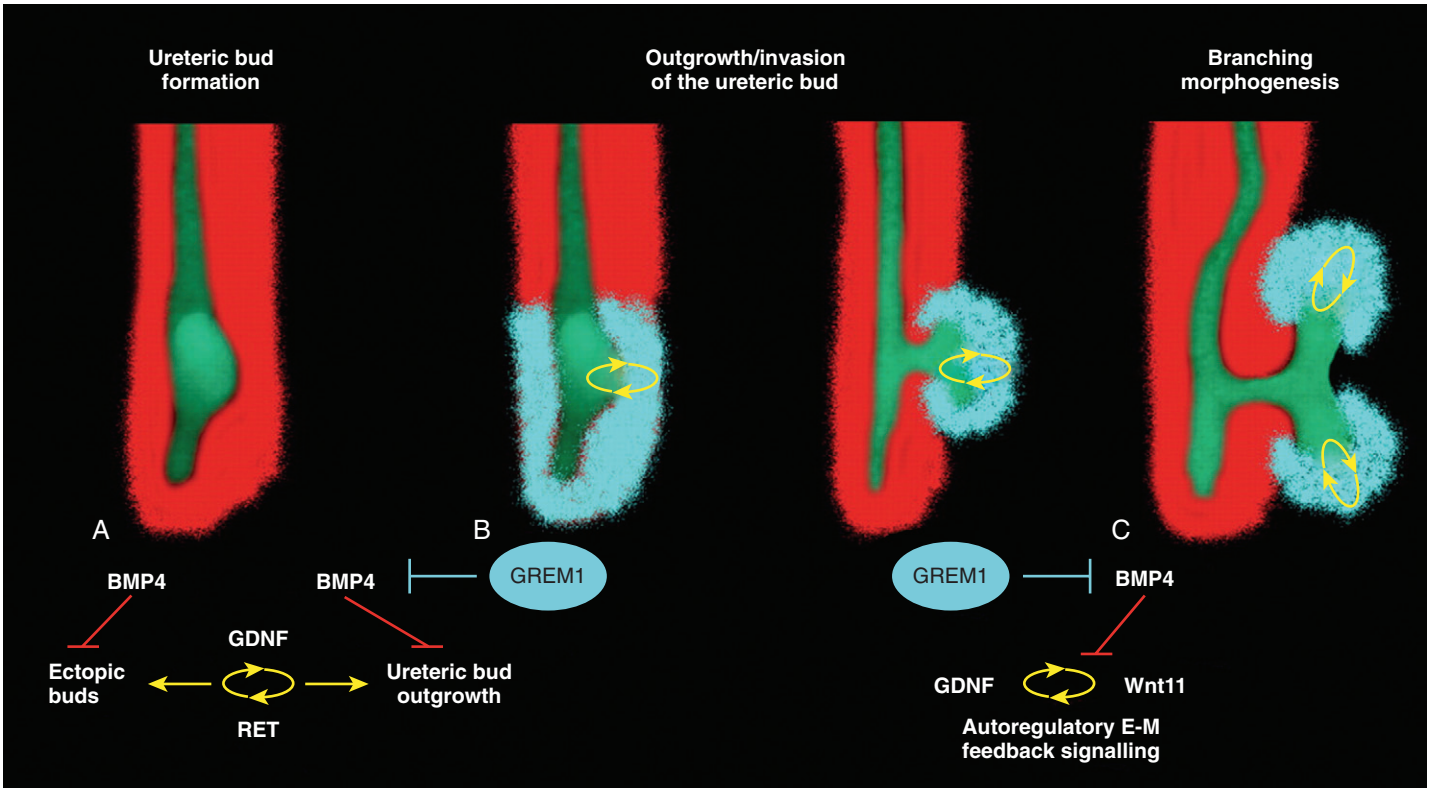

Figure 117–2. Reduction of BMP4 activity by gremlin 1 in the mesenchyme around the ureteric bud is essential to enable ureteric epithelial outgrowth, GDNF-RET– and WNT11-mediated epithelial-mesenchymal (e-m) feedback signaling, and branching morphogenesis. **A,** In mouse, the ureteric bud forms in the caudalmost part of the wolffian duct under the influence of GDNF-RET signaling. During this inductive period, *Bmp4* is expressed by the mesenchyme enveloping the wolffian duct. High levels of mesenchymal BMP4 activity inhibit the formation of ectopic epithelial buds and epithelial branching at this stage (prior to E11.0). At this early stage, only low levels of *Grem1* transcripts are detected (not shown). **B,** Expression of the BMP antagonist *Grem1 is* upregulated in the mesenchyme around the nascent ureteric bud, thereby locally reducing BMP4 signal transduction (around E11.75-11.0). This reduction of BMP4 activity by GREM1 enables initiation of ureteric bud outgrowth and its invasion into the metanephric mesenchyme. **C,** GREM1 is required to maintain and propagate expression of *Wnt11* in the ureteric epithelial tip(s) and *Gdnf* in the mesenchyme by e-m feedback signaling. (From Michos O, Goncalves A, Lopez-Rios J, et al. Reduction of BMP4 activity by gremlin 1 enables ureteric bud outgrowth and GDNF/WNT11 feedback signaling during kidney branching morphogenesis. Development 2007;134:2397–405.)

absent, indicating the abnormality or insult occurred before the fifth week and affected the overall development of the urogenital ridge (Carpentier and Potter, 1959).

In the Ashley and Mostofi series (1960), **about 50% of cases of complete ureteral atresia showed complete absence of the bladder, and in the remainder of cases, a hypoplastic bladder was found consisting only of a muscular tube with a minute lumen.** In Potter's series (1965), the bladders were also hypoplastic and lacked ureteral orifices. A normally closed urachus was observed.

Abnormal development of the bladder is thought to be due to the lack of stimulation by fetal urine production, which starts at 10 to 12 weeks of gestation. Alternatively, it has been postulated that UB and WD structures migrating into the ventral cloacal region are needed to initiate normal bladder development. The absence of the UB, and not the *lack* of urine, may arrest bladder development (Levin, 1952; Katz and Chatten, 1974). This theory is supported by the fact that despite absence of bladder filling in bladder exstrophy, many of these bladders are functional following surgical closure alone, while the bladders associated with bilateral ureteral ectopia almost invariably require augmentation (Jayanthi et al, 1997, Gearhart and Matthews, 2007).

Phenotypic Features. Phenotypic features associated with BRA have been extensively described by Potter. These infants have low birth weights, ranging from 1000 to 2500 g, and intrauterine growth retardation due in part to low iron stores in the liver (Georgieff et al, 1996). At birth, oligohydramnios (absent or minimal amniotic fluid) is present. **The characteristic facial appearance and deformity of the extremities distinguishes these children from normal newborns.** The infants look prematurely senile and have "a prominent fold of skin that begins over each eye, swings down in a semi-circle over the inner canthus and extends onto the cheek" (Potter, 1946a, 1946b). This facial feature is a sine qua non of nonfunctioning renal parenchyma and suggests that its absence confirms the presence of at least one kidney (Fig. 117–3). The nose is blunted, and a prominent depression exists between the lower lip and chin. The ears appear to be low set, are drawn forward, and are often pressed against the side of the head, making the lobes seem unusually broad and exceedingly large. The ear canals are not dislocated, but the appearance of the ear lobes gives the impression that the ears are displaced downward. Periauricular pits and tags have been noted (Wang et al, 2001). The skin can be excessively dry and appears too loose for the body. This may be secondary to severe dehydration or lack of subcutaneous fat. The hands are relatively large and clawlike. The legs are often bowed and clubbed, with excessive flexion at the hip and knee joints (Saing et al, 1998; Carbillon et al, 2001; Das et al, 2002). Occasionally, the lower extremities are completely fused as seen with sirenomelia (Liatsikos

Figure 117–3. An anephric child who lived 2 days has the typical Potter facial appearance. **A,** Note the prominent fold and skin crease beneath each eye, blunted nose, and depression between lower lip and chin. **B,** The ears give an impression of being low set because lobes are broad and drawn forward, but actually the ear canals are located normally.

et al, 1999). A lumbar meningocele with or without the Arnold-Chiari malformation and hydrocephalus is often observed (Davidson and Ross, 1954; Ashley and Mostofi, 1960). In Potter's series (1965), anomalies of the gastrointestinal tract were found in 60% of fetuses.

Anomalies of the external genitalia include absence of the scrotum and clitoral hypertrophy. Penile development is usually normal, but in a few cases, penile agenesis or a rudimentary penis and scrotum have been reported (O'Connor et al, 1993; Potter, 1965). Hypospadias is rare and does not appear to be related to the presence or absence of the testes. **The testes are undescended in 43% of cases** (Carpentier and Potter, 1959). Ashley and Mostofi (1960) found testicular agenesis in 10%. The vas deferens is normal in most cases, implying that the factor responsible for the renal agenesis influenced the UB *only after* it formed from a completely elongated WD or that the insult affected the induction of the MM.

There is a relatively high incidence of anomalies of the MD structures and ovaries (Carpentier and Potter, 1959). The ovaries are frequently hypoplastic or absent. The uterus is usually rudimentary or bicornuate but occasionally absent. The vagina is a short, blind-ending pouch or completely absent.

Role of Amniotic Fluid Production and Pulmonary Development. **The characteristic facial abnormalities and limb features may result from deformations rather than malformations of structures due to the lack of "cushioning" from amniotic fluid** (Fitch and Lachance, 1972; Thomas and Smith, 1974). This observation was confirmed by an experiment in nature in which one twin with BRA did not have the characteristic Potter facies because it shared the same amniotic sac with the second twin who had an adequate volume of amniotic fluid (Klinger et al, 1997). Fetal renal urine is the major source of amniotic fluid, accounting for more than 90% of its volume by the third trimester (Thomas and Smith, 1974; Chevalier and Roth, 2007), but the skin, gastrointestinal tract, and central nervous system also contribute small amounts, particularly before urine production begins at 10 to 12 weeks.

Pulmonary hypoplasia and a bell-shaped chest are common associated findings that were originally thought to be due to uterine wall compression of the thoracic cage as a result of oligohydramnios (Bain and Scott, 1960). Subsequently, it was postulated that the amniotic fluid alone was responsible for pulmonary development (Fitch and Lachance, 1972). However, this theory was rejected when they observed a significant reduction in the number of airway generations as well as a decrease in acini formation in these fetuses (Hislop et al, 1979). Pulmonary airway branching occurs between the 12th and 16th weeks of gestation (Reid, 1977). A reduction in the number of branches implies interference with this process before the 16th week of gestation. Hislop and colleagues (1979) suggested that the anephric fetus fails to produce proline, which is a prerequisite for collagen formation in the bronchiolar tree. The kidney is the primary source of proline (Clemmons, 1977). Thus pulmonary hypoplasia may result from the absence of renal parenchyma and not from diminished amniotic fluid. This hypothesis is supported by the finding of normal lungs in two infants with prolonged leakage of amniotic fluid beginning at a time when pulmonary hypoplasia would have been expected if the amniotic fluid alone were responsible for the defect (Perlman et al, 1976; Cilento et al, 1994).

Peters and colleagues (1991a) **proposed a two-step process in pulmonary development, with a primary "renal growth factor" influencing early lung development and an amniotic fluid volume-dependent phase influencing later gestational lung growth.** Smith and colleagues (2006) studied early lung development using a murine knockout model of renal agenesis/dysgenesis and anuria. They found that pulmonary development occurred early in embryogenesis, and fetal anuria and hypoplastic lung development preceded oligohydramnios. These observations support the two-step model proposed by Peters (1991a). Alternatively, oligohydramnios due to experimentally induced urinary obstruction is associated with pulmonary hypoplasia in fetal sheep, with initially normal renal function (Peters et al, 1991a, 1991b). Restoring amniotic fluid volume only partially restores lung growth. **Therefore uropathy-associated pulmonary hypoplasia appears to be a result of oligohydramnios rather than renal dysfunction** (Peters, 1991b).

Prenatal and Postnatal Diagnosis. **BRA is being diagnosed by prenatal ultrasonography in the second and third trimesters, when severe oligohydramnios is noted and no renal parenchyma can be identified** (Forys et al, 2003). Termination of the pregnancy has been considered when the diagnosis is certain (Rayburn and Laferla, 1986). Additional diagnostic findings include small lung volumes and chest diameter and abnormal adrenal gland appearance (Latini et al, 1998; Sepulveda et al, 1998; Heling et al, 2001; Strouse et al, 2002). **The characteristic Potter facies and the presence of oligohydramnios are pathognomonic.** Amnion nodosum—small, white, keratinized nodules on the surface of the amniotic sac—have been considered a placental hallmark of prolonged, severe, oligohydramnios. Recently, oligohydramnios was diagnosed in only 22% of cases of amnion nodosum, suggesting that it may not be a reliable sign of oligohydramnios. Nevertheless, the finding portends a very poor prognosis (Adeniran and Stanek, 2007).

Ninety percent of newborns void during the first day of life (Sherry and Kramer, 1955). In a study of 500 infants, every infant voided within the first 24 hours of life, regardless of the gestational age (Clarke, 1977). After the first 24 hours, anuria without distention of the bladder suggests BRA (Williams, 1974). However, most neonates with BRA who are born alive experience severe respiratory distress within the first 24 hours of life. When this becomes the focus of attention, the anuria may be initially unnoticed.

Postnatal Radiographic Evaluation. **Renal ultrasonography is the most efficient way to identify the kidneys and bladder and confirm the presence or absence of urine production.** The advent of power Doppler ultrasonography has been highly accurate in determining the status of the renal arteries, even in fetuses with oligohydramnios and suspected BRA (Sepulveda et al, 1998). The finding of a flattened adrenal gland in its normal location supports the diagnosis of an absent kidney (Hoffman et al, 1992). If abdominal ultrasonography is inconclusive, renal scintigraphy can be performed using ^{99m}Tc-dimercaptosuccinic acid (DMSA). The absence of uptake of the radionuclide in both renal fossae above background activity or in an ectopic location confirms the diagnosis of BRA. Historically, umbilical artery catheterization and an aortogram were performed when other modalities were not diagnostic.

Prognosis. **About 40% of the affected neonates are stillborn. Of those neonates who are born alive, most do not survive beyond the first 24 to 48 hours due to respiratory distress associated with pulmonary hypoplasia.** Survival subsequently depends on the rate at which renal failure develops. The longest-surviving child lived 39 days (Davidson and Ross, 1954).

Unilateral Renal Agenesis

Complete absence of one kidney occurs more frequently than BRA but is not easily detected from findings on physical examination. An isolated single umbilical artery has been associated with renal anomalies, including unilateral renal agenesis (URA) (Dursun et al, 2005). More recently, the largest study to date of neonates with an isolated single umbilical artery did not find an increased incidence of URA or other malformations and concluded that postnatal renal ultrasonography was not routinely warranted (Deshpande et al, 2009).

URA may remain undetected unless examination of the external genitalia and/or radiographic evaluation of the female or male pelvis for other reasons reveal an anomaly associated with renal agenesis. **Over the past two decades, prenatal ultrasound examinations have been performed more routinely, and URA is being detected with increased frequency** (Sipek et al, 1997). **These imaging studies have also revealed that a substantial number of cases thought to be URA were a dysplastic or multicystic dysplastic kidney (MCDK) that had undergone involution prior to birth** (Mesrobian et al, 1993; Hitchcock and Burge, 1994; Dell'Acqua et al, 2002; Hiraoka et al, 2002). **A plain film of the abdomen supports this diagnosis if the splenic or hepatic flexure of the bowel is in its normal location and not in the ipsilateral renal fossa, suggesting that a dysplastic kidney or MCDK may have formed in the renal fossa before involuting.** Curvilinear calcifications on a plain radiograph or computed tomography (CT) scan are another sign of a prior MCDK (Nakano et al, 1996). A flattened adrenal or the spleen (on the left) may be mistaken for a kidney in the 20-week structural ultrasound study, but at later gestational weeks, the diagnosis of URA becomes more apparent (Woolf and Hillman, 2006).

Incidence. **Most autopsy series suggest that unilateral renal agenesis occurs once in 1100 births** (Doroshow and Abeshouse, 1961). In an historical survey of excretory urograms, the incidence ranged between 1 in 1500 (Longo and Thompson, 1952) to 1 in 5000 (Wilson and Baird, 1985). Ultrasound screening of 280,000 school children in Taipei revealed the incidence of URA to be 1 in 1200 (Shieh et al, 1990). A similar incidence was found on prenatal screening in the Czech Republic (Sipek et al, 1997).

The high male predominance of BRA is not nearly as striking in the unilateral condition, with a **male to female ratio of 1.8:1** (Doroshow and Abeshouse, 1961). **Absence of a kidney occurs somewhat more frequently on the left side. A familial tendency has been noted** (Arfeen et al, 1993; Selig et al, 1993; Cascio et al, 1999). Siblings within a single family and even monozygotic twins have been affected (Kohn and Borns, 1973; Uchida et al, 1990). In a study of several families, McPherson and colleagues (1987) concluded the inheritance of URA was autosomal dominant with a 50% to 90% penetrance. This inheritance pattern has been confirmed by others who evaluated families with more than one affected individual (Biedel et al, 1984; Roodhooft et al, 1984; Battin et al, 1993). For screening recommendations, see the section Incidence under Bilateral Renal Agenesis.

Genetic/Syndromic Associations. An absent kidney has been noted in a number of genetic disorders in which there is a deletion of several chromosomal loci: 8q13.3 (Pierides et al, 2002), 18q22.2 (Dowton et al, 1997), 22q11 (Anonymous, 1998; Stewart et al,

1999), as well as in X-linked and sporadic cases of Kallmann syndrome (Colquhoun-Kerr et al, 1999; Zenteno et al, 1999; Quinton et al, 2001). Several syndromes have been associated with URA, including Turner syndrome, Poland syndrome (Mace et al, 1972), Frazer syndrome (Fryns et al, 1997), BOR (brachio-oto-renal) syndrome (Pierides et al, 2002), DiGeorge anomaly (when associated with insulin-dependent diabetes mellitus in the mother) (Wilson et al, 1993; Novak and Robinson, 1994), dysmorphogenesis, and Kallmann syndrome. Abnormalities of the *KAL1* locus at Xp22 in the X-linked autosomal-dominant disorder have a 40% incidence of URA (Say and Gerald, 1968; Colquhoun-Kerr et al, 1999; Zenteno et al, 1999; Quinton et al, 2001). Similarly, Townes-Brock syndrome with *SALL1* deletions is associated with a high incidence of URA (Salerno et al, 2000; Nishinakamura et al, 2001; Sato et al, 2003, 2004). Twenty to 30 percent of children with the VACTERL association (*V*ertebral, imperforate *A*nus, *C*ardiac, *T*racheo-*E*sophageal atresia, *R*enal, and *L*imb anomalies) have URA (Barry and Auldist, 1974; Kolon et al, 2000). Children with supernumerary nipples (Urbani and Betti, 1996) and disorders of the ears with hearing loss, especially if it is congenital (Huang et al, 2001), and preauricular pits (Pierides et al, 2002) have been thought to have an increased incidence of URA. Recently, studies have not shown a significant relationship between preauricular pits, minor ear tags, and URA (Arora and Pryce, 2004; Deshpande and Watson, 2006). Nonetheless, a screening renal ultrasonogram is recommended when these ear anomalies are found in the presence of other malformations. In addition, when more than one anomaly is present (e.g., ventricular septal defect [VSD] and an undescended testis) a screening renal ultrasonogram is prudent, but when specific complexes of anomalies associated with renal agenesis are present (for example, VACTERL-associated anomalies), a comprehensive radiographic review of all organ systems is mandatory.

Embryology. The embryologic basis for URA and BRA are thought to be similar. **The etiology is most likely due to the UB, because increased *RET* mutations occur in humans with renal agenesis** (Skinner et al, 2008). Complete absence of a bud or aborted ureteral development prevents reciprocal induction, which is critical for the development of the metanephric blastema into the definitive adult kidney. **The metanephros is likely not to be responsible for the majority of cases, because the ipsilateral gonad (derived from adjacent mesenchymal tissue) is rarely absent, malpositioned, or nonfunctioning** (Ashley and Mostofi, 1960). **The high incidence of absent or malformed proximal WD structures in the male and anomalies of the MD structures in the female suggest that the embryologic insult affects the UB primarily in its early development and influences the development of WD derivatives.** The abnormality most likely occurs no later than the fourth or fifth week of gestation, when the UB forms and the WD begins to develop into the ejaculatory duct, seminal vesicle, and vas deferens. The MD in the female begins its medial migration at this time, crossing over the WD (sixth week) during its differentiation into the fallopian tube, uterine horn and body, and proximal vagina (Woolf and Allen, 1953; Semmens, 1962; Yoder and Pfister, 1976).

Magee and colleagues (1979) **proposed an embryologic classification to explain the association of URA and MD anomalies** (Fig. 117–4). In type I URA, the insult occurs before the fourth week, and there is nondifferentiation of the urogenital ridge structures, including the MD and WD. If unilateral, a uterus consisting of a single MD (unicornate uterus) will form and will be associated with contralateral renal agenesis. In type II URA, the insult occurs early in the fourth week of gestation, affecting both the WD and the UB. Because it is critical that the MD maintains close contact with the WD for MD elongation and subsequent fusion, maldevelopment of the WD affects renal development, MD elongation, contact with the urogenital sinus (UGS), and subsequent fusion. Therefore a didelphys uterus will form with obstruction of the horn and vagina on the side of the URA. Finally, in type III URA, the insult occurs after the fourth week, and the WD and MD elongation and differentiation proceed normally. In this case, only the UB and metanephric blastema are affected, thereby resulting in isolated URA.

Associated Genitourinary and Adrenal Anomalies. **The ipsilateral ureter is completely absent in about 60% of the cases** (Fortune, 1927; Collins, 1932; Ashley and Mostofi, 1960). In the Ashley and Mostofi series, 19 of 232 with URA had only a portion of the lower end of the ureter present. There were no normally developed ureters reaching the level of the normal kidney. In most cases of complete absence of the ureters, the bladder showed no evidence of a ureteric orifice with failure of ipsilateral trigone development (Ashley and Mostofi, 1960). Cell lineage studies using a murine model show that the trigone has a urogenital sinus origin and should form normally (Viana et al, 2007; Mendelsohn, 2009). The trigone may not be distinguishable from the surrounding detrusor when the intramural ureter is absent. Therefore the

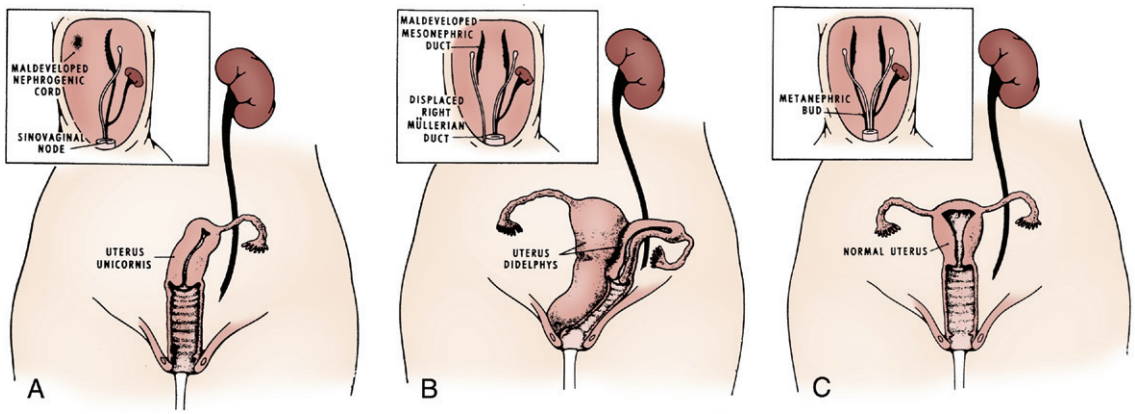

Figure 117–4. **A** to **C,** A proposed categorization of genital and renal anomalies in females. See text for details. (From Magee MC, Lucey DT, Fried FA. A new embryologic classification for urogynecologic malformations: the syndromes of mesonephric duct induced müllerian deformities. J Urol 1979;121:265.)

endoscopic appearance of the trigone in this setting has lead to the probable misnomer in the case of the "hemitrigone" (in association with complete ureteral agenesis) or "asymmetrical trigone" (in the presence of a partially developed ureter). Segmental ureteral atresia on one side has been associated with contralateral ureteral or renal ectopia (Limkakeng and Retik, 1972). Except for ectopia or malrotation, anomalies of the contralateral kidney are infrequent (Longo and Thompson, 1952; Chow et al, 2005) (Fig. 117–5). **However, abnormalities of the contralateral ureter are not uncommon, including ureteropelvic and ureterovesical junction obstruction in 11% and 7%, respectively** (Cascio et al, 1999), **and reflux in 30%** (Atiyeh et al, 1993; Cascio et al, 1999). Other urologic abnormalities are found in 65% with URA (Kaneyama et al, 2004).

Although the ipsilateral adrenal gland may be flattened (Hoffman et al, 1992), **adrenal agenesis occurs in**

Figure 117–5. fewer than 10% of autopsy reports (Fortune, 1927; Collins, 1932; Ashley and Mostofi, 1960) **and in 17% of individuals with URA undergoing a CT scan** (Kenney et al, 1985).

Genital anomalies are much more frequently observed. The incidence of a reproductive tract malformation for both sexes varies from 20% to 40% (Smith and Orkin, 1945; Doroshow and Abeshouse, 1961; Thompson and Lynn, 1966). **Despite the predominance of males with URA, reproductive tract abnormalities in females occur in at least 25% to 50% compared with 10% to 15% in males. Regardless of sex, both gonads are usually normal. Therefore the different phenotypes that occur with URA may result from a primary urogenital ridge defect, which explains the finding of gonadal and adrenal agenesis in the minority of cases, or a primary defect in development of the UB and WD, which leads to the more common cases of URA and frequently observed abnormalities of the WD, MD, and their derivatives.**

Anomalies in the Male. **The testis and head of the epididymis, which contain the efferent ductules derived from the mesonephric tubules, are invariably present; all structures proximal to that point, which develop from the WD (the body and tail of the epididymis, vas deferens, seminal vesicle, ampulla, and ejaculatory duct), are absent in almost 50%** (Radasch, 1908; Collins, 1932; Charny and Gillenwater, 1965; Ochsner et al, 1972). Donohue and Fauver (1989) reported 79% of adult males with an absence of the vas deferens have an absent ipsilateral kidney; left-sided lesions predominated with a ratio of 3.5 : 1. However, bilateral absence of the vas has been noted with URA (McCallum et al, 2001). Occasionally, the WD structures are rudimentary or ectopic rather than absent (Holt and Peterson, 1974). Ipsilateral cryptorchidism rarely occurs. In 1914, Zinner reported a seminal vesicle cyst in association with ipsilateral renal agenesis (Pereira et al, 2009). Seminal vesicle cysts secondary to obstruction of the ejaculatory duct are currently diagnosed with increasing frequency as pelvic ultrasound examinations are performed more often (Lopez-Garcia et al, 1998; Kaneyama et al, 2004). Six cases (5%) were noted among 119 boys who were found to have URA during ultrasound screening of schoolchildren (Shieh et al, 1990). A pelvic ultrasonogram or magnetic resonance imaging (MRI) in boys diagnosed with URA may demonstrate a seminal vesicle cyst (Van den Ouden et al, 1998, Seo et al, 2009) (see Fig. 117–5). In cases of seminal vesicle cysts and URA, the ureter may insert into the prostatic urethra or seminal vesicle. Cystic dysplasia of the rete testis, a rare benign condition, is often associated with ispsilateral renal anomalies, most commonly URA (Wojcik et al, 1997; Camassei et al, 2002).

In males, **the diagnosis of URA should be suspected during a physical examination when the vas deferens or body and tail of the epididymis are impalpable. This may be more common in adults undergoing evaluation for infertility.** In infants and young boys, URA should be considered when vasal and/or epididymal anomalies are incidentally found at the time of orchiopexy.

Anomalies in the Female. A variety of anomalies may result in the female from incomplete MD formation because of alterations in normal WD development. **Approximately one fourth to one third of women with URA have an abnormality relating to WD development** (Thompson and Lynn, 1966; Heinonen, 2004). Conversely, 43% of women with genital anomalies have URA (Semmens, 1962; Heinonen, 1997). The most common MD anomalies are a true unicornuate uterus with complete absence of the ipsilateral horn and fallopian tube or a bicornuate uterus with rudimentary development of the horn on the affected side (Candiani et al, 1997) (see Fig. 117–5). The fimbriated end of the fallopian tube, however, is usually fully formed and is analogous to the head of the epididymis in the male (Shumacker, 1938). Partial or complete midline fusion of the MD may result in a double (didelphys) or septate uterus with either a single or a duplicated cervix (Radasch, 1908; Fortune, 1927). Complete duplication or separation of the vagina, proximal vaginal atresia associated with a small introital dimple, and complete absence of the vagina have been reported (Woolf and Allen, 1953; D'Alberton et al, 1981). **Obstruction of one side of a duplicated system is not uncommon, and unilateral hematocolpos or hydrocolpos associated with a pelvic mass and/or pain has been described in pubertal girls** (Weiss and Dykhuizen, 1967; Vinstein and Franken, 1972; Gilliland and Dick, 1976; Wiersma et al, 1976; Yoder and Pfister, 1976). **Smith and Laufer** (2007) **suggested the acronym OHVIRA to classify the syndrome of *O*bstructed *H*emivagina and *I*psilateral *R*enal *A*nomaly.** In rare instances, this anomalous condition has been mistaken for a large or infected Gartner duct cyst. Sometimes a true Gartner duct cyst has been found in a prepubertal girl in association with an ectopic ureter that is blind ending at its proximal end or one that is connected to a rudimentary kidney (Currarino, 1982). Six percent of girls with URA were found to have a Gartner cyst on mass screening of schoolchildren (Shieh et al, 1990). Infertility occurs in as many as 33% of affected women with renal agenesis and unicornuate uterus (Heinonen, 1997). When specific anomalies of the uterus, including congenital absence of the uterus, unicornuate uterus, and didelphic uterus, are found on ultrasonography or MRI, radiologic investigation of the urinary tract often demonstrates URA or other renal anomalies (Bryan et al, 1949; Phelan et al, 1953; Thompson and Lynn, 1966; Candiani et al, 1997; Heinonen, 1997, Govindarajan et al, 2008; Reichman and Laufer, 2010).

Another important anomaly often associated with URA is the Mayer-Rokitansky-Kuster-Hauser syndrome (MRKH), which is a complex of malformations occurring in 1 in 5000 newborn females (Guerrier et al, 2006). This syndrome not only includes renal anomalies but also genital tract anomalies ranging from upper vaginal atresia to total müllerian agenesis in an otherwise phenotypically normal female with a normal 46, XX karyotype. There are two subtypes reported. Type I is the typical form characterized by the finding of only symmetrical muscular buds or müllerian remnants and normal fallopian tubes. Type II, which is the more common but considered the atypical form, is characterized by asymmetrical hypoplasia of one or two buds with or without dysplasia of the fallopian tubes. Most importantly, the atypical form is often associated with renal anomalies, primarily URA or ectopia of one or both kidneys and horseshoe kidney in about 40% to 60% (Guerrier et al, 2006). In addition, there can be cervico-thoracic anomalies, auditory defects, and digital anomalies. Duncan and colleagues (1979) reported on the most severe constellation of malformations and referred to this as the MURCS association or *MÜ*llerian duct aphasia (96%), *R*enal aphasia or ectopic (86%), and *C*ardiothoracic *S*omite dysplasia (two to four anomalous vertebrae between C5-T1 (80%).

Anomalies of Other Organ Systems. **Anomalies of other organ systems are found frequently in affected individuals. The more common sites involve the cardiovascular (30%), gastrointestinal (25%), and musculoskeletal (14%) systems** (Emanuel et al, 1974) (Fig. 117–6). They include septal and valvular cardiac defects, imperforate anus and anal or esophageal strictures or atresia, and vertebral or phalangeal abnormalities

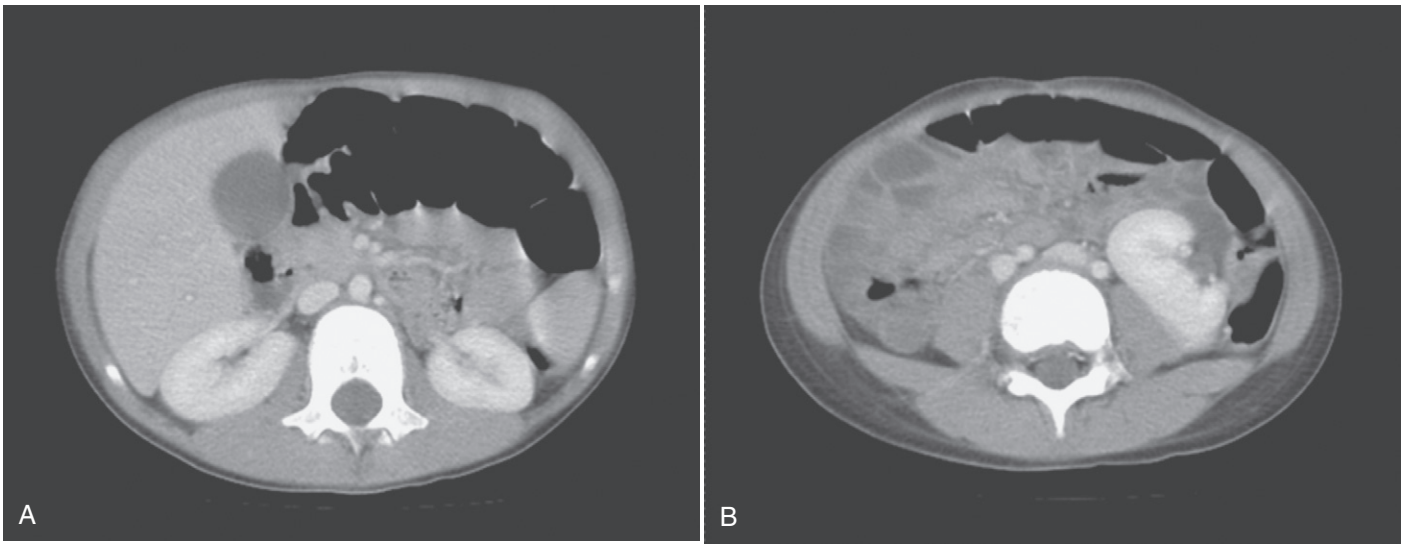

Figure 117–6. Contrast CT scan showing **(A)** right and left orthotopic kidneys. **B,** Right midabdominal malrotated supernumerary kidney.

(Jancu et al, 1976; Wheeler and Weaver, 2001; Rai et al, 2002). Dursun and colleagues (2005) found that 44% of individuals with a congenital solitary kidney, most of whom had URA, had various nonurologic anomalies, but they detected lower incidences of these problems (cardiovascular, 15%; gastrointestinal, 9%; neurologic, 3%; and hematologic, 6%) than previously reported by Emanuel. Chow and colleagues (2005) reported a similar incidence of 42%.

Key Points: Unilateral Renal Agenesis

- Unilateral agenesis occurs once in 1100 births.
- Males predominate with a ratio of 1.8:1.
- Absence of one kidney occurs somewhat more frequently on the left side.
- The ipsilateral ureter is completely absent in about half of the patients.
- Despite the predominance of males with URA, müllerian duct abnormalities occur in 25% to 50% of cases of females with URA compared with wolffian duct anomalies in 10% to 15% of males with URA.
- Approximately one fourth to one third of women with müllerian duct anomalies are found to have URA.
- Anomalies of other organ systems are found frequently in affected individuals. The more common sites involve the cardiovascular, gastrointestinal, and musculoskeletal systems.

Diagnosis and Radiographic Evaluation. **There are no specific symptoms that suggest an absent kidney. Previously, most reports were compiled from autopsy series, but now prenatal screening is detecting URA. The solitary kidney may begin to undergo compensatory hypertrophy in utero** (Mandell et al, 1993; Hill et al, 2000). Recently, prenatal ultrasonography was used to determine compensatory hypertrophy in cases of fetal unilateral empty renal fossa (Cho et al, 2009). These investigators retrospectively measured the ratio of the anteroposterior (AP) and transverse (TR) diameters of the contralateral normal kidney in a set of patients: 12 with URA, 6 with MCDK, and 6 with pelvic kidneys, and these patients were compared with 20 normal controls. They found that when using 0.9 as the discriminating value of the ratio, there was 100% sensitivity, specificity, and accuracy.

Once URA is diagnosed, a retroperitoneal ultrasonogram with color Doppler will show absence of the kidney and ipsilateral renal vessels. A plain film of the abdomen showing the gas pattern of the splenic flexure in the left renal fossa suggests left renal agenesis, ectopia, or crossed ectopia (Mascatello and Lebowitz, 1976), whereas the gas pattern of the hepatic flexure positioned in the right renal fossa suggests congenital absence of the right kidney (Curtis et al, 1977). The diagnosis of URA usually can be confirmed with a DMSA scan showing absent uptake of the isotope on one side, with the contralateral kidney often showing compensatory hypertrophy (Hynes and Watkin, 1970; Cope and Trickey, 1982). A DMSA scan will also detect an ectopic (usually pelvic) or a crossed ectopic kidney in cases where the nonvisualized orthotopic kidney is thought to be absent (Volkan, 2003). In some cases, crossed fused ectopia may be difficult to distinguish from a congenital solitary kidney that has undergone compensatory hypertrophy or a solitary complete duplication. A small dysplastic kidney or MCDK may be misdiagnosed as URA when a kidney is not seen on ultrasonography (Mesrobian, 1993). In these cases, the colonic gas pattern will not be observed in the renal fossa. In addition, calcifications in the renal fossa may suggest an involuted MCDK (Nakano et al, 1996).

Ultrasonography, radionuclide scintigraphy, and MRI have replaced arteriography in diagnosing URA. When a fetus with other suspected organ anomalies undergoes MRI, an absent kidney can be confirmed (Dell'Acqua et al, 2002). URA has also been found incidentally during fluoroscopic monitoring of the renal fossa at the end of a cardiac catheterization or at the end of an echocardiogram. **When URA is diagnosed, a voiding cystourethrogram should be performed, because there is a 28% incidence of contralateral reflux** (Cascio et al, 1999; Kaneyama et al, 2004).

Special Considerations. **The most common question many parents ask is "Will having only one kidney affect my**

child's life, and will there be any restrictions on their activities?" Several North American studies examine the risks of injury to the pediatric kidney through sports. Psooy (2006, 2009) summarizes the results of these studies, which suggest that motor vehicle accidents as passenger and pedestrian result in more renal trauma than sports activities. In addition, bicycling, sledding, downhill skiing/snowboarding, and equestrian activities are the more common causes of high-grade renal trauma. These activities have a more than fivefold relative risk for head injury compared with renal injury. Psooy (2009) notes that children are not generally restricted from these activities on the basis of having "only one head." **Rice and the Council on Sports Medicine and Fitness of the American Academy of Pediatrics** (2008) **advise that each athlete needs individual assessment for their particular sport and that wearing protective padding may reduce the risk of injury to the solitary kidney, thus allowing participation in most sports.**

Prognosis. **In the past, there was no definitive evidence that a solitary kidney predisposes to increased susceptibility to other diseases** (Shapiro et al, 2003). Reviews conducted in the preantibiotic era reported a high incidnce of glomerulonephritis, stones, and tuberculosis. The advent of antibiotics has reduced the incidence of morbidity and mortality for individuals with URA. In the Ashley and Mostofi series (1960), only 15% of the patients died because of renal disease. Renal trauma resulted in death for 5%; some patients in this group might have survived had there been two kidneys. However, because the source of the autopsy material included many military personnel, the potential risk of injury was accentuated. Therefore URA with a normal contralateral kidney is thought to be compatible with normal longevity and the contralateral kidney is not predisposed to greater than normal risks (Gutierrez, 1933; Dees, 1960).

In more contemporary studies, Rugui and colleagues (1986) found an increased occurrence of hypertension, hyperuricemia, and decreased renal function but no proteinuria in a small group of patients with congenital absence of one kidney. Only one patient had a renal biopsy showing focal glomerulosclerosis. This finding has been confirmed in other patients and is similar to observations in the remaining kidney in the hyperfiltration syndrome noted after unilateral nephrectomy (Kiprov et al, 1982; Nomura and Osawa, 1990; Brenner et al, 1996). Oldrizzi and colleagues (1991) reported on URA and progressive renal damage in 39 individuals with a mean age of 33 years. They found prevalence rates of 40% for hypertension, 46% for proteinuria, and 15% for impaired renal function. The limitation of this study is that it was composed of symptomatic patients, and there was no age-matched asymptomatic control population with URA.

Argueso and colleagues (1992) **assessed 157 individuals with congenital URA with a mean age of 37 (age 2 to 84) at diagnosis and noted hypertension, proteinuria (>50 mg/day), and mild renal insufficiency in 47%, 19%, and 13%, respectively.** Only 32 patients actually had their glomerular flow rate (GFR) measured. Of the 13 patients in their seventh to ninth decade, the mean GFR was 65 mL/minute per 1.73 m^2, and the 4 who had renal insufficiency had a GFR between 32 to 53 mL/minute per 1.73 m^2. Six of the 43 deceased patients in this study died from chronic renal failure. Only about 25% of patients had their proteinuria quantified, and less than a third had blood pressure measured. Recognizing these study deficiencies, **the authors concluded that survival was not impaired in this group, because the overall patient survival curve was similar to the general population.** In addition, others have reported that the ability of the kidney to excrete increased loads of protein was not impaired, even in patients with renal insufficiency or proteinuria (DeSanto et al, 1997).

In another study of 206 women with uterine abnormalities, 33 (16%) had URA and 19 had been pregnant and delivered (Heinonen, 2004; Heinonen, 1997). The control group was composed of 44 age-matched women with similar parity and similar uterine malformations but who had two normal kidneys. Eight (42%) of the 19 women with a uterine anomaly and URA (in at least one pregnancy) had gestational hypertension, pre-eclampsia, or gestational proteinuria, compared with only 8 (18%) of the women with two kidneys. The relative risk of gestational hypertension, pre-eclampsia, or gestational proteinuria was significantly higher in women with URA (RR = 2.3). Perinatal outcomes were similar in both groups, with no patient having proteinuria or chronic renal disease, but 2 of the 19 women (11%) with URA were started on long-term antihypertensive medication.

Current Concepts Regarding Prognosis in Adults with Unilateral Renal Agenesis. **There is now evidence that subtle defects in UB branching can cause a reduced nephron number, which may lead to renal disease later in life** (Brenner and Mackenzie, 1997; Costantini and Shakya, 2006; Chevalier, 2009). In humans, there is an eightfold range in normal variation in the number of glomeruli, that is, from 200,000 to 1.8 million (Hughson, 2003). Therefore it is more likely for an individual with nephron numbers at the lower end of the spectrum to be at greater risk for renal insufficiency at any age and from any etiology.

In the past, studies of the renal survival in children with *C*ongenital *A*nomalies of the *K*idney and *U*rinary *T*ract (CAKUT) have been difficult to perform because they involve decades of follow-up and the phenotypes of these disorders are not uniform (Pope et al, 1999; Kerecuk et al, 2008; Zaffanello et al, 2009). Recently, Sanna-Cherchi and colleagues (2009) evaluated the long-term functional outcomes in individuals with CAKUT, including those with URA from a single pediatric nephrology center. Three hundred and twelve patients with CAKUT who had a known defect of the number or size of at least one kidney were followed up to 20 years. Patients with isolated vesicoureteral reflux and duplications were excluded. Dialysis-free survival was evaluated, taking into consideration reflux, age at diagnosis, hypertension, proteinuria, and serum creatinine. Six subgroups were examined, including URA, unilateral and bilateral hypodysplasia, posterior urethral valves, multicystic dysplastic kidney, and horseshoe kidney. These investigators found that by 30 years of age, 19% of all patients were on dialysis, most of whom had posterior urethral valves, bilateral renal hypoplasia, or URA. **Further analysis showed that patients with a solitary kidney had a 50% probability of requiring dialysis by 30 years of age.** Notably, most of the patients with URA in this study were diagnosed during adolescence and had a normal creatinine level at the time of diagnosis. Interestingly, the patients diagnosed at birth had a slightly elevated creatinine level (0.68 mg/dL). These and other studies point out the fundamental differences in individuals with URA and adults who undergo unilateral nephrectomy. The number of nephrons in children with URA may be abnormally low, and those with fewer nephrons may be at greater risk to developing focal glomerulosclerosis.

Current suggestions for children with a normal-appearing single kidney include annual assessments of blood pressure and proteinuria, the hallmarks of a progressive decrease in glomerular filtration rate (Hegde and Coulthard, 2009). Laboratory evaluation, including a blood urea nitrogen and serum creatinine level, can be performed periodically unless abnormalities are denoted. If there is hypertension, proteinuria, and/or impaired renal function,

a pediatric nephrologist should be consulted. They may suggest dietary changes, including limiting salt and avoiding excessive protein intake, depending on the age of the patient. Treatment with an angiotensin-converting enzyme inhibitor may also be indicated (Puddu et al, 2009).

Supernumerary Kidney

Parenchymal development was thought to be controlled by an unidentified substance that limited the amount of functioning renal tissue. Nature has created, albeit rarely, a condition in which three separate kidneys can form. In this condition, the two main kidneys are usually normal and equal in size, whereas the third is small. **The supernumerary kidney is truly an accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchymal mass.** It may be either totally separate from the normal kidney on the same side or connected to it by loose areolar tissue (Geisinger, 1937). The ipsilateral ureters may be bifid or completely duplicated. The condition is not analogous to a single kidney with ureteral duplication in which the collecting systems drain portions of one parenchymatous mass surrounded by a single capsule.

Incidence. The true incidence of this anomaly cannot be determined, because it occurs very infrequently. **About 100 cases have been reported since it was first described in 1656** (Sasidharan et al, 1976; MacPherson, 1987). It affects males and females equally but has a higher predilection for the left side (N'Guessan and Stephens, 1983). Four cases of bilateral supernumerary kidneys have been reported (Campbell, 1970; Oto et al, 2002).

Embryology and Molecular Mechanisms. A second UB or a branching from the initial UB appears as a necessary first step. Next, the nephrogenic anlage may divide into two metanephric tails, which separate entirely when induced to differentiate by the separate or bifid UBs (N'Guessan and Stephens, 1983). The two metanephroi develop only after being penetrated by the bifid or separate UBs. N'Guessan and Stephens do not accept that this condition is the result of widely divergent bifid or separate UBs. Geisinger (1937) proposed that the separate kidneys developed by fragmentation of a single metanephros or by linear infarction producing separate viable fragments that develop only when a second UB is present.

Kidney development is initiated when a single UB forms from the WD in response to GDNF secreted by the adjacent MM. Posterior restriction of *Gdnf* expression is critical for the development of a UB in the normal position, while another intercellular signaling system, including SLIT2 or its receptor ROBO2, is also important in ensuring that a single UB forms in the appropriate location. Grieshammer and colleagues (2004) showed that mutant mice lacking either SLIT2 or its receptor ROBO2 develop supernumerary UBs that are correlated with abnormal maintenance of *Gdnf* expression in anterior MM. The SLIT2/ROBO2 intercellular signaling system restricts, directly or indirectly, the extent of the *Gdnf* expression and plays a critical role in precisely positioning the site of kidney induction.

Description. The supernumerary kidney is a distinct mass of renal parenchyma that may be either completely separate or only loosely attached to the major kidney on the ipsilateral side. In about 60% of cases, it is located caudad to the dominant kidney, which is in its orthotopic position in the renal fossa. When a separate and distinct ureter is present, the supernumerary kidney is more likely to be cranial to the dominant kidney but caudal to the adrenal (Bernik et al, 2001). Occasionally, the supernumerary kidney lies either posterior or superior to the main kidney, or it may even be a midline structure anterior to the great vessels and loosely attached to each of the other two kidneys (see Fig. 117–6). The supernumerary kidney may become wedged between the lower poles of a right and left kidney, leading to the radiographic appearance of a "pseudohorseshoe" kidney (Macpherson, 1987). A pelvic supernumerary kidney has also been reported (Eberle et al, 2002).

Key Points: Supernumerary Kidney

- The supernumerary kidney is a definitive accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchyma.
- The supernumerary kidney may be either completely separate or loosely attached to the kidney on the ipsilateral side.
- The ureteral inter-relationships on the side of the supernumerary kidney can be variable.

The supernumerary kidney is reniform but generally smaller than the main ipsilateral kidney. In about one third of cases, the kidney or its collecting system is abnormal. In almost half of the reported cases, the collecting system is severely dilated with thin parenchyma suggesting obstruction.

The ureteral interrelationships on the side of the supernumerary kidney can be variable (Kretschmer, 1929). Convergence of the ipsilateral ureters distally to form a common stem and a single ureteral orifice occurs in 50% of the cases (Exley and Hotchkiss, 1944; N'Guessan and Stephens, 1983), which suggests "a bud off of a bud" situation. Two completely independent ureters, each with its own entrance into the bladder, are seen in the other 50% of cases. The Weigert-Meyer principle (see Chapter 111) usually is followed, but in 10%, the caudal kidney has a ureter that does not follow the rule and enters the trigone below the ipsilateral ureter (Tada et al, 1981) (Fig. 117–7). Rarely, the supernumerary kidney has a completely ectopic ureter opening into the vagina or introitus (Rubin, 1948; Carlson, 1950). Individual case reports have described calyceal communications between the supernumerary and the dominant kidney, or fusion of the dominant kidney's ureter with the pelvis of the supernumerary kidney (Kretschmer, 1929) to create a single distal ureter that then enters the bladder (Fig. 117–8). The vascular supply to the supernumerary kidney is anomalous and depends on its position in relation to the major ipsilateral kidney. Most investigators believe that the blood supply to the individual parenchymal masses should be separate to consider this a true supernumerary kidney (Kaneoya et al, 1989).

Associated Anomalies. Usually, the ipsilateral and contralateral kidneys are normal. Except for an occasional ectopic orifice from the ureter draining the supernumerary kidney, no genitourinary abnormalities are present in any consistent pattern. A few of the case reports describe anomalies of other organ systems (Janda et al, 2009).

Symptoms. Although this anomaly is present at birth, it is rarely symptomatic but may become symptomatic in early adulthood. The average age at diagnosis was 36 years. Pain, fever, hypertension, and a palpable abdominal mass are the usual presenting complaints. Urinary infection or obstruction, or both, are the major conditions that lead to an evaluation. Ureteral ectopia from the supernumerary kidney may produce urinary

incontinence, but this is extremely rare (Shane, 1942; Hoffman and McMillan, 1948).

A palpable abdominal mass secondary to development of carcinoma in the supernumerary kidney has been described in two patients. In 25% of all reported cases, the supernumerary kidney remains completely asymptomatic and is discovered only at autopsy (Carlson, 1950).

Diagnosis. If the supernumerary kidney is normal and asymptomatic, it is usually diagnosed when abdominal ultrasonography, CT, or MRI is performed for other reasons. The kidney may be inferior and distant enough from the ipsilateral kidney so that it does not alter the position of the normal kidney (Conrad and Loes, 1987). If it is in close proximity, it may displace the predominant kidney or its ureter very slightly.

A supernumerary kidney may become symptomatic from hydronephrosis due to obstruction or stone formation (Koureas et al, 2000). In this case, ultrasonography may demonstrate distortion of the normal ipsilateral kidney and ureter. If the collecting system is bifid, the dominant kidney on that side will usually be involved in the same disease process. If the ureters are separate, the ipsilateral kidney may show the effects of an abnormal supernumerary kidney. Voiding cystourethrography, ultrasonography, or MR urography, and even retrograde pyelography may be needed to help delineate the anomaly. Radionuclide imaging provides information about relative function in the supernumerary and the normal kidneys (Conrad and Loes, 1987). Cystoscopy reveals one or two ureteral orifices on the ipsilateral side, depending on whether the ureters are completely duplicated. Ureteral ectopia may exist in or outside of the bladder. Occasionally, a supernumerary kidney is not accurately diagnosed until the time of surgery or at autopsy, or it may mimic a duplication (Kaneoya et al, 1989).

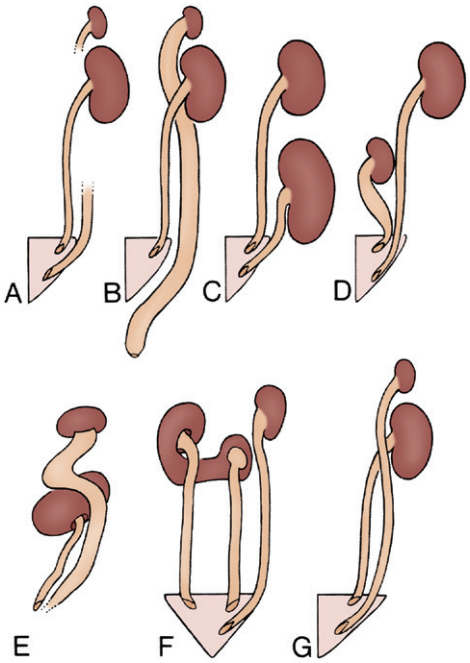

Figure 117–7. **A** to **G,** Various patterns of urinary drainage of supernumerary and ipsilateral kidneys when ureters are completely separated. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. J Urol 1983;130:649.)

ANOMALIES OF ASCENT

Simple Renal Ectopia

When the mature kidney fails to reach its normal location in the "renal" fossa, the condition is known as *renal ectopia.* The term is derived from the Greek words *ek* ("out") and *topos* ("place") and literally means "out of place." It is to be differentiated from renal ptosis, in which the kidney initially is located in its proper place (and has normal vascularity) but moves downward in relation to body position. The ectopic kidney has never resided in the appropriate location. An ectopic kidney can be found in one of the following positions: pelvic, iliac, abdominal, thoracic, and contralateral or crossed (Fig. 117–9).

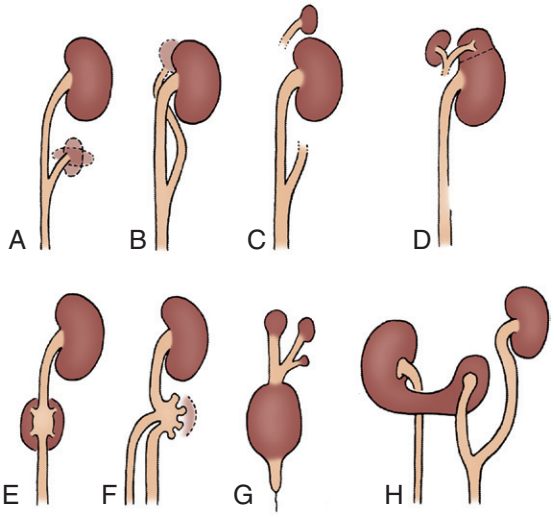

Figure 117–8. **A** to **H,** Various patterns of urinary drainage when ureters form a common stem. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. J Urol 1983;130:649.)

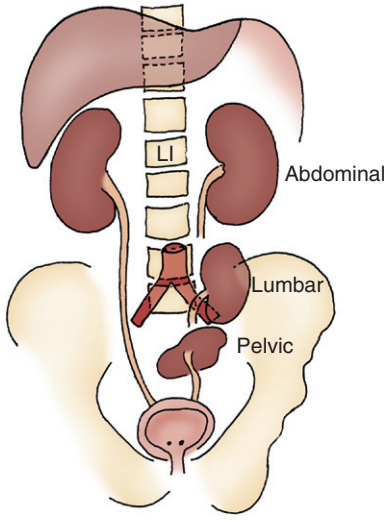

Figure 117–9. Incomplete ascent of kidney. The kidney may halt at any level of its ascent from the pelvis. (From Gray SW, Skandalakis JE. The kidney and ureter. In: Gray SW, Skandalakis JE, editors. Embryology for surgeons. Philadelphia: WB Saunders; 1972.)

Incidence. Renal ectopia has been known to exist since it was described by 16th century anatomists, but it did not achieve clinical interest until the mid-19th century. Recently, with improved imaging, simple renal ectopia has been noted with increasing frequency.

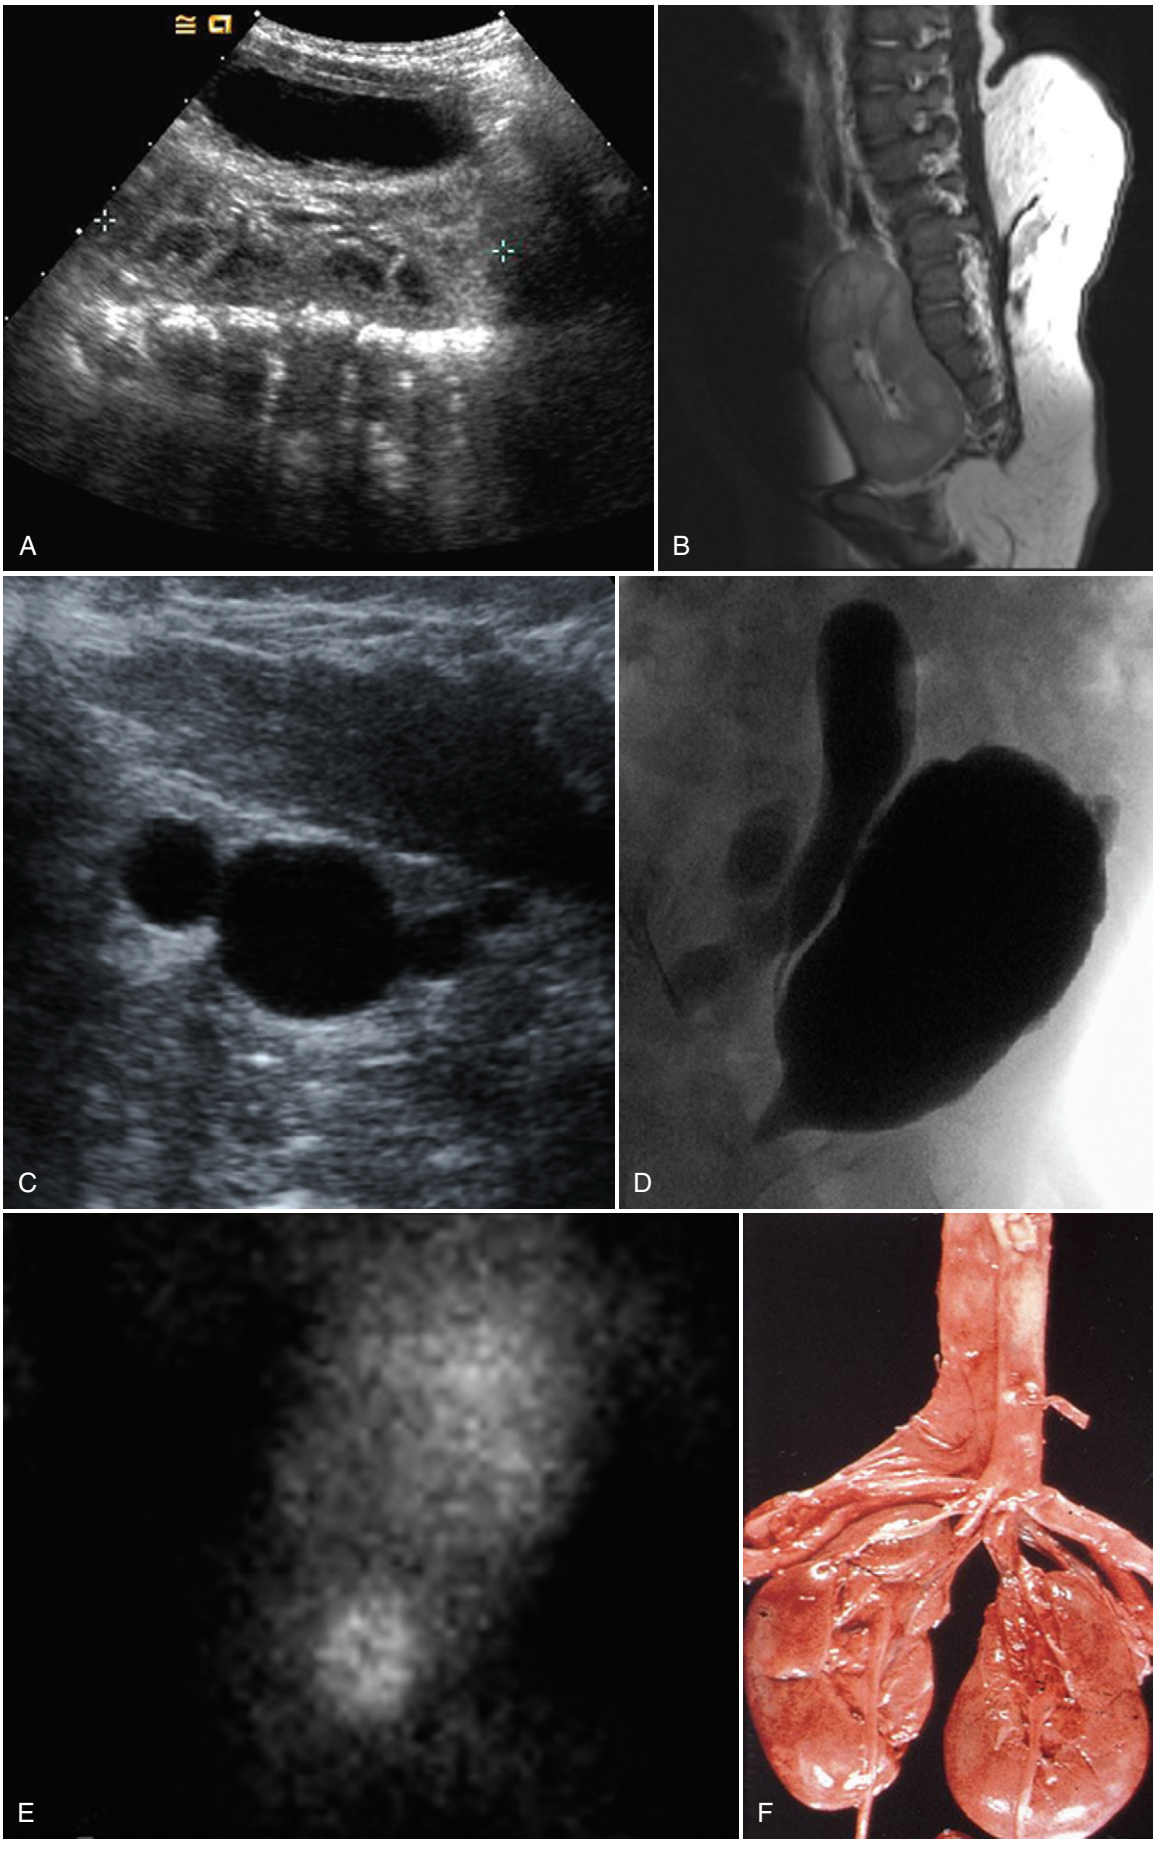
The actual incidence among autopsy series varies from 1 in 500 (Campbell, 1930) **to 1 in 1200** (Stevens, 1937; Thompson and Pace, 1937; Anson and Riba, 1939; Bell, 1946a), **but the average occurrence is about 1 in 900** (Abeshouse and Bhisitkul, 1959). With increasing clinical detection, the incidence among hospitalized patients has approached the autopsy rate (Abeshouse and Bhisitkul, 1959). Autopsy studies reveal no significant difference in incidence between the sexes. A recent review of prenatal ultrasonograms detected an incidence of 0.003% in India, but this likely under-represents its true occurrence (Sanghvi et al, 1998). Clinically, renal ectopia is more readily recognized in females; they undergo uroradiologic evaluation more frequently than males because of their higher rate of UTI and/or associated genital anomalies (Thompson and Pace, 1937).

The left side is favored slightly over the right. Pelvic ectopia has been estimated to occur in 1 of 2100 to 3000 autopsies (Stevens, 1937). A solitary ectopic kidney occurs in 1 of 22,000 autopsies (Stevens, 1937; Hawes, 1950; Delson, 1975). By 1973, only 165 cases of a solitary pelvic kidney had been recorded (Downs et al, 1973). Bilateral ectopic kidneys are even more rarely observed and account for only 10% of all patients with renal ectopia (Malek et al, 1971) (Fig. 117–10).

Embryology. The UB, arising from the WD at the end of the fourth week, grows craniad toward the urogenital ridge, acquiring a cap of metanephric blastema by the fifth week. The developing metanephric tissue and UB migrate cephalad, rotating medially on its long axis. The entire process is completed by the eighth week of gestation. Factors that may prevent the orderly ascent and rotation of kidneys include UB maldevelopment (Campbell, 1930), defective metanephric tissue that fails to induce ascent (Ward et al, 1965), genetic abnormalities, and maternal illnesses or teratogenic causes (Malek et al, 1971). A vascular barrier that prevents upward migration secondary to persistence of the fetal blood supply has also been postulated (Baggenstoss, 1951), but the existence of an "early" renal blood supply does not prevent the affected kidney's movement to its ultimate position. Most probably, this is the end result, not the cause, of renal ectopia.

Description. The classification of ectopia is based on the position of the kidney within the retroperitoneum: The pelvic kidney opposite the sacrum and kidneys below the aortic bifurcation are the most common sites of ectopia; the lumbar kidney resides near the sacral promontory in the iliac fossa and anterior to the iliac vessels; and the abdominal kidney is above the iliac crest and adjacent to the second lumbar vertebra (see Fig. 117–10).

The ectopic kidney is usually smaller, and it may not conform to the usual reniform shape, due to the presence of fetal lobulations. The axis of the kidney is slightly medial or vertical, but it may be tilted as much as 90 degrees laterally so that it lies in a true horizontal plane. **The renal pelvis is usually anterior (instead of medial) to the parenchyma, because the kidney has incompletely rotated. As a result, 56% of ectopic kidneys have a hydronephrotic collecting system. Half of these cases are due to obstruction of the ureteropelvic or the ureterovesical junction (70% and 30%, respectively), 25% from reflux grade III or greater, and 25% from the malrotation alone** (Gleason et al, 1994). Overall, vesicoureteral reflux has been found in 30% of children with ectopic kidneys (Guarino et al, 2004).



The length of the ureter usually conforms to the position of the kidney, but occasionally, it is slightly tortuous. It is rarely redundant, in contrast to the ptotic kidney, in which the ureter has achieved its full length before the kidney drops. **The ureter usually enters the bladder on the ipsilateral side with its orifice positioned normally, except for those unusual cases with ectopic ureters.** The arterial and venous network is anomalous and its vascular pattern depends on the ultimate position of the kidney (Anson and Riba, 1939). There may be one or two main renal arteries arising from the distal aorta or from the aortic bifurcation, with one or more aberrant arteries emanating from the common or external iliac or even the inferior mesenteric artery. The kidney may be supplied entirely by multiple anomalous branches, none of which arises from the aorta. In no instance has the main renal artery arisen from the level of the aorta that would be its proper origin if the kidney were positioned normally.

Associated Anomalies. Although the contralateral kidney is usually normal, it is associated with a number of congenital defects. **Malek and colleagues** (1971) **and Thompson and Pace** (1937) **reported the incidence of contralateral agenesis to be rather high** (Chow et al, 2005). Bilateral ectopia occurs infrequently (10%) (see Fig. 117–10). Hydronephrosis secondary to obstruction or reflux may be seen in as many as 25% of nonectopic contralateral kidneys (Gleason et al, 1994).

Key Points: Simple Renal Ectopia

- The left side is affected slightly more than the right.
- Pelvic ectopia has been estimated to occur in 1 of 2100 to 3000 autopsies.
- Fifty-six percent of ectopic kidneys have a hydronephrotic collecting system. Half of these cases result from obstruction at the ureteropelvic or the ureterovesical junction (70% and 30%, respectively), 25% from reflux grade III or greater, and 25% from the malrotation alone.
- Vesicoureteral reflux has been found in 30% of children with ectopic kidneys.
- The incidence of genital anomalies in the patient with ectopia is about 15%.
- Most ectopic kidneys are clinically asymptomatic, except in cases of associated ectopic ureter.

The most striking feature is the association of genital anomalies and ectopia. The incidence varies from 15% (Thompson and Pace, 1937) **to 45%** (Downs et al, 1973), depending on how carefully the patient is evaluated. Twenty to 66 percent of females have one or more of the following abnormalities of the reproductive organs: bicornuate or unicornuate uterus with atresia of one horn (McCrea, 1942), rudimentary or absent uterus and proximal and/or distal vagina (Tabisky and Bhisitkul, 1965; D'Alberton et al, 1981), and duplication of the vagina. Among male patients, 10% to 20% have a recognizable associated genital defect; undescended testes, duplication of the urethra, and hypospadias are the most common (Thompson and Pace, 1937). Fourteen percent of patients with a cloacal malformation have an ectopic kidney (Warne et al, 2002; Dursun et al, 2005).

Rarely is the adrenal gland absent or abnormally positioned. Twenty-one percent of individuals have anomalies of other organ systems (Downs et al, 1973); most involve the skeletal or cardiac systems.

Diagnosis. With the increasing use of various imaging modalities, the incidence of an asymptomatic ectopic kidney is increasing. **Most ectopic kidneys are asymptomatic.** Vague abdominal complaints or ureteral colic secondary to an obstructing stone are the most frequent symptoms leading to the diagnosis of an ectopic kidney. The abnormal position of the kidney results in a pattern of direct and referred pain that is atypical for colic and may be misdiagnosed as acute appendicitis or as pelvic inflammatory disease in female patients. Symptoms rarely occur due to adjacent organs to the ectopic kidney. Renal ectopia may also present with a UTI or a palpable abdominal mass. Seven cases of concomitant renal and ureteral ectopia presenting with urinary incontinence have been reported (Borer et al, 1993, 1998). The difficulty in diagnosing this condition is related to the poor function of these ectopic kidneys. The kidneys may be very small and/or dysplastic with essentially no function leading to the misdiagnosis of URA. DMSA scanning or MR urography may both be necessary to diagnose these unusual cases (Borer et al, 1998; Leitha, 1998; Pattaras et al, 1999) (see Fig. 117–10).

Malposition of the colon as observed with renal ageneisis will be observed in cases of ectopic lumbar or pelvic kidney. The diagnosis is made when the renal ultrasonogram fails to reveal a kidney in its orthotopic location. Many of these kidneys were not visualized in the past on an excretory urogram because they overlie the bony pelvis, which obscures the collecting system and leads to a misdiagnosis. With a carefully performed power color Doppler study, the main renal artery and intrarenal vasculature can be more easily delineated. Ultrasonography of the pelvic ectopic kidney demonstrated absence of renal sinus echoes, a normal finding associated with the extrarenal position of the pelvis and calyces (Barnewolt and Lebowitz, 1996).

Cystoscopy, if performed, will demonstrate ureteral orifices that are invariably normal unless the ureteral orifice is also ectopic. If surgery is indicated on an ectopic kidney, MR arteriography can be performed preoperatively to define the anatomy of the renal vasculature, which is especially important in cases of solitary ectopia.

Prognosis. **The ectopic kidney is no more susceptible to disease than the normally positioned kidney, except for the development of hydronephrosis or urinary calculus formation** (Gleason et al, 1994; Benchekroun et al, 2002). This may be due to the anteriorly placed pelvis and malrotation of the kidney, which may lead to impaired drainage of urine from a high insertion of the ureter to the pelvis or an anomalous vasculature that partially obstructs one of the major calyces or the upper ureter. In addition, there may be an increased risk of injury from blunt abdominal trauma, because the low-lying kidney is not protected by the rib cage.

Renovascular hypertension secondary to an anomalous blood supply has been reported, but a higher-than-normal incidence is yet to be proved. A recent study by van den Bosch and colleagues (2010) examined the urologic and nephrologic consequences of both simple and crossed renal ectopia. They found no adverse effects on blood pressure or kidney function during childhood. They did note that although global renal function of these kidneys was normal, the relative function of the ectopic kidney on dimercaptosuccinic acid scan (^{99m}Tc-DMSA) was 38% (interquartile range [IQR] 33% to 43%).

Anderson and Harrison (1965), in a review of pregnant women with renal ectopia, found no increased occurrence of difficult deliveries or maternal or fetal complications related to the ectopic kidney (Anderson and Harrison, 1965; Delson, 1975). Dystocia from a pelvic kidney is a very rare finding, but when it does occur, early recognition is mandatory and cesarean section is indicated. Although three cases of cancer in an ectopic kidney have been reported, there does not appear to be an increased risk for malignancy. No deaths have been directly attributable to the ectopic kidney, but in at least five instances, a solitary ectopic kidney has been mistakenly removed, because the kidney was thought to represent a pelvic malignancy (Downs et al, 1973). This should not happen with the current armamentarium of imaging techniques available to accurately diagnose this condition.

Cephalad Renal Ectopia

The kidney may be positioned more craniad than normal when there is an omphalocele (Pinckney et al, 1978). When the liver herniates into the omphalocele with the intestines, the kidneys continue to ascend until their ascent is arrested by the diaphragm. In all reported cases, both kidneys were affected and were positioned immediately beneath the diaphragm at the level of the 10th thoracic vertebra. The ureters are excessively long but otherwise normal. A color Doppler ultrasonogram or MR arteriography demonstrates that the origin of each renal artery is more cephalad than normal, and no other abnormality of the vascular network is present. Patients with this anomaly usually have no symptoms referable to the malposition, and urinary drainage is not impaired.

Thoracic Kidney

The rarest form of renal ectopia exists when the kidney is positioned considerably higher than normal. **Intrathoracic ectopia denotes either a partial or a complete protrusion of the kidney above the level of the diaphragm into the posterior mediastinum** (Fig. 117–11). **Fewer than 5% of all patients with renal ectopia have an intrathoracic kidney, with an incidence of 1:13,000 at autopsy** (Campbell, 1930). This condition must be differentiated from a congenital or traumatic diaphragmatic hernia in which other abdominal organs, as well as the kidney, have advanced into the chest cavity.

Incidence. Before 1940, this condition was only noted at autopsy (DeCastro and Shumacher, 1969). Since that time, **at least 200 patients with a thoracic kidney have been reported** in the literature (Donat and Donat, 1988; Lacasta Garcia et al, 1999), 4 of whom had bilateral thoracic kidneys (Berlin et al, 1957; Hertz and Shahin, 1969; Lundius, 1975; N'Guessan and Stephens, 1984; Liddell et al, 1989). There appears to be a slight left-sided predominance of 1.5:1, and the sex ratio favors males

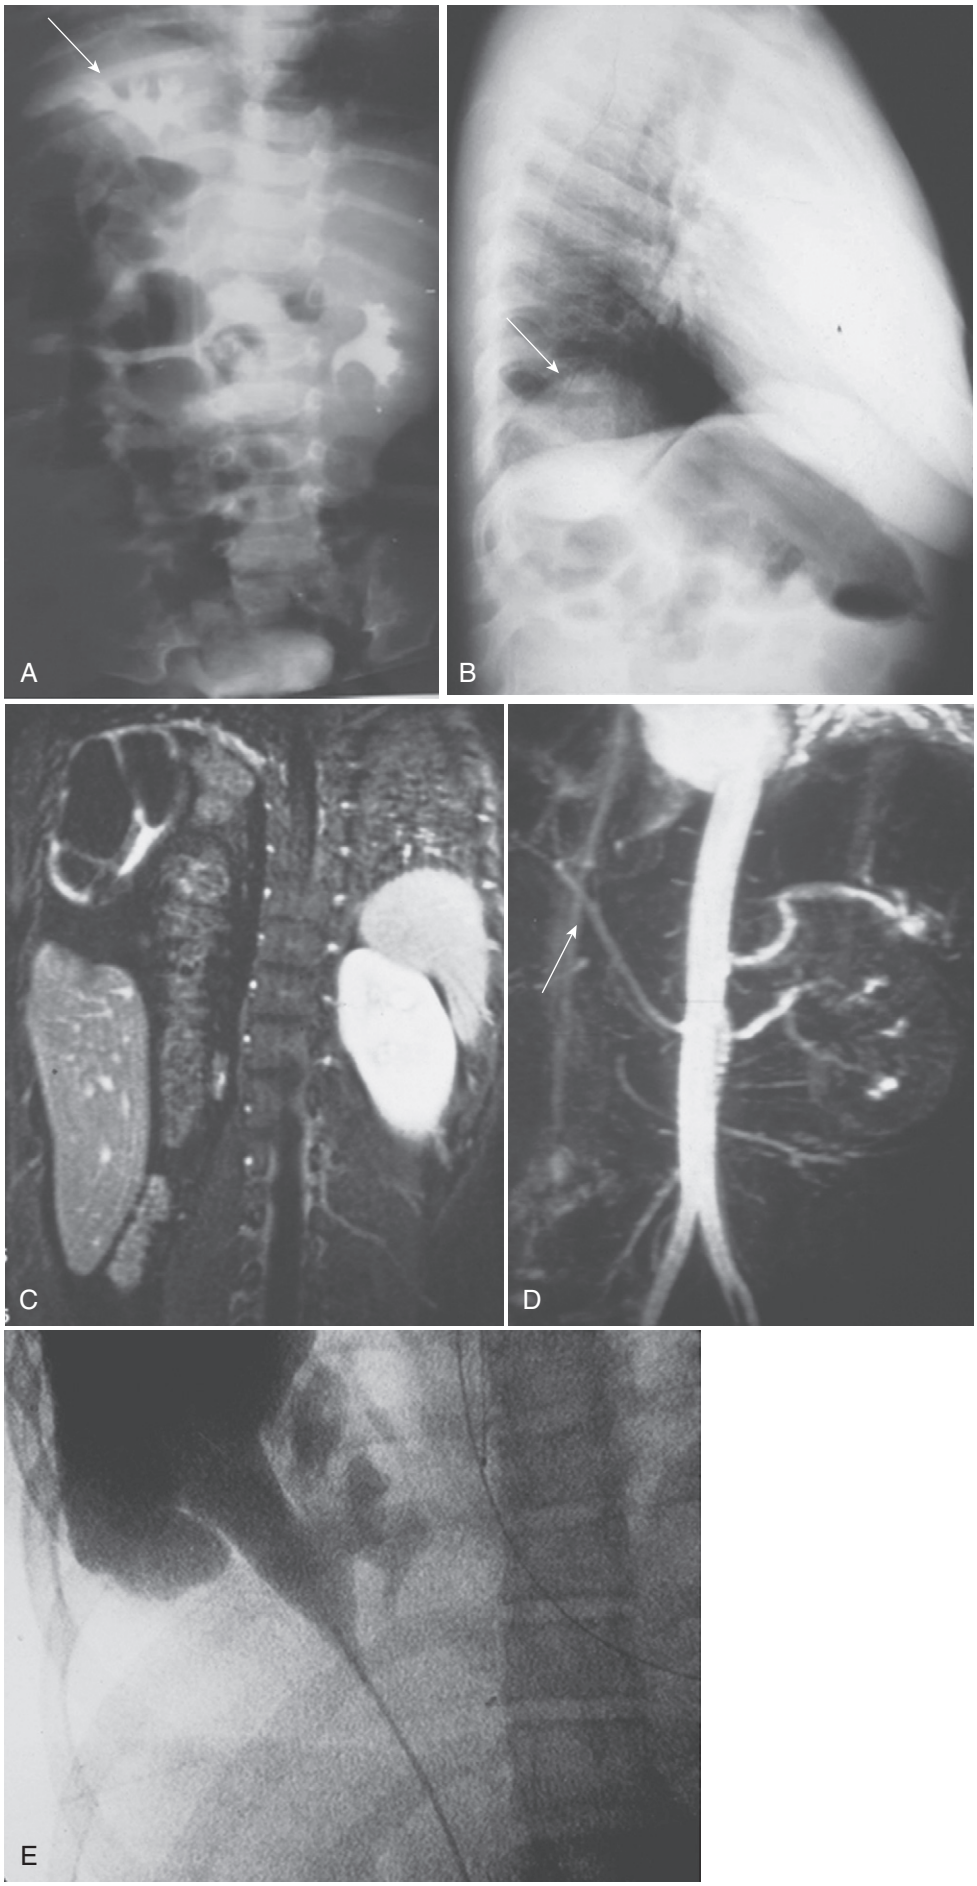

Figure 117–11. One-year-old girl with febrile urinary tract infection (UTI). **A,** Intravenous pyelogram shows a right thoracic kidney *(arrow)* and left orthotopic kidney. She was found to have bilateral vesicoureteral reflux and underwent bilateral ureteral reimplants. At age 16, she developed right back pain and chest tightness. **B,** Chest radiograph demonstrates right diaphragmatic eventration and a right intrathoracic kidney *(arrow)*. **C,** MR urogram shows coronal T1 fat-saturation after contrast images of poorly functioning right hydronephrotic kidney located superior to the liver and inferior to the right lung with absence of the posterior right hemidiaphragm, permitting the colon to enter the right hemithorax. **D,** Angiographic sequence demonstrating right renal artery *(arrow)* arising from the aorta at the normal level of the left renal artery coursing superiorly to enter the right renal hilum. **E,** Intraoperative right retrograde pyelogram shows narrowing at the ureteropelvic junction. by 2:1 (Lozano and Rodriguez, 1975). This entity has been found on prenatal ultrasonography (Masturzo et al, 2001) and in all age groups, from a neonate (Shapira et al, 1965) to a 75-year-old man evaluated for prostatic hypertrophy (Burke et al, 1967), but it is most commonly detected in adults undergoing chest radiography for other reasons (Drop et al, 2003) (see Fig. 117–11).

Embryology. **The kidney reaches its adult location by the end of the eighth week of gestation.** At this time, the diaphragmatic leaflets are formed as the pleuroperitoneal membrane separates the pleural from the peritoneal cavity. Mesenchymal tissues associated with this membrane eventually form the muscular component of the diaphragm. It is uncertain whether delayed closure of the diaphragmatic anlage allows for protracted renal ascent above the level of the future diaphragm or whether the kidney overshoots its usual position because of accelerated ascent before normal diaphragmatic closure (Spillane and Prather, 1952; Burke et al, 1967; N'Guessan and Stephens, 1984). Delayed involution of mesonephric tissue has been proposed as a causative factor (Angulo et al, 1992), because intrathoracic kidneys occur in only 0.25% of patients with a diaphragmatic hernia (Donat and Donat, 1988). Renal angiography has demonstrated either a normal site (Lundius, 1975) or a more cranial origin (Franciskovic and Martincic, 1959) for the origin of the renal artery from the aorta supplying the thoracic kidney (see Fig. 117–11).

Description. **The kidney is situated in the posterior mediastinum and usually has completed the normal rotation process.** The renal contour and collecting system are normal. The kidney usually lies in the posterolateral aspect of the diaphragm in the foramen of Bochdalek. At this point, the diaphragm thins out and a flimsy membrane surrounds the protruding portion of kidney. Therefore the kidney is not within the pleural space (N'Guessan and Stephens, 1984). The lower lobe of the adjacent lung may be hypoplastic secondary to compression by the kidney mass. The renal vasculature and the ureter enter and exit from the pleural cavity through the foramen of Bochdalek.

Associated Anomalies. **The ureter is elongated to accommodate the excessive distance to the bladder, but it never enters ectopically into the bladder or other pelvic sites.** N'Guessan and Stephens (1984) analyzed 10 cases and determined that the **adrenal gland typically occupies its normal location** in most patients. In unilateral cases, the contralateral kidney is usually normal. No consistent anomalies have been described in other organ systems.

Symptoms. **The vast majority of affected individuals are asymptomatic.** Pulmonary and urinary symptoms are exceedingly rare. One case of a pyeloplasty in a thoracic kidney with ureteropelvic junction (UPJ) obstruction and presenting with flank pain has been reported (Hampton and Borden, 2002). A case depicted in Figure 117–11 shows severe hydronephrosis of a previously normal thoracic kidney, presumably due to intermittent obstruction by the muscular fibers of the diaphragm (Shapiro, personal communication).

Diagnosis. **The diagnosis is most commonly made after a routine chest radiograph shows the affected hemidiaphragm slightly elevated.** A smooth, rounded mass is seen extending into the chest near the midline on an anteroposterior film and along the posterior aspect of the diaphragmatic leaflet on a lateral view (see Fig. 117–11). A thoracic kidney may be found at the time of thoracotomy for a suspected mediastinal tumor (DeNoronha et al, 1974). Historically, excretory urography or renal scintigraphy (Williams et al, 1983) provided the diagnosis, while CT or MR urography is currently the imaging modality of choice. Rarely, cardiac or pulmonary arteriography reveals a thoracic kidney (Fusonie and Molnar, 1966).

Prognosis. Neither autopsy series nor clinical reports suggest that a thoracic kidney will usually cause serious urinary or pulmonary complications.

ANOMALIES OF FORM AND FUSION

Crossed Renal Ectopia with and without Fusion

When a kidney is located on the side opposite from that in which its ureter inserts into the bladder, the condition is known as *crossed ectopia*. Ninety percent of crossed ectopic kidneys are fused to their ipsilateral mate. Except for the horseshoe anomaly, they account for the majority of fusion defects. Fusion anomalies are usually diagnosed in children as part of a constellation of malformations, in young adults during evaluation for delayed menarche, and in the elderly as incidental findings (Glodny et al, 2008).

Fusion anomalies of the kidney were first logically categorized by Wilmer (1938), but McDonald and McClellan (1957) refined and expanded that classification to include crossed ectopia with fusion, crossed ectopia without fusion, solitary crossed ectopia, and bilaterally crossed ectopia (Fig. 117–12). The fusion anomalies have been designated as (1) unilateral fused kidney with inferior ectopia; (2) sigmoid, or S-shaped; (3) lump or cake; (4) L-shaped, or tandem; (5) disc, shield, or doughnut; and (6) unilateral fused kidneys with superior ectopia (Fig. 117–13). Although

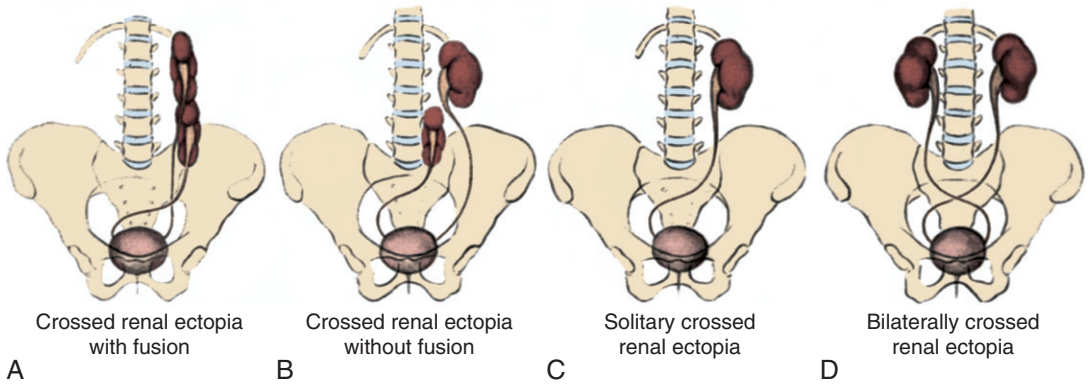

Figure 117–12. **A** to **D,** Four types of crossed renal ectopia.

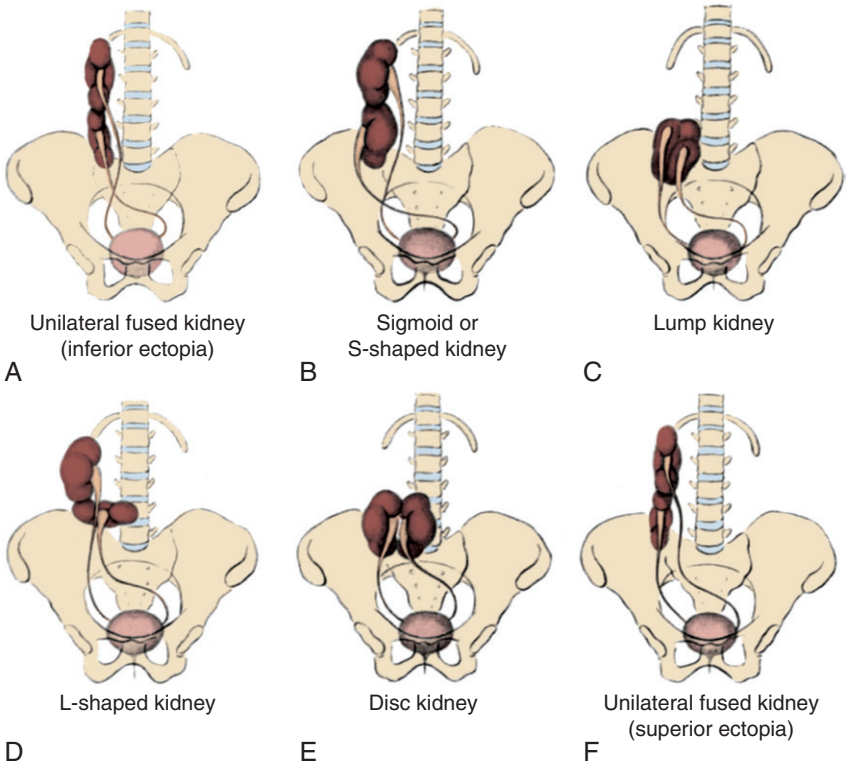

Figure 117–13. **A** to **F,** Six forms of crossed renal ectopia with fusion.

this classification has little clinical significance, it does provide insights into the embryology of renal ascent and rotation.

Incidence. The first reported case of crossed ectopia was described by Pamarolus in 1654. Abeshouse and Bhisitkul, in 1959, conducted the last significant review of the subject and reported 500 cases of crossed ectopia with and without fusion that presented primarily with clinical symptoms. Glodny and colleagues (2008) reported on 24 crossed fused ectopia found on a CT scan performed for nonurologic indications.

Sixty-two patients with crossed ectopia without fusion have been reported (Diaz, 1953; Winram and Ward-McQuaid, 1959). This represents approximately 10% of all crossed ectopic kidneys (Lee, 1949). The anomaly occurs more commonly in males with a ratio of 2:1, and left-to-right ectopia is seen three times more frequently than right-to-left ectopia (Lee, 1949).

Solitary crossed ectopia has been reported in 34 patients (Miles et al, 1985; Gu and Alton, 1991). Males predominate with a ratio of 2:1. The crossed ectopia involves migration of the left kidney to the right side with absence of the right kidney, rather than the reverse, with a ratio of almost 2:1 (Kakei et al, 1976). In most cases, the kidney fails to ascend and rotate completely. The left to right crossed kidney is rarely a multicystic dysplastic kidney. Bilateral crossed renal ectopia has been described in five patients (McDonald and McClellan, 1957; Abeshouse and Bhisitkul, 1959) and is considered the rarest form. Abeshouse and Bhisitkul (1959) compiled 443 reports of crossed ectopia with fusion and estimated its occurrence at 1 in 1000 live births. This figure varies with the type of fusion anomaly; **the unilaterally fused kidney with inferior ectopia is the most common variety, whereas fusion with superior ectopia is the least common.** The autopsy incidence has been calculated at 1 in 2000 (Baggenstoss, 1951). There is a slight male predominance (3:2), and a left-to-right crossover occurs somewhat more frequently than its counterpart.

Embryology. The UB enters the metanephric blastema adjacent to the anlage of the lumbosacral spine. During the next 4 weeks, the developing kidney comes to lie at the level of the L1-L3 vertebrae. Because the mechanisms responsible for normal complete ascent of the kidney during gestation are unknown, **the cause of crossed ectopia is also unknown.** Wilmer (1938) suggested that crossover occurs as a result of pressure from abnormally placed umbilical arteries that prevent cephalad migration of the renal unit, which then follows the path of least resistance to the opposite side.

Potter (1952) and Alexander and colleagues (1950) theorized that crossed ectopia is strictly a ureteral phenomenon, with the developing UB wandering to the opposite side and inducing differentiation of the contralateral nephrogenic anlage. Ashley and Mostofi (1960) deduced that strong but undetermined forces are responsible for renal ascent and that these forces attract one or both kidneys to their final place on the opposite side of the midline. Cook and Stephens (1977) postulated that crossover is the result of malalignment and abnormal rotation of the caudal end of the developing fetus, with the distal curled end of the vertebral column being displaced to one side or the other. As a result, either the cloaca and WD structures lie to one side of the vertebral column, allowing one ureter to cross the midline and enter the opposite nephrogenic blastema, or the kidney and ureter are transplanted to the opposite side of the midline during "normal" renal ascent (Hertz et al, 1977; Maizels and Stephens, 1979).

Kelalis and colleagues (1973) implicated teratogenic factors after they noted an increased incidence of associated genitourinary and other organ system anomalies. Finally, genetic influences may play a role, because familial inheritance of crossed renal ectopia has been reported (Greenberg and Nelsen, 1971; Hildreth and Cass, 1978; Rinat et al, 2001).

Fusion of the metanephric masses may occur when the renal anlagen are still in the true pelvis before or at the

start of cephalad migration, or it may occur during the latter stages of ascent. The extent of fusion is determined by the proximity of the developing renal anlagen to one another. After fusion, advancement of the kidneys toward their normal location is impeded by midline retroperitoneal structures, the aortic bifurcation, the inferior mesenteric artery, and the base of the small bowel mesentery (Joly, 1940).

Description. **Fusion of a crossed ectopic kidney is related to the time at which it comes in contact with its mate.** The crossed kidney usually lies caudad to its normal counterpart on that side. It is likely that migration of each kidney begins simultaneously, but ascent of the ectopic renal unit lags behind because of crossover time. **Therefore it is the superior pole of the ectopic kidney that usually joins with the inferior aspect of the normal kidney. Ascent continues until either the uncrossed kidney reaches its normal location or one of the retroperitoneal structures prevents further migration of the fused mass. The final shape of the fused kidneys depends on the time and extent of fusion and the degree of renal rotation that has occurred.** No further rotation is likely once the two kidneys have joined. Therefore the position of each renal pelvis may provide a clue as to the chronology of the congenital defect. An anteriorly placed pelvis suggests early fusion, whereas a medially positioned renal pelvis indicates that fusion probably occurred after rotation was completed.

Ninety percent of crossed ectopic kidneys are fused with their mate. When they are not fused, the uncrossed kidney usually resides in its normal dorsolumbar location with proper orientation, while the ectopic kidney is inferior and in either a diagonal or a horizontal position with an anteriorly placed renal pelvis. The two kidneys are usually separated by a variable distance, and each is surrounded by its own capsule of Gerota fascia. In every case of crossed ectopia without fusion, the ureter from the normal kidney enters the bladder on the same side, and that of the ectopic kidney crosses the midline at the pelvic brim and enters the bladder on the contralateral side (Fig. 117–14).

In cases of solitary crossed ectopia, the kidney is usually located somewhat low but in the opposite renal fossa at the level of L1-L3 and is oriented anteriorly, having incompletely rotated on its vertical axis (Alexander et al, 1950; Purpon, 1963). When the kidney remains in the pelvis or ascends only to the lower lumbar region, it may assume a horizontal lie with an anteriorly placed pelvis because it has failed to rotate fully (Trabrisky and Bhisitkul, 1965). The ureter crosses the midline above the S2 vertebra and enters the bladder on the opposite side (Gu and Alton, 1991). The contralateral ureter, if present, is often rudimentary (Caine, 1956).

Key Points: Crossed Renal Ectopia with and without Fusion

- When a kidney is located on the side opposite from that in which its ureter inserts into the bladder, the condition is known as crossed ectopia.
- Ninety percent of crossed ectopic kidneys are fused with their mate; the superior pole of the ectopic kidney usually joins with the inferior aspect of the normal kidney.
- In all the types of fusion anomalies, the ureter from each kidney is usually orthotopic.
- The highest incidence of associated anomalies occurs in children with solitary renal ectopia and involves both the skeletal system and genital organs.

The patient with bilateral crossed ectopia may have perfectly normal-appearing kidneys and renal pelves, but the ureters cross the midline at the level of the lower lumbar vertebrae (Abeshouse and Bhisitkul, 1959).

Inferior Ectopic Kidney. Two thirds of all unilaterally fused kidneys involve inferior ectopia. The upper pole of the crossed kidney is attached to the inferior aspect of the normally positioned mate. Both renal pelves are anterior, so fusion probably occurs relatively early.

Sigmoid, or S-Shaped, Kidney. The sigmoid, or S-shaped, kidney is the second most common anomaly of fusion. The crossed kidney is inferior, with the two kidneys fused at their adjacent poles. Fusion of the two kidneys occurs relatively late, after complete rotation on the vertical axis has taken place. Therefore each renal pelvis is oriented correctly, and they face in opposite directions from one another. The lower convex border of one kidney is directly opposite the outer border of its counterpart, creating an S-shaped appearance to the entire renal outline. The ureter from the normal kidney courses downward anterior to the outer border of the inferior kidney, and the ectopic kidney's ureter crosses the midline before entering the bladder.

Cake or Lump Kidney. The cake or lump kidney is a relatively rare form of fusion (Fig. 117–15). Extensive fusion has taken place over a wide margin of maturing renal anlage, resulting in one mass. The total kidney is irregular and lobulated. Usually, ascent progresses only as far as the sacral promontory, but in many instances, the kidney remains within the true pelvis. Both renal pelves are anterior, and they drain separate areas of parenchyma. The ureters do not cross. Only nine cases of pelvic cake kidney drained by a single ureter have been reported (Schwartz, 2010). Recently, a case of cake kidney drained by a single ureter associated with a unicornuate uterus, and another associated with bilateral absence of the vas deferens, have been reported (Rosenkrantz et al, 2010; Schwartz et al, 2010).

L-Shaped Kidney. The L-shaped, or tandem, kidney occurs when the crossed kidney assumes a transverse position at the time of its attachment to the inferior pole of the normal kidney. The crossed kidney lies in the midline or in the contralateral paramedian space anterior to the L4 vertebra. Rotation about the long axis of the kidney produces an inverted or a reversed pelvic position. The ureter from each kidney enters the bladder on its respective side.

Disc Kidney. Disc, shield, doughnut, or pancake kidneys are kidneys that have joined at the medial borders of each pole to produce a doughnut- or ring-shaped mass. More extensive fusion along the entire medial aspect of the kidneys creates a disc or shield shape. The lateral aspect of each kidney retains its normal contour. This type of fusion differs from the lump or cake kidney in that the reniform shape is better preserved owing to a less extensive degree of fusion. The pelves are anteriorly placed, and the ureters remain uncrossed. The collecting system drains each respective half of the kidney and does not communicate with the opposite side.

Superior Ectopic Kidney. The least common variety of renal fusion is the crossed ectopic kidney that lies superior to the normal kidney. The lower pole of the crossed kidney is fused to the upper pole of the normal kidney. The renal units retain a fetal orientation, with both pelves lying anteriorly, suggesting that fusion occurred very early.

Regardless of the type of fusion encountered, the vascular supply to the kidneys is variable and unpredictable. The crossed ectopic kidney is supplied by one or more branches from the aorta or common iliac artery (Rubinstein et al, 1976). The normal kidney frequently has an anomalous blood supply, with multiple

renal arteries originating from various levels along the aorta. In one rare instance, Rubinstein and colleagues (1976) discovered that one renal artery crossed the midline to supply the tandem ectopic kidney. The solitary crossed ectopic kidney generally receives its blood supply from the aorta or iliac artery on the side which it is positioned (Tanenbaum et al, 1970).

Associated Anomalies. **In all the types of fusion anomalies, the ureteral orifice associated with each kidney is usually orthotopic.** Except for solitary crossed ectopia, most patients with crossed ectopia have a normal trigone (Magri, 1961; Tanenbaum et al, 1970; Yates-Bell and Packham, 1972). The incidence of an ectopic ureteral orifice from the crossed renal unit is about 3% (Abeshouse and Bhisitkul, 1959; Magri, 1961; Hendren et al, 1976). Occasionally, the ureter from the uncrossed renal segment of a fusion anomaly has an ectopic orifice (Hendren et al, 1976). Malek and Utz (1970) discovered a case of an ectopic ureterocele associated with the uncrossed kidney. Vesicoureteral reflux is noted in 20% of crossed ectopia and in 71% of bilateral crossed ectopia (Kelalis et al, 1973; Guarino et al, 2004) (see Fig. 117–14). Currarino and Weisbruch (1989) reported 10 cases of midline renal fusion in which a single ureter divided into two pelves that stretched across the midline to drain one respective half of the total parenchymatous mass. In 4 of the 10 cases, a second ureter was present that drained a separate duplex system on either the right or left side. Most of the affected individuals had an imperforate anus or abnormal vertebrae, or both.

Most orthotopic renal units are normal. If an abnormality exists, it usually involves the ectopic kidney and consists of cystic dysplasia, UPJ obstruction (29%), reflux (15%), or carcinoma (Abeshouse and Bhisitkul, 1959; Gerber et al, 1980; Caldamone and Rabinowitz, 1981; Macksood and James, 1983; Nussbaum et al, 1987; Gleason et al, 1994). Only four tumors have been reported, all of which were renal cell carcinomas (Stimac et al, 2004).

The highest incidence of associated anomalies occurs in children with solitary renal ectopia and involves both the skeletal system and genital organs (Miles et al, 1985; Gleason et al, 1994). This may be related more to renal agenesis than to the ectopic anomaly, per se. Fifty percent and 40% of solitary crossed renal ectopia have a skeletal or genital abnormality, respectively (Gu and Alton, 1991). **The most common genital abnormality in the male is cryptorchidism or absence of the vas deferens; in the female, it is vaginal atresia or a unilateral uterine abnormality** (Yates-Bell and Packham, 1972; Kakei et al, 1976). An imperforate anus has also been observed in 20% with solitary crossed ectopia.

In general, the occurrence of an associated anomaly in crossed renal ectopia, excluding solitary crossed ectopia, is low; the most frequent conditions are imperforate anus (4%), orthopedic anomalies (4%), skeletal abnormalities, and septal cardiovascular defects.

Symptoms. **Most individuals with crossed ectopic anomalies have no symptoms.** The defects are often discovered incidentally at autopsy, during routine perinatal ultrasound screening, or after bone scanning. When symptoms occur, they usually develop in the third or fourth decades of life and include vague lower abdominal pain, pyuria, hematuria, and urinary tract infection (UTI) (Gleason et al, 1994). It is believed that the abnormal kidney position and the anomalous blood supply may impede drainage from the collecting system, creating a predisposition to UTI and calculus formation (Collura et al, 2004). Romans and colleagues (1976) observed that when a stone in a crossed ureter causes colic, the pain is lateralized to the anephric side or the side of the embryonic origin of the ureter, while when there is pyelonephritis or obstruction at the UPJ in the crossed kidney, the lumbar pain is on the side of the kidneys. These observations suggest ureteral, not renal, migration as a causative factor in crossed ectopia.

An asymptomatic abdominal mass is the presenting sign in one third of cases (Abeshouse and Bhisitkul, 1959; Nussbaum et al, 1987). Hypertension occasionally leads to the finding of an ectopic fusion anomaly (Abeshouse and Bhisitkul, 1959), and in one case, hypertension was attributable to a vascular lesion in one of the anomalous vessels (Mininberg et al, 1971).

Diagnosis. **In the past, the usual method of detection was by excretory urography, but currently, ultrasonography and radionuclide scintigraphy using ^{99m}Tc-DMSA have revealed more asymptomatic cases** (Volkan et al, 2003).

Multidetector three-dimensional (3D) CT urography is excellent for delineating the renal parenchyma, collecting system, ureters, and vascular supply of the fused kidneys. The main limitation of this modality is the increased risk of significant radiation exposure, which is especially problematic for pediatric patients, pregnant women, and individuals requiring repeat examinations (Türkvatan et al, 2009). Magnetic resonance urography (MRU) and magnetic resonance arteriography (MRA) should be performed in children undergoing extensive surgery on an ectopic kidney. Cystoscopy and retrograde pyelography can be useful in mapping the collecting system and pattern of drainage.

Prognosis. **Most individuals with crossed renal ectopia have normal longevity.** However, those with an obstructive-appearing collecting system are at risk for development of UTI or renal calculi, or both (Kron and Meranze, 1949). Boatman and colleagues (1972a) noted that one third of their symptomatic patients required a pyelolithotomy for an obstructing stone. More recently, extracorporeal shock wave lithotripsy therapy and percutaneous nephrolithotomy have rendered most patients stone free (Semerci et al, 1997; Desai and Jasani, 2000). A rare case of renal cell carcinoma was recently reported in a solitary crossed ectopic kidney (Grotas and Phillips, 2009).

Horseshoe Kidney

The horseshoe kidney is the most common of all renal fusion anomalies. It should not be confused with asymmetrical or off-center fused kidneys, which may give the impression of being horseshoe shaped. The anomaly consists of two distinct renal masses lying vertically on either side of the midline and connected at their respective lower poles by a parenchymatous or fibrous isthmus that crosses the midplane of the body. It was first recognized during an autopsy by Da Carpi in 1522, but Botallo, in 1564, presented the first extensive description and illustration of a horseshoe kidney (Benjamin and Schullian, 1950).

Incidence. **Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 persons** (Dees, 1941; Nation, 1945; Bell, 1946b; Glenn, 1959; Campbell, 1970). A recent review of more than 15,000 radiologic imaging studies revealed an incidence of 1 in 666 individuals (Weizer et al, 2003). Horseshoe kidney is found more commonly in males with a ratio slightly greater than 2:1 (Basar et al, 1999; Weizer et al, 2003). The abnormality has been discovered in all age groups, ranging from fetal life to 80 years. In autopsy series, it is more prevalent in children (Segura et al, 1972). This early age prevalence is related to the high incidence of multiple congenital anomalies associated with the horseshoe kidney, some of which are incompatible with long-term survival (Scott, 2002).

Horseshoe kidneys have been reported in identical twins (Bridge, 1960) and among several siblings (David, 1974). It is doubtful that this anomaly represents a particular genetic predisposition, but it may be the result of a genetic expression with a low degree of penetrance (Leiter, 1972).

Embryology. The abnormality occurs between the fourth and sixth week of gestation, after the UB has entered the renal blastema. In view of the ultimate spatial configuration of the horseshoe kidney, the entrance of the UB had to have taken place before rotation and considerably before renal ascent (Fig. 117–16). Boyden (1931) described a 6-week-old embryo with a horseshoe kidney, the youngest fetus ever discovered with this anomaly. He postulated that at the 14-mm stage (4.5 weeks), the developing metanephric masses lie close to one another; any disturbance in this relationship might result in the masses joining at their inferior poles. A slight alteration in the position of the umbilical or common iliac artery could change the orientation of the migrating kidneys, leading to contact and fusion. It has been postulated that an abnormality in the formation of the tail of the embryo or another pelvic organ accounts for the fusion process (Cook and Stephens, 1977). Domenech-Mateu and Gonzales-Compta (1988), after studying a 16-mm human embryo, suggested that posterior nephrogenic cells migrate abnormally to form an isthmus, or connection, between the two developing kidneys to create the horseshoe shape.

Recently, Tripathi and colleagues (2010) investigated the role of axial structures, including the notochord and floor plate of the neural tube in metanephric kidney development. The notochord, which is replaced by the vertebral column in higher vertebrates, is essential for the formation of the floor plate. In addition, the sonic hedgehog *(Shh)* gene exists in these structures and is thought to affect renal development. Using a murine model, these investigators disrupted the notochord and neural plate, which resulted in kidney fusions. Then they only inactivated *Shh* in the notochord and floor plate, which also resulted in kidney fusion. **These findings suggest that the notochord is *not* necessary for nephrogenesis but *is required* for correct positioning of the metanephric kidney, while the axial SHH signal is critical for kidney positioning along the mediolateral axis. These studies provide insights into the molecular basis for horseshoe kidney formation and provide an explanation for the increased incidence of horseshoe kidneys in children with vertebral and neural tube defects (see Associated Anomalies).**

Description. There are several variations in the basic shape of the horseshoe kidney. **In 95% of cases, the kidneys join at the lower pole, which occurs before the kidneys have rotated on their long axes.** The pelves and ureters of the horseshoe kidney are usually anteriorly placed, crossing ventrally to the isthmus (see Fig. 117–16). Very rarely, the pelves are anteromedial, suggesting that fusion occurred after some rotation occurred. **In a small subset, an isthmus connects both upper poles** (Love and Wasserman, 1975). In addition, migration is usually incomplete, with the kidneys lying lower in the abdomen than normal. It is presumed that the inferior mesenteric artery prevents full ascent by obstructing the movement of the isthmus.

Generally, the isthmus is bulky and consists of parenchymatous tissue with its own blood supply (Glenn, 1959; Love and Wasserman, 1975). Occasionally, it is just a flimsy midline structure composed of fibrous tissue that tends to draw the renal masses close together. The isthmus is located adjacent to the L3 or L4 vertebra just below the origin of the inferior mesenteric artery from the aorta, resulting in the paired kidneys lying lower than normal in the retroperitoneum. The isthmus most often lies anterior to the aorta and vena cava, but it has been reported to pass between the inferior vena cava and the aorta or

even behind both great vessels (Jarmin, 1938; Meek and Wadsworth, 1940; Dajani, 1966). In some instances, the anomalous kidneys are very low, anterior to the sacral promontory or even in the true pelvis behind the bladder (Campbell, 1970). A similar finding of fused pelvic kidneys is observed in the *Foxd1* mouse mutant. These pelvic kidneys also show defects in UB branching and nephron formation (Levinson et al, 2005).

The calyces are normal in number and are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane (on a line drawn from lower to upper poles). The lowermost calyces extend caudally or even medially to drain the isthmus and may overlie the vertebral column (Strauss et al, 2000).

The ureter may insert high on the renal pelvis and lie laterally, probably as the result of incomplete renal rotation. It courses downward and has a characteristic bend as it crosses over and anterior to the isthmus, a deviation that is proportionate to the thickness of the midline structure (Strauss et al, 2000). Despite upper ureteral angulation, the lower ureter usually enters the bladder normally and rarely is ectopic.

The blood supply to the horseshoe kidney can be quite variable. In 30% of cases, it consists of one renal artery to each kidney (Glenn, 1959) (see Fig. 117–16). Duplicate, or even triplicate, renal arteries may supply one or both kidneys. The blood supply to the isthmus and lower poles is also variable. The isthmus and adjacent parenchymal masses may receive a branch from each main renal artery, or they may have their own arterial supply from the aorta originating either above or below the level of the isthmus. Not infrequently, this area is supplied by branches from the inferior mesenteric, common or external iliac or sacral arteries (Boatman et al, 1971; Kolln et al, 1972). Three cases of retrocaval

ureter and isthmus have been reported (Eidelman et al, 1978; Hefferman et al, 1978). A horseshoe kidney drained by a single circumcaval ureter has also been reported (Knutson and Hawas, 2004).

Associated Anomalies. **The horseshoe kidney is frequently associated with other congenital anomalies.** Boatman and colleagues (1972b) reported that almost one third of the 96 cases studied had at least one other abnormality. Many newborns and young infants with multiple congenital anomalies have a horseshoe kidney. The autopsy incidence of other anomalies is greater in children who die at birth or in early infancy than in those who reach adulthood (Zondek and Zondek, 1964; Scott, 2002). This implies that a horseshoe kidney occurs more often in association with other serious congenital anomalies. The organ systems most commonly affected include the skeletal, cardiovascular (primarily ventriculoseptal defects [Voisin et al, 1988]), and central nervous system. Horseshoe kidney is found in 3% of children with neural tube defects (Whitaker and Hunt, 1987). Anorectal malformations are frequently encountered in these patients. Horseshoe kidney is seen in approximately 20% of patients with trisomy 18, in 60% of females with Turner syndrome (Smith, 1970; Lippe et al, 1988), and with Townes-Brock syndrome in those who have a *SALL1* transcription factor defect (Salerno et al, 2000).

Key Points: Horseshoe Kidney

- Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 persons.
- The isthmus is bulky and consists of parenchymatous tissue.
- The calyces, normal in number, are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane.
- The blood supply can be quite variable.
- Horseshoe kidney is frequently found in association with other congenital anomalies.
- UPJ obstruction, causing significant hydronephrosis, occurs in as many as one third of individuals with horseshoe kidneys.
- Sixty percent of patients with horseshoe kidneys remained asymptomatic for an average of 10 years after discovery.

Boatman and his colleagues (1972b) **also discovered an increased occurrence of other genitourinary anomalies associated with a horseshoe kidney.** Hypospadias and undescended testes occurred in 4% of males, and a bicornuate uterus or septate vagina or both were noted in 7% of the females.

Duplication of the ureter occurs in 10% of cases (Zondek and Zondek, 1964; Boatman et al, 1972b); in some cases this has been associated with an ectopic ureterocele (see Fig. 117–16). Vesicoureteral reflux has been noted in more than half of affected individuals (Segura et al, 1972; Pitts and Muecke, 1975; Cascio et al, 2002). UPJ dilation has been seen in over 20%, but on diuretic radionuclide scintigraphy, less than 20% have an obstructive pattern (Cascio et al, 2002; Kao et al, 2003). Cystic disease, including multicystic dysplasia in one half (the upper pole) of one side (Novak et al, 1977; Boullier et al, 1992) and the lower pole of one side (Shapiro, personal communication), and adult polycystic kidney disease, have been reported with horseshoe kidney (Gutierrez, 1934; Campbell, 1970; Pitts and Muecke, 1975; Correa and Paton, 1976). DMSA scanning in 22 patients revealed asymmetrical function in 63% (Kao et al, 2003). **Stone formation has been commonly seen in horseshoe kidney.** Metabolic stone evaluation in 11 of 37 of these stone formers revealed at least one abnormality in all cases, with an average of 2.68 abnormalities per 24-hour urine collection. Hypovolemia, hypercalciuria, and hypocitraturia were the most common metabolic defects (Raj et al, 2004). Because stone formation in the horseshoe kidney is likely due to an anatomic and metabolic etiology, metabolic evaluation should be performed to reduce the risk of recurrent calculus formation.

Symptoms. With increased ultrasound screening for renal anomalies, it is likely that at least 50% with horseshoe kidneys are asymptomatic rather than the 33% incidence previously reported (Glenn, 1959; Kolln et al, 1972). In most instances, the anomaly is an incidental finding at autopsy (Pitts and Muecke, 1975). Symptoms are typically related to hydronephrosis, infection, or calculus formation. The most common symptom is vague abdominal pain that may radiate to the lower lumbar region. Gastrointestinal complaints may also be present. The Rovsing sign is used to elicit right lower quadrant pain of appendicitis when pushing on the left lower quadrant by stretching the peritoneum. It is also used to describe patients with horseshoe kidney who have abdominal pain, nausea, and vomiting on hyperextension of the spine. UTIs occur in 30% of patients, and calculi have been noted in 20% to 80% (Glenn, 1959; Kolln et al, 1972; Pitts and Muecke, 1975; Evans and Resnick, 1981; Sharma and Bapna, 1986; Benchekroun et al, 1998). Five to 10 percent of horseshoe kidneys are confirmed after palpation of an abdominal mass (Glenn, 1959; Kolln et al, 1972).

Previously, up to one third of individuals with horseshoe kidney had hydronephrosis secondary to UPJ obstruction (Whitehouse, 1975; Das and Amar, 1984) (see Fig. 117–16). The high insertion of the ureter into the renal pelvis, its abnormal course anterior to the isthmus, and the anomalous blood supply to the kidney may individually or collectively contribute to this obstruction. **In the modern era, horseshoe kidneys are frequently discovered incidentally, and their apparent hydronephrosis often shows a nonobstructed pattern on radionuclide scanning.** Horseshoe kidneys have been detected after angiography for evaluation of an abdominal aortic aneurysm (Huber et al, 1990; deBrito et al, 1991).

Horseshoe kidneys are also incidentally observed on ^{99m}Tc bone scan as a result of renal uptake and excretion of the isotope (O'Brien et al, 2008).

Diagnosis and Radiographic Appearance. The horseshoe kidney does not by itself produce symptoms (Grandone et al, 1985). The clinical features from a diseased horseshoe kidney are often vague and nonspecific. In the absence of a palpable mass, the anomaly is not suspected until an imaging study is obtained. Prenatal ultrasonography is detecting most horseshoe kidneys (Sherer and Woods, 1992; Van Every, 1992). **The classic radiologic features on a plain film of the abdomen include kidneys that are somewhat low lying and close to the vertebral column and have a vertical or outward axis with the lower poles being more medial than in the normal kidney** (O'Brien et al, 2008). The kidneys may be observed by the delineation of the perinephric fat. Ultrasonography detects the isthmus joining the two lower poles of the kidneys in the midline. This may not always be observed, because the isthmus may be only a thin fibrous band. Ultrasound diagnosis is easily made by scanning horizontally along the midline in a craniocaudal direction, especially in children and thin patients. Radionuclide

scanning demonstrates the abnormal axis of a horseshoe kidney. A continuous band across the midline is observed if the isthmus contains functioning parenchyma. CT and MRU can also be used to evaluate the horseshoe kidney. Both studies characterize the isthmus. MR angiography will accurately delineate the vascular anatomy for preoperative planning (O'Brien et al, 2008).

Prognosis. Although Smith and Orkin (1945) believed that horseshoe kidneys are almost always associated with disease, **Glenn** (1959) **observed patients with horseshoe kidneys for an average of 10 years after discovery and found that almost 60% of these remained asymptomatic.** Only 13% had persistent urinary infection or pain, and 17% developed recurrent calculi. When stone disease is present, extracorporeal shock wave lithotripsy and percutaneous nephrolithotomy yields stone-free rates of 68% and 87.5%, respectively (Kupeli et al, 1999; Raj et al, 2003). In Glenn's series, no patients benefited from division of the isthmus for relief of pain; as a result, this idea has now been largely repudiated (Glenn, 1959; Pitts and Muecke, 1975).

Many disease processes have been described with a horseshoe kidney, but this likely reflects the relative frequency of the congenital defect. **Kidney cancers have been reported in about 150 individuals with horseshoe kidney** (Buntley, 1976; Hohenfellner et al, 1992; Schubert et al, 1998, Stimac et al, 2004). **Renal cell carcinoma accounts for about half of these cases, although the incidence is no greater than that in the general population.** Two cases of bilateral tumors have been reported (Romics et al, 2002). Renal pelvic tumors and Wilms tumor each accounted for about 25% of the total, with sarcoma and carcinoids occurring much less frequently. Overall, 41 of 8617 (0.48%) Wilms tumors in the National Wilms Tumor study occurred in horseshoe kidneys, mostly on the left side, rarely in the isthmus, and practically all with favorable histology (Neville et al, 2002). **This incidence of Wilms tumor in horseshoe kidneys is 1.76 to 7.93 times higher than that expected in the general population** (Mesrobian et al, 1985). Thirty-seven percent of these Wilms tumors were initially inoperable. However, with preoperative chemotherapy, most patients were salvaged, yielding a 75% preservation rate of renal parenchyma (Neville et al, 2002). Wilms tumor may originate in the isthmus (Beck and Hlivko, 1960), creating a very bizarre radiologic picture (Walker, 1977). Except for renal pelvic tumors, a surprisingly high number of renal cancers arise in the isthmus (Blackard and Mellinger, 1968). For this reason, it has been suggested that teratogenic factors are responsible for abnormal migration of nephrogenic cells to form an isthmus, which then leads to the horseshoe shape and the predisposition for the development of cancer in this portion of the kidney (Domenech-Mateu and Gonzales-Compta, 1988; Hohenfellner et al, 1992).

It has been suggested that the increased occurrence of chronic infection, obstruction, and stone formation explains the higher-than-expected incidence of renal pelvic tumors because the incidence exceeds that of the general population (Shoup et al, 1962; Castor and Green, 1975; Dische and Johnston, 1979). Survival from these tumors is related to the pathology and stage of the tumor at diagnosis and not to the renal anomaly (Murphy and Zincke, 1982). Surveillance for tumors in symptomatic horseshoe kidneys may be prudent.

Because a horseshoe kidney is located above the pelvic inlet, it should not adversely affect pregnancy or delivery (Bell, 1946b). Glomerulocystic disease has been reported in children younger than 1 year of age but does not appear to be related specifically to the horseshoe anomaly (Craver et al, 1993). The development of renal failure associated with adult polycystic kidney disease is not any greater in the presence of a horseshoe kidney (Correa and Paton, 1976). According to the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS, McDonald et al, 2000) and the Department of Health and Human Services 2000 Annual Report (U.S. Department of Health and Human Services, U.S. Scientific Registry of Transplant Recipients and the Organ Procurement and Transplantation Network, 2000) no individual with a horseshoe kidney received a renal transplant. A worldwide review from the Netherlands noted that 23 whole and 57 split horseshoe kidneys have been transplanted with initial failure rates of only 4.3% and 13.4% for en bloc and for split transplants, respectively. An overall 80% graft survival rate has been reported at 5 years (Stroosma et al, 2001).

ANOMALIES OF ROTATION

The kidney, as it assumes its final position in the "renal" fossa, orients itself so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as *malrotation* and is often described in conjunction with other renal anomalies, such as ectopia with or without fusion or horseshoe kidney. This discussion centers on malrotation as an isolated renal entity.

Incidence. The true incidence of this developmental anomaly cannot be accurately calculated, because minor degrees of malrotation are not reported. Campbell (1963) found renal malrotation in 1 of 939 autopsies, and Smith and Orkin (1945) noted 1 case per 390 hospital admissions. **It is frequently observed in association with Turner syndrome** (Gray and Skandalakis, 1972b). Males are affected twice as often as females, but there does not appear to be any predilection for one side or the other.

Embryology. It is thought that medial rotation of the collecting system occurs simultaneously with renal migration. The kidney starts to turn during the sixth week, just when it is leaving the true pelvis, and it completes this process by rotating 90 degrees toward the midline by the time ascent is complete at the end of the ninth week of gestation.

In 1912, Felix postulated that rotation is actually the result of unequal branching of successive orders of the budding ureteral tree, with two branches extending ventrally and one dorsally during each generation or division. Each ureteral branch then induces differentiation of the metanephrogenic tissue, surrounding it to encase it as a cap. More parenchyma develops ventrally than dorsally, and the pelvis seems to rotate medially. Weyrauch (1939) accepted this theory of renal rotation as the result of excessive ventral versus dorsal branching of the ureteral tree and concluded that the fault of malrotation lies entirely with the ureter. A late-appearing UB may insert into an atypical portion of the renal blastema, leading to a lessened propensity for the developing nephric tissue to shift. Late appearance of the UB is almost always associated with an aberrant origin from the WD; this translates

Key Points: Anomalies of Rotation

- The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as malrotation.
- It is frequently associated with Turner syndrome.

into ureteral ectopia at the level of the lower urinary tract. Mackie and colleagues (1975), however, did not describe any malrotation anomalies in their study of renal ectopia. The renal blood supply does not appear to be the cause or a limiting factor in malrotation but rather follows the course of renal hyporotation, hyper-rotation, or reverse rotation.

Description. **The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent.** Weyrauch (1939), in a detailed study, categorized the various abnormal phases of medial and reverse rotation according to the position of the renal pelvis (Fig. 117–17).

Ventral Position. The pelvis is ventral and in the same anteroposterior plane as the calyces, which point dorsally because they have undergone no rotation at all. This is the most common form of malrotation. Very rarely, this position may represent excessive medial rotation in which a complete 360-degree turn has occurred. In a case reported by Weyrauch (1939), the vasculature had rotated with the kidney and passed around dorsally and laterally to it before entering the anteriorly placed hilus.

Ventromedial Position. The pelvis faces ventromedially because of an incompletely rotated kidney. Excursion probably stops during the seventh week of gestation when the kidney and pelvis normally reach this position. The calyces thus point dorsolaterally.

Dorsal Position. Renal excursion of 180 degrees occurs to produce this rarest position. The pelvis is dorsal to the parenchyma, and the vessels pass behind the kidney to reach the hilum.

Lateral Position. When the kidney and pelvis rotate between 180 degrees to 360 degrees, or when reverse rotation of up to 180 degrees takes place, the pelvis faces laterally and the kidney parenchyma resides medially. The renal vascular supply provides the only clue to the actual direction of excursion. Vessels that course ventral to the kidney to enter a laterally or dorsolaterally placed hilum suggest reverse rotation, whereas a path dorsal to the kidney implies excessive ventral rotation. Both types of anomalous turning were cited in Weyrauch's series (1939).

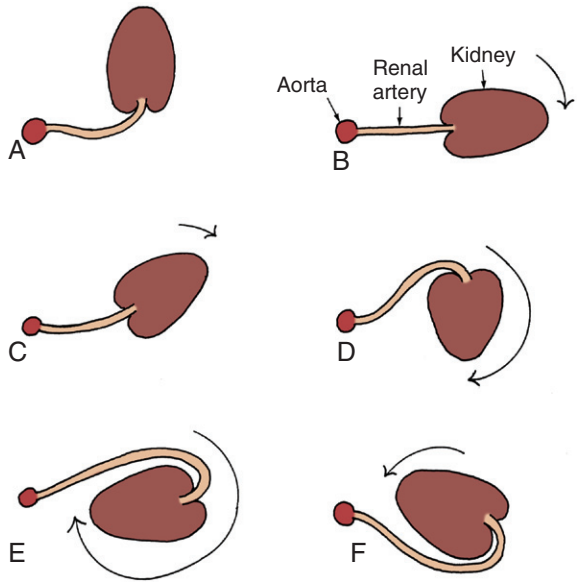

Figure 117–17. Rotation of the kidney during its ascent from the pelvis. The left kidney with its renal artery and the aorta are viewed in transverse section to show normal and abnormal rotation during its ascent to the adult site. **A,** Primitive embryonic position; hilus faces ventrad (anterior). **B,** Normal adult position; hilus faces mediad. **C,** Incomplete rotation. **D,** Hyper-rotation; hilus faces dorsad (posterior). **E,** Hyper-rotation; hilus faces laterad. **F,** Reverse rotation; hilus faces laterad. (From Gray SW, Skandalakis JE. Embryology for surgeons. Philadelphia: WB Saunders; 1972.)

In cases of isolated malrotation, other characteristic features may be present. The kidney shape may be discoid, elongated, oval, or triangular, with flattened anterior and posterior surfaces. Fetal lobulations are invariably present and accentuated beyond normal limits. A dense amount of fibrous tissue encases the hilar area, possibly even distorting and fixing the pelvis. The UPJ may be distorted as well. The upper ureter initially courses laterally, and it, too, may be encased in this fibrous matting. The pelvis is elongated and narrow, and calyces, especially the superior calyx, may be stretched. The blood supply may vary widely, depending on the direction and degree of rotation. The vasculature may consist of a single vessel with or without multiple additional branches entering the parenchyma along the course of the renal artery. Also, there may be a polar vessel in conjunction with the main renal artery. The vascular orientation around the kidney provides the only clue to the type and extent of renal rotation.

Symptoms. Rotation anomalies, per se, do not produce any specific symptoms. The excessive amount of fibrous tissue encasing the pelvis, UPJ, and upper ureter, however, may lead to varying degrees of upper tract obstruction. Vascular compression from an accessory or main renal artery or distortion of the upper ureter or UPJ may contribute to impaired drainage. Symptoms of obstruction may occur during periods of increased urine production. Hematuria associated with hydronephrosis, infection, and calculus formation may also occur secondary to poor urinary drainage.

Diagnosis. The diagnosis should be considered when a renal calculus is detected in an abnormal location, but confirmation should be obtained from a renal ultrasonogram, CT, MRU, or retrograde pyelogram. These studies reveal the abnormal orientation of the renal pelvis and calyces, a flattened and elongated pelvis, a stretched superior calyx with blunting of the remaining calyces, and a laterally displaced upper third of the ureter. Bilateral malrotation is not uncommon and may lead to the diagnosis of a horseshoe kidney. However, careful inspection for an isthmus and observation of the lower pole renal outline should distinguish the two entities.

Prognosis. No abnormality of function of the kidney has been detected secondary to malrotation. Hydronephrosis resulting from impaired urinary drainage may lead to infection and calculus formation.

ANOMALIES OF RENAL VASCULATURE

Aberrant, Accessory, or Multiple Vessels

Knowledge of the anatomy of the renal blood supply is essential for good outcomes following renal surgery. The advent of aortography in the 1940s and 1950s spearheaded a systematic understanding of vascular anomalies (Graves, 1954, 1956; Anson and Kurth, 1955; Merklin and Michele, 1958; Anson and Daseler, 1961; Geyer and Poutasse, 1962).

The kidney is divided into various segments, each supplied by a single "end" arterial branch that usually courses from one main renal artery. *Multiple renal arteries* is the correct term to describe any kidney supplied by more than one vessel. The term *anomalous vessels* or

***aberrant vessels* should be reserved for those arteries that originate from vessels other than the aorta or main renal artery. The term *accessory vessels* denotes two or more arterial branches supplying the same renal segment.**

Incidence. **Between 71%** (Merklin and Michele, 1958) **and 85%** (Geyer and Poutasse, 1962) **of kidneys have one artery that supplies the entire renal parenchyma.** A slightly higher percentage of right-sided kidneys have a single renal artery compared with left-sided organs (Geyer and Poutasse, 1962). True aberrant vessels are rare, except in cases with renal ectopia, with or without fusion, and in individuals with a horseshoe kidney (Degani et al, 2010).

Embryology. **The renal arterial tree is derived from three groups of primitive vasculature that coalesce to form the mature vascular pattern for all retroperitoneal structures.** The cranial group consists of two pairs of arteries dorsal to the suprarenal gland that shift dorsally to form the phrenic artery. The middle group is made up of three pairs of vessels that pass through the suprarenal area and retain the same lateral position, becoming the adrenal artery. Finally, the caudal group of four paired arteries cross ventral to the suprarenal area and become the main renal artery. Sometimes they are joined by the most inferior pair from the middle group (Guggemos, 1962). It is believed that during renal migration this network of vessels selectively degenerates, and the remaining adjacent arteries assume a progressively more important function. By a process of elimination, one primitive renal arterial pair eventually becomes the dominant vessel, the completed process being dependent on the final position of the kidney (Graves, 1956). Polar arteries or multiple renal arteries to the normally positioned kidney represent a failure of complete degeneration of all primitive vascular channels. The multiple vessel pattern that has been described for renal ectopia should be considered as an arrested embryonic state for that particular renal position (Gray and Skandalakis, 1972a).

Description. **On the basis of vascular supply, the renal parenchyma is divided into five segments: apical, upper, middle, lower, and posterior.** The main renal artery divides initially into an anterior and posterior branch. The anterior branch almost always supplies the upper, middle, and lower segments of the kidney. The posterior branch invariably supplies the posterior and lower segments (Sampaio and Aragao, 1990a). The vessel to the apical segment has the greatest variation in origin; it arises from (1) the anterior division (43%), (2) the junction of the anterior and posterior divisions (23%), (3) the main stem renal artery or aorta (23%), or (4) the posterior division of the main renal artery (10%) (Graves, 1954). Rarely, the upper segment is supplied from a branch totally separate from the main renal artery (Merklin and Michele, 1958). The artrial and venous tree of the kidney and its relationship to the collecting system was beautifully depicted in endocasts by Sampaio and Aragao (1990a, 1990b). These investigations showed that the least likely areas to encounter vessels when entering the collecting system, either endourologically or with open surgery, is directly end-on through a fornix or inferiorly on the posterior aspect of the pelvis. Shoja and colleauges (2008) studied the perihilar (extraparenchymal) branching patterns and morphologies of the renal artery. A "fork" pattern with a common branching point (usually duplicated) was the most commonly observed extrarenal division and branching pattern of the main renal artery. They conclude that perihilar branching of the main renal artery was highly variable, with predictable patterns in the majority of kidneys. This information is very useful for the transplant surgeon when interpreting radiodiagnostics of the renal hilum.

The lower renal segment, however, is often supplied by an accessory vessel (Fig. 117–18). This vessel is usually the most proximal branch when it arises from the main renal artery or its anterior division (Graves, 1954). However, it may originate directly from the aorta near the main renal artery, or it may be aberrant, arising from the gonadal vessel. Merklin and Michele (1958) performed an extensive study of the variant renal and suprarenal blood supply. The venous drainage of the kidney has been studied by Sampaio and Aragao (1990b), who noted a close association between the inferior branch to the main renal vein and the anterior inferior aspect of the renal pelvis in 40% of kidneys. Although an endourologic incision for UPJ obstruction is

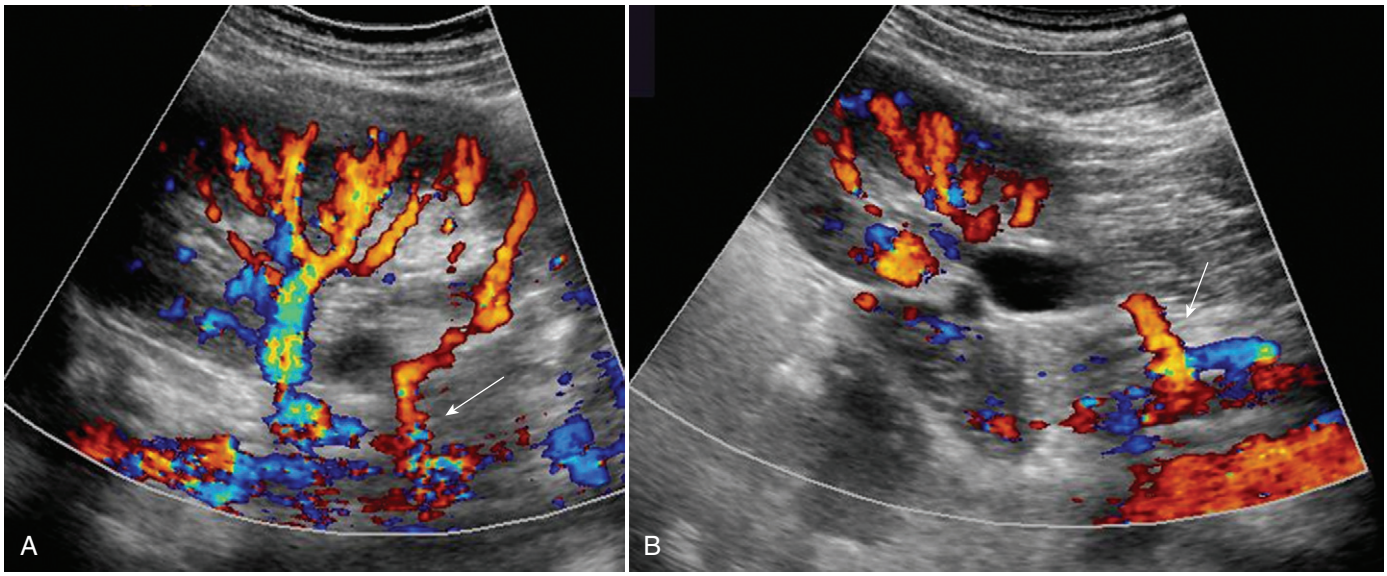

Figure 117–18. Nine-year-old girl with intermittent left flank pain, nausea, and vomiting. **A,** Color Doppler ultrasound study shows normal left renal artery and lower pole accessory vessel. **B,** Oblique sagittal view showing left lower pole accessory vessel supplying the lower pole of the kidney, causing intermittent left ureteropelvic junction obstruction.

now infrequently used, it should be performed laterally and posteriorly instead of anteriorly to avoid injury to this vessel.

Symptoms. Symptoms attributable to renal vascular anomalies are those that might result from inadequate urinary drainage. Multiple, aberrant, or accessory vessels may constrict an infundibulum, a major calyx, or the UPJ (Yen et al, 2004). Pain and hematuria secondary to hydronephrosis, UTI, or calculus may result.

Diagnosis. Historically, excretory urography would reveal multiple renal vessels or an aberrant artery (1) when a filling defect in the renal pelvis is consistent with an anomalous vascular pattern; (2) when hydronephrosis is noted along with a sharp cutoff in the superior infundibulum (Fraley, 1966, 1969); (3) when UPJ obstruction is seen in association with an angulated ureter near the renal pelvis and a kidney whose pole-to-pole axis is more vertical than normal; or (4) when differences are noted in the timing and concentration of one renal segment or in the entire kidney when compared with the opposite side (especially when hypertension is present). Renal angiography has been the gold standard for defining the vascular tree of the kidney, but less invasive imaging studies, including 3D power Doppler ultrasonography, CT, and MRI, provide precise anatomic resolution of vascular variants and associated disease states (Textor and Canzanello, 1996; Salcarga et al, 1999; Park et al, 2003; Degani et al, 2010).

Prognosis. None of these variations in the vascular tree, with the exception of a lower pole crossing vessel, increases the kidney's susceptibility to disease. Hydronephrosis secondary to a vascular anomaly is a very rare finding, especially when one considers the relative frequency of all renal vascular variations. Hypertension is no more frequent in patients with multiple renal arteries than in those with a single vessel (Geyer and Poutasse, 1962).

Renal Artery Aneurysm

Aneurysmal dilation was the first disease process of the renal artery to be recognized (Poutasse, 1957); it was considered a rare occurrence until selective renal angiography became widely available. **Since then, the overall incidence has been calculated to be between 0.1% and 0.3%.** Abeshouse (1951) classified renal artery aneurysms as follows: saccular, fusiform, dissecting, and arteriovenous. The saccular aneurysm, a localized outpouching that communicates with the arterial lumen by a narrow or wide opening, is the most common type, accounting for 93% of all aneurysms (McKeil et al, 1966; Stanley et al, 1975; Hageman et al, 1978; Zinman and Libertino, 1982). Renal artery aneurysms have been associated with autosomal-dominant polycystic kidney disease (Schievink, 1998). When the aneurysm is located at the bifurcation of the main renal artery and its anterior and posterior divisions or at one of the more distal branchings, it is considered to be congenital in origin and is called the fusiform type (Poutasse, 1957). The presence of similar aneurysms at branching points in the vasculature of other organ systems attests to this possible origin (Lorentz et al, 1984). Acquired aneurysms may be located anywhere and may result from inflammatory, traumatic, or degenerative factors. A localized defect in the internal elastic tissue and the media allows the vessel to dilate at that point. It is a true aneurysm, because its walls are composed of most of the layers that make up the normal artery (Poutasse, 1957). The outpouchings may vary in size from 1 to 2 cm up to 10 cm (Garritano, 1957), but 90% are smaller than 2 cm. There is no absolute predilection for side, but the right appears to be favored, and bilateral aneurysms are seen in 15% (Pfeiffer et al, 2003).

Almost half of renal artery aneurysms are silent, especially in children (Sarker et al, 1991). Some produce symptoms at a later age, because the size of the aneurysm increases with time. Pain (15%), hematuria (microscopic and macroscopic) (30%), and hypertension (55%) secondary to compression of adjacent parenchyma or to altered blood flow within the vascular tree can occur (Glass and Uson, 1967; Bulbul and Farrow, 1992). The hypertension is renin-mediated and secondary to relative parenchymal ischemia (Lorentz et al, 1984). Thirteen cases of hydronephrosis secondary to an adjacent renal vessel aneurysm was noted (Miyagawa et al, 2001).

The diagnosis is suspected when a pulsatile mass is palpated in the region of the renal hilum or when a bruit is heard on abdominal auscultation. A wreathlike calcification in the area of the renal artery or its branches (30%) is highly suggestive (Silvis et al, 1956), but this finding is often missed on a plain abdominal radiograph (Bulbul and Farrow, 1992). Color Doppler imaging (Bunchman et al, 1991) will demonstrate decreased flow. Selective renal angiography (Cerny et al, 1968), digital subtraction angiography, color Doppler ultrasonography (Okamato et al, 1992), or MR angiography (Takebayashi et al, 1994) confirms the diagnosis.

Many asymptomatic renal artery aneurysms come to light during a workup of hypertension. Fifty percent are diagnosed when a renal arteriogram is performed for other reasons (Zinman and Libertino, 1982). CT also readily detects the lesion (Miyagawa et al, 2001; Nishimura et al, 2002). Generally, excision is recommended if (1) the hypertension cannot be easily controlled; (2) incomplete ringlike calcification is present; (3) the aneurysm is larger than 2.5 cm (Poutasse, 1975; Pfeiffer et al, 2003); (4) the patient is female and of child-bearing age, because rupture during pregnancy is a likely possibility (Cohen and Shamash, 1987); (5) the aneurysm increases in size on serial angiograms; or (6) an arteriovenous fistula is present. More than 30 cases of a ruptured aneurysm during pregnancy have been reported (Lacroix et al, 2001), so any aneurysm larger than 1.0 cm in younger women should be repaired (Henke and Stanley, 2003). The likelihood of spontaneous rupture (about 10%), with its dire consequences, dictates attentive treatment in the foregoing situations. Recent advances in endovascular techniques dictate early prophylactic treatment (Yamamoto et al, 1998).

Key Points: Renal Artery Aneurysm

- The overall incidence has been calculated to be between 0.1% and 0.3%.
- Most renal artery aneurysms are silent, especially in children. Many asymptomatic renal artery aneurysms are diagnosed during an evaluation of hypertension.
- The diagnosis may be suspected with a pulsatile mass in the region of the renal hilum or when an abdominal bruit is heard. A wreathlike calcification in the area of the renal artery or its branches (30%) is highly suggestive.

Renal Arteriovenous Fistula

Although rare, renal arteriovenous fistulas (AVFs) have been diagnosed with increasing frequency since they were first described by

Varela in 1928. **Two types exist, congenital and acquired** (Maldonado et al, 1964), **with the latter (secondary to trauma, inflammation, renal surgery, or percutaneous needle biopsy) accounting for the recent increased incidence.** Only the congenital variant is discussed here.

Fewer than 25% of all AVFs are congenital, with only 91 reported cases (Takaha et al, 1980). **They are identifiable by their cirsoid configuration and multiple communications between the main or segmental renal arteries and venous channels** (Crummy et al, 1965; Cho and Stanley, 1978). Although congenital, they rarely present clinically before the third or fourth decade. Women are affected three times as often as men, and the right kidney is involved slightly more often than the left (Cho and Stanley, 1978; Ishikawa et al, 2004). The lesion is usually located in the upper pole (45% of cases), but not infrequently, it may be found in the midportion (30%) or in the lower pole (25%) of the kidney (Yazaki et al, 1976).

The condition is thought to be either present at birth or results from a congenital aneurysm eroding into an adjacent vein (Thomason et al, 1972). The pathophysiology involved in the shunting of blood, which bypasses the renal parenchyma and rapidly joins the venous circulation and returns to the heart, results in a varied clinical picture. The symptoms are based on the age and size of the AVF (Messing et al, 1976).

The hemodynamic derangement often produces a loud bruit in 75% of cases. Diminished perfusion of renal parenchyma distal to the fistulous site leads to relative ischemia and renin-mediated hypertension in approximately 50% (McAlhany et al, 1971). The increased venous return and high cardiac output with concomitant diminution in peripheral resistance may result in left ventricular hypertrophy and subsequent high-output cardiac failure in 50% of cases (Maldonado et al, 1964). Macroscopic and microscopic hematuria occurs in more than 75% of affected individuals due to the proximity of the collecting system (Messing et al, 1976; Cho and Stanley, 1978; Montoya et al, 2004). Although flank or abdominal pain may be present, a mass is rarely palpable (10%).

In the past, excretory urography revealed diminished or absent function either in one segment or in the entire portion of the involved kidney (DeSai and DeSautels, 1973), an irregular filling defect in the renal pelvis or calyces (secondary to either clot or encroachment by the fistula), or calyceal distortion or obstruction distal to the site of the lesion (Gunterberg, 1968). Despite these specific radiographic features, an abnormality had been noted in only 50% of excretory urograms in the past. **Three-dimensional Doppler ultrasonography and MR angiography are accurate and noninvasive tests** (Mohaupt et al, 1999; Ishikawa et al, 2004), **but selective renal arteriography or digital subtraction angiography is the most definitive method for diagnosing the lesion.** A cirsoid appearance with multiple small, tortuous channels; prompt venous filling; and an enlarged renal, and possibly gonadal, vein are pathognomonic for arteriovenous malformation (AFM) (DeSai and DeSautels, 1973).

The symptomatic nature of this lesion, which causes progressive alterations in the cardiovascular system, often dictates surgical intervention. The congenital variant rarely behaves like its acquired counterpart, which may disappear spontaneously after several months. Nephrectomy, partial nephrectomy, vascular ligation (Boijsen and Kohler, 1962), selective embolization (Bookstein and Goldstein, 1973), and balloon catheter occlusion (Bentson and Crandalls, 1972) have been used to obliterate the fistula.

ANOMALIES OF THE COLLECTING SYSTEM

Calyceal Diverticulum

A calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or less commonly with the renal pelvis through a narrow isthmus (Estrada et al, 2009). This abnormality, first described by Rayer in 1841, may be multiple, with the upper calyx most frequently affected.

In the past, an incidence of 4.5 per 1000 excretory urograms had been reported (Timmons et al, 1975). A similar incidence was noted in both children and adults, with no predilection for either side or sex. Most diverticula, labeled type I, occur adjacent to an upper or, occasionally, a lower pole calyx. Type II diverticula are larger, communicate with the renal pelvis, and tend to be symptomatic (Wulfsohn, 1980).

Congenital and acquired factors have been suggested to explain the formation of calyceal diverticula. The similar incidence in children and adults is consistent with an embryologic etiology (Abeshouse, 1950; Mathieson, 1953; Devine et al, 1969; Middleton and Pfister, 1974). At the 5-mm stage of the embryo, ureteral branches of the third and fourth generation, which ordinarily degenerate, may persist as isolated branches, resulting in the formation of a calyceal diverticulum (Lister and Singh, 1973).

A localized cortical abscess draining into a calyx has also been postulated as an etiologic factor. Other proposed causes include obstruction from stones or infection within a calyx, progressive fibrosis of an infundibular stenosis, renal injury, achalasia, and spasm or dysfunction of one of the supposed sphincters surrounding a minor calyx (Amar, 1975; Patriquin et al, 1985; Siegel and McAlister, 1979). Vesicoureteral reflux has also been thought be an etiologic factor. Amar (1975) postulated that calyceal tubular backflow of infected urine could result in abscess formation and parenchymal injury leading to diverticular formation. **Small diverticula are usually asymptomatic and are found incidentally by ultrasonography, CT, or MRI.** These diverticula tend to progressively distend with trapped urine (Amar, 1975; Patriquin et al, 1985; Siegel and McAlister, 1979). Infection, milk of calcium (i.e., crystallization of calcium salts without actual stone formation) (Patriquin et al, 1985), or true stone formation are complications of stasis or obstruction that can produce symptoms (Lister and Singh, 1973; Siegel and McAlister, 1979) (Fig.

Key Points: Calyceal Diverticulum

- A calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or, less commonly, with the renal pelvis through a narrow isthmus.
- The incidence based on excretory urography is about 4.5 per 1000.
- The diagnosis is best made by CT or MR urography.
- Laparocopy by a retroperitoneal approach for marsupialization of the diverticulum, fulguration of the epithelial lining, and percutaneous marsupialization/ablation are treatment options.

