Dopaminergic Agonists. Apomorphine (Uprima, TAP Pharmaceutical Products Inc, Lake Forest, IL) is a dopaminergic agent activating D_1 and D_2 receptors at a central level within the paraventricular nucleus of the brain, indicating its particular relevance in the treatment of men with psychogenic ED (Lal et al, 1987). The medication is taken in sublingual form, having a dosage range of 2, 4, and 6 mg, and it has no erectile efficacy if it is swallowed (Heaton, 2000). It has a rapid onset of action, with a mean time to erection of 12 minutes. Apomorphine achieves a maximal plasma concentration in 50 minutes, although its window of opportunity extends for approximately 2 hours from administration. In clinical trials involving men with ED of varying severities and etiologies, the drug achieved a successful sexual intercourse rate of 50.6% at the 4-mg dosage compared with the 33.8% placebo rate (Heaton, 2000). Side effects include nausea (16.9%), dizziness (8.3%), yawning (7.9%), somnolence (5.8%), sweating (5%), and emesis (3.7%). Syncope occurred in 0.6% of patients using the medication at the highest recommended dosage and was accompanied by a prodrome consisting of nausea, vomiting, sweating, dizziness, and light-headedness but no cardiac sequelae. Side effects were minimized when patients were titrated from higher to lower dosages. The drug achieved regulatory approval for commercialization by European authorities in early 2001, but it has not been so approved in the United States.

Melanocortin-Receptor Agonists. Melanocortin analogues (e.g., melanotan II, PT-141) have been studied showing efficacy in inducing erectile responses in early clinical trials (Wessells et al, 2000; Diamond et al, 2004). These drugs operate centrally at melanocortin-4 receptors, which have been implicated in controlling food intake and energy expenditure, as well as modulating erectile function and sexual behavior. Flushing and nausea have been reported as side effects. The drugs have not achieved regulatory approval for the treatment of ED.

Serotonin-Receptor Effectors. Trazodone (Desyrel) is an antidepressant that has been associated with priapism, prompting its "off-label" investigation as a possible treatment for ED (Lal et al, 1990). It is purported to work through mechanisms at the spinal cord level with multiple serotonergic effects (Allard and Giuliano, 2001). The active metabolite of trazodone acts as an agonist of the proerectile 5-HT_{2C} receptor through reuptake inhibition, with some affinity for the 5-HT_{2A} receptor, although it may also operate as an antagonist of antierectile 5-HT_{1A} receptors (Andersson and Wagner, 1995). Rigorous recent evaluations have not shown clinical efficacy that exceeds placebo responses in eliciting penile erection (Costabile and Spevak, 1999). Given its potential side effects (i.e., drowsiness, nausea, emesis, blood pressure changes, urinary retention, and priapism) and general lack of effect, this medication would appear to have a limited role for ED treatment.

Other Oral Therapies. Additional possibilities for the oral treatment of ED including L-arginine (the amino acid precursor of nitric oxide), L-dopa (dopamine precursor), limaprost (prostaglandin E_1), and naltrexone (opioid antagonist) have been proposed

(Burnett, 1999). Each of these agents has a plausible mechanism of action to induce erections. However, they remain insufficiently studied and their clinical roles remain unclear.

Intracavernous Injection

The discovery in 1982 that vasoactive agents, delivered by injection into the penis, induced erections is credited with launching the movement toward medical therapies for the treatment of ED (Virag, 1982; Zorgniotti, 1985). **Since that time, there has been an explosion of basic scientific and clinical research leading to the development and use of various locally administered vasoactive medications having mechanisms of action that result in corporal smooth muscle relaxation.** Although a host of medications have been explored for this purpose, three medications are used regularly in clinical practice: alprostadil, papaverine, and phentolamine (Table 24–9). **These have been administered clinically as a single agent (i.e., monotherapy) or in various combinations (e.g., bi-mix, tri-mix). Combination therapy offers a synergistic mechanism of the vasoactive agents to elicit maximal erectile responses, particularly among patients who have failed monotherapy** (Zorgniotti and Lefleur, 1985; Bennett et al, 1991; Floth and Schramek, 1991). This alternative may also be used to circumvent side effects of a certain agent (e.g., penile pain associated with alprostadil).

A general rule of thumb is to start with a small dose of medication, especially in patients with nonvasculogenic forms of ED. In-office self-injection training and education are recommended before home injection, and this opportunity may also be used to titrate medication toward a dosage that safely yields an erection of sufficient rigidity for sexual intercourse yet lasts no more than an hour (Benard and Lue, 1990; Fallon, 1995). **The therapy is contraindicated for men with psychologic instability, a history or risk for priapism, histories of severe coagulopathy or unstable cardiovascular disease, reduced manual dexterity (although the partner can be trained in the injection technique), and use of monoamine oxidase inhibitors (because of the risk of precipitating a life-threatening hypertensive crisis in the event that an intracavernosal α-adrenergic agonist is used to reverse a priapic episode)** (Sharlip, 1998).

Table 24–9.

Intracavernous Pharmacotherapies

TRADE NAME	DRUG	DOSAGES	EFFICACY (INTERCOURSE)
Caverject	Alprostadil (Prostin VR)	5-40 µg/mL	≈70%
Edex	Alprostadil (Prostin VR)	5-40 µg/mL	≈70%
Bi-mix	Alprostadil + phentolamine	20 µg/mL + 0.5 mg/mL	≈90%
Bi-mix Androskat (EU)	Papaverine + phentolamine	30 mg/mL + 0.5 mg/mL	≈90%
Tri-mix	Alprostadil + papaverine + phentolamine	10 µg/mL + 30/mg/mL + 1.0 mg/mL	≈90%
Invicorp	VIP + phentolamine	NA	≈80%
Thymoxamine	Moxisylyte	NA	≈70%

EU, European Union; VIP, vasoactive intestinal polypeptide.

Alprostadil. Alprostadil (Prostin VR) is a synthetic form of a naturally occurring fatty acid, prostaglandin E_1, which binds with specific receptors on smooth muscle cells and activates intracellular adenylate cyclase to produce cAMP, which in turn induces tissue relaxation through a second messenger system (Palmer et al, 1994). Currently it is the only FDA-approved injectable medication for ED, and it is marketed for this purpose by the trade names Caverject (Pfizer Inc, New York) and Edex (Schwarz Pharma, Milwaukee, WI) (Linet and Ogrinc, 1996; Porst, 1996; Buvat et al, 1998). After intracavernous injection, the medication is locally metabolized by 96% within 60 minutes and does not appreciably enter the peripheral circulation (Van Ahlen et al, 1994). **At dosages of 10 to 20 µg, alprostadil produces full erections in 70% to 80% of patients with ED** (Linet and Neff, 1994). Side effects of treatment are most commonly pain at the injection site or during erection (in 11% of patients), hematoma/ecchymosis (1.5%), prolonged erection/priapism (1% to 5%), and penile fibrotic lesions (2%) (Linet and Ogrinc, 1996). **Perceived advantages of alprostadil for intracavernous pharmacotherapy relative to other agents are lower incidences of prolonged erection, systemic side effects, and penile fibrosis. Disadvantages include a higher incidence of painful erection and higher cost, and once reconstituted into liquid from powder it has a shortened half-life if not refrigerated.**

Papaverine. Papaverine, an alkaloid isolated from the opium poppy, is a nonspecific PDE inhibitor, which prevents the degradation of cAMP and cGMP so that these cyclic nucleotides accumulate in smooth muscle cells and thereby increasingly promote tissue relaxation (Kukovetz et al, 1975). The compound also blocks voltage-dependent calcium channels along the membrane wall, thus impeding calcium influx to the cell, a process known to trigger smooth muscle contraction (Brading et al, 1983; Sunagane et al, 1985). Papaverine is metabolized in the liver, and the plasma half-life is 1 to 2 hours. Its general efficacy in promoting penile erection after intracavernous administration is less than 55%. The drug is inexpensive and stable at room temperature. However, disadvantages of commonly observed liver enzyme elevations, priapism risk (up to 35%), and penile fibrosis risk (1% to 33%) have led to its abandonment as monotherapy (Lakin et al, 1990; Fallon, 1995; Porst, 1996; Moemen et al, 2004).

α-Adrenoceptor Antagonists. Besides its purported oral role for ED therapy, phentolamine mesylate is more familiarly applied as an intracavernous agent (Regitine). Although its erectogenic effect is mediated by blocking the (antierectile) postsynaptic α_1-adrenergic receptor (Sironi et al, 2000), because of its potential inhibition of the prejunctional α_2-adrenergic receptor, which interferes with norepinephrine reuptake, the drug's tissue relaxant effect for penile erection is believed to be antagonized (Juenemann et al, 1986). This dual effect of the drug probably accounts for its limited success when administered intracavernously as a sole agent (Blum et al, 1985). It has a short plasma half-life (30 minutes). Common side effects associated with the drug include systemic hypotension, reflex tachycardia, nasal congestion, and gastrointestinal upset. Moxisylyte (Thymoxamine) is a competitive blocker of α_1-adrenoceptors with impressive erectogenic effects (Buvat et al, 1989). Its availability is restricted in the United States.

Vasoactive Intestinal Polypeptide. Vasoactive intestinal polypeptide (VIP), a hormone having 28 amino acids originally isolated from the small intestine, was proposed early on to be the elusive nonadrenergic noncholinergic (NANC) mediator of penile

erection because of its potent vasodilatory effects in various tissues (Adaikan et al, 1986). Its mechanism of action in smooth muscle is achieved through specific protein receptor binding and activation of adenylate cyclase, therebypromoting synthesis of cAMP and subsequent tissue relaxation (Andersson and Wagner, 1995). The drug has had disappointing effects when administered alone, although in separate combination with other drugs such as papaverine and phentolamine, erection responses were elicited (Kiely et al, 1989; Dinsmore and Wyllie, 2008). VIP in combination with phentolamine (Invicorp) is currently being sought for regulatory approval in the United States.

Intraurethral Suppositories

The administration of vasoactive drugs via the urethral channel of the penis was introduced with the hope of affording a less invasive procedure than intracavernous needle injections to induce penile erection. **This technique relies on the absorption of medication through the mucosal lining into the surrounding corpus spongiosum, with passage via small vascular channels into the main erectile bodies, the corpora cavernosa.** The transfer of drug from the urethra to the cavernous tissue varies across men according to anatomic variability. Following an initial trial that demonstrated prostaglandin E_2 was effective in inducing full tumescence in 30% of patients and partial tumescence in 40% of patients (Wolfson et al, 1993), a synthetic formulation of prostaglandin E_1 was developed and FDA approved in November 1996 as MUSE (Medicated Urethral System for Erection, Vivus, Menlo Park, CA) (Hellstrom et al, 1996; Padma-Nathan et al, 1997). MUSE employs a suppository inserted into the urethral opening that dispenses a semisolid pellet (1 × 3 mm) of alprostadil (125, 250, 500, and 1000 μg dosages) into the distal urethra (3 cm from the external urethral meatus). Several technical procedures optimize the success of the treatment including properly depositing and manually distributing the medication into the penis and the patient's remaining in the upright position for several minutes after its application. In-office training and monitoring of initial response may afford advantages for optimizing technique and making dosage adjustments before performing treatment at home.

A calculated final responder rate to MUSE is approximately 50%, and among responders approximately 70% of administrations result in sexual intercourse (Hellstrom et al, 1996; Padma-Nathan et al, 1997; Guay et al, 2000). The combined use of an adjustable penile constriction band (ACTIS) was designed and FDA approved to enhance the local retention and effect of the medication (Lewis, 2000). A transurethral bi-mix consisting of alprostadil and α_1-adrenergic antagonist prazosin (ALIBRA) was introduced and in a multicenter trial of nearly 400 patients was shown to increase the at-home responder rate for successful sexual intercourse from 47% with alprostadil alone to 70% with ALIBRA (Qureshi, 2001).

The most common side effects of MUSE include local urogenital pain (approximately one third of patients) and minor urethral bleeding (5%) (Padma-Nathan et al, 1997; Guay et al, 2000). Other complications such as hypotension (3%), dizziness (4%), and priapism (0.1%) have been observed as well. MUSE is contraindicated in patients with known hypersensitivity to alprostadil, abnormal penile anatomy, and conditions that increase the risk of priapism. MUSE seems safe for female partners, producing only a 5.8% incidence of vaginal burning or itching, although it should not be used for intercourse with a pregnant woman without a condom.

Transdermal/Topical Pharmacotherapy

The notion to apply vasoactive drugs directly to the surface of the penis is consistent with the general appeal of many transdermal therapies (e.g., gels, creams) in medicine on the basis of their delivery route: convenience, simplicity, and putatively limited systemic adverse effects. Several topical therapies have been explored for ED treatments, although certain obstacles have limited their widespread use. Nitroglycerine, a nitric oxide donor formulated as a 2% paste, was found to produce tumescence but rarely penile rigidity sufficient for sexual intercourse (Owen et al, 1989). This relative inefficacy combined with its headache side effects for both patient and partner following absorption and action of the drug as a potent systemic vasodilator have precluded its use in clinical practice. Papaverine, formulated as a gel, was investigated but then abandoned as a topical ED treatment on finding that its large molecular size (molecular weight 376 Da) interfered with its transdermal absorption (Kim et al, 1995).

Alprostadil has been a more promising prospect, subjected to commercial development by two companies for penile glans administration in combination with transdermal delivery enhancers: alprostadil 1% + SEPA (soft enhancer of percutaneous absorption), referred to as Topiglan (Macrochem, Lexington, MA), and alprostadil + NexACT, referred to as Alprox-TD (NexMed, Inc., Robbinsville, NJ). Applied intrameatally, both agents in clinical trials have shown efficacy with rates of vaginal penetration and intercourse success that were small but significantly greater than placebo rates and caused minor side effects of site-specific burning or warmth that were comparable with placebo rates (McVary et al, 1999; Goldstein et al, 2001; McMahon, 2002; Padma-Nathan and Yeager, 2006; Rooney et al, 2009). Prostaglandin E_1 ethyl ester, which is a prodrug of prostaglandin E_1, is believed to possess an improved transdermal permeation and less skin irritation than enhancing agents because of its esterification (Schanz et al, 2009). Applied to the shaft of the penis in early clinical trials, this drug achieved significantly higher rigidity scores than placebo. In general, transdermal therapy with alprostadil is likely to meet similar clinical roles as that assigned to transurethral pharmacotherapy. Further clinical trials will be useful to define and establish their place in the treatment of ED.

Medical Devices

In patients who do not respond to or decline oral or local vasoactive pharmacotherapeutic options, vacuum erection device therapy may be alternatively explored. **The principle of vacuum erection device therapy is to mechanically create negative pressure surrounding the penis in order to engorge it with blood and then restrain blood egress from the organ to maintain the erection-like effect** (Broderick et al, 1992). Although the treatment does not produce a truly physiologic erection and the engorged blood predominantly consists of venous blood (Bosshardt et al, 1995), the effect resembles a normal erection and is sufficient for coitus. A particular feature is that the glans penis, and not solely the corpora cavernosa, is engorged with blood by the treatment, such that the treatment is further advantageous for patients experiencing glanular insufficiency.

The vacuum erection device standardly consists of a usually clear plastic suction cylinder and vacuum-generating source (manual or battery-operated pump) in one piece. It is placed directly over the flaccid penis and operated, and after the penis is erected an elastic constriction ring or band is positioned at

the base of the penis; then the vacuum is released and the device is removed (Montague et al, 1996; McMahon, 1997). The cylinder has a pressure release valve designed to prevent penile injury from excessive negative pressure. Sexual intercourse may then ensue, although it is recommended that the ring should not be left in place for longer than 30 minutes. Prescription devices are advised, and metal or other inelastic rings are contraindicated.

Efficacy rates in achieving satisfactory erections of 67% to 90% have been reported for ED associated with various severities and etiologies, but satisfaction rates with the device are lower, ranging from 34% to 68% (Hellstrom et al, 2010). Attrition is reported to occur and may relate to lack of efficacy with more severe forms of ED, although long-term continuation rates have ranged from 19% to 42%. Success is limited in patients with severe vascular abnormalities such as proximal venous leakage or arterial insufficiency or fibrosis secondary to priapism or prosthesis infection (Marmar et al, 1988). Patient preferences also dictate long-term success. The device is more acceptable to older men in a steady relationship compared with young, single men.

Among basic expectations of the treatment, patients should be informed of possible local discomfort or pain associated with the constriction band, a pivoting effect of the penis because turgidity exists only distal to the band's location, a cyanotic discoloration and coolness of the penis resulting from extracorporeal congestion, and trapping of the ejaculation caused by urethral constriction (Witherington, 1989; Sidi et al, 1990; Cookson and Nadig, 1993). Common complications are minor and include penile pain and numbness, difficult ejaculation, ecchymosis, and petechiae, and major complications (e.g., penile skin necrosis, urethral varicosities, Fournier gangrene) are infrequent. Patients receiving anticoagulant therapy (e.g., aspirin, warfarin) and patients with bleeding disorders should use the device with caution (Limoge et al, 1996).

Special uses for this therapy have been sought. It has been successfully combined with oral, intracavernous, and intraurethral pharmacotherapies to produce erectile responses (Marmar et al, 1988; Chen et al, 1995; John et al, 1996; Chen et al, 2004; Canguven et al, 2009). The device has enhanced erectile effects in the presence of a malfunctioning penile prosthesis (Sidi et al, 1990; Korenman and Viosca, 1992). Further, it may offer a means to preserve the elasticity of penile tissues after priapism or penile prosthesis explantation (Moul and McLeod, 1989; Soderdahl et al, 1997) or after surgical correction of Peyronie disease (Yurkanin et al, 2001), and it has been suggested to facilitate erection recovery after treatments for prostate cancer (Raina et al, 2006; Kohler et al, 2007).

Surgery

Surgical interventions have always served an important role in the armamentarium of ED treatments. **Often, they are applied in the face of penile injury resulting from genital or pelvic trauma, penile structural deformity occurring in association with Peyronie disease, or possibly cavernosal fibrosis secondary to prolonged ischemic priapism or infection. They are also considered when medical therapy for ED is contraindicated, unsuccessful, or undesirable.**

Penile Prosthesis Surgery

Penile prosthesis or implant surgery is a mechanism for creating penile rigidity that differs from a physiologic or pharmacologically induced erection. Both malleable (semi-rigid) and inflatable (hydraulic) devices are currently available for this purpose. Details of this treatment option are presented elsewhere.

Penile Revascularization Surgery

On the basis of the requirements of inflow of blood and its retention in the penis for penile erection to occur, it is hardly a wonder to think that vascular surgeries have aggressively been pursued to facilitate or restore these biologic processes.

Arterial Revascularization. In concept, arterial revascularization surgery was designed to create arterial inflow to the corpora cavernosa, in turn addressing the presentation of arteriogenic ED. Several procedures have been described to meet this objective, similarly creating an anastomosis of the inferior epigastric artery either to the corpus cavenosum directly or to vascular conduits of the penis such as the dorsal artery (i.e., revascularization), the deep dorsal vein (i.e., arterialization), or the deep dorsal vein with venous ligation (i.e., arterialization with venous reconstruction) (Hellstrom et al, 2010). Success of these surgeries has been variable and depends on careful patient selection. Penile arteriography is required to establish a penile arterial anatomic defect, and other organic causes of ED (e.g., venous incompetence) that would limit surgical success should be excluded. **According to the current literature, the following inclusion criteria should be met to select patients for arterial surgery: age younger than 55 years, nonsmoker, nondiabetic, absence of venous leakage, and radiographic confirmation of stenosis of the internal pudendal artery** (Hellstrom et al, 2010). **The highest success rates are reported in young men (younger than 30 years of age) with isolated arterial stenosis following perineal or pelvic trauma** (Babaei et al, 2009). Complications of arterial revascularization surgery include glans hyperemia (13%), shunt thrombosis (8%), and inguinal hernias (6.5%) (Manning et al, 1998; Kawanishi et al, 2004).

Venous Reconstruction. Venous reconstruction was proposed to prevent the pathologic blood egress from the penis, understandably serving to correct veno-occlusive ED. Most surgical procedures have centered on ligating or embolizing penile veins (e.g., superficial dorsal vein, deep dorsal vein, crural vein) or surgically compressing the penile crura (e.g., crural plication/ligation, pericavernoplasty) (Hellstrom et al, 2010). **Success with these surgeries has not been affirmed, owing primarily to inaccurate or deficient methods for diagnosing and correcting the relevant anatomic defect. The optimal surgical approach remains to be defined, and thus venous reconstructive surgery is presently considered investigational** (Montague et al, 2005; Hellstrom et al, 2010). Reported complications of this surgery include glanular hypoesthesia/anesthesia, skin necrosis, wound infections, penile curvature/shortening, and glans hyperemia.

Combination Therapies

It is well recognized that many patients with ED will not respond acceptably to monotherapy. Some patients indeed may achieve optimal therapeutic responses by combining treatment options. In addition, it is possible that a dose-limiting adverse effect is associated with ED monotherapy such that combined treatments may then seem advantageous. Multiple combinations may certainly be proposed for ED treatment. The extant literature describes several successful combinations: oral PDE5 inhibitors with psychosocial counseling (Althof et al, 2005), oral PDE5 inhibitors with

testosterone replacement therapy (Shabsigh et al, 2004), oral PDE5 inhibitors with transurethral alprostadil (Mydlo et al, 2000; Nehra et al, 2002), oral PDE5 inhibitors and intracavernous pharmacotherapy (McMahon et al, 1999), oral PDE5 inhibitors and vacuum erection device (Chen et al, 2004; Canguven et al, 2009), intracavernous pharmacotherapy and vacuum erection device (Chen et al, 1995), transurethral pharmacotherapy and vacuum erection device (John et al, 1996), and transurethral pharmacotherapy and penile prosthesis surgery (Benevides and Carson, 2000). **Caution is advised when initiating combination therapy to observe for potential complications that may be compounded by combined treatments, and in-office evaluations before continuing treatments at home may be considered to offer an additional measure of safety.**

Alternative Therapies

Alternative therapies have long been considered for the treatment of ED, from herbs, ointments, and concoctions of antiquity to vitamins, nutraceuticals, and dietary supplements in commercial supply today. The movement toward alternative medicines in this field actually gained momentum over the past decade with the emergence of effective oral therapy in the form of PDE5 inhibitors, which created avenues for producing PDE5 inhibitor-like counterfeit and imitation substances and promoting regulatory agency unapproved products in general. Indeed, the true efficacies of proposed alternative therapies (e.g., ginkgo biloba, L-arginine, Korean red ginseng) remain uncertain in the absence of evidenced benefit in randomized, controlled clinical trials (Moyad et al, 2004). The success of these products is ascribed in some measure to the known placebo effect of agents to treat ED, which has been observed to amount to as much as 25% to 50% in properly conducted clinical trials. **Before the use of alternative therapies can be advocated, further research that demonstrates their mechanisms of action and meaningful efficacies must be done.**

Key Points: Treatment Considerations

- An informed decision-making process that combines goals and preferences of the patient (and partner) and balanced and thorough guidance of the clinician should dictate the best therapeutic option.
- Although definitive evidence is necessary to affirm the benefits of risk modification for preserving erectile health, recommendations are offered to maintain a healthy and fit lifestyle for this purpose.
- Patient education and counseling and application of medical therapies as initial forms of ED management constitute basic management in common practice.
- Psychosexual therapy offers a role in the integrative management of ED.
- Several pharmacotherapies administered by various modalities including oral, intracavernous, intraurethral, and transdermal/topical routes are successfully applied or are under study as ED treatments.
- Vacuum erection device therapy offers an alternative to oral or local vasoactive pharmacotherapeutic options for ED.
- Surgical intervention, principally penile prosthesis surgery, represents an important ED treatment and may be considered when medical (nonsurgical) therapy is contraindicated, unsuccessful, or undesirable.
- Arterial revascularization surgery is offered only to select patients with ED meeting stringent clinical and radiographic criteria for surgical success.

FUTURE DIRECTIONS

The National Urology Research Agenda Summit Meeting, which was convened in the fall of 2009 and sponsored by the American Urological Association Foundation, included sexual dysfunctions among its priority research areas for advancing urologic health. Among the assembly of scientific experts and leaders in urologic research, the working group on sexual medicine enumerated several broad thematic categories of research for advancing ED management. These categories encompassed all subject areas of epidemiology, basic scientific research, and clinical investigation. Five top recommendations were submitted.

First, the epidemiologic relationships and pathogenic mechanisms linking ED and its comorbidity risk factors should be further clarified. It was considered that the definition and implementation of health prevention efforts for ED and for general health disorders have potentially mutual gains and should predictably improve overall health and longevity outcomes for patients.

Second, further research emphasis should be given to understanding and addressing iatrogenic ED. This objective recognizes that ED is a complication associated with numerous medical and surgical treatments that are performed in urology and in other disciplines. The scope in urology includes treatments for prostate cancer, benign prostate conditions, voiding dysfunctions, and possibly even pelvic pain disorders.

Third, basic scientific research in such areas as endothelial mechanisms, smooth muscle biology, and neurobiology referable to the sexual organ system must be supported with the understanding that research discoveries are the foundation for continued advances in the clinical practice of sexual medicine. Interdisciplinary research collaborations and interactions with researchers in other urologic research fields in particular are likely to facilitate the translational purpose of this objective.

Fourth, research focus should be given to the development of innovative therapeutics for ED. It is recognized that today's advances in oral pharmacotherapy, despite their noted advantages, do not fully achieve goals of ideal therapy. Ideal therapy for ED management should go further, such as to restore function or improve it effectively for the long term. This prospect underscores the purpose of molecular and cellular therapeutic targeting, which is specific for etiopathogenic factors underlying ED. Exciting directions, from up-and-coming pharmacotherapeutics and technologies to futuristic approaches such as gene therapy, stem cell therapies, and tissue engineering, are all worth investigating.

Fifth, outcomes research is highly relevant for this field. This objective pertains to the rigorous evaluation of diagnostic assessments and treatments associated with ED management to ascertain their roles. It also applies to clinical contexts in which accurate erectile function assessments such as outcome reporting for pelvic surgery are necessary. This research area will profit from the ongoing development, validation and proper use of questionnaires, biomarkers, and other specialized clinical tools.

Conclusions and Recommendations for Research in Priapism

Priapism describes a persistent erection arising from dysfunction of the mechanisms regulating penile tumescence, rigidity, and flaccidity. A correct diagnosis of priapism is a matter of urgency requiring identification of the underlying hemodynamics.

Scientific organizations have recommended guidelines for the management of priapism including the American Urological Association in 2003 (www.auanet.org) and the International Society for Sexual Medicine in 2006 (www.issm.info). Both groups have noted that the literature on priapism is composed mainly of small case series and individual case reports and includes inconsistent definitions and methodologies with little long-term erectile function outcome data. Recent case series have included detailed methodology including duration of priapism, etiology of priapism, and erectile function outcomes. The basic science on the pathogenesis of priapism and clinical research supporting the most effective treatment strategies are summarized in this chapter. Recommendations for best clinical practice and suggestions for research are made.

DEFINING PRIAPISM

Priapism is a full or partial erection that continues more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation.

Ischemic Priapism (Veno-Occlusive, Low-Flow)

Ischemic priapism is a persistent erection marked by rigidity of the corpora cavernosa and little or no cavernous arterial inflow. In ischemic priapism there are time-dependent changes in the corporal metabolic environment with progressive hypoxia, hypercarbia, and acidosis. The patient typically complains of penile pain after 6 to 8 hours, and the examination reveals a rigid erection. The condition is analogous to a muscle compartment syndrome, with initial occlusion of venous outflow and subsequent cessation of arterial inflows. Well-documented histologic changes occur within the corporal smooth muscle as a consequence of prolonged ischemia. **Interventions beyond 48 to 72 hours of onset may help relieve erection and pain but have little benefit in preserving potency.** Histologically by 12 hours corporal specimens show interstial edema, progressing to destruction of sinusoidal endothelium, exposure of the basement membrane, and thrombocyte adherence at 24 hours. After 48 hours thrombus can be found in the sinusoidal spaces and smooth muscle necrosis with fibroblast-like cell transformation is evident (Spycher, 1986). Ischemic priapism is an emergency. **When left untreated, resolution may take days and erectile dysfunction (ED) invariably results** (Fig. 25–1A and B).

Stuttering Priapism (Intermittent)

Stuttering priapism characterizes a pattern of recurrence. The term has historically described recurrent unwanted and painful erections in men with sickle cell disease (SCD) (Serjeant, 1985). Patients typically awaken with an erection that persists for several hours. Unfortunately, males with SCD may experience stuttering priapism from childhood; in these patients the pattern of stuttering may increase in frequency and duration, leading up to a full episode of unrelenting ischemic priapism. Unfortunately, any patient who has experienced an episode of ischemic priapism is also at risk for stuttering priapism.

Nonischemic Priapism (Arterial, High-Flow)

Nonischemic priapism is a persistent erection caused by unregulated cavernous arterial inflow. Typically, the corpora are tumescent but not rigid and the penis is not painful. A history of blunt trauma to the penis or an iatrogenic needle injury is common. Whatever the mechanism of injury, the result is a disruption of the cavernous arterial anatomy creating an arteriolar-sinusoidal fistula. **The cavernous environment does not become ischemic and cavernous blood gases do**

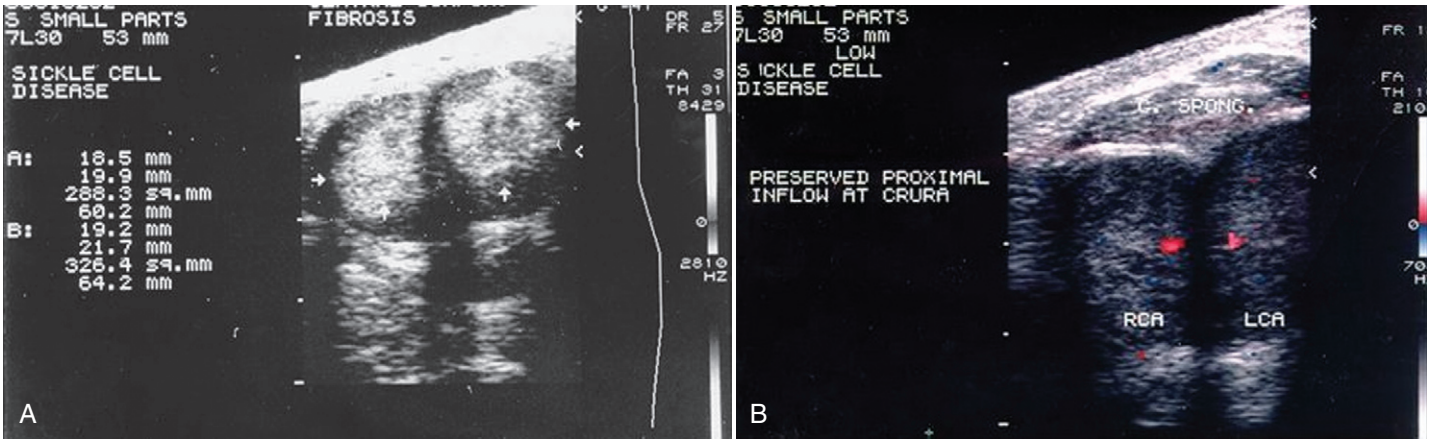

Figure 25–1. **A,** Transverse gray-scale ultrasound image of pendulous penis in a 30-year-old sickle cell disease patient, with history of multiple episodes of priapism, shows hyperechoic corporal fibrosis replacing normal tissues *(arrows)*. **B,** Color duplex Doppler in same patient following intracavernous injection of alprostadil. The right and left (RCA, LCA) cavernous arteries show preservation of blood flow only at the base of the penis.

not show hypoxia, hypercarbia, or acidosis. This type of priapism, once properly diagnosed, does not require emergent intervention. Beyond the acute trauma, patients do not complain of pain. Normal erectile function has been reported after recovery from the initial event, despite persistence of nonsexual partial erection.

PRIAPISM: HISTORICAL PERSPECTIVES

The term *priapism* has its origin in reference to the Greek god Priapus, who was worshipped as a god of fertility and protector of horticulture. Priapus is memorialized in sculptures for his giant phallus. The first recorded account of priapism in English medical literature appears in the *Lancet* and is attributed to Tripe (1845). Historically the most commonly cited observation on this condition in North American literature is Frank Hinman Senior's landmark article describing the natural history of priapism (Hinman, 1914). Subsequently in 1960 his son Frank Hinman Jr. proposed that venous stasis, increased blood viscosity, and ischemia were responsible for priapism and emphasized that failure to correct these abnormalities in the penile environment was essentially responsible for treatment nonresponse (Hinman, 1960). Advances in our understanding of the physiology of erection and the pathophysiology of ED substantiated early hypotheses that prolonged veno-occlusion within the corporal bodies is analogous to a compartment syndrome. Hauri demonstrated the radiologic differences between veno-occlusive and arterial priapism (1983).

Frank Hinman (1914) first described "acute transitory attacks of priapism" as opposed to persistence or rapid recurrence of a single episode. The actual term of stuttering priapism is attributed to Emond and colleagues (1980) in observations of patients with SCD in a Jamaican clinic. Stuttering priapism episodes were seen to increase in frequency and length, leading to major, unrelenting occurrence of ischemic priapism. Attempts to manage SCD patients with stuttering ischemic priapism resulted in the early recommendation for hormonal suppression of nocturnal erections and stuttering with estrogen (Serjeant, 1985).

Nonischemic priapism is described far less commonly than ischemic priapism in the urologic literature. Nonischemic priapism is invariably associated with antecedent perineal or penile trauma. It was first described in the English literature by Burt (1960).

Key Points: Priapism Definitions

- Priapism is a full or partial erection that continues more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation.
- Ischemic priapism (low-flow) is a persistent erection marked by rigidity of the corpora cavernosa, with little or no cavernous arterial inflow.
- Nonischemic priapism (arterial, high-flow) is a persistent erection caused by unregulated cavernous arterial inflow. The corpora are tumescent but not rigid, and the erection is not painful.
- Stuttering priapism describes a pattern of recurrence. The term has traditionally described recurrent prolonged and painful erections in men with SCD.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY OF PRIAPISM

Etiology of Ischemic Priapism (Veno-Occlusive, Low-Flow)

Ischemic priapism accounts for the majority of cases described in the literature. The erection of ischemic priapism may begin with sexual stimulation or the administration of pharmacologic agents. Once an erection persists beyond 4 hours and is not relieved by cessation of sexual stimulation or orgasm, the physiologic phenomena of ischemic priapism have begun. Erections lasting up to 4 hours are by consensus defined as "prolonged"; manufacturers of erection-facilitating pharmacotherapies (oral, injectable, and intraurethral) recommend that the patient seek emergent medical consultation for prolonged erection.

Population-based studies estimate cases per 100,000 person-years (the number of patients with a first episode of priapism divided by the accumulated amount of person-time in the study population). Cases per 100,000 person-years have been calculated in several countries; these data depend on recording of presentations to clinics and hospitals where cases are registered. Kulmala and colleagues (1995) calculated the cases per 100,000

person-years to be 0.34 to 0.52 from 1975-1990 in Finland; Eland and colleagues (2001) calculated the cases in the Netherlands to be 1.5/100,000 person-years; Earle and colleagues (2003) calculated 0.84/100,000 person-years in Australia from 1985-2000. These reported incidences were statistically significantly impacted by the introduction and proliferation of intracavernous vasoactive injections for the management of erectile dysfunction; in Finland during the last 3 years of the study the incidence of priapism doubled to 1.1 cases/100,000 person-years. These and other reports on the epidemiology and etiology of priapism are also greatly influenced by the prevalence of SCD in the populations described. **The life-time probability of a man with SCD developing ischemic priapism ranges from 29% to 42%** (Emond, 1980).

In 1986 Pohl and colleagues reported on 230 cases. The etiology of priapism was identified as idiopathic in the majority, and 21% of cases were associated with alcohol or drug use/abuse, 12% with perineal trauma, and 11% with SCD (Pohl, 1986). Although SCD is a predominant etiology of veno-occlusive priapism cases in the literature, there is a wide variety of reported associations from urinary retention to insect bites (Hoover, 2004). Priapism has even been reported following spider bites and envenomation from the "Brazilian banana spider," *Phoneutria nigriventer* (Andrade, 2008; Villanova, 2009). The genus *Phoneutria* (Greek for murderess) has eight species. *P. nigriventer* is known to hide in dark and moist places, wander the jungle floor, and stowaway within banana shipments. *P. nigriventer* is blamed for most cases of envenomation in Brazil; the venom contains a neurotoxin that has calcium channel blocking properties, inhibits glutamate release, and inhibits calcium reuptake and glutamate reuptake. Bites can cause intense pain, loss of muscle control—paralysis, breathing problems—asphyxiation, and priapism (www.wikipedia.org). Two peptides isolated from the venom of *P. nigriventer* have been directly linked with the induction of persistent and painful erections in mammals (Tx2-5 and TX2-6). The protein has been named *eretina* and has been shown to have highly specific interference at the molecular level with nitric oxide pathway (NO). Penile erection has been induced in vivo with eretina by direct intraperitoneal injection with a minimum effective dosage of 0.006 mcg/kg (Andrade, 2008).

Hematologic dyscrasias are a major risk factor for ischemic priapism. Priapism has been described as a complication of SCD, thalasssemia, hemoglobin Olmsted, and thrombophilia (Burnett, 2005). **Thrombotic disease states have also been cited as precipitants of ischemic priapism:** asplenism, erythropoietin use, hemodialysis with heparin use, and cessation of coumadin therapy. Intracavernous heparin given as a therapy for priapism due to rebound hypercoagulable states has actually worsened the condition (Fassbinder et al, 1976; Bschieipfer, 2001). **Priapism may occur in patients with excessive white blood cell counts.** The incidence of priapism in adult male patients with leukemia is 1% to 5% (Chang et al, 2003). Hyperleukocystosis causes priapism in these patients; it is believed that mechanical pressure on abdominal veins secondary to splenomegaly causes congestion of cavernous outflow and sludging of leukemic cells within the corpora cavernosa. When priapism presents in the oncology setting, evaluation and management of the predisposing condition must accompany interventions directed at the penis. In hematologic malignancies, leukaphresis and cytotoxic therapy (hydroxurea, ctosine arabinoside) may reduce the numbers of circulating white blood cells (Ponniah et al, 2004; Manuel et al, 2007). **Priapism secondary to metastatic infiltrating solid lesions rather than leukemoid reaction is extremely rare.** In most case reports of metastatic priapism, the primary malignancy is genitourinary (prostate and bladder). Metastatic infiltration of the penis may proceed with solid replacement or focal deposits within the corpora cavernosa, glans, and corpus spongiosum. Theoretically, metastatic deposits within the corpora could obstruct venous outflow resulting in ischemic priapism. Depending on the status of the patient, metastatic lesions may be managed expectantly, with partial or total penectomy, chemotherapy, or irradiation. These cases are too rarely and poorly described to define best practice recommendations (Robey, 1984; Chan, 1998; Guvel, 2003; Celma-Domenech, 2008) (Table 25–1).