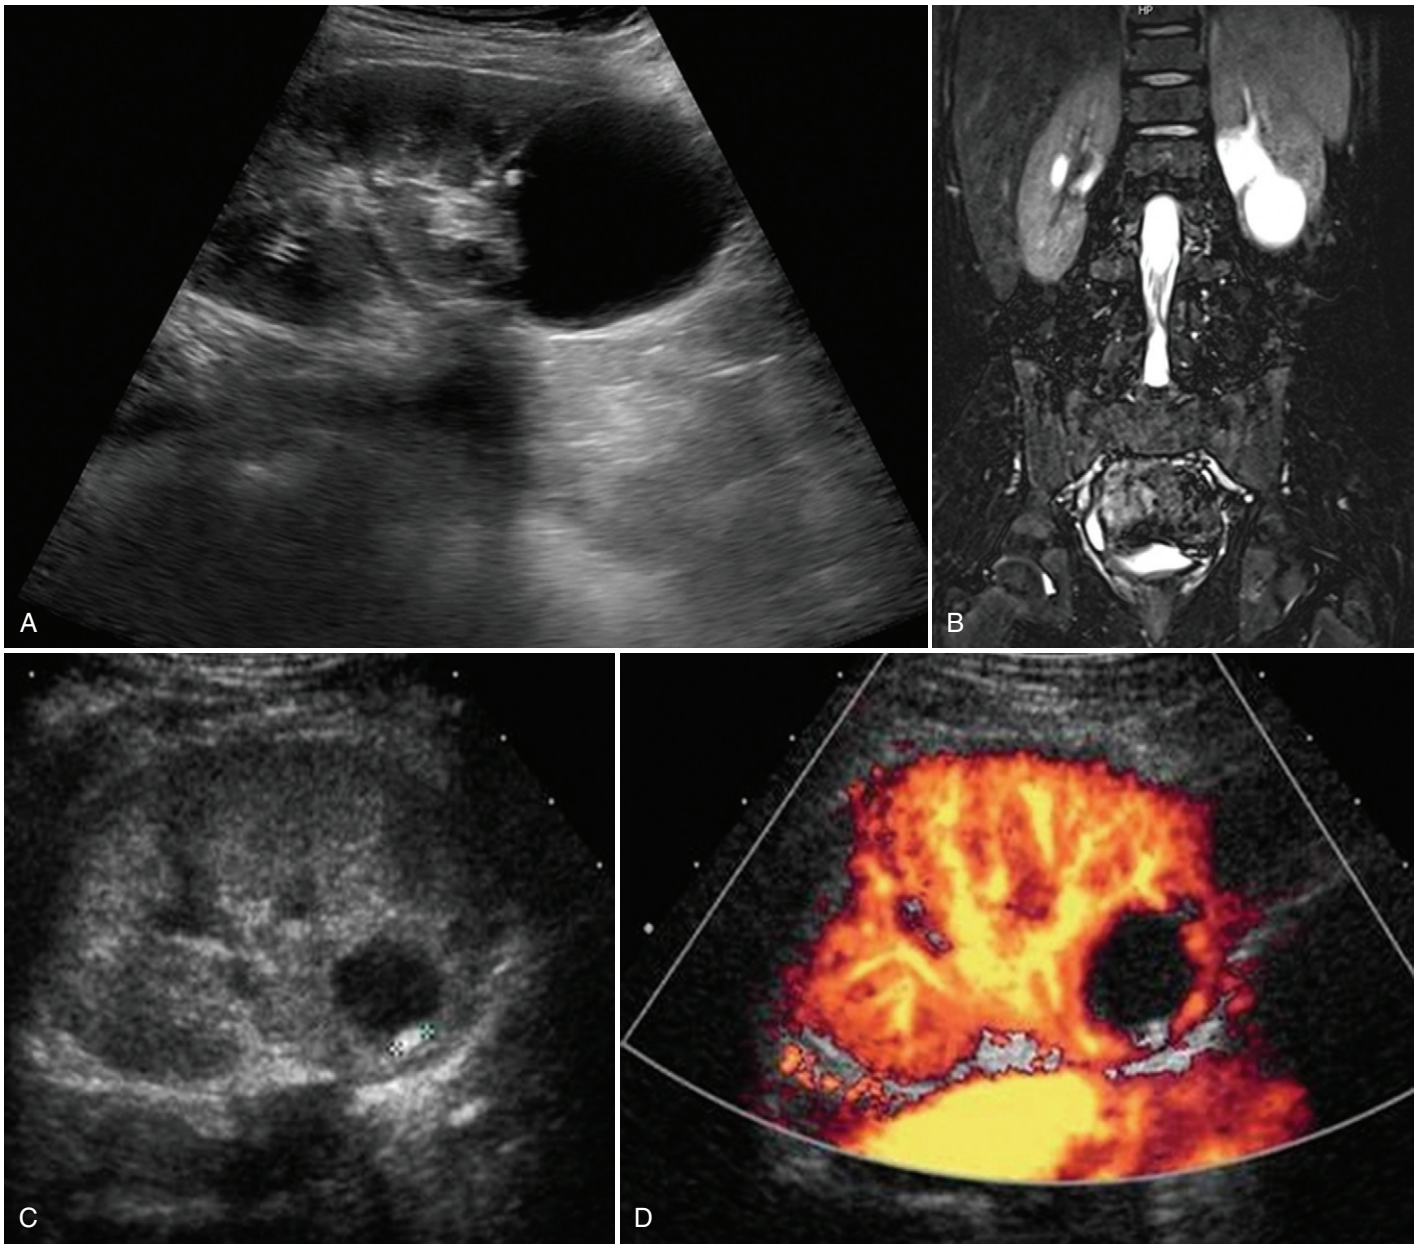

Figure 117–19. Lower pole calyceal diverticulum. **A,** Sagittal ultrasonogram. **B,** Sequence of coronal T2 images. **C,** Sagittal ultrasonogram shows small stone within a diverticulum. **D,** Color Doppler ultrasonogram demonstrates absence of flow. (**B,** Courtesy of Dr. Sara Milla; **C** and **D,** courtesy of Dr. Shpetim Telegrafi.)

117–19). **Hematuria, pain, and UTI may be seen in the presence of stones, which may be present in almost 40% of patients.** In the Mayo Clinic series (Timmons et al, 1975), 39% of patients with calyceal diverticula had calculi.

The diagnosis is suggested on ultrasonography but confirmed on CT scan and MR urography (Ellis et al, 1990; Estrada et al, 2009) (see Fig. 117–19). Delayed films demonstrate pooling of contrast material in the diverticulum. Retrograde pyelography and delayed imaging CT with contrast medium enhancement and MR urography are used to diagnose and define the precise anatomy. Ultrasonography delineates a fluid-filled area more centrally located near the collecting system than a simple renal cyst (see Fig. 117–19). When it is filled with microcalculi, ultrasonography characteristically demonstrates a layering effect, within the diverticulum, between clear fluid above and echo-dense debris without shadowing below (Patriquin et al, 1985). Ultrasonography will image the milk of calcium within the diverticulum as the patient changes position.

Patients who are asymptomatic do not require treatment but should be followed periodically with ultrasonography. Estrada and colleagues (2009) reported 10 of 23 calyceal diverticula (43%) that required treatment at a mean of 27 ± 25 months after initial treatment. Most commonly, these children presented with febrile UTI. The indications for surgery included enlargement of the diverticulum associated with pain or infection, abscess formation, urosepsis, and symptomatic calculus formation. Percutaneous ablation of the communication and fulguration of the diverticular lining was used until 1995. Although percutaneous ablation remains a viable treatment alternative, the availability of pediatric laparoscopic equipment has led to

the retroperitoneal laparoscopic approach for marsupialization of the diverticulum and fulguration of the epithelial lining (Estrada et al, 2009). Ureteroscopy with enlargement of the diverticular communication and removal of the stones has also been reported (Baldwin et al, 1998).

Hydrocalycosis

Hydrocalycosis is a very rare cystic dilation of a major calyx with a demonstrable connection to the renal pelvis (Fig. 117–20). It may be caused by a congenital or acquired intrinsic obstruction, such as a parapelvic cyst.

Dilation of the upper calyx due to obstruction of the upper infundibulum by vessels or stenosis has been described (Fraley, 1966; Johnston and Sandomirsky, 1972). Cicatrization of an infundibulum may result from infection or trauma. Conversely, hydrocalycosis has been reported to occur without an obvious cause (Williams and Mininberg, 1968). It has been postulated that achalasia of a ring of muscle at the entrance of the infundibulum into the renal pelvis causes a functional obstruction (Moore, 1950; Williams and Mininberg, 1968).

Mild upper calyceal dilation caused by partial infundibular obstruction is relatively common but usually asymptomatic. Although the most frequent presenting symptom is upper abdominal or flank pain, hydrocalycosis may be detected on prenatal ultrasonography (see Fig. 117–20). On occasion, a mass may be palpated. Stasis can lead to hematuria or urinary infection, or both.

Hydrocalycosis must be differentiated from multiple dilated calyces secondary to ureteral obstruction, calyceal clubbing as a result of recurrent pyelonephritis or medullary necrosis, renal tuberculosis, a large calyceal diverticulum, and megacalycosis. These entities can be differentiated by a combination of radiographic studies, surgical findings, histology, and cultures of the tissue.

Hydrocalycosis due to vascular obstruction is usually treated by dismembered infundibulopyelostomy. If the cystic dilation is caused by an intrinsic stenosis of the infundibulum, an intubated infundibulotomy or partial nephrectomy has been performed (Lang, 1991). Although clinical improvement is apparent in most instances, the radiologic appearance often is not altered significantly.

Megacalycosis

Megacalycosis is defined as nonobstructive enlargement of calyces resulting from malformation of the renal papillae (Fig. 117–21). It was first described by Puigvert in 1963. The calyces are generally dilated and malformed and may be increased in number (12 to 20) (Gittes, 1984; Pieretti-Vanmarcke et al, 2009). The renal pelvis is not dilated, nor is its wall thickened, and the UPJ is normally funneled without evidence of obstruction. The cortical tissue around the abnormal calyx is normal in thickness. The medulla, however, is underdeveloped and assumes a falciform (crescent) or semilunar appearance instead of its normal pyramidal shape. The collecting tubules are not dilated but are definitely shorter than normal, and they are oriented transversely rather than vertically from the corticomedullary junction (Puigvert, 1963). A mild disorder of maximal concentrating ability has been reported (Gittes and Talner, 1972), but acid excretion is normal after an acid load (Vela-Navarrete and Garcia Robledo, 1983). Other functions of the kidney-glomerular filtration, renal plasma flow, and isotope uptake also are not altered (Gittes, 1984).

Megacalycosis is congenital and has been diagnosed prenatally (Vidal Company et al, 2001). **It occurs predominantly in males with a ratio of 6:1 and has been found only in whites. Bilateral disease has been seen almost exclusively in males, whereas segmental unilateral involvement occurs only in females** (Cacciaguerra et al, 1996), suggesting an X-linked partially recessive gene with reduced penetrance in females (Gittes, 1984). Except for one report of two affected brothers, the entity has not been thought to be familial (Briner and Thiel, 1988).

It was theorized by Puigvert (1964) and endorsed by Johnston and Sandomirsky (1972) that there is transient delay in the recanalization of the upper ureter after the branches of the UB hook up with the metanephric blastema. This produces transient obstruction when the glomeruli start producing urine. The fetal calyces may dilate and retain their obstructed appearance, despite the lack of evidence of obstruction in postnatal life (Gittes and Talner, 1972). **The increased number of calyces may be an aborted response by the branching UB to the obstruction.**

The abnormality is usually diagnosed during radiographic evaluation of a UTI or other congenital anomalies (Arambasic et al, 2003). Adults frequently present with hematuria secondary to renal calculi.

The calyces are dilated and usually increased in number, but the infundibuli and pelvis may not be enlarged. Although the UPJ does not appear obstructed, there may be segmental dilation of the distal third of the ureter (Kozakewich and Lebowitz, 1974). Megacalycosis associated with an ipsilateral segmental megaureter was described in 12 children (Mandell et al, 1987), mostly boys, and predominantly left-sided. A normal-caliber ureter was interposed between the two entities. This anatomic picture may be mistaken for congenital ureteropelvic, ureterovesical junction obstruction, or infundibular stenosis (Redman and Neeb, 2005; Pieretti-Vanmanrcke et al, 2009). Diuretic renography reveals a normal pattern for uptake and washout of the isotope (Gomez Tellado et al, 1997). **Long-term follow-up of these patients does not reveal progression of the anatomic derangement or functional impairment of the kidney** (Gittes, 1984).

Key Points: Megacalycosis

- Megacalycosis is a nonobstructive enlargement of calyces resulting from malformation of the renal papillae.
- It occurs predominantly in males with a ratio of 6:1. Bilateral disease has been seen almost exclusively in males, whereas segmental unilateral involvement occurs only in females.
- Long-term follow-up of patients with this anomaly does not usually reveal progression of the anatomic or functional status of the kidney.

Unipapillary Kidney

The unipapillary kidney is a rare anomaly with only 18 cases reported (Neal and Murphy, 1960; Sakatoku and Kitayama, 1964; Harrison et al, 1976; Morimoto et al, 1979; Toppercer, 1980; Kaneto et al, 1997). This anomaly is present not uncommonly in monkeys, rabbits, dogs, marsupials, insectivores, and monotremes. The cause is thought to be a failure of progressive branching after the first three to five generations (which create the pelvis) of the UB (Potter, cited by Harrison et al, 1976). The solitary calyx drains a ridgelike papilla. Nephrons attach to fewer collecting tubules,

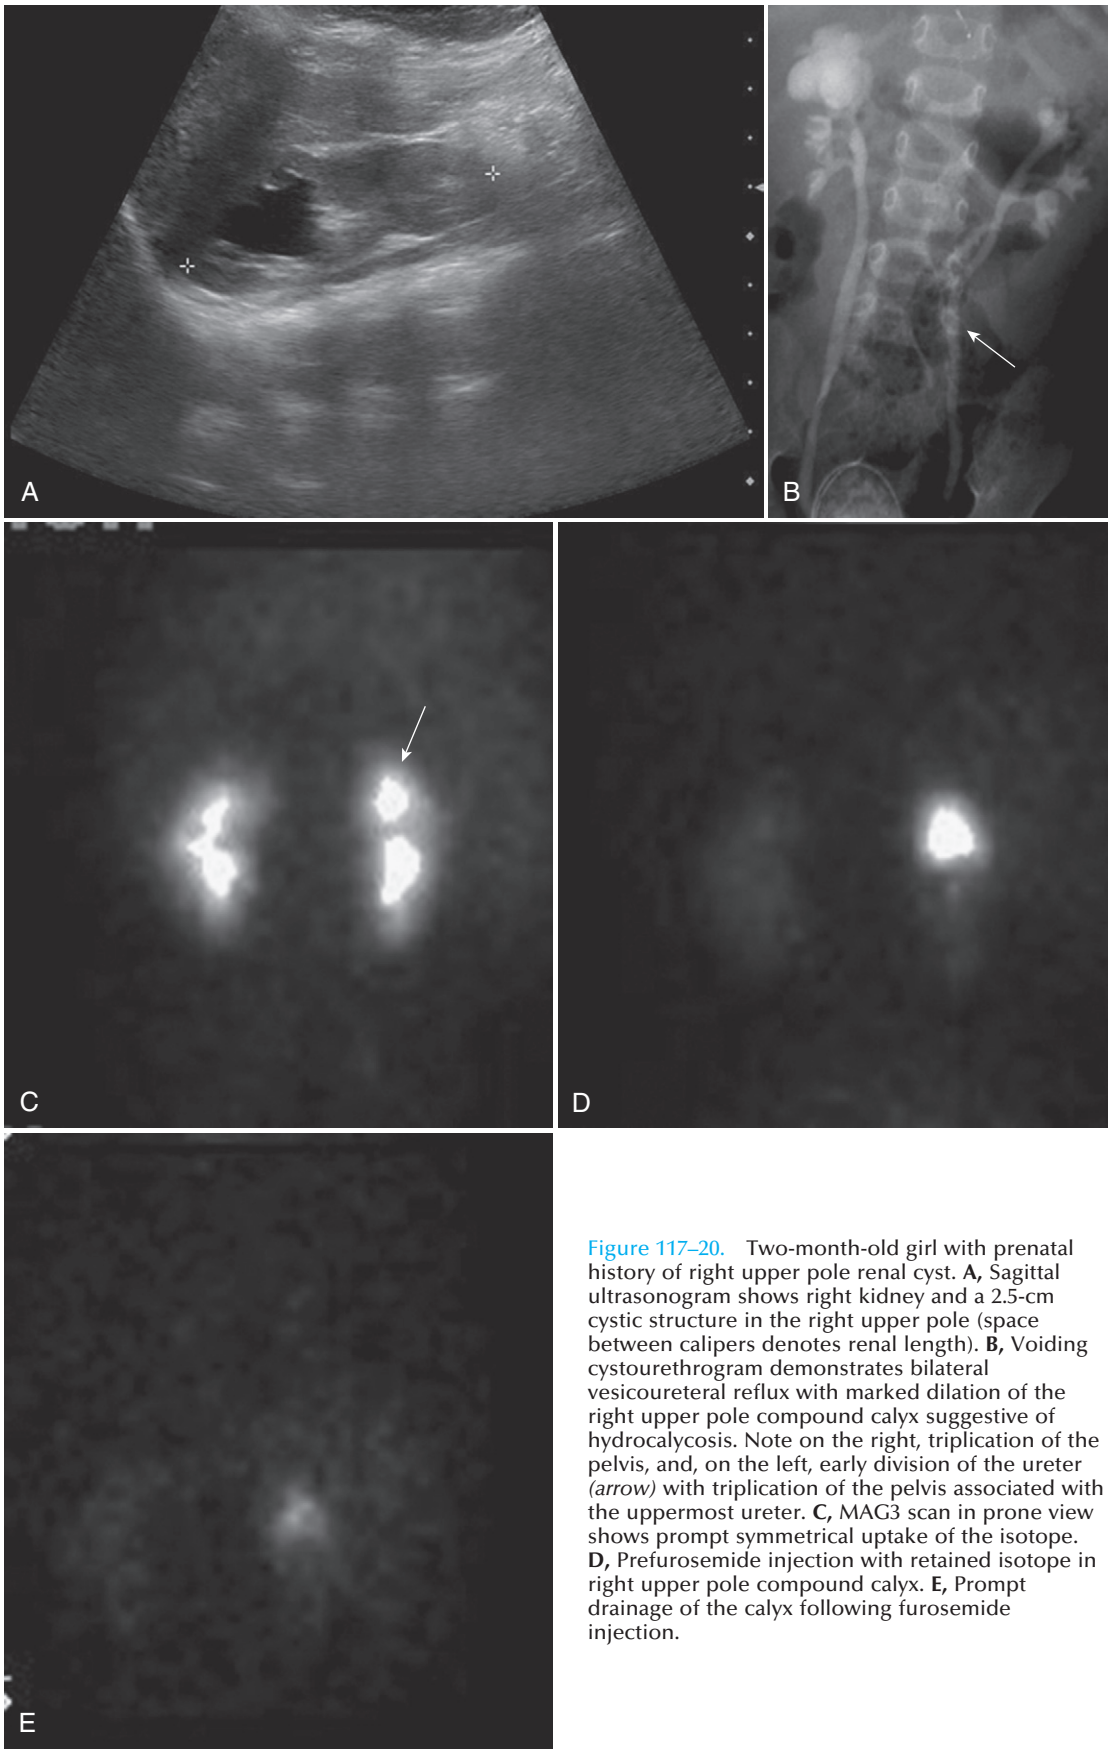

Figure 117–20. Two-month-old girl with prenatal history of right upper pole renal cyst. **A,** Sagittal ultrasonogram shows right kidney and a 2.5-cm cystic structure in the right upper pole (space between calipers denotes renal length). **B,** Voiding cystourethrogram demonstrates bilateral vesicoureteral reflux with marked dilation of the right upper pole compound calyx suggestive of hydrocalycosis. Note on the right, triplication of the pelvis, and, on the left, early division of the ureter *(arrow)* with triplication of the pelvis associated with the uppermost ureter. **C,** MAG3 scan in prone view shows prompt symmetrical uptake of the isotope. **D,** Prefurosemide injection with retained isotope in right upper pole compound calyx. **E,** Prompt drainage of the calyx following furosemide injection.

which then drain directly into the pelvis. Biopsies of these kidneys reveal glomerulosclerosis, tubular atrophy, and increased fibrosis (Bischel et al, 1978).

The kidney is smaller than normal, often with reduced function, but usually is in its correct location (Smith et al, 1984; Kaneto et al, 1997). The sparse arterial tree has a normal configuration. **The contralateral kidney is frequently absent.** Genital anomalies are often present. The condition is frequently asymptomatic. Often there are abnormalities of the proximal ureter (i.e., megaureter, reflux, or ectopic insertion), suggesting an underlying UB defect as the cause (Smith et al, 1984; Kaneto et al, 1997).

Extrarenal Calyces

Extrarenal calyces are an uncommon congenital anomaly in which the major calyces and the renal pelvis are outside the parenchyma of the kidney, with only about 20 cases reported in the literature (Nataraju et al, 2009). This entity was originally reviewed by Eisendrath in 1925 and then more extensively by Malament and colleagues in 1961. The kidney is usually discoid, with the pelvis and the major and minor calyces located outside the renal parenchyma. The calyces may be blunted. The renal vessels have an anomalous distribution into the kidney,

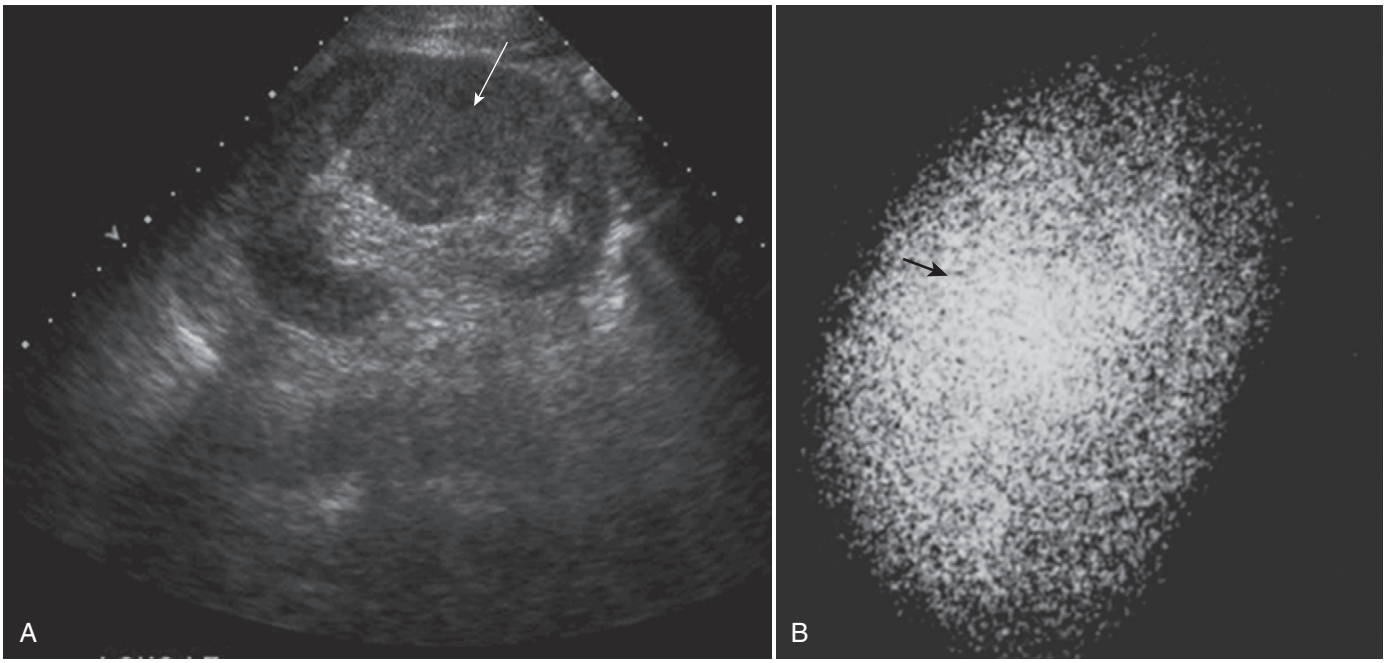

Figure 117–22. Column of Bertin. **A,** Ultrasonogram shows sagittal view of left kidney and possible midpolar mass. **B,** DMSA scan demonstrates normal uptake in the area of the mass *(arrow),* suggesting the pseudotumor, but it is actually a hypertrophied column of Bertin. (**A,** Courtesy of Dr. Shpetim Telegrafi.)

usually at the circumferential edge of the flat, widened hilus. Malament considered this condition to be the result of abnormally slow development of the nephrogenic anlage or a too early and rapidly developing UB, both resulting in abnormal coalescence of the collecting system with the nephrogenic mass. Extrarenal calyces have been associated with ectopic and horseshoe kidneys and renal dysplasia. They usually do not produce symptoms, although hydronephrosis with impairment of normal drainage may lead to stasis, infection, and calculi, requiring surgical intervention (Nataraju et al, 2009).

Anomalous Calyx (Pseudotumor of the Kidney)

A number of normal variants of the pyelocalyceal system in the kidney have been described. **One such entity manifests as a localized mass, usually situated between the infundibula of the upper and middle calyces, and is called a hypertrophied column of Bertin** (Fig. 117–22). The column may be sufficiently large to compress and deform the adjacent pelvis and calyces, suggesting a mass or "pseudotumor." The individual calyces, however, are normally shaped and developed.

It is important to differentiate this calyceal anomaly from true disease of the calyx and from a parenchymal tumor. **A renal ultrasound study shows a normal echogenic pattern of parenchyma in the area in question, and a renal scan shows normal uptake of the radioisotope in this area** (Parker et al, 1976).

Infundibulopelvic Stenosis

Infundibulopelvic stenosis most likely forms a link between cystic dysplasia of the kidney and the grossly hydronephrotic organ (Kelalis and Malek, 1981; Uhlenhuth et al, 1990). This condition includes a variety of radiographically dysmorphic kidneys with varying degrees of infundibular or infundibulopelvic stenosis that may be associated with renal dysplasia (Fig. 117–23). The first case involving the entire pelvis and all the infundibuli of both kidneys was reported by Boyce and Whitehurst in 1976. Rayer had described a focal form of the disease in 1841, and several reports noting narrowing of one or two infundibuli appeared between 1949 and 1976 (Uhlenhuth et al, 1990). These authors tried to link the focal form to cystic dysplasia secondary to obstruction, in which multicystic kidney disease is the severest form in the spectrum. Uhlenhuth and colleagues (1990) believed that this phenomenon is the result of extensive dysgenesis of the pyelocalyceal system but with preservation of renal function. Reflux is not commonly observed in these patients.

Key Points: Infundibulopelvic Stenosis

- Infundibulopelvic stenosis most likely forms a link between cystic dysplasia of the kidney and the grossly hydronephrotic kidney.
- Infundibulopelvic stenosis is usually bilateral and is commonly associated with vesicoureteral reflux, suggesting an abnormality of the entire UB.

Infundibulopelvic stenosis is usually bilateral and is commonly associated with vesicoureteral reflux, suggesting an abnormality of the entire UB (Kelalis and Malek, 1981). Patients usually present with urinary infection, hypertension, or flank pain. Sometimes, an asymptomatic child with multiple anomalies is found to have this condition. Despite extensively dysmorphic kidney features, the function is either normal or only slightly affected (Kelalis and Malek, 1981). In Husmann's study of 21 patients with the longest follow-up to date (median of 11 years), 90% had bilateral renal disease (Husmann et al, 1994). Ten patients had bilateral infundibulopelvic stenosis, 6 had a contralateral dysplastic renal unit, and 3 had contralateral URA. Renal insufficiency or end-stage renal disease developed in 8 (37%), all

(Courtesy of Dr. Pasquale Casale.)

of whom had bilateral kidney anomalies. Renal biopsies in those with end-stage renal disease demonstrated renal dysplasia proximal to the stenotic infundibuli and varying degrees of glomerulosclerosis of the glomeruli that were not involved in the regions with dysplasia. They proposed that the decreased total functional renal tissue leads to hyperfiltration injury. They suggested that routine infundibulotomy should not be performed, but endoscopic or percutaneous surgery should be considered for increasing hydronephrosis (see Fig. 117–23). More recently, Nurzia and colleagues (2002) recommend monitoring of renal function to include a baseline and yearly serum creatinine level, estimation of glomerular filtration rate, and urinalysis. Prevention of hyperfiltration injury with calcium channel blocking agents, angiotensin-converting enzyme inhibitors, and dietary restriction of protein should be considered when a decline in renal function with azotemia, proteinuria, or hypertension occurs (Paddu et al, 2009).

Pelvis

Extrarenal Pelvis

An extrarenal pelvis is of clinical importance only when drainage is impaired and may be associated with malposition and malrotation that predispose to urinary stasis, infection, and calculous disease. UPJ obstruction causing dilation of only the renal pelvis and not the calyces has been reported (Johnson, 1999).

Bifid Pelvis

Approximately 10% of normal renal pelves are bifid, the pelvis dividing first at or just within its entrance to the kidney to form two major calyces. A bifid pelvis should be considered a normal variant. When there is an incomplete duplication and a bifid pelvis, a ^{99m}Tc-mercaptoacetyltriglycine or MAG3 scan may

show the "yo-yo" effect of urine ascending one limb after descending from another, which is thought, but not proven, to infrequently cause flank pain and UTI (Chu et al, 2003). If further division of the renal pelvis occurs, triplication of the pelvis may result, but this is extremely rare (see Fig. 117–20).

Congenital and acquired renal malformations constitute a wide spectrum of clinical entities. Ectopia and fusion anomalies are covered in another chapter. This chapter is devoted to those disorders that lead to dysgenesis of the kidney, cystic lesions of the kidney, or, in some cases, a combination of both.

Many of these conditions are related to maldevelopment of the kidney and urinary tract and are thus the result of anomalous genetic mechanisms, some of which are understood, others of which are not. A basic knowledge of molecular genetics is required to better understand normal renal development, absence of renal development, and the effects of genetic mutations and abnormal signaling proteins on renal maldevelopment and cystic diseases. Within this chapter, the relevant genetic processes will be discussed as they relate to specific disease processes. Further discussion on the specific genes involved with renal development appears in Chapter 111 and in an article by Glassberg in 2002.

OVERVIEW OF GENETICS

Genetic direction of kidney and urinary tract development results when a gene from a specific chromosomal area produces a protein product that then signals certain actions to occur within an individual cell or group of cells. This cellular differentiation is then responsible for the particular action of those cells. In general, when a gene is normal, its protein product is normal as well. When a gene is abnormal, it produces an abnormal protein that can lead to maldevelopment or disease. Obviously, with complex organogenesis, the process is not always this simple. Often, **more than one gene can be responsible for a specific disease. For example, an abnormality of one of two genes is responsible for the entity tuberous sclerosis. One tuberous sclerosis gene, *TSC1,* is located on chromosome 2 and the second, *TSC2,* on chromosome 16.**

Each gene within a cell is one of a set of two; each is called an allele. One defective allele may be the carrier for the defect**. In Knudson's** (1991) **two-hit theory, the first hit is an inherited mutation that is found in all cells of an individual (i.e., a germline mutation). The second hit occurs when the wild-type, normal allele spontaneously mutates within a specific organ, although it may be a different mutation than in the primarily affected allele** (Knudson, 1991). For example, the typical somatic cells in the kidney and all other cells of a patient with von Hippel-Lindau (VHL) disease typically are heterozygous for the *VHL* gene located on chromosome 3; that is, the mutant *VHL* allele is inherited and its mate is the normal wild-type allele. However, the configuration of wild-type *VHL* makes it prone to spontaneous mutation. If the wild-type allele develops a defect within the cells of a specific organ, those cells no longer are able to produce normal pVHL (VHL protein) with its suppressor properties. That organ then has the propensity to develop a tumor. The variability in manifestations of autosomal dominant polycystic kidney disease (ADPKD) may be related to a two-hit phenomenon as well. For example, ADPKD is a

heterozygous condition in which one allele of the *PKD1* or *PKD2* set is responsible for the genetic transmission of the disease but may not be enough for cystogenesis. A spontaneous mutation of the wild-type allele may be responsible for cystogenesis or for other manifestations of the disease. Qian and colleagues (1996) suggested that the *PKD1* gene has an unusual genomic structure that makes it readily mutable for a second hit, and the timing of this second hit may account for the phenotypic variability within one family. The second hit itself may occur only in a few cells, possibly accounting for the fact that less than 1% of nephrons in ADPKD eventually develop cysts (Qian et al, 1996). Within a cyst, many but not all of the lining cells have lost their heterozygosity (Brazier and Henske, 1997; Qian et al, 1999).

RENAL AGENESIS AND DYSPLASIA

There are many terms that can be used to describe anomalous development of the kidney. These terms are often used interchangeably and can result in great confusion. The definitions as adopted in 1987 by the American Academy of Pediatrics (AAP) Section on Urology (Glassberg et al, 1987) will be employed in this chapter.

Renal Agenesis

Renal agenesis, or absent kidney development, can result from anomalous development of the wolffian duct, ureteric bud, and/or metanephric blastema. Bilateral agenesis occurs in 1 of every 4000 births and has a male predominance (Potter, 1965). Fetal demise occurs secondary to the lack of fetal urine production and subsequent oligohydramnios. Affected infants are born with immature lungs and pneumothorax, Potter facies (hypertelorism, prominent inner canthal folds, and recessive chin), and orthopedic defects secondary to intrauterine compression. Most cases of bilateral agenesis are sporadic, and many are associated with other congenital anomalies, including urogenital sinus defects.

Unilateral agenesis is more common, with an incidence of 1 in 450 to 1000 births (Kass and Bloom, 1992). Again, a wolffian duct abnormality is often the cause, and associated other wolffian and müllerian abnormalities may also be present, such as malformation of the ipsilateral uterine horn, fallopian tube or ovary in the female, or absence of the ipsilateral testis, vas deferens, or seminiferous tubules in the male. Mayer-Rokitansky-Küster-Hauser syndrome refers to a group of associated findings that include unilateral renal agenesis or renal ectopia, ipsilateral müllerian defects, and vaginal agenesis. Of men with unilateral or bilateral congenital absence of the vas deferens, 26% or 11%, respectively, had renal agenesis. Congenital bilateral agenesis of the vas deferens is also an expected finding in male patients with cystic fibrosis.

Unilateral renal agenesis can also be associated with other urologic abnormalities in 48% of patients, including primary vesicoureteral reflux (28%), obstructive megaureter (11%), and ureteropelvic junction obstruction (3%) (Cascio et al, 1999)**. These findings are similar to those associated with unilateral multicystic kidney disease, suggesting the possibility that some absent kidneys represent involuted multicystic dysplastic kidneys.**

Additional reading on renal agenesis may be found in Chapter 117.

Key Points: Renal Agenesis

- Bilateral renal agenesis is associated with oligohydramnios and Potter facies (hypertelorism, prominent inner canthal folds, and recessive chin).
- Unilateral agenesis is often associated with other genitourinary anomalies, and these patients should be appropriately screened.

Dysplasia

Definition

Renal dysgenesis is defined as maldevelopment of the kidney that affects its size, shape, or structure. It is composed of two primary subtypes, the first of which is dysplasia. The term dysplasia, while literally and most simply is defined as "abnormal tissue," specifically, as it relates to the kidney, it can only truly be defined on the basis of histopathology. **Dysplasia is a histologic diagnosis made by the presence of embryonic, immature mesenchyme, and primitive renal components** (Fig. 118–1). Ericsson and Ivemark (1958) considered these primitive ducts to be the sine qua non finding of all dysplasia. Cysts may or may not be present. The etiology for the development of dysplasia appears to be twofold: (1) a primary, inherent abnormality in the differentiation of the nephron and collecting duct, often with an underlying genetic cause, and (2) a secondary cause resulting from congenital urinary tract obstruction.

Key Points: Dysplasia

- The hallmark of dysplasia is the "primitive duct," a duct encircled by a collar of fibromuscular cells.
- Dysplasia in its truest form is a histopathologic definition, not a clinical one.
- Dysplasia often is associated with ureteric bud anomalies and/or urinary tract obstruction.

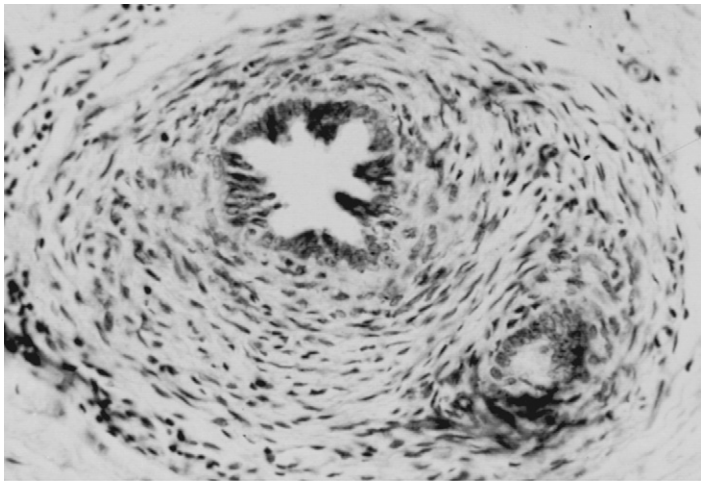

Figure 118–1. Primitive duct lined with columnar epithelial cells. Note concentric arrangement of spindle mesenchymal cells around the duct. Special staining is required to demonstrate smooth muscle cells.

Etiology

Renal dysplasia is the primary cause of childhood end-stage renal disease and two main theories have been considered in its pathogenesis: (1) a primary failure of ureteric bud activity and (2) a disruption in renal development produced by fetal urinary outflow impairment (obstruction).

Currently, there is no direct experimental evidence to prove that an abnormal ureteric bud site leads to ureteric bud penetration at a peripheral area of the blastema. However, there is much data to support the idea that defects in genetic and apoptotic pathways can affect ureteric bud formation, branching morphogenesis within the metanephric blastema, and normal nephrogenesis (e.g., RET, RAR, BMP4, SLIT2-ROBO2, COX-2, AT2) (Mendelsohn et al, 1994; Norwood et al, 2000; Pope et al, 2001; Grieshammer et al, 2004; Thomas et al, 2005). The genetic defect at each point may be the same, but the downstream pathway associated with the defect may vary for each process.

Animal studies of fetal urinary tract obstruction generate some but not all of the anatomic and histopathologic features of human renal dysplasia. Findings in these animal studies include dilatation at various segments of the nephron and collecting duct, inhibition of nephron development in the nephrogenic zone, architectural disorganization, and the appearance of primitive glomeruli as well as S-shaped bodies and cysts. At times, obstruction in these animal models can even lead to dedifferentiation of certain cells. An example is the conversion of renal epithelial cells back into mesenchymal cells and even of mesenchymal cells into myofibroblasts (Peters et al, 1992; Nguyen et al, 1999; Matsell and Tarantal, 2002). Dysplasia arising from obstruction typically appears at the periphery of the kidney, at the nephrogenic zone, and frequently with subcapsular cysts. This type usually develops later in gestation, such as in the case of posterior urethral valves (PUVs) (Fig. 118–2).

Ultrasonographically, dysplastic kidneys have a distinct appearance. The kidney is typically small and is hyperechogenic when compared with the liver. There is loss of the typical corticomedullary differentiation, and there is minimal distinction of the renal parenchyma and the perirenal fat (Fig. 118–3A). Cysts can be seen in conjunction with parenchymal dysplasia (Fig. 118–3B). These cysts can also develop from either abnormal development of the metanephric blastema or from distal obstruction. Again, the exact etiology of the cyst formation can be unclear. The important point is that not all cysts are a result of dysplasia and not all dysplasia is associated with cysts.

HYPOPLASIA AND HYPODYSPLASIA

Renal Hypoplasia

Another form of renal dysgenesis is hypoplasia, which is defined as the underdevelopment of a tissue or organ, and is usually due to a deficiency in the number of cells. Renal hypoplasia is a condition in which there is a reduction in the size of the functioning renal mass. Use of the term *hypoplasia* should be restricted to kidneys that have less than the normal number of calyces and nephrons but are not dysplastic or embryonic. These are kidneys that are morphologically normal but have either a reduced number of nephrons or smaller nephrons, although a hypoplastic kidney may have a normal nephron density despite its small size.

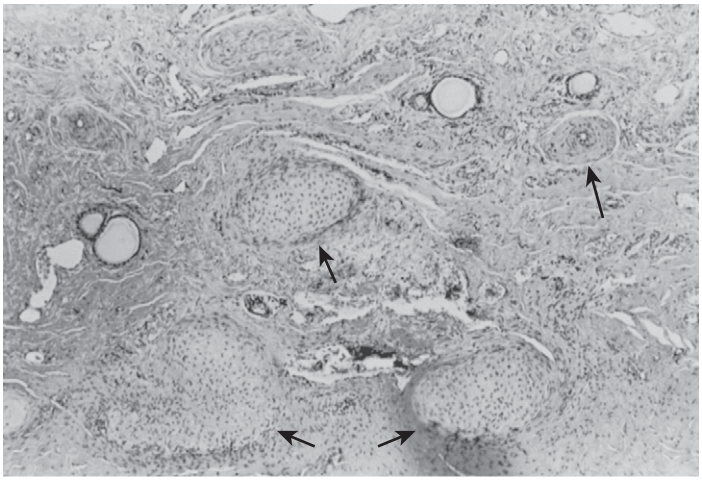

Figure 118–2. Histologic specimen of a nonfunctioning reflux kidney in a patient with posterior urethral valves. Note presence of nests of cartilage *(short arrows)*. Primitive ducts are scattered throughout the specimen *(long arrow)* (100×). The findings are compatible with dysplasia.

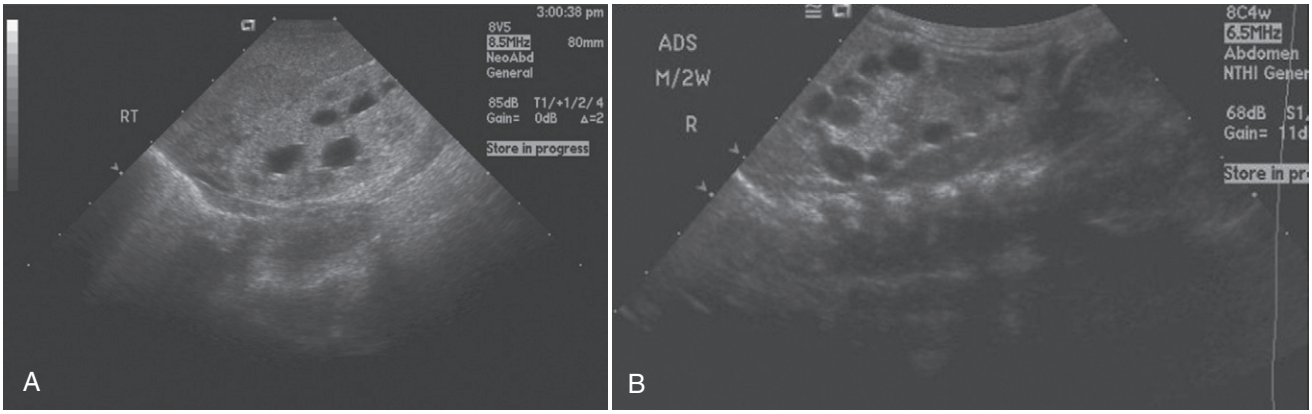

Figure 118–3. Ultrasonographic appearance of renal dysplasia. **A,** Classic dysplasia with hyperechogenic appearance of the kidney relative to the liver, a loss of normal corticomedullary differentiation, and dysmorphic calyces. **B,** Renal dysplasia accompanied by cysts. (Courtesy of Marta Hernanz-Schulman, MD.)

Hypoplasia may be bilateral or unilateral. In unilateral cases, the other kidney usually shows greater compensatory growth than is characteristic in patients with renal atrophy caused by acquired disease. A common cause of renal hypoplasia is vesicoureteral reflux, although the term *reflux nephropathy* is now used to describe the renal changes associated with reflux.

Hypodysplastic kidneys most often occur in conjunction with ectopic ureteric orifices, with the extent of dysplasia correlating with the degree of ectopia (Schwarz et al, 1981). However, hypodysplastic kidneys are seen in a few patients with normal ureteric orifices. In such cases, obstruction may or may not be present.

All forms of hypoplasia can be assessed by ultrasonography with measurement of the kidneys. The size will be reduced in all forms. Dilated calyces may also be seen. The collecting systems will be demonstrated by excretory urography if renal function is not sufficiently impaired to prevent this. Renal function is assessed biochemically and, if there is unilateral hypoplasia, by radionuclide studies.

Oligomeganephronia

First described in 1962 (Habib et al, 1962; Royer et al, 1962), oligomeganephronia is a type of renal hypoplasia that results from a quantitative defect of the renal parenchyma with a reduced number of nephrons and hypertrophy of each nephron. It may occur as a sporadic defect or in association with a number of syndromes. It is usually a bilateral condition, although a few instances of unilateral oligomeganephronia associated with contralateral renal agenesis have been reported (Griffel et al, 1972; Lam et al, 1982; Forster and Hawkins, 1994). Oligomeganephronia results from arrested development of the metanephric blastema at 14 to 20 weeks' gestation, with subsequent hypertrophy of glomeruli and tubules in the kidney. This hypertrophy and hyperfiltration results in further nephron injury and sclerosis. Eventually, this progressive loss of nephrons leads to end-stage renal disease (ESRD). Although oligomeganephronia is associated with some genetic syndromes, most cases are sporadic. Vascular abnormalities and accidents have been associated with this type of renal hypoplasia. The cause of most oligomeganephronia cases is unknown.

Oligomeganephronia is a noninheritable congenital disorder, and boys appear to be affected more often than girls. It frequently is associated with low birth weight (2500 g). The condition is usually discovered within the first 2 years of life. In neonates, kidney disease is often suspected with spontaneous pneumothorax, feeding problems, or laboratory abnormalities. Oligomeganephronia typically presents with anorexia, vomiting, dehydration, intense thirst, polyuria, and failure to thrive. It may also be incidentally diagnosed when renal anomalies are discovered in the evaluation of another illness. Oligomeganephronia is a progressive disorder and many patients go on to renal failure in the second decade.

Meticulous histologic examination of the kidney is the only way to establish an absolute diagnosis of oligomeganephronia (Fig. 118–4). Proteinuria is often the first laboratory manifestation of oligomeganephronia and precedes decline in renal function by several years. Other laboratory manifestations of renal failure are frequently present, including elevated BUN and creatinine levels, hyponatremia, and metabolic acidosis. Treatment is generally supportive and directed at maintaining normal biochemical balance, hemoglobin, and growth. High fluid intake and correction of salt loss and acidosis are the initial steps. Daily dietary protein should be limited to 1.5g/kg during the stable phase (Royer et al, 1962). In addition, angiotensin-converting enzyme inhibitors may be of benefit in slowing progression of renal failure, even if the patient has a normal blood pressure. End-stage renal disease is managed by dialysis and transplantation. The allograft may come from a living related donor because the disease is not familial.

Ask-Upmark Kidney (Segmental Hypoplasia)

In 1929, Erik Ask-Upmark, a Swedish physician, described distinctive small kidneys in eight patients, seven of whom had malignant hypertension; six of these patients were adolescents. Subsequently, this problem was described histologically as focal renal hypoplasia resulting in a segmental renal scar. Segmental renal hypoplasia, or Ask-Upmark kidney, is an extremely rare anomaly, and the patients (usually young women and girls) most frequently present with hypertension. The lesions found in these kidneys are most likely acquired, possibly representing chronic atrophic pyelonephritis due to vesicoureteral reflux, although some appear to be congenital. Segmental vascular (arterial) anomalies have also been cited as a possible cause for these lesions.

Most patients are 10 years of age or older at diagnosis. The disease is associated with severe hypertension, sometimes with headaches, either alone or together with hypertensive encephalopathy (Rosenfeld et al, 1973) and with retinopathy in half of the patients (Royer et al, 1971). Proteinuria and some degree of renal insufficiency may be present if the disease is bilateral. Approximately half of the patients in the series described by Royer and colleagues (1971) had these signs at diagnosis. The disorder is usually unilateral, producing a small kidney with deep, narrow, segmental scars (slit-scar) found in the midzone. These slit scars are the classic radiographic finding.

The Ask-Upmark kidney is smaller than normal—12 to 35 g (Royer et al, 1971). Its distinctive feature is one or more deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. Usually, the hypoplastic segments are easily distinguished from adjacent areas (Fig. 118–5).

Abnormal renin secretion has been proposed as the cause of the hypertension; however, nephrectomy has been shown to normalize blood pressure regardless of plasma renin activities (Babin et al, 2005). In patients with unilateral disease, partial or total nephrectomy may control the hypertension (Royer et al, 1971; Meares and Gross, 1972). Failure of this measure suggests an unrecognized scar or generalized arteriosclerosis in the remaining kidney (Arant et al, 1979). Bilateral disease with renal insufficiency usually is managed medically, although dialysis and transplantation may be needed. Correction of reflux may prevent further renal damage but probably will have no effect on the hypertension.

Renal Hypodysplasia

Hypodysplasia may be associated with a wide spectrum of urologic diseases, such as primary obstructive megaureter and ureteropelvic junction obstruction, ureterocele, urethral obstruction, or prune-belly syndrome, to name a few. It has been previously mentioned that abnormal ureteric budding leads to abnormal renal development that often is manifested as hypodysplasia. Lateral ureteral ectopia usually leads to vesicoureteral reflux and its associated forms of hypodysplasia—be it a developmental anomaly, the result of chronic pyelonephritis, or a combination of both. Medial ureteral ectopia, with or without the presence of an ureterocele, can often result in hypodysplasia as well. The renal cortex may be thin,

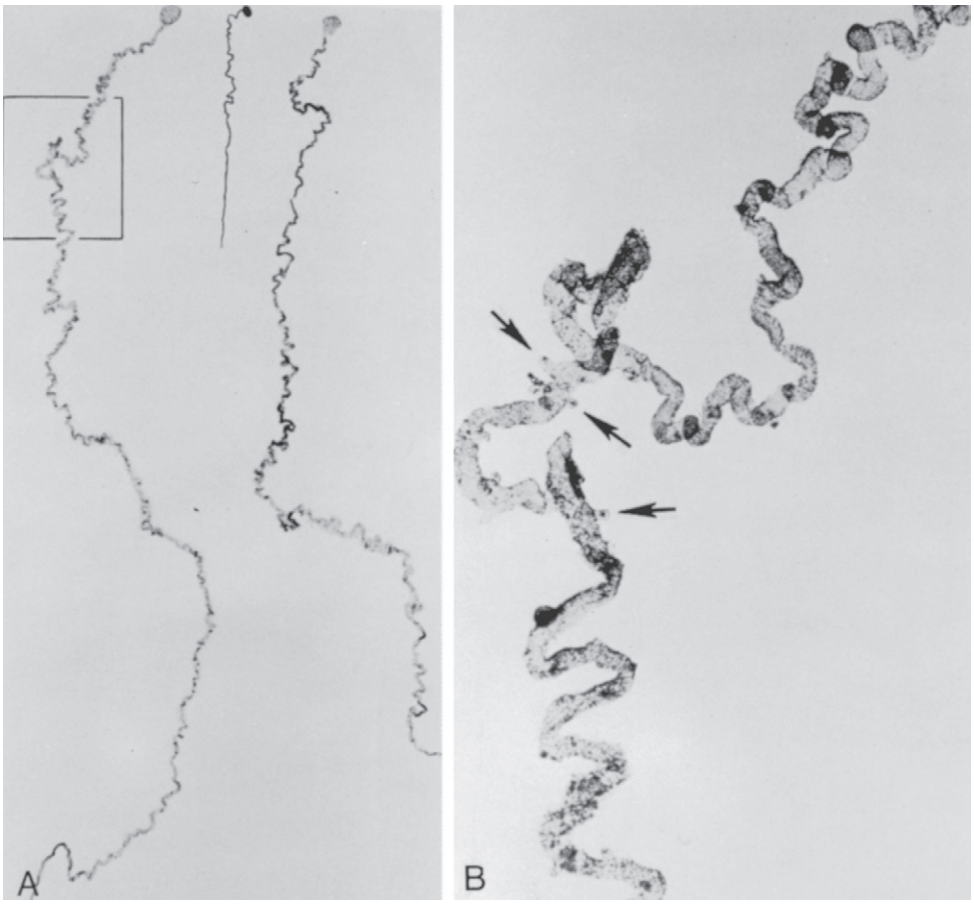

Figure 118–4. **A,** Mosaic photograph of two typical proximal tubules dissected from the kidney of a patient with oligomeganephronia. The silhouette in the top center is a diagrammatic representation to scale of an average proximal tubule from a kidney of an age-matched control. **B,** Enlargement of the *inset* in **A** showing the diverticula along the course of the nephron *(arrows).* (From Fetterman GH, Habib R. Congenital bilateral oligonephronic renal hypoplasia with hypertrophy of nephrons [oligomeganephronia]. Am J Clin Pathol 1969;52:199–207.)

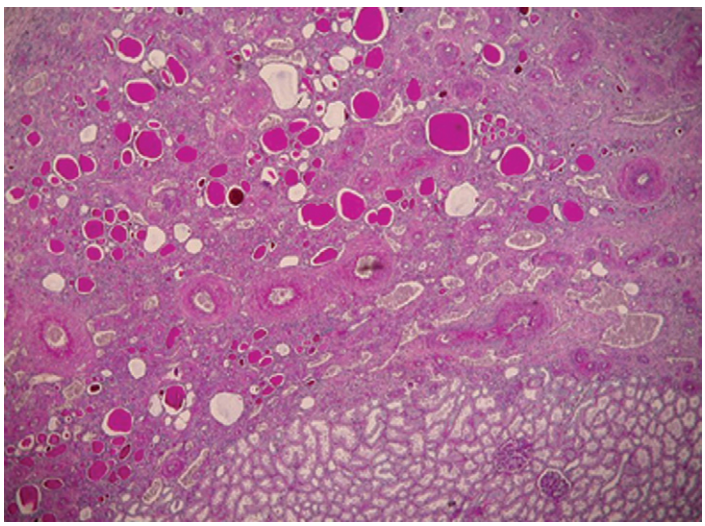

Figure 118–5. Typical microscopic pattern of segmental hypoplasia affecting the cortex with thyroid-like tubules, thick-walled arteries, and the absence of glomerulus. Note the sharp delineation from the surrounding normal kidney *(bottom).* Periodic acid–Schiff stain. (From Babin J, Sackett M, Delage C, Lebel M. The Ask-Upmark kidney: a curable cause of hypertension in young patients. J Hum Hypertens 2005;19:315–6.)

secondary to hydronephrosis, or severely dysplastic, and perhaps with numerous small cysts.

According to Osathanondh and Potter (1964), posterior urethral valves may be associated with two types of renal hypodysplasia. In the less severe form, there are small, usually subcapsular cysts and nearly normal renal function. In the second form, the cysts are larger and more widely distributed, and numerous islands of cartilage are present. This form usually is associated with earlier onset and more severe obstruction and reflux (see Fig 118–2).

The features of the prune-belly syndrome (absent abdominal musculature, triad syndrome) include grossly deformed kidneys, which may have various degrees of hypodysplasia. The ureters are wide and tortuous, often with large and laterally placed orifices. Urethral obstruction or atresia may be present in the most severe cases, but usually there is no lower urinary tract obstruction.

CYSTIC DISEASES OF THE KIDNEY

The kidney is one of the most common sites in the body for cyst formation. Renal cystic diseases encompass a broad spectrum of sporadic and genetically determined congenital or acquired conditions that have in common the presence of cysts in one or both kidneys. These diseases often require a multidisciplinary approach to evaluation and treatment.

Renal cysts are cavities derived primarily from tubules and are composed of a layer of partially dedifferentiated epithelial cells enclosing a cavity filled with urine-like liquid or semisolid material. They may develop in any tubular segment between the Bowman capsule and the tip of the renal papilla, depending on the nature of the underlying disorder. Some cysts are saccular or fusiform structures that resemble diverticula. Other cysts may or may not communicate with a glomerulus, tubule, collecting duct, or calyx, or they may initially have communicated only to become isolated later. **Multicystic dysplasia is an exception in that it arises before formation of the nephron, from abnormal induction of metanephric development, from a primary abnormality of the nephrogenic blastema, or from obstruction occurring early in renal development. Another exception, benign multilocular cyst, represents a neoplastic growth.**

Key Points: Hypoplasia and Hypodysplasia

- Hypoplasia and hypodysplasia often are associated with ectopic orifices and sometimes with obstruction.
- Oligomeganephronia is a condition with a reduced number of nephrons and hypertrophy of each nephron.
- Ask-Upmark kidneys have segmented dysplasia, are seen most frequently in association with reflux, and are often the cause of severe hypertension.

The fundamental processes that are essential for the development and progressive enlargement of renal cysts include (1) proliferation of epithelial cells in segments of renal tubule, (2) accumulation of fluid within the expanding tubule segment, and (3) disturbed organization and metabolism of the extracellular matrix (Fig. 118–6).

An imbalance of the secretory and absorptive properties in proliferating epithelial cells leads to a net accumulation of fluid

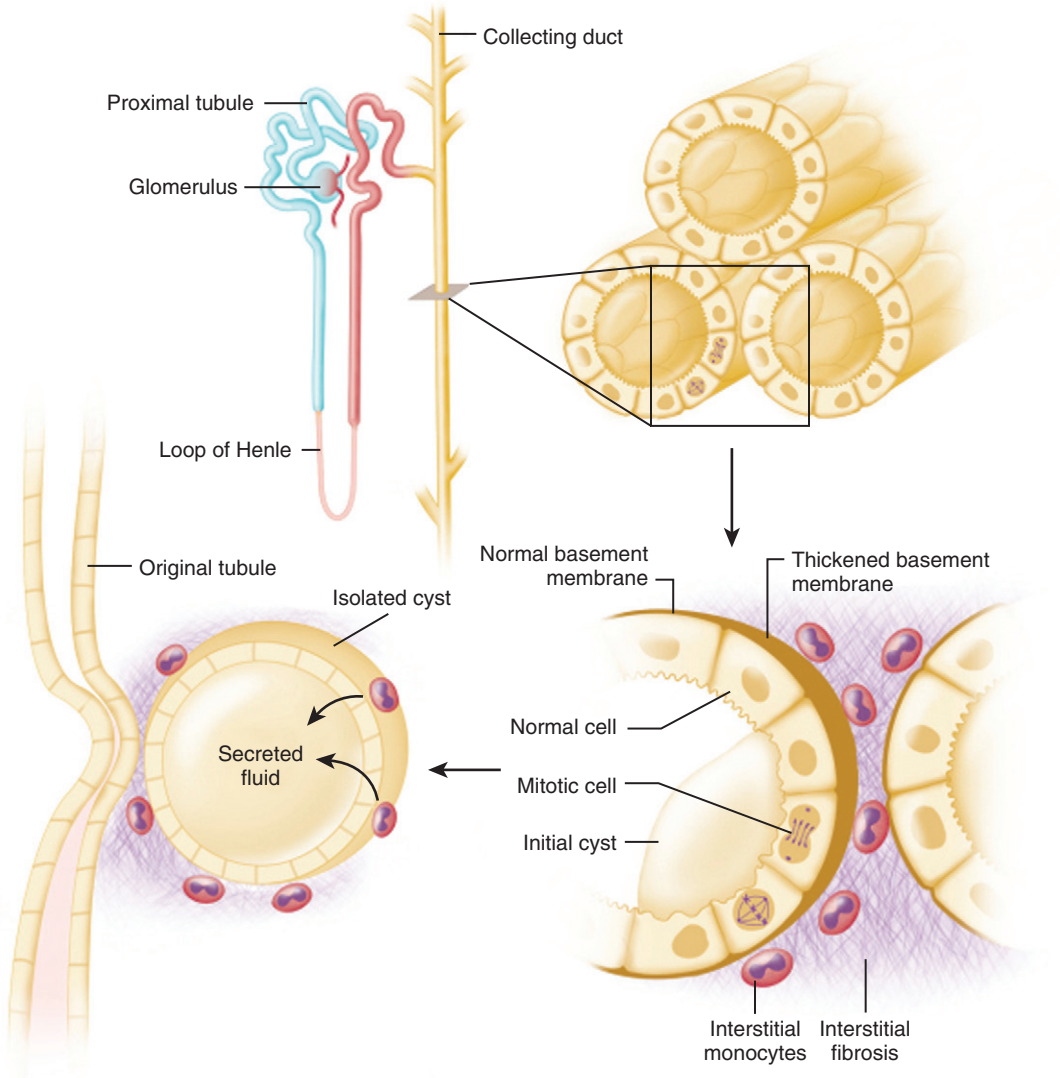

Figure 118–6. Evolution of cysts from renal tubules. Abnormal proliferation of tubule epithelium begins in a single cell after a "second-hit" process disables the function of the normal allele. Repeated cycles of cell proliferation lead to expansion of the tubule wall into a cyst. The cystic epithelium is associated with thickening of the adjacent tubule basement membrane and with an influx of inflammatory cells into the interstitium. The cystic segment eventually separates from the original tubule, and net epithelial fluid secretion contributes to the accumulation of liquid within the cyst cavity. (From Brenner BM, editor. Brenner and Rector's the kidney. 8th ed. Philadelphia: WB Saunders; 2007. p. 1428.)

in otherwise normal renal tubules. Recent evidence indicates that, beyond the loop of Henle, tubule cells have the capacity to secrete solutes and fluid on stimulation with 3′,5′-cyclic adenosine monophosphate (cAMP) (Wallace et al, 2001). This secretory flux operates in competition with the more powerful mechanism by which sodium (Na^+) is absorbed through apical epithelial Na^+ channels (ENaC). Under conditions in which Na^+ absorption is diminished, the net secretion of sodium chloride (NaCl) and fluid occurs.

Abnormalities of the extracellular matrix in and about renal cysts are seen in all cystic disorders. In the early stages of renal cyst development, changes in expression of collagen I and IV, metalloproteinase activators and inhibitors, integrins, and β-catenin may forecast a vital role for extracellular matrix remodeling in the pathogenesis of renal cysts. Recently, a hypomorphic mutation in the mouse laminin α5 gene was found to cause polycystic kidney disease (PKD) (Joly et al, 2006; Shannon et al, 2006).

Until recently, the mechanisms responsible for the abnormal differentiation and functional behavior of the epithelial cells that give rise to the cysts were largely unknown. Evidence now strongly suggests that a long-neglected structure, the primary cilium, is essential in maintaining epithelial cell differentiation. Structural and functional defects in the primary apical cilia of tubular epithelia may have a central role in determining cyst development and the abnormal differentiation and behavior of the cystic epithelium, and in various forms of human and rodent cystic diseases (Torres, 2008).

Cystic kidneys of different etiologies may appear morphologically similar, whereas the same etiologic entity may cause a wide spectrum of renal abnormalities. For example, in ADPKD, tuberous sclerosis, von Hippel-Lindau (VHL) disease, and acquired renal cystic disease (ARCD), the cysts have a hyperplastic lining, sometimes with nodules of hyperplasia or polyps that project into the cyst lumen. However, these hyperplastic conditions are very different from each other. Another example of such similarities is the ectatic collecting ducts seen in two very different clinical entities, autosomal recessive polycystic kidney disease (ARPKD) and medullary sponge kidney.

Classification

In this chapter, the classification of renal cystic disease as outlined in 1987 by the Committee on Classification, Nomenclature, and Terminology of the AAP Section on Urology is used. **The primary distinction is between genetic ("inheritable") and nongenetic ("noninheritable") disease**. Table 118–1 gives an overview of characteristics associated with the various forms cystic disease.

The terms *multicystic* and *polycystic* should not be confused, even though both terms literally mean "many cysts." *Multicystic* typically refers to a dysplastic kidney resulting from aberrant renal development. *Polycystic* refers to renal units that developed in a normal fashion, all of which have no dysplasia and have nephrons throughout the kidney. The term *polycystic kidney disease* traditionally is used in reference to two conditions: ARPKD and ADPKD. Many of the polycystic kidney disease entities progress to renal failure as the nephrons become more diseased. In other conditions, such as tuberous sclerosis and VHL disease, there are hyperplastic cysts, and the individual nephrons are normal. Only occasionally do the nephrons become compressed by the cysts or by associated tumors, and only in such situations does renal failure ensue.

Table 118–1

Cystic Diseases of the Kidney

Inheritable
Autosomal recessive (infantile) polycystic kidney disease
Autosomal dominant (adult) polycystic kidney disease
Juvenile nephronophthisis/medullary cystic disease complex
Juvenile nephronophthisis (autosomal recessive)
Medullary cystic disease (autosomal dominant)
Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
Familial hypoplastic glomerulocystic disease (autosomal dominant)
Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel-Lindau disease)
Noninheritable
Multicystic kidney (multicystic dysplastic kidney)
Benign multilocular cyst (cystic nephroma)
Simple cysts
Medullary sponge kidney
Sporadic glomerulocystic kidney disease
Acquired renal cystic disease
Calyceal diverticulum (pyelogenic cyst)

Among the noninheritable cystic diseases, benign multilocular cysts, cystic renal cell carcinoma, and other variants are considered neoplasms. Medullary sponge kidney is a disease principally of dilated ectatic collecting ducts, with cysts playing a lesser role, although the size of the ducts by definition makes them cysts. The nephrons initially are normal.

Inheritable Cystic Disease

Genetic (inheritable) cystic diseases can be classified based on their mode of transmission: autosomal dominant, autosomal recessive, X-linked, among others. Some of these disorders are caused by a single gene defect, some by an X-linked gene defect, and others by chromosomal defects. The modes of inheritance of these diseases and the specific gene or gene locus, where identified, are summarized in Table 118–2.

AUTOSOMAL RECESSIVE (INFANTILE) POLYCYSTIC KIDNEY DISEASE

Autosomal recessive polycystic kidney disease (ARPKD) is typified by relatively rapid, symmetrical, and bilateral enlargement of the kidneys in infants secondary to collecting duct cysts. It is invariably associated with some degree of congenital hepatic fibrosis (Zerres et al, 1988; Guay-Woodford and Desmond, 2003; MacRae Dell and Avner, 2003). ARPKD has been referred to as the "infantile" form in the past; however, the disease can present in adolescents and young adults, although significantly less frequently. **ARPKD has a spectrum of severity, with the most severe forms appearing earliest in life. If it is not apparent at birth, the disease will become apparent later in childhood (up to age 13 years or, rarely, up to age 20 years).**

The reported incidence of ARPKD varies from 1 in 10,000 to 50,000 live births (Zerres et al, 1988; Kaplan et al, 1989a). However, as many as 50% of affected newborns die in the first few days of life, making for a significantly lower incidence among children who live for at least 1 year. Of those infants who survive the neonatal period, approximately 50% are alive at 10 years of age (Kaplan et al, 1989a).

Table 118–2

Characteristics of Major Inheritable and Noninheritable Cystic Kidney Diseases

Inheritable

DISEASE ENTITY	CHROMOSOMAL DEFECT	RENAL FINDINGS	EXTRARENAL MANIFESTATIONS
Autosomal recessive polycystic kidney disease (ARPKD)	Chromosome 6	In newborn usually large, homogeneous, echogenic kidneys	Congenital hepatic fibrosis; biliary dysgenesis
Autosomal dominant polycystic kidney disease (ADPKD)	*PKD1:* chromosome 16 *PKD2:* chromosome 4 *PKD3;* not mapped	Renal cysts scattered throughout parenchyma; large kidneys	Diverticulitis; liver, spleen, pancreatic cysts; mitral valve prolapse; intracranial (berry) aneurysms
Juvenile nephronophthisis/ medullary cystic disease complex	Chromosome 2; not mapped	Cysts of corticomedullary junction; develop after onset of renal failure; always thickened tubular basement membrane	Retinitis pigmentosa (16%; also known as Senior-Løken syndrome); rarely skeletal abnormalities, hepatic fibrosis, Bardet-Biedl syndrome, ocular motor apraxia, and other neurologic defects
Juvenile nephronophthisis (autosomal recessive)		Cysts of corticomedullary junction; develop before onset of renal failure; tubular basement membrane may NOT be thickened	None
Medullary cystic disease (autosomal dominant)			
Tuberous sclerosis (autosomal dominant)	*TSC1:* Chromosome 9 *TSC2:* Chromosome 16	Cysts and angiomyolipomas throughout kidney; cysts even present in utero; 3% incidence of RCC	Adenoma sebaceum; epilepsy; mental retardation; cranial tumors
von Hippel-Lindau disease (autosomal dominant)	Chromosome 3	Cysts, adenomas, and clear cell RCC (35%-38% of cases)	Cerebellar hemangioblastomas; retinal angiomas; pheochromocytomas; cysts of pancreas and epididymis

Noninheritable

DISEASE ENTITY	RENAL FINDINGS	EXTRARENAL MANIFESTATIONS
Multicystic dysplastic kidney	Renal maldevelopment with diffuse cysts and remnants of early metanephros; minimal, if any, nephron development; most frequent renal cystic disease in newborns	Unusual
Benign multilocular cyst	Benign cystic neoplasm of the kidney; remainder of kidney has normal nephrons that may be compromised by growing mass; present more often in males when less than 4 years of age and females when greater than 30 years of age	None
Simple cysts	Single or multiple cysts; normal nephrons throughout kidney; very common in normal kidneys with increasing age	None
Medullary sponge kidney	Ectatic collecting ducts; nephrons usually normal	None
Acquired renal cystic disease	Diffuse cysts; adenomas; occasionally RCC; increases with duration of ESRD	None

ESRD, end-stage renal disease; RCC, renal cell carcinoma.

Genetics

Once the diagnosis of ARPKD is strongly suspected, referral for genetic evaluation and counseling is appropriate. A detailed history should be taken of at least three generations. **Because the disease is transmitted as an autosomal recessive trait, siblings of either sex have a 1 in 4 chance of being affected.**

Despite the clinical variability of ARPKD, it appears that only mutations of a single gene, named *PKHD1* and located on chromosome 6 (6p12), are responsible for the disease. The gene produces a protein called fibrocystin (also known as polyductin) (Onuchic et al, 2002; Ward et al, 2002). This protein is a member of a larger family of proteins involved in regulation of cell proliferation and of cellular adhesion and repulsion.

Clinical Features

Affected children typically present in utero with enlarged, echogenic kidneys. Oligohydramnios is common because of the lack of normal urine production by the fetus. The infant often displays Potter facies and deformities of the limbs and may have respiratory distress as a consequence of pulmonary hypoplasia. The affected newborn usually has enormous, kidney-shaped, nonbosselated flank masses that are hard and do not transilluminate. In some cases, the kidneys are large enough to impede delivery. The infant's serum creatinine and BUN concentrations are those of the mother's at birth but soon begin to rise. Thirty to 50 percent of the affected individuals die shortly after birth as a result of uremia or respiratory failure (Kaplan et al, 1989c; Capisonda et al, 2003; Guay-Woodford, 2003). The earlier the age at which the disease is identified, the more severe the disease. **No matter what the severity of the renal disease, all patients with ARPKD have liver involvement in the form of congenital hepatic fibrosis and vary in the degree of biliary ectasia and periportal fibrosis** (Habib and Bois, 1973; Kissane and Smith, 1975).

Patients who survive the neonatal period have a milder form of the disease and are likely to survive into adulthood. Some diagnosed as neonates can live beyond age 3 or 4 years before going into renal failure (Cole et al, 1987; Avni et al, 2002).

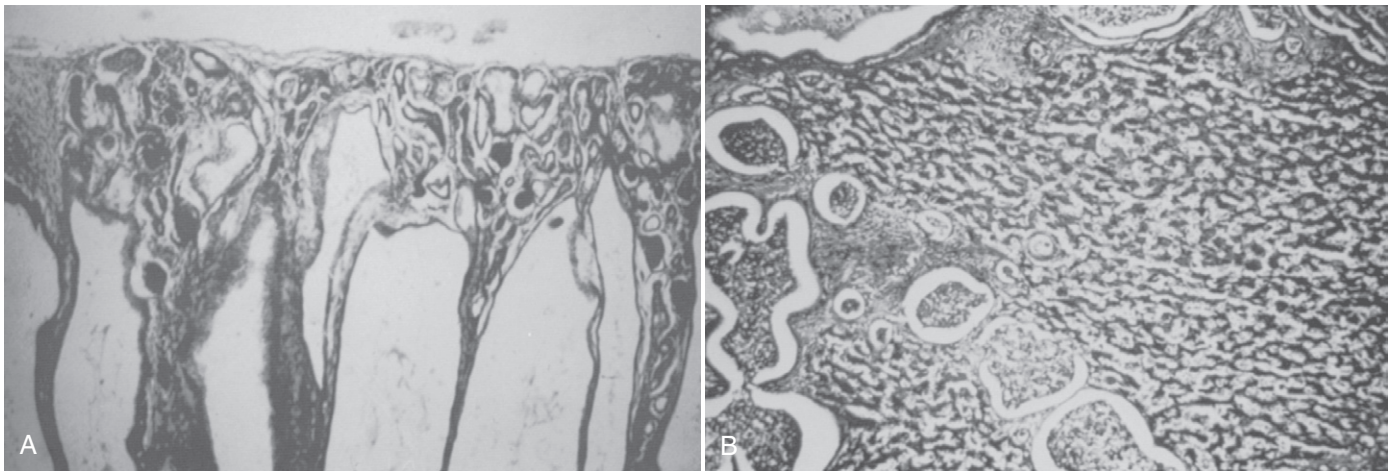

Figure 118–7. Newborn with abdominal mass and pulmonary hypoplasia. Neither parent had a history of renal cysts. **A,** Renal histology demonstrates dilated ducts radiating out to the periphery of the kidney. **B,** On liver histology, ectatic biliary ducts are seen in the left half of the figure, and periportal fibrosis is seen at the upper edge. These findings confirm the diagnosis of autosomal recessive polycystic disease.

Hypertension and renal insufficiency are the major manifestations in surviving children, with liver disease becoming more prevalent in older patients.

Patients whose disease appears later in life develop renal failure and hypertension more slowly. In general, their clinical problems are the consequence of liver disease rather than the renal disease, with hepatic fibrosis leading to portal hypertension, esophageal varices, and hepatosplenomegaly. Hepatocellular function is rarely abnormal, with liver enzymes typically remaining normal. The kidneys in these patients are often normal in appearance.

No association of ARPKD with renal neoplasms has been reported to date.

Histopathology

The kidneys are symmetrically enlarged (up to 20 times their normal size) and retain a reniform configuration. The parenchyma exhibits small subcapsular cysts, representing generalized fusiform dilations of the collecting tubules radiating from the medulla to the cortex with their long axis perpendicular to the renal surface (Bisceglia et al, 2006). Almost 100% of collecting ducts are affected in the most severe cases. The cortex is crowded with minute cysts (Fig. 118–7A). The renal pedicle is normal, as are the renal pelvis and ureter.

ARPKD affects both the kidneys and the liver in approximately inverse proportions (Torres, 2008). The disease may be viewed as a spectrum ranging from severe renal disease and mild liver changes at one extreme to mild renal damage and severe liver disease at the other. The form with severe renal disease is the most common and the one typically seen at or near the time of birth. The form with less severe renal disease and more significant liver damage is present in older children. **All children with ARPKD have lesions in the periportal areas of the liver** (Habib and Bois, 1973; Kissane and Smith, 1975) (Fig. 118–7B).

Evaluation

The diagnosis may be suspected from in utero ultrasound examination and may be associated with oligohydramnios, a finding secondary to low urinary output. **In both fetus and newborn, ultrasonography identifies bilateral, very enlarged, diffusely echogenic kidneys, especially when compared with the echogenicity of the liver** (Fig. 118–8A)**. The increased echogenicity is due to the presence of numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces. Compared with normal newborn kidneys, in ARPKD, the pyramids are hyperechogenic because they blend in with the rest of the kidney, and the kidneys typically have a homogeneous appearance** (see Fig. 118–8A). In ADPKD, the cysts, if apparent in newborns, are usually diffuse and large (Fig. 118–8B). Also included in the differential diagnosis is severe bilateral hydronephrosis (the kidneys are enlarged with hypoechogenic calyces), multicystic kidney (hypoechogenic cysts lie within a nonreniform mass that has very little parenchyma), sporadic glomerulocystic kidney disease, bilateral mesoblastic nephroma, Wilms tumor, and bilateral renal vein thrombosis. If the diagnosis is in doubt, computed tomography is valuable because it is more sensitive to inhomogeneity (and therefore to tumor) within abdominal masses.

Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD. Occasionally, a newborn with severe ADPKD can also have enlarged, homogeneously hyperechogenic kidneys. Age at onset can overlap, and typically, when ADPKD manifests at birth, cysts are apparent on the sonographic image. Macrocysts are rare in newborns with ARPKD but do increase in frequency as the child gets older, sometimes producing an appearance similar to that of the dominant disease. Cysts less than 1 cm appear more often than large cysts (Avni et al, 2002) (Fig. 118–9). Hepatic fibrosis can rarely occur in patients with ADPKD, as can brain aneurysms with ARPKD (Cobben et al, 1990; Neumann et al, 1999). The correct diagnosis of ARPKD depends on the overall clinical data: positive family history with a recessive mode of inheritance, a positive liver biopsy, and the lack of the extrarenal malformations often associated with other renal cystic diseases.

Treatment

No cure has been found for ARPKD. Respiratory care can ease or extend the child's life. Severely affected neonates may require unilateral or bilateral nephrectomy, because of respiratory and nutritional compromise. Patients who survive may require treatment for hypertension, congestive heart failure, and renal and

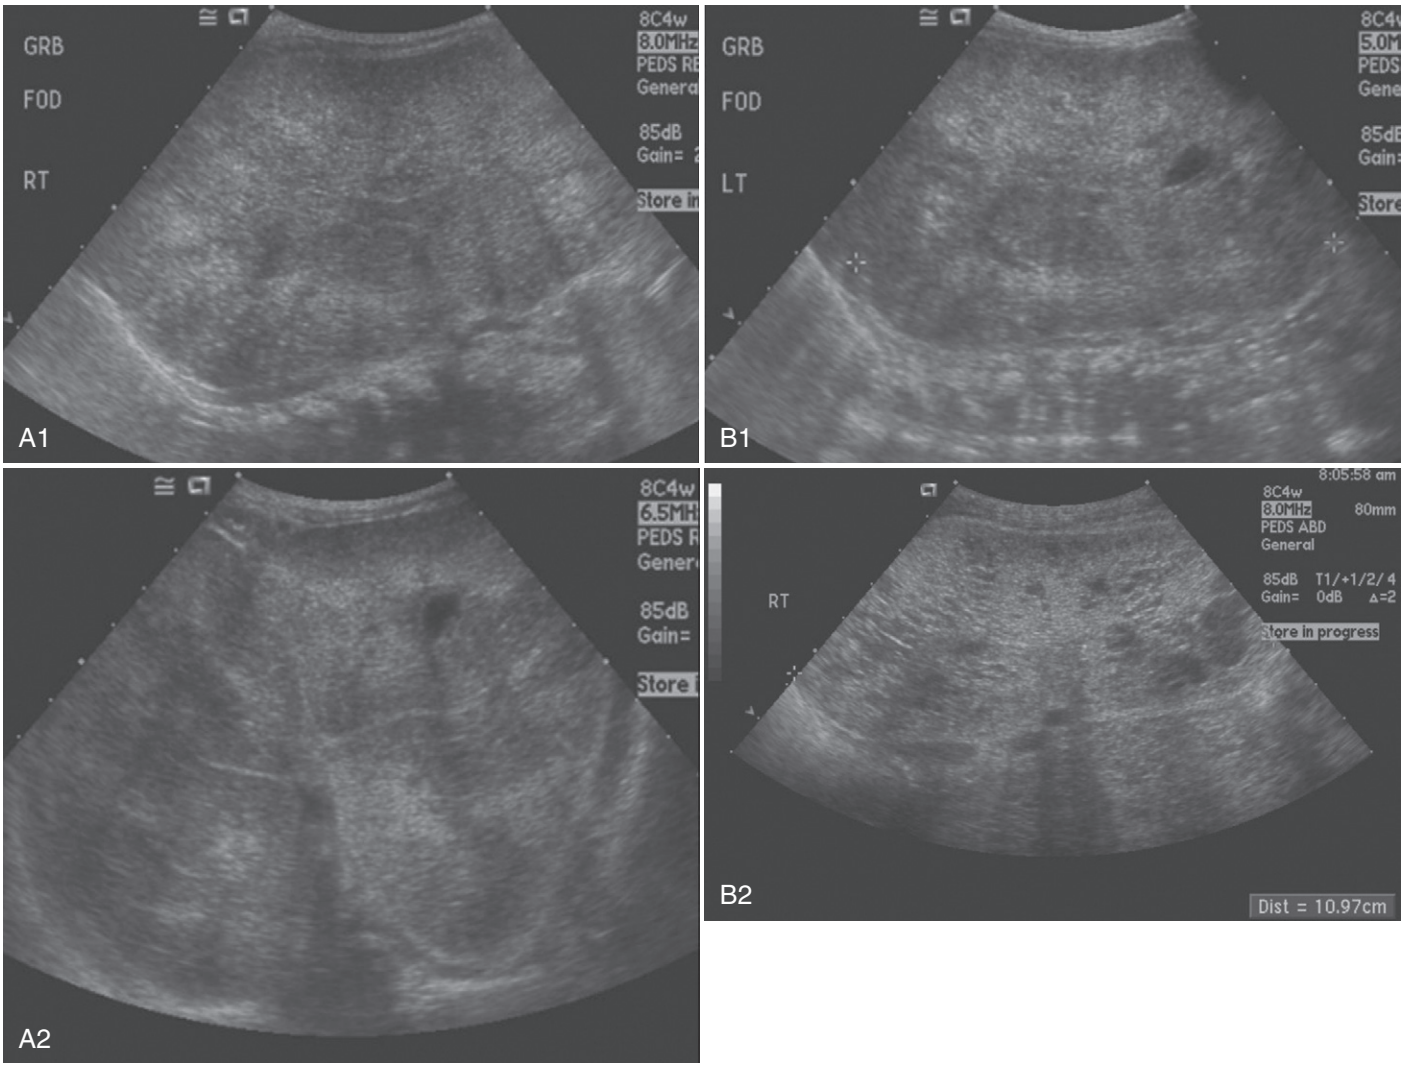

Figure 118–8. Ultrasonographic appearance of the kidneys in neonates with autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD) can be similar. **A1** and **A2,** Newborn with ARPKD. **A1,** Note the large size and hyperechogenic, homogeneous appearance of the renal parenchyma. **A2** is a cross-sectional cut of the baby's abdomen showing both kidneys to be quite large and occupying a large portion of the abdominal cavity. **B1** and **B2,** Newborn with ADPKD. Again note the abnormal renal architecture and the hyperechogenic appearance of the kidneys. The parenchyma consists of multiple tiny cysts, with some being slightly larger than others. (Courtesy of Marta Hernanz-Schulman, MD.)

hepatic failure. Portal hypertension may be dealt with by decompressive procedures such as a splenorenal shunt. Esophageal varices may be managed, at least temporarily, by gastric section and reanastomosis. Endoscopic sclerotherapy is widely employed in pediatric and adults with bleeding varices. Hemodialysis and renal transplantation must eventually be considered in many patients.

AUTOSOMAL DOMINANT (ADULT) POLYCYSTIC KIDNEY DISEASE

Autosomal dominant polycystic kidney disease is by far the most common inheritable form of renal cystic disease, with an incidence of approximately 1 in 400 to 1000 live births (Iglesias et al, 1983; Grantham, 1996). It is an important cause of renal failure, accounting for 7% to 15% of patients who receive hemodialysis (Hildebrandt, 1995; Grantham, 1996; Wilson, 2004). The trait theoretically has a 100% penetrance, and, on average, because it is transmitted in an autosomal dominant fashion, 50% of an affected individual's offspring will likewise be affected. Although a positive family history is one of the major criteria for the diagnosis of ADPKD, 10% of cases occur sporadically. Ninety-six percent of affected persons will manifest the disease clinically by age 90 years (Gabow, 1991).

Although most cases are identified between the fourth and fifth decades of life, the condition has been reported in newborns and infants (Proesmans et al, 1982). All affected individuals manifest the disease (although not necessarily symptomatically) if they live long enough, but renal failure is seldom seen before the age of 40 years, unless the disease manifests during infancy, in which case it is much more aggressive.

A number of associated anomalies are common, including cysts of the liver, pancreas, spleen, and lungs; aneurysms of the circle of Willis (berry aneurysms); colonic diverticula; aortic aneurysms; and mitral valve prolapse (Table 118–3).

Table 118–3

Comparison of Autosomal Recessive and Autosomal Dominant Polycystic Kidney Disease

	AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE	AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE
Gene defect	Chromosome 6	Chromosome 4 and 16
Incidence	1: 5000-40,000	1: 500-1100
Usual age at clinical presentation	Perinatal	Third to fifth decades
Typical ultrasonographic appearance of kidneys	Symmetrically enlarged, homogeneous, hyperechogenic	Large, cystic kidneys, sometimes asymmetrical
Histology	Collecting duct ectasia; cysts derived principally from collecting duct	Microcysts and macrocysts derived from the entire nephron
Liver	Always with congenital hepatic fibrosis but of varying severity	Cysts, mostly in adults
Other organ system(s) involvement	None	Intracranial (berry) aneurysms, colonic diverticuli; mitral valve prolapse; cysts of other organs (seminal vesicle, arachnoid membrane, pancreas)

Key Points: Autosomal Recessive Polycystic Kidney Disease

- ARPKD is secondary to a mutation of the *PKHD1* gene on chromosome 6.
- The severe form presents in utero or in infancy; milder cases can present later in childhood and rarely into the early 20s.
- All affected individuals have some degree of congenital hepatic fibrosis.
- When it manifests early, it is associated most often with very large kidneys that are homogeneously hyperechogenic.
- Discrete cysts appear more often as the child gets older.
- Renal ultrasonography reveals bilateral, very enlarged, diffusely echogenic kidneys, and the increased echogenicity is due to the presence of numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces.
- Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD.

Genetics

There are two major genetic forms of ADPKD caused by mutation in the genes *PDK1* and *PDK2* (Reeders et al, 1985; Breuning et al, 1987; Ryynanen et al, 1987; Pieke et al, 1989). *PDK1* has been localized to the short arm of chromosome 16, with its gene product being polycystin-1. Mutations in the *PDK1* gene account for 85% of ADPKD cases. These patients typically have a more rapidly progressive form of the disease, with cysts usually developing by the age of 20 years (64% of children have cysts by the age of 10 years and 90% by the age of 20 years) and ESRD occurring in their 50s (Chakraborty and McHugh, 2005). The *PKD2* gene has been mapped to the long arm of chromosome 4 (Peters et al, 1992), and it encodes the protein polycystin 2. *PDK2* mutations account for about 15% of ADPKD cases, and in these patients, the disease progresses more slowly. ESRD usually does not occur until these patients are in their 70s (Hateboer et al, 1999). The presence of a third locus *(PKD3)* is now accepted as the cause of disease in a very small percentage of patients who have been found to have neither a *PKD1* nor a *PKD2* gene defect (Dauost et al, 1993). **When either the *PKD1* or the *PKD2* gene is abnormal, cystic kidneys can develop.** Because defects of *PKD1* and *PKD2* manifest similarly, it has been suggested that the gene product of each is involved in the same pathway and that an abnormality of either product results in similar manifestations of the disease (Qian et al, 1996).

Every cell of the nephron and collecting duct has the *PDK1* or *PDK2* mutation; however, only 1% to 2% of these glomerular units are affected by cyst formation. Only those nephrons that undergo a disruption of a second allele undergo cystic enlargement. This is the "second hit" of the Knudson theory, which has been proposed to explain the focal nature of the cysts (Knudson, 1991).

Occasionally, the classic ADPKD phenotype is seen in conjunction with tuberous sclerosis. This association is a classic example of a "contiguous gene syndrome," which is a disorder due to deletion of multiple gene loci that are adjacent to one another. Contiguous gene syndromes are characterized by multiple, apparently unrelated, clinical features caused by deletion of the multiple adjacent genes. Due to the fact that the *PDK1* gene is immediately adjacent to the *TSC2* gene (the most important gene in tuberous sclerosis) on chromosome 16, large deletions in this area can involve both the *PDK1* and *TSC2* genes. Thus these patients have the classic features of tuberous sclerosis in addition to the renal cystic phenotype of ADPKD.

Pathogenesis

The PDK1 and PDK2 proteins, polycystin 1 (PC1) and polycystin 2 (PC2), are transmembrane proteins that in all likelihood form a functional complex. When working properly, PC1 and PC2 inhibit cell proliferation by several pathways. Polycystin 1 functions as a mechanoreceptor located on the primary cilium of renal tubular cells. These cilia project from the surface of the cell into the lumen of the ducts and tubules. Mutations that block the assembly of these cilia are known to cause many cystic diseases of the kidney. The products of the *ADPKD, ARPKD,* and nephronophthisis genes are at least partially localized to these primary cilia. Polycystin 1 is linked to polycystin 2, which contains a calcium (Ca^{++}) channel. When the mechanoreceptor of polycystin 1 is stimulated by calcium-containing urine flowing through the tubule, the calcium channel of polycystin 2 opens and calcium enters the cell (Nauli et al, 2003; Braun, 2009). This process regulates the proliferative state of the renal tubular cells through a

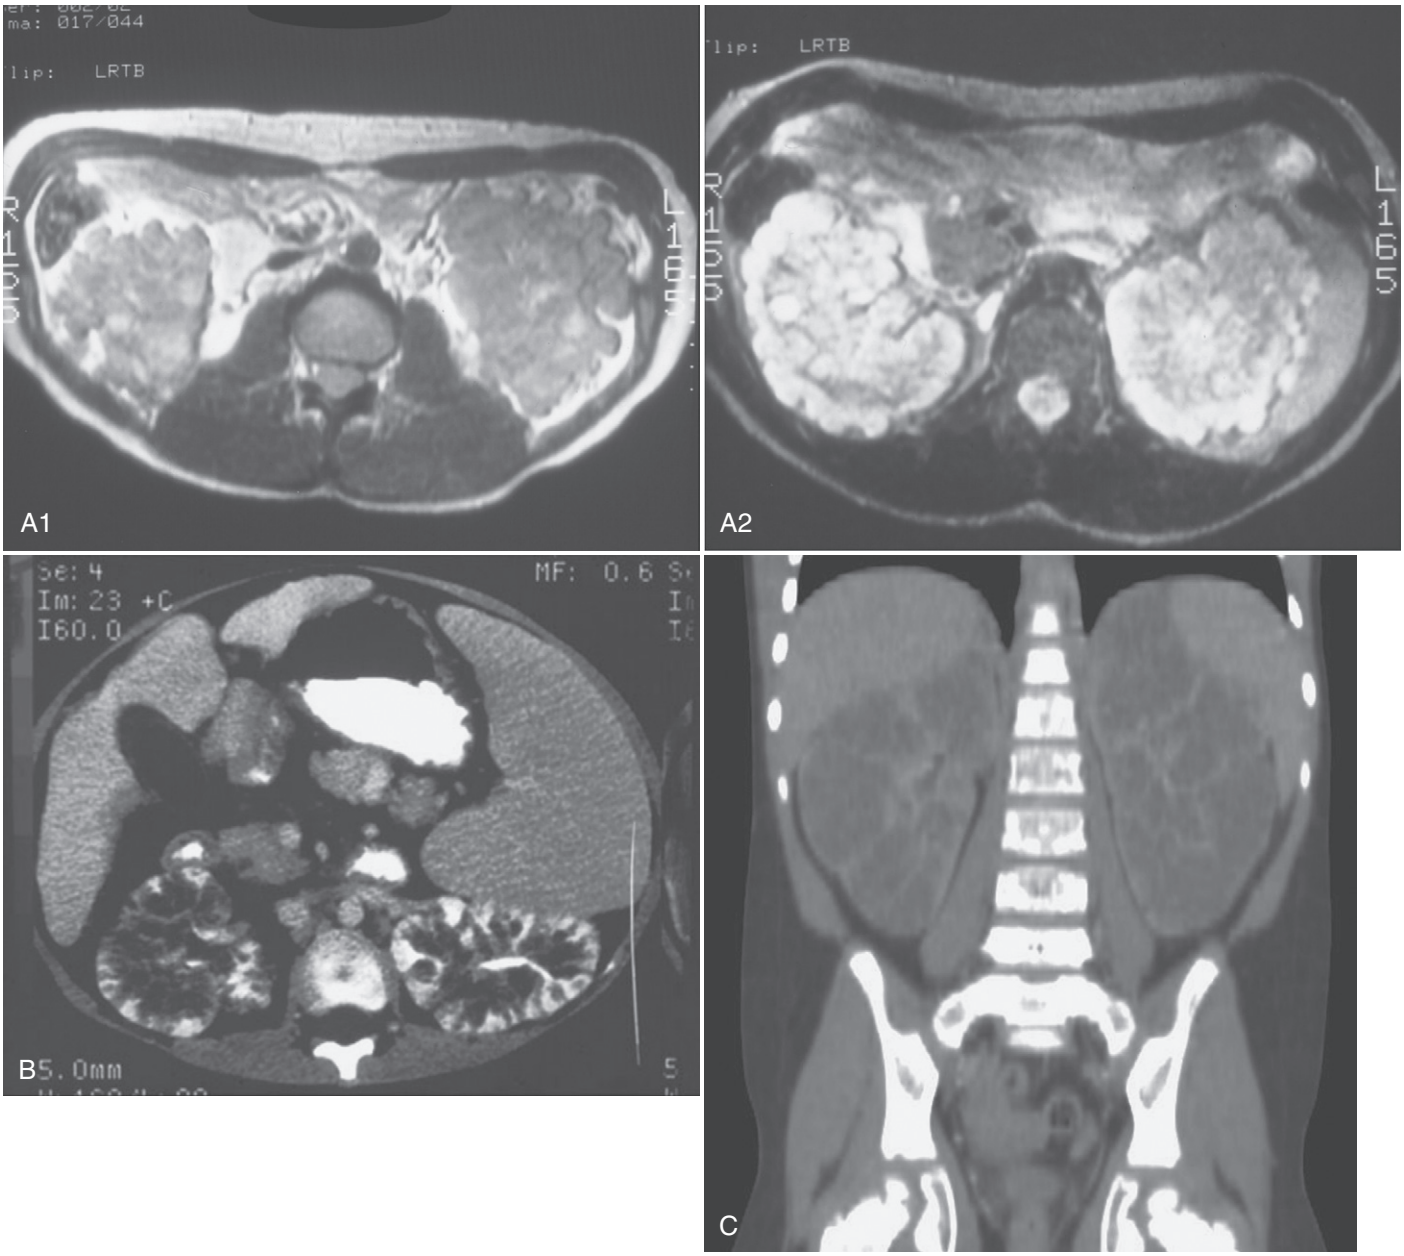

Figure 118–9. **A1** and **A2**, MR images of an 8-month-old child with autosomal recessive polycystic kidney disease (ARPKD) demonstrating multiple renal cysts. **A1**, On T1-weighted image, fluid content of cysts appears dark. **A2**, On T2-weighted image, the fluid content appears white. **B**, CT scan of a child with ARPKD. Horizontal cuts showing contrast puddling in collecting ducts. **C**, Coronal cut. Note the kidneys are enlarged, and the enhancing renal parenchyma is effaced by nonenhancing cysts and represents the progression/normal history of the disorder. (**A**, Courtesy of Walter Berdon, MD. **B**, Courtesy of Marta Hernanz-Schulman, MD.)

variety of signaling pathways (cAMP, extracellularly regulated kinase [ERK], mammalian target of rapamycin [mTOR], etc.). The cilia likely serve as organization centers for this signal transduction (Pazour, 2004).

In ADPKD, the polycystins do not function properly, and these proliferative pathways are unopposed and cyst formation occurs to varying degrees.

Increased levels of cAMP have been noted in multiple animal models of ADPKD, and biochemical processes that alter cAMP appear to affect the presence and size of renal cysts. For example, cAMP is broken down by phosphodiesterases. Caffeine and methylxanthine products, such as theophylline, interfere with phosphodiesterase activity, raise cAMP in epithelial cell cultures from patients with ADPKD, and increase cyst formation in canine kidney cell cultures (Mangoo-Karim et al, 1989; Belibi et al, 2002). Upregulation of the vasopressin V2 receptor has also been shown to increase cAMP levels. Vasopressin receptor antagonists have been shown to decrease cAMP and ERK, to prevent or reduce renal cysts, and to preserve renal function (Gattone et al, 2003; Wang et al, 2005).

Clinical Features

Phenotypes associated with ADPKD are highly variable in penetrance. This variability related to the severity of renal disease can range from fetal demise and neonatal death to adequate renal

function into old age. Characteristics of the associated liver disease and extrarenal manifestations can also be quite variable. *PDK1* and *PDK2* gene mutations are obviously critical, but intrafamilial variability also indicate that genetic background and environmental factors can also affect ultimate clinical expression of the disease (Rossetti and Harris, 2007).

Typically, signs or symptoms first occur between the ages of 30 and 50 years (Glassberg et al, 1981). These include microscopic and gross hematuria, flank pain, gastrointestinal symptoms (perhaps secondary to renomegaly or associated colonic diverticula), renal colic (secondary either to clots or stones), and hypertension. Microscopic or gross hematuria is seen in 50% of patients, and, in 19% to 35%, it is the presenting symptom (Milutinovic et al, 1984; Delaney et al, 1985; Zeier et al, 1988; Gabow et al, 1992). Because patients with ADPKD have increased renal mass, erythropoietin levels are increased, making anemia unusual even when ESRD is present (Gabow, 1993).

Pain (flank and/or abdominal) is the most common presenting symptom in adults. This results from a number of possible factors: mass effect (cysts impinging on abdominal wall or neighboring organs), bleeding into the cysts, urinary tract infection (including infected cysts), and nephrolithiasis. Twenty to 30 percent of patients with ADPKD develop stones (Fick et al, 1994), and these are treated by conservative means if possible (i.e., urine alkalinization, spontaneous stone passage, extracorporeal shock wave lithotripsy). Uric acid stones and calcium oxalate stones are equally prevalent. The finding of hydronephrosis, which helps make the diagnosis of stones, may not be as useful in ADPKD patients because of the number of cysts camouflaging the findings (Choyke et al, 1995). Urinary tract infections are more frequent in female patients. Cyst aspiration for both diagnostic and therapeutic reasons should be considered in the setting of suspected cyst infection.

As blood pressure screening has become more widespread, hypertension has become a very common form of presentation (Zeier et al, 1988). Hypertension is present in roughly 50% of patients 20 to 35 years old having ADPKD with normal renal function. Virtually 100% of patients with ESRD will have hypertension (Kelleher et al, 2004). The hypertension seems to be renin mediated, secondary to stretching of the intrarenal vessels around cysts, causing distal ischemia (Gabow, 1993). Diagnosis and treatment of this hypertension is critical to slow the progression of renal failure, as well as to decrease morbidity and mortality from heart disease and cerebral aneurysms.

The development of renal failure is highly variable. Renal function is usually maintained, despite increasingly rapid cyst growth, until the fourth to sixth decade of life. Risk factors for earlier onset of ESRD include *PKD1* gene mutation, male gender, first episode of hematuria before age 30 years, onset of hypertension before age 35 years, hyperlipidemia, and sickle cell trait (Yium et al, 1994; Johnson and Gabow, 1997). There is a strong relationship between the decline in renal function and the size of the kidneys and cyst volumes. As the cysts, and thus the kidneys, become larger, the renal function declines proportionately (Gabow et al, 1990a). Hypertension and vascular remodeling secondary to cyst expansion also contribute to progressive renal failure.

Extrarenal Manifestations

Hepatic cysts, usually identified incidentally by ultrasonography, are the most common extrarenal manifestation of ADPKD. These cysts are associated with *PKD1* and non-*PKD1* genotypes. They are rare in children, and their frequency increases with age. They are present in virtually all ADPKD patients by the age of 50 years (Bae et al, 2006). Hepatic cysts are more prevalent and their size greater in females (Fick et al, 1994). Several studies have shown an estrogen effect on hepatic cyst growth (Gabow et al, 1990b; Sherstha et al, 1997). Hepatic cysts are usually asymptomatic but can occasionally cause symptoms due to mass effect or from complicating infection or hemorrhage. In rare instances, enlargement of hepatic cysts leads to portal hypertension and bleeding esophageal varices (Campbell et al, 1958). When secondary portal hypertension appears, differentiating ADPKD from ARPKD can be difficult. In ARPKD, portal hypertension is seen much more frequently and is always secondary to congenital hepatic fibrosis. However, congenital hepatic fibrosis, on very rare occasions, may accompany ADPKD as well, particularly when the diagnosis is made perinatally.

Intracranial aneurysms (ICAs)—predominately aneurysms of the circle of Willis (berry aneurysm)—occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages (Hartnett and Bennett, 1976; Grantham, 1979; Wakabayashi et al, 1983; Sedman and Gabow, 1984; Ryu, 1990). The most common symptom of subarachnoid hemorrhage is the sudden onset of a severe headache, frequently associated with nausea and vomiting. When this occurs, immediate medical evaluation is obviously imperative. Morbidity and mortality from these aneurysms are strongly influenced by positive family history and the *PDK1* genotype. Now, with MRI, even small berry aneurysms can be detected. These aneurysms, when diagnosed, average only 6.1 mm. Although small aneurysms (1 cm) have a lower risk of rupture, patients with small aneurysms have a greater risk of rupture when there is a positive family history of ruptured ICAs or the presence of ADPKD (Huston et al, 1993). Control of hypertension is critical to minimize the risk of aneurysm rupture. **In some patients with ADPKD, hemorrhage follows the rupture of *intracerebral* arteries, which is the usual type of intracranial hemorrhage seen in patients with hypertension who do not have ADPKD.**

Cysts may also occur in the seminal vesicles (40%), arachnoid membrane (8%), and pancreas (5%). Seminal vesicle cysts rarely cause infertility; however, many of these men may have problems with sperm motility. Arachnoid membrane and pancreatic cysts are typically asymptomatic. Other abnormalities associated with ADPKD are mitral valve prolapse and colonic diverticulosis (Scheff et al, 1980; Hossack et al, 1986; Kupin et al, 1987). Patients who have diverticulosis are more likely to have hepatic cysts and symptomatic berry aneurysms (Kupin et al, 1987).

Association with Renal Cell Carcinoma

The incidence of renal adenomas is almost as high in ADPKD as in ARCD associated with ESRD (i.e., one in four to five patients). However, whereas ESRD is associated with an increased incidence of renal cell carcinoma (RCC), especially when associated with ARCD (3 to 6 times the incidence seen in the general population), **the incidence of RCC in patients with ADPKD is no higher than that in the general population**. However, there are certain findings considered typical of a predisposition to RCC that are seen more frequently in patients with ADPKD than in the general population. For example, RCC in ADPKD is often diagnosed at a younger age, is more often concurrently bilateral (12% vs. 1% to 5% in the general population), multicentric (28% vs. 6%), and sarcomatoid in type (33% vs. 1% to 5%) (Keith et al, 1994). The diagnosis of RCC in the context of

ADPKD can be quite difficult, because tumor may be masked by the complex cystic appearance of the kidney. In addition, cystic hemorrhage, degenerating blood clots, proteinaceous debris, and infection can also complicate the diagnosis.

Histopathology

ADPKD kidneys typically maintain their reniform shape, and their size can range from minimally enlarged in early disease to massive enlargement in more advanced disease. Both kidneys are usually equally affected, and the cysts range from a few millimeters to a few centimeters in diameter and appear diffusely throughout the cortex and medulla with communications at various points along the nephron (Kissane, 1974). The cysts appear to begin as focal tubular outpouchings, and, as they enlarge, they usually become detached from their tubule of origin. The first pathologic finding in fetuses is focal tubular dilatation, which may occur anywhere along the nephron (Choyke et al, 1995) (Fig. 118–10).

Epithelial hyperplasia or even adenoma formation in the cyst wall is common, and the basement membrane of the wall is thickened. Arteriosclerosis is present in more than 70% of patients with preterminal or terminal renal failure; and interstitial fibrosis, with or without infiltrates, is common (Zeier et al, 1988). This fibrosis may be secondary to infection or to an inflammatory reaction set off by spontaneously rupturing cysts.

Evaluation

To make the diagnosis, it is important to have at least three generations of the patient's family history. Questions should be asked about renal disease, hypertension, and strokes. Patients and families should be counseled before any imaging or other testing is undertaken. Genetic testing can be used when the imaging results are equivocal and when a definite diagnosis is required. Benefits of testing include making a diagnosis that may affect family planning, early detection and treatment of disease complications, and selection of genetically unaffected family members for living donor–related renal transplantation. Disadvantages to testing include discrimination in terms of insurability and employment associated with a positive diagnosis, as well as the psychologic stress of impending organ failure.

Abdominal ultrasonography may reveal renal cysts (Fig. 118–11) as well as cysts in other organs**. Ultrasonographic diagnostic criteria for individuals at 50% risk for the disease include at least two unilateral or bilateral cysts in individuals younger than 30 years of age, two cysts in each kidney in individuals 30 to 59 years of age, and four cysts in each kidney in individuals 60 years of age or older** (Ravine et al, 1994). The sensitivity of these criteria is nearly 100% for individuals 30 years or older and for younger individuals with *PKD1* mutations but only 67% for individuals with *PKD2* mutations younger than 30 years (Nicolau et al, 1999). When there is no family history to support a diagnosis of ADPKD, a presumptive diagnosis can be made if bilateral renal cysts are present and two or more of the following symptoms are present as well: bilateral renal enlargement, three or more hepatic cysts, cerebral artery aneurysm, and a solitary cyst of the arachnoid, pineal gland, pancreas, or spleen (Grantham, 1993).

CT or MRI (or both) may be helpful in some cases and often is superior to ultrasonography for detecting cysts in organs other than the kidney (Fig. 118–12A). CT is helpful in making the diagnosis of hemorrhage within a cyst. More acute hemorrhage has a higher density (50 to 90 Hounsfield units [HU]) than old hemorrhage (Choyke et al, 1995). MRI also may be helpful, particularly in patients with compromised renal function, because no contrast agent is needed (Fig. 118–12B).

When ADPKD is manifested in utero or in infancy, 50% of affected kidneys are large with identifiable macrocysts (Pretorius et al, 1987). However, the kidneys may appear identical to those

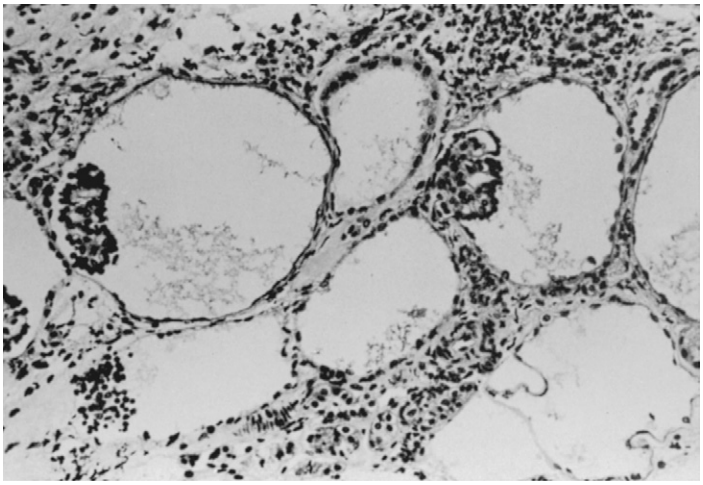

Figure 118–10. Glomerular cysts with a pattern compatible with autosomal dominant polycystic kidney disease in early childhood (190×). Figure 118–12. **A,** CT scan of an adult male patient with autosomal dominant polycystic kidney disease (ADPKD). Bilateral renal cysts are seen in enlarged kidneys with calcification. Large asymptomatic cysts are seen throughout the liver as well. **B** and **C,** A 55-year-old woman with ADPKD. Patient has had a left nephrectomy for pain. Right renal and hepatic cysts are seen on both T1- and T2-weighted coronal images. **B,** T1-weighted image demonstrates renal cysts with low and high (white) signals. High-signal cysts correlate with intracystic hemorrhage. **C,** On T2 weighting, hemorrhagic cysts are dark, and cysts without hemorrhage are white. On T2 weighting with the patient in the supine position, cysts with blood tend to get darker more posteriorly *(arrow)*. (Courtesy of H. Zinn, MD.)

seen in ARPKD, having no apparent macrocysts and showing only enlargement and homogeneous hyperechoic features. In such situations, one must look for a parent with ADPKD to confirm the diagnosis. With time, cysts often larger than 1 cm will develop in most children (Avni et al, 2002).

Treatment and Prognosis

Current therapy is directed toward lessening the complications of ADPKD and delaying the onset of ESRD. There is no known cure at this time. More than 60% of patients with ADPKD who do not yet have renal impairment have hypertension (Gabow et al, 1984), which can worsen renal function, cause cardiac disease, and predispose the patient to intracranial hemorrhage. **The complications of ADPKD can be reduced significantly by controlling the blood pressure**. There is no proven antihypertensive agent of choice; however, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor antagonists would seem to be logical first-line choices.

Chronic pain must be evaluated and entities such as infection, stone, and tumor treated accordingly. The use of chronic nephrotoxic analgesics (nonsteroidal anti-inflammatory diseases [NSAIDs]) must be avoided. The use of narcotic analgesics should be limited to acute pain episodes, because patient dependence on narcotics is a significant risk in this patient population. When conservative measures fail, surgical management must be considered. Ultrasonography- or CT-guided cyst aspiration is a straightforward procedure and may be both diagnostic and therapeutic. Surgical unroofing of multiple or very large cysts can potentially alleviate symptoms of pain and can be performed either laparoscopically or through open flank or dorsal lumbotomy incisions (Elzinga et al, 1992; Lee and Lee, 2003; Lee and Clayman, 2004). The effect of laparoscopic unroofing in those patients with hypertension was quite variable. Surgical intervention appears to only improve symptomatology and does not appear to either accelerate the decline of renal function or preserve declining renal function. Nephrectomy is indicated for symptomatic patients with ESRD.

Upper urinary tract infections are common in patients with ADPKD, especially women, and must be treated appropriately. If a patient with suspected pyelonephritis does not respond to an appropriate antibiotic, one must consider whether the infection may be present in a noncommunicating cyst (Gabow, 1993). Actual cyst infections can be quite challenging to treat due to poor cyst penetration of many antibiotics. Lipophilic antibiotics, such as trimethoprim-sulfamethoxazole, chloramphenicol, and fluoroquinolones, are the best choices (Schwab et al, 1987; Bennett et al, 1990). If appropriate antibiotic therapy fails, percutaneous or surgical drainage of infected cysts may be required. Complicating factors, such as urinary tract obstruction, renal or perinephric abscess, or urolithiasis, must be excluded.

Screening for asymptomatic berry aneurysms is not currently recommended UNLESS the patient has a family history of aneurysm or subarachnoid hemorrhage, previous aneurysm rupture, need for screening in preparation for major elective surgery, high-risk occupation (e.g., airline pilot), or a high anxiety level over the possibility

of ICA (Pirson et al, 2002). CT and MR angiography are the imaging studies of choice, although the former requires intravenous contrast. Aneurysm rupture occurs most often in people with larger aneurysms and/or poorly controlled high blood pressure. Screening of low-risk patients is not recommended because aneurysms are rare in this group, and most aneurysms that are found have a low risk of rupture. Conservative management is usually recommended for ADPKD patients with small (<7 mm) aneurysms detected by presymptomatic screening. Aneurysms that are greater than 7 to 10 mm in size have a higher risk of rupture (up to 2% per year for larger aneurysms). Cerebral aneurysms of this size and those that cause symptoms may be corrected with open surgical clipping or with endovascular procedures, placing a coil within the aneurysm. Smaller aneurysms that do not cause symptoms are much less likely to rupture and are not routinely corrected, except in patients with a history of a bleeding aneurysm.

Emerging Therapeutics

New studies are underway to better investigate the value of inhibition of the renin angiotensin system (RAS) in patients with ADPKD. New therapeutic approaches have also been undertaken to reduce the levels of cAMP in the kidneys of ADPKD patients.

Key Points: Autosomal Dominant Polycystic Kidney Disease

- ADPKD is the most common inheritable form of renal cystic disease.
- ADPKD most often becomes clinically apparent after age 30 years but may present at any age, including in utero.
- Ninety-nine percent of affected individuals have a mutation either of the *PKD1* gene on chromosome 16 or, less often, of the *PKD2* gene on chromosome 4.
- The protein products of *PKD1* and *PKD2* are polycystin-1 and polycystin-2, and they inhibit cell proliferation through several pathways.
- Cysts can be identified sonographically before age 20 years in almost all affected individuals.
- ADPKD is associated with a high incidence of liver cysts that increases with age.
- Signs or symptoms first occur between the ages of 30 and 50 years and include hematuria, flank pain, gastrointestinal symptoms, renal colic, and hypertension.
- Hepatic cysts occur in virtually all patients with ADPKD by the age of 50 years and are rarely symptomatic.
- ICAs of the circle of Willis (berry aneurysm) occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages.
- The incidence of RCC in ADPKD patients is no higher than that of the general population.

JUVENILE NEPHRONOPHTHISIS/ MEDULLARY CYSTIC DISEASE COMPLEX

Juvenile nephronophthisis (NPH) (first described by Fanconi and colleagues in 1951) and medullary cystic disease (MCKD) (first reported by Smith and Graham in 1945) describe a group of genetic (inheritable) disorders with both similar and unique characteristics. Similarities include the gross and histopathologic appearance of the kidneys, with the hallmark being interstitial fibrosis. Distinguishing features are the mode of inheritance, the age of onset of ESRD, and the type of extrarenal organ involvement. Juvenile nephronophthisis is the more common condition and is responsible for 10% to 20% of cases of renal failure occurring in children and 1% to 5% of all patients undergoing dialysis or transplantation (Cantani et al, 1986).

Although either condition can occur sporadically, **juvenile nephronophthisis usually is inherited as an autosomal recessive trait.** It is genetically heterogeneous, and six responsible genes have been identified for various forms of NPH (Hildebrandt et al, 1997; Saunier et al, 1997; Olbrich, 2003; Mollet et al, 2005; Otto et al, 2003, 2005; Sayer et al, 2006). The majority of patients are homozygous for an *NPHP1* deletion (Konrad et al, 1996). *NPHP1*, *NPHP4*, *NPHP5*, and *NPHP6* mutations may be associated with the Senior-Løken syndrome (a combination of NPH and retinitis pigmentosa). **Medullary cystic disease usually is inherited in an autosomal dominant fashion** (50% of all offspring will have the disease) caused by mutations in either the *MCKD1* or *MCKD2* genes.

Juvenile nephronophthisis and medullary cystic disease both cause polydipsia and polyuria in more than 80% of cases, but not to the extent observed in patients with diabetes insipidus (Gardner and Evan, 1984; Cantani et al, 1986). The polyuria is caused by a renal tubular urinary concentrating defect that leads to salt wasting, and this process is resistant to vasopressin. Subsequently, a large dietary salt intake frequently is necessary. One major difference in the two entities is the presence of hypertension. There is no hypertension associated with juvenile nephronophthisis, while patients with medullary cystic disease can have significant hypertension. Renal failure usually ensues 5 to 10 years after initial presentation (Cantani et al, 1986). Another important difference between the two entities is that renal failure develops in patients with NPH at a mean age of 13 years and almost always before 25 years (Neumann et al, 1997). MCKD is a milder disease when it presents in early adulthood, but it will manifest in all patients by 50 years of age (Bernstein and Gardner, 1979). ESRD in patients with MCKD most often develops in the third or fourth decade.

Twenty percent of juvenile nephronophthisis families have extrarenal manifestations, while MCKD usually only affects the kidneys (Neumann et al, 1997). Sixteen percent of patients with juvenile nephronophthisis have associated **retinitis pigmentosa** (Hildebrandt et al, 1993). When the two entities coexist, the condition is referred to as renal-retinal or Senior-Løken syndrome.

Pathologically, NPH and MCKD are similar. Grossly, the kidneys are small to normal in size with multiple cysts at the corticomedullary junction. Histologically, there is a characteristic triad present that includes (1) irregular thickening and disintegration of the tubular basement membrane, (2) marked tubular atrophy with cyst development, and (3) interstitial cell infiltration with fibrosis.

Evaluation

Diagnosis of NPH/MCKD can be difficult early in its onset due to the relative vagueness and nonspecificity of symptoms; thus a high index of suspicion is required. Excretory urography and ultrasonography frequently fail to detect cysts because they are small (Chang and Udupa, 1989; Ala-Mello et al, 1998). Cysts may be seen on imaging studies if they are large enough (Rosenfeld et al, 1977), but, early in the disease, cysts are rarely visible. The parenchyma may also appear hyperechogenic secondary to

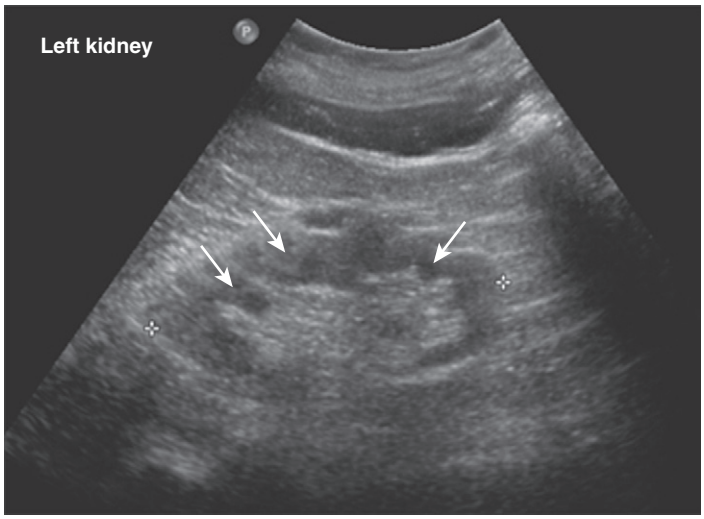

Figure 118–13. Features of medullary cystic kidney disease. Ultrasonogram demonstrating corticomedullary cysts, some of which are indicated by *arrows*. The hyperechogenicity is secondary to the tubulointerstitial fibrosis. (From Simms RJ, Eley L, Sayer JA. Nephronophthisis. Eur J Hum Gen 2009;17:406–16.)

tubulointerstitial fibrosis (Resnick and Hartman, 1990) (Fig. 118–13). Contrast-enhanced CT and MRI scans are more sensitive for detecting small corticomedullary and medullary cysts, but failure to detect cysts does not exclude the diagnosis.

Treatment

The treatment of NPH is supportive. Because of the tendency to sodium wasting, volume contraction, and renal azotemia, sodium replacement is indicated early in the course of the disease, and unnecessary sodium restriction or use of diuretics should be avoided. Later, dialysis and transplantation must be considered.

Key Points: Juvenile Nephronophthisis/Medullary Cystic Disease Complex

- Juvenile nephronophthisis, an autosomal recessive disease, is responsible for 10% to 20% of cases with renal failure in children and leads to early ESRD (early teens).
- Medullary cystic disease, an autosomal dominant disease, manifests in early adulthood.
- Polyuria, polydipsia, and hypertension are clinical hallmarks of these disease entities.
- Both have almost identical histology, with severe interstitial nephritis; many demonstrate cysts at the corticomedullary junction.

MULTIPLE MALFORMATION SYNDROMES WITH RENAL CYSTS

Renal cysts are a feature of several syndromes characterized by multiple malformations (see Table 118–2). Tuberous sclerosis and VHL disease are autosomal dominant disorders and are the ones most likely to be encountered by urologists. Meckel syndrome, Jeune asphyxiating thoracic dystrophy, and Zellweger cerebrohepatorenal syndrome are some of the more common autosomal recessive syndromes. Many of these conditions involve glomerular cysts, and some have cystic dysplasia as a feature.

Tuberous Sclerosis Complex (TSC)

Bourneville described tuberous sclerosis in 1880. It is usually an autosomal dominant neurocutaneous disorder with an incidence of up to 1 in 6000 individuals (Webb et al, 1991; O'Hagan et al, 1996). It is characterized by benign growths called hamartomas, which can develop in nearly every organ of the human body.

Classically, tuberous sclerosis has been described as the triad of *Bourneville phakomatosis* (epilepsy) (80% of cases), mental retardation (60% of cases), and adenoma sebaceum (facial angiofibromata) (75% of cases) (Lagos and Gomez, 1967; Pampigliana and Moynahan, 1976). Adenoma sebaceum are firm, discrete, red or brown telangiectatic papules located in the nasolabial folds, chin, and cheeks. They usually appear after the age of 2 years, gradually become more prominent with time and persist throughout life. An earlier skin lesion that is a white papule in the shape of an "ash leaf" is sometimes identified (Shepherd et al, 1991). An examination of the skin with ultraviolet light may reveal cutaneous lesions earlier and should be part of a diagnostic evaluation.

Definitive diagnosis, however, is no longer dependent on this triad but rather on the presence of certain major and minor clinical features (Roach et al, 1998). The diagnosis of TSC requires two major features (renal angiomyolipoma, facial angiofibromas or forehead plaques, nontraumatic ungual or periungual fibroma, three or more hypomelanotic macules, shagreen patch, multiple retinal nodular hamartomas, cortical tuber, subependymal nodule, subependymal giant cell astrocytoma, cardiac rhabdomyoma, lymphangioleiomyomatosis) or one major plus two minor features (multiple renal cysts, nonrenal hamartoma, hamartomatous rectal polyps, retinal achromic patch, cerebral white matter radial migration tracts, bone cysts, gingival fibromas, "confetti" skin lesions, multiple enamel pits).

The kidneys of these patients may be free of lesions (Stillwell et al, 1987) or may display cysts, angiomyolipomas, or both (Figs. 118–14 and 118–15).

Genetics

Although it is transmitted as an autosomal dominant trait in 25% to 40% of cases, in the remainder, tuberous sclerosis occurs either sporadically or as an example of the genetic condition with variable or incomplete penetrance. Because it is a heterogeneous genetic disorder with variable manifestations, it usually is referred to as tuberous sclerosis complex (TSC). It is caused by mutations in one of two genes. ***TSC1* is located on chromosome 9 (9q34) and encodes the protein hamartin, and *TSC2* is on chromosome 16 (16p13) and encodes the protein tuberin** (Jones et al, 1999; Dabora et al, 2001; Sancak, 2005). Both of these genes are characterized as tumor suppressor genes, and the loss of function of either gene leads to hamartoma formation. Both hamartin and tuberin function as a complex to inhibit the mTOR (mammalian target of rapamycin) pathway. This pathway serves to modulate cell signaling pathways that are important in the regulation of cell growth and migration, as well as cell number and organ size. Therefore a mutation of either gene will lead to similar clinical manifestations.

Clinical Features

Renal involvement in TSC is second only to central nervous system abnormalities and includes predominately

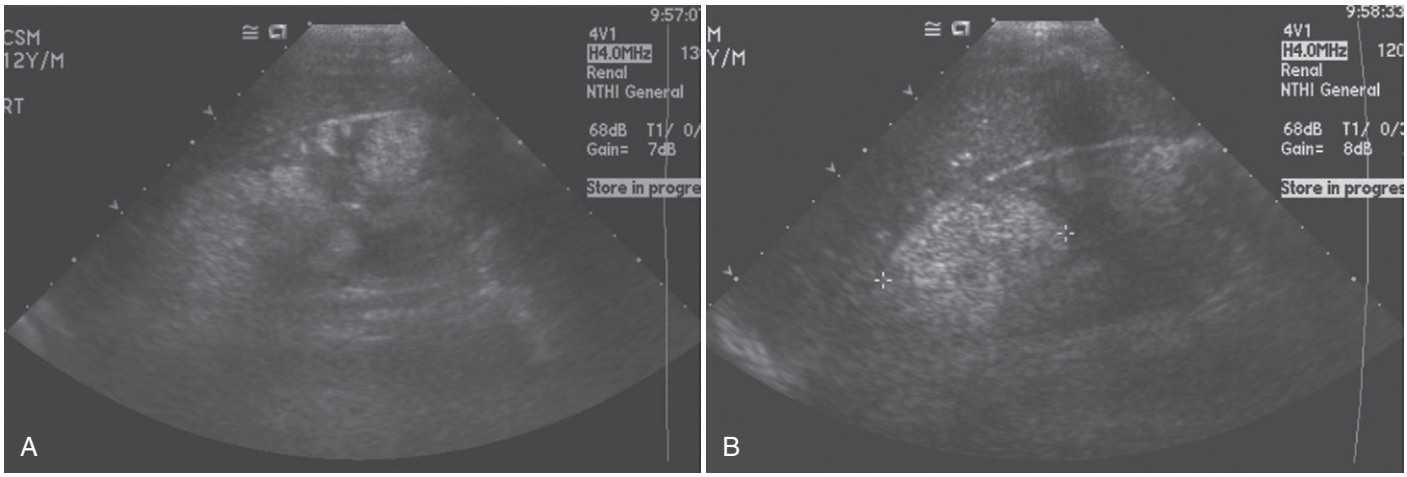

Figure 118–14. **A** and **B,** Renal ultrasonogram of 13-year-old patient with tuberous sclerosis. Multiple hyperechoic lesions of varying size are visible, consistent with angiomyolipomas. (Courtesy of Marta Hernanz-Schulman, MD.)

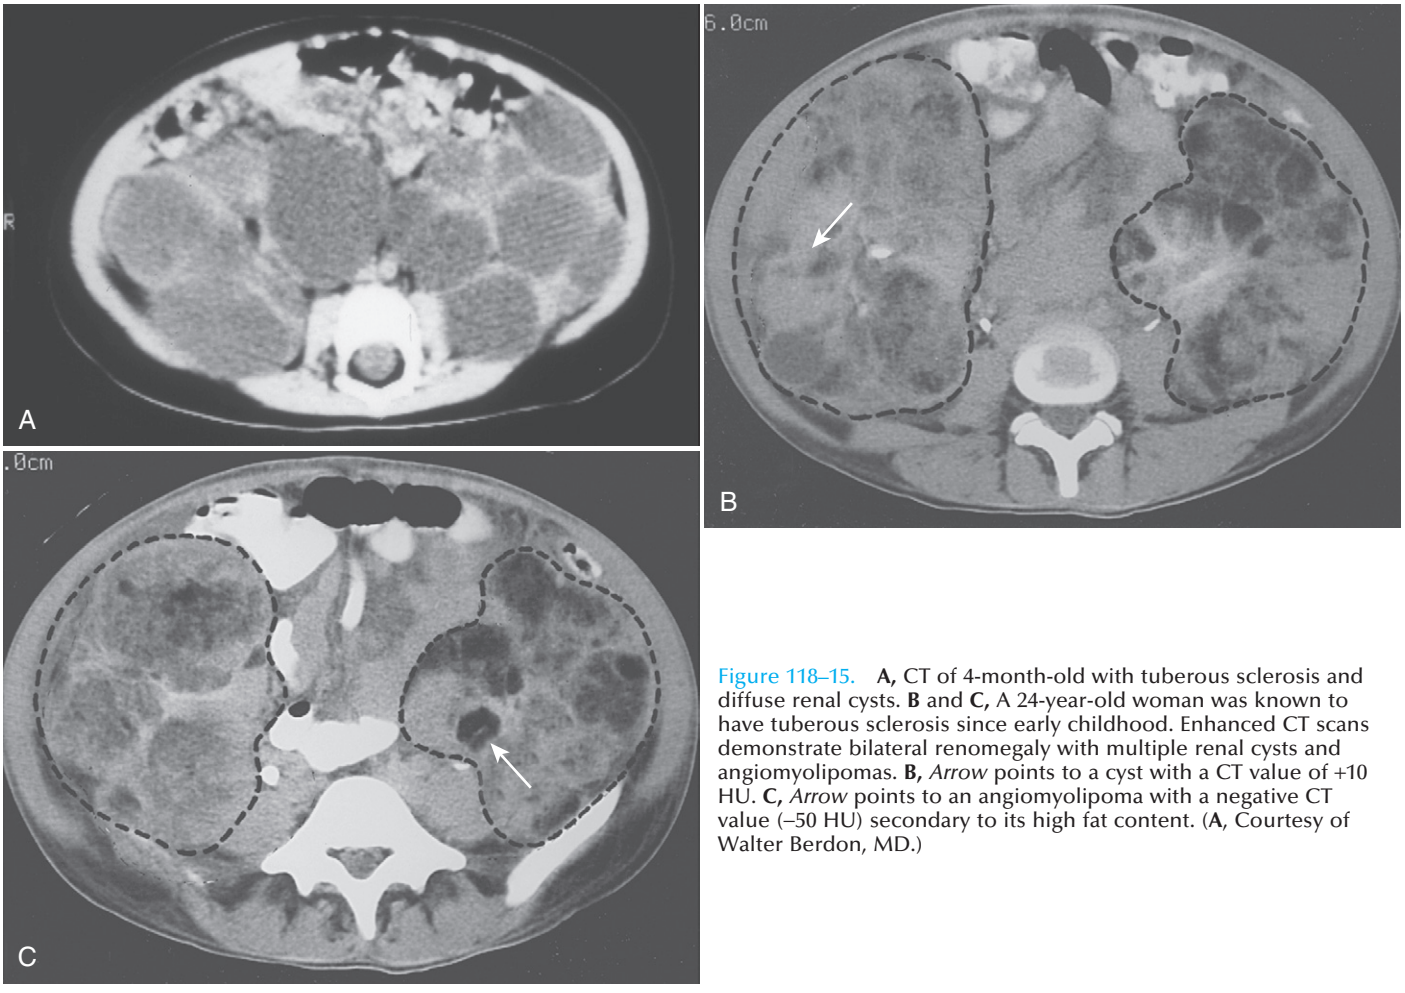

Figure 118–15. **A,** CT of 4-month-old with tuberous sclerosis and diffuse renal cysts. **B** and **C,** A 24-year-old woman was known to have tuberous sclerosis since early childhood. Enhanced CT scans demonstrate bilateral renomegaly with multiple renal cysts and angiomyolipomas. **B,** *Arrow* points to a cyst with a CT value of +10 HU. **C,** *Arrow* points to an angiomyolipoma with a negative CT value (–50 HU) secondary to its high fat content. (**A**, Courtesy of Walter Berdon, MD.)

angiomyolipoma (AML), renal cysts, and RCCs. AMLs are extremely common in TSC and are usually bilateral, multiple, and affect both genders, whereas in the general population, they are uncommon, usually single, and are found mainly in middle-age women. **Renal angiomyolipomas occur in 40% to 80% of patients with TSC** (Chonko et al, 1974; Gomez, 1979). They are rarely identified before the age of 6 years but are common after age 10 years (Bernstein et al, 1986). The primary risk of these lesions relates to their potential for to hemorrhage or mass effect. Abdominal or flank mass and tenderness, hypertension, and renal insufficiency can

also occur as a result of these lesions. By themselves, these lesions probably do not cause renal failure (Okada et al, 1982; Bernstein et al, 1986). Also, belying their aggressive histologic appearance, which is characterized by pleomorphism and mitoses, no evidence of metastases has been presented.

Unlike angiomyolipomas, renal cysts may be present in the first year of life, and cystic disease may be the presenting manifestation of TSC. **Renal cysts develop in approximately 20% of patients and most often manifest before 3 years of age; one third of children are younger than 1 year of age at presentation.** Patients with large cysts or polycystic kidney disease may be identified by in-utero ultrasonography or may present with an abdominal mass and distended abdomen in the first year of life. Most patients with renal cysts do not develop any serious renal compromise, but when the disease is more widespread within the kidney and large cysts are present, renal failure may develop in the milder form with polycystic kidney disease. If any renal failure develops, it is uncommon before the fourth decade (Glazier et al, 1996).

TSC2 and *PKD1* lie adjacent to each other in a tail-to-tail orientation on chromosome 16 at 16p13.3. Deletions inactivating both genes are associated with polycystic kidneys diagnosed during the first year of life or early childhood (*TSC2/PKD1* contiguous gene syndrome) (Brook-Carter et al, 1994; Sampson et al, 1997). Therefore TSC should be considered in children with renal cysts and no family history of PKD. Rarely, *TSC2/PKD1* contiguous gene syndrome can be diagnosed in adults (Martignoni et al, 2002). Patients with the contiguous gene syndrome usually reach ESRD at an earlier age than that of patients with ADPKD alone. Patients with *TSC1* or *TSC2* mutations without the contiguous gene syndrome also have an increased frequency of renal cysts. The combination of cystic kidneys and angiomyolipomas has been said to be virtually pathognomonic for tuberous sclerosis.

Association with Renal Cell Carcinoma

The numerous reports of RCC in patients with tuberous sclerosis make it clear that this association is more than coincidental and may be as frequent as 2% (Bernstein et al, 1986; Bernstein, 1993). However, the incidence of RCC is considerably less than that seen in VHL disease and ARCD of chronic renal failure. Compared with sporadic RCCs, there is a female predominance, earlier age of presentation, and increased bilaterality. Early detection is essential. RCC should be suspected in cases of enlarging lesions without demonstrable fat and in the presence of calcifications within the lesions.

Radiographic Evaluation

Sometimes both renal cysts and angiomyolipomas can be identified by ultrasonography in tuberous sclerosis, the former lesions being sonolucent and the latter having a fluffy, white appearance. When renal cysts are present without angiomyolipomas, the ultrasonographic appearance of the kidneys in tuberous sclerosis is very similar to that in ADPKD. Therefore it is not that unusual for a patient with cysts identified as typical of ADPKD to be diagnosed as having ADPKD, only to develop the stigmata of tuberous sclerosis a few years later. To help make the diagnosis, abdominal CT can be useful in demonstrating angiomyolipomas that may be present in the kidney or other organs (findings that are compatible with tuberous sclerosis) and in revealing cysts in other organs (compatible with ADPKD) (see Fig. 118–15). MRI or CT of the head may demonstrate the classic cranial calcifications associated with tubers or gliosis (Okada et al, 1982).

Treatment

Because more patients with tuberous sclerosis now survive their central nervous system lesions than in the past, the urologist is more likely to be asked to manage the renal problems (Stillwell et al, 1987). Shepherd and colleagues (1991) found that renal disease was the leading cause of death in these patients (11 of 40 deaths). Of these 11 patients, 2 died of metastatic RCC, 2 of massive hemorrhage associated with renal angiomyolipomas, and 6 of renal failure secondary to the cysts, angiomyolipomas, or both.

AMLs are benign lesions that usually are asymptomatic and do not require treatment. Large angiomyolipomas are more likely to bleed. Van Baal and colleagues (1994) have recommended careful monitoring of the size of angiomyolipomas and prophylactic embolization or surgical excision if they enlarge to greater than 4 cm. Annual surveillance with renal ultrasonography (RUS) or CT are necessary to assess for growth of the lesions and to detect the development of other complications. Renal-sparing surgery is indicated for symptoms such as pain and hemorrhage, growth of the lesions to the point it compromises renal function, and the inability to exclude RCC. Reports of hemorrhagic complications during pregnancy have led to the recommendation that patients with multiple or large AMLs be warned about the potential risk of pregnancy and estrogen administration.

Hypertension and renal failure must also be treated accordingly. Bilateral nephrectomy should be considered prior to transplantation due to the risk of life-threatening hemorrhage and the development of RCC.

Finally, in rodent models of TSC, treatment with rapamycin before the onset of disease reduces the development of renal tumors without affecting the number of precursor lesions (Kenerson et al, 2005). Phase I/II clinical trials of the mTOR inhibitor rapamycin have demonstrated reduction in the size of tuberous sclerosis–associated renal, lung, and brain tumors. Larger scale randomized control trials of mTOR inhibitors are currently underway (Clark and Cookson, 2008; Sampson, 2009).

von Hippel-Lindau Disease

In 1904, Eugene von Hippel, a German ophthalmologist, first described retinal angiomatosis—angiomatous lesions of the retina that caused blindness in association with similar cerebellar tumors. One of his patients developed renal cancer, and this was reported in 1921. In 1926, Arvid Lindau, a Swedish pathologist, published a series about patients with retinal and cerebellar tumors, with four of his patients also having renal cysts and renal cancer. He was also the first to propose these lesions had an inherited origin.

VHL disease is an autosomal dominant syndrome manifested by cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney, and epididymis; epididymal cystadenoma; pheochromocytoma; and clear cell RCC. It is found in all ethnic groups, both sexes are affected, and it has an incidence ranging from 1 in 30,000 to 1 in 50,000 individuals. It has over 95% penetrance by the age of 65 years in affected individuals. It is grouped with the phakomatoses (Sturge-Webber-Krabbe syndrome, TSC, and neurofibromatosis), because they all have a common inheritance pattern and propensity for neoplasm.

Etiology

VHL disease is caused by a germline mutation in the tumor suppressor gene known as *VHL*, located on

chromosome 3 (3p25) (Latif et al, 1993; Lesho, 1994; Kondo and Kaelin, 2001). A tumor suppressor gene is one in which both copies of the gene must be disabled for a cancer to develop. Seventy percent of patients will have a mutation of one *VHL* allele. As long as one copy of the *VHL* gene is producing functional VHL protein in each cell, tumors do not form. If a mutation occurs in the second copy of the *VHL* gene during a person's lifetime (another example of a "second hit" as proposed by Knudson's two-hit hypothesis (Knudson, 1991), the cell will have no working copies of the gene and will produce no functional VHL protein. A lack of this protein allows tumors characteristic of von Hippel-Lindau syndrome to develop. The discovery and characterization of the *VHL* gene, and its role in cell regulation, is a prime example of how discoveries in the basic science arena can revolutionize treatment of human disease (Clark and Cookson, 2008).

Clinical Features

The mean age at presentation is 35 to 40 years (Neumann et al, 1997). There is no sex preference for the disease or for RCC development. Sporadic RCC in individuals without VHL disease occurs more often in males and usually after age 50 years. **Renal cysts, the most common and often earliest manifestation, are seen in 76% of patients** (Levine et al, 1982). The cysts are bilateral in 75% of affected persons and multifocal in 87% (Reichard et al, 1998). RCC occurs in approximately 50% of affected persons. The renal cysts, as well as the tumors, usually are asymptomatic, although large tumors may cause pain or a mass. Hematuria may occur after rupture of the tumor into the pelvicalyceal system. When cysts are present, typically they are large. Only rarely do images demonstrate ADPKD, and, even less often, do cysts cause renal failure.

Pheochromocytoma occurs in 10% to 17% of affected persons and appears to be confined to specific families (Horton et al, 1976; Levine et al, 1982). Patients may present with seizures or dizziness secondary to hemangioblastomas of the central nervous system. **Cerebellar hemangioblastomas** usually become symptomatic between 15 and 40 years of age (Jennings and Gaines, 1988). These lesions are the most frequent, characteristic, and clinically specific tumors seen in VHL (Zbar et al, 1996; Shehata et al, 2008). Although benign tumors, they often result in major morbidity and mortality. They cause a mass effect because of their location, and, due to their vascular nature, they tend to rupture and bleed. **Retinal angiomas** (hemangiomas) frequently manifest early. Bleeding may cause blurred vision, retinal detachment, and blindness. Early diagnosis is important, because these tumors respond to laser therapy or cryotherapy. The pancreas is commonly involved with either cysts or true neoplasms. **Pancreatic cysts** can occur in up to 70% of patients with VHL but are usually asymptomatic and benign. Islet cell tumors occur in approximately 12% of VHL patients, and metastatic RCC of the pancreas is not unusual (Cheng et al, 1997; Kogire et al, 2000). Other clinical findings in patients with VHL can include **endolymphatic sac tumor, which is a papillary tumor of the petrous bone and can cause hearing loss; papillary cystadenomas of the epididymis; and the female counterpart, cystadenoma of the broad ligament** (Zbar et al, 1996; Shehata et al, 2008).

Because of the high incidence of RCC in patients with VHL disease, the urologist's primary role is careful surveillance so that small tumors can be identified and treated before they metastasize. Although central nervous system hemangioblastomas account for more than half of the deaths in these patients, metastatic RCC is also a major cause of mortality and, in some accounts, is the leading cause of death in this population (Maher et al, 1990; Reichard et al, 1998). Accordingly, annual or perhaps biannual CT examinations are advised.

Table 118–4

Classification of von Hippel-Lindau Disease

Type: Clinical Characteristic
1: Without pheochromocytoma
2: With pheochromocytoma
2A: Without renal cell carcinoma or pancreatic cysts
2B: With renal cell carcinoma and pancreatic cysts
2C: Familial pheochromocytoma without hemangioblastomas and clear cell renal cell carcinoma

Classification

Patients with VHL are subdivided into groups based on disease presentation, and each group has a specific *VHL* gene aberration. VHL type 1 is the most common form of the disease and is characterized by a tendency to develop tumors in the eyes, brain, spinal cord, kidney, and pancreas. VHL type 2 is less common. VHL type 2 differs from type 1 in that affected family members are at high risk to develop pheochromocytomas. VHL type 2 is further divided into types 2A, 2B, and 2C. Individuals in families with VHL type 2A develop pheochromocytomas but have a low risk for RCC (this type of VHL is uncommon). Those with VHL type 2B develop pheochromocytomas and have a high risk for RCC. Patients with type 2C VHL have familial pheochromocytoma without hemangioblastomas and clear cell RCCs (Zbar et al, 1996; Shehata et al, 2008) (Table 118–4).

Histopathology

When present, renal cysts and tumors often are multiple and bilateral. The cysts usually simulate simple benign cysts, with flattened epithelium that some investigators consider precancerous. In VHL patients, cysts larger than 2 cm are more likely than smaller cysts to have components of RCC (Poston et al, 1993). Frank cancer usually appears between the ages of 20 and 50 years (Jennings and Gaines, 1988). Others found that the hyperplastic cells lining cysts frequently resembled the clear cell type of RCC, the most common type in these patients (Loughlin and Gittes, 1986). Ibrahim and colleagues (1989) studied the cysts adjacent to carcinomas and found, much as in tuberous sclerosis, that the karyotype resembled that of the tumors. This similarity is evidence that the hyperplastic cells of the cyst lining are precursors of the carcinomas.

Solomon and Schwartz (1988) believed that a spectrum of pathology is found within the kidneys of patients with VHL disease. At one extreme is a simple cyst with a single layer of bland epithelium. The next step is a typical proliferative cyst with layers of epithelial cells. In the ensuing step, there are complex neoplastic projections into the cyst lumen. If one agrees with the arbitrary distinction between adenoma and carcinoma on the basis of size, the next stage would be adenoma. Finally, there is the full-blown RCC. All of these stages may be found within a single kidney (Solomon and Schwartz, 1988).

Evaluation

In patients with a known family history of VHL, the diagnosis can be made based on the presence of a single retinal or cerebellar hemangioblastoma, RCC, or pheochromocytoma (Melmon and

Rosen, 1964; Couch et al, 2000). In such families, germline mutations may be present without clinical manifestations, and the patient should be screened for this mutation. For those patients who do not have a family history, the diagnosis requires two or more cardinal manifestations, such as retinal or cerebellar hemangioblastomas, or a single hemangioblastoma and an additional characteristic lesion.

Ultrasonography is useful in diagnosing the typical benign renal cystic features of VHL disease: absence of internal echoes, well-defined margins, and acoustic enhancement. On CT, sharp thin walls are seen around homogeneous contents without enhancement after contrast medium injection. Because multiple lesions (cysts, tumors, or both) are often present, CT frequently is more useful than ultrasonography. CT often is useful in examining the adrenal glands for pheochromocytomas.

When the lesions are small, it is impossible to distinguish tumors from cysts. In such cases, patients should have regular CT scans with narrow-screen collimation (Levine et al, 1982). With larger lesions, and whenever RCC is suspected, renal angiography with magnification or subtraction is advisable. This type of study helps to reveal any additional tumors and indicates the appropriateness of conservative surgery (Kadir, 1981; Loughlin and Gittes, 1986). Intra-arterial administration of epinephrine is sometimes helpful, because it causes vasoconstriction of the normal vessels but has no effect on tumor neovascularity.

MRI has not been very useful for small tumors of the kidney, unless the shape of the kidney is altered. The lesions on MRI have a signal intensity that is similar to that of normal renal parenchyma on T1- and T2-weighted images. However, gadolinium is useful because it enhances RCC. The heterogeneous nature of the larger tumors makes them more readily diagnosed (Rominger et al, 1992).

Table 118–5

Screening Protocol for Patients and Families with von Hippel-Lindau Disease

STUDY	AFFECTED PERSONS	RELATIVES AT RISK
Physical exam	Annual	Annual
24-hour urine collection for metanephrins and normetanephrins	Annual	Annual
Fundoscopy	Annual	Annual (age 10-60 years)
Gadolinium MRI brain scan (or CT)	Every 3 years from age 10-50 years; every 5 years thereafter	Every 3 years from age 15-40 years then every 5 years until age 60 years
Abdominal evaluation	Annual renal US with abdominal CT scan every 3 years (more frequently if multiple renal cysts present)	Annual renal US with abdominal CT scan every 3 years from age 20-65

CT, computed tomography; MRI, magnetic resonance image; US, ultrasonogram.
From Maher ER, Yates JR, Harris R, et al: Clinical features and natural history of von Hippel-Lindau disease. QJ Med 1990;7:1151–63.

Screening

The genetic nature of VHL disease mandates careful screening. However, because of molecular genetic advances, the screening process for the disease in family members can now be more selective. Previously, asymptomatic relatives required routine ophthalmoscopic examination to rule out retinal angiomas, as well as frequent abdominal CT scans. Now only genetically affected family members require screening (Table 118–5).

Treatment

The treatment of patients with VHL requires a multidisciplinary approach, because the involvement of multiple organ systems and numerous medical problems are inherent to this disease. Because the tumors that characterize VHL disease are frequently multiple, bilateral, and recurrent, the goals of treatment for patients who have VHL disease are not as straightforward as the goals of treatment for patients who have sporadic tumors. Close surveillance and minimization of surgical procedures constitute the mainstay of treatment. **For patients who have VHL disease, and all patients who have hereditary cancer syndromes, the goal of treatment is cancer control, not cancer cure, and preservation of functional parenchyma to avoid the morbidity associated with renal or adrenal loss.** In patients who have VHL disease, surgical resection is performed with the understanding that microscopic disease probably is left behind. At present, open nephron-sparing surgery should be considered the standard of care for treating low-grade RCC in the setting of VHL disease. Patients with high-grade disease are still probably best served with bilateral nephrectomy. With the objective of sparing as much renal parenchyma as possible and preventing metastasis of the lesions already present, it is not curative surgery (Reed and Parekh, 2009). Although this approach does not reduce the risk of recurrence, reported to be 75% to 85%, the 10-year disease specific survival rates are quite high (81% to 94%) (Malek et al, 1987; Steinbach et al, 1995; Roupret et al, 2003; Ploussard et al, 2007). Classically, the survival rate after nephrectomy has been only 50%. Because most of these tumors are low grade, a nephron-sparing approach provides very good survival rates while avoiding the diminished quality of life that comes with bilateral nephrectomy and subsequent dialysis/transplantation. Laparoscopic and percutaneous image-guided ablative techniques, such as radiofrequency ablation and cryoablation, have also been used and are currently under investigation.

Given the high risk of multiple and bilateral pheochromocytomas in patients who have VHL disease, bilateral adrenalectomy can lead to the loss of all adrenal function. Preservation of normal adrenocortical function should be a primary surgical goal, because medical replacement therapy is associated with decreased quality of life (Telenius et al, 1989). Partial adrenalectomy can preserve normal adrenal function and avoid this morbidity. Identification of small pheochromocytomas may enable laparoscopic preservation of adrenal function and maintain quality of life in these complicated patients. The small size and lack of function of these tumors make them ideal for partial adrenalectomy; however, recurrences may develop in 15% of patients (Walther et al, 1999a, 1999b).

Papillary cystadenomas (PCs) of the epididymis can be unilateral or bilateral and occur in approximately 10% to 26% of men who have VHL disease (Horton et al, 1976; Lamiell et al, 1989). They seem to have no malignant potential. Surgery is not performed for these lesions unless the patient experiences severe pain.

Key Points: Multiple Malformation Syndromes

- Tuberous sclerosis complex is an autosomal dominant condition that includes the triad of epilepsy, mental retardation, and adenoma sebaceum. It is associated with renal cysts (20% of patients), renal angiomyolipoma (40% to 80%), and RCC (2%).
- There are two different gene mutations associated with tuberous sclerosis: *TSC1* on chromosome 9 and *TSC2* on chromosome 16.
- von Hippel-Lindau (VHL) disease is an autosomal dominant syndrome associated with cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney (76%), and epididymis; pheochromocytoma (10% to 12%); and clear cell RCC (50% incidence and 30% to 40% of death).
- VHL disease is associated with an inherited mutation of the *VHL* gene on chromosome 3.
- *VHL* is a tumor suppressor gene involved in regulation of hypoxia-inducible factor (HIF) target genes, including *VEGF*; abnormal or absent VHL leads to increased tissue levels of specific growth factors and, in particular, VEGF, the most prominent growth factor in RCC.

MULTICYSTIC DYSPLASTIC KIDNEY

Multicystic dysplastic kidney is a developmental anomaly resulting in multiple cysts of varying sizes, without identifiable normal renal parenchyma. These kidneys have no function by definition, and usually the contralateral kidney is normal and exhibits compensatory hypertrophy. Only unilateral involvement is compatible with life. The kidney often does not have a reniform appearance, and they are typically associated with an atretic ureter with no connection between glomerulus and calyces. Typically, the kidney has the appearance of "a bunch of grapes," with little stroma between the cysts (Fig. 118–16). Renal size is highly variable, ranging from a small nubbin of tissue to a very large mass that fills most of the abdomen. In fact, MCDK is the second most common cause of an abdominal mass in a newborn, after hydronephrosis.

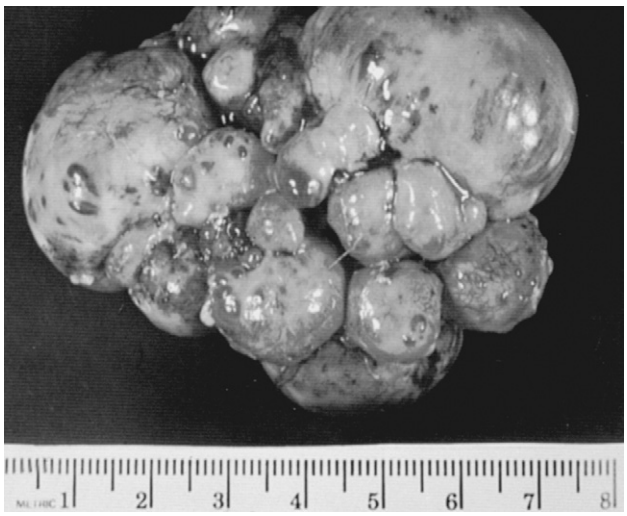

Figure 118–16. A typical multicystic dysplastic kidney having the appearance of a bunch of grapes. The kidney was composed almost entirely of cysts with very little stroma.

MCDK can be of two types: the infundibulopelvic type, with the atresia involving both the renal pelvis and the ureter, and the less common hydronephrotic type, where only the upper ureter is atretic (Felson and Cussen, 1975). In both cases, the ureters are absent or atretic, and the renal vessels are hypoplastic. MCDK can also rarely be secondary to ureteroceles that have caused complete obstruction. It can rarely be seen in one half of a duplex kidney (usually the upper pole associated with an ectopic ureter) or in other abnormalities such as a horseshoe kidney.

Etiology

Many theories have been offered to explain the etiology of MCDK. Clearly, it is a result of an error in renal development. Some have proposed that the multicystic kidney is an extreme form of obstructive hydronephrosis that occurs secondary to atresia of the ureter or renal pelvis. The fact that the left kidney is the one more often affected supports this view, because this is the kidney more often associated with primary obstructive megaureter (Glassberg, 1977) and ureteropelvic junction obstruction (Johnston et al, 1977). Several investigators have attempted to establish an animal model of MCDK by ligating the ureter at various points in gestation (Beck, 1971; Tanagho, 1972; Fetterman et al, 1974). This approach is not effective in middle or late gestation; early ligation of the fetal lamb ureter produces renal dysplasia but not multicystic dysplasia (Beck, 1971). Similarly, other investigators have been able to induce dysplasia, but no one as yet has been able to induce a multicystic dysplastic kidney.

Another theory stems from the "ureteric bud theory" as proposed by Mackie and Stephens (1975). This theory hypothesizes that MCDK may result from abnormal interaction between the ureteric bud and metanephric mesenchyme. Mutations in genes such as *EYA1, SIX1, WNT, WT-1, GNF, AT2,* and *PAX2* are known to have important roles in ureteric bud development and have been identified in multiple human syndromes with renal dysplasia (Pope et al, 1999). These studies linking genetic mutations with renal dysplasia support the ureteric bud theory in the pathogenesis of MCDK and may also explain its frequent association with other urinary tract anomalies (Hains et al, 2009). In addition, Hildebrandt (1894) suggested that failure of the union between the ureteric bud and the metanephric blastema leads to cystic dilatation in the latter; this hypothesis, like the obstructive view, is supported by the high incidence of concomitant ureteral atresia.

Although the ureteric bud theory and the obstruction theory may at some level go hand in hand, there is no question that there are several gene-mediated processes that go awry in the process of making a developmentally abnormal MCDK. These genes and their proteins are currently potential targets for both therapeutic intervention and research to further elucidate the mechanism that cause MCDK.

Clinical Features

Multicystic dysplasia is the most common type of renal cystic disease and is the second most common cause of an abdominal mass in infants (Longino and Martin, 1958; Melicow and Uson, 1959; Griscom et al, 1975). Most cases in the current era are diagnosed by prenatal ultrasonography, and the incidence is 1 per 1000 to 4000 live births (Kalyoussef et al, 2006). There is a male preponderance (55% to 70%), and studies conflict as to whether MCDK is more common on the right or left side.

The contralateral system frequently is abnormal. For example, contralateral ureteropelvic junction obstruction is found in 3% to 12% of infants with MCDK, and contralateral vesicoureteral reflux is seen in 18% to 43% of infants (Heikkinen et al, 1980; Atiyeh et al, 1992; Flack and Bellinger, 1993; Wacksman and Phipps, 1993; Al-Khaldi et al, 1994).

The natural history of MCDK is benign; the incidence of complications is extremely rare; and approximately 40% of MCDKs will spontaneously involute. Although anecdotal case reports exist, available large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm (Wacksman and Phipps, 1993; Tilemis, 2003; Truong et al, 2003; Rabelo et al, 2004; Farnham et al, 2005; Narchi, 2005a, 2005b; Onal and Kogan, 2006). Although hypertension is a rare but recognized sequela of MCDK, it is reasonable to follow patients with MCDK conservatively. The primary care provider should monitor patients with multicystic dysplastic kidney for hypertension, abdominal mass, and urinary tract infection.

Histopathology

Multicystic kidneys with large cysts tend to be large with little stroma, whereas those with small cysts generally are smaller and more solid. Likewise, the blood supply is variable, ranging from a pedicle with small vessels to no pedicle at all (Parkkulainen et al, 1959). Usually the ureter is partly or totally atretic, and the renal pelvis may be absent. Griscom and colleagues (1975) referred to the form without a renal pelvis as "pyeloinfundibular atresia" and reported finding no evidence of communication between the cysts. However, others have shown distribution of contrast medium among the cysts by means of connecting tubules (Saxton et al, 1981). Microscopically, the cysts are lined by low cuboidal epithelium, are surrounded by collars of spindle cells, and are filled with proteinaceous or sanguinous fluid. They are separated by thin septa of fibrous tissue and primitive dysplastic elements, especially primitive ducts. Immature-appearing cartilage is often present in the tissue. Frequently, immature glomeruli are present, and, on occasion, a few mature glomeruli are seen (Fig. 118–17).

Key Points: Multicystic Dysplastic Kidney

- Multicystic dysplastic kidney is a developmental anomaly resulting in multiple cysts of varying sizes, is without identifiable normal renal parenchyma, is associated with active expression of genes involved with nephrogenesis, and has a changing morphology.
- Kidneys usually get smaller or disappear from view on imaging studies (i.e., renal aplasia), very occasionally increase in size, and, very rarely, are associated with Wilms tumor.
- There is no clear indication for removal of the kidney, unless an increased amount of solid tissue is identified.
- Large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm.
- Fifteen percent of patients have associated contralateral reflux, and debate exists regarding whether or not to obtain a voiding cystourethrogram in all or only in those with some degree of fullness in the contralateral collecting system.

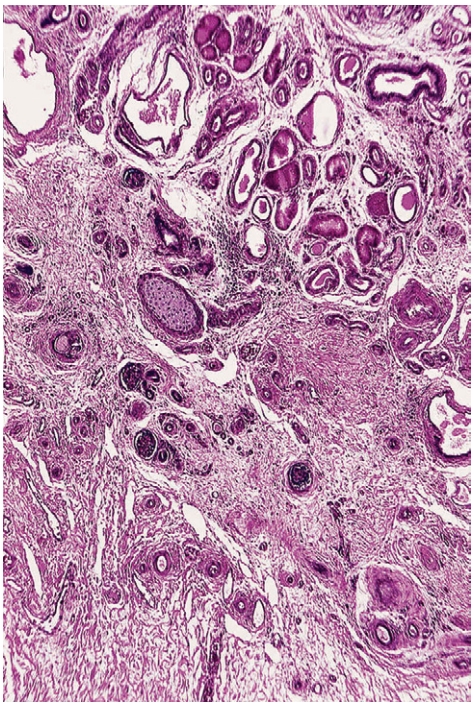

Figure 118–17. Disorganized development of kidney consistent with multicystic dysplastic kidney showing primitive glomeruli, tubules, and mesenchyme. (From Ordonez NG, Rosai J. Urinary tract. In: Rosai and Ackerman's surgical pathology. 9th ed. Edinburgh: Mosby; 2004.)

Evaluation

MDCK is most often identified by prenatal ultrasonography, and, in newborns, ultrasonography is usually repeated (one within the first few days of life and another one month later) to confirm the diagnosis and to evaluate the contralateral kidney and bladder. In a few cases, it is difficult to differentiate multicystic kidney disease from severe hydronephrosis (Gates, 1980; Hadlock et al, 1981). **In general, the multicystic kidney has a haphazard distribution of cysts of various sizes without a larger central or medial cyst and without visible communications between the cysts. Frequently, very small cysts appear between the large cysts. By comparison, in ureteropelvic junction obstruction, the cysts or calyces are organized around the periphery of the kidney; connections usually can be demonstrated between the peripheral cysts and a central or medial cyst that represents the renal pelvis; and there is an absence of small cysts between the larger cysts** (Fig. 118–18).

In these difficult cases, radioisotope studies may be helpful. **Hydronephrotic kidneys usually show some function on a dimercaptosuccinic acid (DMSA) or technetium-99m mercaptoacetyltriglycine (^{99m}Tc MAG3) scan, whereas renal uptake is seldom seen in multicystic kidneys** (Fig. 118–19). Angiography reveals an absent or small renal artery in the multicystic kidney, but this study is rarely indicated. Cystoscopy may reveal a hemitrigone and absent ureteric orifice on the affected MCDK side; however, more often an orifice is present, but retrograde urography demonstrates ureteral atresia. Again, this study is seldom performed. As mentioned previously, voiding cystourethrography (VCUG) is usually indicated in the workup, because of the high incidence of reflux into the contralateral single

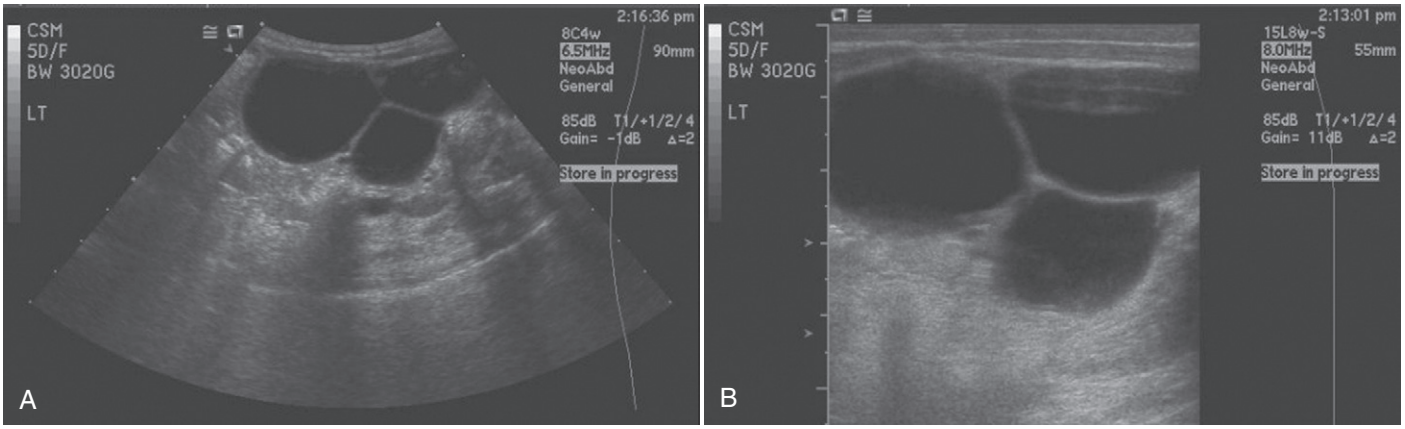

Figure 118–18. **A** and **B,** Renal ultrasonogram of large left multicystic dysplastic kidney. There are multiple large cysts. No definite renal cortex is seen.

functioning kidney. Some authors, however, have started to advocate that VCUG is of little value if serial high-quality ultrasound findings are consistent with MCDK and demonstrate a normal bladder and contralateral kidney. A VCUG is not necessary unless clinically indicated later in life (Ismaili et al, 2005; Welch and Wacksman, 2005; Onal and Kogan, 2006).

Treatment and Prognosis

It has often been stated that the multicystic kidney can be ignored unless its bulk is inconvenient (Pathak and Williams, 1964; Griscom et al, 1975), and attention should be directed instead to identifying any abnormalities of the contralateral urinary tract. Large MCDKs are known to interfere with respiratory and digestive function simply due to their mass effect. Intervention for these large masses may need to be undertaken to relieve these problems. Nephrectomy for MCDK may also be necessary to correct the rare cases of associated hypertension or if a cyst has ruptured spontaneously or secondary to trauma (to relieve pain or hemorrhage).

A nonfunctioning hydronephrotic kidney could be mistaken for a multicystic kidney, although complete nonfunction on a nuclear medicine study is unusual in kidneys affected by ureteropelvic junction obstruction. Fortunately, if the correct diagnosis is missed in such a case, there are unlikely to be significant consequences, because a totally nonfunctioning hydronephrotic kidney is rarely salvageable and probably will cause no problems other than a predisposition to infection or hypertension.

The probability of malignant transformation is estimated to be extremely low and believed by many to be nonexistent (Avni et al, 1987; Gordon et al, 1988; Wacksman and Phipps, 1993; Narchi, 2005b). Less than 15 cases of malignant degeneration have been reported in MCDK. Roughly half have been identified as RCC, half as Wilms tumor, and there has been one reported mesothelioma. Recommendations for addressing this risk range from early nephrectomy of the MCDK to minimal follow-up with no imaging and only periodic abdominal examination by the primary care physician (PCP). Many pediatric urologists will do ultrasound surveillance every 3 to 12 months, but there has been no conclusive evidence that this is beneficial or cost effective (Perez et al, 1998; Onal and Kogan, 2006).

There has also been much debate in contemporary series regarding hypertension in MCDK. The various case reports and small series that were reviewed offer conflicting data on the issue. An additional confounding factor is that MCDK is often associated with contralateral abnormalities, such as ureteropelvic junction (UPJ) obstruction and reflux. Thus groups have had difficulty determining if hypertension is associated with contralateral abnormalities or with MCDK. Several small series have reported patients with MCDK and hypertension who were cured with nephrectomy (Javadpour et al, 1970; Susskind et al, 1989; Angermeier et al, 1992; Webb et al, 1997; Snodgrass, 2000). Although these reports demonstrate that hypertension can occur with MCDK, most large series support the rarity of hypertension in association with MCDK. Several studies, including the report from the Multicystic Kidney Registry in 1993, have demonstrated the incidence of hypertension in patients with MCDK and long-term follow-up to be less than 1% (Wacksman and Phipps, 1993; Gough et al, 1995; Perez et al, 1998; Farnham et al, 2005). One study, however, demonstrated a much higher incidence of hypertension than the other MCDK series (Seeman et al, 2001). This could be due to the more stringent measurement of blood pressure applied, although these patients were examined at a much later age than in other series, which may also have contributed to the higher detected incidence of hypertension. Two of those four patients with hypertension had concomitant abnormalities; thus it was concluded that increased blood pressure is mainly associated with contralateral kidney damage regardless of the presence or absence of the dysplastic kidney (Seeman et al, 2001). In summary, hypertension is a rare but recognized sequela of MCDK. However, there is a suggestion that with more diligent monitoring, its incidence would increase. Therefore it is reasonable to follow patients with MCDK conservatively, realizing that hypertension can exist and should be assessed periodically. Because hypertension can be discovered on an examination by the primary care physician, the potential for this problem does not require urologic follow-up, only an informed primary care physician and family (Farnham et al, 2005).

BENIGN MULTILOCULAR CYST (CYSTIC NEPHROMA)

Benign multilocular cyst (multilocular cystic nephroma) is a multilocular cystic neoplastic lesion in the kidney that falls in a spectrum of diseases along with multilocular cyst with partially differentiated Wilms tumor, a multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor (Fig. 118–20). These four lesions form a spectrum, with benign multilocular cyst at the most benign extreme and

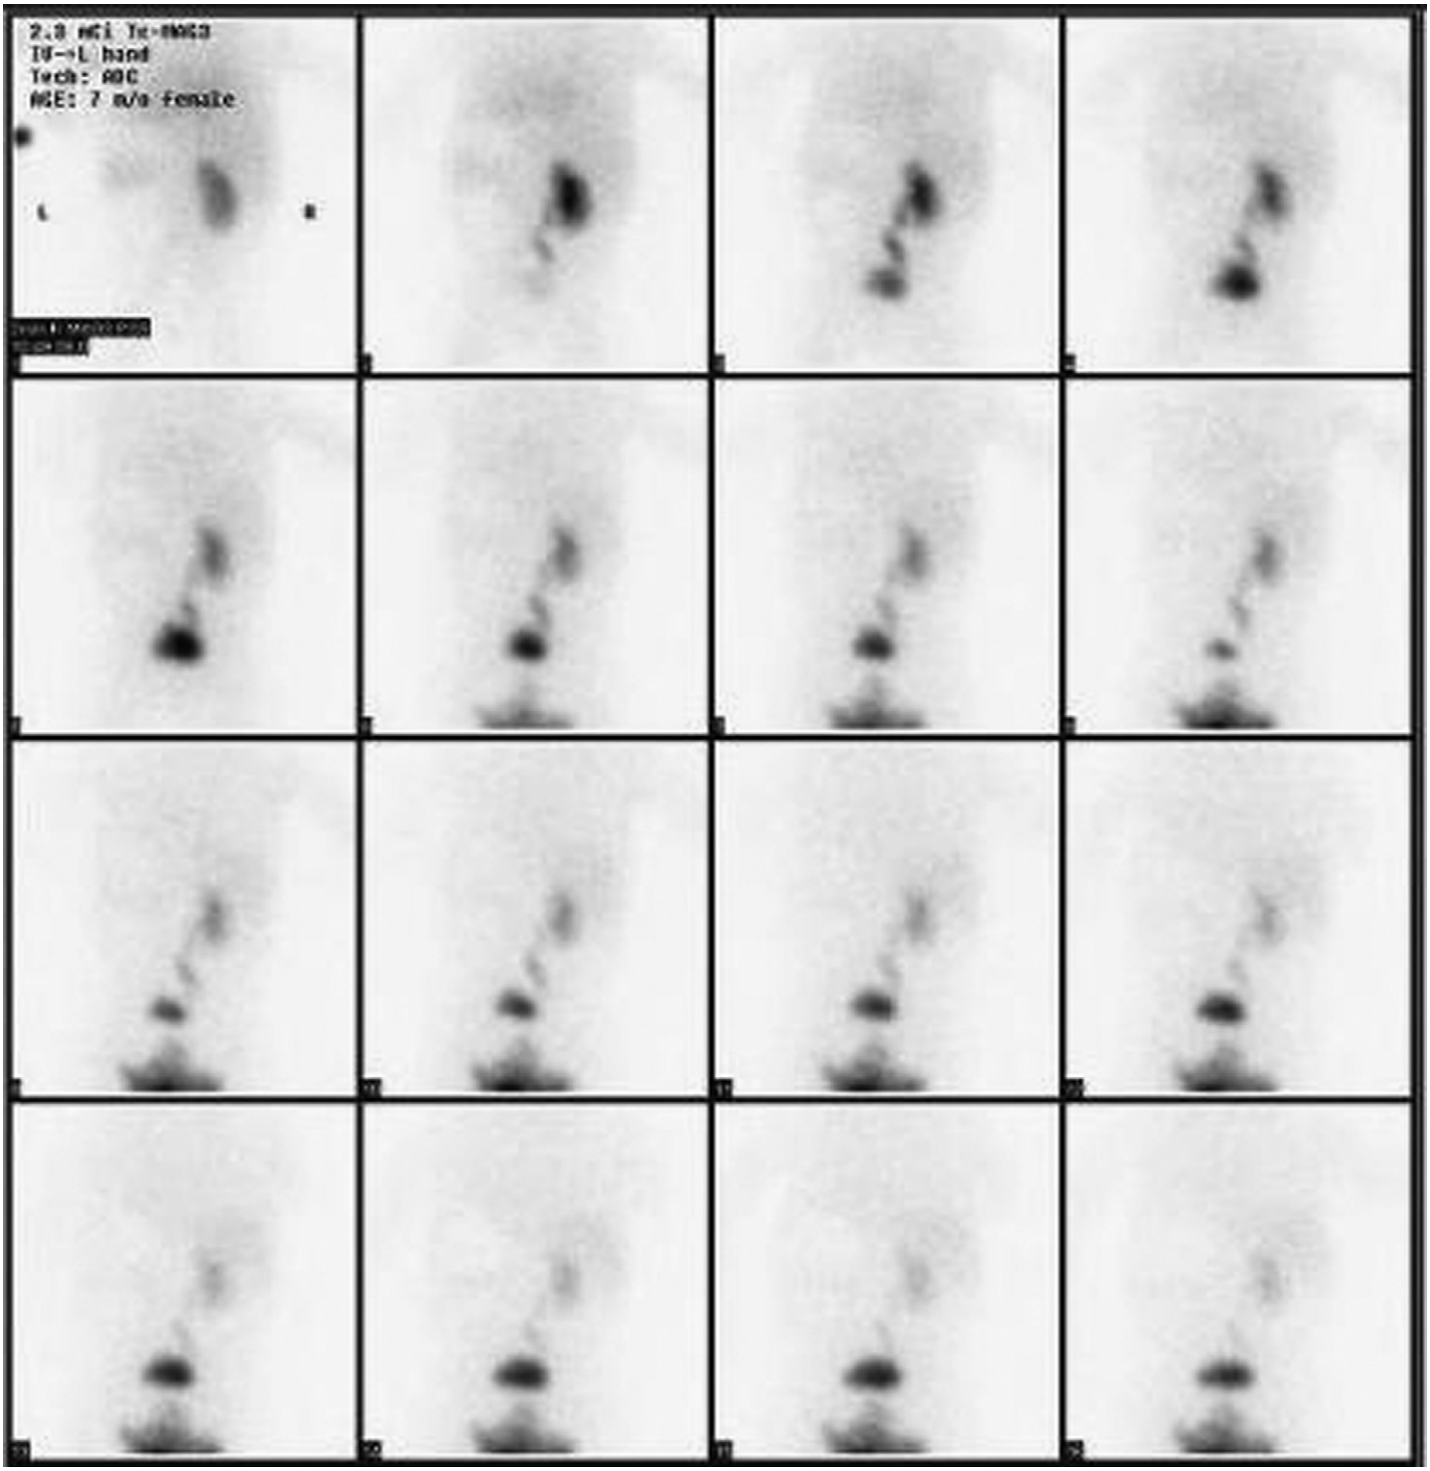

Figure 118–19. MAG3 renogram revealing a normally functioning right kidney and no function on the left, which is consistent with a left multicystic dysplastic kidney.

cystic Wilms tumor at the most malignant extreme. There has been some debate as to whether these lesions represent a spectrum of one disease with a common etiology.

A multilocular cyst is not a renal segment affected by multicystic kidney disease; these conditions differ clinically, histologically, and radiographically. However, controversy continues about whether the multilocular cyst is a segmental form of renal dysplasia (Powell et al, 1951, Osathanondh and Potter, 1964; Johnson et al, 1973), a hamartomatous malformation (Arey, 1959), or a neoplastic disease (Boggs and Kimmelsteil, 1956; Christ, 1968; Fowler, 1971; Gallo and Penchansky, 1977). The confusion arises in part from the variability of the histologic picture: the appearance of the primitive stroma; the maturity of tubular, and, even on occasion, of muscle elements; and the degree of epithelial atypical that differs not only from patient to patient but also within the same lesion.

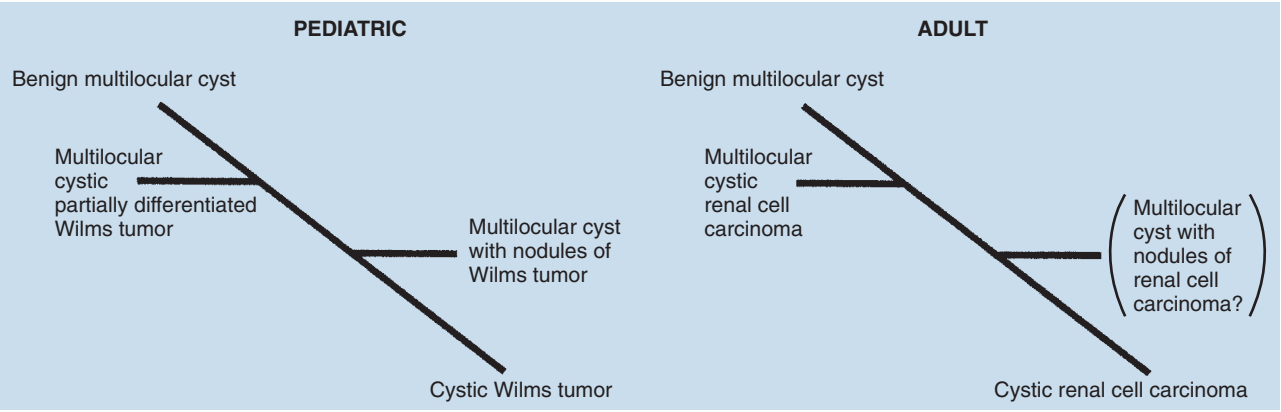

Figure 118–20. The spectrum of multilocular cystic lesions in children and adults. There is no evidence that one lesion can convert into the other. Benign cystic, partially differentiated Wilms tumor and multilocular, cystic renal cell carcinoma act as benign lesions. When nodules of tumor are present, the lesion should be considered malignant, although the prognosis of this lesion, as well as cystic Wilms tumor and cystic renal cell carcinoma, seems to be better than that of the corresponding solid lesions. It is not clear whether clinical examples of "multilocular cyst with nodules of renal cell carcinoma" actually exist, but this entity is placed in the spectrum for consideration. For simplicity, the multilocular-appearing lesions of other cystic tumors (e.g., cystic oncocytoma, cystic hamartoma of the renal pelvis) are not included in the figure.

Clinical Features

The great majority of patients (95%) present before the age of 4 years or after 30 years. If less than 4 years of age, the patient is 2 times as likely to be male; if older than 30 years of age, the patient is 8 times as likely to be female (Eble and Bonsib, 1998).

The signs and symptoms differ according to the age at presentation. **In children, an asymptomatic flank mass is the most common finding, whereas most adults present with either a flank mass, abdominal pain, or hematuria.** The bleeding is felt to be secondary to herniation of the cyst through the transitional epithelium into the renal pelvis (Uson and Melicow, 1963; Aterman et al, 1973; Madewell et al, 1983).

Seven cases of bilateral benign multilocular cysts of the kidney have been described (Castillo et al, 1991), and recurrence after excision has been rarely described (Geller et al, 1979). There are also at least two instances in which multilocular cysts arose in kidneys known to have been normal previously (Uson and Melicow, 1963; Chatten and Bishop, 1977). Such cases support a neoplastic theory of the origin of this lesion.

Histopathology

These lesions are bulky and are circumscribed by a thick capsule. Normal renal parenchyma adjacent to the lesion frequently is compressed by it. The lesion may extend beyond the renal capsule into the perinephric space or renal pelvis. The loculi, which range from a few millimeters to centimeters in diameter, do not communicate. They contain clear, straw-colored or yellow fluid and are lined by cuboidal or low columnar epithelial cells. In some cases, eosinophilic cuboidal cells project into the cyst lumen, creating a hobnail appearance (Madewell et al, 1983). The septa of a benign multilocular cyst are composed of fibrous tissue in which well-differentiated tubules may be present, but poorly differentiated tissues and blastemal cells are not present (Joshi and Beckwith, 1989).

In children, although there may be a continuum from benign multilocular cyst to cystic Wilms tumor, and although all of these lesions may be derived from similar cells or tissues, no evidence suggests that one entity transforms into another. Furthermore, **none of the genetically determined conditions associated with Wilms tumor (e.g., hemihypertrophy, aniridia) has accompanied a benign multilocular cyst** (Banner et al, 1981).

In adults, there also is a spectrum of multilocular cystic lesions. Multilocular cystic RCC in adults falls in the spectrum between a benign multilocular cyst and a cystic malignant tumor, such as a **multilocular cystic RCC, a cystic RCC, a cystic oncocytoma, or a cystic hamartoma of the renal pelvis** (Eble and Bonsib, 1998; Kirsh et al, 1999). The cystic component of the tumor at the carcinomatosis end of the spectrum in both children and adults (i.e., cystic Wilms tumor and cystic RCC) improves the prognosis of the malignant lesion (Kirsh et al, 1999). In adults, as in children, there is no evidence that one lesion can convert into another (Fig. 118–21).

Key Points: Benign Multilocular Cyst

- A benign multilocular cyst is a benign, nondysplastic, neoplastic lesion that occurs most commonly either before the age of 4 years, most frequently in males, or after the age of 30 years, predominantly in females.
- The only way to determine the diagnosis of a multilocular cystic lesion identified on imaging studies, in either a child or adult, is by surgical excision.
- Benign multilocular cyst is thought to fall at the benign end of a spectrum of the same disease process that also includes multilocular cyst with partially differentiated Wilms tumor, multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor at the most malignant end of the spectrum.

Evaluation

A number of tests may be useful, including ultrasonography, CT, MRI, cyst puncture with aspiration and double-contrast cystography, and arteriography. **Ultrasonography and CT can**

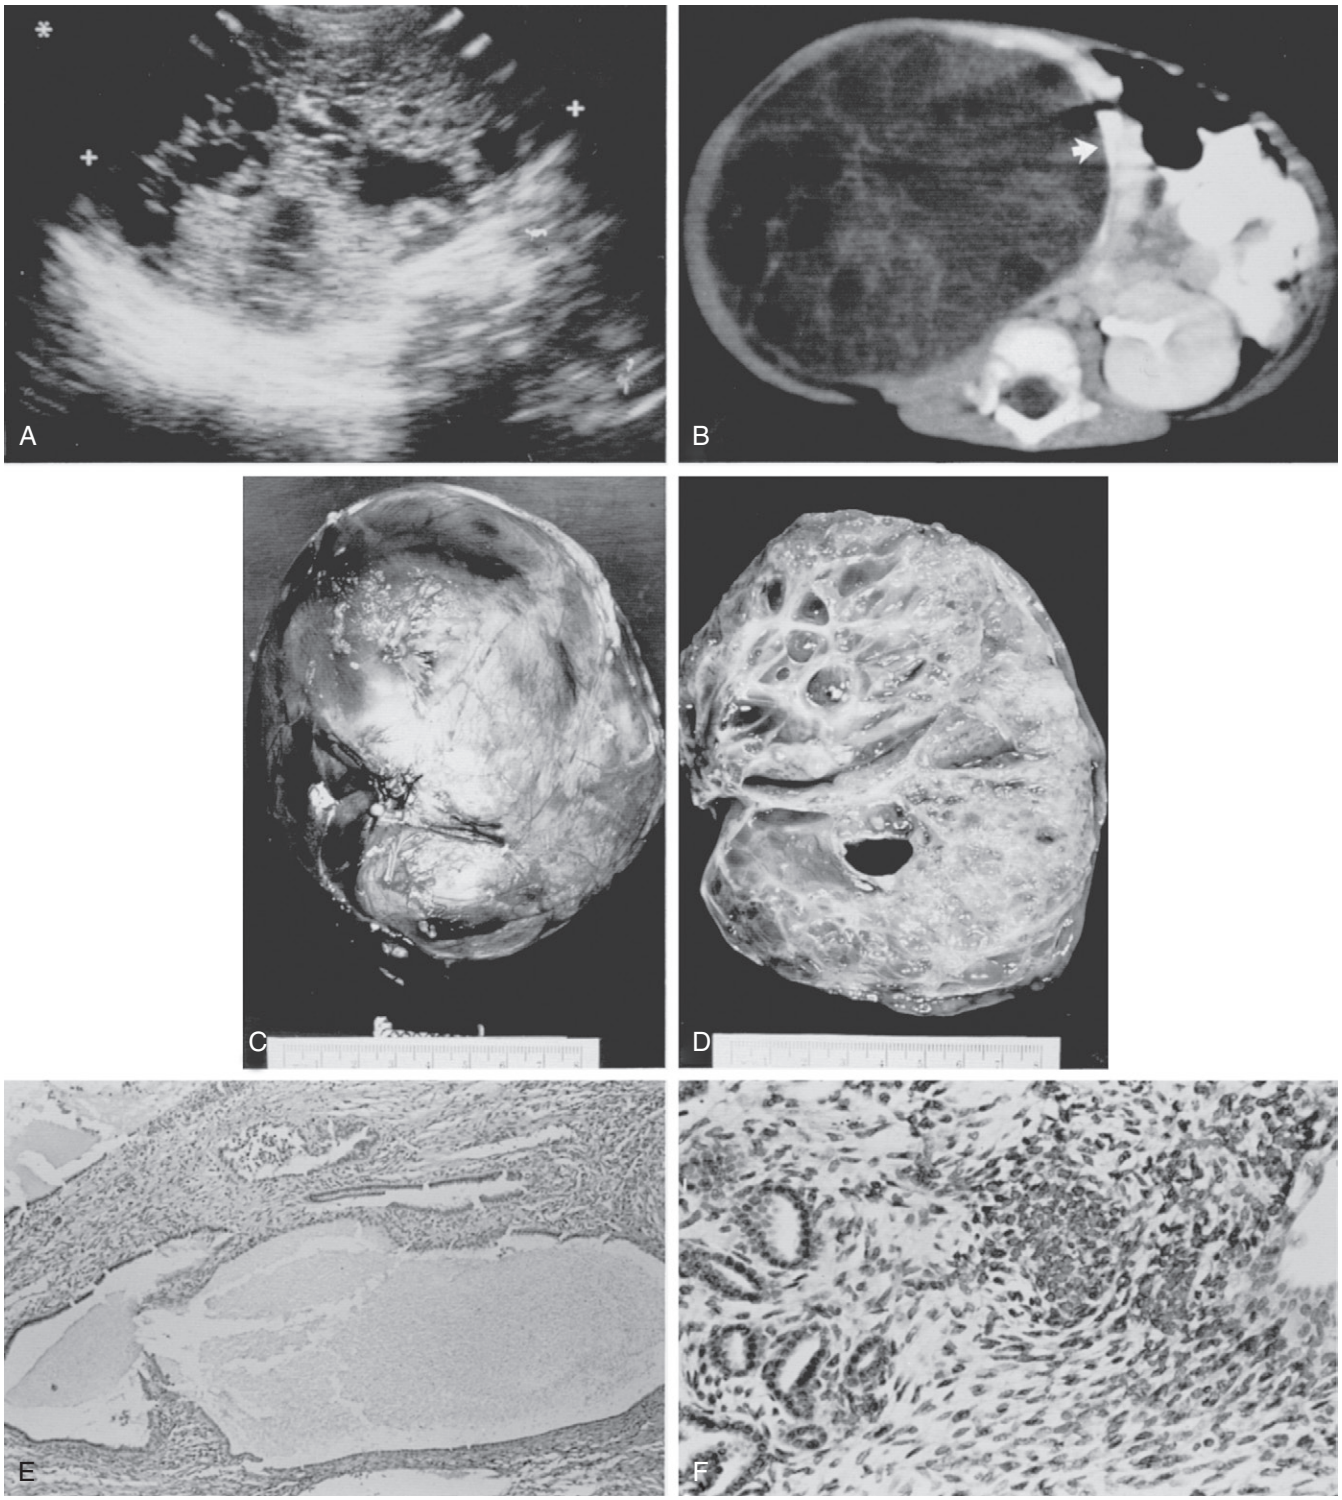

Figure 118–21. A 4-year-old girl with a right-sided abdominal mass. **A,** Renal ultrasonogram shows multiple cysts throughout the left kidney. **B,** On contrast medium–enhanced CT scan, a large, smoothly outlined left renal mass is seen with fine septa throughout the mass. Residual preserved parenchyma and the pelvicalyceal system are compressed medially and pushed to the contralateral side *(arrow)*. **C,** Uncut gross specimen reveals a smooth-walled, encapsulated renal mass. **D,** Cross section of mass reveals multiple noncommunicating loculations. **E,** On histology, a hypocellular cystic area is seen with monotonous stroma (100×). **F,** Between loculi, nests of blastemal cells are visualized along with tubular elements *(left),* making the diagnosis of multilocular cyst with partially differentiated Wilms tumor (200×).

distinguish multicystic kidneys from multilocular cysts, but neither study is sufficiently reliable to distinguish between multilocular cysts, multilocular cysts with foci of Wilms tumor or adenocarcinoma, mesoblastic nephromas, cystic Wilms tumors, and clear cell sarcomas. Typically, the septa are highly echogenic with sonolucent loculi, although, if there is debris in a loculus, it may appear more solid. On CT, the septa are less dense than normal parenchyma. Calcification is rarely visible in such lesions in children (Madewell et al, 1983).

Treatment

The treatment for any multilocular cystic lesion, even the most benign variant, is nephrectomy. If the lesion is localized enough and there is well-preserved normal tissue, excision of the lesion or partial nephrectomy is feasible. Children who have a multilocular cyst with nodules of Wilms tumor or a cystic Wilms tumor should be treated as for Wilms tumor, according to the National Wilms Tumor Study (NWTS) recommendations for the appropriate stage of disease, recognizing the generally favorable outlook. Similarly, cystic RCC in adults should be managed as a malignant lesion, however, again recognizing its better prognosis. In adults, benign multilocular cysts more often are associated with larger amounts of normal renal tissue, making partial nephrectomy more often feasible.

If enucleation or partial nephrectomy is chosen, recurrence is possible. However, with more Wilms tumors being treated by local excision, the case for enucleation or partial nephrectomy combined with close follow-up by ultrasonography and CT is stronger, even if malignancy is found within the lesion. By comparison, if a clear cell sarcoma is found after enucleation, the remaining ipsilateral renal tissue should be removed, because of the aggressiveness of this cancer. The recurrence of a multilocular cyst not containing malignancy probably reflects inadequate excision of the initial lesion.

SIMPLE CYSTS

Simple cysts are the most common cystic lesions found in the human kidney. They are usually oval to round, may be solitary or multiple, unilateral or bilateral, and are filled with plasma-like clear or straw-colored fluid (Nahm and Ritz, 2000; Terada et al, 2002). They are not connected to any part of the nephron, although they may originate initially from a portion of the nephron.

Simple cysts may manifest at any time in utero and have been diagnosed as early as 14 weeks of gestation. Ultrasonography done on 29,984 fetuses in succession revealed 0.09% of 11,000 pregnancies to have renal cysts (Blazer et al, 1999). Between birth and 18 years of age, the incidence of simple renal cysts is fairly stable, ranging from 0.1% to 0.45%, with an average incidence of 0.22% (McHugh et al, 1991). However, in adults the frequency rises with age, with an incidence of 20% by age 40 years and as high as 50% after age 60 years (Kissane and Smith, 1975; Laucks and McLachlan, 1981). Most reports show no gender predilection; however, in at least two studies, men were affected more frequently than women (Bearth and Steg, 1977; Tada et al, 1983).

Clinical Features

In both children and adults, cysts rarely call attention to themselves. Instead, they are discovered incidentally on ultrasonography, CT, or urography. However, cysts can produce an abdominal mass or pain, hematuria secondary to rupture into the pelvicalyceal system, and hypertension secondary to segmental ischemia (Rockson et al, 1974; Lüscher et al, 1986; Papanicolaou et al, 1986). Cysts can cause calyceal or renal pelvic obstruction as well (Wahlqvist and Grumstedt, 1966; Evans and Coughlin, 1970; Hinman, 1978; Barloon and Vince, 1987). They may or may not increase in size with time.

Cysts can rupture into the pelvicalyceal system, maintain a communication, and become a pseudocalyceal diverticulum. The reverse is also possible: Closure of the communication of a diverticulum can create a simple cyst (Mosli et al, 1986; Papanicolaou et al, 1986). These two sequences of events can be distinguished only by histologic examination. Theoretically, diverticula should have linings of transitional epithelium, whereas simple cysts should be lined by a single layer of flattened or cuboidal epithelium.

Key Points: Simple Cysts

- Simple cysts are seldom seen in children; in adults, simple cysts are seen increasingly more frequently with age.
- To diagnose a benign simple cyst on ultrasonography, it should (1) have no internal echoes, (2) have a sharply defined, thin, distinct smooth wall, (3) be spherical or oval with no internal echoes, and (4) have good transmission of sound waves with acoustic enhancement behind the cyst. When these criteria are not met, CT with contrast enhancement must be performed.
- Relevant guidelines for determining when to explore or remove a complex cyst are often based on the Bosniak CT classification (Table 118–6).

Evaluation

Most simple cysts are identified incidentally. One can safely make the diagnosis of a classic benign simple cyst by ultrasonography when the following criteria are met: **(1) absence of internal echoes, (2) presence of a sharply defined, thin, distinct wall with a smooth and distinct margin, (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst, and (4) a spherical or slightly ovoid shape** (Goldman and Hartman, 1990). If all of these criteria are satisfied, the chance that malignancy is present is negligible (Fig. 118–22) (Lingard and Lawson, 1979; Livingston et al, 1981).

Table 118–6

Bosniak's Classification of Simple and Complex Cysts

Category I
Simple benign cyst with (1) good through-transmission (i.e., acoustic enhancement), (2) no echoes within the cyst, (3) sharply, marginated smooth wall; requires no surgery

Category II
Looks benign with some radiologic concerns, including septation, minimal calcification, and high density; requires no surgery

Category II F
Although calcification in wall of cyst may even be thicker and more nodular than in category II, the septa have minimal enhancement, especially those with calcium; requires no surgery

Category III
More complicated lesion that cannot confidently be distinguished from malignancy, having more calcification, more prominent septation of a thicker wall than a category II lesion; more likely to be benign than malignant; requires surgical exploration and/or removal

Category IV
Clearly a malignant lesion with large cystic components, irregular margins; solid vascular elements; requires surgical removal

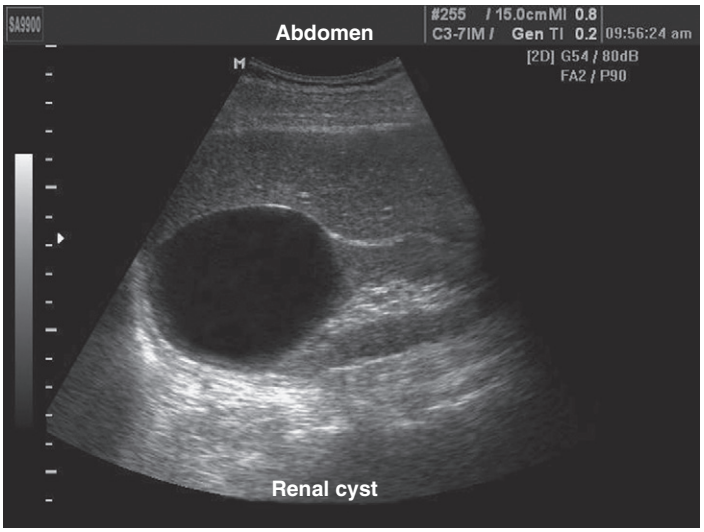

Figure 118–22. Ultrasonographic appearance of a 4-cm simple renal cyst. Note this meets the definition of a true simple cyst: (1) absence of internal echoes; (2) sharply defined, thin, distinct wall with a smooth and distinct margin; (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst; and (4) spherical or slightly ovoid shape.

When some of these criteria are not met (e.g., when there are septations, irregular margins, calcifications, or suspect areas), further evaluation by CT, or perhaps needle aspiration or MRI, is indicated (Bosniak, 1986). A cluster of cysts is another indication for further study, because they may be hiding a small carcinoma. CT is better than ultrasonography in defining such a camouflaged lesion (Bosniak, 1986). Peripelvic cysts often require CT confirmation, because they frequently are interspersed between structures of the collecting system and hilum, which can create artificial echoes (Bosniak, 1986).

The CT criteria for a simple cyst are similar to those used in ultrasonography: (1) a sharp, thin, distinct, smooth wall and margin, (2) a spherical or ovoid shape, and (3) homogeneous content. When these criteria are respected, the accuracy of diagnosis of a simple cyst by CT approaches 100% (Fig. 118–23) (McClennan et al, 1979). The density ranges from –10 to +20 HU, similar to the density of water, and no enhancement should occur after the intravenous injection of contrast medium.

When the cyst fluid is hyperdense (i.e., between 20 and 90 HU), it still is likely to be a simple cyst if no enhancement occurs when intravenous contrast agent is injected

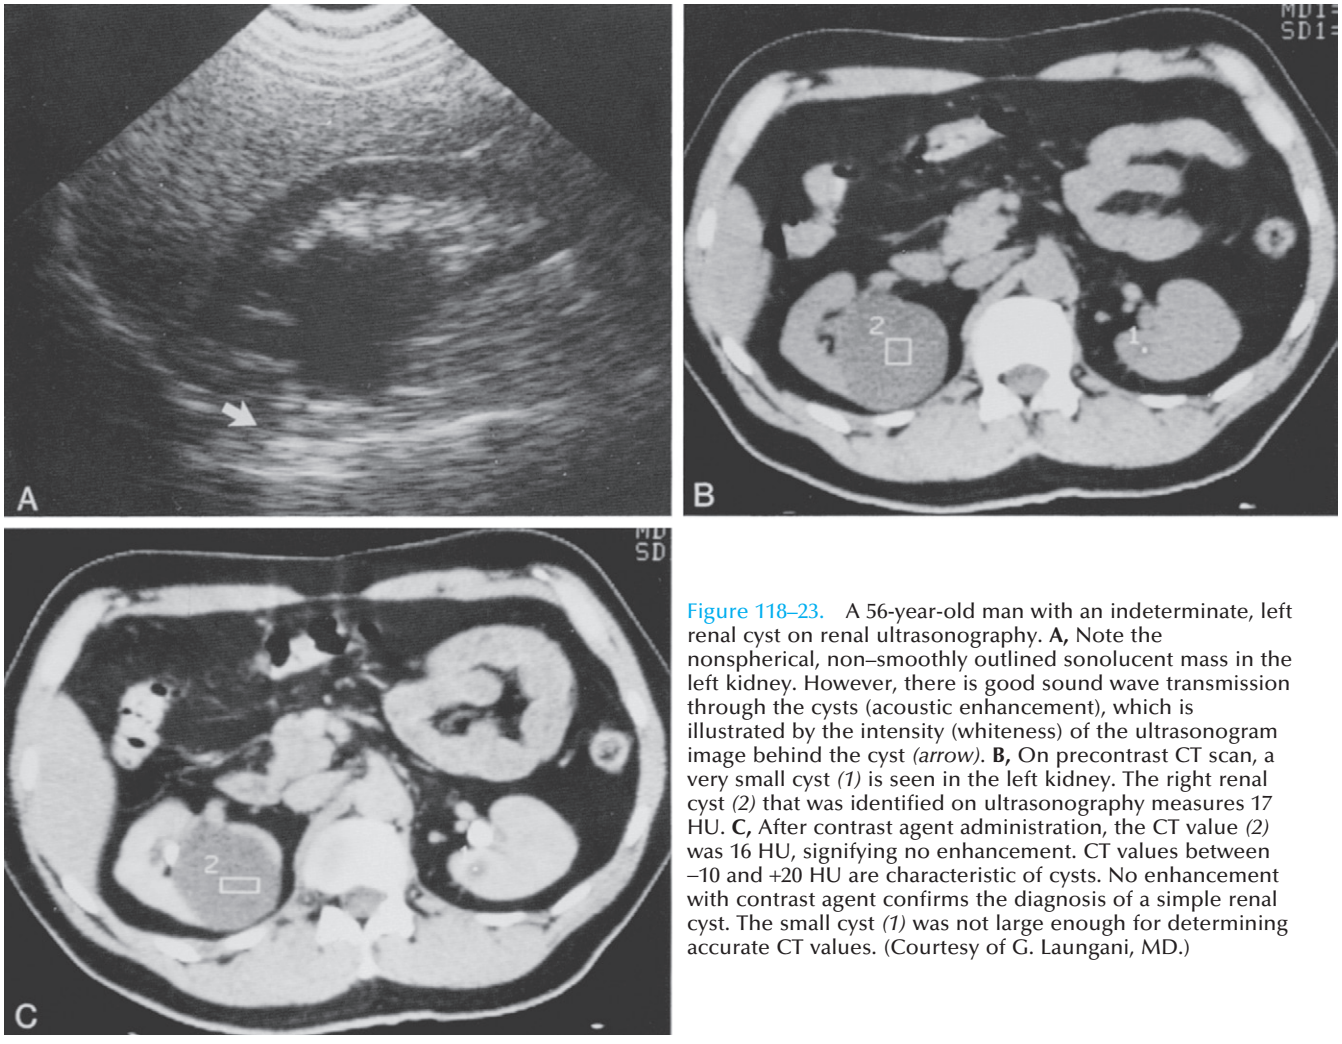

Figure 118–23. A 56-year-old man with an indeterminate, left renal cyst on renal ultrasonography. **A,** Note the nonspherical, non–smoothly outlined sonolucent mass in the left kidney. However, there is good sound wave transmission through the cysts (acoustic enhancement), which is illustrated by the intensity (whiteness) of the ultrasonogram image behind the cyst *(arrow)*. **B,** On precontrast CT scan, a very small cyst *(1)* is seen in the left kidney. The right renal cyst *(2)* that was identified on ultrasonography measures 17 HU. **C,** After contrast agent administration, the CT value *(2)* was 16 HU, signifying no enhancement. CT values between –10 and +20 HU are characteristic of cysts. No enhancement with contrast agent confirms the diagnosis of a simple renal cyst. The small cyst *(1)* was not large enough for determining accurate CT values. (Courtesy of G. Laungani, MD.)

and if the other criteria of CT and ultrasonography are met. Hyperdense cysts must be evaluated with narrow window settings to make sure that they are homogeneous. Other criteria that must be met to avoid further evaluation of hyperdense cysts (e.g., cyst puncture or exploration) include size (the lesion should be 3 cm or smaller) and location (at least one fourth of the cyst's circumference should extend beyond the renal contour so that the smoothness of a good portion of the cyst can be evaluated) (Bosniak, 1991; Hartman et al, 1992). **Because cysts have no blood vessels and do not communicate directly with nephrons, they should not enhance; enhancement therefore implies vascular tissue or contrast medium mixing with fluid.** Enhancement of the lesion with contrast is taken as proof of vascularity within the lesion, and thus there should be a high index of suspicion for neoplasm.

When ultrasonographic or CT criteria are not met, conditions other than a simple cyst must be considered, such as complicated cysts (i.e., those containing blood, pus, or calcification) and cystic neoplasms. Cyst puncture and aspiration with or without contrast medium injection has been popular in the past, but with current imaging modalities, the need for cyst puncture is very rare. The remaining indications for cyst puncture are (1) suspected infection, in which case puncture may be therapeutic as well as diagnostic, (2) the presence of low-level echoes on ultrasonography but a classic cyst on CT, and (3) a borderline lesion in a poor surgical candidate.

Two percent of simple cysts and 10% of RCCs contain calcium deposits, but calcification in simple cysts appears to be peripheral, whereas in tumors it is more central. When the cysts are numerous and bilateral, differentiation from ADPKD may be difficult if liver cysts are not also found. Because of the obvious implications, it is important to avoid a diagnosis of ADPKD in questionable cases, unless a familial history consistent with autosomal dominant transmission can be documented or the diagnosis confirmed by genetic testing.

MRI offers little information beyond that available from ultrasonography and CT, although it is more specific in identifying the nature of the cyst fluid. Marotti and colleagues (1987) found that if the fluid has low signal intensity (similar to that of urine) on T1-weighted images, the cyst is benign even if the wall is thick or septa are present. If this report is substantiated by additional studies, MRI may prove valuable in deciding which indeterminate cysts are benign and which should be considered for exploration. The T2-weighted images identify bloody fluid with an extremely bright image.

Classification

In an attempt better categorize surgical and nonsurgical cysts in the kidney, Bosniak suggested a classification in 1986 that was clarified further in 1997 and modified by Israel and Bosniak in 2003 (see Table 118–6).

Category I cysts are the typical benign cysts. Category II cysts are benign cystic lesions that are minimally complicated, such as by septations, small calcifications, infection, or high density, and do not require surgery. For example, when all the criteria for a simple cyst are met, except that a fine line of calcification or a short segment of slightly thickened calcification is seen in the wall or septa, the lesion should be considered a benign cyst, and exploration is not required. Another example is the cyst with fine traversing strands, perhaps containing calcium. In this case, exploration is not required unless the septa are numerous, irregular, or thick.

Category II F cysts (Israel and Bosniak, 2003) are complex cysts that cannot be classified either as category II or III. These lesions may contain increased calcification. The calcification may even be thicker and nodular, but although the septa may have minimal enhancement those septa with calcium do not enhance. Calcification seems to represent a less significant finding in making a lesion suspicious as a malignancy than previously thought. More focus is placed on tissue enhancement. There is little concern if calcification increases with time but much concern if the wall or septa becomes thicker or irregular. **Category II F does not require surgical exploration** (Israel and Bosniak, 2003) (Fig. 118–24).

Category III cysts are more complicated lesions with radiologic features that are also seen in malignancy. One example is the lesion with more extensive calcification, especially if the wall is not pencil-point thin or is irregular. Other category III cysts are those with septations, suggesting a multilocular cystic lesion, or chronic infection with a thickened wall. These lesions are more problematic and require a surgical approach that is individualized. In some cases, one might consider violating the Gerota fascia to expose the kidney for examination of the lesion or partial nephrectomy.

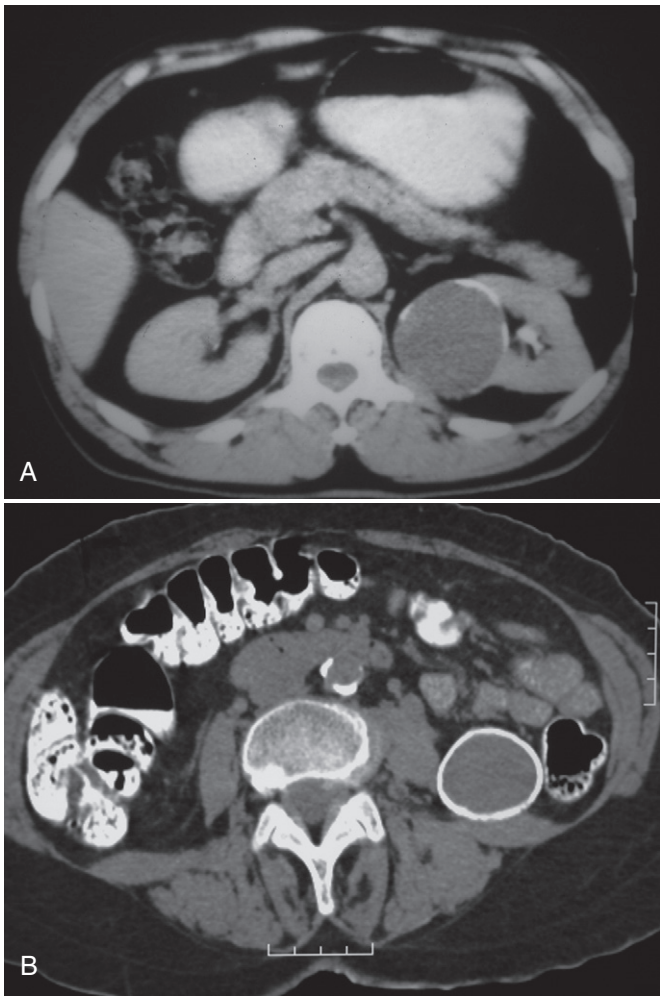

Figure 118–24. **A** and **B,** Two examples of Bosniak category II F cysts with diffuse calcification but no enhancement of septa on CT. (Courtesy of Jeffrey Newhouse, MD.)

Bosniak category IV lesions are cystic malignant tumors and are dealt with as such, namely, by radical nephrectomy.

Treatment and Prognosis

Once malignancy has been ruled out, surgical intervention for an asymptomatic cyst is not indicated (Gordon et al, 1979; Bartholomew et al, 1980; Ravden et al, 1980; Siegel and McAlister, 1980). Large renal cysts may cause abdominal or flank pain, although this pain may be caused by a coexisting problem (i.e., nephrolithiasis), and other sources of pain should be ruled out. Other symptoms that may arise as a result of simple cysts are pain resulting from hemorrhage into the cyst or calyceal or infundibular obstruction due to cyst impingement. In rare cases, hypertension may occur, presumably from cyst compression causing segmental renal ischemia of the surrounding renal parenchyma. Cyst infection is a rare but potentially severe complication, with patients presenting with fever, flank pain, and, often, a sympathetic pleural effusion (Torres, 2008). Most of these patients are women, the most common pathogen is *Escherichia coli,* and urine cultures can often be negative.

Treatment of the simple cyst must thus be directed to the symptomatology. When a benign simple cyst causes pyelocalyceal obstruction or hypertension, the problem may be corrected either surgically, by unroofing the cyst, or percutaneously, by aspirating the fluid and perhaps injecting a sclerosing agent, particularly if fluid has reaccumulated after an earlier aspiration. Several sclerosing agents have been used, including glucose, phenol, iophendylate (Pantopaque), bismuth phosphate, and absolute ethanol, but none has been sufficiently impressive for its use to become dominant (Holmberg and Hietala, 1989). Infected cysts must be drained and appropriate antibiotics given. Percutaneous resection, intrarenal marsupialization (Hubner et al, 1990; Hulbert and Hunter, 1990; Meyer and Jonas, 1990), and laparoscopic unroofing (either transperitoneally or retroperitoneally) are all reasonable options for the treatment of symptomatic simple cysts.

Unilateral renal cystic disease is characterized by cysts of varying size appearing side by side, often more numerous at one pole. Except for its unilateral location, no extrarenal cyst formation, and the fact that these patients show no genetic background or progressive deterioration in **renal** function, the gross and histologic findings of are indistinguishable from those of asymmetrical ADPKD (Lee et al, 1978; Kossow and Meek, 1982). It is important not to overdiagnose unilateral simple cyst disease, because the entity itself is rare, and when first identified in an individual, it is more likely to represent a unilateral asymmetrical presentation of ADPKD. Because the entity seems to represent nothing more than multiple simple cysts lying side by side within a kidney, it seems reasonable to consider it as a variation of the presentation of simple cysts. Now that genetic studies are becoming available for ADPKD, tuberous sclerosis, and VHL disease, the diagnosis of unilateral renal cystic disease can more readily be confirmed (Fig. 118–25).

MEDULLARY SPONGE KIDNEY

The condition known as medullary sponge kidney (also known as precalyceal canalicular ectasia) was recognized by Beitzke in 1908, and its radiographic features were described by Lenarduzzi in 1939. The name of this disorder dates from a 1949 publication by Cacchi and Ricci. **It is characterized by tubular dilatation of the distal portion of the collecting ducts with numerous associated cysts and diverticula strictly confined to the medullary pyramids.** These dilated ducts have the appearance of the bristles on a brush and often are more ectatic and filled with calcifications, giving an appearance suggestive of a "bouquet of flowers" (Fig. 118–26).

Clinical Features

Medullary sponge kidney is usually a benign process, and it may remain asymptomatic and undetected for life. Clinical presentation usually occurs after age 20 years, with the most common presentation being renal colic (50% to 60%), followed by urinary tract infection (20% to 33%) and gross hematuria (10% to 18%) (Kuiper, 1976). The incidence of medullary sponge kidney in stone formers differs widely in the reported series, ranging from 2.6% to

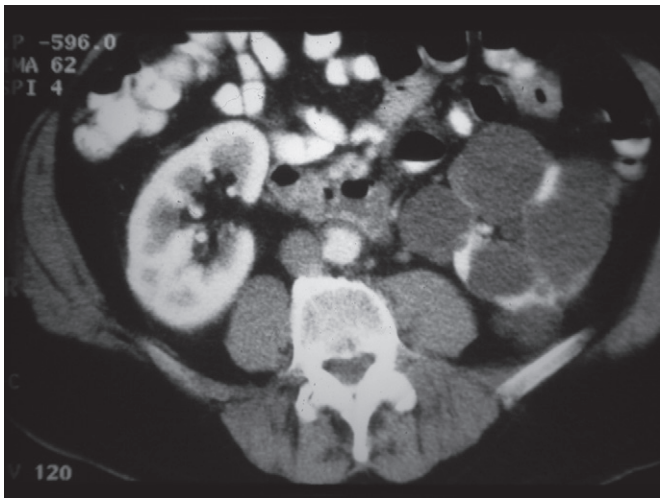

Figure 118–25. Unilateral renal cystic disease. Diffuse simple cysts were evident in one kidney. There was no discrete mass or evidence of multiple malformation syndrome. (Courtesy of Jeffrey Newhouse, MD.)

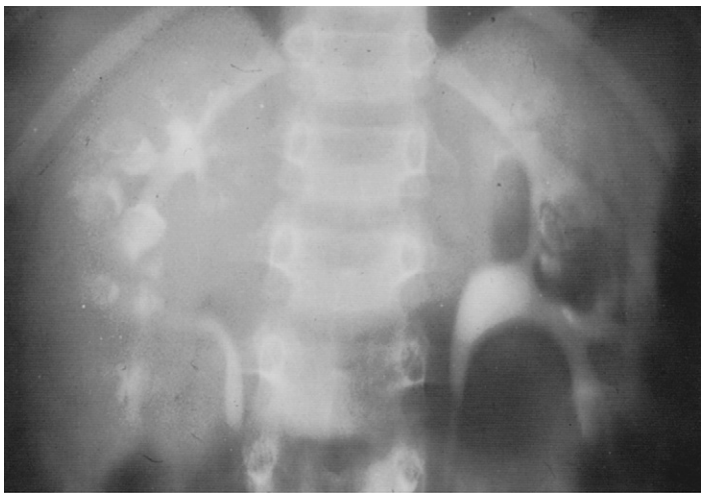

Figure 118–26. Intravenous urogram of a 9-year-old girl with hematuria. Characteristic puddling of contrast medium in the ectatic papillary collecting ducts makes the diagnosis of medullary sponge kidney. (From Glassberg KI, Hackett RE, Waterhouse K: Congenital anomalies of the kidney, ureter and bladder. In: Kendall AR, Karafin L, editors. Goldsmith's practice of surgery: urology. New York: Harper & Row; 1981. p. 1–82.)

Key Points: Medullary Sponge Kidney

- Medullary sponge kidney is usually a nonheritable condition associated with dilated collecting ducts that appear as bristles on a brush on intravenous pyelography, and the ducts are sometimes filled with calcifications.
- There is a high incidence of renal colic (50% to 60%), urinary tract infections (20% to 33%), gross hematuria (10% to 18%), and hypercalciuria (33%).

21%. The incidence appears to be higher in female than in male stone formers (Palubinskas, 1961; Lavan et al, 1971; Parks et al, 1982; Sage et al, 1982; Wikstrom et al, 1983; Vagelli et al, 1988; Yendt, 1990). Urinary tract infections, likewise, seem to be more common in female patients with medullary sponge kidney (Parks et al, 1982).

One third to one half of the patients with medullary sponge kidney has hypercalciuria (Ekstrom et al, 1959; Harrison and Rose, 1979; Parks et al, 1982; Yendt, 1990). Incomplete distal renal tubular acidosis may be found in as many as 30% to 40% of these patients (Torres, 2008). In the absence of infection, the stones passed by patients with medullary sponge kidney are composed of calcium oxalate, either alone or in combination with calcium phosphate. Medullary sponge kidney has also been reported in association with rare congenital anomalies, such as hemihypertrophy, Beckwith-Wiedemann syndrome (macroglossia, omphalocele, and gigantism), Ehler-Danlos syndrome, anodontia, and Caroli disease.

Diagnosis

In general, intravenous urography is more sensitive than CT in detecting mild cases of medullary sponge kidney. **The urographic features of the disorder are as follows: (1) enlarged kidneys, sometimes with calcification, particularly in the papillae; (2) elongated papillary tubules or cavities that fill with contrast medium; and (3) papillary contrast blush and persistent medullary opacification** (Gedroyc and Saxton, 1988). Calcium deposits within the tubules may appear as renal calculi or nephrocalcinosis.

Treatment and Prognosis

It is the complications of medullary sponge kidney, calculus formation and infection, that require management. In addition to liberal fluid intake, **thiazides are effective for lowering hypercalciuria and limiting stone formation. If thiazides cannot be used, inorganic phosphates may be appropriate;** however, they should not be used in patients with urinary tract infections caused by urease-producing organisms, because of the risk of struvite stones. **For those patients with renal lithiasis, thiazides should be administered even if hypercalciuria is not present.**

Because infections are not unusual in patients with medullary sponge kidney, especially if stones are present, cultures should be obtained frequently, and long-term prophylaxis should be considered in some cases. Infections by coagulase-positive staphylococci are common in patients with stones and should be treated even when the colony count in the cultures is less than 100,000/mL (Yendt, 1990). Repeated investigations for hematuria should be avoided. In cases where stones require surgical therapy, standard procedures, such as extracorporeal lithotripsy and percutaneous nephrolithotomy, may be employed.

ACQUIRED RENAL CYSTIC DISEASE

Acquired renal cystic disease (ARCD), also known as acquired cystic kidney disease (ACKD), is defined as bilateral cystic renal change in patients with end-stage renal disease due to causes other than inherited renal cystic disease. A minimum of three cysts in each kidney is required for diagnosis. This disease entity was first described in 1977 in **patients receiving hemodialysis; however, it soon became apparent that the disorder is almost as common in patients receiving peritoneal dialysis** (Dunhill et al, 1977; Thomson et al, 1986). It is now known that dialysis is not a prerequisite of ARCD, and it is likely that the uremic state causes the pathologic changes seen; dialysis merely prolongs patient survival and the amount of time available for the cystic changes to occur (Fisher and Horvath, 1972; Ishikawa et al, 1980; Kutcher et al, 1983; Miller et al, 1989; Truong et al, 2003).

The prevalence and severity of this disease increase with the duration of azotemia and the subsequent need for dialysis. Acquired cysts are found in roughly 10% of patients with ESRD prior to dialysis. The incidence increases to 44% within 3 years after beginning dialysis, to 60% at 5 years after beginning dialysis, and to greater than 90% if the patient is on dialysis for 10 or more years. ARCD is 3 times more common in men than in women and is generally thought to be unrelated to age or the cause of renal failure. African-Americans, and perhaps Japanese, are more prone than Americans of European descent to develop ARCD (Reichard et al, 1998). **ARCD can occur in children as well (an incidence of ≈23% has been reported)** (Hakim et al, 1994). A successful renal transplant was previously thought to delay or even reverse the cystic changes, but this is not supported by more recent data (Heinz-Peer et al, 1995; Doublet et al, 1997; Kliem et al, 1997).

Etiology

Several etiologic theories have been proposed for ARCD, although the exact cause has not been identified. One theory suggests that tubular obstruction resulting from fibrosis, oxalate crystals, vascular occlusion, or ischemia leads to cyst formation. A number of other findings suggest a role for toxins. First, the cysts, adenomas, and carcinomas usually are multiple and bilateral, as are the carcinomas induced experimentally in rats by toxins. Second, there is often a regression of the cysts after successful transplantation (Ishikawa et al, 1983), suggesting that some cystogenic or carcinogenic toxin of uremia is being eliminated by the allograft. Third, if transplantation fails and dialysis is resumed, the cysts return even in chronically rejected transplanted kidneys. Another hypothesis suggests that the accumulation of growth factors, such as epidermal growth factor (EGF), and other stimulatory chemicals (present with uremia) lead to the development of cysts (Bisceglia et al, 2006). Yet another theory suggests that loss of functioning renal tissue leads to the production of renotrophic agents that induce hyperplasia of remaining glomeruli, cyst development, and, in extreme cases, renal tumors (Harris et al, 1983; Yamamoto et al, 1983).

Clinical Features

Most patients with ARCD are asymptomatic. **The majority of clinical manifestations result from spontaneous**

Key Points: Acquired Renal Cystic Disease

- Acquired renal cystic disease is associated with chronic renal failure and is most often seen in patients on long-term hemo- and peritoneal dialysis.
- Acquired renal cystic disease consists of hyperplastic renal cysts and frequently adenomas; either can progress to RCC.
- The incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population. If RCC develops, it mostly does so before 10 years of dialysis.
- The cysts usually regress with transplantation, and even when this occurs, there still is some suggestion that the risk of developing RCC still persists, but at a much lower incidence.

bleeding into one or more of the cysts, making the most common presentation loin pain, hematuria, or both conditions. Bleeding occurs in as many as 50% of patients (Levine, 1996). When significant bleeding occurs, it may cause a subcapsular or retroperitoneal hematoma and may be secondary to renal cysts or to RCC. This bleeding may be complicated by coagulation defects induced by uremia or heparinization during dialysis. Other much less common complications are cyst infection, urolithiasis, and a rapid rise in hematocrit, which is probably related to increased renal synthesis of erythropoietin (Shalhoub et al, 1982; Ratcliffe et al, 1983; Mickisch et al, 1984).

Renal neoplasms, principally adenomas, occur in 10% of patients receiving chronic hemodialysis, and, when ARCD is present, the incidence of neoplasms is even higher, ranging from 20% to 25% (Gardner and Evan, 1984). The overall prevalence of RCC in hemodialysis patients is approximately 1%. Carcinoma is 3 times more likely in the presence of ARCD and 6 times more common in large cystic kidneys than in small cystic kidneys (Torres, 2008). **Overall, the incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population** (Resseguie et al, 1978; Port et al, 1989; Levine et al, 1991; Ishikawa, 1993; Truong et al, 1995).

Compared with the sporadic form, RCC associated with ARCD is characterized by younger patient age, male predominance, frequent multicentricity and bilaterality, and less aggressive behavior (Gronwald et al, 1999; Denton et al, 2002; Truong et al, 2003). Approximately 20% of ARCD-associated RCC metastasizes versus 50% for sporadic RCC. **The risk factors for tumor development include male gender, duration of dialysis, and kidney weight, but not type of dialysis.** Children on dialysis can also develop RCC, despite its rarity in the general pediatric population. Most tumors (86%) are asymptomatic, and the symptomatic ones are related mostly to bleeding from tumor. Many manifest exclusively as persistent hematuria and are not seen by any available imaging techniques. Nephrectomy is recommended for tumors larger than 3 cm or for smaller ones that are associated with persistent hematuria or rapid growth (Ishikawa, 2000; Truong et al, 1995).

Histopathology

Both kidneys are usually smaller than normal, and the cysts are multiple and bilateral. The cysts develop predominantly in the cortex, although the medulla may be affected, especially later in the disease process (Fig. 118–27). The cysts average 0.5 to 1.0 cm in diameter, but some have been reported to reach 5.0 cm (Miller et al, 1989). Larger cysts, a frequent feature of ADPKD, are rare. The cysts are unilocular and contain clear, straw-colored, or gelatinous fluid, with frequent bleeding and/or neoplastic transformation.

Most cysts are lined by a single layer of epithelium composed of flat nondescript cells, cells with abundant cytoplasm and hyaline droplets, or small cuboidal cells resembling those from distal tubules or collecting ducts. Cysts usually show secondary changes, including luminal deposition of degenerated blood, hemosiderin, or calcium oxalates (Hughson et al, 1986; Ishikawa, 1991; Truong et al, 1995). The nuclei of the epithelial cells in these cases are round and regular, without prominent nucleoli (Hughson et al, 1980).

Differentiating renal tumors into adenomas and carcinomas is arbitrary at times. Most renal nodules that are smaller than 1 cm in diameter are adenomas, and most that are larger than 3 cm in diameter are carcinomas. Tumors between 1 and 3 cm in diameter must be considered equivocal. It is not clear whether renal adenomas undergo malignant transformation. It is believed that atypical hyperplastic epithelium occurs even without cyst formation and that these cells are the precursors of both atypical cysts and adenomas (Hughson et al, 1986). It is thus possible that either hyperplastic cysts or adenomas can become RCCs. Therefore one must not ignore the native kidney left in situ during a renal transplantation. Hyperplastic cyst epithelium has also been considered a possible precursor of RCC in other cystic diseases (VHL disease and tuberous sclerosis) (Fayemi and Ali, 1980).

Evaluation

Ultrasonography is the most common modality used to diagnose and monitor patients with ARCD. CT and MRI identify more cysts, and MRI is probably better at demonstrating and characterizing small lesions in particular (Heinz-Peer et al, 1998). Ultrasonography usually shows small, hyperechoic kidneys with cysts of various sizes. Cyst wall calcification may be visible, but it is more readily seen on CT. CT with and without contrast is better for distinguishing kidneys with a few simple cysts from those with multiple acquired cysts and is the most useful for detecting neoplasms. In patients with ESRD not yet on dialysis, however, the use of CT contrast should be avoided for fear of causing further deterioration of renal function. Ultrasonography and MRI with gadolinium enhancement are better alternatives to contrast-enhanced CT in these patients. **A word of caution, however: Nephrogenic systemic fibrosis (NSF) is a rare but serious and life-threatening disorder observed in patients with renal impairment, and is associated with the infusion of gadolinium as a MRI contrast agent in patients with ESRD. Caution should be used when using gadolinium in this patient population.**

In uremic patients with fever, one should consider the diagnosis of ARCD and the possibility of an infected cyst (Bonal et al, 1987). Infection should be suspected if ultrasonographic examination shows internal echoes or a thickened wall. Cyst puncture can be used to confirm the diagnosis and to identify the infecting microorganism. CT examination may identify cyst wall thickening in cases with infection.

In the differential diagnosis of ARCD, the etiology of the renal failure must be considered and, in particular, the possibility of ADPKD. Usually, patients with ARCD have smaller kidneys and

Figure 118–27. Bilateral multiple renal cysts and diffuse calcification in enlarged kidneys in a patient undergoing chronic hemodialysis. The findings simulate those of ADPKD. However, cystic disease was not the cause of the uremia, and the diagnosis of acquired renal cystic disease was made. (Courtesy of D. Gordon, MD.)

smaller cysts and are free of the extrarenal manifestations of ADPKD. In patients receiving hemodialysis, kidneys affected by ARCD usually are less than 300 g; ADPKD kidneys usually are larger than 800 g (Feiner et al, 1981).

Treatment

Bleeding episodes are often treated conservatively with bed rest and symptom control. Persistent bleeding and pain, however, may require nephrectomy or renal embolization. If heparinization is associated with hematuria during hemodialysis, peritoneal dialysis may be substituted. Because the risk of undetected RCC is high in patients with retroperitoneal hemorrhage, nephrectomy is recommended in those cases in which carcinoma cannot be ruled out. If a few larger cysts are associated with flank pain, percutaneous aspiration (with cytologic examination) is a reasonable temporizing measure, because ARCD may regress after successful renal transplantation (Torres, 2008). For an infected cyst, percutaneous drainage may be effective. When it is not, surgical drainage or nephrectomy should be considered.

Although small renal tumors may metastasize, it is known that those less than 3.0 cm in diameter rarely do so (Bell, 1935; Talamo and Shonnard, 1980). Thus it is currently recommended that renal masses larger than 3 cm detected in ACKD be treated by surgical excision. For tumors smaller than 3 cm, some advise nephrectomy for the acceptable surgical candidate, whereas others recommend annual CT follow-up with resection only if the tumors enlarge.

It has been recommended that patients who have been receiving hemodialysis for longer than 3 years be screened by ultrasonography and CT and then monitored by ultrasonography every 6 months if the kidneys are without cysts and tumors or by both ultrasonography and CT on the same schedule if cysts or tumors smaller than 2 cm are identified (Sarasin et al, 1995).

A number of investigators have found that the cysts of ARCD regress after renal transplantation (Ishikawa et al, 1983; Kutcher et al, 1983; Thomson et al, 1986). Therefore it was considered that the incidence of RCC might fall after transplantation as well. Unfortunately, 18% of patients developed new cysts after transplantation, and renal carcinoma can occur in the native kidney 3 to 8 years after transplantation (Ishikawa, 1991; Levine and Gburek, 1994). It appears that the malignant potential of ARCD may persist for many years after transplantation, especially in older transplantation patients and in men (Heinz-Peer et al, 1995). Finally, it must be remembered that immunosuppression, in and of itself, makes these patients vulnerable to carcinoma. Native kidneys account for 4.5% of all malignancies in renal transplantation recipients (Penn, 1979).

CALYCEAL DIVERTICULUM (PYELOGENIC CYST)

A calyceal diverticulum is an outpouching of the collecting system into the corticomedullary region of the kidney, and it usually arises from the fornix of a calyx. It is a transitional epithelial-lined, smooth wall, spherical cavity that communicates with the pelvicalyceal system by a thin channel or neck, typically in the upper or lower pole. It is sometimes known as a pyelogenic cyst, especially if it arises from the renal pelvis. The size of such lesions can range from a few millimeters to several centimeters. Most diverticula are presumed to be congenital; however, similar lesions may occur due to blunt renal trauma or obstruction of a calyceal infundibulum. Diverticula are usually asymptomatic but may occasionally develop calculi. The calculi may be a single larger stone or multiple tiny stones. Occasionally, milk of calcium may be present. Passage of a stone through the narrow channel into the calyx may cause pain and hematuria.

Radiographically, these diverticula are seen as a spherical collection of contrast medium adjacent to a papilla on intravenous pyelography (IVP); however, the connecting channel is often too narrow to be demonstrated. On upright films, the urine and contrast media form a fluid level. Calyceal diverticula can also be seen on CT, MRI and ultrasonography, but the distinction between an obstructed calyx and a renal cyst may be difficult unless contrast is administered (Fig. 118–28).

This entity is discussed in more depth in Chapter 117.

PARAPELVIC AND RENAL SINUS CYSTS

Parapelvic cysts, renal sinus cyst, peripelvic cyst, pelvic cyst, parapelvic lymphatic cysts, hilus cysts, cysts of the renal hilum, and parapelvic lymphangiectasia are all terms used to describe cysts that are adjacent to the renal pelvis or within the hilum. Although some "peripelvic" cysts are simple cysts that arise from the renal parenchyma and impinge upon the renal pelvis, true cysts derived from the renal sinus have no parenchymal etiology. Thus the terms *parapelvic* and *peripelvic* are terms better used to describe the location of parenchymal cysts, while the term *renal sinus cyst* more accurately describes all other cysts in the hilum that are not derived from the renal parenchyma but rather from the other structures of the renal sinus, such as arteries, lymphatics, and fat. These are all benign lesions found in 15% to 2% of patients at autopsy. With modern imaging techniques, they can easily be distinguished from more serious lesions of the renal pelvis or renal parenchyma (Fig. 118–29).

The predominant type of renal sinus cyst appears to be due to dilation of lymphatics; however, the mechanism responsible for these changes is not known. Most often these cysts are

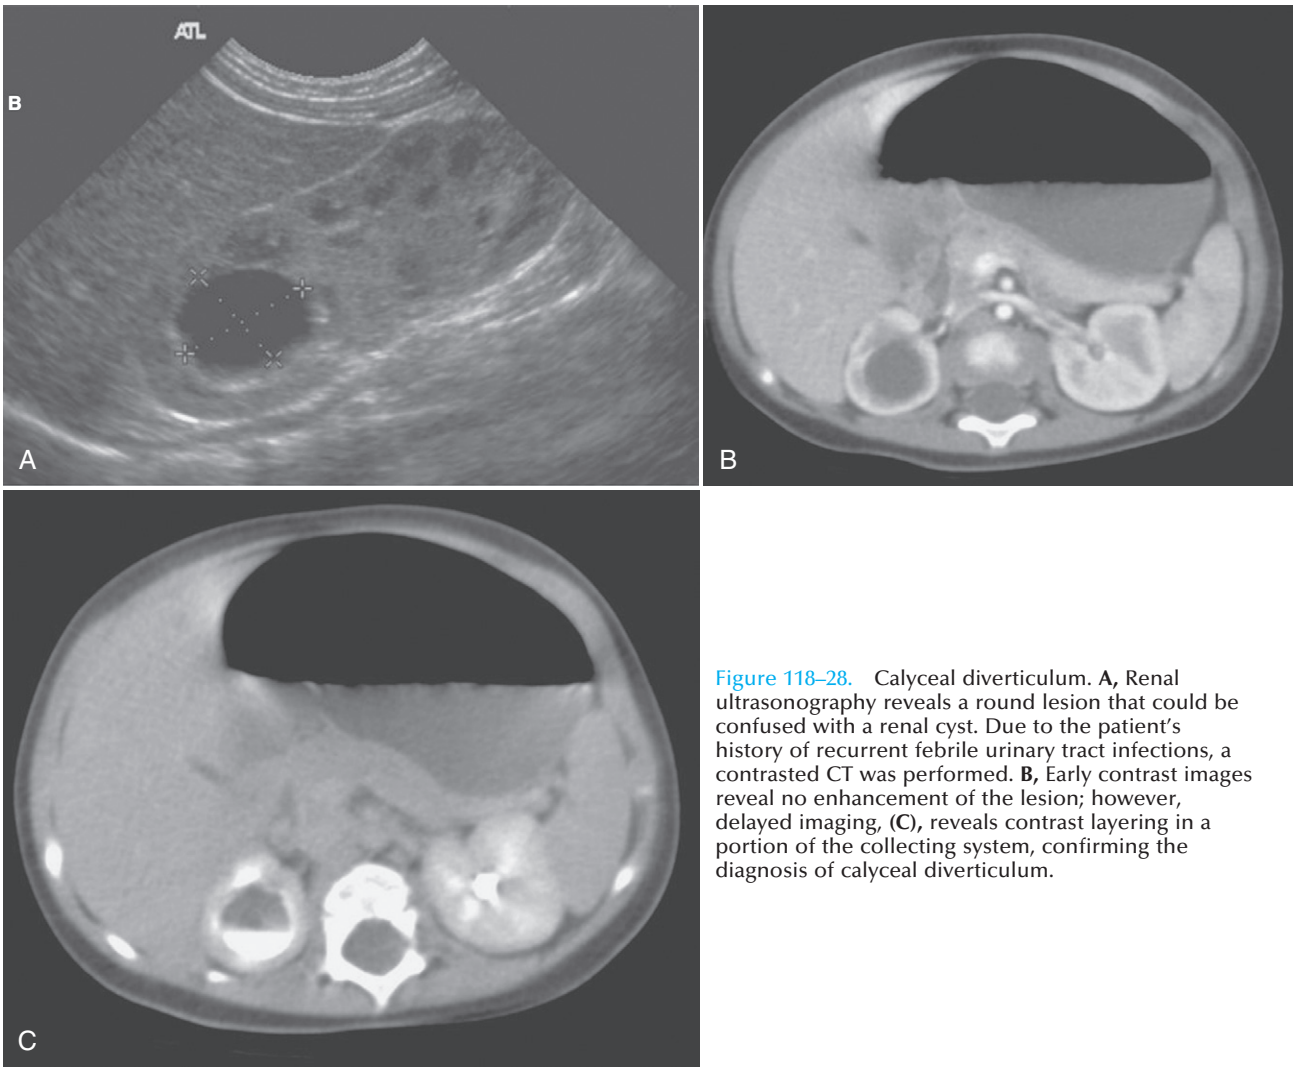

Figure 118–28. Calyceal diverticulum. **A,** Renal ultrasonography reveals a round lesion that could be confused with a renal cyst. Due to the patient's history of recurrent febrile urinary tract infections, a contrasted CT was performed. **B,** Early contrast images reveal no enhancement of the lesion; however, delayed imaging, **(C),** reveals contrast layering in a portion of the collecting system, confirming the diagnosis of calyceal diverticulum.

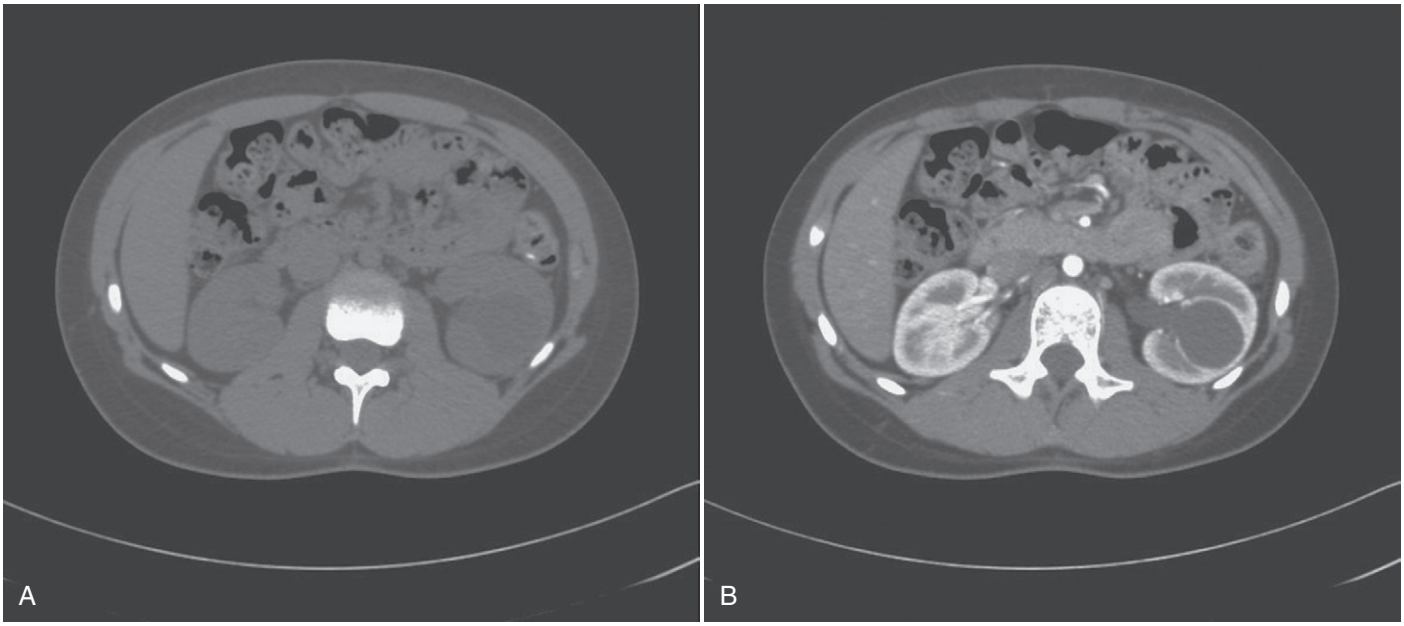

Figure 118–29. Parapelvic cyst. **A,** A hypoechoic, well-circumscribed, round focus in the peripelvic region of the kidney. **B,** There is no delayed enhancement following the administration of intravenous contrast. There is no hydronephrosis or hydroureter. Note contrast within the ureter on the contrasted images.

multiple, and often they are bilateral. Other renal sinus cysts are due to fluid replacing adipose tissue in the renal sinus as the kidney becomes affected by local vascular disease and atrophy.

Patients are usually in their fifth or sixth decades and are almost always asymptomatic. These cysts are usually discovered incidentally in the course of evaluation for other conditions, such as urinary tract infections, nephrolithiasis, hypertension, and prostatism. There are rare instances of obstruction of a collecting system from these cysts. Ultrasonography will show multiple echo-free areas in the region of the renal sinus. Differentiation from hydronephrosis may be difficult. A diagnosis of hydronephrosis is established without question when dilated calyces are seen to communicate with a dilated renal pelvis. On CT, renal sinus cysts have the attenuation value of water, and they can often be seen within the renal sinus as they displace the calyces peripherally. On nonenhanced scans, multiple renal sinus cysts resemble a dilated renal pelvis and thus mimic hydronephrosis. Differential diagnosis should include renal sinus lipomatosis (fat density), lymphoma, hemorrhage, and urinoma. The therapeutic approach to renal sinus cysts should be conservative.

Core Principles of Perioperative Management in Children

Carlos R. Estrada, Jr., MD ● Lynne R. Ferrari, MD

Growth and Maturation
Perioperative Fluids
Pediatric Anesthesia and Analgesia
Surgical Preparation
Intraoperative Considerations
Postoperative Care

The maxim "children are not small adults" is a critically important concept that must be remembered when contemplating surgical intervention in the pediatric population. Children have unique anatomy, physiology, and emotional and psychologic needs, all of which vary with the child's age. In addition, we are increasingly involved in prenatal counseling and care, and therefore an understanding of fetal development and physiology is necessary. This chapter reviews the core principles of pediatric perioperative care with which any pediatric surgeon must be familiar to ensure optimal surgical outcomes.

GROWTH AND MATURATION

Prematurity and Intrauterine Growth Restriction

A baby born before 37 weeks' gestation is considered premature. The severity of prematurity may be indicated by the birth weight, although these two factors are not necessarily related. Infants weighing 2500 g or less at birth are considered low birth weight (LBW) in prematurity, but in an infant born full term, this weight would indicate intrauterine growth restriction (IUGR). This is an important distinction, because full-term neonates with IUGR usually have different problems than premature infants. In the United States, approximately 30% of LBW infants are born after 37 weeks' gestation. Premature infants weighing 1500 to 2500 g are referred to as moderately low birth weight (MLBW); those less than 1500 g are referred to as very low–birth-weight (VLBW) infants; and infants who weigh less than 1000 g are considered extremely low–birth-weight (ELBW) infants. MLBW infants account for 82% of premature infants, VLBW 12%, and ELBW 6%. In 2006, 12.8% of live births in the United States were premature, and 8.3% were LBW. Between 1996 and 2006, the rate of premature births in the United States increased more than 16%. With respect to race, the rate of prematurity in the United States is highest for black infants (18.3%), followed by Native Americans (14.1%), Hispanics (12.1%), whites (11.6%), and Asians (10.7%). **The clinical implications of prematurity are profound, and premature infants accounted for 16.6% of all infant deaths in the United States in 2005.** These implications are especially relevant to the VLBW and ELBW infants, who are surviving in increasing numbers due to remarkable advances in neonatal critical care. These infants account for a large proportion of neonatal deaths and long-term disability, and because of their extreme prematurity are predisposed to hyaline membrane disease, leading to chronic lung disease, retinopathy of prematurity, intraventricular hemorrhage, and necrotizing enterocolitis (Teitelbaum and Coran, 2003b; Pierro, 2006; Eichenwald and Stark, 2008; Goldenberg et al, 2008).

IUGR is defined on prenatal ultrasonography as a fetus whose estimated weight is below the 10th percentile for its gestational age. At term, the birth weight below 2500 g is considered IUGR. Approximately 70% of infants with a birth weight that qualifies for IUGR are constitutionally small, and in the remaining 30%, the cause of IUGR is pathologic. IUGR can be limited to intrauterine development, resulting in a normal-sized baby at birth. General causes of IUGR include placental insufficiency, chronic maternal disease, abnormal placentation, genetic disorders, malformations, immunologic diseases, maternal infections, metabolic diseases, maternal substance abuse, and multiple gestations. IUGR is typically classified as symmetrical or asymmetrical. Symmetrical IUGR describes a fetus whose entire body is proportionally small, and is considered the more severe form (Styne, 2004). Asymmetrical IUGR is related to processes that require the fetus to direct its energy to the maintenance of vital organs, usually the heart and brain. Therefore the fetus with asymmetrical IUGR typically has a normal head circumference but small abdominal circumference, small limbs, reduced skeletal muscle mass, and decreased subcutaneous and abdominal fat. Infants with asymmetrical IUGR more frequently exhibit catch-up growth than their symmetrical IUGR counterparts. However, of all infants with IUGR, 10% to 30% will have short stature as adults. Given the wide variety of causes, the management of IUGR is individualized, and often complex decisions are required, weighing elective preterm delivery and the risks of prematurity against the risks associated with IUGR (Teitelbaum, 2003b; Pierro, 2006; Alberry and Soothill, 2007; Goldenberg et al, 2008).

Intrauterine Growth and Lung Development

Proper intrauterine growth and development are dependent on presence of normal amniotic fluid volume. Of particular relevance to urologists is lung development, which is dependent on amniotic fluid. Early in pregnancy, the placenta produces amniotic fluid. **At 10 to 12 weeks' gestation, the fetal kidneys begin to produce urine, which comprises the majority of amniotic fluid.** Lung development is a highly complex orchestration of molecular processes, and is divided into three stages: embryonic, fetal, and postnatal or alveolar stages.

The embryonic stage begins with a ventral bud from the foregut at 3 weeks' gestation, which divides into the primordial segments that give rise to all lung tissue (Teitelbaum, 2003b; Wilson, 2006). **The fetal stage of lung development begins at 7 weeks' gestation and proceeds to term.** This stage is further subdivided into three phases: pseudoglandular (7 to 17 weeks), canalicular (16 to 25 weeks), and saccular (25 weeks to term). The pseudoglandular phase is of particular interest, because its timing coincides with the replacement of placenta-derived amniotic fluid with fetal urine-derived amniotic fluid. **By the end of the 16th week of gestation, all lung branching occurs, resulting in the terminal bronchial airways.** After this time, the only further growth that occurs is elongation and widening of existing airways. **A large body of experimental data indicates that these early and critical events in lung development are dependent on lung fluid dynamics, and any restrictive process, including tracheal occlusion (e.g., atresia) or oligohydramnios, results in pulmonary hypoplasia, which can be fatal at birth.** The severity of the restrictive process is proportional to the degree of hypoplasia (Teitelbaum, 2003b; Wilson, 2006).

The postnatal stage continues for one year after birth. This stage is characterized by maturation of the terminal saccules into alveoli. At birth, the lung contains approximately 20 million saccules, and at approximately 5 weeks postnatal, these begin to develop into the 300 million alveoli expected to be present by 8 years of age. The most robust development of the alveoli occurs before 4 years of age. After 8 years of age, lung volume increases because of increase in alveolar size, not from an increase in alveolar number (Teitelbaum, 2003b; Wilson, 2006).

Postnatal Considerations

In the postnatal period, growth and development in children occurs at a rapid pace, especially in early childhood. A full-term newborn grows at a rate of 25 to 30 g/day over the first 6 months of life, leading to a doubling of the birth weight during this period. In the first 12 months of life, an infant's birth weight is typically tripled. By 3 years of age, birth weight is expected to quadruple, and by 10 years of age it will increase 20-fold from the birth weight. Body length increases by approximately 50% in the first year of life, and by threefold by 10 years of age (Teitelbaum and Coran, 2003c).

Cardiovascular

A detailed description of pediatric cardiovascular physiology and management is beyond the scope of this chapter, but a few principles are important for the urologist to consider. These include the basic differences between pediatric and adult cardiovascular physiology and an understanding of the common congenital heart defects that may affect urologic patients.

The neonatal and pediatric myocardium is stiffer and less compliant compared with the adult heart. This results in diminished preload capacity, so that increases in end-diastolic ventricular volume and increases in right ventricular pressure result in decreased cardiac output at lower levels than in adult patients. In addition, infants and children have relatively higher resting heart rates. **As a result, cardiac output in children is heart rate dependent, because the stroke volume is relatively fixed. Decreases in heart rate in infants and children will result in decreases in cardiac output to a greater extent than a similar decrease in heart rate in an adult patient.** A reduction of a child's heart rate to that of a typical adult would result in marked decrease in cardiac output. Finally, the pediatric heart is significantly less responsive to inotropic agents, because it has reduced intramyocardial calcium release (Hirschl, 2003a; Rocchini, 2006).

Congenital heart defects are very common, occurring in approximately 1 of every 120 live births. In general, they are classified as hypoplastic, septal, cyanotic, or obstruction defects. The septal defects are the most common, of which ventricular septal defect (VSD) is most prevalent. Most infants with septal defects have no symptoms during the first month. However, after 4 to 6 weeks of life, pulmonary resistance reaches normal levels, and thus during the second month of life, congestive heart failure can occur. Hypoplasia of the heart is rare, but is the most serious form of congenital heart disease. These defects typically result in the failure of either the right ventricle or the left ventricle to develop adequately, leaving only one side of the heart capable of pumping blood to the body and lungs. In hypoplastic left heart syndrome, the presence of a patent ductus arteriosus is critical for the infant's ability to survive until emergency surgery can be performed. Without this pathway, blood cannot circulate to the body. In hypoplastic right heart syndrome, a patent foramen ovale serves the same function. Obstruction defects occur when heart valves, arteries, or veins are abnormally narrow or blocked. Common obstruction defects include pulmonary valve stenosis, aortic valve stenosis, and coarctation of the aorta, with other types, such as bicuspid aortic valve stenosis and subaortic stenosis, being comparatively rare. Any narrowing or blockage can cause enlargement of the heart or hypertension. Cyanotic heart defects are named thus because they result in cyanosis. These defects include persistent truncus arteriosus, total anomalous pulmonary venous connection, tetralogy of Fallot, transposition of the great vessels, and tricuspid atresia. From a noncardiac surgery perspective, it is important to remember that many children with complex cardiac anomalies are on medications, such as aspirin and sildenafil, that predispose them to bleeding. In addition, certain types of surgically induced circulation—for instance, induced by the Fontan procedure—purposely increase systemic venous pressure, which can be problematic for postoperative bleeding. Careful consideration of these variables and planning with a pediatric cardiac anesthesiologist is obligatory (Hirschl, 2003a; Rocchini, 2006).

Immunologic

Neonates have increased susceptibility to bacterial infections, which is predominantly due to deficiencies in neonatal host defense mechanisms. Premature infants are at even higher risk. This susceptibility is due to several factors related to the immaturity of neonatal leukocytes, including neutrophils, monocytes, T and B lymphocytes, and NK cells, and also with deficiencies in the complement activation system.

Although the number of neutrophils is near the adult level at term (approximately 60% of circulating leukocytes), neonates have a relative inability to increase their circulating levels in response to stress or infection. This is thought to be due to a decreased neutrophil storage pool and to increased margination of neutrophils. Premature infants have the added problem of having a significantly lower neutrophil count at birth. Neonatal neutrophils are also less adhesive to activated endothelium, a process that is critical to chemotaxis and migration to sites of inflammation and infection. This may be due to decreased neonatal neutrophil expression of L-selectin and β_2 integrin. In addition, neonatal serum is deficient in opsonins, which are necessary for neutrophil phagocytosis. Therefore even though neonatal neutrophils are fully competent to kill bacteria, they may do so less efficiently. Unlike a decreased neutrophil storage pool, the number of monocytes in neonates is equal to or greater than in adults. For unclear reasons, however, the migration of monocytes to sites of inflammation and infection is significantly delayed (Hirschl, 2003b; Upperman, 2006).

T-lymphocyte function is also impaired in neonates, despite having a significantly greater number of circulating T cells compared with adults. In addition, unlike adults, there is a greater proportion of CD4+ T cells than CD8+ T cells. The impaired function is believed to be related to their naive phenotype that is due to their lack of exposure to foreign antigens and because they produce relatively limited amounts of key inflammatory cytokines, including tumor necrosis factor-alpha (TNF-α), interferon-gamma (IFN-γ), interleukin (IL)-3, IL-4, IL-5, and IL-10. B-lymphocyte function is also impaired in neonates, which is due to their inability to differentiate into immunoglobulin (Ig)G- or IgA-secreting plasma cells. They are able to differentiate into IgM-secreting plasma cells but rely on maternal placental transfer for essentially all IgG. This reliance continues until the third or fourth month of life, after which time the proportion of neonatal IgG overtakes maternal IgG. Although maternal IgG is adequate for protection against most infections, strains of bacteria, such as *Escherichia coli* and *Salmonella,* can elicit a different immunoglobulin subtype, leaving the fetus and neonate with suboptimal immune protection. Premature infants are at even greater risk, because they are born without sufficient levels of maternal IgG (Hirschl, 2003b; Upperman, 2006).

Another lymphocytic deficiency in neonates involves the natural killer (NK) cells, which play an important role in protection against intracellular pathogens by targeted cell lysis. At term, the proportion of NK cells is similar to that in adult circulation, but they are functionally and phenotypically immature. For unclear reasons, their lytic potential is only 50% of adult NK cells, and it is not until late infancy that they reach their full functional potential (Hirschl, 2003b; Upperman, 2006).

The relative deficiency of immunoglobulins in neonates results in the increased reliance on the alternative, that is, antibody-independent pathway of complement activation. However, in neonates there are a reduced number of classic and alternative complement activation pathway factors. Specifically, the level of C9 is diminished, which is critical for protection against gram-negative bacteria. Breast-feeding is believed to partially compensate for these intrinsic neonatal immunologic deficiencies. Human milk contains immunoglobulins, including IgG, IgM, and secretory IgA; lymphocytes; macrophages; polymorphonuclear leukocytes; and components of the complement cascade. Because of these and other benefits, the American Academy of Pediatrics recommends continuing breast-feeding for the first 12 months of life. **Although the neonatal period presents the highest risk of infection for children, the immune system is not fully competent until approximately 8 years of age** (Hirschl, 2003b; Upperman, 2006).

Renal

A detailed discussion of renal development can be found in Chapter 112 of this text, and therefore this section represents a very brief synopsis. Renal function begins in utero, with the first functional nephrons appearing at 8 weeks' gestation. Nephrogenesis is complete by 34 weeks. Urine production begins between 10 and 12 weeks' gestation, coinciding with the start of glomerular filtration. In utero, renovascular resistance is high, limiting renal blood flow. Immediately following birth, the distribution of renal cortical blood flow changes, with increased perfusion of the outer cortex and increased reactivity of the renal vascular bed. Consequently, the glomerular filtration rate (GFR) rises quickly despite renal blood flow remaining unchanged. In addition, water and electrolyte homeostasis is difficult to predict. **GFR and tubular function double by 1 month of age** (Kaskel et al, 1987), **and over the first 3 months of life, renovascular resistance continues to decrease, which results in further rises in GFR. Following this relatively rapid rise, GFR continues to increase more slowly toward adult levels, which are reached by 12 to 24 months of life.** The maturation of renal tubular function lags behind the maturation of glomerular function, and therefore the neonate can concentrate urine to only approximately 50% of adult capability (Greco, 2002; Teitelbaum and Coran, 2003a; Pierro, 2006).

Key Points: Growth and Maturation

- Infants with a history of prematurity and/or IUGR are at risk for adverse events and account for a large proportion of neonatal deaths and long-term disability.
- Proper intrauterine growth and development are absolutely dependent on the presence of normal amniotic fluid volume, the majority of which is composed of urine after 10 to 12 weeks' gestation.
- Lung development, in particular, depends on fluid dynamics, and processes such as oligohydramnios result in pulmonary hypoplasia.
- Neonatal and pediatric myocardium is stiffer and less compliant than in an adult, resulting in significant differences in physiologic responses and cardiovascular care.
- Many children with complex cardiac anomalies are on medications, such as aspirin and sildenafil, that predispose them to bleeding. In addition, certain types of surgically induced circulation, for instance, induced by the Fontan procedure, purposely increase systemic venous pressure, which can be problematic for postoperative bleeding.
- Neonates have increased susceptibility to bacterial infections due to deficiencies in host defense mechanisms, and the immune system is not fully competent until 8 years of age.
- The normalization of renal function is a rapidly evolving process at birth, and adult-level GFR is not reached until 12 to 24 months of life.

PERIOPERATIVE FLUIDS

Maintenance of hydration is a fundamental and critically important concept in pediatric care. For the pediatric urologist,

administration of fluids is usually for maintenance therapy in the postoperative period or for deficit therapy in the setting of postoperative dehydration. Appropriate intraoperative fluid therapy is critical to simplify postoperative fluid management and optimize the postoperative course. This is increasingly important given the increase in ambulatory surgery and the shorter length of hospital stays. **Perioperative fluid therapy begins with an estimation of fluid deficit by the anesthesia team.** If possible, urine output should be carefully monitored for the duration of surgery, and in the setting of an open lower urinary tract, the urologist should provide feedback to the anesthesiologist to ensure that the patient remains well hydrated.

Maintenance fluid replaces two losses: insensible, or evaporative, losses and urinary losses. In the perioperative period, insensible losses can vary widely with the presence or severity of several variables, including fever, tachypnea, and other conditions. Insensible losses represent loss of free water and generally account for one third of maintenance fluids. Urine losses are calculated as 280 to 300 mOsm/kg of water with a specific gravity of 1.008 to 1.015, but this concentration can vary depending on the patient's ability to concentrate urine. Urinary losses account for two thirds of total maintenance fluids. **The total requirements for maintenance fluids can be calculated using the Holliday-Segar formula as shown in** Table 119–1 (Holliday and Segar, 1957). **After calculating the fluid requirement, children usually receive either 5% dextrose (D5) ¼ normal saline (NS) + 20 mEq/L potassium chloride (KCl) or D5 ½ NS + 20 mEq/L KCl.** Children who are younger than 6 months are generally given the solution with ¼ NS because of their high water needs per kilogram. Children 6 months and older, however, should receive the solution with ½ NS (Greenbaum, 2007).

In the setting of postoperative dehydration, the severity is determined as described in Table 119–2 (Siker, 2002). **Generally, deficit replacement should begin with a balanced salt solution, such as lactated Ringer (LR) solution or normal saline, to increase intravascular volume.** Typically, a bolus of 10 to 20 mL/kg is used, but a rate of up to 40 mL/kg during the first 1 to 2 hours is well tolerated (Carvajal, 1994). The type of fluid deficit can be estimated from the patient's history, physical examination findings, electrolyte values, and serum tonicity. Types of dehydration include isotonic (serum osmolarity 270 to 300 mOsm/L, serum sodium [Na^+] concentration 130 to 150 mEq/L), hypotonic (serum osmolarity < 270 mOsm/L, serum Na^+ concentration < 130 mEq/L), or hypertonic (serum osmolarity > 310 mOsm/L, serum Na^+ concentration > 150 mEq/L). Patients with hypertonic dehydration require careful consideration of fluid type and rate, because complications, such as cerebral edema, may occur during rehydration (Friedman, 2005; Greenbaum, 2007).

Table 119–1.

Daily Maintenance Fluid Requirements

WEIGHT (kg)	DAILY REPLACEMENT	HOURLY REPLACEMENT
0-10	100 mL/kg/day	4 mL/kg/hr
11-20	1000 mL/day + 50 mL/kg/day	40 mL/hr + 2 mL/kg/hr
>20	1500 mL/day + 25 mL/kg/day	60 mL/hr + 1 mL/kg/hr

From Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. Pediatrics 1957;19:823–32.

Table 119–2.

Estimation of Fluid Deficit

DEFICIT	CLINICAL FINDINGS
Mild (1%-5%)	Dry mucous membranes, poor skin turgor, irritability, decreased urination
Moderate (6%-10%)	No tears, tenting of skin, lethargy, oliguria
Severe (≥11%)	Sunken eyes and fontanelles, cold skin, anuria, tachycardia and tachypnea, hypotension, coma

Modified from Siker D. Pediatric fluids, electrolytes, and nutrition. In: Gregory GA, editor. Pediatric anesthesia. New York: WB Saunders; 2002.

Key Points: Perioperative Fluids

- Maintenance of appropriate hydration is a fundamental and critically important concept in pediatric care.
- Fluid therapy must begin with an assessment of fluid deficit.
- Replacement fluids should begin with a balanced salt solution such as LR or NS.
- Maintenance fluids can be calculated using the Holliday-Segar formula.
- For maintenance fluids, children usually receive either D5 ¼ NS + 20 mEq/L KCl or D5 ½ NS + 20 mEq/L KCl, depending on their age and weight.

PEDIATRIC ANESTHESIA AND ANALGESIA

Psychologic and Emotional Preparation

The psychologic state of a child and family, as well as the clinical state of each child, must be thoroughly understood before anesthesia and surgical intervention. If the child is not treated in an age-appropriate manner, the entire perioperative experience will likely be compromised. Conversely, if the psychologic and emotional aspects of a child's condition distract caregivers from the primary medical and surgical concerns, a successful outcome may be compromised. Therefore it is imperative that the entire health care team find the ideal balance between these two considerations (Ferrari, 2008).

It is well known that significant preoperative anxiety is associated with a difficult and often prolonged anesthetic induction (Kain et al, 1996a, 1996b). Factors including the temperament and age of the child, as well as the situational distress of the parent and the outcome of previous medical experiences, will affect the child's anxiety level. For many children, the immediate postoperative course is a mirror of the induction experience. Children who go to sleep peacefully generally awaken in the same manner and are known to have fewer difficulties in the postanesthetic care unit (PACU). It is therefore necessary to take the time to prepare the child for the anesthetic experience in an age-appropriate manner. There is consensus among anesthesiologists regarding the need for the treatment of a child's anxiety before surgery (McCann and Kain, 2001). The development of coping skills is considered the most effective preoperative intervention, followed by modeling, play therapy, an operating room (OR) tour, and printed material (Kain et al, 1996a; O'Byrne et al, 1997; Moynihan and Kurkar, 1999; Ferrari, 2008).

The level of maturity affects a child's understanding of and response to illness (Moynihan and Kurkar, 1999). **Infants fear separation from their primary caregivers and exhibit stranger anxiety; therefore it is important that parental involvement in the perioperative experience be maintained. Toddlers fear loss of control, so enabling a child to make choices, such as asking if the child has a color preference for his or her hospital gown, will diminish anxiety. Preschool-age children fear injury; they may fear, for example, that a blood draw may result in not enough blood being left in their bodies.** They tend to think in concrete terms and therefore may take statements literally, so one must be cautious when choosing the language used with this age group. **The school-age child typically fears that he or she may not meet the expectations of adults.** They may nod with understanding and listen intently, despite not grasping what the adult is saying. They are reluctant to ask questions for fear that they should already know the answer. It is therefore imperative that expectations are clearly explained. **Adolescents fear death and usually do not understand bodily functions.** They are often panic-stricken preoperatively but try to not show any sign of this. As a result, they might remain very quiet. It is the responsibility of the care team to anticipate this anxiety and reassure the adolescent without prompting (Ferrari, 2008).

Risk of Anesthesia

Most parents will express that they experience more anxiety about the anesthetic than the risks of the surgery. Fear of anesthesia among parents originates largely from a lack of information regarding modern anesthesia practice rather than from a high probability of risk. For many families, it may be helpful to discuss specific risks of anesthesia for their child (Olsson and Hallen, 1984; Ferrari, 2008). **For a healthy child undergoing uncomplicated surgery, the risk of an adverse event is approximately 1 in 200,000** (Eichhorn, 1993). The risk of death under anesthesia is the most feared complication. This risk is 1 in 10,000 for all patients of any age undergoing any surgical procedure (Keenan and Boyan, 1985; Tiret et al, 1986; Holzman, 1994). **However, the risk of death directly attributable to the anesthetic approaches zero, although the risk of cardiac arrests due to anesthesia remains approximately 4.5 in 10,000** (Gobbo Braz et al, 2006). The incidence of anesthetic-related complications and death is highest during the first year of life at 43:10,000, but this decreases dramatically during the second year of life to 5:10,000 (Tiret et al, 1988). **Anesthetic risks increase by a factor of 6 during emergency procedures in all age groups** (Ferrari, 2008; Holzman, 2008).

Basic Preoperative Preparation

A complete medical history is always the first step in a thorough preoperative assessment. The history should include the prenatal course and neonatal period, because events during pregnancy and delivery may influence the child's current state of health (Means, 1997). Any prior hospital admissions should be noted. A complete review of systems is performed to evaluate for medical comorbidity that could influence the choice or outcome of anesthesia (Cote, 2001). The presence of cough, asthma, or a recent upper respiratory infection (URI) might predispose the child to bronchospasm, atelectasis, or pneumonia. New-onset heart murmur, cyanosis, hypertension, exercise intolerance, or a history of rheumatic fever can suggest an evolving issue that could be exacerbated by an anesthetic or with a surgical procedure. Parents should be queried for the presence of vomiting, diarrhea, malabsorption, black stools, gastroesophageal reflux, or jaundice to interrogate for electrolyte imbalance, dehydration, hypoglycemia, anemia, or the need for a rapid-sequence induction. A history of seizures, head trauma, or difficulty swallowing may indicate a metabolic derangement, increased intracranial pressure, or sensitivity to muscle relaxants. Urinary tract abnormalities may impact the state of hydration and renal function, and the urologist should clearly communicate the significance of these. Abnormal development, alterations in serum glucose levels, or a history of chronic steroid use may indicate an endocrinopathy, diabetes mellitus, hypothyroidism, or adrenal insufficiency. Lastly, a history of anemia, bruising, or excess bleeding may suggest a transfusion requirement or coagulopathy (Ferrari, 2008).

The family history should be obtained with particular attention to anesthesia-related events. Specifically, a history of liver problems in family members after anesthesia is important to elicit, because certain anesthetic agents are known to rarely cause liver damage. Malignant hyperthermia (MH) is always a concern in the pediatric population. Although most pediatric anesthesiologists refrain from routinely using succinylcholine, a family history of prolonged paralysis or mechanical ventilation after general anesthesia should be obtained. Finally, families should be asked if there is a history of unexpected death, sudden infant death syndrome, genetic defects, or familial conditions, such as muscular dystrophy, cystic fibrosis, sickle cell disease, bleeding tendencies, or human immunodeficiency virus infection (Ferrari, 2008).

Obtaining a complete medication history is essential. This includes prescription medications, nonprescription medications, and herbal or alternative therapies. Many over-the-counter cold remedies contain aspirin, nonsteroidal anti-inflammatory drugs, or other compounds that may interfere with coagulation. Herbal and alternative therapies are known to have significant deleterious interactions with certain prescription medications and must be considered prior to administration of anesthesia and proceeding with surgery (Cupp, 1999).

The practice of body piercing is becoming increasingly common in adolescents and young adults. Metal objects in the skin during surgery and anesthesia increase the risk of burn injury if there is an intraoperative electrocautery malfunction. In addition, metal objects can become caught on equipment in the OR, resulting in tears of the skin and subcutaneous tissue. Tongue piercing may interfere with laryngoscopy and make securing the airway unnecessarily challenging. Therefore patients should be counseled to remove all metal objects and disclose any body piercing that cannot be seen during the preoperative interview (Ferrari, 2008).

The physical examination of children must begin with simple observation from a distance, because the infant or child may become frightened when approached directly. A great deal can be learned about relevant physical findings without touching the child. The color of the skin, including the presence of pallor, cyanosis, rash, jaundice, unusual markings, or prior surgical scars, may reveal the presence of organ system dysfunction. Because congenital anomalies often occur in association with others, abnormal facies may indicate additional anomalies. The respiratory system examination should specifically address any signs of an URI. The cardiovascular examination specifically addresses the presence of heart murmurs, which must be accurately diagnosed as innocent versus pathologic. Lesions in which bacterial endocarditis prophylaxis or protection from paradoxic air embolism are required must be documented (Wilson et al, 2007; Ferrari, 2008).

Routine diagnostic testing in preparation for surgery is rarely indicated in healthy children, and studies that are ordered should be selected based on the general medical health of the patient and the procedure being performed. In general, measurement of hemoglobin/hematocrit in a healthy child undergoing elective surgery is unnecessary (Steward, 1991). **A hemoglobin/hematocrit should be measured if significant blood loss is anticipated or if the child is younger than 6 months or was born prematurely.** Neither the routine measurement of a coagulation profile nor a history of "easy bruising" is reliable in predicting surgical bleeding (Burk et al, 1992). A history of a prior hematoma and excessive bleeding following circumcision or large bruises should prompt an appropriate hematologic evaluation. Routine preoperative urinalysis is not indicated in children, and serum chemistries should only be performed when an abnormality is suspected. Children who are treated with anticonvulsants should have these medication levels checked, and an electrocardiogram or chest radiograph should only be ordered if the general medical condition warrants. Routine pregnancy testing is controversial, and the policy of one's medical facility should be followed (Ferrari, 2008).

None per Os (NPO) Guidelines

It is no longer advisable or safe to restrict children to "NPO after midnight" (Cote, 1990). This outmoded restriction increases the child's chance of undergoing induction of anesthesia when dehydrated, hypoglycemic, and cranky, all of which lead to a suboptimal situation. The risk of pulmonary aspiration of gastric contents in healthy children undergoing elective surgery is only 0.04% (Warner et al, 1999). The American Society of Anesthesiologists (ASA) has proposed practice guidelines that may be followed when determining NPO restrictions in children (Practice guidelines, 1999). **The ASA recommends fasting from clear fluids for 2 hours prior to anesthesia.** Clear liquids consist of water, nonparticulate juices (e.g., apple, white grape), Pedialyte, and Popsicles. **Fasting from breast milk for 4 hours and formula for 6 hours is recommended. The suggested fasting period for solid food is 6 hours for regular meals and 8 hours for fat-containing meals.** However, a large survey of pediatric institutions recommends fasting from all solids for at least 8 hours in all children (Ferrari et al, 1999). However, individual institutions may have specific practice guidelines that differ from the above.

Immunizations

The timing of vaccinations in the perioperative period has been a controversial topic. It is known that both anesthesia and surgery exert immunomodulatory effects, and some believe that these effects may exert additive or synergistic influences on vaccine efficacy and safety (Siebert et al, 2007). This risk, however, is theoretic and there are no guidelines that address the issue. Based on an exhaustive review of the literature, Siebert and colleagues (2007) concluded that the immunomodulatory influence of anesthesia during elective surgery is both minor and transient, lasting about 48 hours, and that the current evidence does not provide any contraindication to the immunization of healthy children scheduled for elective surgery. **However, respecting a minimal delay of 2 days (inactivated vaccines) or 14 to 21 days (live attenuated viral vaccines) between immunization and anesthesia may be useful to avoid the risk of misinterpretation of vaccine-driven adverse events as postoperative complications**. Of utmost importance is the distinction between postvaccine and postoperative temperature elevation.

Special Circumstances

Child with an Upper Respiratory Infection

Whether to proceed with an elective operation in a child with an active URI is one of the most difficult and fundamental questions in pediatric anesthesia (Hinkle, 1989). Children typically experience three to nine URI episodes per year, and the majority occur during the winter months (Van der Walt, 1995). The classic signs and symptoms include fever, irritability, restlessness, sneezing, nasal discharge, nasal obstruction, headache, malaise, and anorexia (Tait and Malviya, 2005). Children between the ages of 3 months and 3 years also have fever early in the course of the illness, and, in general, younger children have more severe infections than older children. It is likely that during the winter months a child *has* a cold, is just *recovering* from a cold, or is *about to catch* a new cold (Tait and Malviya, 2005; Ferrari, 2008).

A cough is a sign of lower respiratory involvement and should be evaluated for origin (upper airway or bronchial) and quality (wet or dry). Most children will have clear breath sounds when auscultated during quiet respirations. It is during coughing and crying that rales and rhonchi will be best detected (Ferrari, 2008).

Definitive criteria for canceling surgery have not been established, and the decision is often subjective. **Criteria that suggest that cancellation should be considered, including the necessity for endotracheal intubation, parental observation that the child is acutely ill on the day of surgery, the presence of nasal congestion and cough, a history of secondary smoke exposure, and active sputum production** (Cohen and Cameron, 1991; Parnis et al, 2001). Decisions to cancel surgery should be made collaboratively between the anesthesiologist and surgeon and based on the type of procedure, the urgency of the procedure, and the child's overall medical condition. **Most authors agree that surgery may be scheduled after the acute symptoms have resolved and no sooner than 3 to 4 weeks after the initial evaluation** (Ferrari, 2008). A suggested algorithm is provided in Figure 119–1 (Tait and Malviya, 2005; Zuckerberg, 2009).

Asthma

Asthma is one of the most common chronic pediatric illnesses and is characterized by bronchoconstriction, hypersecretion of mucous, mucosal edema, and desquamation of inflammatory cells. The hyperactive airways are very sensitive to stimulation, and endotracheal intubation is one of the most noxious stimulants resulting in bronchoconstriction in the susceptible airway. In preparing children with asthma for surgery, it is important to note if a child is on maximal medical therapy and if wheezing persists despite this. **All asthma medications, both inhaled and oral, should be administered up to and including the morning of surgery.** If children are not on maintenance therapy and only require treatment during acute exacerbations, this therapy should be administered for the 48 hours prior to anesthesia even if the child is asymptomatic. If performed, recent pulmonary function test (PFT) results should be available, and children as young as 5 years can cooperate with PFT (Ferrari, 2008).

Former Premature Infant

Advances in neonatology have resulted in an increasing number of premature infants surviving. These infants generally have

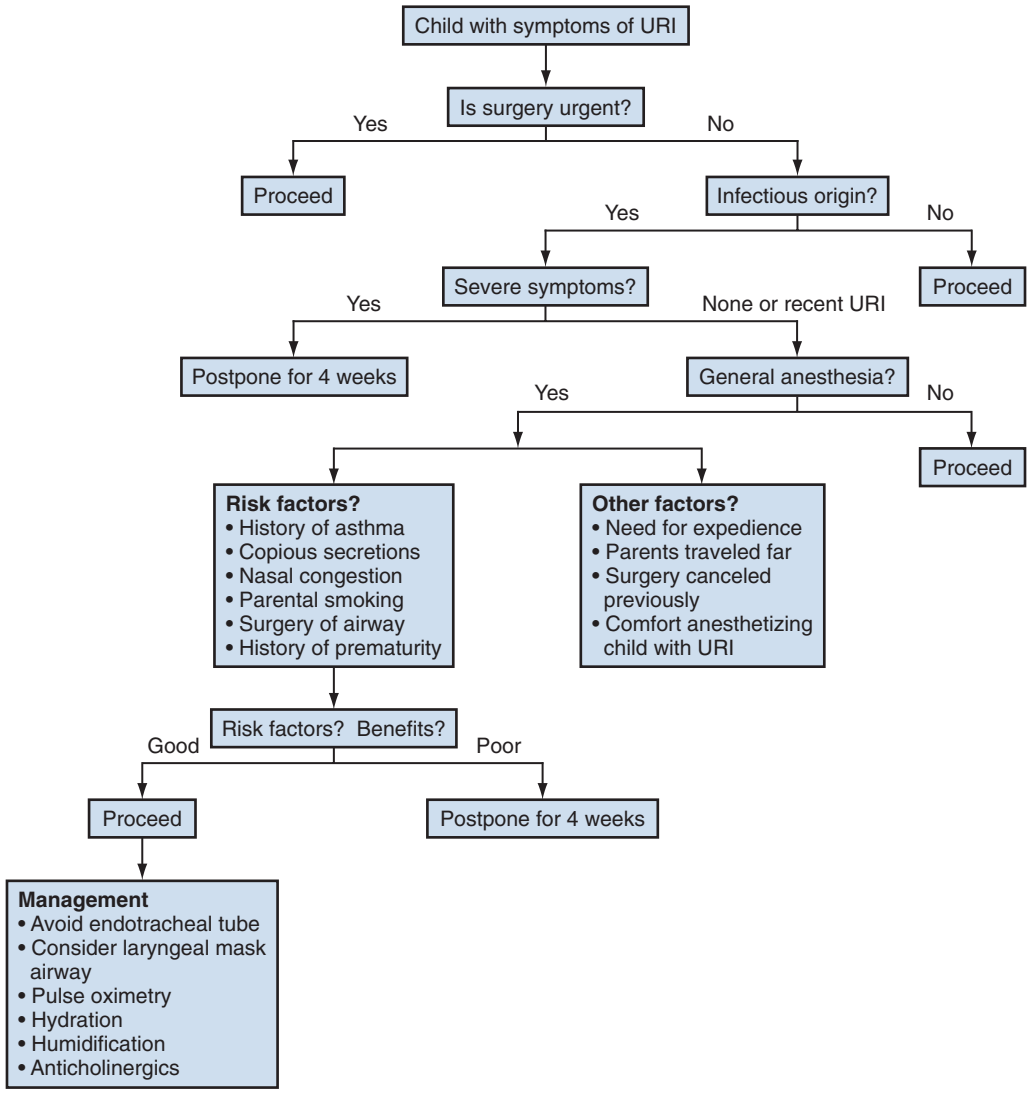

Figure 119–1. Preoperative decision making in children with upper respiratory infection symptoms (URI). (From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory infection: still a dilemma? Anesth Analg 2005;100:59–65.)

complex medical issues and often require surgery for a variety of reasons. Urgent urologic surgery in these babies, however, is rare. From a perioperative perspective, the major issue with these infants is the risk of apnea. Apnea is usually central and is the result of brainstem immaturity, which predisposes these infants to more significant apnea during the postoperative period (Kurth et al, 1987). This risk is less than 1% in a 35-week former premature infant if surgery is delayed until after 54 weeks postconceptual age (Cote et al, 1995). If surgery cannot wait, then postanesthetic apnea monitoring is required for 24 hours. Postanesthetic apnea has also been reported in full-term infants younger than 4 weeks of age, and therefore similar monitoring is required (Noseworthy et al, 1989). **In addition, a hematocrit less than 30 is associated with an increased risk of postanesthetic apnea in the former preterm infant, and therefore a preoperative hematocrit is warranted in all premature infants undergoing surgery** (Welborn et al, 1991; Ferrari, 2008).

Spina Bifida

Spina bifida is one of the most common birth defects, and urologists should be involved in the care of these patients beginning immediately after birth. The average incidence of spina bifida in the United States is 0.7 per 1000 live births. The incidence is higher on the East Coast than on the West Coast, and higher in whites (1 case per 1000 live births) than in blacks (0.1 to 0.4 cases per 1000 live births) (Lemire, 1988). These children are frequent visitors to the OR and require careful preoperative preparation, given their frequent comorbidities. **There is a high incidence of sensitivity to latex-containing products, so all patients with spina bifida should be regarded as having a latex allergy.** A significant number of children with spina bifida have ventriculoperitoneal (VP) shunts to manage the hydrocephalus. At Children's Hospital Boston, we have a mandatory protocol for elective surgery preparation in children with VP shunts to ensure that they are functional prior to administration of anesthesia (Fig. 119–2).

Children with Cancer

Children with a current or prior malignancy should have all chemotherapy documented. Anthracyclines (doxorubicin [Adriamycin]) can cause myocardial dysfunction, and others such as mitomycin C and bleomycin can cause pulmonary dysfunction. Children who have been treated with anthracycline agents require echocardiography if the cumulative dose is greater than 150 mg

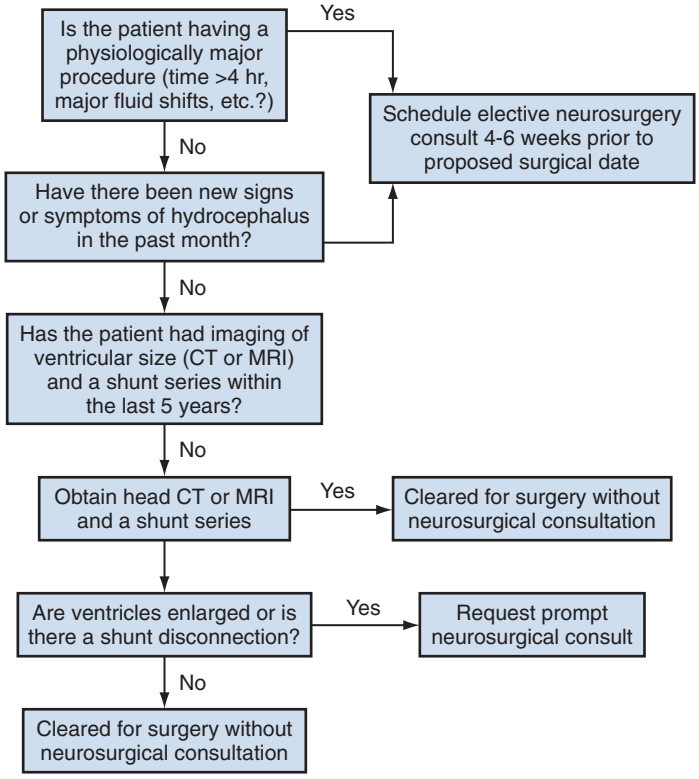

Figure 119–2. Preoperative assessment of patients with shunted hydrocephalus. (From Children's Hospital Boston, copyrighted 2008.)

per m^2 (Lipshultz et al, 1991). Any child with a history of congestive heart failure, who has not had a postanthracycline echocardiogram or an echocardiogram within 2 years before the time of anesthesia, requires a preoperative echocardiogram (Ferrari, 2008).

Child of a Jehovah's Witness

Jehovah's Witnesses refuse blood transfusions because of the belief that the "life force" resides in their blood. Although adult Jehovah's Witness patients may choose to refuse lifesaving blood transfusions, pediatric patients, as minors, do not have that same right. It is therefore imperative that the surgical and anesthesia teams define a plan with the parents in the event that blood is required. Perioperative volume expanders, such as albumin, and hemodilution and blood banking are acceptable to some individuals, depending on their interpretation of biblical passages (Benson, 1989). **Most medical care providers agree that in an emergency it is unacceptable for a parent to make a conscious decision that could result in the loss of a minor child's life; in such cases, appropriate medical therapy, including transfusion of blood products, is administered against the wishes of the family** (Swartz, 1985). In most circumstances, the courts have intervened to allow blood transfusions over the religious objections of the parents. No child of Jehovah's Witness parents should die for lack of transfused blood without a physician seeking a court order to do so (Waisel, 2001). Consultation with a pediatric hematologist may be helpful to optimize the preoperative preparation, which may include oral iron therapy 2 to 3 weeks before surgery.

Congenital Adrenal Hyperplasia

Patients with congenital adrenal hyperplasia (CAH) are frequently treated by pediatric urologists, and their condition requires careful perioperative preparation. The most common form of CAH is 21-hydroxylase deficiency, which results in an excess of progesterone and 17-hydroxyprogesterone. These hormones are then peripherally converted to androgens, which result in virilization of affected girls. Approximately 75% of these patients are also salt-wasters, because of impaired mineralocorticoid production. In addition, adrenal catecholamine production is deficient in patients with CAH. The cornerstone of medical management of CAH is lifelong hormonal replacement. Children are given hydrocortisone, and salt-wasting patients also require fludrocortisones and sodium chloride supplementation. **Perioperatively, it is critical to be clear on the nature of the child's CAH and how well and stably it is medically managed.** Baseline parameters, including hydration status, blood pressure, and electrolytes are determined. The usual doses of hydrocortisone are inadequate to cover the physiologic stress of surgery, and thus CAH patients are typically given 100 mg/m^2 hydrocortisone in four divided intravenous doses for the first 24 hours and then slowly tapered (Zuckerberg, 2009). A clear perioperative plan for hormonal supplementation should be developed in conjunction with the child's endocrinologist.

Regional Anesthesia

There has been increased interest in regional anesthesia in children mainly due to two general factors: decreased general anesthetic requirement and improved postoperative pain management. At Children's Hospital Boston, the authors routinely use two related types of regional anesthesia: single-shot caudal blocks and epidurals. Caudal blocks are typically used in patients undergoing bilateral groin surgery, open ureteroneocystostomy, and neonatal patients in whom we would like to limit the administration of narcotics. Epidural anesthesia is generally used in children undergoing renal surgery or extensive pelvic surgery.

Single-shot caudal blocks are one-time injections of local anesthetic agents into the epidural space, and can provide analgesia in the T10 to S5 dermatome region. The most common local anesthetic used is bupivacaine 0.125% to 0.25%, with epinephrine administered in volumes of 0.5 to 2 mL/kg (not to exceed toxic doses measured in mg/kg) (Kraemer and Rose, 2009). **The addition of clonidine, 1 to 2 μg/kg to a maximum of 30 μg, may enhance the duration and intensity of the caudal block** (Constant et al, 1998). In addition to the one-time injection, an angiocatheter may be left in place in the caudal region for additional postoperative local anesthetic administration. One of the most frequent complications with caudal blocks is the inadvertent needle placement into the vasculature, intrathecal space, or even bone in very young children; however, this rate is low (0.7 per 1000) (Kraemer and Rose, 2009).

Continuous epidural analgesia (CEA) provides excellent perioperative analgesia in infants and children undergoing thoracic, abdominal, pelvic, and perineal surgery. The epidural space may be accessed at any level, but is most frequently approached at the lumbar or caudal region in children. If the epidural needle touches the spinal cord, a patient who is awake will react, and spinal cord injury can be thereby avoided. However, the vast majority of epidural catheters in children are placed under general anesthesia, because it is generally considered safer to place epidurals in children who are not moving. The risk of neurologic injury with lumbar epidural catheter placement is exceedingly low, but thoracic placement does carry a higher risk of spinal cord injury should the needle be advanced too far. As such, direct thoracic placement under general

anesthesia should be performed only by very experienced personnel and with careful consideration of the potential risks and benefits (Greco, 2002). In selected cases, catheters can be advanced to the thoracic level from a lumbar or caudal route under fluoroscopic guidance. The location of the catheter tip can be confirmed with a contrast epidurogram (Greco, 2002). Epidural drug selection is individualized and varies with site of surgery, location of the epidural, and patient-specific factors. In general, local anesthetics are infused in combination with opioids, clonidine, or both. Clonidine is used because of the same benefits as discussed for single-shot caudal blocks, and is used preferentially over opioids, if possible, because it does not cause adverse effects typical of opioids, including pruritus, nausea, ileus, urinary retention, or respiratory depression (Greco, 2002; Hirschl, 2003c). The risk of local anesthetic toxicity is one of the main concerns that require continuous monitoring during CEA. Hospitals should have a dedicated team of anesthesiologists and nurses immediately available to manage any emergent problems with pain control or adverse effects with CEA. The epidural site should be evaluated daily for signs of infection. Protocols and CEA order sets should include patient monitoring parameters and neurologic assessment every 4 hours (Kraemer and Rose, 2009).

A related topic is the use of local anesthetic drugs for peripheral sensory nerve blockade, an approach commonly used in pediatric urology with the dorsal penile block. This technique is routinely used for penile surgery including circumcision, circumcision revision, and hypospadias repair. **It has been shown to be simple, safe, and effective, and provides equivalent analgesia to a one-shot caudal block** (Cyna and Middleton, 2008). The most commonly used drug is bupivacaine (0.25%) in volumes of 1 mL/kg. Compared with lidocaine, it has a longer onset time but also significantly longer duration. However, it has greater potential for cardiotoxicity if inadvertently injected intravascularly. A newer alternative is ropivacaine (0.75%), which has an onset time and duration of action comparable with bupivacaine but is associated with less toxicity (Ecoffey, 2005). However, ropivacaine has theoretical vasoconstrictive properties and has been associated with a case of penile ischemia (Burke et al, 2000). The safest technique is to inject the appropriate volume of the local anesthetic bilaterally just below the pubis. This avoids the midline, where the dorsal penile vessels are located, thereby reducing the risk of hematoma formation and provides the most direct route to the dorsal penile nerves located lateral to the midline in the Buck fascia. In addition, the authors prefer to inject half of the allotted dose of the local anesthetic at the beginning of the case and half at the completion of surgery, because this has been shown to provide significant improvement in postoperative pain control (Chhibber et al, 1997).

Postoperative Pain Management

It is incumbent upon pediatric care providers to make every attempt possible to assess their patients' pain, which may be very challenging given the limited cognition and language skills of infants and children. Pain assessment tools are well established and widely available, but assessing pain in neonates, infants, and nonverbal or developmentally delayed children is still limited (Kraemer and Rose, 2009). In general, the younger the child, the less likely he or she can clearly delineate between levels of pain using pain scales. **In general, however, children 8 years and older can reliably report pain on the visual analog scale used for adults. Children between the ages of 3 and 7 years can better report pain using a faces scale that uses a series of drawings depicting increasing levels of distress** (Kraemer and Rose, 2009). Table 119–3 provides examples of some routinely used pediatric pain scales. In addition to the child, parents are very often an excellent source of information regarding their child's pain.

Table 119–3.
Pediatric Pain Scales

SCALE	TYPE	AGES	SCORING INDICATORS
PIPP	Behavioral and physiologic parameters Procedural pain	Term and preterm infants	Gestational age Behavioral state Heart rate, SpO_2 Facial expression
CRIES	Behavioral and physiologic parameters Postoperative pain	32-60 weeks	Crying, increased O_2 Increased vital signs Expression Sleeplessness
FLACC	Behavioral parameters	<3 years or unable to self-report	Face, legs, activity, cry, consolability
FACES	Self-report	3-12 years	Happy face to saddest face yield numeric 0-10 score
VAS	Self-report	>7 years	0 = no pain 10 = maximum pain

CRIES, crying, increased O_2, increased vital signs, facial expression, sleeplessness; FLACC, face, legs, activity, cry, consolability; PIPP, premature infant pain profile; VAS, visual analog scale.

Modified from Kraemer FW, Rose JB. Pharmacologic management of acute pediatric pain. Anesthesiol Clin 2009;27:241–68.

Based on severity, pediatric pain management involves targeting several of the complex elements of pain transduction, transmission, modulation, and perception (Kraemer and Rose, 2009). Common multimodal plans include nonsteroidal anti-inflammatory drugs (NSAIDs) acting on the periphery; regional block of peripheral nerves, nerve roots, or spinal cord; and/or opiates acting centrally. Such a balanced approach can minimize the adverse effects of each modality and work synergistically to best manage acute pain.

For children who undergo nonambulatory surgery and who do not have CEA, patient-controlled analgesia (PCA) is an excellent option for treating moderate to severe pain. **Children as young as 5 years old have successfully used PCA with proper education and guidance, but PCA is routinely used in children age 7 years and older** (McDonald and Cooper, 2001). The use of PCA mandates institutional/departmental monitoring requirements that include respiratory rate, pulse oximetry, heart rate, blood pressure, pain assessment, and level of consciousness. When used with appropriate monitoring, PCA is safe, effective, and highly reliable. In younger children or those unable to reliably control their PCA, nurse- or parent-controlled analgesia can be used with similar success and efficacy.

Oral pain medications include nonopioid and opioid analgesics. Nonopioid options include acetaminophen and NSAIDs. **Acetaminophen is the most widely used antipyretic and analgesic medication in pediatrics and is commonly combined with opioids for patients with moderate to severe pain.** When dosed appropriately, acetaminophen can be used safely in neonates. It is normally metabolized in the liver primarily by glucuronidation and sulfation. Neonates and infants primarily conjugate by sulfation, and the mature ratio of glucuronidation/

Table 119–4.
Acetaminophen Dosing

ROUTE OF ADMINISTRATION	PRETERM INFANTS (28-32 WEEKS)	PRETERM INFANTS (>32 WEEKS)	FULL-TERM INFANTS AND CHILDREN <52 kg	CHILDREN >52 kg, ADOLESCENTS, AND ADULTS
Oral	12.5 mg/kg q6h PRN for 72 hours	12.5 mg/kg q4h PRN for 72 hours	12.5 mg/kg q4h PRN for 72 hours	325-975 q4h PRN for 72 hours
Rectal	20 mg/kg q12h PRN for 72 hours	15 mg/kg q8h PRN for 72 hours	15-20 mg/kg q4h PRN for 72 hours	325-975 q4h PRN for 72 hours
Maximum dose	50 mg/kg/day	90 mg/kg/day	90 mg/kg/day (up to 4 g/day)	4 g/day

Based on Children's Hospital Boston formulary.

sulfation is reached at approximately 12 years of age. **The concerning feature of acetaminophen is that overdose can lead to liver necrosis and failure.** This is because supranormal doses of acetaminophen are metabolized by the oxidative cytochrome P450 pathway, which results in a highly hepatotoxic metabolite. Acetaminophen is available in several formulations, including drops (80 mg/0.8 mL), elixir (160 mg/5 mL), chewable tablets (80 mg and 160 mg), dissolvable tablets (160 mg), tablets (325 mg and 500 mg), and suppositories (80 mg, 120 mg, 325 mg, and 650 mg). Intravenous acetaminophen preparations do exist but are currently not available in the United States. The suggested dosing of acetaminophen is provided in Table 119–4.

NSAIDs are commonly used for postoperative pain, because they provide excellent analgesia and are well tolerated. **A review of short-term ibuprofen use in a large cohort of children revealed no increase in renal or gastrointestinal adverse effects compared with acetaminophen** (Lesko and Mitchell, 1995). NSAIDs are more similar than they are different. Adult clinical trials, outcome studies, and systematic reviews indicate that no NSAID possesses uniquely greater analgesic effect than others and that the oral, rectal, and parenteral routes of administration are equally effective (Greco, 2002). Like acetaminophen, ibuprofen is available in several preparations, including drops (50 mg/1.25 mL), elixir (100 mg/5 mL), chewable tablets (50 mg and 100 mg), and tablets (200 mg, 400 mg, 600 mg, and 800 mg). Intravenous ibuprofen is available in the United States, but has not been approved for use in pediatric patients for the treatment of pain. Ibuprofen should be used routinely in children age 6 months and older. For analgesia, a single dose of 15 mg/kg can be used. However, if repeated doses are anticipated or planned, dosing should be 4 to 10 mg/kg/dose every 6 to 8 hours, with a maximum daily dose of 40 mg/kg/day.

Ketorolac is the only parenteral NSAID (15 mg/mL and 30 mg/mL) available for in the United States to treat pediatric pain, and it has been used as an adjuvant to opioids and a single agent for the treatment of postoperative pain. The authors routinely use ketorolac in children at least 6 months of age, but it is approved for use in children 2 years or older. **The authors have found that in addition to excellent analgesia, ketorolac significantly reduces the incidence and severity of bladder spasms** (Park et al, 2000), **and the authors routinely use ketorolac following bladder surgery.** However, significant adverse effects have been reported, including acute renal failure, prolongation of bleeding times, and hypersensitivity reactions, and therefore caution is warranted (Kraemer and Rose, 2009). Because of this, the authors do not use ketorolac in patients with renal insufficiency, renal scarring, a solitary kidney, NSAID sensitivity, or a patient in whom a risk of significant postoperative bleeding is feared. Dosing of ketorolac is 0.25 to 0.5 mg/kg every 6 hours, with no loading dose requirement.

Table 119–5.
Opioid Dosing

OPIOID	ROUTE/AGE GROUP	DOSE/INTERVAL
Morphine	**Intravenous bolus:**	
	Full-term neonate	10-25 µg/kg every 2-4 hr
	Preterm neonate	25-50 µg/kg every 3-4 hr
	Infants and children	50-100 µg/kg every 3-4 hr
	IV infusion:	
	Preterm neonate	2-5 µg/kg/hr
	Full-term neonate	5-10 µg/kg/hr
	Infants and children	15-30 µg/kg/hr
Codeine	Oral	0.5-1 mg/kg every 4 hr
Oxycodone	Oral	0.05-0.15 mg/kg every 4 hr

Modified from Kraemer FW, Rose JB. Pharmacologic management of acute pediatric pain. Anesthesiol Clin 2009;27:241–68.

Opioids are commonly used for moderate to severe pain, and for the vast majority of children, provide excellent analgesia with a wide margin of safety. They affect analgesia by central nervous system neuronal inhibition. The commonly used opioids in the pediatric population are mu_1 agonists and include morphine, hydromorphone, methadone, fentanyl, codeine, oxycodone, and hydrocodone (Table 119–5). Opioids can be administered through several routes, including oral, intravenous, intramuscular, subcutaneous, rectal, transdermal, or transmucosal. Oral administration is usually the easiest route and provides relatively constant drug plasma levels. **Despite their general efficacy, there is substantial individual variation in opioid dose requirements. The adequate opioid dose is that which provides pain relief but does not result in excessive somnolence or respiratory depression.** Morphine is the standard opioid to which all others are compared (Greco, 2002; Kraemer and Rose, 2009). It is metabolized in the liver, and the elimination half-life is longer and the clearance is decreased in newborns. This difference is even more substantial in preterm neonates. Within 2 months of age, however, the elimination half-life and clearance reach adult levels. There is no established optimal morphine plasma concentration, and therefore the appropriate dose needs to be established for each patient, while carefully monitoring for respiratory depression.

Codeine is available in elixir form and is the most common orally administered opioid in young children. It is often combined with acetaminophen (acetaminophen 120 mg with codeine 12 mg/5 mL), and, in this form, is more effective. Dosing of codeine is 0.5 to 1 mg/kg every 4 hours, but the dose of acetaminophen needs to be carefully considered to avoid

acetaminophen toxicity. The maximum dose based on acetaminophen content for children weighing less than 45 kg is acetaminophen 90 mg/kg/day, and for children weighing more than 45 kg it is acetaminophen 4 g/day. **Codeine itself is a relatively weak opioid, given its extremely low affinity for opioid receptors, and most of its analgesic effect is due to the 10% that is metabolized to morphine.** The metabolism to morphine is predominantly by *O*-demethylation by the cytochrome P450 enzyme CYP2D6, which is known to show genetic polymorphism (Williams et al, 2001). **Therefore variations in CYP2D6 will result in variable abilities to metabolize codeine.** In this way, individuals may be classified as poor metabolizers or ultrarapid metabolizers, depending on the phenotype of their CYP2D6 enzyme. **Three percent of whites and 40% of people of North African descent are ultrarapid metabolizers, resulting in dangerously high plasma levels of morphine** (Gasche et al, 2004). **Conversely, 7% to 10% of whites are poor metabolizers of codeine, and receive little or no analgesia from codeine administration** (Kraemer and Rose, 2009). The disastrous consequences of CYP2D6 variability is highlighted by the recent report of the death of a 2-year-old child who was given codeine at home following a routine tonsillectomy (Ciszkowski et al, 2009). Genotyping of the patient revealed duplication of the CYP2D6 allele (ultrarapid metabolizer), and the plasma concentration of morphine was 32 ng/mL (>20 ng/mL results in respiratory depression). **Because of this risk, the authors generally prefer oxycodone, which appears to have less variable metabolism.**

Oxycodone is available in tablet and liquid form and is also commonly combined with acetaminophen. The combined preparation is commonly used in children and is available in solution (oxycodone 5 mg and acetaminophen 325 mg/5 mL) and in tablet form (oxycodone 2.5 to 10 mg and acetaminophen 300 to 650 mg). The initial dose is based on the oxycodone content, but the maximum daily dose is based on the acetaminophen content. Based on pain severity, the initial oxycodone dose is 0.05 to 0.3 mg/kg/dose. The maximum dose based on acetaminophen content for children weighing less than 45 kg is acetaminophen 90 mg/kg/day and for children weighing more than 45 kg is acetaminophen 4 g/day.

Key Points: Pediatric Anesthesia and Analgesia

- Surgical preparation is a multifaceted endeavor that involves consideration of medical and psychological needs of children and their families, all of which vary with the child's age and developmental status.
- The risks associated with anesthesia in a healthy child undergoing uncomplicated surgery are extremely low.
- Routine diagnostic testing for surgery is rarely indicated in healthy children, and studies that are ordered should be selected based on the general health of the patient and the procedure being performed.
- Children should not be kept "NPO after midnight"; the ASA has provided guidelines to optimize patient hydration and minimize risk.
- URI is very common in childhood; elective surgery should be scheduled after the acute symptoms have resolved and no sooner than 3 to 4 weeks after the initial evaluation.
- Children with VP shunts should undergo evaluation to ensure proper shunt function prior to major surgery.
- Regional anesthesia plays an important role in several urologic surgeries, and the most commonly performed are the single-shot caudal block and continuous epidurals.
- Based on severity, pediatric pain management involves targeting several of the complex elements of pain transduction, transmission, modulation, and perception.
- Acetaminophen is the most widely used analgesic in pediatrics; ibuprofen is also commonly used, and children are unlikely to experience renal or gastrointestinal adverse effects.
- Opioids are used for moderate to severe pain, and there is substantial variation in individual opioid dose requirements.
- Codeine has highly variable efficacy due to genetic polymorphism of the CYP2D6 liver enzyme; patients may be poor metabolizers, resulting in little or no analgesia, or rapid metabolizers, resulting in dangerous plasma levels of postmetabolism opioid.