Sickle Cell Disease

Blood dyscrasias are a risk factor for ischemic priapism. **SCD priapism has traditionally been ascribed to stagnation of**

Table 25–1.
Etiologies of Priapism

α-Adrenergic Receptor Antagonists
Prazosin, terazosin, doxazosin, tamsulosin

Antianxiety Agents
Hydroxyzine

Anticoagulants
Heparin, warfarin

Antidepressants and Antipsychotics
Trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine, resperidone, olazapine, chlorpromazine, thoridazine, phenothaizines

Antihypertensives
Hydralazine, guanethidine, propanolol

Drugs (Recreational)
Alcohol, cocaine (intranasal and topical), crack cocaine, marijuana

Genitourinary
Straddle injury, coital injury, pelvic trauma, kick to penis/perineum, arteriovenous or arteriocavernous bypass surgery, urinary retention

Hematologic Dyscrasias
Sickle cell disease, thalassemia, granulocytic leukemia, myeloid leukemia, lymphocytic leukemia, multiple myeloma, haemoglobin Olmsted variant, fat emboli associated with hyperalimentation, hemodialysis, glucose 6-phosphate dehydrogenase deficiency

Hormones
Gonadotropin-releasing hormone, testosterone

Infectious (Toxin Mediated)
Scorpion sting, spider bite, rabies, malaria

Metabolic
Amyloidosis, Fabry disease, gout

Neoplastic (Metastatic or Regional Infiltration)
Prostate, urethra, testis, bladder, rectal, lung, kidney

Neurogenic
Syphilis, spinal cord injury, cauda equina compression, autonomic neuropathy, lumbar disk herniation, spinal stenosis, cerebral vascular accident, brain tumor, spinal anesthesia, cauda equina syndrome

Vasoactive Erectile Agents
Papaverine, phentolamine, prostaglandin E_1, oral phosphodiesterase type 5 inhibitors, combination intracavernous therapy

Modified from Lue TF. Physiology of penile erection and pathophysiology of erectile dysfunction and priapism. In: Walsh PC, Retik AB, Vaughan ED, et al, editors. Campbell's urology. Philadelphia: WB Saunders; 2002. p. 1610–96.

blood within the sinusoids of the corpora cavernosa during physiologic erection, secondary to obstruction of venous outflow by sickled erythrocytes (Lue, 2002). Nelson and Winters described a series of cases in which SCD was the primary etiology of ischemic priapism in 23% of adults and 63% of children (Nelson, 1977). **Sickle cell hemoglobinopathy accounts for at least a third of all cases of priapism,** and indeed prevalence of ischemic priapism will vary significantly with the population of males in a community with SCD. **From** Emond and colleagues' 1980 **observational study comes the most commonly quoted incidence: Among 104 men attending an outpatient sickle cell clinic in Kingston, Jamaica the incidence of priapism in men with homozygous sickle cell (SS) disease was 42%** (Emond, 1980). In a U.S. clinical series, Tarry and Duckett (1987) found that 6.4% of male children in an outpatient sickle cell clinic had history of priapism (Tarry, 1987). Adeyoju and colleagues (2002), in an international multicenter observational study of SCD, mailed or interviewed 130 patients attending SCD clinics in the United Kingdom and Nigeria. Respondents ranged in age from 4 to 66 years old with the mean age of 25. The authors cited mean age of onset of priapism as 15 years, with 75% of patients having their first episode before age 20 and rare first-time presentations by the third decade of life. In the questionnaires a clear distinction was made between acute severe prolonged priapism lasting longer than 24 hours requiring emergency attention and stuttering recurrent priapism of shorter and self-limiting duration. In this population the incidence of acute priapism was 35%; of these patients 72% gave a history of stuttering. The median frequency of occurrence of stuttering priapism was three times per month; the median duration of each espisode was 1.2 hours, with the longest being 8 hours. Precipitating events reported from greatest to least were sexual arousal/intercourse, fever, sleep, cold weather, and dehydration. Self-administered regimens were analgesics, drinking water, and exercise. Twenty-one percent of patients reporting history of priapism also reported erectile dysfunction. Only 7% of young men who had not experienced priapism were even aware that priapism was a potential complication of their SCD. On the basis of the World Health Organization global prevalence map of SCD, Aliyu (2008) estimates that 20 to 25 million individuals worldwide have homozygous SCD: 12 to 15 million in sub-Saharan Africa, 5 to 10 million in India, and 3 million in other world regions. Aliyu (2008) also found that 70,000 patients with SCD live in the United States.

The sickle cell genetic mutation is the result of a single amino acid substitution in the beta-globin subunit of haemoglobin. The clinical features are seen in homozygous SCD patients: chronic hemolysis, vascular occlusion, tissue ischemia, and end-organ damage. HbS polymerizes when deoxygenated, injuring the sickle erythrocyte, activating a cascade of hemolysis and vaso-occlusion. Membrane damage results in dense sickling of red cells, causing adhesive interactions among sickle cells, endothelial cells, and leukocytes. Hemolysis releases hemoglobin into the plasma. Free Hbg reacts with nitric oxide (NO) to produce methemoglobin and nitrate. This is a scavenging reaction; the vasodilator NO is oxidized to inert nitrate. Sickled erythrocytes release arginase-I into blood plasma, which converts L-arginine into ornithine, effectively removing substrate for NO synthesis. Oxidant radicals further reduce NO bioavailability. The combined effects of NO scavenging and arginine catabolism result in a state of NO resistance and insufficiency termed *hemolysis-associated endothelial dysfunction* (Morris, 2005; Rother, 2005; Kato, 2007; Aliyu, 2008).

Contemporary science implicates hemolysis and reduced nitric oxide in the pathogenesis of pulmonary hypertension, leg ulcers, priapism, and stroke in SCD patients. Increased blood viscosity is believed to be responsible for painful crises, osteonecrosis, and acute chest syndrome. SCD patients with priapism have a fivefold greater risk of developing pulmonary hypertension. SCD priapism is also associated with reduced hemoglobin levels and increased hemolytic markers: reticulocyte count, bilirubin, lactate dehydrogenase, and aspartate aminotransferase (Kato, 2006). Cerebral vascular accidents are more frequent, close to episodes of full-blown priapism; the ASPEN syndrome (priapism, exchange transfusion, and neurologic events) describes cerebral vascular accidents in SCD patients who have received exchange transfusions (Siegel, 1993; Merritt, 2006). Sickle cell trait is considered a benign condition; a few complications have been associated with extreme physical exertions. There have been case reports of sickle cell trait as the predisposing factor to ischemic priapism (Larocque, 1974; Birnbaum, 2008).

Iatrogenic Priapism: Intracavernous Injections

Prolonged erection is more commonly reported than is priapism, following therapeutic or diagnostic injection of intracavernous vasoactive medications (Broderick, 2002). Despite the introduction of effective oral medications for ED in 1998, ICI remains an important therapeutic option for men with severe ED failing a phosphodiesterase type-5 inhibitor or for men who cannot take PDE-5 inhibitors because they require or carry nitrates. In many communities patients receiving intracavernous medications for ED will outnumber patients with SCD. **Priapism following intracavernous injection (ICI) is a problem all urologists will encounter and must be prepared to manage.** In a review of worldwide reports on intracavernous injection (ICI) programs, Junemann and colleagues (1990) noted that diagnostic injection resulted in 5.3% of men getting ischemic priapism and 0.4% of men reported priapism after injecting at home (Junemann, 1990). In papaverine-based ICI programs, reports of prolonged erections and priapism are poorly distinguished and range from 0% to 35% (Broderick, 2002). In worldwide clinical trials of the Alprostadil Study Group, prolonged erection (defined as 4 to 6 hours) was 5%, and priapism (>6 hours) was described in 1% of subjects (Porst, 1996). In papaverine/phentolamine/alprostadil ICI programs prolonged erections have been reported in 5% to 35% of patients (Broderick, 2002).

Iatrogentic Priapism: Oral Phosphodiesterase Type 5 Inhibitors

All PDE5 inhibitors have similar side effects related directly to their mode of action, tissue content of substrate, and pharmacologic selectivity for type 5 inhibition versus other phosphodiesterase enzymes. Those side effects include headache, flushing, dyspepsia, rhinitis, light sensitivity, and myalgia. Morales and colleagues (1998) analyzed data from 4274 men who received double-blind treatment with sildenafil or placebo for up to 6 months and 2199 who received long-term open-label sildenafil for up to 1 year (Morales, 1998). No cases of priapism (erection lasting >4 hours) were reported. No cases of priapism were reported by Montorsi and colleagues (2004) in a multicenter, open-label, 24-month extension of 8- or 12-week double-blind, placebo-controlled studies assessing the long-term efficacy, safety, and tolerability of tadalafil in 1173 men with ED (Montorsi, 2004). Nonetheless, the **INDICATION and USAGE section of the U.S. Food and Drug Administration (FDA)-approved product labeling**

for PDE type 5 inhibitors (USPI) does contain this warning: **There have been rare reports of prolonged erection greater than 4 hours and priapism (painful erections >6 hours duration) for this class of compounds.** Both the USPI and European Summary of Product Characteristics label information contain warning or precautionary language about the use of these agents in men who have conditions predisposing them to priapism. Tadalafil has recently been approved in many regions of the world for daily dosing in the management of ED and is currently being studied for use in the management of symptoms due to benign prostatic hypertrophy. Tadalafil 5-mg daily dosing caused no priapism in a phase II clinical study of 281 men with history of lower urinary tract symptoms secondary to benign prostatic hyperplasia for 6 weeks, followed by dosage escalation to 20 mg once daily for 6 weeks (McVary, 2007).

From 1999-2007 there have been at least nine case-based reports of oral phosphodiesterase type 5 inhibitor dosing and adult priapism and at least one pediatric case: Aoyagi (1999), Sur (2000), Kassim (2000), Goldmeier (2002), McMahon (2003), Wilt (2004), Gallati (2005), King (2005), Kumar (2005), and Wills (2007). **The majority of cases reports detailing priapism following a PDE type 5 inhibitor reveal histories of men with increased risk for priapism: SCD, spinal cord injury, men who used PDE5 inhibitor recreationally, men who used PDE5 inhibitor in combination with intracavernous injection, men with history of penile trauma, men on psychotropic medications, and men abusing narcotics.** Wills (2007) described a 19-month-old male child weighing 10 kg who accidentally ingested up to 6 tablets of sildenafil 50 mg. The child presented with persistent sinus tachycardia and partial erection for 24 hours; the authors presume this was a high-flow priapism (HFP) because the shaft was neither completely rigid nor painful. Erection in the child subsided spontaneously after overnight intravenous hydration and observation.

Key Points: Ischemic Priapism as a Complication of Erectile Dysfunction Therapy

- Prolonged erection is more commonly reported than is priapism, following therapeutic or diagnostic injection of intracavernous vasoactive medications.
- In worldwide clinical trials of alprostadil, prolonged erection (defined as 4 to 6 hours) occurred in 5% of administrations and priapism (>6 hours) in 1%.
- In clinical practice, intracavernous injection of trimix (papaverine/phentolamine/alprostadil) results in prolonged erections in 5% to 35% of administrations.
- Few case reports have documented priapism following a PDE type 5 inhibitor therapy. These reports suggest men were at increased risk for priapism: SCD, spinal cord injury, men who used PDE5 inhibitor recreationally, men who used a PDE type 5 inhibitor in combination with intracavernous injection, men with a history of penile trauma, men on psychotropic medications, and men abusing narcotics.

Etiology of Stuttering (Intermittent) Priapism

Stuttering (intermittent) priapism describes a pattern of recurrent priapism. The term has traditionally been used to describe recurrent unwanted and painful erections in men with SCD. **Patients typically awaken with an erection that persists up to 4 hours and becomes progressively painful secondary to ischemia. SCD patients may experience stuttering priapism from childhood. Any patient who has experienced ischemic priapism is at risk for stuttering priapism. Patients with stuttering priapism will experience repeated painful intermittent attacks up to several hours before remission.** Affected young men suffer embarrassment, sleep deprivation, and performance anxiety with sexual partners (Chow, 2008). In a study of 130 patients with SCD, Adeyoju and colleagues (2002) reported that 46 (35%) had a history of priapism and, of these, 33 (72%) had a history of stuttering priapism. In 75% of patients the first episode of stuttering occurred before the age of 20. Two thirds of males presenting with SCD ischemic priapism will describe prior stuttering attacks (De Jesus, 2009). **Commonly reported precipitants of full-blown SCD priapism are stuttering nocturnal/early morning erections, dehydration, fever, and exposure to cold.**

Etiology and Pathophysiology of Nonischemic (Arterial, High-Flow) Priapism

HFP is a persistent erection caused by unregulated cavernous arterial inflow. The epidemiologic data on nonischemic priapism is almost exclusively derived from small case series or individual case reports**. Nonischemic priapism is much rarer than ischemic priapism, and the etiology is largely attributed to trauma. Forces may be blunt or penetrating, resulting in laceration of the cavernous artery or one of its branches within the corpora. The etiology most commonly reported is a straddle injury to the crura. Other mechanisms include coital trauma, kicks to the penis or perineum, pelvic fractures, birth canal trauma to the newborn male, needle lacerations, complications of penile diagnostics, and vascular erosions complicating metastatic infiltration of the corpora** (Witt, 1990; Brock, 1993; Dubocq, 1998; Burgu, 2007; De Jesus, 2009). Although accidential blunt trauma is the most common etiology, **HFP has been described following iatrogenic injury: cold-knife urethrotomy, Nesbitt corporoplasty, and deep dorsal vein arterialization** (Wolf, 1992; Liguori, 2005). Any mechanism that lacerates a cavernous artery or arteriole can produce unregulated pooling of blood in sinusoidal space with consequent erection. Nonischemic priapism is typically delayed in onset compared with the episode of blunt trauma (Ricciardi, 1993). Sustained partial erection may develop 24 hours following perineal or penile blunt trauma. It is believed that the hemodynamics of a nocturnal erection disrupts the clot and the damaged artery/arteriole ruptures; the unregulated arterial inflow creates a sinusoidal fistula. As healing progresses with clearing of clot and necrotic smooth muscle tissue, the fistula forms a pseudocapsule. **Formation of a pseudocapsule at the site of fistula may take several weeks to months.**

Contemporary reports suggest that HFP may have a unique subvariety. **Several authors have noted that following either aggressive medical management of ischemic priapism or surgical shunting, priapism may rapidly recur with conversion from ischemia to high flow.** HFP has been reported after aspiration and injection of α-adrenergics in the

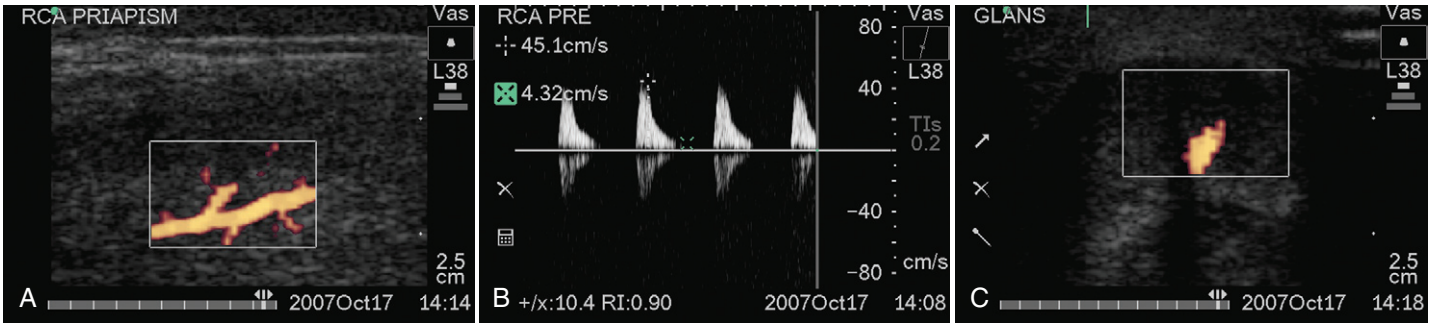

Figure 25–2. **A,** Color duplex Doppler ultrasound, showing right cavernous arterial inflow (RCA). The patient had a 30-hour ischemic priapism reversed with a Winter shunt. He developed a persistent partial erection, converting from ischemia to high-flow priapism. **B,** Peak systolic velocity in right cavernous artery is 45 cm/sec. **C,** Arterial sinusoidal fistula has formed at the site of the previous Winter shunt, as shown in this transverse color Doppler image of the glans penis.

management of ischemic priapism (McMahon, 2002; Rodriguez, 2006; Bertolotto, 2009). Color Doppler ultrasound has shown formation of an arteriolar-sinusoidal fistula at the site of intervention (needle laceration or shunt site) (Fig. 25–2A to C). On rare occasion following reversal of ischemic priapism, a new high-flow hemodynamic state of the cavernous arteries occurs with no evidence of fistula. **This presentation of HFP should be suspected in cases where rapid recurrence, persistence of erection with partial penile rigidity, or stuttering priapism not associated with pain is evident.** Nonfistula type of arterial priapism is the result of dysregulation of cavernous inflows. Nonfistula arterial priapism is a rare complication following management ischemic priapism (Seftel, 1998; Cruz-Guerra, 2004; Wallace, 2009). Penile tenderness to palpation is easily confused with the ongoing ache of persistent ischemia. Soft tissue edema and ecchymosis render the physical examination equivocal after medical and surgical maneuvers to alleviate priapism. **Dysregulated arterial inflows with or without a fistula can best be distinguished from persistent ischemic priapism by color Doppler ultrasound.**

Key Points: High-Flow Priapism

- Nonischemic priapism is much rarer than ischemic priapism.
- HFP results from laceration or disruption of a cavernous artery or arteriole.
- The most common cause is a straddle injury to the crura.
- Other mechanisms include coital trauma, kicks to the penis or perineum, pelvic fractures, birth canal trauma to the newborn male, needle lacerations, complications of penile diagnostics, and vascular erosions complicating metastatic infiltration of the corpora.
- HFP has been described following iatrogenic trauma: cold-knife urethrotomy, corporoplasty, and penile revascularization procedures.

Priapism in Children

Priapism in children and adolescents is most commonly related to SCD. The literature suggests that the incidence of priapism in pediatric sickle cell clinics is 2% to 6% (Tarry and Duckett, 1987; De Jesus, 2009). The majority of SCD priapism is ischemic. In the newborn period, fetal hemoglobin predominates, not hemoglobin S (Burgu, 2007). SCD phenotypes related to ischemic or occlusive crises are unlikely to be evident while fetal hemoglobin persists. Newborn priapism is an extremely rare phenomenon with only limited case reports and rare application of contemporary diagnostic modalities. Erection is frequently elicited in males during the newborn period. In newborn males simple tactile stimulation such as diaper changing, bathing, and urethral catheterization may result in erection; the erection quickly subsides following cessation of stimuli. Fewer than 20 cases of newborn priapism have been reported in the literature; rarely has etiology been defined: polycythemia, blood transfusion, and birth canal trauma (Amlie, 1977; Leal, 1978; Shapiro, 1979; Walker, 1997). The majority of cases have been conservatively managed with spontaneous resolution reported from hours to days. Minimally invasive diagnostics (color Doppler ultrasound) should be performed (Pietras, 1979; Meijer, 2003). In children who develop priapism following straddle trauma, every effort should be made to localize the arteriolar-sinusoidal fistula. Hatzichristou and colleagues (2002) reported that identification of the fistula by Doppler ultrasound coupled with direct manual compression softens the high-flow erection and may speed spontaneous resolution. They suggested that this noninvasive therapy likely works in children and not adults because the perineum has considerably less subcutaneous fat and crural bodies are more easily compressed (Hatzichristou, 2002).

MOLECULAR BASIS OF ISCHEMIC AND STUTTERING PRIAPISM

Advances in our understanding of the molecular basis of priapism have drawn significantly from both in vitro and in vivo experimental studies using animal models. Data on the true inciting mechanisms involved in ischemic priapism are emerging. **Ischemic priapism consists of an imbalance of vasoconstrictive and vasorelaxatory mechanisms predisposing the penis to hypoxia and acidosis. In-vitro studies have demonstrated that when corporal smooth muscle strips and cultured corporal smooth muscle cells are exposed to hypoxic conditions, α-adrenergic stimulation fails to induce corporal smooth muscle contraction** (Broderick, 1994; Saenz de Tejada, 1997; Muneer, 2005). Extended periods of severe anoxia significantly impair corporal smooth muscle contractility and cause significant apoptosis of smooth muscle cells and, ultimately, fibrosis of the corpora cavernosa.

In experimental animal models of ischemic priapism, lipid peroxidation, an indicator of injury induced by reactive oxygen

species (ROS), and increased hemo-oxygenase expression occurs in the penis during and after ischemic priapism (Munarriz, 2003; Jin, 2008). Additional pathophysiologic mechanisms involved in the progression of ischemia-induced fibrosis are the upregulation of hypoxia-induced growth factors. TGF-β is a cytokine that is vital to tissue repair. However, excess amounts may induce tissue damage and scarring. Upregulation of TGF-β occurs during hypoxia and in response to oxidative stress (Moreland, 1995; Jin, 2008). It is hypothesized that TGF-β may be involved in the progression of the corporal smooth muscle to fibrosis (Bivalacqua, 2000; Jeong, 2004).

Transgenic mouse models of SCD manifest priapism (Beuzard, 1996; Bivalacqua, 2009). There have been two major discoveries in elucidation of the molecular mechanism of ischemic priapism. Mi and colleagues (2008) have shown that transgenic sickle cell mice corpora cavernosa have enhanced smooth muscle relaxation to electrical field stimulation. Transgenic sickle cell mice and mice lacking endothelial nitric oxide synthase (eNOS) gene expression display supraphysiologic erections and spontaneously phasic priapic activity in vivo (Bivalacqua, 2006, 2007).

Endothelial cells actively regulate basal vascular tone and vascular reactivity, by responding to mechanical forces and neurohumoral mediators with the release of a variety of relaxing and contracting factors. In the penis the vascular endothelium is a source of vaso-relaxing factors such as NO and adenosine, as well as vaso-constrictor factors such as RhoA/Rho-kinase. Recent evidence suggests that in states of priapism there may be aberrant NO and adenosine signaling, thus identifying a potential role for NO/cGMP, as well as adenosine and RhoA/Rho-kinase signaling in the pathophysiology of ischemic priapism (Champion, 2005; Mi, 2008; Bivalacqua, 2009).

eNOS–/– mutant mice have an exaggerated erectile response to cavernous nerve stimulation and have phenotypic changes in erectile function consistent with priapism (Champion, 2005; Bivalacqua, 2006). Mice lacking the eNOS gene manifest a priapism phenotype through mechanisms involving defective phosphodiesterase type 5 (PDE5) regulatory function in the penis, resulting from altered endothelial nitric oxide/cGMP signaling in the organ (Lin, 2003; Bivalacqua, 2006). Supporting this hypothesis, PDE5 expression is significantly reduced in corpora cavernosa smooth muscle cells (CCSMC) grown under anoxic and hypoxic cell culture conditions (Lin, 2003). **In the context of molecular dysregulation, the cyclic nucleotide cGMP is produced in low steady-state amounts under the influence of priapism-related destruction of the vascular endothelium and thus reduced endothelial nitric oxide activity; this situation thereby downregulates the set point of PDE type 5 function, secondary to altered cGMP-dependent feedback control mechanisms** (Champion, 2005; Bivalacqua, 2006; Burnett, 2007). **Under these conditions, when NO is neuronally produced in response to an erectogenic stimulus or with nocturnal erections, cGMP production surges in a manner that leads to excessive erectile tissue relaxation because of basally insufficient PDE type 5 enzyme to degrade the cyclic nucleotide. Additionally, reduced Rho-kinase activity (contractile mediator) may contribute to the susceptibility of corporal tissue to excessive relaxation via two distinct molecular mechanisms. These two distinct molecular mechanisms may act in concert to promote stuttering ischemic priapism: enhanced vaso-relaxation by uninhibited cGMP and diminished contractile effects of Rho-kinase.** Transgenic sickle cell mice also have significant reductions in penile NO/cGMP signaling leading to deficient PDE5 expression/activity, as well as reduced RhoA/Rho-kinase expression from which they manifest enhanced erectile responses and recurrent priapism (Champion, 2005). Another potential cause of enhanced corporal smooth muscle relaxation in SCD-associated priapism is elevated penile adenosine levels, thus causing the corpora cavernosa to be in a chronically vasodilated state (Mi, 2008). **Taken together, these data suggest that ischemic priapism and most importantly stuttering priapism is a direct result of NO imbalance resulting in aberrant molecular signaling, PDE5 dysregulation, adenosine overproduction, and reductions in Rho-kinase activity, translating into enhanced corporal smooth muscle relaxation and inhibition of vasoconstriction in the penis.**

Key Points: Sickle Cell Disease and Priapism

- Sickle cell hemoglobinopathy accounts for at least a third of all cases of ischemic priapism.
- The sickle cell genetic mutation is the result of a single amino acid substitution in the β-globin subunit of hemoglobin.
- Clinical features are seen in homozygous SCD patients: chronic hemolysis, vascular occlusion, tissue ischemia, and end-organ damage.
- Hemolysis and reduced nitric oxide are central in the pathogenesis of pulmonary hypertension, leg ulcers, priapism, and stroke in SCD patients.
- Increased blood viscosity is responsible for painful crises, osteonecrosis, and acute chest syndrome.
- SCD patients may experience stuttering priapism from childhood.
- SCD patients with stuttering priapism will experience repeated painful intermittent attacks up to several hours before remission.
- Stuttering priapism in SCD is the result of molecular dysregulation with enhanced corporal smooth muscle vaso-relaxing forces and inhibition of vasocontractile forces in the penis.

EVALUATION AND DIAGNOSIS OF PRIAPISM

History

In order to initiate appropriate management, the physician must determine whether the underlying priapism hemodynamics are ischemic or nonischemic. Emergency management of ischemic priapism is recommended. **Ischemia should be suspected when** the patient has progressive penile pain, associated with the duration of erection; has used a known drug associated with priapism; has SCD or another blood dyscrasia; or has a known neurologic condition, especially those affecting the spinal cord. Stuttering priapism history is one of recurrent episodes of prolonged erections, usually nonresolving morning erections. **Nonischemic priapism should be suspected when** there is no pain and the erection duration has not been accompanied by progressive discomfort. There is a history of straddle injury, coital trauma, blunt trauma to the penis or perineum, penile injection, penile surgery or a diagnostic procedure of the pelvic and penile vessels. The onset of post-traumatic HFP in adults and children

may be delayed by hours to several days following the initial injury (Table 25–2).

Physical Examination

Inspection and palpation of the penis is recommended to determine the extent and degree of tumescence and rigidity; the involvement of the cavernous bodies; the presence of pain; and the evidence of trauma to the perineum. In ischemic priapism the corporal bodies will be completely rigid; the glans penis and corpus spongiosum are not. Although malignancies rarely cause priapism, examination of the abdomen, testicles, perineum, rectum, and prostate may help identify a cancer primary. Malignant infiltration of the penis causes indurated nodules within or replacing corporal tissue. The subtle differences in the penile examination may be apparent to the experienced urologist but can be overlooked by emergency personnel on initial evaluation (Fig. 25–3A and B). If physical examination reveals the penis is nontender, tumesced, or partially erect, nonischemic priapism is suspected. In nonischemic priapism the corpora will be tumescent but not completely rigid. In children and adults with high-flow priapism, depending on the location of trauma and time since the traumatic event, there may be residual bruising at the perineum from straddle injury (Table 25–3).

Laboratory Testing

Evaluation should include a CBC, WBC with blood cell differential, platelet count, and coagulation profile to assess anemia, rule out infection, detect hematologic abnormalities, and ensure that the patient can safely tolerate surgical interventions should initial medical management fail. **In African-Americans a sickle cell prep and hemoglobin electrophoresis should be requested.** Other hematologic abnormalities may cause priapism and should be sought if etiology is not evident: leukemia, platelet abnormalities, and thalassemia. An elevated reticulocyte count is nonspecific and may be elevated in both priapism due to SCD and thalassemia. Urine and serum toxicology panels should be done if recreational narcotic or prescription psychoactive drugs are suspected from the history**. A corporal blood gas by aspiration is recommended in the emergency evaluation of priapism. The corporal blood aspirate differentiates ischemic from nonischemic priapism. Aspiration may be both diagnostic and therapeutic. Visual inspection of the color and consistency of an initial penile aspirate will reveal dark deoxygenated blood, with a "crankcase oil" appearance in ischemic priapism. The initial corporal apirate may be sent for blood gas testing to document pH, Po_2, and Pco_2** (Table 25–4). **Color duplex Doppler ultrasonography should be initiated if the history suggests penile/perineal**

Table 25–2.

Elements in Taking the History of Priapism

Duration of erection
Presence of pain
Previous episodes of priapism and method of treatment
Baseline erectile function
Use of any erectogenic therapies (both prescription and nutritional supplements)
Medications and recreational drugs
Sickle cell disease, hemoglobinopathies, hypercoagulable states
Trauma to the pelvis, perineum, or penis

Table 25–3.

Key Findings in Priapism

FINDINGS	ISCHEMIC PRIAPISM	NONISCHEMIC PRIAPISM
Perineal trauma	Seldom	Usually
Hematologic abnormalities	Usually	Seldom
Recent intracorporal injection	Sometimes	Sometimes
Corpora cavernosa fully rigid	Usually	Seldom
Penile pain	Usually	Seldom
Abnormal penile blood gas	Usually	Seldom
Cavernous inflow (by Doppler)	Seldom	Usually

trauma or if the corporal aspirate reveals well-oxygenated blood (Fig. 25–4A and B).

Penile Imaging

Color duplex Doppler ultrasonography (CDU) of the penis and perineum is recommended in the evaluation of priapism. CDU is an adjunct to the corporal aspirate in differentiating ischemic from nonischemic priapism. **Patients with prolonged ischemic priapism will have no blood flow in the cavernous arteries;** the return of the cavernous artery waveform will accompany successful detumescence. **Patients with nonischemic priapism have normal to high blood flow velocities** detectable in the cavernous arteries; an effort should be made to localize the characteristic blush of color emanating from the disrupted cavernous artery/arteriole (Broderick, 2002). Examination of the entire penile shaft and perineum is recommended; this can be done with the patient supine but frog legged (Fig. 25–5). **Penile arteriography should be reserved for the management of high-flow priapism, when embolization is planned; arteriography is too invasive as a diagnostic procedure to differentiate ischemic from nonischemic priapism** (Burnett, 2004). The data from penile blood gas assessments become confusing following interventions. **Color Doppler ultrasound should always be considered in the evaluation of a full or partial erection after treatments for ischemic priapism.** The differential diagnosis includes resolved ischemia with penile edema, persistent ischemia, and conversion to high-flow state. Chiou and colleagues (2009) have recommended that to accurately categorize presentations as nonischemic or ischemic, careful interpretation of color Doppler ultrasound hemodynamics must be done in conjunction with the clinical assessment. They describe eight patients with priapism following intracavernous injection (duration ≤7 hours), all of whom showed presence of cavernous arterial inflows with varied peak systolic velocities and end-diastolic velocities. They concluded that most patients with priapism following ICI (and duration <7 hours) have a hemodynamic picture of mixed arteriogenic and veno-occlusive priapism. In their series, men with idiopathic ischemic priapism longer than 20 hours showed no detectible cavernous arterial inflows.

There have recently been reports on the use of magnetic resonance imaging in priapism. Kirkam and colleagues (2008) noted that there are **three possible roles for magnetic resonance imaging (MRI)** to help in the assessment of priapism; the primary role would be in the **imaging of a well-established arteriolar-sinusoidal fistula** (Kirkham, 2008). The authors acknowledge a limitation of MRI is resolution; MRI cannot demonstrate small vessels as clearly as high-frequency Doppler sonography or angiography. The second would be in ischemic priapism

Table 25–4.

Typical Blood Gas Values

SOURCE	Po_2 (mm Hg)	Pco_2 (mm Hg)	pH
Normal arterial blood (room air)	>90	<40	7.40
Normal mixed venous blood (room air)	40	50	7.35
Ischemic priapism (first corporal aspirate)	<30	>60	<7.25

Key Points: Priapism Imaging

- Color Doppler ultrasound (CDU) is an adjunct to the corporal aspirate in differentiating ischemic from nonischemic priapism.
- CDU imaging should include corporal shaft and transperineal assessment of the crural bodies when there is a history of penile trauma or straddle injury.
- CDU should always be considered in the evaluation of a persistent or partial erection after treatments for ischemic priapism.
- Penile arteriography is too invasive as a diagnostic procedure to differentiate ischemic from nonischemic priapism.
- MRI has three possible roles: imaging of a well-established arteriolar-sinusoidal fistula, identifying corporal thrombus, and identifying corporal metastasis.

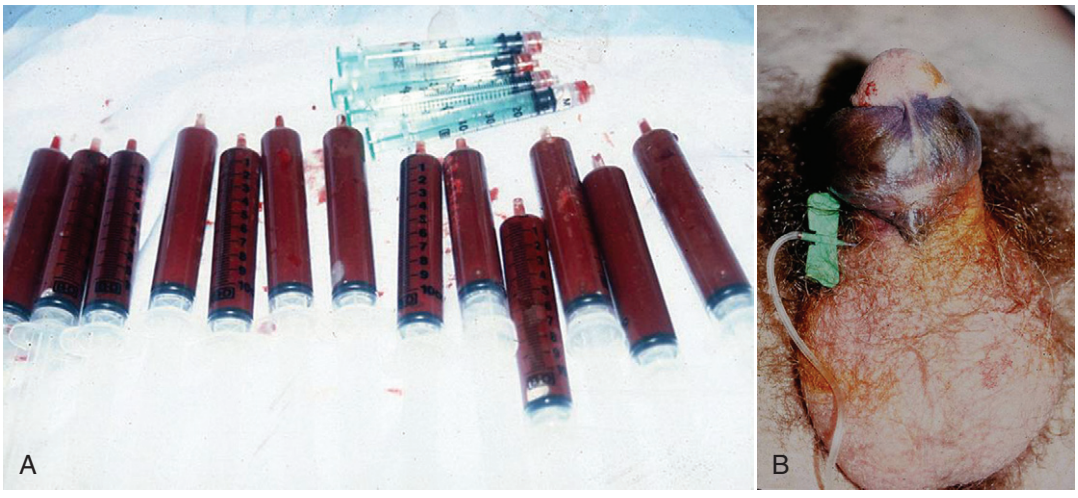

Figure 25-4. **A,** Initial corporal aspirate in ischemic priapism show dark, deoxygenated blood. Subsequent aspirations will show brighter blood as corpus cavernosum is reoxygenated by inflow. Empty syringes are from successive injections of phenylephrine. **B,** A butterfly needle for aspiration and injection should be placed at the penoscrotal junction. Initial failed efforts in the emergency room were due to distal placement of butterfly needle and failure to repeat aspirations.

to **demonstrate the presence and extent of tissue thrombus and corporal smooth muscle infarction.** Ralph (2009) used MRI in the prospective management of 50 patients with refractory ischemic priapism failing medical/surgical management from 24 to 72 hours. Patients underwent MRI to characterize the extent of smooth muscle necrosis before placement of penile prosthesis (Fig. 25–6A and B). The third role for MRI would be in the **imaging of corporal metastasis** mimicking priapism, or causing true ischemic priapism by obstruction of venous outflow.

MEDICAL TREATMENTS

Ischemic Priapism

Historically, first aid was applied by the patient or recommended by a health practitioner unfamiliar with the hemodynamics of priapism; these interventions included ejaculation, ice packs, cold baths, and cold water enemas. Each of these remedies was thought to end erection by inducing vasoconstriction. Some historical reports advised voiding and exercise. Oral sympathomimetic drugs (etilefrine, pseudoephedrine, phenylpropanolamine, and terbutaline) have been reported to effectively reverse prolonged erection (<4 hours) initiated by intracavernous injection therapies with efficacies of 28% to 36% (Lowe, 1993). Lowe and Jarow (1993) compared oral terbutaline with pseudoephedrine or placebo in 75 patients with prolonged erection induced by intracavernous injection of Alprostadil; they reported detumescence in 38% of cases following terbutaline, 28% following pseudoephedrine, and 12% following placebo. In a follow-up study Priyadarshi (2004) specifically investigated the efficacy of oral terbutaline in the management of prolonged erection following intracavernous injections (papaverine/chlorproamazine); he administered oral terbutaline 5 mg or placebo to men with persisting erection for more than 2.5 hours. Detumescence was acheieved in 42% and 15% of cases, respectively, treated with terbutaline/placebo. Terbutaline treatment was unsuccessful in 58% of cases; all of those patients responded to intracavernous injection of an α-adrenergic. In this author's experience, when diagnostic injections result in prolonged erections with duration from 2 to less than 4 hours, aspiration may not be necessary. An ultrafine needle and 1-mL syringe (phenylephrine 200 μg) may be used for single injection of α-adrenergic.

Oral agents are not recommended in the management of acute ischemic priapism (>4 hours). The recommended initial treatment of ischemic priapism is the decompression of the corpora cavernosa by aspiration. Aspiration will immediately soften the erection and relieve pain. Aspiration alone may relieve priapism in 36% of cases. The AUA Guidelines Panel (2003) advised that there were not sufficient data to conclude that aspiration followed by saline intracorporal irrigation was any more effective than aspiration alone (Montague, 2003). Subsequently, Ateyah (2005) reported that a combination of corporal blood aspiration and cold saline irrigation effectively terminated priapism in 66% of cases compared with aspiration alone (24%). Data to support the efficacy of cold saline are limited. **Aspiration should be repeated until no more dark blood can be seen coming out from the corpora and fresh bright red blood is obtained. This process leads to a marked decrease in the intracavernous pressure, relieves pain, and resuscitates the corporal environment removing anoxic, acidotic, and hypercarbic blood.** A single, large-bore, 19-gauge needle should be inserted at the peno-scrotal junction at 3 or 9 o'clock, to avoid piercing the dorsal neurovascular bundle. The surgeon should compress the penile shaft between the thumb and first digit, just below the 19-gauge needle, aspirating the shaft until it is soft. Leaving the needle in place, the shaft is permitted to refill. Compression is reapplied and aspiration repeated. These maneuvers may need to be serially repeated. Several small, empty syringes should be available (3-mL to 12-mL syringes).