SURGICAL PREPARATION

Antimicrobial Prophylaxis

Because there are no available guidelines from any of the pediatric urologic or surgical societies, whether to use prophylactic antibiotics in children undergoing surgery remains an individual and non–evidence-based decision. This decision is generally not controversial for major surgery when surgical antimicrobial prophylaxis (SAP) is routinely administered, but it is for minor procedures, such as orchidopexy, herniorrhaphy, and circumcision. The Centers for Disease Control and Prevention (CDC) provided guidelines for SAP (Mangram et al, 1999), but these were broad and general and did not specifically address urologic surgery. In 2001, the European Association of Urology published urology-specific guidelines, but pediatric procedures were not specifically addressed. Recently, the Japanese Urological Association published comprehensive SAP guidelines that included pediatric procedures (Matsumoto et al, 2007), but these were not evidence based and were formulated based on the opinions and practice patterns of academic pediatric urologists. The CDC surgical wound classification system of clean (class I), clean-contaminated (class II), contaminated (class III), and dirty/infected (class IV) can be applied to pediatric urologic procedures, and examples are provided in Table 119–6. **In general, SAP is recommended for (1) all surgery in neonates less than 72 hours of age because of possible exposure to maternal pathogens and, particularly, compromised immunologic capacity, (2) major class II surgery, and (3) all class III and IV surgical procedures** (Antimicrobial prophylaxis for surgery, 2004). Antibiotic use in class I and minor class II operations has not been studied, and remains based on individual surgeon's preference. Recommendations for SAP are provided in Table 119–7. **The timing of SAP administration is critically important, and the first dose should be given 30 minutes to 3 hours prior to incision to achieve bactericidal levels of the antibiotic at the site of incision.**

Thromboembolism Prophylaxis

Venous thromboembolic events (VTEs) in children are rare when compared with adults. The incidence of VTEs in

children is estimated to be 0.07 to 0.14 per 10,000 in the general population and 5.3 per 10,000 for pediatric hospital admissions (Andrew et al, 1994; van Ommen et al, 2001). In general, the frequency of VTEs in children is one tenth that of adults (Levy et al, 2004), and several factors are believed to contribute to this difference. These include lower levels of thrombin in childhood, enhanced levels of thrombin inhibitors in children, and significantly lower levels of various clotting factors at different times in childhood (Jackson and Morgan, 2008). Despite the rare incidence, it is believed to be increasing, most likely owning to increased awareness and diagnosis and improved life expectancy of children with serious prothrombotic diseases, such as congenital heart disease, cancer, and extreme prematurity (Jackson and Morgan, 2008). **The incidence of VTE in the pediatric population is bimodal, occurring most often in infants aged less than 1 year and in adolescents.** These two age groups account for more than 70% of VTEs. Risk factors in infants include diminutive blood vessels, a unique hemostatic system, and the use of central venous catheters (CVCs). Risk factors in adolescents include smoking, contraception, and obesity (Sandoval et al, 2008). In general, the greatest risk factor is the presence of a CVC. There are no clear guidelines in pediatric surgery for the use of thromboprophylaxis, and typically individual institutions develop local policy. In general, for pediatric noncancer urologic surgery, the authors use thromboprophylaxis in the postpubertal period, because it is assumed that the adult risk of VTE develops after sexual maturation. **The extent of thromboprophylaxis, which can include compression stockings and/or sequential compression devices (SCDs) plus or minus subcutaneous enoxaparin, is made on a case-by-case basis, depending on the assessment of an individual child's risk factors.**

Table 119–6.

Wound Classification in Pediatric Urologic Surgery

WOUND CLASSIFICATION	PROCEDURES
Clean	Nephrectomy, adrenalectomy, retroperitoneal tumor resection, orchidopexy, herniorrhaphy
Clean-contaminated	Nephroureterectomy, partial nephrectomy, pyeloplasty, ureteral reimplant, other intravesical procedures, exstrophy closure, partial cystectomy, hypospadias repair, other genital surgery, cystoscopy, transurethral incision of ureterocele, transurethral ablation of posterior urethral valves
Contaminated	Bladder enterocystoplasty, continent urinary diversion
Dirty	Open trauma of the urinary tract, operations for infected kidney, ruptured bladder augmentation

Modified from Yamamoto S, Shima H, Matsumoto T. Controversies in perioperative management and antimicrobial prophylaxis in urologic surgery. Int J Urol 2008;15:467–71.

Hair Removal

Peripubertal children and postpubertal adolescents may have a significant amount of hair at the sites of urologic procedures. The questions of appropriate timing and method of hair removal have been debated because they are thought to significantly impact the development of surgical-site infections (SSIs). The most recent data indicate that there is a higher risk of SSI when hair is removed on the day or night prior to surgery and also with the use of razors. **Lower rates of SSI are achieved by using clippers or depilatory agents immediately prior to surgery** (Tanner et al, 2007)**.** Based on this, the authors' policy is to remove hair, using clippers, at the time of immediate presurgical preparation in the operating room. Razors are no longer available in our operating rooms.

Table 119–7.

Recommendations for Surgical Antimicrobial Prophylaxis

OPERATION	LIKELY PATHOGENS	PROPHYLACTIC ANTIBIOTICS	PREOPERATIVE DOSE
Neonatal (<72 hr old) Surgery	Group B streptococci, enteric gram-negative bacilli, enterococci	Ampicillin + gentamicin	50 mg/kg ampicillin 2.5-3 mg/kg gentamicin
Class I (clean)	*Staphylococcus epidermidis, Staphylococcus aureus,* streptococci, gram-negative enteric bacilli	Cefazolin or Vancomycin (if MRSA or MRSE likely)	25 mg/kg 10 mg/kg
Class II (clean-contaminated)	Enteric gram-negative bacilli, enterococci	Cefazolin or Ampicillin + gentamicin	25 mg/kg 50 mg/kg ampicillin 2.5-3 mg/kg gentamicin
Class III (contaminated)	Gram-negative enteric bacilli, enterococci, anaerobes	Cefoxitin or Cefotetan	40 mg/kg 40 mg/kg
Class IV (dirty/infected)	Gram-negative enteric bacilli, enterococci, anaerobes	Cefoxitin or Cefotetan ± gentamicin or Gentamicin + clindamycin	40 mg/kg 40 mg/kg (±2 mg/kg gentamicin) 2 mg/kg gentamicin + 10 mg/kg clindamycin

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.

Modified from McInerny TK, Adam HM, Campbell DE, et al, editors. American Academy of Pediatrics textbook of pediatric care. Elk Grove Village (IL): American Academy of Pediatrics; 2009.

INTRAOPERATIVE CONSIDERATIONS

Blood Loss and Transfusion Requirement

Blood volume in children varies with age, but can be estimated as 70 to 80 mL/kg (Linderkamp et al, 1977). In general, transfusion of packed red blood cells (PRBCs) is indicated for a hematocrit of less than 24% with signs and symptoms of anemia in the perioperative period or blood loss of more than 15% of the blood volume (Roseff et al, 2002). In cases of blood loss less than 15% of the blood volume, volume replacement with crystalloids is usually adequate. Massive bleeding involving the loss and replacement of one blood volume in 24 hours can lead to serious complications, and the mortality rate associated with this situation is approximately 40% (Radel, 2009). In an extreme situation, non–cross-matched O Rh-negative blood may be used, but all efforts should be made to use blood type–specific blood products. In general, platelet transfusion is reserved for a platelet count of less than 50,000/μL. Fresh frozen plasma (FFP) is used if the prothrombin time (PT) or partial thromboplastin time (PTT) is more than 1.5 times normal (Radel, 2009). **In the authors' experience, complete primary repair of bladder exstrophy in the newborn has been the pediatric urologic surgical case most likely to require transfusion of PRBCs, with 75% of boys and 29% of girls requiring intraoperative transfusion** (Borer et al, 2005).

The risks associated with transfusion are minimal but are a consistent source of worry for parents. The elimination of paid donors, more thorough donor screening, and increasingly sophisticated donor blood testing have led to a significant decrease in the incidence of infection transmitted by transfusion (Zuckerberg, 2009). **The incidence of transfusion-associated hepatitis B is 1:63,000, and the risk of transfusion-transmitted hepatitis C is 1:103,000** (Schreiber et al, 1996). **The risk of transfusion-transmitted human immunodeficiency virus (HIV) is estimated to be between 1:450,000 and 1:600,000** (Schreiber et al, 1996). In addition to the risk of transmission of infection, transfusion reactions occur in 2% to 3% of cases. Of these, 41% are febrile and nonhemolytic, 58% are urticarial, and 1% are delayed hemolytic (American Medical Association, 1985).

Thermoregulation

Infants and children experience heat loss as a result of convection, conduction, and evaporation. As a result, they are more susceptible than adults to changes in ambient temperature due to a relatively large body surface to mass ratio; less insulating tissue, such as fat or hair; and limited energy reserves. Neonates are especially sensitive to cold exposure, because they are unable to shiver and rely on brown adipose tissue for generation of heat. **Maintaining normal body temperature intraoperatively is important, because hypothermia increases the incidence of intraoperative and postoperative complications, including bleeding, acidosis, impaired immune function, and delayed wound healing.** During anesthesia, children are exposed to all the factors of heat loss: convection, radiation, evaporation, and conduction. Measures including humidification and warming of inspired air, warmed fluids for intravenous administration, and the use of warming devices, such as the BAIR Hugger (Arizant, Eden Prairie, MN), may be used as needed (Pierro, 2006; Wetzel, 2007).

Key Points: Surgical Preparation and Intraoperative Considerations

- In general, SAP is recommended for (1) all surgery in neonates less than 72 hours of age, because of possible exposure to maternal pathogens and particularly compromised immunologic capacity, (2) major class II surgery, and (3) all class III and IV surgical procedures; antibiotic use in class I and minor class II operations remains based on the individual surgeon's preference.
- The timing of SAP administration is critically important, and the first dose should be given 30 minutes to 3 hours prior to incision.
- VTEs in children are rare, but the incidence is believed to be increasing and is bimodal, occurring most often in infants less than 1 year of age and in adolescents.
- Lower rates of SSI are achieved by using clippers of depilatory agents immediately prior to surgery for hair removal.
- Blood volume in children varies with age but can be estimated as 75 to 80 mL/kg.
- The risks associated with blood transfusion are very low; the incidence of transmission of hepatitis B is 1:63,000; for hepatitis C it is 1:103,000; and for HIV it is 1:450,000 to 1:600,000.
- Infants and children are more susceptible than adults to changes in ambient temperature, because they have a relatively large body surface to mass ratio; less insulating tissue, such as fat or hair; and limited energy reserves.
- Maintaining normal body temperature intraoperatively is important, because hypothermia increases the incidence of intraoperative and postoperative complications, including bleeding, acidosis, impaired immune function, and delayed wound healing.

POSTOPERATIVE CARE

A majority of pediatric urologic operations are performed as outpatient procedures, and there continues to be a push to expand the number of these. Routine outpatient urologic procedures include orchidopexy, herniorrhaphy, circumcision, laparoscopic procedures for maldescended testes, and hypospadias repair. Some groups are also performing operations once performed exclusively as inpatient surgery, such as unilateral extravesical ureteral reimplants, in this manner (Palmer, 2008). Certainly, outpatient surgery has many advantages, including cost savings, lessened psychologic trauma, fewer nosocomial infections, and faster recovery (Yaster et al, 1994). However, adequate perioperative patient and family education are vital to obtaining good outcomes and requires collaborative efforts from the surgeon, anesthesiologist, and nursing staff.

Complications

The vast majority of children who undergo urologic surgery are healthy, and in this population, the incidence of serious complications is less than 1% (Hannallah, 1987). A detailed discussion of complications specific to various urologic procedures is beyond the scope of this chapter, but broad postoperative complications will be addressed instead.

Although not a surgical complication, per se, postoperative nausea and vomiting (PONV) is the most common early complication associated with the administration

Table 119–8.

Common Causes of Postoperative Fever

SITE	ETIOLOGY	TIME	INCIDENCE	SIGNS/SYMPTOMS	THERAPY
Wind	Atelectasis	24-48 hours	Very common	Cough, shortness of breath, retractions	Cough, deep breathing, incentive spirometry
Wound	Surgical-site infection	<24 hours–7 days	Rare	Pain, erythema, induration	Antibiotics, open drainage, and debridement
Water	Urinary tract infection	3-5 days	Very rare	Dysuria, hematuria	Remove indwelling catheter as early as possible, antibiotics
Walking	Deep vein thrombosis	>3 days	Extremely rare	Swelling, lower extremity pain, superficial venous congestion, palpable cord	Bed rest, elevation, anticoagulation, thrombolytics

Modified from Maxwell LG. Postoperative care. In: McInerny TK, Adam HM, Campbell DE, et al, editors. American Academy of Pediatrics textbook of pediatric care. Elk Grove Village (IL): American Academy of Pediatrics; 2009. p. 552–63.

of anesthesia (Maxwell, 2009). PONV is the most common cause of delayed discharge from the postanesthesia care unit (PACU) and unscheduled hospitalization following outpatient procedures, representing the cause of almost 25% of unplanned admissions (Patel and Hannallah, 1988; Blacoe et al, 2008). The cause of PONV is multifactorial, but some procedures are known to be associated with higher rates, including orchidopexy, which has been associated with a greater than 50% incidence of PONV (Maxwell, 2009). Another significant contributing factor is the use of opioids in the perioperative period. Several measures can be taken to limit PONV, including avoiding opioids if possible, using antiemetics perioperatively, providing adequate intravenous hydration with glucose supplementation, and limiting oral intake postoperatively (Maxwell, 2009). Avoidance of nitrous oxide in the intraoperative period may also help to decrease the incidence of PONV. The commonly used antiemetics include benzamides (metoclopramide [Reglan]), serotonin antagonists (ondansetron [Zofran]), phenothiazines (prochlorperazine [Compazine]; promethazine [Phenergan]), and antihistamines (diphenhydramine [Benadryl]). The authors most commonly use ondansetron, because it is the only antiemetic drug for children that does not routinely result in sedation. Ondanstron is contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. The use of promethazine (Phenergan) in children is strongly discouraged, given the U.S. Food and Drug Administration warning issued in 2006 warning that it should not be used in children less than 2 years of age because of the potential for fatal respiratory depression and used with caution in children 2 years of age and older. In general, children in the PACU should not be forced fluids, and their administration should be based on the child's request. In the setting of PONV, forced fluids to encourage timely discharge will most likely be counterproductive.

Postoperative fever is a very common early surgical problem, and its etiology is taught in the first days of medical school surgery clerkships as the four Ws: wind, wound, water, and walking. "Wind" refers to atelectasis, "wound" to a surgical-site infection (SSI), "water" to an infection in the urinary tract (UTI), and "walking" to fever caused by deep vein thrombosis (DVT) in the lower extremities. **Fever, defined as greater than 38.5° C rectal temperature, is common within 24 hours of surgery and is usually caused by atelectasis.** Pulmonary toilet with deep breathing, coughing, and ambulation is usually effective in otherwise healthy children. In patients too young to participate in pulmonary toilet, measures such as blowing bubbles can be effective. The other causes, SSI, UTI, and DVT, are rare to extremely rare in the pediatric population. These common causes are summarized in Table 119–8. In addition, other common causes of fever in children should be considered, including upper respiratory infections, gastroenteritis, and otitis media.

Postoperative SSIs were traditionally characterized as incisional (superficial) or deep, but this fails to consider the total operative site. **The Centers for Disease Control and Prevention has modified the definition of SSIs, which now are reported as incisional SSI–superficial versus deep or organ/space SSI** (Ashcroft, 2005; Ziegler, 2003). **It is critically important to diagnose early and intervene promptly to avoid morbidity and even mortality.** The wound is examined for classic signs of infection and inflammation, including erythema, edema, tenderness, and warmth. If there appears to be a SSI, a Gram stain and culture should be obtained with a sterile swab. Treatment should be tailored according to the extent of the infection and may include oral or parenteral antibiotics, incision and drainage, or extensive debridement. **The incidence of SSIs varies from 1% to 11% in clean wounds and from 6% to 21% in contaminated wounds** (Ashcroft, 2005). **In general, most SSIs occur between the 5th and 10th postoperative days.** The rare exceptions are β-streptococcal, *Clostridium difficile,* and *Clostridium perfringens* (welchii) infections, which produce SSIs that can become clinically apparent within 24 to 48 hours postoperatively. **Clostridial and streptococcal infections may be life threatening, and children with these develop high, spiking fevers (39° C to 41° C), become irrational, and may develop jaundice** (Maxwell, 2009). Table 119–9 provides a summary of SSIs.

Significant postoperative bleeding is rare in pediatric urology. Persistent bleeding at the surgical incision for more than 6 to 8 hours postoperatively usually indicates inadequate hemostasis and is usually due to a superficial skin artery. The two most common postoperative bleeding situations encountered in pediatric urology involve circumcisions and scrotal hematomas following herniorrhaphy/hydrocelectomy or orchidopexy, with rates of persistent bleeding of approximately 1% to 2% and 2% to 11%, respectively (Caruso et al, 2000; Brisson et al, 2002; Cathcart et al, 2006). Persistent bleeding following circumcision usually responds to direct digital pressure, and reoperation is exceedingly rare. Scrotal hematomas are usually self-limited, and generally resolve during a period of 4 to 6 weeks. However, fever, erythema of the overlying scrotal skin, tenderness, and progressive enlargement may indicate close monitoring and surgical re-exploration. In patients with thrombocytopenia, prophylactic platelet transfusion is prudent for platelet counts below 50,000/μL (Gmur et al, 1991).

Table 119–9.

Postoperative Surgical-Site Infections

ONSET (POSTOPERATIVE DAY)	USUAL PATHOGENS	WOUND APPEARANCE	OTHER SIGNS
1-3	*Clostridium welchii*	Brawny, hemorrhagic, cool Occasional gaseous crepitance Putrid dishwater exudate Intense local pain	High standard fever (39° C–40° C) Irrational behavior Leukocytosis (WBC count > 15,000/mL) Occasional jaundice
2-3	*Streptococcus*	Erythematous, warm, tender Occasionally, hemorrhagic with blebs Serous exudate	High, spiking fever (39° C–40° C) Irrational at times Leukocytosis (WBC count > 15,000/mL) Rare jaundice
3-5	*Staphylococcus*	Erythematous, warm, tender Purulent exudate	High, spiking fever (39° C–40° C) Irrational at times Leukocytosis (WBC count 12,000-20,000/mL)
>5	Gram-negative rods	Erythematous, warm, tender Purulent exudate	Sustained low-grade to moderate fever (38° C–40° C) Rational behavior Leukocytosis (WBC count 10,000-16,000/mL)
>5	Symbiotic (usually anaerobes plus gram-negative rods)	Erythematous, warm, tender Focal necrosis Purulent, putrid exudate	Moderate to high fever (38° C–40° C) Leukocytosis (WBC count > 15,000/mL) Occasional jaundice Mentation variable

Modified from Maxwell LG. Postoperative care. In: McInerny TK, Adam HM, Campbell DE, et al, editors. American Academy of Pediatrics textbook of pediatric care. Elk Grove Village (IL): American Academy of Pediatrics; 2009. p. 552–63.

Key Points: Postoperative Care

- PONV is the most common early complication associated with the administration of anesthesia.
- Certain procedures are associated with high rates of PONV; the rate approaches 50% following orchidopexy.
- Fever, defined as greater than 38.5° C rectal temperature, is common within 24 hours of surgery and, as in adults, is usually caused by atelectasis.
- In cases of SSI, it is critically important to diagnose early and intervene promptly to avoid morbidity and even mortality.
- The incidence of SSIs varies from 1% to 11% in clean wounds and from 6% to 21% in contaminated wounds; most SSIs occur between the 5th and 10th postoperative days.

Megaureters
Symptoms/Presentation
Surgical Repair
Outcome and Complications
Procedures for Recurrent Ureteropelvic Junction Obstruction
Conclusions

There is ongoing debate as to whether a hydronephrotic kidney is obstructed, primarily because the tools we use to measure or define obstruction are less than precise. A ureteropelvic junction (UPJ) obstruction can be considered a restriction to flow of urine from the renal pelvis to the ureter, which, if left uncorrected, will lead to progressive renal deterioration (Whitaker, 1975; Koff et al, 1986; Koff, 1990). The same notion occurs when one considers a ureterovesical junction (UVJ) obstruction, in which both the renal pelvis and ureter are dilated with the restriction occurring within the distal portion of the ureter. The response to UPJ obstruction is the development of renal pelvic hypertrophy, in which the kidney compensates to maintain adequate urinary flow. Eventually, there are further changes to the renal pelvis and pressure-induced injury that lead to irreversible renal damage.

This chapter considers congenital UPJ and UVJ obstruction along with those unusual situations in which midureteral strictures or ureteral polyps exist. The focus of this chapter will be on surgical repair, with consideration of open repair along with the continually evolving minimally invasive repairs. Increasingly, robotic-assisted repairs are supplanting the open procedures that many pediatric urologists consider among their favorite procedures. Other conditions that delay drainage of the proximal urinary tract and secondarily affect the UPJ are discussed elsewhere in this text.

EVIDENCE

UPJ obstruction occurs in all pediatric age groups, but there tends to be a clustering in the neonatal period because of the detection of antenatal hydronephrosis and again later in life because of symptomatic occurrence. Once, about 25% of cases were discovered within the first year of life (Williams and Kenawi, 1976), but today the majority of cases are identified and diagnosed in the perinatal period (Brown et al, 1987). **UPJ obstruction is the most common cause of significant dilation of the collecting system in the fetal kidney,** accounting for 48% of all dilation of the collecting system and far exceeding the incidence of multicystic dysplastic kidney (Colodny et al, 1980; Brown et al, 1987). Those kidneys with an anteroposterior (AP) diameter of greater than 20 mm seen prenatally are certainly at greater risk for requiring surgery postnatally (Dhillon, 1998). The problem existing today is that the diagnosis of UPJ is "made" at the time of prenatal ultrasonography so that expectant parents are often informed their fetus will most likely require surgical intervention as a neonate. This contributes to ongoing anxiety and altered parental enjoyment during pregnancy (Harding et al, 1999).

Beyond the neonatal period, UPJ obstruction is seen during childhood and adolescence but to a lesser degree. Often, the cause is an aberrant lower pole parenchymal vessel that crosses over the UPJ (Lowe and Marshall, 1984). **Obstruction occurs more commonly in boys than in girls** (Williams and Karlaftis, 1966; Kelalis et al, 1971; Johnston et al, 1977), especially in the newborn period, where the ratio exceeds 2:1 (Robson et al, 1976; Williams and Kenawi, 1976; Johnson et al, 1977). Left-sided lesions predominate, particularly in the neonate (approximately 67%). Bilateral UPJ obstruction is present in 10% to 40% of cases (Nixon, 1953; Uson et al, 1968; Robson et al, 1976; Williams and Kenawi, 1976; Johnson et al, 1977; Lebowitz and Griscom, 1977), with both synchronous and asynchronous occurrences. This tends to occur in infants younger than 6 months of age (Perlmutter et al, 1980; Snyder et al, 1980), and it has been known to affect members of more than one generation (Cohen et al, 1978).

ETIOLOGY

The precise cause of UPJ obstruction remains elusive despite investigation along a number of lines: embryologic (Osathanondh and Potter, 1963; Allen, 1973; Ruano-Gil et al, 1975), anatomic (Nixon, 1953; Johnston, 1969), functional (Whitaker, 1975), and histologic (Murnaghan, 1958; Notley, 1968; Hanna et al, 1976). A narrowing of the UPJ is often found (Allen, 1973; Lebowitz and Griscom, 1977), but whether this is a result of developmental arrest (Osathanondh and Potter, 1963; Allen, 1973) or of an incomplete recanalization of the ureter (Ruano-Gil et al, 1975) is not yet known.

Megaureter is simply a descriptive term that indicates a dilated ureter. The underlying pathophysiology remains to be defined, as ureters can become dilated due to obstruction, reflux, or a combination of both. What has been observed is that all dilation of the urinary tract does not necessarily equate with a physiologically significant obstructive process with renal functional implications despite the anatomic distortion of the collecting system that it represents. Prudent observation, rather than hasty surgical solutions, has shown that improvement can occur in many situations.

Intrinsic

The typical finding on pyeloplasty is a narrowed segment of the ureter at the UPJ that is probe patent (Fig. 120–1). This finding may be the result of an interruption in the development of the circular musculature of the UPJ (Murnaghan, 1958) or an alteration of collagen fibers and composition between and around the muscle cells (Notley, 1968; Hanna et al, 1976; Hanna, 2000). **The muscle fibers become widely separated and attenuated, leading to a functional discontinuity of the muscular contractions and ultimately to insufficient emptying.** Further characterization of the UPJ by Starr and colleagues (1992) noted a significant increase in the lamina muscularis and in the number of inner longitudinal muscular bundles of the UPJ complex of obstructed kidneys in infants younger than 1 year of age compared with age-matched normal infants. These findings suggest a dramatic response by the muscular layers to obstruction. Further work has shown that the expression of transforming growth factor-β (TGF-β) is increased in the pelvis of partially obstructed kidneys (Seremetis and Maizels, 1996), which may help explain some of the histologic and electron microscope findings that were described by Notley and Hanna and their colleagues.

Other causes of intrinsic UPJ obstruction include valvular mucosal folds (Maizels and Stephens, 1980), **persistent fetal convolutions** (Leiter, 1979), **and upper ureteral polyps** (Colgan et al, 1973; Gup, 1975; Williams and Kenawi, 1976; Williams et al, 1980; Thorup et al, 1981). Congenital folds are a common finding in the upper ureter of fetuses after the fourth month of development and may persist until the newborn period. Such folds are mucosal infolds with an axial offshoot and adventitia that do not flatten when the ureter is distended or stretched. The epithelial folds are secondary to differential growth rates of the ureter and the body of the child, with excessive ureteral length occurring in early gestation. This provides a "length reserve" for the ureter, which traverses a shorter distance in the newborn period than in the adult (Östling, 1942). Östling thought that these folds were a precursor of UPJ obstruction, because they frequently were discovered in babies who had contralateral UPJ obstruction. This concept has evolved, and "Östling folds" are now considered folds that are not obstructive and disappear with a person's linear growth (Leiter, 1979) (Fig. 120–2). They are rarely seen in an older child or adult. On the other hand, persistent fetal folds containing muscle and high insertion of a valvular leaflet at the UPJ may become obstructive (Maizels and Stephens, 1980). This type of obstruction sometimes can be relieved by dissections of the folds and elimination of the kinking (Johnston, 1969), but, more commonly, the ureteral portion containing the valve must be excised.

Extrinsic

An aberrant, accessory, or early-branching lower-pole vessel is the most common cause of extrinsic UPJ obstruction (Fig. 120–3). These vessels pass anteriorly to the UPJ or proximal ureter and contribute to mechanical obstruction. Nixon (1953) reported that 25 of 78 cases of UPJ obstruction were secondary to vascular compression; other reported incidences have varied between 15% and 52% (Ericsson et al, 1961; Williams and Kenawi, 1976; Johnston et al, 1977; Stephens, 1982; Lowe and Marshall, 1984). This a major cause of UPJ obstruction in adults. **Whether the**

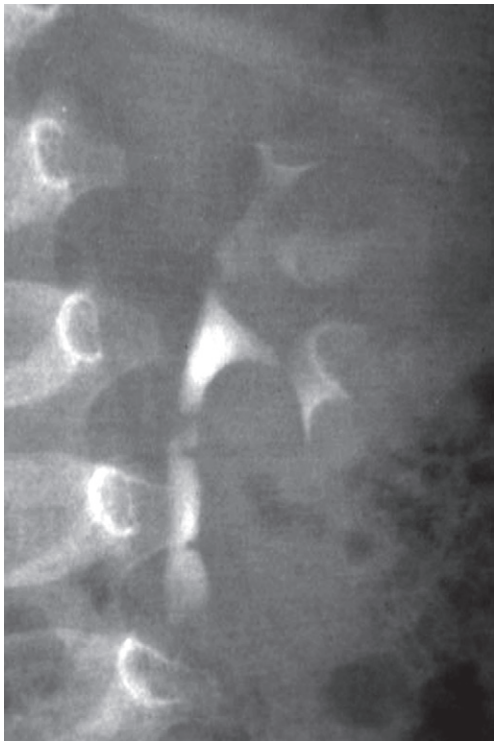

Figure 120–2. Early image of left kidney from intravenous urogram of 4-month-old girl with prenatal hydronephrosis depicting Östling's folds.

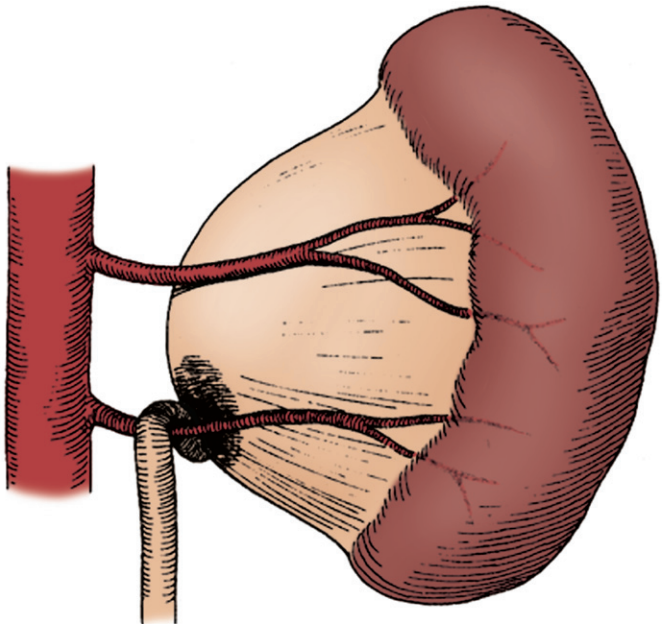

Figure 120–3. A lower pole–crossing vessel contributes to significant kinking at the ureteropelvic junction and resultant intermittent obstruction. Often, when the ureter is mobilized, no evidence of intrinsic narrowing is found. Insertional anomaly and peripelvic fibrosis may also be present as secondary obstructive factors.

aberrant vessel causes the obstruction or is a covariable that exists along with intrinsic narrowing is unclear. Stephens (1982) theorized that when an aberrant or accessory renal artery to the lower pole of the kidney is present and the ureter courses behind it, the ureter may angulate at both the UPJ and the point at which it traverses over the vessel as the pelvis fills and bulges anteriorly. Further angulation of the ureter occurs as it becomes adherent to the UPJ secondary to an inflammatory process. A two-point obstruction ensues, with kinking of the ureter at the UPJ and at the point where the ureter drapes over the vessel. Stephens (1982) could find no evidence of stricture or fibrosis at these points when the ureter was freed of its adhesions and lifted off the vessel. However, he suggested that, over time, these areas may become ischemic, fibrotic, and finally stenotic.

Secondary Ureteral Pelvic Junction Obstruction

UPJ obstruction may also be seen with severe vesicoureteral reflux (VUR); these conditions coexist in 10% of cases. **The ureter elongates and develops a torturous course in response to the obstructive element of reflux. A kink may develop in the UPJ area, a point of relative fixation, and may cause an obstruction secondarily** (Lebowitz and Blickman, 1983). In such a situation, the obstructive lesion needs to be corrected initially, even though the VUR contributed to the initial problem (Fig. 120–4). With the advent of injectable biomaterials, such as Deflux (Q-Med, Uppsala, Sweden) and Macroplastique (Uroplasty, Inc., Minneapolis, MN), consideration should be given to correcting the proximal obstruction, as well as the distal reflux, by an endoscopic approach.

Lower Pole Ureteral Pelvic Junction Obstruction

Lower pole ureteral pelvic junction obstruction can occur in kidneys with an associated incomplete renal duplication. Hydronephrosis of the lower pole moiety can be delineated with a well-performed ultrasonogram. Such a finding can suggest the presence of a lower pole ureteropelvic junction obstruction, which is an unusual finding. The incidence of renal duplication is predicted to be 0.3% to 6%. Incomplete duplications are found approximately 70% of the time in comparison with complete duplications (Privett et al, 1976). The anatomy of lower pole UPJ obstruction is either a short bifurcating ureteral segment distal to the ureteropelvic junction or a longer bifurcating ureteral segment. Such a long ureteral segment lends itself to a typical dismembered pyeloplasty, whereas the short ureteral segment is better handled by opening the renal pelvis, excising the stenotic ureteral bifurcation, and performing an end-to-side pyeloureterostomy (Fig. 120–5) (Joseph et al, 1989).

Associated Anomalies

Congenital renal malformations are commonly seen in association with UPJ obstruction. Other urologic abnormalities may be found in 50% of affected infants (Uson et al, 1968; Robson et al, 1976; Lebowitz and Griscom, 1977). **UPJ obstruction is the most common anomaly** encountered in the opposite kidney; it occurs in 10% to 40% of cases. Renal dysplasia and multicystic kidney are the next most frequently observed contralateral lesions (Williams and Karlaftis, 1966). In addition, unilateral renal agenesis has been noted in almost 5% of children (Robson et al, 1976; Williams and Kenawi, 1976; Johnston et al, 1977). UPJ obstruction may also occur in the lower or, very rarely,

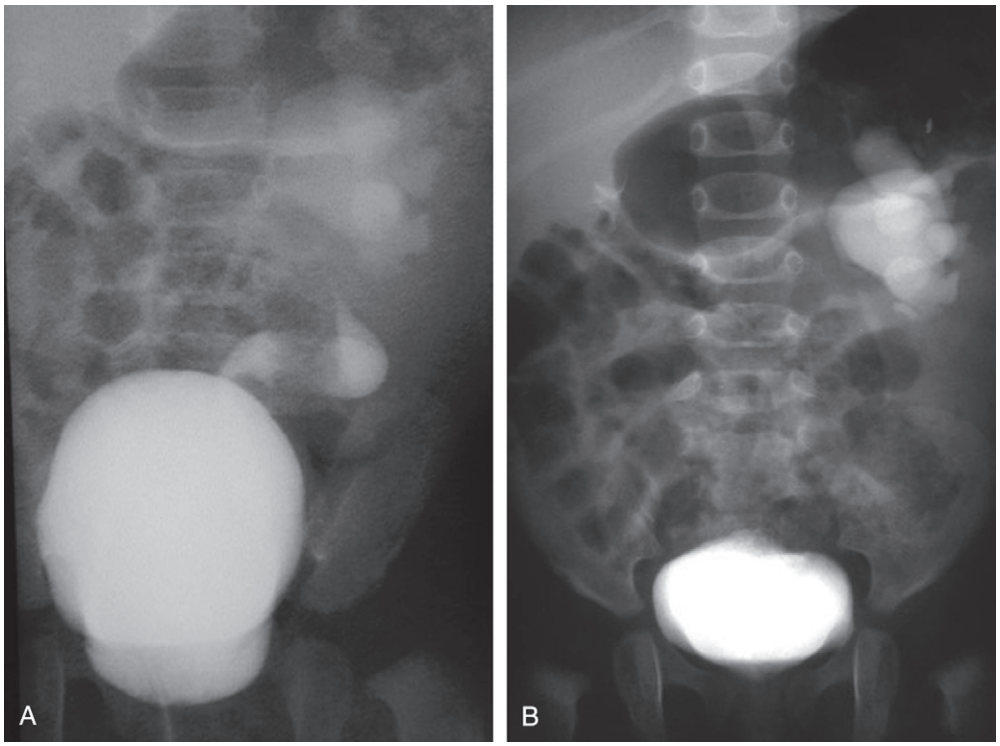

Figure 120–4. **A,** Voiding cystourethrogram demonstrating left vesicoureteral reflux. Note dilutional effect of contrast in renal pelvis. **B,** Postvoid view demonstrating right grade II vesicoureteral reflux and significant retained contrast in left renal pelvis. Patient developed worsening left hydronephrosis, which was observed on subsequent ultrasound imaging, and underwent a left dismembered pyeloplasty. There was evidence of a lower pole–crossing vessel contributing to intermittent kinking of the ureter.

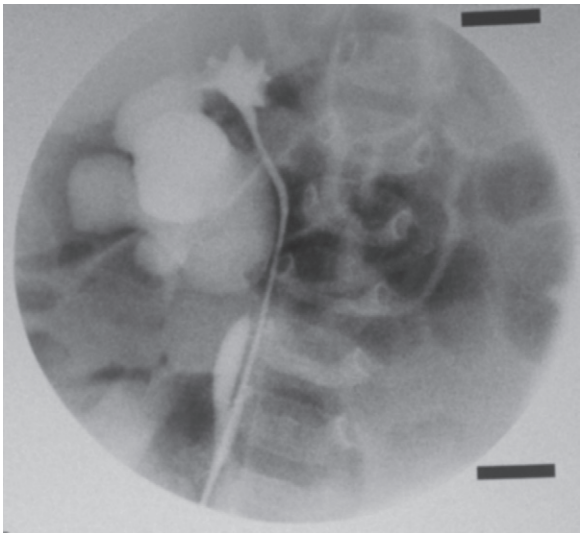

Figure 120–5. Retrograde pyelogram demonstrating anatomy of right incomplete renal duplication with lower pole–ureteropelvic junction obstruction.

the upper segment of a duplicated collecting system (Amar, 1976; Joseph et al, 1989) (see Fig. 120–5) or of a horseshoe or ectopic kidney (Fig. 120–6).

UPJ obstruction was noted in 21% of children with the VATER (*V*ertebral defects, imperforate *A*nus, *T*racheoesophageal fistula, and *R*adial and *R*enal dysplasia) association (Uehling et al, 1983), whereas a more recent review showed a 9% incidence of ureteropelvic junction obstruction, along with the majority of patients having some degree of hydronephrosis but no obstruction or reflux and solitary renal kidneys, or a small percentage may have multicystic dysplastic kidneys (Kolon et al, 2000).

VUR has been found in as many as 40% of affected children (Williams and Kenawi, 1976; Juskiewenski et al, 1983; Lebowitz and Blickman, 1983). This degree of reflux is often low grade, not contributing to upper urinary tract obstruction, and with a high likelihood of spontaneous resolution. In certain situations, high-grade VUR can have a profound effect on the UPJ, as previously noted. Anomalies of other organ systems are frequently observed but without any consistent pattern of inheritance.

MEGAURETERS

Megaloureter is a term introduced by Caulk to describe a dilated ureter. The condition was felt to be similar to large atonic dilatation of the colon. Ultimately the condition became known as megaureter, which referred primarily to two gross pathologic types: (1) megaureter caused by massive vesicoureteral reflux (either or primary or secondary to a distal obstruction, such as posterior urethral valves) and (2) obstructive megaureter from segmental narrowing of the terminal ureter or aperistalsis. In both types, the ureter can be very dilated and tortuous. Finally, a minority of megaureters can be a composite of the two above-described types with evidence of reflux and obstruction.

A normal ureteral diameter is rarely greater than 5 mm (Cussen, 1971), whereas ureters wider than 7 to 8 mm can all be considered megaureters (Hellström et al, 1985). This measurement is subject to variability owing to the imaging modality and concomitant insults, such as infection or inflammation (Hellström et al, 1987). An international classification dating back to the 1970s has become the basis for today's designations and categorization for management. Thus **a megaureter may be obstructed,**

Figure 120–6. **A,** Intravenous urogram (10-minute image) showing delayed uptake and excretion of contrast from left kidney. **B,** Thirty-minute image demonstrating horseshoe kidney and wisp of contrast in proximal left ureter. Patient was found to have high insertion and intermittent kinking of the ureter, which was contributing to periodic abdominal pain. He presented with gross hematuria after being struck by a soccer ball.

refluxing, both refluxing and obstructed, or unobstructed and not refluxing, either from a primary (idiopathic cause intrinsic to the ureter or secondary to specific pathophysiologic processes, such as outlet obstruction, neurogenic dysfunction, polyuria, or infection). This practical division is of diagnostic and therapeutic importance and underscores the effects that the bladder can have on ureteral anatomy and pathophysiology. Secondary causes should always be sought, because management would be directed at the specific problem rather than dealing with the consequence of the problem. In the same way that it can be difficult to define a ureteropelvic junction obstruction, a ureterovesical junction obstruction may be even more problematic. The treatment of a megaureter needs to be geared to preventing renal damage and, ultimately, irreversible loss of function rather than reacting to a worrisome radiographic finding.

Key Points: Megaureter

- Megaureter (MGU) is a nonspecific term implying a spectrum of anomalies associated with pathologically excessive ureteral diameter.
- Primary (at the UVJ; adynamic segment) or secondary (e.g., bladder malfunction) origins influence management and must therefore be differentiated.
- Indications for correction are often driven by serially increasing pelvicalyceal dilation, increasing ureteral diameter, or pyelonephritis and ureteral pyuria.
- Antibiotic prophylaxis should be used to protect the dilated ureter regardless of cause.
- Many cases of antenatally diagnosed MGU will resolve spontaneously. If there is improvement in degree of hydroureteronephrosis, but not resolution, imaging at puberty is advised.

SYMPTOMS/PRESENTATION

The dichotomy of presentation in infants and children with UPJ obstruction is that **most infants are asymptomatic, and most children are discovered because of their symptoms.** Previously, infants were discovered to have UPJ obstruction because of a palpable mass (Williams and Karlaftis, 1966; Robson et al, 1976; Johnson et al, 1977). Now, the almost universal use of prenatal sonography has made discovery of UPJ obstruction a common occurrence. It has changed our approach to evaluation, because now we are attempting to prove that a problem exists in an otherwise asymptomatic infant. Occasionally, there are still infants who present with failure to thrive, feeding difficulties, sepsis secondary to urinary tract infection, or pain or hematuria related to nephrolithiasis. Urinary tract infection is the presenting sign in 30% of affected children beyond the neonatal period (Snyder et al, 1980).

In the older child, episodic flank or upper abdominal pain, sometimes associated with nausea and vomiting due to intermittent UPJ obstruction, is a prominent symptom (Kelalis et al, 1971; Williams and Kenawi, 1976) (Fig. 120–7). This is clearly less often seen with an obstructive megaureter. At other times, **cyclic vomiting alone is caused by intermittent UPJ obstruction.** The pathology may be manifested only during the episode of cyclic vomiting and/or abdominal pain. Hematuria, which is seen in 25% of children, may occur after minor abdominal trauma (Kelalis et al, 1971; Williams and Kenawi, 1976). This hematuria is believed to be caused by disruption and rupture of mucosal vessels in the dilated collecting system (Kelalis et al, 1971). In the young adult, episodic flank or abdominal pain, particularly during diuresis, is a common

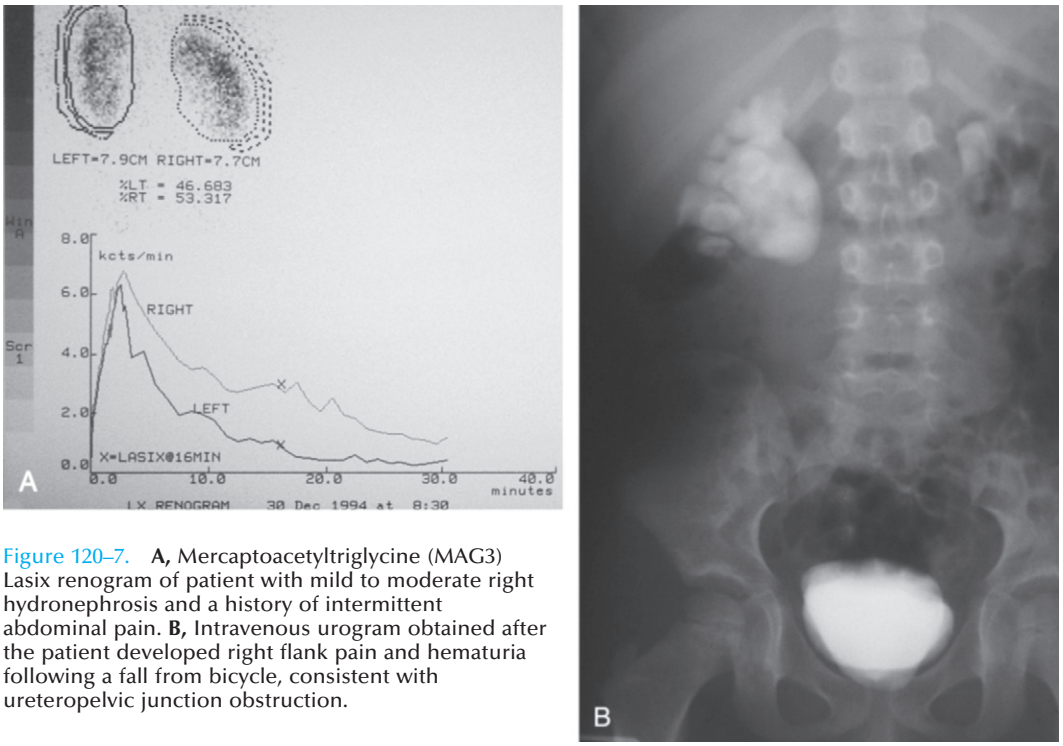

Figure 120–7. **A,** Mercaptoacetyltriglycine (MAG3) Lasix renogram of patient with mild to moderate right hydronephrosis and a history of intermittent abdominal pain. **B,** Intravenous urogram obtained after the patient developed right flank pain and hematuria following a fall from bicycle, consistent with ureteropelvic junction obstruction.

manifestation. Occasionally, a patient with the UPJ obstruction presents with hypertension (Squitieri et al, 1974; Johnson et al, 1977; Munoz et al, 1977; Grossman et al, 1981). The pathophysiology is thought to be a functional ischemia with reduced blood flow caused by the enlarged collecting system that produces a renin-mediated hypertension (Belman et al, 1968).

SURGICAL REPAIR

The evolution in the surgical correction of UPJ obstruction and obstructive megaureter has occurred on a number of fronts, with **open surgical techniques yielding way to endoscopic, laparoscopic, and robotic-assisted approaches.** The open techniques that have had the greatest applicability can be classified into three main groups: the flap type, the incisional-intubated type, and the dismembered type. The Anderson-Hynes pyeloplasty (1949) has become the most commonly employed "open" surgical procedure for the repair of UPJ. This repair had as its underpinnings both the Foley Y-V plasty (1937) and the Davis intubated ureterotomy (1943).

The Foley operation was designed for the correction of UPJ with a high ureteral insertion (Fig. 120–8). As such, this technique cannot be used in conjunction with transposition of a lower pole vessel, nor does it allow for any significant reduction of the renal pelvic size. The Davis intubated ureterotomy depends on secondary epithelialization from the incised ureter. It is applicable when multiple or extensive strictures of the proximal ureter are present but cannot be bridged by a pelvic flap (Fig. 120–9). Its use requires maintenance of ureteral continuity on at least one side and the presence of an indwelling ureteral stent for 6 weeks, the time needed for full circumferential regeneration of all layers of the ureter.

The spiral flap described by Culp and DeWeerd (1951) is created from the renal pelvis, which is used to repair the defect at the UPJ. Such a flap is able to bridge the gap between the pelvis and healthy ureter over a distance of several centimeters (Fig. 120–10). Scardino and Prince (1953) described a vertical flap that can be used in the situation of a dependent UPJ with a large, square-shaped extrarenal pelvis (Fig. 120–11). The rare cases of giant hydronephrosis that may be associated with a completely atretic ureter can be corrected by reconstructing the entire ureter using redundant pelvic tissue (Kheradpir, 1983).

Dismembered Pyeloplasty

The technique of dismembering the ureter was borne out of necessity in the repair of a retrocaval ureter (Anderson and Hynes, 1949) (Fig. 120–12). This technique was embraced by English surgeons in the repair of UPJ obstruction, but there was reluctance on the part of surgeons elsewhere because of concerns about severing the neural continuity between pelvis and ureter. Later work, however, demonstrated that the bolus of urine is the peristaltic stimulus. Furthermore, injection studies (Douville and Hollingshead, 1955) demonstrated that the arborization of blood vessels in the renal pelvis would ensure appropriate healing even with dismembering.

The principal reasons for the universal acceptance of the dismembered pyeloplasty are (1) broad applicability, including preservation of lower pole or crossing vessels, (2) excision of the pathologic UPJ and appropriate repositioning, and (3) successful reduction pyeloplasty. This operation is generally easy to perform and can be accomplished by a number of surgical approaches, including anterior subcostal, flank, and posterior lumbotomy.

A dismembered pyeloplasty may be problematic if there is inadequate ureteral length. A spiral flap from the renal pelvis can overcome this problem. Alternatively, excision of all scar tissue along with a dismembered technique is often possible when the kidney is completely mobilized and brought down as a "reverse" nephropexy. This can provide an additional 5 cm of length,

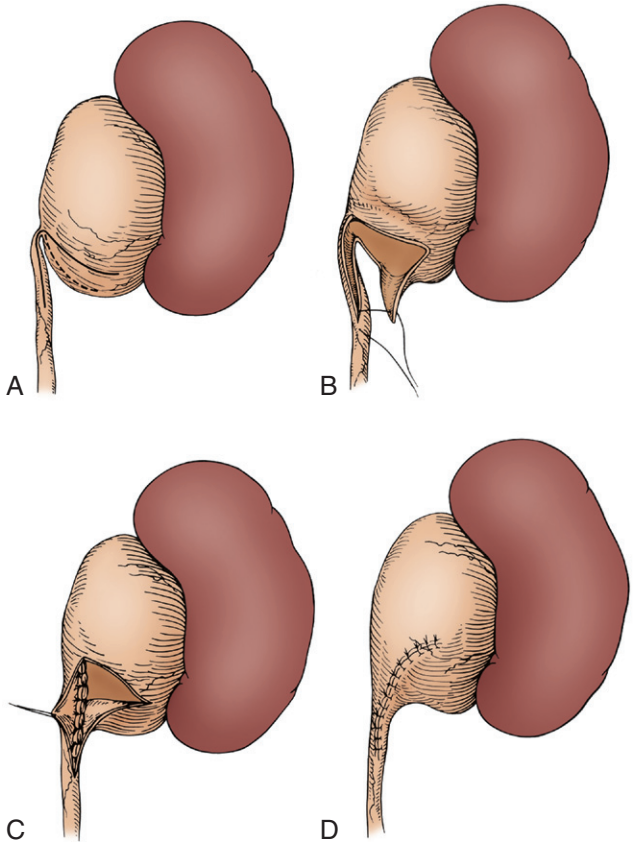

Figure 120–8. **A,** A Foley Y-V plasty is best applied to a ureteropelvic junction obstruction associated with a high insertion of the ureter. The flap is outlined with tissue market or stay sutures. The base of the V is positioned on the dependent, medial aspect of the renal pelvis and the apex at the ureteropelvic junction. The incision from the apex of the flap, which represents the stem of the Y, is then carried along the lateral aspect of the proximal ureter well into an area of normal caliber. **B,** The flap is developed with fine scissors. The apex of the pelvic flap is brought to the most inferior aspect of the ureterotomy incision. **C,** The posterior walls are approximated using interrupted or running fine absorbable sutures. **D,** The anastomosis is completed with approximation of the anterior walls of the pelvic flap and ureterotomy.

avoiding such maneuvers as bowel interposition, ureterocalicostomy, or autotransplantation.

The age and size of the patient and the position of UPJ are factors that must be considered when choosing a surgical approach. **A posterior lumbotomy affords good exposure in the neonate but may not be a good choice in a muscular adolescent.** The position of the UPJ can be determined from an intravenous urogram, but most surgeons now perform renal scans instead. Therefore retrograde pyelography can be used for making this determination. Cockrell and Hendren (1990) noted the benefits of performing retrograde pyelography at the time of pyeloplasty. Findings included a discrete area of narrowing, a long segment of narrowing, tortuosity of the upper ureter, more than one area of narrowing, high insertion of the ureter on the renal pelvis, and compression of the ureter by the lower pole of the kidney. Rushton and colleagues (1994) noted that their surgical findings confirmed obstruction at the UPJ in all patients. Undiagnosed distal ureteral obstruction was not seen, and therefore routine retrograde pyelography was deemed unnecessary.

The actual repair for the modified Anderson-Hynes dismembered pyeloplasty, as performed through an anterior subcostal incision, is as follows:

1. The anterior subcostal incision is a muscle-splitting incision that is made with the patient supine and a roll placed transversely beneath the patient to elevate the flank (Fig. 120–13).
2. Each muscle layer encountered is split in the direction of the muscle fibers until the Gerota fascia is identified by sweeping the peritoneum medially. The fascia is then incised posteriorly over the lateral aspect of the kidney.
3. The renal pelvis is identified by medial retraction of the peritoneum and lateral traction of the kidney. If the renal pelvis is significantly dilated, an angiocatheter can be inserted to decompress the pelvis and facilitate identification of the UPJ.
4. Anterior exposure is usually better when a dismembered pyeloplasty is being performed. **Once the ureter and UPJ are identified, a traction suture is displaced anteriorly through the proximal ureter** to minimize subsequent handling.
5. The area of UPJ is dissected free to allow for a clear area in which to perform the anastomosis. **Traction sutures** of 6-0 Prolene may be placed in the renal pelvis superiorly, medially, laterally, and inferiorly to the UPJ. Once adequate ureteral length is confirmed and the pathology of UPJ identified, the ureter can be transected at the UPJ. If the ureter is short, the kidney is completely mobilized to determine whether it can be brought down sufficiently to allow for a primary tension-free anastomosis.
6. After transection of the UPJ, the renal pelvis may not spontaneously drain until it is incised. This should be done after the site for anastomosis is chosen.
7. The **ureter is spatulated on the side opposite to the traction suture** using Potts tenotomy scissors. The distance over which the ureter is opened is variable, until healthy ureter is encountered, which springs open when forceps are placed into it.
8. A **portion of pelvis is excised,** usually a diamond-shaped segment that is present within the traction sutures that were placed in the renal pelvis. It is better to leave too much renal pelvis than too little, especially when resecting along the medial aspect of the renal pelvis. Infundibula can be encountered if one is not careful (Fig. 120–14).
9. The ureter and renal pelvis are aligned to ensure that the anastomosis can be accomplished without tension. If a nephrostomy tube is to be used, it is placed at this time. An inferior calix is chosen, preferably where the overlying parenchyma is not too thick. A Malecot catheter works well and is positioned away from the repair to minimize the chance of the catheter causing urinary blockage through the reconstructed UPJ.
10. The anastomosis is started by placing the first 7-0 Maxon (Davis and Geck, Norwalk, CT) suture at the apex of the "V" in the ureter and into the tip of the inferior pelvic flap. As the suture is tied down, the ureter and renal pelvis are brought together to minimize tension on the repair. A small feeding tube is placed into the ureter; it can be used to stabilize the ureter during the anastomosis. **A "no-touch" technique is employed with the ureter to minimize trauma** and edema to the ureteral tissue. Either interrupted sutures or a running closure may be used, depending on the surgeon's preference. The inferior

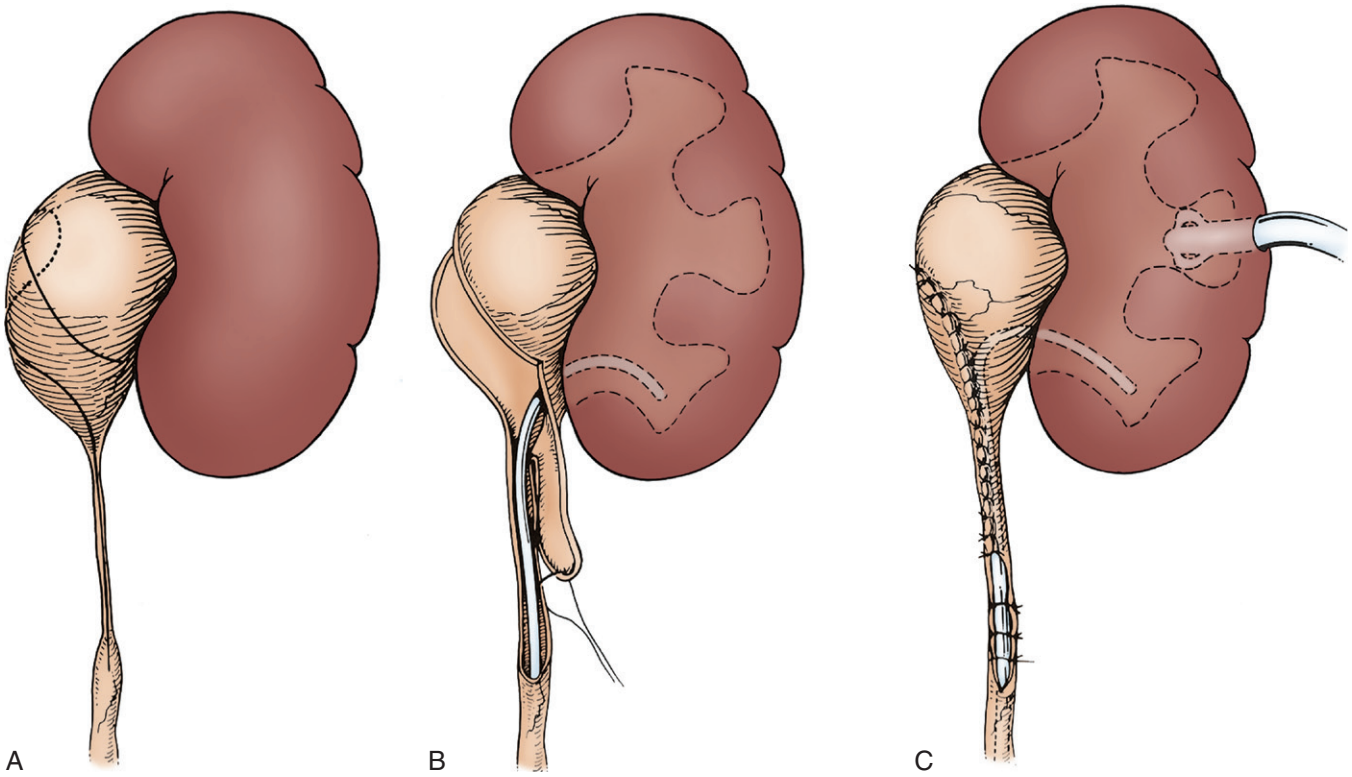

Figure 120–9. **A,** The intubated ureterotomy may be of value when a ureteropelvic junction obstruction is associated with extremely long or multiple ureteral strictures. A spiral flap is outlined and developed as described in Figure 120–10. The ureterotomy incision will be carried completely through the long strictured area or through each of the multiple areas of stricture. **B,** The flap is developed, taking care to use minimal dissection of the ureter to preserve its blood supply. In contrast to uncomplicated repairs, nephrostomy tube drainage is used routinely. A self-retaining, soft, inert internal ureteral stent is placed and positioned proximally in the renal pelvis or lower infundibulum and distally in the bladder. The apex of the flap is brought as far down as possible over the stent on the ureterotomy. The flap is closed with interrupted or running absorbable sutures. **C,** The distal aspect of the ureterotomy is left open to heal secondarily by ureteral regeneration. A few fine absorbable sutures may be placed loosely to keep the sides of the ureter in apposition to the stent.

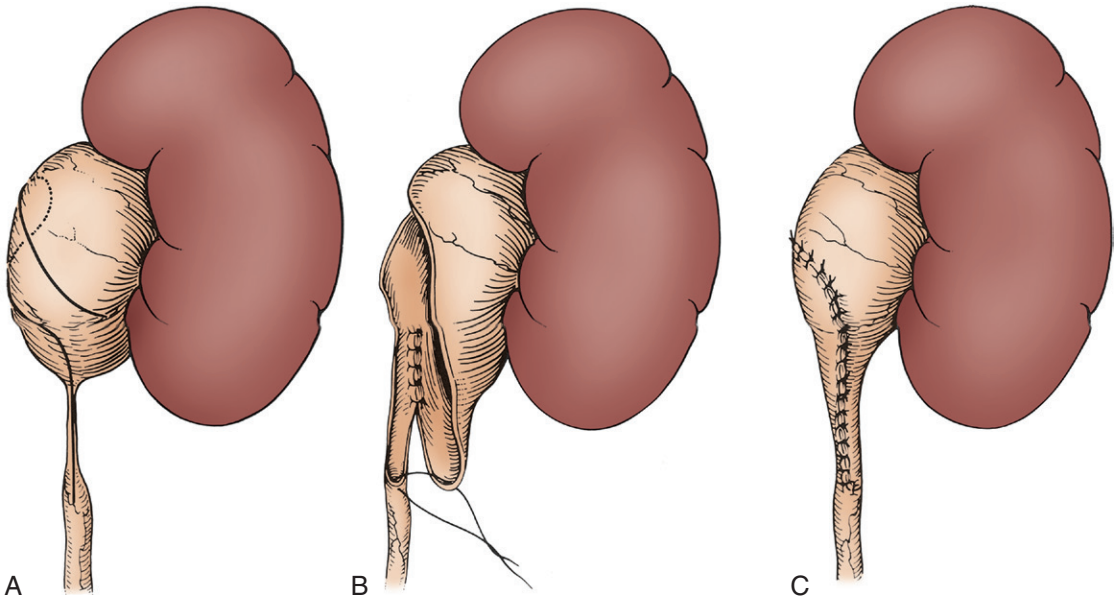

Figure 120–10. **A,** Spiral flap may be indicated for relatively long areas of proximal ureteral obstruction when the ureteropelvic junction is already in a dependent position. The spiral flap is outlined with the base situated obliquely on the dependent aspect of the renal pelvis. The base of the flap is positioned anatomically lateral to the ureteropelvic junction between the ureteral insertion and the renal parenchyma. The flap is spiraled posteriorly to anteriorly, or vice versa. The anatomically medial line of incision is carried down completely through the obstructed proximal ureteral segment into normal-caliber ureter. The site of the apex for the flap is determined by the length of the flap required to bridge the obstruction. The longer the segment of proximal ureteral obstruction, the farther away is the apex because this will make the flap longer. To preserve vascular integrity to the flap, however, the ratio of flap length to width should not exceed 3 to 1. **B,** Once the flap is developed, the apex is rotated down to the most inferior aspect of the ureterotomy. **C,** The anastomosis is completed, usually over an internal stent, using fine absorbable sutures.

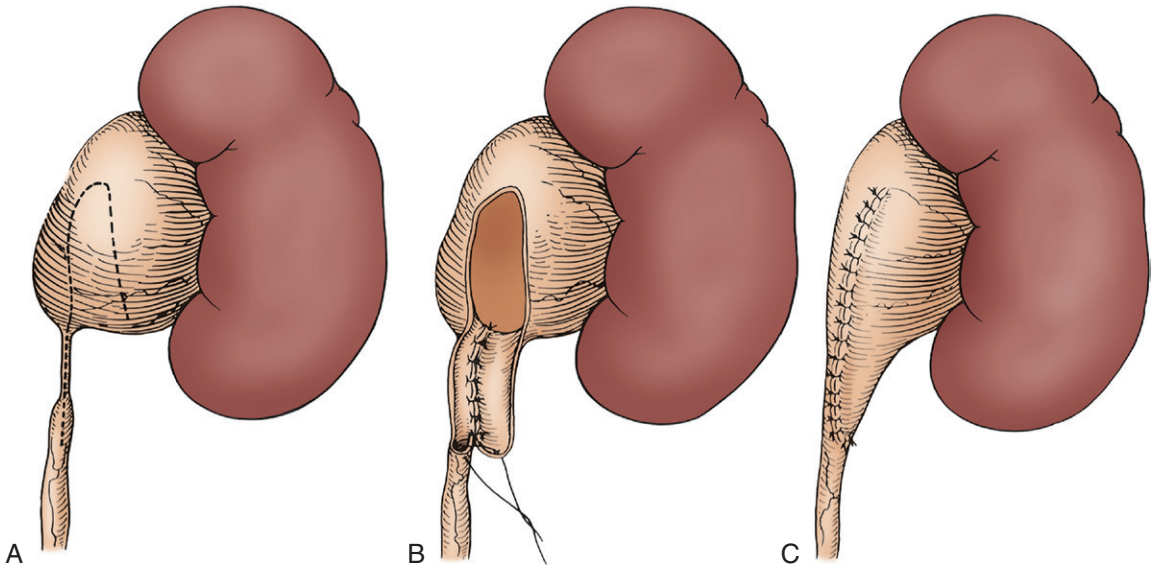

Figure 120–11. **A,** Vertical flap technique may be used when a dependent ureteropelvic junction is situated at the medial margin of a large, box-shaped extrarenal pelvis. In contrast to the spiral flap, the base of the vertical flap is situated more horizontally on the dependent aspect of the renal pelvis, between the ureteropelvic junction and the renal parenchyma. The flap itself is formed by two straight incisions converging from the base vertically up to the apex on either the anterior or posterior aspects of the renal pelvis. As for the spiral flap, the position of the apex determines the length of the flap, which should be a function of the length of proximal ureter to be bridged. The medial incision of the flap is carried down the proximal ureter completely through the strictured area into normal-caliber ureter. **B,** The apex of the flap is rotated down to the most inferior aspect of the ureterotomy. **C,** The flap is closed by approximating the edges with interrupted or running fine absorbable sutures.

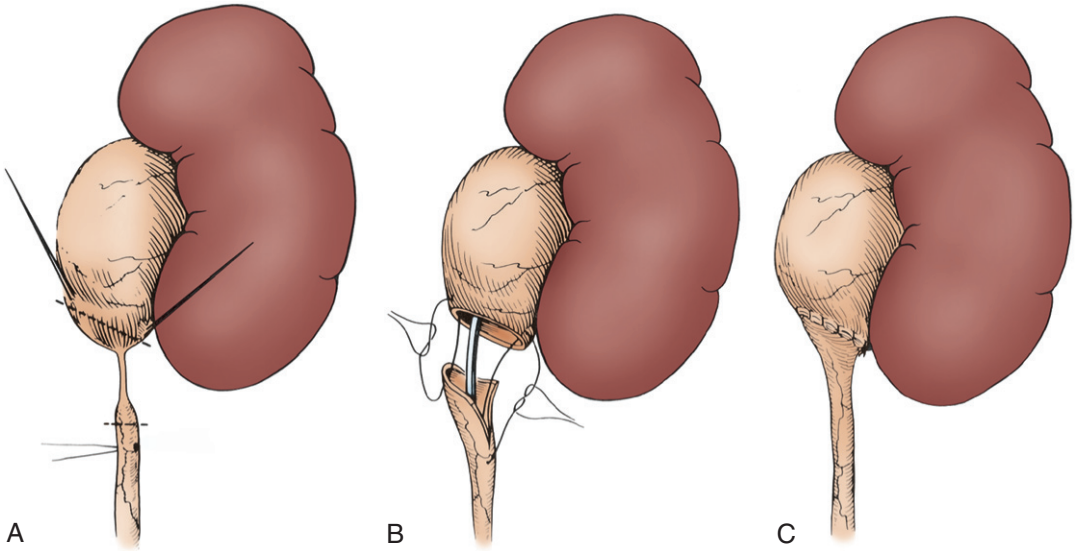

Figure 120–12. Anderson-Hynes dismembered pyeloplasty. **A,** Traction sutures are placed on the medial and lateral aspects of the dependent portion of the renal pelvis in preparation for dismembered pyeloplasty. A traction suture is also placed on the lateral aspect of the proximal ureter below the level of the obstruction. This suture will help maintain proper orientation for the subsequent repair. **B,** The ureteropelvic junction is excised. The proximal ureter is spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the ureter is then brought to the inferior border of the pelvis while the medial side of the ureter is brought to the superior edge of the pelvis. **C,** The anastomosis is performed with fine interrupted or running absorbable sutures placed full thickness through the ureteral and renal pelvic walls in a watertight fashion. In general, the authors prefer to leave an indwelling internal stent in adult patients. The stent is removed 4 to 6 weeks later.

aspect of the anastomosis at the vertex of the spatulation is critical to ensuring a watertight closure.

11. Before the repair is completed, the renal pelvis is irrigated to remove any blood clots or debris that could obstruct the UPJ. If an indwelling double-J ureteral stent is employed, it should be placed now, with care taken to place the stent into the bladder and renal pelvis without kinking it.
12. A Penrose drain is placed adjacent to the repair and brought out through a separate stab wound.
13. The kidney is returned to its native position, and perinephric fat, if available, is placed over the anastomosis.
14. Closure of the three fascial layers is readily accomplished, followed by closure of the Scarpa fascia and subcuticular skin.

15. A Foley catheter, which was placed at the beginning of the procedure, may be left in place for 24 to 48 hours postoperatively. The Penrose drain usually can be removed before discharge or, if left in place, it can easily be removed in the office 7 to 10 days postoperatively.

Posterior Lumbotomy

The patient is placed in a prone position with a roll under the chest, pelvis, and knees (Fig. 120–15). After the skin incision, the Scarpa fascia is sharply incised and a vertical incision is made through the lumbodorsal fascia (posterior lamella). The lateral edge of the lumbodorsal fascia is elevated, and the sacrospinalis muscle is medially retracted. An incision is made through the middle and anterior lamella of the lumbodorsal fascia, taking care not to injure the iliohypogastric nerve. The quadratus lumborum muscle is retracted, exposing the Gerota fascia beneath the paranephric fat, and then this fascia is opened. The renal pelvis is

Figure 120–13. A 3-month-old male with left ureteropelvic junction obstruction positioned for anterior subcostal approach to dismembered pyeloplasty. The tip of the 11th and 12th ribs are marked, and the patient is placed on a gel roll for elevation of flank.

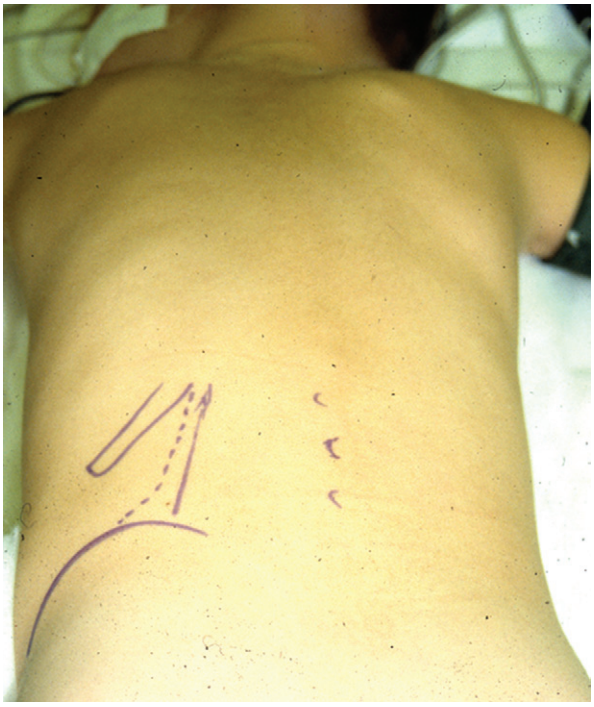

Figure 120–15. Positioning of patient for left posterior lumbotomy incision. An oblique incision is made from the angle of the 12th rib down to the iliac crest at a point one third of the distance from the anterior superior iliac spine to the spinal processes.

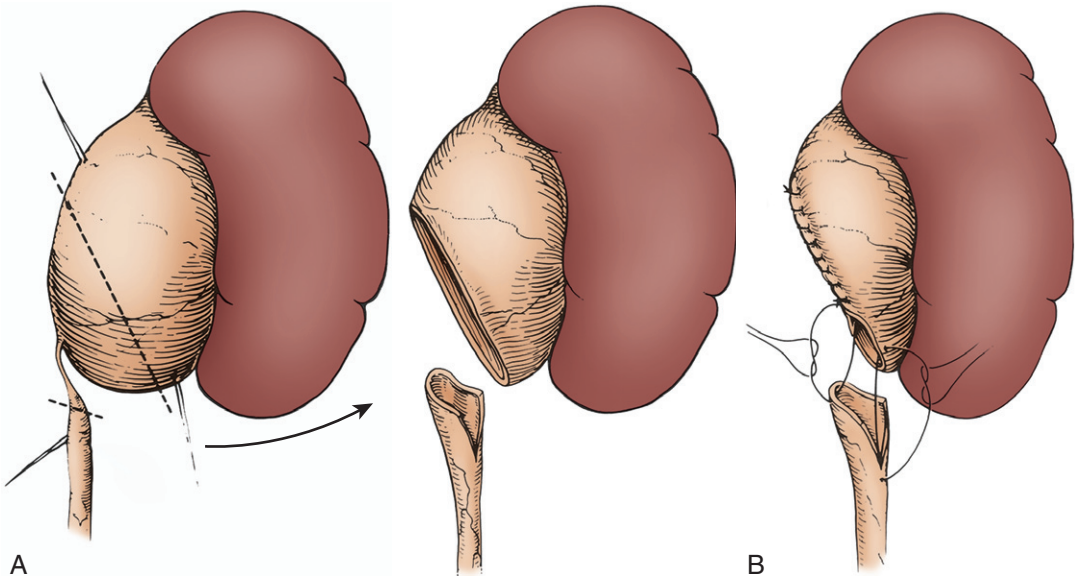

Figure 120–14. **A,** For a large or redundant pelvis, a reduction pyeloplasty is performed by excising the redundant portion between traction sutures. **B,** The cephalad aspect of the pelvis is then closed with running absorbable sutures down to the dependent portion. The dependent aspect of the pelvis is anastomosed to the proximal ureter as described in Figure 120–12.

identified, and several holding stitches are placed in the pelvis. The ureter is identified, a holding stitch is placed in the ureter, and the surgeon proceeds with the dismembered pyeloplasty.

Flank Approach

The patient is placed over the kidney rest in a flank position; the kidney rest is elevated; and the operating room table is flexed. The skin incision is made off the tip of the 12th rib, or, if necessary, a supracostal 12th rib incision is made. The external oblique and latissimus dorsi muscles are divided. Next the internal oblique and serratus posterior inferior muscle are divided. The transversalis muscle is often thin and can be divided with digital dissection. The peritoneum is identified and retracted medially. The Gerota fascia is then encountered and opened longitudinally to gain exposure to the perinephric space. After identification of the renal pelvis and the ureter, a dismembered pyeloplasty can be performed as described earlier.

Minimally Invasive Techniques

Minimally invasive approaches in the repair of UPJ obstruction include endoscopic approaches and pyeloplasties performed laparoscopically (Schuessler et al, 1993; Chen et al, 1998; Tan, 1999) or with the assistance of the da Vinci robotic system (Intuitive Surgical, Sunnyvale, CA).

Endoscopic Approaches

The endoscopic approach to the UPJ has been successful in both an antegrade and retrograde fashion. The initial attempts at balloon dilation (Tan et al, 1995) have been superseded by the use of an Acucise device (ureteral cutting balloon catheter, 5 Fr; Applied Medical, Rancho Santa Margarita, CA) (Bolton et al, 1994). Postoperative stenting is required for 6 weeks, with a 100% success rate being reported in a small series of patients. In a much larger series of adult patients, Kim and colleagues (1998) reported an overall success rate of 78%. Two patients required angiographic studies and embolization of lower pole branching arteries because they developed gross hematuria after Acucise endopyelotomy.

Antegrade endopyelotomy can readily be accomplished in both adults and preadolescent or adolescent patients. Figenshau and Clayman (1998) recommended this procedure for any patient with a reasonably functioning kidney, mild to moderate hydronephrosis, and no evidence of a crossing vessel. Computed tomography or magnetic resonance imaging (MRI) can be used for preoperative assessment of a crossing vessel, or endoluminal ultrasonography can be performed before the procedure. **Antegrade endopyelotomy requires access to the kidney by a midpole posterior calix.** Direct visualization of UPJ obstruction allows use of a cold knife, electrocautery, and even a contact laser fiber to achieve the endopyelotomy (Renner et al, 1998). After fluoroscopic documentation of successful incision and/or dilation of the UPJ, a double-pigtail ureteral stent is placed under direct vision in the renal collecting system and fluoroscopically positioned into the bladder.

The need for fluoroscopy for urologic intervention, along with two and sometimes three anesthetics for preoperative stent placement (nephrostomy tube placement), endopyelotomy, and subsequent stent removal, must be weighed against the more invasive open dismembered pyeloplasty. Older pediatric patients may be managed with the less invasive procedures, with the expectation of good results (80% to 85% success) and improved postoperative convalescence. In one of the largest pediatric experiences to date, endopyelotomy in children ranging in age from 4.5 to 17 years was successful 89% of the time (Tallai et al, 2004); yet, use of this method in children is rare. Endopyelotomy was considered an option in the case of a failed pyeloplasty, because the UPJ should be in a dependent location (Fig. 120–16). A nephrostomy tube may already be in place, and a stricture or stenosis is most likely to be encountered at the UPJ. After a successful endopyelotomy, a double-pigtail ureteral stent is maintained for 6 weeks. Unlike the adult endopyelotomy stent (14 Fr/7 Fr), a pediatric endopyelotomy stent does not exist. The ideal stent would be a biodegradable stent that would not require removal (Lumiaho et al, 2000). Despite early optimistic reports, endopyelotomy for either primary or secondary UPJ obstruction appears to have limited utility.

Laparoscopic Pyeloplasty

Laparoscopic pyeloplasty was introduced in adults in 1993 (Kavoussi and Peters, 1993; Schuessler et al, 1993). In the initial report of five cases, the operative time ranged from 3 to 7 hours. The procedure has gained in popularity, and more recent series have reported a success rate of greater than 95% (Ben Slama, 2000). Laparoscopic pyeloplasty in children has followed the same evolution as nephrectomy. The procedure was first described using a transperitoneal approach. Tan (1999) reported the first pediatric series of transperitoneal laparoscopic dismembered pyeloplasty in 18 children aged 3 months to 15 years. Mean operative time was 89 minutes. Two patients with persistent obstruction underwent repeat laparoscopic pyeloplasty.

Yeung and colleagues (2001) have reported their initial experience with retroperitoneal dismembered pyeloplasty in 13 patients, one of whom required open conversion. The mean operative time was 143 (range 103 to 235) minutes. The longer time needed for the retroperitoneal approach is probably related to the limits of the working space that renders suturing more difficult.

Robotic-assisted surgery may be ideally suited for a pyeloplasty, allowing one to overcome the difficulties encountered with laparoscopic suturing. Peters (2004) presented the first preliminary results of robotic-assisted laparoscopic transperitoneal pyeloplasty in children. Olsen and Jorgensen (2003, 2004) reported their unique experience of retroperitoneal robotic-assisted pyeloplasty. They compared a group of 8 children operated by the robotic-assisted procedures with a previous group of 15 children operated by the standard procedure laparoscopic procedure. The median operative time with the robot was lower than with standard equipment (172 vs. 210 minutes); the shortest operative time with robot was 110 minutes. This early experience has been corroborated by a number of centers, including the authors', demonstrating that advanced laparoscopic reconstructive surgery is feasible. The concern, though, is that the skill set needed for laparoscopic surgery is not being achieved before advancing to a robotic-assisted surgery. The opinion has been voiced that if a robotic malfunction occurs, the more difficult skills of laparoscopic suturing would be needed.

Soulie and colleagues (2001) compared retroperitoneal laparoscopic versus open pyeloplasty with a minimal incision in 53 consecutive nonrandomized adults. The mean operating time (165 vs. 145 minutes) was similar in both groups. Incidence of complications, hospital stay, and functional results were equivalent for both groups, but the return to painless activity was more rapid with laparoscopy in younger patients. Bauer and colleagues (1999) did a similar study, with no difference in the postoperative outcome between laparoscopic and open pyeloplasty. Comparisons between laparoscopic and robotic-assisted anastomoses have begun to define the improvements observed (Franco et al, 2007).

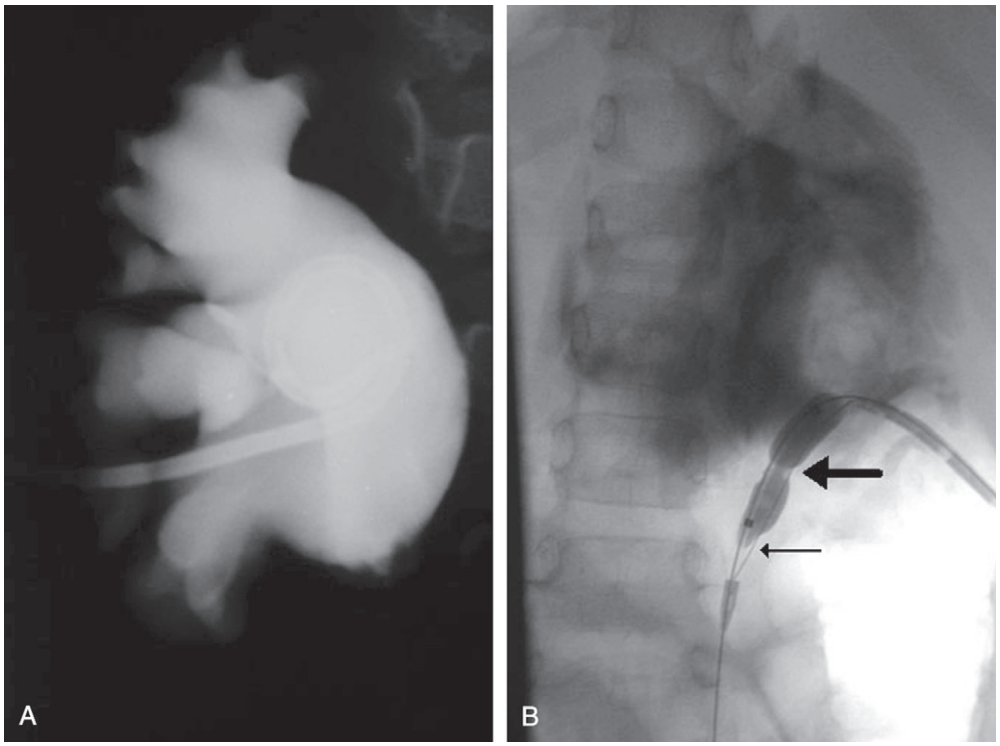

Figure 120–16. **A,** Right antegrade nephrostogram performed 2 months after dismembered pyeloplasty, demonstrating persistent obstruction at the ureteropelvic junction. A nephrostomy tube was placed 2 weeks after surgery, after the patient developed flank pain, fever, and *Staphylococcus aureus* urinary tract infection. **B,** Acucise balloon being inflated across the ureteropelvic junction narrowing. Note waist present in balloon *(upper arrow)* and cutting wire positioned laterally *(lower arrow)*.

The authors' experience thus far encompasses over 300 minimally invasive procedures, thus providing a unique perspective on the learning curve for the minimally invasive approach. The authors' operative times decreased steadily at a rate of 26 minutes, on average with a 35 case interval in between each major time decrease until just over 100 procedures were performed. The attending surgeon's operative time in the first 30 cases lasted, on average, 155 minutes, and now all operative times are less than 90 minutes from incision to skin closure completion. A similar learning curve is seen with trainees, with an extension of the operative times to be 35 minutes on average. Proficiency with instrumentation and suture manipulation is paramount in training. These tasks are accomplished outside the operating arena using surgical simulation tasks with a laparoscopic trainer.

In performing robotic pyeloplasty, one must take into account that a small work space can cause collision of the robotic arms and could be a limiting factor while performing complex manipulative procedures, such as suturing and anastomosis between the renal pelvis and ureter in a restricted space (Thakre, 2008). Robotic pyeloplasty is technically possible but a challenging procedure in small infants. For this reason, the authors' current practice is to perform open pyeloplasties in those infants younger than 6 months. Either a posterior lumbotomy or an anterior subcostal incision is well tolerated in this age group, and the benefits of a laparoscopic approach are more apparent in those patients who are slightly older.

Instruments and Supplies

Typically, an open access technique is used for the camera port. The camera port is placed in the superior aspect of the umbilicus. The abdomen is insufflated with CO_2 at a pressure of 8 to 15 mm Hg with a flow rate of 3 to 10 liters per minute. **The rule is to use enough insufflation to see the relevant anatomy using as little pressure and flow as possible.** Two additional working trocars are usually inserted, typically, 8 or 5 mm for robotics and 5 mm for conventional laparoscopy. A fourth trocar can be placed for additional grasping and retraction, but the space is limited in tiny children, especially infants. The techniques and technology have evolved, allowing identical results and using 5-0, 6-0, and 7-0 suture as in open surgeries. The authors typically use 6-0 monofilament absorbable suture, but one can use any 5-0 or 6-0 suture, depending on the size of the patient.

Surgical Technique

General Procedures. The patient is placed in a modified flank position with a 40- to 60-degree elevation of the flank (Fig. 120–17). **The patient is placed as close to the edge of the bed as possible, and secured with towels and silk tape.** The urethral catheter can be introduced in the sterile operative field for intraoperative access, allowing instillation of saline with or without an indicator for verification of reaching the bladder during the antegrade double-pigtail ureteral stent placement, as described below.

In prepubertal children and teenagers, the ports are placed in the umbilicus for the camera port, along with two working ports in the midclavicular line above and below the umbilicus. On the other hand, in infants, the upper working port should be placed subxyphoid in the midline and the lower working port as lateral as possible to the rectus muscle and close to the inguinal region (Fig. 120–18). For robotics, it is helpful after the port placement to visualize the organ site and decide whether any rotation or reposition of the patient is necessary because it is impossible to

Figure 120–17. The patient is placed in a modified 40- to 60-degree decubitus position. The ipsilateral arm is typically placed along the patient's side as shown in the figure. The authors find this arm configuration to be less obstructive to the laparoscopic field, especially when robotics is employed. It is important to note that with the use of robotics, the entire patient positioning, including bed rotation, must be done prior to docking the robot. Once the robot is docked, any change in patient or bed position requires undocking it.

make such changes after robotic docking without first undocking.

The choice of the transperitoneal or retroperitoneal approach depends on the surgeon's experience. The UPJ is exposed transmesenterically on the left (Fig. 120–19) or by slightly mobilizing the colon on the right, as described below. If one chooses colonic mobilization on the left, it must be taken medially over the aorta. A precise dissection of the UPJ is required to evaluate the cause of UPJ obstruction (UPJO), including lower pole–crossing vessels, additional small arterial branches, or small lumber or gonadal veins crossing the ureter (Rassweiler, 2008) and the renal pelvis. Any crossing vessels should be completely isolated. The ureter also should be free from surrounding structures, such as crossing vessel or periureteral bands. After exposure of UPJO, a hitch stitch is passed through the abdominal wall to elevate and stabilize the pelvis, if so desired. We use a hitch stitch if a pyelolithotomy is necessary. **The choice of dismembered** (Fig. 120–20) **or nondismembered pyeloplasty** (Fig. 120–21) **depends on the surgeon's experience or the anatomy of the renal pelvis and ureter, such as the presence of crossing vessels,** as described below in detail. After the pelvis is incised, the ureter is spatulated laterally, and the anastomosis is performed using a running suture (Fig. 120–22). A double-pigtail ureteral stent is placed after the posterior wall closure is completed (Fig. 120–23). This affords visualization of the anterior wall closure and prevents twisting of the ureter. The double-pigtail ureteral stent placement is performed by placing a 14- or 16-gauge angiocatheter through the anterior abdominal wall. A guidewire is then placed in an antegrade fashion, and the stent is passed over the guidewire. One can fill the bladder with saline or methylene blue to observe the efflux of urine, once there is access into the bladder by the stent. The stent can also be placed retrograde, using a dangling string to allow removal in the office.

Transperitoneal or Retroperitoneal Approach. Recently, several reports have demonstrated the usefulness of conventional retroperitoneoscopic pyeloplasty for children. Canon and colleagues (2007) reported their comparison study of transperitoneal and retroperitoneal approaches in children. They showed no major difference between the two approaches for correcting UPJO, although the average operative time for the retroperitoneoscopic approach was significantly longer than for the transperitoneal approach. Metzelder and colleagues (2006) concluded that no disadvantage was attributable to the transperitoneal approach in children.

Robotic pyeloplasty can be also performed using the transperitoneal or retroperitoneal approach, but there have been no large-scale randomized, prospective studies comparing the approaches. The authors choose a transperitoneal approach because they find that the working space is not limiting and are more comfortable with this approach. **Robotic pyeloplasty using retroperitoneal approach remains a technically challenging procedure in children. This is due to the difficult manipulation within the limited retroperitoneal space, particularly prior to opening the Gerota fascia.** In fact, there are only two reports on the experiences of pediatric robotic pyeloplasty using a retroperitoneal approach (Olsen et al, 2007). This difficulty may be overcome with improvement in operative skill and advancement of robotic technology.

Retrocolic or Transmesenteric Access. Traditionally, a transperitoneal laparoscopic approach to UPJO has been performed in retrocolic fashion by reflecting the colon and its mesentery medially to expose the renal pelvis and ureter; however, **transmesenteric access to the retroperitoneum is a better option for left transperitoneal laparoscopic pyeloplasty, because it allows direct access to a left UPJ with little or no bowel manipulation and shorter operative time** (Lee et al, 2006). The authors also prefer to perform robotic left pyeloplasty for children by transmesenteric access.

Procedures: Dismembered or Nondismembered Robotic Pyeloplasty. The surgical procedures of robotic and laparoscopic dismembered pyeloplasty follow the same steps as the open Anderson-Hynes technique. The stenotic segment is excised and, if necessary, reduction of the renal pelvis accomplished. Position stay sutures should be used with caution to avoid recurrent UPJO, because they may leave the renal pelvis and the ureter in an unfavorable position once released and allowed to fall back (Olsen and Rawashdeh, 2008).

On the other hand, nondismembered pyeloplasty includes the "Fenger-plasty using the Heinecke-Miculicz principle" of a longitudinal incision of the UPJO and vertical suturing, "Y-V plasty" with a V-shaped incision of the renal pelvis, an additional incision of the stenosis including spatulation of the ureter (Y-shaped), and a subsequent closure as a V-flap and "bypass pyeloplasty" with side-to-side anastomosis between the dilated portion of the ureter just distal to the UPJO and the lower and dependent portion of the hydronephrotic renal pelvis (Mesrobian, 2009). Bypass pyeloplasty may be a more physiologic procedure in patients with mid- to high insertion of the ureter. The Heinecke-Mikulicz principle has been abandoned due to inferior long-term success rates. Y-V plasty is better suited for a high insertion of the ureter into the pelvis or for small extrarenal pelvis (Casale et al, 2004). The authors have recently performed a robotic-modified bypass

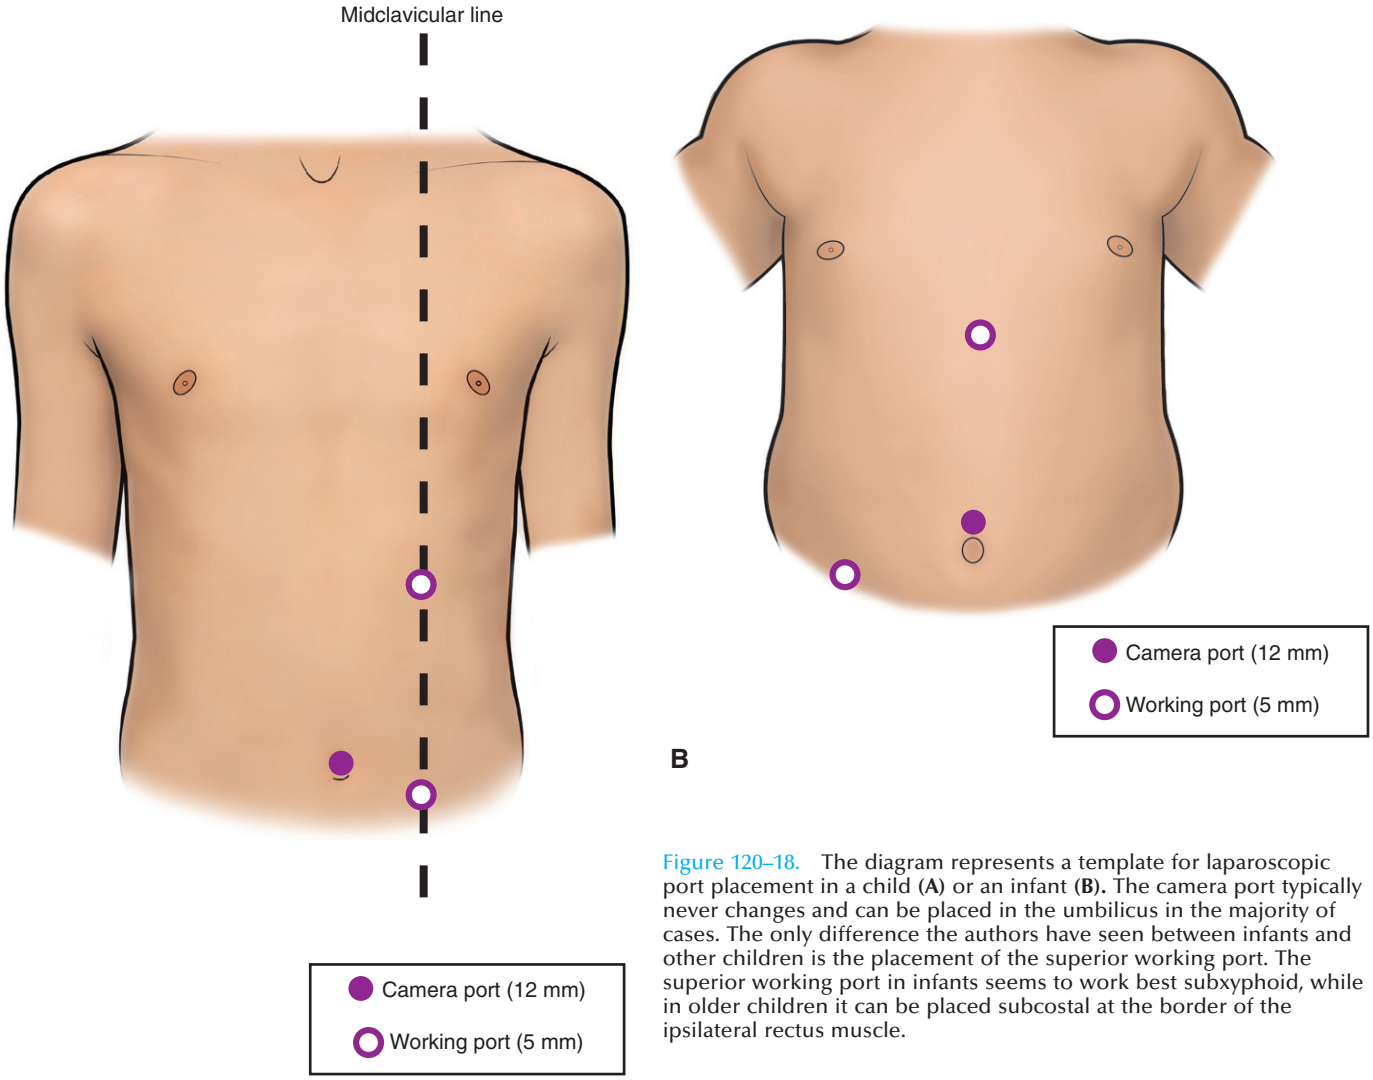

Figure 120–18. The diagram represents a template for laparoscopic port placement in a child **(A)** or an infant **(B)**. The camera port typically never changes and can be placed in the umbilicus in the majority of cases. The only difference the authors have seen between infants and other children is the placement of the superior working port. The superior working port in infants seems to work best subxyphoid, while in older children it can be placed subcostal at the border of the ipsilateral rectus muscle.

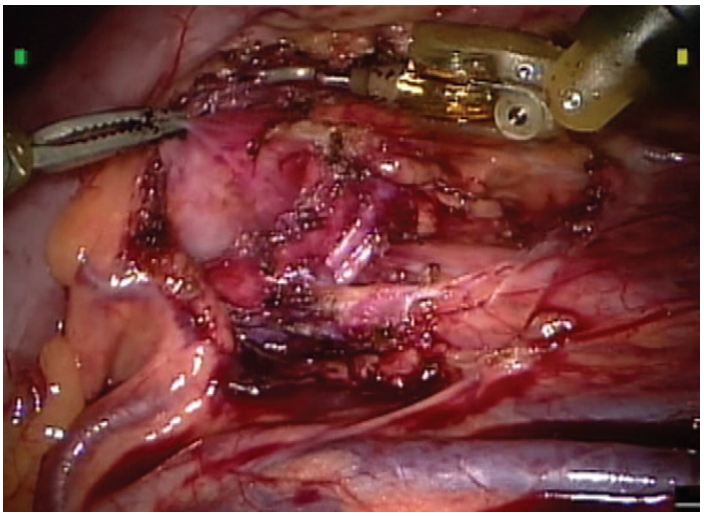

Figure 120–19. Intraoperative laparoscopic view of a transmesenteric approach to the left kidney. Note the crossing vessels seen at the level of the ureteropelvic junction.

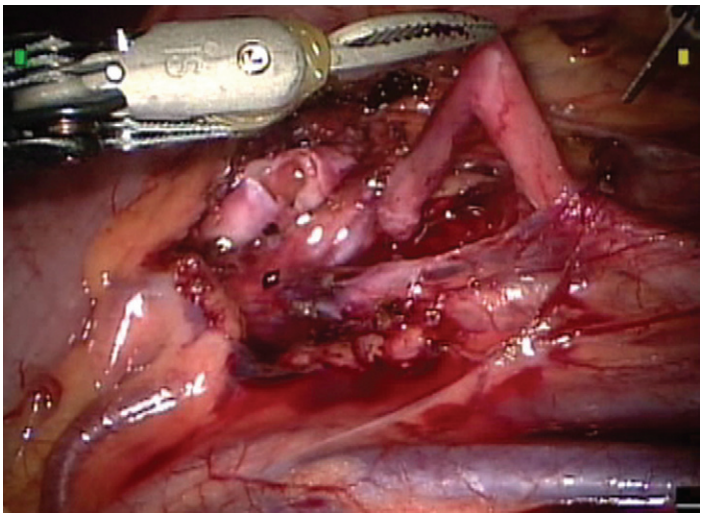

Figure 120–20. Intraoperative laparoscopic view of a transected ureter from the renal pelvis with lower pole–crossing blood vessel pathology. The ureter is then slid out from underneath the vessels with manipulation of the adventitia only.

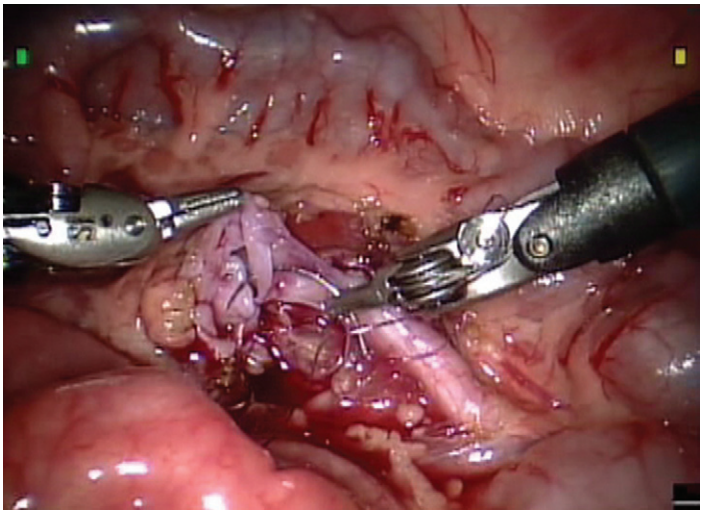

Figure 120–21. Laparoscopic view of a nondismembered pyeloplasty using a side-to-side ureteropyelostomy technique described as a "bypass pyeloplasty." It is imperative that the dependent new ureteropelvic junction be within 1 cm of the lower pole parenchyma.

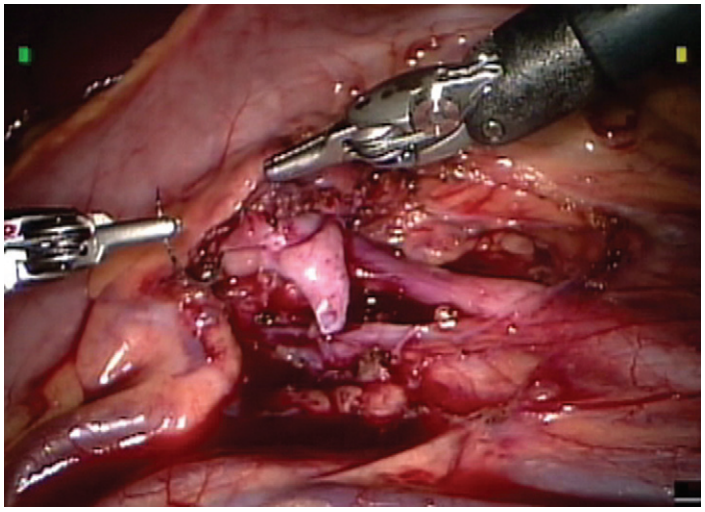

Figure 120–22. Laparoscopic view of the posterior anastomosis of the pyeloplasty. A 6-0 or 5-0 absorbable suture is used in a running fashion.

pyeloplasty for children without crossing vessels, which involves an extended longitudinal incision on the lateral side from the renal pelvis to ureter through the stenotic segment of UPJ. A side-to-side anastomosis between the renal pelvis and ureter is accomplished with a running suture (Fig. 120–24).

One can argue that **an advantage of dismembered pyeloplasty is the complete excision of a stenotic segment of UPJ. Conversely, nondismembered pyeloplasty is technically easier because the ureter is not completely transected from the renal pelvis, facilitating tension-free suturing,** especially with placement of the first stitch (Casale et al, 2004). Maintaining the stenotic segment helps prevent twisting of the ureter and reduces suturing time. A comparison study may be required to clarify which procedure is more suitable in children, although the choice between these types of procedures basically depends on the surgeon's experience along with the anatomy of the renal pelvis and ureter.

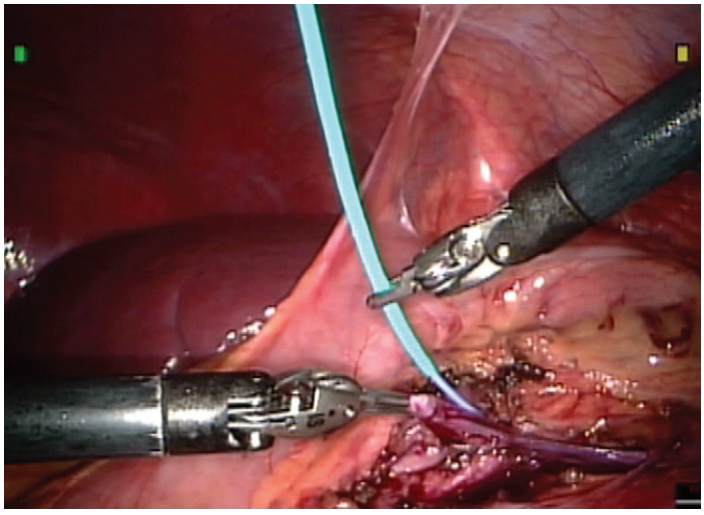

Figure 120–23. Antegrade placement of a double-pigtail catheter after the posterior anastomosis is completed. A 16-gauge angiocatheter is placed percutaneously through the abdominal wall just over the site of the pyeloplasty. A guidewire is then passed with the stent on the wire as one unit traversing the ureter to the bladder. It is important to allow 5 cm of wire to extrude from the stent so that the stent will not get caught at the ureteral orifice below. The bladder catheter can be clamped at the beginning of the posterior anastomosis as to allow bladder filling to allow verification of stent placement into the bladder or dilute methylene blue instilled in the bladder to allow for efflux of blue once the stent enters bladder.

OUTCOME AND COMPLICATIONS

Open Pyeloplasty

Adherence to sound surgical principles, minimal handling of the ureter at the time of repair, and judicious use of internal stenting or nephrostomy tube drainage ensure a successful outcome (Austin et al, 2000). Success is defined as improvement in hydronephrosis and stabilization or improvement in function on renal scan along with a decrease in washout time. In those situations in which symptomatic presentation occurred, resolution of flank/abdominal pain or vomiting should also occur.

Imaging of the kidneys postoperatively depends on whether a nephrostomy tube has been used. A nephrostogram performed 10 to 14 days after surgery allows visualization of the anastomosis. Others have simply clamped the nephrostomy tube for 24 hours and checked the residual in the renal pelvis. If the residual is less than 15 mL, then the nephrostomy tube is removed (Flint et al, 1998). If a double-pigtail ureteral stent is left indwelling, it is removed 2 to 6 weeks after the initial procedure. A renal ultrasonogram is obtained 6 to 8 weeks after pyeloplasty or after stent removal to ensure that the hydronephrosis (pelvocaliectasis) is improving or at least remaining stable. A renal scan may be obtained 1 year after the pyeloplasty to provide a relative assessment of the overall renal function. This is particularly helpful if the initial renal scan showed diminished renal function to the affected kidney. A new baseline is then established, which may be helpful for long-term outcome. On the other hand, if the renal function was not significantly affected at the time of surgery, an overall decrease in the degree of pelvocaliectasis over time is a good indication that the obstruction has been relieved. Long-term imaging at 3 to 5 years may be obtained to look for that

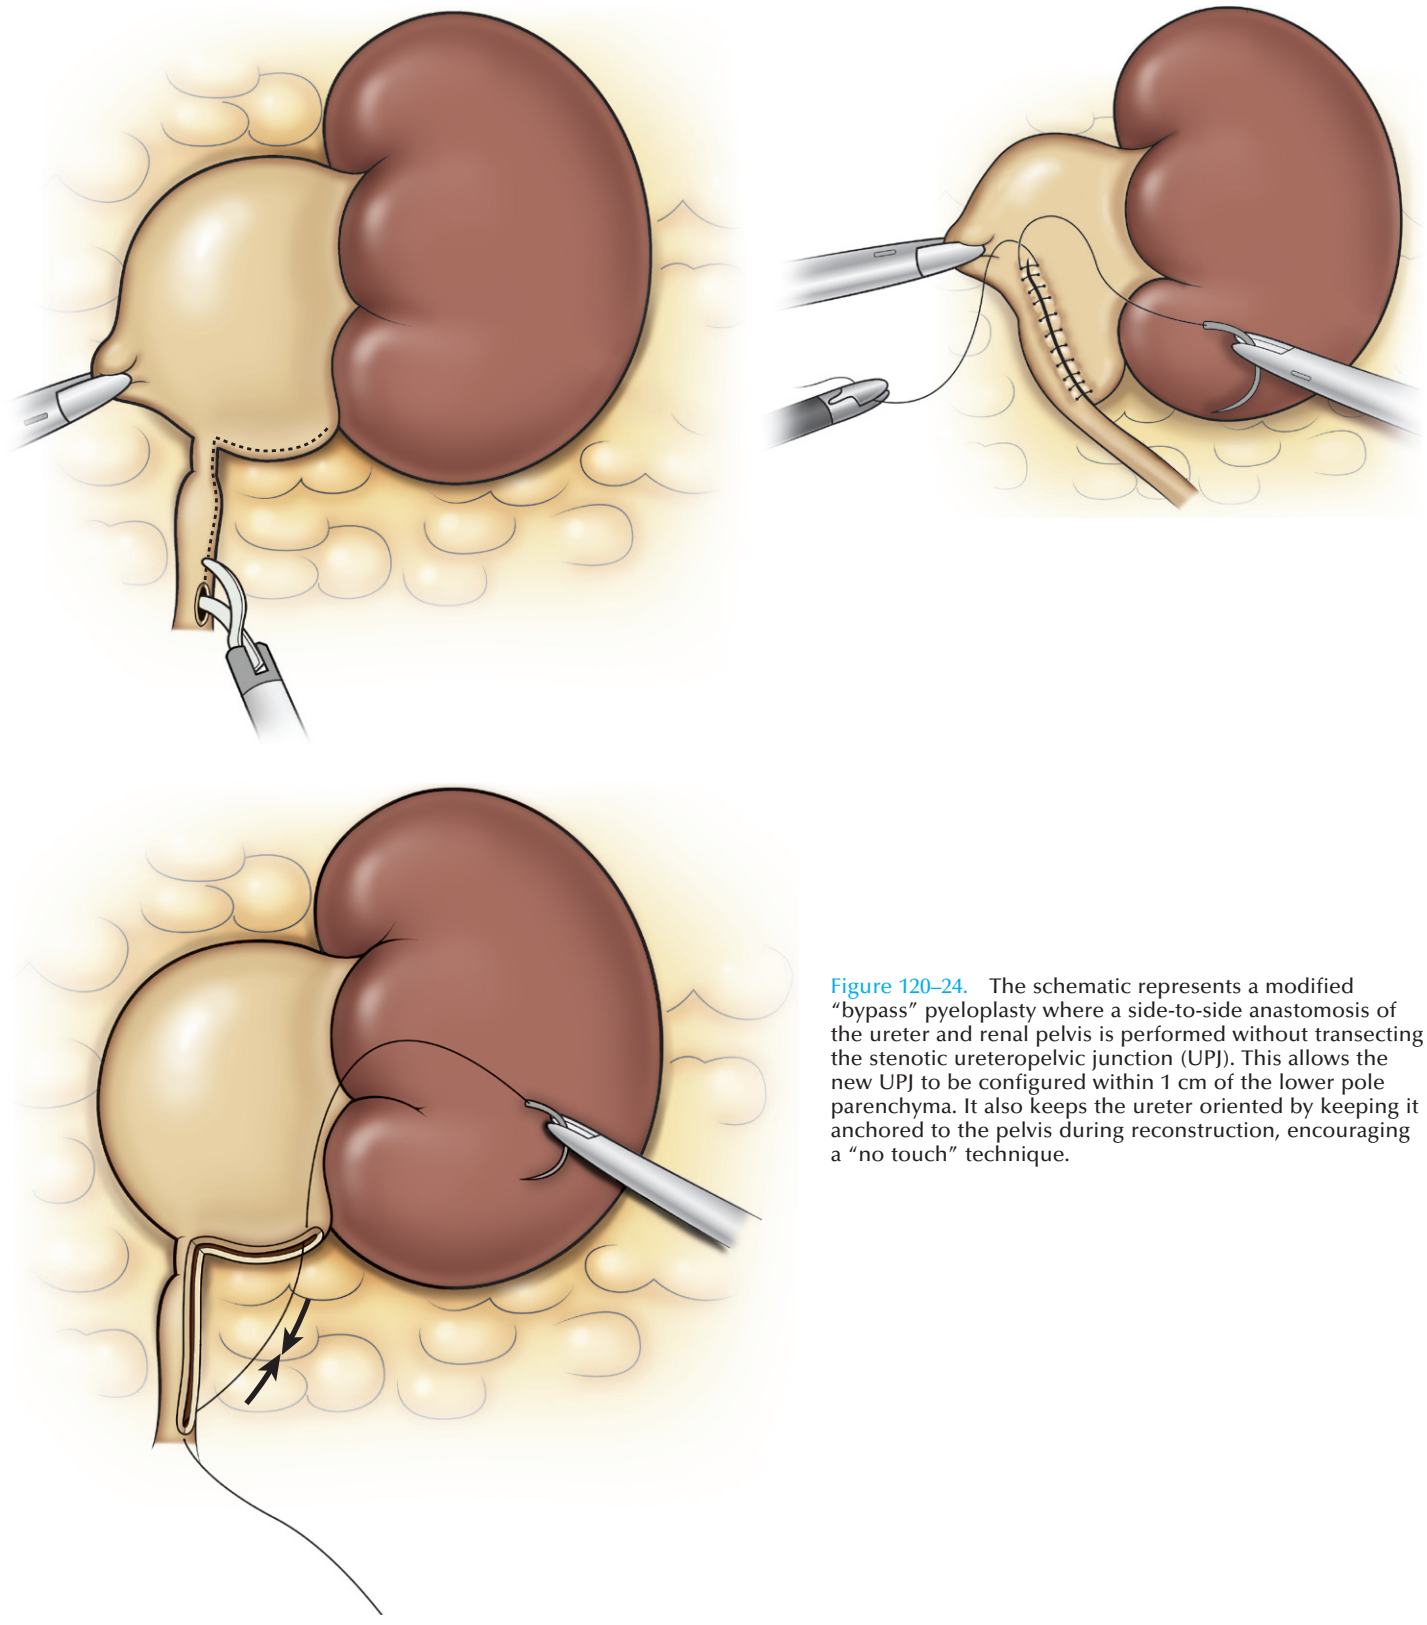

Figure 120–24. The schematic represents a modified "bypass" pyeloplasty where a side-to-side anastomosis of the ureter and renal pelvis is performed without transecting the stenotic ureteropelvic junction (UPJ). This allows the new UPJ to be configured within 1 cm of the lower pole parenchyma. It also keeps the ureter oriented by keeping it anchored to the pelvis during reconstruction, encouraging a "no touch" technique.

rare situation of delayed cicatrization and restenosis of the UPJ. Generally, once the trend of improved pelvocaliectasis is documented postoperatively and confirmed with an evaluation 1 year following surgery, further imaging is not needed. Table 120–1 lists the results from a number of contemporary series of pyeloplasties.

Early complications of pyeloplasty are uncommon and usually involve prolonged urinary leakage from the Penrose drain. Depending on the amount of drainage, observation is generally the best approach. If it persists beyond 10 to 14 days, placement of a retrograde ureteral stent can often rectify the situation. Spontaneously delayed opening of the anastomosis has

Table 120–1.

†Retroperitoneal laparoscopic.

occurred as late as several months after the repair. If a patient presents postoperatively with fever, flank pain, and significant hydronephrosis, a nephrostomy tube may be necessary to decompress the kidney. Lack of drainage for a prolonged period would necessitate further imaging with repeat antegrade nephrostogram and consideration of retrograde pyelography as well.

Minimally Invasive Procedures

Complications of the pediatric minimally invasive surgery (MIS) pyeloplasty series published to date include prolonged drainage (Atug et al, 2005) and ileus (Yee et al, 2006), conversion to an open procedure, postoperative nephrectomy, urinary tract infection, hematuria, and displaced double-pigtail ureteral stents (Olsen et al, 2007). Potential intra- and postoperative complications are basically similar to those with conventional laparoscopic procedures as noted below.

Intraoperative Complications

Potential intraoperative complications with MIS pyeloplasty include bleeding requiring transfusion, trocar damage to viscera or vessels, and thermal damage to tissues or organs (Canon et al, 2007). A rare, but significant, complication is bowel injury, the risk of which might be higher if a transperitoneal or even a transmesenteric access is used. Diligent inspection of the viscera at the end of every procedure may help identify an injury (Moore et al, 1995). In some cases, a double-pigtail ureteral stent cannot be advanced into the bladder and urethroscopic repositioning of the stent might become necessary. Technical problems during a robotic pyeloplasty, such as robotic failure, can lead to a conventional laparoscopic conversion.

Postoperative Complications

Potential postoperative complications include hernia internally or at the port site, wound infection, persistent urine leakage and urinary tract infection. Postoperative ileus is a complication with the transperitoneal approach due to leakage of urine from the anastomosis. **Postoperatively, a child should make steady, consistent progress in the first few hours after surgery and dramatically day by day over the first week.** Prompt action should ensure assessing the child and minimizing adverse outcomes (Atug et al, 2005; Canon et al, 2007).

PROCEDURES FOR RECURRENT URETEROPELVIC JUNCTION OBSTRUCTION

Although open laparoscopic and robotic pyeloplasties have favorable outcomes with success rates exceeding 90%, recurrent UPJO sometimes occurs in all procedures. Factors such as young age at initial surgery (less than 6 months), prolonged urinary diversion (dry anastomosis), missed anatomic findings at the first intervention (crossing vessels or long ureteral segment narrowing), and lack of retrograde pyelogram have been related to pyeloplasty failure (Thomas et al, 2005; Braga at al, 2008). Second-line therapies have previously been shown to fail at a higher rate than the initial therapeutic procedure (Atug et al, 2005). It is a serious complication for which treatment remains challenging, because of the extensive scarring and fibrosis from the prior procedure. Patients with recurrent UPJO sometimes present a treatment dilemma to pediatric urologists.

Open or Minimally Invasive Surgery (MIS) Redo Pyeloplasty

Usually, repeat dismembered pyeloplasty has been successful in correcting the problem. An anteriorly elongated flank incision facilitates exposure; a transperitoneal approach avoids some of the dense scarring that often occurs; and a nephrostomy tube postoperatively is recommended (Rohrmann et al, 1997). Alternatively, MIS redo pyeloplasty is reported to be a safe and effective option in the treatment of these challenging patients (Passerotti et al, 2007; Hemal et al, 2008). Basically, the procedure is performed as described for the primary MIS pyeloplasty. Although both dismembered and nondismembered pyeloplasties are possible, for cases in which scarring prevents extensive mobilization of the renal pelvis and ureter to allow dismembered pyeloplasty, Y-V plasty is an excellent option when crossing vessels were not missed the first time around (Passerotti et al, 2007).

Careful preoperative planning is mandatory before embarking upon the redo surgery. **The location and the extent of the diseased segment is assessed with preoperative imaging, including antegrade, retrograde, or intravenous urography and nuclear renography or magnetic resonance urography to assess renal function and location.** The available options for management of recurrent UPJO are balloon dilation, endopyelotomy, open, or MIS pyeloplasty. Braga and colleagues (2007) compared retrograde endopyelotomy, using a holmium laser or cautery/balloon dilation, with redo pyeloplasty through a flank incision or laparoscopy for the treatment of failed pyeloplasty in children. They demonstrated that retrograde endopyelotomy had a significantly lower success rate (39%) than redo pyeloplasty (100%) for correction of recurrent UPJO (Braga et al, 2007). Piaggio and colleagues (2007) assessed the feasibility of pediatric redo conventional laparoscopic pyeloplasty in comparison with redo open pyeloplasty and demonstrated that the success rate was the same in both groups (80%). However, surgical time for redo conventional laparoscopic pyeloplasty was longer than for redo open pyeloplasty. Redo conventional laparoscopic pyeloplasty is technically more challenging than primary conventional laparoscopic pyeloplasty with longer operative times. Because the most time-consuming part of the operation is the laparoscopic exposure and suturing for recurrent UPJO, robotic procedures, such as redo pyeloplasty and ureterocalicostomy, for these children can be alternative options.

Dissection of the UPJ area may be one of the most technically difficult parts of performing redo MIS pyeloplasty. Because of the presence of scar tissue, care must be taken to avoid injury to the ureter or major vessels. The magnification and dexterity afforded by the robot might allow more precise dissection (Atug et al, 2006). The degree of adhesion and fibrosis is highly variable, which may be secondary to healing factors of the patients as well as to technical problems in the primary operation, such as incomplete or unfavorable position of the anastomosis between the renal pelvis and ureter or urinoma (Brito et al, 2007). Crossing vessels that may have been missed during the primary operation must be identified, because it can be a cause of recurrent UPJO (Rehman et al, 2001). The ureter should be free from surrounding structures and spatulated clearly enough to encounter healthy tissue. Passerotti and colleagues (2007) reported redo robotic pyeloplasty for 6 children with uniform success and no complications. Hemal and colleagues (2008) reported their experience of redo robotic pyeloplasty for 5 children younger than 15 years as a salvage procedure, and all children had improvement of obstruction.

Key Points: Pyeloplasty

- Ureteropelvic junction obstruction is typically due to either an intrinsic narrowing in which the ureteral segment has an interruption in the development of the circular musculature of the ureteropelvic junction, an alteration in collagen fibers in and around the muscular cells, or an extrinsic obstruction that is seen in association with aberrant, accessory, or an early branching lower pole vessel that passes anteriorly to the UPJ or proximal ureter and contributes to mechanical obstruction.
- Congenital renal malformations can be commonly seen in association with a ureteropelvic junction, with a contralateral UPJ obstruction being the most common anomaly, followed by renal dysplasia and multicystic dysplastic kidneys.
- The surgical approach favored in the repair of a ureteropelvic junction obstruction is the dismembered pyeloplasty, which has been shown to be effective because of its broad applicability, means of allowing excision of the pathologic segment question, and facilitation of a reduction pyeloplasty when necessary.
- Laparoscopic pyeloplasties provide excellent visualization of the anatomy, enhance cosmesis, and duplicate the results of open pyeloplasties with short-term follow-up. The technical challenges of this approach have been facilitated by the use of a robotic-assisted procedure that improves the anastomotic repair.
- Complications from a pyeloplasty include prolonged urinary drainage postoperatively, lack of improvement in renal function or improvement in washout, and, occasionally, worsening hydronephrosis and diminished renal function postoperatively. Such a situation may lend itself to a repair using ureterocalicostomy or a redo dismembered pyeloplasty.

Open, Robotic, or Laparoscopic Ureterocalicostomy

In performing a ureterocalicostomy, key points include amputating the lower pole of the kidney; preserving all periureteral tissue and blood supply; creating a widely spatulated, tension-free, mucosa to mucosa anastomosis; and adequate internal stenting. Retroperitoneal fat can be placed around the anastomosis, but closing the lower pole capsule over the renal parenchyma should be avoided (Matlaga et al, 2005) (Fig. 120–25).

Laparoscopic ureterocalicostomy is a potential option not only in patients with failed pyeloplasty but also in patients with UPJO and significant lower pole calicectasis and a minimal pelvis, or in patients with an exaggerated intrarenal pelvis (Casale et al, 2008). If the pelvis is not readily accessible, robotic ureterocalicostomy will be a better choice than redo robotic pyeloplasty. The colon is reflected, exposing the massively dilated kidney. The ureters are transected and ligated with absorbable sutures at the level of the renal pelvis or crossing vessels. The ureter is spatulated before transection (Fig. 120–26). The most dependent lower pole calyx is amputated with a hot shears. There is a minimal amount of bleeding from the thinned parenchyma of the lower pole system, and the electrocautery of the hot shears easily controls any bleeding. The posterior anastomosis is performed with 5-0 absorbable suture in a running fashion (Fig. 120–27). The ureteral stent is then placed in the same fashion as for a robotic pyeloplasty, as described above. The anterior anastomosis is performed in an interrupted manner, allowing visualization and approximation of the renal collecting system to the ureteral mucosa without placing tension on the renal parenchyma. The anterior sutures are then tied in groups so that the last few suture placements are unobstructed and precise. The stent is removed at 6 weeks after surgery with a retrograde ureteropyelogram to visualize the anastomosis. The authors performed robotic ureterocalicostomy for nine patients with UPJO (mean age 6.5 years). Mean operative time was 168 minutes and mean hospital stay was 21 hours (Casale et al, 2008). There was no evidence of obstruction after operation in any patient.

Key Points: Minimally Invasive Surgery

- Use enough insufflation pressure to afford visualization without compromising venous return and pulmonary performance. Typically, 10 mm Hg is sufficient in children.
- Postoperatively, a child should make steady, consistent progress in the first few hours after surgery and dramatically day by day over the first week. If this sequence does not occur, then one must be wary of a missed injury or incomplete or failed anastomosis.

Megaureter

The decision to repair a megaureter is dependent on the clinical presentation, because megaureters, much like hydronephrotic kidneys, can be detected at the time of prenatal ultrasonography. Experience has shown that many, in fact **the majority of megaureters, can be successfully managed by a nonoperative approach.** Megaureters that have been deemed nonobstructed often will show gradual improvement over time (Keating et al, 1989; Baskin et al, 1994; McLellan et al, 2002). It is helpful to document resolution with periodic ultrasonography. **Megaureters that improve but do not resolve warrant a follow-up ultrasound evaluation around the time of puberty, because the authors have several patients return with worsening but asymptomatic hydroureteronephrosis**

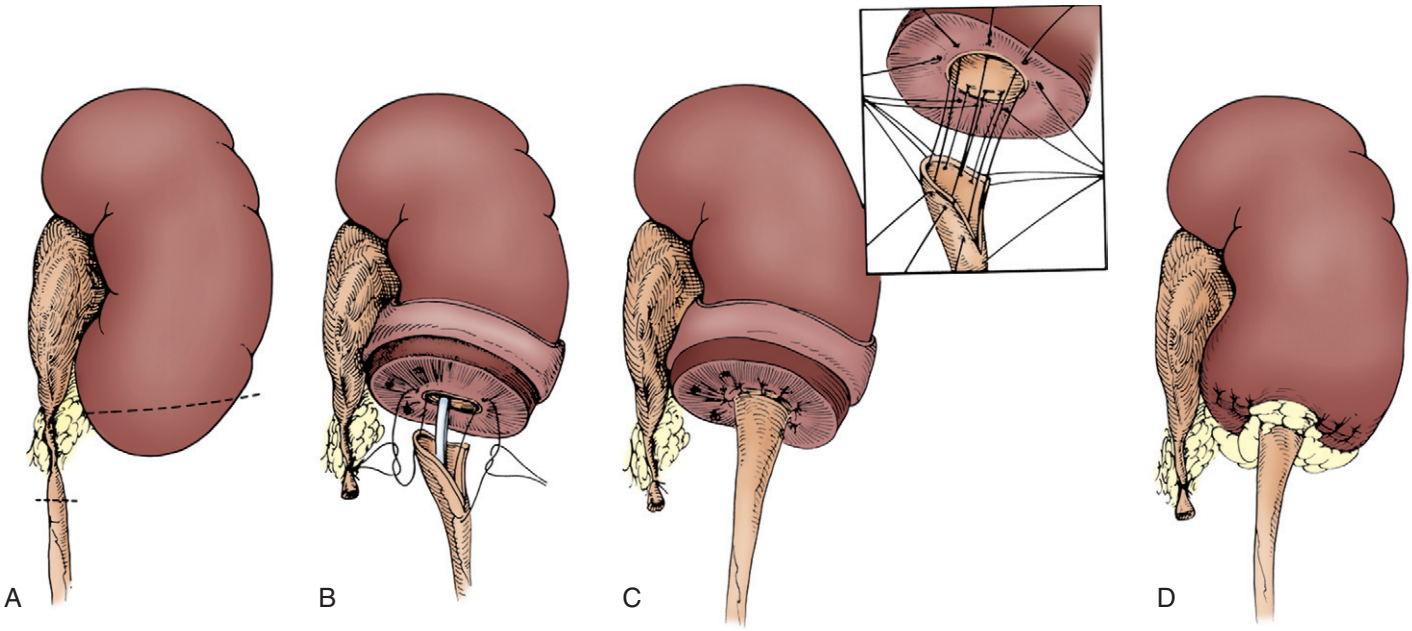

Figure 120–25. **A,** The ureter is identified in the retroperitoneum and dissected proximally as far as possible. The kidney is mobilized as much as necessary to gain access to the lower pole and to subsequently perform the anastomosis without tension. A lower pole nephrectomy is performed, removing as much parenchyma as necessary to widely expose a dilated lower pole calyx. **B,** The proximal ureter is spatulated laterally. The anastomosis should subsequently be performed over an internal stent and consideration given to leaving a nephrostomy tube. The initial suture is placed at the apex of the ureteral spatulation and the lateral wall of the calyx, with another suture placed 180 degrees from that. **C,** The anastomosis is completed in an open fashion, placing each suture circumferentially but not securing them until the anastomosis has been completed. **D,** The renal capsule is closed over the cut surface of the parenchyma whenever possible. However, the capsule should not be closed close to the anastomosis itself because that may compromise the lumen by extrinsic compression. Instead, the anastomosis should be protected with a graft of perinephric fat or with a peritoneal or an omental flap.

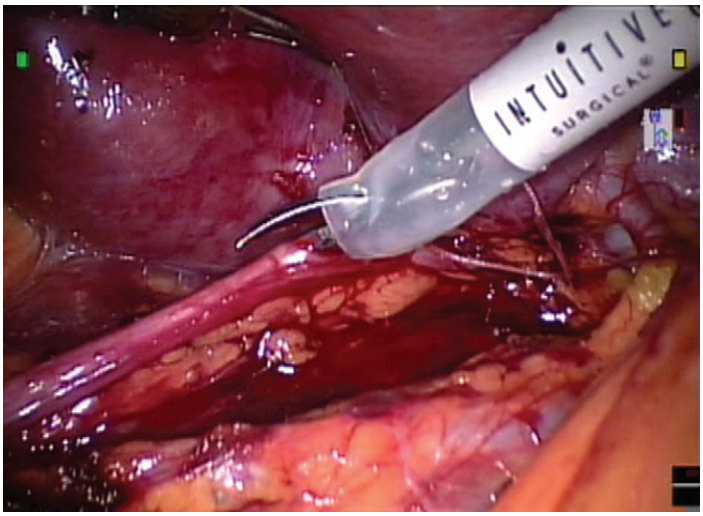

Figure 120–26. Laparoscopic view of ureteral spatulation before transaction of the ureter from the renal pelvis during a robotic ureterocalicostomy for an exaggerated intrarenal pelvis with giant hydronephrosis.

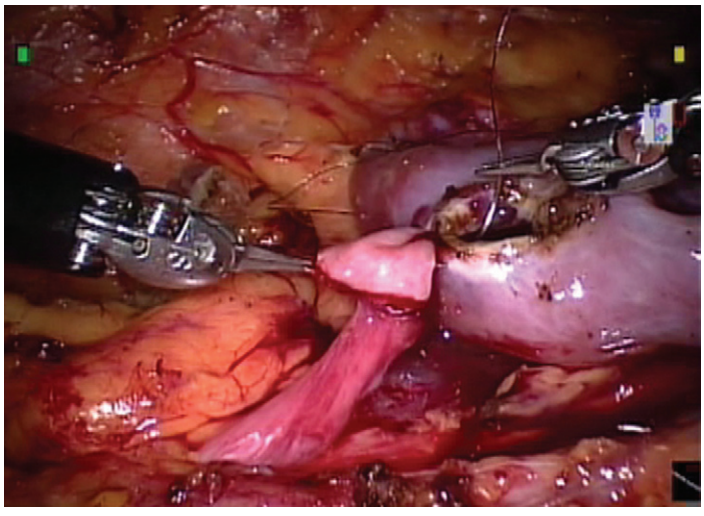

Figure 120–27. Intraoperative laparoscopic view of a robotic ureterocalicostomy. After the most dependent lower pole calix is amputated with a hot shears, the posterior anastomosis is performed with 5-0 absorbable suture in a running fashion.

(Shukla et al, 2005). Dilatation of the urinary tract does not necessarily equate to a physiologically significant obstructive process with renal functional impairment despite the anatomic distortion of the collecting system.

Surgical Management

The repair of a megaureter, whether obstructed, refluxing, refluxing and obstructed, involves a narrowing of the ureteral caliber (tapering or plication) so that an adequate length-to-diameter ratio can be achieved and resection of the obstructive segment. This narrowing allows successful coaptation of the ureteral walls and aids effective peristalsis. Once the obstruction is relieved and distal tortuosity corrected, proximal ureteral dilation improves. Previously, megaureters were approached distally, and then, several months later, proximal narrowing was performed. This was found not to be necessary when the patient demonstrated significant improvement once distal obstruction was relieved (Hendren, 1969).

Two methods can be used to remodel a megaureter. **Plication or infolding** (Kaliciński et al, 1977; Starr, 1979) **is reserved for a moderately dilated ureter.** Ureteral vascularity is preserved, and the repair can be reversed if vascular compromise is suspected (Bakker et al, 1988). **Excisional tapering is reserved for a more severely dilated ureter or a ureter that is markedly thickened, avoiding reimplantation of a bulky ureter** (Hendren, 1969). Plication of ureters greater than 1.75 cm in diameter has been associated with more complications (Parrott et al, 1990). Options for reimplantation included a standard intravesical technique in addition to extravesical repairs (Perovic, 1994, DeFoor et al, 2004). The success with reimplantation of remodeled megaureters, regardless of the technique, is not as high as nondilated ureters; yet, a 90% to 95% success rate may be anticipated (Hendren, 1969; Retik et al, 1978; Parrott et al, 1990). A review of Dr. Hendren's megaureter cases until 1993 demonstrated greater initial success with obstructed (93%) versus refluxing (83%) megaureters and clearly greater success in those patients with normal bladders (91%) versus abnormal bladders (81%, posterior urethral valves, neuropathic, ureteroceles, prune belly syndrome (Hendren, personal communication).

Another approach to an infant with a markedly dilated megaureter is early diversion by an end-cutaneous ureterostomy as a temporizing measure, with subsequent ureteral reimplantation. Successful decompression of significant hydroureteronephrosis, in addition to bladder growth, can allow for a straightforward reimplantation at 15 to 18 months of age, often avoiding additional ureteral plication (Kitchens et al, 2007). Alternatively, a primary obstructive megaureter can be converted to a temporary refluxing system by anastomosing the ureter proximal to the obstruction to the dome of the bladder (Lee et al, 2005). Reimplantation is performed 12 to 15 months later following successful improvement in ureteral size, again obviating the need for ureteral plication prior to reimplantation.

Just as laparoscopic pyeloplasties and robotic-assisted pyeloplasties have become surgical options in the management of UPJ obstruction, ureteral reimplantations are increasingly being performed in a minimally invasive fashion. Robotic-assisted plication of ureters can be accomplished by an extravesical approach, and even formal excisional tapering of the ureter can be done as well. To date, just a handful of institutions are performing such surgery.

Description of the Surgical Technique

After making a Pfannenstiel incision, the bladder is opened in the midline and the ureter is dissected from its intravesical and extravesical attachments (Fig. 120–28). In some instances, the ureter can be adequately mobilized by staying within the bladder. In such cases, the approach for a reimplantation by either the Cohen or the Politano-Leadbetter method is repeated after ureteral tailoring. However, when very large ureters are being tapered, it is advisable to work outside the bladder, as well in order to better define and preserve the blood supply.

If a method of reimplantation similar to the Politano-Leadbetter technique is chosen, a new hiatus should be created prior to moving extravesically. The hiatus is widened with a right angle clamp, and the peritoneum is swept from the base of the bladder using either a lighted suction tip or Senn retractors or a right angle clamp. The clamp is incised upon and spread at an appropriate superior-medial location for the new hiatus. A red rubber catheter or vessel loop, which helps guide the ureter through its new hiatus, is engaged and carried extravesically and then back into the bladder, where it is snapped.

Dissection outside the bladder is begun by sweeping the lateral peritoneal attachments superiorly with a Kittner dissector. A right angle clamp is used to pass the ureteral cuff stitch through the old hiatus to the perivesical space, and the ureter is brought extravesically.

The adventitia and blood supply to the lower ureter, which usually emanate medially, are carefully preserved. When working outside the bladder, it is helpful to divide the obliterated hypogastric (umbilical artery) to aid in the dissection and to eliminate it as a possible source of obstruction. Excessive mobilization plus removal of proximal kinks is unnecessary.

After excision of any obstructive distal ureter or excessive length, ureteral tailoring is done over a 10-Fr red rubber catheter (8 Fr in an infant) unless the ureter is already snug over the catheter, in which case revision is unnecessary. Tailoring is achieved by one of the following methods: In the tapering method (Fig. 120–29), the technique used is similar to that originally described by Hendren (1969). Baby Allis clamps are placed laterally to define redundant ureter while preserving the medial vascular supply. Atraumatic clamps are applied around the catheter and excess ureter is excised. Excessive narrowing of the lumen should be avoided, and the more proximal ureter should be left slightly wider to create a funneled configuration. A running, locking 6-0 polydioxanone suture is used to reapproximate the proximal two thirds of the tapered ureter. Interrupted sutures complete the repair and allow for any shortening that may be necessary. The proximal portion of the tailored ureter must remain outside the bladder after completion of the reimplantation with either tapering or plication. Secondary obstruction is likely if the entire tailored segment is located within the intravesical tunnel.

Starr Plication. Ureteral redundancy is again defined by briefly applying atraumatic clamps to mark the extent of plication and preserve the best-vascularized portion of the ureter. Starting proximally, the ureter is plicated with interrupted 5-0 polydioxanone sutures placed in Lembert fashion along the clamp impressions (Fig. 120–30) (Starr, 1979).

Kaliciński Plication. Two 6-0 polydioxanone sutures are placed along the clamp impressions, one at the proximal extent of the proposed revision and the other at the new meatus. The ureter is divided longitudinally by weaving one suture through the ureter in running fashion along the clamp impression, thus creating two lumens. The ureter is then reduced by folding its nonfunctional portion over the catheterized lumen (Fig. 120–31) (Kaliciński, 1977).

The reimplantation is completed with either the cross trigonal, Politano-Leadbetter, or extravesical technique. It is often helpful to secure the repair with a psoas hitch, especially in smaller children, patients who require a long submucosal tunnel, and cases in which the surgeon is particularly concerned about angulation of the tailored ureter as it enters the bladder. Tapered ureters are stented for 5 to 7 days. A feeding tube can simply be left in place and is brought out through the anterior abdominal wall or, alternatively, a double-J stent can be placed, which requires removal in 4 weeks. Stentograms are not necessary to look for leaks but can confirm that drainage will occur once the stent is removed.

Results and Complications

Reimplantations of megaureters is associated with the same complications (i.e., persistent reflux and obstruction) as reimplantation of nondilated ureters but at increased rates. Complications can occur regardless of whether excisional tapering or a folding technique is used (Ehrlich, 1985; Daher et al, 1999; Fretz et al,

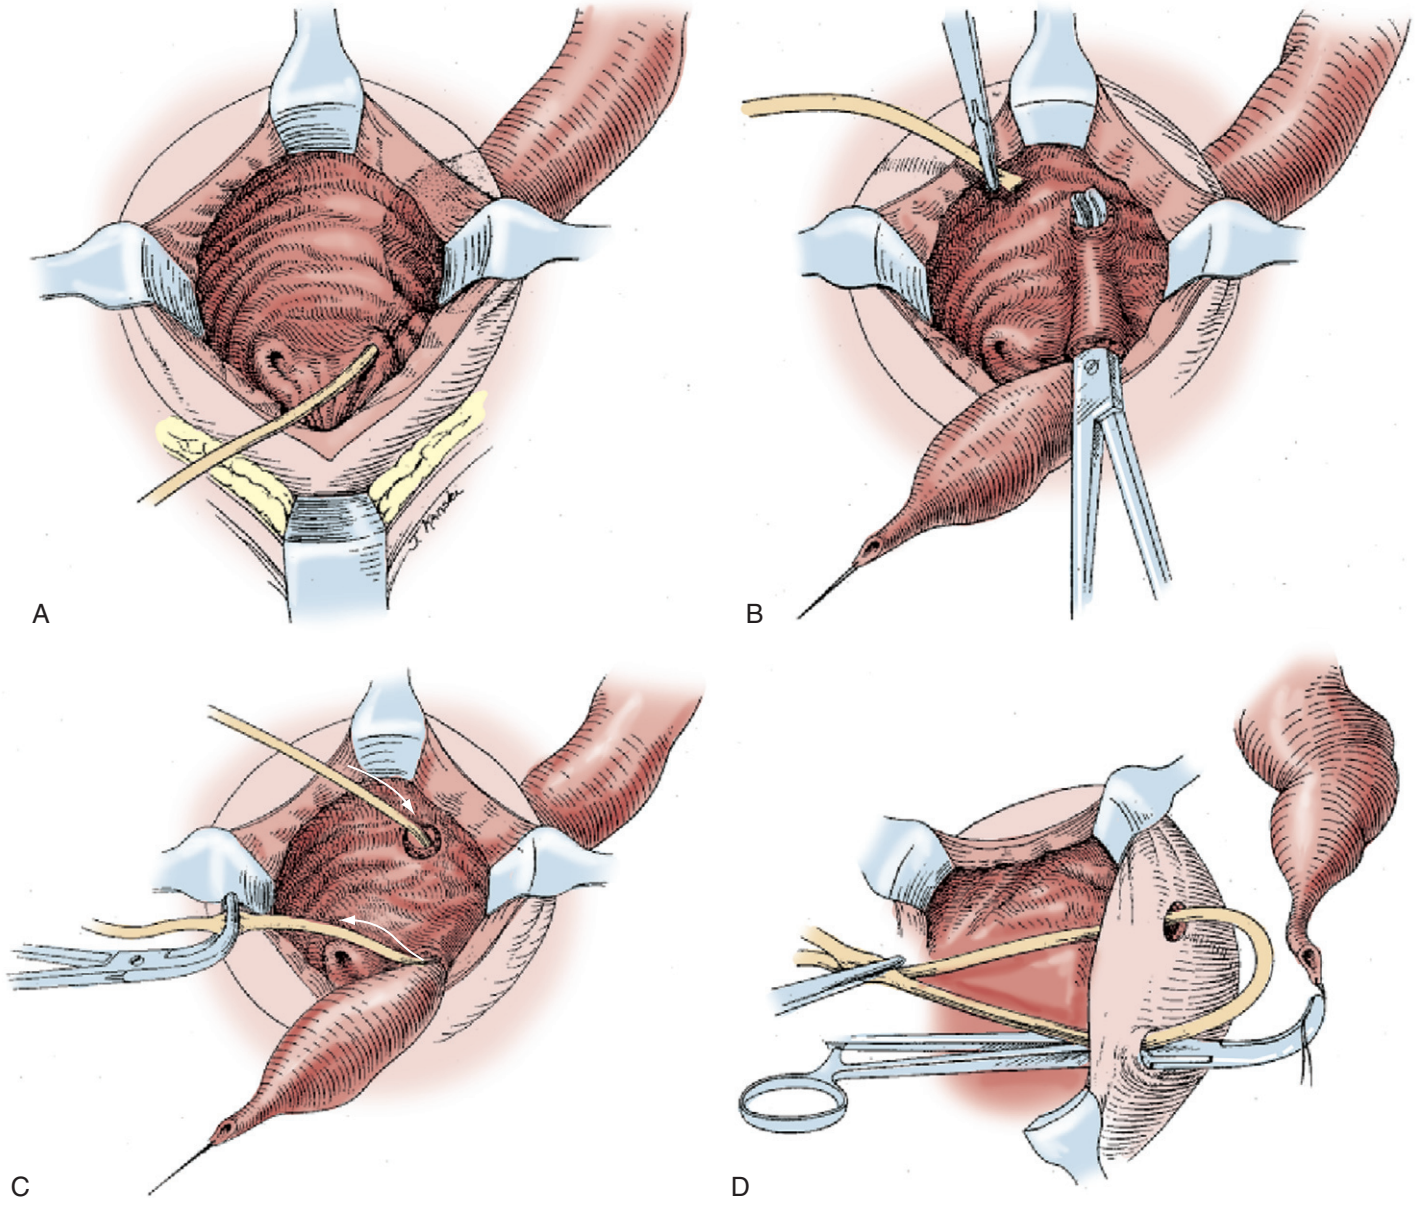

Figure 120–28. Technique for repair of megaureter. **A,** A 5-Fr feeding tube typically passes up a normal-caliber intravesical segment of primary obstructive megaureter. **B,** After the megaureter is freed from its intravesical and extravesical attachments, a blunt right angle clamp is used to clear the peritoneum from the posterior and base of the bladder. If extravesical dissection is necessary, it is advisable to make the new hiatus before moving outside the bladder. A right-angle clamp is incised upon and spread. **C,** A fine red rubber catheter marks the new hiatus by being pulled from within the bladder to the outside and then through the old hiatus. **D,** A right angle clamp is guided from within the bladder to the perivesical space, where it is identified and incised upon. The ureter is brought extravesically by grasping the traction suture in the ureter.

2004). Perdzyński and Kaliciński (1996) cited good results in 52 (93%) of 56 megaureters. Two cases of stenosis and two cases of reflux occurred in failures. Some authors have noted better results with obstructive megaureters and higher rates of unresolved reflux after tailoring of refluxing variants (Johnston and Farkas, 1975; DeFoor et al, 2004), a finding that could be explained by the previously mentioned studies of Lee and colleagues (1998, 2005) in which **abnormal collagen deposition in the refluxing variants could cause an intrinsically stiffer ureter and lessen surgical success.** This has been attributed to a higher incidence of bladder dysfunction associated with the latter and to more significant abnormalities in their musculature. It has been suggested that extravesical reimplantation and excisional tapering can be performed with a high success rate in patients with primary obstructive megaureters and that intravesical reimplantation can be reserved as a better option for children with voiding dysfunction or associated vesicoureteral reflux (DeFoor, 2004). Postoperative success is often documented with the use of follow-up voiding cystourethrogram (VCUG) studies in refluxing megaureters and nuclear renal scans in addition to renal ultrasonography. Improvement or resolution of hydroureteronephrosis is not always the case. **Male patients, those operated on at a younger age, and those with a lower preoperative grade of hydronephrosis are more likely to demonstrate improvement or**

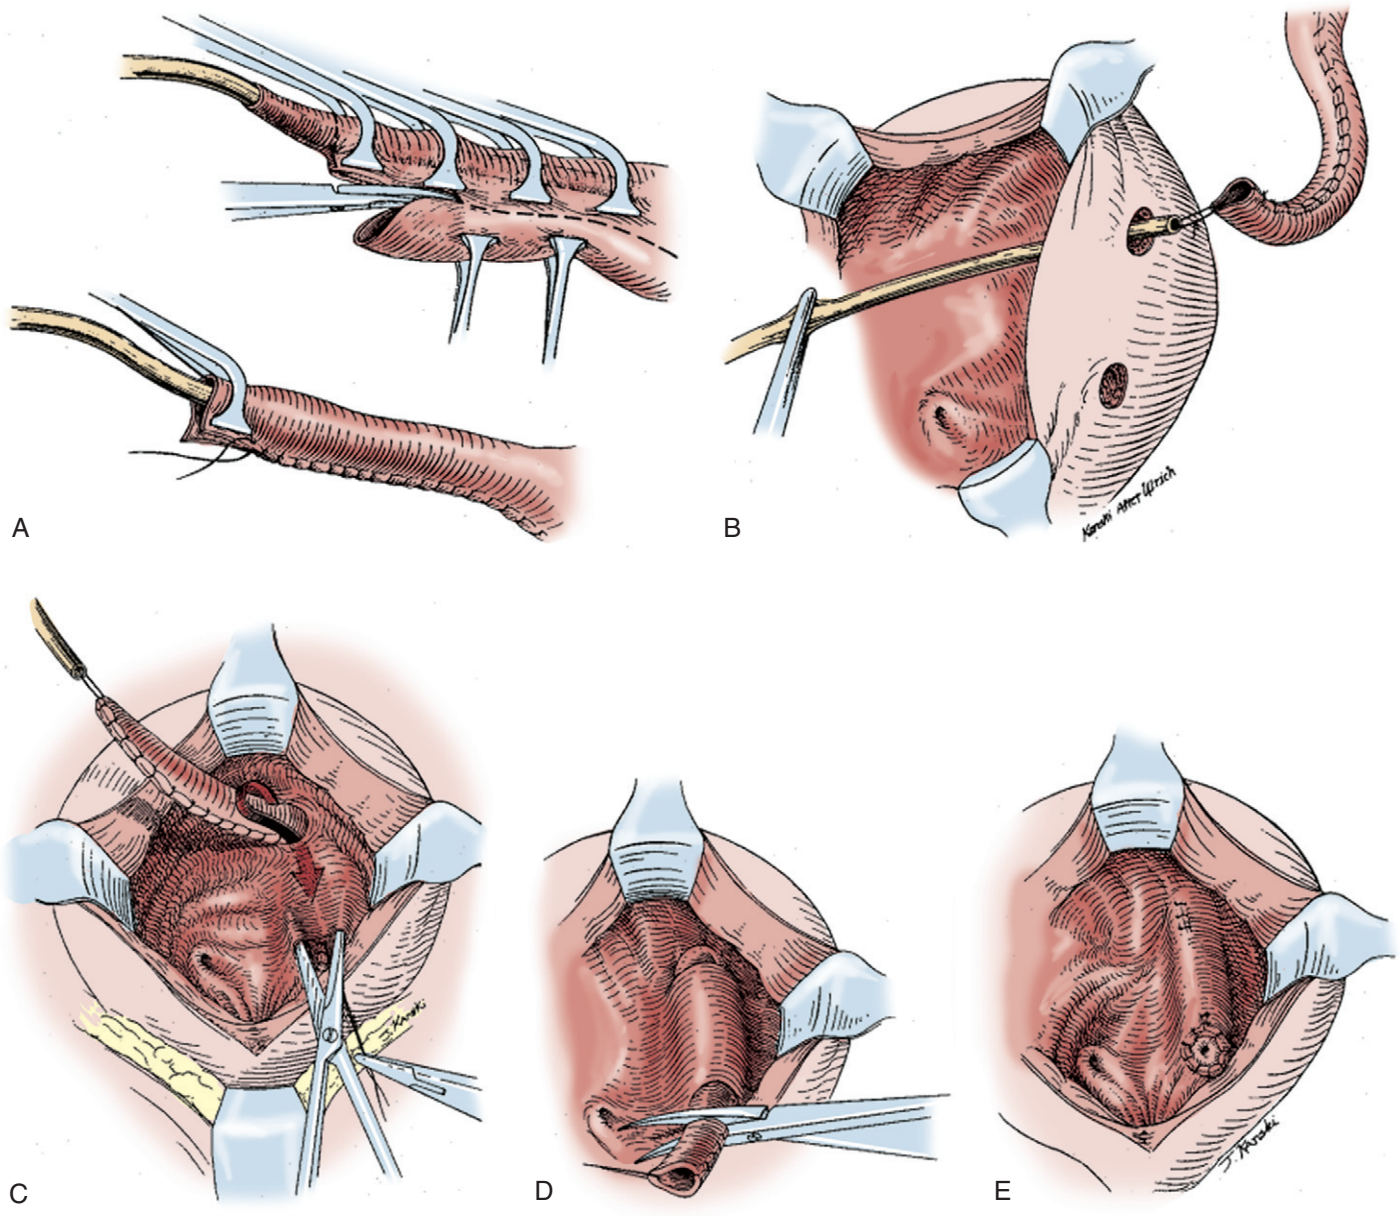

Figure 120–29. **A,** Ureteral tailoring is completed. Tapering is done over an 8-Fr red rubber catheter in infants or a 10-Fr catheter in older children and adults. After vascularity is defined, special atraumatic clamps are placed over the catheter. Baby Allis clamps help retract the portion of ureter to be resected, which is usually lateral. It is important to not resect too much ureter. Running 5-0 polydioxanone or chromic suture is used to reapproximate the proximal two thirds of the ureter. Its distal third is closed with interrupted sutures to allow for shortening. **B,** The tailored ureter is brought back into the bladder through the new hiatus. **C,** After closing the original hiatus, a new submucosal tunnel is made to the new hiatus. **D,** The distal portion of ureter is resected to match the length of the tunnel. **E,** The revised ureter is anastomosed to the bladder with fine interrupted sutures.

resolution of hydronephrosis. Thus it is not uncommon to see persistent hydroureteronephrosis following excisional tapering and reimplantation of megaureters in children (Link et al, 2007).

On rare occasions, reflux persists despite ureteral tunnels deemed adequate intraoperatively by both tapered and normal-sized ureters. Postoperative vesicoureteral reflux can occur in a higher percentage of patients than with normal-caliber ureters (Hendren, 1969; Peters et al, 1989; Fretz et al, 2004). The possibility of dysfunctional voiding patterns should be considered. Mild cases may improve with time. When associated with complications (e.g., recurrent episodes of pyelonephritis), surgical correction is indicated. Even though the experience is limited, subureteric injection therapy may be considered initially. Selected cases may proceed to open surgery, with the difficulties imposed by scarring and a potentially limited blood supply. If severe, the rigid distal ureter is incapable of normal peristalsis or appropriate coaptation during bladder contractions, because of the intrinsic ureteral dysfunction caused by transmural scarring. Transuretero-ureterostomy is ideal for unilateral disease (Mure et al, 2000). Bilateral cases can be approached by excising the scarred distal ureter and creating an exaggerated ureteral tunnel length whose diameter-to-length ratio may exceed 10:1. In-situ tailoring is

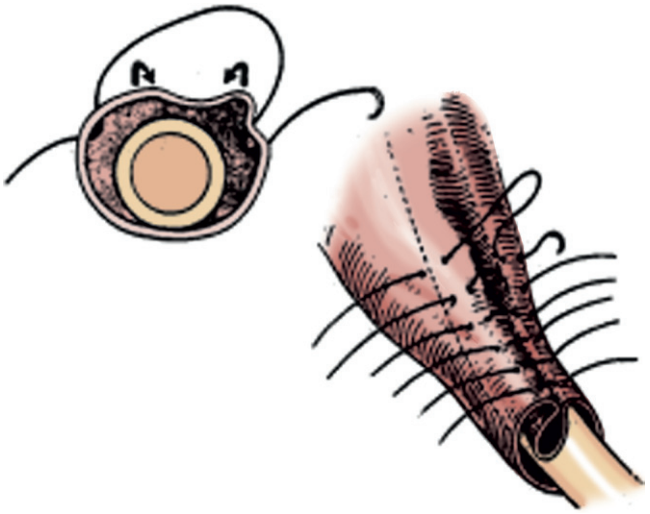

Figure 120–30. Ureteral plication is performed over the appropriate catheter, with interrupted 5-0 polyglycolic sutures placed in Lembert fashion (after Starr). (From Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, editor. Difficult problems in urologic surgery. Chicago: Year Book Medical; 1989. p. 131.)

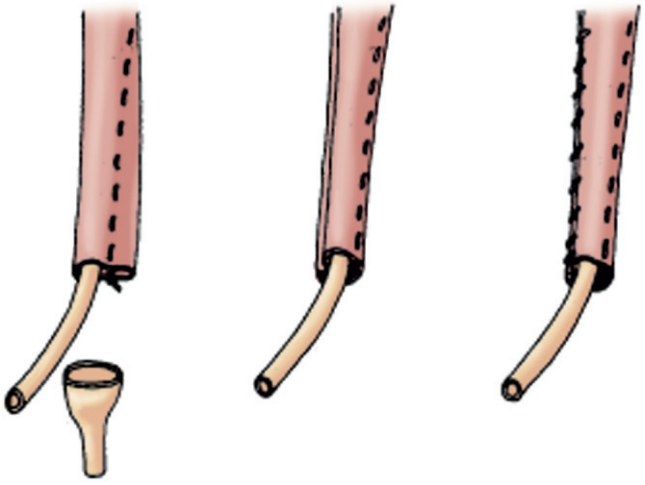

Figure 120–31. Ureteral folding technique. A running suture is longitudinally woven through the megaureter to create two lumens. This isolates the best-vascularized portion as a functional ureter (catheter within) and excludes redundancy. The redundant portion is then folded, and the two are tacked together with interrupted sutures. (From Kalicinski ZH, Kansy J, Kotarbinska B, et al. Surgery of megaureters: modification of Hendren's operation. J Pediatr Surg 1977;12:183.)

another option for dilated ureters that continue to reflux after initial reimplantation. Vascularity is preserved and injury to the contralateral ureter avoided in unilateral cases (Diamond and Parulkar, 1998).

Ureteral obstruction is related to postoperative edema in many cases, and the edema generally resolves with time (up to 8 weeks) and requires temporary diversion most commonly with a percutaneous nephrostomy tube or antegrade double-J stenting. If persistent, the usual cause is ureteral ischemia, which requires revision and excision of the ischemic segment followed by reimplantation. Given our changing notions with vesicoureteral reflux, it is certainly better to have a child with low-grade reflux than one who has an obstructed ureter.

Special Situations

Midureteral Stricture

Rare situations exist in which proximal ureteral dilation is present due to a midureteral stricture. In a series of seven patients who were found to have midureteral strictures, five of seven patients had prenatal hydronephrosis. Retrograde pyelography in all seven patients led to an accurate diagnosis of midureteral narrowing. Six patients were managed with excision of the narrowed area, along with primary ureteroureterostomy of the dilated proximal ureter to the normal caliber distal ureter. The excised segments were funnel-shaped, leading to a stenotic zone that was generally less than 0.1 cm in internal diameter. Significant acute or chronic inflammation, fibrosis, hemosiderin, and vasculopathy were not identified at the sites of ureteral stenosis. Ureteral valves or folds were not identified either grossly or microscopically in any of the patients who underwent surgical repair (Hwang et al, 2005).

Ureteral Polyps

Ureteral polyps are an unusual cause of obstruction, both at the ureteral pelvic junction and within the ureter. A strong index of suspicion is necessary to make this diagnosis, along with exquisite imaging to detect a polyp(s). The use of intravenous urography, ultrasonography, and enhanced CT imaging may allow a preoperative diagnosis. Children often present with hematuria and/or flank pain. Polyps tend to be one of two types: filiform, which are multiple or single, or bilobed and of varying sizes (Niu et al, 2007). Occasionally, the polyps are discovered at the time of ureteroscopy for ureteral stones. Ureteroscopy and laser ablation or urethroscopic snaring of the polyps has been an effective treatment. Recently, the authors have had several patients with multiple ureteral polyps who were discovered at the time of laparoscopic pyeloplasties. Subsequent ureteroscopy was used to remove the residual polyps at the time that the double-J stents were removed.

Ureteral Stricture

Finally, there is the rare occurrence of ureteral damage that obviates the use of the ureter. In such a situation, ureteral replacement has been accomplished with the use of ileum. Ileoneoureters can bypass the abnormal ureter but tend to be rather redundant. The Yang-Monti principle for creation of a catheterizable channel of narrow caliber is ideally suited for ureter replacement therapy (Kamat and Khandelwal, 2007). Two segments can be anastomosed if a long ureteral substitution is needed. Stenting of the ileoneoureter is needed for several weeks. This technique has been used in isolated cases, but long-term follow-up is needed to ensure durability.

CONCLUSIONS

Future progress will be made in understanding the underlying factors that contribute to the formation of UPJ and UVJ obstruction, along with continuing improvements in successful surgical approaches. There will continue to be debate as to what constitutes surgical obstruction. The tools that are used to define and measure the problem are imprecise. Newer modalities, such as magnetic resonance urography, may shed light on the problem and help surgeons in their decision-making process. In the end,

however, it is an assimilation of radiographic studies, the patient's history, and the surgeon's experience that collectively guide the therapy.

Minimally invasive surgery is revolutionizing reconstructive renal and ureteral surgery in children. The advent of robotic surgery enables further advancement for pediatric urologic surgery with enhanced visualization and dexterity. MIS pyeloplasty for adults has been established as one of the most suitable urologic operations. Although further outcome studies and prospective randomized comparison studies with open surgery are needed, conventional pediatric laparoscopic and robotic pyeloplasty and ureteral reconstruction should become an established alternative in the near future.

CLASSIFICATION AND ANATOMIC DESCRIPTION

General Patterns

Abnormalities of ureteral development including ectopic ureters and ureteroceles represent a large component of clinical urology and continue to challenge clinical management, despite their wide recognition and well-defined surgical strategies. The wide spectrum of involvement and the variable patterns of presentation underlie the clinical challenge and require a thorough understanding of both normal and abnormal embryology of the lower urinary tract. This chapter presents the embryology, clinical manifestations, pathology, evaluation, and management strategies for ectopic ureters and ureteroceles, as well as other less common ureteral anomalies of formation. Obstructive ureteral pathologies including ureteropelvic junction (UPJ) obstruction and ureterovesical junction obstruction are reviewed in Chapter 120.

Although ectopic ureter and ureterocele are typically presented as distinct entities, they apparently share many common features and may well have the same underlying developmental mechanisms with slight variations that induce the obvious differences in their appearances. In many ways, they may be approached in a similar manner, with slight variation in management due to their particular differences. It is also apparent that clinical cases may represent manifestations that lie between the two entities, suggesting a continuum of embryologic maldevelopment.

Ectopic Ureter

By definition, an ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder (Glassberg et al, 1984). **In a duplex system this is inevitably the upper pole ureter, presumably due to its budding from the mesonephric duct later than the lower pole ureteral bud.** If it is simply near the bladder neck, it is not technically ectopic, which requires entry at the level of the bladder neck or distal. **In females the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus, and even rectum** (Weight et al, 2006). It may be associated with a cyst of Gartner duct, the remnant of the wolffian duct from which the ureter buds, and may include cystic dilation of the duct. The duct typically runs parallel to the vagina (the müllerian structure) and with rupture of the cystic ductal structure, communication with the vagina is established (Weiss et al, 1984; Rosenfeld and Lis, 1993). This is the basis for incontinence, the frequent presentation of an ectopic ureter in females. **In males the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor and usually into the wolffian structures including vas deferens, seminal vesicles, or ejaculatory duct.** These may be associated with cystic dilation, presumably due to continued urine production. Males do not present with incontinence but with infection and pain of the affected organs (testicles and epididymis).

Single-system ectopic ureters may present in a similar fashion but may also be associated with an apparently absent kidney. This usually reflects an inability to identify the kidney on typical imaging and has led to the use of computed tomography (CT) imaging with contrast to detect small poorly functioning renal units associated with an ectopic ureter (Borer et al, 1998). Either single or duplex systems with an ectopic ureter may present with severe hydronephrosis reflecting distal obstruction. This may have impaired normal renal development to the point that the affected segment is nonfunctional, which needs to be clinically assessed.

A rare entity of bilateral single-system ectopic ureters occurs and may be associated with a hypoplastic bladder and bilateral renal abnormalities, typically dysplasia (Noseworthy and Persky, 1982; Johnin et al, 2007). Some of these children may be considered to have bladder agenesis due to the absence of a recognizable bladder structure, presumably due to the absence of bladder filling and emptying in utero (Weight et al, 2006).

Ureterocele

Ureteroceles may be seen to represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra. Studies in mouse

Key Points: Ectopic Ureter

- An ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder.
- In a duplex system the ectopic ureter is inevitably the upper pole ureter due to its budding from the mesonephric duct later (more cephalad) than the lower pole ureteral bud.
- In females the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus, and even rectum. One of the classic symptoms is continuous wetting.
- In males the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor, and usually into the wolffian structures including vas deferens, seminal vesicles, or ejaculatory duct.

models suggest that ureteroceles may reflect defective ureteral maturation, the process by which the developing ureteric bud detaches from the mesonephric duct and moves to the bladder (see later) (Mendelsohn, 2009). As with the ectopic ureter, ureteroceles may be associated with a single or duplex system and in duplex systems they are associated with the upper pole. Ureteroceles can extend into the urethra but do not form entirely within the urethra, nor do they attach to the wolffian ductal structures.

Several classification systems exist for ureteroceles, but the most useful one for clinical practice separates intravesical from extravesical ureteroceles. The intravesical ureterocele is entirely within the bladder and above the bladder neck. This would include a "simple" ureterocele that may be seen in the adult with minimal dilation and mild to no upper tract dilatation. This term, however, should be discouraged and the term *single intravesical ureterocele* used instead (Glassberg et al, 1984). An ectopic ureterocele includes those "in which some portion of the ureterocele is situated permanently at the bladder neck or urethra" (Glassberg et al, 1984). The orifice may be in the bladder, at the bladder neck, or in the urethra. This should be distinguished from an intravesical ureterocele that prolapses into the urethra with voiding.

Further descriptive subdivision of ureterocele types has been published, particularly by Stephens (Stephens, 1971; Stephens et al, 1996). These include cecoureterocele, stenotic, sphincteric, sphincteric-stenotic, blind, and nonobstructed ureteroceles (Figs. 121–1 and 121–2). **From a clinical perspective, the most important subgroup to recognize is the cecoureteroceles. In these cases the orifice of the affected ureter is within the bladder, but the cavity of the ureterocele extends beyond the bladder neck into the urethra.** These may not be readily identified preoperatively (Smith and Parrott, 1994) and their complexity may create surgical challenges, particularly with endoscopic incision (see later).

An unusual but diagnostically challenging ureterocele variant is the so-called "nonobstructive" ureterocele with duplication (Bauer and Retik, 1978) or "ureterocele disproportion" (Share and Lebowitz, 1989). These are associated with a duplex kidney, but the affected upper pole is nondilated and typically dysplastic to such a degree that it is not readily detected on most imaging and the affected ureter is not dilated beyond the bladder. A typical-appearing ureterocele is seen in the bladder, but the ipsilateral kidney appears normal.

There is some association of ureterocele type with outcomes of various therapeutic measures, but these have not proven to be as predictable as initially reported. Churchill and colleagues (1992) proposed a classification system on the basis of the impact of the ureterocele on the upper urinary tract including all renal units. This functional system separates those in which the upper pole only is in jeopardy, from those in which an entire ipsilateral kidney is threatened, to those in which the contralateral system is also at risk due to reflux or bladder outlet obstruction. The latter group comprised 26% of the reported cases.

Embryology and Etiology

The specific mechanisms responsible for ectopic ureters and ureteroceles remain undefined, but our emerging understanding of normal and abnormal ureterotrigonal development, along with new investigational tools, are likely to provide valuable insights (Mendelsohn, 2009). Although these molecular mechanisms will be of scientific importance, they will also permit potential separation between variants of these conditions that are likely to have therapeutic relevance, as well as perhaps ultimately permitting

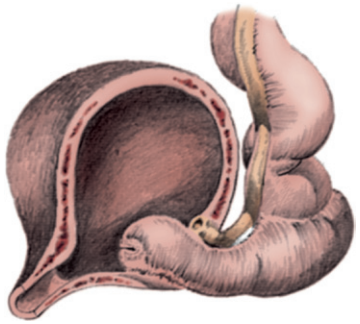

Figure 121–1. The orifice of a stenotic ectopic ureterocele may be located at the tip or at the superior or inferior surface of the ureterocele.

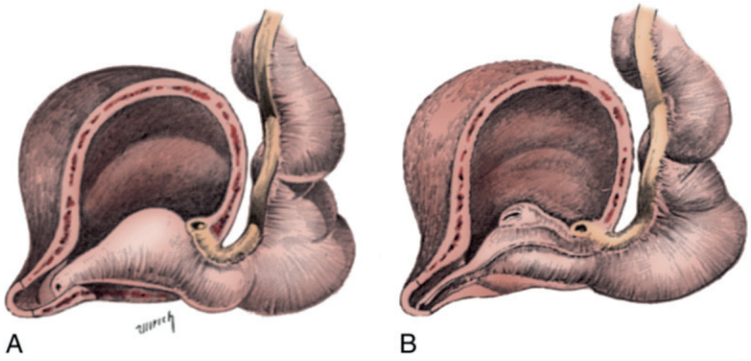

Figure 121–2. **A,** Sphincterostenotic ectopic ureterocele. **B,** Cecoureterocele lumen extends distal to the orifice as a long tongue beneath the ureteral submucosa. The orifice communicates with the lumen of the bladder and is large and incompetent.

Key Points: Ureterocele

- Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra.
- Several classification systems exist for ureteroceles, but the most useful one for clinical practice separates intravesical from extravesical ureteroceles.
- The most important subgroup to recognize is the cecoureterocele.
- In a cecoureterocele the orifice of the affected ureter is within the bladder, but the cavity of the ureterocele extends beyond the bladder neck into the urethra.

early detection (i.e., in utero) and intervention. The latter is a distant but not implausible horizon. At present experts remain uncertain as to fundamental mechanisms and yet need to know which ureteroceles and ectopic ureters may be associated with bladder neck and trigonal maldevelopment sufficient to cause incontinence. These children will require more aggressive therapy to achieve continence. Early identification may permit earlier and more effective surgical therapies.

Clinical Relevance

Understanding the potential relationships of the abnormal ureter associated with ectopia or a ureterocele, which is based on aberrations in normal development of the wolffian and müllerian ducts, ureteral bud, urogenital sinus (UGS), and bladder, can facilitate clinical interpretation of these conditions. Knowledge of the sites of ectopic insertion may be useful in planning imaging and in surgical correction. Recognition of the possible effects of abnormal ureteral development on bladder and urethral development is essential in determining reconstructive strategies, and an awareness of the possible coexistence of ureteral and müllerian abnormalities is important.

Ureteral-Trigonal-Renal Development

The pathogenesis of ureteral ectopia with or without a ureterocele rests in ureterotrigonal and renal development. This involves the common nephric duct (CND), ureteral budding, ureterometanephric interactions, and bladder and trigone development. Ectopic ureters can arise due to abnormal timing or location of the primary ureteral budding from the mesonephric ducts, or abnormalities at the stage of ureter. That temporospatial location will determine both the character of the ureter incorporated into the emerging bladder, as well as the development of the trigone and kidney. **Ureter maturation occurs after the ureteric bud sprouts from the mesonephric duct when the posterior nephric duct segment (the common nephric duct, CND) expands and is absorbed into the bladder where the CND undergoes apoptosis. At this point, ureteral cells merge with bladder epithelia and undergo a second wave of apoptosis, generating a new ureteral orifice, which is now in the bladder neck. Growth and expansion of the bladder moves the ureteral orifice, which is now inserted in the bladder epithelium, farther away from the mesonephric duct to the final position.** Of course, these elements can all be affected with both ureteral ectopia and ureterocele.

Classical understanding of uretero-trigonal development has indicated that the trigone originates from the mesodermal CND, as does the ureter, and is distinct from the endodermal origin of the bladder. According to this model, the CND expands, moving the ureter away from the mesonephric duct, and is incorporated into the primitive bladder, repositioning the ureter orifice at the bladder neck (Wesson, 1920; Tanagho and Pugh, 1963; Woodburne, 1965). Normal regulation of ureter remodeling permits fusion of the ureter and the UGS, as well as separation of the ureter and the wolffian duct (Mendelsohn, 2009; Tanaka et al, 2010).

However, the observation that the CND degenerates during ureter maturation suggests that it may not give rise to the trigone as previously thought (Batourina et al, 2002, 2005; Viana et al, 2007; Chi et al, 2009; Mendelsohn, 2009; Uetani et al, 2009; Tanaka et al, 2010). Consistent with this, **lineage studies and tissue recombination studies in mice suggest that the trigone is formed by bladder mesoderm/muscle and muscle surrounding the intravesical ureter. One possibility is that intersection between ureteral fibers and bladder muscle give the trigonal region its distinct morphology.**

A revised model of ureteral bud–trigonal maturation based on these studies requires coordinate expansion and subsequent apoptosis of the CND between the developing ureter and wolffian duct. Expansion of the CND permits correct alignment of the ureter with the UGS and may be seen to determine the position of the attachment of the ureter to the bladder and trigone. In contrast to the classic model, however, in which the CND forms the trigone, the revised model includes regression of the CND in the normal animal through apoptosis (Batourina et al, 2002, 2005; Viana et al, 2007; Chi et al, 2009) (Fig. 121–3).

The revised model of ureteral maturation provides possible mechanisms for ureteral ectopia and ureterocele formation. Abnormal apoptosis may maintain the connection between the ureter and the wolffian duct and prevent incorporation of the ureter and the UGS. This defect would produce a ureter attached to the wolffian remnants in girls (Gartner duct) or to the vas deferens or ejaculatory system in boys. Abnormal timing of ureteral budding may be one cause of this dysregulated apoptosis and would explain the occurrence of these defects with duplicated systems, particularly the upper pole (later budding) ureter. A lesser defect, either by timing or completeness of the defect, might explain the ectopic ureter to the urethra distal to the bladder neck in girls. Specific defects in the signaling molecules, as seen in knockout mouse models, may produce isolated defects, but by disruption of the normal sequence both temporally and spatially, could produce a range of downstream abnormalities. Similar phenotypes may be caused by multiple mechanisms, with more subtle variation among individuals. This may explain some of the variation seen in both ectopic ureters and ureteroceles.

The expansion of the CND that permits normal alignment of the developing ureter appears to be in response to contact with the UGS (Batourina et al, 2005) and must be coordinated with later apoptosis of the CND, as well as being regulated by local factors and CND cellular responsivity. Impaired expansion may produce ectopia due to delayed or limited movement of the ureter relative to the UGS, whereas unregulated expansion may prevent normal communication of the ureter with the UGS and perhaps

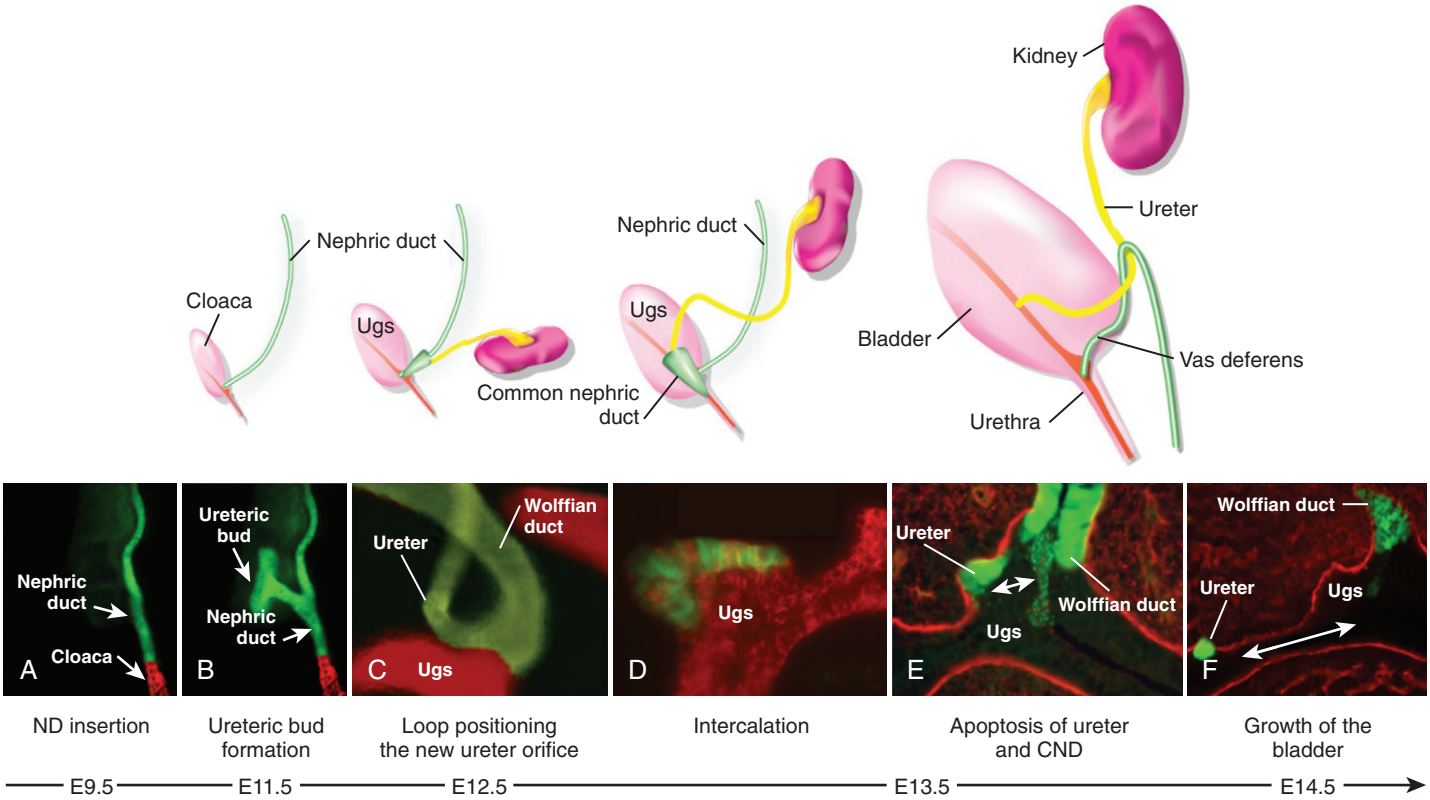

Figure 121–3. *Top:* schematic showing a revised model of ureter maturation. *Bottom:* images of Hoxb7-Gfp expressing embryos showing different stages of urinary tract morphogenesis. In the lower urinary tract, the Hoxb7-Gfp transgene is localized in the ureter, mesonephric (wolffian) duct, and common nephric duct (CND) (Srinivas et al, 1999). **A,** Whole mount urogenital tract from an E9 Hoxb7-Gfp embryo counterstained with E-cadherin to reveal the mesonephric duct *(green)* inserting into the primitive bladder *(red)*. **B,** A whole mount urogenital tract from an E11 Hoxb7-Gfp embryo counterstained with E-cadherin *(red)*. The CND lies below the primary ureteric bud branch, which at this stage has invaded the kidney blastema (not visible). **C,** Whole mount urogenital tract from an E12 Hoxb7-Gfp embryo *(green)* stained with cytokeratin *(red)*. Apoptosis of the CND has brought the caudal-most ureter into close contact with the bladder, where it aligns, setting the position of the future ureteral orifice. **D,** A vibratome section from an E13 Hoxb7-Gfp urogenital tract stained with E-cadherin *(red)*. Cells from the most distal ureter epithelium have now merged with the bladder epithelium, where they will undergo apoptosis, creating a new ureteral bud connection. **E,** A whole mount urogenital tract from an E13.5 Hoxb7-Gfp embryo stained with Laminin to reveal the basement membrane of the bladder epithelium *(red)*. The ureter orifice is now inserted in the epithelium and is separated from the mesonephric duct by a short distance. **F,** Expansion and elongation of the bladder has moved the ureter orifice farther away from the mesonephric (wolffian) duct. Ugs, urogenital sinus.

be the initiation of terminal ureteral expansion as seen in ureteroceles. Tanagho (1976) postulated that ureteroceles resulted from the distal ureter being inappropriately exposed to the factors inducing expansion of the UGS and bladder. Nearly all growth during development is the result of balanced stimulatory and inhibitory factors, regulated by temporal and spatial gradients, proximity, and cofactors that are, in turn, regulated by similar mechanisms. Altered timing and coregulation of these systems are likely the basis of altered development.

The classic explanation of ureterocele formation is that of Chwalle (1927), postulating that distal ureteral expansion is produced by failure of rupture of a distal membrane at the ureteral orifice (Chwalle membrane). Obstruction is unlikely to be a major and certainly not the only factor producing ureteral dilation, as seen with ureteroceles. Ureteroceles with large orifices and no apparent obstruction are well recognized clinically. Ectopic ureters with insertion into the bladder neck are dilated but do not have the disproportionate distal dilation characteristic of the ureterocele. Obstruction plays some role in ureterocele pathophysiology, however, as is evident in the frequent occurrence of decompression with ureterocele puncture. Whether this is determined by the degree of muscularization of the ureterocele is undefined. Recent studies support the idea that degeneration of Chwalle membrane is important for generating a patent connection between the ureter orifice and the bladder. These studies suggest that Chwalle membrane, which has been thought to form from the UGS, may in fact be derived from luminal cells in the ureter that undergo apoptosis at a relatively late stage, before the onset of renal function, which may be important for generating a patent connection between the distal ureter and bladder.

Relationship with Embryonic Ductal Structures

The embryologic relationships of the developing ureter and the metanephric (wolffian) and müllerian ducts are important to understand the possible sites of ectopic ureteral insertion. Because the ureteral bud derives from the wolffian duct, the ectopic ureter will not insert directly into the müllerian structures (i.e., vagina, cervix, uterus) but will be associated with them through the remnant of the wolffian duct, Gartner duct, that

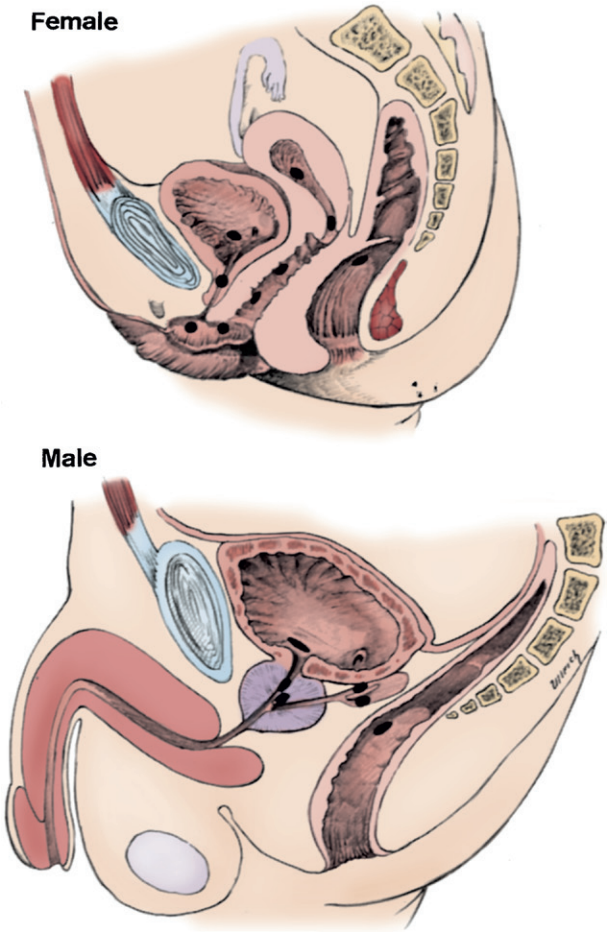

Figure 121–4. Sites of ectopic ureteral orifices in the male and female.

runs alongside the mature müllerian structures. Communication into these structures is likely due to rupture of Gartner duct or of a cyst of Gartner duct into the vagina (see later).

The possible sites of ectopic ureteral insertion are shown in Figure 121–4, including the common locations that are associated with normal wolffian duct development; however, more aberrant locations have been reported. It is unclear what the embryologic mechanisms of these locations, including rectum, might be, but they probably reflect more diffusely deranged overall development. Given that the wolffian duct in the male is never associated with any structures below the pelvic floor and sphincter, males do not present with urinary incontinence, as is seen in females. Abnormal bladder function is recognized in children with ureteroceles and is characterized by larger than normal bladders with inadequate emptying (Abrahamsson et al, 1998). This is potentially consistent with not only the obstructive effect the ureterocele can have on the bladder outlet, but also abnormal bladder and trigone development.

Patterns Associated with Duplication

As the developing ureteral buds incorporate into the developing UGS, the lowest bud, associated with the lower pole of the kidney, is incorporated first and migrates more laterally. The upper pole ureter is later to be incorporated and thereby is closer to the bladder neck. The Weigert-Meyer rule (Fig. 121–5) (see also Chapter 111) **describes the inverse relationship of the duplex ureteral orifices, in which the ectopic ureter or ureterocele associated with the upper pole is caudal to the lower pole ureteral orifice.** The association of the upper pole ureter and renal segment with the abnormally developed distal ureter further supports the principle that ectopic ureters and ureteroceles result from aberrant temporo-spatial signaling as the CND merges with the UGS.

Key Points: Embryology

- In contrast to the classic model in which the common nephric duct (CND) forms the trigone, the revised model includes regression of the CND in the normal animal through apoptosis and formation of the trigone from the endoderm, as is the bladder.
- The classic explanation of ureterocele formation is that of Chwalle, postulating that distal ureteral expansion is produced by failure of rupture of a distal membrane at the ureteral orifice (Chwalle membrane).
- Because the ureteral bud derives from the wolffian duct, the ectopic ureter will not insert directly into the müllerian structures (i.e., vagina, cervix, uterus) but will be associated with them through the remnant of the wolffian duct, Gartner duct, that runs alongside the mature müllerian structures.
- The Weigert-Meyer rule describes the inverse relationship of the duplex ureteral orifices, in which the ectopic ureter or ureterocele associated with the upper pole is caudal to the lower pole ureteral orifice.

CLINICAL PRESENTATION

Imaging

Prenatal Detection

The majority of ureteroceles and ectopic ureters are detected through prenatal ultrasound (US) imaging, even if the specific diagnosis is not made. The abnormality prompts postnatal imaging, which will invariably determine the specific cause, induce further studies, and permit an adequate characterization of the condition. The prenatal imaging patterns are identical to those seen postnatally on US imaging yet may be misinterpreted. These are described in Chapter 114, but several elements should be emphasized here.

The identification of a duplex system prenatally may be difficult except when one of the moieties is dilated. The report of an upper pole "cyst" in a fetus should be interpreted as being upper pole hydronephrosis until proven otherwise. Minor degrees of hydronephrosis may not be as readily identified, although changes over time may prompt recognition. The expected ureteral dilation may not be readily detected but can be traced to the bladder. The bladder must be inspected in all such cases to identify a ureterocele, but it may be required to await bladder filling to make this observation. A large ureterocele can fill a bladder and mask its own presence.

The character of the renal parenchyma of the upper pole should be noted, both thickness and echogenicity. This should never be

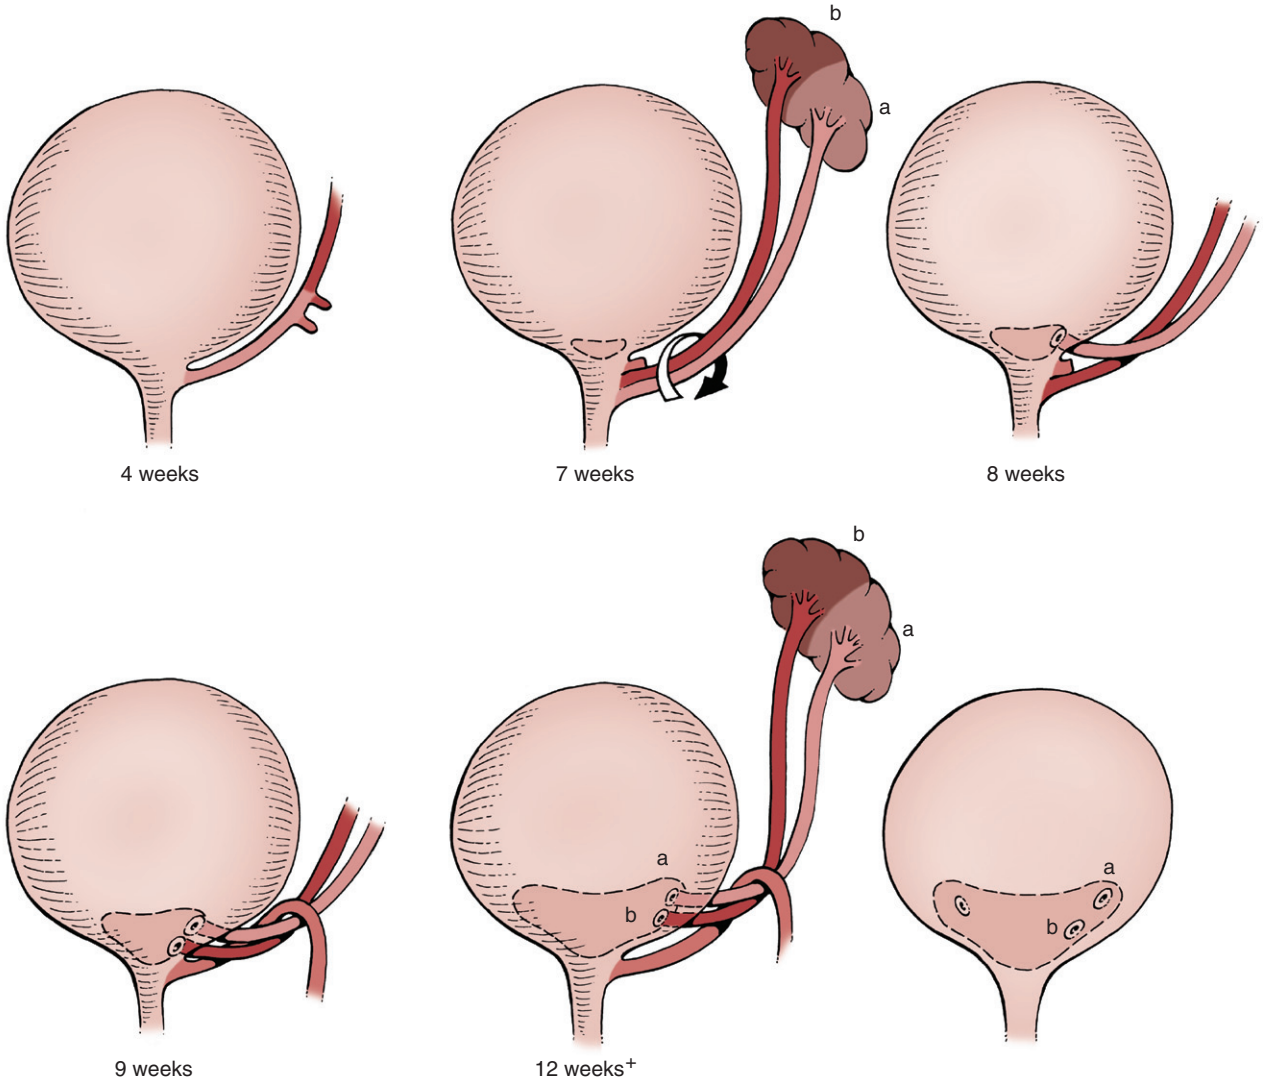

Figure 121–5. The Weigert-Meyer rule is depicted. The upper pole ureter and the lower pole ureter rotate on their long axes to yield an upper pole orifice *(b)* that is medial and caudal to the lower pole orifice *(a)*.

used alone to determine salvageability of the upper pole but may be useful in making clinical decisions.

The ectopic ureter can appear identical to a ureterocele with a dilated upper pole, tortuous ureter, but no intravesical component. On occasion, a large ectopic ureter may impinge on the bladder and appear as an intravesical structure, termed a *pseudoureterocele* (Sumfest et al, 1995). These patterns are identical to those seen postnatally but do require an experienced maternal-fetal ultrasonographer to recognize.

With a tentative diagnosis of a ureterocele or ectopic ureter made, careful evaluation of the other renal units and bladder should be made. Ipsilateral lower pole or contralateral dilatation suggests reflux or less commonly obstruction from the ureterocele or the dilated ectopic ureter. Bladder outlet obstruction by a ureterocele can occur and present with hydronephrosis of all renal units. It is unusual to identify bladder obstruction to the extent to produce oligohydramnios, but this has been reported (Gloor et al, 1996; Crane, 2000) including in-utero decompression (Quintero et al, 2001; Ashmead et al, 2004). Contralateral renal dysplasia may be evident and associated with reduced amniotic fluid. The need for prenatal intervention or early delivery is exceptional and unlikely to provide any significant benefit.

A single system ureterocele or ectopic ureter will be evident with dilatation of the entire kidney and ureter. It may be impossible to differentiate this from an obstructive megaureter or severe reflux, but this will have little immediate prenatal clinical impact.

Incidental

When significant hydronephrosis is present with either an ectopic ureter or ureterocele, an incidental diagnosis will occasionally be made. In some cases, however, this may result from a search for an explanation of general abdominal pain that was not considered to be due to a renal cause. It is also possible that the dilated ureter may not be recognized as such, and cases of presumed ovarian cysts that were actually markedly dilated ureters have been seen (Fig. 121–6).

Infection

Infection remains a significant reason for clinical presentation of both ectopic ureters and ureteroceles, and these may be at any age and have a highly variable pattern.

Figure 121–6. Magnetic resonance urogram of 15-year-old girl with intermittent abdominal pain attributed to ovarian cysts but, in fact, caused by an ectopic ureter. The association with the upper pole of the left kidney and the insertion just below the bladder neck are evident on this image.

Clinical Patterns

Although there is great variability in the presentation of either ectopic ureter or ureterocele, several patterns may be anticipated. In either case, generalized urosepsis may be the presenting clinical scenario and a renal bladder US will usually provide the diagnosis. It has been reported that an acute US study is unnecessary if a child presents with a febrile urinary tract infection (UTI) and has a history of a normal prenatal US after 30 to 32 weeks (Hoberman et al, 2003). The extreme variability in quality of prenatal imaging makes this recommendation tenuous, and it would seem prudent that an US be obtained in all children with urosepsis. In those with a febrile UTI, there is rarely urgency if they are clinically responding. The value of early detection is the potential for early treatment, which may be a simple drainage procedure. If the child is recovering rapidly, imaging may be elective.

In the acute setting, with evidence of an ectopic ureter or ureterocele, the initial clinical response to antibiotic therapy will determine the timing of intervention and is discussed later. Certainly the septic child who is not responding rapidly to appropriate therapy may require urgent transurethral incision (TUI) of an infected ureterocele or percutaneous or open drainage of an ectopic ureter. Open drainage in this setting is often an end ureterostomy, as described later.

Ectopic ureters will frequently present with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, urine cultures will be negative because the infected ectopic system is not draining into the bladder. Parents may describe a purulent discharge from the perineum. This clinical pattern should prompt an US study, which will usually reveal a dilated upper pole or entire system. It is rare for the unobstructed ectopic ureter to present with infection, but it is associated with incontinence.

In the male, a similar subacute pattern of infection may be present, but more often, these boys present with epididymitis. Although this may be an unusual subset of young boys with an acute scrotum, they will have a true bacterial epididymitis and may or may not have infected urine. In the setting of a suspicion for epididymitis in a young boy, it is prudent to perform a brief US of the upper tracts to ensure no abnormality. Older males will also present in this manner, although it is unclear why it may be so delayed. Some have had recurrent episodes of epididymitis or scrotal abscess before the underlying cause is detected. Xanthogranulomatous pyelonephritis in the upper pole segment of an infant has been reported as well (Perez et al, 1999).

Incontinence

Clinical Patterns

Urinary incontinence may be due to an ectopic ureter in a girl but not in a boy. Untreated ureteroceles are rarely associated with incontinence. The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter. Imaging studies may not immediately detect this condition because the affected renal moiety may not be dilated, and the level of suspicion must be guided by a careful history and occasionally physical examination. Before toilet training it may be difficult to detect continuous incontinence, although some parents will note persistent dribbling during diaper changing. In early training, the wetting may be falsely attributed to lack of motivation. Persistence will usually prompt evaluation, and the characteristic history can be obtained. This is usually one of persistent low-volume dampness at all times. When asked if the child can be dry for 30 to 60 minutes, the parent will usually say no. It is important to be cautious in questioning because some parents with a child who wets for other reasons may state "she is always wet," when in fact the child can be dry for periods of time. The dampness associated with an ectopic ureter typically occurs throughout the day and does not relent, yet the children have normal sensation of bladder filling, no urgency or frequency, and empty completely. It may seem to be worse with activity in some. In rare cases it is intermittent, perhaps due to intermittent leakage through a membrane of Gartner duct. This pattern has been seen only in adolescents.

In older children in whom the diagnosis has not been recognized, attribution of the symptoms may be due to dysfunctional voiding, laziness, and even sexual abuse (Heidemeier et al, 2007). During the history taking, signs of typical voiding dysfunction such as voiding postponement, posturing, and constipation should be sought to assess the likelihood of these being an explanation for the wetting.

Pain

Pain is uncommonly associated with either an ectopic ureter or ureterocele. The exceptions are acute infection, as well as episodic obstruction of the ectopic ureter or bladder pain due to an obstructing ureterocele. Occasional cases of intermittent drainage of an ectopic ureter in older children have been experienced and are characterized by abdominal pain followed by perineal drainage of urine or purulent material. It is presumed that this reflects accumulation of urine in a system that is obstructed at the level of the orifice with subsequent drainage and relief of symptoms. One such

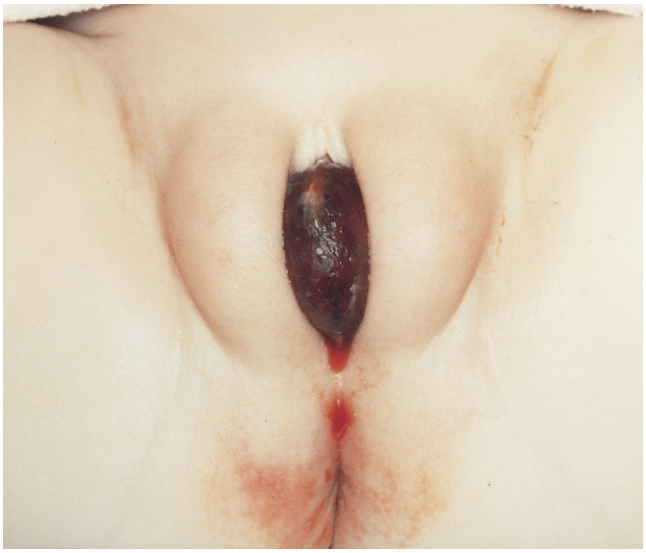

Figure 121–7. A prolapsed ureterocele presented as an interlabial mass in a 3-week-old girl.

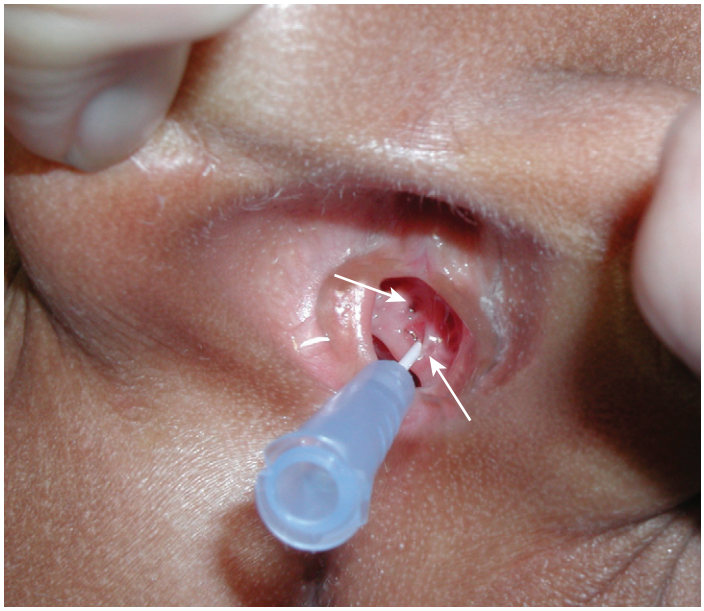

Figure 121–8. Perineal ectopic ureteral orifice *(bottom arrow)* cannulated with an angiocatheter, situated between the urethral orifice *(top arrow)* and the vagina, just to the left of midline.

case was attributed to an ovarian cyst, supported by the finding of a large cystic structure in the pelvis, which was in fact a dilated ureter.

Prolapse

Ureterocele prolapse is an unusual but distinctive presenting sign that may still confuse the clinician. These are usually smooth, congested, mucosa-covered intralabial masses, and the child may be experiencing difficulty voiding. The mass protrudes from the urethra, distinct from the vagina, and is not circumferential as a urethral prolapse will be (Fig. 121–7). It is not lobulated as a sarcoma botryoides appears. An US of the bladder will usually confirm the diagnosis, and kidney images will further support this.

Key Points: Clinical Presentation

- The majority of ureteroceles and ectopic ureters are detected through prenatal US imaging, even if the specific diagnosis is not made.
- Ectopic ureters will frequently present with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, urine cultures will be negative because the infected ectopic system is not draining into the bladder.
- In the male a similar subacute pattern of infection may be present, but more often, these boys present with epididymitis.
- Urinary incontinence may be due to an ectopic ureter in a girl but not in a boy. The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter.
- Ureterocele prolapse is an unusual but distinctive presenting sign; these are usually smooth, congested, mucosa-covered intralabial masses, and the child may be experiencing difficulty voiding.

Evaluation

Management of ectopic ureter or ureterocele is based on a thorough assessment of the affected anatomy and the functional implications of the condition. This may usually be obtained readily but in some cases will require more involved imaging such as magnetic resonance (MR) urography.

Anatomic Assessment

Physical Examination

With both ectopic ureter and ureterocele, physical findings may facilitate diagnosis. The prolapsed ureterocele is diagnostic and dramatic but unusual. Further study of the anatomy is necessary. It is unusual to be able to detect an ectopic perineal ureteral orifice in a child, but this will provide much information as to the character of the situation and best treatment (Fig. 121–8). A search for the perineal orifice in a child with continuous wetting or a known leaking ectopic ureter is worthwhile. Rarely, the dilated Gartner duct cyst may be detected on careful perineal examination (Fig. 121–9). These orifices or cystic structures may then be imaged by injection of contrast. Continuous dripping or pooling of urine may be seen in the introitus of females. Visualizing the actual orifice in the introitus is difficult due to the many mucosal folds. However, absence of dripping of urine does not exclude the diagnosis of ectopic ureter. The ectopic ureter may be connected to renal tissue so dysplastic that it rarely produces urine.

The dilated upper pole of either an ectopic ureter or ureterocele may be palpable in the relaxed infant, but this is difficult in the older child.

Ultrasound

The US image will usually provide the anatomic diagnosis and permit inference of functional assessment. The typical findings are as with the prenatal imaging of a

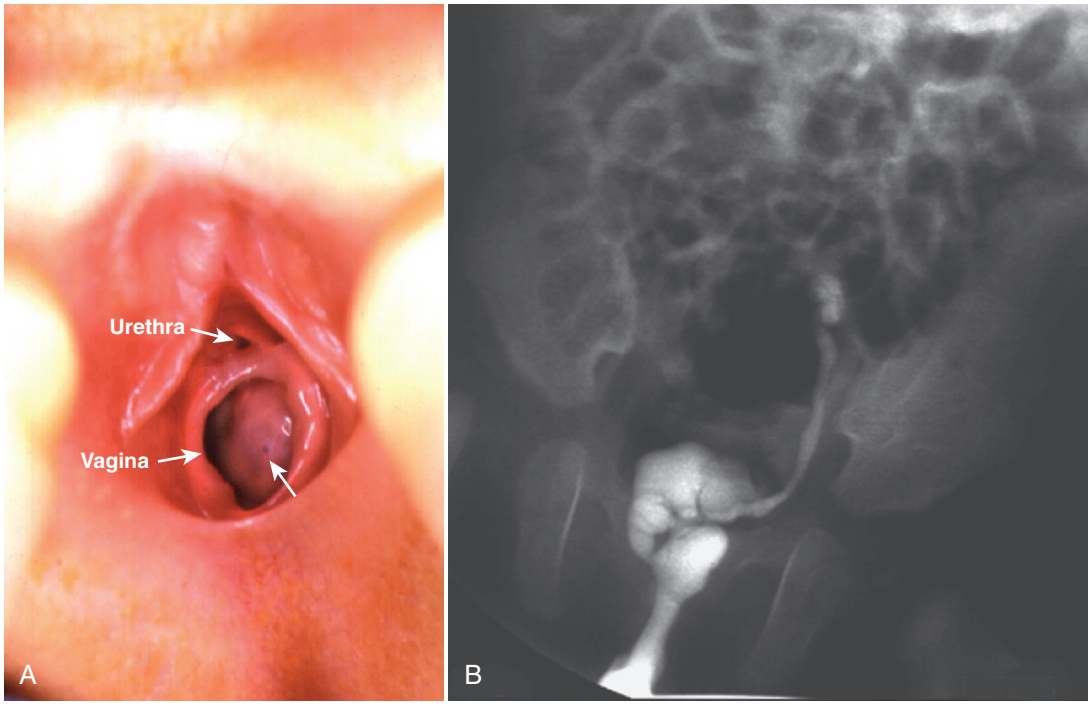

Figure 121–9. **A,** Gartner duct cyst *(bottom right arrow)* in newborn with a left multicystic dysplastic kidney. **B,** Injection of the cyst communicated with the ureter and dysplastic kidney.

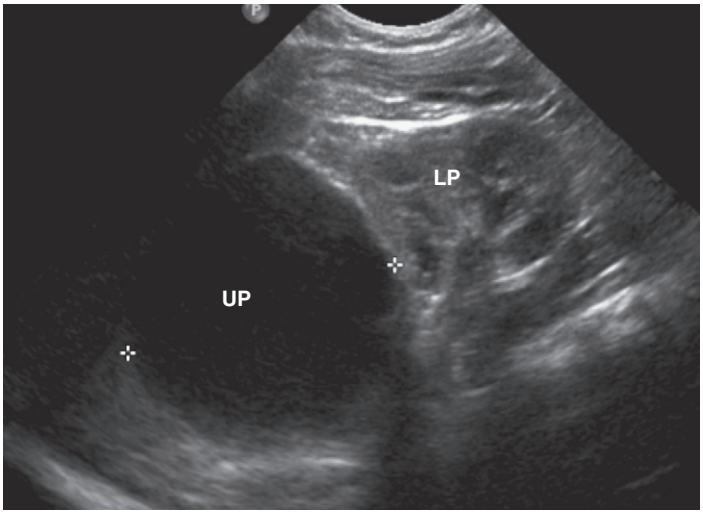

Figure 121–10. Ultrasound image of dilated upper pole (UP) associated with a ureterocele, demonstrating limited renal parenchyma (same patient as Fig. 121–30). LP, lower pole.

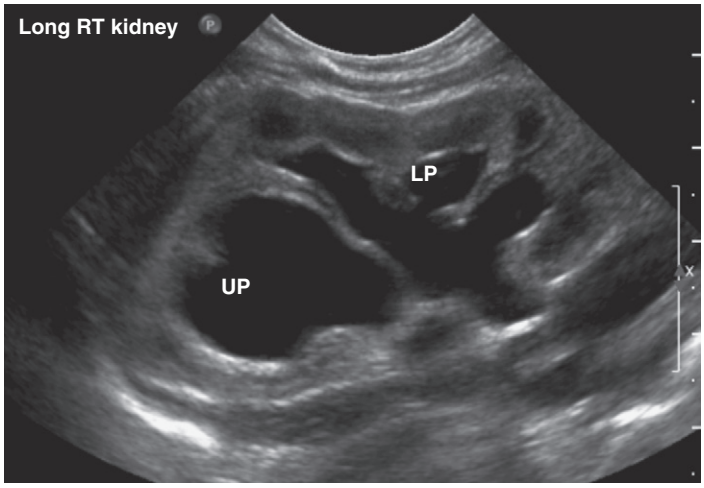

Figure 121–11. Ultrasound demonstrating dilated upper pole (UP) and lower pole (LP) associated with a ureterocele. The upper pole has evident renal parenchyma. The lower pole is dilated due to compression of the dilated upper pole ureter on the lower pole system, creating a partial obstruction.

dilated upper pole with ureteral dilation or a dilated single system (see Fig. 121–9). The character of the renal parenchyma will be more readily seen postnatally, and if it appears healthy, the true need for functional upper tract imaging can be questioned. Depending on the chosen treatment algorithm, it may be argued that this is unnecessary because it will not change treatment. The difference between functioning upper poles and those with little to no function are usually apparent (Figs. 121–10 and 121–11).

No characteristics permit differentiation between a dilated ectopic ureter and ureterocele above the bladder. The bladder images therefore become critically important because management is different.

Bladder views should be diagnostic to differentiate ureterocele from ectopic ureter (Fig. 121–12). **The ureterocele is characterized by a thin-walled, cystic dilation within the bladder and not extending beyond its walls.** The laterality of the ureterocele is usually apparent but may appear midline if large. A lobulated ureterocele may appear as two structures, but careful examination should show communication. It is difficult to visualize extension of a cecoureterocele into the bladder neck, so nonvisualization is not diagnostic.

Several US patterns may produce confusion in diagnosis. **A large ureterocele may completely fill a bladder with no urine in the bladder itself. A full bladder with an effaced ureterocele may be mistakenly considered an ectopic**

ureter. Observation of the bladder over time will usually avoid these errors. A ureterocele may also evert and has been seen outside the bladder and mistakenly diagnosed as a diverticulum. **A dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele** (the previously noted "pseudoureterocele") as noted in fetal diagnosis, **but the wall will be clearly bilaminar and much thicker than typically seen with a ureterocele. Further, the lumen of the ectopic ureter will extend well outside the bladder walls** (Fig. 121–13).

Magnetic Resonance Imaging

MR urography can provide the most detailed images of an affected urinary tract as a whole along with functional information yet is rarely useful to provide more data than may be obtained with less expensive methods not requiring sedation. Eventually, however, MR imaging (MRI) is likely to become the modality of choice. **At present the value of MRI rests with cases in which other imaging cannot define complex anatomy.** This may occur with massive dilation in which the existence of duplication may be uncertain or in which anatomic relationships are significantly distorted (Fig. 121–14). Not all ectopic ureters are massively dilated, and the MR can also be helpful in identifying a small, dysplastic upper pole and its ectopic ureter that was unrecognized on US. If this type of anatomic delineation is necessary, MR offers the addition of functional information that is an equally important aspect of evaluation. The ability to integrate detailed anatomic assessment of MR with functional assessment can be useful in the detection of the occult ectopic ureter causing incontinence with minimal function (Fig. 121–15).

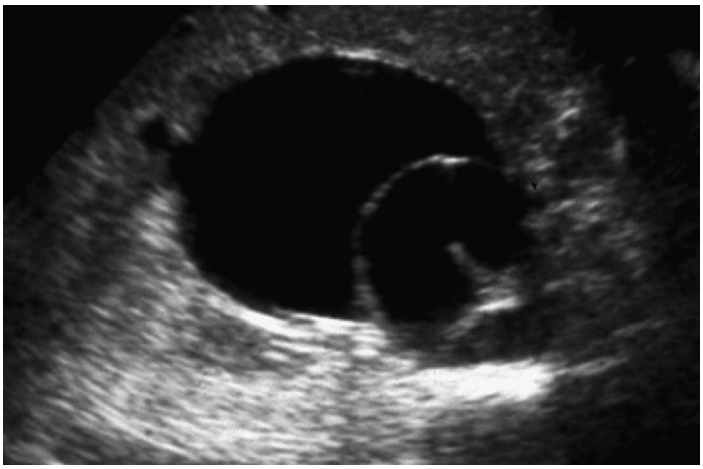

Figure 121–12. Ultrasound image of an intravesical ureterocele at the bladder level.

Functional Assessment

Functional urinary assessment in association with an ectopic ureter or ureterocele is the foundation for both initial management and postoperative care. Both renal and bladder function are affected by the developmental abnormalities of abnormal ureteral formation and may ultimately require complex surgical interventions.

Renal Function

Nuclear Imaging

Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best provided by dimercaptosuccinic acid (DMSA) imaging. The function of the affected upper pole is the principal

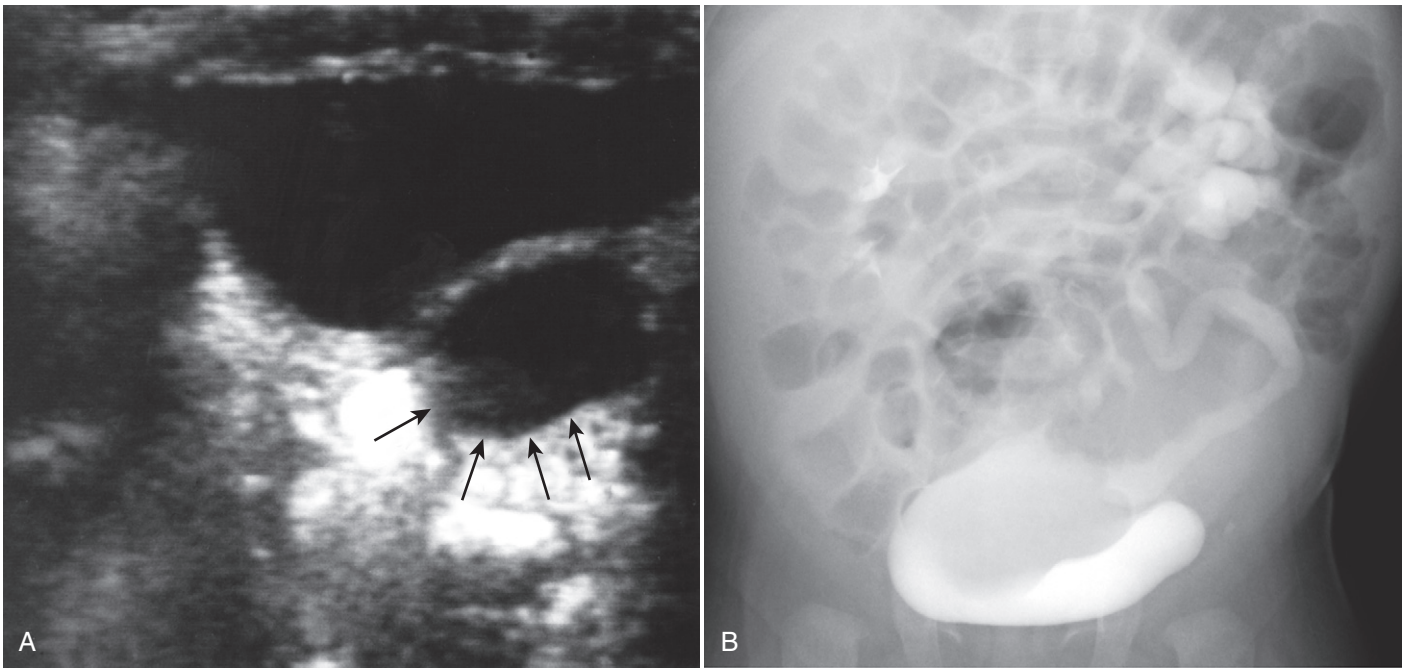

Figure 121–13. **A,** Ultrasound image of bladder in a child with an ectopic ureter extending into the bladder. The wall of the ureter is thicker than a ureterocele, and the lumen of the ureter extends well outside the bladder lumen, indicating that this is an ectopic ureter rather than a ureterocele. **B,** Voiding cystourethrogram of a large ectopic ureter pushing inward on the back of the bladder and appearing as a filling defect in the bladder (pseudoureterocele). (**B,** Courtesy of Dr. Jeanne Chow, Assistant Professor of Radiology, Harvard Medical School and Children's Hospital Boston.)

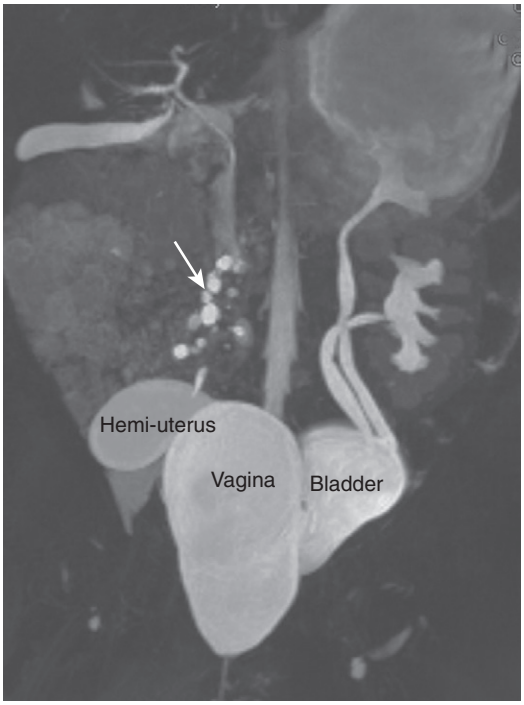

Figure 121–14. Use of magnetic resonance imaging to define the complex anatomy of a child with an ectopic ureter associated with a right dysplastic, cystic kidney *(arrow)* draining into an obstructed hemi-vagina and producing urinary dilation of the right hemi-uterus. Initial therapy constituted creating a distal window between the two vaginae. Subsequently she underwent right nephrectomy.

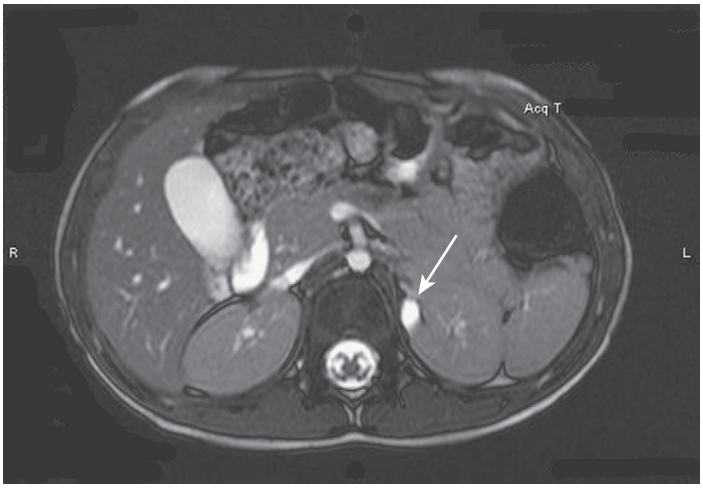

Figure 121–15. Magnetic resonance urography demonstrating the presence of an occult upper pole associated with an ectopic ureter producing incontinence. The left upper pole ureter is marked by the *arrow* at the level of the lower pole pelvis.

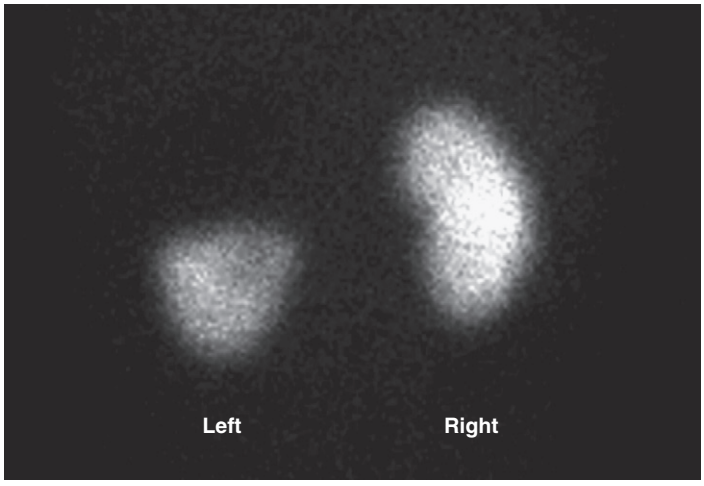

Figure 121–16. Dimercaptosuccinic acid renal scan in a child with a left ureterocele demonstrating no function in the affected upper pole.

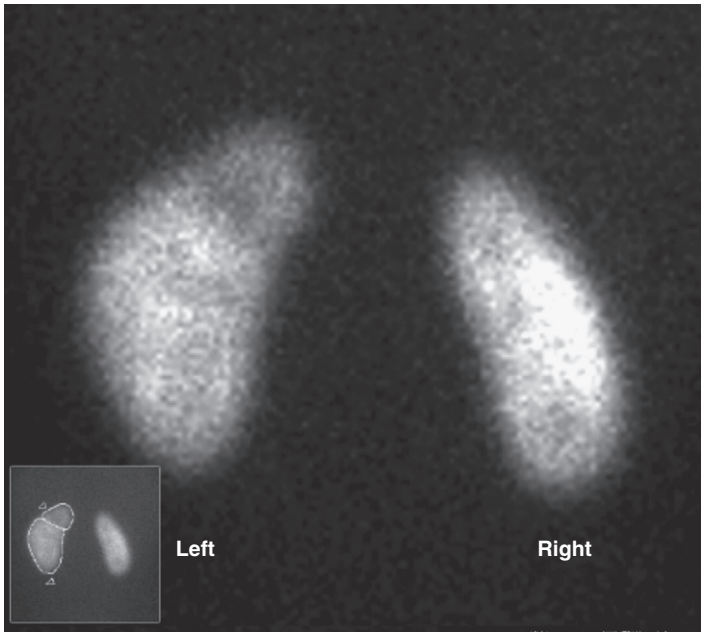

Figure 121–17. Dimercaptosuccinic acid renal scan in a child with a ureterocele with evidence of upper pole function after transurethral incision to decompress the ureterocele. The upper pole was separately assessed as contributing approximately 18% of total renal function.

focus, but the health of the other renal moieties must be determined as well, particularly if there is lower pole reflux or hydronephrosis of any unit. Although there have been some attempts to define what the "normal" function of an upper pole associated with an ectopic ureter or ureterocele should be, there are no criteria to define this. The clinical impact comes with the decision to preserve the upper tract or not, yet there are no objective parameters to determine what level of functional contribution should be preserved. The functional assessment therefore offers the dichotomy of "some function" versus "no function," and this may or may not determine clinical management (see later) (Figs. 121–16 and 121–17). In general, this is clear, but there will always be ambiguous cases. Preoperative assessment is further confused by the lack of ability to predict the effect of decompression.

The assessment of drainage function is rarely of practical utility in that a purely observational approach is only rarely entertained and usually not on the basis of functional parameters. There are no guidelines as to the level of obstructive effect that will cause a clinical problem, particularly infection, although this has been used as a selection tool for nonoperative management (Han et al, 2005).

Intravenous Pyelogram

In unusual situations the intravenous pyelogram (IVP) may offer adequate functional information with anatomic delineation without the complexities of MRI. Because the quantitative measure of upper pole function is rarely necessary with any precision, the IVP can offer an efficient means to complete the renal functional assessment (Fig. 121–18). The IVP may be of particular value in the ectopic ureter without ureteral or upper pole dilation.

Bladder Function

Although the bladder is not usually the focus of clinical attention in the evaluation of the ectopic ureter or ureterocele, the potential for impaired bladder function cannot be ignored. This may be due to bladder outlet obstruction from a ureterocele or impaired continence due to inadequate bladder neck function with an ectopic ureter or ureterocele. In the extreme case of bilateral single-system ectopic ureters, bladder development may be severely impaired due to the absence of developmental bladder filling.

Ultrasound Imaging Interpretation

A simple bladder US image may be useful in completing the functional evaluation of these patients. This requires some patience to wait for bladder filling and emptying yet will yield information on bladder capacity, emptying efficiency, trabeculation, and bladder wall thickness (indicative of possible outlet obstruction). The character, location, and size of the ureterocele can usually be assessed as well (see Fig. 121–12). In some cases the ectopic nature of a dilated ureter may be identified ultrasonographically (see Fig. 121–13A). At times, the distinction between a ureterocele and ectopic ureter may be difficult, as discussed earlier.

Voiding Cystourethrogram

The voiding cystourethrogram (VCUG) provides the most definitive evaluation of the bladder and distal ureters, as well as the urethra, and is an obligate imaging test. This should almost always be performed before any intervention to define the baseline situation. The unusual situation in which a VCUG may not be obtained would be where decompression of a ureterocele producing bladder outlet obstruction or severe bilateral upper tract obstruction is urgent. It is unlikely that the findings on VCUG would alter treatment in that unusual case, which would nearly always be transurethral puncture.

Reflux

The presence of reflux may determine initial treatment for some practitioners and is an important parameter in clinical management after initial decompression of the ureterocele. Lower pole reflux may be of any degree and can often be associated with a massively dilated ureter (Fig. 121–19). In the setting of an ectopic ureter, ipsilateral lower pole reflux is unlikely to resolve spontaneously and will determine definitive treatment options.

Following endoscopic incision of a ureterocele, the presence of reflux either ipsilaterally or contralaterally will be critical in therapeutic decision making.

Ureterocele and Bladder Outlet

The appearance of the bladder base with filling and voiding demonstrated on VCUG will also be useful in therapeutic decisions because massive eversion indicates a weak trigonal floor that may be more likely to require surgical repair. Prolapse of a ureterocele into the urethra and demonstration of a cecoureterocele are important factors in planning and performing a TUI. These factors may be more

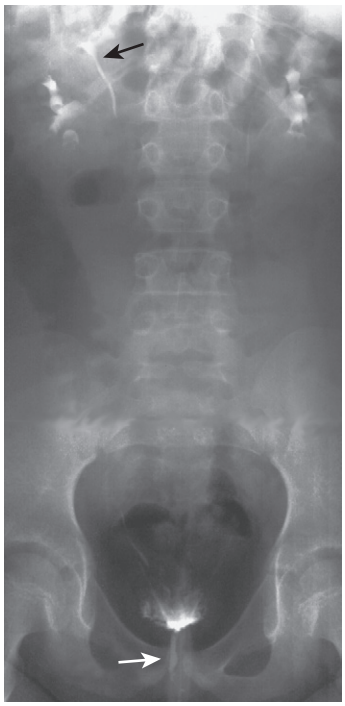

Figure 121–18. Intravenous pyelogram image of a 10-year-old child with life-long wetting and evidence of ureteral duplication *(black arrow—upper pole)* with no hydronephrosis. The distal ureter *(white arrow)* can be seen passing by the bladder and bladder neck and inserting into the urethra near the perineum.

Figure 121–19. Voiding cystourethrogram image of child with a ureterocele appearing as a filling defect within the bladder and massive ipsilateral lower pole reflux.

predictive of the subsequent need for secondary surgery. The usual descriptive terms in the context of a ureterocele include effacement or flattening of the ureterocele with bladder filling; prolapse, which is movement of the ureterocele into the urethra; eversion; diverticulum-like protrusion of the bladder base and trigone with filling and voiding (Fig. 121–20); and intussusception, or protrusion of the ureterocele into its ureter (Fig. 121–21).

Although it is difficult to predict continence at initial presentation, the ureterocele or ectopic ureter associated with a patulous bladder neck may be complicated by later urinary incontinence. Cecoureteroceles are of particular risk (Fig. 121–22), but we have also observed bladder neck ectopic ureters with wide-open bladder necks and later incontinence after resection of the distal ectopic ureter and external bladder neck reinforcement. These patients may benefit from more aggressive bladder neck tightening at the time of definitive resection of the ureterocele or ectopic ureter, but this entails some risk of disturbing what may be normal bladder neck function. Video-urodynamic evaluation may be helpful in such cases.

Endoscopic Evaluation

The final element of evaluation of a ureterocele or ectopic ureter can be endoscopic. Although this is not always essential, most cases of both ureterocele and ectopic ureter will come to operative intervention and concurrent endoscopic evaluation is important, if not essential. Certainly when endoscopic incision is to be performed, this is a critical element and should be performed thoroughly before incision to permit selection of the most effective site.

Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter. The location of other ureteral orifices should be documented. The orifice of the affected ureter should be sought but may not be identified. The urethra is examined carefully for the orifice if not seen in the bladder. **The appearance of the ureterocele will vary with bladder filling, and it is best to start with little filling and slowly increase bladder volume** (Fig. 121–23). The

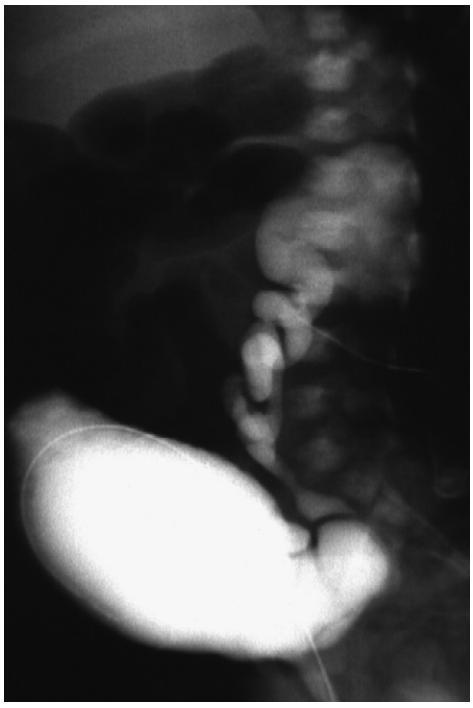

Figure 121–21. Voiding cystourethrogram in a child with a ureterocele and evidence of ureterocele eversion with voiding. The apparent diverticulum is the ureterocele extending outside the bladder wall with increased intravesical pressure. This pattern may be seen with the ureterocele everting or intussucepting into its dilated ureter. There is lower pole reflux as well.

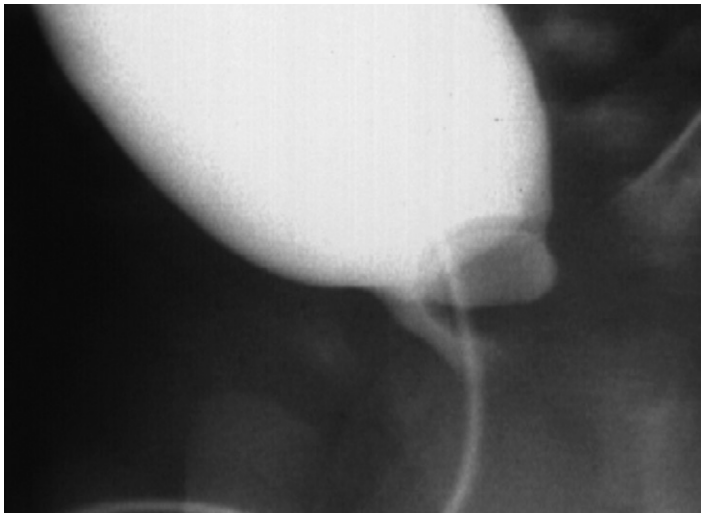

Figure 121–20. Voiding cystourethrogram of child with ureterocele and evidence of prolapse of the ureterocele into the bladder neck with voiding. This is distinct from a cecoureterocele where the ureterocele is part of the urethra. This pattern of prolapse can cause bladder outlet obstruction.

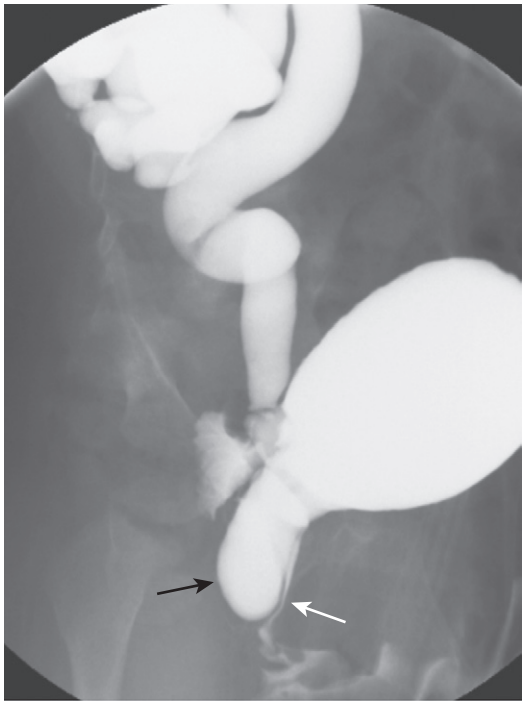

Figure 121–22. Voiding cystourethrogram image of a cecoureterocele where the ureterocele *(black arrow)* is attached to the urethra *(white arrow)* and the lumen extends into the urethra. These are the most challenging ureteroceles due to the involvement of the bladder neck and urethra.

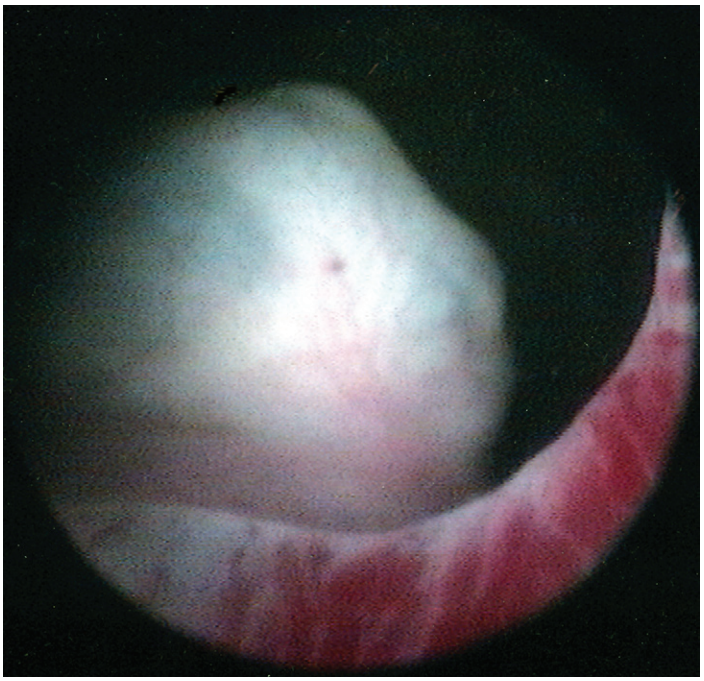

Figure 121–23. Endoscopic image of an intravesical ureterocele just inside the bladder neck.

ureterocele will be seen to slowly flatten. Its true limits are best appreciated with limited bladder filling, and this will provide the lowermost portion, which is probably the best site for incision. Extension of the ureterocele into the urethra, indicative of a cecoureterocele, may be detected and this would indicate the need to make sure this section does not cause obstruction with incision. Retrograde contrast injection can confirm the presence of ureterocele disproportion because there will be only a narrow proximal ureter and no filling of an upper pole segment (Fig. 121–24). Unusual connections with the genital ducts may also be demonstrated, as in the example of a boy with a ureterocele and communication among the ureter, vas deferens, and seminal vesicles (Fig. 121–25).

An ectopic ureteral orifice may be difficult to find endoscopically, but if in the bladder neck it is often patulous (Fig. 121–26). The anatomic connections of the ectopic ureter may be demonstrated using retrograde contrast studies. The authors have identified ectopic ureters that appear to have a thin layer of tissue separating it from the urethra, looking much more like a ureterocele than ectopic ureter (Fig. 121–27A). These may be associated with defects in the bladder neck and incontinence (Fig. 121–27B). Consideration for more extensive removal of these patulous segments with reconstruction of the bladder neck may be part of the clinical decision, and their endoscopic appearance can facilitate this decision.

Clinical Management

Management Goals

It should once again be stressed that, before any surgical intervention for ectopic ureters or ureteroceles, the surgeon must obtain as much information as possible regarding the patient's altered anatomy and physiology. Only then can a rational treatment plan be devised. Although specific and definitive management for ectopic ureters and ureteroceles differs in some individuals, the

Figure 121–24. Ureterocele disproportion demonstrated via retrograde pyelography. Note the disparity between the large ureterocele and the thin ureter and nondilated collecting system.

Key Points: Evaluation

- The US image will usually provide the anatomic diagnosis of an ectopic ureter or ureterocele and permit an inference of function.
- The typical findings are of a dilated upper pole with ureteral dilation or a dilated single system.
- The ureterocele is characterized by a thin-walled, cystic dilation within the bladder and not extending beyond its walls.
- A dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele.
- Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best provided by DMSA imaging.
- The function of the affected upper pole is the principle focus, but the health of the other renal moieties must be determined as well.
- VCUG provides the most definitive evaluation of the bladder and distal ureters, as well as the urethra.
- The appearance of the bladder base with filling and voiding demonstrated on VCUG will also be useful in therapeutic decisions because massive eversion indicates a weak trigonal floor that may be more likely to require surgical repair.
- Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter.

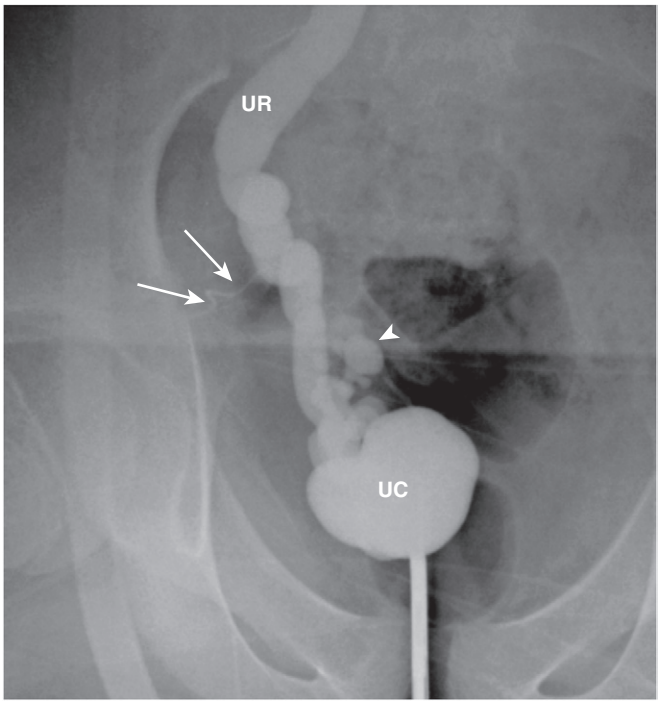

Figure 121–25. Retrograde injection study of a boy with abdominal pain and a ureterocele associated with a hypoplastic right kidney. The intravesical ureterocele (UC) is being injected and demonstrates communication with the right seminal vesicle *(arrowhead)* and vas deferens *(arrows)* with the ureter (UR) leading to the dysplastic kidney. At surgical resection, the ureter and vas joined just above the seminal vesicles.

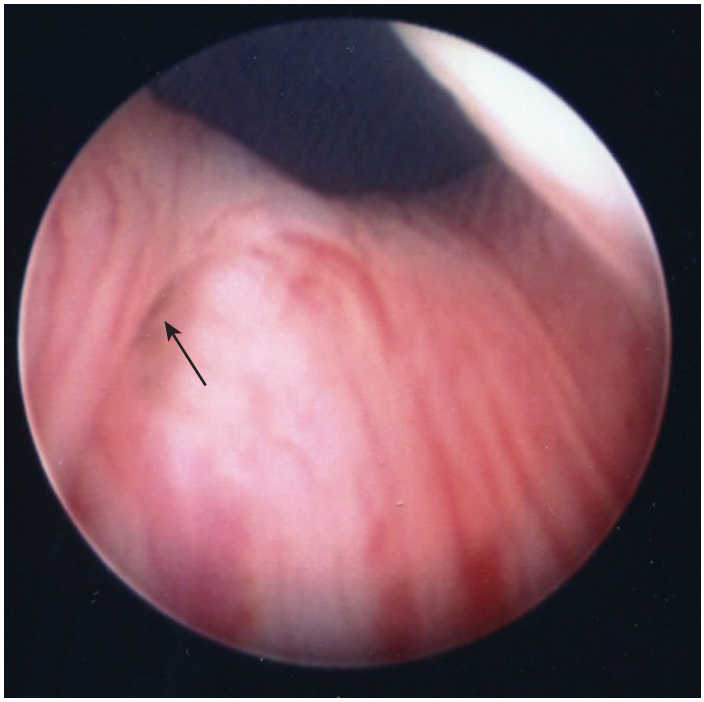

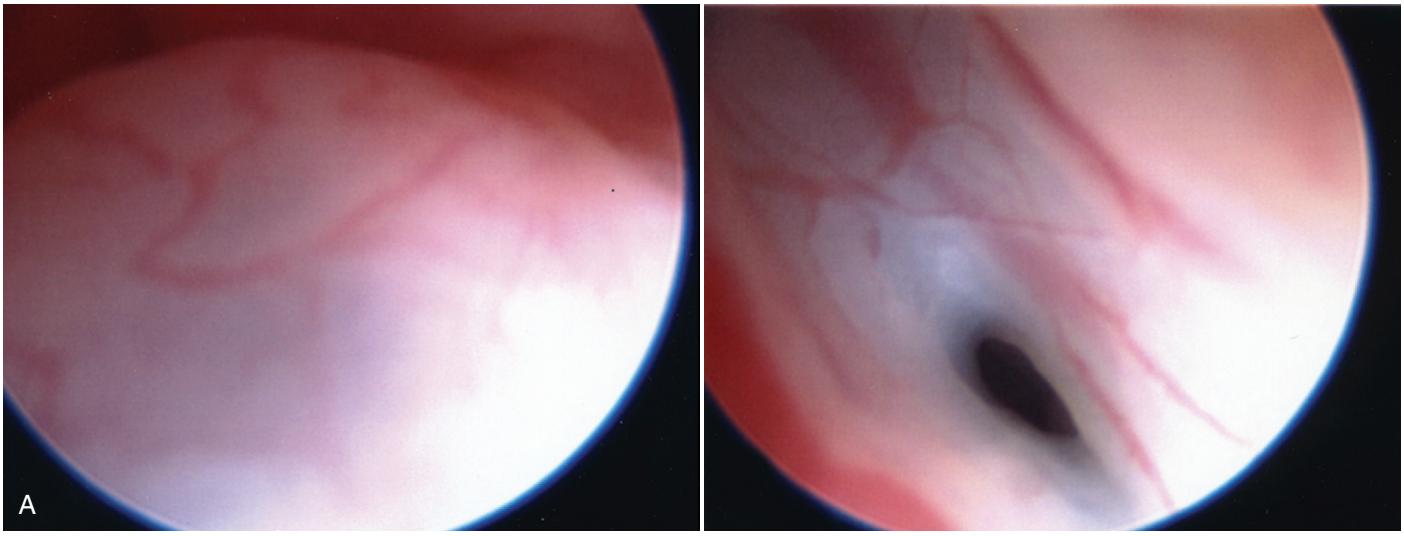

Figure 121–26. Endoscopic views of the bladder neck and the ectopic ureteral orifice marked by the *arrow*. Bladder neck ectopic ureteral orifices are often patulous but do not always reflux.

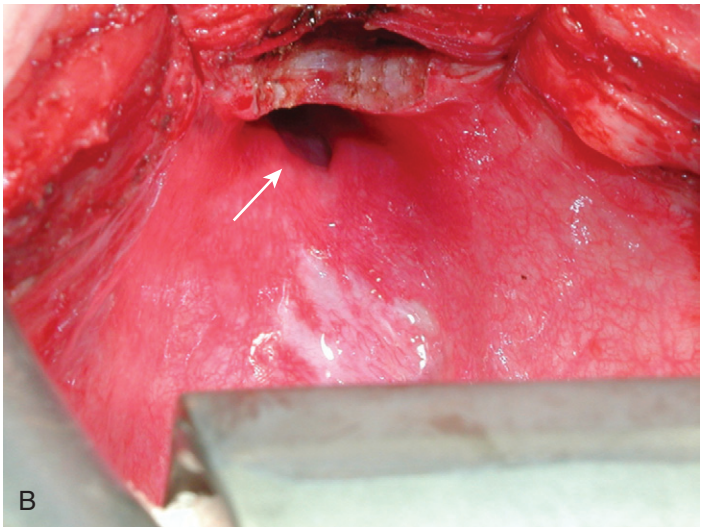

Figure 121–27. **A,** Endoscopic images of the bladder neck orifices of an ectopic ureter with an appearance similar to that of a ureterocele without the dilated intravesical portion. The membrane overlying the orifice was thin and fluttered with irrigation, just as a ureterocele would. **B,** At open surgery, these bladder neck ectopic ureters can have the appearance of a defect in the bladder neck *(arrow)* and be associated with incontinence. It remains unclear how these ectopic ureters are related to ureteroceles.

goals of management are the same and, in many cases, the approaches are identical.

The goals of therapy should be clearly defined and factored into the clinical decisions. These goals are preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence. Minimizing surgical morbidity is a goal that must be included in this consideration. Although the goals of treatment could certainly generate a consensus, the means to achieving those goals have not necessarily been agreed on. One area of at least partial agreement is that early institution of daily prophylactic antibiotics can reduce the risk of urinary tract infections in those cases in which there is significant hydronephrosis.

Preservation of Renal Function

For both ectopic ureter and ureterocele associated with a duplicated system, a primary concern is the preservation of functional renal parenchyma if at all possible. This goal is achieved by correcting obstruction and preventing reflux with its risks of renal parenchymal damage from infection. At times it is necessary to balance one against the other because relieving the obstruction of an ectopic ureter or ureterocele may induce reflux in either or both poles of the involved kidney. In other instances the same action may cause existing lower pole reflux to resolve. Several means of achieving these goals are available.

For an ectopic ureter, this can mean common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis. For a ureterocele, this can be accomplished by TUI, as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy. In both cases, acute decompression may be necessary due to sepsis and the age of the child. For the ectopic ureter, acute decompression is best achieved with an end ureterostomy near the bladder, whereas for a ureterocele, TUI is usually effective.

The decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving. As noted earlier, this is a subjective determination. The presence of vesicoureteral reflux (VUR) into either of the ureters must be considered as well, and every effort to correct this with the drainage procedure should be made.

Ectopic ureters and ureteroceles are overwhelmingly dealt with postnatally. Although one might reason that a prenatal diagnosis could lead to earlier relief of obstruction and presumably a greater chance of recovery of upper pole function, the evidence in the literature seems to show that there is a limited recovery of function, even with early decompression. The observations by Tank using early endoscopic puncture demonstrated function that had not been detected before drainage (Tank, 1986). Impaired function of the upper pole occurs equally in those diagnosed prenatally and postnatally (Upadhyay et al, 2002). In most instances the upper pole contributes little to overall renal function, but as discussed earlier, there are no criteria for what should be normal upper pole function.

Upper Pole Ablation and Lower Tract Reconstruction

Partial Nephrectomy. The goal of elimination of infection and reflux may be achieved through removal of the abnormal segment associated with either a ureterocele or ectopic ureter, which has been the traditional means of "definitive" surgical intervention. It may need to be accompanied by reimplantation of the lower pole ureter combined with ureterocele excision or removal of the distal ectopic ureter. This can be accomplished in a single-stage procedure, often with two incisions, or in a conditional or planned staged procedure.

The technique of upper pole nephrectomy for nonfunctioning upper poles due to ureteroceles is the same technique as that for ectopic ureters (Fig. 121–28). Upper pole nephrectomy can be performed laparoscopically even in children younger than 12 months.

Ureterocele Excision and Reimplantation. In the case of a ureterocele, excision at the bladder level with reimplantation of the affected ureter and its lower pole mate can be accomplished to both relieve obstruction and eliminate reflux. As described later, this is a complex procedure in which the upper pole ureter may need to be tapered for reimplantation and there are risks of injury to the vagina and bladder neck.

Observational Management

Coplen and Austin (2004) described a subset of patients with ureteroceles and multicystic dysplastic kidneys in the associated upper tract segment. This group had either low-grade or no reflux and no ureteral dilatation. These prenatally diagnosed patients were managed nonoperatively and had a benign clinical course. Other groups have reported nonoperative management of ureteroceles meeting criteria of no obstruction of the ipsilateral lower pole or contralateral kidney, as well as limited reflux to the lower pole (≤grade 3) (Shankar et al, 2001; Direnna and Leonard, 2006), no function of the upper pole, or no obstruction on diuretic renography (Han et al, 2005). Clearly, some children will do well for a period of time without intervention and in some cases, resolution of upper pole dilation and lower pole reflux has been reported. It is challenging to know how to counsel families regarding this approach because the potential for later, unpredictable acute presentation is real. For that individual, even if with a low statistical incidence, it is clinically significant. The long-term risk and relative balance of morbidities of this strategy, as well as the robustness of clinical predictors, has yet to be determined.

Key Points: Clinical Management—Goals of Treatment

- The goals of therapy are preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence.
- Minimization of overall procedural morbidity is also a goal of treatment.
- For both ectopic ureter and ureterocele associated with a duplicated system, a primary concern is the preservation of functional renal parenchyma.
- Decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving.
- For an ectopic ureter, this can mean common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis.
- For a ureterocele, this can be accomplished by TUI, as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy.

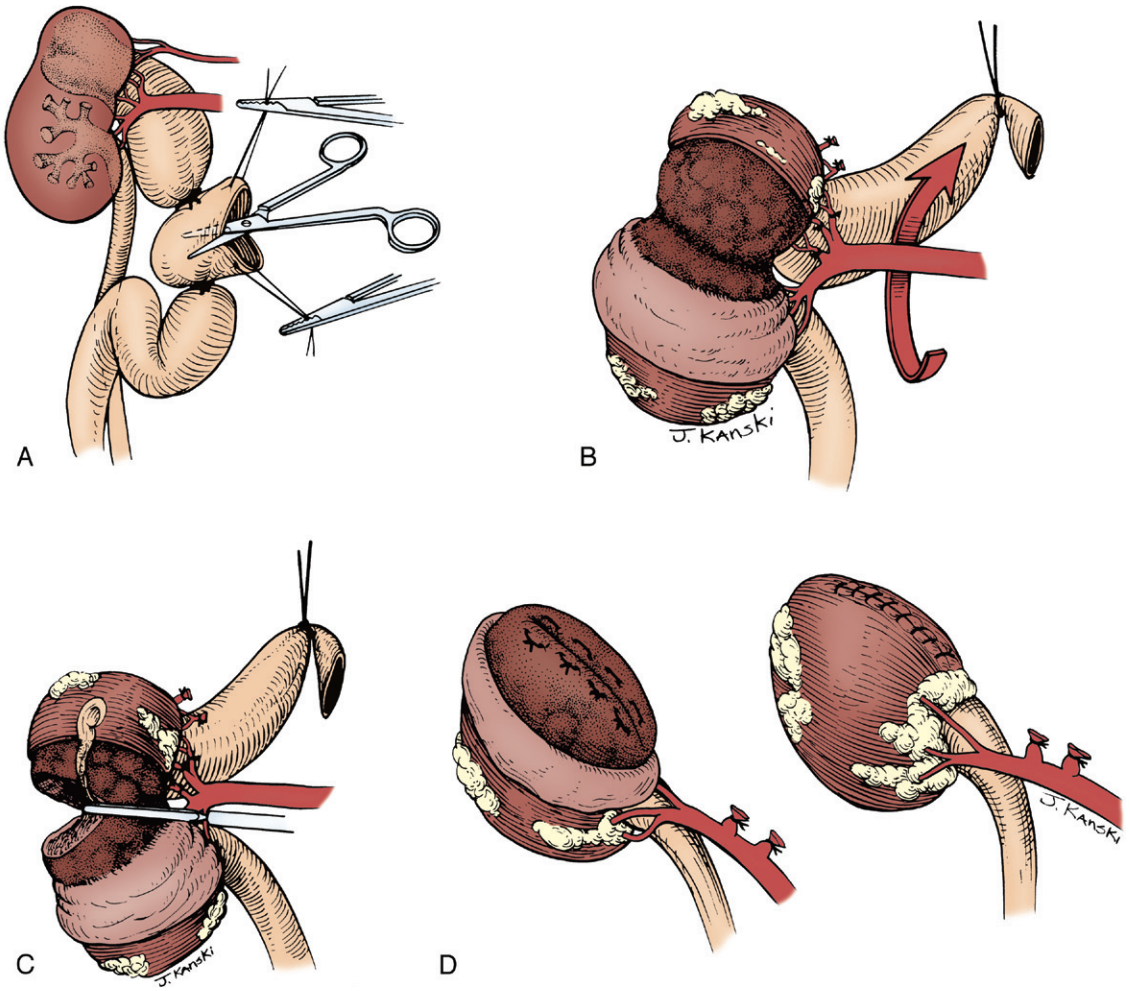

Figure 121–28. Technique of upper pole nephrectomy. **A,** The upper pole ureter is usually dilated and tortuous and can be identified readily at the lower pole of the kidney. It is separated carefully from the lower pole ureter, divided, and used to improve access to the upper pole moiety. **B,** The upper pole ureter is passed beneath the hilar renal vessels and retracted upward. Small feeding vessels to the upper pole are individually ligated and divided. Any larger vessels that may be supplying the upper pole can be temporarily clamped to determine the extent of their distribution. The capsule of the upper pole is bluntly stripped away, exposing the often coarse and cystic parenchyma of the upper pole. This can usually be distinguished from the smooth texture of the normal lower pole. Often, an indented demarcation is seen between the two poles. **C,** While traction is applied to the lower pole ureter, the upper pole is excised with the use of electrocautery. Vascular control is achieved by temporary clamping of the lower pole vessels. This may also be accomplished by gentle finger compression of the lower pole. Individual vessels are identified and ligated during this part of the procedure. **D,** The parenchyma of the lower pole is approximated at the site of removal of the upper pole with the use of broad mattress sutures. The redundant capsule is then brought over the site of repair and sewn together with a running suture.

Procedural Descriptions

Transurethral Incision of Ureterocele

The authors' preferred method of incising the ureterocele is similar to the one described by Rich and colleagues (1990): a transverse incision through the full thickness of the ureterocele wall using the cutting current. Making the incision as distally on the ureterocele and as close to the bladder floor as possible lessens the chance of postoperative reflux into the ureterocele. One can either use a Bugbee electrode or an angled tip wire. The authors favor the latter instrument because it has a finer tip and allows for more precision, and the angle allows for easier manipulation. In older children the resectoscope with the Collins hot knife may be used to make the incision. Laser incision has been reported with equivalent results (Marr and Skoog, 2002; Jankowski and Palmer, 2006). Cold-knife incision has been used as well.

The ureterocele should be incised deeply because ureteroceles may be thick walled. Adequacy of ureterocele incision is confirmed by either the escape of a jet of urine from the ureterocele or viewing the urothelium of the inside of the ureterocele (Fig. 121–29). For the ectopic ureterocele that extends into the urethra, adequate drainage may be achieved by either a longitudinal incision that extends down from the intravesical portion into the urethral portion or two separate punctures, one in the intravesical portion of the ureterocele and one in the urethral portion of the ureterocele.

No bladder catheter is left in place, and most children are treated as outpatients. A follow-up US is performed in 4 to 6 weeks to assess the degree of decompression. Most series have reported greater than 90% decompression (Fig. 121–30), and it is uncommon to require a second incision. A voiding cystogram is performed in 2 to 3 months to determine the status of lower pole

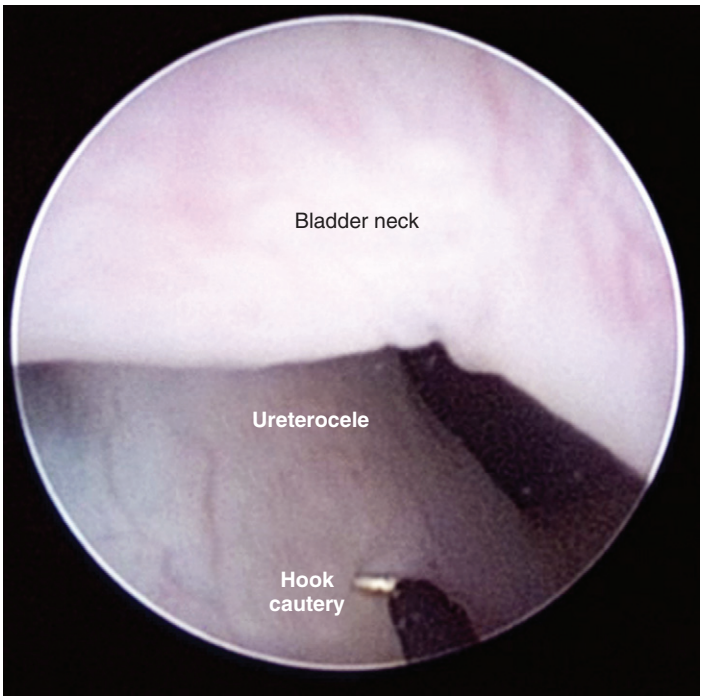

Figure 121–29. Endoscopic image of a ureterocele about to be incised with a hook cautery. The incision should be made inferior and medial to limit the risk of reflux, but the key goal is decompression. The ureterocele should be incised with the bladder partially filled, but not so much as to efface the ureterocele.

Figure 121–31. Voiding cystourethrogram demonstrating reflux into the upper pole of a duplex system after ureterocele incision. This type of reflux will rarely resolve spontaneously, Although the clinical risk is uncertain, the reflux is most often repaired.

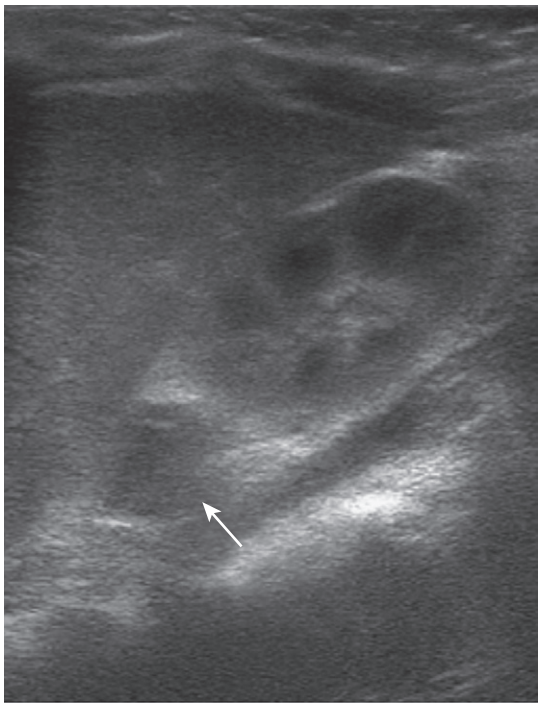

Figure 121–30. Appearance of the decompressed upper pole from Figure 121–10, following endoscopic incision of the ureterocele.

reflux and whether new reflux has been created into the ureterocele (Fig. 121–31).

The reported incidence of new reflux ranges from 0% to 50% and may depend on the method used for incision (Tank, 1986; Rich et al, 1990; Blyth et al, 1993; Jelloul et al, 1997; Dahm and King, 1998; Husmann et al, 1999; Jayanthi and Koff, 1999; Shekarriz et al, 1999; Cooper et al, 2000; Singh and Smith, 2001; Upadhyay et al, 2002; Chertin et al, 2007). Some authors favor puncture instead of incision, but no data are available to demonstrate a clear difference. **The type of ureterocele is a clear determinant of the outcomes of TUI with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision. Decompression with no reflux can be expected to be achieved in 70% to 80% of cases. Extravesical ureteroceles, however, are more likely to have persisting or new reflux and may require secondary surgery on the basis of the presence of reflux in 70% by some series.** In the meta-analysis by Byun and Mergurian (2006), the presence of lower pole reflux and the location of the ureterocele are similar in their impact on outcomes. In this analysis, the relative risk of reoperation was 1.74 times greater in the presence of reflux as without and 2.78-fold times higher if extravesical. These factors did not seem to be additive, suggesting they represented similar underlying causes. In comparison with an open approach of any modality, however, the simplicity of ureterocele incision coupled with the potential for definitive cure, even if not in a large fraction, is appealing. TUI also acts to better prepare the patient for a secondary major surgery if necessary, by decompressing dilated ureters.

Ureterostomy for Ectopic Ureter

The ectopic ureter presenting with sepsis or with massive dilation in a neonate may be best managed with a temporary end ureterostomy (el Ghoneimi et al, 1996). **This has the advantage of permitting acute decompression to manage sepsis and permit later assessment of any**

function in the affected renal unit before definitive management. By performing an end ureterostomy, the ureter can decompress and it is in position to be reimplanted if the renal unit is felt to be salvageable. No resection of redundant ureter is performed because this will shorten in time and some length will be necessary to perform the reimplantation. The stoma should be positioned at what would be the lateral end of a Pfannenstiel incision. Percutaneous ureterostomy has been reported as well (Bilen et al, 2006). Assessment of functional status is performed shortly before definitive surgery, usually in 4 months or after age 6 months. DMSA scanning is probably the most efficient means, but differential urine collection is an option as well. If there is no function appreciable, partial or total nephrectomy is performed with removal of the entire ureter to the stoma.

Ureteroureterostomy and Pyeloureterostomy

When the upper pole of either an ectopic ureter or ureterocele is to be maintained due to function or surgeon preference, pyeloureterostomy or ureteroureterostomy may be carried out. Both proximal and distal approaches may be used, and these have been described with open and laparoscopic techniques.

Open. **Ureteroureterostomy can be performed distally to create an anastomosis between the upper pole ureter to the lower pole ureter in an end-to-side fashion.** This can be done at the distal ureter via an inguinal, open approach (Huisman et al, 1987; Lashley et al, 2001; Chacko et al, 2007; Prieto et al, 2009). It is critically important in this type of procedure to correctly identify the recipient lower pole ureter, and it is strongly recommended to cystoscopically place a stent into the lower pole ureter at the start of the procedure. In the authors' experience, many of these reconstructive procedures have resulted in decreased dilatation of the upper urinary tract and improved function.

Other options to achieve this goal are the proximal anastomotic techniques of ureteroureterostomy or ureteropyelostomy. This results in the upper pole system's draining into the lower pole system. **Such high anastomoses may be preferable to a distal ureteroureterostomy with a dilated upper pole because the latter may have more urinary stasis with a distal anastomosis.** Whether the "yo-yo" phenomenon is clinically significant remains uncertain, but the authors prefer a proximal anastomosis when there is a significant mismatch in ureteral size.

When performing upper tract anastomoses, dissection should be limited to an absolute minimum, especially medially, to prevent disruption of either ureter's blood supply. The upper pole ureter may be considerably larger than the lower pole ureter. A generous longitudinal pyelotomy or ureterotomy made in the lower pole ureter is performed to overcome such disproportion, and the anastomosis is performed in an end-to-side fashion. The distal portion of the upper pole ureter should be aspirated with a feeding tube to decompress it. The distal upper pole ureter is resected as far inferiorly as possible, with care taken to stay directly on this ureter's wall and avoid the vasculature of the adjacent lower pole ureter. If there is no reflux, the resection is taken as distally as possible and the remnant lower portion of ureter may be left open. If reflux is present in an ectopic ureter, it should be taken as close to the bladder neck as possible. If associated with a ureterocele, it may be possible to avoid resection of the ureterocele as long as it is well decompressed.

Laparoscopic. Both ureteroureterostomy and pyeloureterostomy can be readily performed laparoscopically (Gonzalez and Piaggio, 2007; Steyaert et al, 2009), which is aided with robotic control (Kutikov et al, 2007; Smith et al, 2009). The author prefers stenting across the anastomosis, but others have indicated that this may not be necessary and only to stent the recipient ureter.

Key Points: Transurethral Incision of Ureterocele and Drainage Procedures

- The reported incidence of new reflux following TUI of a ureterocele ranges from 0% to 50% and may be dependent on the method used for incision.
- The type of ureterocele is a clear determinant of the outcomes of TUI with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision.
- TUI also acts to better prepare the patient for a secondary major surgery, if needed, by decompressing dilated ureters.
- Persisting reflux into the upper or lower poles is typically an indication for ureterocele excision and reimplantation.
- It has not been generally possible to predict with any accuracy in an individual how they might respond to a TUI based upon clinical parameters.
- The ectopic ureter presenting with sepsis or with massive dilation in a neonate may be best managed with a temporary end ureterostomy.
- Ureteroureterostomy can be performed distally or proximally to create an anastamosis between the upper pole ureter to the lower pole ureter in an end-to-side fashion.

Upper Pole Partial Nephrectomy

Upper pole removal, using a partial nephrectomy or heminephrectomy of a duplex system, is typically the preferred treatment when there is clearly no function in the upper pole and if there is concern about how effective a drainage procedure may be due to massive dilation. There are numerous series advocating one or another approach with variable results dependent upon factors such as degree of reflux, age, and underlying pathology, but there are no clear data to indicate that one approach is so definitively better as to be the universal choice.

The surgical methods for partial nephrectomy have been described and remain useful and similar whether being used with open surgery, conventional laparoscopy or robotic laparoscopy. These apply to both ectopic ureters and ureteroceles in duplex systems.

Open Partial Nephrectomy or Heminephrectomy

Heminephrectomy is a standardized procedure, with relatively little recent evolution (Mor et al, 1994), but several technical points deserve emphasis (Fig. 121–28). A flank approach for heminephrectomy usually offers better exposure to the upper pole vessels. The procedure may be performed through a dorsal lumbotomy approach, which is both effective and less morbid than a muscle-dividing flank incision. In older children this exposure can become less effective, however.

In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole. The kidney should be retracted gently so as not to cause any vascular injury through traction and spasm of small vessels. Transecting the upper pole ureter and placing a traction stitch on the proximal portion of this ureter affords the surgeon a good method of retraction and

manipulation of the upper pole. Once at the pedicle, dissection of the ureter both below and above the vessels allows for easier, safer freeing of the ureter. The ureter is passed behind the main renal vessels. The dissection around the renal vessels should be done carefully to avoid damage to the lower pole. The upper pole vessels (most often two to three in number) are sequentially ligated. Demarcation of the upper pole parenchyma becomes apparent after the upper pole vessels are ligated. Stripping the capsule off the upper pole in continuity allows it to be used in the closure. Several mattress sutures incorporating a pedicle of retroperitoneal fat are used for closure.

During upper pole nephrectomy, atraumatic clamping of the renal pedicle can be used, enabling work in a bloodless field. Administration of an intravenous osmotic diuretic (e.g., mannitol) moments before and after clamping of the pedicle helps prevent acute tubular necrosis. Topical vasodilating agents (e.g., papaverine) should be available in case vasospasm occurs. In general, vascular control is not essential in upper pole partial nephrectomy as the polar vessels may be identified and controlled. Resection of the upper pole renal tissue can then be carried out with electrocautery or other cutting device.

When performing the upper pole ureterectomy, it is of utmost importance to maintain the dissection immediately on the wall of the upper pole ureter as much as possible to preserve the blood supply to the remaining lower pole ureter.

If, in addition to obstruction, there is concomitant reflux into the ectopic ureter, some recommend a second incision (i.e., a Gibson incision) to resect the ureter in its entirety. Care must be taken to avoid injury to the vas deferens in male patients. As mentioned previously, dissection should be performed strictly along the wall of the upper pole ureter. To prevent complications that may arise from dissection within a common sheath of two ureters (especially distally), the back wall of the upper pole ureter can be left attached to the lower pole ureter. The remainder of the upper pole ureter should be removed (Fig. 121–32). Such a maneuver prevents damage to the lower pole ureteral blood supply, which courses between both ureters. Resection is carried out to the level of the bladder, where several vesicle sutures are placed to close the upper pole ureteral hiatus.

Other surgeons are comfortable ligating the distal refluxing ureteral stump and leaving it in situ with few subsequent problems attributed to the small volume of reflux into that stump (Cain et al., 1998; Kim et al., 2001). The refluxing, obstructed ectopic ureter raises the most concern regarding a later infection and as much of the ureter should be removed as is possible without injury to the bladder neck.

A Penrose drain (brought through a separate stab wound or at the edge of the incision) is placed in such a fashion as to drain the renal fossa and the area of the ureteral dissection. **Postoperative evaluation is best performed with a Doppler sonogram to demonstrate normal postoperative anatomy, absence of a urinoma, and normal blood flow to the lower pole.** Optionally, a functional study such as a nuclear renal scan may be performed if there is concern regarding viability of the lower pole.

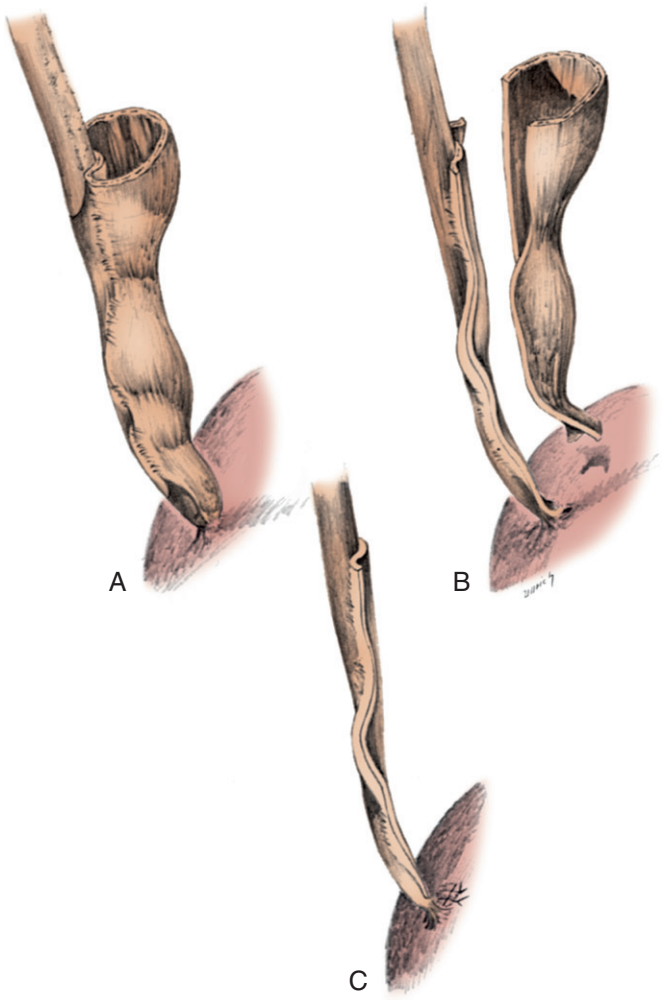

Figure 121–32. Surgical management of the refluxing ureteral stump. **A,** It is difficult to completely separate the distal 2 to 3 cm of the upper pole ureter from the lower pole ureter. The ectopic ureter is excised to this point. **B,** The outer wall of the ectopic ureter is excised to the bladder level. **C,** A transfixing suture obliterates its lumen, with care being taken not to injure the orthotopic ureter.

Laparoscopic Partial Nephrectomy

Another surgical option is laparoscopic nephrectomy or heminephrectomy. This can be done by either a transabdominal or a retroperitoneal approach, and robotic assistance is now available. Laparoscopic procedures may offer reduced morbidity with less postoperative pain, earlier return of gastrointestinal function, earlier discharge home, and presumably a quicker return to work for the parents (Jordan & Winslow, 1993; Janetschek et al, 1997; El-Ghoneimi et al, 1998; Wang et al, 2004; Lee et al, 2005; Wallis et al, 2006; Lee et al, 2009; You et al, 2009). Other advantages include enhanced visualization and increased magnification of the operative field, improved cosmesis, and avoidance of a second incision that is often needed for the distal ureterectomy of a nephroureterectomy.

Laparoscopic heminephrectomy can be performed in very small infants, and the operative time has decreased as experience and skill have increased (El-Ghoneimi, 2003; Wang et al, 2004; Sydorak and Shaul, 2005; Piaggio et al, 2006). Equipment such as the LigaSure device (Valleylab, Boulder, CO) and the Harmonic Scalpel (Ethicon EndoSurgery, Cincinnati, OH) allow for resection of the upper pole in a bloodless field.

Some authors believe that cystoscopic placement of a ureteral catheter allows for easier identification of the ureter at the time of laparoscopy (Yao & Poppas, 2000). The authors have not felt this to be essential given the usual marked size difference in the ureters.

Laparoscopic heminephrouretectomy begins similarly to the open procedure in that the pathologic ureter is grasped as a handle and dissected closely to its wall to avoid compromise of the blood supply to the normal ureter. The upper pole ureter is passed behind the vessels and used to facilitate dissection of the upper pole. The polar renal vessels are then ligated with clips or divided with electrocautery; this allows for a more discernible demarcation of the affected upper pole (Fig. 121–33A). The plane between the upper pole collecting system and the upper parenchyma of the lower pole is developed bluntly to facilitate identifying and transecting the upper pole attachments to the lower pole (Fig. 121–33B). After the polar element is removed with electrocautery, one can check for collecting system leakage with intravenous injection of methylene blue (Yao and Poppas, 2000). Janetschek and colleagues place fibrin glue and hemostatic agents on the cut surface and then cover it with Gerota fascia to aid in hemostasis (Janetschek et al, 1997). The authors have not used these agents, but have closed the defect over a pedicle of local fatty tissue (Fig. 121–33C).

When performing a partial nephrectomy, robotic-assisted laparoscopy offers advantages over standard laparoscopy (Lee et al, 2009). The magnification is augmented and the dexterity of the robotic instruments allows for greater precision when working around the renal pedicle and controlling the upper pole vessels, as well as the visual advantages of a 3-dimensional image. Patient and port positioning is the same as for pyeloplasty. Vascular control may be by absorbable or metal clips or even with suture ties. The latter may be preferable by reducing the risk of avulsing a clip during later dissection. The defect is usually closed with a tongue of retroperitoneal fat laid into the defect, which is then closed with 2 or 3 mattress sutures of 3-0 PDS or Vicryl.

Laparoendoscopic single-site ("LESS") nephrectomy has been described for a single-system ectopic ureter. This technique represents the newest horizon for minimally invasive surgery as only one 22-mm multitrocar port site (recessed in the umbilicus) is used to perform the entire surgery (Park et al, 2009).

Outcomes

Results of upper pole removal for ectopic ureters and ureteroceles are generally very good, but this must be integrated with the overall clinical decision making. This is rarely any problem with ectopic ureters, as the residual stump is rarely problematic. In cases of ureteroceles in which lower pole reflux is present, resolution may be expected in up to 20% (Husmann et al, 1999), **and new reflux may be seen in 15% to 50% of those where no reflux was present preoperatively.** The overall secondary

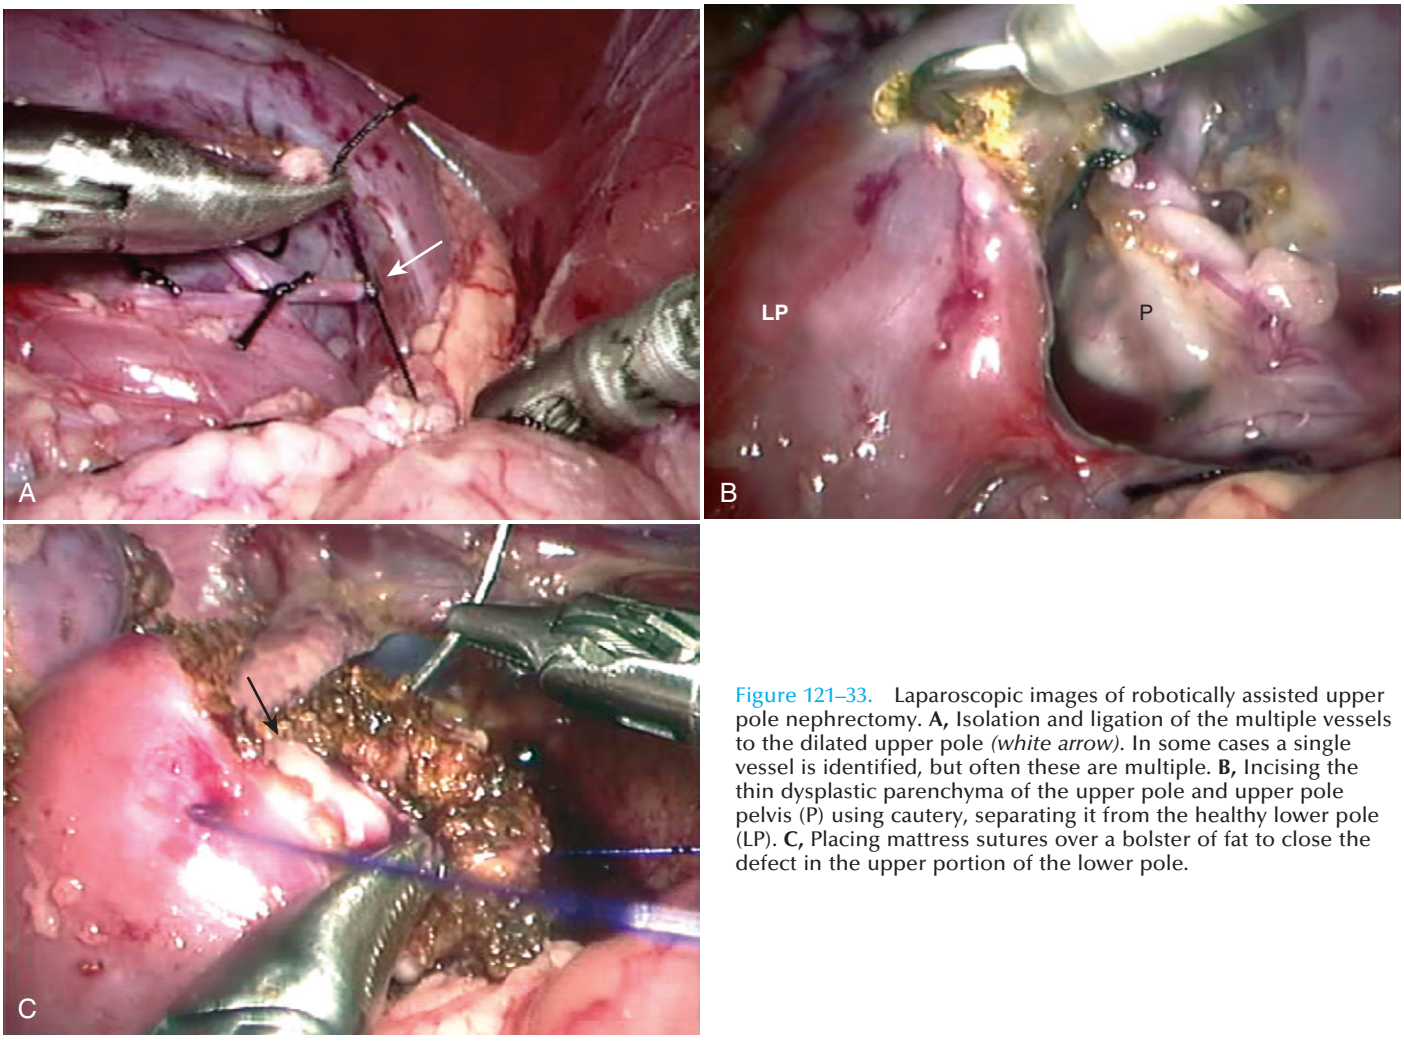

Figure 121–33. Laparoscopic images of robotically assisted upper pole nephrectomy. **A,** Isolation and ligation of the multiple vessels to the dilated upper pole *(white arrow)*. In some cases a single vessel is identified, but often these are multiple. **B,** Incising the thin dysplastic parenchyma of the upper pole and upper pole pelvis (P) using cautery, separating it from the healthy lower pole (LP). **C,** Placing mattress sutures over a bolster of fat to close the defect in the upper portion of the lower pole.

surgery rate after primary upper pole nephrectomy for ureterocele is between 35 and 45% based on the literature. The difficulty in interpreting the literature rests in variable indications for secondary surgery. In some, reflux was simply followed and within the short follow-up did not cause any problems, while in others it was felt that removal of a nonfunctioning upper pole was necessary. Neither of these approaches has been validated by long-term data.

Complications

Complications related to heminephrectomy include loss of lower pole function (Mandell et al, 1980; Wallis et al, 2006; You et al, 2009) and development of postoperative upper pole urinomas (Valla et al, 2003; You et al, 2009). Loss of function may be a long-term issue and may not be recognized immediately. Clinical signs of fever, increasing pain, and hematuria may be evident in the first week after surgery. Urinomas have been reported mostly in series in which there is no formal closure of the polar defect. Whether these urinomas are due to injury to the lower pole or remnant upper pole is unclear. Urinomas, if causing no symptoms and not expanding, can be observed. Other less common problems can include inferior vena cava laceration, duodenal perforation and total nephrectomy, and peritoneal tears (if done via the retroperitoneum).

Key Points: Upper Pole Nephrectomy

- In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole.
- Postoperative evaluation is best performed with a Doppler sonogram to demonstrate normal postoperative anatomy, absence of a urinoma, and normal blood flow to the lower pole.
- Definitive cure by partial nephrectomy for ectopic ureters is generally successful because the residual stump is rarely problematic.
- In ureteroceles in which lower pole reflux is present, resolution may be expected in up to 20%, and new reflux may be seen in 15% to 50% of those where no reflux was present preoperatively.
- Complications related to heminephrectomy include loss of lower pole function and development of a postoperative upper pole urinoma.
- Separation of the duplicated ureters during intravesical dissection should be discouraged because it can lead to injury of the common blood supply running longitudinally between the two ureters.

Ureterocele Excision and Common-Sheath Reimplantation

The intravesical approach to the ureterocele begins with a transverse incision of the ureterocele between two stay sutures (Figs. 121–34 and 121–35A). Proximally, a plane is obtained between the ureterocele wall and the wall of the bladder. The ureterocele is dissected off the bladder to the point at which it joins the lower pole ureter. Then the two ureters are dissected as a unit, the upper pole ureter is tapered as needed, and both ureters are reimplanted submucosally. Amar (1978) advocated submucosal saline injection to facilitate creation of the submucosal tunnel. The distal portion of the ureterocele is dissected in the same plane (Fig. 121–35B) to the level of the bladder neck, where it is resected. The detrusor muscle is plicated if it is attenuated, and it appears that it may offer insufficient backing. Bladder mucosal flaps are raised to cover the area of the removed ureterocele (Fig. 121–35C).

Once again, several technical points regarding ureterocele excision and common sheath reimplantation deserve mention. **Separation of the duplicated ureters during intravesical dissection should be discouraged because it can lead to injury of the common blood supply running longitudinally between the two ureters.** Plication of the detrusor muscle underlying the ureterocele may be necessary to reinforce any areas of muscle deficiency. Furthermore, **the distal portion of the ureterocele may extend below the bladder neck. Extreme care must be taken in this part of the dissection to avoid injury to the sphincter mechanisms. If the entire ureterocele cannot be excised, it can be fulgurated carefully and closed over with two layers.**

Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting as a "wind sock" behind the urethra. Options include resection by gentle retraction of the ureterocele if it is not large, closure of the opening with two layers of tissue, or fulguration of the lumen to cause collapse and closure. Careful postoperative assessment is necessary in any case to identify what can be progressive voiding dysfunction if the remnant cecoureterocele creates obstructive voiding (Fig. 121–36).

An alternative approach to ureterocele resection is that of marsupialization in which the thin intravesical aspect is removed and the edge is sutured. No attempt is made to reinforce the back wall on the basis of empirical observation that this is not always necessary. Reported results have been satisfactory (Scherz et al, 1989; Lewis et al, 2008). Although this eliminates the need to dissect out the ureterocele and avoids injury to the underlying vagina, it is the authors' impression that this approach has inherent risks that can be avoided by a controlled and predictable surgical approach of trigonal reconstruction. A major problem with marsupialization may be rare, but it seems preferable to definitively correct the anatomic and functional defect on the first open operation when necessary.

Reported results of ureterocele excision and common sheath reimplantation are good, although persisting reflux can be an issue in 5% to 10% of cases. This may be more common when ureteral tapering is necessary. Although in some reports it is claimed that these patients do not require surgery, persisting reflux in this context must be viewed with caution.

Total Reconstruction

Total reconstruction of both upper and lower tracts has been advocated by some authors as being the most definitive procedure for ureteroceles (Hendren and Mitchell, 1979; Kroovand and Perlmutter, 1979). **Upper pole nephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive, but is an extensive operation performed with two incisions.** Although the reported success rates are good, it remains uncertain if this is appropriate in most children when long-term relief from obstruction and reflux may be achieved in one or at most two lesser procedures. No clear clinical situations have been reported to be such that two procedures are always

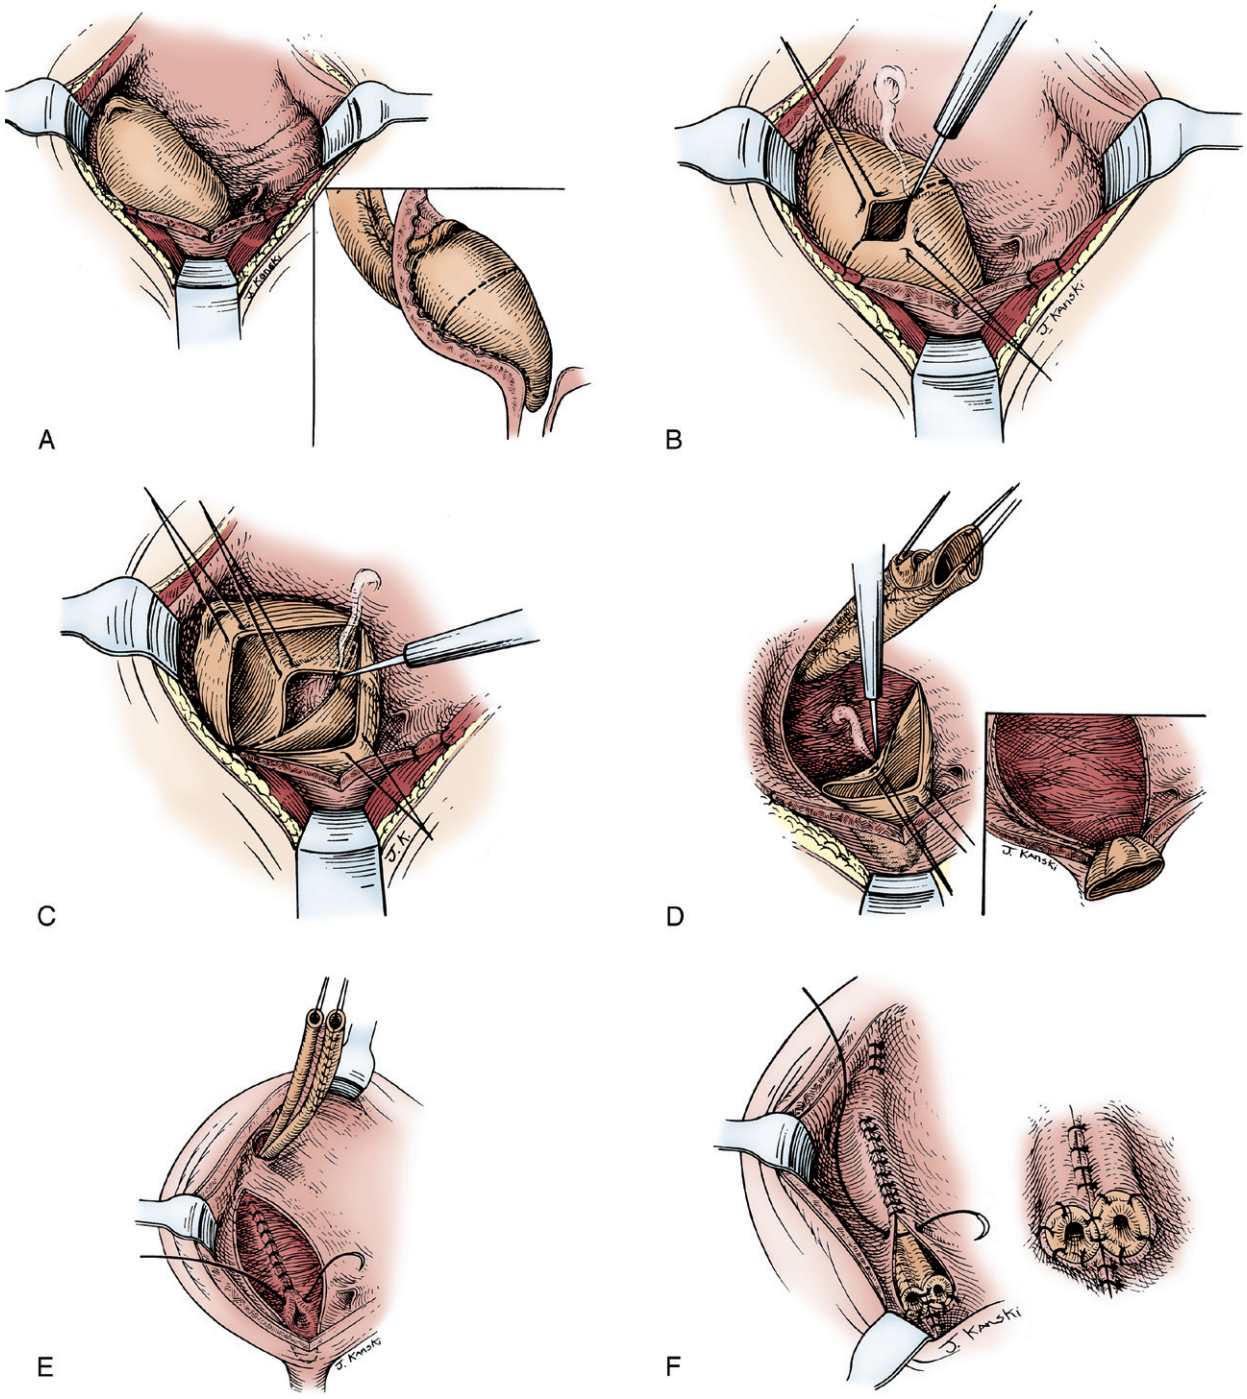

Figure 121–34. Technique for excision of ectopic ureterocele and common sheath reimplantation of upper and lower pole ureters. **A,** Appearance of right-sided ureterocele with open bladder, viewed from below. Note proximity of the contralateral ureteral orifice. *Inset,* Cutaway side view demonstrating the close association of the two polar ureters with a common vascular supply. The *dotted line* indicates the planned initial incision of the ureterocele. **B,** After stay sutures are placed, the ureterocele is incised with electrocautery in a transverse direction, exposing the inner cavity of the ureterocele. **C,** The posterior mucosal wall of the ureterocele is incised transversely, revealing the often thinned posterior muscular wall of the bladder. This incision will then be continued around the bladder mucosal edge of the ureterocele including the orifice of the lower pole ureter. Stay sutures are important to provide adequate exposure. **D,** The upper and lower pole ureters have been mobilized and are retracted into the bladder. The distal aspect of the ureterocele is being mobilized in a similar fashion. The bladder mucosal surface will also be incised around the edge of the ureterocele to permit complete removal of the ureterocele. *Inset,* The fully mobilized distal ureterocele is retracted caudally, revealing its narrowing attachment at the bladder neck. **E,** The dilated upper pole ureter associated with the ureterocele has been tapered and remains in continuity with the lower pole ureter. Both have been brought into the bladder through a newly formed muscular hiatus to provide adequate tunnel length for the ureteral reimplantation. The thinned-out posterior bladder wall has been repaired with multiple interrupted sutures to provide adequate muscular backing for the ureters. The bladder mucosa surrounding the ureterocele defect has been mobilized to permit covering of the ureters. **F,** *Left,* the ureters have been reimplanted into the new ureteral tunnel, have been sutured distally after spatulation, and are being covered with bladder mucosa. The lower pole orifice is medial. *Right,* Final appearance of the ureteral tunnel after completion of the reimplantation.

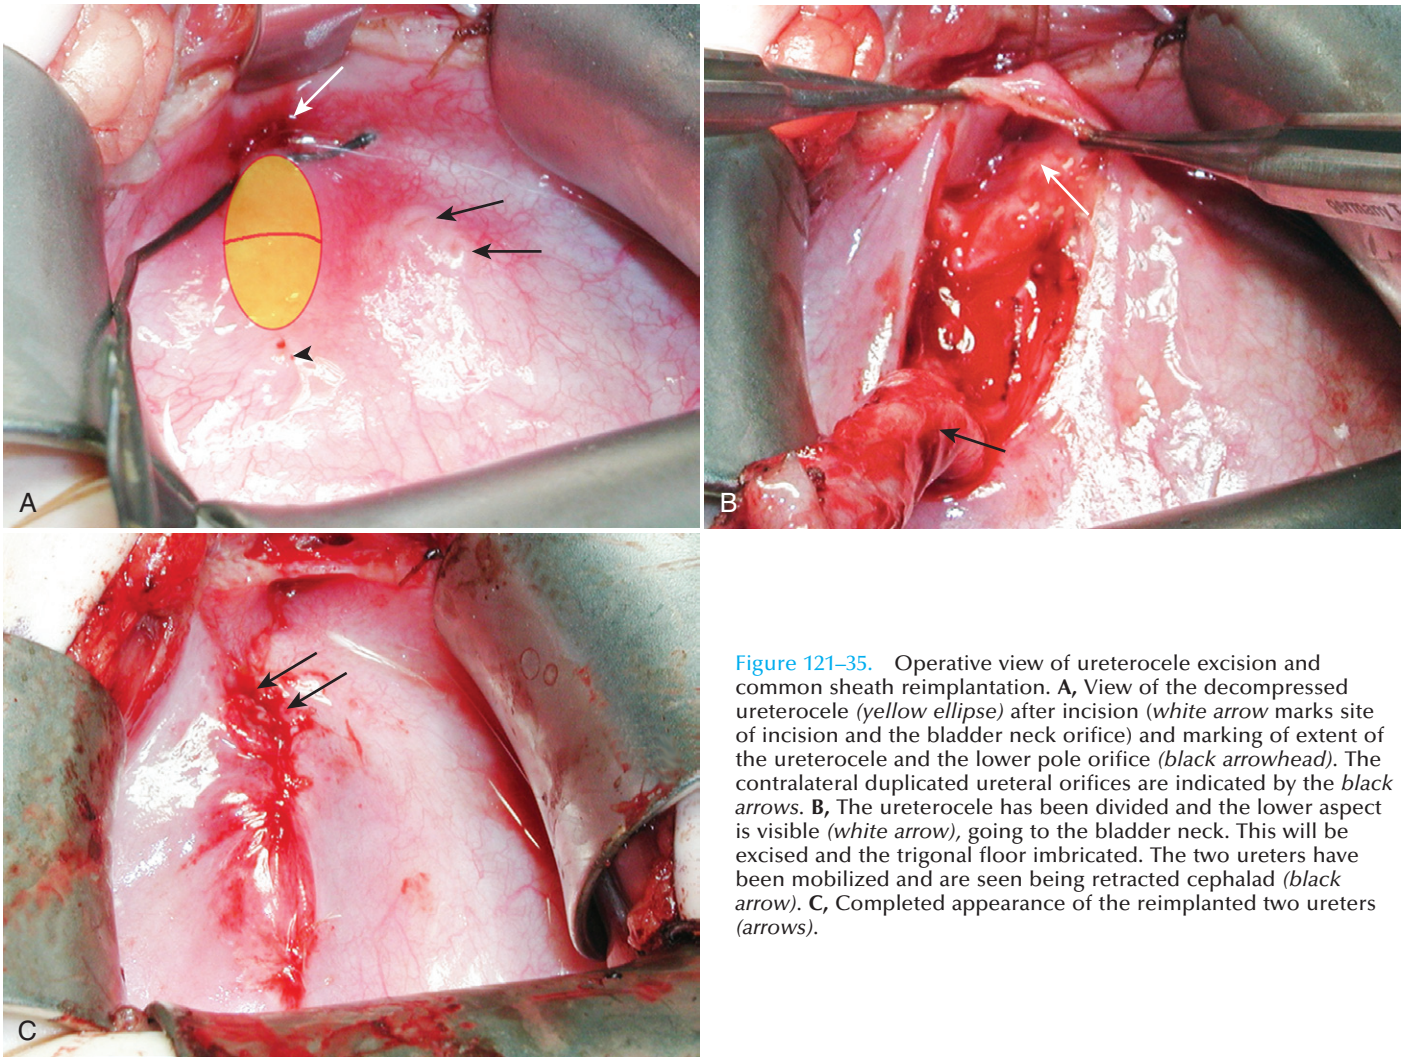

Figure 121–35. Operative view of ureterocele excision and common sheath reimplantation. **A,** View of the decompressed ureterocele *(yellow ellipse)* after incision (*white arrow* marks site of incision and the bladder neck orifice) and marking of extent of the ureterocele and the lower pole orifice *(black arrowhead)*. The contralateral duplicated ureteral orifices are indicated by the *black arrows*. **B,** The ureterocele has been divided and the lower aspect is visible *(white arrow)*, going to the bladder neck. This will be excised and the trigonal floor imbricated. The two ureters have been mobilized and are seen being retracted cephalad *(black arrow)*. **C,** Completed appearance of the reimplanted two ureters *(arrows)*.

Key Points: Ureterocele Excision and Reimplantation

- Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting as a "wind sock" behind the urethra.
- An alternative approach to ureterocele resection is that of marsupialization in which the thin intravesical aspect is removed and the edge is sutured.
- Results of ureterocele excision and common sheath reimplantation are good, although persisting reflux can be an issue in 5% to 10% of cases.
- Total reconstruction including upper pole nephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive but is an extensive operation performed with two incisions.

required, and if TUI is the first procedure, it is not comparable with either an upper or lower tract procedure. The older child with a massive ureterocele and no function of an upper pole with significant lower pole reflux might be reasonably treated with upper pole nephrectomy, ureterocele excision, and bladder reconstruction. At present, the partial nephrectomy would be reasonably performed laparoscopically with a lower Pfannenstiel incision for the bladder reconstruction and reimplantation. This is an unusual clinical scenario.

CLINICAL DECISION MAKING SUMMARY

For ectopic ureters, clinical decision making is much more straightforward than for ureteroceles and rests on whether to maintain the upper pole of a duplex system. If this is chosen, then the surgical approach depends on the presence of reflux in the lower pole; if present, a common sheath reimplantation or a lower pole reimplantation with distal upper to lower pole ureteroureterostomy is performed. If there is no lower pole reflux, either proximal or distal ureteroureterostomy is performed. If the degree of function is ambiguous, a temporary end ureterostomy can be used to permit assessment out of the acute setting, particularly with a massively dilated ureter. Also, if reflux is present, the need for lower surgery to correct the reflux may influence the choice to avoid upper tract surgery. If removal of the upper pole is chosen on the basis of the degree of dilation or the preference for removal of nonfunctioning, dysplastic tissue, an upper pole nephrectomy is performed.

For the single-system ectopic ureter, preservation or removal is also based on degree of function and surgeon preference. No objective outcome data are available to advocate clearly for one or another approach.

For a ureterocele in a duplex system, the availability of endoscopic incision creates more options (Table 121–1) (Fig. 121–37). It is important to recognize that although TUI is an "operation," it is of a totally different nature than either an upper pole nephrectomy or a lower tract reconstruction. It is inappropriate to equate them as an "operation" in a comparative manner. **It has not been generally possible to predict with any accuracy in an individual how they might respond to a TUI on the basis of clinical parameters.** Because in some cases, significant lower pole reflux and upper tract dilation may be treated with a brief outpatient procedure with documented long-term results, it would seem reasonable to offer that option before moving directly to a more complex upper or lower tract reconstruction. **Even if half of those cases may need subsequent surgery, it can be safely deferred until the child is older. There is also the further appeal of TUI in that it may make a subsequent surgical procedure less complex by decompressing a dilated upper pole ureter.** Reimplantation may be much more effective and not require excisional tapering. This lessens overall morbidity, another goal of management. The appeal of TUI

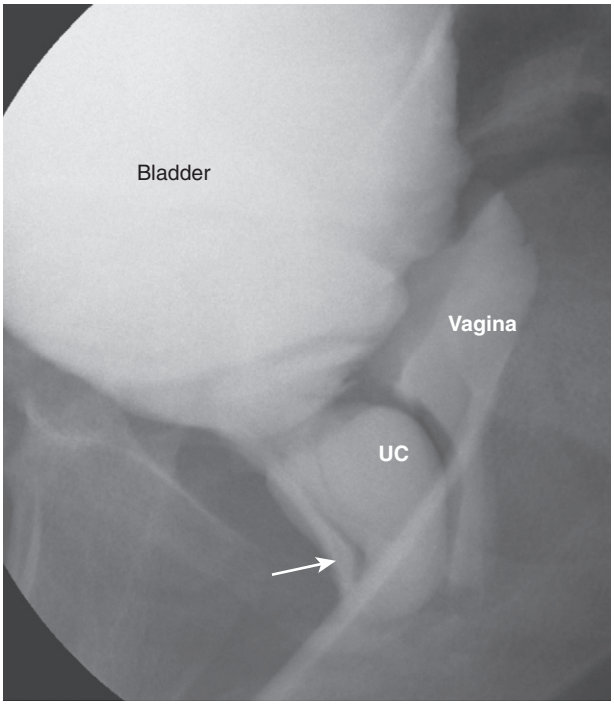

Figure 121–36. Voiding cystourethrogram appearance of a large cecoureterocele (UC) extending down the urethra and causing bladder outlet obstruction with voiding. The ureterocele fills, acting like an obstructive wind sock. The lumen of the urethra is marked with the *arrow*.

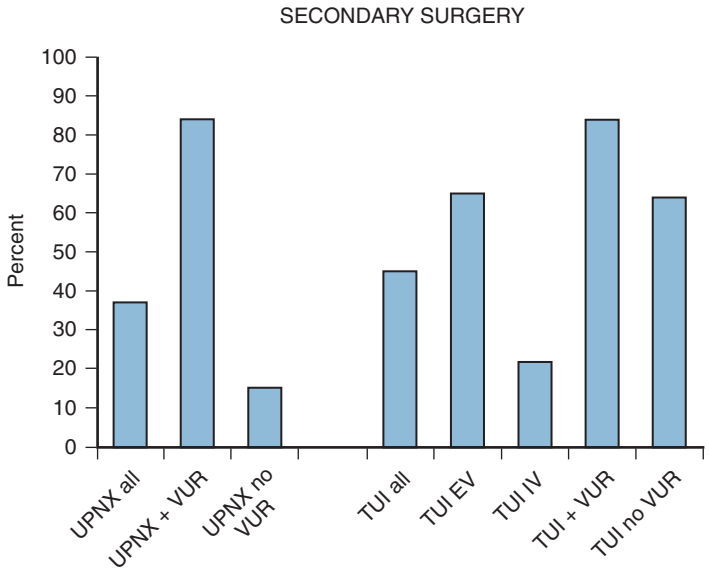

Figure 121–37. Chart showing incidence of secondary major surgery for patients with ureterocele following either transurethral incision or partial nephrectomy. The specific incidences are also shown when reflux is present or absent. Data are based on multiple reports as indicated in Table 121–1. EV, extravesical; IV, intravesical; TUI, transurethral incision; UPNX, upper pole nephrectomy; VUR, vesicoureteral reflux.