Corporal aspiration, if unsuccessful, should be followed by α-adrenergic injection or irrigation. Aspiration followed by the intracavernous injection of sympathomimetic drugs is recommended by the AUA Guidelines Panel, 2003 (Montague, 2003). Sympathomimetic drugs (phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine, metaraminol) cause cavernous smooth muscle (CSM) contraction. In the laboratory, normal CSM preparations from humans, rabbits, and rodents show concentration-dependent contractions on exposure to phenylephrine, if the corporal environment is well oxygenated and has a normal pH (Broderick, 1994; Muneer, 2008). Broderick and Harkaway (1994) described time-dependent changes in the corporal environment beginning within 6 hours of persistent erection (Broderick, 1994) in humans. Animal models of

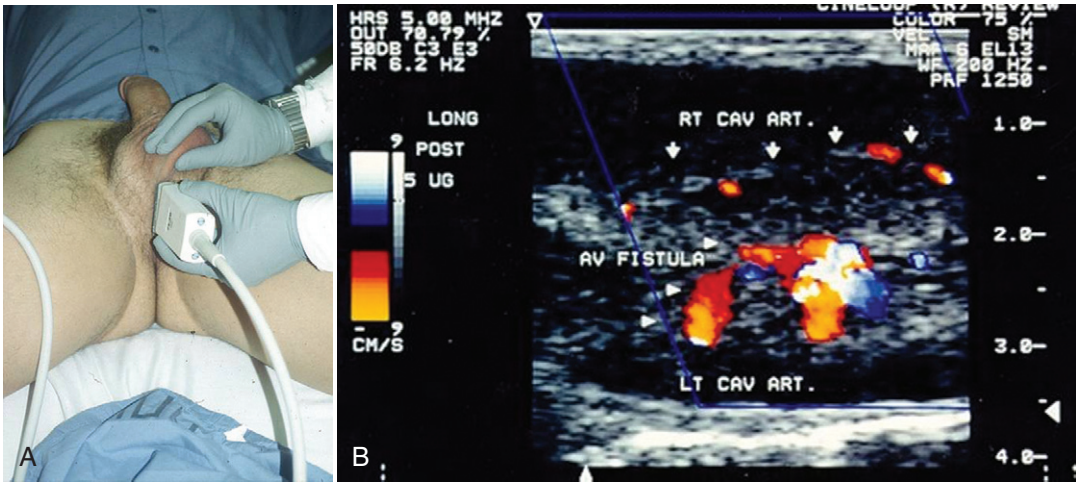

Figure 25–5. **A,** Examination of the crural bodies is required when searching for arterial sinusoidal fistula following straddle injury. **B,** Color Doppler image of arterial sinusoidal fistula of left cavernous artery.

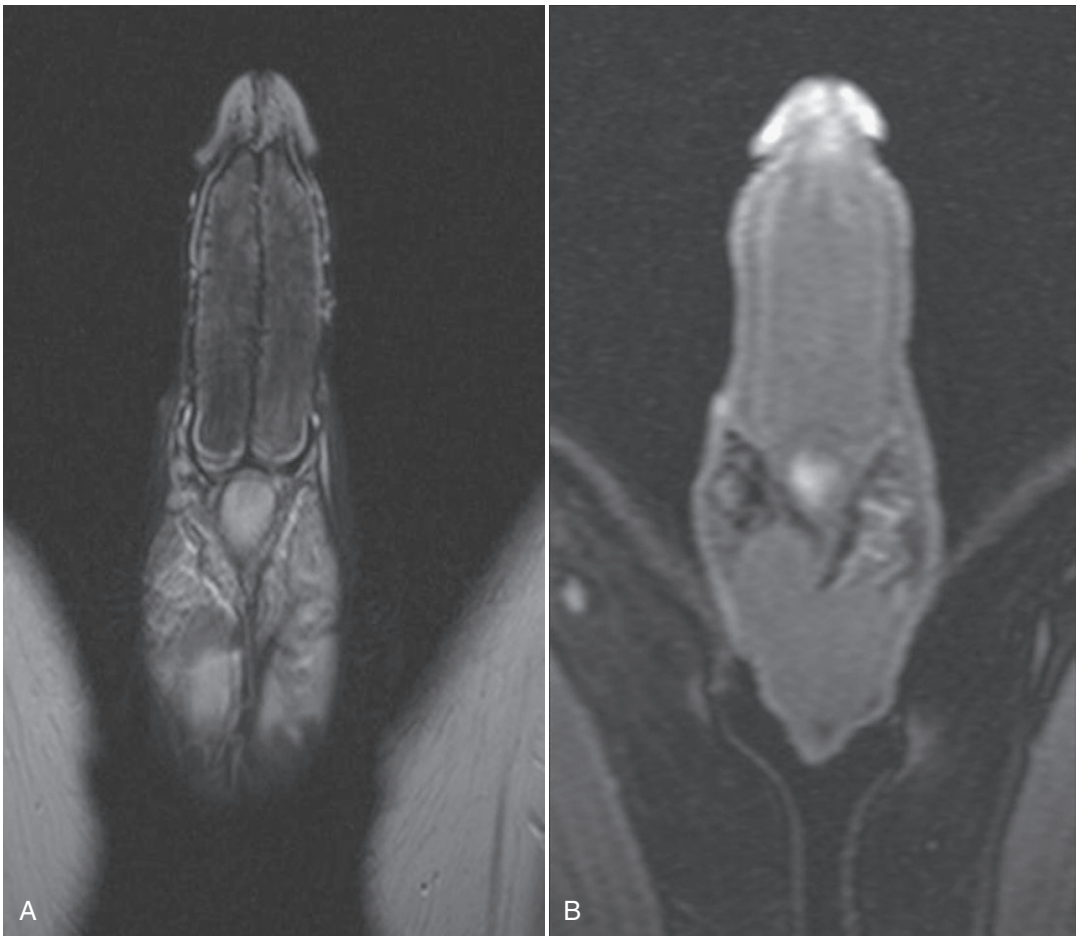

Figure 25–6. **A,** T2-weighted MRI showing cavernous body thrombosis. **B,** Same patient. There is no enhancement following gadolinium infusion. At operation, extensive smooth muscle necrosis and thrombus was found. Patient had untreated ischemic priapism lasting several days. (Courtesy of David Ralph.)

ischemic priapism have demonstrated impairment in smooth muscle contraction with progressive acidosis, hypoxia, and glucopenia (Broderick, 1994; Saenz de Tejada, 1997; Munnarriz, 2006; Muneer, 2008). Corpus cavernosum specimens from patients presenting with prolonged priapism show no contractions to high-dose phenylephrine in vitro.

Phenylephrine is a selective α_1-adrenergic receptor agonist without β-mediated ionotropic and chronotropic cardiac effects; it is the agent of choice by AUA consensus recommendation (Montague, 2003; Pryor, 2004). There are no comparative trials of sympathomimetics in the management of priapism, nor are there dosage-tolerating studies to report. Case reports vary in efficacy from 43% to 81%, with time-dependent efficacies for each agent reported. Phenylephrine is usually diluted in normal saline with a concentration of 100 to 500 μg/mL and given in 1-mL dosages every 3 to 5 minutes. Dosing should be intermittent over the course of an hour. **In this author's experience phenylephrine can be concentrated as 200 μg/mL in saline and administered intermittently as 0.5 mL to 1.0 mL, every 5 to 10 minutes to a maximum dosage of 1 mg. This will permit up to 10 separate injections of 0.5 mL (100 μg each) or 5 separate injections of 1 mL (200 μg each). Aspirate the penis between successive injections by tightly pinching the shaft at the peno-scrotal junction, just below the site of needle insertion. Aspirate until distal shaft is empty. Then inject phenylephrine, releasing the compression at the peno-scrotal junction, allowing the shaft to refill with fresh blood.** Extremes of age and preexisting cardiovascular diseases should be taken into consideration before intracavernous sympathomimetic dosing. **Serial monitoring of blood pressure and pulse should be performed during and immediately following intracavernous injection of sympathomimetic drugs. Potential side effects of intracavernous sympathomimetics include headache, dizziness, hypertension, reflex bradycardia, tachycardia, and irregular cardiac rhythms.** Davila (2008) reported subarachnoid hemorrhage in a case of SCD ischemic priapism. The patient was a 24-year-old African-American male who reported sudden and severe headache immediately following phenylephrine intracorporal dosing of 500 μg/mL repeated every 3 minutes for a total 4 mL (2000 μg = 2 mg). In 2005 in its Patient Safety News: Caution on Fatal Dosing Errors with Epinephrine (#35), the FDA reported a case of a 16-year-old boy who received 4 mL of undiluted 1:1000 epinephrine solution intracavernously to treat priapism. A 1:1,000,000 solution should have been used, so the boy received a massive overdosage; he arrested and could not be resuscitated (www.fda.gov/psn). **Whichever intracavernous sympathomimetic agent is chosen for the management of ischemic priapism, urologists are well advised to consult their pharmacies and develop clear mixing and dosing protocols for safe administration** (Fig. 25–7).

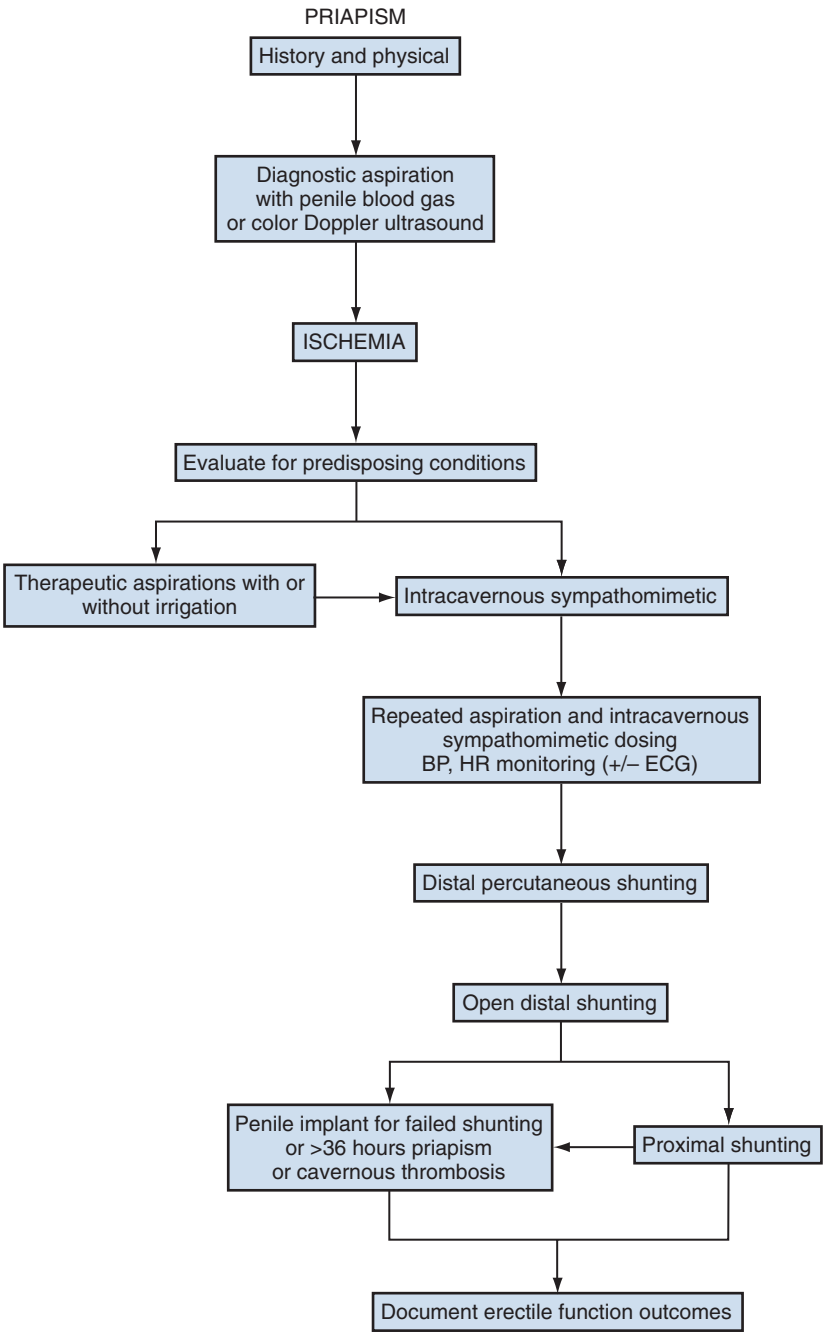

Figure 25–7. Algorithm for managing ischemic priapism.

SCD and hematologic malignancies are rare but important causes of ischemic priapism. Classically, treatment of SCD-induced ischemic priapism involved analgesics, hydration, oxygen, bicarbonate, and blood transfusion. However, **systemic therapy alone is not effective management of SCD priapism** (Rogers, 2005). A recent report suggested that blood transfusion may have no effective role in the treatment of sickle cell-induced priapism (Merritt, 2006). **Reports from hematology centers suggest high success rates using penile aspiration/injection/irrigation of intracavernous sympathomimetics for SCD priapism** (Mantadakis, 2000). Mantadakis and colleagues (2000) conducted a prospective trial for the management of children with SCD presenting with prolonged erection, ages 3 to 18 years (no placebo group). For erections lasting longer than 4 hours and less than 12 hours, emergency department interventions were local anesthetic, cavernous aspiration, and irrigation with 10 mL of a 1:1,000,000 solution of epinephrine. If detumescence lasted for 30 minutes, patients were discharged to home. They described 15 patients receiving 39 interventions, of which 37 were successful; 67% required only one aspiration and irrigation treatment. **In the management of SCD pediatric patients with stuttering priapism, several levels of escalating intervention are necessary with parental and emergency department staff education comprising the first level.** Gbadoe and colleagues (2001) described the treatment of 11 SCD patients (ages 30 months to 15 years) who presented with acute ischemic priapism or stuttering priapism. In their series of cases if the patient presented with priapism lasting less than 6 hours, aspiration and injection of 5 mg of etilefrine was given in the emergency department; for stuttering priapism, patients were

given oral etilefrine 0.5 mg/kg nightly for 1 month, or 0.25 mg/kg twice daily. Patients (parents) also administered injections at home to reverse painful erection lasting longer than 1 hour. The authors reported no significant hypertension and only one case of "agitation" attributed to daily dosing.

Key Points: Medical Management of Ischemic Priapism

- Oral therapy is not recommended for the treatment of acute ischemic priapism.
- The initial treatment of ischemic priapism is decompression by aspiration.
- Aspiration should be repeated until oxygenated blood is seen to refill the corpora.
- Aspiration should be followed by the intracavernous injection (or irrigation) of a diluted α-adrenergic drug.
- Worldwide availability of adrenergic agents varies; effective reversal of priapism has been documented with dilute injections of ephedrine, epinephrine, etilefrine, metaraminol, or phenylephrine.
- Clinicians are advised to consult their pharmacies and develop clear mixing and dosing protocols for safe administration of adrenergic solutions.
- Phenylephrine is a sympathomimetic drug with selective α_1 adrenergic receptor actions; it lacks β-mediated ionotropic and chronotropic cardiac effects. As such, if available it is the recommended agent for intracavernous management of ischemic priapism (AUA Guidelines, 2003).
- Phenylephrine should be concentrated as 200 μg/mL in normal saline and administered intracavernously as 0.5 mL to 1 mL. Lower concentrations should be used in children and adults with cardiovascular disease. Dosing and aspiration may need to be repeated. No recommendations can be made about maximum safe dosing. Hypertensive stroke has been reported as a complication of cumulative dosing of 2 mg.
- Some sympathomimetic drugs are activators of both α- and β-adrenergic receptors. Physicians should monitor patients for subjective complaints and objective findings consistent with known undesirable effects: headache, chest discomfort, acute hypertension, reflex bradycardia, tachycardia, palpitations, and cardiac arrhythmia. Patients and parents should be informed about these potential complications.
- Blood pressure monitoring is recommended if repeated sympathomimetic dosing is given. In patients with significant cardiovascular risks, electrocardiogram monitoring is recommended.
- Ischemic priapism associated with SCD requires intracavernous treatment. A hematologist may provide concurrent systemic therapies, but the best resolution rates are achieved with therapies directed at the penis.

Stuttering Priapism

Various factors need to be considered when treating stuttering priapism. **Although an episode may last less than 4 hours, increasing frequency or duration of stuttering episodes may herald a major ischemic priapism.** Multiple frequent visits to the emergency department to resolve the priapism are disruptive to the patient's life and embarrassing. If attacks follow sexual activity, patients may become sexually avoidant (Adeyoju, 2002; Chow, 2008). Safety and efficacy of various treatments are poorly characterized in the literature. The side effects of recommended medications should be understood by the patient. Patients on chronic medical therapy to decrease the frequency of stuttering episodes may significantly benefit from performing a single sympathomimetic intracorporal injection at home as part of a personal treatment algorithm (Virag, 1996; Teloken, 2005). Multiple treatment options have been described: oral and injectable α-adrenergic agonists, terbutaline, digoxin, antisickling agent hydroxacabamide, estrogens, GnRH analogues, antiandrogens, baclofen, gabapentin, and recently phophodiesterase type 5 inhibitors (Chow, 2008).

Etilefrine is an α agonist available as an oral or injectable treatment in some European countries. Maximum oral dosing is 100 mg in 24 hours (Okpala, 2002). Okpala (2002) followed 18 adults (17 SCD patients and one with sickle trait), all with history of stuttering priapism. Patients were given oral etilefrine in escalating dosages from 25 mg at bedtime to a maximum of 100 mg each day. Stuttering episodes were reduced in frequency and duration in 72%. A small series of six SCD children were followed with dosing twice daily with 0.25 mg/kg of etilefrine (Gbadoe, 2002). **The experience of multiple investigators using oral α-adrenergic dosing in the management of SCD stuttering ischemic priapism suggests that oral α-adrenergics at limited daily dosing should be considered in the management of stuttering priapism; drug therapy is typically initiated at bedtime.**

Hormonal Therapies

The primary action of systemic hormonal therapy in stuttering priapism is the suppression of the androgenic effects on penile erection. Attempts to treat stuttering priapism with hormones have exploited known regulators of male sexual function by targeting the pituitary gland (GnRH agonists), suppressing pituitary function through feedback inhibition (diethylstilbestrol), blocking androgen receptors (antiandrogens), and reducing testicular and adrenal synthesis (ketoconazole). In the only randomized placebo-controlled trial, a synthetic estrogen, diethylstilbestrol (DES), caused termination of the stuttering episodes in all patients subjected to treatment (Chinegwundoh, 2004). However, in more than 50% of patients (five of nine) priapism recurred after treatment cessation. Similar results are described by others in case reports (Gbadoe, 2002; Shamloul, 2005). Long-term estrogen therapy is not recommended due to the potential cardiovascular side effects. GnRH analogues, goserelin acetate and leuprolide acetate, have been described in case reports (Levine, 1993; Shamloul, 2005). Chronic dosing with GnRH analogues in combination with penile injection of alpha adrenergics as needed have been reported in the management of ischemic stuttering priapism (Steinberg, 1995). Discontinuation of GnRH analogues typically leads to stuttering resumption. Antiandrogens carry their actions by direct suppression of the penile androgen receptors. These agents including flutamide, bicalutamide, and chlormadinone have been able to cause considerable relief of stuttering priapism in a number of case reports; antiandrogens may have benefit to the patients over the GnRH analogues—orally administered patients have reported continued ability to have sexually stimulated erections (Costabile, 1998; Dahm, 2002; Yamashita, 2004). Rachid-Filho and colleagues (2009) have recently described the efficacy of oral finasteride in the management of sickle cell stuttering priapism. They administered

finasteride to 35 patients over 120 days in dosages that decreased monthly from 5 mg/day to 3 mg/day and then 1 mg/day in the final month. This was not a controlled trial, but careful observation of stuttering episodes was made; they found at the beginning of treatment the mean episode of stuttering priapism per patient was 22.7, and at the end of 4 months the mean episodes per patient were 2.1. The optimal effects were found at 5- and 3-mg daily dosing. Finasteride is a 5-α-reductase inhibitor approved in the United States for management of symptomatic benign prostatic hyperplasia and male pattern alopecia; it is not approved for use in stuttering ischemic priapism, and this was not a placebo-controlled trial. Six of 35 patients in this study developed painless gynecomastia. Abern and Levine (2009) used nightly dosing with oral ketoconazole and prednisone to suppress nocturnal erections as a preventive strategy for recurrent ischemic priapism; their protocol required titrating dosages and monitoring of nocturnal erections and serum testosterone levels.

Baclofen

Studies in both rats and humans suggest that baclofen inhibits penile erection and ejaculation, through GABA receptor activity. In rats, stimulation of $GABA_B$ receptors in the lumbosacral spinal cord inhibits erection (Bitran, 1988; Paredes, 1995; Vaidyanathan, 2004). Denys and colleagues (1998) reported on nine men with multiple sclerosis or spinal cord injuries who were treated for 44 months with intrathecal baclofen for muscle spasticity; eight of nine reported decreased erectile function, which reversed on cessation of baclofen. Rourke and colleagues (2002) first reported on the use of oral nightly baclofen 40 mg in the management of recurrent priapism in patients with neurologic lesions. D'Aleo and colleagues (2009) were the first to report on the use of an intrathecal pump dosing baclofen 180 μg daily for the management of skeletal muscle spasm and recurrent priapism in a patient with spinal cord injury; the patient was refractory to treatment with oral dosing of 75 mg/day but responded to a test dosage of 25 μg intrathecally. The neurologic literature generally fails to categorize these erectile events as ischemic or nonischemic. Triggering events may be tactile nonsexual stimulation causing repeated reflexogenic erections. Better characterization of these unwanted reflexogenic erections is necessary to appreciate hemodynamics, inciting events, duration, and impact on erectile function. In nonneurogenic patients baclofen daily dosing is associated with drowsiness, nausea, complaints of fatigue, and ED. Recurrent reflexogenic erections are clearly an unwanted condition associated with muscle spasticity in men with spinal cord lesions and neurologic disease, but it remains to be demonstrated that the duration and hemodynamics of such erectile events are similar to ischemic stuttering priapism in SCD.

Phophodiesterase Type 5 Inhibitors in the Management of Stuttering Priapism: a Counter-Intuitive Treatment Strategy

Bialecki and Bridges (2002) first reported on sildenafil having a paradoxical effect in controlling stuttering priapism in three patients with SCD (Bialecki, 2002). Although this proposal would immediately seem illogical on the basis of the understanding that PDE5 inhibitors exert erectogenic effects, there is a scientific basis for using these agents to treat priapism.

In a small case series, Burnett and colleagues have shown that daily sildenafil or tadalafil therapy reduces ischemic priapism episodes in men with stuttering priapism (Burnett, 2006). **When used in long-term dosing regimens unassociated with erection stimulatory conditions, PDE5 inhibitor therapy alleviates recurrent priapism episodes in men with SCD-associated priapism without affecting normal erectile capacity** (Burnett, 2006; Bivalacqua, 2009). The working theory is that surges of cGMP go unchecked because of down-regulated levels of PDE type 5; this results in stimuli like nocturnal erection, which causes unchecked corporal smooth muscle relaxation. In initial series, the short-acting PDE5 inhibitor sildenafil citrate was given in a dose of 25 mg oral daily, with escalation to 50 mg daily. Subsequently these investigators have reported on tadalafil at a dose of 5 or 10 mg oral dosage taken three times weekly. Multicenter, randomized, double-blind, placebo-controlled clinical trials are under way. PDE5 Inhibitors should be started under conditions of complete penile flaccidity, not during a stuttering episode. Efficacy is seen after a week or more of dosing.

Key Points: Medical Management of Stuttering Priapism

- The goals of managing a patient with stuttering priapism (SP) include prevention of future episodes, preservation of erectile function, and balancing the risks versus benefits of various treatment options.
- A trial of daily oral α-adrenergic may be used in the management of patients (adults and children) with SP associated with hemoglobinopathies. Dosing efficacy should be monitored for frequency and duration of stuttering episodes, blood pressure, and normal erectile capacity.
- A trial of daily oral PDE5 inhibitor therapy may be used in the management of patients (adults and children) with SP associated with hemoglobinopathies. Dosing should be initiated under conditions of complete penile flaccidity. Dosing efficacy should be monitored for frequency and severity of stuttering episodes, as well as PDE5 inhibitor side effects and normal erectile capacity.
- A trial of gonadotropin-releasing hormone (GnRH) agonists or antiandrogens may be used in the management of adult patients with SP. Hormonal agents should not be used in patients who have not achieved full sexual maturation and adult stature. Chronic GnRH or antiandrogen dosing in adult males may affect libido, may affect fertility, cause gynecomastia, cause hot flushes, promote osteoporosis, and worsen sexual function.
- When administered at home for prolonged morning erections, an injection of an intracavernous α-adrenergic may overt a full-blown episode of ischemic priapism. Intracavernous injection of phenylephrine (by the adult patient or parent) should be considered as an adjunct to daily systemic therapies in patients with SP.

SURGICAL MANAGEMENT OF ISCHEMIC PRIAPISM

Surgical management of ischemic priapism is indicated after repeated penile aspirations and injections of sympathomimetics have failed or if such an attempt has resulted in a significant cardiovascular side effect. At present there is a paucity of data regarding the timing of surgical intervention following initiation of medical treatment, although the 2004 International Consultation on Sexual Medicine in Paris

recommended corporal aspiration and α-adrenergic agonists for at least 1 hour before consideration of surgery (Pryor, 2004). Early surgical intervention may be preferable in patients with malignant or poorly controlled hypertension or for men who are using monoamine oxidase inhibitor medications contraindicating α-adrenergic therapies. A comprehensive discussion and documentation that includes baseline erectile function, duration of priapism, risks and benefits of the surgery, and ED should be held with the patient/guardian and an informed consent form signed by the patient/guardian.

Shunting

It is generally accepted that the longer an episode of ischemic priapism lasts, the greater the likelihood of compromised erectile function will be in the future. Previous reviews have concluded that priapism lasting longer than 24 hours was associated with a 90% ED rate (Pryor, 1982). Kulmala and colleagues (1995) reported 92% erectile function preservation among patients with ischemic priapism reversed in less than 24 hours, but only 22% preservation of erectile function among men with priapism lasting longer than 7 days. Recommendations based on well-documented erectile function outcomes are few. One recent study does document erectile function outcomes by contemporary standards (International Index of Erectile Function). Bennett and Mulhall (2008) carefully documented 39 cases of SCD priapism presenting to their emergency department over 8 years; men were routinely interviewed for erectile function status within 4 weeks of priapism/interventions. Of the 39 African-American men followed, 73% acknowledged prior episodes of stuttering; 85% had previously been diagnosed with SCD; and only 5% had been counseled in SCD clinics or were aware that priapism was a complication of SCD. A standard protocol of aspiration and phenylephrine injection was performed; shunting for failure of medical management was performed in 28%. In those patients where priapism was reversed, spontaneous erections (with or without use of sildenafil) were reported in 100% of men when priapism was reversed by 12 hours; 78% when reversed by 12 to 24 hours; and 44% when reversed by 24 to 36 hours. No patient reported spontaneous erections after priapism duration of longer than 36 hours. **The International Society for Sexual Medicine Standards Committee (expert opinion) stated that shunting is to be considered for ischemic priapism events lasting 72 hours or less.** Consideration should be given to foregoing a shunt in priapism events lasting longer, in particular where cavernous thrombosis is evident and no blood can be aspirated from the corporal bodies (Pryor, 2004; Mulhall, 2006).

The objective of shunt surgery is reoxygenation of the cavernous smooth muscle. The shared principle of shunt procedures is to reestablish corporal inflow by relieving venous outflow obstruction; this requires creation of a fistula between the corpora cavernosa (CC) and glans penis, CC and corpus sponsigosum, or CC and dorsal/saphenous veins. Shunt procedures are subdivided on the basis of anatomic location on the penis (Lue, 2006) (Figs. 25–8 and 25–9).

- Percutaneous distal shunts—Ebbehoj (1974), Winter (1976), or T-shunt (Brant, 2009)
- Open distal shunt—Al-Ghorab (Hanafy, 1976; Borrelli, 1983) or Corporal Snake (Burnett, 2009)
- Open proximal shunt—Quackles (1964) or Sacher (1972)
- Saphenous vein—Grayhack (1964)
- Deep dorsal vein shunt—Barry (1976)

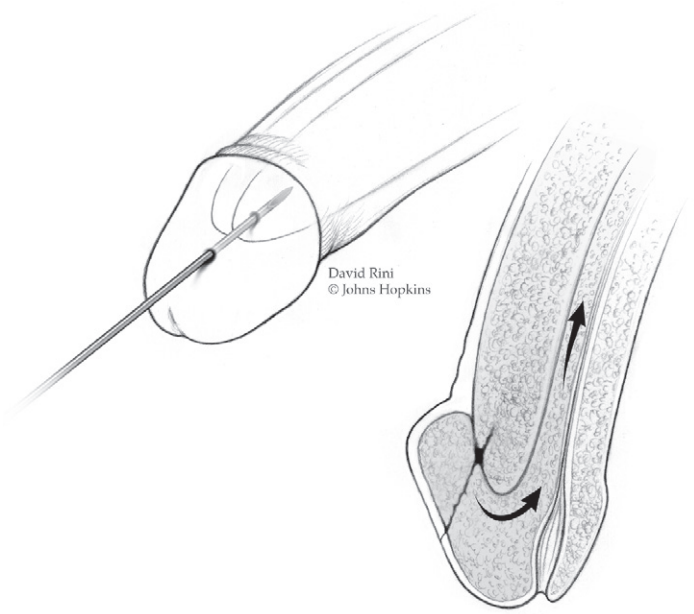

Figure 25–8. Winter shunt. A distal cavernoglanular shunt procedure is depicted by the transglanular placement of a large-bore needle or angiocatheter in the distal glans and corpus cavernosum. (© Brady Urological Institute.)

A distal cavernoglanular shunt should be the first choice of shunting procedures because it is technically easier to perform than proximal shunting. Percutaneous distal shunting is less invasive than open distal shunting and can be performed with local anesthetic in the emergency department. The most recently described distal shunt (Brant, 2009) creates a T-shaped shunt between the CC and glans penis. Brant (2009) describes 13 men with priapism durations longer than 24 hours (6 of 13 had failed other distal or proximal shunt procedures). All T shunts were performed following penile anesthetic block; 12 of 13 patients were successfully reversed by initial intervention. In T shunting a No. 10 blade is placed vertically through the glans 4 mm away from the meatus; the blade pierces through the glans to CC and is rotated 90 degrees away from the urethra and removed. Deoxygenated blood is milked out of the wound. The glans is then sutured with absorbable suture. The authors recommend discharge home if the penis remains flaccid for 15 minutes. If erection returns or persists, a second T shunt is recommended on the opposite side of the meatus. In those cases where ischemic priapism has been present for more than 36 hours, the authors recommend immediate bilateral T shunts with passage of 20-Fr dilators into the fistula tract and well into the CC down to the crus. This technique is more traumatic and will require anesthetic. Burnett and Perorazio (2009) have described a similar technique to resolve ischemic priapism refractory to first-line interventions. Their procedure known as the "corporal snake" is a modification of the Al-Ghorab corporoglanular shunt (Fig. 25–10). Under general anesthetic, a 2-cm transverse incision is made on the glans; the distal tips of the rigid CC are incised and grasped with 2-0 stay sutures or Kocher clamps. Deoxygenated blood is milked out of the CC, but rather than excising a wedge of tunica and underlying CC muscle, a 7/8 Hegar dilator is advanced through each of the tunica windows proximally several centimeters to release blood and thrombus. The penis is made flaccid by repeated manual compression and release; the glans skin is then approximated with 4-0 chromic sutures;

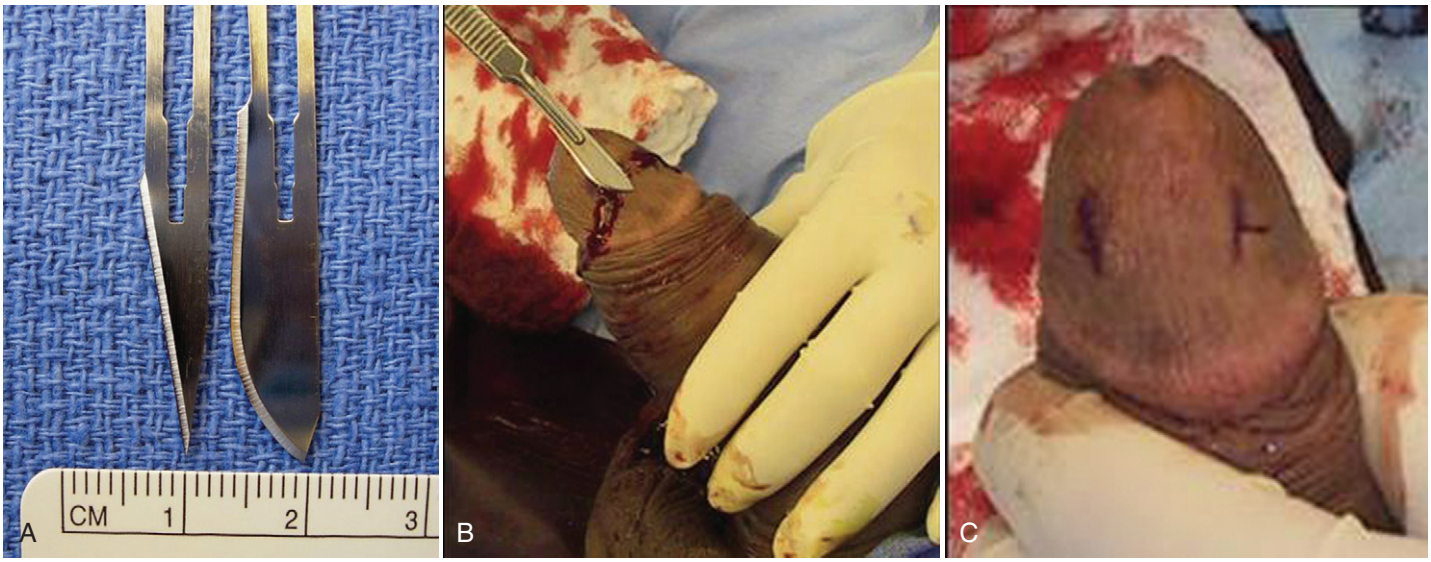

Figure 25–9. **A,** A No. 11 blade is used for an Ebbehoj percutaneous cavernoglanular shunt, and a No. 10 blade is used for a T shunt. **B** and **C,** Note the differences between the Ebbehoj and T shunts. In the Ebbehoj technique the No. 11 blade leaves a straight incision into the glans and corporus cavernosum. In the creation of a T shunt the No. 10 blade is rotated 90 degrees after insertion and withdrawn. In both the percutaneous techniques deoxygenated blood is milked out of the open wounds; once bright red blood is seen, the skin is closed, leaving the deeper incision as the open fistula. In either procedure the maneuver may be repeated on the opposite corpora. (Courtesy of Tom Lue.)

Corporal blood gas
Color Doppler ultrasound
Measurement of intracavernous pressure
Penile compression maneuver (squeeze and release)

urethral catheter is placed and lightly compressive dressing is applied to the genitalia.

The key factors determining successful surgical reversal of ischemic priapism are evacuation of thrombus, reestablishing cavernous inflow, and patency of shunt. Theoretically, larger open shunt procedures are likely to result in higher shunt patency rates; there are no data comparing percutaneous and open distal shunts. The surgeon must be guided by familiarity with various techniques: percutaneous shunting, open distal shunting, proximal shunting, and vein shunting. Although distal shunting can be performed with penile block and sedation in the emergency department, open shunting, especially that requiring passage of dilators into the CC, will likely require general anesthesia and an operating room suite. At the completion of the shunt, patency can be verified in the operating room and subsequently recovery room in a number of ways: bright oxygenated blood should be seen emanating from the corporal bodies; intracavernous pressures should fall; the penis should detumesce and refill with sequential compression and release; and color Doppler ultrasound will show resumption of cavernous artery inflow (Lue, 2002; Nixon, 2003; Chiou, 2009) (Table 25–5). Complications of shunting include penile edema, hematoma, infection, urethral fistula, penile necrosis, and pulmonary embolism.

The most commonly described proximal shunt is the unilateral shunt, described by Quackles in 1964 (Fig. 25–11). Proximal corpus cavernosum to spongiosum (CC-CS) shunt procedures require a transscrotal or transperineal approach (Quackles, 1964). There are no data comparing bilateral (Sacher, 1972) and unilateral CC-CS shunts (Quackles, 1964). Typically, bilateral shunts are staggered; the right side and left side are separated by a distance of at least 1 cm in an effort to minimize the risk of urethral stricture at the point of CC-CS communication (Fig. 25–12). In cases where proximal shunt fails, some have advocated saphenous vein bypass or deep dorsal vein shunt (Fig. 25–13A and B). A wedge of tunica albuginea is removed and the vein is anastamosed end to side of CC. There are no comparative trials of vein shunting for ischemic priapism. Authors have described a significant risk of sapheno-femoral vein thrombus and pulmonary embolism with vein shunting (Kandel, 1968).