Table 121–1.

Options for Ureterocele Management

PROCEDURE	IDEAL INDICATIONS	ADVANTAGES	LIMITATIONS
Transurethral incision	Infant Large ureterocele with VUR	Outpatient procedure, effective decompression Occasionally definitive	May produce reflux into ureterocele segment, requiring bladder surgery
Upper pole nephrectomy	Older patient Large nonfunctioning upper pole No VUR	May be definitive Removes pathology Avoids bladder level surgery	May not be definitive Significant surgery Risk to lower pole May still require lower surgery in bladder
Ureteroureterostomy or ureteropyelostomy	Older patient Functioning upper pole No VUR	Drains obstructed segment with little risk of obstruction or UTI	Leaves ureterocele in bladder May develop reflux
Ureterocele excision and common sheath reimplantation	Reflux Functioning upper pole without significant dilation	Eliminates obstruction and reflux, removes ureterocele No renal risk	Complex surgery Risk to vagina and bladder neck May require ureteral tapering

UTI, urinary tract infection; VUR, vesicoureteral junction.

may therefore be less in the older child presenting with a massive upper pole in whom removal may be preferable and definitive surgery can be performed at diagnosis.

OTHER URETERAL ANOMALIES

Anomalies of Number

Bifid Ureters

Ureteral duplication may be associated with ectopia or a ureterocele but is also compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication. Ureteral duplication is a common condition, described in approximately 1 in 125 (0.8%) people on the basis of autopsy series, which tend to be less selective (Nation, 1944). There is a slightly higher incidence in females, estimated to be approximately 1.6:1. Duplication is unilateral six times more than it is bilateral; however, **it is clinically prudent to carefully look for contralateral duplication when unilateral duplication is documented.** This may be critical in the setting of nonhydronephrotic upper poles and ureteral ectopic causing incontinence. Right and left sides appear to be affected similarly with unilateral duplication (Table 121–2).

A bifid renal pelvis includes only a single ureter, but confluence of the upper and lower ureters lower than the UPJ constitutes partial duplication of the ureter or bifid ureter.

An increased incidence of ureterorenal pathology has been documented with duplication anomalies. The clinical implication of duplication depends largely on the ureteral insertion. A useful clinical rule is to consider that **conditions that routinely affect the single-system kidney are those that affect the lower pole including UPJ obstruction and VUR. The upper pole is more likely affected by conditions due to abnormal ureteral formation including ectopia and ureterocele,** as previously discussed.

Lower pole UPJ obstruction (UPJO) evaluation and management are similar to a single-system UPJO. Lower pole UPJO may be identified with partial and complete ureteral duplication. Recognition of the presence of the duplication may be challenging with massive hydronephrosis, but in most cases the normal upper pole will be identified on functional imaging such as a renal scan, even if not detected on US. MRI can help clarify the anatomy in these cases. Lower pole UPJO may resolve spontaneously, just as a single system with comparable severity of dilation. Repair may be optionally accomplished using a pyeloureterostomy of the dilated renal pelvis of the lower pole to the normal upper pole ureter (Ulchaker et al, 1996; VanderBrink et al, 2009).

Upper pole UPJO has been reported including in association with lower pole UPJO but is exceptionally rare (Jain et al, 2008).

Hydronephrosis of the lower pole moiety may also represent VUR, and this is often of high grade. The presence of a dilated ureter on ultrasonographic evaluation will usually be present. This rarely represents ureterovesical obstruction and more often indicates VUR. Lower pole VUR is often associated with significant functional reduction in the lower pole, which is usually congenital but may also be associated with prior infection. Evaluation and management are similar to reflux into a single system, but spontaneous resolution may be more delayed (Afshar et al, 2005). Common sheath ureteral reimplantation and endoscopic injection are surgical options, as well as low ureteroureterostomy of the refluxing lower pole ureter to the upper pole ureter. Lower pole reflux associated with severe hydronephrosis and scant lower pole function may necessitate lower pole nephrectomy.

Triplication

Triplication of the ureter, either complete or partial, is rare. These conditions typically have presented with infection or wetting. The classification by Smith, in which triplex ureters are divided into four types, remains useful (Smith, 1946). Type 1 constitutes three entirely separate ureters with unique attachment to the bladder or distally and accounts for 35% of triplications. Type 2 is an incomplete separation with two ureteral orifices, occurring in 21%. Type 3 is a trifid ureter with a single ureteral orifice, seen in 31%, and type 4 describes two ureters with three orifices. This occurs with an inverted Y bifurcation. The positioning of the ureteral orifices generally follows the Weigert-Meyer law (Zaontz and Maizels, 1985).

The ureters may be associated with ureteroceles (Park, 2008) and may be ectopic to the bladder neck, urethra, or vagina (Engelstein et al, 1996; Patel et al, 2001). Lower and midpole (Sivrikaya et al, 2007) ureteropelvic junction obstruction may be present, as well as ureterovesical obstruction (Merlini, 1983). VUR is also described (Ander et al, 1997), as well as contralateral duplication (Srivastava et al, 1996). Fusion anomalies may be present in some (Pode et al, 1983; Golomb and Ehrlich, 1989).

Quadruple Ureters

Even more rare is ureteral quadruplication with only eight cases reported. Most have been in adults, but three recent cases included four ureters draining into a large ureteral cyst and connecting to the bladder through a single ureter (Klinge et al, 2001; Vicentini et al, 2007; Koszutski et al, 2008). One report of a young adult presenting with incontinence defines three of the four ureters merging and entering the bladder orthotopically and the fourth ureter drained to the perineum. This ectopic ureter was associated with the lower midcalyx, contrary to what the Weigert-Meyer law would predict.

Fibroepithelial Polyps

Polyps of the ureter may present clinically with flank pain, hematuria, or by incidental detection of hydronephrosis. The most common site of attachment is at the UPJ, although polyps may originate from any part of the ureter. As a cause of UPJ obstruction, they are uncommon, reported as 0.5% of all UPJ cases undergoing pyeloplasty (Adey et al, 2003). A large majority were male (89%) and on the left side (78%). They are uncommonly bilateral, but this has been reported with clinical effects on both kidneys (Bartone et al, 1990; Lavelle et al, 1997; Bhalla et al, 2002; Adey et al, 2003). In a recent series, two of nine patients had bilateral clinically obstructive UPJ polyps. They may also be multiple. The authors have seen one case in which the polyp protruded from the urethra and produced severe voiding symptoms. The polyp was ultimately found to originate from the proximal third of the ureter.

Smaller polyps may not be evident on modern imaging, and in a recent series they were detected in 22% of cases preoperatively for UPJ obstruction (Adey et al, 2003). They would usually be seen on intravenous pyelography but may be mistaken for ureteral blood clots, particularly in the setting of hematuria (Fig. 121–38). Filling defects on retrograde pyelography in anticipation of a pyeloplasty should trigger a search for the polyps. It is unlikely that this would alter the surgical approach unless the polyp was significantly distal to the UPJ.

Key Points: Other Ureteral Anomalies

- Ureteral duplication is compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication.
- It is clinically prudent to look for contralateral duplication when unilateral duplication is documented.
- An increased incidence of ureterorenal pathology has been documented with duplication anomalies.
- Conditions routinely affecting a single-system kidney are those that affect the lower pole including UPJ obstruction and VUR. The upper pole is more likely affected by conditions due to abnormal ureteral formation including ectopia and ureterocele.
- Polyps of the ureter may present clinically with flank pain, hematuria, or by incidental detection of hydronephrosis.
- The most common site of attachment of fibroepithelial polyps is at the ureteropelvic junction, although they may originate from any part of the ureter.
- UPJ polyps are best treated with pyeloplasty, although the question of whether endoscopic resection might suffice is not settled.
- Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ.

The etiology of fibroepithelial polyps is unclear, although progressive traction due to ureteral peristalsis may promote edema and growth. The senior author has seen one in which the ureter was being intussuscepted into itself due to traction on the polyp in the midureter. Histologically, they are considered benign neoplasms with fibroepithelial and vascular elements, with overlying normal to hypertrophied urothelium. There is usually a fibrovascular core with significant stromal edema. Little inflammation is seen.

Management of the polyp is dictated by the presentation and location. **For polyps at the UPJ, most have undergone pyeloplasty, although the question of whether simple endoscopic resection might suffice is not settled because there are too few cases. Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ on the basis of combined adult and pediatric reports** (Minevich et al, 2005; Childs et al, 2009). Earlier reports advocated sleeve resection and reanastomosis of the ureter to prevent recurrence, yet the persisting success with ureteroscopic resection would suggest that to be unnecessary. Even earlier reports recommended nephrectomy, which cannot be justified.

ANOMALIES OF POSITION

Vascular Anomalies Involving the Ureter

A variety of vascular lesions can cause ureteral obstruction. With these lesions, the vascular system rather than the urinary system is anomalous. With the exception of accessory renal blood vessels, all of these lesions are relatively uncommon, although all have clinical relevance.

Preureteral Vena Cava

Anatomy

This anomaly is commonly known to urologists as circumcaval or retrocaval ureter, terms that are anatomically descriptive but misleading in regard to development (Lerman et al, 1956; Dreyfuss, 1959). **The term *preureteral vena cava*** emphasizes that the circumcaval ureter results from altered vascular, rather than ureteral, development. This is the more accurate term.

This disorder involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding about and crossing in front of it from a medial to a lateral direction, to resume a normal course, distally, to the bladder. The renal pelvis and upper ureter are typically elongated and dilated in a J or fishhook shape before passing behind the vena cava. The collecting system is not inevitably obstructed. Circumcaval ureters can be classified into two clinical types (Bateson and Atkinson, 1969; Kenawi and Williams, 1976): (1) the more common type 1 has hydronephrosis and a typically obstructed pattern demonstrating some degree of fishhook-shaped deformity of the ureter to the level of the obstruction and (2) type 2 has a lesser degree of hydronephrosis or none at all. Here, the upper ureter is not kinked but passes behind the vena cava at a higher level, with the renal pelvis and upper ureter lying almost horizontal before encircling the vena cava in a smooth curve. In type 1, the obstruction appears to occur at the edge of the iliopsoas muscle, at which point the ureter deviates cephalad before passing behind the vena cava.

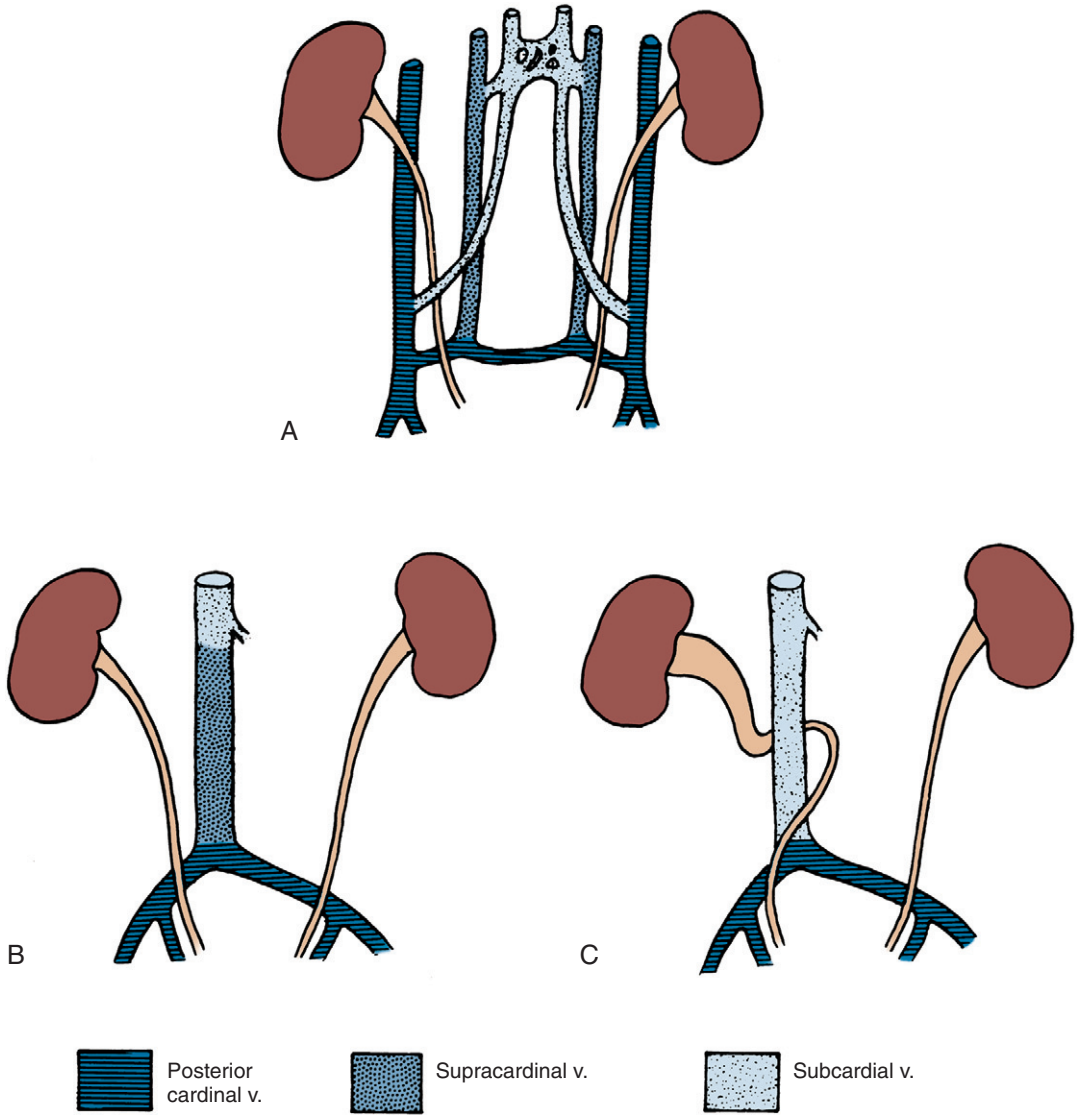

Figure 121–39. Fetal venous ring **(A)**, normal vena cava **(B)**, and preureteric vena cava **(C).** (Redrawn from Hollinshead WH. Anatomy for surgeons, vol 2. New York: Hoeber Medical Division of Harper and Row; 1956.)

Embryology

The definitive inferior vena cava develops on the right side from a plexus of fetal veins (Fig. 121–39). Initially, the venous retroperitoneal pathways consist of symmetrically placed vessels, both central and dorsal. The posterior cardinal and supracardinal veins lie dorsally, and the subcardinal veins lie ventrally. These channels, with their anastomoses, form a collar on each side through which the ascending kidneys pass. Normally, the left supracardinal veins and the lumbar portion of the right posterior cardinal vein atrophy. The subcardinal veins become the internal spermatic veins. The definitive right-sided inferior vena cava forms from the right supracardinal vein. **If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.**

When the definitive vena cava forms normally and the ventral portion of the primitive ring also persists, a double right vena cava is formed because of the persistence of both the right subcardinal vein dorsally and the right subcardinal vein ventrally. This double vena cava traps the right ureter between its limbs (Sasai et al, 1986).

Although bilateral vena cava or left-sided vena cava can occur (Clements et al, 1978; Mayo et al, 1983), a bilateral circumcaval ureter has been described in a case of situs inversus (Brooks, 1962). In cases of bilateral vena cava associated with a circumcaval ureter, the circumcaval ureter has been reported only on the right side, denoting that the right vena cava developed abnormally from a persistent subcardinal vein, whereas the left vena cava developed from the left supracardinal vein but otherwise normally (Pick and Anson, 1940).

Incidence

The incidence of preureteral vena cava at autopsy is about 1 in 1500 (Heslin and Mamonas, 1951), and the anomaly is three to four times more common in male than female cadavers. A literature review reported a ratio of 114:41 males to females (2.8:1) (Kenawi and Williams, 1976).

The symptoms of preureteral vena cava are those of obstruction. **Although the lesion is congenital** (Soundappan and Barker, 2004; Acharya et al, 2009)**, most patients do not present until the third or fourth decade of life** (Kenawi and Williams, 1976).

Diagnosis

Clinically, patients may present with symptoms of flank or abdominal pain or infection or the disorder may be discovered incidentally during other radiologic tests. Excretory urography often fails to visualize the portion of the ureter beyond the J hook (i.e., extending behind the vena cava), but retrograde ureteropyelography demonstrates an S curve to the point of obstruction with the retrocaval segment lying at the level of L3 or L4 (Kenawi and Williams, 1976). Cavography is no longer a necessary diagnostic test.

US (Murphy et al, 1987) and CT or MRI have also been useful in defining the vascular malformation. CT urography may be the procedure of choice to confirm the diagnosis and avoid retrograde ureteropyelography (Sasai et al, 1986; Kellman et al, 1988). Nuclear renal furosemide scanning can categorize the anomaly as obstructed or nonobstructed (Pienkny et al, 1999). **MRI can demonstrate the course of a preureteral vena cava and may be a more detailed and less invasive imaging modality when compared with CT and retrograde pyelography** (Uthappa et al, 2002).

Treatment. Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic. It is important to be mindful of the ureter's blood supply from the renal artery and aorta superiorly and the iliac vessels inferiorly. As stated earlier, the preferred approach for the obstructed ureter is ureteral division and relocation. Laparoscopic (Miyazato et al, 2002; Ramalingam and Selvarajan, 2003; Tobias-Machado et al, 2005; Fernandez-Fernandez and Pachano-Arenas, 2008) and robotic (Gundeti et al, 2006; Smith et al, 2009) reconstruction of the ureter in a preureteral vena cava has been described both via the transperitoneal and retroperitoneal approaches in children.

OTHER ANOMALIES OF POSITION

Several instances of horseshoe kidney have been reported (Cukier et al, 1969; Cendron and Reis, 1972; Heffernan et al, 1978; Taguchi et al, 1986). Anomalies include a variety of left renal anomalies such as agenesis, hydronephrosis, malrotation, and hypoplasia (Kenawi and Williams, 1976). An obstructing branch of the right spermatic vein and a lumbar vein have mimicked circumcaval ureteral obstruction (Dreyfuss, 1959; Psihramis, 1987), as has an anomalous tendon of the iliopsoas muscle (Guarise et al, 1989).

Key Points: Preureteral Vena Cava (Circumcaval Ureter, Retrocaval Ureter)

- This disorder involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding about and crossing in front of it from a medial to a lateral direction, to resume a normal course to the bladder.
- If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.
- Patients may present with symptoms of flank or abdominal pain or infection, or the disorder may be discovered incidentally.
- Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic.

Preureteral Iliac Artery (Retroiliac Ureter)

A ureter coursing behind the common iliac artery is rare (Corbus et al, 1960; Seitzman and Patton, 1960; Hanna, 1972; Radhkrishnan et al, 1980). Either side can be involved; in two cases, the condition was bilateral (Hanna, 1972; Radhkrishnan et al, 1980). Obstruction occurs at the level of L5 or S1 as the ureter is compressed behind the artery. Coexisting anomalies are common (Nguyen et al, 1989), particularly vasal anomalies (Seitzman and Patton, 1960; Radhkrishnan et al, 1980).

Like the preureteral caval, the preureteral iliac artery is considered to be of vascular origin without definitive proof. Normally, the primitive ventral root of the umbilical artery is replaced by development of a more dorsal branch between the aorta and distal umbilical artery. Persistence of the ventral root as the dorsal root fails to form traps the ureter dorsally.

Ureteral or mesonephric duct ectopia is often present (Nguyen et al, 1989). The case of Seitzman and Patton involved an ectopic ureter that emptied, along with the ipsilateral vas deferens, via a persistent common mesonephric duct into the proximal posterior urethra (Seitzman and Patton, 1960). In the case of Radhrishnan and colleagues, bilateral retroiliac ureters also involved bilateral ectopic termination of the vasa deferentia into the ureters (Radhkrishnan et al, 1980). Iuchtman and colleagues (1980) described ectopic vaginal termination of the involved ureter, with urometrocolpos from an imperforate hymen.

Taibah and colleagues (1987) reported the unusual finding of left ureteral obstruction from a retrointernal iliac artery ureter in an otherwise normal young woman.

Vascular Obstruction of the Distal Ureter

Obstruction of the distal ureter from uterine, umbilical, obturator, and hypogastric vessels close to the bladder has been described (Campbell, 1936; Young and Kiser, 1965; Scultety and Varga, 1975). However, it is not always clear that vascular impressions on a dilated ureter are the cause of the obstruction. At times, these findings may be an artifact, as when a dilated ureter from an intrinsic obstruction is secondarily compressed against the adjacent vessel. Judging from the paucity of contemporary reports describing this lesion, it is likely that primary terminal ureteral obstruction by vascular lesions is a rare occurrence.

Herniation of the Ureter

Herniation of the ureter is another extremely rare condition. Dourmashkin (1937) searched the literature and tabulated a series of inguinal, scrotal, and femoral herniations of the ureter. Most of these were paraperitoneal (i.e., a loop of herniated ureter extended alongside a peritoneal hernial sac). Only a minority were extraperitoneal (i.e., with no hernial sac present). In paraperitoneal ureteral hernias, the ureteral loop is always medial to the peritoneal sac. Of six scrotal hernias, four did not have peritoneal sacs. When the ureter extended into the scrotum, it was more likely to be dilated, causing upper tract obstruction.

In children, herniated ureters have presented with hydronephrosis, associated with megaureters and persistent hydronephrosis after posterior urethral valve ablation (Jewett and Harris, 1953; Powell and Kapila, 1985; Burgu et al, 2009).

Internal hernias of the ureter are even more exceptional. Reports have been published of a sciatic hernia containing a ureter (Oyen et al, 1987; Witney-Smith et al, 2007; Tsai et al, 2008; Hsu et al, 2010), herniation between the psoas muscle and iliac vessels (Page, 1955), and lumbar triangle herniation (Cabello et al, 2008). Ureteral herniation with obstruction has been reported as a rare complication of renal transplantation (Ingber et al, 2007).

chapter 122

Vesicoureteral Reflux

Antoine E. Khoury, MD, FRCSC, FAAP ●
Darius J. Bägli, MDCM, FRCSC, FAAP, FACS

Historical Perspective

Vesicoureteral reflux (VUR) represents the retrograde flow of urine from the bladder to the upper urinary tract. VUR is a common clinical entity. Its clinical challenges arise from the fact that it is usually asymptomatic. When it is not, however, it is responsible for pyelonephritic scarring and can be associated with congenital renal dysmorphism. There are many unresolved issues regarding the etiology, diagnosis, and management of VUR. This chapter attempts to reconcile some of these areas by interpreting the best available information in the literature. Some areas, however, will continue to await more rigorous study. Some may remain unresolved for quite some time.

HISTORICAL PERSPECTIVE

VUR has a unique distinction of having evolved from an anatomic curiosity around the first century AD into one of the most contentious and complex areas of urology today. Galen and da Vinci made the first references to VUR by Western Medicine when they alluded to the ureterovesical junction (UVJ) as a mediator of unidirectional flow of urine from the kidneys to the bladder. Although VUR was first demonstrated to be a normal finding in dogs and rabbits (Semblinow, 1907), it was a gynecologic misadventure. It revealed that VUR in human adults may not be a normal state (Pozzi, 1893). Sampson, in 1907, suggested that the oblique course of the ureter through the bladder wall created a locking mechanism at the UVJ and was also the first to imply that VUR might lead to renal infection. Although it was not possible to uniformly demonstrate VUR in all people in cadaveric studies (Young, 1989), it was not until the UJV had been more clearly dissected that it was realized the incidence of VUR varied with the length of the ureter's obliquity in the bladder and the formation of the trigone (Gruber, 1929).

Pivotal discoveries occurred when Hutch (1952) reported on a relationship between VUR and chronic pyelonephritis in paraplegic patients and Hodson (1959) observed that urinary tract infection (UTI) and renal scarring carried a high likelihood of VUR in children.

Two seminal bodies of work defined the modern era of VUR. The first, the work of Ransley and Risdon (1979), defined the pathophysiology of reflux nephropathy by demonstrating the relationship among infection, reflux, and pyelonephritic scarring. Secondly, these observations complemented the clinical studies of Smellie (1991) and colleagues, who galvanized the related concepts inherent in clinical UTI, bacterial pyelonephritis, renal scarring, and VUR. In 1985 a consensus system for the grading of reflux was published by Lebowitz and colleagues (1985) on the basis of the International Reflux Study Group's deliberations.

Until recently, the virtues of medical therapy to avert infections and surgical therapy to correct reflux itself have been evenly debated for more than 20 years. However, the recent introduction of the biodegradable cross-linked polysaccharides dextranomer and stabilized hyaluronic acid for use in injectable endoscopic correction of reflux, as well as re-examination of the basis for medical therapy and the risks of reflux, have initiated a re-examination of virtually all aspects of reflux. From the age-related impact of reflux, through use of antibiotics for medical prophylaxis, invasiveness of cystography, and traditional indications for surgery, the impact of reflux and its management are being openly explored. Although the fundamental biologic importance of reflux disease is not in question, many facets of how reflux diagnosis and management are approached may take new shape in the coming decade.

Demographics

Prevalence

The tendency for VUR to resolve spontaneously on the one hand or persist beyond its natural resolution rate due to abnormal bladder dynamics makes it difficult to confidently generalize the true prevalence of reflux from a given population. In one meta-analysis of studies of children undergoing cystography for various indications (Sargent, 2000), the prevalence of reflux was estimated to be approximately 30% for children with UTI and 17% without infection. **In contrast, reflux may be present in up to 70% of infants who present with UTI** (Baker et al, 1966). In a population of 157 adults investigated for incidental hypertension without any evidence of renal abnormality, the prevalence of VUR was estimated to be 19%, with high-grade reflux in more than half of the refluxing group (Barai et al, 2004). Reflux is relatively uncommon in adult males (Chapple et al, 1990). In asymptomatic infants followed up for antenatal hydronephrosis, the prevalence of reflux ranges from 15% in infants with absent or mild hydronephrosis on postnatal ultrasound (Phan et al, 2003) to 38% in a group of neonates with various postnatal upper tract sonographic anomalies including hydronephrosis, renal cysts, or renal agenesis (Zerin et al, 1993).

Gender

Differences in reflux rates between males and females may suggest a sexual dichotomy in the function of the lower urinary tract, bladder outlet, and urethra. In one study of 117 infants assessed for reflux following fetal upper tract dilation, 76% of refluxing infants were male (Ring et al, 1993). In later life, the likelihood of having reflux if presenting with a UTI is higher if male than female

(Shopfner, 1970), even though the great majority (85%) of prevailing reflux in older children is in females. A confounding factor in understanding true gender differences in reflux between males and females is the gender-driven predisposition to UTI. Uncircumcised male infants show a 12-fold greater risk for UTI than circumcised males, as well as a greater propensity for harboring periurethral uropathogenic flora (Wiswell et al, 1988; Wiswell and Hachey, 1993). The greater incidence of UTI will necessarily invite more frequent evaluation and therefore detection of VUR in this population. It is not known whether the incidence of reflux detection would rise in females if they were to be incidentally evaluated for reflux as often as infant males. In a related finding, only 10% of patients entered into the International Reflux Study in Children from the United States were boys compared with 24% entered from Europe. The circumcision rate in the latter group was only 5% compared with 62% in the U.S. group ($P < .001$) (Weiss et al, 1992b).

Reflux in the Fetus

Most studies of fetal reflux do not in fact detect reflux per se in the fetus but relate fetal hydronephrosis parameters to reflux in the neonatal period. However, fetal hydronephrosis is common, often resolves, and has low specificity for postnatal VUR. Nevertheless, fetal hydronephrosis is commonly associated with postnatally detected reflux. Zerin described a 38% detection rate of reflux in 130 neonates with prenatal hydronephrosis (Zerin et al, 1993). In 19% the reflux was bilateral. It is suggested that the lower the threshold for defining hydronephrosis (in millimeters of pelvic diameter) in the fetus, the more often reflux will be detected postnatally (Anderson et al, 1997). This leads to speculation as to whether reflux is a normal variant in the population but becomes clinically relevant only in some because of a predisposition to UTI, a conclusion supported by the observation that reflux without infection is of questionable clinical significance. Boys appear to harbor postnatal reflux more commonly—a 6:1 male-to-female ratio was reported in one study of 27 cases (Marra et al, 1994). The highest grades of reflux are most commonly associated with renal scintigraphic abnormalities. In many cases, even in the absence of any infection history from birth, the presence of a small kidney with globally reduced scintigraphic function may indicate that such renal scintigraphic abnormalities may be associated with a developmental ureteral bud abnormality associated with high-grade reflux or secondary to the reflux itself (Oliveira et al, 1998; Stock et al, 1998).

Age

As stated previously, because the natural history of reflux involves spontaneous resolution over time, it is self-evident that less primary reflux would be prevalent in older children compared with infants (Table 122–1). Even in the presence of infection or asymptomatic bacteriuria, reflux is more common in younger patients (Smellie, 1991).

Table 122–1.

Incidence of Reflux in Patients with Urinary Tract Infections

AGE (yr)	INCIDENCE (%)
<1	70
4	25
12	15
Adults	5.2

From Baker R, Maxted W, Maylath J, et al. Relation of age, sex, and infection to reflux: data indicating high spontaneous cure rate in pediatric patients. J Urol 1966;95:27.

Race

Little is known about racial predisposition to reflux worldwide because reflux studies have generally been restricted to western countries. **One difference established over several studies is the relative 10-fold lower frequency of reflux in female children of African descent** (Skoog and Belman, 1991; Chand et al, 2003). In addition, reflux resolved sooner in this population ($P < .005$). In a series of non-Caucasian children with a 4:1 male-to-female ratio, 58% of whom were younger than 1 year of age presenting with UTI (72%), voiding difficulties (10%), or other malformations (14%), reflux was present in only 10% (West and Venugopal, 1993). Even in follow-up of antinatal hydronephrosis, reflux was found in 17.6% of 51 nonblack versus 0% of 58 black infants (Horowitz et al, 1999). Such differences may involve a delay in maturation of the antireflux mechanism in Caucasian patients as the race-associated frequency of reflux becomes equal regardless of race after 10 years of age (Melhem and Harpen, 1997).

Inheritance and Genetics

Sibling Reflux

A recent meta-analysis of sibling reflux studies suggests the prevalence of VUR in siblings to be approximately 32% (Hollowell and Greenfeld, 2002). However, the prevalence may be as low as 7% in older siblings (Connolly et al, 1996) or as high as 100% in identical twin siblings (Kaefer et al, 2000). **The latter finding undeniably supports the notion that VUR can be an inherited condition** and that the genetic mode of transmission may be autosomal dominant. Although a heightened prevalence of reflux exists in siblings of refluxing index patients, the natural history of reflux would suggest that siblings who are older harbor reflux less often compared with relatively younger siblings because of spontaneous reflux resolution (Connolly et al, 1996). However, none of the existing sibling studies rigorously state whether the prevalence of sibling reflux is dependent on whether the sibling is younger or older than the index patient herself. By virtue of its detection by screening, sibling reflux is usually asymptomatic at the time of diagnosis. Furthermore, the tendency for reflux to have resolved before any renal changes such as focal scarring detected by imaging can be reliably ascribed to the reflux itself further complicates the management of reflux in siblings. These clinical features underscore the difficulties inherent in formulating meaningful recommendations for the management of sibling reflux detected by screening.

Much of the concern for sibling reflux detected by screening stems from reports of renal abnormalities detected by ultrasound or nuclear scintigraphy in these patients.

In one retrospective study of 123 screened siblings, 44 (36%) demonstrated VUR on voiding cystography (Houle et al, 2004). Thirty-seven of these patients underwent renal imaging. Ultrasound was abnormal in 30% and renal scintigraphy, when used, was abnormal in 28%. However, in siblings older than 2 years, renal scintigraphic abnormalities were twice as common as in the entire group of siblings. The authors concluded that renal damage is therefore progressive in the older siblings and proposed earlier screening of siblings of refluxing index patients. However, this study fails to address the fact that renal damage or aberrant formation may have occurred very early and over time (beyond 2 years of age), renal growth may have exaggerated the appearance of such scintigraphic abnormalities. Scintigraphic results may become

exaggerated by normal cortical growth surrounding a scarred region that has failed to grow or by compensatory hypertrophy of a contralateral kidney. **The missing link is a prospective scintigraphic or sonographic follow-up of asymptomatic refluxing infant sibling children from birth onward.** Finally, the reporting of scintigraphic results by many sibling reflux studies is confounded by failing to differentiate between aberrant renal development often associated with higher grades of reflux and true scarring secondary to infection and inflammation. Moreover, the ability to modulate the course of the processes that mediate congenital dysplasia is not possible presently, as it is with scarring. In the absence of such data and faced with the invasive nature of the gold standard test for reflux, the cystogram, one is left with the following questions.

Is asymptomatic reflux in a sibling of clinical concern? If the propensity for UTI itself, with or without VUR, could reliably be determined to be genetically regulated, it would strengthen the case for screening for reflux in a sibling. Because biologic infection propensity cannot be reliably determined in either an index patient or his or her sibling, the mere likelihood of developing a UTI cannot be used to support screening siblings for reflux. Therefore one must rely on the aggregate clinical information available for the sibling in question. **Because it is renal consequences of reflux that are at issue, rather than reflux itself, siblings may be better served by noninvasively screening for cortical abnormalities first, before screening for reflux itself.** The intensity of renal assessment, using ultrasound for general screening or a nuclear scan for highest accuracy, could then be tempered by clinical factors including family history, patient and family compliance with follow-up, blood pressure, a history of UTIs and fevers, and voiding dysfunction. The absence of renal structural abnormalities would allow the clinician to conclude that reflux, if present, has not yet been of any renal consequence.

Should screening depend on sibling age? Because the risk for new renal scarring following pyelonephritis is lower in children older than 5 years of age, older siblings would likely suffer fewer consequences from a recent reflux-induced pyelonephritis and therefore stand to benefit less from confirming a diagnosis of reflux and instituting antibiotic prophylaxis than an infant or younger sibling. Nevertheless, a history of untreated febrile infections would support a decision to consider renal assessment or even obtain a cystogram in an older sibling.

Thus by imaging the kidneys first followed by assessing the integrity of the ureterovesical junctions, a rational top-down approach to sibling reflux screening emerges. Such an approach helps to strike a balance between the invasive nature of reflux detection and classic commitment to prophylaxis versus first detecting existing renal cortical abnormalities that might be the result of past or ongoing reflux. If consideration of age and renal integrity is combined, a possible graded approach to screening can be developed for siblings older or younger than 5 years of age, with or without renal structural abnormalities. The proximate urologic and voiding history must also play a deciding role in whether a sibling is ultimately screened by cystography for VUR. Thus in siblings 5 years or older with normal kidneys, little would be gained from detecting reflux that could not be addressed by responding to a febrile UTI in the usual fashion as for the general pediatric population. Indeed, the knowledge that the index patient has VUR might heighten the attention to family or self-reporting regarding urinary symptoms in the older sibling. In siblings 5 years or older with renal abnormalities, the suggestion would be of past or continuing reflux. Ruling the diagnosis in or out by cystography could then depend on prevailing voiding habits and proximate urologic history. The sibling younger than 5 years of age with normal kidneys would be managed on the basis of clinical judgment regarding likelihood for infection rather than an immediate need to diagnose reflux. The sibling younger than 5 years with cortical renal defects would have the most to lose by a febrile infection in the face of reflux and attendant risk of additional cortical loss following reflux-induced pyelonephritis triggered by an infection. In this case, knowledge of the potentially higher prevalence of reflux in siblings would logically support obtaining a screening cystogram. In any sibling, if reflux is diagnosed, the indications for reflux correction remain the same as for the general refluxing pediatric population.

Genes Involved

In addition to sibling reflux, a prospective screen of progeny of refluxing patients revealed a 66% rate of reflux in the offspring (Noe et al, 1992), which further strengthens the notion of an autosomal dominant component to the genetic mechanism of reflux. The substantially higher rate of reflux in siblings and progeny of index patients than in the general population defines these patients as susceptible to renal morbidity. Segregation and linkage analyses have implicated a number of loci in the pathogenesis of VUR, though no specific gene product or functional role for these loci in reflux has yet been identified (Chapman et al, 1985; Feather et al, 2000). Several studies have used a morphogenetic approach to search for candidate genes, which may underlie VUR. The original ureteral budding studies of Mackie and Stephens (1975), which correlate the position of ureteral budding from the mesonephric (wolffian) duct with that of the final ureteral orifice (UO), provide a modern basis for a genetic interpretation of VUR. Several genes have been observed to regulate these developmental processes and, by extension, are believed to serve as potential regulators of ureterovesical junction integrity. Indeed, genetic misregulation of ureteral budding is believed to underlie many congenital anomalies of the kidney and urinary tract (often referred to as CAKUT) (Miyazaki and Ichikawa, 2003). *PAX2* is a transcription factor regulating kidney, central nervous system, and ocular development in mice. It is necessary for ureteric budding in mice (Keller et al, 1994). *PAX2* is located on human chromosome 10q, and mutations have been reported in human syndromes involving colobomas and renal anomalies including hypoplasia, dysplasia, glomerulonephritis, and VUR (Sanyanusin et al, 1995). However, *PAX2* has not been shown to be a major determinant of primary VUR (Choi et al, 1998; Cunliffe et al, 1998). Glial-derived neurotrophic factor (Gdnf) and its receptor RET show strong involvement in ureterovesical junction formation in mice (Yu et al, 2004). Overexpression of RET in mice leads to abnormal placement of the ureteral bud and is associated with a 30% incidence of VUR at birth compared with 4% in wild-type mice. Nevertheless, the Gdnf RET signaling complex has not been found to mediate VUR in humans (Shefelbine et al, 1998). Another fascinating animal model of VUR is observed following depletion of the uroplakin III gene (Hu et al, 2000). However, no structural uroplakin III gene alterations have been noted in human cohorts with VUR (Giltay et al, 2004; Jiang et al, 2004). One explanation for this current finding may be that major uroplakin mutations are developmentally lethal in humans. Finally, members of the renin-angiotensin family of proteins have been implicated in several renal and ureteral developmental anomalies including ureteropelvic junction (UPJ) obstruction and megaureter (Hohenfellner et al, 1999). Although associations between angiotensin receptor-2 (Agtr2) (Yoneda et al, 2002) and angiotensin-converting

enzyme (ACE) (Liu et al, 2004) genes with VUR have been sought, no definitive etiologic link with VUR has been found. Notwithstanding an observed pattern of autosomal dominant inheritance in some families, the failure to identify any strong genetic mechanism in primary VUR in humans despite the presence of convincing animal genetic models of reflux argues for a more complex polygenetic mechanism of disease in humans.

Embryology of the Ureterovesical Junction

A full discussion of the embryology of the trigone and ureteric orifice is found elsewhere in the text. In brief, two events proceed simultaneously to govern the ultimate position and integrity of the UVJ. At one point, the embryonic ureter buds from the mesonephric or wolffian duct to define the metanephric duct or early fetal ureter. The wolffian duct (early vas deferens) and early ureter can be thought of as forming the two upper arms of a Y with the distal mesonephric duct as the stem of the Y. While budding is occurring, the distal mesonephric duct is being drawn and incorporated into the region of the urogenital sinus, which later becomes the bladder. Incorporation continues until the entire stem is absorbed, leaving the two arms of the Y to enter the bladder separately: one as the ureter and the other as the vas and ejaculatory duct in the male prostatic urethra (or the vestigial Gartner duct in the female vagina). The two arms of the Y also rotate relative to each other once they contact the urogenital sinus (UGS)/bladder wall resulting in the UO being proximal to the ejaculatory duct orifice. If the ureteral bud reaches the UGS too soon (believed to be due to early budding), over-rotation draws it high and lateral in the bladder wall, leading to inadequate incorporation, insufficient intramural length in the bladder wall, and reflux (Mackie et al, 1975). If the ureteral bud reaches the UGS too late (due to budding late), insufficient rotation occurs, resulting in an ectopic ureter that is drawn distally and medially, often obstructing in the bladder neck region or elsewhere. Furthermore, early or late budding is also thought to mistarget the contact between bud epithelium and the metanephros, leading to renal malformations, dysplasia, hypoplasia, or even agenesis.

Functional Anatomy of the Antireflux Mechanism

The phenomenon of vesicoureteral reflux represents a balance of several factors. Abnormality in any of these factors alone or in combination will allow or cause the retrograde flow of urine from the bladder up the ureter and ultimately to the renal pelvis and tubules. These factors include the functional integrity of the ureter, the anatomic composition of the ureterovesical junction (UVJ), and the functional dynamics of the bladder.

First, for purposes of reflux prevention, the ureter represents a dynamic conduit, which adequately propels the urine presented to it in a bolus fashion, antegrade, by neuromuscular propagation of peristaltic activity. In so doing, reflux is actively opposed. Moreover, if reflux were to occur, depending on its degree and timing, antegrade flow might be expected to keep refluxing urine from reaching the renal pelvis. The second component is the anatomic design of the UVJ. At the heart of this unique mechanism lies an intramural portion of ureter that travels within the detrusor muscle as it traverses the bladder wall (Fig. 122–1) (Elbadawi, 1972). At the extravesical bladder hiatus, the three muscle layers of the ureter separate. The outer ureteral muscle merges with the outer detrusor muscle to form Waldeyer sheath. The latter contributes to formation of the deep trigone. The intramural ureter remains passively compressed by the bladder wall during bladder filling, preventing urine from entering the ureter. Adequate intramural length and fixation of the ureter between its extravesical and intravesical points is required to create this antirefluxing

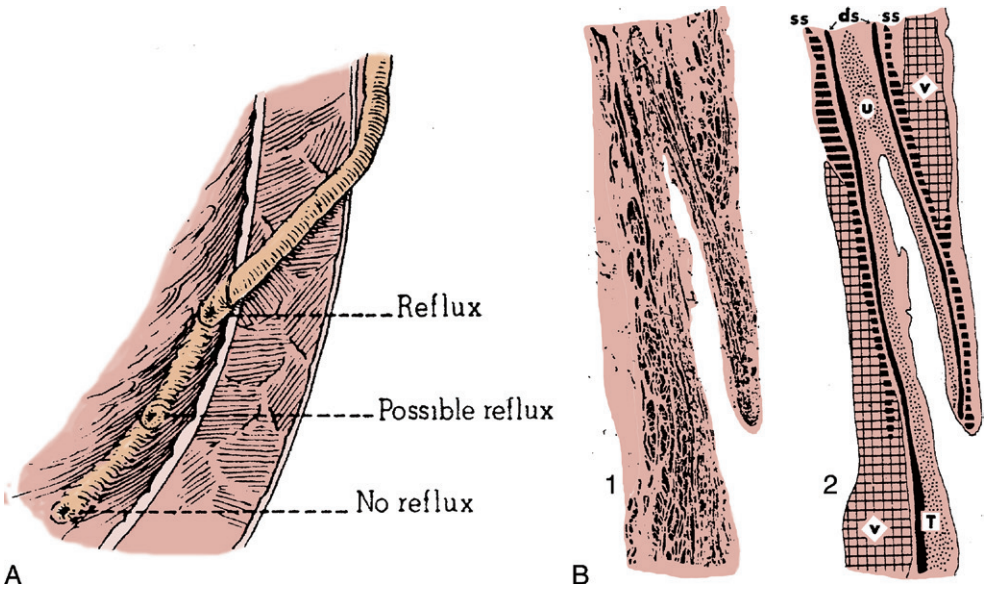

Figure 122–1. **A,** A refluxing ureterovesical junction has the same anatomic features as a nonrefluxing orifice, except for inadequate length of the intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. **B,** Ureterovesical junction in longitudinal section. 1, Photomicrograph; 2, diagrammatic representation. The ureteral muscularis (u) is surrounded by superficial (ss) and deep (ds) periureteral sheaths that extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle (t). The relationship of the superficial sheath to the vesical muscularis (v) is clearly seen. Transverse fascicles in the superior lip of the ureteral orifice belong to the superficial and deep sheaths. No true space separates ureter from bladder. (**A,** From Glenn J, editor. Urologic surgery. 2nd ed. New York: Harper & Row; 1975; **B,** from Elbadawi A. Anatomy and function of the urethral sheath. J Urol 1972;107:224.)

Table 122–2.

Mean Ureteral Tunnel Length and Diameter in Normal Children

AGE (yr)	INTRAVESICAL URETERAL LENGTH (mm)	SUBMUCOSAL URETERAL LENGTH (mm)	URETERAL DIAMETER AT THE URETEROVESICAL JUNCTION (mm)
1-3	7	3	1.4
3-6	7	3	1.7
6-9	9	4	2.0
9-12	12	6	1.9

From Paquin AJ. Ureterovesical anastomosis: the description and evaluation of a technique. J Urol 1959;82:573.

compression valve. Paquin's early dissections of the UVJ in children revealed an approximately 5:1 ratio of tunnel length to ureteral diameter in nonrefluxing junctions compared with a 1.4:1 ratio in refluxing UVJs (Paquin, 1959) (Table 122–2). Intravesically, the inner muscle of the ureter merges with detrusor muscle to contribute to the superficial trigone. Some of these inner ureteral fibers pass medially to contribute to the intraureteric ridge (Mercier bar). The cellular and molecular details that characterize normal and refluxing UVJs are still unknown. However, it is likely that in addition to architectural deficiencies of tunnel length, abnormalities in UV smooth muscle and extracellular matrix composition and neural function may contribute to reflux (Oswald et al, 2004).

Opening of the UVJ is achieved by active contraction of the longitudinal muscles within the tunnel. This draws the extravesical and intravesical points of the intramural ureter closer together, shortening and widening the tunnel, and allows passage of the urine bolus into the bladder. Indeed, when viewed cystoscopically, a lateral displacement of the UO accompanies the classic jet of urine into the bladder. Although such lateral displacement is functionally normal and necessary to permit urine to pass, permanent lateral displacement by virtue of a constitutively short tunnel characterizes the cystoscopic position of the refluxing UO. Closure of the UVJ results both from compression of the intramural ureter and a return to its full tunnel length as the ureteral muscle relaxes. Thus active and passive mechanisms dynamically reconfigure the tunnel as needed to allow antegrade passage of urine while preventing retrograde flow. Finally, the existence of local efferent and afferent neuromuscular coordination between the UVJ and the periureteric bladder wall is suggested by neurophysiologic studies that induce elevation or decrease in intraluminal UVJ pressure during bladder filling (Shafik, 1996).

Etiology of Vesicoureteral Reflux

As mentioned previously, the occurrence of VUR represents a balance of several factors. The degree to which each contributes to the pathology largely defines whether reflux is considered primary or secondary. In general, **reflux is considered primary if the main reason for it is a fundamental deficiency in the function of the UVJ antireflux mechanism while remaining factors (bladder and ureter) remain normal or relatively noncontributory. Secondary reflux, then, implies reflux caused by overwhelming the normal function of the UVJ. Bladder dysfunction of a congenital, acquired, or behavioral nature is often the root cause of secondary reflux.** It is also accepted that reflux is often considered secondary if its absence was documented at some point before its detection.

Primary Reflux

As stated earlier, primary reflux represents a congenital defect in the structure and therefore function of the UVJ. Reflux occurs despite an adequately low pressure urine storage profile in the bladder. The length-to-diameter ratio of the intramural ureteral tunnel is almost always less than that described by Paquin. Although inadequate tunnel length rather than excessive ureteral diameter usually underlies primary reflux, the dilated ureter often poses a challenge when a nonrefluxing ureterovesicostomy is required. This has traditionally prompted both long tunnels (>5 cm) or reduction of ureteral diameter by tapering or plication, or both, to reconstruct a successful antireflux mechanism. On the other hand, construction of a new tunnel with a full 5:1 length-to-diameter ratio may not be absolutely required to correct reflux.

Secondary Reflux

Any number of obstructing bladder pathologies can create hostile and excessive storage and emptying pressures that eventually overwhelm a normal antirefluxing intramural flap-valve mechanism. Such abnormalities can be functional or anatomic.

The natural history of reflux to resolve suggests the length-to-diameter ratio gradually evolves toward functional competency. Given that there is likely a range of tunnel lengths that can protect against reflux, as well as a spectrum of obstructional voiding etiologies in the refluxing population, it is reasonable to assume some degree of secondary reflux may coexist with primary reflux.

The most common anatomic obstruction of the bladder in the pediatric population is posterior urethral valves (PUVs). Reflux is present in 48% to 70% of PUV patients (Reuter and Lebowitz, 1985; Puri and Kumar, 1996; Hassan et al, 2003; Priti et al, 2004). Relief of PUV obstruction appears responsible for resolution of reflux in about one third of the patients. In one of these series, 78% of reflux resolved within 6 months of valve ablation (Priti et al, 2004). Such observations argue for the secondary nature of reflux due to elevated voiding pressures in PUV bladders. Even prostatic enlargement and its relief are associated with VUR and its resolution, respectively (Morita, 1987). In females, anatomic bladder obstruction is rare. The most common structural obstruction is from a ureterocele, which prolapses into the bladder neck (Merlini and Lelli Chiesa, 2004). In such cases, reflux in a contralateral ureter is likely due to the ensuing outlet obstruction and often resolves with decompression of the ureterocele. In general, then, if relief of the obstruction results in rapid reflux resolution, the reflux was likely secondary.

In contrast to anatomic obstruction, neurofunctional etiologies of elevated bladder pressures also predispose to VUR. In particular, neurogenic bladder associated with spina bifida is at risk for reflux (Bauer et al, 1982). This fact must be borne in mind during evaluation of the child with UTI. Special attention to the potential for occult spinal dysraphism including sacral dimple or hairy patch, gluteal cleft abnormality, diminished rectal tone, or significant constipation or encopresis should prompt consideration of investigation for coexistent spinal cord abnormalities.

Urodynamic extremes that predispose to reflux in the absence of overt neurologic pathology may also exist. Some studies suggest that a secondary aspect to neonatal reflux is a peculiarity of male infants. In a study by Yeung and colleagues (1998), 22 of 24 refluxing infants showing urodynamic evidence of instability (overactivity), inadequate, or obstructive voiding patterns were male. Normal or immature voiding patterns were observed in all infants in the nonrefluxing control group, of which 16 of 21 were male. In infants, higher voiding pressures are associated with reflux,

particularly in boys (Chandra et al, 1996), and may contribute to the male preponderance of reflux in infants. Urodynamic evaluation suggests these elevated infant bladder pressures may be due to inadequate sphincter relaxation (Chandra and Maddix, 2000) during this stage of development. However, detrusor activity in such infants is largely normal during filling, with slightly diminished bladder capacities in some (Podesta et al, 2004), though uninhibited activity during filling has been observed, again predominantly in male infants (Yeung et al, 1998). Considering that the high prevalence for reflux in infants coexists with urodynamic evidence of elevated voiding pressures, these observations suggest that infant voiding patterns may be a part of normal development. Thus even though the UVJ matures with age, infant voiding patterns predispose to a form of secondary reflux that resolves with normalization of urodynamic parameters as these infants grow older.

In older children, acquired abnormalities in voiding parameters commonly known as *dysfunctional voiding* or *dysfunctional elimination* have been associated with reflux. The precise cause of voiding dysfunction is variable but may evolve from a persistence of the expected early attempts to suppress bladder contractions during the toilet training months by volitional contraction of the external sphincter (Allen, 1985). If this behavior becomes prolonged or intensifies, often driven by the child's overwhelming desire for continence, bladder voiding pressures increase. Continence is gradually exchanged for incomplete emptying, resulting in a higher UTI risk. Although investigation of UTI might necessarily diagnose some subjects with persistence of primary reflux, the elevated bladder pressures gradually distort bladder and UVJ architecture and may create (secondary) reflux (Koff and Campbell, 1992). Structural failure of the UVJ is likely a critical determinant because high voiding pressures of approximately 100 cm of water are common in normal bladders and structurally intact nonrefluxing UVJ. Indeed, with structural failure of the UVJ, reflux occurs easily and at low voiding pressures or during early filling and is a poor prognostic factor for reflux resolution (Koff and Campbell, 1992; Hinman et al, 2002). Uninhibited bladder contraction is the most common urodynamic abnormality associated with reflux in neurologically normal children. In one study of 37 girls with "primary" reflux, 75% had uninhibited contractions (Taylor, 1982). However, the observation that treatment of such patients with oxybutynin can virtually eliminate reflux in up to 80% of refluxing ureters strongly argues that an overactive bladder can frequently be responsible for reflux, either by causing secondary reflux or perpetuating primary reflux (Koff and Murtagh, 1983; Homsy et al, 1985; Seruca, 1989). **Thus it is apparent that primary and secondary reflux may not always be mutually exclusive or that what is perceived as primary reflux in some children may, in fact, be secondary to abnormal voiding patterns.**

Clinical Correlates

The previous discussion clearly suggests that multiple opportunities exist for modifying the course of reflux if secondary causes are appreciated, identified, and treated. Van Gool and coworkers (1992) identified that 18% of children enrolled in the European arm of the International Reflux Study in Children harbored voiding dysfunction associated with more frequent UTI and greater persistence of reflux compared with those subjects without voiding dysfunction. Similar findings were reported from the recent Swedish Reflux Trial in which a cohort of children 1 year of age to younger than 2 years of age with grade 3 and 4 reflux were assessed and followed for 2 years for lower urinary tract dysfunction prevalence and type (Sillen et al, 2010). Twenty percent of children harbored some form of dysfunction at entry. This dysfunction prevalence increased to 34% at 2 years of follow-up. A negative correlation was found between dysfunction at follow-up and reflux improvement (P = .002). In addition, scintigraphic renal abnormalities (defined in Brandström et al, 2010a) at study entry and at follow-up were also associated with dysfunction (P = .001). Failure to address voiding abnormalities can also adversely affect outcome of antireflux surgery (Koff et al, 1998).

Indeed, compelling meta-analytic evidence recently compiled by the American Urological Association (AUA) Panel on VUR Guidelines now suggests that bladder and bowel dysfunction (BBD) is by far one of the most critical and modifiable variables that affect VUR management and attendant UTIs. Composite study analysis now indicates that **BBD is associated with a higher incidence of UTIs while on antibiotic prophylaxis, as well as after surgical correction of VUR, with less VUR resolution at 24 months from diagnosis and with reduced success of endoscopic surgery. In the studies selected by the Panel that qualified as having acceptable levels of evidence, BBD did not appear to reduce the success of open surgical reflux correction** (Fig. 122–2).

Thus although dysfunctional elimination syndromes are discussed in detail elsewhere in the text, a thorough evaluation of the toilet-trained child with reflux must recognize dribbling, urgency, or incontinence as signs of coexisting voiding disorders. Girls will also exhibit procrastination about voiding or demonstrate curtsying behavior, and boys may squeeze the penis, in attempts to suppress bladder contractions. The close proximity of the bladder and anal outlets often leads to sympathetic contraction of the anal sphincter as well, resulting in the frequent association of constipation and encopresis with reflux and UTI, in what is probably a mutually aggravating pattern (O'Regan and Yazbeck, 1985; O'Regan et al, 1986; Chase et al, 2004). **Constipation must be recognized and eliminated as much as possible in order to establish optimal conditions for successful spontaneous or surgical resolution of reflux.** The initial report of McGuire and colleagues (1981) suggested that pressures in excess of 40 cm of water measured at full capacity is associated with reflux and upper tract deterioration. Treatments to maintain pressures below this value result in significant reflux resolution (Flood et al, 1994).

Lower Tract Urinary Tract Infection and Reflux

Reflux is not a general cause of UTI. In the absence of bladder symptoms or inflammation, reflux is most readily considered a clinical accelerant of bacteriuria, by mechanically delivering infected urine to the renal pelvis. Infection-related cystitis is expected to incite bladder irritability and dysuria, upsetting the voiding pattern and lowering the threshold for reflux in a given UV junction. However, animal studies differ on whether infection itself can perpetuate UV reflux. In primate studies, surgically created reflux followed by introduction of pathogenic bacteria into the bladder was associated with reflux persistence (Roberts et al, 1988), compared with spontaneously occurring primary reflux in the presence of chronic infection (Lewis and Roberts, 1986), where infection did not delay reflux resolution.

Significant hydroureter and hydronephrosis associated with high-grade reflux could, in theory, act as a reservoir for the repeat

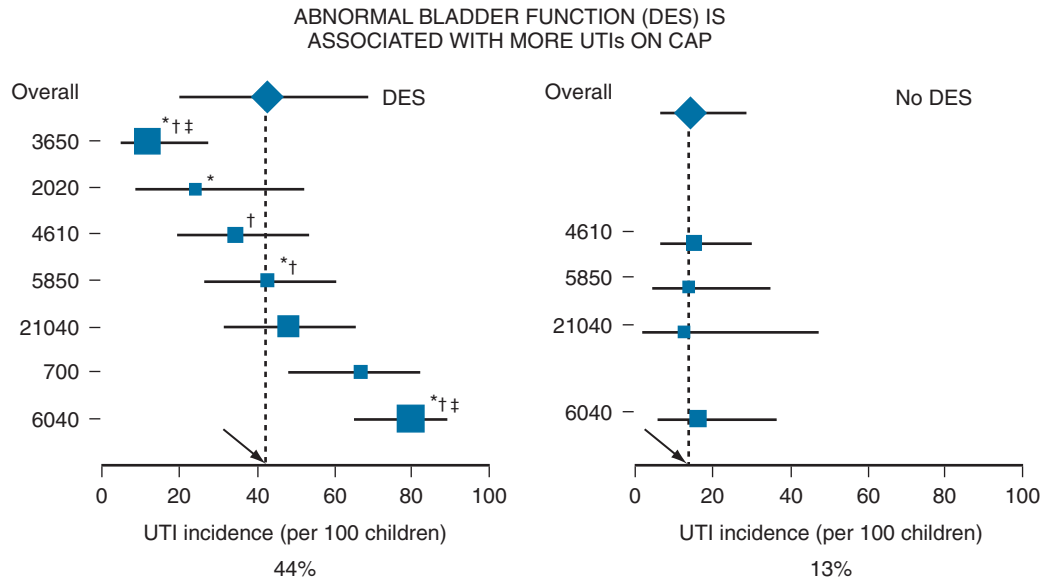

Figure 122–2. Dysfunctional elimination syndrome (DES) and urinary tract infection (UTI). CAP, continuous antibiotic prophylaxis. (From Peters CA, Skoog SJ, Arant BS, et al. Summary of the AUA Guideline on Management of Primary Vesicoureteral Reflux in Children. J Urol 2010;184:1134–44.)

antegrade reintroduction of pathogenic organisms to the bladder. Colonized urine might then cyclically reflux retrograde to the upper tracts. Similarly, ureteral atony secondary to the effects of endotoxin could fail to expel infected urine from the upper tracts, but this does not appear to reduce the ultimate resolution of reflux (Roberts and Riopelle, 1978). Indeed, the dilated upper tracts seen in high-grade reflux explored in the Swedish Reflux randomized prospective controlled trial were associated with a higher rate of recurrent febrile UTI in patients on surveillance without antibiotic prophylaxis (57%) (Brandström et al, 2010b). Reflux correction or antibiotic prophylaxis reduced the recurrent infection rate to approximately 20% (P = 0.0001). Interestingly, the finding was restricted to girls, which may reflect an anatomic predisposition to bacterial colonization of the bladder in girls versus boys; the febrile nature of the infection was likely due to reflux washing of bacteria to the upper tracts and renal parenchyma.

Grading of Reflux

Grading systems generally exist to help prognosticate the behavior of the disease they classify. In 1981 the International Reflux Study Committee proposed a system of five grades of reflux that remains in current use today in North America (Duckett and Bellinger, 1982; Lebowitz et al, 1985). **Five grades of reflux are currently used to depict the appearance of the ureter, renal pelvis, and calyces as seen on the radiographic contrast images generated by the voiding cystourethrogram** (Table 122–3 and Fig. 122–3). Using such a system serves several purposes. Grading standardizes the description of the degree of reflux for clinical management of the individual patient, as well as for grouping research subjects in the design of clinical studies and trials. Grading facilitates documenting the natural history of the reflux process in the individual patient. It also permits establishing quantitative associations between reflux and other clinical parameters, in order to determine whether such associations hold multivariate clinical relevance. Most importantly, description of initial grade in primary reflux is the most significant parameter associated with prediction of reflux resolution (see later).

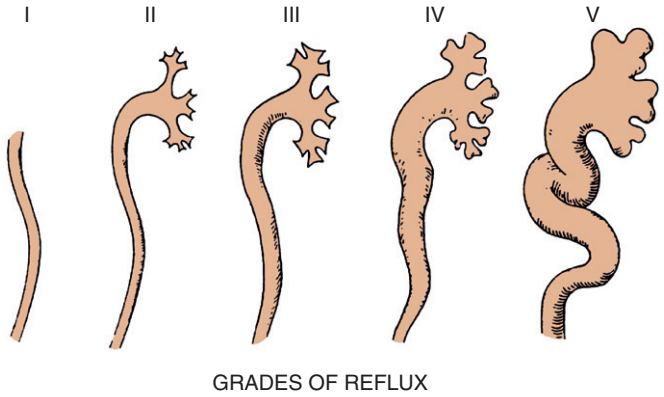

Figure 122–3. International classification of vesicoureteral reflux.

Table 122–3.

International Classification of Vesicoureteral Reflux

GRADE	DESCRIPTION
1	Into a nondilated ureter
2	Into the pelvis and calyces without dilatation
3	Mild to moderate dilatation of the ureter, renal pelvis, and calyces with minimal blunting of the fornices
4	Moderate ureteral tortuosity and dilatation of the pelvis and calyces
5	Gross dilatation of the ureter, pelvis, and calyces; loss of papillary impressions; and ureteral tortuosity

Despite the widespread use of the five-point grading system, several shortcomings exist. For example, the expected concordance between ureteral and calyceal dilation does not always occur (Fig. 122–4). Either the ureter or the calyces may demonstrate dilation out of proportion to the calyces or ureter, respectively. Whether this reflects an anomaly in the biomechanical tissue properties or peristaltic activity of the excessively dilated structure, as compared with the typical refluxing upper tract is unknown. Nevertheless, such anatomy is difficult to grade using

Figure 122–4. A refluxing ureter with significant dilatation of the lower segment but no distortion of the collecting system may be different from the typical system with grade 2 reflux.

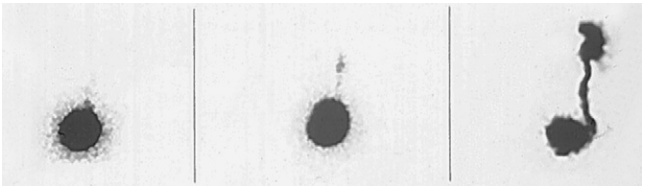

Figure 122–5. Nuclear voiding cystography showing right-sided reflux. Radionuclide tracer can be quantitated (from left to right) as grade 1 (grade I of the international grading system), grade 2 (grades II to III of the international grading system), and grade 3 (grades IV to V of the international grading system).

the current system. Similarly, it is unknown whether the propensity to either scarring in the face of infection or reflux resolution is altered in such systems.

Attempts have also been made to grade reflux using radionuclide cystography (RNC). Because RNC does not provide discrete images of the ureteral and calyceal architecture required to assign reflux grade, classifying reflux by RNC is difficult. Alternative RNC grading has been proposed (Zhang et al, 1987). This provides reasonable concordance to the objectives of the classic grading system by collapsing grades 2 and 3, as well as grades 4 and 5, into low-grade and high-grade reflux, respectively (Fig. 122–5). The impact of the reduction in grading detail from five grades (1 to 5) to two (low and high) on understanding reflux pathophysiology and on the design of clinical studies has yet to be determined.

Although grading is purely a classification of the appearance of contrast in the upper tract, ascribing an absolute value to the grade has the potential to cast the reflux in unequivocal terms, to the exclusion of other factors that modulate reflux at the time the images are acquired. Inherent bladder dynamics, the bladder outlet, and even ipsilateral UVJ obstruction all influence the degree of reflux at any given assessment (Lebowitz, 1992). Grade, reflux detection, and reflux resolution are all interrelated and are influenced by the degree of bladder filling, the voiding cycle, the number of filling cycles during the contrast cystogram, and whether the reflux occurs during filling or only during voiding. None of these parameters is built into the grading system for reflux used currently. However, given the principal role of a reflux grading system is to help prognosticate reflux resolution, future incorporation of other parameters may provide additional clinical acumen. Finally, it must be remembered that reflux grade is still presently determined by an imaging study that requires invasion of a sensitive anatomic region. For a given reflux grading result, the aforementioned variables of bladder dynamics, filling, and voiding cannot necessarily be replicated with certainty in a given patient each time he or she is studied. It is reasonable to speculate that reflux grade could easily vary up or down by at least one grade if sequential studies were performed in a given patient. Thus the entire reflux literature itself, which historically reports results in terms of five separate grades, must be considered with some circumspection because the veracity of grade at the time of the contrast study may be, to some extent, arbitrary.

Diagnosis and Evaluation of Vesicoureteral Reflux

Confirmation of Urinary Tract Infection

Because preventable reflux nephropathy is predicated on the combined effects of UTI and reflux, confirming and documenting true UTI is paramount in the appropriate management of the patient with reflux. Many variables are responsible for the accurate assessment and interpretation of UTI in the context of reflux. These include clinical history and presence of fever; age of the patient; circumcision status; method of urine specimen collection, storage, and delivery; and the results of urine dipstick and microscopic analyses. Although confirming true pyuria by dipstick or microscopic analysis, in addition to the presence of bacteriuria, will help to differentiate infection from colonization, colonization alone in the presence of reflux may still pose a threat to the upper tracts. Attention to these details cannot be overemphasized because major management decisions including operative intervention for correction of reflux often rest solely on a diagnosis of UTI. Conversely, confirming microbial growth in a urine specimen is of little value if the mode of collection is highly suspect and likely to harbor contamination. Confirmation of UTI begins with collection of the urine specimen. If storage is necessary, specimens should be maintained at 4° C until transfer to the laboratory.

In infants, specimen collection will often entail the placement of an adhesive urine collection bag over the genitalia. Although topical cleansing of the area is reasonable to reduce contamination and false-positive cultures, care must be taken to avoid introducing the disinfection agent into the specimen. Unfortunately, routine practice is so variable that such guidelines are often difficult to follow or confirm and **microbial contamination of bagged specimens is common. Conversely, this method is most useful if the resulting urine culture is negative.** Although fevers are common in infants, UTI comprises only 5% of children presenting with fever (Hoberman and Wald, 1997). Thus the ability to easily rule out a UTI in the febrile infant with reflux facilitates management. If there is a high clinical suspicion for UTI in an infant, the more accurate method is to obtain a catheterized specimen. Even this method may prove suspect in the uncircumcised infant male whose preputial skin is not yet

retractable to easily reveal the urethral meatus. In this and other instances where the urethral route is difficult or compromised in patients of any age, a suprapubic needle aspiration of bladder urine provides the most accurate method of obtaining a urine sample. In the younger child, however, repeated catheterization for specimen acquisition and radiographic assessment (see later) should be considered carefully. This hitherto routine practice is coming under greater scrutiny as the long-term sequelae of this invasive maneuver become appreciated (Stashinko and Goldberger, 1998) and could become a factor in patient compliance with follow-up (and therefore management decisions for reflux).

In patients who can void spontaneously, a clean voided midstream catch specimen is preferred. The initial urine is discarded because it is rich in periurethral organisms.

The previously mentioned guidelines pertain to patients with both unknown and known reflux status. In the former, the decision to look for reflux will depend on the propensity for acquired reflux nephropathy in the individual patient. In the patient known to have reflux, the prevailing propensity for acquired reflux nephropathy and compliance with proper voiding habits, antibiotic prophylaxis, and timely reporting will influence further management (see later).

Evaluating Urinary Tract Infection

Numerous factors support a search for reflux in the patient with UTI. The probability of finding VUR in children with a UTI is 29% to 50% (Anonymous, 1981). Furthermore, in some patients, higher grades of reflux may be associated with various degrees of existing renal parenchymal maldevelopment (see embryology section earlier) (Nakai et al, 2003). In addition, because reflux tends to resolve over time, it is reasonable that UTI is more commonly associated with reflux in younger patients (Smellie et al, 1981b), whose renal parenchyma is at more risk for scarring following a given pyelonephritis, compared with the older child. Smellie also suggests that the presence of reflux does not usually provide any unique clinical features in the patient with a UTI. Thus as with the search for sibling reflux, radiologic investigation of the patient with UTI is tailored to those patients who are placed at greatest renal functional risk from the presence of VUR. For this reason, **radiographic investigation for VUR has generally been directed to children younger than 5 years old, all children with a febrile UTI, and any male with a UTI regardless of age or fever, unless sexually active.**

The high repeat UTI rate after a first UTI has prompted a recommendation for some form of VUR work-up (Fig. 122–6). However, the current state of the VUR debate makes it difficult to know which patients, by such evaluations, might harbor clinically significant reflux, given how common UTI is in children. Some reassurance can be provided if a voiding study is negative for VUR. However, the parental concern over the invasiveness of the cystogram may first limit the evaluation to ultrasonography only, to rule out any existing gross structural defects. As such, taking the appropriate voiding, fever, and family histories into account, a sonographic study of the bladder and kidneys can be considered a reasonable minimum evaluation in the infant or child following a UTI, if a cystogram is deemed overly aggressive by the family or treating physician. Even the detection of reflux following treatment for UTI could be of questionable significance if the child is older and/or no fever accompanies the UTI. On the other hand, the presence of structural renal anomalies or significant asymmetry would support proceeding with a cystogram. More recent studies of racial predilection for reflux have supported a lower prevalence in children of African origin (Askari and Belman, 1982; Horowitz et al, 1999), but the prevalence in children of Hispanic origin (Pinto, 2004) is similar to that of Caucasians.

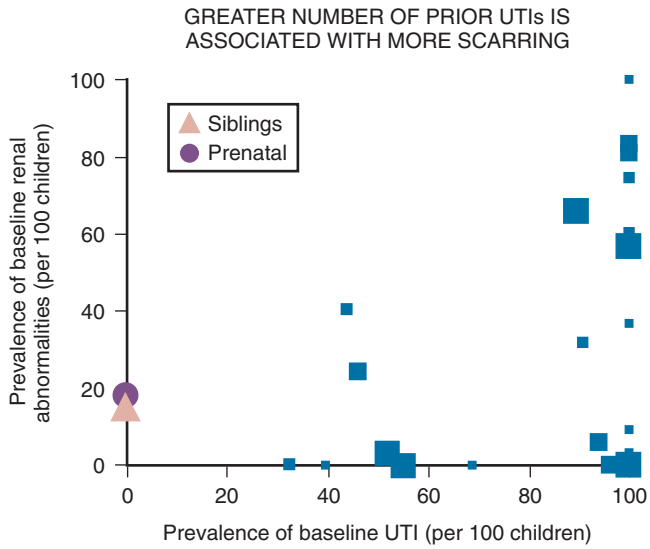

Figure 122–6. Urinary tract infection (UTI) history. (From Peters CA, Skoog SJ, Arant BS, et al. Summary of the AUA Guideline on Management of Primary Vesicoureteral Reflux in Children. J Urol 2010;184:1134–44.)

The advent of prenatal ultrasound has likely augmented the detection of asymptomatic reflux in newborns, as a result of mass surveillance for persistent postnatal hydronephrosis and the ensuing performance of cystography in these infants. It must be remembered that the sonographic finding of hydronephrosis is generally much more common than hydronephrosis due to a renal moiety actively refluxing at the time of the sonogram. Indeed, there is little correlation between the degree of antenatal hydronephrosis and the existence of reflux (Farhat et al, 2000). A corollary study also demonstrated normal postnatal ultrasounds in 25% of patients with VUR and antenatal hydronephrosis (Lebowitz, 1993).

Assessment of the Lower Urinary Tract

Cystographic Imaging

The basis of reflux detection lies in demonstrating the retrograde passage of an imaging contrast material from the bladder to the ureter and renal pelvicalyceal system. The currently available methodologies require a source of contrast agent in the bladder. Two approaches, the so-called *indirect* and *direct cystograms,* can be performed depending on whether the contrast enters the bladder indirectly following excretory urography or directly, usually by urethral catheterization. Indirect cystography, although avoiding the invasive nature of urethral catheterization, is prone to false-positive interpretation due to contrast that does not originate from the bladder, remaining in the ureter or pelvis after filtration and antegrade passage, and false-negative results in lower grades of reflux (Conway et al, 1975). However, it has been suggested that the value of indirect cystography may lie in ruling out the presence of VUR (Carlsen et al, 1986).

The voiding cystourethrogram (VCUG) and radionuclide cystogram (RNC) therefore are the two common forms of direct cystography and constitute the present-day gold standard approaches to reflux detection. More recently, to eliminate the need for ionizing radiation, some studies have demonstrated a growing interest in sonographic detection of reflux using either color Doppler imaging (Haberlik, 1997; Oak et al, 1999; Galia et al, 2004) or

echo-enhancing contrast agents (Berrocal et al, 2001; Darge et al, 2001; Darge and Troeger, 2002; McEwing et al, 2002; Tasic and Todorovska, 2003; Valentini et al, 2004; Vassiou et al, 2004; Darge et al, 2005). Direct imaging of reflux is affected by several parameters. These include bladder contraction during voiding, the fluid volume instilled into the bladder, and presence of infection and therefore inflammation of the UVJ mucosa. Reflux may occur during filling or only during the active bladder contraction associated with voiding. Consequently, if a patient is unable to void in the artificial setting of the radiography suite, false-negative results may ensue. More importantly, even during voiding, reflux may not be demonstrated on a single filling-voiding cycle. Several studies have demonstrated a roughly 12% to 20% greater detection rate for VUR if a cyclic study is performed (Paltiel et al, 1992; Papadopoulou et al, 2002; Novljan et al, 2003). A cyclic VCUG involves a second or third cycle of bladder filling and emptying under fluoroscopic observation. A similar cyclic strategy is commonly employed for the RNC as well (Fettich and Kenda, 1992). Reflux may also be demonstrated during catheter filling of the bladder. Because filling assumes far lower intravesicle pressure than that of voiding, reflux during filling, or passive reflux, is generally considered a poor prognostic sign for reflux resolution and suggests the presence of a fixed decompensation of the UVJ. This is a common finding in patients with acquired or neurogenic voiding dysfunction, wherein high-resistance voiding gradually remodels the bladder wall and UVJ, leading to complete failure of the latter's antireflux mechanism, and immediate reflux at virtually any volume of the filling phase (Koff, 1992). This is in contrast to reflux that only occurs during the higher-pressure milieu of bladder emptying and contraction. Thus technical inconsistencies in the ratio of instilled volume-to-bladder capacity during the radiographic technique can lead to variations in rates of reflux detection: if the bladder is overfilled or underfilled for a given degree of progressive UVJ incompetency, reflux may be overdetected or underdetected, respectively.

One difficult dilemma in the performance of voiding studies involves cystography during active infection. On one hand, some UVJs maintain only borderline antireflux mechanisms, which are competent in a sterile milieu but become incompetent from edema and inflammation associated with mucosal inflammation during cystitis. Such patients may have VCUG studies negative for reflux in the absence of infection but suffer from repeated pyelonephritic episodes. Cystograms in such patients may demonstrate reflux if obtained during active infection. On the other hand, evoking reflux during an active cystitis, by definition, will transmit bacteria to the upper urinary tract and renal pelvis and risks iatrogenic pyelonephritis. Nevertheless, the general consensus has been to delay the voiding study for at least a week or longer to allow for adequate recovery from the acute infection episode (Craig et al, 1997). Only if it is imperative to make the diagnosis of reflux in children with a history of recurrent pyelonephritis and repeatedly negative voiding studies in the intercurrent periods should cystography during UTI be considered.

The VCUG is a fluoroscopic study that provides information on both the functional dynamics and structural anatomy of the urinary tract. The detailed technique of the VCUG is discussed more fully elsewhere in the text. Bladder contrast is instilled by gravity following urethral catheterization. Bladder capacity is recorded when contrast influx ceases. Static images record bladder contour, presence of diverticula or ureteroceles, grade of reflux, configuration and blunting of calyces, and intrarenal reflux. Passive or active reflux is demonstrated dynamically during fluoroscopy while filling and voiding, respectively. In addition, bladder neck anatomy, funneling or dilation, and urethral patency are parameters derived from the VCUG. **Delayed or postvoid films are crucial in documenting clearance of contrast from the upper tracts because retained contrast, particularly with dilated pelvicalyceal systems, could signify the presence of a concomitant UPJ obstruction (UPJO)**, either primarily or secondarily due to distortion of the UPJ by massive retrograde filling of the pelvis by the reflux (Hollowell et al, 1989). **If both the UPJ and UVJ meet criteria for operative repair, the UPJ should be repaired first to avoid the incipient obstruction that may ensue if resistance is added to the UVJ when reflux is corrected** (Hollowell et al, 1989). With care, both processes may be repaired simultaneously when it is clear that they are independent significant problems.

The RNC has historically enjoyed a reputation for requiring approximately 1% the radiation exposure generated by the VCUG (Blaufox et al, 1971; Diamond et al, 1996a). Presently, the reduced radiation requirements of modern digital techniques have significantly narrowed the difference between fluoroscopy and RNC. Although little anatomic detail is afforded by the RNC, it is ideal as both a screening modality and for monitoring the natural history or surgical follow-up of reflux. In contrast to the VCUG, the instilled bladder contrast material, usually Technetium Tc99 pertechnetate, is itself the radiation source. Reflux is detected on scintigraphic gamma camera images (Fig. 122–7). **Lack of confounding imaging densities typical of fluoroscopy, as well as the ability to obtain prolonged exposures, allow for greater sensitivity of the RNC in grade 2 to 5 reflux.** Ironically, **grade 1 reflux into the distal ureter is often poorly detected due to the overlying exposure generated by contrast within the bladder itself.** Thus RNC and VCUG imaging can be used complementarily, balancing radiation exposure with the need for dynamic information and anatomic detail. Notwithstanding the forgoing discussion, modern digital fluoroscopic equipment has further reduced the radiation exposure of conventional fluoroscopy, thereby narrowing the difference in radiation exposure between the two modalities.

Another modality gaining popularity in some centers is ultrasonic cystography to detect reflux. Modern transducers coupled with the use of echo-enhancing contrast agents can image reflux well in older children (Novljan et al, 2003; Riccabona et al, 2003; Tasic and Todorovska, 2003; Galia et al, 2004), but the technique remains of limited use in neonates (McEwing et al, 2002).

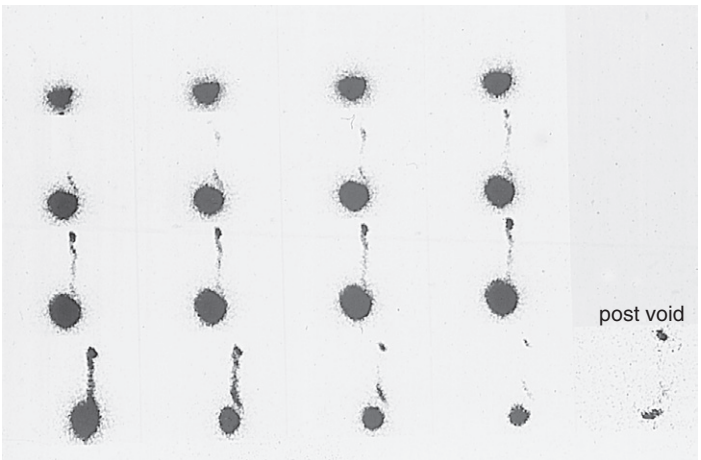

Figure 122–7. Radionuclide cystogram showing right-sided reflux that worsens with bladder filling. The upper collecting system drains fully with voiding.

Furthermore, while radiation exposure is eliminated, bladder catheterization remains a necessary feature with this approach.

Diagnostic Controversies: Challenging the Assessment of Reflux

The well-recognized distress of the family and patient associated with urethral catheterization, particularly in children, coupled with the advent of low-morbidity outpatient correction of reflux using endoscopic approaches appears to be challenging conventional reflux management and therapy. All aspects of VUR including modern incidence of renal scarring and failure, peak ages of renal susceptibility, and indications for reflux correction, including the assumption that permanent correction of reflux is an absolute necessity, are coming under scrutiny. This has given rise to added pressure to avoid bladder catheterization. The cystogram can have traumatic aftereffects in young patients (Stashinko and Goldberger, 1998; Elder, 2005) and must be approached with sensitivity and awareness of the developmental stage of the patient. Sedation (Stokland et al, 2003), topical urethral anesthetic (Gerard et al, 2003), and more recently hypnosis (Butler et al, 2005) have all been effective in mitigating the deleterious psychologic effects of cystography. Nevertheless, it is clear that **parental perception of the nature of the medical modalities involved in reflux management will influence their choice of therapy** for their children (Ogan et al, 2001). **This should in no way be construed as license for the abandonment of conventional observational therapy including antibiotic prophylaxis and periodic cystography in favor of immediate reflux correction in all patients** (Aaronson, 2005). Rather, the evolution of less invasive imaging modalities for reflux detection and reduced morbidity of reflux correction should be encouraged in parallel.

Uroflowmetry

Evaluation of the lower urinary tract during clinical assessment of VUR cannot rely solely on imaging. Because reflux is a dynamic phenomenon, the prevailing functional status of the bladder must also be considered. Although full pressure-volume urodynamic studies of the bladder are not required in all reflux patients, a minimal survey of bladder emptying characteristics can be obtained by uroflowmetry. The details of uroflowmetry technique are discussed elsewhere in the text. In refluxing patients, it is important to establish whether the bladder outlet is functioning relatively normally or harbors more resistive characteristics that are highly prevalent in younger patients. Elements of the uroflow such as lack of smoothness of the flow-velocity curve suggest incomplete relaxation of the bladder outlet during voiding. This implies the existence or development of relatively higher pressures during voiding, which could delay the natural history of reflux resolution or even perpetuate reflux. An increased postvoid residual volume may be a risk factor for UTI. In the setting of passive reflux, carrying infected postvoid residual urine can also lead to ascending infection and pyelonephritis.

Top-Down Approach

The top-down approach is an interesting concept based on the notion that only clinically relevant reflux with potential to cause renal injury is worthy of uncovering. Only a dimercaptosuccinic acid (DMSA) renal scan is obtained following a febrile UTI, with cystography reserved only for patients with abnormal scintigraphy. Children with a negative DMSA require no further evaluation unless they develop recurrent UTI, in which case a VCUG should be obtained.

Hansson and colleagues (2004) retrospectively reviewed 303 children younger than 2 years of age who had undergone evaluation by DMSA and VCUG within 3 months of their first UTI. Although 82% of these infections were febrile, VUR was found in only 26% of the children (80/303), 66% of whom had abnormal DMSA scans, while no abnormalities were detected in the remaining 27 patients. An approach based on identifying renal cortical abnormalities before obtaining a VCUG would have identified the 66% of children with VUR presumably at risk for further scarring, and it would have excluded 120 children (40%) without VUR or renal abnormalities from an unnecessary VCUG.

Implementation of a top-down approach would obviously not have detected 34% (27/80) of the cases of VUR. However, the patients in Hanson's study did receive prophylaxis as the top-down approach was being studied only from a theoretic viewpoint. In applying the top-down approach, these infants would not have been started on antibiotic prophylaxis and potentially might have been at risk to develop recurrent UTI. However, in 74% (27/80) of these patients, VUR was low grade and the remaining seven cases (grade 3 to 5 VUR) either resolved or improved significantly during a 2-year follow-up period with one of them developing a renal scar on repeat DMSA scintigraphy.

In a follow-up study from the same institution, Preda and colleagues (2007) prospectively confirmed these observations in 290 children younger than 1 year of age with UTI (79% febrile) with VCUG and DMSA renal scans. Fifty-one percent of the patients had positive scans including 85% (44/52) of the children later found to have VUR. Seven of the eight cases of VUR with normal DMSA scans were low grade, the remaining boy having grade 3 VUR with no acquired renal scars in follow-up despite an episode of breakthrough UTI.

The potential ability to detect those children with significant VUR who are at risk for renal scarring while avoiding invasive evaluation and unnecessary treatment of those who are not is clearly appealing. These data underscore the importance of further prospective analysis with longer follow-up to establish the validity and safety of the top-down approach.

National Institutes for Clinical Excellence Guidelines

In an attempt to streamline the investigations and treatment in infants and children presenting with UTI, the National Institutes for Clinical Excellence (NICE) in the United Kingdom proposed a set of guidelines aimed at reducing morbidity, antibiotic usage, and cost. Investigations are limited to an ultrasound of the urinary tract with cystography reserved for infants younger than 6 months and in older infants when dilation is observed by ultrasound. They do not recommend early DMSA renal scans to confirm or exclude renal involvement and rely solely on ultrasound in the sicker patients to determine the need for further investigation. Hence the major criticism to this approach lies in the poor correlation between the appearance of the kidneys on ultrasound and the presence of renal parenchymal changes or the presence and grade of VUR. The NICE committee did not provide any clinical outcomes to validate these guidelines and until confirmation of the safety of this approach is established prospectively, it cannot be recommended for general clinical use.

Cystoscopy and the Positioning of the Installation of Contrast Cystogram

Modern management of reflux does not include routine cystoscopy. It is rare for cystoscopy to add any information that will alter management of a patient with reflux, either at the time of

initial diagnosis or during follow-up. Its routine use, especially in children with UTI or reflux, should be considered an anachronism. Similarly, the appearance and configuration of the UOs and intramural tunnel length that are afforded by cystoscopy and once considered useful parameters have over time provided little correlation with either the diagnosis or grade of reflux (Duckett, 1983). Cystoscopy can provide useful information immediately before open surgery, such as confirmation of orifice position and duplication and the proximity of diverticula to the orifice, and clarify urethral patency if indicated. Similarly, such cystoscopic parameters will become immediately available in all patients at the time of endoscopic reflux correction.

A recently developed, although still controversial (Elder, 2005), cystoscopic modality termed the *PIC technique* (*P*ositioning of the *I*nstillation of *C*ontrast at the UO) purports to detect reflux under general anesthesia in patients with a history of febrile UTIs but a normal VCUG. The technique of PIC cystography (Edmondson et al, 2006) involves cystoscopy using a 9.5-Fr or 14-Fr rigid cystoscope. With the bladder empty, the cystoscope beak is positioned close to and facing the UO. Contrast is instilled at the UO using the irrigation port of the cystoscope from a height of 1 meter above the bladder. Fluoroscopic spot imaging is done simultaneously with the instillation. PIC-VUR is confirmed if retrograde flow of contrast into the ureter/kidney pelvis is observed. The bladder is emptied before the procedure is repeated on the contralateral side.

It is conceivable that antireflux mechanisms may be barely functional in some patients with recurrent UTI. The unique but unphysiologic nature of the PIC technique may then reveal reflux in such cases. Furthermore, PIC cystography does not allow for age-adjusted instillation pressures; some pressures may be too high in younger patients and may be creating iatrogenic reflux rather than unmasking relevant, physiologically borderline reflux.

A multi-institutional study by the PIC Cystography Group (2008) examined the clinical significance of reflux discovered by PIC in 118 children with a history of febrile UTIs and negative VCUGs. VUR diagnosed by PIC was treated by surgery (endoscopic injection in 104, reimplantation in 3) or by antimicrobial prophylaxis (11). In the 98 evaluable patients, VUR grade was 1-3 and was unilateral in 34 patients and bilateral in 64 patients. Treating occult VUR identified by PIC cystography, with either antibiotics or surgery, reduced the incidence rate of febrile UTI by 20-fold (from 0.161 per patient per month before PIC-VUR treatment to 0.008 per patient per month after treatment).

It is generally believed that VUR does not cause UTI; however, in this nonrandomized study (with the patients acting as their own controls), PIC cystography provides seductive evidence and rationale for antireflux therapy in a new subset of patients, particularly because endoscopic correction could theoretically and easily follow the fluoroscopy at the same time. However, **the urologist must exercise caution in this approach until prospective studies randomizing patients with PIC-VUR to treatment or observation confirm its clinical importance.**

Assessment of the Upper Tract

Rationale for Serial Assessment of Upper Tracts

The known effects of VUR on the upper tracts are largely what direct the need for reflux diagnosis and correction. Pyelonephritis propagated by reflux causes renal scarring, impedes attainment of full renal growth potential, and increases risk of renovascular hypertension. Therefore imaging of the upper tracts is directed at assessing renal structure and function with attention to the aforementioned parameters. A fundamental goal in upper tract imaging with VUR is to ascertain whether abnormalities are due to ongoing or resolved reflux and differentiate them from intrinsic developmental disturbances, medical renal disease, or antegrade flow resistance. Almost always, particularly in the youngest patients in whom VUR has the greatest potential to adversely effect renal function, these goals are best achieved through serial imaging of the kidneys over a period of months to years.

However, a meta-analysis of 63 studies assessing the value of routine diagnostic imaging after initial UTI in children for the prevention of renal damage found no accurate evidence to support this practice (Dick and Feldman, 1996). Many observational studies raised concern for the sequelae of UTIs and highlighted the potential for successful intervention. **The reason to image the upper tracts following a UTI may occur with or without knowledge of the reflux status of the lower tract. Reflux status may be known, suspected, or completely unknown. These three considerations, coupled with the age of the patient, gender, race, family history of reflux, and bladder functional status serve as a guide to selective imaging, which attempts to balance intensity of imaging studies with propensity for renal damage.**

Renal Sonography

The mainstay of renal imaging in VUR management is ultrasonography. As a nonionizing, noninvasive imaging platform, coupled with its ability to assess renal vasculature, it is ideally suited to serial follow-up of renal growth and development. Ultrasonography has supplanted routine excretory urography as the imaging modality of choice to monitor renal status over time.

Ultrasound lends itself well to quantitative assessment of renal dimensions (Rodriguez et al, 2001; Chen et al, 2002), which can then be used to follow renal growth over time. Renal growth can be referenced to standard renal growth curves. In reflux diagnosed in the neonatal period, baseline renal dimensions are obtained and appropriate renal growth can be monitored over time. The impact of any intercurrent febrile urinary infection can be gauged by observing the effects on renal growth. Similarly, if the UTI history between follow-up visits for reflux is unclear, serial assessment of renal dimensions can help the urologist advise on the need for further assessment of renal function by scintigraphy or on the need for reflux correction. Indeed, in the presence of reflux, modern postnatal renal sonography provides excellent correlation between renal length and scintigraphic hypoplasia (Farhat et al, 2002a).

Ultrasonography also images the degree of corticomedullary differentiation in the kidney. Loss of corticomedullary differentiation, or an increase in the overall echogenicity of the kidney, is associated with some degree of renal functional impairment. In neonates in particular, these parameters can be useful in assessing overall status of a renal unit in the context of higher grades of reflux, even before any history of UTI or pyelonephritis has occurred. Coupled with a relatively smaller ipsilateral kidney, loss of corticomedullary differentiation or increased echogenicity suggests a degree of intrinsic renal dysplasia that developmentally accompanies high-grade reflux. In the neonate with no infection history, such findings should not be confused with renal scarring, which is the direct sequela of inflammation and infectious pyelonephritis. In general, the routine sonogram is noninvasive, performed relatively quickly, and does not require intravenous access for contrast agents. From a practical point of view, it is virtually

an extension of the urologic physical examination and is still commonplace in urologists' offices. As such, just as serial documentation of height, weight, and blood pressure are basic components of most pediatric encounters, most urologists commonly perform serial sonography every 6 to 24 months during follow-up of reflux, if only to confirm that renal growth is proceeding normally.

Notwithstanding the value of renal sonography, it must be remembered that a single ultrasound study cannot reliably diagnose VUR. Although it is tempting to speculate on the presence of reflux in the presence of postnatal hydronephrosis on sonography, particularly of higher grades, there is no significant correlation between a normal ultrasound and the absence of reflux (Farhat et al, 2000; Zamir et al, 2004). Similarly, renal sonography is limited in its ability to visualize renal cortical abnormalities. Sonography is better suited to the noninvasive detection of larger cortical defects or renal size asymmetry (Merguerian et al, 1999).

Modern enhancements in ultrasound technology permit imaging of perfusion abnormalities in tissue. In reflux nephropathy using color Doppler ultrasound, renal resistive index measurements derived from blood flow in interlobar and arcuate arteries are significantly increased in higher grades of reflux and correlate positively with scintigraphic findings from the same renal unit (Radmayr et al, 1999). Resistive indices are also higher in patients with bona fide pyelonephritis confirmed by nuclear scintigraphy compared with patients with lower UTI alone (Ozcelik et al, 2004). Animal studies have also demonstrated that contrast-enhanced harmonic ultrasound can detect histologically confirmed regions of reflux-induced pyelonephritis with great sensitivity and more than 80% positive and negative predictive value (Farhat et al, 2002b).

Renal Scintigraphy

The gold standard for imaging functioning renal parenchyma is scintigraphy using ^{99m}Tc-labeled DMSA. The radiotracer is taken up only by functioning proximal tubular tissue mass, where it binds for several hours. The uptake of DMSA provides a good proportional representation of glomerular filtration (Taylor et al, 1982). Because pyelonephritis impairs tubular uptake of radiotracer, these areas will fail to radioemit photons and appear as unexposed or underexposed regions in the resultant renal cortical images (Fig. 122–8). Although many such affected areas in the kidney resolve, especially if prompt medical treatment is possible (Fernández-Menéndez et al, 2003), when they persist, irreversible renal damage or scarring is said to have occurred (Rushton and Majd, 1992). In a study of 79 children followed for 1 to 4 years, DMSA scanning provided a 98% sensitivity and 92% specificity for scar detection (Merrick et al, 1980). Although Rushton's study suggested that subsequent scarring was independent of the presence or absence of VUR (Rushton and Majd, 1992), a more recent meta-analysis found that reflux conferred an approximately threefold increased risk of detecting renal cortical abnormalities after infection (Faust et al, 2009). Indeed, considering the overall incidence of pyelonephritis in children, VUR is present in 22% to 39% of such patients (Hoberman et al, 2003; Lin et al, 2003). Nonetheless, the importance of VUR lies in the realization that it remains a spontaneously resolving or surgically treatable etiology for this ascending group of renal infections (Majd et al, 1991).

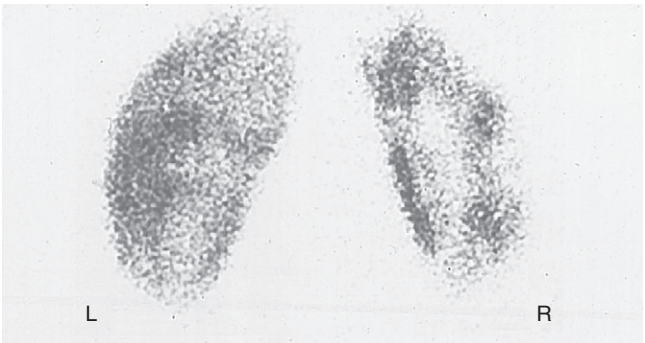

Figure 122–8. Dimercaptosuccinic acid renal scintigraphy. Pinhole images show a normal left kidney and a right kidney with multiple cortical defects.

One advance in nuclear scintigraphy of the kidneys is SPECT imaging (single-photon emission computed tomography). This approach reconstructs three-dimensional images of the renal cortical architecture, which can be viewed in any aspect in 360 degrees of rotation. Although SPECT images provide slightly higher sensitivity for detection of cortical defects, they do not add appreciably to standard pinhole DMSA images in the clinical management of reflux (Majd et al, 1996).

Much has been written in the literature on the role of DMSA scanning in the management of VUR, as an indirect entrée to the diagnosis of reflux itself, for the detection of reflux-associated renal damage and acute pyelonephritic changes, and for follow-up of reflux. However, no consensus exists on the precise use of DMSA scanning in reflux management. For example, growing concerns over the nature and frequency of voiding studies has prompted some to propose cystography after UTI only in those children with persistent postinfection renal lesions on DMSA scan, citing that only a minority of post-UTI cystograms are positive for reflux (Hansson et al, 2004). DMSA and ultrasound are often used complementarily, particularly when knowledge of relative renal function is desired (Riccabona et al, 1993). As a general rule, the utility of scintigraphy can best be appreciated in the context of the data it provides relevant to reflux: imaging cortical defects and relative renal function. The usefulness of this information will depend on which associated clinical and radiology data are at hand. If reflux and infection history are unclear or unknown in a new patient referred for evaluation after UTI, scintigraphy can provide the gold standard for demonstration of cortical defects for any reason and help with counseling on additional studies. If the significance or febrile nature of a potential pyelonephritis is unclear, particularly in a younger patient, a follow-up DMSA scan 4 to 6 months post-UTI can rule out subsequent scarring, particularly if a normal scan exists from a prior evaluation. DMSA scanning can be particularly useful if the diagnosis of pyelonephritis is unclear during an acute infection. Confirmation of photopenic radioemission and acute pyelonephritis can help to ensure that adequate antimicrobial therapy is provided. If surgical intervention is planned and significant renal asymmetry exists on ultrasound, quantification of relative function by scintigraphy can help to decide between reflux correction and nephrectomy.

DMSA scanning has also demonstrated that congenital cortical maldevelopment can exist, particularly in high-grade reflux, even in the absence of any history of UTI or outlet obstruction (Nguyen et al, 2000; Wallin and Bajc, 1994). This underscores the fact that cortical defects detected by DMSA scanning are not always the byproduct of infection; all DMSA defects are not necessarily scars. The distinction is an important one in the design of clinical studies and interpretation of the reflux literature, where congenital cortical defects may be erroneously construed and evaluated as if they were due to postinfection scarring. One corollary to this observation is that scintigraphic renal defects detected for the first

time in a child in whom the reflux history from birth cannot be confidently known could be secondary to reflux-associated pyelonephritic scarring, even though the reflux has resolved by the time of the study. Failure to appreciate that reflux often resolves in early childhood before scanning detects cortical defects for the first time makes it difficult to know whether these defects were or were not associated with reflux.

Cortical Defects

Congenital Defects versus Acquired Scar

The term *scar* is defined as fibrous tissue replacing normal tissues destroyed by injury or disease. In a renal context, the term is most accurately used to describe the fibrous, contracted regions of the kidney that have been destroyed by infection. These areas of scar tissue often appear smaller and photopenic by scintigraphy or hyperechoic and shrunken on sonographic images. The importance of such scars lies in the realization that they are the preventable complication of pyelonephritis, the latter being directly influenced by VUR in the presence of a bladder infection.

However, VUR, particularly of higher grades, may result in renal maldevelopment that often appears scintigraphically or sonographically identical to postinfection pyelonephritic scars. Thus over time in the literature and in clinical practice, the terminology of scarring, which is ideally defined to describe an end product of infection, has become contaminated by the inclusion of reflux-associated congenital dysmorphism. However, until such time that primary reflux can be averted prenatally (Gobet et al, 1998) or during the early postnatal phase of continued renal development, dysmorphism will remain the nonpreventable developmental sequela of reflux. Failure to appreciate this important distinction has tainted and confused study design and interpretation in the reflux literature.

Reflux-Associated Renal Dysmorphism

The association of renal maldevelopment with the highest grades of reflux is expected by the theory of Mackie and Stephens (1975), which suggests that an abnormal origin of the ureteral bud will interact suboptimally with the metanephric blastema (Fig. 122–9). The latter process is currently believed to be the likely cause of renal dysmorphism associated with reflux. Several studies have confirmed the association between VUR and a smaller than normal ipsilateral kidney, an overall reduced relative renal function, and global (Najmaldin et al, 1990; Burge et al, 1992) or focal (Risdon, 1993) areas of poor uptake by scintigraphy. These infants tend to be male, and the preponderance of refluxing renal units are grade 4 or 5 (Marra et al, 1994, 2004) (Table 122–4 and Fig. 122–10). Indeed, boys tend to be spared an infectious etiology of reflux-associated scarring because they have a lower incidence of recurrent UTIs (Wennerstrom et al, 2000).

Renal dysplasia is not unique to primary isolated VUR but may also occur in a variety of urologic settings. Duplex renal moieties (Mackie et al, 1975), prune-belly syndrome (Manivel et al, 1989), and posterior valves may all exhibit reflux-associated renal dysmorphism, particularly when the grade of reflux has been high.

Requirement for Urinary Microorganisms

It is now firmly established that nephropathy from primary VUR requires the colonization of urine with pathogenic bacteria, in the face of normal voiding dynamics. Indeed, the basis of current expectant medical management of reflux is to maintain urinary sterility while allowing reflux to resolve naturally. In the absence of infection, sterile urinary reflux is insufficient to cause renal damage. This concept has been most definitively demonstrated by the elegant series of experiments by Ransley and Risden. Reflux was induced experimentally in a pig model by unroofing the intravesicle ureteral tunnel. Only if the urine was subsequently infected could pyelonephritis and reflux nephropathy be induced. Without urine infection, no nephropathy could be created (Ransley and Risden, 1981). Large clinical studies have also reiterated these experimental findings, demonstrating new reflux-associated scarring only in children with recurrent UTIs (Smellie et al, 1975; Huland and Busch, 1984). These observations conflict somewhat with earlier animal studies by Hodson and colleagues (1975), which induced reflux with sterile urine. However, bladder outflow obstruction was also included in this model, leading to a finding of atrophic pyelonephritis similar to obstructive nephropathy. Scarring was nevertheless intensified by the presence of urinary microorganisms. Thus abnormal hydrodynamic bladder characteristics may modulate even sterile reflux, but reflux is unlikely to be of any clinical significance in the absence of infection with relatively normal bladder function. These earlier observations of Hodson, however, underscore the importance of normalizing bladder and bowel function while awaiting reflux resolution.

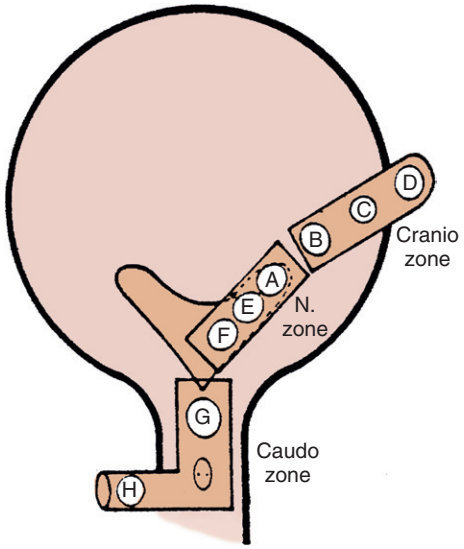

Figure 122–9. Classification of ureteral orifice position. Obstruction usually occurs in the caudo zone, and ureters positioned in the cranio zone are likely to result in reflux. Ureters positioned in the normal (N) zone are associated with normal kidneys. Because of ureteral bud abnormality, renal dysplasia occurs with ureters projecting from both abnormal positions. (From Mackie GC, Stephens FD. Duplex kidneys: a correlation of renal dysplasia with position of the ureteral orifice. J Urol 1975;114:274.)

Table 122–4.

Congenital Renal Scarring

GRADE OF VESICOURETERAL REFLUX	NO. OF PATIENTS NORMAL	SLIGHT DAMAGE	SEVERE DAMAGE
1-3	13 (100%)	—	—
4	8 (53%)	5 (34%)	2 (13%)
5	2 (15%)	5 (38%)	6 (46%)

Modified from Marra G, Barbieri G, Dell'Agnola CA, et al. Congenital renal damage associated with primary vesicoureteric reflux. Arch Dis Child Fetal Neonatal Ed 1994;70:F147.

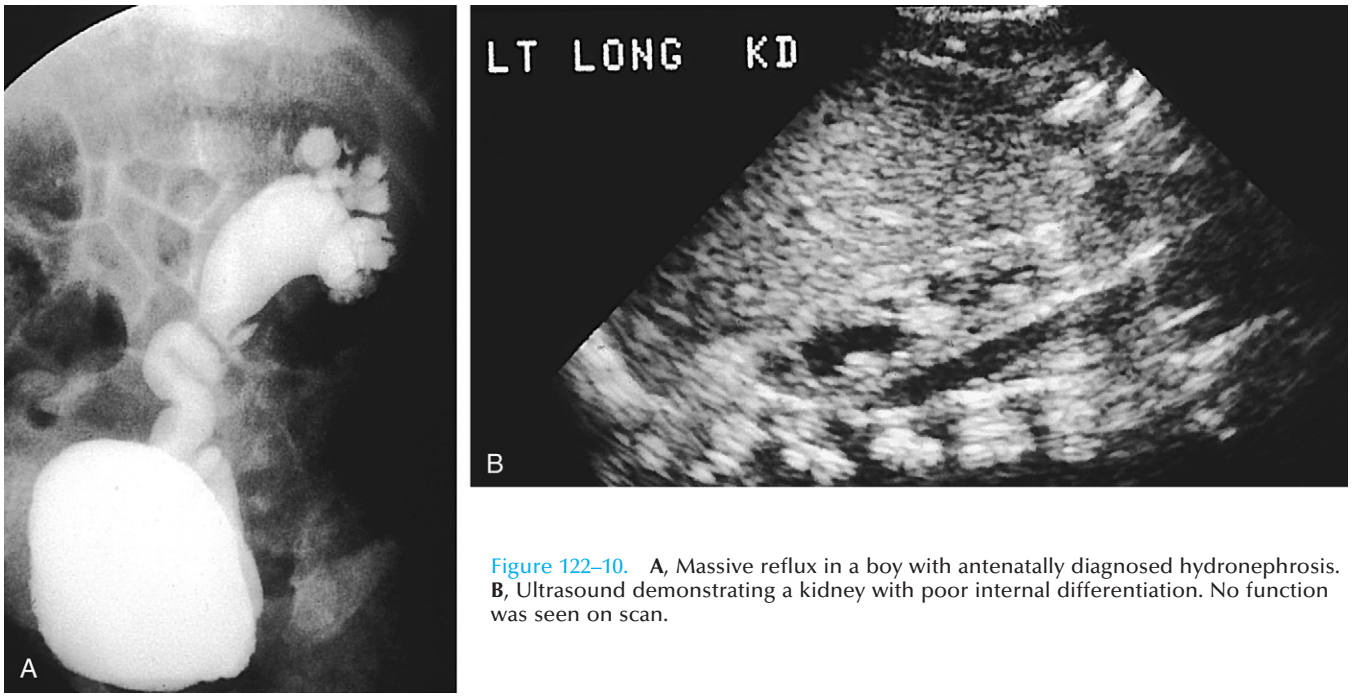

Figure 122–10. **A**, Massive reflux in a boy with antenatally diagnosed hydronephrosis. **B**, Ultrasound demonstrating a kidney with poor internal differentiation. No function was seen on scan.

Pathophysiology of Acquired Scarring

Renal scarring is a sequela of infectious pyelonephritis. A full discussion of the pathophysiology of renal scarring is covered elsewhere in the text. However, VUR exploits several conditions that predispose to scarring. Most importantly, **reflux provides a mechanical hydrodynamic mechanism that facilitates the ascension of microorganisms from the bladder to the kidneys. As such, reflux may be considered an accelerant for renal tissue infection, following bacterial colonization of the bladder.** This principle has been confirmed by studies showing an increased incidence of pyelonephritis in higher-grade reflux compared with lower-grade reflux (Majd et al, 1991). Furthermore, the frequency of scarring itself appears to be directly proportional to the grade of reflux with which it is associated (Winter et al, 1983; Weiss et al, 1992a). This principle is also supported by observations following reflux correction. In one study of 74 patients in whom preoperative and postoperative scintigraphy studies were available, more than 90% of renal units corrected for reflux showed no new scars during a mean follow-up period of 19 months, despite asymptomatic bacteriuria in 47% of the patients during follow-up (Choi et al, 1999).

Age. **The kidney's predilection for postpyelonephritic scarring is inversely proportional to age. This point is a guiding principle, which must be considered in all decisions regarding reflux diagnosis and choice of therapy. The greatest risk for postinfectious renal scarring occurs within the first year of life** (Winberg, 1992). Similarly, patients younger than 4 years are more prone to developing scarring after a single UTI than older children (Smellie and Normand, 1985), though scarring may still occur beyond 5 years of age (Smellie and Normand, 1985; Benador et al, 1997). Indeed, while younger patients are the most vulnerable to scarring, scarring in older children is often the result of late diagnosis, delayed or inadequate treatment of infection, and social factors that often interfere with patient management. Thus in older children with reflux in whom a consideration to relinquish care from the urologist back to the family physician is being considered, it is vital that fundamental principles of an adequate clinical index of suspicion for UTI and prompt UTI management be reiterated before transfer.

The seminal studies of **Ransley and Risdon (1981) proposed a "Big Bang" theory for the origin of scars following infant pyelonephritis. They observed that most of the scarring to which the kidney is ultimately susceptible occurs after the initial bout of pyelonephritis and that further scarring in the absence of repeated pyelonephritic episodes is unlikely to occur.** Consequently, the assumption is that little change in the initial scarring pattern is to be expected in follow-up scintigraphic imaging. **However, the uncertainties introduced by such factors as (1) the weakly substantiated assumption that a relatively greater scarring propensity exists in younger kidneys, (2) the reports of new follow-up scarring in the landmark reflux studies (see later), (3) the failure to differentiate between postpylonephritic imaging defects due to infection versus intrinsic developmental dysmorphism associated with reflux, (4) the changing appearance of such imaging defects with renal growth over time, and (5) the limited ability to compare disparate imaging modalities in the reflux literature (urograms vs. nuclear scans) together must challenge the notion that the greatest postinfection parenchymal loss occurs following the first infection.**

Papillary Anatomy. Another factor governing renal susceptibility to scarring is the configuration of the papillae as their ducts open to the calyces. Papillae with a concave architecture (compound papillae) present their ducts at right angles, whereas more convex papillae possess ducts that end obliquely, producing a valvular effect that guards against backflow of urine into the medullary collecting ducts (Fig. 122–11). The more polar calyces are composed preferentially of compound papillae compared with the middle calyces. The former are more commonly the site of intrarenal reflux (reflux into the ducts) and are the prime regions of susceptibility to scarring. Furthermore, necropsy studies have

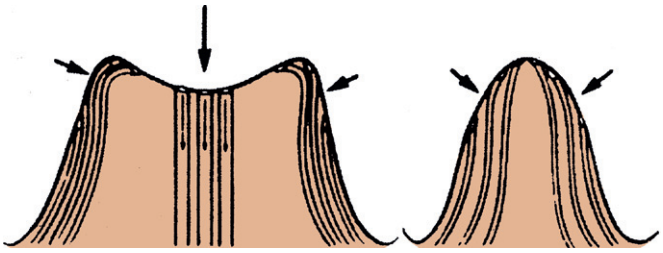

Figure 122–11. Papillary configuration in intrarenal reflux. A convex papilla *(right)* does not reflux because the crescentic or slitlike openings of its collecting ducts open obliquely onto the papilla. In contrast, a concave *(left)* or flat papilla refluxes because its collecting ducts open at right angles onto a flat papilla. (From Ransley PG, Risdon RA. Reflux and renal scarring. Br J Radiol 1978;14[Suppl.]:1.)

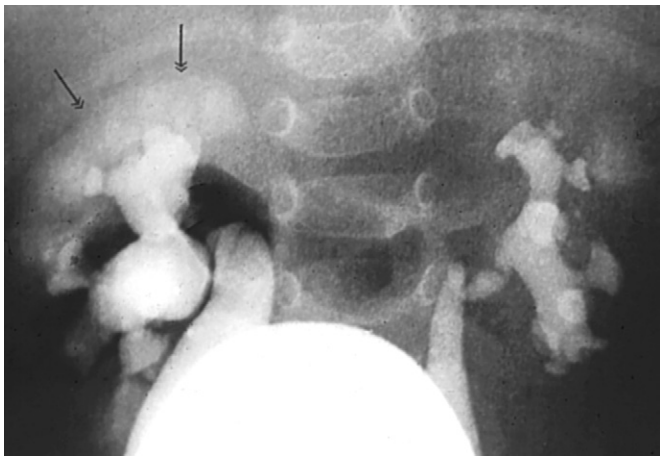

Figure 122–12. Intrarenal reflux (*arrows*) shown on a voiding cystourethrogram.

determined that reflux into compound papillae occurs at lower pressures than into simple papillae (Funston and Cremin, 1978). Intrarenal reflux can occur with as little as 2 mm Hg pressure in the neonate (Fig. 122–12). By 1 year of age, the pressure required is one order of magnitude greater (Funston and Cremin, 1978) and helps to explain the relative infrequency of intrarenal reflux in older children.

Bacterial Virulence. Bacteria possess phenotypes that provide infective advantage when exposed to the lumen of the urinary tract. Chief among these is the ability to adhere to uroepithelium. Adherence is mediated by interaction between specific molecules or ligands located on bacterial fimbriae and with specific receptors on host uroepithelial cells. A full discussion of the mechanism of action of uropathogenic bacteria is found elsewhere in the text. Once bacteria bind to host epithelium, specific biologic responses are activated in both the microorganism and host cell. Bacterial responses are designed to facilitate their survival and proliferation, as well as inhibit host defenses. These include release of endotoxin and reduction of ureteral peristalsis, which may lead to urinary stasis and reduced antegrade flow of urine. The host inflammatory response perpetuates the classic symptoms of UTI. Although a more systematic understanding of bacterial-host interactions in the propensity for reflux-associated renal scarring is not yet available, it appears that bacteria responsible for postpyelonephritic scars in the presence of reflux often express fewer than three virulence factors (Lomberg et al, 1984). Ironically, then, less virulent bacteria are most often sufficient to produce scarring in the presence of reflux.

Host Susceptibility and Response. Nonhematogenous bacterial access to the urinary tract rests essentially with periurethral organisms. Thus the type and number of vaginal and preputial organisms will determine individual propensity for bladder colonization. Local factors such as hygiene and bowel habits will also influence the bacterial load presented to the perineal surface from the intestinal tract, the latter being the principal repository for organisms that infect the urinary tract. The functional diversity of the host receptors for bacterial adherence also plays a role in the success or failure of bacteria to gain entry to the bladder. In one study, girls with recurrent UTI harbored far heavier periurethral colonization than a control group of girls who were infection free, suggesting a variation in the function of antibacterial defenses in susceptible females (Bollgren and Winberg, 1976a). Furthermore, such factors may exhibit both gender- and age-related dimorphism (Bollgren and Winberg, 1976a). The great majority of UTIs in both sexes younger than 6 months old is confined to uncircumcised boys (Rushton et al, 1992) and is consistent with the observation that *Escherichia coli* colonization is dense in infant boys but sparse in girls (Bollgren and Winberg, 1976b).

Perhaps the greatest tangible factor in promoting susceptibility to UTI is urinary dwell time. The postvoid urine volume is traditionally singled out as being suspect in providing sanctuary for ascending urethral organisms. Perhaps more important, however, is the overall dwell time between voids, which provides the greatest advantage to bacterial proliferation. **When the average doubling time for *E. coli* is measured in minutes, it is self-evident that a quantity of micoroorganisms sufficient for clinical infection can easily incubate exponentially in a bladder that is not emptied for several hours.**

Recent advances have also been made in understanding the renal epithelial response to pathogens. The classic components of the innate immune response to infection include activation of the complement system; recruitment of neutrophils and macrophages with scavenging ability; and production of a variety of cytokines, chemokines, and defensins (antimicrobial peptides). One family of receptors, the Toll-like receptors (TLR), respond to highly constant antigens expressed in bacteria (Chowdhury et al, 2004). The best studied of these, TLR4, detects lipopolysaccharide (LPS). A breakthrough in understanding renal infection came with the demonstration that mutations encoding the TLR4 gene were responsible for LPS hyporesponsiveness (Hoshino et al, 1999). Nevertheless, molecules accessory to TLR4 are important to its response to LPS. Similarly, molecules such as CXCR1 and CXCR2 are receptors for interleukin-8, the principle renal epithelial secreted chemokine responsible for neutrophil migration (Godaly et al, 2000). Deficiencies of CXCR expression and function may underlie human susceptibility to pyelonephritis (Frendeus et al, 2000, 2001). Such advances placed into the context of VUR provide interesting and powerful opportunities to modify the natural history of the condition.

As well as orchestrating the assembly of the phagosome for bacterial clearance, **the fallout of these renal epithelial processes that is the inflammatory response leads to local tissue damage and scarring.** Hallmarks of the response include capillary congestion, ischemia and reperfusion injury, and free oxygen radical and inflammatory cytokine release (Roberts, 1990, 1992). Microabscess formation later coalesces into scar tissue typical of the histologic changes of chronic pyelonephritis

(Roberts, 1995). Although limiting the inflammatory response to reduce scarring may appear logical, no specific pyelonephritis anti-inflammatory pharmacotherapy is yet available. Traditional non-specific anti-inflammatory agents, both steroidal and nonsteroidal, are not currently indicated in the treatment of pyelonephritis; in their current formulations the latter poses a threat to renal function (Schaller and Kaplan, 1998). Nevertheless, the concept has been demonstrated experimentally in animals (Huang et al, 1999). A full understanding of the specific pathways involved in reflux-associated pyelonephritis could provide key strategies to limiting specific renal inflammatory fallout without limiting bacterial clearance. Until then, antimicrobial prophylaxis instituted in a timely fashion, usually within 24 to 48 hours, is the single most effective pharmacologic strategy to date to limit the scarring consequences of pyelonephritis in both young and older children (Smellie et al, 1985; Ransley and Risdon, 1981).

Hypertension. VUR has long been held as the primary cause of significant hypertension in children. Arterial derangements in the renin-angiotensin system and sodium-potassium adenosine triphosphatase activity (Goonasekera and Dillon, 1998) may be involved, though the precise pathophysiology is not clear. Although methodologic flaws (Farnham et al, 2005) taint many studies of hypertension in the pediatric urology population, one study using continuous ambulatory blood pressure monitoring revealed some correlation between progression to hypertension and more severe reflux nephropathy in children (Lama et al, 2003). A recent adult review of 157 patients with hypertension, but no evidence of abnormal renal parameters, discovered by cystography that latent VUR was present in 20% of the subjects, demonstrating that a significant association between reflux and hypertension exists in adulthood (Barai et al, 2004). The striking association between VUR diagnosed for the first time only in adulthood and arterial hypertension continues to underscore the importance of remaining vigilant about untreated infections in the reflux population (Kohler et al, 1997). Nevertheless, it remains unclear whether it is the nephropathy associated with postinfection scarring, congenital dysmorphism associated with reflux, or some combination of both that predisposes to hypertension (Wolfish et al, 1993). This latter observation questions, then, whether prevention of postinfection scarring per se in the management of VUR will specifically help to offset future hypertensive risk in those cases where congenital renal dysmorphisms are already present. There is obvious potential for the etiology of reflux-associated hypertension to rest with deranged renal microvascular mechanisms associated with parenchymal defects. This suggests that successful correction of reflux alone is unlikely to ameliorate blood pressure (Wallace et al, 1978). Indeed, removal of renal segments verified by selective renal vein sampling of arteriolar or segmental vessel renin levels has provided durable normalization of blood pressure in carefully selected patients (Tash et al, 2003). On occasion, complete removal of a small unilateral congenitally dysmorphic or globally scarred and shrunken kidney may also correct renovascular hypertension (Dillon and Smellie, 1984) because such kidneys are clearly not amenable to partial nephrectomy for any discrete segment.

Renal Growth. Several studies have attempted to demonstrate that correction of reflux will restore retarded renal growth associated with reflux, particularly when the growth defect is in a unilaterally affected kidney. However, reflux correction is a poor predictor of catch-up upgrowth in such kidneys (Hagberg et al, 1984; Shimada et al, 1988). A significant factor governing growth of an ipsilateral kidney is the function of its contralateral mate. Although forestalling infection in the presence of VUR will maintain the normal trajectory of renal growth in most cases (Smellie et al, 1981a), it must be remembered that compensatory hypertrophy of the contralateral kidney will magnify the perceived impact of infection on renal growth because the contralateral developing kidney will assume the required renal function whenever the ipsilateral kidney is unable to contribute optimally to function. When reflux correction has been associated with improved renal growth, it is likely this is due to removal of the propensity for ascending infection rather than the elimination of the reflux per se (Willscher et al, 1976a, 1976b).

Renal Failure and Somatic Growth. Today, renal failure due to primary VUR-associated infection should be an anachronism, although it is still seen. This is largely due to the virtual paradigm shift in reflux management championed by Smellie and colleagues during their pivotal studies of reflux and infection in children during the 1970s and 1980s. Over the past 30 years, chronic pyelonephritis as a primary cause of end-stage renal disease has fallen from 15% to 25% (The 12th Report of the Human Renal Transplant Registry, 1975) to less than 2% (Committee, 2004). Reflux nephropathy in all its forms, however, was the fourth most common primary diagnosis in nonblack pediatric transplant recipients (Committee, 2004). The medical renal disease (Hinchliffe et al, 1994) that accompanies renal scarring can include hyperfiltration, concentrating defects, proteinuria, microalbuminuria (Lama et al, 1997), renal tubular acidosis (Guizar et al, 1996), and increased fractional excretion of sodium and magnesium. Although all of these parameters are likely the direct result of tubular and parenchymal damage or dysmorphism, concentrating defects and increased concentrations of tubular enzymes (Carr et al, 1991) have been reported in the presence of sterile reflux, independent of any history of infection per se (Walker et al, 1973). The concentrating defect is proportional to reflux grade and improves following reflux cessation. These observations have suggested that a relative flow resistance may be created by retrograde nature of reflux and raises the possibility of a functionally obstructive parameter in reflux pathogenesis. However, the precise relationship between antegrade flow, retrograde flow, and bladder dynamics in this theoretic mechanism has not been more fully articulated.

One of the best global parameters of renal function in children is the somatic growth curve. Many children with VUR fall below the normal age-adjusted growth curve, particularly in patients with bilateral reflux and some degree of renal damage. Furthermore, successful suppression of pyelonephritis through either medical prevention of infection or surgical correction of reflux itself can result in catch-up growth, both for height and weight (Polito et al, 1996, 1997). Although a clear superiority has yet to be demonstrated between medical and surgical therapy to affect growth improvement or subsequent renal scarring following an initial pyelonephritic insult, surgical correction of reflux can benefit somatic growth when recurrent breakthrough infection indicates failure of antibiotic prophylaxis (Sutton and Atwell, 1989).

Associated Anomalies and Conditions

Ureteropelvic Junction Obstruction

VUR and ureteropelvic junction obstruction are two of the most common pathologic conditions in pediatric urology. Thus it is not unusual that these two conditions coexist. Whether the concomitant presence of these two conditions is a random event or

is causally related remains unclear. It has been speculated that a developmental ureteral bud anomaly may be responsible for the imperfect formation of both the UVJ and the UPJ (Bomalaski et al, 1997a).

The incidence of VUR associated with UPJO ranges from 9% to 18% (Lebowitz and Blickman, 1983; Maizels et al, 1984; Hollowell et al, 1989; Bomalaski et al, 1997a; Kim et al, 2001). When the two conditions were primarily present, most of the patients in these studies had reflux that was coincidentally discovered, was of low grade, and resolved spontaneously with time. Such patients typically exhibited a significant discrepancy between the minimal degree of ureteral dilatation and the significantly dilated renal pelvis. Thus the apparent grade of reflux may be overestimated, and management decisions based on the grade of reflux are inaccurate at best.

Conversely, the incidence of UPJO in patients with reflux ranges from 0.75% to 3.6% (Lebowitz and Blickman, 1983; Bomalaski et al, 1997a), with **high-grade reflux being five times more likely to be associated with UPJO than lower grades of reflux** (Lebowitz and Blickman, 1983; Bomalaski et al, 1997a). Indeed, in one study of children with reflux and hydronephrosis, 50% of high-grade sonographic hydronephrosis, commonly associated with the highest grades of reflux, showed an obstructive pattern on lasix scintigraphy (Stauss et al, 2003).

Three radiology signs might suggest the existence of UPJO in the setting of reflux. First, if the pelvis shows little or no filling, while the ureter is dilated by contrast, this may indicate a point of kinking secondary to reflux or from a primary UPJO itself (Fig. 122–13). Secondly, contrast that does enter the pelvis may be poorly visualized due to dilution in a large pelvic volume and

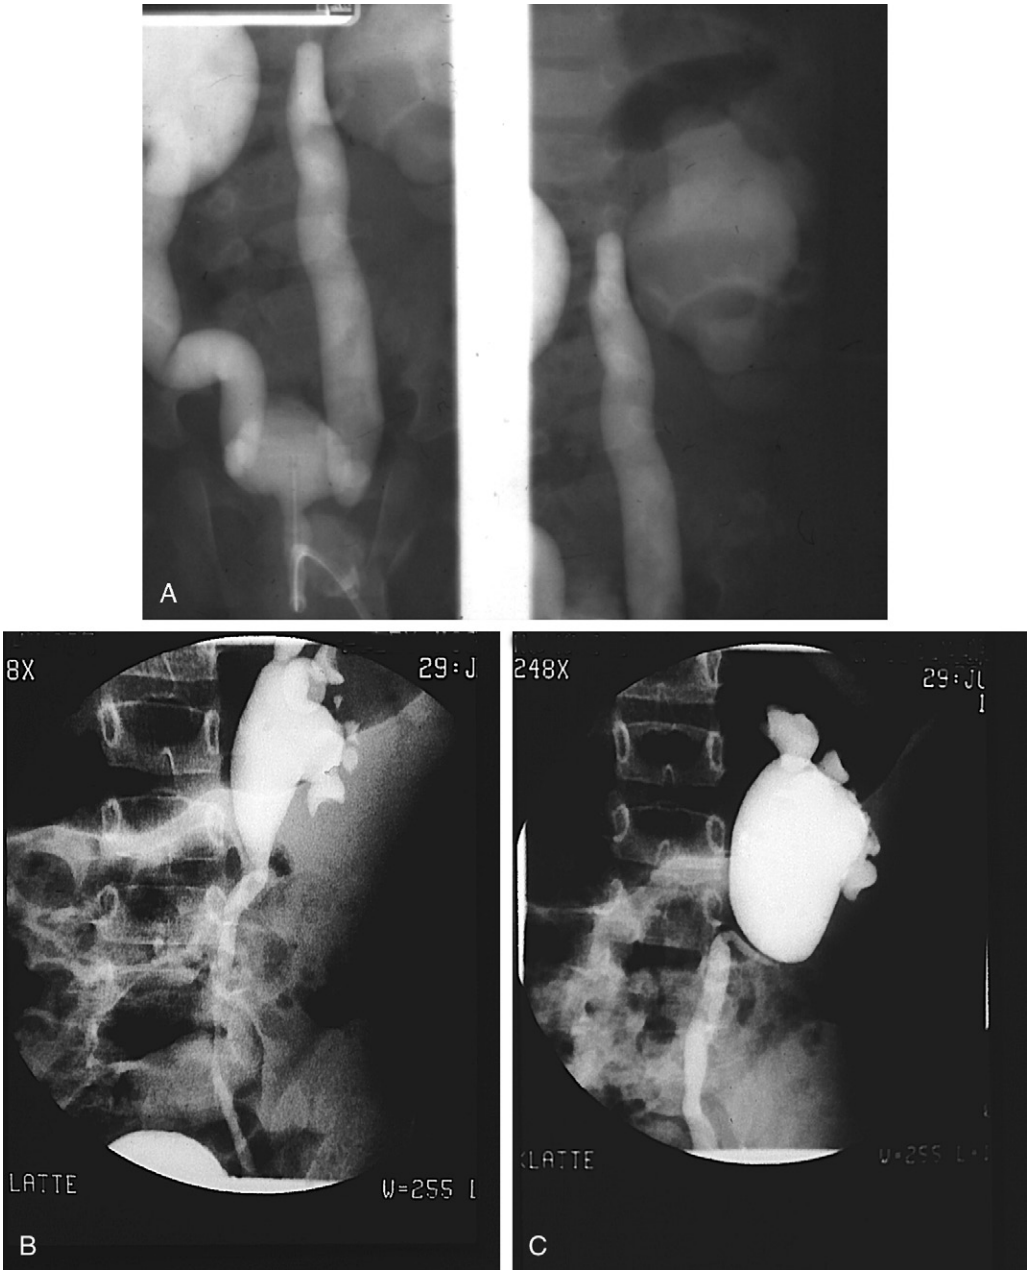

Figure 122–13. Reflux and ureteropelvic junction (UPJ) obstruction. **A,** Significant reflux fills the left ureter to the level of the UPJ. Minimal filling of the pelvis can be a sign of obstruction at this level. **B,** In a different patient, reflux is seen as the bladder fills. **C,** Significant kinking of the UPJ occurs with voiding.

exhibits a markedly reduced radiodensity compared with the ureter or bladder. Finally, a large pelvis that fails to exhibit prompt drainage but retains contrast is also suggestive of UPJO.

Radiographic studies of UPJO associated with VUR may indicate true anatomic obstruction or simply dilation associated with pelvic-ureteral dilation from higher grades of reflux. Hollowell and colleagues (1989) referred to three clinical categories of concomitant obstruction and reflux. Group 1 had primary UPJO and incidental low-grade reflux, and group 2 had secondary UPJO from high-grade reflux. These two groups represent true anatomic obstruction for which pyeloplasty is recommended. Group 3 represents only significant dilation of the upper tracts, which is confirmed by documenting good drainage images by cystography or renal scintigraphy.

The etiology of secondary UPJO is unclear. Several factors are thought to predispose or even aggravate a potential narrowing at the level of the UPJ. High-grade reflux may result in kinking of the upper ureter and adjacent pelvic junction. The chronic effects of reflux may also stretch the renal pelvis so that atonicity and an inability to propel urine through the UPJ may occur (Whitaker, 1973). In the setting of UTI propagated to the upper tracts by reflux, inflammation and ureteritis can also contribute to transient or chronic obstruction at the UPJ.

The convergence of two ureteral anomalies in the same patient raises additional management questions where treatment of one anomaly may affect the natural history of the other. **Nevertheless, the guiding therapeutic principle is the preservation of renal function. Although sterile reflux may be observed, obstruction even in the absence of infection may jeopardize renal function. Therefore in the presence of reflux, if scintigraphy with catheter drainage confirms obstruction, pyeloplasty should be performed.** The secondary insult to the UPJ from reflux is an evolving process that cannot be efficiently or adequately corrected by surgical repair of the reflux itself. Furthermore, reflux correction alone risks amplifying upper tract dilation during the phase of postoperative edema in the lower ureter, as well as risks introducing infection to a renal pelvis still harboring obstruction at the UPJ.

The simultaneous open correction of UPJO and reflux has always raised a concern over surgical manipulation of both the upper and lower ureter at the same time, as well as its potential negative impact on ureteral vascularity. However, the advent of endoscopic injection raises the possibility of correcting reflux at the time of pyeloplasty for secondary or primary UPJO. The indications for reflux correction are being re-evaluated since the advent of endoscopic therapy and are discussed in the section on endoscopic management later.

Ureteral Duplication

VUR is the most common abnormality associated with complete ureteral duplications. The embryologic origin of the duplicated ureter supports the observation that reflux occurs most commonly into the lower pole. This relationship is based on the studies of Weigert (1877) and Meyer (1946), who documented the more lateral and proximal insertion of the lower pole ureter associated with a shorter intramural ureter at the UVJ (Fig. 122–14).

The incidence of reflux is increased in patients with complete ureteral duplication (Privett et al, 1976). Earlier studies provide a limited view of whether reflux in a duplex moiety carries increased patient risk due to lack of control groups, arbitrary patient selection, and short follow-up. There has been some tendency to correct reflux on the basis of the existence of the duplication anomaly itself. Even in the absence of obstruction from a ureterocele or ureteral ectopia, duplication with low-grade reflux may take longer to resolve than in single-system reflux (Estrada et al, 2009), though it carries no increased risk of increasing grade, breakthrough infection, or scarring (Ben-Ami et al, 1989; Husmann and Allen, 1991). The most recent series supports this finding in low-grade reflux but notes that high-grade reflux into lower pole ureters in females is more prone to breakthrough infection and scarring and therefore may warrant more aggressive management (Afshar, 2005; Estrada et al, 2009).

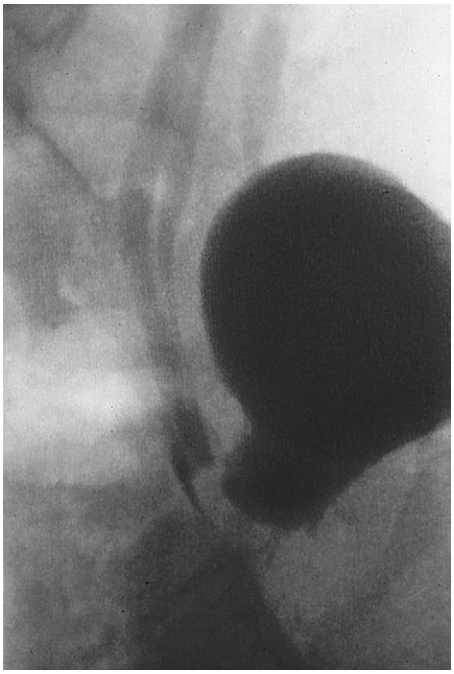

Figure 122–14. Reflux into both ureters of a complete duplication, as shown here, is less common than reflux into the lower pole ureter alone.

Bladder Diverticula

A full discussion of bladder diverticula is found elsewhere in the text. The outpouching of mucosa between detrusor muscle bundles, which lacks any true muscle backing itself, commonly defining a bladder diverticulum, has the theoretic potential to affect the natural history of VUR in two ways. Most commonly, if the UVJ is distorted by the so-called paraureteral diverticulum, which shares an anatomic point of origin at or near the UVJ, it is theoretically possible that the configuration of the diverticulum could compromise the antireflux configuration of the UVJ to cause reflux (Fig. 122–15). Secondly, and more rarely, a large paraureteral diverticulum could expand within Waldeyer fascia to cause ureteral obstruction or project forward into the bladder to obstruct the bladder outlet, much as a ureterocele, and incite secondary reflux (Boechat and Lebowitz, 1978). Although the latter would require cystoscopic confirmation, neither cystoscopy nor imaging is predictive of whether paraureteral diverticula truly compromise the resolution of reflux, as has been commonly believed. Hutch (1961) was the first to recognize that bladder diverticula were congenital abnormalities that occurred primarily in smooth-walled normal bladders in children. A 40-year review of the literature from 1966-2004 fails to provide any objective case control or cohort studies to support the routine repair of reflux where the

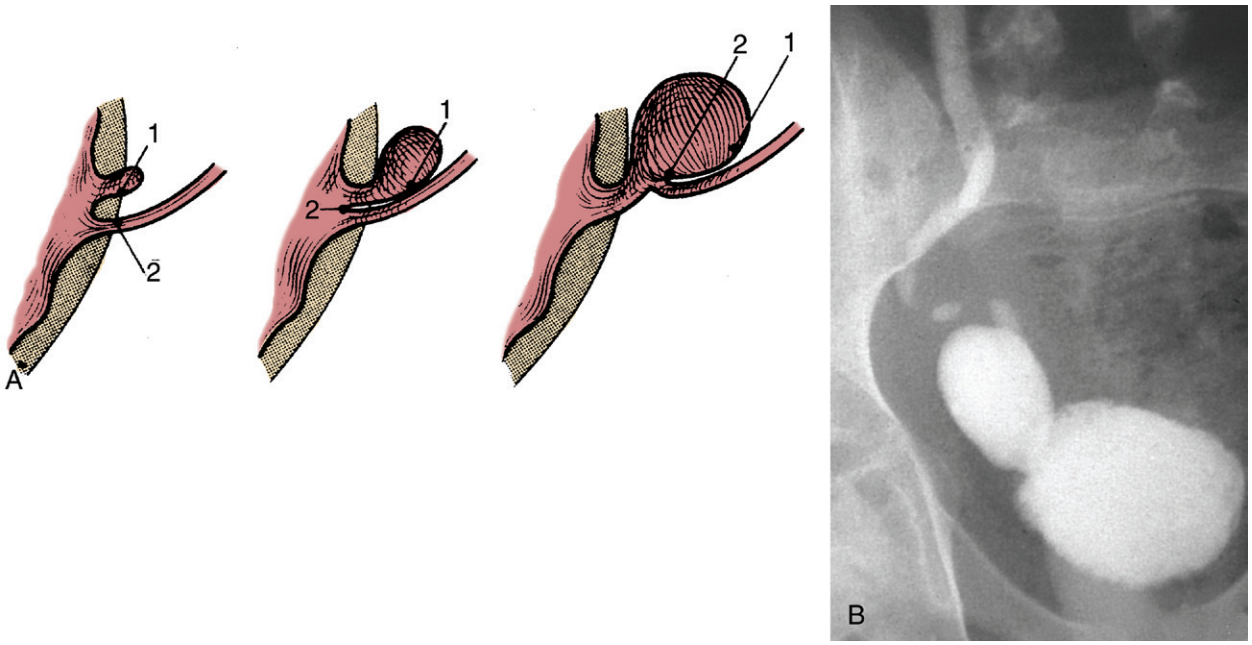

Figure 122–15. **A,** Schematic representation of a bladder diverticulum. A small amount of mucosa initially herniates through a congenital defect in the bladder musculature. The defect enlarges with voiding. Finally, the ureteral orifice is incorporated into the diverticulum. **B,** Reflux into a right-sided paraureteral diverticulum and ureter seen on voiding cystography. (**A,** From Hernanz-Schulman M, Lebowitz RL. The elusiveness and importance of bladder diverticula in children. Pediatr Radiol 1995;15:399–402.)

sole indication was the presence of a paraureteral or Hutch diverticulum. However, a contemporary retrospective cohort analysis of 84 patients with paraureteral diverticula and reflux showed no significant difference in spontaneous resolution rates (60%, 39%, and 22% for grades 1 to 2, 3, and 4 to 5 reflux with paraureteral diverticulum vs. 52%, 28%, and 33% in a matched control group of 95 refluxing patients without diverticulum). Rates of UTI and scarring were similar in both groups. Multivariate analysis revealed reflux grade to be the only predictor of resolution in both groups (Afshar, 2005). Thus **reflux associated with paraureteral diverticula resolves at rates similar to primary reflux and should be managed according to the prevailing indications for the reflux itself, irrespective of the diverticulum.** However, when a refluxing ureter enters a diverticulum, the latter is no longer paraureteral. With no muscular support to the UVJ, reflux is not expected to resolve. In a given patient, indications for repair require the combined consideration of the potential impact of unresolved reflux, if any, along with whether the diverticulum itself is of sufficient size or conformation to incite complications.

Renal Anomalies

By definition, primary reflux represents a dysfunction of the ureterovesical junction. Because the development of both the UVJ and the kidney itself are linked to the origin and fate of the ureteral bud, it is reasonable to consider the existence of reflux whenever an anomaly of renal form or number is present. **The cardinal renal anomalies associated with reflux are multicystic dysplastic kidney (MCDK) and renal agenesis, and the presence of either condition mandates a VCUG.** In the largest series to date, 75 patients with MCDK showed a prevalence of contralateral reflux of 26% (19 patients) and half of these were low grade (1 to 2) (Miller et al, 2004). Spontaneous resolution occurred in a mean of 4.4 years, regardless of grade. Only one patient had reflux corrected surgically. In a small series of ureteral ectopia, one patient with MCDK had the contralateral ureter enter into the ductus deferens (Wunsch et al, 2000), further underscoring the importance of documenting the contralateral kidney's ureteral conformation in patients with MCDK. Although contralateral renal growth often displays compensatory hypertrophy, one study observed somewhat less compensatory hypertrophy by 1 year of age (Zerin and Leiser, 1998) than may be expected if contralateral reflux is absent (5.1 cm vs. 6.2 cm median renal lengths, $P < .001$).

Renal agenesis is associated with an even higher prevalence of contralateral VUR. In a retrospective study of 46 children with solitary renal agenesis, the rate of contralateral renal pathology was 46%. VUR was by far the most common contralateral defect (28%) (Cascio et al, 1999) with UVJ and UPJO seen in 11% and 7%, respectively. Both UPJ and reflux were present in 1 patient. In another study, 19 cases of contralateral reflux were observed in 51 patients with ipsilateral renal agenesis (Song et al, 1995). Reflux repair or persistence was documented in nine and seven patients, respectively, with spontaneous resolution observed in only three patients. Whether renal agenesis represents one extreme on a continuum that includes MCDK is unclear. Nevertheless, these data suggest that contralateral reflux associated with renal agenesis may show less tendency to spontaneous resolution than that associated with MCDK.

Megacystis-Megaureter Association

Massive bilateral VUR can cause a gradual remodeling of the entire upper urinary tract. The gross inefficiency of the bladder that expels urine to both the exterior and the upper tracts results in gradual bladder dilation as the refluxed urine returns to the bladder. This perpetuates marked ureteral dilation leading to the radiographic appearance of massive hydroureter and a thin-walled enlarged bladder (Burbige et al, 1984). The phenomenon is referred to as the megacystis-megaureter association or syndrome. This configuration is even discernable in utero (Mandell et al, 1992). It

is more frequent in males, and the differentiation from posterior valves is crucial (Kaefer et al, 1997). Although the latter is due to an obstructive lesion, megacystis-megaureter is a nonobstructive condition akin to cardiac dilation by regurgitation from incompetent valves. Voiding studies will readily demonstrate an open posterior urethra and differentiate megacystis-megaureter from posterior valves or prune-belly syndrome. The persistent large residual urine volume is a significant risk factor for recurrent UTI. Vesicostomy can temporize by eliminating the residual urine volume and establishing safe drainage of the upper tracts until ureteral reimplantation can be performed. Given the propensity for reflux to exacerbate the effects of bacteriuria and the fact that ureterovesical junction dysfunction is the primary factor perpetuating the syndrome, surgical correction for the reflux is indicated. Treatments aimed at improving an already patent bladder outlet are contraindicated, risk infection, and fail to correct the primary etiology. A period of bladder rehabilitation by strict attention to emptying in the postoperative period (Koefoot et al, 1981) will usually result in a return to normal bladder volume and contractile behavior. This suggests that potentially normal underlying bladder physiology can be realized if the propensity for reflux is corrected.

Other Anomalies

VUR has also been described in association with a number of congenital conditions and syndromes. No precise common genetic insult has been determined to explain such associations. A complete survey of the Online Mendelian Inheritance in Man Database developed by Johns Hopkins University, maintained by the of the National Center of Biotechnology Information, reveals more than 40 different syndromes where VUR has been described (http://www.ncbi.nlm.nih.gov/Omim/getmap.cgi?l193000). These include the VACTERL association (*V*ertebral, *A*nal, *C*ardiac, *T*racheo*E*sophageal, *R*enal, and *L*imb anomalies), CHARGE syndrome (*C*oloboma, *H*eart disease, *A*tresia choanae, *R*etarded development, *G*enital hypoplasia, and *E*ar anomalies), and imperforate anus. In cases where VUR is anticipated, a VCUG is the initial study of choice to disclose both dysfunction at the UVJ, as well as overall bladder and bladder outlet anatomy.

Pregnancy and Reflux

The morphology of the urinary tract is altered with the onset of pregnancy and increases throughout gestation (Beydoun, 1985). **Bladder tone decreases because of edema and hyperemia, changes that predispose the patient to bacteriuria. In addition, urine volume increases in the upper collecting system as the physiologic dilatation of pregnancy evolves.** The slower drainage that results can enhance the growth of organisms and increase the propensity to develop pyelonephritis. It seems logical to assume that during pregnancy the presence of VUR in a system already prone to bacteriuria would lead to increased morbidity. A number of studies have been conducted to examine this relationship.

The presence of active reflux appears to present a risk factor for the affected mother. In 1958 Hutch described a higher incidence of pyelonephritis during pregnancy in 23 women with a history of reflux and recurrent bacteriuria. Heidrick and colleagues (1967) evaluated 321 women with cystography either during the last trimester or within 30 hours after delivery. The incidence of pyelonephritis was 33% in women with reflux compared with less than 5% in women without reflux. Finally, cystograms performed 4 to 6 months postpartum in 100 women with a history of asymptomatic bacteriuria during pregnancy showed reflux in 21%. Bacteriuria was easier to clear in patients without reflux (67%) than in those with reflux (33%) (Williams and Hulme-Moir, 1970).

Maternal history also becomes a factor if past reflux, renal scarring, or a tendency to UTIs is included. Martinell and colleagues (1990) compared the outcome of pregnancy in matched controls with that in 41 women with and without renal scarring after childhood UTIs. They found that women with a history of prior infections had a high incidence of bacteriuria during pregnancy, whereas those with renal scarring and persistent reflux were more prone to develop acute pyelonephritis. In a similar study, the outcome of pregnancy was assessed in 88 women with previous bacteriuria. Women with known scars had a 3.3-fold increased incidence of hypertension, a 7.6-fold increased risk of preeclampsia, and a higher rate of obstetric interventions. Women with normal kidneys and reflux also had an increased risk of hypertension during the last trimester (McGladdery et al, 1992). Pregnant women with bilateral renal scars were also shown to have a higher incidence of pre-eclampsia than those with unilateral scarring (24% vs. 7%, respectively) (El-Khatib et al, 1994), and those with creatinine elevation are also at risk (Jungers et al, 1987). In a large study of 158 women with reflux nephropathy, pregnancy was uneventful in patients with normal blood pressure and renal function, whereas the risks of fetal demise and accelerated maternal renal disease were increased in women with impaired renal function (Jungers et al, 1996).

The implications of reimplantation surgery were studied by Austenfeld and Snow (1988), who found an increased risk of UTI and fetal loss in 31 women who had undergone ureteral reimplantation as children, despite correction of the anomaly. In a follow-up study comparing these patients with a new cohort of historical controls, women with UTIs and reflux who underwent reimplantation (suggesting an initially higher degree of reflux and increased renal scarring) were still at significant risk of UTI during pregnancy (Mansfield et al, 1995). However, they were not at a higher risk of miscarriage than the general population. In a larger study of 77 pregnancies in 41 women whose ureters had been reimplanted, Bukowski (1998) and colleagues reported that the incidence of pyelonephritis during pregnancy was slightly higher than in the general population but that the fetus and mother were at significant risk when renal scarring or hypertension was present. Although these studies may at first suggest a limited benefit to reimplantation during a subsequent pregnancy, several factors must be borne in mind. None of these studies document any associated BBD in these women, which may have existed in childhood and continued unrecognized into the fertility years. Also, the bladder dynamics change during pregnancy as a result of increasing uterine size (see elsewhere). Although it is assumed that reflux remains absent during pregnancy following correction in childhood, radiologic verification that the surgically corrected UVJ remains competent (reflux free) is not feasible, and such data are not available. Finally, it is not known whether formerly refluxing renal units in such adult patients carry a latent predisposition or heightened susceptibility to pyelonephritis during the pregnancy as a consequence of previous postinfection damage during childhood and/or any inherent reflux-associated dysmorphism (both of which would persist despite surgery at the bladder level). When combined with the known physiologic renal and bladder changes during pregnancy, it is reasonable to speculate that such kidneys may carry a heightened predisposition to pyelonephritis.

In summary, the majority of studies examining the effects of VUR on pregnancy suggest that women with a history of reflux have increased morbidity during pregnancy because of

infection-related complications, whether the reflux has been corrected or not. **Women with hypertension and an element of renal failure are particularly at risk.** Those with uncorrected reflux appear to be particularly at risk and should have their reflux corrected before pregnancy to minimize maternal and fetal morbidity. The morbidity during pregnancy of women with persistent reflux without renal scarring remains poorly defined, but the tendency to UTI seems to be increased. Because of the difficulty in predicting an outcome for this subset of patients, most clinicians recommend surgical correction for girls with reflux that persists beyond puberty, although there has been a trend toward discontinuation of prophylactic antibiotics in older girls with active reflux. Long-term follow-up studies of these patients through puberty are unavailable (see later discussion).

Natural History and Management

Spontaneous Resolution

The one feature of VUR that provides the greatest relief to parents and caregivers but at the same time creates confusion in reflux study design and literature interpretation is spontaneous resolution. Indeed, the basis of contemporary medical therapy is predicated on an expected rate of spontaneous resolution. At birth, the probability of spontaneous resolution of primary reflux is roughly inversely proportional to the initial grade. If a patient is encountered at a later age, resolution from any point in time forward will depend on initial grade of reflux, if it is known, and age at presentation. For example, unilateral grade 3 reflux at birth should resolve in 70% of cases by age 5. However, if a 6-year-old with normal bladder function presents with grade 3 reflux, it is much less likely to resolve. However, given a growing tendency among some clinicians to reassess females for persistent reflux and possible endoscopic correction following a "holiday period" of nonfollow-up (between 5 years and the teenage years), it is possible new information remains to be learned about reflux resolution. Reflux likely resolves spontaneously due to remodeling of the UVJ over time, with progressive elongation and consolidation of the intravesical ureter and antireflux mechanism, as well as stabilization of bladder dynamics. Conversely, failure of the latter likely accounts for reflux persistence beyond the statistical norms in many patients. Indeed, inability to strictly understand bladder dynamics may have skewed earlier determinations of absolute reflux resolution rates but in doing so provided a "real-world" picture of spontaneous resolution.

Resolution by Grade

Most cases of low-grade reflux (grade 1 and 2) will resolve. Several studies have documented this high rate of spontaneous resolution. However, the variance in reported resolution rates for low-grade reflux was 63% of grade 2 (Duckett, 1983); 80% of grade 2 (Arant, 1992); and 85% of grade 2 (Edwards et al, 1977). This belies the fact that lower urinary tract dynamics may also play a role in mitigating spontaneous resolution.

Grade 3 reflux will resolve in approximately 50% of cases (Duckett, 1983; McLorie et al, 1990). Very few cases of higher-grade reflux (grades 4 and 5, and bilateral grade 3) will resolve spontaneously. Analyses from several sources including the International Reflux Study in Children support a uniformly low prevalence of resolved high-grade reflux with no more than 25% (Weiss et al, 1992b) and as little as 9% (Skoog et al, 1987) of patients demonstrating spontaneous resolution. It is possible no real difference exists in resolution rates in high-grade reflux (Tamminen-Mobius et al, 1992). When one considers the fact that any given reflux grade is assigned on the basis of a dynamic voiding study, the possibility for variability by at least one grade, especially in assigning higher grades to reflux, is quite real. Thus attempting to discriminate true differences in resolution rates for grades 3 and higher reflux may not be particularly clinically relevant.

Resolution by Age

The age at which reflux begins or is first encountered will play a more potent role in the management of the patient with reflux than the grade itself. It is self-evident that if reflux is a congenital disorder with an inherent tendency to resolve spontaneously over time, it will (1) be most prevalent in neonates and young children, and (2) will demonstrate the greatest tendency to resolve in this group. Conversely, in any analysis, if reflux is truly primary and encountered in an older child where it has been present since birth, it has already demonstrated a propensity to persist and therefore is self-selected for reflux, which is unlikely to resolve (Skoog et al, 1987). The 1997 AUA Guidelines data provide a synthesis of large numbers and reasonable statistical estimates of resolution rates segregated by age and grade (Elder et al, 1997) (Fig. 122–16). Interpretation of more recent follow-up studies

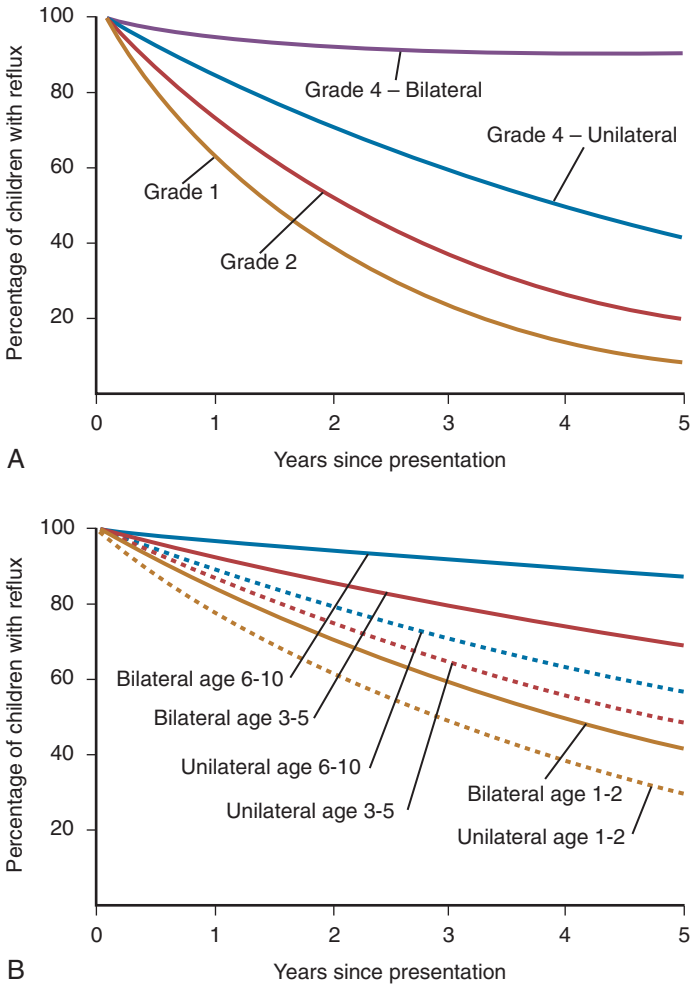

Figure 122–16. **A,** Percent chance of persistence of grades 1, 2, and 4 reflux for 1 to 5 years after initial evaluation. **B,** Percent chance of persistence of grade 3 reflux by age for 1 to 5 years after initial evaluation. (From American Urological Association. Report on the Management of Vesicoureteral Reflux in Children. Baltimore: American Urological Association, Pediatric Vesicoureteral Reflux Clinical Guidelines Panel; 1997.)

(Connolly et al, 2001) suggest that diagnosis at age 5, as well as in infancy, is associated with a similar resolution rate (20% per year), regardless of age. However, as stated at the outset, it must be remembered that resolution 5 years after age 5 implies reflux has required 10 years to resolve versus resolution 5 years after birth. Moreover, the observation by McLorie and colleagues (1990) that high-grade reflux in patients presenting after birth showed no difference in resolution rates between subjects younger and older than 1 year of age may reflect the generally poor resolution rate of high-grade reflux to begin with. Thus persistence in early life will imply persistence when older. These principles likely underlie the observation that when reflux resolves, it often does so within the first few years of life. The study by Skoog and colleagues (1987) observed that 30% to 35% of subjects resolved their reflux each year. Younger patients (<12 months old) resolved more quickly (1.44 vs. 1.85 years, $P < .02$), with grade 3 requiring slightly more time than grade 2 to resolve (1.56 vs. 1.97 years, $P < .04$).

The traditional period of observation for resolution is 5 years, probably because the greatest proportion of growth and anatomic remodeling of the UVJ is complete. In the McLorie and coworkers study (1990), 92% of resolved grade 3 reflux occurred within 4 years. There is a tendency to ascribe a benefit to the observation of interval reduction in grade. Such a finding could herald progression to resolution, but in the end it still carries the same risk of escalating a UTI to pyelonephritis and so should be interpreted with caution when counseling families. The resolution rates for VUR followed into the teenage and adult years remain unknown. **Clearly then, what constitutes reflux resolution depends on the period over which resolution is sought.**

Principles of Management

The medical and surgical therapy for reflux has purported to offer similar benefit to patients (Table 122–5). This has fueled the debate between fundamental choices of therapy for decades. The tension embedded in decision making for reflux management stems from the almost perfect results attainable by surgical correction of reflux, now commonly successful in more than 98% of cases. However, traditional practice in reflux management has held that the end does not justify the means: Reflux correction is not indicated merely because it can be corrected easily and reliably. As stated earlier, almost 80% of low-grade and half of grade 3 reflux will resolve spontaneously. Walker (1994) summarized the essential tenants of reflux management as follows:

1. Spontaneous resolution of reflux is very common.
2. High-grade reflux is less likely to resolve spontaneously.
3. Sterile reflux is benign.
4. Extended use of prophylactic antibiotics is benign.
5. Success of (open) surgical correction is very high.

Table 122–5.

Outcomes of Medical and Surgical Therapy for Children with Primary Vesicoureteral Reflux and Renal Scarring

REGISTRANT	NO. OF PATIENTS	NEW SCARS	THINNING
Europe			
Medical	155	19 (12%)	11 (7%)
Surgical	151	20 (13%)	15 (10%)
United States			
Medical	66	14 (20%)	9 (13%)
Surgical	64	16 (25%)	2 (3%)

Rather than providing strict guidelines for treatment, these principles provide ample room to individualize treatment on the basis of the particular preferences and tolerances of physicians, families, and patients for the various burdens each of the principles entails. **The classic approach has been to offer daily low-dose prophylactic antibiotic suppression of infections as the first line of treatment under the principle that every case of reflux should be offered time to resolve spontaneously, despite grade.** Clearly, age at presentation and grade will factor into predicting when and if resolution is likely to occur. In addition, in patients diagnosed after one or more episodes of pyelonephritis, the presence of scarring on renal scintigraphy may temper a decision for extended prophylaxis and observation, particularly if scarring is extensive, the reflux is high grade, renal function is already globally depressed, or congenital dysmorphism of one or both kidneys is present. In such cases, tolerance for yet another infection despite the presence of prophylaxis may be low, or simple disquiet with the notion of ongoing reflux may invite strong consideration for reflux correction.

As stated previously, it is not clear how long to wait for reflux resolution in the individual patient. In newborn patients, it is reasonable to wait until approximately 5 years of age assuming no intercurrent breakthrough infections occur. Beyond this age, it is commonly believed that the kidneys become less prone to scarring after pyelonephritis (Olbing et al, 2003), although the previously mentioned limitations in the interpretation of imaging inherent in the reflux literature should be remembered. Thus some practitioners are withdrawing prophylaxis as the child approaches the age of 5. After this age, boys with asymptomatic reflux will require little or no formal follow-up as long as lifelong attention to good bladder habits is reinforced, and they are counseled to seek prompt medical attention if a pyelonephritis were to occur in the future, as well as reassessment of their reflux status. Nevertheless, there would remain disagreement whether to correct asymptomatic bilateral high-grade reflux with normal renal parenchyma and function in an older boy despite the belief that sterile reflux is benign. Girls have traditionally undergone open surgical correction, even for asymptomatic reflux that fails to resolve by the age of 5, on the premise that it will reduce maternal and fetal morbidity during a future pregnancy. Using the rationale of antibiotic withdrawal in the older child, one study demonstrated that less than 10% of patients will subsequently develop recurrent febrile UTIs mandating surgical correction of reflux (Cooper et al, 2000), albeit with limited clinical follow-up and using only ultrasound imaging to assess renal health. Clinical guidelines for reflux management in children are presented in Table 122–6.

Adult patients who present with nonobstructive flank pain, febrile UTIs, or pyelonephritis and are found to have VUR have traditionally been offered antireflux surgery. Endoscopic correction of uncomplicated adult reflux should also be possible (Arce et al, 2009).

Emerging Role for Endoscopic Correction of Reflux. Endoscopic management is discussed in greater detail later. In North America the relative ease and low morbidity of endoscopic correction has begun to transform the indications for unresolved reflux correction in females. Indeed, although open antireflux surgery is more technically demanding, as well as more taxing on the older female patient, endoscopic correction can be easily performed well into the teenage years and beyond. Between the age of 5 and mid-to-late teens, girls with asymptomatic reflux may be treated in the same fashion as boys and have their antibiotic prophylaxis withdrawn and follow-up imaging suspended for several years, in the absence of any febrile UTI. This will also afford the opportunity

*Recommendations were derived from a survey of preferred treatment options from 36 clinical categories of children with reflux. The recommendations are classified as follows:
Guidelines: treatments selected by 8 or 9 of 9 panel members, given the strongest recommendation language.
Preferred Options: treatments selected by 5 to 7 of 9 panel members.
Reasonable Alternatives: treatments selected by 3 to 4 of 9 panel members.
No Consensus: treatment selected by no more than 2 of 9 panel members.
†For patients with persistent uncomplicated reflux after extended treatment with continuous antibiotic therapy.
‡No consensus was reached regarding the role of continued antibiotic prophylaxis, cystography, or surgery.
§See the text regarding the length of time that clinicians should wait before recommending surgery.
From American Urological Association. Report on the management of vesicoureteral reflux in children. Baltimore: American Urological Association, Pediatric Vesicoureteral Reflux Clinical Guidelines Panel; 1997.

for a new cohort of older patients to provide longer-term resolution rates on a systematic basis. Girls may then return for a final cystogram. If reflux is still present, endoscopic injection is performed followed by a postinjection cystogram. Formal prospective trials of this proposition will be required to validate the principle.

Moreover, studies of parental preference in reflux management are revealing that endoscopic treatment may sometimes be preferred over either antibiotic prophylaxis or open surgery depending on the perceived duration for reflux resolution (Ogan et al, 2001; Capozza et al, 2003). However, such studies must be interpreted with caution in that any therapy that combines low morbidity and technical ease can become a seductive choice, especially since endoscopic therapy was preferred despite an acknowledged lower success rate than open surgery and potential for more than one anesthetic. Alternatively, others may tolerate only definitive open surgical correction.

Notwithstanding the ethical considerations of proffering endoscopic treatment for reflux correction, endoscopic indications have a wider theoretic potential than open surgery. For example, even if the durability of endoscopic correction is not indefinite, recognizing that the prime age for postpyelonephritic scarring is younger than 5 years, one could conceive of temporary reflux correction by endoscopy for the early years, obviating the need for several years of prophylaxis in either males or females. Beyond 5 years, postinjection recurrence of asymptomatic reflux in males, were it to occur, would be of little clinical consequence. Males would require re-evaluation only if pyelonephritis were to occur anytime after the age of 5 years. In females, demonstration of durability of injection therapy extending from infancy to at least the end of the childbearing years would be required. One recent long-term study documents only a 5- to 7-year durability of 80% (Dodat et al, 2004); thus in one fifth of patients, reflux recurs. Moreover, these results represent the brand of injectable agent called Macroplastique. Similar data are as yet unavailable for Deflux. Nevertheless, regardless of the substance injected and the uneven durability reported to date compared with open reflux correction, the endoscopic approach to reflux management has gained favor over the past several years in both Europe (Puri et al, 2003; Lendvay et al, 2006) and the United States.

Medical Management: Watchful Waiting

Although some reports have suggested the existence of "water-hammer" renal damage from high-grade reflux of sterile urine against the renal papillae (Hodson et al, 1975; Hagen and Klevmark, 1991), no such clinical entity has been predictably demonstrated. Because it is not reflux per se that is actually being managed, **the hallmark of observational therapy in reflux disease can be more accurately termed "watchful waiting" while maintaining urinary sterility through the judicious use of single daily low-dose antimicrobial prophylaxis.** Often, antibiotics are given as oral suspensions once per day and preferably at night. **Nighttime dosing allows for antibiotic concentration in the bladder urine over the longest period of expected physiologic retention, when infection is most likely to develop.** For children younger than 2 months of age, the most commonly used medications are trimethoprim and amoxicillin. **Children younger than 2 months of age possess relative hepatic immaturity and are unable to clear sulfamethoxazole efficiently; the drug displaces fetal bilirubin and leads to jaundice.** After 2 months of age, the antibiotic of choice becomes trimethoprim-sulfamethoxazole (TSX, Septra, Bactrim). Like virtually any drug, some mild side effects should be kept in mind and include gastrointestinal upset and allergy. Although transient leucopenia has been reported with TSX, it is rare, resolves with discontinuation of the drug, and is not believed to be significant enough to warrant regular monitoring of white blood cell counts in all children taking the drug. The other drug most commonly used is nitrofurantoin (Macrodantin). Nitrofurantoin may minimize the development of resistance to fecal organisms, the latter being the largest reservoir for urine infectivity. This drug is known to cause pulmonary fibrosis and, rarely, interstitial pneumonia. However, oral tolerance is less than with TSX due to taste, and gastrointestinal symptoms are subjectively worse. A recent comprehensive literature review of the use of these drugs by Karpman and Kurzrock (2004) in children revealed a low incidence of significant hepatic (five patients) or pulmonary (nine patients) involvement, almost always associated with full-dose rather than once-a-day low-dose therapy. Finally, a growing literature on the use of probiotics (live microorganisms such as strains of *Lactobacillus,* which may displace and suppress the growth of uropathogenic bacteria) is addressing UTI prophylaxis in children (Bruce and Reid, 2003; Reid and Devillard, 2004; Salvini et al, 2004). The mechanisms that underlie the demonstrated benefit of probiotic use are now emerging (Reid, 2006; Storm, 2011). Further studies will be required to define the use of this attractive approach in the medical treatment of patients with reflux.

Breakthrough febrile UTIs or pyelonephritis while on antibiotic prophylaxis are generally considered an indication for termination of watchful waiting and correcting the reflux. However, individual documentation and verification of true breakthrough infection varies widely. As such, it is likely that instances of premature reflux correction (false positive) and failure to proceed with reflux correction (false negative) are to be expected. This possibility underscores the importance of proper antibiotic dosing, patient and parental acceptance and compliance with the chosen therapy, and meticulous attention to proper collection and handling of urine culture specimens (see earlier). Although the interaction between host defenses and bacterial virulence factors is what ideally dictates breakthrough infection, **Smellie has provided useful interpretations surrounding practical causes of breakthrough infection: 1. If the organism is sensitive to the prescribed prophylactic antibiotic, the child or parent has likely not been compliant or the dose is too low, 2. If the organism is resistant to the prescribed antibiotic, either the residual bladder volume is too high too often or the dose is too high** (Smellie, 1991). Indeed, many referrals for definitive reflux correction result from breakthrough UTI following full-dose antibiotic usage for extended periods.

Once the radiographic resolution of reflux has been documented, antibiotic prophylaxis is terminated, usually a few days after the cystogram. **However, because reflux resolution will likely herald a tapering off or discharge from regular urologic follow-up, this also is the precise time for reinforcing a lifelong adoption of good toileting and bladder behaviors.**

Landmark Studies

The efficacy of medical management rests with a few key studies that came to define and establish watchful waiting as a cornerstone of therapy for reflux disease. Smellie and colleagues led a series of studies that repeatedly demonstrated the ability of low-dose prophylactic antibiotics to prevent infection and renal scarring while reflux resolved in a significant majority of children (Edwards et al, 1977). Since then two additional large-scale

prospective studies validated this approach and helped to further define the natural history of VUR.

International Reflux Study in Children. The International Reflux Study in Children was a North American (Weiss et al, 1992a) and European (Tamminen-Mobius et al, 1992) cooperative study that randomized children younger than 9 years old with high-grade reflux to watchful waiting with prophylaxis or corrective open surgery (see Table 122–5). **Although surgery was complicated by temporary postoperative obstruction in some patients, it was more effective than prophylaxis in reducing, but not eliminating, the occurrence of pyelonephritis. Nevertheless, the incidence of UTI (38%) was the same with both modalities. Furthermore, both modalities were equally effective in reducing, but not eliminating, new scar formation.** Only the European arm stratified data for the effect of dysfunctional voiding behaviors (18%) (van Gool et al, 1992). **When untreated, voiding dysfunction was associated with more UTIs, more persistent cases of reflux, and greater grade variation during follow-up.**

Birmingham Reflux Study. Medical and surgical management was prospectively compared in a randomized cohort of 104 patients with high-grade reflux (Birmingham-Reflux-Study-Group, 1987) over a 5-year period. Again, the incidence of new scars was the same using either treatment modality. Although more than half the patients continued to reflux at 5 years, all cases of new scarring occurred within the first 2 years, consistent with the "Big Bang" concept of postinfectious renal injury mentioned previously.

Additional Prospective Studies. Medical management alone was assessed in 59 patients (84 refluxing ureters, grades 1 to 3) by the Southwest Pediatric Nephrology Group (Arant, 1992). Resolution occurred in 67%, breakthrough infection in 33%, and new scarring in 10% of the low-grade and 28% of the grade 3 patients. Scholtmeijer (1993) demonstrated resolution in 57% of 47 cases of grade 3 to 4 reflux followed by watchful waiting and prophylaxis for 5 years. Interestingly, 15 cases underwent surgical correction after breakthrough infection and 6 of these subsequently developed new scars, whereas 2 of the patients managed medically developed new scars.

RIVUR Study. Despite the long-standing standard of care regarding medical management of VUR using prophylactic antibiotics, there exist mounting countervailing concerns over the long-term use of low-dose antimicrobials. These concerns are likely fueled at least in part by the documented abundant use of antibiotics both within the medical arena and in the food chain, as well as the rising incidence of antimicrobial resistance (Cheng et al, 2008; Alam et al, 2009). Furthermore, newer prospective studies are beginning to question the ability of daily antibiotic prophylaxis to reduce the incidence of UTI (see later). Reflux management is being further challenged by discordant and seemingly random recommendations variously for watchful waiting with or without antibiotic prophylaxis or first-line endoscopic, laparoscopic, or open correction of the reflux, depending on the individual consultant. The lack of appropriate (placebo) controls or observational arms in prior retrospective reflux studies has further called their conclusions into question. If daily low-dose antimicrobial prophylaxis is to maintain any position as a first-line treatment, its true efficacy will require greater scrutiny. One major study addressing this question is termed the RIVUR study (*R*andomized *I*ntervention for the Management of *V*esico*U*reteral *R*eflux). RIVUR is a National Institutes of Health multicenter, double-blind, randomized, placebo-controlled trial designed to evaluate the effectiveness of antimicrobial prophylaxis in children found to have reflux after an initial UTI. Fifteen collaborating centers have enrolled approximately 600 children with grade 1 to 4 reflux following an initial febrile UTI. Study participants have been randomized to oral placebo versus oral trimethoprim-sulfamethoxazole antibiotic prophylaxis. The primary outcome measure is the development of recurrent febrile or symptomatic UTI (Chesney et al, 2008; Greenfield et al, 2008; Keren et al, 2008; Matthews et al, 2009).

Antibiotic Controversies and Potential New Approaches

The principal rationale for antibiotic use in the management of reflux is in the prevention of urinary infection, principally febrile pyelonephritis, which may lead to permanent postinfection renal scarring. Driving this rationale in part is the belief that the *first* febrile UTI, in the presence of reflux, will create the greater proportion of clinically significant postinfection scarring, despite the fact that this concern is based on models of postinfection scarring in experimentally induced reflux in animals with a priori **normal** renal development (Torres et al, 1985). This belief, in turn, spawned the now routine and widespread sonographic follow-up of prenatal hydronephrosis for evidence of postnatal hydronephrosis, which, if present, then triggers the documentation of reflux by cystography in order to prevent the first febrile UTI by instituting immediate antibiotic prophylaxis if reflux is found.

However, several recent prospective studies have brought into question the ability of chronic low-dose antibiotic prophylaxis to prevent UTI in children. For example, in children with grade 2 to 4 reflux, following an initial UTI, randomization of 50 patients each to antibiotic prophylaxis versus no treatment groups showed no difference in the rate of subsequent UTI or renal scarring (Pennesi et al, 2008). One multicenter trial of 225 children with reflux aged 1 to 3 years, randomizing subjects to antibiotic prophylaxis versus no treatment, found no statistical overall reduction in UTI incidence with prophylaxis, although subset analysis did suggest some benefit in boys with grade 3 reflux (Roussey-Kesler et al, 2008). As a corollary, patients with ongoing reflux in whom prophylactic antibiotics have been withdrawn have not suffered any increased incidence of UTI when compared with age-matched refluxing control patients who remain on prophylaxis (Leslie et al, 2009). Similarly, patients who have failed endoscopic reflux correction and remain uncorrected fail to show any increased incidence of UTI whether they remain on prophylaxis or not (Moore et al, 2009).

Such studies are plagued with a host of important shortcomings including small patient numbers, high dropout rates, inaccurate urine collection methods (i.e., bags), no placebo controls, routine screening rather than evaluation in response to symptoms including screening bagged sample collections in uncircumcised infants, and lack of distinction between febrile and febrile UTIs. Many of these shortcomings are being addressed in the large RIVUR study mentioned earlier. Nevertheless, despite their limitations, these studies have succeeded in casting new doubt on the true and precise effectiveness and role of antibiotic prophylaxis in reflux management. However, in the recent Swedish Reflux trial (Brandström et al, 2010c) girls 1 to 2 years old with grade 3 to 4 VUR prospectively randomized to antibiotic prophylaxis had a significantly lower incidence of new renal scars compared with those randomized to surveillance (no antibiotics) and endoscopic treatment. New scars were more prevalent following febrile UTIs (11/49 or 22%). In contrast, only 3% (4/152) of nonfebrile

UTIs were associated with new renal damage ($P < .0001$). The rate of new renal damage was low in boys (observed in 2 of 75 males enrolled). These data support the use of antibiotic prophylaxis in girls younger than 2 years of age with grade 3 to 5 VUR.

Endoscopic correction of VUR did not reduce the incidence of new renal scars or febrile UTIs. However, the relatively low success rate of endoscopic treatment in this study (54% complete resolution with an additional 17% downgraded to grades 1 to 2) may have negated any potential benefit of endoscopic correction.

When added to the underlying concern for the long-term use of antibiotics in general, studies that bring into question the efficacy of antibiotic prophylaxis are giving rise to reflux management alternatives. Where low-dose antibiotic prophylaxis may be of questionable value, the effectiveness of appropriate full-dose antibiotic treatment of UTI by eliminating fever and symptoms of acute illness, as well as eradicating the infection, is not in question. Therefore one alternative is close observation for UTI symptoms without prophylaxis, coupled with precise treatment of culture-proven UTI. However, two recent pediatric nephrology studies of UTI (Doganis et al, 2007; Hewitt et al, 2008) suggest that early (within 24 hours) versus later (within 4 to 7 days) antibiotic treatment does not necessarily reduce the incidence of postpyelonephritic scarring if the kidneys become involved in the UTI, though early treatment may reduce initial renal involvement (Doganis et al, 2007). Moreover, in both studies, reflux was not found to be a significant variable affecting scarring incidence. In both studies, limitations such as precise knowledge of timing of UTI onset and the previously mentioned limitations of DMSA scanning in differentiating pre-existing renal dysmorphism from true postinfection renal scarring (none of the foregoing study subjects had preinfection scans) remain.

With regard to endoscopic correction of reflux, the aforementioned chemoprophylaxis and invasive imaging concerns, the ease of endoscopic therapy, and parental preference for endoscopic correction despite knowledge of a lower success rate versus open surgery (Ogan et al, 2001) may be among the factors driving the resurgence and ever-increasing use of endoscopic correction of reflux. If this trend continues without rigorous prospective analysis, it could erode equipoise, to potentially position this technique as another first-line therapy following reflux diagnosis. Although studies of primary endoscopic therapy are emerging from South America and Europe (Nortes Cano et al, 2008), no North American studies endorsing this as a primary approach for low-grade reflux management are yet available. One uncontrolled retrospective study has suggested that endoscopic correction may reduce incidence of subsequent UTI, similar to the conclusion of the International Reflux Study, though endoscopic correction was not primary therapy (Wadie et al, 2007). More importantly, the durability of endoscopic reflux correction is in question, with two recent studies documenting 20% and 27% delayed recurrence of reflux following initial successful reflux correction (Sedberry-Ross et al, 2008; Holmdahl et al, 2010). Thus the indications for primary endoscopic correction of reflux will require carefully designed prospective randomized trials taking into account patient age and concomitant stage of renal development and renal susceptibility to scarring. In addition, other patient factors known to modify surgical outcomes such as pre-existence or subsequent onset of elimination dysfunction must be considered. Finally, given the high incidence of incidental and clinically silent reflux in the normal population, as well as the high propensity for reflux to resolve over time, primary endoscopic correction of reflux without knowing which patients will benefit physiologically and clinically will likely result in both unnecessary correction of reflux destined to resolve naturally and/or correction of reflux with no clinical benefit.

Antibiotic prophylaxis is not a panacea—this approach is destined to fail without adequate teaching and periodic review of perineal hygiene techniques, timely bladder emptying habits, and anticonstipation measures. Similarly, family compliance with the antibiotic administration and follow-up visits for imaging may vary widely (Wan et al, 1996). Careful discussion of obligations and expectations should take place to assess whether watchful waiting is appropriate in each case. Given the need for strict compliance with such an approach, alternative regimens such as alternate-day dosing of prophylactic antibiotics, or early aggressive treatment of UTI with full-dose antibiotics with no prophylaxis otherwise, while conceptually attractive, will be at risk for decreasing compliance, especially when new opportunities for relaxing a daily routine and awareness are introduced into the management profile. If families or patients are willing but unable to maintain all the elements of a watchful waiting treatment regimen, then consideration for open or endoscopic correction of VUR may be relatively indicated.

Surgical Management

Starting with Hutch's initial report on the successful correction of VUR in seven out of nine paraplegic patients (Hutch, 1952), multiple surgical techniques have been described to effectively correct VUR. Currently, the principles from these techniques have been incorporated into a handful of procedures with excellent results. The choice of procedure is individualized according to the surgeon's experience and the patient's condition.

Surgical Principles of Reflux Correction

The principles of surgical correction of reflux include the following:

- Exclusion of causes of secondary VUR
- Adequate mobilization of the distal ureter without tension or damage to its delicate blood supply
- Creation of a submucosal tunnel that is generous in caliber and satisfies the 5:1 ratio of length to width recommended by Paquin (1959)
- Attention to the entry point of the ureter into the bladder (hiatus), the direction of the submucosal tunnel and the ureteromucosal anastomosis to prevent stenosis, angulation, or twisting of the ureter
- Attention to the muscular backing of the ureter to achieve an effective antireflux mechanism
- Gentle handling of the bladder to reduce postoperative hematuria and bladder spasms

The surgical procedures can be classified on the basis of the approach to the ureter as *intravesical, extravesical* or *combined*. Furthermore, they can be classified on the basis of the position of the submucosal tunnel in relation to the original hiatus into *suprahiatal* or *infrahiatal*.

The following components apply to all of the various surgical techniques. The surgeon is free to select the appropriate components tailored to the patient's anatomy to achieve a successful ureteral reimplant. Prophylactic antibiotics may be administered with induction of anesthesia. The patients are generally admitted the morning of the surgery unless there are specific reasons requiring preoperative admission. Enemas are only reserved for select cases because all issues related to dysfunctional elimination should be addressed when the diagnosis of VUR is made.

Cystoscopy

Historically, many centers performed cystoscopy following the diagnosis of VUR with the premise that it offers a predictive assessment of the likelihood of spontaneous resolution of VUR. Parameters such as shape (except for the golf hole orifice associated with high-grade reflux) and location of the ureteral orifice and the submucosal tunnel length were subsequently found not to have a predictive value (Duckett and Bellinger, 1982). Therefore cystoscopy in the course of conservative management of VUR is only indicated to confirm or manage abnormalities found on other imaging modalities (Ferrer et al, 1998).

Some surgeons choose to perform cystoscopy at the time of ureteral reimplantation surgery following the induction of anesthesia. This is helpful in identifying subtle anomalies not detected on preoperative imaging, particularly if an extravesical technique is employed and the bladder is not opened. Preoperative cystoscopy may uncover inflammatory changes, trabeculation, duplication anomalies, or anatomic anomalies at the ureterovesical junction such as small ureteroceles or diverticula.

The bladder should be examined as it is distending because a paraureteral diverticulum may not be apparent until the bladder is moderately to fully distended. Some authors have suggested the use of hydrodistension of the ureteral orifice (Kirsch et al, 2004), particularly of the contralateral ureter, as a predictor of which ureters will develop contralateral reflux after surgery. PIC cystography (Rubenstein et al, 2003) has also been recommended for the detection of occult reflux in children who have had febrile UTI and a negative VCUG. In both of these techniques the tip of the cystoscope is positioned at the ureteral orifice and the irrigating fluid flow (with or without radiographic contrast) is directed at the ureter. The elevation of the anterior wall of the ureter, allowing visualization of the ureteral lumen, and/or the retrograde flow of contrast detected by fluoroscopy is considered to be indicative of an incompetent UVJ that might reflux during a UTI or following contralateral surgery but remains to be validated.

At the completion of cystoscopy the bladder is left half full if an intravesical technique is contemplated. If an extravesical technique will be used, a Foley catheter connected to a three-way adapter can be inserted to allow bladder distension to facilitate the dissection of the detrusor flaps.

Positioning

The child is positioned supine. To facilitate exposure of the bladder, especially in older children and adolescents, a rolled towel may be placed at the level of the upper sacrum or a slight break in the table is used to raise the lower pelvis and hips. All pressure points are appropriately padded, and a wide surgical prep is performed. The hips are abducted slightly to allow access to the urethra in girls if required; in boys the penis is prepped and draped in the field.

Incision

A Pfannenstiel skin incision, along a skin crease, is made about 2 cm above the symphysis pubis to the lateral edges of the rectus muscles. If the child is exceptionally overweight, the classic Pfannestiel can be extended. The anterior rectus fascia is opened in a transverse fashion and elevated superiorly to just below the umbilicus and inferiorly to the symphysis pubis. The pyramidis muscles attach between the pubic bone and the anterior rectus sheath. Thus they should not be separated from the rectus sheath. The bellies of the recti are then separated in the midline exposing the bladder. Alternatively, after the skin and Scarpa fascia are incised, the skin can be mobilized off the anterior rectus sheath and the linea alba can be opened in the midline vertically.

Intravesical Procedures

Approaching the Ureters

The peritoneum is gently swept off the dome of the bladder. This is easier with a moderately full bladder. The bladder is opened in the midline down to about 2 cm proximal to the bladder neck. Figure-of-eight stay sutures, using 3-0 Prolene, are placed at the junction of the lateral edges with the bladder dome and at the inferior apex of the incision to prevent extension of the incision into the bladder neck. A Dennis-Brown retractor provides excellent exposure. Saline-soaked sponges are folded and gently packed into the dome of the bladder and also placed along the lateral edges of the bladder incision. Three blades of the retractor are used to retract the lateral walls of the bladder and the dome. The retractor blades should be placed with the utmost care, and minimal touching, suctioning, or rubbing of the bladder mucosa are recommended to prevent edema or inflammation of the mucosa, which can lead to bleeding and difficult mucosal dissection and may aggravate the bladder spasms in the postoperative period.

Intravesical Mobilization of the Ureter

The ureter(s) is cannulated with a 3- or 5-Fr Silastic feeding tube that is sutured to the bladder mucosa at the inferior edge of the ureteral orifice with 5-0 Prolene. This serves to maintain orientation of the ureter during all phases of the procedure and is used to handle the ureter and apply gentle traction. Before ureteral mobilization, some surgeons inject epinephrine 1:200,000 submucosally to reduce the bleeding. Using needlepoint cautery, a circumscribing incision is made in the bladder mucosa about 1 to 2 mm away from the ureteral orifice. With gentle traction on the feeding tube, the ureter can now be mobilized into the bladder. Mobilization of the ureter is best started at the 6 o'clock position by spreading the blades of the tenotomy scissors gently in a posterior direction initially. Once the correct plane is entered, the dissection is carried out circumferentially. The adventitia of the ureter must not be violated to prevent ischemic injury to the ureter. The ureter is freed from its attachments to the bladder using a fine right-angle clamp and electrocautery. This is aided by gentle traction on the feeding tube. Dissection of the ureter is continued until it can reach the contralateral bladder wall without tension. At that point the surgeon is ready to develop the submucosal tunnel using the same ureteral hiatus or a suprahiatal technique depending on experience and preference.

Suprahiatal Tunnels

Politano-Leadbetter Technique

The principle behind this technique, which was originally described by Politano and Leadbetter (1958), is to bring the ureter in through a new hiatus superior to the original insertion. A submucosal tunnel is created in the direction of the trigone, medial to the original orifice. The advantage of this technique is that a long tunnel can be created, which is valuable in the higher grades of reflux. This antireflux mechanism can also be further supported by a psoas hitch.

Technique

After completion of the ureteral mobilization intravesically, the location of new hiatus is selected in a **straight line superior to the original orifice** (Fig. 122–17). With the bladder open

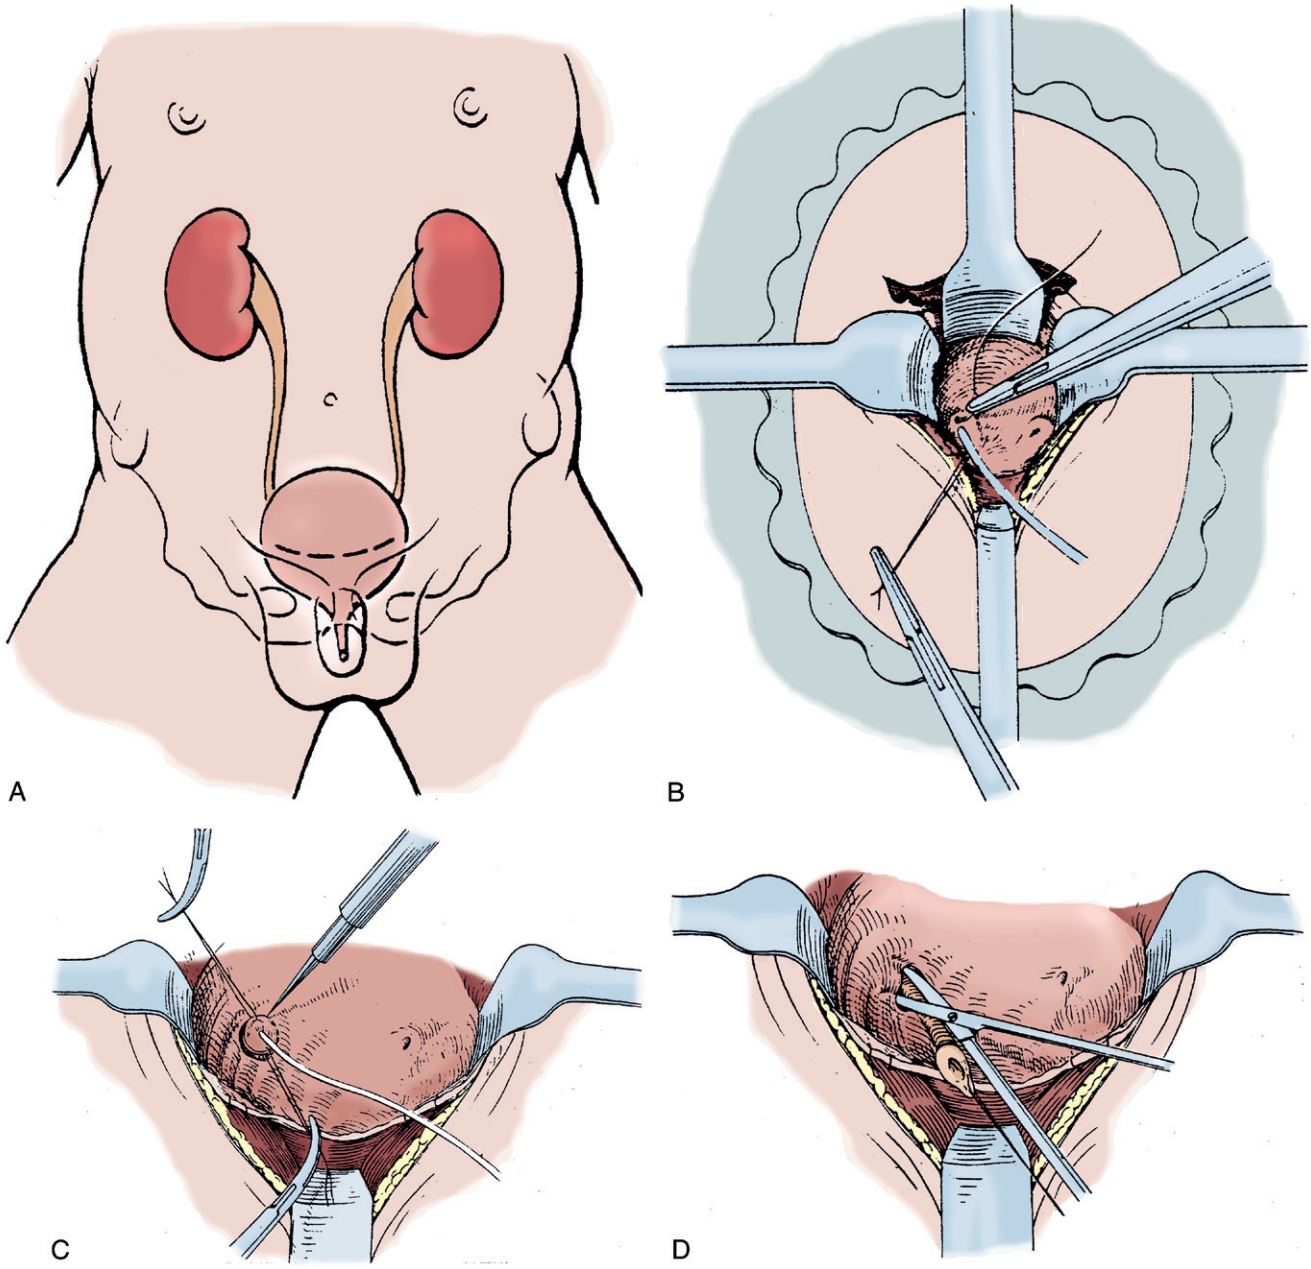

Figure 122–17. Politano-Leadbetter technique. **A,** Typical approach to the bladder for reimplantation. A transverse, lower abdominal incision is made along a skin crease one or two fingerbreadths above the symphysis pubis. **B,** Fine sutures are placed above and below the ureteral orifice for handling. A feeding tube in the ureter aids in the initial dissection. **C,** A needle-tip cautery outlines a circumferential incision around the orifice. **D,** Tenotomy scissors initially establish the plane of dissection inferiorly, where ureteral damage can be avoided. The plane is then carried around the ureter.

Continued

and the lateral walls retracted, the inexperienced surgeon might be inclined to position the new hiatus too laterally on the posterior wall. Once the bladder is closed and full, the ureter enters on the anterolateral wall and then hooks back posteriorly toward the trigone, creating the classic "hooking," which is an important cause for postoperative ureteral obstruction. In the original description of the Politano-Leadbetter technique, the new hiatus was created blindly by passing a right-angle clamp from the original hiatus behind the bladder to puncture through the posterior wall of the bladder at the new hiatal opening. This blind maneuver must be discouraged because it is the cause of significant complications that may be associated with this procedure such as routing the ureter intraperitoneally, injury to bowel, vas deferens, vagina, or other nearby structures. The current approach is to retract the superior lip of the original hiatus with a stay suture or a vein retractor and to clear the back wall of the bladder bluntly under direct vision. A right-angle clamp is then used to create a new hiatus through which the ureter enters the bladder. The submucosal tunnel is created in the direction of the trigone, medial to the original orifice. The length of the tunnel depends on the diameter of the ureter. A 5:1 ratio (length to width) as suggested by Paquin is a helpful guide. It is important to lift the mucosa off the detrusor at the point of entry of the ureter into the bladder so that the mucosa can be closed properly over the new hiatus. The

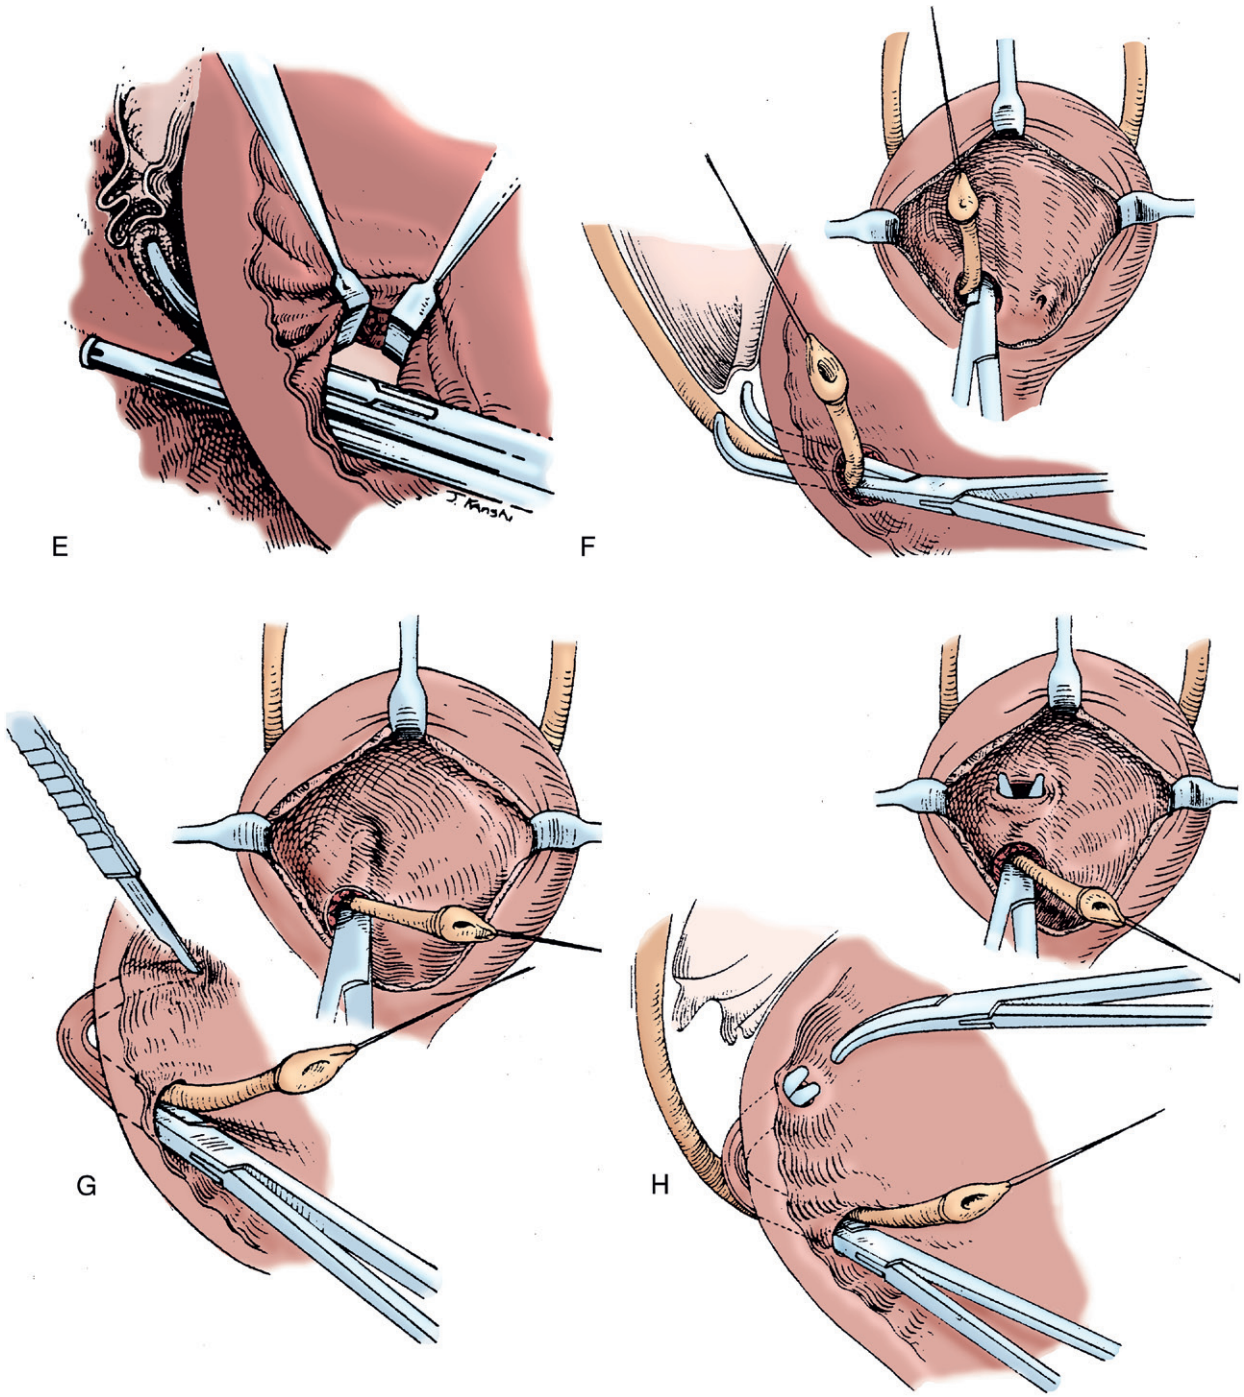

Figure 122–17, cont'd. **E,** With the aid of a lighted suction tip and two Senn retractors, a fine gauze dissector is used to sweep the peritoneum from the posterior bladder wall. **F,** After sweeping the peritoneum away, a blunt right-angle clamp indents the bladder from behind at a new hiatus approximately 2.5 cm superior and somewhat medial to the original hiatus. **G,** The clamp is incised on from within and generously spread to make certain that the new hiatus is wide enough. **H,** A second right-angle clamp follows the first from within the bladder to the original hiatus.

tunnel should be capacious enough to prevent constriction of the ureter. The ureter is pulled through the tunnel, and the feeding tube is removed.

Ureteral Anastomosis. The ureter is spatulated ventrally (at the 6 o'clock position), and the edges are freshened if necessary. Three interrupted sutures of 5-0 polyglactin placed relatively close to each other anchor the ureter to the trigone by suturing it to the bladder muscle and mucosa. The anchoring sutures should be placed carefully because the apex of the spatulation is the narrowest point of the ureter. The remainder of the ureteral anastomosis is carried out with interrupted 5-0 polyglactin sutures at the 3, 9, and 12 o'clock positions. The 12 o'clock suture may also be used to evert the anterior wall of the ureter, thus creating a small cuff. Although a 5-Fr feeding tube passed up the ureter confirms patency and absence of kinks, the most reassuring sign that the ureteral reimplant is not obstructed is to see the jet of urine emerging from the orifice. It is thus important to communicate to the anesthesiologist the importance of adequate fluid

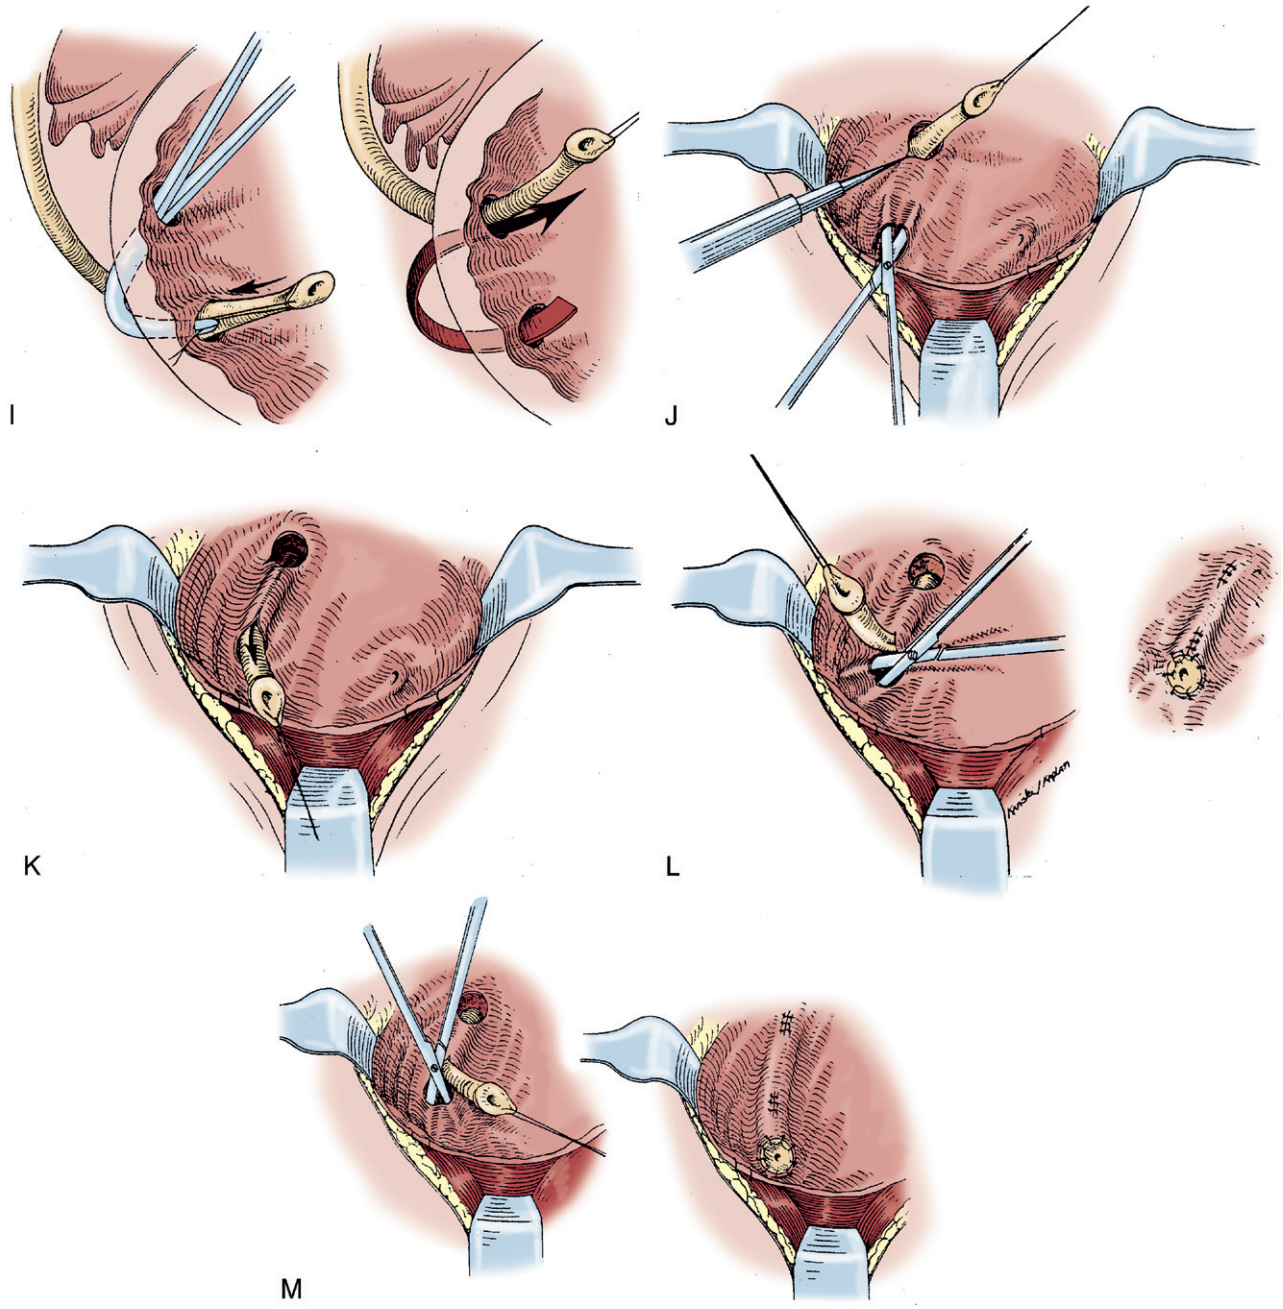

Figure 122–17, cont'd. **I,** The right-angle clamp grasps the stay suture, and the ureter is pulled through the new hiatus. **J,** The inferior lip of muscle at the new hiatus is divided for a few millimeters to eliminate any ureteral angulation at its entrance to the submucosal tunnel that is created with scissors. **K,** The ureter is brought through the new tunnel to the original hiatus. **L,** The ureter is anastomosed to the original hiatus in the classic Politano-Leadbetter technique. Proximal mucosa can be closed over the ureter to give the tunnel additional length. **M,** Ureteral advancement is also helpful, especially if the original hiatus is laterally positioned. A second submucosal tunnel can be created toward the bladder neck to place the new orifice in a more inferior position and gain additional length for the reimplant. (**A** to **D** and **F** to **M,** From Retik AB, Colodny AH, Bauer SB. Pediatric urology. In: Paulson DF, editor. Genitourinary surgery, vol. 2. New York: Churchill Livingstone; 1984. p. 757–63; **E,** from Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, editor. Difficult problems in urologic surgery. Chicago: Year Book; 1989. p. 121.)

administration throughout the case. The mucosa overlying the new hiatus is closed with a running 5-0 polyglactin suture. The bladder is closed in two layers using a 3-0 polyglactin suture. A Foley catheter is used to drain the bladder for 48 hours; drains and stents are only employed for the more complex cases.

Paquin Technique

Paquin described this combined extravesical/intravesical technique in 1959 (Paquin, 1959). The new ureteral hiatus is created from outside the bladder, thus avoiding the difficulties associated with this maneuver in the Politano-Leadbetter technique. As with most of the other open techniques, a success rate greater than 95% for primary VUR is achieved with this method (Woodard and Keats, 1973).

The ureter in the Paquin technique can be approached extravesically (see Extravesical Mobilization of the Ureter) before opening the bladder. A right-angle clamp is applied at the ureterovesical junction, the ureter is divided, and a 3-0 polyglactin suture

is used to suture ligate the original hiatus. The bladder is then opened in the midline, and a new hiatus is created, located cephalad to the prior position. The peritoneum is carefully cleared off the back wall of the bladder at the site of the new hiatus. A right-angle clamp is passed from inside the bladder under direct vision, and one end of a 5-mm Penrose drain is pulled into the bladder. A mosquito snap is applied to the Penrose drain, which acts as a holder and facilitates the creation of the submucosal tunnel. The mucosa is dissected off the detrusor circumferentially at the new hiatus. The length of the submucosal tunnel is governed by the diameter of the ureter, and a 5:1 ratio is usually achievable. In more complex cases a psoas hitch may be required to achieve a longer tunnel length. The tunnel is developed by carefully lifting the mucosa off the detrusor using tenotomy scissors. Countertraction on the mucosa is helpful, especially in redo cases and when the bladder wall is trabeculated. Once the tunnel is developed the remainder of the reimplants is similar to the Politano-Leadbetter procedure.

The modified Paquin technique is particularly suited for dilated ureters and complex (El-Sherbiny et al, 2002) and failed reimplants (Mesrobian et al, 1985) because of the versatility offered by the combined extravesical/intravesical approach to the ureter and the ability to achieve longer submucosal tunnel lengths.

Infrahiatal Tunnels

Glenn-Anderson Technique (Fig. 122–18)

In 1967 Glenn and Anderson described their technique of ureteral reimplantation (Glenn and Anderson, 1967). By using the same hiatus and advancing the ureter distally toward the bladder neck, the potential complications associated with the Politano-Leadbetter technique, specifically kinking of the ureter, are avoided. The ureter is mobilized as described earlier. A submucosal tunnel is created toward the bladder neck using tenotomy scissors. The distance from the hiatus to the bladder neck limits the length of the tunnel. Glenn later described a modification that allows creation of a longer tunnel by incising the detrusor proximally at the original hiatus (Glenn and Anderson, 1978). The detrusor edges are then reapproximated distal to the ureter. With advancement of the ureter toward the bladder neck, the distal anastomosis of the ureter could be challenging with this technique. As with the other procedures, the results with this technique are excellent with a 98% success rate (Gonzales et al, 1972).

Cohen Cross-Trigonal Technique

Cohen's technique (1975) overcomes the limitation of the tunnel length in the Glenn-Anderson technique by directing the tunnel across the trigone toward the contralateral bladder wall (Figs. 122–19 and 122–20). The difficulty with the distal anastomosis in the Glenn-Anderson technique is also eliminated.

Cohen's technique is particularly suited for small bladders or thick-walled bladders (PUV or neuropathic) because the ureteral advancement across the back wall of the bladder rarely results in kinks or obstruction. The cross-trigonal reimplant is also the procedure of choice in conjunction with bladder neck reconstructive procedures because the superior displacement of the ureters provides room for adequate elongation of the bladder neck.

As a result of its simplicity and reliable results (up to 99% [Glassberg et al, 1985; Kennelly et al, 1995; McCool and Joseph, 1995; El-Ghoneimi et al, 1999]), Cohen's procedure has become the most commonly employed intravesical reimplant.

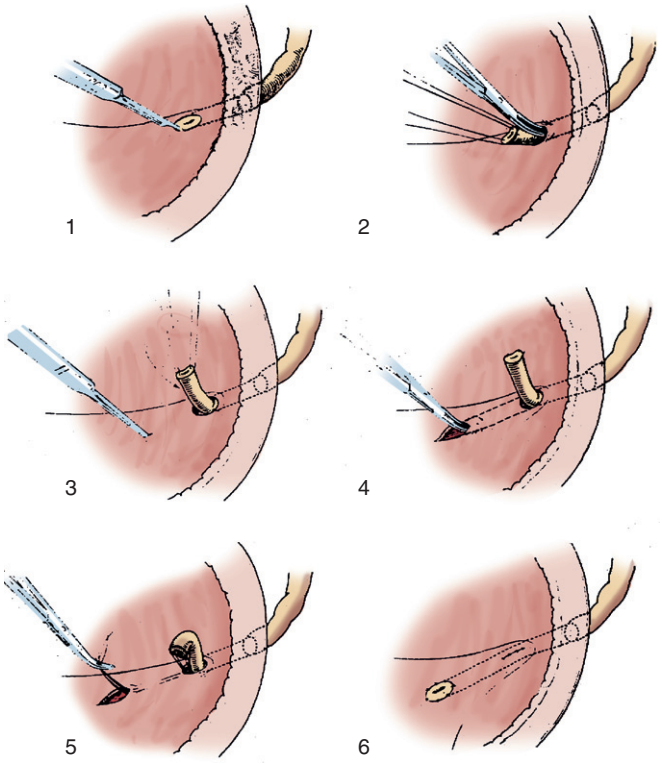

Figure 122–18. Glenn-Anderson technique. The ureter is mobilized and advanced beneath a new submucosal tunnel. (From Glenn JF, Anderson EE. Distal tunnel ureteral reimplantation. J Urol 1967;97:623.)

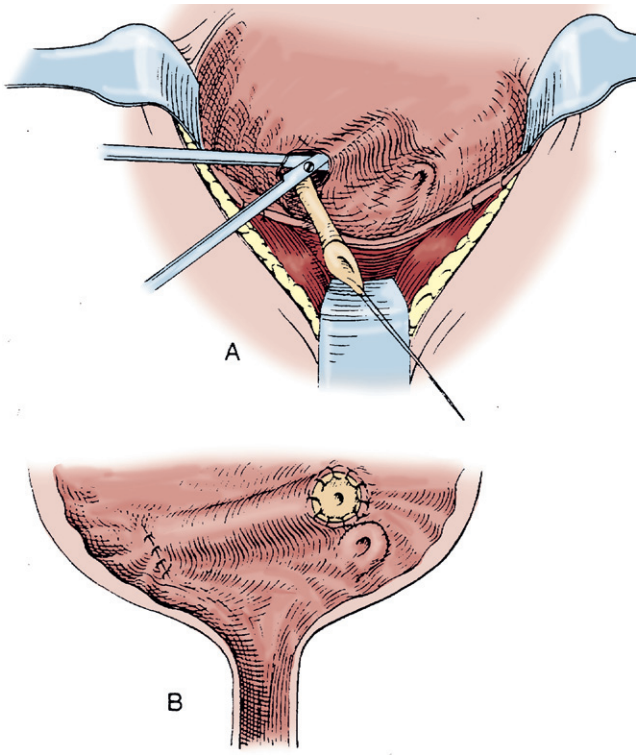

Figure 122–19. Cohen cross-trigonal technique, unilateral reimplantation. After the ureter is freed **(A),** a submucosal tunnel is made, with the new mucosal hiatus just above the contralateral ureteral orifice **(B).** (From Retik AB, Colodny AH, Bauer SB. Pediatric urology. In: Paulson DF, editor. Genitourinary surgery, vol. 2. New York: Churchill Livingstone; 1984. p. 764.)

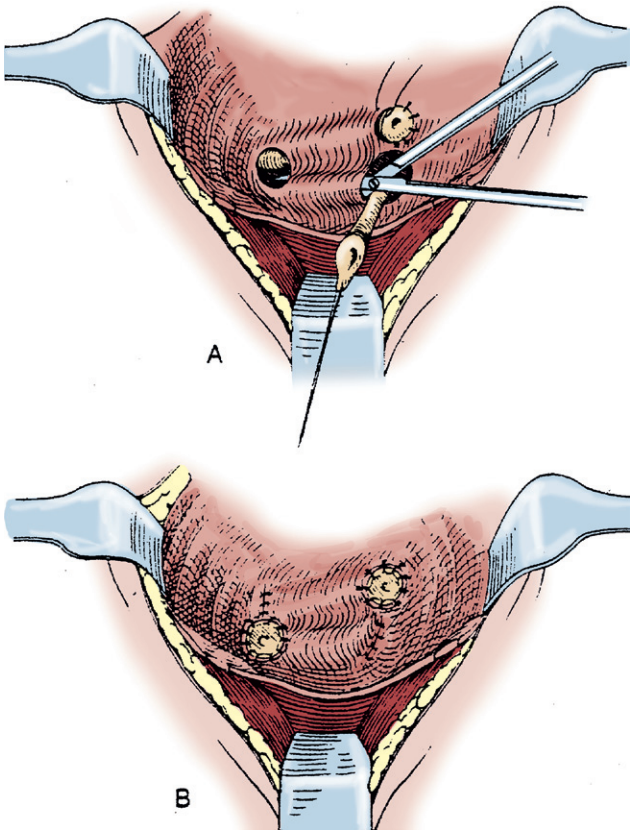

Figure 122–20. Cohen cross-trigonal technique, bilateral reimplant. **A,** The more superior ureter is tunneled transversely, with its new orifice just above the contralateral orifice. **B,** The other ureter is tunneled inferiorly, with its new orifice located at the inferior-most portion of the contralateral hiatus. (From Retik AB, Colodny AH, Bauer SB. Pediatric urology. In: Paulson DF, editor. Genitourinary surgery, vol. 2. New York: Churchill Livingstone; 1984, p. 765.)

Critics of this technique cite the difficulty of retrograde catheterization of the superolaterally positioned ureteral orifice for radiographic studies, insertion of stents, and management of ureterolithiasis as significant disadvantages. Suggested approaches to overcome this include suprapubic cystotomy by trocar (Lamesch, 1981) or 14-gauge 5-cm intravenous cannula in conjunction with cystoscopy to direct the ureteral catheter into the ureter or by using a curved tip vascular access catheter and an angle-tipped glide wire with a torque device (Wallis et al, 2003) or the use of a flexible ureteroscope.

Method

1. The technical methods of the Cohen and Glenn-Anderson procedures are similar in many aspects.
2. The ureter is approached and mobilized using the standard intravesical approach.
3. A hiatal groove may be created on the medial side of the ureter to reduce the angulation of the ureter as it crosses transversely, especially when the bladder wall is thickened. If the hiatus is excessively patulous, it can be reapproximated with one or more interrupted 3-0 polyglactin sutures to avoid diverticulum formation (Ahmed and Tan, 1982). The hiatus should easily accommodate the tips of a large right-angle clamp alongside the ureter to avoid obstruction of the ureter.
4. The submucosal tunnel is developed using the tenotomy scissors as previously described. When only one ureter is reimplanted, the tunnel is directed superior to the contralateral ureteral orifice. If both ureters are reimplanted, the tunnel for the more laterally displaced ureter is directed superior to the contralateral orifice. The second tunnel is directed toward the inferior edge of the orifice of the laterally displaced ureter. A common submucosal tunnel has been used successfully for bilateral reimplants (Androulakakis et al, 2003).
5. The ureter is spatulated and anastomosed to the bladder mucosa as described in the Politano-Leadbetter technique. The mucosa over the old hiatus is closed with 5-0 polyglactin sutures.
6. Alternatively, the mucosal cuff of the ureteral orifice may be preserved and anastomosed to the bladder mucosa without spatulation.
7. The ureter is catheterized with a 5-Fr feeding tube to ensure patency, although the continuous efflux of urine from the orifice provides the best assurance of patency.
8. Closure of the bladder and drainage is completed as described previously.

Extravesical Procedures

Lich and colleagues (1961) in the United States and Gregoir (1964) in Europe independently described the extravesical approach to ureteral reimplantation (Fig. 122–21). The technique became more popular following the modifications described by Daines and Hodgson (1971), and Zaontz and colleagues (1987) popularized anchoring the ureter with advancement sutures. These modifications allow for a combined advancement of the ureter and lengthening the tunnel proximally. In addition, anchoring sutures fix the ureter distally and thus maintain stability of the tunnel. The advantage of the extravesical technique is that the bladder is not opened; thus postoperative hematuria and bladder spasms are minimized. The technique is simple to learn and is readily taught.

The main concern with this technique has been the development of transient voiding inefficiency that is seen in up to 20% (Fung et al, 1995; Lapointe et al, 1998; Lipski et al, 1998; Barrieras et al, 1999; Marotte and Smith, 2001) of children who undergo bilateral extravesical reimplants. The mechanism is thought to be due to disruption of the nerves to the bladder bilaterally possibly due to excessive use of cautery during the detrusorotomy. The population most at risk appears to be boys younger than 3 years of age with bilateral high-grade reflux (Barrieras et al, 1999).

Leissner and colleagues (2001) used human cadavers to study the topography of the pelvic plexus in an effort to understand the mechanism of injury to the plexus resulting from extravesical reimplant surgery. They demonstrated that the main portion of the pelvic plexus is located approximately 1.5 cm to 2 cm dorsal and medial to the UVJ in adult cadavers. Smaller branches travel along the medial aspect of the ureter, outside the thin layer of tissue (the mesoureter) that surrounds the ureter. On the basis of their anatomic description, injury to the branches of the pelvic plexus is avoided if dissection of the distal ureter is carried out between the mesoureter and ureteral adventitia. Yucel and Baskin (2003) further refined the description of the neuroanatomy of the distal ureter and UVJ using immunohistochemical analysis and three-dimensional imaging techniques in normal human fetuses (21 to 40 weeks' gestation). They confirmed the localization of the nerves along the medial aspect of the ureter just outside the Waldeyer sheath. At the UVJ the nerves surround the ureter in a

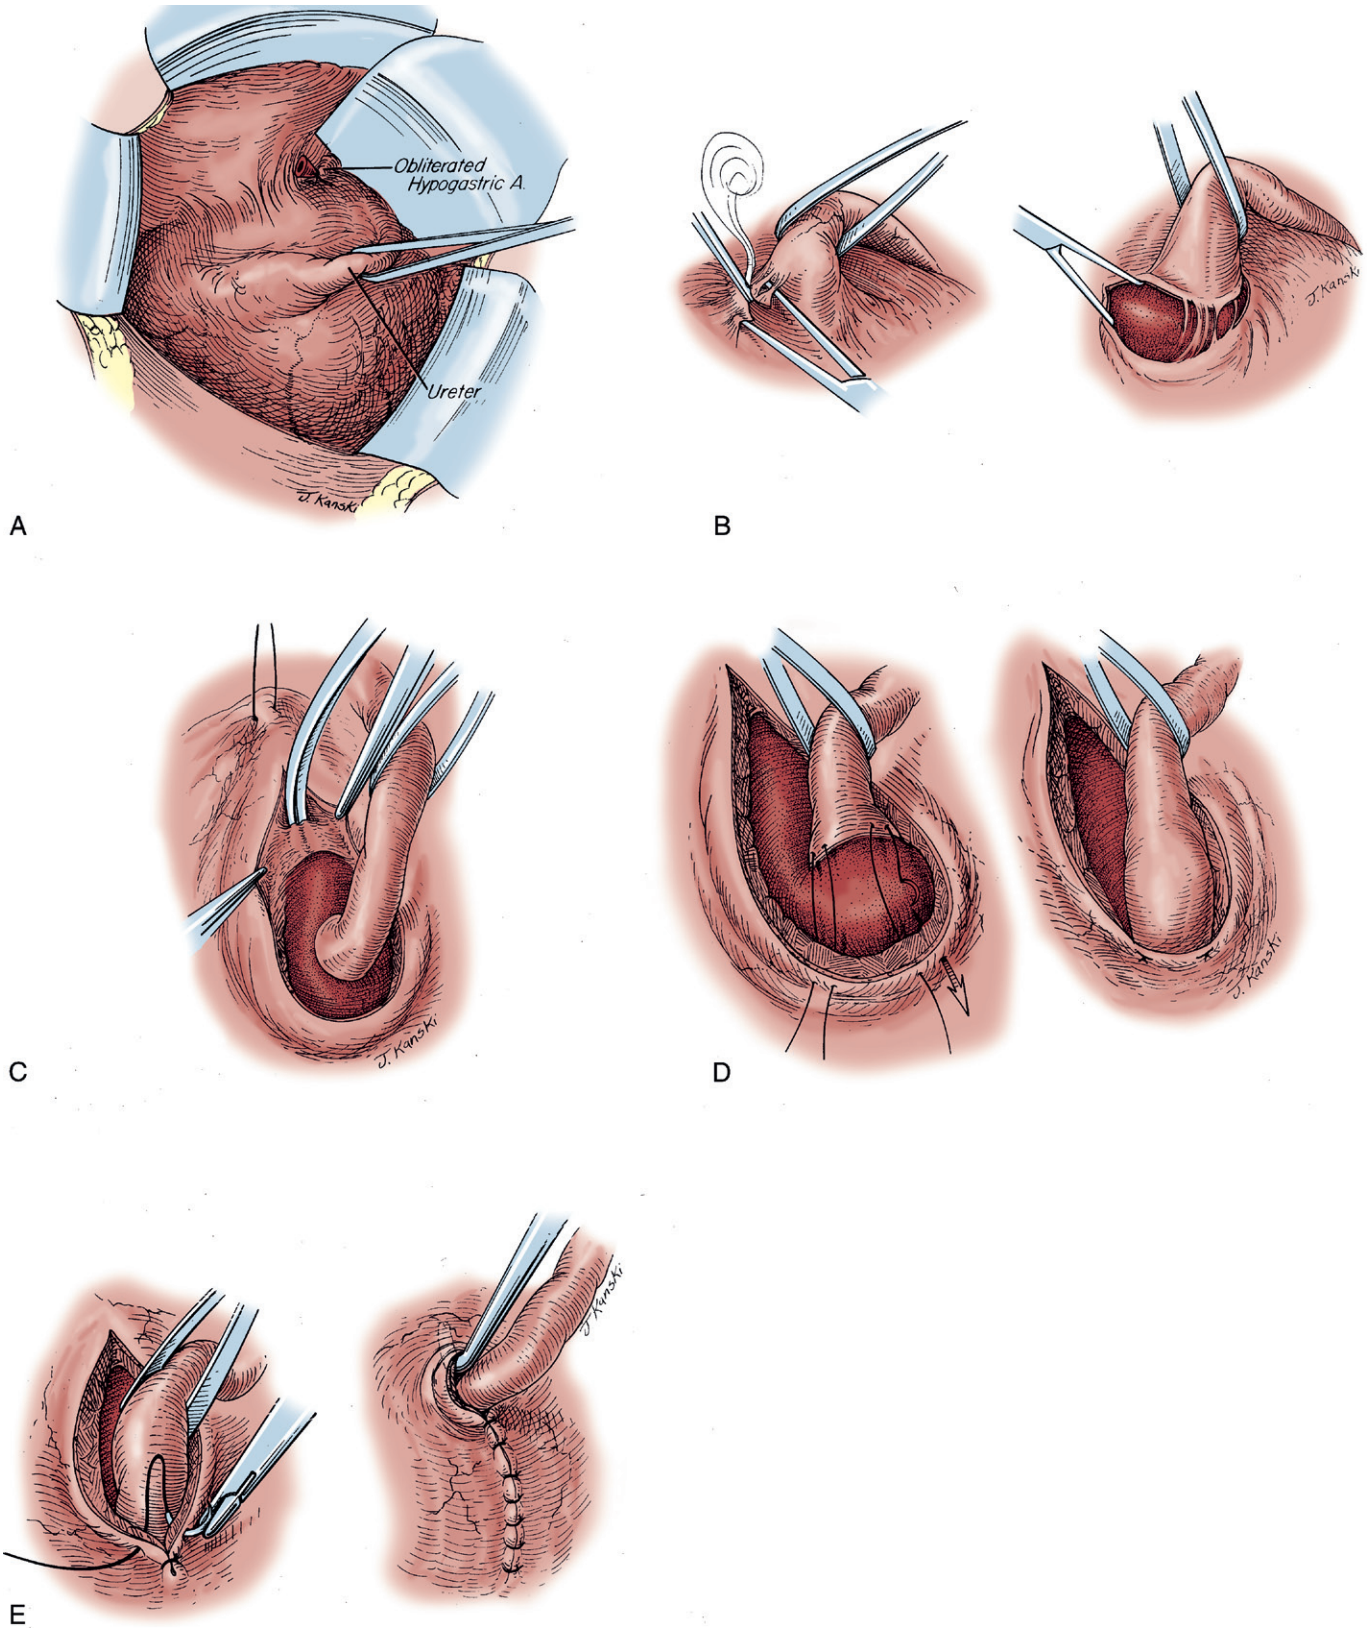

Figure 122–21. Modified Lich-Gregoir/detrusorrhaphy technique. **A,** The ureter is identified and gently grasped after ligation of the obliterated hypogastric artery. **B,** The ureter is circumferentially mobilized at its intersection with the bladder by incising the detrusor at the level of the ureteral hiatus. **C,** The serosal and muscular layers of the bladder (4 to 5 cm) are opened along a straight course cephalad and lateral from the ureterovesical junction to create the trough for reimplantation. A tacking suture aids in orientation. **D,** The bladder mucosa is elevated off muscle wall, and vest-type sutures are placed from the detrusor at the distal limit of dissection to the proximal ureteral adventitia and back again through same tissue planes. Tying of the vest sutures advances and anchors the ureter onto the trigone. **E,** Reapproximation of the detrusor creates a long submucosal tunnel and completes the repair. (From Peters C, Retik AB. Ureteral reimplantation including megaureter repair. In: Marshall FF, editor. Textbook of operative urology. Philadelphia: WB Saunders; 1996. p. 868–70.)

network-like fashion; distally, once the ureter enters the bladder, the nerves localize on the detrusor muscle distal and lateral to the ureter. From these two studies it is suggested that the incidence of voiding inefficiency observed after bilateral extravesical reimplants depends on the surgical technique. The injury is limited to the smaller nerve branches rather than the actual pelvic plexus, which is located medially and posteriorly. The neural damage may be due to transection of the nerves, electrocautery, or neuropraxia caused by surgical trauma. Injury to the nerves may be prevented by limiting the dissection to the correct plane, just outside the ureteral adventitia, reducing the use and power of electrocautery, restricting the incision of the detrusor distal to the UVJ, and gentle handling of the tissues (David et al, 2004).

Patients who develop urinary retention, requiring insertion of a Foley catheter or intermittent catheterization, are able to void within 1 to 2 weeks (Minevich et al, 1998a; Barrieras et al, 1999) indicating the reversibility of the neurologic lesion.

Approaching the Ureters

A Pfannensteil incision is used as described earlier. It is best to have the bladder somewhat distended to this point to facilitate dissection of the peritoneum of the lateral bladder wall. The obliterated umbilical artery is identified. The ureter crosses medial to the point of origin of the obliterated umbilical artery from the internal iliac artery. This is an excellent anatomic reference point for identification of the distal ureter. Dividing the obliterated umbilical artery facilitates dissection and mobilization of the ureter. Some authors were concerned that the injury to the bladder innervation occurs when the obliterated umbilical artery is divided. However, Lipski and colleagues (1998) demonstrated that there was no difference between two groups of patients whether the obliterated umbilical artery was divided or not. The peritoneum is meticulously reflected off the anterior surface of the ureter. In order to avoid injury to any of the branches of the pelvic plexus, it is recommended that the surgeon stay right on the ureter during its dissection being careful not to injure blood vessels running in the ureteral adventitia. A vessel loop is passed around the ureter and used as a handle. Dissection and mobilization of the ureter is carried distally to the point where it tunnels under the detrusor muscle.

Creation of the Extravesical Tunnel

With the bladder in its normal anatomic position, the course of the ureter along the posterior wall of the bladder is identified and marked for a distance of 5 cm. The bladder is reflected medially; a Dennis Brown retractor is quite helpful for this procedure. The outlined course of the ureter is inspected. The peritoneal reflection may need to be gently lifted off the wall of the bladder. With the bladder retracted, the tunnel direction will appear to be pointing toward the anterior abdominal wall. It is important to have the bladder full and somewhat tense but not overstretched. The detrusor is incised using low current electrical cautery (15 watts) to create the new submucosal tunnel. Following that, tenotomy scissors are used to divide the detrusor fibers along the same line of the initial incision down to the bladder mucosa. Care should be taken to incise the detrusor fibers along one line, without wandering sideways, in order to facilitate lifting the detrusor off the mucosa with minimal disruption to the detrusor muscle and its innervation. Blood vessels are easily seen as one incises the detrusor fibers, and these are cauterized selectively with bipolar cautery. It is critical that all detrusor muscle bundles are divided before elevation of the detrusor flaps. When the last detrusor bundles have been divided, a **uniform** mucosal dome bulges out. This provides the surgeon with an excellent point of reference that the tunnel has been established in the correct plane.

The detrusor is dissected off the mucosa on either side of the incision, for a width slightly larger than the circumference of the ureter. This dissection is best carried out from proximal to distal, leaving the dissection around the ureter as the final step of the tunnel creation.

There is a definite **avascular** plane between the muscle and the mucosa. The most efficient method to realize this dissection is to have the assistant grasp the detrusor bundles closest to the mucosa with two forceps elevating the muscle off the mucosa. The surgeon gently depresses the mucosal bulge with one hand and uses the tenotomy scissors to sharply separate the muscle bundles off the mucosa, on either side, along the length of the tunnel. Injury to the mucosa during dissection of the tunnel is quite avoidable unless the bladder is thick walled and trabeculated. Inadvertent injury to the mucosa could be closed with a 6-0 polyglactin figure-of-eight suture. It is not necessary to create a wide tunnel unless the ureter is very dilated.

Particular attention is necessary when dissecting around the ureter. The detrusor fibers attached to the ureter are carefully divided, staying close to the ureter to avoid injury to any of the terminal nerve branches entering the bladder. The dissection is carried out along the lateral and medial attachments of the ureter but is not extended distally.

The original modification described by Zaontz and colleagues (1987) for the extravesical procedure included incision of the detrusor distal to the ureteral orifice for 5 to 10 mm with advancement of the ureter using two vest sutures. Leissner and colleagues (2001) demonstrated that this particular aspect of the procedure may be responsible for injury to the bladder innervation at the trigonal area and may be the lead cause of urinary retention in bilateral extravesical reimplants. Therefore in order to avoid damage to the nerves, this maneuver should be avoided unless there is a paraureteral diverticulum that requires repair simultaneously (Jayanthi et al, 1995). In those cases, dissection of the detrusor distal to the ureter should be carried out in a limited fashion.

Once creation of the submucosal tunnel is complete, the bladder is decompressed before reapproximation of the detrusor. The ureter is positioned in the new tunnel, and the detrusor reapproximated using interrupted 3-0 polyglactin sutures. To achieve alignment of the tunnel, it is best to place the most proximal suture first at the new ureteral hiatus and to leave it untied and tagged on a mosquito snap. Tension applied to this suture straightens and elevates the detrusor flaps, allowing the surgeon to reapproximate the detrusor without risk of injury to the ureter or the mucosa. The suturing commences at the most distal portion. The adventitia of the ureter may be incorporated in one or two of these sutures to stabilize the tunnel and prevent a diverticulum from forming at the most distal or proximal portion of it. At the completion of the suture line, the caliber of the hiatus should be tested with a right-angle clamp to ensure absence of any constriction or compression of the ureter.

The bladder is refilled and the retractor is removed. The course of the ureter is reinspected to ensure absence of any kinks in the retroperitoneum or any bulging of the mucosa at either end of the tunnel.

A Foley catheter is left for 24 to 48 hours; some authors recommended not leaving a catheter at all (Marotte and Smith, 2001). If an epidural caudal catheter is inserted for postoperative analgesia, it should be discontinued 6 to 12 hours before removal of the Foley catheter.

If the child is observed to void without problems, he or she is discharged, to return for a follow-up ultrasound and a VCUG usually 3 months postoperatively.

Postoperative Evaluation

In expert hands the success rate for ureteroneocystostomy in patients with low-grade primary VUR approaches 100%. As a result of these outstanding outcomes, several centers have evaluated the need for postoperative invasive imaging. Most agree that an ultrasound is necessary at 6 to 12 weeks postoperatively. In a large study by Barrieras and colleagues (2000), 723 renal units were evaluated. At 1 year postoperatively there was a significant difference between children who had undergone surgery for low-grade primary VUR (99% resolution) versus those with high-grade reflux (94%). Thus in patients who initially had low-grade primary reflux, in whom the preoperative and postoperative ultrasound was normal and do not have voiding dysfunction or recurrent UTIs (Lavine et al, 2001), the success rate with uncomplicated ureteroneocystostomy approaches 100% (Bisignani and Decter, 1997; Bomalaski et al, 1997b; El-Ghoneimi et al, 1999; Barrieras et al, 2000; Grossklaus et al, 2001). On the basis of these reports, it has been suggested that the postoperative VCUG can be avoided in this group of patients. This recommendation should be individualized on the basis of the family situation and the expertise of the center performing the surgery. Some families have followed reflux for several years and are anxious to know with certainty that the reflux has resolved. In other families, the children are quite reluctant to undergo another VCUG, and in this situation it may be reasonable not to perform a postoperative study unless the child has a dysfunctional bladder or develops postoperative hydronephrosis or UTIs. However, the lower success rate for high-grade reflux would still support complete postoperative studies in most cases.

Following ureteroneocystostomy, the presence of minimal ureteral dilatation and low-grade hydronephrosis on early postoperative ultrasound is not unusual (Barrieras et al, 2000; Bomalaski et al, 1997b). Indeed, this common finding should argue against performing such studies too early after surgery. On the other hand, persistence of this dilatation beyond 3 months or its progression should be further investigated (Aboutaleb et al, 2003). Additionally, the development of new renal scars on late follow-up ultrasound, a discrepancy in renal growth, or recurrent UTIs may warrant complete radiologic re-evaluation of the patient.

As discussed previously, children with renal scarring should have their blood pressure measured at every visit with their family physician.

Complications of Ureteral Reimplantation

Early Complications

Persistent Reflux. Early reflux following ureteroneocystostomy is usually not a significant clinical problem and commonly resolves by 1 year on repeat cystography. In the report by Barrieras and colleagues (2000), 49 out of 723 renal units had reflux at 3 months, 11 of which were contralateral. At 12 months' follow-up, reflux resolved spontaneously in 20 of the 38 ipsilateral and in 8 of the 11 contralateral ureters. Persistent reflux at 1 year was more common in patients who had high-grade reflux preoperatively. In their study 30% of patients undergoing surgery had high-grade reflux. Two thirds of those with persistent reflux at 1 year (12/18) were from that group. Thus the majority of low-grade postoperative reflux detected in the initial VCUG at the 3-month follow-up point disappeared spontaneously, likely due to the resolution of the bladder inflammation and improvement in bladder dysfunction that may be present in the early postoperative period.

Contralateral Reflux. The issue of contralateral reflux has been the subject of several reports in the literature over the past 15 years, most of which are retrospective. Minevich and colleagues (1998b) and Burno and colleagues (1998) noted a low incidence of contralateral reflux after unilateral extravesical detrusorrhaphy in 5.6% and 11.6% of their patients, respectively. Diamond and colleagues (1996b), in a multicenter trial of 141 patients, reported an 18% incidence of contralateral VUR. These patients were analyzed according to grade of initial reflux, presence of a Hutch diverticulum or duplex system, and the surgical technique employed to correct the reflux. There was no difference noted among the various surgical techniques, but there was a significant trend toward development of contralateral reflux with the higher grades of ipsilateral corrected reflux and correction of reflux in duplex systems. They concluded that the distortion of the contralateral hemi-trigone was not a responsible factor for contralateral reflux but rather the severity (grade 5) of reflux, and the presence of a duplex system put patients at risk for development of contralateral reflux postoperatively. Conversely, Kumar and Puri (1997) reported on 495 children with unilateral reflux who had undergone subureteral Teflon injections. New contralateral reflux was diagnosed in only 37 children (7%). They were unable to find any correlation between the grade of preoperative ipsilateral reflux and postoperative contralateral reflux and suggested that low incidence of new contralateral VUR may be due to a relative noninterference with the contralateral trigone afforded by endoscopic compared with open reflux correction. They refuted the existence of the pop-off mechanism accounting for new contralateral reflux in their series because the risk of new contralateral reflux did not correlate with the preoperative reflux grade (grades 4 and 5). Sparr and colleagues (1998) reviewed a series of 143 patients on conservative management and initially diagnosed with unilateral reflux but subsequently developed metachronous contralateral reflux. Contralateral reflux appeared in 33%, suggesting a different etiology for the appearance of contralateral reflux unrelated to surgical correction. They speculated that the contralateral reflux was in fact synchronous (i.e., bilateral) but missed on initial cystogram or that the natural history of unilateral or bilateral reflux may involve intermittent appearance and disappearance of VUR on one side.

Prophylactic bilateral reimplantation for unilateral reflux, to avoid contralateral reflux, is not warranted on the basis of the high spontaneous resolution rates (Burno et al, 1998). Recommendations for management of contralateral reflux range from observation in the majority of cases to intervention for control of clinical pyelonephritis episodes. In asymptomatic children, younger than 4 to 5 years of age, prophylactic antibiotics are warranted for postoperative contralateral reflux, particularly if one is to be consistent with the medical therapy for the previous ipsilateral reflux. If the child remains asymptomatic and infection free, repeat VCUGs may not be necessary because contralateral reflux resolves spontaneously in the majority of children. In girls around the age of puberty, controversy persists as to whether a VCUG and correction of reflux at that point become necessary.

Obstruction. It is not unusual to detect a mild to moderate degree of hydronephrosis in the early postoperative period by ultrasound (see earlier). This should resolve spontaneously with time. Acute postoperative obstruction may be related to technical issues such as twisting or kinking of the ureter in its new tunnel,

intramural blood clots, or extramural compression by submucosal hematoma or edema at the site of anastomosis. Progressive, significant obstructions usually become apparent in the first 2 weeks after surgery. The children typically present with symptoms of acute ureteral obstruction including acute abdominal pain, nausea, and vomiting. Although infection is less common, if it occurs it is quite significant in the obstructed system. The diagnosis is readily made on ultrasound where the severe hydroureteronephrosis is confirmed by delayed function and excretion on renal scintigraphy. In the more significant cases, drainage of the system either by retrograde insertion of a double-J stent or a percutaneous nephrostomy tube may be necessary. The nephrostomy tube should be internalized as early as possible to avoid a dry reimplant. Many of these cases resolve without requiring additional surgery.

Long-Term Complications

Obstruction

Progressive dilatation of the ureter and kidney following reimplantation surgery can be due to several factors and can be classified on the basis of the location of the obstructive lesion:

Suprahiatal—twist of the ureter or ischemia due to poor handling of the ureter are the most common causes of suprahiatal obstruction.

Hiatus—at the point of entry into the new hiatus angulation of the ureter, most commonly due to a hiatus that is positioned too lateral or anterior such that when the bladder fills, the ureter becomes carried laterally and anteriorly, resulting in the "high reimplant" phenomenon. These ureters drain better when the bladder is empty. This situation may resolve spontaneously but on occasion requires stenting or redo surgery.

Tunnel—A submucosal tunnel that is not adequately developed can lead to compression of the ureter causing obstruction within the tunnel. The submucosal tunnel is obviously more difficult to develop in an abnormal bladder such as the valve or neuropathic bladder. Developing a smooth, capacious, submucosal tunnel can be quite challenging because of the irregularities created by the muscular hypertrophy, trabeculation, and cellule formation. Ischemia to the ureter and the submucosal tunnel is another important factor that results from improper handling of the ureter, leading to its devascularization. Significant obstruction in the submucosal tunnel can be overcome by balloon dilatation and stenting for a period of time. If conservative measures are unsuccessful, redo reimplantation is required.

Orifice—The anastomosis of the ureter to the bladder and the new hiatal position is an important technical aspect of the reimplant procedure. The most vulnerable point for obstruction is the apex of the ureteral spatulation. The apical sutures must be placed with the utmost of care to ensure an adequate orifice caliber. Stenosis can also occur as a result of ischemic changes. Isolated obstruction of the orifice can be managed by dilatation and stenting. If the submucosal tunnel is of adequate length, endoscopic unroofing of the distal few millimeters including the orifice may relieve the obstruction while maintaining the antireflux mechanism.

Recurrent or Persistent Reflux

Failure of antireflux procedures in primary low-grade reflux is extremely rare. Most failures are due either to high-grade reflux or to an inadequate ratio of tunnel length to ureteral diameter. Development of a short tunnel and failure to taper the excessively wide ureter are obvious important factors. Another significant cause of persistent or recurrent reflux is due to failure to recognize secondary reflux, especially associated with neurogenic bladders and posterior urethral valve bladders. **Reflux in these situations is secondary to the poor storage or emptying characteristics of the bladder. These issues need to be addressed and optimized before reimplant surgery is attempted.** In most situations improving bladder storage and/or emptying with a combination of an anticholinergic and intermittent self-catheterization results in spontaneous resolution of secondary reflux (Agarwal et al, 1997). Proceeding with reimplantation surgery in the presence of an abnormal bladder only results in worsening of the ureteral dilatation and deposition of scar tissue in the pelvis, which would render future attempts at correcting the reflux even more difficult.

Redo Reimplantation

Redo reimplantation is technically more challenging and requires careful attention to detail and meticulous surgical technique. Dissection of the ureter and extensive mobilization is required in order to achieve an adequate submucosal tunnel. Careful dissection of the ureter is best accomplished by a combination of extravesical and intravesical mobilization as needed. The ureter should be carefully evaluated and ischemic segments excised. Free bleeding from the divided distal end should be observed in addition to peristaltic activity, assuring normal musculature and blood supply. It is preferable to create a new hiatus and submucosal tunnel. If the ureter is shorter, a psoas hitch (Fig. 122–22) can be used to facilitate the creation of the antireflux mechanism. The psoas hitch should be carried out with nonabsorbable suture before creation of the submucosal tunnel. The bladder is fixed to the psoas muscle sheath on either side of the iliac vessels, providing a stable posterior bladder wall. In children, the bladder can be mobilized sufficiently to bring it up almost to the bifurcation of the common iliac vessels. This may provide adequate bridging for a distal ureteral defect. A psoas hitch can be achieved only on one side. Attempting a psoas hitch on both sides will not provide adequate length on either side and thus should be avoided. If both

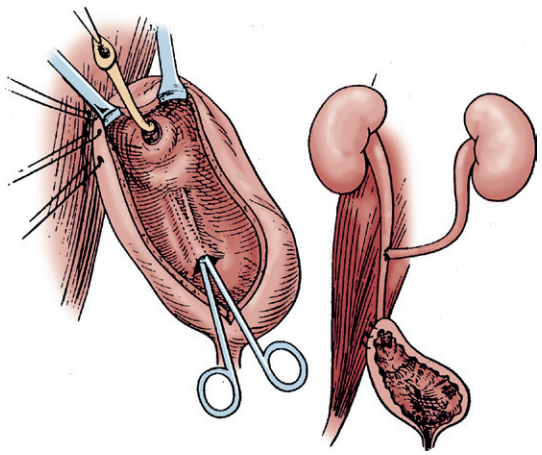

Figure 122–22. A psoas hitch can be used to effectively bridge significant ureteral defects. Its combination with transureteroureterostomy is ideal when both ureters are addressed in a reoperative setting. (From Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, editor. Difficult problems in urologic surgery. Chicago: Year Book; 1989. p. 140.)

ureters are shortened, consider a psoas hitch on one side to achieve a satisfactory antireflux mechanism with a transureteroureterostomy for the other ureter.

Other techniques to consider for the short ureter include the Boari flap, where a flap extending from the dome to the anterior wall of the bladder based on the posterior wall can be rotated proximally. The flap should be wide enough to allow creation of a submucosal tunnel and tubularization of this flap. In the short ureter a nipple valve can be created in association with a short submucosal tunnel. The nipple valve is particularly useful in dilated ureters and is fashioned by spatulating the ureter and folding it back onto itself.

In situations where the ureter is significantly foreshortened, it can be replaced using a reconfigured segment of bowel as described by Pope and Koch (1996). The colon or ileum is reconfigured similar to the Monti procedure. This technique offers important advantages over the classic tapered ileal ureter, allowing a long tube to be created from a short segment of colon without tapering, thus eliminating the metabolic consequences; additionally, the mesentery is in the center of the tube, which facilitates creation of the submucosal tunnel.

Endoscopic Treatment of Vesicoureteral Reflux

Matouschek (1981) first described the injection of polytetrafluoroethylene (PTFE) paste at the ureteral orifice to correct VUR. It was O'Donnell and Puri (1986) who popularized the technique when they published their initial report on the successful endoscopic correction of primary VUR in 103 ureters with a success rate of 75% after one injection. They coined the term STING (*S*ubureteric *T*eflon *I*njection). This procedure became popular in many countries but never achieved widespread use in the United States because of lack of U.S. Food and Drug Administration (FDA) approval over concerns regarding the potential migration of PTFE particles (Malizia et al, 1984a, 1984b; Aaronson et al, 1993). The ability to correct reflux in a large proportion of patients (the more recent studies report success rates approaching 90% after one injection of Deflux in low-grade primary reflux [Kirsch et al, 2004]) on an outpatient basis using a simple procedure with minimal morbidity prompted the search for safer materials. One caveat when evaluating the results of the reported results of endoscopic correction is to interpret with caution those reports in which the authors regard downgrading of reflux to grade 1 or 2 (Sweden) as a successful outcome. Because this would not be acceptable to most surgeons carrying out open surgery, the definition of success should be applied uniformly.

Due to the minimal morbidity of the procedure, the benefit of endoscopic injection in newly diagnosed patients has been evaluated using computer modeling with a view to reduce the morbidity and cost of repeated VCUGs and long-term antibiotics (Kobelt et al, 2003). Rigorous comparisons of various treatment approaches need to be undertaken and **until the outcome of such studies are available, the indications for correction of reflux should remain unchanged whether reflux is corrected by open surgery, endoscopy, or laparoscopy.**

Two key challenges with endoscopic treatment of reflux are reproducibility and durability of the results. Long-term follow-up will determine whether endoscopic therapy, with the currently available materials, will stand the test of time or if open surgery with its 95% to 99% success rate will remain the most cost-effective way of **permanently** correcting reflux.

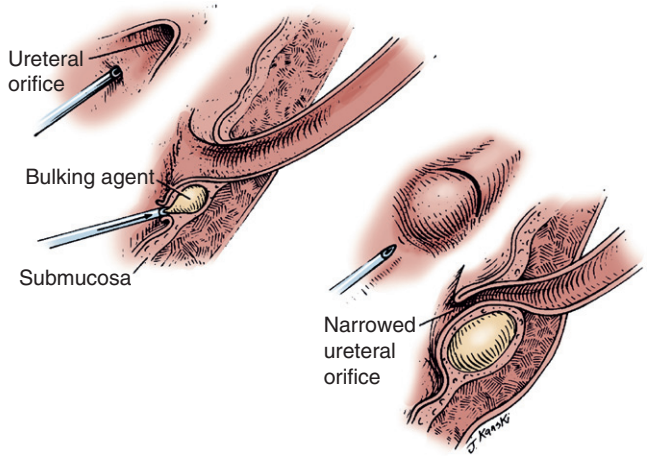

Figure 122–23. Principle of endoscopic treatment of reflux. A bulking agent is injected beneath the ureteral orifice with a needle. The buttress that is provided helps coapt the distal end of the ureter.

Technique of Endoscopic Injection

The classic STING technique was described by O'Donnell and Puri (1984) (Fig. 122–23). Prophylactic antibiotic is usually administered with induction of anesthesia. A cystoscopy should be carried out before opening the materials in case the procedure is cancelled due to inflammatory changes in the bladder. If a rigid needle is used, an offset lens injection scope should be used. If a flexible needle is used, a standard 0- or 30-degree lens cystoscope can be used. The size of the needle varies depending of the viscosity of the material and ranges from 3.7 Fr to 5 Fr. The viscosity of the material also determines whether injecting the material can be carried out using a regular syringe or requires a ratcheted metal syringe holder. A 3-Fr ureteric catheter may be introduced to lift up the anterior wall of the ureter and identify the axis of the tunnel. The needle is inserted with the bevel facing up at the 6 o'clock position. The original description by O'Donnell and Puri suggested entering the mucosa 2 to 3 mm distal to the ureterovesical junction and advancing the needle in the submucosal plane for a distance of 4 to 5 mm. For high-grade reflux and ureters without submucosal tunnel, the Dublin group suggested inserting the needle directly inside the ureter to increase the length of the intravesical ureter (Chertin et al, 2002, 2003). Kirsch and colleagues (2004) popularized this approach (submucosal implantation within the intramural ureter) and reported improved results with all grades of reflux compared with the classic technique (92% vs. 79% of ureters).

The accuracy of the needle entry point and needle placement are important components for success of the procedure (Fig. 122–24). An improper puncture may not result in the desired mound formation and thus may not provide adequate support for the UVJ. If the needle requires repositioning, the implanted material may leak out of the first puncture site, resulting in failure of the procedure.

Injection should be carried out slowly. If the needle is positioned in the submucosal plane, the mound becomes apparent with the initial injection of 0.1 to 0.2 mL. This is a key point in the procedure; unsatisfactory mound formation and location after this initial injection is an indicator that the tip of the needle is not in the proper position. Repositioning of the needle by withdrawing it slowly and then advancing it while injecting, in addition to rotating the bevel gently (depending on the lateral location

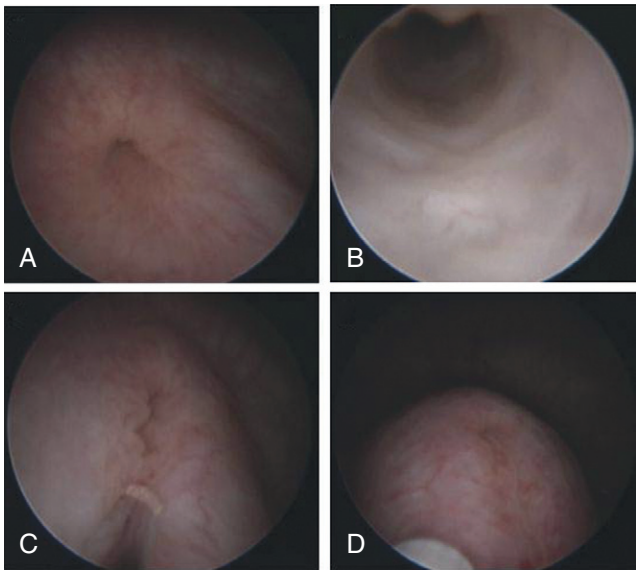

Figure 122–24. The classic STING technique. **A,** Appearance of the orifice before hydrodistention **(B). C,** The entry point of the needle is 2 mm distal to the 6 o'clock position. **D,** Appearance of the mound after completion of the injection.

of the mound), should help achieve the desired effect. Once a volcano appearance with the ureteral meatus on top of the mound is achieved, additional volume is injected until the ureteral orifice becomes crescent or slit shaped. The shape of the achieved mound was found to be a significant predictor of a successful outcome. Achieving a volcano-shaped mound was associated with an 87% success rate, whereas other morphologies were only associated with a 53% successful rate (Lavelle et al, 2005). For most materials, the needle should be kept in place for 1 minute at the end of the injection to reduce extrusion of the material at the injection site. With Deflux this step is not essential. The bladder is emptied, and the mound is inspected with an empty and a full bladder to ensure that adequate support of the ureter is persistent. Rarely, bleeding occurs at the puncture site. This is best dealt with by emptying the bladder and applying gentle pressure with the tip of the scope until the bleeding stops. Cauterizing the area is not advisable because it results in sloughing of the mucosa and extrusion of the injected material. At the end of the procedure lidocaine gel may be instilled in the urethra; catheter drainage is not necessary. In general the child spends a brief amount of time in the recovery room followed by discharge. All activities can be resumed immediately.

There is a significant learning curve with endoscopic correction of VUR (Kirsch et al, 2003). In a study by Herz and colleagues (2001), the importance of the learning curve was highlighted. In the first 6 months of their study the success rate was 46% in 18 children with 28 refluxing ureters. In the remaining 18 months of that study, the overall correction rate was 93% in 56 children with 84 refluxing ureters after a single endoscopic injection. Although the technique is quite simple once learned, there are some technical nuances and details that require specific attention.

Follow-up

The child is maintained on antibiotics for 3 months when a follow-up ultrasound and VCUG are obtained. If reflux is persistent, a repeat injection can be considered 6 months after the initial injection. If there is still no resolution, then open surgery is recommended.

Table 122–7.

Agents used for Endoscopic Correction of Vesicoureteral Reflux

Nonautologous Materials
Polytetrafluoroethylene (PTFE)
Cross-linked bovine collagen
Polydimethylsiloxane
Dextranomer hyaluronic copolymer (Deflux)
Coaptite
Autologous Materials
Chondrocytes
Fat
Collagen
Muscle

Most reports to date have not indicated any additional difficulty with open surgery following endoscopic correction using Deflux (Herz et al, 2001; Lackgren et al, 2001), but some have experienced difficulty with other substances. At open surgery the injected material is either not seen at all or is found well encapsulated but in a wrong plane or wrong location inside or outside the bladder. The material is easily removed en bloc, and the open reimplant procedure carried out without difficulty.

Materials Used for Endoscopic Correction of Reflux

In order for an injectable biomaterial to be ideal, it must be nontoxic and stable without migration to vital organs. It should cause minimal local inflammation, while at the same time be well encapsulated by normal fibrous tissue and fibrocytes. The material should be easy to inject through a long needle that passes easily through most standard endoscopic instruments. It must be viscous enough to prevent leakage from the puncture site and maintain its injected volume and the mound shape after the normal process of exchange and excretion of any carrier molecules.

Several agents have been used for endoscopic correction of VUR. These materials can be classified as **particulate** or **degradable and autologous or nonautologous** (Table 122–7).

The concern with the particulate agents is **migration** and with degradable agents is **durability.** Distant migration can occur by two mechanisms. The first is expansion of the injected bolus, which may lead to disruption of the small vessels in the area of the distal ureter and trigone, resulting in the material gaining intravascular access. Particles smaller than 50 µm may bypass the pulmonary vascular bed and thus access the systemic circulation and reach other organs in the body. The second migration mechanism is by phagocytosis of the injected particles by tissue macrophages or blood-borne monocytes. The particle size determines whether phagocytosis can occur, as it is generally agreed that phagocytosis requires a particle less than 80 µm in diameter.

Nonautologous Materials

Polytetrafluoroethylene Paste (Teflon Paste)

PTFE has been in use as a component of many biomaterials and injectable agents for many years. It has been used for the manufacturing of vascular grafts, cardiac valves/implants, surgical sutures, cosmetic surgery, and patches for hernia repairs (Monaghan and Meban, 1991; Godin et al, 1995; Sayers et al, 1998; Briguori et al, 2001). Teflon paste was also used as an injectable agent for

embolization of vessels (Weingarten and Kauffman, 1977) and for injection of vocal chords (Kasperbauer, 1995) and as a bulking agent for urinary incontinence (Politano, 1992).

Matouschek (1981) first reported on the use of Teflon paste as a bulking agent for correction of reflux. O'Donnell and Puri (1984) and Chertin and Puri (2002) popularized this technique and reported on its use in hundreds of patients with long-term follow-up (Puri, 1995; Chertin and Puri, 2002). A large European multicenter survey reported on 6216 ureters and 4166 children with 10 years' follow-up and demonstrated a cure rate of 86% after one to four injections (Puri et al, 1995). The longest follow-up is available from Dublin; 247 patients treated with Teflon paste with 11 to 17 years of follow-up demonstrated a sustained success rate of 95% with a 5% recurrence rate (Chertin and Puri, 2002).

Teflon paste is relatively inexpensive; it is viscous and requires a ratcheted syringe for injection. Despite its widespread use in Europe, Teflon paste never gained FDA approval in the United States because of concerns regarding distant migration of the PTFE particles. Malizia demonstrated in experimental studies that the particles can migrate to regional lymph nodes and to distant organs including the lung and the brain (Malizia et al, 1984a, 1984b). Malizia's findings were substantiated by several clinical reports confirming particle migration (Claes et al, 1989; Aaronson et al, 1993; Dewan and Fraundorfer, 1996; Steyaert et al, 2000). Particle migration is thought to be related to the small size of the Teflon paste particles that range from 4 to 100 μm with 90% of the particles less than 40 μm.

With the availability of other, presumably, safer injectable agents, PTFE has fallen totally out of favor and been all but abandoned.

Cross-Linked Bovine Collagen

Apart from concerns regarding allergy to bovine collagen in 3% of the population, this material is otherwise safe and causes minimal local inflammatory changes (Leonard et al, 1990). It is easily injectable through a 25-gauge needle with standard endoscopic equipment. The downside to cross-linked collagen is the fact that the results are not durable because of the variable degree of ingrowth of native fibroblasts and replacement of the injectable collagen with native collagen (Leonard et al, 1990, 1991; Frey et al, 1992). Despite the odd report of sustained effect (Reunanen, 1995), the inconsistency, and questionable durability of cross-linked collagen (Haferkamp et al, 2000a, 2000b), most centers have abandoned its use for correction of reflux.

Polydimethylsiloxane (Macroplastique)

Polydimethylsiloxane (PDS) is a solid silicone elastomer that has been used as a soft tissue bulking agent. The injectable material is composed of soft, flexible, highly textured implants of heat-vulcanized PDS suspended in a bioextractable carrier gel. The carrier gel is a water-soluble low-molecular-weight polyvinylpyrrolidone hydrogel (Povidone). The carrier gel is absorbed and replaced with host fibroblasts that subsequently deposit collagen, encapsulating the implant. The implant retains its size and shape. To minimize the risk of migration, PDS is engineered to create an elastomer, instead of the less cross-linked silicone gels or non–cross-linked silicone oils. Although 76% of particles are greater than 100 μm in diameter, **7% are less than 50 μm in diameter.** The smaller particles (Henley et al, 1995) and possible intramuscular injection of the agent are responsible for migration of particles to the lungs, kidneys, brain, and lymph nodes demonstrated in animal models. Unlike Teflon paste, Macroplastique does not cause an intense local inflammatory response. In patients requiring open surgery after failed injection with Macroplastique, the injectable bolus was found encapsulated and easily removed without adherence to the ureter or bladder (Herz et al, 2001). Histologic examination of the bladder muscle biopsies and pelvic lymph nodes at the time of open surgery revealed a mild inflammatory reaction with no evidence of PDS particle migration in either the wall of the bladder or the draining lymph nodes.

The efficacy of PDS as a bulking agent for correction of reflux is well documented. Dodat and colleagues (2004) reported on the long-term outcomes of Macroplastique injections for correction of VUR. Results in 590 refluxing ureters in 389 patients who were injected with a minimum follow-up of 5 years revealed a sustained success rate of 79.4%. Herz and colleagues (2001) demonstrated a reflux resolution rate of 81% after a single injection and 90% after a second injection with a 12-month follow-up. Similarly, van Capelle and colleagues (2004) reported an 82.3% success rate in 311 ureters in 195 children over a 10-year period from two European centers.

The main advantage of PDS is that it is a permanent material that remains well encapsulated, causing minimal local inflammatory changes. Although it has a demonstrated long-term track record, PDS has yet to achieve FDA approval for correction of VUR in the United States, possibly because of concerns regarding migration, particularly particles that are smaller than 80 μm, and the negative connotations associated with silicone implants.

Dextranomer/Hyaluronic Copolymer (Deflux)

Dextranomer/Hyaluronic Copolymer (DX/HA) is formed of cross-linked dextranomer microspheres (80 to 250 μm in diameter) suspended in a carrier gel of stabilized sodium hyaluronate. DX/HA is biodegradable, the carrier gel is reabsorbed, and the dextranomer microspheres capsulated by fibroblast migration and collagen ingrowth. DX/HA loses about 23% of its volume beyond 3 months of follow-up (Stenberg and Lackgren, 1995).

Deflux was first introduced by the Swedish group of Stenberg and Lackgren (1995) and received FDA approval in 2001. Since then there have been several clinical reports from Europe and the United States documenting success rates ranging from 68% to 89% (Lackgren et al, 2001; Puri et al, 2003; Kirsch et al, 2004; Lavelle et al, 2005). The 89% success rate was achieved by Kirsch and colleagues (2004) using the intraureteral injection technique. In a long-term follow-up study by Lackgren and colleagues (2001), 68% of 221 children followed for a mean of 5 years maintained grade 1 VUR or less at the last VUCG. No significant long-term adverse effects were noted. In patients who fail endoscopic treatment with Deflux and proceed to open surgery, the bulking agent is noted to have completely disappeared. Whether this represents a technical error in the injection technique or is due to complete reabsorption of the injectable agent remains unproven.

The appeal of Deflux is that it is a natural product that is easily administered without a ratcheted syringe through a smaller-gauge needle. It is currently the preferred agent for endoscopic correction in most centers; however, the durability of correction of VUR with Deflux remains to be proven.

Coaptite

Calcium hydroxyl apatite is synthetic bone material. The particles have a uniform spherical shape and range in size from 75 to 125 μm. The material injects easily through a 21-gauge needle without the need for a ratcheted syringe. At the AUA meeting in 2002, Mevorach and colleagues presented the initial results in a clinical trial including 98 patients and 155 ureters with grade 2 to 4 reflux (Mevorach et al, 2002). Reflux resolved in 67% of the

patients and 75% of the ureters. There are no published reports at this point, and the FDA is currently evaluating the clinical trials.

Autologous Materials

Fat, collagen, muscle, and chondrocytes have all been evaluated as bulking agents. The key advantage of these agents is that they are not foreign materials, but the obvious disadvantage is the observed volume loss (up to 100% in the case of fat [Matthews et al, 1994]) that they need to be harvested and expanded (in the case of chondrocytes and muscle) before injection. Autologous materials behave as a free graft at the injection site, so reabsorption of the material is worrisome and may be responsible for the inconsistent results.

Chondrocytes

Atala and colleagues (1993, 1994) described the harvesting and expansion of chondrocytes in vitro and successful correction of VUR in animal models. Subsequently, human trials using chondrocytes harvested from the posterior auricular cartilage were conducted (Diamond et al, 1999; Caldamone and Diamond, 2001). The chondrocytes were grown in culture for 6 weeks, quantitated, concentrated, and then suspended in a mixture of sodium alginate and calcium sulfate solution for injection. At 3 months' follow-up, reflux was corrected in 55% (27 of 47) of the ureters. This improved to 86% after one or two repeat injections. At 1-year follow-up, reflux correction was maintained in 70% (32 of 46) of the ureters and 60% of the patients (19 of 29). At subsequent endoscopy, failures were attributable to volume loss and shifting of the subureteral mounds.

Recurrence of Vesicoureteral Reflux Following Endoscopic Correction

The **true incidence** of recurrent VUR after successful endoscopic correction with any specific material is difficult to determine because a repeat VCUG is not obtained beyond the initial negative study except in the context of a research protocol.

Only a handful of series have reported long-term follow-up with repeat VCUG beyond the initial negative study. Chertin and colleagues (2002) reported a 5% recurrence rate using Teflon paste with follow-up up to 17 years. A 13% recurrence rate with Deflux is reported by Lackgren and colleagues (2001) 2 to 5 years after an initial negative VCUG. The higher rate with Deflux, an absorbable agent, is not unexpected. In the absence of UTIs, the significance of confirming the long-term absence of VUR is less important. Furthermore, even if absorbable bulking materials were to lose volume or reabsorb completely over time, VUR resolution may be maintained by growth of the child and maturation of the UVJ. The injectable agent may just have bought time for this process to conclude. The implication of recurrent reflux in young adulthood for these patients is inadequately defined at present. More recent evidence suggests that children undergoing endoscopic correction with a preinjection history of multiple febrile UTIs, BBD, and renal scarring are at a higher risk for recurrent infections and late recurrence of VUR despite initial negative VCUG (Sedberry-Ross et al, 2008).

Laparoscopy as Applied to Correction of Reflux

The laparoscopic approach to ureteral reimplantation should theoretically provide the success rate and durability of open surgery while avoiding its morbidity. Three procedures have been attempted laparoscopically: the extravesical reimplant, the Gil-Vernet procedure, and the Cohen cross-trigonal reimplant.

In addition to the long operative times and steep learning curve, the initial experience with laparoscopic reimplantation identified significant technical challenges in the creation of the submucosal tunnel while maintaining an intact bladder urothelium and with the suturing aspects of the procedures. Although the robot may assist with the suturing aspect, the current port size required is still not ideal for smaller children. The continued refinement of open reimplantation surgery, more recently dispensing with the use of both postoperative bladder catheters and the need for overnight hospital stays, will place even greater onus on the proponents of the laparoscopic approach to better define the ideal conditions for this minimally invasive technique.

Laparoscopic Surgical Procedures

Gil-Vernet Procedure

In this procedure the trigonal mucosa is incised vertically and the two ureters are approximated into the midline with a single submucosal suture. This procedure has been accomplished laparoscopically transvesically with limited success. Okamura and colleagues (1999) and Cartwright and colleagues (1996) reported success rates of 59% and 62.5%, respectively. The recurrence of reflux is thought to be due to splitting of the trigone and lateral displacement of the ureters.

Laparoscopic Extravesical Reimplant. This is likely the most commonly reported procedure for laparoscopic correction of reflux. The technique has a steep learning curve; initial experiences described challenges with exposure of the ureter, trauma to the ureter, and difficulty developing the extravesical tunnel without injuries to the urothelium in addition to long operative times.

Separation of the urothelium from the detrusor is difficult laparoscopically because the adequately distended bladder protrudes into the limited pelvic working space and hinders the laparoscopic dissection. Additionally, the ability to adequately retract the incised detrusor edges to create a wider trough is limited because of the exposure and the angles at which the instruments enter the abdomen.

Several modifications of the technique have been described by Lakshmanan and Fung (2000), leading to a more effective procedure with shorter operative time and results that approximate those of open surgery.

Trocar Placement. A 5-mm, 0-degree laparoscope is inserted through the umbilicus. Three additional working ports are inserted in the lower abdomen along the lines of a Pfannenstiel incision in the middle and on either end.

Ureteral Dissection. The ureter is best identified at the pelvic brim and followed distally. The overlying peritoneum is incised transversely. Ureteric catheters placed cystoscopically may aid in identification of the ureter in the older patient. Once the ureter is identified, it can be grasped with Babcock forceps and freed from the surrounding tissues. In the male the incision of the peritoneum should be carried out caudal to the vas deferens so that the vas can be reflected with the peritoneum in a cephalad direction. A vessel loop or a Diamond-Flex retractor can be passed around the ureter and used as a holder.

Creation of the Tunnel. It is important to mark the direction of the tunnel with electrocautery while the bladder is semidistended in its normal position. A 4-0 Prolene traction suture is applied at the proximal end of the detrusor tunnel. This suture is passed through the abdominal wall on a straight needle and used to hitch

the bladder, and then the needle is passed out again providing external control to achieve the desired tension and elevation of the detrusor. The incision of the detrusor is carried out starting from proximal to distal. The serosa is scored with cautery, but most of the dissection should be carried out using scissors to prevent injury to the bladder innervation as described in the open extravesical reimplant earlier in the chapter. Elevation of the detrusor flaps is more difficult in the laparoscopic procedure, and therefore a trough as wide as that developed with open surgery may not be achievable. The incision is continued distally around the ureter, leaving the distal attachments intact. The mucosal bulge is also not as obvious as in open surgery because the bladder is not as distended and is also compressed by the peritoneal insufflation.

Closure of the Myotomy (Detrusorrhaphy). The ureter is placed in the new tunnel, and a 3-0 polyglactin suture is placed at the most proximal end to stabilize the ureter and facilitate reclosure of the detrusor with interrupted sutures starting at the ureteral orifice distally. Anchoring sutures are not required because the distal attachments of the ureter are left intact.

After completion of the detrusorrhaphy, the bladder retraction suture is released and the bladder is filled. The ureter is observed in its new tunnel to confirm the absence of angulation or kinking. A catheter may be left in the bladder for 12 to 24 hours postoperatively.

The largest published series is that of Lakshmanan and Fung (2000) in which 71 ureters were reimplanted laparoscopically. Early on in that series, three ureteral injuries required open reimplantation in two and stenting in one to drain a urinoma. The remaining patients are free of reflux and obstruction. More recently, Casale and colleagues (2008) reported a 97.6% success rate in 41 patients using a transperitoneal robotic-assisted approach.

Endoscopic Cross-Trigonal Reimplant

In order to avoid transgressing the peritoneum and the challenges associated with the small pelvis in the child, other groups have developed a transvesical approach, similar to the Cohen cross-trigonal reimplant, using carbon dioxide insufflation of the bladder (pneumovesicum).

Yeung and colleagues (2005) initially described the procedure using standard laparoscopic instruments. Peters and Woo (2005) followed with a report describing a robotically assisted technique to facilitate the creation of the submucosal tunnel and the ureteral anastomosis.

Port Placement. The patient is positioned supine with the legs separated to allow access to the urethra for cystoscopy and bladder catheterization intraoperatively. Cystoscopy is carried out, and the bladder is distended with saline. A traction suture is passed percutaneously at the level of the bladder dome under cystoscopic vision to anchor the bladder wall to the abdomen and prevent it from pulling away when the camera port incision is made at the dome. Following that, a 5-mm port is inserted under cystoscopic vision. The cystoscope is removed, and a urethral catheter is inserted. CO_2 insufflation to 10-mm mercury pressure is started, and a 5-mm 30-degree lens is inserted. Two additional 3-mm working ports are inserted on either side of the bladder under direct vision.

Dissection of the Ureter. A 5-cm segment of a 5-Fr feeding tube is inserted in the ureter and secured with a 4-0 Prolene suture. The catheter facilitates handling and dissection of the ureter as described in the open Cohen procedure. The ureteral mobilization begins with the usual circumscribing incision using the hook electrocautery. The 3-mm endoscopic scissors are used to develop the plane of dissection starting on the distal aspect of the ureter. The dissection is carried out circumferentially for a distance of 2 to 3 cm. The muscular defect in the ureteral hiatus is repaired using 4-0 absorbable sutures.

Creation of the Submucosal Tunnel. An incision is made using the hook cautery at the site of the new ureteral orifice across the back wall of the bladder. The submucosal tunnel is started from the old hiatus toward the new hiatus using fine endoscissors. A fine grasper is then inserted through the new hiatus, and the feeding tube is used to pull the ureter through the tunnel.

Ureteral Neocystostomy. The ureter is spatulated at the 6 o'clock position and anastomosed at the new location using 6-0 interrupted sutures. Peters and Woo (2005) described using the robot to facilitate the delicate suturing laparoscopically and improve the efficiency of the procedure. The port sites in the bladder are closed, and an indwelling urethral catheter is maintained for 24 hours. Reflux resolution was demonstrated in 15 of 16 patients in Yeung's series (2005) and in five of six patients in Peters' series (2005). Providing a detailed description of the nuances of the vesicoscopic technique, Jayanthi and Patel (2008) reported a 94% success rate in a larger series of 103 patients, 10 of whom had failed endoscopic injection. Three patients were converted to open surgery early in their experience. Of the 77 patients who have undergone postoperative cystograms, reflux resolution was confirmed in 72 of 77 (94%). The failures were all in the first 30 patients of the series with no reported failures in the last 47 patients.

Although open surgical correction of reflux is still the gold standard against which the endoscopic and laparoscopic approaches are compared, the technical advances and improved results achieved using minimally invasive techniques are gradually becoming more enthusiastically endorsed.

Prune-Belly Syndrome

Anthony A. Caldamone, MD, MMS, FAAP, FACS • John R. Woodard, MD

Genetics
Embryology
Clinical Features of Prune-Belly Syndrome
Presentation
Evaluation and Management
Long-Term Outlook

Prune-belly syndrome (PBS) represents a constellation of anomalies with variable degrees of severity. The three major findings are a deficiency of the abdominal musculature, bilateral intra-abdominal testes, and an anomalous urinary tract. The urinary tract is characterized by variable degrees of hydronephrosis, renal dysplasia, dilated tortuous ureters, an enlarged bladder, and a dilated prostatic urethra. Additional associated anomalies involve the respiratory tract, gastrointestinal tract, cardiac system, and musculoskeletal system. There is a broad spectrum of severity of the syndrome, with some children not surviving the newborn period and others being minimally affected. The single most important determinant of survival is usually the severity of the urinary tract anomaly, in particular, the degree of renal dysplasia.

The characteristic abdominal wall was first described by Frolich in 1839, and the full triad of anomalies by Parker in 1895. Osler's vivid description of the abdominal wall of an infant with the characteristic findings led to the term *prune-belly syndrome* (Osler, 1901). Other names that have been applied to this syndrome include *triad syndrome, Eagle-Barrett syndrome,* and *abdominal musculation syndrome* (Eagle and Barrett, 1950; Greskovich and Nyberg, 1988).

The incidence of PBS has been reported to be 1 in 29,000 to 1 in 40,000 live births, similar to that of bladder exstrophy (Williams and Burkholder, 1967), **with 95% occurring in males** (Wheatley et al, 1996). Females with PBS have the abdominal wall deficiency and urinary tract dysmorphism without any gonadal anomaly (Rabinowitz and Schillinger, 1977; Reinberg et al, 1991b). A higher incidence is noted in twins, blacks, and children born to younger mothers. The incidence appears to be declining, possibly because of prenatal diagnosis and a decision to terminate the pregnancy.

GENETICS

The high male-to-female ratio, occasional occurrence in male siblings and cousins, and increased occurrence in twins suggest a genetic basis for PBS. Yet most cases are sporadic and have a normal karyotype. One in 23 children with PBS is the product of a twin pregnancy (Ives, 1974). However, the majority of reported twins have been discordant for PBS, evidence against a genetic etiology. It has been suggested that the etiology in twins may be due to an uneven distribution of mesenchymal tissue at a critical time of primitive streak development during the third week of embryogenesis (Coplen et al, 1996). There is a reported association with Turner syndrome, monosomy 16, trisomy 13, and trisomy 18 (Amacker et al, 1986; Hoagland and Hutchins, 1987). A variety of inheritance patterns have been proposed including X-linked recessive (Frydman et al, 1993), a two-step autosomal dominant mutation (Riccardi and Grum, 1977), and polygenetic transmission (Garlinger and Ott, 1974; Lockhart et al, 1979; Adeyokunnu and Familusi, 1982). A report by Ramasamy and colleagues (2005) suggested a sex-influenced autosomal recessive mode of inheritance in familial PBS. The consensus, however, remains that an associated chromosomal abnormality is the exception rather than the rule because most have a normal karyotype. Other reports have noted an association between PBS and Beckwith-Wiedemann syndrome (Silengo et al, 2002; Sinico et al, 2004).

EMBRYOLOGY

Several theories about the embryogenesis of PBS have been proposed. However, because there is no experimental model that can be used to test these theories, the exact mechanism remains elusive. The four chief theories are (1) early in utero posterior urethral obstruction resulting in severe dilation of urinary tract and possible fetal ascites and oligohydramnios (Strumme, 1903; Pagon et al, 1979; Wheatley et al, 1996; Beasley et al, 1988); (2) primary defect in the lateral plate mesoderm, which is the precursor of the ureters, bladder, prostate, urethra, and gubernaculum (Ives, 1974; Gonzalez et al, 1990); (3) an intrinsic defect of the urinary tract leading to ureteral dilation and fetal ascites (Symonds and Driscoll, 1974; Monie and Monie, 1979; Smythe, 1981; Nakayama et al, 1984; Cazorla et al, 1997); and (4) a yolk sac defect (Stephens, 1983; Stephens and Gupta, 1994). None of these theories have universal acceptance, and there is some overlap between them.

CLINICAL FEATURES OF PRUNE-BELLY SYNDROME

Genitourinary Anomalies

Kidneys

A spectrum of renal abnormalities extends from normal renal parenchyma to dysplasia (Fig. 123–1). The more severely dysplastic kidneys are generally associated with bladder outlet obstruction

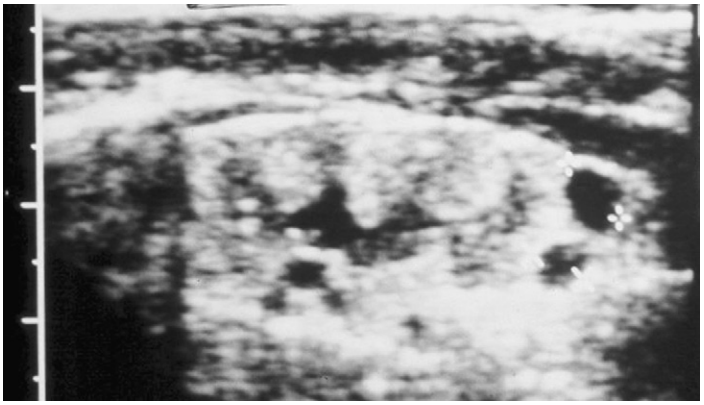

Figure 123–1. Ultrasound scan of a kidney of a newborn with prune-belly syndrome demonstrating markedly echogenic renal parenchyma and cortical cysts indicative of renal dysplasia.

in which there has not been decompression through a patent urachus (Potter, 1972). **Dysplasia is present in 50% of cases; however, it may vary in degree and laterally** (Rogers and Ostrow, 1973; Stephens, 1983). **Renal dysplasia in PBS of the Potter type II and IV varieties is seen.** The Potter type II variety with few nephrons and parenchymal disorganization is more indicative of a renal mesenchymal defect, whereas the Potter type IV with cortical and tubular cysts is associated with outlet obstruction (Wigger and Blanc, 1977).

The renal collecting system is characteristically dilated, often to a severe degree. The degree of dilation, however, does not correlate with the degree of renal dysplasia. Calyceal morphology may be well preserved, even in the presence of massively dilated ureters and renal pelves (Berdon et al, 1977). Ureteropelvic junction obstruction can occur on a primary or secondary basis; however, nonobstructive hydronephrosis is the rule (Woodard and Parrott, 1978b). It is renal infection rather than obstruction that poses the greatest risk to renal function.

Ureters

The ureters are typically dilated, tortuous, and redundant (Fig. 123–2). The proximal (upper) portions of the ureters are usually less abnormal than the distal segments, although massive dilation and stenosis can occur at all levels. Histologic sectioning demonstrates a lack of smooth muscle cells and an increase in fibrous connective tissue. Generally there are more normal-appearing smooth muscle cells in the proximal segments (Palmer and Tesluk, 1974; Stephens, 1983). This fact is critical when ureteral reconstruction is undertaken. The ratio of collagen to smooth muscle cells in prune-belly ureters has been noted to be elevated, especially in refluxing ureters (Gearhart et al, 1995). A decreased number of thick and thin myofibrils noted on ultrastructural examination is thought to contribute to the poor peristalsis (Berdon et al, 1977; Stephens, 1983).

Vesicoureteral reflux is present in 75% of children with PBS (Berdon et al, 1977; Fallat et al, 1989) (Fig. 123–3). Obstruction is not common but has been reported at both the ureteropelvic and ureterovesical junctions (Wigger and Blanc, 1977; Moerman et al, 1982; Manivel et al, 1989).

These large ureters may have ineffective peristalsis because of poor ureteral wall coaptation. The ureteral conduction wave reaches a reduced smooth muscle cell population of poor contractile potential related to reduced myofibrils, often separated by patches of collagen with a resulting bolus of urine reaching more dilated ureteral segments as it progresses toward the bladder (Woodard and Smith, 1998). This can be seen fluoroscopically as ineffective peristalsis, resulting in upper tract stasis, which may lead to infection (Nunn and Stephens, 1961; Williams and Burkholder, 1967).

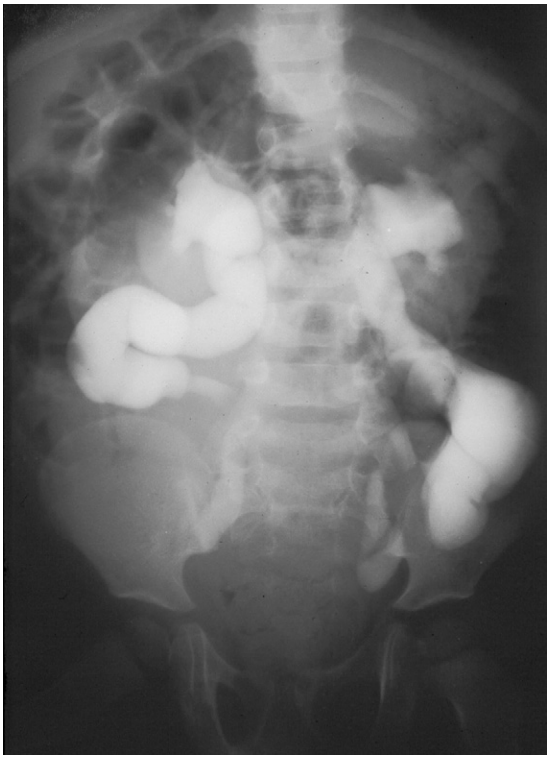

Figure 123–2. Excretory urogram of a patient with prune-belly syndrome; note ureters displaced laterally and calyces relatively well preserved.

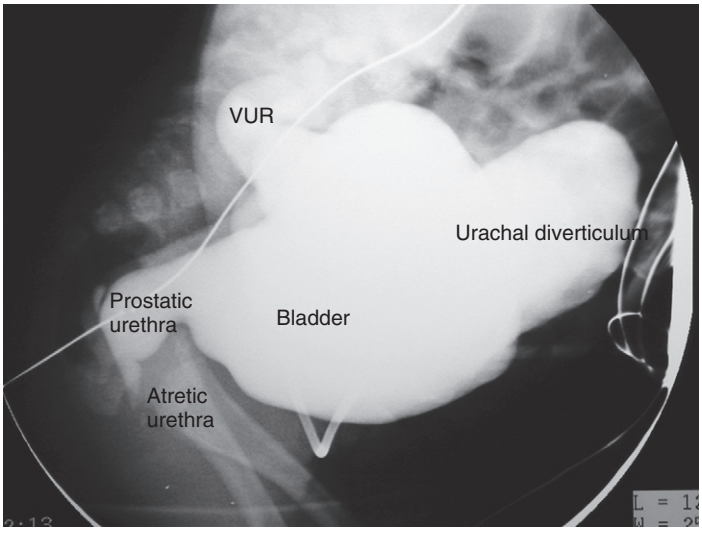

Figure 123–3. Voiding cystourethrogram of a child with prune-belly syndrome demonstrating urethral atresia, urachal diverticulum, and vesicoureteral reflux (VUR).

Bladder

The bladder usually appears massively enlarged with a pseudodiverticulum at the urachus (Fig. 123–4). **The urachus is patent at birth in 25% to 30% of children**

Key Points: Clinical Features

- Hydroureteronephrosis is often to a severe degree; however, the calyceal morphology may be well preserved.
- The proximal portion of the ureters has more normal muscle than the distal portions.
- The bladder is large with a pseudodiverticulum at the urachus and a wide bladder neck opening into a dilated prostatic urethra.

(Lattimer, 1958; Wigger and Blanc, 1977; Stephens and Gupta, 1994). **Histologically, the bladder has an increased ratio of collagen to muscle fibers in the absence of obstruction** (Workman and Kogan, 1990). The wall is smooth, unlike that seen in obstructed bladders. The pelvic distribution of ganglion cells has been shown to be normal (Nunn and Stephens, 1961; Burke et al, 1969). Smooth muscle hypertrophy is seen, however, in the obstructed prune bladder (Perlmutter, 1976). Stephens demonstrated that the trigone is splayed with the ureteral orifices displaced laterally and superiorly, possibly contributing to the high incidence of reflux (Williams and Burkholder, 1967).

On voiding, the bladder neck opens widely into a dilated prostatic urethra (see Fig. 123–4). Urodynamic assessment generally shows normal compliance; however, there is a delayed first sensation to void and large capacity (Snyder et al, 1976). The ability to empty the bladder is variable, with some emptying well and others carrying a significant postvoid residual. This is thought to be due to a relative outlet obstruction and the ability of the bladder to generate sufficient pressure with a detrusor contraction. When the relative outflow resistance prevents effective bladder emptying, the term *unbalanced voiding* is used (Snyder et al, 1976; Kinahan et al, 1992). **Despite these limitations, about 50% of prune-belly patients void spontaneously with normal voiding pressures, normal flow rates, and low postvoid residuals** (Nunn and Stephens, 1961; Kinahan et al, 1992). However, as Kinahan and colleagues (1992) demonstrated, deterioration of balanced voiding can occur, resulting in significant postvoid residuals, emphasizing the need for periodic assessment.

Prostate and Accessory Sex Organs

The dilation of the posterior urethra is due to prostatic hypoplasia, probably related to abnormal mesenchymal-epithelial development (Stephens and Gupta, 1994). Histologically, there are few prostatic cellular elements with a reduction of both epithelial and smooth muscle cells and an increase in connective tissue cells (Moerman et al, 1982; Popek et al, 1991; Stephens and Gupta, 1994). Various obstructive lesions of the distal posterior urethra have been described—urethral atresia, valves, urethral stenosis, urethral membrane, and urethral diverticulum—and are thought to occur in 20% of cases (Hoagland and Hutchins, 1987). Stephens (1983) described an angulation of the urethra during voiding, referred to as *type IV valves,* which results from lack of prostatic parenchymal tissue. Prostatic hypoplasia, the etiology of which is controversial, is thought to be a factor in the ejaculatory failure of PBS patients (Volmar et al, 2001). **The vas deferens and seminal vesicles are often atretic, although either may be dilated or thickened** (Stephens and Gupta, 1994). **The epididymis may be poorly attached to the testis, as is seen commonly in abdominal undescended testes. There may also be lack of continuity between the efferent ductules and the rete testis.** Ejaculation is usually in a retrograde fashion because of an incompetent bladder neck.

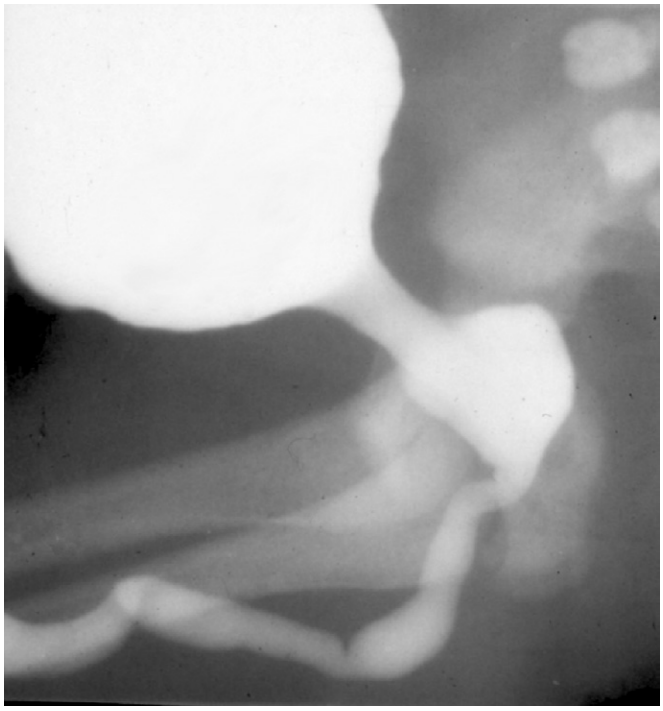

Figure 123–4. Voiding cystourethrogram of a child with prune-belly syndrome demonstrating prostatic urethral enlargement related to a hypoplastic prostate.

Anterior Urethra

Although the anterior urethra of the PBS child is usually normal, several anomalies of the anterior urethra have been reported, the most common being urethral atresia and megalourethra (Kroovand et al, 1982; Perrotin et al, 2001). **Unless it is associated with a patent urachus, urethral atresia is often lethal** (see Fig. 123–3). It has been postulated that urethral atresia or microurethra occurs because the urethra is unused rather than malformed. Spontaneous bladder rupture with fistula formation has also been reported (Reinberg et al, 1993).

PBS is associated with two variations of megalourethra (Shrom et al, 1981; Mortensen et al, 1985). **The fusiform type is a deficiency of the corpus cavernosum, as well as the spongiosum, and the scaphoid variety is a deficiency of the spongiosum only with preservation of the glans and corpora cavernosa** (Fig. 123–5). **With the scaphoid variety, the ventral urethra dilates with voiding, whereas with the fusiform variety the entire phallus dilates with voiding.** The fusiform variety is thought to result from a mesenchymal deficiency of the urethral folds, whereas the scaphoid variety results from a mesenchymal deficiency of the urethral supportive tissues (Dorairajan, 1963). Megalourethra is more commonly seen in PBS than any other syndrome (Appel et al, 1986). Transient in utero obstruction of the junction between the glanular and penile urethra has been proposed to cause megalourethra.

Testes

Bilateral intra-abdominal testes lying over the iliac vessels are the most typical findings. Although mechanical forces such as a distended bladder and intra-abdominal pressure have been

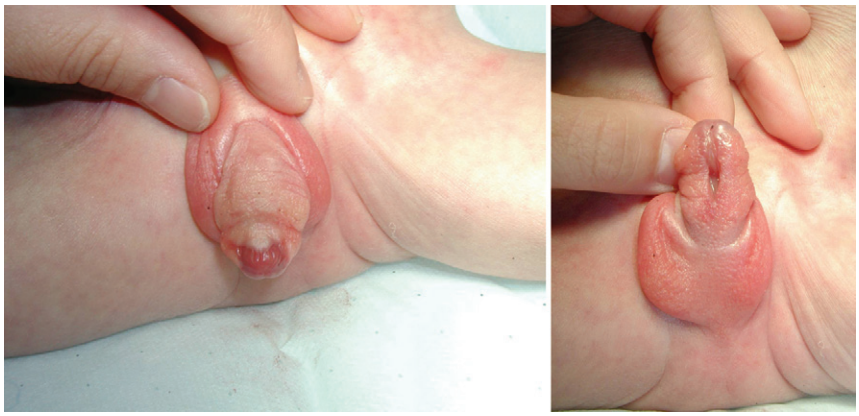

Figure 123–5. Scaphoid megalourethra with hypospadiac orifice of prune-belly syndrome. (Courtesy of C. Peters.)

implicated in maldescent of the testes (Kaplan et al, 1986; Hutson and Beasley, 1988), the fact that some patients with the typical urinary tract and abdominal musculature anomalies (termed *pseudoprune patients*) may have descended testes raises some doubt about pure mechanical factors.

Pak and colleagues (1993) compared the histology of the testes in PBS patients with that of non–prune-belly intra-abdominal testes and that of age-matched control subjects. **They found no difference in germ cell counts, Ad spermatogonia, and Leydig cells between PBS testes and non-PBS intra-abdominal testes. However, because germ cell counts in PBS patients younger than 1 year are similar to those of age-matched controls, the implication is that the environmental state of the abdomen is a major factor in their later spermatogenic potential** (Nunn and Stephens, 1961; Coplen et al, 1996). This mirrors findings of Nunn and Stephens (1961) of normal germinal epithelium of fetal and newborn PBS testes. Alternatively, Orvis and colleagues (1988) noted decreased numbers of spermatogonia and Leydig cell hyperplasia in fetal PBS testes, implying an intrinsic testicular abnormality. Azoospermia was found in adult PBS patients, and no PBS patient has been reported to have fathered a child (Woodhouse and Snyder, 1985). More recently, Ross and colleagues (1998) have documented paternity in three adults with classic PBS, achieved by sperm retrieval techniques and intracytoplasmic sperm injection. The infertility is thought to be due to a combination of testicular histologic abnormalities, structural defects of the ducts, and prostatic abnormalities (Tayakkanonta, 1963).

Three cases of testis tumor have been reported (Woodhouse and Ransley, 1983; Sayre et al, 1986; Massad et al, 1991; Parra et al, 1991). Massad and colleagues (1991) described histologic testicular patterns similar to those in intratubular germ cell neoplasia in three infants. Although the risk of malignancy may be relatively low considering the lack of germinal epithelium (Uehling et al, 1984), it is clear that placement of the testis in the scrotum and long-term follow-up are necessary to reduce the risk of testicular malignancy and enhance detection.

Extragenitourinary Abnormalities

Of all children with PBS, 75% have non–urinary tract abnormalities (Geary et al, 1986). After the obvious abdominal wall defect, the most common are cardiac, pulmonary, and orthopedic (Table 123–1).

Table 123–1.
Extragenitourinary Abnormalities

Cardiac	Patent ductus arteriosus
	Ventricular septal defect
	Atrial septal defect
	Tetralogy of Fallot
Pulmonary	Lobar atelectasis
	Pulmonary hypoplasia
	Pneumothorax
	Pneumomediastinum
Gastrointestinal	Intestinal malrotation
	Intestinal atresias or stenosis
	Omphalocele
	Gastroschisis
	Hirschsprung disease
	Imperforate anus
	Hepatobiliary anomalies
Orthopedic	Pectus excavatum, pectus carinatum
	Scoliosis
	Sacral agenesis (partial)
	Congenital hip subluxation or dislocation
	Genu valgum
	Talipes equinovarus
	Severe leg maldevelopment
Miscellaneous	Splenic torsion
	Adrenal cystic dysplasia

Modified from Woodard JR, Smith EA. Prune-belly syndrome. In: Walsh PC, Retik AB, Vaughan Jr ED, Wein AJ, editors. Campbell's urology. 7th ed. Philadelphia: WB Saunders; 1998. p. 1991.

Abdominal Wall Defect

The appearance of the abdominal wall gives PBS of newborns their most characteristic feature (Fig. 123–6). Although in some cases the musculature of the abdominal wall may be totally absent (Manivel et al, 1989), most commonly there is uneven involvement with the medial and inferior muscular typically most deficient (Mininberg et al, 1973; Randolph, 1977). The appearance at birth is that of wrinkled, redundant skin with an abdomen that bulges in the flanks. One may be able to discern intra-abdominal organs through the thinned abdominal wall. **The most severely affected areas may have skin, subcutaneous fat, and a single fibrous layer on the peritoneum** (Mininberg et al, 1973; Baird and Sadovnick, 1987). **Randolph conducted electromyographic mapping and demonstrated the inferior**

Figure 123–6. Wrinkled abdomen of a newborn with prune-belly syndrome. (Courtesy of C. Peters.)

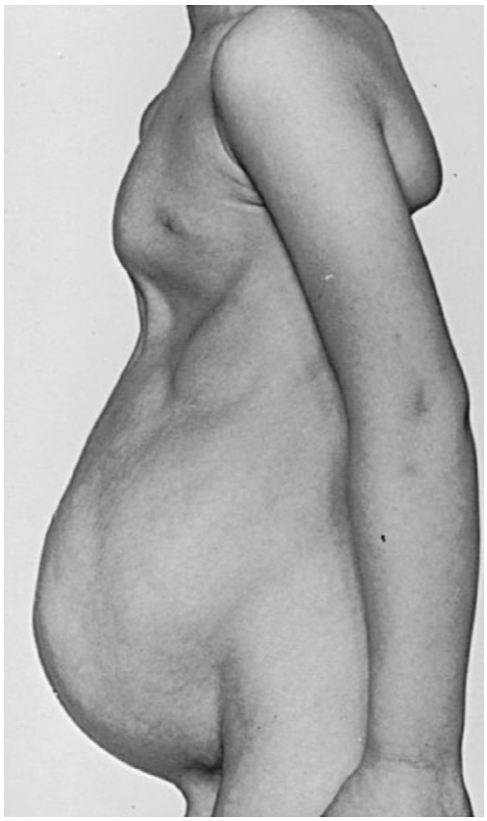

Figure 123–7. Older child with prune-belly syndrome, showing the absence of wrinkling, the "potbelly" appearance, and the consequent deformity of the lower ribs.

and medial segments to be most consistently affected (Randolph et al, 1981a). Electron microscopy has demonstrated a nonspecific pattern of myofilament disarray, Z-line disorganization, and mitochondrial proliferation (Afifi et al, 1972; Randolph et al, 1981b; Woodard and Smith, 1998). The fact that normal spinal anterior horn cells have been shown rules out a neuropathic etiology for the muscular deficiency (Nunn and Stephens, 1961). The muscular deficiency, however, is typically inconsistent and patchy.

As the child grows older, the abdomen becomes less wrinkled and takes on more of a pot-bellied appearance (Fig. 123–7). Gait is usually not affected, although it may be delayed, and the children tend to roll to their side and use their arms to sit from a supine position. The poor support of the lower chest wall results in flaring of the costal margin (Woodard and Smith, 1998). These children are more vulnerable to respiratory illness because their cough effectiveness is compromised. In spite of these abdominal wall issues, Woodard and Smith (1998) reported good wound healing without a tendency toward infections or incisional hernias.