Immediate Implantation of Penile Prosthesis

Unfortunately **the natural history of untreated ischemic priapism or priapism refractory to interventions is severe fibrosis, penile length loss, and complete ED** (see Fig. 25–1). Kelami (1985) described the implantaion of the Small-Carrion penile prosthesis through an infrapubic incision in the management of postpriapic erectile dysfunction. Bertram and colleagues (1985) described six postpriapic cases of penile prosthesis; five of six men had successful implantation of semirigid prostheses. Both groups described extensive corporal fibrosis and suggested that semirigid implants were preferable because inflatable implants would not overcome the corporal fibrosis sufficiently to erect the penis. Douglas and colleagues (1990) reported on penile prosthesis in five SCD postpriapic men; they described a surgical technique of tunneling and corporal excavation. Inadvertent damage to the tunica albuginea was common, as was subsequent migration of hardware; 11 additional procedures were required following the initial implants. The average time from priapism to implant in Douglas's series was 4 years. Monga and colleagues (1996) described implants in young SCD patients (six patients, average age 26); inflatable implants were placed to both treat ED

Key Points: Surgical Management of Ischemic Priapism

- Shunt surgery should be considered for all cases of ischemic priapism (IP) failing aspiration and intracavernous injection of α-adrenergics.
- Patients should be counseled that erectile function outcomes decline significantly when IP has lasted longer than 24 hours and that complete ED is anticipated if IP persists for longer than 36 hours.
- The objective of shunt surgery is reoxygenation of the cavernous smooth muscle.
- The key factors determining successful surgical reversal of IP are evacuation of thrombus, patency of shunt, and resumption of cavernous inflow.
- A distal cavernoglanular shunt should be the first choice of shunting procedures.
- Percutaneous distal shunting is less invasive than open distal shunting and may be performed with local anesthetics.
- There are a number of distal shunting procedures and the surgeon should be familiar with these procedures and their complications.
- Open distal shunting should be considered if percutaneous shunting fails. There are no comparative trials of safety, efficacy, or erectile function outcomes for percutaneous versus open distal shunting techniques.
- If distal shunting fails, then proximal shunting is recommended. Proximal shunting establishes a communication between the corpora cavernosa and spongiosa at the base of the penis. The surgeon must be aware of the unique anatomic relationship between the corpus spongiosum and urethra.
- Shunting may also be accomplished with vein grafting to the corpora cavernosa. Venous shunts have increased the risk of thromboembolism.
- Following medical or surgical reversal of IP, penile tumescence rather than complete flaccidity may be evident. A phenomenon of conversion from IP to HFP has been described. In cases where the examination may be equivocal, color Doppler ultrasonography or cavernous blood gas is recommended to demonstrate patency of shunt and restoration of cavernous inflows.
- After shunting, follow up with the patient on erectile function and any subsequent ED therapies.

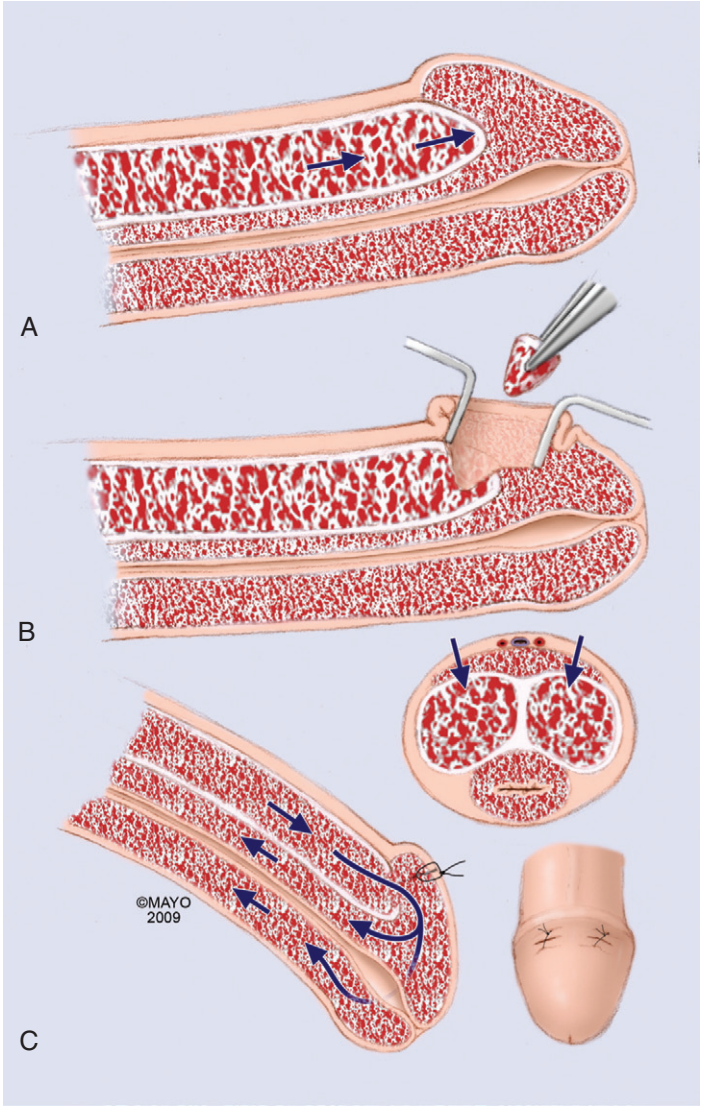

Figure 25–10. **A-C,** An open corporoglanular shunt is indicated if percutaneous shunting fails to reestablish cavernous blood inflow. The Al-Ghorab shunt requires the excision of circular cone segments of the distal tunica albuginea (5 × 5 mm). (By permission of Mayo Foundation for Medical Education and Research. and circumvent ongoing episodes of stuttering priapism. They suggested that both potency and recurrent episodes of ischemic priapism could be managed by "early" implantation. **Some have suggested performing immediate penile prosthesis in the acute management of ischemic priapism, when the patient has failed sympathomimetic intracavenous therapies and shunting** (Rees et al, 2002). There are two distinct advantages to immediate implantation: corporal fibrosis is not yet established, and penile length may be preserved. **The exact time point at which prosthetic insertion becomes a reasonable option for managing ischemic priapism is unclear.** Should medical management of ischemic priapism be followed by distal percutaneous shunt, by open distal shunt, and subsequently by proximal shunting before penile implant? Should men with delayed presentation of ischemic priapism and evident corporal thrombus be triaged to immediate penile implant? What is clear is that any discussion pertaining to early prosthesis insertion should be documented and include a comprehensive review of the theoretic advantages and actual risks. Compared with prosthesis insertion in a typical patient with erectile dysfunction, **there are significantly higher rates of complications noted in priapism cases: infection, urethral injury, device migration, device erosion, and revision surgeries.** The surgeon must be familiar with the additional technical concerns posed by weaknesses in the tunica albuginea in the region of prior shunts.

The advantages of early penile implantation in the acute management of ischemic priapism are preservation of penile length and technically easier implant insertion. Delayed placement of penile prosthesis is technically challenging due to corporal fibrosis. Ralph (2009) reported on 50 patients with ischemic priapism. All patients failed conservative management with the instillation of α-adrenergic agents (200 μg phenylephrine repeated to a maximum dosage of 1500 μg). Unsuccessful shunts were performed in 13 of 50 cases

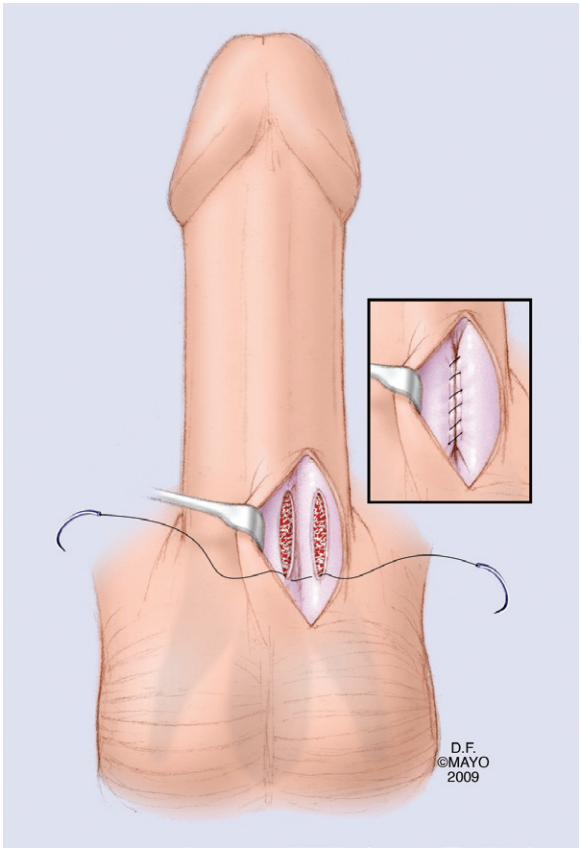

Figure 25–11. The proximal open shunt technique to establish communication between the corpus spongiosum and corpus cavernosum was first described by Quackles in 1964. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

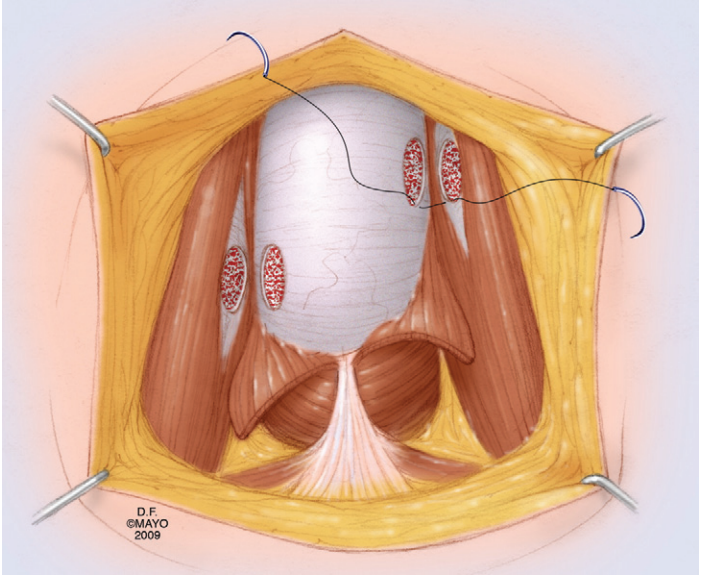

Figure 25–12. Bilateral shunts are staggered. The right and left sides are separated by a distance of at least 1 cm in an effort to minimize the risk of urethral stricture at the point of corpus cavernosum to spongiosum communication (Sacher, 1972). (Ralph, 2009). Mean duration of priapism was 209 hours (range 24 to 72 hours). All patients had evidence of cavernous thrombus and smooth muscle necrosis on MRI and all 50 underwent insertion of penile prosthesis in the acute setting of refractory ischemic priapism. Revision rates were significantly high 24% (12 of 50 patients). The infection rate of 6% was also notably high and likely related to multiple factors including ischemic tissues and preceding penile interventions.

Key Points: Surgical Management of Ischemic Priapism with Immediate Penile Implant

- The natural history of untreated IP or priapism refractory to interventions is severe fibrosis, penile length loss, and complete erectile dysfunction.
- The advantages of early penile implantation in the acute management of IP are preservation of penile length and easier insertion.
- Document baseline erectile function, duration of priapism, history of stuttering, and prior interventions.
- Consider penile prosthesis if:
  - The patient has failed aspiration and sympathomimetic intracavernous injection.
  - The patient has failed distal and proximal shunting.
  - Ischemia has been present for longer than 36 hours.
- Consider an MRI before surgery or corporal biopsy at the time of implant to document corporal smooth muscle necrosis.
- There are higher rates of revision surgery and complications noted in priapism cases due to infection, urethral injury, device migration, and device erosion.

INTERVENTIONAL ANGIOGRAPHY IN THE MANAGEMENT OF ARTERIAL (NONISCHEMIC, HIGH-FLOW) PRIAPISM

Arterial priapism is not an emergency. Spontaneous resolution or response to conservative therapy has been reported in up to 62% of published series (Montague et al, 2003; Pryor et al, 2004). Persistent partial erection from HFP may be evident for months to years, without adverse impact on erectile function (Bastuba et al, 1995). Kumar et al (2006) described a case of HFP in a 24-year-old patient 10 days after straddle injury on a bicycle. The patient had no erection for the first 4 days following injury. Examination revealed a tumescent penis that was compressible. Penile aspiration and blood gas analysis revealed oxygenated corporal blood. Color Doppler ultrasound of the cavernous artery revealed arterio-sinusoidal fistula. Partial erection spontaneously resolved 4 days after diagnostic evaluation, with the patient reporting normal erections 2 weeks later. The authors hypothesized that in cases of blunt penile and perineal trauma an arterio-lacunar fistula forms; these fistulae, unlike arteriovenous communications, may spontaneously resolve as the less rigid walls of the lacunae are prone to spontaneous thrombosis.

There are no comparative outcome studies of intervention versus conservative management in high-flow priapism; there are sufficient case descriptions, especially in children, to recommend initial watchful waiting (Nehra, 2006). Initial

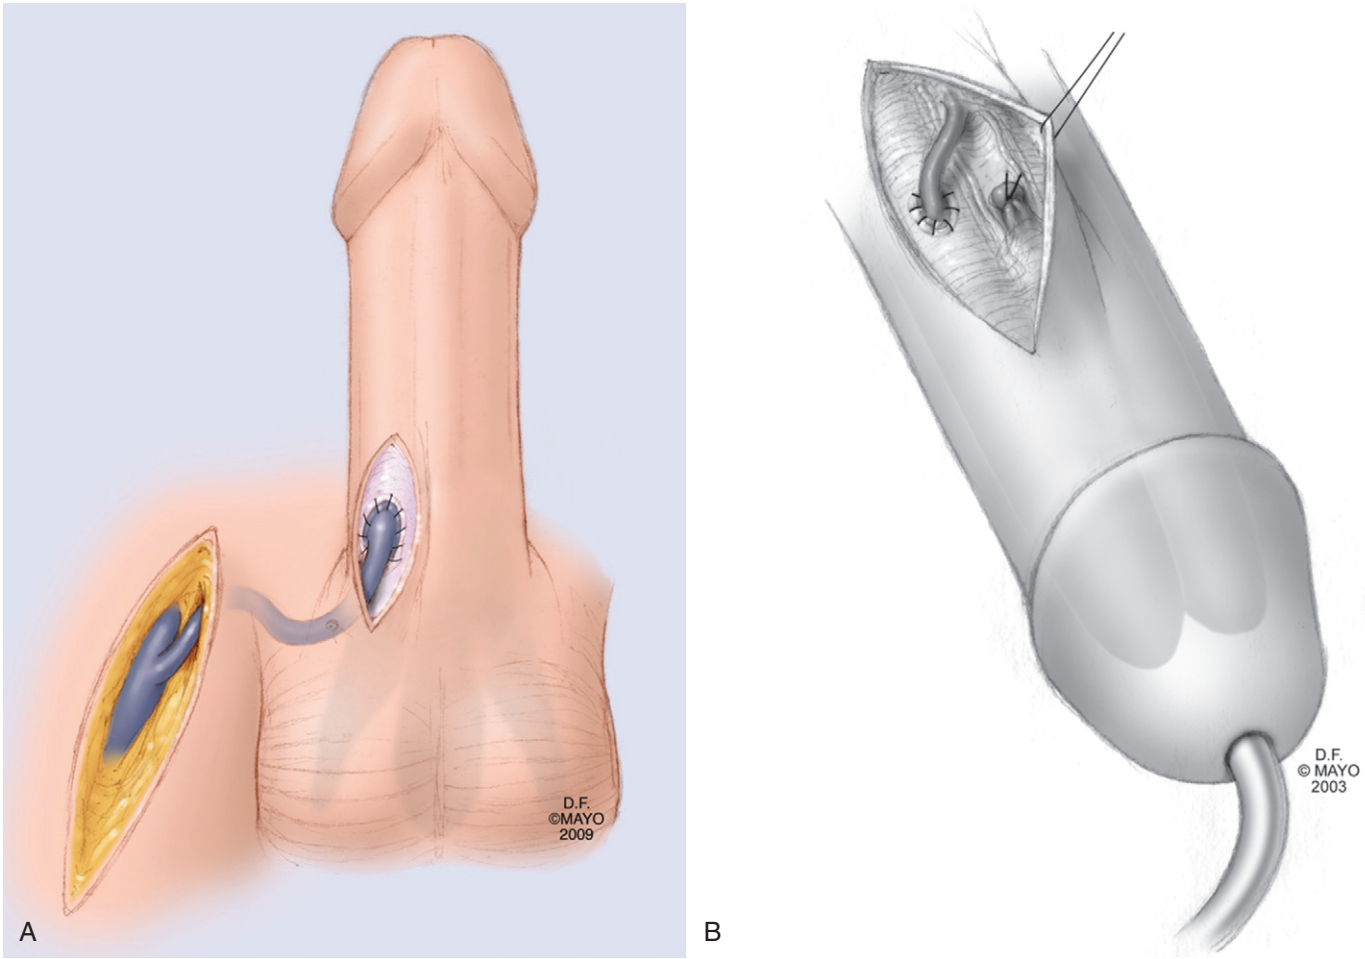

Figure 25–13. **A,** Venous bypass to control ischemic priapism was first described by Grayhack in 1964. The Grayhack shunt mobilizes the saphenous vein below the junction of the femoral vein and anastamoses the vein end to side into the corpus cavernosum. **B,** Deep dorsal vein (DDV) shunt with distal ligation of DDV and anastamosis of proximal DDV to corpus cavernosum. A wedge of tunica albuginea is removed. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

observation is recommended for this type of priapism. Conservative measures include ice applied to the perineum and site-specific compression. **Cavernous aspiration has only a diagnostic role in high-flow priapism. Repeated aspirations, injection, and irrigation with intracavernous sympathomimetics have no role in the treatment of nonischemic priapism.**

Patients demanding immediate relief can be offered selective arterial embolization. The pathognomonic arteriographic finding is an arterial-lacunar fistula; a characteristic intracavernosal cone-shaped blush of contrast is seen at the site of the cavernous artery or arteriole laceration (Fig. 25–14). Selective internal pudendal catheterization and subsequent embolization have been reported with various agents: microcoils, polyvinyl alcohol, N-butylcyanoacrylate, gel-foam, and autologous blood clot (Kuefer, 2005). Permanent materials pose a greater theoretic risk of erectile dysfunction; many authors recommend use of autologous blood clot and absorbable gels (Pryor, 2004; Kim, 2007). Autologous blood clot has a low risk of foreign body reaction, or antigenicity; it is a temporary occlusive agent and should permit recanalization of the cavernous artery (Park, 2001). The success rates with selective pudendal artery catherterization followed by embolization are quite high (89% to 100%), regardless of the embolization material used (Kuefer, 2005; Numan, 2008). Similar results have been reported by others (Savoca, 2004; Alexander, 2006). Normal postembolization erectile function has been reported in 75% to 86% of patients (Cakan, 2006; Numan, 2008). **It should be noted that a single treatment of embolization carries a recurrence rate of 30% to 40%** (Ciampalani, 2002; Gandini, 2004; Ozturk, 2009). **Although ultimately successful, embolization of HFP may require retreatment**. **The most notable side effect of arterial embolization is erectile dysfunction.** Although it was previously reported that nonpermanent embolization materials cause less ED than permanent ones (5% vs. 39%), recent reports employing International Index of Erectile Function in evaluation of postembolization erectile function describe similar rates of erectile dysfunction, 15% and 20% (Savoca, 2004; Alexander, 2006). Other reported adverse effects include penile gangrene, gluteal ischemia, purulent cavernositis, and abscess of the perineum (Hakim, 1996; Sandock, 1996) (Fig. 25–15).

Puppo (1985) compared perineal duplex ultrasound and selective internal pudendal arteriography showing excellent sensitivity in detecting the arterial-lacunar fistula on ultrasound that is seen angiographically (12 of 12 cases). Several reports describe combined ultrasound-guided compression with selective arterial embolization to increase success rates in the treatment of nonischemic priapism (Hatzichristou, 2002; Bartsch, 2004; Cakan, 2006).

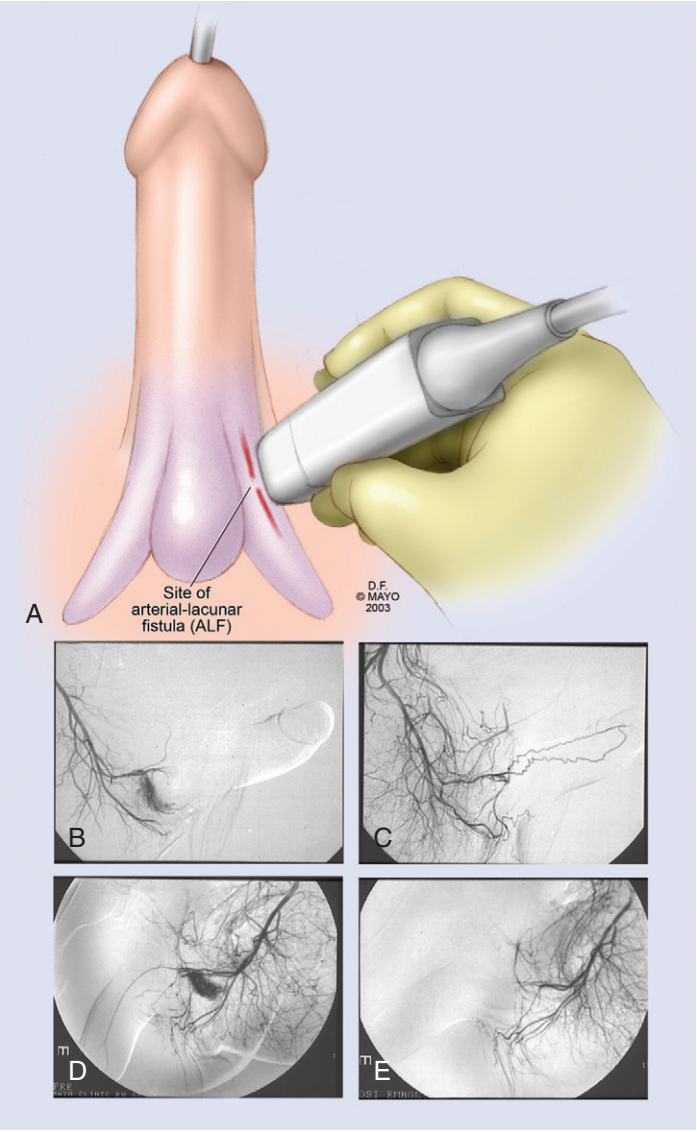

Figure 25–14. Color Doppler ultrasonography of the penis and perineum is recommended in the evaluation of priapism, when the history or examination suggests penile trauma (**A**). Doppler sonography for localization of a fistula correlates well with selective pudendal angiography (**B, C, D, E**); a characteristic fistula blush is shown (**B, D**), along with normal arteriograms (**C, E**). (**A,** By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

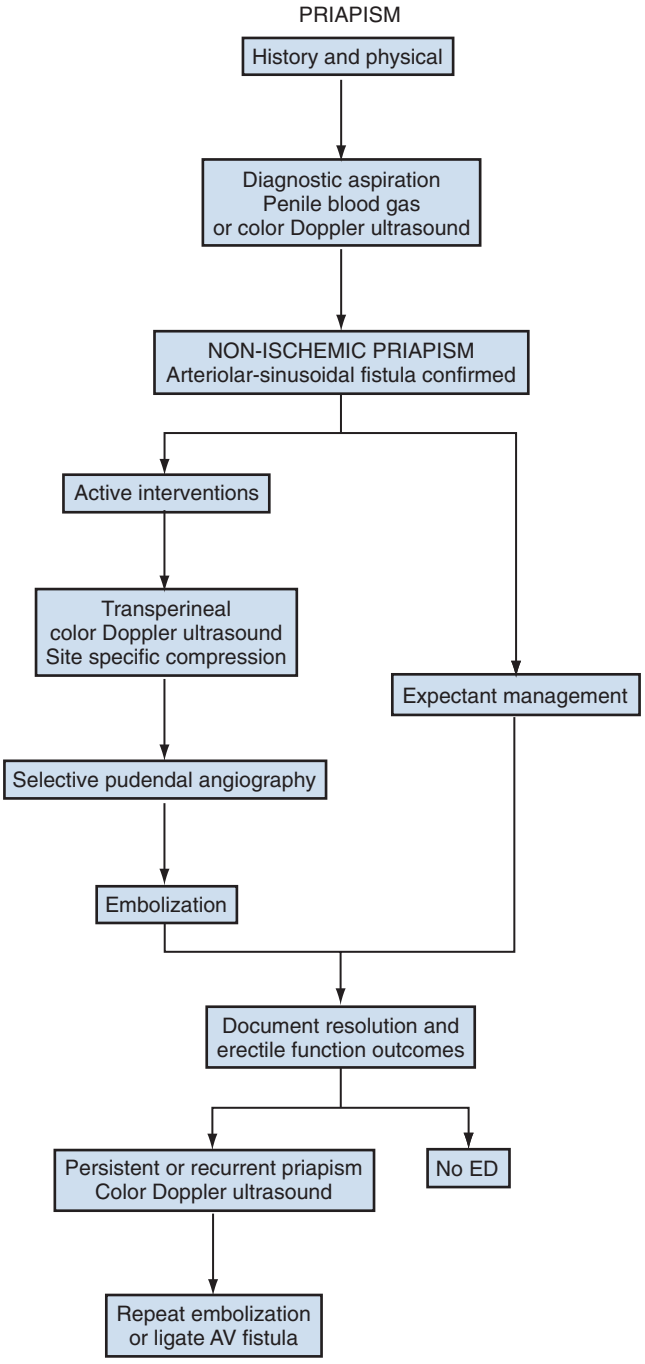

Figure 25–15. Algorithm for managing high-flow priapism. AV, arteriovenous; ED, erectile dysfunction.

If the follow-up clinical examination is equivocal for recurrence of high-flow priapism, a perineal duplex Doppler ultrasound can determine the need for repeat arteriography and embolization (Kim, 2007).

SURGICAL MANAGEMENT OF ARTERIAL (NONISCHEMIC, HIGH-FLOW) PRIAPISM

Arterial priapism is not a urologic emergency. HFP is painless and there have been reports of partial erection persisting for years (Nehra, 2006). Any intervention must follow a comprehensive discussion with the patient regarding risks and benefits of any of the procedures advocated by the clinician. **In cases of long-standing arterial priapism where a pseudocapsule around the fistula has developed, surgical ligation has been reported to be successful. Formation of a pseudocapsule may take weeks to months following trauma. Corporal exploration before the formation of a pseudocapsule may result in ligation of cavernous artery rather than selective ligation of the fistula.** Currently this intervention is reserved for patients who do not wish to pursue expectant management or who are poor candidates for angio-embolization. It is also reserved for patients who refuse the procedure; for patients in places where technology is not available; and for patients whose angio-embolization failed (Ji, 1994; Berger, 2001; Mulhall, 2006). The surgical approach is transcorporal. Intraoperative Doppler ultrasound guidance is recommended.

Key Points: Evaluation and Management of High-Flow Priapism

- Arterial priapism is not an emergency and may be managed expectantly.
- Diagnosis of HFP is best made by penile/perineal color Doppler ultrasound.
- Penile aspiration and injection of α-adrenergic agents is not recommended for HFP.
- Angio-embolization should be preceded by a thorough discussion of chances for spontaneous resolution, risks of treatment-related ED, and lack of significant consequences expected from delaying interventions.
- Overall success rates with embolization are high, although a single treatment carries a recurrence rate of 30% to 40%.
- Where angio-embolization fails or is contraindicated, surgical ligation is reasonable.
- Formation of a pseudocapsule at the site of a sinusoidal fistula may take weeks to months following trauma.
- Color Doppler ultrasound guidance is recommended during exploration to locate fistula.

CONCLUSIONS AND RECOMMENDATIONS FOR RESEARCH IN PRIAPISM

Prompt diagnosis and appropriate management of priapism are necessary to spare patients ineffective interventions and optimize erectile function outcomes. Future research is necessary to understand each type of priapism: (a) corporal smooth muscle pathology associated with genetic and acquired conditions that result in ischemic priapism; (b) the molecular mechanisms involved in the pathogenesis of stuttering ischemic priapism; (c) documentation of onset of HFP in relation to time of injury and response to conservative management versus angiographic or surgical interventions. Future research should include animal models to study the physiology of ischemic priapism. These models should examine the clinical observation that interventions for ischemic priapism may result in a phenomenon of conversion to high flow. Specific questions need to be addressed: Is cavernous arterial dysregulation a normal postischemic response? When does postischemic high flow resolve? Sickle cell patients should receive education on priapism and its management. Recent studies suggest that only 5% of SCD patients recalled learning that priapism was a complication of SCD. Urologists preparing case reports should document pre-priapism erectile function, duration of priapism with respect to initiation of each intervention, history of stuttering priapism, and recovery of erectile function using standardized questionnaires. Documenting erectile function outcomes on the basis of duration of ischemic priapism, time to interventions, and types of interventions will establish evidence-based guidance on how and when to apply those interventions.

Treatment Overview

PHYSIOLOGY OF EJACULATION

Alongside developments in the field of erectile physiology and pathophysiology, the past decade has witnessed increased understanding of central and peripheral mechanisms involved in ejaculatory control. **Usually accompanied by orgasm, ejaculation constitutes the final phase of the sexual response cycle in the male and represents a reflex comprising sensory stimuli, cerebral and spinal control centers, and efferent pathways. Ejaculation is a reflex, which requires a complex interplay among somatic, sympathetic, and parasympathetic pathways involving predominantly central dopaminergic and serotonergic neurons** (McMahon et al, 2004). In antegrade ejaculation, two basic phases are involved: emission and expulsion (Giuliano, 2005). **Emission,** as the first phase of ejaculation, is a sympathetic spinal cord reflex and defined as the deposition of seminal fluid into the posterior urethra. **Expulsion** is due to the combined action of sympathetic and somatic pathways. **An antegrade ejaculation requires a synchronized interplay between periurethral muscle contractions and bladder neck closure, contemporaneous with the relaxation of the external urinary sphincter. Orgasm,** generally associated with ejaculation, is a pleasurable sensation resulting from cerebral processing of the increased pressure in the posterior urethra and contraction of the bulbar urethra bulb and accessory sexual organs.

Coordination of Ejaculation

Peripheral and central centers, as well as sympathetic, parasympathetic, and somatic pathways, participate in the physiologic control of the ejaculatory reflex (Fig. 26–1 on Expert Consult website). A normal ejaculatory response requires synchronized neurochemical interplay coordinated at different levels of the nervous system (Giuliano, 2005). In humans, the composition of the ejaculate is released from participating organs in a particular order. **The first portion of the ejaculate is provided by the bulbourethral glands followed by some fluid from the prostate. Afterwards, the main fraction of the ejaculate including the bulk of the spermatozoa is contributed by the epididymis and vas deferens, along with prostate and seminal vesicle contributions.**

Adequate sensory stimulation of the dorsal penile nerve and posterior urethral distention appears to be sufficient to trigger an ejaculatory response. McKenna, describing a urethrogenital reflex, showed that urethral distension in anesthetized rats induced contractions of the striated perineal muscles (McKenna et al, 1991). The **emission of the seminal fluid is controlled by the sympathetic nervous system activating propulsive contraction of the smooth muscle of the prostate, vas deferens, and seminal vesicles, as well as prostatic glandular secretion. Clear clinical evidence for a functional role of parasympathetic innervation involved in the ejaculatory process is missing** thus far (Giuliano, 2005). The important role of the sympathetic system in the ejaculatory process in humans is emphasized by the fact that an **interruption of the innervation of the bladder neck, vas deferens, and prostate might lead to a retrograde ejaculation or failure of emission.** Protection of sympathetic efferents during surgical procedures in the retroperitoneum or in the pelvis preserves normal ejaculatory function. In patients with spinal cord injury, ejaculation can be achieved acquiring a semen sample with electric stimulation of the hypogastric plexus activating sympathetic efferents (Ohl et al, 1997, 2001).

The somatic nervous system (represented by the pudendal nerve) is exclusively responsible for the expulsion phase of the ejaculate. The synchronous activation of ischiocavernosus, bulbospongiosus, and levator ani muscles as the perineal striated muscles and the anal and urethral external sphincters innervated by the pudendal nerve causes the expulsion of seminal fluid from the urethra. Patients with sacral spinal cord injuries (pudendal nerve arises from sacral segments S2-4) after trauma or patients with neuropathies (e.g., diabetes) typically show a dribbling ejaculation due to the missing motor innervation of the propulsive pelvic musculature.

Using positron emission tomography (PET) scanning, the areas of the brain most activated during ejaculation include the mesodiencephalic transition zone including the ventral tegmental area (VTA), medial and lateral thalamus, and SPFp (Holstege et al, 2003). Other PET and functional magnetic resonance imaging (MRI) studies have suggested that there is intense activation of the parietal cortex during ejaculation (Arnow et al, 2002; Holstege et al, 2003). This site appears to receive sensory signals from the pudendal sensory nerve fibers (Perretti et al, 2003). The VTA zone

contains A10 dopaminergic neurons, purported to be involved in rewarding behaviors (also activated by cocaine).

Neuropharmacology of Ejaculation

Experimental studies in animals advocate **a fundamental role for dopamine (D) and serotonin** (5-hydroxytryptamine, 5-HT) in the regulation of ejaculation. Cerebral serotonin (5-HT) plays an inhibitory role in ejaculation, demonstrated in several animal studies in rats (Giuliano and Clement, 2006). Within the group of 14 different 5-HT receptor subtypes, some subtypes may have proejaculatory and other antiejaculatory effects. **Current literature supports at least the involvement of 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2C} receptors in ejaculatory control** (Waldinger et al, 2004a). **The stimulation of 5-HT_{1A} receptors at various places including cerebral, spinal, or peripheral autonomic ganglia has a generally positive effect on ejaculation, whereas stimulation of 5-HT_{2C} has the opposite effect.** Activation of 5-HT_{1A} autoreceptors has resulted in shortening of the ejaculatory latency time. On the other hand, the stimulation of presynaptic 5-HT_{1B} autoreceptors and postsynaptic 5-HT_{2C} receptors has shown an inhibition of ejaculatory behavior in male rats. Serotonergic neurons originate adjacent to the reticular formation in the brainstem and are self-regulated via a negative feedback system.

Serotonin is released into the synapse by the presynaptic neuron (Fig. 26–2). **Once in the synapse, serotonin binds to receptors located on the postsynaptic membrane. Following this, serotonin returns to the presynaptic neuron. The return of serotonin to the presynaptic neuron is assisted by serotonin transporters. Selective serotonin reuptake inhibitor (SSRI) medications block serotonin transporters, thus preventing the reabsorption of serotonin into the presynaptic neuron. In the immediate term, there are increased levels of serotonin in the synapse. Due to this increased synaptic serotonin level, 5-HT_{1A} receptors and 5-HT_{1B} receptors on the postsynaptic and presynaptic membranes, respectively, become activated, resulting in a reduction in secretion of serotonin into the synapse. These receptors then become desensitized (failure of inhibition of serotonin secretion from the presynaptic neuron), resulting in the serotonin release into the**

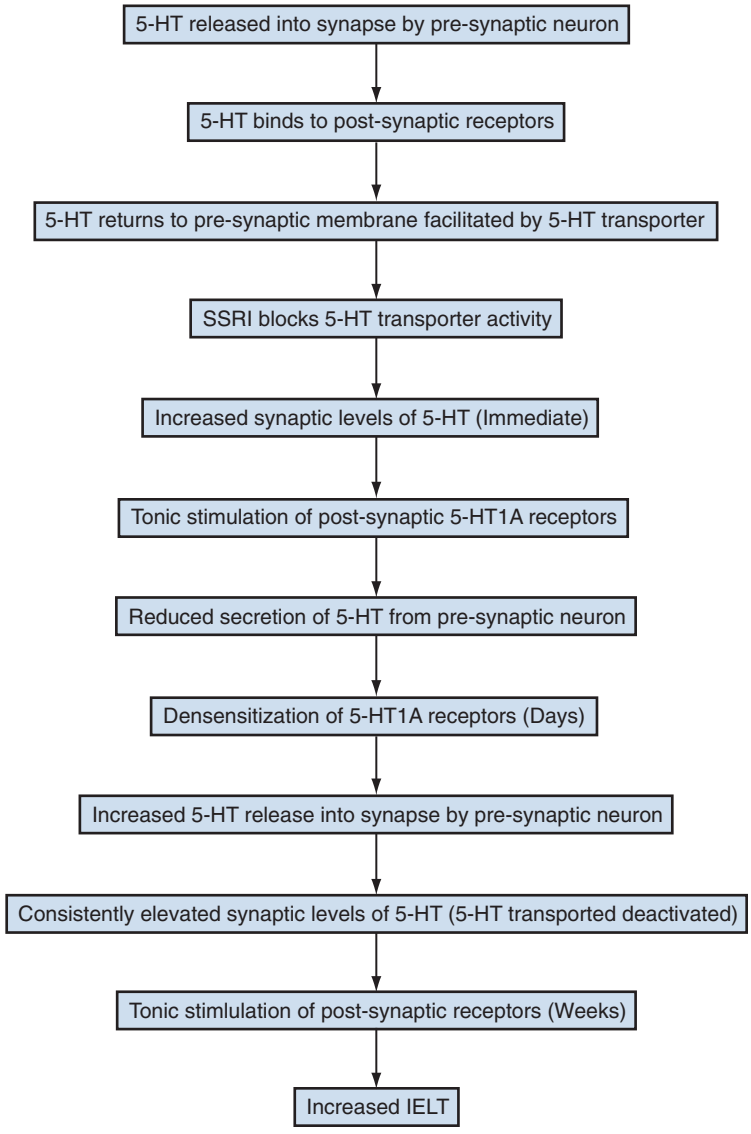

Figure 26–2. Schema depicting the effect of selective serotonin reuptake inhibitor (SSRI) medications on intravaginal ejaculatory latency time (IELT).

synapse, but this time because of transporter inhibition by the SSRI, the synaptic serotonin levels remain high, resulting in persistent activation of postsynaptic receptors, which translates into the clinical effects of SSRI medications including prolongation of ejaculatory latency time.

- Ejaculation is a reflex, requiring a complex interplay among somatic, sympathetic, and parasympathetic pathways involving predominantly central serotonergic neurons.
- The somatic nervous system represented by the pudendal nerve is exclusively responsible for the expulsion phase of ejaculation.
- Current literature supports the concept that stimulation of 5-HT_{1A} receptors shortens ejaculatory latency time and stimulation of 5-HT_{2C} prolongs ejaculatory latency time.
- SSRI-induced elevated levels of serotonin in the synapse result in prolongation of ejaculatory latency time.