Cardiac Anomalies

Cardiac anomalies such as patent ductus arteriosus, atrial septal defect, ventricular septal defect, and tetralogy of Fallot occur in 10% of children with PBS (Adebonojo, 1973). Cardiac abnormalities at birth may take precedence over urologic issues.

Pulmonary

Pulmonary difficulties can be observed at any age in patients with PBS. **Pulmonary hypoplasia can result from severe oligohydramnios related to renal dysplasia or severe bladder outlet obstruction and may result in newborn demise. In addition, pneumothorax and pneumomediastinum can be seen with or without pulmonary hypoplasia** (Skoog, 1992). **Significant pulmonary difficulties have been reported in 55% of PBS survivors** (Geary et al, 1986). **The lack of ability to generate significant intra-abdominal pressure may contribute to pneumonia and lobar atelectasis** (Alford et al, 1978; Ewig et al, 1996). Acute respiratory illnesses or an anesthetic procedure can easily lead to respiratory insufficiency in the PBS patient, who may have underlying chronic bronchitis from repeated respiratory illnesses. Many patients demonstrate significant restrictive lung disease secondary to musculoskeletal abnormalities such as scoliosis, rib cage abnormalities, and compromised abdominal musculature (Coplen et al, 1996).

Gastrointestinal Abnormalities

In at least 30% of cases, gastrointestinal anomalies are observed. The majority of the anomalies result from incomplete rotation of the midgut giving way to a wide mesentery, which results in increased bowel mobility with intestinal malrotation, volvulus, atresias, and stenosis (Silverman and Huang, 1950; Wright et al, 1986). Splenic torsion related to abnormal mesenteric fixation has also been reported (Heydenrych and Du Toit, 1978; Teramoto et al, 1981). Omphalocele, gastroschisis, and anorectal abnormalities have been reported (Petersen et al, 1972; Morgan et al, 1978; Wilbert et al, 1978; Short et al, 1985; Walker et al, 1987). With a limited ability to generate intra-abdominal pressure, constipation becomes a lifelong problem and leads to acquired megacolon (Woodard and Smith, 1998).

Orthopedic

Orthopedic abnormalities, ranging in incidence from 30% to 45%, are second in frequency to those of the genitourinary tract and abdominal wall. Many of these abnormalities result from the compressive effects of oligohydramnios. Some think the musculoskeletal defects result from the abnormal mesenchymal development at 6 weeks of gestation (Loder et al, 1992). Green and colleagues (1993), however, pointed out that because many of the deformities are unilateral, oligohydramnios is the most likely etiology. Dimpling of the lateral aspect of the knees is a common finding in

oligohydramnios. Oligohydramnios may also result in talipes equinovarus (26%), hip dysplasia (5%), and congenital scoliosis (4%) (Woodard and Smith, 1998). It has been proposed that a distended bladder that may impinge on the external iliac vessels may compromise the blood supply to the lower extremities and in severely affected cases result in lower extremity hypoplasia, absence, or amputation (Smith, 1913; Green et al, 1993).

PRESENTATION

Prenatal Diagnosis and Management

Prenatal ultrasonography has played a major role in the identification of congenital genitourinary abnormalities. Fetal hydronephrosis can be diagnosed accurately in the second trimester and is present in approximately 1% of all pregnancies. However, the etiology of the hydronephrosis cannot be accurately determined in all cases. Elder (1990) estimated that the accuracy of determining the etiology of fetal hydronephrosis varies from 30% to 85%.

In particular, PBS presents prenatally with findings similar to those of other causes of bladder outlet obstruction (Fig. 123–8), **as in posterior urethral valves, or megacystis megaureter syndrome** (Kramer, 1983). **Although an accurate diagnosis of PBS has been made as early as 11 to 14 weeks of gestation** (Shimizu et al, 1992; Yamamoto et al, 2001) (Fig. 123–9), **the classic findings of hydroureteronephrosis, a distended bladder, and an irregular abdominal circumference are not consistently seen at 30 weeks** (Okulski, 1977; Bovicelli et al, 1980; Christopher et al, 1982; Shih et al, 1982). Early fetal ascites has been suggested to correlate with PBS (Scarbrough et al, 1988). It is imperative to remember that the majority of patients with PBS do not have demonstrable urinary obstruction and that the degree of hydroureteronephrosis does not correlate with the postnatal renal function (Gadziala et al, 1982).

Whereas some have recommended in utero intervention for relief of urinary tract dilation and oligohydramnios (Gadziala et al, 1982; Glazer et al, 1982; Nakayama et al, 1984; Scarborough et al, 1988; Estes and Harrison, 1993; Leeners et al, 2000), others have recommended termination of pregnancy (Pescia et al, 1982). **It is difficult to justify the advocacy of pregnancy termination in light of our inability to diagnose precisely the etiology of prenatal hydronephrosis and inability to predict postnatal renal function on the basis of the**

degree of urinary tract dilation, except in rare cases of early and severe oligohydramnios. Prenatal intervention has been applied to PBS with no proven benefit in terms of postnatal renal function (Elder et al, 1987; Sholder et al, 1988; Freedman et al, 1999; Biard et al, 2005; Blaicher et al, 2005). The only circumstances in which prenatal intervention may be justified are the rare situations of urethral atresia with progressive oligohydramnios (Steinhardt et al, 1990; Reinberg et al, 1993; Perez-Brayfield et al, 2001) or cases in which decompression of the urinary tract is necessary to prevent dystocia (Gadziala et al, 1982).

Neonatal Presentation

The appearance of the abdominal wall immediately suggests the diagnosis of PBS (see Fig. 123–6) whether or not the diagnosis was suspected prenatally. It should be remembered that other associated abnormalities such as cardiac or pulmonary often should take precedence over the urinary tract because in the absence of true bladder outlet obstruction, as seen with urethral atresia, the hydroureteronephrosis is not life threatening.

Spectrum of Disease

With the number of variable anomalies present in PBS, it is understandable that there is a wide spectrum of clinical presentations. There are three major categories of presentation in the neonatal period as described by Woodard (1985) (Table 123–2).

Category I consists of neonates who have experienced marked oligohydramnios as a result of renal dysplasia or severe bladder outlet obstruction with resultant pulmonary hypoplasia and skeletal abnormalities. Most infants with urethral atresia fall in this category. The exceptions to this are patients with urethral atresia and a patent urachus (Rogers and Ostrow, 1973). Those in this category who are not stillborn commonly succumb within a few days of life to pulmonary hypoplasia or later to renal failure. Approximately 20% of newborns with PBS die in the perinatal period (Woodard and Parrott, 1978b; Burbige et al, 1987; Fallat et al, 1989). It would be unusual for any urologic intervention in this category of patients to alter the course of events. Simple catheter drainage is all that is justifiable.

Category II demonstrates the full spectrum of the disorder with moderate or unilateral renal insufficiency and moderate to severe hydroureteronephrosis. Pulmonary hypoplasia is not a prominent feature of this group of patients. The clinical course is that of stabilization of renal function at or somewhat below normal or progressive azotemia. It is in this group of patients that significant controversy over management exists (Waldbaum and Marshall, 1970; Randolph, 1977; Woodard and Parrott, 1978b).

Category III consists of patients with mild features of the triad or incomplete forms of PBS. This category comprises the majority of PBS patients in whom hydroureteronephrosis is present to some degree but renal function is well maintained (Woodhouse et al, 1982; Woodard, 1998). **There is no evidence of pulmonary insufficiency.** There is little controversy that urologic intervention in the group is reserved for patients who demonstrate repeated urinary tract infections, probably related to urinary stasis or vesicoureteral reflux, or development of upper tract deterioration (Woodard and Smith, 1998). As previously noted, there is poor correlation between the extent of abdominal wall deficit and the degree of hydronephrosis or renal dysplasia, or both. This is also apparent in other variants of the syndrome. Some children have markedly dilated urinary tracts with minimal or no dysplasia and therefore normal renal function. Therefore the appearance of the abdominal wall or the degree of hydronephrosis may have little bearing on the long-term prognosis of children with PBS.

Table 123–2.

Spectrum of Prune-Belly Syndrome

CATEGORY	CHARACTERISTICS
I	Renal dysplasia Oligohydramnios Pulmonary hypoplasia Potter features Urethral atresia
II	Full triad features Minimal or unilateral renal dysplasia No pulmonary hypoplasia May progress to renal failure
III	Incomplete or mild triad features Mild to moderate uropathy No renal dysplasia Stable renal function No pulmonary hypoplasia

Incomplete Syndrome

These are male patients who may not have all the features of the triad syndrome but share other features. **Most typically, these incomplete forms of the syndrome would lack the typical abdominal wall features but have the common uropathy and cryptorchidism. Many of these patients may go on to experience renal failure and therefore require close observation, monitoring, and selective intervention.** Bellah reported a relatively high (8/15) tendency to progressive renal failure in his population of pseudoprune patients. This may be partially attributed to a delay in diagnosis in the absence of the obvious abdominal musculature deficiency and therefore a tendency to present with recurring urinary tract infections (Bellah et al, 1996).

Adult Presentation

Patients with incomplete forms of PBS and specifically those who lack the abdominal wall features may present as late as adulthood with symptoms of renal failure and hypertension (Lee, 1977; Kerbl and Pauer, 1993). Although there have been isolated reports of adults with no history of urinary tract infections, most others who present in adulthood eventually develop urinary tract infections from the chronic urinary stasis associated with the syndrome (Culp and Flocks, 1954).

Female Syndrome

Five percent of PBS patients are female, most of whom have the abdominal wall deficiency and the abnormal urinary tract (Reinberg et al, 1991b). Rabinowitz and Schillinger (1977) reported female patients with the typical abdominal wall deficit and a normal urinary tract. In the series of Reinberg and colleagues (1991b), bladder outlet obstruction was commonly seen along with a 40% occurrence of anorectal anomalies similar to the statistics for the male; 40% did not survive the newborn period.

EVALUATION AND MANAGEMENT

The initial evaluation of the newborn with PBS requires a team consisting of a neonatologist, a nephrologist, and a urologist. As dictated, other specialists, particularly a cardiologist, may be indicated. Early orthopedic evaluation is also warranted. The major initial concern is that of management of cardiac and respiratory issues. An immediate chest radiograph is necessary to exclude commonly associated pulmonary abnormalities such as pneumothorax, pneumomediastinum, and pulmonary hypoplasia, which is commonly a result of oligohydramnios (Perlman and Levin, 1974). Early urologic intervention is indicated only for neonates with evidence of bladder outlet obstruction, in whom a percutaneous suprapubic tube can be inserted in the neonatal intensive care unit.

Initial evaluation of renal function and the urinary tract status is important but must be tempered by transitional neonatal physiology. Although an initial creatinine level is important in establishing a baseline, it may be more reflective of the mother's renal function, and therefore the trend in creatinine levels over the course of the early postnatal days or weeks is much more predictive of long-term renal function.

Key Points: Initial Management

- A team consisting of neonatology, nephrology, urology, and other specialties such as cardiology is necessary.
- A voiding cystourethrogram (VCUG) is indicated in the neonatal period if there is renal insufficiency or evidence of bladder outlet obstruction and only after antibiotic prophylaxis.
- A chest radiograph to evaluate for pneumothorax, pneumomediastinum, and pulmonary hypoplasia is necessary.
- Baseline assessment of renal function should include renal and bladder ultrasonography, blood urea nitrogen (BUN), creatinine, and electrolytes.
- Circumcision is advisable in the absence of a structural penile abnormality.
- Early intervention is indicated for evidence of bladder outlet obstruction and preferably with a percutaneous suprapubic tube.

Serum, blood urea nitrogen, and electrolytes are necessary to assess for the potential systemic acidosis and electrolyte imbalances that may be seen in renal insufficiency. It has been shown in multiple reports that a baseline creatinine level of less than 0.7 mg/dL is predictive of adequate renal function through childhood, in the absence of repeated insults from pyelonephritis (Geary et al, 1986; Reinberg et al, 1991a; Noh et al, 1999).

Early renal and bladder ultrasonography, once the newborn is stabilized, is necessary to assess the renal parenchyma for its thickness, density, and presence or absence of cortical cysts and degree of urinary tract dilation (see Fig. 123–1).

Avoidance of urinary tract infection is essential in light of the urinary stasis and often compromised baseline renal function. Circumcision is advisable in the absence of a structural penile abnormality to reduce the risk of infant urinary tract infections. Similarly, prophylactic antibiotic therapy is recommended, especially before urinary tract instrumentation, including the initial voiding cystourethrogram (VCUG). Although instrumentation without a defined purpose that may alter management should be avoided, a VCUG to assess the bladder outlet and bladder emptying ability, especially in the presence of renal insufficiency, is warranted (Woodard and Smith, 1998). The VCUG is necessary in neonates with renal insufficiency to rule out bladder outlet obstruction as the etiology versus urinary stagnation. In up to 70% of children with PBS, vesicoureteral reflux is diagnosed (Berdon et al, 1977; Fallat et al, 1989). Any instrumentation should be carried out with strict attention to sterile technique to reduce the risk of inoculation of a static urinary system. One can avoid an early VCUG in the presence of normal renal function and evidence of adequate bladder drainage per urethra or a patent urachus.

As noted, neonates can be categorized on the basis of their spectrum of disease (see Table 123–1). There is little disagreement on the management of category I PBS patients. There is no evidence that anything beyond supportive care is justifiable; in particular, intervention in the urinary tract is not indicated beyond simple bladder drainage because their fate cannot be altered (Woodard and Smith, 1998).

At the other end of the spectrum, category III patients rarely require urologic intervention for the urinary tract because they are in a balanced state of hydronephrosis with good, if not normal, renal function. Early in infancy their cryptorchidism requires correction. Children in this category require regular monitoring of urinary tract dilation (ultrasonography) and renal function (serum creatinine).

Category II patients require individualization of evaluation and management on the basis of the fact that within this category there are variable degrees of severity of each facet of PBS. There is, however, much controversy over their management. Evaluation of renal function or renal drainage, or both, is required in those with renal insufficiency. Excretory urography, while providing dramatic images of the urinary tract (see Fig. 123–2), does not provide sufficient information on comparative function. Renal parenchymal function is best assessed by a technetium-99m (^{99m}Tc) dimercaptosuccinic acid (DMSA) renal scan at 4 to 6 weeks of age to prevent difficulties in interpretation related to transitional neonatal physiology. Renal outflow obstruction is best assessed by ^{99m}Tc mercaptoacetyltriglycine (MAG3), which also provides an assessment of comparative renal function with massive hydronephrosis and resultant stasis. In the presence of poor renal function, assessment of renal outflow obstruction by nuclear scan techniques may be limited; therefore selective use of the Whitaker antegrade perfusion test may be helpful.

Controversies in Management of Category II Prune-Belly Syndrome

Aggressive surgical intervention was initially derived from early observations of the poor prognosis for category II infants as a group. Compilation of the cases reported in the literature between 1950 and 1970 by Waldbaum and Marshall (1970) revealed that 86% of the 56 accurately traceable patients had died, with or without surgical intervention. The obvious implication was that a more aggressive approach was necessary to improve the fate of the infant with PBS. **With the recognition that infection and progressive renal insufficiency are the factors that most often pose the greatest threat to quality of life and survival, surgical reconstruction to normalize the anatomy and function of the genitourinary tract was advocated.**

Early retailoring of the urinary system to reduce stasis and eliminate reflux or obstruction has included ureteral shortening, tapering, and vesicoureteral reimplantation and reduction cystoplasty. Reconstruction is best delayed until the child is at least 3 months of age to allow for pulmonary maturation. This approach has been successful in achieving anatomic and functional improvement as evidenced by stable radiographic studies, stable creatinine values, and a reduced occurrence of infection (Waldbaum and Marshall, 1970; Jeffs et al, 1977; Woodard and Parrott, 1978b; Randolph et al, 1981b). In the personal reconstructive experience of one of the authors (JW), 15 patients have maintained a normal creatinine level and only 2 have demonstrated moderate renal insufficiency, with follow-up ranging from 2 to 27 years.

An alternative approach of limited surgical intervention has also been applied. Proponents advocate close surveillance with medical management of bacteriuria and surgical intervention only in patients with proven obstruction or intractable infection. Opinions vary about the management of vesicoureteral reflux in the PBS population, although there is no reason to believe that reflux in this population is any less important, and correction of high-grade reflux seems prudent. Success with minimal surgical intervention has been reported (Woodhouse et al, 1979; Duckett et al, 1980; Tank and McCoy, 1983; McMullin et al, 1988). Woodhouse and colleagues (1979) reviewed a series of patients with PBS managed conservatively. Nine of these 11 patients, who were monitored from infancy, remained well except for a few urinary tract infections for periods of up to 24 years. They were said to have normal voiding patterns and normal renal function. Certainly, patients in category III are candidates for this type of management.

The paucity of long-term data for category II patients, the probable variation in assignment of disease severity in treatment groups, and the variable natural history of the disease make comparisons of these retrospective studies difficult. **Spontaneous improvement in ureteral appearance and function may occur with normal growth and elongation of the ureters** (Duckett et al, 1980). **Also, some patients with gross abnormalities of the urinary collecting system have survived decades without medical attention** (Asplund and Laska, 1975; Lee, 1977; Texter and Koontz, 1980). **Yet progressive uropathy is also well known to occur, and many patients with PBS ultimately require renal transplantation** (Reinberg et al, 1989). Controversy will persist over category II patients until accurate application of a medical or surgical approach is possible on the basis of distinct clinical features. Dénes and colleagues (2004) emphasize the individualization of care in their 17-year experience with 32 patients.

Surgical Management of the Prune-Belly Syndrome Patient

Surgical management of children with PBS can be divided into three categories: urinary tract reconstruction, abdominal wall reconstruction, and orchidopexy. Urinary tract reconstruction is generally reserved for children with progressive or severe hydronephrosis, recurrent upper tract infections, true obstructive uropathy, and progressive renal failure. Temporary urinary diversion also has a role in the very young or the very ill child.

Supravesical Urinary Diversion

In certain instances the occurrence of repeated upper tract infections or deterioration of renal function dictates temporary urinary diversion. Although cutaneous vesicostomy usually provides adequate upper tract drainage and decompression, in rare instances more proximal diversion is indicated because of ureteropelvic or ureterovesical junction obstruction. Here a cutaneous pyeloplasty is advocated rather than proximal ureterostomy because it provides the best upper tract drainage and avoids sacrificing a normal proximal ureter that might be useful in later reconstruction.

Cutaneous Vesicostomy

Urinary diversion may be necessary as a temporary measure in children with acute renal failure, urinary sepsis, or bladder outlet obstruction from urethral atresia with limited patency of the urachus (Fig. 123–10) (Teramoto et al, 1981; Joseph, 1999). **When temporary urinary diversion is indicated, a cutaneous vesicostomy is the procedure of choice. This is best done by the Blocksom technique as described by** Duckett (1974, 1986) and colleagues. If there is a large urachal diverticulum, it

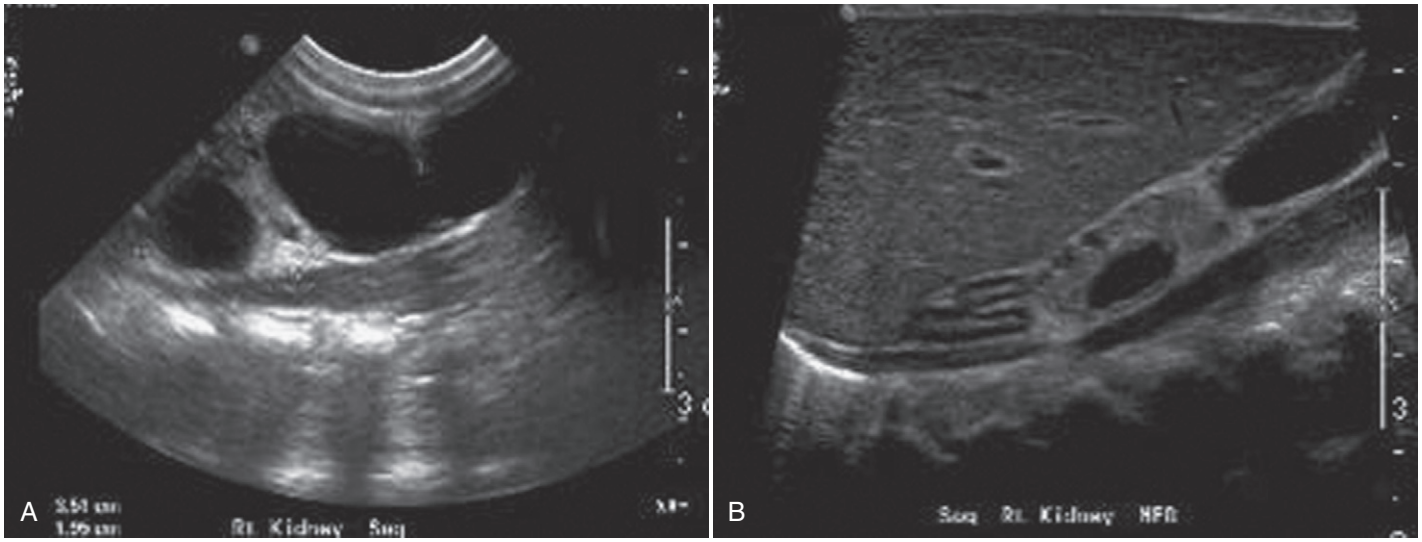

Figure 123–10. **A,** Prevesicostomy ultrasound of the right kidney demonstrating massive hydronephrosis with echogenic parenchyma. **B,** Postvesicostomy ultrasound demonstrating a decompressed kidney with echogenic parenchyma and cortical cysts. (Courtesy of C. Peters.)

can be excised at that time. It is advisable to create a larger than normal stoma in the PBS patient because stenosis is common, probably because of the decreased intra-abdominal pressure (Snow and Duckett, 1987).

Internal Urethrotomy

In the absence of urethral atresia, true anatomic obstruction of the urethra is rare in PBS. However, the normal resistance of the urinary sphincter has been implicated in "unbalanced" urethrovesical function contributing to large postvoid residuals. Snyder and Cukier proposed lowering urethral resistance by internal urethrotomy to improve bladder emptying (Snyder et al, 1976; Cukier, 1977). In patients studied by urodynamic flow rate profilometry, improved flow rates with reduced residual urine and improvement in the radiographic appearance of the upper tracts were found (Snyder et al, 1976; Woodhouse et al, 1979). Although sustained long-term success has not been demonstrated, internal urethrotomy should be considered in PBS children with high postvoid residuals, increasing hydroureteronephrosis, or vesicoureteral reflux with recurrent upper tract infections. Williams (1979) advocated using an Otis urethrotome achieving a No. 24- to 30-Fr caliber with one or two incisions made anteriorly or anterolaterally; however, direct visual urethrotomy would seem preferable and should be performed at the distal end of the prostatic urethra (Smith and Woodard, 2002). It is interesting to note that internal urethrotomy does not result in incontinence in this population.

Reduction Cystoplasty

In many PBS patients, poor bladder contractibility leads to incomplete and infrequent emptying from the complicating urinary stasis and vesicoureteral reflux issues. This leads to the concept of reducing the size of the bladder and remodeling it into a more spherical shape to better direct the contractible forces (Perlmutter, 1976). A variety of approaches have been proposed, from simple excision of the urachal diverticulum to the excision of redundant mucosa with the creation of overlapping between flaps to improve contractibility (Williams and Parker, 1974; Woodard and Trulock, 1986). Over time, however, high bladder capacity and residual volumes seem to recur (Bukowski and Perlmutter, 1994). It seems therefore that reduction cystoplasty would be justified only to remove the larger urachal diverticulum or as part of a more extensive internal reconstruction. Intermittent catheterization through the urethra or through an appendicovesicostomy channel is likely to afford better long-term bladder emptying with reduction of residual urinary volumes (Joseph, 1999).

Anterior Urethral Reconstruction

On one end of the spectrum of urethral maldevelopment is urethral atresia, sometimes referred to as *microurethra* (see Fig. 123–3). Passerini-Glazel and colleagues (1988) reported on progressive gentle urethral dilation with good success. This technique may be used in situ or through and through in cases in which a vesicostomy has been performed (Fig. 123–11). As reported by Reinberg and colleagues (1993), however, this technique is not uniformly successful and one may require a more formal urethroplasty with skin flaps or grafts, or both.

Megalourethra in PBS may be either fusiform or scaphoid (Appel et al, 1986). This is best approached with a circumferential subcoronal incision and penile degloving (Fig. 123–12A-F). The redundant urethra can be excised, and the urethra reconstructed over an appropriately sized catheter. Alternatively, some of the urethra can be used to reinforce the urethroplasty because in either form of megalourethra the spongiosum is deficient.

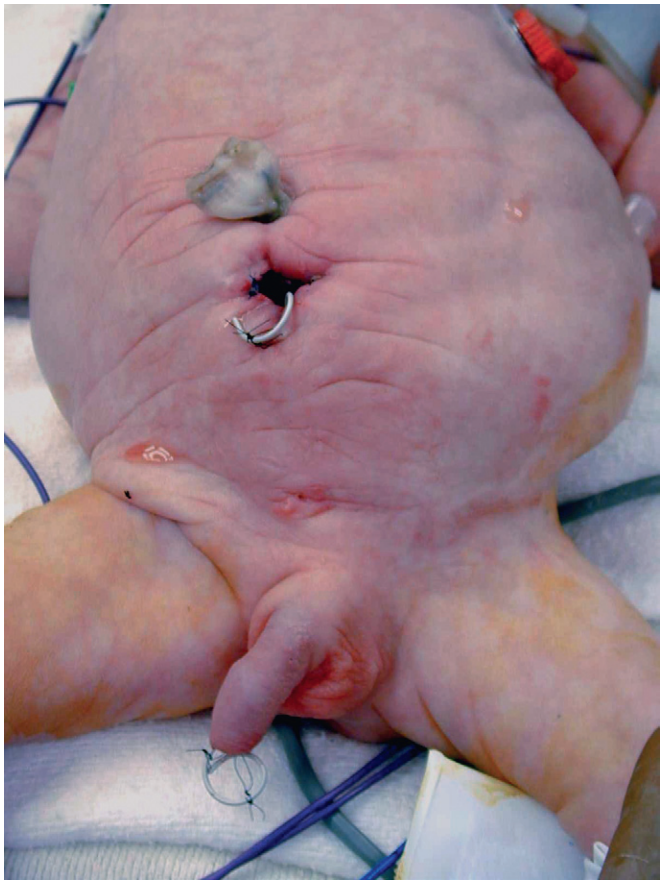

Figure 123–11. Prune-belly syndrome patient with urethral atresia. Note vesicostomy and double-J stent through the urethra for urethral progressive dilation.

Ureteral Reconstruction

Ureteral remodeling remains controversial. It is best undertaken in children who demonstrated repeated nonsuppressible upper urinary tract infections or those with progressive upper tract deterioration. The goal of remodeling is to reduce urinary stasis. The key to success relies on meticulous surgical technique and preservation of the upper few centimeters of proximal ureter for reconstruction. Ureteral reimplantation into the abnormal bladder can be difficult in that the creation of a submucosal tunnel can be challenging (Woodard and Trulock, 1986). Woodard and his colleagues have demonstrated excellent success in this population when these procedures were performed in the neonatal period or in the older child (Woodard and Parrott, 1978b; Woodard and Zucker, 1990). They no longer, however, recommend such extensive reconstructive surgery before the age of 3 to 6 months. Dénes and colleagues (2004) have reported excellent results of reconstruction of the prune upper and lower urinary tracts in a large group of patients, with an experience of more than 17 years.

Orchidopexy

The timing of orchidopexy is dictated by our current understanding of the need for early treatment of the undescended testis in non-PBS patients along with individual PBS patients' needs for either temporary or reconstructive surgery. Although the fertility

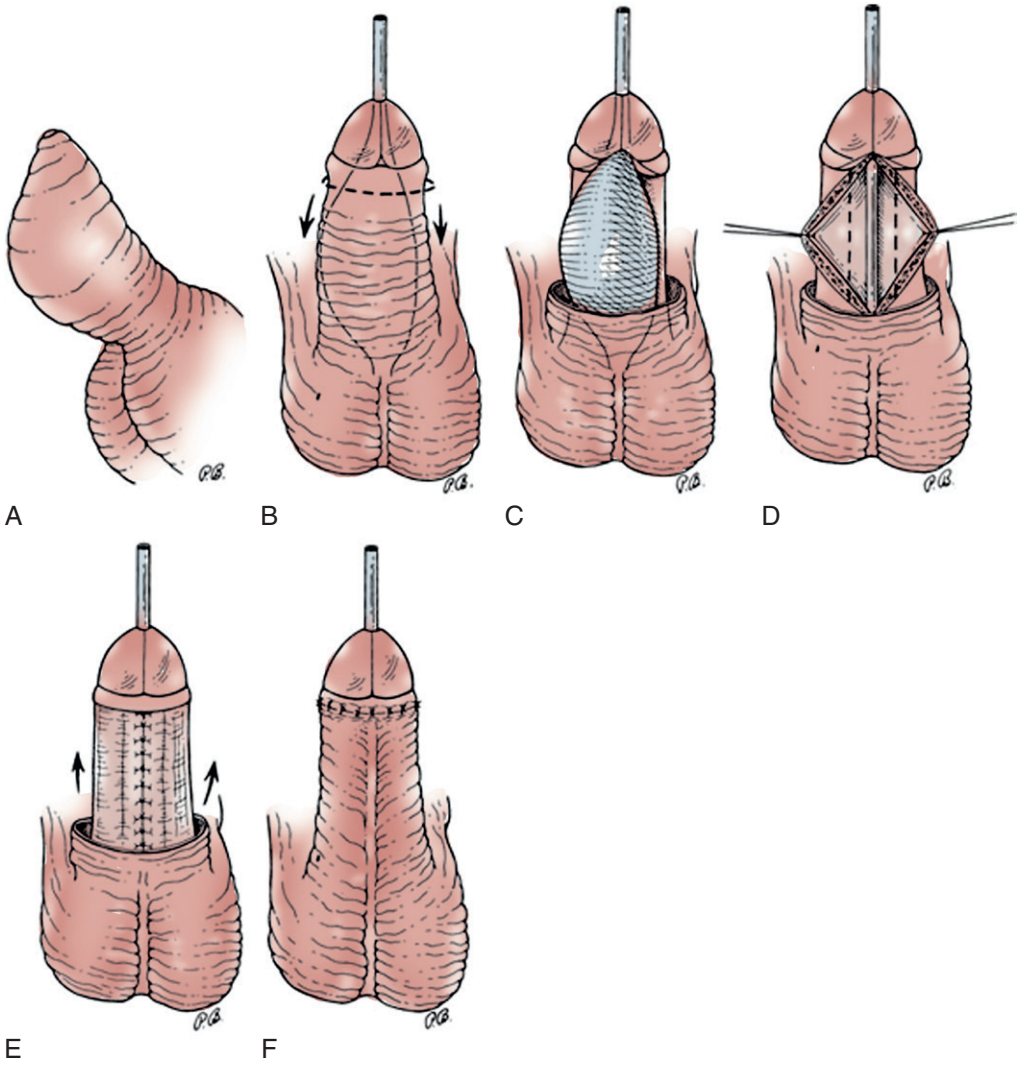

Figure 123–12. **A,** The prepuce is reduced, and a circumcising incision is made, preserving a mucosal collar. **B,** With a catheter in place to assist with identification of the urethra, the penis is degloved along the subdartos plane. **C,** The involved segment of the urethra is opened longitudinally, and the redundant urethral wall is excised to allow tapering of the urethra over a catheter of appropriate size. **D,** The urethra is closed with absorbable running sutures and is bolstered with a second layer of sutures placed in an interrupted fashion if possible. **E,** The penile skin is brought forward, the excess foreskin is removed with a second circumferential incision, and the penile shaft skin is approximated to the mucocutaneous border **(F).**

Key Points: Surgical Reconstruction

- Upper urinary tract reconstruction is controversial but clearly indicated for evidence of declining renal function in the presence of hydronephrosis, recurrent upper tract infections, or progression of the hydroureteronephrosis.
- Orchidopexy is best performed early in life because this affords the most likely prospect of a successful single-stage procedure.
- Abdominal wall reconstruction has demonstrated improved bladder emptying, a more effective cough, and improved defecation in addition to psychosocial benefits.

potential of the PBS patient is known to be compromised, germ cells are present in the testes of infants with PBS. In addition, the prognosis for normal hormonal function at puberty is excellent. These factors, along with the potential risk of testicular carcinoma (Uehling et al, 1984; Massad et al, 1991), would justify early orchidopexy. Because the testes are uniformly located in the abdomen, most commonly on a broad mesorchium overlying the iliac vessels (Coplen et al, 1996), standard inguinal approaches are not usually successful in achieving a satisfactory scrotal position. Four alternative approaches may be considered.

Transabdominal Orchidopexy. Woodard, Parrott, and other researchers noted that if an orchidopexy is done in the neonatal period and up to 6 months of age by a transabdominal approach, adequate spermatic vessel mobilization can usually be achieved for scrotal placement (Woodard and Parrott, 1978a, 1978b; Randolph et al, 1981a; Fallat et al, 1989). **Transabdominal bilateral orchidopexy at about 6 months of age is currently considered the approach of choice.** This approach is often used in conjunction with other abdominal surgeries, either a vesicostomy, urinary tract reconstruction, or abdominal wall reconstruction. In the absence of need for other abdominal surgeries, this can be accomplished laparoscopically.

Spermatic Vessel Ligation. When successful transabdominal orchidopexy cannot be accomplished in the first few months of life, the other options that may be considered

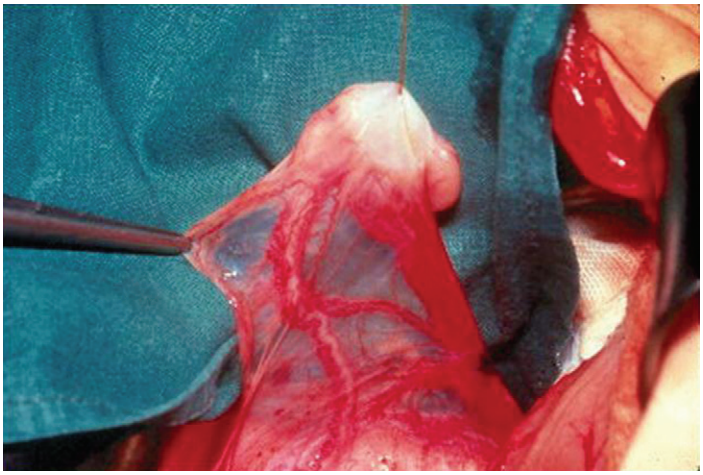

Figure 123–13. Operative photograph showing increased vacularity along vas deferens 4 months after first stage Fowler-Stephens orchidopexy.

are (1) Fowler-Stephens orchidopexy (Fowler and Stephens, 1959; Gibbons et al, 1979; Boddy et al, 1991; Kirsch et al, 1998), **(2) staged Fowler-Stephens orchidopexy** (Fig. 123–13) (Ransley et al, 1984; Bloom, 1991; Caldamone and Amaral, 1994; Docimo, 1995; Yu et al, 1995), **and (3) microvascular autotransplantation** (MacMahon et al, 1976; Wacksman et al, 1980; Boddy et al, 1991). A meta-analysis report by Docimo (1995) indicated comparative success rates of 67% and 77% for standard and staged Fowler-Stephens techniques, respectively. In a multi-institutional report of laparoscopic orchidopexy, Baker and colleagues (2001) noted a success rate of 81% for a standard Fowler-Stephens approach compared with 90% for a staged approach. In a long-term follow-up report, Patil and colleagues (2004) reported a satisfactory outcome in PBS with a one- or two-stage Fowler-Stephens orchidopexy. Some authors have recommended several technical adjustments during laparoscopic orchiopexy in children with PBS, particularly port placement because there is little resistance to cannula placement in these children (Saxena and Brinkmann, 2007).

Reconstruction of the Abdominal Wall

Children with mild degrees of abdominal muscular deficiency may show improvement in the abdominal wall laxity as they mature. However, most others with moderate to severe degrees of abdominal wall laxity are left with a potentially psychologically crippling defect (Ehrlich et al, 1986; Parrott and Woodard, 1992). An elasticized corset can improve the external appearance when they are fully clothed; however, it is quite inconvenient to use. There is general agreement about the cosmetic benefit of abdominal wall reconstruction. However, whether it improves bladder, bowel, and pulmonary function is controversial (Smith et al, 1998; Woodard, 1998). Smith and colleagues demonstrated improved bladder emptying following abdominal wall reconstruction; however, some of their reconstructed patients underwent concomitant urinary tract remodeling as well. Potential effects include a more effective cough and improvement in defecation. The timing of abdominal wall reconstruction should be dictated by the need for other surgical interventions, particularly if upper urinary tract remodeling is necessary. If upper tract remodeling is not anticipated, the abdominal wall can be addressed at any time and has been done as young as 6 months of age along with transabdominal orchidopexy (Smith and Woodard, 2002). However, if the procedure is done in infancy, one must be prepared to place the infant on a respirator postoperatively for a period of time. Of the following techniques, the consensus currently is that the Monfort and Ehrlich techniques provide the best functional and cosmetic results.

Randolph Technique

Randolph and colleagues (1981) first popularized a technique for abdominal wall reconstruction based on electromyographic mapping, which indicated that the most severely affected area of the abdomen is the infraumbilical regions and the lateral and supraumbilical regions are generally least affected. This technique makes a transverse incision from the 12th rib to the pubic symphysis to the opposite 12th rib with a full-thickness removal of the skin, lower abdominal musculature, and peritoneum. The healthy fascia is then approximated to the anterior iliac spines, pubic tubercle, and inferior fascia. Although this technique is successful in establishing a waistline, lateral abdominal bulging often persists. Of the 16 patients reported, 9 had excellent cosmetic results and there was some residual protuberance in 7 (Fallat et al, 1989).

Ehrlich Technique

The technique described by Ehrlich used a vertical midline incision and allows preservation of the umbilicus on a vascular pedicle from the inferior epigastric artery (Ehrlich et al, 1986; Ehrlich and Lesavoy, 1993). The skin and subcutaneous tissues are elevated off the muscle and fascial layers, and an overlapping, pants over vest advancement of each side to the contralateral flank is performed, preserving the less affected lateral muscles and fascia.

Monfort Technique

Monfort described a technique that is vertically oriented similar to that of Ehrlich's approach; however, an elliptically oriented incision is used to isolate the redundant skin (Monfort et al, 1991). The incision extends from the tip of the xiphoid to the pubis. A second incision is made around the umbilicus to preserve it in situ (Fig. 123–14). The skin and subcutaneous tissue are dissected off the attenuated fascia and muscle with the dissection extending laterally to the anterior axillary line. Vertical fascial incisions are made lateral to the superior epigastric arteries, leaving a central fascial bridge. If intra-abdominal surgery is necessary, excellent exposure to the urinary tract or abdominal testes is afforded through these lateral fascial incisions. The lateral fascial is then advanced over the central fascial bridge from both sides, alleviating the redundancy and increasing the thickness of the abdominal wall (Figs. 123–15 and 123–16).

Furness and colleagues (1998) described a modified midline approach with less abdominal wall dissection that avoids entering the peritoneum, which may be useful if intra-abdominal surgery is not planned. A modification of the Monfort technique uses laparoscopy to protect the abdominal contents (Franco, 2005).

LONG-TERM OUTLOOK

The nadir creatinine value during infancy has proved to be a useful predictor of long-term renal function. If the nadir value is less than 0.7 mg/dL, renal function tends to be stable during childhood unless there is further renal compromise by pyelonephritis (Geary et al, 1986; Reinberg et al 1991b; Noh et al 1999). The importance of urinary tract monitoring by periodic cultures and prompt treatment of urinary tract infections cannot be overemphasized. Unfortunately, the risk of infection is constant in the setting of urinary

tract dilation and stasis. Up to 30% of patients, generally those with impaired renal function at initial evaluation, develop chronic renal failure during childhood or adolescence (Geary et al, 1986). Renal transplantation is necessary for these patients to ensure normal growth and development, and success with transplantation in PBS patients can be expected to equal that in other age-matched groups (Reinberg et al, 1989). Fusaro and colleagues (2004) have reported on five boys with PBS who underwent renal transplantation. The 5-year graft survival rate was 66.7%, with all maintaining their native urinary tracts. Normal growth can be expected in most of the patients with normal renal function, although growth retardation in the absence of renal compromise was observed in one third of patients in one series (Geary et al, 1986). A normal pattern of secondary sexual development can be expected (Woodhouse and Snyder, 1985). Although primary fertility is not expected in the PBS population, fertility with assisted reproductive techniques may be feasible in those having had successful early orchidopexy.

The overall outlook for the PBS patient, both for survival and for quality of care, has improved considerably, largely through advances in medical, surgical, and urodynamic management. The key to management of the PBS patient is individualization of care because some require major urologic reconstruction, and others require little if any reconstruction. Long-term surveillance of the urinary tract is essential because functional dynamics can change over time.

EXSTROPHY-EPISPADIAS COMPLEX

The exstrophy-epispadias complex of genitourinary malformations can be as simple as a glanular epispadias or as overwhelming as a multisystem defect such as cloacal exstrophy (Fig. 124–1). This chapter provides a comprehensive overview of the entire spectrum of the exstrophy-epispadias-cloacal exstrophy defects. In addition, all modern methods of exstrophy management, their complications, and outcomes are discussed.

Historical Aspects

In older texts, the first account of bladder exstrophy was ascribed to Assyro-Babylonian sources dating from the first and second millennia BC. At that time, birth anomalies in both humans and animals were carefully recorded on tablets for their importance as omens on the basis of their interpretation by divination experts. Feneley and Gearhart (2000) examined Assyro-Babylonian descriptions of congenital anomalies from cuneiform texts at the British Museum in London. Although references to anomalies involving the external genitalia were frequent (e.g., hermaphroditism, absence of external genitalia, unilateral and bilateral undescended testes), references to renal and bladder anomalies were few and difficult to interpret medically. Duplication and laterality of anomalies were described in detail owing to their distinct significance, but malformations in combination were not recorded. On the basis of these studies performed with a prominent Assyriologist, a definitive description of bladder or cloacal exstrophy was not corroborated. **The first recorded case of epispadias is attributed to the Byzantine Emperor Heraclius** (AD 610-641) and the first description of bladder exstrophy to Schenck in 1595 (Feneley and Gearhart, 2000).

Incidence and Inheritance

The incidence of bladder exstrophy has been estimated as between 1 in 10,000 and 1 in 50,000 (Lattimer and Smith, 1966) live births. However, data from the International Clearinghouse for Birth Defects monitoring system estimated the incidence to be 3.3 cases in 100,000 live births (Lancaster, 1987). The male-to-female ratio of bladder exstrophy derived from multiple series is 2.3:1 (Shapiro et al, 1985). However, two series reported a 5:1 to 6:1 male-to-female ratio of exstrophy births (Ives et al, 1980; Lancaster, 1987).

The risk of recurrence of bladder exstrophy in a given family is approximately 1 in 100 (Ives et al, 1980). Shapiro and colleagues (1985) conducted a questionnaire of pediatric urologists and surgeons in North America and Europe and identified the recurrence of exstrophy and epispadias in only 9 of approximately 2500 indexed cases. Lattimer and Smith (1966) cited a set of identical twins with bladder exstrophy and another set of twins in whom only one child had exstrophy. Shapiro's series identified five sets of male and female nonidentical twins in whom only one twin was affected with exstrophy; five sets of male identical twins in whom both twins were affected; one set of identical male twins in whom only one twin was affected; and three sets of female identical twins in whom only one twin had the exstrophy anomaly (Shapiro et al, 1985). Evidence by Reutter and colleagues has demonstrated six families with two occurrences of exstrophy-epispadias complex, one in which the proband was the product of a consanguineous union and four discordant twin pairs. Also, Boyadjiev and colleagues (2004a) found four multiplex families (2.7%) in a cohort of 151 families with the exstrophy-epispadias complex. There were three twin pairs, two of which were monozygotic, and concordance was

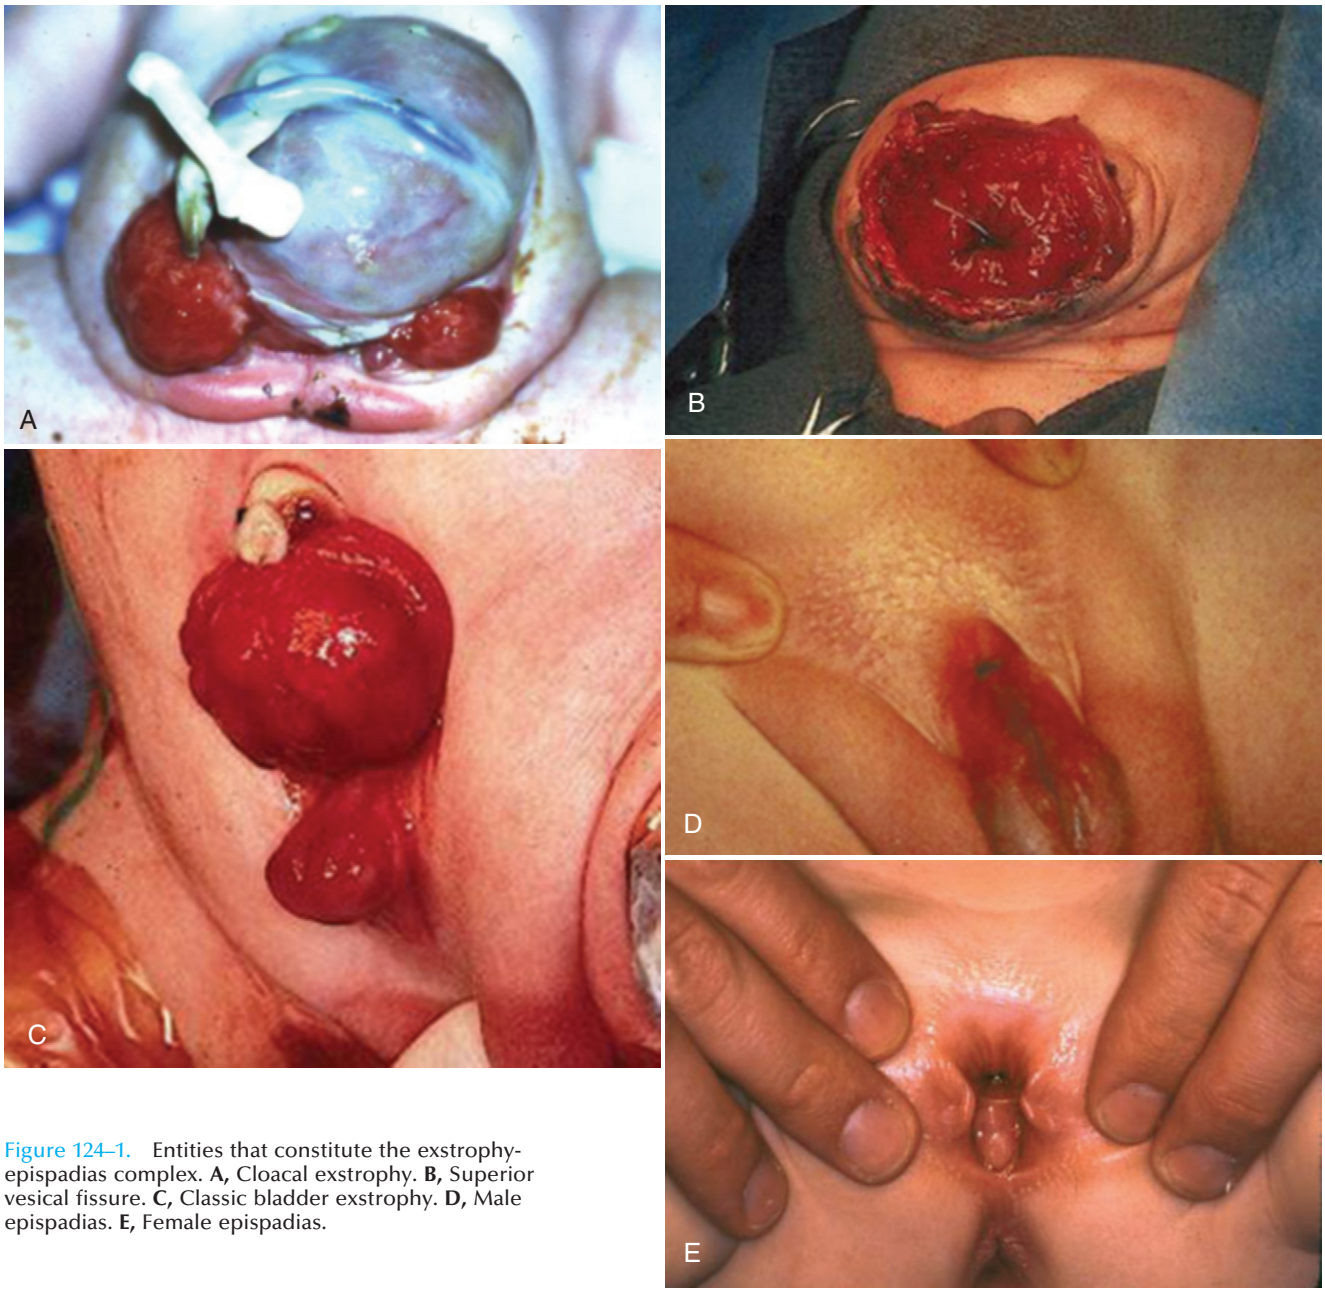

Figure 124–1. Entities that constitute the exstrophy-epispadias complex. **A,** Cloacal exstrophy. **B,** Superior vesical fissure. **C,** Classic bladder exstrophy. **D,** Male epispadias. **E,** Female epispadias.

present in only one of the twin pairs. Consanguinity was present in one family. Bladder exstrophy or epispadias was not reported until the 1980s in the offspring of parents with the exstrophy-epispadias complex. Shapiro and colleagues (1985) described two women with complete epispadias who gave birth to sons with bladder exstrophy. They also reported that another woman with bladder exstrophy gave birth to a son with bladder exstrophy. The inheritance of these three cases of bladder exstrophy was identified in a total of 225 offspring (75 boys and 150 girls) produced by individuals with bladder exstrophy and epispadias. **Shapiro and colleagues** (1985) **determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is 1 in 70 live births, a 500-fold greater incidence than in the general population.** Boyadjiev and colleagues (2004a) studied sibling data from 200 families and found 259 unaffected children in addition to the probands with exstrophy. Twenty-six probands had first-, second-, or third-degree relatives with congenital anomalies unrelated to the exstrophy-epispadias complex, most of which were midline defects and oral clefts. Four probands had a total of seven biologic children that were unaffected. In a multinational review of exstrophy patients (Lancaster, 1987), two interesting trends were found: (1) Bladder exstrophy tends to occur in infants of younger mothers, and (2) an increased risk at higher parity is observed for bladder exstrophy but not for epispadias. Boyadjiev's (2004a) data, however, differ from these trends, indicating that the average maternal age was 34 years and the average paternal age was 32 years. In addition, 49% of probands were born from first pregnancies. This change may represent societal changes, indicating advancing maternal age for first pregnancies and

increasing utilization of assisted reproductive techniques in first pregnancies.

Exploration of possible etiologies for the exstrophy-epispadias complex continues. A report from Israel indicated a 10-fold increase in exstrophy births to mothers who had received large doses of progesterone in the early part of the first trimester. Wood and colleagues (2003) reported on a sizable series of children with exstrophy conceived using assisted reproductive techniques. A 7.5-fold increase in incidence was noted when in vitro fertilization was used. These two reports indicate a role for hormonal changes in the etiology of the exstrophy-epispadias complex. In a large series of 214 females, no association of parental age, maternal reproductive history, or periconceptual material exposure to alcohol, drugs, radiation, or infections was found (Gambhir et al, 2008). However, periconceptual maternal exposure to smoking was significantly more common in patients with cloacal exstrophy than in the combined group of patients with classic exstrophy/epispadias. Periconceptual use of folic acid offered no protection to this anomaly (Gambhir et al, 2008).

Genetic studies to identify a genetic locus for the exstrophy-epispadias complex are under way. Boyadjiev and colleagues (2004b) have reported finding a breakpoint disruption in the 5′ region of the *CASPR3* gene on chromosome 9. This observation is the first to suggest a possible genetic basis for development of the exstrophy-epispadias complex. In another recent study by Ludwig and colleagues (2009), risk loci for the exstrophy spectrum were found in seven separate chromosomes with susceptibility genes in several regions.

Embryology

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy-epispadias complex (see Fig. 124–1). The cause of this complex is thought to be the failure of the cloacal membrane to be reinforced by ingrowth of mesoderm (Muecke, 1964). The cloacal membrane is a bilaminar layer situated at the caudal end of the germinal disk that occupies the infraumbilical abdominal wall. Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane results in formation of the lower abdominal muscles and the pelvic bones. The cloacal membrane is subject to premature rupture, and, depending on the extent of the infraumbilical defect and the stage of development during which the rupture occurs, bladder exstrophy, cloacal exstrophy, or epispadias results (Ambrose and O'Brien, 1974).

After mesenchymal ingrowth occurs, the urorectal septum grows in a caudal direction and divides the cloaca into a bladder anteriorly and a rectum posteriorly (Fig. 124–2). Distally, the septum meets the posterior remnant of the bilaminar membrane, which eventually perforates and forms the urogenital and anal openings. The paired genital tubercles migrate medially and fuse in the midline, cephalad to the dorsal membrane before perforation.

The theory of embryonic maldevelopment in exstrophy held by Marshall and Muecke (1968) is that the basic defect is an abnormal overdevelopment of the cloacal membrane, which prevents medial migration of the mesenchymal tissue and proper lower abdominal wall development. The timing of the rupture of this defective cloacal

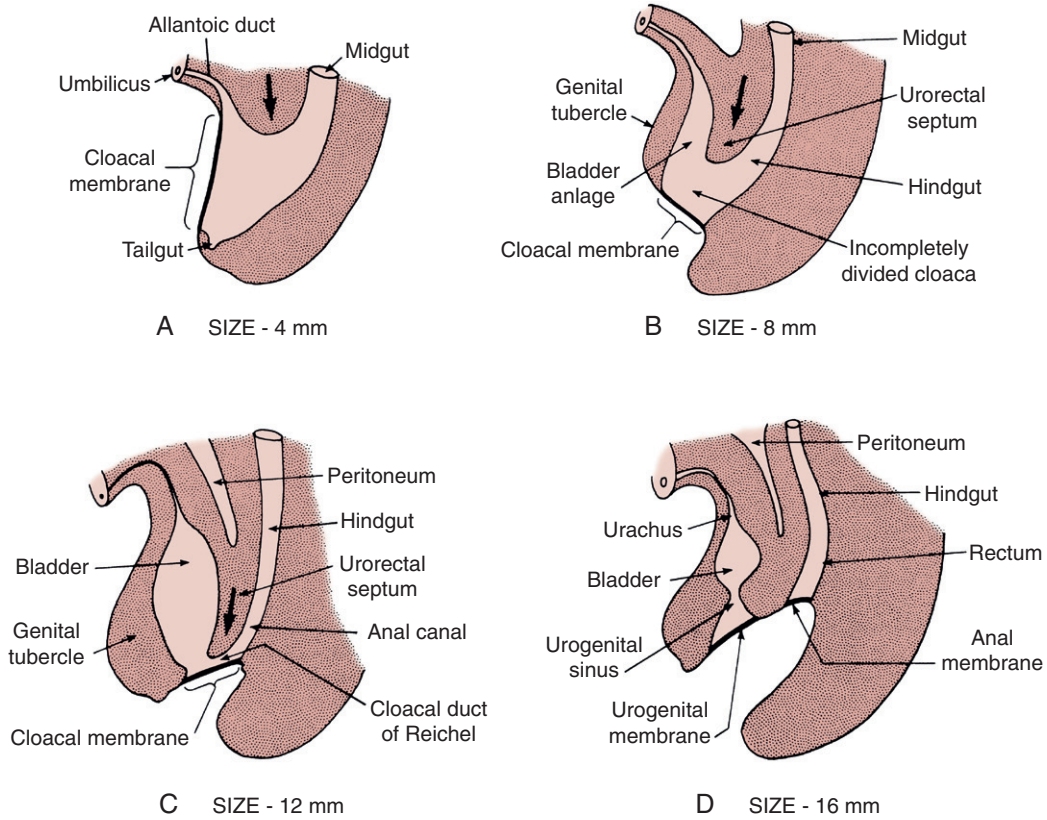

Figure 124–2. Development of the cloaca and cloacal membrane in the 4- to 16-mm embryonic stages. Caudal growth of the urorectal septum leads to separation of the anterior urogenital sinus from the posterior rectum.

membrane determines the variant of the exstrophy-epispadias complex that results. This theory is supported by Muecke's work in the chick embryo and by the high incidence of expected central perforations, resulting in the preponderance of classic exstrophy variants. Classic exstrophy accounts for more than 50% of the patients born with this complex (Muecke, 1964; Marshall and Muecke, 1968). Martinez-Frias and colleagues (2001) using epidemiologic factors of low birth weight, twinning, single umbilical artery, and associated defects postulated that cloacal exstrophy and exstrophy of the bladder are two different expressions of a primary developmental field defect with cloacal exstrophy being an early defect. New theories have been offered regarding the origins of these ventral body wall defects. It has been postulated that failure of one or both of the lateral body wall folds to move far enough ventrally to meet its counterpart in the midline (Sadler and Feldkamp, 2008). The associate defect results in one or more of the internal organs protruding through the defective region. Thus if closure fails in the abdominal and pelvic region, cloacal exstrophy results. If in the pelvis alone, only classic exstrophy occurs.

Other plausible theories concerning the cause of the exstrophy-epispadias complex exist. Abnormal development of the genital hillocks caudal to the normal position, with fusion in the midline below rather than above the cloacal membrane, has been embraced by other investigators (Patton and Barry, 1952; Ambrose and O'Brien, 1974). Another interesting hypothesis that remains controversial describes an abnormal caudal insertion of the body stalk, which results in a failure of interposition of the mesenchymal tissue in the midline (Mildenberger et al, 1988). As a consequence of this failure, translocation of the cloaca into the depths of the abdominal cavity does not occur. A cloacal membrane that remains in a superficial infraumbilical position represents an unstable embryonic state with a strong tendency to disintegrate (Johnston and Kogan, 1974). The lack of ability of the Meucke hypothesis to explain the absence of the ileocecal region of the digestive system and the superior mesenteric blood supply of the exstrophied intestinal region has led to a suggestion that there may be involvement of the allantois in the development of cloacal exstrophy (Zarabi and Rupani, 1985). Absence of migration, ascent, or alignment of the allantois with the yolk sac with its persistence at the dome of the cloaca can be used to explain the bowel abnormalities noted in cloacal exstrophy. Maldevelopment of the bony pelvis rather than soft tissue defects has been suggested to be the inciting issue for the development of exstrophy. Beaudoin and colleagues (1997) have suggested that lack of "rotation" of the pelvic ring primordium prevents structures attached to the pelvic ring from joining in the midline, allowing herniation of the bladder to occur. The cause of this inadequate rotation remains elusive. Stec and colleagues (2003) were able to demonstrate that the anatomic microstructure of the pelvic ring in exstrophy was similar to that in age-matched control subjects.

CLASSIC BLADDER EXSTROPHY

Anatomic Considerations

Exstrophy of the bladder is part of a spectrum of anomalies involving the urinary tract, the genital tract, the musculoskeletal system, and sometimes the intestinal tract. In classic bladder exstrophy, most anomalies are related to defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus. Because of the involved nature of this defect, the deficits are described here as they affect each system.

Skeletal Defects

Formerly, classic bladder exstrophy was thought only to show the characteristic widening of the pubic symphysis caused by malrotation of the innominate bones in relation to the sagittal plane of the body along both sacroiliac joints. In addition, there was an outward rotation or eversion of the pubic rami at their junction with the iliac bones. More recently, Sponseller and colleagues (1995), using computed tomography (CT) of the pelvis with three-dimensional (3D) reconstruction, have further characterized the bone defect associated with both classic bladder exstrophy and cloacal exstrophy. **In reviewing a large group of patients with exstrophy of the bladder, using pelvic CT scans and age-matched controls, Sponseller and colleagues (1995) found that patients with classic bladder exstrophy have a mean external rotation of the posterior aspect of the pelvis of 12 degrees on each side, retroversion of the acetabulum, and a mean 18 degrees of external rotation of the anterior pelvis, along with 30% shortening of the pubic rami, in addition to the previously described diastasis of the symphysis pubis** (Fig. 124–3). In long-term follow-up there was a foot progression angle of 20 to 30 degrees of external rotation beyond the normal limits seen in early childhood, but this rotation improved with age. Likewise, patients with cloacal exstrophy not only had pelvic deformities to a greater degree but also had asymmetry of the preceding parameters between the right and left sides of the pelvis, malformation of the sacroiliac joints, and occasional dislocations of the hip (Sponseller et al, 1995).

Data from Stec and colleagues (2001a) using 3D models from CT scans have provided further insight into the bone defect of children born with classic bladder exstrophy. Using age-matched controls, they found that the sacroiliac joint angle (before closure) was 10 degrees larger in the exstrophy pelvis, being 10 degrees more toward the coronal plane than the sagittal (Fig. 124–4). Also, the bony pelvis in exstrophy has 14.7 degrees more inferior rotation than in healthy patients. Lastly, the sacrum in exstrophy patients has a 42.6% larger volume and 23.5% more surface area than in controls. These new findings will help with planning better osteotomies and better reduction of both the pubic diastasis and pubic long-term undergrowth in these patients.

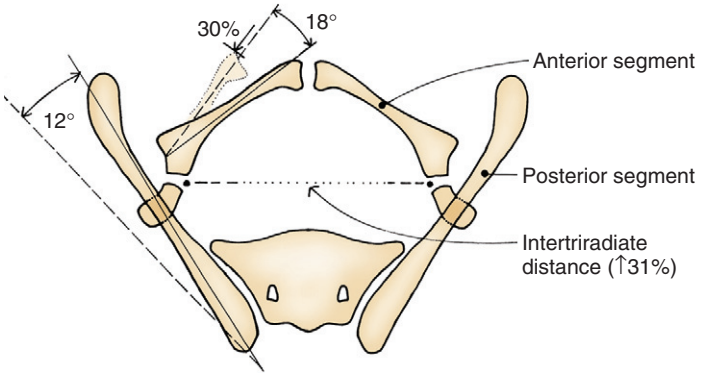

Figure 124–3. Pelvic bone abnormalities noted in classic bladder exstrophy. The posterior bone segment is externally rotated (12 degrees mean on each side), but the length is unchanged. The anterior segment is externally rotated (18 degrees mean on each side) and shortened by 30%. The distance between the triradiate cartilage is increased by 31%.

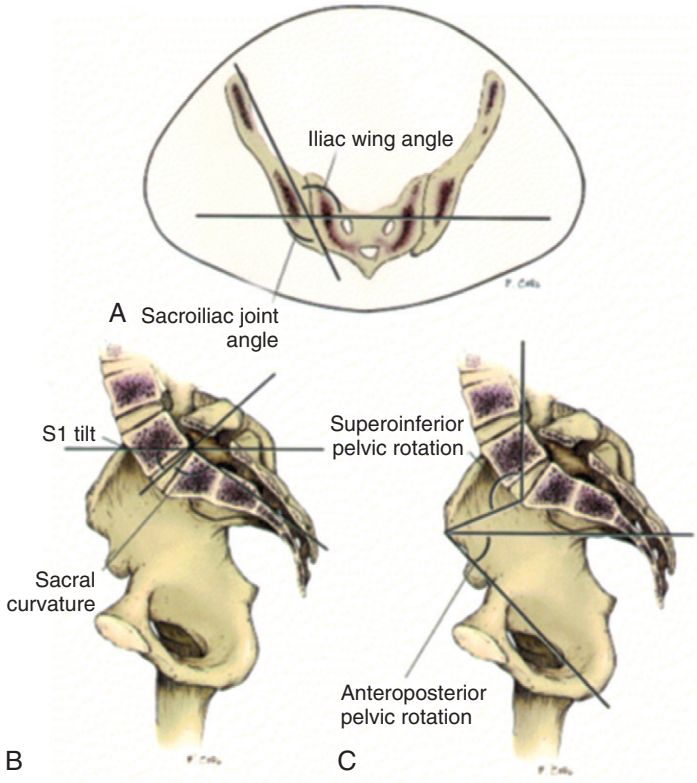

Figure 124–4. **A** to **C,** Sacroiliac joint angles before closure in children with classic exstrophy 10 degrees larger than normal controls. The bony pelvic has 14.7 degrees inferior rotation compared with normal controls. (From Stec AA, Pannu HK, Tadros YE, et al. Evaluation of the bony pelvis in classic bladder exstrophy using 3D CT—further insights. Urology 2001;58:1030.)

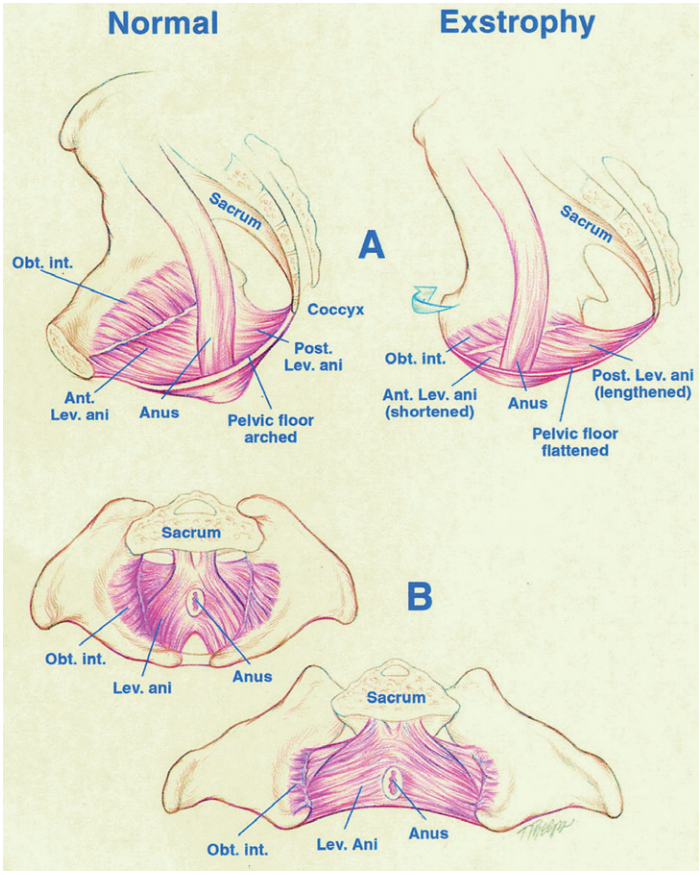

Figure 124–5. Pelvic floor changes in the patient with exstrophy; levator ani group is positioned more posteriorly (68% located posterior to the rectum) compared with normal controls.

These rotational deformities of the pelvic skeletal structures contribute to the short, pendular penis seen in bladder exstrophy. Outward rotation and lateral displacement of the innominate bones also account for the increased distance among the hips, waddling gait, and outward rotation of the lower limbs in these children, which in itself causes little disability and usually corrects to some degree over time. Data from Sponseller and colleagues (2001) show an increased incidence of premature osteoarthritis of the hip in adult patients who were closed without an osteotomy. Although these findings do not affect function, periodic radiologic evaluation of the pelvis and lumbosacrum should be performed in adult life. The 30% shortage of bone in exstrophy pelvis has largely gone unexplained. Data by Stec and colleagues (2003) using sections from the bony pelvis in fetal exstrophy and normal aborted fetuses found that the ultrastructure, bone development, microscopic growth patterns, and endochondrial ossification were absolutely the same. Thus restoration of the physiologic shape of the pelvis would likely lead to more normal gross bone growth, decreases in shortage of bone, and a more appropriate distribution of the mechanical and development forces on a more closed normally functioning pelvic ring.

Spinal abnormalities have frequently been noted in children with cloacal exstrophy, but incidence in bladder exstrophy has not been studied. A study of 299 children with bladder exstrophy indicated spinal variations without clinical significance (spina bifida occulta, lumbarization or sacralization of vertebrae) in 11%, uncomplicated scoliosis in 2.7%, and spinal dysraphism in 4% including myelomeningocele, lipomeningocele, scimitar sacrum, and hemivertebrae, but only one patient demonstrated any evidence of neurologic dysfunction (Cadeddu et al, 1997). Thus although present in classic bladder exstrophy, symptomatic spinal anomalies appear rare.

Pelvic Floor Defects

Stec and colleagues (2001b), using 3D models created from CT scans of children with classic bladder exstrophy and normal age-matched controls, found that the puborectal slings were supporting two times more body cavity area than normal. The levator ani group is positioned more posteriorly in exstrophy patients, with 68% located posterior to the rectum and 32% anterior (vs. 52% posterior and 48% anterior in healthy controls) (Fig. 124–5). The levators are also rotated outward 15.5 degrees, and in the coronal aspect the levators are 31.7 degrees more flattened than normal. This deviation from normal makes the exstrophy puborectal sling more flattened than its normal conical shape. There was no significant difference in the length or thickness of these muscles between patients with exstrophy and normal controls.

These new insights further elucidate the entire exstrophy defect, especially in regard to pelvic reconstruction. Interest in development of continence after primary closure in some patients has led to further investigation of the pelvic floor anatomy. Differences in orientation and anatomy of the pelvic floor musculature may directly affect development of continence following closure alone. The successful application of 3D magnetic resonance imaging (MRI) in anorectal anomalies has led to its use for the anatomic definition of the pelvic floor musculature in exstrophy. A

comparison of 3D MRI in children with exstrophy before closure and in normal controls indicated that the levator ani group was less dome shaped and more irregular in those with exstrophy (Williams et al, 2004). Also, there was no relationship between the amount of pubic diastasis and the extent of disproportionate curvature of the levator ani group. In addition, Halachmi and colleagues (2003) reported on the postoperative appearance of the pelvic floor with 3D MRI. In two patients who had some degree of continence, the intrasymphyseal distance was noted to be shortest, the angle of the levator ani divergence sharpest, and the bladder neck most deeply positioned in the pelvis. Gargollo and colleagues (2005), reporting on a series of patients who had MRI before and after exstrophy closure, noted that the puborectalis angle in those with dry intervals was decreased compared with that before closure. These two studies correlate well with earlier findings of Gearhart and colleagues (1993c) showing that in the adult patients who were dry, the puborectalis angle was less than 65 degrees. These data reinforce the necessity for aggressive dissection and posterior placement of the posterior urethra and bladder and the role for osteotomy and pelvic fixation.

Abdominal Wall Defects

The triangular defect caused by the premature rupture of the abnormal cloacal membrane is occupied by the exstrophy bladder and posterior urethra. The fascial defect is limited inferiorly by the intrasymphyseal band, which represents the divergent urogenital diaphragm. This band connects the bladder neck and posterior urethra to the pubic ramus on anatomic study. The anterior sheath of the rectus muscle has a fanlike extension behind the urethra and bladder neck that inserts into the intrasymphyseal band. Investigations into the relationship of the rectus muscle and fascia to the urogenital diaphragm (Wakim and Barbet, 2002) have found no gross or histologic evidence of the presence of the striated sphincter. However, clear evidence of bladder musculature extending laterally to the pubis was found where it interdigitates with fibers from the rectus fascia forming the fibrous urogenital diaphragm (Wakim and Barbet, 2002). Gearhart and colleagues (1991) have shown the importance of radical incision of these fibers lateral to the urethral plate down to the level of the inferior pubic ramus and levator hiatus for the bladder and posterior urethra to be placed in a deep pelvic position. Data from failed exstrophy closures show these fibers to be intact in many patients at the time of reclosure.

At the upper end of the triangular fascial defect is the umbilicus. In bladder exstrophy, the distance between the umbilicus and the anus is always foreshortened. Because the umbilicus is situated well below the horizontal line of the iliac crest, there is an unusual expanse of uninterrupted abdominal skin. Although an umbilical hernia is usually present, it is usually of insignificant size. The umbilical hernia is repaired at the time of the initial exstrophy closure. Omphaloceles, although rarely seen in conjunction with bladder exstrophy, are frequently associated with cloacal exstrophy. Omphaloceles associated with classic bladder exstrophy-epispadias complex are usually small and can be closed at the time of bladder closure.

The frequent occurrence of indirect inguinal hernias is attributed to a persistent processus vaginalis, large internal and external inguinal rings, and lack of obliquity of the inguinal canal. Connolly and colleagues (1995), **in a review of 181 children with bladder exstrophy, reported inguinal hernias in 81.8% of boys and 10.5% of girls.** At the time of closure of the bladder exstrophy, these hernias should be repaired by excision of the hernial sac and repair of the transversalis fascia and muscle defect to prevent recurrence or a direct inguinal hernia. The contralateral side should also be explored because the incidence of synchronous or asynchronous bilaterality is high.

Anorectal Defects

The perineum is short and broad, and the anus is situated directly behind the urogenital diaphragm; it is displaced anteriorly and corresponds to the posterior limit of the triangular fascial defect. The anal sphincter mechanism is also anteriorly displaced and should be preserved intact in case internal urinary diversion is required in future management.

The divergent levator ani and puborectalis muscles and the distorted anatomy of the external sphincter contribute to varying degrees of anal incontinence and rectal prolapse. Anal continence is usually imperfect at an early age. In rare patients, the rectal sphincter mechanism may never be adequate to control the liquid content of the bowel. Rectal prolapse frequently occurs in untreated exstrophy patients with a widely separated symphysis. It is usually transient and easily reduced. Prolapse virtually disappears after bladder closure or cystectomy and urinary diversion. The appearance of prolapse in an infant is an indication to proceed with definitive management of the exstrophied bladder. **If rectal prolapse occurs at any time after exstrophy closure, posterior urethral/bladder outlet obstruction should be suspected and immediate evaluation of the outlet tract by cystoscopy should be performed** (Baker and Gearhart, 1998).

Male Genital Defect

The male genital defect is severe and is probably the most troublesome aspect of the surgical reconstruction, independent of the decision whether to treat with modern staged closure, combined closure, or a form of urinary diversion (Fig. 124–6). Formerly, it was thought that the individual corpora cavernosa were of normal caliber but appeared shorter because of the wide separation of the crural attachments, the prominent dorsal chordee, and the shortened urethral groove. **However, Silver and colleagues** (1997b) **described the genital defect for the first time in bladder exstrophy in greater detail. MRI was used in adult men with bladder exstrophy and compared with results for age- and race-matched controls. They found that the anterior corporal length of male patients with bladder exstrophy was almost 50% shorter than that of normal controls** (Fig. 124–7). However, although the posterior length of the corporal body was the same as in age-matched controls, the diameter of the posterior corporal segment was greater than in normal controls. It was also found on MRI that the diastasis of the symphysis pubis increased the intrasymphyseal and intercorporal distances, but the angle between the corpora cavernosa was unchanged because the corporal bodies were separated in a parallel fashion. Therefore the penis appears short not only because of the diastasis of the pubic symphysis, as thought in the past, but also because of marked congenital deficiency of anterior corporal tissue (Silver et al, 1997b). In a recent surgical anatomic study by Perovic and Djinovic (2007), precise description of the penile defect included (1) corporal bodies separated and triangular in shape; (2) a long convex ventral surface and a short wedge-shaped dorsal surface; and (3) neurovascular bundle length determined by its lie on the individual corporal bodies.

A functional and cosmetically pleasing penis can be achieved when the dorsal chordee is released, the urethral groove lengthened, and the penis somewhat lengthened by mobilizing the crura in the midline.

Figure 124–6. Newborn male with classic bladder exstrophy. Note the dorsal chordee, short urethral plate, and flattening of the scrotum.

In a study by Gearhart and colleagues (1993c), 13 adult men born with bladder exstrophy were evaluated with MRI of the pelvis to evaluate the size and configuration of the prostate and sex accessory organs. The volume, weight, and maximum cross-sectional area of the prostate appeared normal compared with published control values (Fig. 124–8). However, in none of the patients did the prostate extend circumferentially around the urethra, and the urethra was anterior to the prostate in all patients. Except for studies to document the presence of the prostate gland or its size, data do not exist concerning the function of the prostate gland in the patient with exstrophy. Silver and colleagues (1997a) reported free and total prostate-specific antigen levels for a group of adult men with bladder exstrophy. Although they were measurable, they were below the upper limits of established age-specific reference ranges for normal men. The vas deferens and ejaculatory ducts are normal in the exstrophy patient, provided they are not injured iatrogenically. Also, the mean seminal vesicle length in men with exstrophy was normal compared with published controls. Additional evaluation of the puborectalis muscle group was undertaken, and these muscles were found to be widely separated and provided lateral support of the prostate with a narrower puborectalis angle in those who were continent and had undergone prior iliac osteotomy.

Autonomic innervation of the corpus cavernosum is provided by the cavernous nerves. These autonomic nerves are displaced laterally in patients with exstrophy (Schlegel and Gearhart, 1989). These nerves are preserved in almost all exstrophy patients because potency is preserved after surgery. However, retrograde ejaculation may occur after bladder closure and later bladder neck reconstruction.

Testis function has not been studied in a large group of postpubertal exstrophy patients, but it is generally believed that fertility is not impaired by testicular dysfunction. The testes frequently appear undescended in their course from the widened separated pubic tubercles to the flat, wide scrotum. Most testes are retractile and have an adequate length of spermatic cord to reach the scrotum without the need for orchiopexy.

Female Genital Defects

Reconstruction of the female genitalia presents a less complex problem than in the male (Fig. 124–9). **The vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly, the clitoris is bifid, and the labia, mons pubis, and clitoris are divergent. The uterus enters the vagina superiorly so that the cervix is in the anterior vaginal wall. The fallopian tubes and ovaries are normal.** The clitoral halves should be joined, and the two ends of the labia minora joined to make a fourchette at the time of primary closure. Vaginal dilatation or episiotomy may be required to allow satisfactory intercourse in the mature female. The defective pelvic floor may predispose mature females to the development of uterine prolapse, making uterine suspension necessary. This usually occurs after childbirth but can occur even in the nulliparous patient. When studied in a large adult female population, 10 of 56 women developed uterine prolapse at a mean age of 16 years. Six patients had been managed with reconstruction that included a posterior iliac osteotomy (Mathews et al, 2003). Mean age at the time of osteotomy was 2.1 years. The use of the modern combined anterior innominate and vertical iliac osteotomy early in life may lead to reduction in the incidence of later prolapse.

Urinary Defects

At birth, the bladder mucosa may appear normal; however, ectopic bowel mucosa, an isolated bowel loop, or more commonly a hamartomatous polyp may be present on the bladder surface. If the bladder mucosa is not frequently irrigated with saline and protected from surface trauma by the interposition of some form of protective membrane before closure, cystic or metaplastic changes in the mucosal surface of the bladder may occur.

Figure 124–9. Newborn girl with classic bladder exstrophy. Notice the open urethral plate, bifid clitoral halves, and anterior displacement of the vaginal orifice.

The size, distensibility, and neuromuscular function of the exstrophied bladder, as well as the size of the triangular fascial defect to which the bladder muscles attach, affect the decision to attempt repair. In the past several years, multiple basic science studies that further delineate the exact nature of the exstrophied bladder in the newborn have been published. **One of the first papers to characterize the neuromuscular function of the bladder was published by** Shapiro and colleagues (1985). **In their work, muscarinic cholinergic receptor density and binding affinity were measured in control subjects and in patients with classic bladder exstrophy. The density of the muscarinic cholinergic receptors in both the control and exstrophy groups was similar, as was the binding affinity of the muscarinic receptor.** Therefore it was thought by the authors that the neurophysiologic composition of the exstrophied bladder is not grossly altered during its anomalous development. Studies have investigated both the neural innervation of the newborn exstrophy bladder and its muscle and collagen content. Lee and colleagues (1996) looked at bladder biopsies obtained from 12 newborns with bladder exstrophy, compared with age-matched controls, and found an increase

in the ratio of collagen to smooth muscle in the newborns with bladder exstrophy. In addition, using anticollagen antibodies, they evaluated various types of collagen in these bladders. Compared with normal control bladders, there was no statistical difference in the amount of type I collagen in the bladders of newborns with exstrophy at initial closure, but there was a threefold increase in type III collagen. Peppas and colleagues (1999) studied patients who gained adequate bladder capacities and were awaiting bladder neck reconstruction and found that the ratio of collagen to smooth muscle decreased markedly after a successful closure and infection-free follow-up. Lais and colleagues (1996) reported similar findings, but they measured the ratio of smooth muscle to collagen and found it increased after a successful closure.

In an extension of the studies just cited, Mathews and colleagues (1999b) **looked at the number of myelinated nerves per field in the newborn bladders of normal subjects and those with exstrophy. The average number of myelinated nerves per field was reduced in the exstrophy bladders compared with controls, and the difference was statistically significant. This reduction in nerve fibers appears to be the result of a lack of small fibers with preservation of larger nerve fibers. In light of the findings already mentioned, it is believed that bladder exstrophy in a newborn probably represents an earlier stage in bladder development.**

In a large study by Rosch and colleagues (1997) **from Germany, multiple immunocytochemical and histochemical markers were examined in patients with epispadias or classic bladder exstrophy. These studies involved indirect immunocytochemistry for vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY), substance P (SP), calcitonin gene–related product (CGRP), protein gene product (PGP) 9.5, and nicotinamide adenine dinucleotide phosphate diaphorase (NADPHd). No evidence of bladder muscle dysinnervation was found morphologically in any cases of classic bladder exstrophy.** Cases of bladder exstrophy after failed reconstruction had muscle innervation deficiencies that increased subepithelial and intraepithelial innervation. Therefore although a newborn with bladder exstrophy may have a maturational delay in bladder development, these bladders have the potential for normal development after a successful initial closure.

When the bladder is small, fibrosed, inelastic, and covered with polyps, functional repair may be impossible (Fig. 124–10). Novak and colleagues (2005) investigated the pathology and malignant potential of the polyps found in these small bladders. Two types of polyps were observed, with some overlap in findings: fibrotic and edematous. Both were associated with overlying squamous metaplasia in approximately 50% of cases. Varying degrees of von Brunn nests, cystitis cystica, and cystitis glandularis were noted. Cystitis glandularis was noted in a higher percentage of secondary closures. Because of the potential risk of adenocarcinoma associated with cystitis glandularis, future surveillance of these patients with urine cytology and cystoscopy as they enter adulthood is recommended. The more normal bladder may be invaginated, or it may bulge through a small fascial defect, indicating the potential for satisfactory capacity after successful initial closure. **Also, not until examination under anesthesia can the true defect be adequately evaluated because bladders that appear small in the nursery may have a good bit of bladder sequestered below the fascial defect. The depth of this extension often cannot be appreciated unless the infant is totally relaxed under anesthesia.**

Figure 124–10. Small inelastic bladder template covered with polyps, unsuitable for primary closure.

Bladder function was assessed in a group of continent exstrophy patients with normal reflexive bladders. Normal cystometrograms were obtained in 70% to 90% of cases (Toguri et al, 1987). Diamond and colleagues (1999), looking at 30 patients with bladder exstrophy at various stages of reconstruction, found that 80% of patients had compliant and stable bladders before bladder neck reconstruction. After bladder neck reconstruction, approximately half of the patients maintained normal bladder compliance and a lesser number maintained normal stability. The authors believed that compliance and stability were impaired after bladder neck reconstruction and that 25% of patients with exstrophy may maintain normal detrusor function after reconstruction. In an earlier paper by Hollowell and colleagues (1993), 13 of 21 children revealed involuntary contractions and only 4 revealed stable bladders before bladder neck reconstruction. Also, 7 of 21 had increased pressures (>10 cm H_2O), suggesting decreased compliance. The difference in findings between these two urodynamic studies is difficult to explain from an experimental perspective. However, standardized methods of bladder neck repair do not exist, and these differences may be reflected in the different urodynamic findings after bladder neck repair in these two groups of patients.

Several interesting aspects of the microstructure of the bladder in children with bladder exstrophy were noted by Mathews and colleagues (2004) using specimens obtained from children with bladder exstrophy at various stages of reconstruction (newborn bladder closure, bladder neck reconstruction, augmentation cystoplasty). At the cellular level, important differences were noted. Caveoli, which are important intracellular structures involved in cell-cell signaling, were found to be normal in the patients with a successful closure and improvement in bladder capacity and significantly lacking in the patients who required eventual augmentation cystoplasty (Fig. 124–11). In addition, the ultrastructure of cells in the patients in whom closure failed was noted to be abnormal.

The urinary tract is usually normal, but anomalous development does occur. Horseshoe kidney, pelvic kidney, hypoplastic

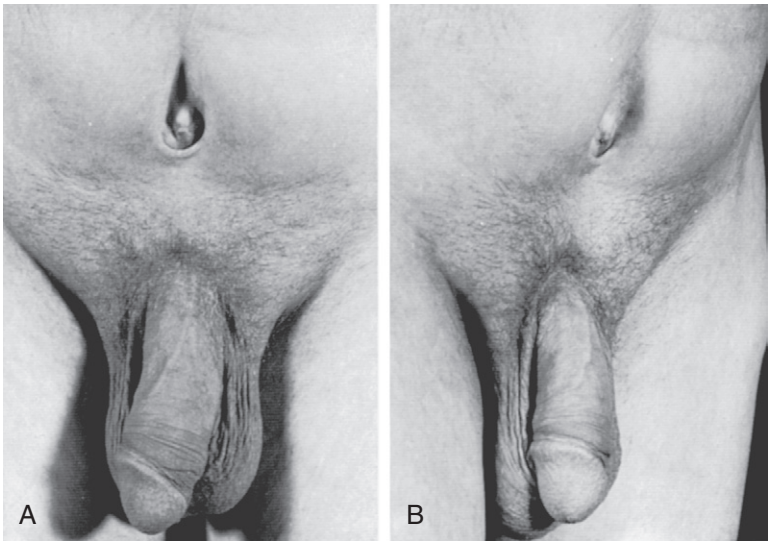

Figure 124–12. **A** and **B,** Pseudoexstrophy in an adult male patient. Musculoskeletal deformity characteristic of the exstrophy complex is present, but the urinary tract is intact.

kidney, solitary kidney, and dysplasia with megaureter are all encountered in these patients. The ureters have an abnormal course in their termination. The peritoneal pouch of Douglas between the bladder and the rectum is enlarged and unusually deep, forcing the ureter down laterally in its course across the true pelvis. The distal segment of the ureter approaches the bladder from a point inferior and lateral to the orifice, and it enters the bladder with little or no obliquity. **Therefore reflux in the closed exstrophy bladder occurs in 100% of cases, and subsequent surgery is usually required at the time of bladder neck reconstruction. If excessive outlet resistance is gained at the time of either initial closure or combined epispadias and bladder exstrophy closure and recurrent infections are a problem even with suppressive antibiotics, ureteral reimplantation or Deflux injection is required before bladder neck reconstruction.**

Exstrophy Complex and Variants

Exstrophy complex includes a spectrum of anomalies ranging from epispadias to cloacal exstrophy. Many variations in anatomy and types of defects have been noted. Because there is probably a common embryologic origin for all of these defects, they all share many or some of the defects noted in the three major components of the complex—skeletal, urinary, and genital. The presence of a characteristic musculoskeletal defect of the exstrophy anomaly with no major defect in the urinary tract has been named "pseudoexstrophy" (Marshall and Muecke, 1968). Predominant characteristics include an elongated, low-set umbilicus and divergent rectus muscles that attach to the separated pubic bones (Fig. 124–12). In this variant, the mesodermal migration has been interrupted in its superior aspect only, thus wedging apart the musculoskeletal elements of the lower abdominal wall without obstructing the formation of the genital tubercle.

In the superior vesical fissure variant of the exstrophy complex, the musculature and skeletal defects are exactly the same as those in classic exstrophy; however, the persistent cloacal membrane ruptures only at the uppermost portion, and a superior vesical fistula that actually resembles a vesicostomy results. Bladder extrusion

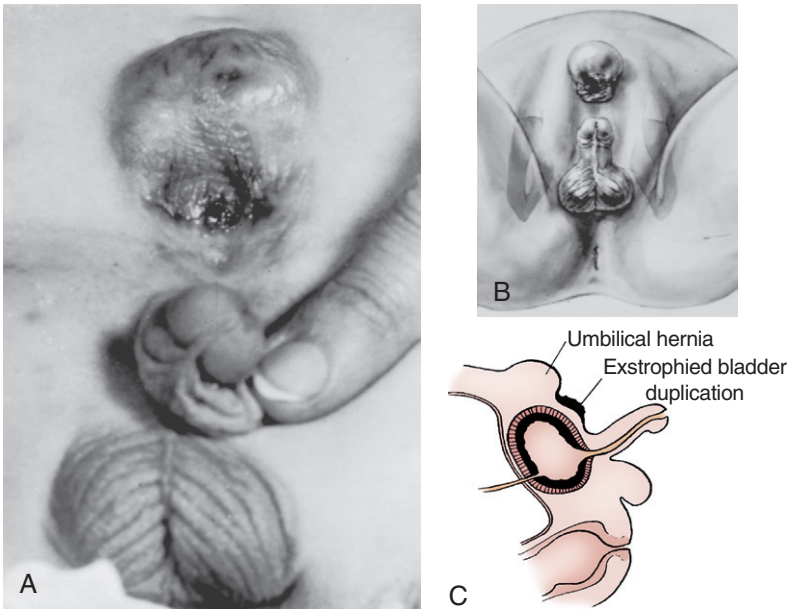

Figure 124–13. **A** to **C,** Duplicate exstrophy in a boy with an intact lower urinary tract.

is minimal and is present only over the normal umbilicus (see Fig. 124–1B).

In a large review of an exstrophy database of more than 815 patients, Lowentritt and colleagues (2005) reported 25 exstrophy complex variants, 6 of which were cloacal exstrophy variants. Continence rates after bladder neck repair were compatible with classic exstrophy (Fig. 124–13). Three cases were reported by Arap and Giron (1986) in which the patients had classic musculoskeletal defects, and two of the three were continent. Of the two male patients, one had an associated complete epispadias and the other had a completely normal penis. Therefore the external genital manifestations in duplicate exstrophy can be quite variable.

In addition to pseudoexstrophy, superior vesical fissure, and duplicated exstrophy, isolated occurrences of a fourth entity, "covered exstrophy," have been reported (Cerniglia et al, 1989). This has also been referred to as *split symphysis variant*. A common factor in these patients is the presence of musculoskeletal defect associated with classic exstrophy but no significant defect of the urinary tract. Chandra and colleagues (1999) reported a covered exstrophy with incomplete duplication of the bladder. However, in most cases of covered exstrophy (Narasimharao et al, 1985; Cerniglia et al, 1989), there has been an isolated ectopic bowel segment present on the inferior abdominal wall near the genital area, which can be either colon or ileum with no connection with the underlying gastrointestinal tract and only epispadias in the male. A patient seen at our institution had the standard appearance of most split symphysis variants, and one could actually see the bladder through a thin membrane of lower abdominal skin. Although all of the classic musculoskeletal defects of exstrophy were present, there was no isolated ectopic bowel segment present on the lower abdominal wall (Fig. 124–14). These patients should all undergo formal exstrophy closure at birth.

There are two different forms of duplication, anteroposterior duplication and side-by-side duplication. The first form is considered a duplicate exstrophy with a patch of everted bladder mucosa on the anterior abdominal wall with a second bladder lying in the pelvis. The ureters attach to the closed bladder, rendering the

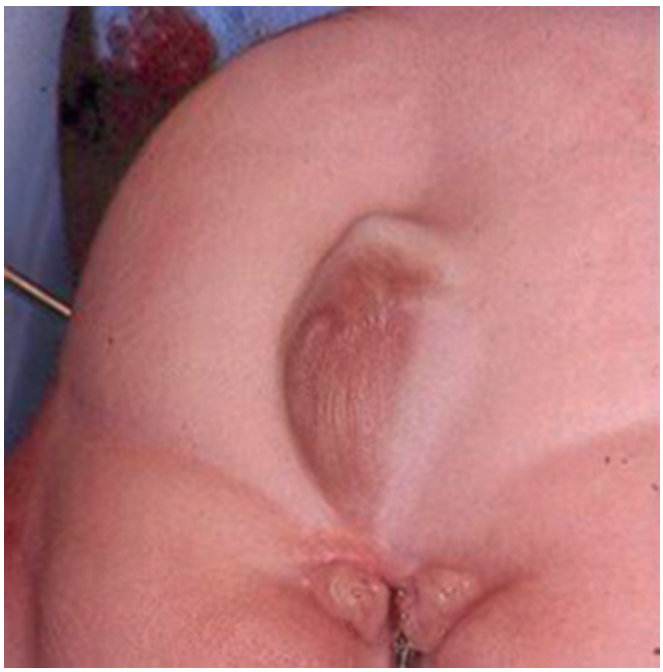

Figure 124–14. Skin-covered exstrophy in a female patient. Note urethral sound in the bladder and the subcutaneous position below the skin of the abdominal wall. No bowel is sequestered on the abdominal wall, as has been reported in some patients with this variant.

superficial mucosa dry (see Fig. 124–13). The mainstay of treatment has been resection of the ectopic mucosa and closure of the abdominal wall defect. The other form of duplication involves patients who have two separately formed bladder halves in a left-right orientation with a midline septum between the bladders containing muscle. Each bladder has its own ureter and an intact sphincter. Oftentimes there is diastasis of the pubis and rectus muscle.

Cloacal Exstrophy Variants—Covered Cloacal Exstrophy and Duplicate Bladder. Cloacal exstrophy usually includes an open and

everted intestinal segment situated between two hemibladders, an omphalocele and a blind ending tailgut with an imperforate anus. The pubic symphysis and the rectus muscles are widely separated. The phallus is bifid, and the scrotum or labia are split and laterally displaced. In girls the vagina is bifid with two uteri. Given that cloacal exstrophy encompasses abnormalities of the genitourinary, gastrointestinal, and musculoskeletal systems, and often the neurologic system, it is not surprising that a wide range of variants from the classic presentation have been reported. The treatment of cloacal exstrophy has evolved from palliation of an almost universally fatal disorder into complex genitourinary and gastrointestinal reconstruction and a near-normal life span.

Of six cases reported by Lowentritt and colleagues (2005) with cloacal variants, five were covered by skin and one involved duplication of the bowel and hemibladders. Cases of cloacal exstrophy are challenging in their surgical management, and the variations of the complex add to the difficulties of initial diagnosis and management. Only by using a combination of genitograms, retrograde ureterograms, and bowel continence studies was it possible to understand the complex anatomy of the patients in these groups. Interestingly, three patients had no spinal abnormalities and one had spina bifida occulta. Three patients in this group had innervation of the pelvic floor, enabling successful Pena procedures in two, with the third patient awaiting the procedure.

The epispadias-bladder/cloacal exstrophy complex has a wide range of presentations. Variants are rare, but it is important to recognize the different appearances at birth because the initial treatment will greatly influence the long-term outcome. Two patient groups had better outcomes than those with classic presentations—superior vesical fissure and skin-covered cloacal exstrophy. Because the sphincter is intact, patients with superior vesical fissure went through regular toilet training and became continent without the need for a later bladder neck procedure. Many reports of exstrophy variants include these patients, leading to the wrong belief that all patients with variants perform better than those with bladder exstrophy. Lowentritt (2005) suggests that other than superior vesical fissure, all variants should be managed with formal exstrophy closure at birth and followed in the same manner as their classic presentations. Duplicated organs can be useful in later reconstruction. Cloacal variants have a lower incidence of spinal abnormalities and a higher rate of fecal continence compared with their classic presentations. Overall, these patients had a low incidence of severe comorbid conditions. Therefore appropriate treatment of these genitourinary malformations can significantly impact and improve the quality of life.

Prenatal Diagnosis

Currently, the prenatal diagnosis of bladder exstrophy is difficult to delineate. Often, a diagnosis of omphalocele or gastroschisis is made and the exstrophy condition is overlooked. Ultrasound evaluation of the fetus, by means of high-resolution real-time units, allows a thorough survey of the fetal anatomy, even during routine obstetric ultrasound examinations (Gearhart et al, 1995a). Several groups have outlined important criteria for the diagnosis of classic bladder exstrophy prenatally. In these reviews, the absence of a normal fluid-filled bladder on repeated examinations suggested the diagnosis, as did a mass of echogenic tissue on the lower abdominal wall (Mirk et al, 1986; Verco et al, 1986). **In a review of 25 prenatal ultrasound examinations with the subsequent birth of a newborn with classic bladder exstrophy** (Gearhart et al, 1995a), several observations were made: (1) absence of bladder filling, (2) a low-set umbilicus, (3) widening pubis ramus, (4) diminutive genitalia, and (5) a lower abdominal mass that increases in size as the pregnancy progresses and as the intra-abdominal viscera increases in size (Fig. 124–15).

The application of 3D ultrasonography and fetal MRI has improved the antenatal diagnosis of bladder and cloacal exstrophy. In the authors' practice, fetal MRI is reserved for patients in whom 3D ultrasound is not sufficient to differentiate satisfactorily between classic and cloacal exstrophy or when other severe anomalies are suspected. The main reason for the prenatal diagnosis of bladder exstrophy is so that the parents can be counseled regarding the risks and benefits and other aspects of the condition. After appropriate counseling, arrangements can be made for delivery of the baby in a specialized exstrophy center where immediate reconstruction of the exstrophy can occur. Presentations from various centers have shown that the sooner the bladder is closed, the more likely it is that the bladder will grow and will not require augmentation. Delivery in a specialized exstrophy center allows the parents to be exposed to the expertise of multiple disciplines including the all-important psychologic support these young parents need when a child with a birth defect of this magnitude is delivered.

SURGICAL RECONSTRUCTION OF BLADDER EXSTROPHY

Sweetser and colleagues (1952) initially described a staged surgical approach for bladder exstrophy. Four to 6 days before bladder closure, bilateral iliac osteotomies were performed. Epispadias repair was performed as a separate procedure. The continence procedure was limited to freeing the fibers from the intrasymphyseal band and wrapping this band around the urethra at the time of closure to increase outlet resistance.

The initial staged approach to functional bladder closure included three separate stages: bladder, abdominal wall, and posterior urethral closure; bladder neck reconstruction and antireflux procedure; and later epispadias repair. This approach was recommended for most cases of exstrophy reconstruction beginning in the early 1970s (Cendron, 1971; Jeffs et al, 1972; Williams and Keaton, 1973; Gearhart and Jeffs, 1989b). **Although this procedure was successful, it has been significantly modified to include bladder, abdominal wall closure, and posterior urethral closure well onto the penis in the newborn period with bilateral innominate and vertical iliac osteotomy, if indicated; epispadias repair at 6 months to 1 year of age; and bladder neck reconstruction along with antireflux procedure at age 4 to 5 years, when the child has achieved an adequate bladder capacity for bladder neck reconstruction and is motivated to participate in a postoperative voiding program** (Gearhart and Jeffs, 1998).

Other methods of treatment of the newborn with bladder exstrophy have been offered. Grady and Mitchell (1999) proposed combining bladder exstrophy closure with epispadias repair in the newborn period. Baka-Jakubiak (2000) recommended newborn exstrophy closure alone and combined bladder neck reconstruction and epispadias repair when the child reaches a satisfactory age for participation in a voiding program. Kelly (1995) and colleagues have recommended a staged repair in which no osteotomy is used and supplanted by a second-stage "radical soft tissue mobilization" before later urethral repair. Schrott and colleagues (1984) recommended bladder closure, ureteral reimplantation, epispadias repair, and bladder neck reconstruction in the newborn period. Lastly, Stein and colleagues (1999) recommended ureterosigmoidostomy in the newborn period with abdominal wall and bladder closure. This chapter offers a comprehensive look at all of these repairs, their outcomes, and most importantly overall complications and those specific to the different types of repairs.

Evaluation and Management at Birth

At birth, although the bladder mucosa is usually smooth, pink, and intact, it is also sensitive and easily denuded. In the delivery room the umbilical cord should be tied with 2-0 silk close to the abdominal wall so that the umbilical clamp does not traumatize the delicate mucosa and cause excoriation of the bladder surface. The bladder can then be covered with a nonadherent film of plastic wrap (e.g., Saran Wrap) (Fig. 124–16) to prevent sticking of the bladder mucosa to clothing or diapers. In addition, each time the diaper is changed the plastic wrap should be removed, the bladder surface irrigated with sterile saline, and clean plastic wrap placed over the bladder surface area.

The distraught parents need reassurance at this stage. Counseling of the parents and decisions regarding eventual therapy should begin prenatally if the condition is diagnosed by prenatal ultrasonography. The parents should be educated by a surgeon with a special interest and experience in managing cases of bladder or cloacal exstrophy. An exstrophy support team should be available and should include a pediatric orthopedic surgeon, pediatric anesthesiologist, social workers, nurses with special interest in bladder exstrophy, and a child psychiatrist with expertise and experience in genital anomalies. The Association of Bladder Exstrophy Children, based in La Salle, MI, has a website for parents and family members to obtain further information about this condition. In addition, should the parents desire, websites are available in some major exstrophy centers for further information.

Figure 124–16. Use of plastic wrap to keep bladder plate moist before closure.

Although it is true that parents need to be educated as fully as possible about the exstrophy condition, this is especially true regarding the sex of rearing males with bladder exstrophy. We have seen several families who were made even more distraught by being told that their child had ambiguous genitalia in addition to bladder exstrophy and that the child would need a change of gender. The need for changing the sex of rearing in classic bladder exstrophy is almost nonexistent in the male infant.

Cardiopulmonary and general physical assessment measures can be carried out in the first few hours of life. Radionuclide scans and ultrasound studies can provide evidence of renal structure, function, and drainage, even in the first few hours of life before the patient undergoes closure of the exstrophy defect.

Circumstances may be less than ideal at birth. A thorough neonatal assessment may have to be deferred until transportation to a major children's medical center can be arranged. In these days of modern transportation, no child is ever more than a few hours away from a neonatal center with full diagnostic and consultative services. During travel the bladder should be protected by a plastic membrane, as in the nursery, to prevent damage to the delicate newborn bladder mucosa.

Selection of Patients for Immediate Closure

Successful treatment of exstrophy with functional closure demands that the potential for success in each child be carefully considered at birth. The size and functional capacity of the detrusor muscle are important considerations for the eventual success of functional closure. Correlation between apparent bladder size and the potential bladder capacity must not be confused. In minor grades of exstrophy that approach the condition of complete epispadias with incontinence, the bladder may be small yet may demonstrate

acceptable capacity, either by bulging when the baby cries or by indenting easily when touched by a sterile gloved finger in the operating room with the child under anesthesia. **Sometimes a good bit of previously unappreciated bladder can be discovered behind the fascia under examination with anesthesia** (Gearhart and Jeffs, 1998). Once the bladder is relieved of surface irritation and repeated trauma, the small bladder can enlarge and increase in capacity with the absence of sphincter activity and with minimal outlet resistance. The exstrophied bladder that is estimated at the time of birth to have a capacity of 5 mL or more and demonstrates elasticity and contractility can be expected to develop useful size and capacity after successful bladder, posterior urethral, and abdominal wall closure with early epispadias repair (Gearhart and Jeffs, 1998).

Small Exstrophy Bladder Unsuitable for Newborn Closure

A small, fibrotic bladder patch that is stretched between the edges of the small triangular fascial defect without elasticity or contractility cannot be selected for the usual closure procedure (Gearhart and Jeffs, 1998) (see Fig. 124–10). **Examination with the patient under anesthesia may at times be required to assess the bladder adequately, particularly if considerable edema, excoriation, and polyp formation have developed between birth and the time of assessment. Decisions regarding the suitability of bladder closure or the need for waiting should be made only by surgeons with a great deal of experience in the exstrophy condition** (Gearhart and Jeffs, 1998). Neonatal closure, even when the bladder is small, can allow assessment of bladder potential, provides an initial step in genital reconstruction, and is helpful in reassuring the family. Some conditions preclude primary closure, including penoscrotal duplication, ectopic bowel within the extruded bladder (a relative contraindication), a hypoplastic bladder, and significant bilateral hydronephrosis.

In a recent review by Lakshmanan and colleagues (2008) of cases at our institution, it was found on initial judgment that the bladder was too small for closure in 34 patients evaluated at birth. There were 27 males and 6 females who underwent delayed closure at a mean age of 13.2 months. Osteotomy was performed on 29 (85%). All had a successful delayed primary closure. Eleven (41%) of the boys had a simultaneous epispadias repair. Sixty one percent developed sufficient capacity for bladder neck reconstruction and 39% are continent. Compared with newer data by Novak and colleagues (2010), these rates are over double the continence rates seen in bladder neck repair after failed primary closure and successful secondary closure.

Thus waiting for the bladder template to grow for 6 to 12 months in the child with a small bladder is not as risky as submitting a small bladder template to closure in an inappropriate setting, resulting in dehiscence and allowing the fate of the bladder to be sealed at that point. If the bladder does not grow to sufficient size after 6 to 12 months, other options include excision of the bladder and a nonrefluxing colon conduit or ureterosigmoidostomy. Another alternative involves urinary diversion with a colon conduit and placing the small bladder inside to be used later for the posterior urethra in an Arap-type procedure. Lastly, if the bladder is small and the presentation is for late primary closure, bladder augmentation, ureteral reimplantation, and an outlet procedure, in addition to a continent urinary stoma, can be considered.

Osteotomy

Children born with bladder exstrophy have an exposed bladder and a wide diastasis of the pubic rami, resulting in an open pelvic ring. The musculoskeletal function appears to be normal throughout childhood; the gait is characterized by external foot progression, which lessens with growth, even if osteotomy is not performed.

Several types of pelvic osteotomies have been developed to help close the pelvic ring, decrease the stress on the abdominal wall during initial exstrophy closure, and improve the outcome of future genitourinary reconstruction. Shultz was the first researcher known to the authors to describe bilateral posterior iliac osteotomy as part of a two-stage repair of bladder exstrophy. This early osteotomy was shown to lower rates of wound dehiscence and help obtain a more secure and better genitourinary reconstruction than was formerly obtained with reconstruction without osteotomy. The success in achieving continence has been reported to be related to the reduction in the diastasis and has been thought to result from better approximation of the muscles of the pelvic floor around the urethra.

Patients may undergo pelvic osteotomy at any stage of exstrophy repair if the diastasis prevents attainment of these urologic goals. In general, the authors rarely perform osteotomy on newborns unless the diastasis is over 4 cm because the laxity of the sacroiliac ligaments allows closure of the defect without undue tension.

Types of osteotomies that have been used include bilateral osteotomy of the superior pubic ramus, diagonal osteotomy of the iliac wing, and anterior innominate osteotomy with or without posterior iliac osteotomy. The combined anterior innominate and vertical osteotomy was developed for several reasons. The osteotomy is performed with the patient in the supine position as is the urologic repair, thus avoiding the need to turn the patient. The anterior osteotomy also allows placement of an external fixator under direct vision. A greenstick-type closing-wedge osteotomy of the ilium is also performed adjacent to the sacrum in most patients, creating two large bony fragments that are easily movable.

Following failure of initial closure and in children with significant pubic diastasis, as seen in cloacal exstrophy, osteotomy is also required. Pubic approximation may not be possible in a single step at the time of abdominal closure when the diastasis is extensive. The use of staged closure of the pelvis following osteotomy has been used successfully in this circumstance. This technique has been used with great success for the treatment of children presenting with extreme diastasis, even in younger patients.

Pelvic osteotomy performed at the time of initial closure confers several advantages including (1) easy approximation of the symphysis with diminished tension on the abdominal wall closure and elimination of the need for fascial flaps; (2) placement of the posterior vesicourethral unit deep within the pelvic ring, enhancing bladder outlet resistance; and (3) bringing the large pelvic floor muscles near the midline, where they can support the bladder neck and aid in eventual urinary control (Fig. 124–17). After pubic approximation with osteotomy, some patients show the ability to stop and start the urinary stream, experience dry intervals, and in some cases become completely continent (Gearhart and Jeffs, 1991a). In a review of a large number of patients referred to our institution after failed exstrophy procedures, it was found that a majority of the patients who had partial or complete dehiscence of the bladder or major bladder prolapse had not undergone a prior osteotomy at the time of

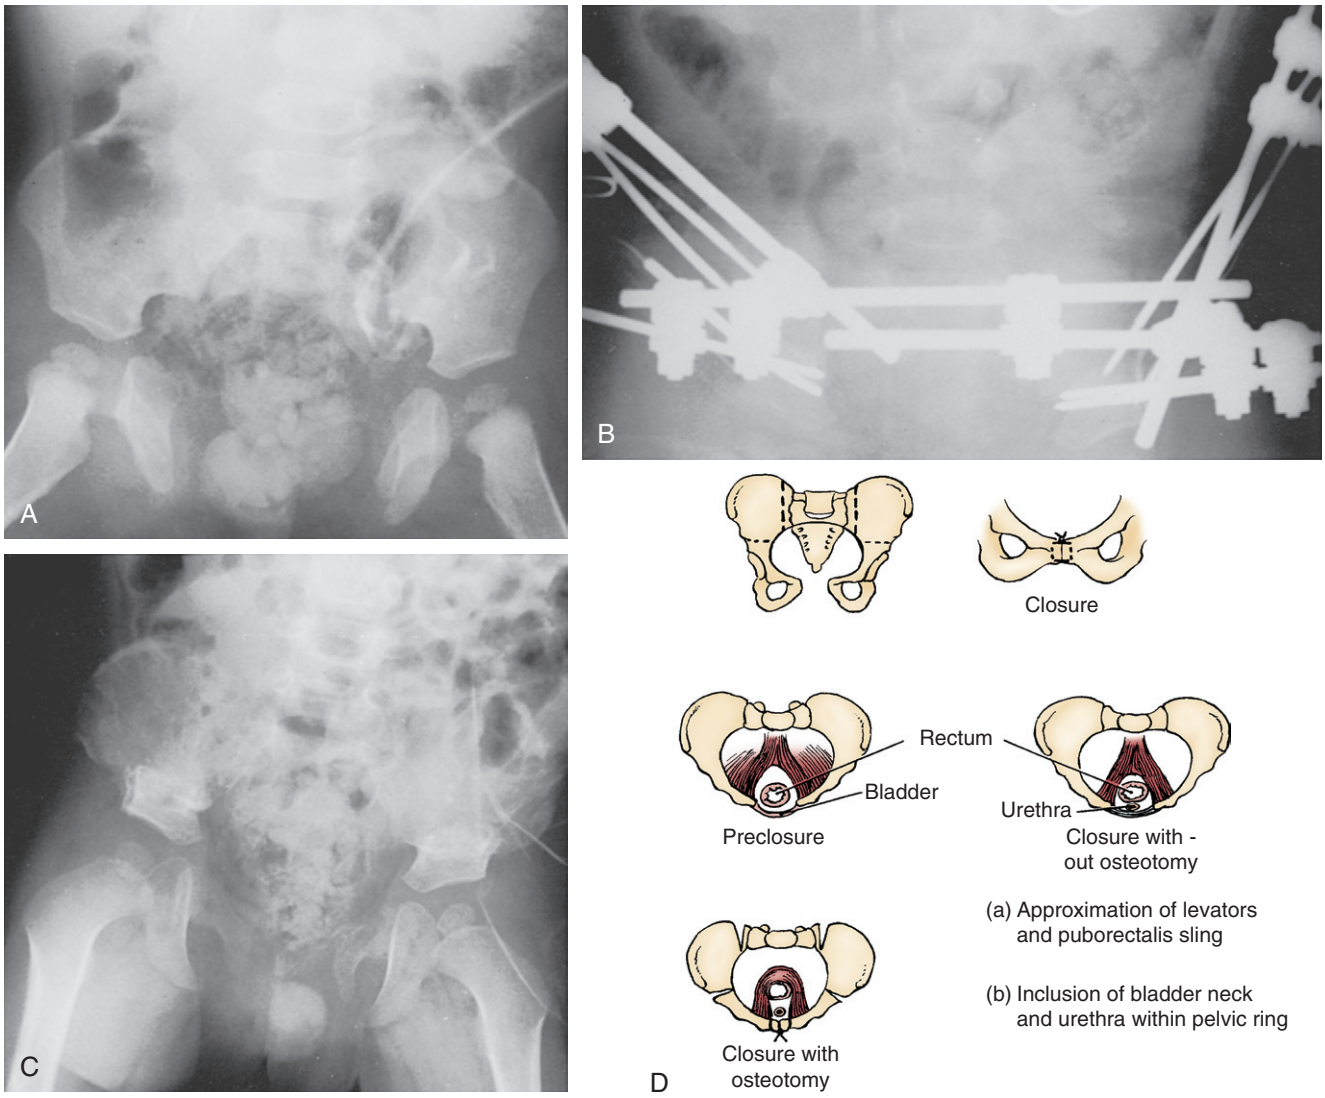

Figure 124–17. **A,** Eight-month-old patient with classic bladder exstrophy closed at birth without osteotomy with complete dehiscence. Patient was initially seen at 8 months of age. **B,** Patient after having undergone anterior innominate and vertical iliac osteotomy and placement of intrafragmentary pins and external fixator. **C,** The same patient 4 months after removal of external fixator and pins. Successful closure was achieved. **D,** The technique of combined osteotomy showing incision sites.

initial bladder closure (Gearhart et al, 1993b). The authors recommend performing bilateral transverse innominate and vertical iliac osteotomy when bladder closure is performed after 72 hours of age (Fig. 124–18). In addition, if the pelvis is not malleable or if the pubic bones are more than 4 cm apart at the time of initial examination under anesthesia, osteotomy should be performed, even if closure is done before 72 hours of age. A well-coordinated surgery and anesthesia team can perform osteotomy and proceed to bladder closure without undue loss of blood or risk of prolonged anesthesia in the child. However, it must be realized that osteotomy together with posterior urethral and bladder closure and abdominal wall closure is a 5- to 7-hour procedure in these infants.

If the patient is younger than 72 hours old and examination under anesthesia reveals that the pubic bones are malleable and able to be brought together easily in the midline by medial rotation of the greater trochanters, the patient can undergo closure without osteotomy. However, no chances should be taken with a decision of this magnitude. If there is any doubt, an osteotomy should be performed.

The most frequently used osteotomy today is the bilateral anterior innominate and vertical iliac osteotomy, popularized by Gearhart, Sponseller, and colleagues in 1996 (Gearhart et al, 1996b). This approach improves the ease of symphyseal approximation in the patient with exstrophy compared with posterior approaches, which require turning the patient. In our experience, this osteotomy is superior to the pubic mobilization seen with simple bilateral transverse anterior innominate osteotomy or even pubic ramotomy. With the ease of approximation obtained with this combined osteotomy, tension on the midline abdominal closure is lessened and the rates of bladder dehiscence and bladder prolapse are markedly decreased (Gearhart and Jeffs, 1998). In addition, pelvic closure allows approximation of the levator ani to strengthen the puborectalis sling, with positioning of the bladder neck and posterior urethra deep within the pelvic ring and improved continence rates. **Besides the ease of approximation, combined osteotomy was developed for three reasons: (1) Osteotomy is performed with the patient in the supine position, as is the urologic repair, thereby avoiding the need to turn the patient; (2) the anterior**

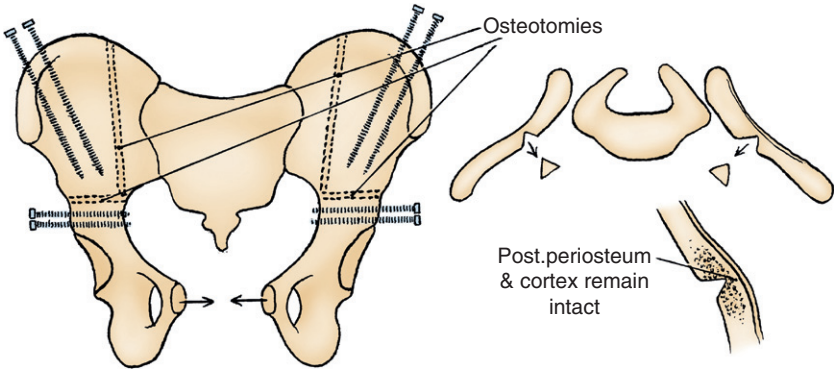

Figure 124–18. Depiction of the new combined transverse innominate and vertical iliac osteotomy indicated intrafragmentary pin placement sites and bone approximation.

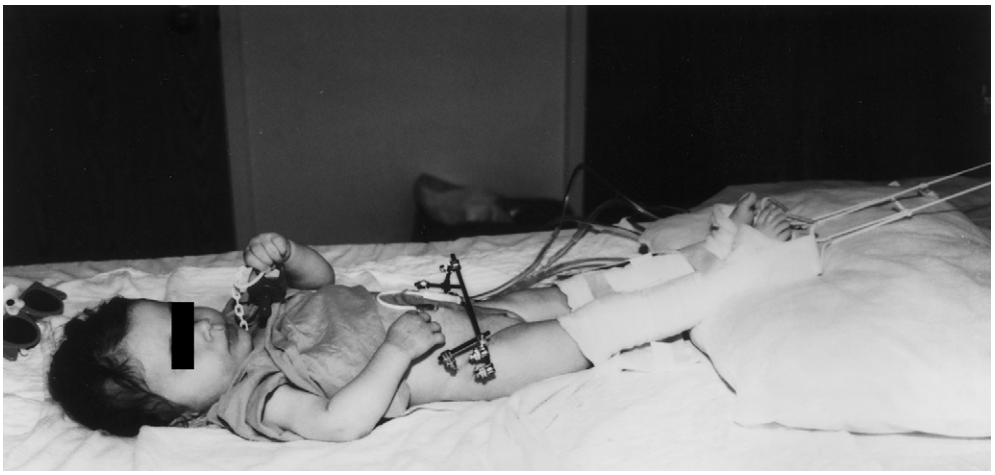

Figure 124–19. Fifteen-month-old patient following reclosure of bladder exstrophy with external fixator in place and modified Buck traction.

approach to this osteotomy allows placement of an external fixator device and intrafragmentary pins under direct vision; and (3) the cosmetic appearance of this osteotomy is superior to that of the posterior iliac approach (Gearhart et al, 1996b).

In the posterior approach there was occasional malunion of the ileum, the blood loss was greater in the posterior approach, and the need to turn the patient intraoperatively from the prone to the supine position was always worrisome. The results of the combined horizontal transverse innominate osteotomy and vertical iliac osteotomy are so satisfactory that the approach is now being used in all primary closures of bladder exstrophy that require pelvic osteotomy (Gearhart et al, 1996b).

Combined osteotomy is performed by placing the patient in the supine position, preparing and draping the lower body below the costal margins, and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the iliac wings inferiorly to the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated, and a Gigli saw is used to create a transverse innominate osteotomy exiting anteriorly at a point halfway between the anterior-superior and anterior-inferior spines (see Fig. 124–18). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy in order to allow placement of external fixator pins in the distal segments. In addition to the transverse osteotomy, the posterior ileum may be incised from the anterior approach in an effort to correct the deformity more completely. This is important because anatomic studies have shown that the posterior portion of the pelvis is also externally rotated in patients with exstrophy, and as patients age they lose elasticity of the sacroiliac ligaments. For this part of the osteotomy, an osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joints. The proximal posterior iliac cortex is left intact and used as a hinge (see Fig. 124–18). This combination osteotomy easily corrects the abnormalities in both the anterior and posterior segments of the pelvis.

Two fixator pins are placed in the inferior osteotomized segment, and two are placed in the wing of the ileum superiorly. Radiographs are obtained to confirm pin placement, soft tissues are closed, and the urologic procedure is performed (see Fig. 124–17). At the end of the procedure, the pelvis is closed with a suture between the two pubic rami. The external fixators are then applied between the pins to hold the pelvis in a correct position. In a newborn with less than optimal amounts of cancellous bone, only one pin is placed inferiorly and superiorly in the wing of the ileum, whereas older children have two pins in each bone wing.

Radiographs are taken 7 to 10 days after surgery to look for complete reduction of the symphyseal diastasis. If this diastasis has not been completely reduced, the right and left sides can be gradually approximated by means of the fixator bars over several days. Longitudinal skin traction is used to keep the legs still (Fig. 124–19). The patient remains supine in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for 4 to 6 weeks, until adequate callus is seen at the site of the osteotomy (see Fig. 124–15B and C). Postoperatively, in newborns who undergo

Figure 124–20. Newborn closure without osteotomy with patient in modified Bryant traction.

closure without osteotomy in the first 48 to 72 hours of life, the baby is immobilized in modified Bryant traction in a position in which the hips have 90 degrees of flexion. When modified Bryant traction is used, the traction is employed for 4 weeks (Fig. 124–20). A horizontal mattress suture of No. 2 nylon is placed between the fibrous cartilage of the pubic rami and tied anteriorly to the pubic closure at the time of bladder closure. **Evidence obtained by** Sussman and colleagues (1997) **from biomechanical testing in an intact piglet pelvic model revealed that all methods of pubic approximation were weak compared with the intact symphysis. However, the best technique with the strongest load-to-failure ratio was a No. 2 nylon horizontal mattress suture.** Should this suture work loose or cut through the tissues during healing, the anterior placement of a knot in the horizontal mattress suture ensures that it will not erode into the urethra and interfere with the bladder or urethral lumen.

Complications of Osteotomy and Immobilization Techniques

Complications of immobilization can include failure of the closure and skin breakdown with resultant ulceration. Meldrum and colleagues (2003) reviewed a series of 86 patients in whom initial exstrophy closure failed. Most had been immobilized with a "mummy wrap" or spica cast. Successful closure was noted in 97% of those immobilized with an external fixator and modified Buck traction. In addition, in those failing initial closure, six had severe skin ulcerations from the mummy wrapping or spica cast and two of these children required later skin grafting.

Sponseller and colleagues (2001) reported on a total of 86 combined bilateral anterior innominate and vertical iliac osteotomies performed in 88 children. Ten of these children had cloacal exstrophy, and 72 had bladder exstrophy with at least 2 years of clinical follow-up (mean 4.8 years). Complications included seven cases of transient left femoral nerve palsy, which resolved fully by 12 weeks after surgery. There were no cases of right femoral nerve palsy, although the same surgeon performed the same technique on both sides. Patients with transient femoral nerve palsy were on bed rest for the first 6 to 8 weeks; use of a knee immobilizer was necessary for the remaining 6 weeks until resolution. Other complications included three cases with delayed ileal union, one case of superficial infection of the ileal femoral incision that required irrigation and débridement, one case of transient right thigh abductor weakness, one infection of the ileum around a pin site requiring irrigation and débridement, and one case of transient right peroneal palsy. Almost all patients had skin inflammation around the pins, particularly those in the proximal (iliac crest) segments. This was always controlled with the use of oral antibiotics. In a recent paper by Satsuma and colleagues (2006), comparisons were made between patients who underwent posterior iliac or the combined osteotomy. Pubic approximation was better, and the mean recurrence far less in the combined transverse innominate and posterior iliac osteotomy. Thus the combined approach corrected and maintained the pelvic ring with fewer complications than a post-pelvic osteotomy.

Whichever type of osteotomy is used, pelvic ring closure not only allows midline approximation of the abdominal wall structures but also allows the levator ani and puborectalis muscles to lend potential support to the bladder outlet, thus increasing resistance to urinary outflow (see Fig. 124–17D) (Sponseller et al, 1991; Gearhart et al, 1993b, 1996b; Schmidt et al, 1993; McKenna et al, 1994). Furthermore, a continence procedure can be performed later on the bladder neck and urethra deep within the closed pelvic ring at a distance from the surface without independent movement of the two halves of the pubis. The urethra and bladder neck are set more deeply in the true pelvis, in a more normal relationship than when acutely angulated.

When good callus formation is seen on radiography, the fixating device and pins are removed with the patient under light sedation. The age of the patient plays a role in the amount of correction of the diastasis that is maintained over time. On review of the previously described types of osteotomy, both classic and cloacal exstrophy patients gained approximation, although the former group gained greater correction toward normal (Gearhart et al, 1996b). Greater postoperative diastasis, as well as less optimal bone density in the newborn, contributes to the greater difficulty in obtaining and maintaining closure of the pelvic bone deformity over time.

The authors' impression is that partial recurrence of diastasis in classic exstrophy occurs by two mechanisms. First, the pelvis may partially derotate owing to early loosening of pins before the time of osteotomy healing; this is seen mostly in infants. In the older child, increased bone density allows more rigid external fixation and thus better maintenance of the corrected position. Second, there is long-term undergrowth of the ischiopubic segment, which has been shown to be 33% smaller than normal in the adult with exstrophy, as the pelvis grows. Pubic diastasis increases with growth in the patient with uncorrected exstrophy. Therefore even with some loss of approximation, significant correction remains in comparison with the unoperated state. The authors regard the main role of osteotomy to be relaxation of tension on the bladder, posterior urethra, and abdominal wall repair during healing. Therefore they use osteotomy rarely in newborns and young infants because ligament laxity allows the pelvis to be closed without tension. However, it becomes essential in the older child with a failed exstrophy repair, in the patient with cloacal exstrophy, and in a newborn with a wide diastasis and excellent bladder template. **In patients undergoing combined exstrophy closure and epispadias repair, osteotomy allows the pubis to be joined, making it easier for the corpora to be brought over the closed proximal urethra** (Gearhart et al, 1998). In a recent large series of failed exstrophy reclosures, 56 patients were found who underwent repeat pelvic osteotomy (Nelson et al, 2006). All of the reclosures were successful, and 95% had a normal gait after reoperative osteotomy. There were no femoral or sciatic nerve palsies and only five local pin site

infections, which were easily treated. Thus even repeat pelvic osteotomy is safe in experienced hands.

Surgical Options in the Newborn with Classic Bladder Exstrophy

Although the modern staged repair of exstrophy (MSRE) currently enjoys widespread popularity, other methods have been described for the primary reconstruction of exstrophy. This section discusses the other types of repair, their use, and application. The outcomes and complications are discussed in separate sections because many are similar and their correction the same.

Warsaw Approach

First described by Baka-Jakubiak in 2000, this procedure involved closing the bladder, posterior urethra, pubis, and abdominal wall at the time of primary closure with or without osteotomy but always with appropriate immobilization. Osteotomy is used in all patients older than 72 hours or in any with a diastasis greater than 5 cm. A spica cast is used for 3 weeks and an elastic bandage for 3 further weeks. When the bladder had achieved suitable capacity (>70 mL) and the child was interested in continence, bladder neck repair was performed along with epispadias repair. Baka-Jakubiak has used this approach in more than 100 with classic exstrophy and complete epispadias. The intersymphyseal band is routinely divided to allow better visualization of the bladder neck and posterior urethra region. An additional proposed benefit of this procedure is that the bladder neck and posterior urethral unit is straighter at the second procedure and this allows easier catheterization and cystoscopy following reconstruction. A 10% complication rate, mainly urethral fistula or stricture, was noted in this procedure.

Kelly Repair

The radical soft tissue mobilization procedure was developed by Kelly in the late 1980s and early 1990s as a means to improve on the technique described by Ansell and to obviate pelvic osteotomies that were often required to obtain a tension-free closure. It is a multistaged repair that includes (1) closure of the bladder dome and hernia repair at birth, followed at age 3 to 6 months by (2) reconstruction of the proximal urethra with associated sphincteric tissue with penile lengthening and creation of a penoscrotal urethrostomy in males; and (3) repair of the resulting penoscrotal hypospadiac around 3 years of age. The unique aspects relate to the second stage, where a more radical mobilization of the pelvic floor muscles is performed. Specifically, the dissection includes the periosteum of the ischium and pubis where one encounters the attachment of the voluntary and involuntary sphincter muscles, as well as the pudendal nerves and vessels. The muscles are then wrapped around the reconstructed proximal urethra in an attempt to provide a continence mechanism. The neourethra itself is constructed from the urethral plate on the dorsum of the penis after it is dissected from the corporal bodies, much as in the penile disassembly technique. However, unlike the penile disassembly technique, the meatus is always brought to the penoscrotal junction and later brought distally.

Complete Repair

Developed by Mitchell, the complete repair combines the standard bladder closure with the "penile disassembly" technique for epispadias repair in an effort to decrease the number of procedures required for reconstruction and potentially provide continence without the need for formal bladder neck reconstruction (Grady and Mitchell, 1999). The urethral plate is dissected from the corporal bodies, and the urethra and bladder plate are moved posteriorly into the pelvis. Mitchell emphasizes the importance of dissecting the perineal membrane from the pubis, allowing the bladder and posterior urethra to be set deep into the pelvis. This feature is common to all properly performed exstrophy reconstructions and helps ensure success. The dissection of the urethral plate from the corpora leaves 60% to 75% of patients with hypospadias (Hafez and El-Sherbiny, 2005), and 50% of children require ureteral reimplantation in the first year of life (Grady and Mitchell, 1999).

Mainz Repair

Hohenfelner and colleagues first began using ureterosigmoidostomy for both failed exstrophy patients and for patients with small bladder templates, which led to its use as a technique in primary exstrophy closures. Beginning in 1964, this was begun in all newborns with exstrophy irrespective of bladder template size at birth. At the age of 2, ureterosigmoidostomy is performed. Some of the remnant bladder is made into a small seminal receptaculum, and the penis is reconstructed during the same procedure. In girls, the external genitalia are reconstructed and anterior fixation of the uterus is performed. In both boys and girls, cosmetic correction is usually necessary later. However, this usually means only one further operation. In 1996 Fisch and Hohenfelner modified this technique with the introduction of the Mainz Sigma pouch. This was designed to reduce intracolonic pressure and to maintain better fecal continence. Most of the patients are immediately started on oral alkalinization.

Erlangen Approach

This approach is clearly the most involved of any of the primary closure techniques. In the Erlangen approach developed by Schrott and popularized by Roesch, if the bladder template is deemed of adequate size, the "total" repair is done at 8 weeks of age. If the template is too small at birth, the bladder only is closed with bilateral groin exploration, closure of the pubis, epispadias repair, and no osteotomy. In the classic Erlangen "total repair," the bladder is closed along with bilateral reimplantations, bladder neck plasty, bilateral groin exploration, epispadias repair, pubic closure, no osteotomy, and an epidural catheter for 5 days. Osteotomy is only done in cloacal exstrophy and reoperative closures. Thus the Erlangen repair is truly a "complete repair" encompassing all phases of exstrophy repair in one setting (Ebert et al, 2010).

Regardless of the modern method of reconstruction chosen for the newborn, certain surgical principles remain: (1) radical mobilization of the bladder and posterior urethra from surrounding tissue; (2) combined closure with epispadias repair in only carefully selected patients; (3) tension-free closure of the abdominal wall and pelvic bones with adjunctive osteotomy if needed; and (4) definition of strict criteria for selection of patients to undergo newborn closure.

Modern Reconstruction of Bladder Exstrophy

The primary objective in functional closure is to convert the bladder exstrophy into a complete epispadias with the urethra well onto the penis with completion of the epispadias in only highly select patients. The resultant incontinence with balanced posterior outlet resistance not only preserves renal function but also stimulates bladder growth. Typically, epispadias repair is now performed around 6 months of age, after testosterone stimulation. Bladder

neck repair usually occurs when the child is 4 to 5 years of age, has an adequate bladder capacity, and, most importantly, is ready to participate in a postoperative voiding program. Many repairs such as the Erlangen, Kelly, and complete primary repair of exstrophy (CPRE) were purported to establish continence without the need for bladder neck repair, but recent reports have shown the need for an outlet procedure in most patients (Gearhart et al, 2007; Shoukry et al, 2009).

Bladder, Urethral, and Abdominal Wall Closure

Various steps in primary bladder closure are illustrated in Figure 124–21. A strip of mucosa 2 cm wide, extending from the distal trigone to below the verumontanum in the male and to the vaginal orifice in the female, is outlined for prostatic and posterior urethral reconstruction in the male and adequate urethral closure in the female. The male urethral groove may be adequate, in which case no transverse incision of the urethral plate need be performed for urethral lengthening (see Fig. 124–21A). The authors tend to not incise a urethral plate unless the length of the urethral groove from the verumontanum to the urethral glans is so short that it interferes with eventual penile length and produces dorsal angulation. If so, the urethral groove is lengthened after the manner of Johnston (1974) or Duckett (1977). The drawings in Figure 124–21B and C show marking of the incision just above the umbilicus, down the junction of the bladder and paraexstrophy skin, to the level of the urethral plate.

An appropriate plane is entered just above the umbilicus, and a plane is established between the rectus fascia and the bladder (see Fig. 124–21D). The umbilical vessels are doubly ligated and incised and allowed to fall into the pelvis. The peritoneum is taken off the dome of the bladder at this point so that the bladder can be placed deep into the pelvis at the time of closure. The plane is continued caudally down between the bladder and rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. The pubis is encountered at this junction, and a double-pronged skin hook can be inserted into the bone at this time and pulled laterally to accentuate the urogenital diaphragm fibers. This helps the surgeon radically incise these fibers among the bladder neck, posterior urethra, and pubic bone (see Fig. 124–21E). Gentle traction on the glans at this point shows the insertion of the corporal body on the lateral inferior aspect of the pubis. These urogenital diaphragm fibers are taken down sharply with electrocautery down to the pelvic floor in their entirety (see Fig. 124–21F). If this maneuver is not performed adequately, the posterior urethra and bladder will not be placed deeply into the pelvis, and when the pubic bones are brought together, the posterior vesical unit will be brought anteriorly into an unsatisfactory position for later Cantwell-Ransley epispadias repair. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate in order to create as much additional urethral and penile length as possible. Further urethral lengthening can be performed at the time of epispadias repair.

Penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments on the anterior part of the inferior pubic rami. **However, because Silver and colleagues (1997b) showed that there is a 50% shortage of length of the corporal bodies in exstrophy versus normal controls, any penile length that is obtained is more correction of chordee and change in angulation of the penis rather than true penile lengthening.** The wide band of fibers and muscular tissue representing the urogenital diaphragm is detached subperiosteally from the pubis bilaterally (see Fig. 123–21F). Reluctance to free the bladder neck and urethra well from the inferior ramus of the pubis moves the neobladder opening cephalad should any separation of the pubis occur during healing, thus increasing the chance of bladder prolapse. The mucosa and muscle of the bladder, bladder neck, and urethra are then closed well onto the penis in the midline anteriorly (see Fig. 123–21G). This should be tapered over a 10- to 12-Fr sound comfortably. The size of the opening should allow enough resistance to aid in bladder adaptation and to prevent prolapse but not enough outlet resistance to cause upper tract changes. The posterior urethra and bladder neck are buttressed with a second layer of local tissue if possible. If a CPRE is performed, a penile disassembly is done with many of the patients being made hypospadiac. The bladder is drained by a suprapubic non-latex Malecot catheter for a period of 4 weeks. The urethra is not stented in order to avoid necrosis with accumulation of secretions in the neourethra. Stents provide drainage during the first 10 to 14 days after closure because swelling caused by the pressure of closure of a small bladder can obstruct the ureters and give rise to obstruction and transient hypotension. If there are no problems with the stents during healing, the authors leave the stents in as long as 2 to 3 weeks.

When the bladder and urethra have been closed and the drainage tubes placed, pressure over the greater trochanters bilaterally allows the pubic bones to be approximated in the midline. Horizontal mattress sutures are placed in the pubis and tied with a knot away from the neourethra (see Fig. 123–21H). Often, it is possible to use another stitch of No. 2 nylon at the most caudal insertion of the rectus fascia onto the pubic bone. This maneuver adds to the security of the pubic closure. A V-shaped flap of abdominal skin at a point corresponding to the normal position of the umbilicus is tacked down to the abdominal fascia, and a drainage tube exits this orifice. The method described by Hanna (1986) is our most commonly performed procedure. Before and during the procedure, the patient is given broad-spectrum antibiotics in an attempt to convert a contaminated field into a clean surgical wound.

If the decision is made at this point that the urethral groove is to be transected, the groove is cut distal to the verumontanum with continuity maintained between the thin, mucosal, non–hair-bearing skin adjacent to the posterior urethra and bladder neck and the skin and mucosa of the penile skin and glans. Flaps in the area of the thin skin are subsequently moved distally and rotated to reconstruct the urethral groove, resurfacing the penis dorsally. The corporal bodies are not brought together at this juncture because later Cantwell-Ransley repair is planned.

Combined Bladder Closure and Epispadias Repair

The modern staged repair of bladder exstrophy has yielded consistently good cosmetic and functional results, and the utilization of osteotomy has improved the potential for successful initial closure and later continence. **In an effort to decrease costs, decrease the morbidity associated with multiple operative procedures, and possibly affect continence, there has been interest in performing single-stage reconstruction or combining procedures in appropriately selected patients.** This technique was first described by Lattimer and Smith (1966) but was abandoned in the 1970s because of high complication and failure rates. The technique was revisited by Gearhart and Jeffs (1991a) for failed exstrophy closures and more

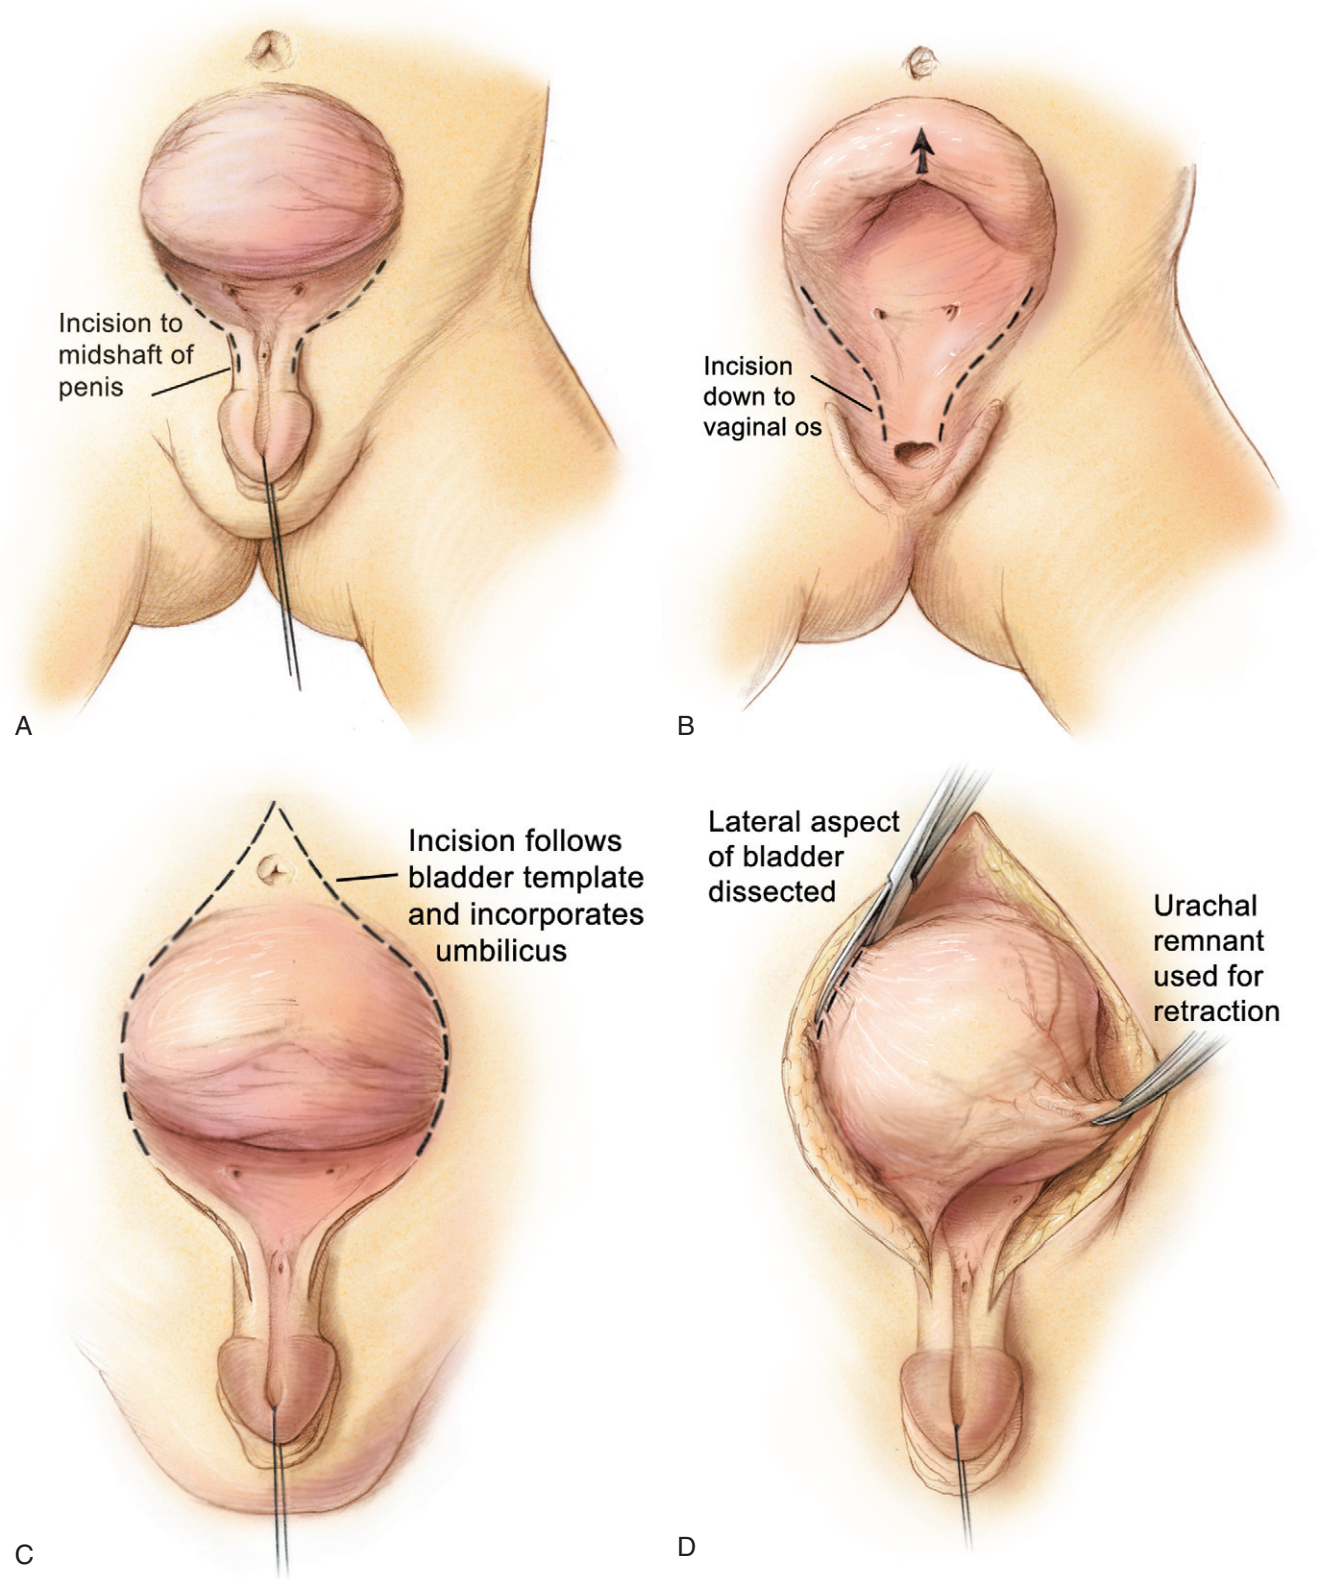

Figure 124–21. Steps in the initial closure of the bladder and posterior urethra with or without osteotomy. recently by Grady and Mitchell for newborn patients (1999). In the combined exstrophy and epispadias repair, bladder closure is combined with the modified Cantwell-Ransley epispadias repair (Gearhart et al, 1998; Baird et al, 2005c). This technique can be applied to both delayed primary closure and failed closures. As with the complete repair, many require early ureteral reimplantation, but none were made hypospadiac.

Results have now emerged in groups of boys undergoing single-stage reconstruction (bladder closure and epispadias repair) in infancy (Gearhart et al, 1998; Baird et al, 2005c). In our opinion, this technique should be limited to boys of older age (older than 4 to 6 months) because of evidence indicating that potential complication of these combined procedures is significant loss of penile and corporal tissue that makes further reconstruction problematic (Husmann and Gearhart, 2004). Patients should be carefully selected, and utilization of these extensive procedures by the occasional exstrophy surgeon is not recommended. **Selection should take into account phallic size and length, depth of the urethral groove, and size of the bladder template in those with delayed primary closures, as well as perivesical and urethral scarring in those who have undergone a prior failed closure** (Gearhart and Jeffs, 1991a; Gearhart et al, 1998; Baird et al, 2005c).

Management after Primary Closure

The initial step of the MSRE converts a patient with exstrophy into one with penile epispadias and incontinence. **Before removal of the suprapubic tube, 4 weeks after surgery, the bladder outlet is calibrated by a urethral catheter or a urethral sound to ensure free drainage. A complete ultrasound examination is obtained to ascertain the status of the renal pelves and ureters, and appropriate urinary antibiotics are administered because all patients have reflux after closure.** Residual urine is estimated by clamping the suprapubic tube, and specimens for culture are obtained before the patient leaves the hospital and at subsequent intervals to detect infection and ensure that the bladder is empty. If the initial ultrasound examination shows good drainage, upper tract imaging by ultrasonography is repeated 3 months after discharge from the hospital and at intervals of 6 months to 1 year during the next 2 to 3 years to detect any upper tract changes caused by reflux, infection, or obstruction. Prophylactic antibiotics should be continuous because all patients with bladder exstrophy, once closed, have vesicoureteral reflux. If a useful continence interval has resulted from the initial closure, a further operation for incontinence may not be required; however, this situation is quite unusual. In the authors' experience with more than 85 primary closures, this has occurred in three patients, all of whom were girls. After the conversion from exstrophy to complete epispadias with incontinence, the bladder gradually increases in capacity as inflammatory changes in the mucosa resolve.

Cystoscopy and cystography at yearly intervals are used to evaluate the degree of reflux noted in almost 100% of patients and to provide an estimate of bladder capacity (Gearhart and Jeffs, 1998). Even in a completely incontinent patient, bladder capacity gradually increases to a point at which the bladder can be distended at cystography to its true capacity. This must be done under anesthesia in young children because the values obtained differ markedly from those obtained when trying to fill the bladder of a crying, squirming infant on an x-ray table (Gearhart and Jeffs, 1998). If the bladder has not achieved a capacity of at least 30 mL by 1 to 2 years, concern must be voiced to the parents about the overall ability of the bladder to undergo a continence procedure. Currently, the only parameters available to predict overall success are the size of the bladder template at birth and a successful primary closure with absence of infections.

Should bladder outlet resistance be such that urine is retained within the bladder and reflux and ureteral dilatation develop with infected urine, it may be necessary to dilate the urethra or to begin intermittent catheterization (Baker et al, 1999). Sometimes the posterior urethral obstruction can be such that it requires a transurethral incision of the stricture to maintain an adequate posterior urethral outlet. If bladder outlet resistance persists and infections continue, an antireflux procedure may be required as early as 6 months to 1 year after initial closure (Mathews and Gearhart, 2003). After primary closure with the CPRE repair, 50% will require ureteral reimplantation in the first year after closure. Because of this problem, some units are trying ureteral reimplantation at the time of bladder closure but the numbers of patients treated in this fashion is small (Braga et al, 2008a). If severe upper tract changes occur, surgical revision of the bladder outlet by advancing skin flaps into the orifice or even patching the stricture may be necessary to prevent scarring and further obstruction. As mentioned previously, transurethral incision of the urethral stricture to obtain a balanced outlet should be tried before surgical revision. Judgment is required to know when to avoid attempts at functional closure and to know when to return to urinary diversion as a means to preserve renal function. This change of plan is seldom necessary if an adequate outlet has been constructed at the initial closure and if careful attention has been paid to the details of follow-up of the bladder and posterior urethra. An important caveat is that if there are recurrent urinary tract infections (UTIs) and if the bladder is distended on ultrasonography, cystoscopy should be performed and the posterior urethra should be carefully examined anteriorly for erosion of the intrapubic stitch, which may be the cause of the recurrent infections (Baker et al, 1999). If the intrapubic stitch is seen in the posterior urethra, a small suprapubic incision should be made and the stitch should be removed, or, if it can be grasped, it should be removed transurethrally. Husmann and colleagues (1990) have shown acceptable levels of upper tract function after primary closure as long as prophylactic antibiotics were used after initial closure and elevated urinary residuals were kept below 50 mL.

Selected Technical Aspects of Other Methods of Closure

Kelly Repair