DEFINITION OF PREMATURE EJACULATION

In 1943 Shapiro published the first report on premature ejaculation (PE; synonyms *rapid ejaculation, ejaculatio praecox*), reporting on more than 1000 men with this condition (Optale, 1943). Between then and the publication of Seaman's seminal paper (Semans, 1956), little appeared in the literature. **Since that time, the definition of PE has been a source of debate for clinicians and researchers and has undergone radical review in the past few years, culminating in a new definition developed by a consensus panel of the International Society for Sexual Medicine (ISSM)** (McMahon et al, 2008). Shapiro discussed PE of types A and B in his 1943 article. These types became retermed in 1989 as *life-long* (also termed *primary*) and *acquired* (also termed *secondary*) by Godpodinoff (1989). Historically, there are numerous definitions, some defined by individuals, some by professional organizations (Table 26–1). **The two definitions for PE that have been used most often have come from the American Psychiatric Association and the World Health Organization. Both groups used expert panels to arrive at their definitions, and both were devoid of any evidence-based medicine to support such definitions.** In the Diagnostic and Statistical Manual of Mental Disorders (DSM IV) overseen by the American Psychiatric Association, the PE definition has as its core element the concept of "patient distress or interpersonal difficulty." **According to the International Classification of Diseases (ICD-10), a time cutoff is used and the time limit arrived at was 15 seconds, without any validation of this time point.**

No single factor defines PE, and the definition should involve multiple dimensions such as time, perceived control over ejaculation, personal and partner distress, reduced sexual satisfaction, and relationship difficulty (Waldinger, 2007a). **Time is measured by the intravaginal ejaculatory latency time** (IELT, also known as *IVELT*), the duration in seconds or minutes that pass from the first moment of vaginal penetration to ejaculation/orgasm. Waldinger has made a cogent argument that there is a difference between a disorder (all men with PE) and a dysfunction (those bothered by their PE) (Waldinger, 2007a). Thus given that previous definitions are based on expert opinion and are not based on epidemiologic or controlled studies, the ISSM set forth to convene a panel of experts in 2007 to review the current medical literature and to arrive at a functional definition for lifelong PE. **The panel defined PE as having three components: (1) ejaculation that always or nearly always occurs before or within about 1 minute of vaginal penetration, (2) the inability to delay ejaculation on all or nearly all vaginal penetrations, and (3) negative personal consequences such as distress, bother, frustration, and/or the avoidance of sexual intimacy.**

A recent proposal has been put forth by Waldinger to categorize PE into four subtypes: lifelong, acquired, natural variable PE, and premature-like ejaculatory dysfunction (Table 26–2) (Waldinger, 2007a). This subcategorization has clinical utility because as a group these categories describe nearly all patients seen in clinical practice.

Table 26–1.

Definitions of Premature Ejaculation

ORGANIZATION	PUBLICATION	YEAR	DEFINITION
ISSM	J Sex Med	2008	• Ejaculation within about a minute • Inability to delay ejaculation • All or nearly all vaginal penetrations • Negative personal consequences
WHO	ICD-10	2004	• Inability to delay ejaculation • Sufficient to enjoy lovemaking • Ejaculation before/soon after beginning of intercourse (15 sec)
AUA	J Urol	2004	• Ejaculation occurring sooner than desired • Before or shortly after penetration • Causes distress to one/both partners
EAU	Website	2001	• Inability to control ejaculation for sufficient time before vaginal penetration
APA	DMS-IV-TR	2000	• Persistent or recurrent ejaculation • Minimal sexual stimulation • Before, on, or shortly after penetration • Before the person wishes it
Masters & Johnson	Human Sexual Inadequacy		• Inability to control ejaculation for sufficient time during intercourse • Inability to satisfy partner on at least 50% of intercourse attempts

APA, American Psychiatric Association; AUA, American Urological Association; EAU, European Association of Urology; ISSM, International Society for Sexual Medicine; WHO, World Health Organization.

Table 26–2.
Variations of Premature Ejaculation

TYPE	FEATURES
Lifelong	• PE at all or nearly all intercourse attempts • With all or nearly all women • In majority of cases within 1 minute • Consistent during life • Inability to control ejaculation may be lacking (not obligatory)
Acquired	• Rapid ejaculation occurring at some point in life • Normal ejaculation before onset of premature ejaculation • Often source of problem identifiable (organic, psychologic) • Inability to control ejaculation may be lacking (not obligatory)
Natural variable	• Rapid ejaculation inconsistent and irregular • Inability to control ejaculation may be lacking (not obligatory)
Premature-like ejaculatory dysfunction	• Subjective perception of rapid ejaculation • Intravaginal ejaculatory latency time in normal range • Preoccupation with imagined rapid ejaculation • Preoccupation with poor control of ejaculation • Preoccupation not accounted for by another mental disorder • Inability to control ejaculation may be lacking (not obligatory)

Adapted from Waldinger MD. Premature ejaculation: state of the art. Urol Clin North Am 2007;34:591–9, vii–viii.

EPIDEMIOLOGY

Prevalence

In the Multicountry Concept Evaluation and Assessment of PE (MCCA-PE) study, **the self-reported time taken for an average man to ejaculate varied greatly from 7 to 14 minutes** (Montorsi, 2005). These figures were highly geography dependent, being shorter in Germany (7 minutes), longer in the United States (14 minutes), and average in England, France, and Italy (10 minutes). Furthermore, the partners' estimates were also country dependent with North American women estimating coital times lower than that of their male partners and German women estimating coital times higher than their partners.

Over the course of the past 5 years our understanding of the epidemiology of PE has been expanded significantly by several prospectively conducted studies. Further discussion and data on this topic (including Fig. 26–3 and Table 26–3) are included on the Expert Consult website.

Impact of Premature Ejaculation

PE burdens the patient on two different levels: emotional and relational (Sotomayor, 2005). Men have a sense of shame and embarrassment at not being able to satisfy their partner and they often have low self-esteem and feelings of inferiority. These findings are supported by the study of Symonds and colleagues (2003), which conducted 28 in-person interviews of men with self-reported PE in the United States. The main concern for these patients was erosion of sexual self-confidence, and two thirds of the interviewees mentioned that sexual and general confidence was affected by their PE. Anxiety was also common in these PE patients with one third of interviewees specifically linking their anxiety to PE. The Global Study of Sexual Attitudes and Behaviors demonstrated that PE may result in depressive symptoms in some men (Laumann et al, 2005).

The impact of PE on relationships is an important consideration for men with PE and a significant driver for treatment seeking. Rowland and colleagues (2007) reported that men with PE are more likely to report being dissatisfied with their sexual relationship compared with men without PE. The PE patients may find it difficult to initiate and maintain relationships. Women's feelings about their partners' PE range from understanding and support to anger and frustration. Often the man is perceived as selfish, and women have difficulty realizing that many men have poor control over their ejaculation and that they feel badly about the condition. Rowland and colleagues, in a subanalysis of the original Patrick data, assessed the psychologic burden of PE. In this analysis, a number of questionnaires were administered to patients including the Premature Ejaculation Profile (PEP) and the Self-Esteem And Relationship (SEAR) questionnaire. Overall, all inventory scores indicated significantly worse sexual functioning and satisfaction in men with PE compared with those without PE.

In the Patrick study the PRO inventory (Patrick et al, 2009) used demonstrated higher levels of distress in men with PE compared with those without PE (Patrick et al, 2005). Distress was also experienced by partners. These findings were confirmed in the counterpart European study (Giuliano et al, 2008). In an earlier U.S. Internet-based survey, men with PE reported that they had difficulty relaxing in sexual situations and were more anxious about sexual intercourse compared with a non-PE group (Rowland et al, 2004). The PEPA study (Porst et al, 2007) showed a greater percentage of men with PE reported anxiety, depression, and psychologic distress compared with men who did not have PE.

It is clear from the current literature that PE has a significant negative impact on the psychologic status of the sufferer and his partner.

PATHOPHYSIOLOGY OF PREMATURE EJACULATION

As the biologic mechanisms involved in ejaculatory function and dysfunction become clearer, a greater understanding of the pathophysiology of PE is being appreciated. Although there has been significant research in this area in recent times, a complete understanding of the pathophysiologic mechanisms involved in PE has not yet been achieved. **The final common pathway in the genesis of PE appears to be either a hyposensitivity of 5-HT_{2C} receptors or a hypersensitivity of the 5-HT_{1A} receptors** (Waldinger, 2002). It is believed that the ejaculatory threshold for men with low 5-HT levels and/or 5-HT_{2C} receptor hyposensitivity may be genetically set at a lower point, resulting in more rapid ejaculation. In contrast, men with a high set point may experience delayed ejaculation. This theory is supported in part by research that has demonstrated the efficacy of SSRI medications in inhibiting PE.

A number of potential explanations have been postulated for the genesis of PE including **(1) genetic etiologies, (2) psychologic causes, (3) hormonal aberrations, (4) penile sensory changes, and (5) chronic prostatitis.**

Genetic Factors

Recently, research has been conducted into serotonin transporter (5-HTT) promoter region polymorphisms. 5-HTT is a specific protein transporter that permits serotonin reuptake from the synapse and is the target of SSRI medications. Having a high affinity for serotonin, 5-HTT controls the duration, availability, and signaling capacity of 5-HT in the synapse. If short IELT values in men with PE are associated with diminished synaptic 5-HT neurotransmission, an increase in the function of 5-HTT may be related to PE development and such an increase in 5-HTT function might be related to genetic polymorphisms of the protein. Further discussion and data on this topic are included on the Expert Consult website.

Psychologic Factors

Despite decades of discussion regarding psychologic mechanisms involved in PE development, there is as of yet no definitive evidence to prove such a link. Further discussion and data on this topic are included on the Expert Consult website.

Hormone Alterations

At this time, the role of hormones in the genesis of PE is not completely understood. Ongoing research is aimed at elucidating the role of thyroid hormones and androgens in ejaculatory control and dysfunction. Further discussion and data on this topic are included on the Expert Consult website.

Penile Sensitivity and Circumcision Status

Although the link between circumcision status and sexual function has been studied extensively, in the final analysis the data are conflicting and no definitive link can be declared. Further discussion and data on this topic are included on the Expert Consult website.

Chronic Prostatitis

A number of studies suggest that chronic prostatitis is more prevalent among men with a diagnosis of PE. Screponi and colleagues (2001) studied 46 patients with PE and compared them with 30 healthy volunteers.

The mechanism behind the link between chronic prostatitis and PE and the mean by which antibiotic treatment improved IELT are at this point unclear. Further discussion and data on this topic are included on the Expert Consult website.

- The definition of PE revolves around rapid ejaculation (consistently within about a minute of penetration) combined with negative personal effects (bother, frustration, interpersonal difficulty).
- Epidemiologic studies demonstrate that PE is common, affecting up to 30% of men of all ages.
- PE is more common in younger men when adjusted for acquired premature ejaculation in older men resulting from erectile dysfunction.
- PE often has significant negative consequences on the patient's relationship, sexual and otherwise, and this represents a major driver for treatment seeking.
- Accumulating evidence supports roles in the genesis of PE for genetic factors, hyperthyroidism, and chronic prostatitis. However, the link between circumcision status and premature ejaculation is incompletely defined.

PATIENT EVALUATION

Sexual History and Physical Examination

In spite of the negative effect of sexual dysfunction on life satisfaction and perceived quality of life, it has been well documented that men and women are rarely asked by their physicians about their sexual health. The GSSAB suggested that in North America less than 15% of patients were asked about their sexual health by their physician in the preceding 12 months (Laumann et al, 2005). The PEPA study showed that 80% of men with PE who sought treatment reported that they had to initiate the conversation about PE with their physician (Porst et al, 2007). Another survey found that 90% of physicians state that conversations about sexual problems occur rarely during patient visits. Thus the data suggest that routine office visits rarely include physician inquiries about sexual function including PE.

The American Urological Association (AUA) guidelines on PE management state that clinicians should "explicitly communicate the circumstances of the condition" because it is the "fundamental basis of assessment with time to ejaculation (IELT) as the most important feature" (Montague et al, 2004). **In addition to evaluation of IELT, the AUA recommends the following be taken into consideration: (1) the duration and frequency of PE, (2) the rate of occurrence of PE with some or all sexual encounters and partners, (3) the degree to which sexual stimuli cause PE, and (4) the nature and frequency of sexual activity including foreplay, masturbation, and intercourse.**

Although numerous definitions of PE exist and it is likely that the recently developed ISSM definition (see Table 26–1) will become the de facto definition, IELT measurement in clinical practice is difficult (McMahon et al, 2008). In contrast to clinical trials where partner-held stopwatch assessment of IELT is routine, the clinician generally must rely on a patient's self-reported IELT to define PE. However, IELT should not be taken into account alone and other key factors including perceived control over ejaculation, bother experienced by the patient because of the rapidity of ejaculation, and the impact on the patient's sexual relationship should be considered. So **a simple PE history algorithm that can be undertaken is as follows: (1) asking how long he has experienced PE,** that is, whether it is lifelong or more recently acquired. Because lifelong PE is believed to be a potential neuroendocrine problem with alterations in serotonin levels or serotonin receptor sensitivity, most of these men are not considered curable, although they are eminently treatable. On the other hand, men with PE related to the presence of ED or some underlying medical comorbidity, as has been previously outlined, or related to a major life stressor may be potentially curable; **(2) defining the IELT from a patient is useful, appreciating that some men overestimate this.** If a partner is present, seeking corroboration of the estimated IELT is helpful; urologists

have all been faced with the young man presenting to the office complaining of PE with an estimated IELT of 30 minutes. Most would agree that treating this man for PE with pharmacologic therapy is not indicated and referral to a mental health professional is likely to be the best choice of treatment. Likewise, we see men who on review of systems declare IELT values of 1 minute yet do not believe that they have PE. These scenarios are in keeping with the Patrick study demonstrating significant overlap in IELT values between those with self-declared PE and those without, as well as the classification system proposed by Waldinger (see Table 26–2); **(3) asking the patient to define whether his control over ejaculation is good, fair, or poor** is another useful step; irrespective of his IELT, if a man expresses good control over his ejaculation, treatment for PE is not indicated. Some men ejaculate quickly routinely because of partner issues (including rapid orgasm on behalf of the partner). Men with IELT values of 5 minutes or more who express poor control over ejaculation present a challenge and are often best managed by combined short-term pharmacotherapy of PE and mental health evaluation. Many of these men have acquired PE and for much of their lives were able to keep IELT values of 10 minutes plus and have more recently had shortening of their IELT; and **(4) assessing the bother related to PE and the impact PE has on his relationship.** As with control, low bother and little impact on the relationship usually translate into no need for treatment, whereas high-bother, high-negative impact on the relationship irrespective of IELT or sense of control may warrant treatment.

Using Waldinger's model for variations of PE, in which four variations exist (lifelong, acquired, natural variable, and premature-like ejaculatory dysfunction), the clinician can discuss this problem with the patient. **For many men with natural variable PE, rapid ejaculation occurs inconsistently or irregularly and control over ejaculation may be fair or even good in these patients. Premature-like ejaculatory dysfunction is also a common presentation in which men have a subjective perception of rapid ejaculation despite having IELT values well within the normal range.** These men may also have a preoccupation with imagined rapid ejaculation and poor control over ejaculation.

Finally, from a patient history standpoint it is critically important to be able to differentiate PE from ED. Both are common conditions and may coexist in the same patient. However, there are many patients who have ED, specifically with loss of sustaining capability, who are erroneously diagnosed with PE and vice versa. Indeed, some patients have undergone penile implant surgery because of complaints of inability to sustain erectile rigidity, while in fact, PE was the cause for his rapid penile detumescence. The critical point in the history is defining the onset of the patient's problem. For example, there are many patients who have ED and develop secondary PE. This is commonly seen in men who have loss of sustaining capability, whether organically or psychologically based, who condition themselves to ejaculate more rapidly so that they can achieve orgasm before loss of erectile rigidity. This patient clearly has primary erectile problems with secondary ejaculatory problems and his treatment should be aimed at his ED first. Doing this often translates into improvement not only of his erectile problems but also of the acquired PE. On the other hand, there are patients who have lifelong PE who develop ED as they age. Although the treatment of the latter patient may commence with erectogenic pharmacotherapy, it is likely that his eventual management, if the patient's bother is high, will require pharmacologic therapy for his PE as well.

Although it is recommended that a physical examination be conducted, more often than not it yields little information pertaining to the patient's PE complaint. Such examination should include an assessment of signs and symptoms of conditions believed to be associated with PE such as thyroid dysfunction and chronic prostatitis. A routine urologic genital examination should be conducted, and some recommend assessment of the sacral reflexes and lower limb neuromuscular evaluation. It must be stated, however, that **it is rare to find anything on physical examination that would help define the etiology of the patient's PE or that would change the management plan.** No specific investigations have been designed for the patient with PE, and any adjuvant testing should be aimed at confirming findings uncovered by the history and physical examination such as thyroid dysfunction or prostatitis.

A number of instruments have been developed to assess the impact of treatment on men with PE including the Premature Ejaculation Profile (PEP) (Patrick et al, 2009) developed by Johnson & Johnson, the Index of Premature Ejaculation (IPE) (Althof et al, 2006), the Male Sexual Health Questionnaire-Ejaculation (MSHQ-EjD) (Rosen et al, 2007), and the Premature Ejaculation Diagnostic Tool (PEDT) (Althof et al, 2006; Symonds et al, 2007) developed by Pfizer. All of the aforementioned questionnaires have been validated and have demonstrated robust psychometrics, although they have yet failed to infiltrate their way into routine clinical practice. Although other questionnaires exist such as the PEQuest (Hartmann et al, 2005) and the Yonsei-Sexual Function Inventory (Lee et al, 1996), no validation information can be found in the literature for these measures. As with the ED, the impetus behind the development of these questionnaires has largely been industry investigation of potential candidate agents for the treatment of PE.

TREATMENT OVERVIEW

Behavioral Therapy

Behavioral psychosexual therapies are a well-recognized treatment for PE, and their use predates the use of pharmacologic agents by decades. Interestingly, the earliest method of behavioral therapy was described by urologist James Semans from Duke University in 1956. The maneuver he described involved the partner stimulating the man's penis until he has the sensation of almost climaxing (inevitable orgasm), at which time stimulation is abruptly stopped until this feeling disappeared. The partner must repeat this cycle until the ejaculation can be controlled voluntarily. This technique became known as the "stop-start" technique. In 1970 Masters and Johnson reported a similar maneuver in which the partner is advised to squeeze the penile frenulum or glans, just on cessation of penile stimulation at the time of inevitable orgasm, and then the female partner restarts the stimulation at least 30 seconds later. This is known as the "squeeze" technique.

Both methods focus on distraction and a reduction of excitement or stimulation, which may also detract from overall sexual satisfaction, and are based on the theory that the reason PE occurs is that the patient fails to pay sufficient attention to preorgasmic levels of sexual tension (Althof, 2006). **The main goal of traditional psychosexual treatment for PE is to help men identify the premonitory sense of ejaculation/orgasm and work with the patient to improve self-control.** Secondary benefits may include improved sexual self-confidence, less anxiety, resolution

of any interpersonal difficulties, and increased couple communication. **Although behavioral therapy has been shown to have success rates between 45% and 65%, the benefits are generally short-lived** (De Amicis et al, 1985; Hawton, 1988). Hawton and colleagues (1988) reported that 75% of men with PE who initially responded to behavioral therapy showed no long-lasting improvement after 3 years of follow-up. De Amicis and colleagues (1985) also found that although men treated for PE with couples' therapy experienced significant immediate benefits, these gains were not maintained when measured at a follow-up visit 3 years later.

Currently, a combination of pharmacotherapy and psychotherapy is suggested as the modern approach to PE treatment. The severe PE patient may often require greater levels of intervention than drugs alone (Althof, 2006). Clinicians and sex therapists can work as one team to manage such severe PE patients and have obtained better results than monotherapy (Althof, 2006).

Oral Agents

Centrally Acting Agents

The agents with proven efficacy in the treatment of PE include clomipramine and the older SSRI agents paroxetine, fluoxetine, sertraline, and citalopram. Newer agents fluvoxamine and venlafaxine (Kilic et al, 2005) have not demonstrated any significant effectiveness in the treatment of PE. No pharmacologic therapy has been approved by the U.S. Food and Drug Administration, but in Europe a novel SSRI (Dapoxetine) has been approved (Pryor et al, 2006).

Clomipramine. Clomipramine is a tricyclic antidepressant (TCA) that inhibits the uptake of noradrenaline and 5-HT by adrenergic and 5-HT neurons. Eaton (1973) published the first report on the use of clomipramine in PE, and numerous subsequent publications have confirmed its efficacy. In a randomized, placebo-controlled crossover trial in 36 men with PE, daily use of clomipramine significantly increased stopwatch-measured IELT compared with a placebo (Kim and Seo, 1998). A meta-analysis has shown that, on daily use, clomipramine increases IELT more than fourfold, similar in magnitude to sertraline and fluoxetine (Haensel et al, 1998; Waldinger et al, 2004a). On-demand dosing with clomipramine has significantly increased IELT compared with placebo (Haensel et al, 1998; Strassberg et al, 1999; Waldinger et al, 2004a). In three double-blind, placebo-controlled, crossover studies, on-demand use of clomipramine (25 mg, 12 to 24 hours before intercourse) increased IELT fourfold in PE patients (Haensel et al, 1998; Strassberg et al, 1999; Waldinger et al, 2004a).

Selective Serotonin Reuptake Inhibitors. The ability of SSRIs to delay ejaculation was accidentally discovered when these drugs were being evaluated for the treatment of depression in the 1970s. **Although none of these agents have received U.S. Food and Drug Administration approval for PE treatment, the current guidelines from AUA** (Montague et al, 2004) **and recommendations of the 2009 International Consultation on Sexual Medicine (ICSM) suggest the off-label use of SSRI for managing PE.** Prolongation of IELT is seen as early as a few days after treatment initiation but is maximized and plateaus at 2 to 4 weeks with an average of a twofold to eightfold increase in IELT depending on the agent and the study analyzed (Table 26–4) (McMahon et al, 2004).

In one study using a daily treatment regimen, paroxetine showed the highest efficacy (IELT fold increase of nine), followed by sertraline (four) and fluoxetine (four). This increase was significantly greater than placebo (1.5-fold) (Waldinger, 2007b). The aforementioned meta-analysis on SSRI use in PE focused on eight randomized, double-blind studies of the SSRI and clomipramine for treatment of PE including stopwatch assessment of IELT. The rank order of efficacy of IELT increase was paroxetine, sertraline, clomipramine, fluoxetine, and placebo. Of note, the IELT-prolonging capability of SSRI was noted to be less in the randomized controlled trials than in the noncontrolled studies (Waldinger et al, 2004b).

Only a small number of studies address on-demand use of SSRI agents. Waldinger and colleagues (2004a) investigated the ejaculation delay induced by on-demand treatment of paroxetine and clomipramine in a randomized, double-blind, fixed-dose study of 30 PE patients. It was found that on-demand treatment of 20 mg of paroxetine did not cause clinically relevant delay in ejaculation, but with the daily use of the same SSRI for 6 weeks, the IELT increased significantly. The issue of daily versus on-demand SSRI use remains unanswered, and further well-designed studies are required to address this issue.

SSRI medications are associated with well-recognized side effects. The most common short-term adverse effects are yawning, mild nausea, excessive sweating, fatigue, and changes in bowel function. Loss of bone mineral density is the most concerning adverse effect of long-term treatment (Haney et al, 2007). **Sexual side effects such as reduced libido and erectile rigidity decrease have been reported** (Montejo-Gonzalez et al, 1997). These adverse effects are usually mild, and some patients experience gradual disappearance with continued use of the medications over the first month of utilization. **A sudden reduction or cessation of long-term treatment of SSRIs can lead to the "SSRI discontinuation syndrome," a group of symptoms including nausea, vomiting, dizziness, headache, ataxia, drowsiness, anxiety, and insomnia. These symptoms begin 1 to 3 days after the drug cessation and may continue for more than a week in some patients. This syndrome is usually reversible by SSRI reintroduction** (Giuliano and Clement, 2006). **Thus it is recommended that SSRI agents should be gradually withdrawn over a 2- to 4-week period, and all patients using SSRI for PE should be forewarned about this.**

Drug-drug interactions with SSRI is common (Table 26–4), **leading potentially to the "serotonin syndrome," a group of serious, persistent symptoms including myoclonus, hyperreflexia, sweating, shivering, motor discoordination, and mental status changes** (Giuliano and Clement, 2006).

Dapoxetine. Given side effects and the need for daily use of SSRI, the search for short-acting SSRI agents that could be used on demand has been conducted in earnest over the past 5 years (Giuliano, 2007). An example of such a drug is dapoxetine. Available research suggests that dapoxetine is a powerful inhibitor of serotonin transporter (Andersson et al, 2006). Although its pharmacologic activity is similar to clomipramine, as well as conventional SSRI, its pharmacokinetic profile differentiates it from other SSRI agents (Andersson et al, 2006). **Dapoxetine has a time to maximum serum concentration (Tmax) of 1.3 hours and a short half-life (T½) of 1.5 hours** (Andersson et al, 2006).

Two placebo-controlled trials were conducted in the United States in almost 3000 men who (1) met the DSM-IV-TR criteria for PE, (2) had an IELT of less than or equal to 2 minutes in 75% or more intercourse episodes in a 2-week baseline period, and (3)

Table 26–4.

Characteristics of the Most Commonly Used Oral Agents for Premature Ejaculation Treatment

AGENT	TRADE NAME	STANDARD DAILY DOSE	T½H	ADVERSE EFFECTS	CONTRAINDICATION	DDI
Clomipramine	Anafranil	25-50 mg/day	19-37	Dry mouth, constipation	MAOI	Anticholinergics, antipsychotics, barbiturates, charcoal, cimetidine, clonidine oral contraceptives
Fluoxetine	Prozac Sarafem	5-20 mg/day	36	Nausea, anxiety, insomnia, anhidrosis, libido loss, ED	MAOI	5-HT1 agonists, benzodiazepines, β blockers, buspirone, carbamazepine, clozapine, cyclosporine, cyproheptadine haloperidol, hydantoins, lithium, sympathomimetics TCA
Paroxetine	Paxil Seroxat Pexeva	10-40 mg/day	21	Nausea, anxiety, insomnia, anhidrosis, libido loss, ED	MAOI	Alcohol, anticoagulants, cimetidine, cyclosporine, cyproheptadine, drugs metabolized by CYP2D6, digoxin, phenobarbital, phenytoin, procyclidine, St. John's wort, sympathomimetics, theophylline, thioridazine, TCA, tryptophan, zolpidem
Sertraline	Zoloft	25-200 mg/day	26	Nausea, anxiety, insomnia, anhidrosis, libido loss, ED	MAOI	Alcohol, cimetidine, clozapine, disulfiram, hydantoins, pimozide, St. John's wort, sympathomimetics, tolbutamide, TCA, antiarrhythmics (1C), zolpidem
Dapoxetine*	Priligy	15-60 mg†	1.5	Nausea, diarrhea, headache, dizziness, somnolence	MAOI	Ketoconazole, lithium, linezolid, nefazadone protease inhibitors, tryptophan St. John's wort, thioridazine, tramadol, sumatriptan
Tramadol	Ultram	25-50 mg†	5-7	Nausea, dizziness, insomnia, dyspepsia, seizures	MAOI SSRI TCA	Digoxin, erythromycin, ketoconazole, quinidine, rifampin, St. John's wort, tegretol, warfarin

*Not currently FDA approved but approved in Europe.
†For on-demand use.
ED, erectile dysfunction; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; T½H, half-life; TCA, tricyclic antidepressants.

reported a PE severity of moderate or severe. On-demand administration (within 1 to 4 hours of the sexual encounter) of dapoxetine 30 or 60 mg significantly improved outcomes compared with placebo. The IELT was significantly increased 3.5-fold from baseline compared with 2-fold for placebo. Patient-reported perception of control over ejaculation and satisfaction with sexual intercourse was also significantly better compared with both baseline values and end of treatment with placebo (Pryor et al, 2006). The most common adverse events with dapoxetine 30 and 60 mg compared with placebo were, respectively, nausea (9%, 20%, 2%); diarrhea (4%, 7%, 1.5%); headache (6%, 7%, 4%); and dizziness (3%, 6%, 1%). About 5% of all subjects discontinued because of adverse events (Andersson et al, 2006).

A second randomized, double-blind, multicenter, placebo-controlled, phase III, randomized, clinical trial involving 618 men with PE was conducted (Buvat et al, 2009). Dapoxetine 30 mg, 60 mg, and placebo groups were studied. IELTs and PROs improved significantly in the treatment arm versus placebo. Results from a 9-month, open-label extension study that assessed dapoxetine 60 mg showed that the most common adverse events were nausea, dizziness, and headache.[120]

Tramadol. **Tramadol is a synthetic opioid analgesic** (Frink et al, 1996; Lintz et al, 2000). Tramadol has been used for many years for pain control and has a recognized safety profile. The mechanism of action of tramadol in PE is not fully understood. From animal experiments, inhibition of norepinephrine and serotonin reuptake may be the main mechanism (Salem et al, 2008). Two recently published studies have assessed the effectiveness of on-demand use of tramadol for the treatment of PE (Safarinejad and Hosseini, 2006; Salem et al, 2008). In a double-blind, placebo-controlled study, on-demand use study, tramadol 50 mg, taken 2 hours before sexual intercourse, was associated with clinically discernible ejaculation delay with 28% of patients reporting adverse effects. The most common side effects were nausea (15%), vomiting (6%), and dizziness (6%) but were reported as being mild. Another study by Sharon and colleagues was a single-blind, placebo-controlled, crossover, two-period prospective study to evaluate on-demand tramadol 25 mg treatment. The treatment group experienced a sixfold increase in IELT compared with approximately a twofold increase for the placebo group. Thirteen percent of patients reported adverse effects with tramadol including dyspepsia and mild sleepiness. Further studies are required to define the role of tramadol in PE treatment.

Phosphodiesterase-5 Inhibitors (PDE5i). At least 30% of men with PE have coexisting erectile dysfunction (ED) (Laumann et al, 1999, 2005, 2006, 2007). It is generally believed that PE secondary to ED is a psychogenic issue (Jannini et al, 2005). The efficacy of PDE5i alone (Abdel-Hamid, 2004; McMahon et al, 2005) or in combination with SSRI (Abdel-Hamid et al, 2001; Salonia et al, 2002) for the treatment of PE has been explored. In PDE5i monotherapy, a single placebo-controlled, parallel group study of sildenafil citrate for treatment of PE has been conducted. This study demonstrated that although there was no significant improvement in IELT compared with placebo, the sildenafil group had a

statistically significant increase in self-report ejaculation control (McMahon et al, 2005). In another study, on-demand sildenafil use increased vibrator-assisted ejaculation time compared with placebo group.

In an open-label comparison trial, Abdel-Hamid and colleagues (2001) showed superiority of combining sildenafil to the stop-start technique over SSRI therapy. However, the magnitude of effect has not been replicated and may have been due to a significant number of men with combined PE and ED. An industry-sponsored, double-blind, placebo-controlled study showed no significant difference in IELT when sildenafil was compared with placebo. In men with IELT less than 1 minute, on-demand administration of sildenafil 50 mg combined with 20 mg paroxetine (1 hour before planned sexual intercourse) after 21 days of daily administration of 10 mg paroxetine alone showed superiority compared with daily administration of 10 mg paroxetine alone for 21 days and on-demand dosing of 20 mg paroxetine 3 to 4 hours before intercourse (Salonia et al, 2002). Patients in the sildenafil group had a higher incidence of headache and flushing compared with those in the paroxetine-only group. In another study, men with PE who were dissatisfied with lidocaine ointment were given 20 mg paroxetine daily for 30 days and 20 mg paroxetine combined with 25 to 100 mg sildenafil 7 hours before intercourse. Psychologic and behavioral counseling was also provided throughout the study. Sildenafil combined with paroxetine and psychologic and behavioral counseling alleviated PE in nearly all patients, by significantly improving the grade of PE and increasing IELT (Chen et al, 2003).

A recent systematic review of published reports of PDE5i in PE treatment has concluded that there is limited evidence to support the role of PDE5i monotherapy in PE treatment, although some evidence suggests that PDE5i might benefit men with concomitant PE and ED (McMahon et al, 2006). **Thus at this time, the weight of the evidence would suggest that PDE5i monotherapy for PE treatment has no solid foundation. However, in difficult-to-treat cases the addition of a PDE5i to an SSRI may offer select patients some benefit.**

α_1-Adrenoceptor Antagonist. In an effort to modulate sympathetic tone, α blockers have been studied in a limited fashion (Kim et al, 2004). In a single clinical study of an α_1-adrenergic receptor antagonist, significant improvement was seen in 50% of PE patients who failed to respond to psychotherapy alone (Cavallini, 1995). This drug class will require significant further exploration before its role as a first line therapy in PE is defined.

Topical Agents

Sixty years ago Schapiro described local anesthetic agent use for PE (Optale, 1943). Currently, such off-label topical treatment is widespread. Compared with systemic therapy in PE management, there is the palatability of local treatment because of its immediacy and minimal systemic side-effect profile. **However, the application of a local anesthetic agent on the penis still has a number of potential drawbacks such as the loss of penile sensitivity, ED, female genital anesthesia, and skin irritation. The topical drugs for PE treatment include the SS cream, lidocaine alone, and lidocaine-prilocaine combinations.**

Severance Secret-Cream

Severance secret-cream (SS-cream) (CJ Co Ltd, Seoul, Korea), developed at Yong-Dong Severance Hospital in Korea, is made with the extracts of nine natural products. It is applied on the penis 1 hour before sexual intercourse and washed off before sexual intercourse. SS cream is available only in Korea and is not approved for use in Europe or the United States. After applying SS-cream, sensory thresholds have been shown to increase (Xin et al, 1996, 2000). Xin and colleagues (1997) reported ejaculation latency was significantly prolonged more than 2 minutes in 89% of patients using SS-cream. In a multicenter, double-blind study involving 106 cases, the use of the SS-cream was reported to increase the mean stopwatch-measured IELT from a baseline value of 1.5 to 11 minutes, compared with end-of-treatment IELT with placebo of 2.5 minutes (Choi et al, 2000). The main disadvantage of SS-cream is an unpleasant odor, which makes it unpalatable to many patients. The main challenge for this agent is the absence of large, randomized, controlled trials using standardized end points. Furthermore, the failure to disseminate publicly the constituents of this product has raised concerns regarding the reproducibility of the published data.

Lidocaine

This topical agent has been available for more than 25 years. Reliable data from clinical trials is absent; therefore its efficacy and safety cannot be assessed (Morales, 2000, 2007).

Lidocaine-Prilocaine

EMLA (AstraZeneca, United Kingdom) is a local anesthetic cream containing 2.5% lidocaine-prilocaine for topical use that can anaesthetize intact skin. Published studies of lidocaine-prilocaine cream use in PE are scarce. The first pilot study of lidocaine-prilocaine cream evaluation in the treatment of PE included 11 men only (Berkovitch et al, 1995). Nine of 11 cases reported their performance as "excellent" or "better," and all 11 partners were satisfied with the treatment. A placebo-controlled study reported by Atikeler and his colleagues (2002) showed that the best application time was 20 minutes before sexual relations. The largest double-blind clinical trial of lidocaine-prilocaine cream included 42 cases and demonstrated a 5.5-fold increase in IELT in the treatment arm. However, only 29 of 42 participants completed the study. Sixteen percent of patients reported adverse effects including penile numbness, retarded ejaculation, penile irritation, and decreased vaginal sensitivity (Busato and Galindo, 2004).

The topical eutectic mixture for PE (TEMPE, also known as *PST-502*, Sciele Pharma, Inc.) is a recently developed metered-dose spray of lidocaine and prilocaine. The metered-dose aerosol-delivery system is specifically designed for use in PE. The system delivers 7.5 mg lidocaine plus 2.5 mg prilocaine per spray. The mixture is alcohol free and can easily be wiped off if necessary, so no condom is required (Henry and Morales, 2003). The product is incapable of penetrating keratinized skin, hence only anesthetizing the glans and reducing the incidence of penile shaft numbness-related ejaculatory failure. The first open-label pilot study involved 11 men whose IELT was recorded by stopwatch at baseline and on five subsequent encounters when using the spray 15 minutes before intercourse. The average IELT increased from 1.5 minutes to 11 minutes, which was equivalent to a mean eightfold increase over baseline. In addition, 8 of 11 patients and 7 of 11 partners reported their sexual satisfaction as "better" or "much better." In a phase II, placebo-controlled trial (Dinsmore et al, 2007; Dinsmore and Wyllie, 2009), 54 men reported prolongation of their IELT from a baseline of 1 minute to 5 minutes at end of treatment. It is a well-tolerated treatment, having a low incidence of penile hypoesthesia and erectile impairment.

Key Points

- The diagnosis of premature ejaculation is based on taking a thorough sexual history.
- It is critically important to differentiate premature ejaculation from erectile dysfunction when loss of sustaining capability is the primary issue.
- Besides assessing patient self-reported ejaculatory latency time, defining the patient's perceived control over ejaculation, his level of bother, and the bother level of his partner are important.
- Validated instruments for the evaluation of premature ejaculation exist but to date have largely been confined to research use.
- Behavioral approaches as monotherapy have been associated with poor long-term benefits.
- Combining pharmacotherapy and psychotherapy is the modern approach to PE treatment.
- SSRI agents are the first-line (albeit off-label) pharmacotherapeutic approach to the treatment of premature ejaculation.
- There is little evidence for the effective use of other oral agents (tramadol, PDE5 inhibitors).
- Properly formulated transdermal agents are of benefit to some patients with premature ejaculation.

Intracavernosal Injection Therapy

In cases refractory to first-line and combination therapy, intracavernosal injection (ICI) has been used for years to increase sexual satisfaction in men with recalcitrant PE. Fein (1990) reported on eight patients who used this strategy. The patients reported improved sexual confidence, and although they ejaculated early, they maintained their erections, which permitted them to continue penetrative relations. Of note, three of the eight patients were cured of their PE, suggesting these men had acquired PE.

Surgical Treatment

Although there are mixed data on the issue of the link between penile sensation and PE, some Asian workers have explored the role of surgery, specifically dorsal penile nerve division, in the management of PE. Shi and colleagues (2008) studied 483 patients with lifelong PE who underwent selective resection of branches of the dorsal penile nerve and were followed for up to 3 years after surgery. The authors report decreased penile sensitivity in all patients and significantly prolonged ejaculation latency in 352 (73%) patients. In a more recent study, Zhang and colleagues (2009) reported on a total of 314 men with lifelong premature ejaculation who underwent selective neurectomy of the dorsal penile nerve (Zhang et al, 2009). This operative intervention achieved an intravaginal ejaculation latency of 4.5 minutes compared with 1.5 minutes before surgery. **Such seemingly radical therapeutic approaches have not gained any significant traction in the United States or Europe and given the absence of definitive data linking penile sensitivity issues to PE development, it is not likely that such an approach will be accepted in the near future.**

Penile Prosthesis Implantation in Special Cases
Results

Three sentinel events define the history of the treatment of erectile dysfunction (ED): the **introduction of the inflatable penile prosthesis** (Scott et al, 1973); **intracavernous injection therapy** (Virag, 1982); and effective **systemic therapy** with sildenafil citrate (Goldstein et al, 1998). Today the treatment of ED can be compared with the treatment of osteoarthritis, another common disorder that also becomes more prevalent with age. In both, a progressive treatment model may be employed (Table 27–1). Most men with ED will initially be offered systemic therapy with a PDE5 inhibitor. If that fails and the men want to continue treatment, second- and third-line therapies should be discussed. If these fail or are rejected, penile prosthesis implantation is usually appropriate.

TYPES OF PROSTHESES

Currently available penile prostheses in the United States are shown in Table 27–2. Malleable prostheses are semirigid devices with a central core that allows the penis to be bent down for dressing and bent upward for coitus. However, for most men this malleable core does not maintain these positions well. Malleable devices have the advantage of low mechanical failure rates and ease of use. Disadvantages include constant penile rigidity and an increased risk of erosion (Steidle and Mulcahy, 1989; Zermann et al, 2006).

The positionable penile prosthesis (Dura II) is a semirigid device with a central series of articulating segments held together with a spring on each end. This device, compared with malleable prostheses, is better able to maintain its upward and downward positions.

The two-piece inflatable penile prosthesis (AMS Ambicor) consists of two cylinders connected to a small scrotal pump (Levine et al, 2001; Lux et al, 2007). Squeezing this pump transfers a small volume of fluid from the rear tip reservoirs of the cylinders into a nondistensible central chamber producing rigidity comparable with that of a malleable device. When the device is deflated, the central chamber partially collapses, providing better flaccidity than a malleable implant. The two-piece prosthesis has as its primary advantage ease of implantation because there is no third piece (abdominal fluid reservoir). A disadvantage compared with malleable devices is the increased risk of mechanical failure. Excel, a two-piece inflatable prosthesis (Coloplast), is not available in the United States.

The ideal prosthesis would provide its recipient with a penis that resembles as closely as possible normal penile flaccidity and erection. Only three-piece inflatable devices that transfer a large volume of fluid into the penile cylinders for erection and out of the cylinders for flaccidity approach this ideal. Three-piece prostheses have paired corporeal cylinders, a scrotal pump, and an abdominal fluid reservoir. An example of a three-piece inflatable prosthesis is the *Coloplast Titan Inflatable Penile Prosthesis* (Fig. 27–1). All three-piece devices provide penile girth expansion and rigidity similar to that of a normal erection. One device, the *AMS 700 LGX Inflatable Penile Prosthesis*, also provides length expansion (Fig. 27–2).

PREOPERATIVE PATIENT-PARTNER COUNSELING

Ideally, discussions regarding the treatment of ED should include the partner; however, this is not always possible. Once a decision has been made that penile prosthesis implantation should be considered, it is important to inform the patient about alternative treatments and the advantages and disadvantages of each. By this time the patient has either failed or is not a candidate for systemic treatment with PDE5 inhibitors. He should be aware that in addition to penile prosthesis implantation, therapies with vacuum constriction devices, intraurethral prostaglandin, and intracavernous injection are available. **An option such as penile prosthesis implantation should not be considered to treat a man with erectile dysfunction that is situational, the result of a relationship conflict, or one that is potentially reversible. For these men and their partners, psychologic consultation and sex therapy are more appropriate.**

Table 27–1.

Progressive Treatment Model

	OSTEOARTHRITIS	ERECTILE DYSFUNCTION
First-line therapy	NSAIDs	PDE5 inhibitors
Second-line therapy	Joint injections	VCDs, IUD
Third-line therapy	Arthroscopic surgery	Intracavernous injections
Fourth-line therapy	Prosthetic joint replacement	Penile prosthesis implantation

IUD, intraurethral drugs; NSAIDs, nonsteroidal antiinflammatory agents; PDE5, type 5 phosphodiesterase; VCDs, vacuum constriction devices.

Figure 27–2. AMS 700 LGX three-piece inflatable penile prosthesis. (Courtesy of American Medical Systems, Inc., Minnetonka, MN.)

The various types of penile prostheses along with their advantages and disadvantages (see above) should be explored. Most penile prosthesis implantation is done under spinal or general anesthesia on an outpatient basis with discharge on the same or next day. The intensity and duration of postoperative pain is variable. Most men require oral narcotics for about 1 week. After that pain can often be managed with a nonsteroidal antiinflammatory agent. When an abdominal fluid reservoir has been placed, strenuous activity and heavy lifting are proscribed for 4 weeks. Patients can drive and return to nonstrenuous work once they are no longer taking narcotics. Coitus is usually possible in 4 to 6 weeks.

The patient should understand that penile prostheses produce an erection-like state. The following considerations refer to the three-piece inflatable devices. With the prosthesis deflated most men feel comfortable in a locker room situation. With inflation the erection-like state produces girth expansion and rigidity that for most men approaches that of a normal erection. **The glans, however, is not included in the erection, and for most men the erection will be shorter than their normal erection. We demonstrate to men their stretched penile length and tell them that this will be the approximate length of their prosthetic erection.** One device, the *AMS 700 LGX* (formerly the *AMS 700 Ultrex*), produces both girth and length expansion with length expansion ranging from 1 to 4 cm (mean 1.9 cm) (Montague and Lakin, 1992).

Many men with ED have normal libido, and most have normal penile sensation and orgasm with ejaculation. If present, penile prosthesis implantation will preserve orgasm and ejaculation but not restore them if absent.

The patient should be informed that infection will probably require complete removal of the implant with resulting scarring of the corporeal smooth muscle. With prosthesis reimplantation after infection, the penis is frequently smaller and cylinder implantation is usually difficult. On rare occasions reimplantation may not be possible. Erosion of the prosthesis through the skin or into the urethra also requires device removal. **The potential implant recipient should understand that mechanical failure is possible and correcting this requires device revision or replacement.**

Key Points: Patient Expectations

- The glans penis does not increase in size with a prosthetic erection.
- A prosthetic erection is usually shorter than a normal erection and is about equal to the patient's stretched penile length.
- Using AMS LGX cylinders in appropriately selected patients can provide an additional 2 cm of penile length with device inflation.

Table 27–3.

Comparison of Infrapubic and Penoscrotal Implant Approaches

	INFRAPUBIC APPROACH	PENOSCROTAL APPROACH
Advantages	Reservoir placement under direct vision	Better corporeal exposure No dorsal nerve injury Pump fixation possible
Disadvantages	Limited corporeal exposure Possible dorsal nerve injury Inability to anchor pump	Blind reservoir placement

SURGICAL APPROACHES

Surgical approaches for penile prosthesis implantation include subcoronal (used only for implantation of malleable or positionable devices), infrapubic, and penoscrotal. We prefer the penoscrotal approach for the reasons listed in Table 27–3. When corporeal fibrosis is present, the penoscrotal incision can be extended to expose almost the entire extent of both corpora cavernosa.

A potential disadvantage of the penoscrotal incision not listed in Table 27–3 is the presence of excess tubing in the scrotum or at the base of the penis. We avoid this by implanting the preconnected cylinders and pump first using a penoscrotal incision with a transverse flap through the deep layers of dartos fascia. A second incision is made through dartos fascia in the midline of the scrotum to develop a pouch for the pump. A stab incision is then made deep through the back wall of the pouch (the transverse dartos flap), and the pump is brought through this to place it into the pouch. This helps anchor the pump in the pouch and buries the tubing in the upper scrotum. This is advantageous not only from a cosmetic standpoint but also because it reduces the risk of device infection. **If a superficial penoscrotal wound infection occurs and the fascia is intact, a deep infection in the space around the prosthesis, which would require device removal, is not likely to occur.**

Increasingly, men who have had radical prostatectomy require penile prosthesis implantation. Some question the feasibility of three-piece inflatable prosthesis implantation in this group because of scarring of the lower abdominal fascia and concern regarding scarring in the retropubic (prevesical) space. Lane and colleagues (2007) reported 115 consecutive implants of three-piece inflatable penile prostheses done through a single transverse penoscrotal incision with no reservoir-related complications. The use of LGX cylinders in men who have had radical prostatectomy may be of particular benefit because radical prostatectomy has been shown to result in a loss of penile length in many individuals (Gontero et al, 2007; Mulhall, 2005; Savoie et al, 2003).

AMS 700 LGX INFLATABLE PENILE PROSTHESIS IMPLANTATION BY A COMBINED LONGITUDINAL-TRANSVERSE PENOSCROTAL APPROACH

The authors perform this procedure with the patient in the supine position under either spinal or general anesthesia. Shaving of the skin is done in the operating room to avoid bacterial colonization of small skin breaks that might occur if shaving were done before the surgery. A 10-minute skin prep is performed. Paper drapes are used because when cloth drapes become wet, they do not provide a good bacterial barrier. We do not place a urethral catheter at this point because it is easier to judge the quality of the erection when a catheter is not present.

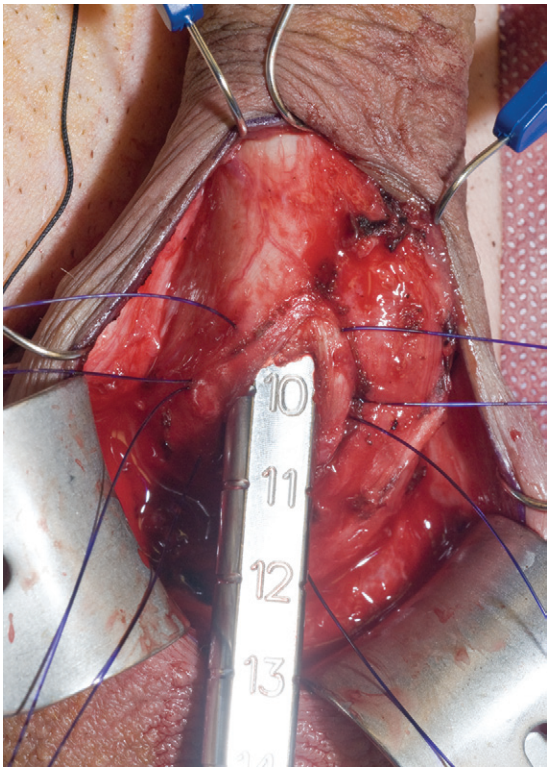

Figure 27–3. The distal measurement is 10 cm.

A longitudinal penoscrotal incision is made, and the superficial layers of dartos fascia are divided longitudinally. At the penoscrotal junction the deep layers of dartos fascia are divided transversely. This transverse incision through the fascia should be directed toward the urethra and corporeal bodies rather than toward the scrotum. Allis clamps are placed on the lower margin of the fascia, and the underside of dartos fascia is dissected off the urethra and the proximal corpora (crura). This combined longitudinal-transverse penoscrotal incision provides a transverse dartos flap to bury tubing in the upper scrotum with the cosmetic advantages of a skin incision along the midline penoscrotal raphe. The authors use a ring retractor they have modified by placing slits in it so that exposure may be maintained by a combination of hook stays and retractor blades.

Two-centimeter corporotomies are made, and two horizontal mattress sutures of 2-0 PDS II (polydioxanone, Ethicon, Inc., Somerville, NJ) are placed on each side of the corporotomy. These sutures are used as guide sutures during corporeal dilation and measurement, and they are also used to close the corporotomy after the cylinders are placed (Montague, 1993). Dilation starts with an 8-mm Hegar dilator and proceeds to 16 mm proximally and 14 mm distally. The greater proximal dilation is necessary to accommodate both the cylinder and cylinder tubing. If dilation to these diameters is not possible, the smaller-diameter AMS 700 CXR or the Mentor Titan Narrow Base prosthesis should be used.

Using a sizing instrument, the distal measurement taken from the distal end of the corporotomy is 10 cm (Fig. 27–3), and the

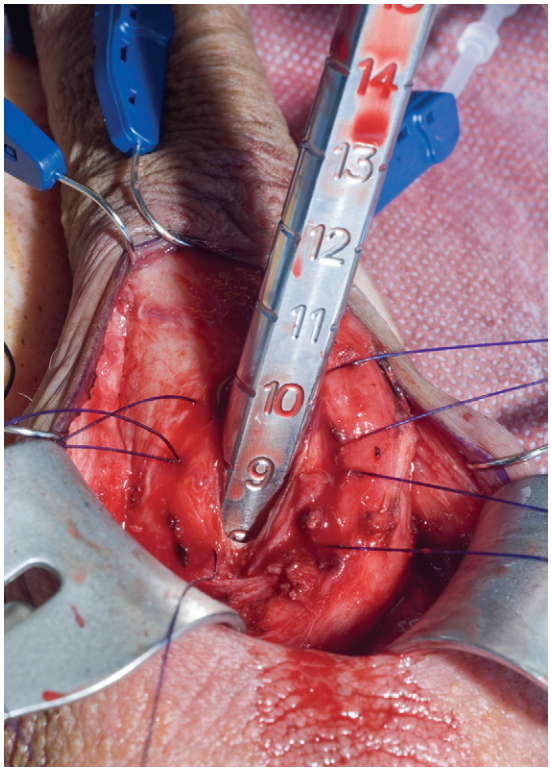

Figure 27–4. The proximal measurement is 8 cm.

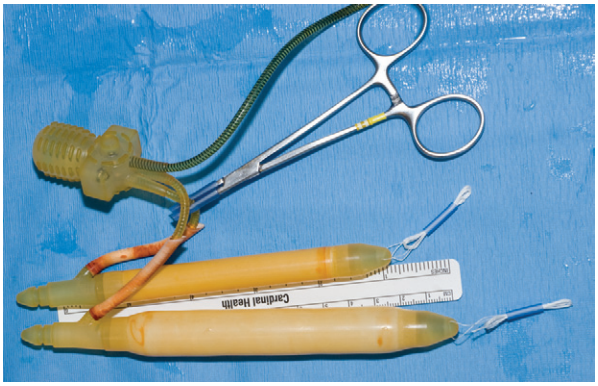

Figure 27–5. The prosthesis components prepared for implantation. One cylinder is inflated to demonstrate its girth- and length-expanding properties. It is deflated before insertion.

proximal measurement taken from the proximal end of the corporotomy is 8 cm (Fig. 27–4). **It is important to size cylinders exactly to fill the entire corpora. Cylinders should be neither too short, producing the supersonic transporter (SST) deformity (Ball, 1980), nor too long, producing bucking within the corpora. We do not include the 2-cm corporotomy in the measurement because we believe that surface sizing with a rigid measuring tool introduces a 2-cm measuring error** (Montague et al, 2003). With standard measuring techniques from a midcorporotomy reference point, the cylinder placed is about 2 cm too long. When the length-expanding LGX cylinder is used, this leads to the so-called S-shaped cylinder deformity (Wilson et al, 1996). Although no data support this, the authors believe that with non–length-expanding cylinders, a too-long cylinder may cause premature failure (cylinder failures are most common in the area where the buckling with a too-long cylinder occurs).

After corporeal measurements are taken, the appropriate cylinder size is selected. LGX and CX cylinders come in the following lengths: 12, 15, 18, and 21 cm. Adjustments between these sizes are made by the addition of rear tip extenders. The cylinders are filled with normal saline, and the authors inject saline until the cylinders are full (rounded) but not inflated under pressure. Having the cylinders full rather than collapsed makes it easier to judge whether the cylinder fit following insertion is correct. The pump is filled by cycling the pump while the pump tubes are submersed in a basin of normal saline. The reservoir is filled with normal saline to displace air; the saline is then removed because the reservoir will be filled after it is implanted. In this case the total corporeal length was 18 cm (10 cm + 8 cm), and the authors elected to use 15-cm LGX cylinders with 3-cm rear tip extenders. Figure 27–5 shows the filled prosthesis components ready for implantation. For illustrative purposes one cylinder is inflated to show both its girth and length expansion. It will be deflated before implantation.

Distal cylinder insertion is aided by the use of the Furlow cylinder inserter (American Medical Systems, Minnetonka, MN). The guide sutures in the tip of the cylinder are threaded through the needle provided in the accessory package, and this needle with its sutures is placed into the distal end of the inserter. The inserter is then placed to the distal end of the corpus cavernosum. The plunger of the cylinder inserter is pushed in delivering the needle and guide sutures through the tip of the corpus cavernosum and out through the glans. The guide sutures are used to pull the distal cylinder into the distal corpus cavernosum. If rear tip extenders are necessary, they are added now and the proximal portion of the cylinder is manually inserted. If the cylinder fit is proper, the proximal portion will be all the way down to the attachment of the crus to the pelvic bone, and the distal portion will be in the distal corpus cavernosum under the mid glans penis. When these conditions have been met, the rounded visible portion of the cylinder will lie flatly in the open corporotomy (Fig. 27–6). The penis should then be released from the retractor, and the distal position of the cylinders and glans support should be evaluated (Fig. 27–7). If the cylinder is too long or too short, the proximal portion can be removed and length adjustment can be made by adding or removing rear tip extenders. The corporotomies are closed by tying the proximal ends and then the distal ends of the preplaced horizontal mattress sutures (Montague, 1993).

In preparation for pump placement, a second incision through dartos fascia is made in the scrotal septum. A deep septal pouch is developed with ring forceps. A passage way is made with a right angle clamp through the back wall of this pouch deep in the scrotum, and the pump is brought through this passage way into the pouch (Fig. 27–8). After irrigation with antibiotic solution, the second dartos incision is closed with running 3-0 Dexon II (polyglycolic acid suture, United States Surgical, Tyco Healthcare Group, Norwalk, CT).

A 50-mL syringe filled with normal saline, which serves as a temporary reservoir, is then connected to the reservoir tube from the pump. The pubis to glans tip penile length measurement is 15 cm with the cylinders deflated (Fig. 27–9) and 17 cm with the cylinders inflated (Fig. 27–10). **The use of a device with LGX cylinders in this patient has given him a prosthetic erection that is 2 cm longer than that obtainable with any other inflatable device.**

Safe reservoir insertion into the retropubic space through the primary penoscrotal incision is possible

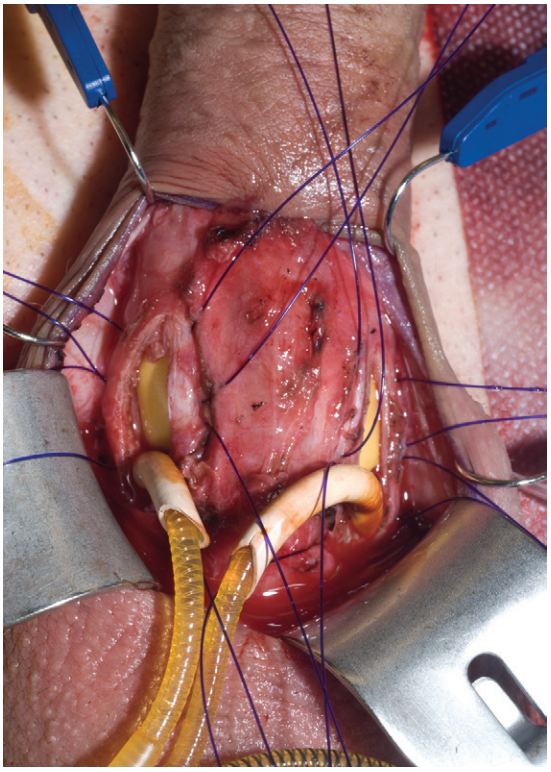

Figure 27–6. The cylinders, which have been correctly sized, lie flat within the corpora.

Figure 27–7. The penis has been released from the retractor. Both cylinder tips reach the ends of the corpora and provide excellent glans support.

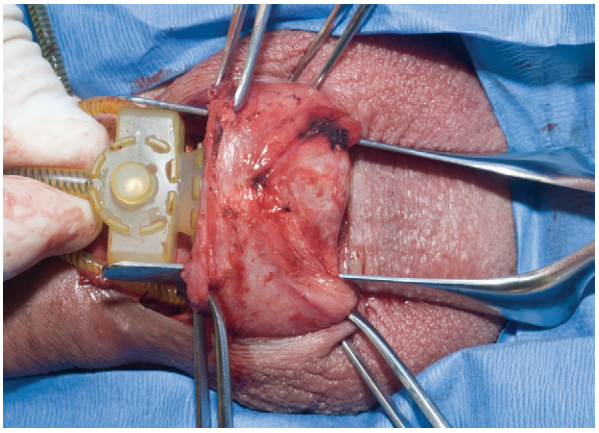

Figure 27–8. The pump is brought through a stab incision deep through the back wall of the subdartos pouch.

Figure 27–9. The length of the penis with the cylinders deflated is 15 cm.

only if the bladder is completely empty. The authors insert an 18-Fr urethral catheter attached to closed gravity drainage and apply suprapubic pressure over the bladder until it is empty. The surgeon introduces his or her finger into the incision and moves this up to the external inguinal ring on either side. If the external ring is not palpable, a point just above the pubic tubercle is chosen. Metzenbaum scissors or a Kelly clamp is used to perforate the transversalis fascia. **If all layers of the fascia are perforated, the surgeon's index finger enters the retropubic space. Correct entry is confirmed if the back of the symphysis pubis and the balloon in the empty bladder are palpated.** A nasal speculum with long blades is substituted for the finger; this maintains the fascial opening (Fig. 27–11). The empty reservoir is introduced into the retropubic space; the

Figure 27–10. The length of the penis with the cylinders inflated is 17 cm.

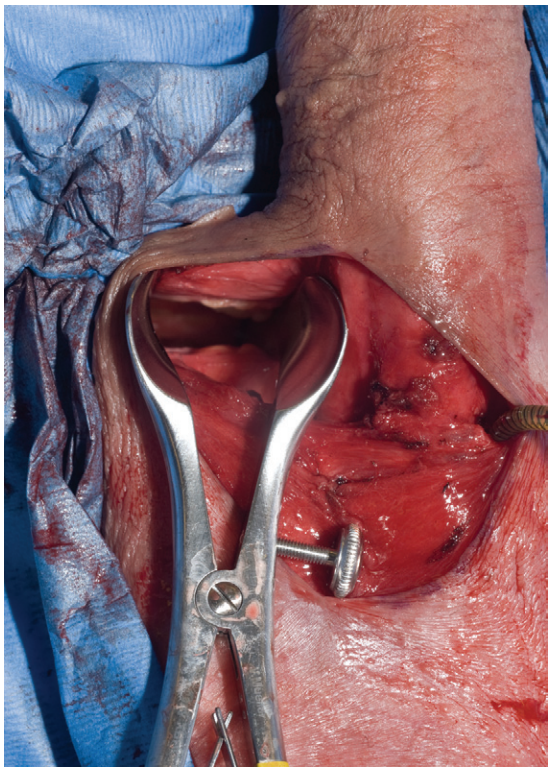

Figure 27–11. A nasal speculum maintains the fascial opening for reservoir insertion.

hublike junction between the reservoir and the tube should be located in the fascial defect.

The AMS reservoirs are available in two sizes: 65 mL and 100 mL. The former is recommended for all cylinder sizes except for the 18- and 21-cm LGX cylinders, which require the 100-mL reservoir size. The reservoir is then filled with the requisite amount of normal saline, and then the position of the reservoir is confirmed by palpation. The reservoir itself, which is below the fascia, should not be palpable. The tubing hub should be palpable as it protrudes through the fascia. A back pressure test is done; if fluid exits under pressure, as little as 85 mL can be left in a 100-mL reservoir and as little as 50 mL can be left in a 65-mL reservoir. The reservoir tubing is brought down into the incision in the upper scrotum, where a connection to the pump-reservoir tubing is made over a sutureless straight connector.

A long right-angle clamp is introduced through the incision to the inguinal area on the side of the reservoir. A stab incision is made and through this a closed-suction type of drain is introduced. The drain is brought down to the base of the penis, where it will lie on top of the tubes and connectors. Dartos fascia is then closed transversely with running 3-0 Dexon. The skin is closed with running subcuticular 4-0 Vicryl.

POSTOPERATIVE CARE

The urethral catheter and the closed suction drain are removed the next morning after an overnight stay in the ambulatory surgery center. Most men require an oral narcotic for about 1 week. After that a nonsteroidal antiinflammatory agent will usually suffice. If an abdominal fluid reservoir has been placed, lifting and other activities that might result in reservoir displacement from the retropubic space into the inguinal area are proscribed for 1 month. The patient is instructed to keep his penis up on the lower abdomen pointing to the umbilicus. If the penis is worn in a downward position as healing takes place, ventral curvature of the penis may result.

One month after surgery most men are ready for instructions on cycling the device. We instruct the patient to fully inflate and deflate his device twice daily for 1 month. This serves a dual purpose: practice on cycling, as well as activity that stretches the pseudo capsule that by now has formed around the cylinders. In the beginning pumping requires considerable force, but with time it becomes much easier.

The patient is given permission to begin coitus whenever inflation can be accomplished without discomfort. Because anxiety on the part of the partner may inhibit vaginal lubrication, the couple is advised to use a water-soluble lubricant at least initially. **Retarded ejaculation (failure to reach orgasm) may occur when men first use their prosthesis for coitus. To avoid this, the couple is counseled to have adequate foreplay so that both partners are sexually aroused before intromission.**

COMPLICATIONS

Infection

Infection in the periprosthetic space usually does not cause significant illness; however, to eradicate the infection, removal of all components of the prosthesis is almost always required. Therefore infection is considered by many to be the most significant complication of genitourinary prosthetic surgery.

Penile prosthesis implantation should be delayed in patients with urinary tract infections or cutaneous infections in the operative area. Shaving of the operative area is done just before surgery to avoid bacterial colonization of small skin breaks that might occur if shaving was done before the day of surgery. The operative

area is prepared with a 10-minute skin prep. Broad-spectrum prophylactic antibiotics are given 1 hour before the case begins so that adequate tissue levels are present when the incision is made. We use gentamicin and vancomycin for this purpose. Paper rather than cloth drapes are used because the latter are permeable to bacteria when wet. The prosthesis is kept in its sterile package until it is ready to be filled and implanted. It is then submersed in an antibiotic solution unless it has an antibiotic coating, in which case it is placed in a sterile basin and covered with a paper towel. Silicone has a positive charge and attracts air borne particles; therefore as it is placed in the body, it is irrigated with antibiotic solution and irrigated again as tissues are closed over it. For our antibiotic solution we use 50,000 units of bacitracin in a liter of normal saline.

Infections occurring after penile prosthesis are either early (in the first few weeks following implant) or late (6 months to 1 or 2 years after implant). The former are often associated with gram-negative bacteria. whereas the latter are usually associated with gram-positive bacteria such as *Staphylococcus epidermidis* (Kabalin and Kessler, 1988; Licht et al, 1995). Infections with other organisms such as fungi (Peppas et al, 1988) and gonococci (Nelson and Gregory, 1988) have also been rarely reported. It was originally believed that all infections originated from the time of surgery. Carson showed that late prosthetic infections can occur by hematogenous spread from a distant source (Carson and Robertson, 1988). The authors have shown that late infection can also arise after a mechanical malfunction (fluid leak) from a prosthetic device (Milbank et al, 2004). Fluid leak likely disrupts the balance with a biofilm, favoring bacterial growth (Silverstein et al, 2003). Alternatively, the fluid itself could be a bacterial reservoir.

Evidence is divided as to whether men with diabetes mellitus are at increased risk for infection following penile prosthesis implantation and whether the degree of diabetes control at the time of surgery is related to the risk of infection. In one study four infections occurred in 13 diabetics with a glycosylated hemoglobin above 11.5%, whereas in 19 diabetics with a glycosylated hemoglobin under 11.5%, only one infection occurred (Bishop et al, 1992). In another study of penile prosthesis recipients, infections occurred in 10 of 114 diabetics (8.7%) and in 11 of 275 nondiabetics (4%). However, there was no statistically significant increased infection rate with increased levels of glycosylated hemoglobin (Wilson et al, 1998). In a study of 556 prosthesis recipients, there was no significant difference in the incidence of infection in diabetic versus nondiabetic patients (Montague et al, 2001).

In a study looking at the surgical approach for penile prosthesis implantation, 4 of 139 devices implanted via the infrapubic approach became infected (2.9%), whereas 2 of 221 implanted via the penoscrotal approach became infected. This difference was not statistically significant (Garber and Marcus, 1998).

Early infections are likely to be evident by swelling, erythema, tenderness, possible purulent drainage, and occasionally fever. Late infections may only be manifested by persistent or recurrent long-term pain. With long-term infections the scrotal skin may be adherent to the pump. Infections are sometimes evident by erosion, particularly of the pump through the scrotum (Fig. 27–12). **This should never be considered infection of the pump alone. All components of the device are connected by tubing, and the entire device is considered to be infected.**

Treatment of a prosthetic infection with appropriate antibiotics usually results in clinical improvement; however, antibiotic treatment will rarely permanently eradicate this type of infection. This

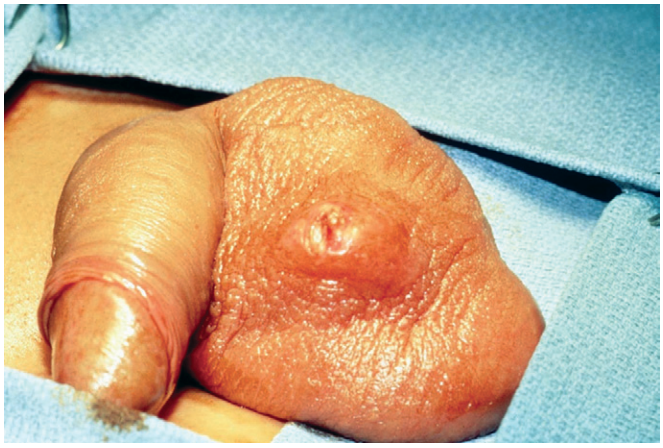

Figure 27–12. Impending scrotal pump erosion in a patient with an infected prosthesis.

is thought to be due to the harboring of microorganisms within a biofilm that is adherent to the device (Abouassaly et al, 2004). **For this reason, when a prosthetic infection is present, all components of the prosthesis should be removed.**

Penile prosthesis reimplantation following infected device removal presents certain difficulties. Pump and reservoir reimplantation is seldom a problem. However, after infected device removal, the corporeal smooth muscle becomes replaced in varying degrees with scar. In the past reimplantation was often delayed as long as a year. During this time the scar within the corpora would mature, resulting in contraction, a smaller penis size, and more difficulty with dilation before cylinder reimplantation. **To minimize loss of penile size and to facilitate corporeal dilation, the authors now perform prosthesis reimplantation as soon as possible after device removal for infection.** Once all incisions have healed and postoperative edema has resolved (usually 6 to 12 weeks after device removal), reimplantation is advised because early fibrosis is easier to dilate and the scar contraction that leads to shortening has not yet occurred.

Mulcahy introduced the concept of prosthesis salvage for infection in 1996 (Brant et al, 1996), and he updated his experience with this in 2000 (Mulcahy, 2000). His protocol involves removal of all prosthetic components and foreign bodies followed by irrigation with seven antibacterial solutions. A new device is implanted, and the patient is placed on antibiotics. In 55 patients available for follow-up, 45 (82%) were free of infection with follow-up ranging from 6 to 93 months. **When salvage procedures are successful, they maintain penile size and correct the problem with only one operation.**

Recent advances in prosthetic design have been made in attempts to reduce infection. A surface treatment combining rifampin and minocycline (InhibiZone) was introduced in 2001 by American Medical Systems for its three-piece inflatable penile prosthesis product line. In a report comparing 2261 rifampin-minocycline–coated devices with 1944 controls, the infection rate at 180 days was 0.68% in the treated group compared with 1.61% in the control group (Carson, 2004).

Mentor (now Coloplast) introduced a hydrophilic surface coating for their three-piece inflatable prosthesis in 2002 (Coloplast Titan). This coating, polyvinylpyrrolidone (PVP), reduces bacterial adhesion and absorbs the antibiotics in which the prosthesis is submerged by the surgeon just before implantation. In a report comparing 2357 hydrophilic-coated devices with 482 controls, the infection rate was 2.07% in the treated group

compared with 1.06% in the control group (Wolter and Hellstrom, 2004).

The incidence of infection during first-time penile prosthesis implantation ranges from 1% to 3%, whereas with revision surgery it is considerably higher (7% to 18%) (Kabalin and Kessler, 1988; Wilson and Delk, 1995; Jarow, 1996; Henry et al, 2005). In the early days of penile prosthesis surgery, mechanical failures were common and frequently occurred within the first few years following device implantation. The reports of increased infection rates following prosthesis revision occurred when only the failed component of the prosthesis was replaced. **If the entire device is explanted and all prosthesis compartments are thoroughly irrigated before a new prosthesis is implanted, the infection rate is not significantly different from the rates seen with first-time prosthesis implantation** (Montague et al, 2001; Henry et al, 2005).

Mechanical failures today are less common and typically occur more than 5 years after implantation.

Key Points: Prosthesis Infections

- Primary prosthesis infection rates range from 1% to 3%. Revision surgeries for penile prostheses have similar infection rates if all prosthesis components are removed and replaced with new ones.
- In surgery for infected penile prostheses, all prosthetic components and associated prosthetic material should be removed.
- Salvage surgery for infected penile prostheses is successful in approximately 80% of cases and avoids loss of penile length.
- Early (1- to 3-month) penile prosthesis reimplantation after removal of an infected penile prosthesis minimizes loss of penile length.

Perforation and Erosion

Perforation is an event that occurs intraoperatively; whereas erosion is an event that occurs or is only recognized postoperatively. When the surgeon is dilating the proximal corpora (crura), a sudden give of the dilator suggests the crus has been perforated on its medial aspect near its attachment to the pelvic bone. The dilator, almost always a smaller size, travels out into the soft tissues of the perineum. Although Mulcahy (1987) suggested the "wind sock" correction for this, it is rarely necessary if the perforation is recognized and larger-diameter dilators are used to dilate the correct tract. When the proximal portion of the cylinder is inserted, it will stay within the crus and the small area of perforation will heal over it.

With distal dilation, crossover to the opposite side may occur or the urethra may be perforated. **If urethral perforation occurs, the implant procedure should be abandoned and a urethral catheter should be left in for 7 to 10 days.** Prosthesis reimplantation may be done at a later date. To avoid urethral perforation, the surgeon should keep the tip of the dilator under the dorsolateral surface of the corpus cavernosum. This maneuver also helps to prevent crossover to the opposite side. After the first cylinder is implanted, the surgeon should resound the other side both proximally and distally to see if crossover in either direction has occurred.

Erosion of the distal cylinder lateral to the distal corpus cavernosum is usually most effectively corrected by a technique described by Mulcahy (1999). With this approach the distal cylinder is removed (folded back) and an incision through the back wall of the capsule of the cylinder compartment is made in an area proximal to the site where the erosion has occurred. This allows distal dilation within the true corpus cavernosum. Using the Furlow cylinder inserter, the distal cylinder is then reimplanted within the distal corpus cavernosum.

Erosion of the distal end of the prosthesis may occur into the urethra, in which case it is visible through the meatus. This occurs more commonly after semirigid rod implantation, presumably due to constant internal pressure from the rod device (Steidle and Mulcahy, 1989). It also occurs more commonly in men with spinal cord injury because of their lack of sensation (Zermann et al, 2006). In the case of a semirigid rod device, only the eroded side needs to be removed and this can usually be done in the office by grasping the distal end of the rod with a towel clip and then pulling it out. In the case of urethral erosion, a urethral catheter is placed for 10 days to allow urethral healing. Many patients can have adequate coitus with only one rod in place; hence a procedure to reimplant the second rod is usually unnecessary.

In the case of erosion of one cylinder of an inflatable device into the meatus or through the glans, this cylinder should be removed as soon as possible to avoid spread of bacteria along the cylinder to its tubing and thus to the rest of the prosthesis. After the cylinder is removed, an implantable plug (supplied by the device manufacturer) is placed in the pump tubing that led to that cylinder. Again, many men can have coitus with only one inflatable cylinder; thus a later procedure to reimplant the second cylinder is not always necessary.

Poor Glans Support

Poor support of the glans penis by cylinder or rod tips leads to a drooping appearance of the glans, which is commonly referred to as the "SST deformity" after the supersonic transport (Concorde) nose appearance on takeoff and landing (Ball, 1980). This may result from inadequate distal dilation; too short cylinders; or in the case of minor deformity, variations in anatomy.

Correction of this deformity can be done in one of two ways. The definitive correction involves removing both cylinders, perforating the distal capsule with Metzenbaum scissors, redilating the distal corpora, resizing, and then inserting longer cylinders or the same cylinders with longer rear tip extenders. Alternatively, dorsal plication of the glans back onto the shaft of the penis can be performed (Fig. 27–13) (Ball, 1980; Mulhall and Kim, 2001). This latter procedure is preferable when there are minor but otherwise bothersome degrees of SST deformity.

Oversized Cylinder or Rod

When a semirigid rod prosthesis that is too long is implanted, the patient may complain of pain that does not subside as healing takes place following device implantation. Alternatively, this may lead to erosion of the rod either into the meatus or through the glans. Reoperation with placement of smaller rods will usually relieve the pain and avoid impending erosion.

As already discussed, cylinders that are too long may result in a sigmoid (S) penile deformity in the case of Ultrex or LGX cylinders. In the case of non–length-expanding cylinders, usually there is no problem, although theoretically it might lead to premature cylinder failure.

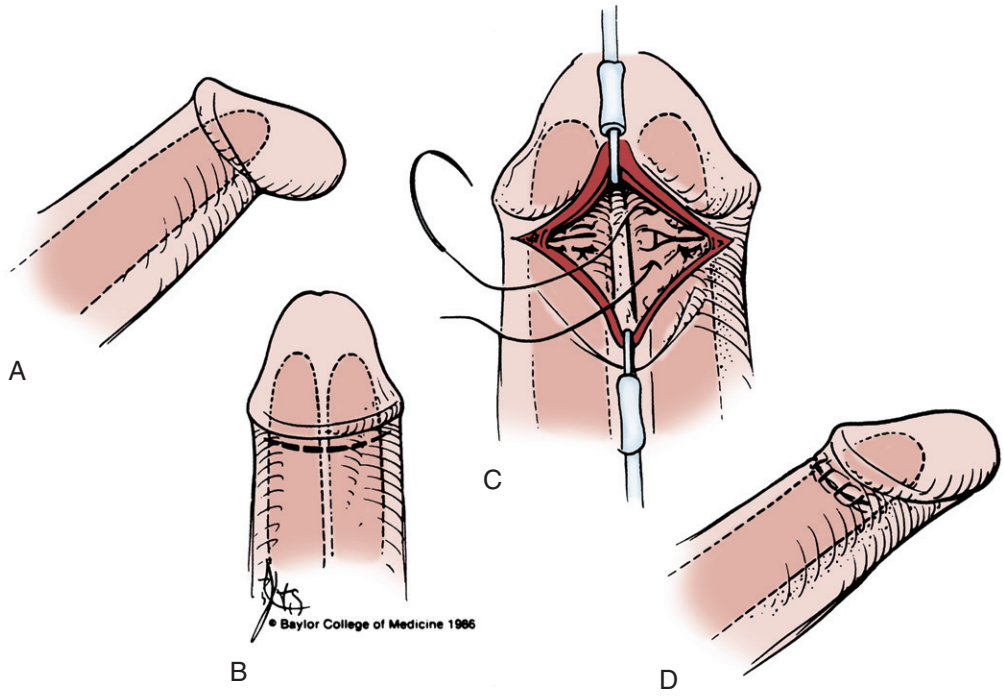

Figure 27–13. Plication sutures pull the dorsal aspect of the glans back onto the corporeal bodies to correct an SST (supersonic transporter) deformity. (© Baylor College of Medicine.)

Pump Complications

The technique for pump implantation discussed earlier helps to avoid upward pump migration, which tends to take place during healing because of the action of the cremasteric muscles. If upward pump migration occurs, the pump may impinge on the base of the penis, making use of the pump difficult and also interfering with intromission. Revision is sometimes necessary, at which time the pump is relocated to its correct position.

The pump may also be difficult to use if a hematoma or seroma forms around it. These may reabsorb with time; if they do not, pump revision may be necessary.

Autoinflation

Autoinflation occurs when the inflatable penile prosthesis partially inflates with physical activity. This can be minimized by placing the reservoir in the prevesical (retropubic) space and by performing the back pressure test as described earlier. The cylinders should also be kept deflated during healing after surgery and when the prosthesis is not being used.

The Coloplast Titan prosthesis has a reservoir with a lock-out valve in the stem. Initial experience with this device suggests that it reduces the incidence of this complication (Hollenbeck et al, 2002; Wilson et al, 2002). The MS pump of the AMS 700 series three-piece inflatable penile prostheses has a lock-out valve in the top, deflation portion of the pump.

PENILE PROSTHESIS IMPLANTATION IN SPECIAL CASES

Peyronie Disease

Men who have acquired erectile deformity secondary to Peyronie disease along with significant ED may be candidates for penile prosthesis implantation. When prosthesis implantation by itself does not produce satisfactory straightening of the penis, a corporoplasty may also be necessary (Mulcahy and Wilson, 2002). Corporoplasty was frequently necessary when girth- plus length-expanding Ultrex cylinders were used and not necessary when girth-only expanding CX cylinders were used (Montague et al, 1996). Wilson showed that modeling or forcefully bending the penis with the cylinders inflated usually obviated the need for corporoplasty (Wilson et al, 2001).

Multiple relaxing incisions to correct curvature and increase penile length have been used in men with Peyronie disease undergoing penile prosthesis implantation (Montorsi et al, 2001; Rajpurkar et al, 1999). When a relaxing incision leaves a gap greater than 1 cm, covering the defect to prevent herniation of the cylinder is recommended. Materials used to cover the defect include human cadaveric dura mater (Fallon, 1990), polytetrafluoroethylene (Fig. 27–14) (Herschorn and Ordorica, 1995), human cadaveric pericardium (Palese and Burnett, 2001), and porcine small intestinal submucosa (Knoll and Center for Urological Treatment, 2002).

Cavernosal Fibrosis

In contrast to Peyronie disease, in which scarring is present in the tunica albuginea, scarring may occur in the cavernosal smooth muscle that forms much of the contents of the corporeal bodies. **Cavernosal fibrosis is most often seen after removal of an infected penile prosthesis; it also occurs in men with ED as a result of ischemic priapism. In both cases, the penis is often significantly smaller owing to decreased volume of the corpora cavernosa. Dilation of the corpora and placement of semirigid rods or cylinders is also frequently quite difficult.**

In preparing the corpora for cylinder implantation, the authors start with a 2-cm standard corporotomy. If the corpora cannot be

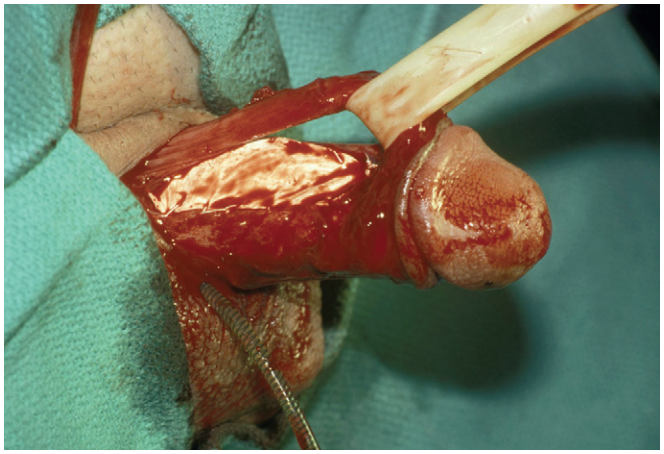

Figure 27–14. After inflatable penile prosthesis implantation, a large plaque required excision. The exposed cylinders are covered with a polytetrafluoroethylene patch.

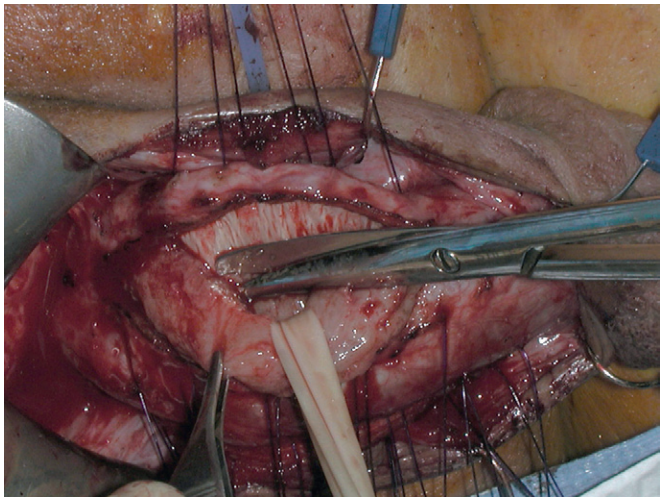

Figure 27–16. A Penrose drain is used to place traction of the fibrotic core, facilitating further dissection.

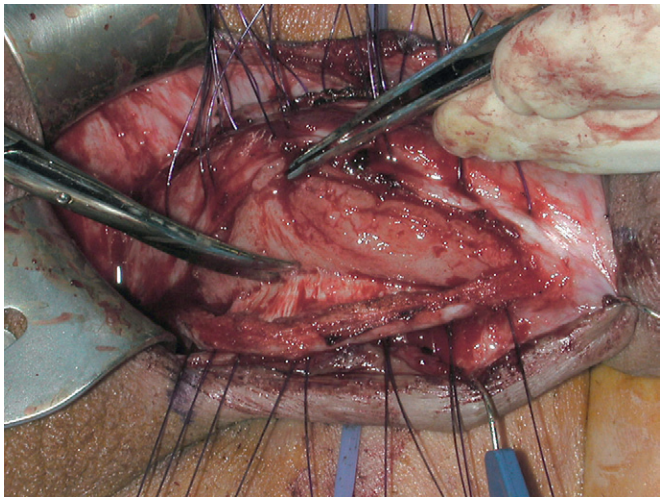

Figure 27–15. A plane of dissection is established between the fibrotic core and the inner surface of the tunica albuginea.

Figure 27–17. The excised core of fibrotic tissue.

dilated without force, they abandon the use of Hegar dilators and instead use Metzenbaum scissors with rounded tips. Gently spreading the tips as the scissors are advanced is often effective. After the scissors tips reach the distal and proximal ends of the corpora, dilation with special cutting dilators is helpful (Mooreville et al, 1999).

If these maneuvers are not successful, the authors extend the penoscrotal incision to the frenulum. Extended corporotomies are made permitting either dilation with more control or resection of scar tissue by establishing a plane between the fibrotic core and the inner surface of the tunica albuginea (Fig. 27–15), and this is facilitated by placing a Penrose drain around the core (Fig. 27–16) (Montague and Angermeier, 2006). The result is removal of the fibrotic contents of the corpus cavernosum (Fig. 27–17). Multiple horizontal mattress sutures of 2-0 PDS are then placed along the edges of the tunica albuginea (Fig. 27–18). The prosthetic cylinder can then be laid into the empty corporeal shell (Fig. 27–19), with primary closure of the tunica albuginea being possible (Fig. 27–20).

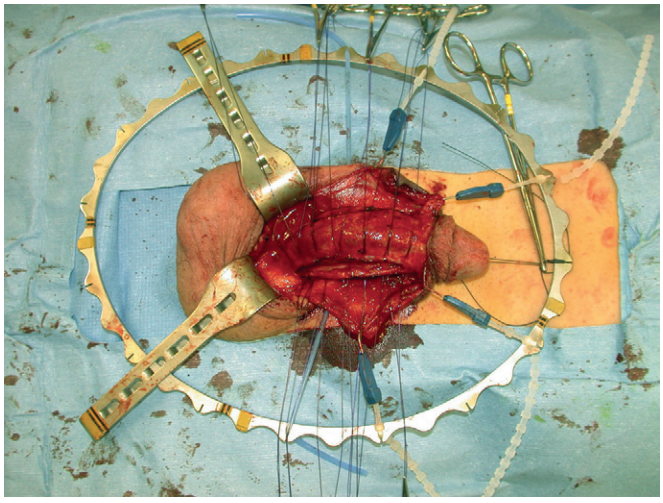

Figure 27–18. Multiple horizontal mattress sutures are placed along the cut edges of the tunica albuginea.

RESULTS

Mechanical Failure Rates

Much of the early reporting of penile prosthesis results in terms of survival free of mechanical failure was limited because of data that usually gave only the range and mean follow-up for the entire series. It was not possible with this type of reporting to meaningfully compare different devices or the same device in different series because of failures to take into account differences in follow-up. **Contemporary reporting standards should require reporting device survival free of mechanical failure by using Kaplan-Meier projections** (Kaplan and Meier, 1958; Montague et al, 2005).

The results reported herein are limited to the three-piece inflatable penile prostheses available today (the AMS 700 CX/CXM, the AMS 700 Ultrex, and the Mentor Alpha-1) and include only those studies that report Kaplan-Meier projections. Eight such studies were found (Table 27–4). The AMS 700 CX/CXM prosthesis was introduced in 1987; no significant design changes have occurred with this device since its introduction. Five studies with a total of 949 implant recipients reveal that freedom from mechanical failure ranges from 83.9% (63 months) to 93.1% (5 years).

The AMS 700 Ultrex prosthesis was introduced in 1990, and the cylinders were modified in 1993. Results from two studies (Dubocq et al, 1998; Montorsi et al, 2000) with a total of 213 device recipients included both pre- and post-1993 Ultrex modified devices. Survival free of mechanical failure ranges were 79.4% (5 years) and

84.2% (63 months). One study compared 5-year device survival before the 1993 cylinder modification (64.7%, $N = 85$) to after the 1993 cylinder modification (93.7%, $N = 52$) (Milbank et al, 2002).

The Mentor Alpha-1 prosthesis introduced in 1989 underwent pump modification in November 1992. Two studies with a total of 55l implant recipients included both prepump and postpump modification devices. Survival free of mechanical failure was 85% at 3 years (Goldstein et al, 1997) and 95.7% at 63 months (Dubocq et al, 1998). One study compared 5-year device survival before pump modification (75.3%, $N = 410$) and after pump modification (92.6%, $N = 971$) (Wilson et al., 1999).

Dhar and colleagues reported on 455 men implanted with CX/CXM devices. Median follow-up was 91.5 months. Ten-year Kaplan-Meier estimates of freedom from mechanical failure were 81.3% (95% CI, 75.7 to 87.3) (Dhar et al, 2006).

Patient (Partner) Satisfaction

Early satisfaction studies were retrospective and used nonstandardized questionnaires. In one such study of the AMS 700 inflatable (pre-CX and pre-Ultrex) prosthesis, 387 recipients were mailed questionnaires and 272 were returned. This retrospective review showed that 83% of the men and 70% of their partners were satisfied with the use of this device (McLaren and Barrett, 1992). In another retrospective study of 145 AMS 700 Ultrex inflatable penile prosthesis recipients using a nonstandardized questionnaire, 85% of the men and 76% of their partners were satisfied (Holloway and Farah, 1997).

Prospective studies using structured questionnaires can provide more useful information regarding patient and partner satisfaction following penile prosthesis implantation. In one such study a psychosexual questionnaire containing 13 questions scored on a scale of 1 to 5 was administered to 35 inflatable penile prosthesis recipients preoperatively and again at 3, 6, and 12 months after surgery. This study demonstrated significant improvements in the psychosexual well-being of these prosthesis recipients with attainment of a high level of patient satisfaction up to 1 year after surgery. This study permitted these results to be broken down into erectile ability, libido, frequency of sexual activity, satisfaction with sexual activity, and a decrease in feelings of sadness, depression, anxiety, anger, frustration, and embarrassment related to sexual activity (Tefilli et al, 1998).

In another prospective study of 96 inflatable penile prosthesis recipients, the International Index of Erectile Function (IIEF) (Rosen et al, 1997) and the Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) (Althof et al, 1999) were administered preoperatively and 3, 6, and 12 months postoperatively (IIEF) and 3, 6, and 12 months postoperatively (EDITS). All 12 month scores were significantly higher than baseline scores, and the 12-month scores were significantly higher than the 6-month scores for the IIEF satisfaction domain and for EDITS (Mulhall et al, 2003).

One study compared penile prosthesis implantation to penile injection therapy. In this retrospective study a structured telephone questionnaire was administered to 115 intracavernosal injection patients and 65 penile prosthesis recipients. Mean follow-up of all patients was 5.4 years. At the time of contact 70% of the patients with prostheses were still sexually active, whereas only 41% of the penile injection patients were sexually active (Sexton et al., 1998).

Another retrospective study compared erectile function status and satisfaction in patients receiving treatment with sildenafil citrate, intracavernous injection therapy, and inflatable penile prosthesis implantation. The patients were administered EDITS and the erectile function domain of the IIEF. There were 31 patients in the sildenafil citrate group, 22 in the penile injection therapy group, and 32 who had received a penile prosthesis. At a mean follow-up of 19.54 months, penile prosthesis recipients had significantly better erectile function and treatment satisfaction than did patients in the other two groups (Rajpurkar et al, 2003).

In a study of 114 penile prosthesis recipients, IIEF was administered preoperatively and IIEF, EDIT, and a Global Satisfaction Questionnaire were given at least 6 months postoperatively (Akin-Olugbade et al, 2006). Subgroups evaluated included recipients with Peyronie disease, body mass index (BMI) greater than 30 $kg \cdot m^2$, radical prostatectomy, and patient age older than 70 years. All groups showed significant improvement in IIEF and EDITS scores. Men with Peyronie disease, radical prostatectomy, and BMI greater than 30 had lower satisfaction rates than the general penile implant group.

Anatomic Considerations and Etiologic Factors
Pathophysiology and Natural History
Symptoms
Evaluation of the Patient
Management
Conclusion

Credit for the first description of Peyronie's disease is given to François Gigot de la Peyronie in 1743 (Peyronie, 1743). Fallopius, however, first reported the entity in 1561. Peyronie's disease is also known as induratio plastica of the penis. **In most patients, reassurance is sufficient and a necessity.** For others, medical therapy is useful. Fortunately, only a minority of patients will have deformity that precludes them from having intercourse. **Most of the patients with Peyronie's disease do not require surgery. Surgery, at best, can be viewed as palliation for the mechanical effects of Peyronie's disease and erectile dysfunction.**

The literature associates Peyronie's disease with many entities. Some have stood the test of time; in others, the association has not. In a study by Nyberg and colleagues (1982), **Peyronie's disease was associated with Dupuytren disease. Dupuytren disease has a familial pattern known to be transmitted in an autosomal dominant pattern. Thirty percent to 40% of men with Peyronie's disease will also have Dupuytren disease** (Nyberg et al, 1982; Ralph et al, 1997). **Other associated fibrotic conditions are contracture of the plantar fascia (Ledderhose disease) and tympanosclerosis.** Peyronie's disease is also reported to occur in patients after external trauma to the penis (e.g., seat belt injuries). To the authors' knowledge, no reported incidence rate appears in the literature for such patients. However, all urologists who see any volume of patients with Peyronie's disease will inevitably encounter one or two such patients a year who can attribute the onset of Peyronie's disease only to an incident of external trauma to the penis. The relationship of Peyronie's disease to diabetes mellitus likewise remains unclear. Certainly if one accepts the notion that erectile dysfunction can be an inciting event for the development of Peyronie's disease, the relationship with diabetes mellitus will follow. To date, however, the incidence of Peyronie's disease as associated with diabetes mellitus has not been defined, although patients with diabetes mellitus were shown to have statistically significant more curvature and worse vascular status compared with patients without diabetes mellitus (Kendirci et al, 2007; El-Sakka and Tayeb, 2009). The relationship to gout can only be regarded as anecdotal.

The relationship with Paget disease of the bone, however, was noted in a nicely done study reported by Lyles (1997) in which patients with Paget disease were noted to have Peyronie's disease at an incidence rate higher than that quoted for the population in general. Certain human leukocyte antigen subtypes have been incriminated as being causally related to the development of Peyronie's disease. However, for a subtype to be positively linked to the development of Peyronie's disease, a study of many thousands of patients would be required. Nyberg and associates, in 1982, Leffell, in 1997, and Ralph and colleagues, in 1997, suggested an association.

The use of β-adrenergic blockers has been causally incriminated with regard to the development of Peyronie's disease. However, the association was made when first-generation β blockers had just been released to the market. Like diabetes mellitus, those first-generation β blockers were also causally associated with erectile dysfunction. Thus, as possibly the case with diabetes mellitus and hypertension, the same relationship could hold true for the relationship to β blockers. Further study substantiating the relationship to diabetes exists (Lindsay et al, 1991; Kendirci et al, 2007; El-Sakka and Tayeb, 2009).

Urethral instrumentation has been implicated as a cause of Peyronie's disease. Any urologist who sees a large volume of patients with Peyronie's disease will encounter, on a one or two per year basis, patients who had straight erections before transurethral surgery but with the resumption of intercourse after surgery noted curvature. Most of these patients do not complain of ventral curvature. This association should not be confused with Kelami syndrome, which is fibrosis of the corpus spongiosum so severe that it limits expansion of the ventral corpora cavernosa. Again, to the authors' knowledge, no incidence figures exist for the relationship to urethral instrumentation (Carrieri et al, 1998).

A prime example of an association that has never stood the test of time is the association with phenytoin. In the postmarketing study for phenytoin there were patients taking phenytoin who developed Peyronie's disease. Because phenytoin is associated with hyperplastic tissue growth phenomena (gingival hyperplasia) the association of Peyronie's disease with phenytoin was thought logical and published in the *Physicians' Desk Reference*. No other report of a causal relationship, and in fact no other report linking phenytoin use with Peyronie's disease, has been published.

The symptomatic incidence of Peyronie's disease has been estimated at 1%. In white men the average age at onset of Peyronie's disease is 53 years. The asymptomatic prevalence is estimated at 0.4% to 1.0%. In a study of 100

men without known Peyronie's disease, at autopsy 22 were found to have fibrotic lesions of the tunica albuginea compatible with Peyronie's disease (Smith, 1969; Gelbard et al, 1990; Lindsay et al, 1991; Carson et al, 1999; Greenfield and Levine, 2005). Clearly, many think that the clinical incidence of Peyronie's disease is increasing. The increase, however, may be associated with, and seems to coincide with, the increased use of erection-enhancing medications. The phosphodiesterase-5 (PDE5) inhibitor medications and the approved intracavernosal injection agents are not indicated for Peyronie's disease. That does not mean that they are contraindicated but that during the final phase studies reviewed for drug approval that patients with Peyronie's disease were excluded. **To the authors' knowledge there has never been any suggestion that PDE5 inhibitors are in any way directly causally related to the development of Peyronie's disease nor is there suggestion that their use would worsen the course of Peyronie's disease** (Jalkut et al, 2003). Data are emerging to suggest that certain endothelial impairment may be reversed with the initiation of PDE5 inhibitor therapy. However, the concept of "endothelial rehabilitation" with PDE inhibitor therapy should be considered as suggested only (Rosano et al, 2005). Rajfer's work suggests the opposite. PDE5 therapy or therapy with other promoters of cyclic guanosine monophosphate (cGMP) (pentoxifylline) actually suggests that in the animal model cGMP functions as an antifibrotic and thus PDE5 medication and pentoxifylline therapy may actually counter the fibrotic process. Likewise, it is the authors' belief that the scarring seen with intracavernosal injection therapy is related not to the medications necessarily but rather to the injection technique. There are certainly patients who can recall a given event in which they used their injection medication. The injection was accompanied by undue pain, a good erection was not achieved, and the patient then noticed an area of induration in the penis. After that, patients often notice deformity of the penis. Also, it could be theorized that the repetitive trauma of the needle may initiate a "Peyronie's-like process." The prolonged use of papaverine and phentolamine (Regitine) has been implicated as a cause of intracorporeal fibrosis, which is different from the fibrotic process of the tunica albuginea that is recognized as Peyronie's disease.

Key Points: Epidemiology

- Peyronie's disease presents as a variety of deformities of the penis. The symptomatic incidence has been estimated at 1%, but most think that the incidence is increasing and now can be conservatively estimated at 4% to 5%. Fortunately, most patients do not require surgery. Most do require reassurance and education. Surgery for Peyronie's disease is considered palliation for the mechanical effects of the disease.
- Peyronie's disease has been related to a number of conditions. The strongest relation is to Dupuytren disease.
- Although the increased incidence of Peyronie's disease seems to correspond with the use of pharmacotherapy for the management of erectile dysfunction, to the authors' knowledge there has never been any suggestion that PDE5 inhibitors are in any way directly causally related to the development of Peyronie's disease nor is there any evidence that intracavernosal injection therapy is directly implicated in the process of Peyronie's disease. The development of Peyronie's disease does seem to be related to the unique anatomy of the tunica albuginea and its relationship to the septal fibers.

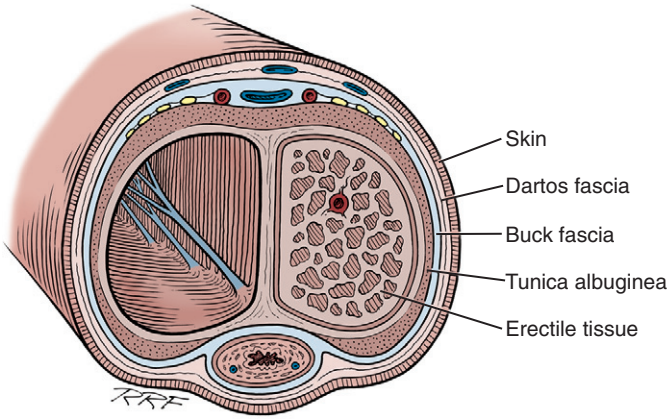

Figure 28–1. Diagram of the penis. The fibers of the septum are attached to the inner layer of the tunica albuginea of the corpora cavernosa along the dorsal and ventral midlines. Plaques of Peyronie's disease occur in the tunica albuginea at the site of attachment of the septal fibers.

ANATOMIC CONSIDERATIONS AND ETIOLOGIC FACTORS

In examining the etiology of Peyronie's disease it is important to review some facts concerning the anatomy of the corpora cavernosa (Fig. 28–1). The tunica albuginea is bilaminar throughout most of its circumference. It is composed of an outer longitudinal layer and an inner circular layer. The corpora are separated by an incompetent septum. In the pendulous portion of the penis there are intracavernous supporting fibers that anchor the inner layer of the corpora cavernosa at the 2-o'clock and 6-o'clock positions. The tunica albuginea varies in thickness from 1.5 to 3.0 mm, depending on the position on the circumference. The outer longitudinal layer attenuates in the ventral midline, and thus the tunica is monolaminar at that point. The outer longitudinal layer is thickest on the ventrum adjacent to the corpus spongiosum and on the dorsum and thinnest on the lateral aspects (El-Sakka et al, 1998b). **Most patients with Peyronie's disease demonstrate lesions dorsally.** Because the tunica albuginea is bilaminar on the dorsum it is possible that these layers might delaminate with buckling trauma. Also, on the ventrum, the longitudinal layer is absent, thus potentially allowing dorsal buckling more easily (Devine and Horton, 1988; Border and Ruoslahti, 1992; Brock et al, 1997; Devine et al, 1997; Jarow and Lowe, 1997). The authors, as have others, note that in the case of calcified plaques the calcification seems to involve the inner circular lamina and, in fact, can be removed, leaving the outer lamina intact. The outer lamina is not normally compliant, but the predilection for calcification of the inner lamina calls to question the preciseness of the typical delamination hypothesis.

Somers and Dawson (1997), **in studies, have shown that Peyronie's disease most likely begins with buckling trauma that causes injury to the septal insertion of the tunica albuginea.** Intravasation of blood occurs with activation of fibrinogen (Fig. 28–2). The body responds to the effects of trauma; and macrophages, as well as neutrophils and mast cells, migrate to the area. Platelets are present because of the intravasation of blood, and fibrin becomes incarcerated in the healing process. Platelets, neutrophils, and mast cells secrete cytokines, autacoids, and vasoactive factors, many of which become involved in fibrosis. Platelets release serotonin and platelet-derived growth

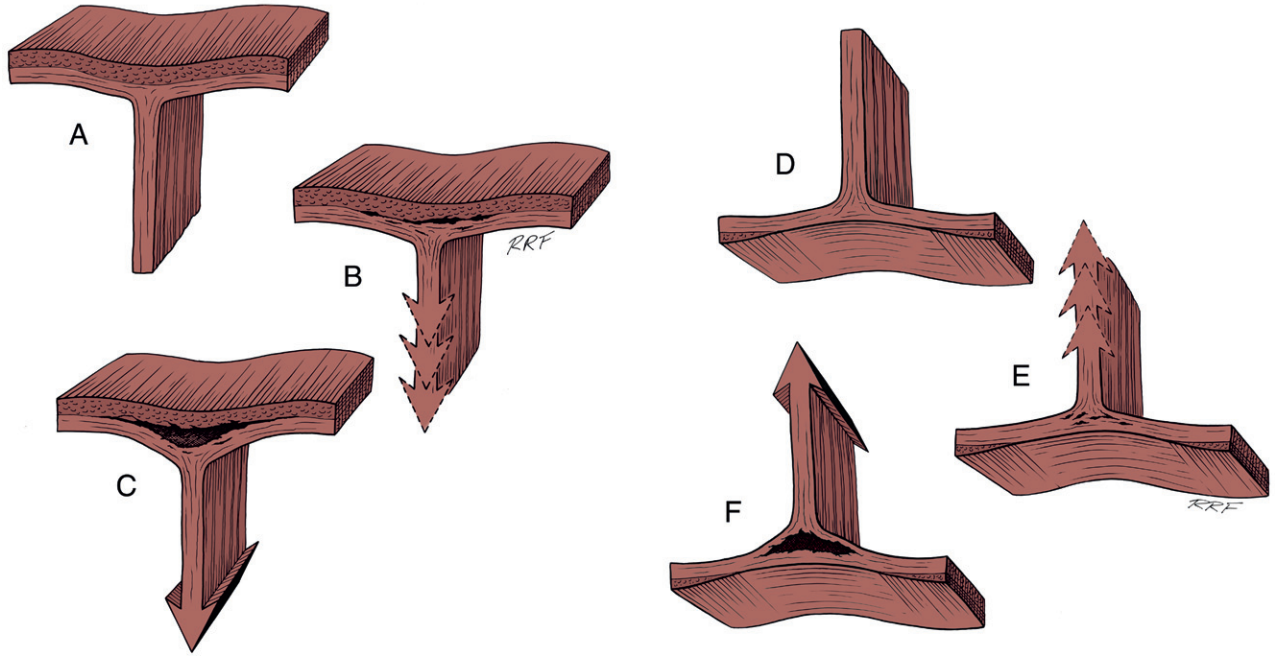

Figure 28–2. Demonstration of the mechanism of injury during buckling injuries to the penis. **A,** Fibers of the septal strands dorsally fan out and are interwoven with the inner circular lamina fibers of the tunica albuginea. The outer lamina consists of longitudinal fibers. **B,** In the chronic mechanism of Peyronie's disease, less turgid erections allow flexion of the penis during intercourse, producing elastic tissue fatigue, further reducing elasticity of the tissue and leading to multiple smaller ruptures of the fibers of the tunica with smaller collections of blood, possibly producing multiple scars. **C,** In the acute mechanism of Peyronie's disease, bending the erect penis out of column produces tension on the strands of the septum, delaminating the layers of the tunica albuginea. Bleeding occurs, and the space fills with clot. The
scar generated by the response of the tissue to this process becomes the Peyronie's disease plaque. **D,** Illustration of the situation on the ventrum of the penis, where the bilaminar arrangement of the tunica albuginea becomes thinned, with the midline being monolaminar. The fibers of the septal strands fan out and are interwoven with the inner circular layer. There is no outer circular layer. **E,** In the chronic

factors as well as transforming growth factors. The formation of thrombus leads to the deposition of fibronectin, which binds a number of growth factors, keeping them localized to the area of injury. Fibrinogen leakage leads to the deposition and incarceration of fibrin (Fig. 28–3).

It has been proposed that the avascular nature of the tunica albuginea may impede clearance of many of these growth factors. The transforming growth factors, particularly transforming growth factor-β (TGF-β), are capable of autoinducement. Thus, the accumulation of TGF-β1 is capable of inducement of further accumulation. The presence of TGF-β stimulating further release of TGF-β1 could possibly lead to an ongoing, smoldering, inflammatory process ending with disordered healing. There is good reason to suspect TGF-β1 as possibly involved with the formation of Peyronie's plaque because it has been implicated in a number of soft tissue fibroses as well as with erectile dysfunction (Border and Ruoslahti, 1992; Border and Noble, 1994; Davis, 1997; Diegelmann, 1997; Van De Water, 1997; Moreland, 1998; Mulhall et al, 2001b).

TGF-β1 is synthesized as a latent peptide by many cells; those pertinent to this discussion are platelets, macrophages, and fibroblasts. On activation, TGF-β1 binds to cell surface receptors and eventually results in synthesis of connective tissues with inhibition of collagenase (El-Sakka et al, 1997a, 1997b, 1998a). Also noted was that the expression and activity of Smad transcription factors of the TGF-β pathway is increased in fibroblasts of patients with Peyronie's disease. The net result of this trauma with disordered healing is the formation of plaques that appear as scars and impede expansion of the tunica albuginea during erection, which results in curvature, and/or indentation, and/or foreshortening (Fig. 28–4). On histologic examination there is aberrant cicatrization with nonpolarization of collagen and diminished and erratic distribution of the elastin fibers (Fig. 28–5).

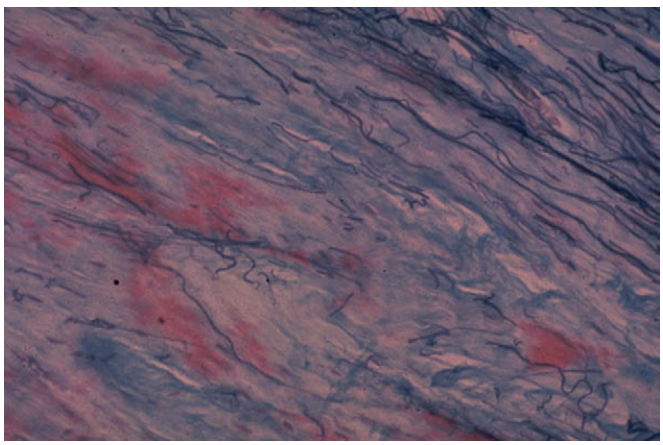

Figure 28–3. Photomicrograph of Peyronie's plaque demonstrating entrapped fibrin. The fibrin stains pink; the collagen fibers stain prussian blue.

Recent work at the University of California, San Francisco, has examined the role of matrix metalloproteinase in this abnormal

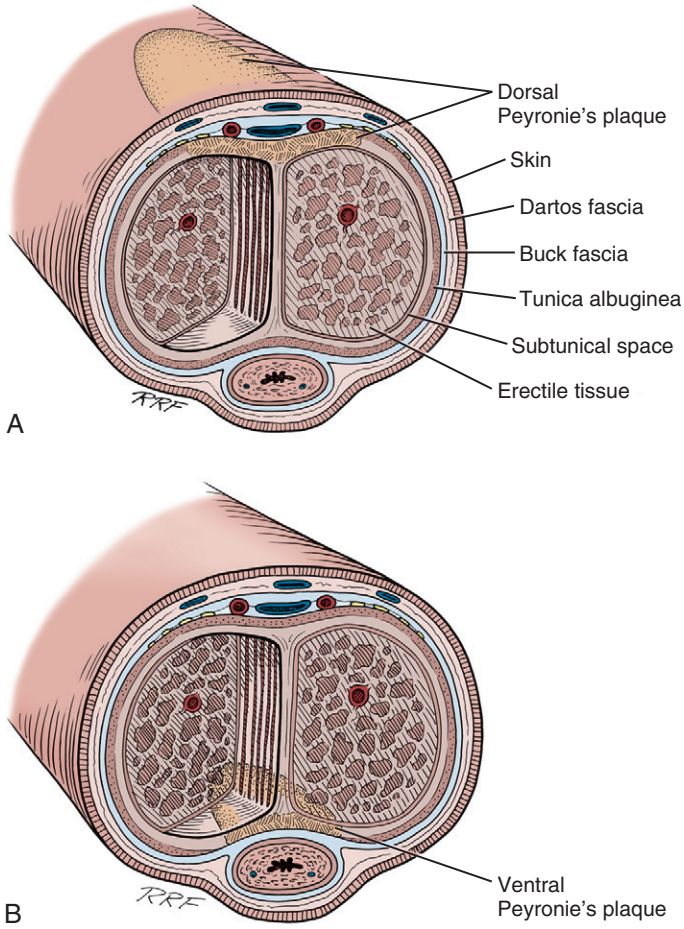

Figure 28–4. **A** and **B,** Under the influence of inflammation and cytokines the disease progresses through an active or immature phase during which there appears to be disordered healing that eventually leads to a scar, which almost always is associated with the septal fibers.

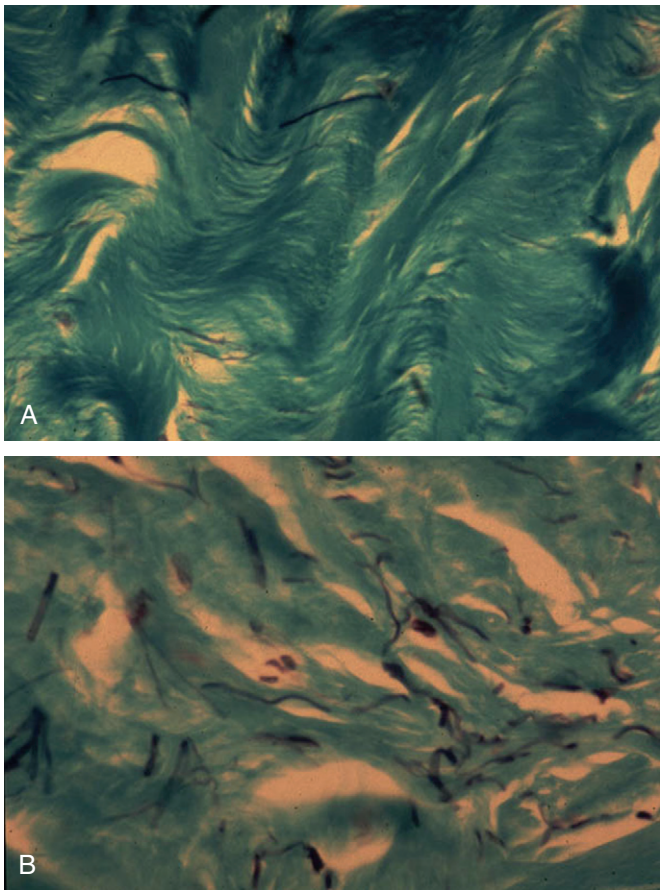

Figure 28–5. Photomicrographs of the tunica albuginea. **A,** Normal tunica albuginea demonstrating the polarized arrangement of collagen. **B,** Peyronie's plaque demonstrating the nonpolarized arrangement of collagen and the haphazard arrangement of elastin. Collagen stains green; the elastin stains black.

scarring process. Matrix metalloproteinases are enzymes that are involved in the remodeling of extracellular matrix proteins. These remodeling enzymes are regulated by tissue inhibitors of metalloproteinase. **Failure or downregulation of matrix metalloproteinase has been implicated in a number of disease processes. In the case of Peyronie's disease, if matrix metalloproteinases are downregulated that could function as a possible mechanism for the scarring process in Peyronie's disease.** In the studies, image analyses were used to examine the cavernosal tissues of Peyronie's disease patients compared with control subjects having only prosthetic placement for other reasons. Those analyses showed a higher expression of the tissue inhibitors of metalloproteinase in all of the components of the Peyronie's plaques compared with the control subjects. **Thus, inhibition of antiscarring enzymes can perhaps represent another facet of the etiology of the lesion that is recognized as the Peyronie's plaque** (Grazziotin et al, 2004).

In a similar vane, Hauck and coworkers (2004) examined the role of α_1-antitrypsin, which is a proteinase inhibitor, as a possible factor in the development of Peyronie's disease. Reduction in α_1-antitrypsin levels could result in a change in collagen metabolism. Previous work had suggested diminished levels, and such diminished levels could be associated with diminished tissue degradation (remodeling) and hence increased cicatrization. Hauck and coworkers did find diminished α_1-antitrypsin levels in patients with Peyronie's disease; however, compared with age-matched controls the levels were not diminished in Peyronie's disease with regard to the control subjects. **Thus α_1-antitrypsin levels may vary with age but the association with Peyronie's disease was not made.**

Studies also demonstrate the role of oxidative stress in addition to cytokine release in the development of Peyronie's disease plaques. Acting as profibrotic factors, they interact with antifibrotic defense mechanisms, which, as already mentioned, may be inhibited. Oxidative stress intensifies in the fibroblasts of human Peyronie's disease plaques and rat-modeled fibrosis (Ferrini et al, 2002; Vernet et al, 2002; Valente et al, 2003). Reactive oxygen species trigger profibrotic processes in a number of disease processes (Becker et al, 2001; Intengan et al, 2001). There is interplay between a number of mechanisms as they relate to fibrosis. Possibly of particular importance as previously mentioned is cGMP, one of the mediators of penile erection. cGMP has been found to be antifibrotic in Peyronie's disease plaques. Long-term administration of PDE5 inhibitors prevents plaque formation in rat fibrosis models. PDE5 is expressed in tunical and Peyronie's disease fibroblasts (Valente et al, 2003). Thus, as previously mentioned, the use of PDE5 inhibitors and cGMP promoters in patients with Peyronie's disease may be helpful in a number of ways.

Key Points: Etiologic Factors

- Buckling trauma of the penis, usually occurring during intercourse, has been implicated in the development of Peyronie's disease. TGF-β has been found to be related to the disordered healing process that leads to the scarring of the Peyronie's plaque. In addition, failure of downregulation of a number of "antifibrotic" factors has been implicated.
- Basic science research into the etiology of Peyronie's disease is limited by the failure, to date, to develop a true animal model of Peyronie's disease. There are animal models and models of fibrosis, however, that have led to a number of interesting proposals, many of which are becoming translational with therapeutic options.

PATHOPHYSIOLOGY AND NATURAL HISTORY

Basic science research into the etiology of Peyronie's disease is limited by the failure, to date, to develop a true reliable animal model of Peyronie's disease. A couple of animal models have examined the injection of cytomodulin, a TGF-β promoter, and the injection of blood. Clearly, in both models, fibrotic lesions were produced. Whether these represent true models of Peyronie's disease remains to be proved or disproved. These models of fibrosis, however, have led to interesting research regarding the pathogenesis of Peyronie's disease. In addition, a number of cell culture models have been proposed and have allowed significant enlightenment with regard to cell cycle regulators and gene expression. The obvious comment about these models is that, of course, these do enlighten us with regard to the essential cell aberrations; however, most probably fail to truly represent what would be the in-vivo condition. They do allow, however, investigation with regard to agents that potentially can manipulate the behavior of the individual cell (El-Sakka et al, 1999; Perinchery et al, 2000; Bivalacqua et al, 2001; Mulhall et al, 2001a; Ferrini et al, 2002; Gonzalez-Cadavid et al, 2002; Lin et al, 2002; Magee et al, 2002; Hauck et al, 2003b; Kim et al, 2004; Piao et al, 2008).

Several studies have examined the natural history of Peyronie's disease (Hellstrom, 2003). **In most cases there are two phases. The first is an active phase, which not uncommonly is associated with painful erections and changing deformity of the penis. This is followed by a quiescent secondary phase, which is characterized by stabilization of the deformity, with disappearance of painful erections, if they were present, and, in general, stability of the process. Up to a third of patients, however, present with what appears to be sudden development of painless deformity.** It has been said that Peyronie's disease totally resolves in some patients, but this is probably a misstatement. Clearly there are some patients who traumatize their penises and then develop curvature secondary to the inflammatory process and its associated loss of compliance. In some, the inflammation resolves without seeming to enter into the phase of smoldering inflammation that ends in disordered healing and scar formation. Thus the process is resolved. Semantically, however, these patients probably cannot be said to have resolved Peyronie's disease; rather, the trauma has resolved without the development of Peyronie's disease. In Mulhall's study of men diagnosed promptly after development of Peyronie's disease symptoms and findings who elected to avoid all therapy, few were found to show much improvement in curvature during a period of 12 months (O'Brien et al, 2004). Obviously this study could be faulted for not having observed the patients longer, but the point is made that "spontaneous resolution" of Peyronie's disease is an infrequent occurrence.

When the urologist is confronted with a patient with Peyronie's disease it is imperative that he or she understand the mindset of that patient and indeed of the couple. It has been shown that couples in which the man has Peyronie's disease, compared with age-matched adult couples, seem to engage in more frequent and more vigorous intercourse and often use positions that are potentially traumatic to the penis. These couples seem to relate by intercourse. It could be stated that Peyronie's disease is a disease of aging tissue in a patient with a youthful libido (Williams and Thomas, 1970; Gelbard et al, 1990; Carson et al, 1999; Rosen et al, 2008). An association to trauma and position of intercourse has been proposed for some time, based on the assumption that certain positions of intercourse can be traumatic to the penis. However, this premise has not been well verified. The hypothesis is that patients with Peyronie's disease have a higher incidence of penile trauma associated with intercourse (Jarow, 1997; Zargooshi, 2004). It has also been proposed that patients with Peyronie's disease use positions of intercourse that are different and varied compared with a "control population" and may have less firm erections than a "control population," therefore creating a situation in which intercourse could traumatize the penis.

A study at the Eastern Virginia Medical School examined these hypotheses. Control subjects and Peyronie's disease patients were aged matched. Peyronie's disease patients had a higher incidence of Dupuytren disease as well as Ledderhose disease. It was found that patients with Peyronie's disease reported traumatic intercourse in a much higher rate than control subjects, and this was highly statistically significant. However, compared with the control population in this study, Peyronie's disease patients seemed to have firmer erections. When positions of intercourse were looked at, with the female superior position being believed to be potentially traumatic, Peyronie's patients and control patients used different positions of intercourse at almost an identical rate. Further studies are obviously required (Logan et al, 2008).

The relationship of erectile dysfunction with Peyronie's disease is a difficult one to ascertain. Mention of erectile dysfunction after surgery begins with the first report of surgery for Peyronie's disease (Lowsley and Boyce, 1950) using excision and grafting. In that series, erectile dysfunction postoperatively was a major source of failure. Interestingly, patients with ventral curvature were singled out as particularly at risk for postoperative problems with erectile dysfunction. The poor prognosis for that group of patients seems to persist into current series. Returning to articles concerning the natural history (Williams and Thomas, 1970; Gelbard et al, 1990), erectile dysfunction again is prominently mentioned. In Gelbard and colleagues' manuscript (1990), a large number of patients discussed poor erections and erectile dysfunction. In the authors' experience, erectile dysfunction precedes the onset of Peyronie's disease in many patients. In an analysis in 1993 (Jordan and Angermeier, 1993) it was clear that erectile dysfunction is a significant factor in patients examined preoperatively. A review by Mulhall further clarifies the association of erectile dysfunction with Peyronie's disease (Palese et al, 2004). In that analysis a large cohort of men were questioned with the International Index of Erectile Function, Erectile Function domain (IIEF/EF). The data showed that one third of men with Peyronie's disease presented with erectile dysfunction at the time that they presented with Peyronie's

disease. Furthermore, a significant percentage of them had erectile dysfunction that preceded their notice of the onset of Peyronie's disease and its diagnosis. The investigators also examined patients with dynamic infusion cavernosometry and cavernosography and found that venous leak is seen more commonly in men who develop erectile dysfunction with Peyronie's disease; however, site-specific venous leak was not noted. There also was the confusing factor of those men with normal vascular parameters who by questionnaire had erectile dysfunction. This further emphasizes the strong psychological component seen in these patients and also the role of destabilization of rigidity by curvature and indentation.

In that analysis, almost 80% of the patients complained of "the psychological effects" of Peyronie's disease. Of note is that of those 80%, 70% complained that their psychological complaints did not improve despite the fact that their disease went into a quiescent phase. A major failure of the literature is that patients are not stratified with regard to functional issues versus organic issues as they relate to erectile dysfunction. Nelson and associates (2008) using validated instruments showed that 48% of patients with Peyronie's disease were shown to have clinically meaningful depression.

Since Brock and Lue's analysis (1993) **there are now a number of reports that have attempted to stratify patients preoperatively with functional testing. In those articles there is wide variance of opinion concerning the coexistence of erectile dysfunction with Peyronie's disease.** Jordan and Angermeier (1993) showed erectile dysfunction in almost 100% of patients; Jarow and Lowe (1997) showed that 76 of 95 patients were impotent by testing; and Ralph and coworkers (1992) showed that of 20 patients with erectile dysfunction who were studied with duplex ultrasonography, 90% had complaints of erectile dysfunction because of functional, not organic, causes. In Mulhall's study cited earlier, by IIEF/EF criteria, 30% of that cohort had erectile dysfunction associated with Peyronie's disease (Palese et al, 2004). Hellstrom's analysis of more than 500 men, all evaluated with duplex ultrasonography, showed a significant relationship between the type of penile deformity and penile hemodynamics. The study showed that patients with hourglass deformity most commonly had arterial insufficiency. Veno-occlusive dysfunction was most prevalent in patients with ventral curvature. This fact makes Lowsley's final statement in his 1950 paper almost prophetic: "Patients with ventral curvature do not do well with graft operations." However, Hellstrom's study did not demonstrate any statistical relationship between the type of deformity and the frequency of erectile dysfunction. All patients were evaluated with the IIEF/EF questionnaire (Kendirci et al, 2005).

Thus what is in the literature is not clear other than the fact that patients preoperatively complain in large numbers of the psychological impact of their Peyronie's disease and that those psychological aspects continue to plague good surgical results (Jones, 1997).

On the basis of a study still to be published, men with and without Peyronie's disease participated in a series of focus groups that were conducted in several cities. Most men indicated that the impact Peyronie's disease has had on their life has been severe (Rosen et al, 2008). **The emotions expressed by many of the men who were interviewed ranged from anger to frustration to hopelessness.** Although many men—even those not in a steady relationship—were still having sex, most of those who were still having sex said that it was different from what it used to be and many were concerned that their condition would worsen and that they would not be able to have sexual intercourse in the future. In every focus group, most men said they had become resigned to the fact that there was nothing that could be done. Additional work is being done to develop a questionnaire to measure the impact of Peyronie's disease on various aspects of a man's life (Rosen et al, 2008).

Jones (1997) deals best with the counseling issues of men with sexual dysfunction resulting from Peyronie's disease. His comments are based on interviews of more than 1500 men with Peyronie's disease. **He describes counseling a patient with Peyronie's disease as being much the same as counseling a person who has suffered a death and is grieving.** As with death, grieving is complicated by denial, ambivalence, anxiety, depression, shame, embarrassment, and, in the case of this particular group of patients, self-disgust. Most of these patients are not good talkers. Jones (1997) suggests that these patients tend not to like to talk about their problems with their spouses and initially spurn counseling in many instances.

A major point made by Jones (1997) **in dealing with patients with Peyronie's disease is that to avoid or to limit emotional factors patients and their partners need to hear the suggestion that they must "keep sexual expression alive, be active to whatever degree possible at every stage of the progression or regression of their Peyronie's disease course."** Patients' understanding of Peyronie's disease is made worse many times by the comments of urologists and primary care physicians, who in general do not understand the disease. Many patients have been told that Peyronie's disease is probably the end of their sex life. Many of these couples have related by the belief that "sex is intercourse." Thus, when coitus is precluded, they avoid all sexual activity. Most men with Peyronie's disease have ignored, at one point, the plea of their partners who have asked for intimacy regardless of whether there was intercourse. As mentioned, the relationship of the functional

Key Points: Pathophysiology and Natural History

- Studies that examine the natural history of Peyronie's disease show that Peyronie's disease presents usually as two phases. The first is an active phase; the second is a quiescent phase. Thus studies to evaluate the efficacy of pharmacotherapy are difficult; when the disease process enters the quiescent phase, many things noted during the acute phase disappear or become less apparent.
- The relationship of Peyronie's disease to erectile dysfunction has been difficult to determine. Studies estimate the occurrence of simultaneous erectile dysfunction with Peyronie's disease to be in some cases as high as 100%. A study showed that one third of a cohort of patients with Peyronie's disease presented with erectile dysfunction at the time they presented with Peyronie's disease. A significant percentage of them noted that the erectile dysfunction preceded their notice of Peyronie's disease.
- Older articles fail to stratify patients with regard to their erectile function, and this has led to the variance of opinion concerning the relationship of erectile dysfunction with Peyronie's disease. It is clear that the issues of erectile dysfunction make the psychological effects of Peyronie's disease worse. Recent data suggest that one major concern of patients with Peyronie's disease is that the condition will worsen and eventually they will completely lose the ability to have sexual intercourse. Patients must be encouraged to keep their sexual expression alive.

aspects to the organic aspects remains elusive. To define these aspects there must be uniformity in history-taking; there must be uniformity in preoperative assessment with regard to erectile function; and, in failures, there must be uniformity in postoperative assessment with regard to erectile dysfunction.

SYMPTOMS

The presenting symptoms of Peyronie's disease include, in many patients, penile pain with erection; penile deformity, both flaccid and erect; shortening with and without an erection; plaque or indurated areas in the penis; and, in many patients, erectile dysfunction. On physical examination, virtually all patients have either a well-defined plaque or an area of induration that is palpable. The plaque is usually on the dorsal surface of the penis, intimately associated with the insertion of the septal fibers. Patients not uncommonly can remain sexually active with significant dorsal curvature (up to 45 degrees). Patients with lateral components or ventral Peyronie's disease tolerate the deformity far less well. Mulhall's analysis of the natural history of Peyronie's disease in a group of men who avoided treatment but were observed carefully documents the frequent occurrence of penile shortening in this population (O'Brien et al, 2004).

An interesting variant of Peyronie's disease has been reported by Brock, who has coined the term *septal-only Peyronie's disease*. In his description (cited in Bella, 2007), patients had nonpalpable scarring of the penile septum that caused deformity of the erect penis. In the authors' experience there is palpable scarring; however, the scarring appears to be in the substance of the corpora cavernosa as opposed to the tunica albuginea associated with the insertion as is usually seen. In septal-only disease, the authors have found it difficult to tell whether the scarring is indeed Peyronie's disease or perhaps a Peyronie's lookalike. Fortunately, tumors of the erectile tissue of the corpora cavernosa are quite rare, but it is the authors' practice to evaluate these patients with magnetic resonance imaging (MRI).

Pain may be persistent in the inflammatory stage of the disease; it is usually not severe, but it can interfere with sexual function. Some patients also complain of being awakened in the morning or at night with pain during erection. **Spontaneous improvement in pain virtually always occurs as the inflammation resolves.** A small group of patients with extensive disease will have "circumferential plaques" and an unstable penis owing to the resulting hinge effect. Most patients complain of distal flaccidity. In dynamic infusion cavernosometry and cavernosography it was found, however, that the pressures were equal proximal and distal to the plaque (Jordan and Angermeier, 1993). Opinions vary with regard to the cause of distal tip flaccidity; one ultrasound study seemingly showed cavernosal fibrosis that ostensibly could interfere with distal perfusion of the corpus cavernosum (Ralph et al, 1992). However, in the authors' experience, the fibrotic process is limited to the tunica albuginea, although the process can clearly involve the septal fibers and thicken them appreciably. Thus there is no corroboration of the finding of diffuse cavernosal fibrosis when these patients are taken to the operating room (Ralph et al, 1996).

EVALUATION OF THE PATIENT

When the urologist is confronted with the patient with Peyronie's disease the medical history should include the mode of onset (sudden vs. gradual) and time at onset. The course of disease is helpful with regard to determining the phase the patient is in. The history is obtained of prior penile surgery, urethral instrumentation or external trauma, medication or drug abuse, and fibromatosis including Dupuytren disease and Ledderhose disease. Family history of the other fibromatoses is revealing. **Because most patients with Peyronie's disease have an element or at least the aura of erectile dysfunction, risk factors for erectile dysfunction should also be assessed.** The recent literature suggests that erectile dysfunction may be a sensitive hallmark of many vasculopathic conditions. Endothelial dysfunction is an important abnormality contributing to a decrease in penile vascular responses to sexual stimuli. Vascular disease has been shown to be the most common cause of erectile dysfunction. Cardiovascular disease and erectile dysfunction share a host of risk factors, including age, smoking, hyperlipidemia, hypertension, and diabetes mellitus. Furthermore, the severity of coronary artery disease has been shown to correlate with the severity of erectile dysfunction (Feldman et al, 1994; Greenstein et al, 1997; Lue, 2000; Martin-Morales et al, 2001; Roumeguere et al, 2003). Thus, in addition to trying to glean factors from the patient about smoking, hypertension, diabetes mellitus, and other suggestions of vascular disease, the inquiries must also extend to the patient's family with regard to those same issues. Likewise, because a few of these patients will require surgery, the surgeon must carefully assess the need for screening with regard to a patient's total vascular health.

A detailed psychosexual history is imperative. In the authors' opinion, photographs of the patient's erect penis are helpful in identifying the direction of curvature and degree of curvature and they provide some information about the patient's erectile function.

The penis should be examined on stretch. This amplifies the plaque and often allows the examiner to feel plaques that are not obvious when the penis is examined in the nonerect state. The location and size of the plaque as well as the consistency (e.g., tender, indurated) are better defined. Most of the recent clinical trials examining intralesional injection have included a diagram in the chart. The diagram illustrates the plaque or plaques both longitudinally and in cross section. Most of these protocols emphasize the need to measure total penile length (pubis to mid glans coronal margin) as well as length of the plaque. It can certainly be argued that measuring the length of the plaque really does not offer much clinical information because plaques that are indurated tend to feel much larger and more prominent than mature plaques; thus the actual diagram of the plaque may be more useful in tracking the course of the disease. The hands and feet must be examined; and in the rare patient examination of the ears will identify tympanosclerosis. Although many patients will have thickening in the palmar area of the dominant hand, except in manual laborers, callus formation in the palmar area of the nondominant hand is indicative of noncontractile Dupuytren disease. Contractile Dupuytren disease is obvious. Examination of the feet for Ledderhose disease often will reveal nodules compatible with plantar fascial involvement. Whether Ledderhose disease is just a manifestation of plantar fasciitis remains to be seen, and certainly the authors' experience would suggest that in the current American population an element of plantar fasciitis is almost a ubiquitous finding in well more than half of men older than age 50 years.

Imaging of the plaque is important for one purpose only, that is, the demonstration of calcification. Imaging to record plaque size is probably as useful as measuring plaque size and recording it on a diagram. **Demonstration of calcification is easily**

accomplished with ultrasound examination. The calcified plaque will be shown as shadowed areas (Fig. 28–6). The plaque itself will be prominently imaged (Altaffer and Jordan, 1981; Balconi et al, 1988; Hauck et al, 2003a). **Plain radiography is also equally effective in demonstrating calcification within the plaque** (Fig. 28–7). The authors use a high-definition film (Kodak X-Omat ready-pack 8 × 10). This is accurate in imaging the calcification and allows minimal radiation exposure (20 mA at 49 kV). The testes are shielded with a lead sheet. Zero radiography is an effective way of demonstrating the plaque; however, the technology is not readily available with the increase in other imaging modalities. **Computed tomography has no place in the examination of the penis for Peyronie's disease.** However, MRI, which does not effectively demonstrate plaque calcification, does image the plaque well. **There is not universal agreement about the use of MRI for imaging of the plaque** (Helweg et al, 1992; Vosshenrich et al, 1995; Andresen et al, 1998; Hauck et al, 2003a; Moncada, 2003; Perovic, 2003). In the authors' opinion, at present, MRI evaluation is probably excessive; however, for the purposes of assessing the results of clinical trials MRI may have a place.

Figure 28–6. B-mode ultrasound examination of calcified Peyronie's plaque. The plaque is imaged as an echodense area (1); the area of calcification is accompanied by shadowing (2).

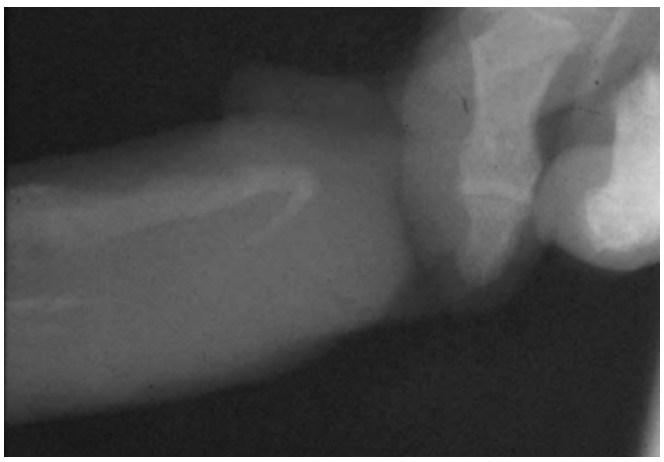

Figure 28–7. Radiograph of an extensively calcified dorsal plaque.

The place of vascular testing is not clearly defined. Currently the use of vascular testing is variable. Some centers perform duplex ultrasound testing on all patients with Peyronie's disease; other centers do not perform vascular testing at all, despite that patients are routinely operated on for Peyronie's disease and, in some cases, receive prostheses as the primary treatment option (Kendirci et al, 2004, 2005; Pak et al, 2004). At the authors' center, vascular testing is done on all patients who are prospective surgical candidates and who indicate motivation for the option of surgery. Initially, these patients are examined with color Doppler ultrasonography. If the peak systolic velocity, end-diastolic velocity, and resistive index are normal the patients are not further tested. If the end-diastolic velocity and the resistive indices are not normal, the patients are tested with dynamic infusion cavernosometry and cavernosography. Our studies have reported that there is a linear association between preoperative erectile function and postoperative results (Jordan and Angermeier, 1993). The authors thus lean heavily on these results in discussing potential options for surgical management. One group of patients whose results are clear outliers are those with ventral Peyronie's disease. As mentioned, in the authors' experience and that of many others, patients with ventral Peyronie's disease do not do well with surgery that involves grafting. In Hellstrom's analysis of the relationship of penile deformity to the vascular status of Peyronie's patients, patients with ventral curvature have the greatest likelihood of having cavernous veno-occlusive dysfunction (Lowsley and Boyce, 1950; Jordan and Angermeier, 1993; Kendirci et al, 2005).

There are a number of proposed treatment protocols or algorithms. The original classification system proposed by Kelami sought to include all categories of importance in evaluation of the patient with Peyronie's disease. Indeed, most of the important entities were included with the exception of erectile dysfunction (Kelami, 1983). In 1993, Gelbard, as part of the original collagenase intralesional injection protocol, used a modification of the Kelami classification. Several other treatment algorithms have been proposed (Gelbard, 1993; Novak et al, 2001; Levine and Greenfield, 2003; Bokarica et al, 2005; Viviano and Honig, 2005). It is imperative to understand that these algorithms serve only as guidelines. **Individualization with regard to patients' requirements and their findings and assessments is imperative.** This individualization will allow us to determine which patients require only reassurance, which need vigorous investigation, which are appropriately treated with medical management, and which few patients are appropriately treated with surgery. Shabsigh and colleagues (2003) published a Peyronie's disease index that is derived from a standardized patient questionnaire. That questionnaire seeks to specifically address issues most pertinent to the patient with Peyronie's disease. Issues such as duration of disease, recollection of injury, and presenting symptom or symptoms are addressed. Strategies to ideally assess degree and direction of curvature could include the use of visual analog scales. In association with future studies to examine intralesional injection protocols, a validated questionnaire has been developed. Interviews with Peyronie's disease patients have highlighted areas of concern, and the questions have been or are in the process of being validated for various populations (Moncala-Iribarren et al, 2004; Fragas, 2004; Rosen et al, 2008).

Key Points: Evaluation of the Patient

- Patients with Peyronie's disease present with a variety of deformities of the penis. In addition, most have noted an indurated area in the penis that has been identified as the plaque. Many patients have noticed erectile dysfunction. It is important to understand that pain with erection, if it is present, inevitably disappears as patients progress to the quiescent stage. It is not unusual for the deformities to be migratory before stabilizing.
- All patients must be evaluated with a medical history as well as a detailed psychosexual history. Approximately one third of the patients will develop dystrophic calcification in the plaque that can be demonstrated by ultrasonography or plain radiography. The place for MRI in the evaluation of Peyronie's plaque has not been defined, nor has the place for vascular testing been clearly defined. However, most investigators now would agree that in patients who are to be operated on, vascular testing to stratify the vascular parameters of erectile function is a necessity. Once all of the data have been assembled, individualization with regard to the patient's requirements, findings, and assessment is imperative.

MANAGEMENT

Medical Management

Any section on the medical management of Peyronie's disease must begin with the disclaimer that few medical methods of management have been subjected to double-blind drug testing. The use of vitamin E was proposed by Scardino and Scott (1949). Vitamin E, a tocopherol, is an antioxidant. In 1983, Pryor and Farrell convened a randomly allocated placebo-controlled study. Men were randomized to vitamin E, 200 mg three times a day, versus placebo for a 3-month course. Basic disease status was assessed, with particular emphasis on pain and deformity. In that study, no difference was found between vitamin E and placebo. In 1990 Gelbard and associates also conducted a controlled study, and again that study failed to demonstrate any significant difference between vitamin E and placebo with regard to overall disease status and in particular pain and curvature. A placebo-controlled study comparing vitamin E and propionyl-L-carnitine, separately or in combination, showed no significant improvement in pain, curvature, or plaque size in patients with Peyronie's disease (Safarinejad et al, 2007). That said, however, vitamin E is inexpensive and probably safe. Recent cautions have been raised about the use of high-dose vitamin E. It has long been recognized that vitamin E in high dose, in some individuals, can have a significant warfarin effect. Interestingly, however, in the moderate dose range, vitamin E has been implicated as causing thrombolytic phenomena and thus is of concern to cardiologists and neurologists. If one chooses to use vitamin E for Peyronie's disease it should be used in divided doses of 800 to 1000 units a day. Treatment should be continued for no longer than 3 to 6 months, and patients must be cautioned about the possibility of anticoagulative side effects and/or thrombolytic effects. Should they notice anticoagulative effects, the vitamin E should be stopped and the physician should be notified. As mentioned, in addition, concerns have been raised about general cardiac health and vitamin E. That stated, it is still probably a reasonable treatment to initiate during the early phases of the disease.

Zarafonetis and Horrax (1959) published an article on the use of potassium aminobenzoate (Potaba). This drug has been looked at in a small blinded study that showed it to be efficacious (Hasche-Klunder, 1978). Two subsequent reports examining the use of potassium aminobenzoate for Peyronie's disease have been published. First, a multicenter study with random allocation between 12 g of *p*-aminobenzoate and matching placebo showed little benefit to treatment with the exception possibly of improving pain (Shah et al, 1983). A subsequent randomized placebo-controlled double-blind prospective multicenter trial showed no improvement with regard to pain but less worsening of other symptoms. A study by Weidner and colleagues (2005) enrolled 103 patients, with 75 completing follow-up. Many were excluded because of side effects (predominantly gastrointestinal side effects) or noncompliance for reasons not stated. Fifty-one patients were randomized against 52 patients receiving placebo control. Patients received potassium aminobenzoate or placebo at a dose of 3 g, four times a day. End points studied were plaque regression and reduction of curvature. No reduction in curvature was noted; however, regression of plaque size was noted to be significantly better in the treatment group. Interestingly, progression of curvature or "deterioration of disease" was noted at a significantly increased rate in the placebo group. The dosage of potassium aminobenzoate is 12 g/day in 4 to 6 doses. The literature supports the fact that **potassium aminobenzoate is poorly tolerated by many patients because of gastrointestinal upset and is relatively expensive. The use of potassium aminobenzoate cannot be strongly advocated on the basis of the evidence to date.**

Jordan (personal experience) has used terfenadine (Seldane) and now fexofenadine (Allegra). Its use is clearly anecdotal. It is used as a nonspecific antihistamine and has been used in patients who have had an unusually long, painful course. The medication is expensive; it is well tolerated and, if used, should be in a dosage of 60 mg twice a day.

Ralph and coworkers (1992) have suggested the use of oral tamoxifen. Tamoxifen, it is believed, facilitates the release of TGF-β from fibroblasts. Teloken and coworkers (1996, 1999), **in a small controlled report, used tamoxifen versus a placebo and did not demonstrate a therapeutic advantage.** Should one desire to prescribe tamoxifen, it is used at a dosage of 20 mg twice daily.

The use of colchicine was originally proposed by Gelbard (personal communication, 1995). There are no blinded or controlled studies that have examined the use of colchicine. Akkus and coworkers (1994), in an uncontrolled study of 24 patients, reported some efficaciousness for colchicine. The patients were in the early phase of disease and received colchicine at a dose of 0.6 mg three times a day. **In that study, diminished plaque size and improved penile curvature were reported in approximately 50% of the patients.** Four actions are attributed to colchicine. Colchicine binds tubulin and causes it to depolymerize; thus, it inhibits mobility and adhesion of leukocytes as well as wound contracture. It inhibits cell mitosis by disrupting spindle cell fibers and thus functions as a potent anti-inflammatory agent. It blocks the lipoxygenase pathway of arachidonic acid metabolism, furthering its anti-inflammatory effect. It interferes with the transcellular movement of protocollagen. Colchicine is reasonably well tolerated. Approximately one third of patients, however, will have diarrhea. It is inexpensive. If it is used, the dosage is 0.6 mg three times per day with meals.

Biagiotti and Cavallini (2001) convened a study of 48 patients with Peyronie's disease, approximately one third in the acute phase and two thirds in the chronic phase. The groups were randomized between tamoxifen, 20 mg twice daily for 3 months, and acetyl-L-carnitine, 1 g twice daily for 3 months. Oral carnitine is thought to have several mechanisms of action involving free radical metabolism. It has been useful in degenerative oxidative diseases and vasculitides. **The authors found that the carnitine was more effective in reducing pain and seemed to inhibit disease progression. Thus they thought it was more effective and safer than tamoxifen in the treatment of Peyronie's disease.** Propionyl-L-carnitine in the same dose can also be used for oral therapy.

Nonsteroidal anti-inflammatory drugs and corticosteroids have been used anecdotally on the basis of the belief that inflammation is integral to the development of Peyronie's disease. No studies support an indication for the use of these drugs.

A number of intralesional injection protocols have been examined. Teasley (1954) reported the use of intralesional corticosteroids, as did others (Bodner et al, 1954). **It is the recommendation of the consensus committee on penile curvatures that the use of intralesional corticosteroids be eliminated or at least initiated with extreme caution because of the significant local side effects, the inconsistent pattern of improvement in well-established curvature, the lack of studies showing proven efficacy, and the reports of patients who believed that their condition deteriorated after the injections** (Jardin et al, 2000).

The calcium antagonist verapamil was first used as intralesional therapy by Levine and colleagues (1994). Verapamil is thought to have efficacy on the basis of its ability to inhibit the exocytosis of collagen, fibronectin, and glycosaminoglycans. This inhibition works at the basic metabolic step involved with the manufacture of collagen and hence is thought to inhibit the ultimate formation of scar. Since that report, several observational studies have been performed. **A single-blind controlled study comparing verapamil with saline showed a diminished plaque volume but no change in deformity** (Rehman et al, 1998). **In a prospective study of 156 patients, of those who completed the protocol 60% had a decrease in curvature and 80% reported improvement in tip flaccidity** (Levine et al, 2002). A number of injection protocols have been discussed. A "full course" could consist of 12 injections (10 mg/10 mL) given once every 2 weeks, although Cavallini and colleagues (2002) showed that patients receiving verapamil, 10 mg/20 mL, had significant improvement in plaque size and penile curvature compared with 10 mg/10 mL. In many hands, up to that total dose, injections are discontinued when satisfactory improvement is noted. Patients must understand that improvement may not be noted immediately, and hence they must be prepared to proceed with the entire 12-injection series. **The use of intralesional verapamil for patients with acute disease is thought reasonable on the basis of the available data to date. At the authors' center they have combined intralesional injection of verapamil with daily use of a vacuum erection device and have noted improved outcomes compared with using each individually. At present, however, these findings are anecdotal at best and need to be substantiated with controlled studies.**

The use of purified clostridial collagenase was first studied in vitro by Gelbard and associates (1982, 1983, 1993). Collagenase is a naturally occurring enzyme that has been found to be intimately involved with the process of scar remodeling. Simply stated, the use of collagenase as an intralesional agent is thought to create "chemical incisions," thus initiating areas of remodeling. **Collagenase has since been subjected to two double-blind studies and an additional small pilot study using intralesional collagenase combined with modeling** (Gelbard, 1993; Glina et al, 2007). **In that study, 25 patients were enrolled and were treated with three intralesional injections of 10,000 in 0.25 mL over 7 to 10 days. A significant decrease from baseline was seen in mean deviation angle and plaque length and width at 3 and 6 months; it also was noted that more than 50% of patients were much improved** (Glina et al, 2007). **Ten patients were enrolled, and 9 completed follow-up; improvement was noted in curvature in all 9, as judged by photographs submitted at intervals by the patients and questionnaire end points** (Jordan, unpublished). A double-blind, placebo-controlled, multicenter study has just been completed but the data are not yet available. Intralesional collagenase is thus currently available only on study protocol.

The use of interferons as intralesional therapy for Peyronie's disease was reported in 1991 by Duncan and associates. Interferons are thought to have action based on their abilities to inhibit the synthesis of collagen, fibronectin, and glycosaminoglycans (Hakim and Khater, 2004). Thus, the mechanism of action of interferon is thought to be similar to that proposed for verapamil. An observational study using interferon alfa enrolled 35 patients. Some of the patients received a 12-week course and some a 24-week course. **Seventy-five percent of the patients reported treatment satisfaction as judged by improvement in their ability to have intercourse.** The authors thought that treatment with interferon can be done safely and is reasonable to offer patients (Hellstrom et al, 2006).

A number of topical therapies have been reported, with delivery often combined with iontophoresis or electromotive therapy. Agents used are orgotein (recently withdrawn from all markets), steroids, verapamil, and β-aminopropionitrile, either singly or as "cocktails." A single blinded study showed efficacy for verapamil. Further studies have not verified the findings of that study (Montorsi et al, 2000a; Levine et al, 2002; Fitch et al, 2007). These are only single observational reports. Corticosteroids have been used in association with ultrasound (iontophoresis). Again, no blinded studies have shown statistical improvement.

Radiation therapy has been proposed as a treatment of Peyronie's disease. In recent years, radiation therapy was proposed for the treatment of pain that was thought to be "abnormally persistent." In 1975, a retrospective study examined the use of radiation therapy and found it to be no more effective than "no treatment." **It is the consensus of the World Health Organization committee that radiation therapy be avoided because of potential risk of malignant change and the potential for increasing the risk of erectile dysfunction in aging patients** (Lue et al, 2004).

Extracorporeal shockwave therapy has been proposed as a treatment of Peyronie's disease since 1989 (Lebret et al, 2002). There has been little standardization with regard to the treatment (varying dosages and machines) (Butz and Teichert, 1998; Colombo et al, 1999; Gianneo et al, 1999; Lebret et al, 2002; Manikandan et al, 2002; Sytenko, 2004). **There are no controlled trials, but one case-controlled trial reported favorable results** (Hauck et al, 2000). No studies examining the efficacy of extracorporeal shockwave lithotripsy in the treatment of Peyronie's disease have been convened in the United States.

The vacuum erection device or traction devices have been proposed as a treatment of Peyronie's disease. Kirsch-Noir and coworkers (2004) examined six patients with Peyronie's disease treated with the vacuum erection device and concluded that the vacuum device might limit penile fibrosis, but no comment was made concerning plaque volume or curvature. Verheyden is quoted as stating that in a series of patients treated with vacuum therapy for Peyronie's disease at the Andrology Unit, Department of Urology, Antwerp, Belgium, more than 50% stated that their plaques softened and they noted improvement in curvature (Augusta Medical Systems, product information, 2005). Moncada (2007) has examined the use of penile traction in both the preoperative and postoperative patient with Peyronie's disease. He believes strongly that, with grafting surgery, traction to keep the graft distended is essential to maximizing results.

Levine, in 2008, looked at penile traction therapy as a treatment for patients with Peyronie's disease in 10 patients. All patients noted subjective improvement in curvature penile length and girth; objective improvements were seen in reduction in curvature (average 33%), increased penile stretched length, and improvement in IIEF. **Treatment of Peyronie's disease with the vacuum erection or penile traction device alone thus has not been adequately studied.**

A number of studies have examined combined medical management. These include a study of intralesional injection and oral therapy with interferon alfa-2b plus vitamin E (Novak et al, 2001). Another study examined the use of oral vitamin E plus colchicine (Prieto Castro et al, 2003), and another series of studies of intralesional injection and oral therapy looked at the combination of verapamil with carnitine and verapamil with tamoxifen (Cavallini et al, 2002). These single observational studies represent the thrust of current work with regard to medical management. Rajfer has proposed the use of PDE5 inhibitors. As briefly discussed earlier there is an interplay between oxidative and nitrosative mechanisms in fibrosis that is not restricted to Peyronie's disease fibroblasts. cGMP, the mediator of penile erection, is produced by nitric oxide activation of guanylate cyclase, which is also antifibrotic in Peyronie's disease plaques. Long-term administration of sildenafil, a phosphodiesterase inhibitor that impedes guanosine monophosphate breakdown, has prevented Peyronie's disease plaque formation in rat models (Gonzalez-Cadavid and Rajfer, 2005). Unfortunately, in the authors' opinion, the future of nonoperative therapy in Peyronie's disease lies in multimodal therapy. However, such studies probably have little hope of being accomplished within the confines of U.S. Food and Drug Administration oversight.

Key Points: Medical Management

- The efficacy of medical management of Peyronie's disease is difficult to determine because, in the past, few studies were properly done. Vitamin E has been used historically. Potassium aminobenzoate, in a small study, was found to reduce plaque size, not curvature, and thus in that study was found "efficacious." However, the side effects make it difficult to tolerate. From an intellectual standpoint, the use of colchicine makes a great deal of sense in patients with Peyronie's disease who are in the acute phase. For the most part, colchicine is reasonably well tolerated. Tamoxifen, in a small controlled study, was not found to demonstrate any therapeutic advantage. The neutraceutical carnitine, in either its propionyl or acetyl ester, in preliminary studies was thought to be effective for certain disease parameters.
- A number of intralesional protocols have been proposed. The use of verapamil as an intralesional agent has been studied. A prospective study did show decrease in curvature in about 80% of the patients. The use of collagenase as an intralesional agent has been subjected to a number of double-blind placebo-controlled protocols, and, in all, efficacy was suggested. However, collagenase is currently available only as part of clinical trials.
- Radiation therapy should be avoided.
- The vacuum erection device has not been adequately studied.
- Penile traction has not been adequately studied.
- The place of extracorporeal shockwave therapy has likewise not been adequately determined.

Surgical Management

For a patient to be a surgical candidate his disease must be stable and mature. In review, the signs of disease stability (quiescence) include resolution of pain and stabilization of curvature or other deformity. Likewise, the experienced examiner will recognize the palpatory findings of a mature plaque. Most investigators arbitrarily impose a 12- to 18-month period from onset of disease. Most suggest a period of at least 6 months of disease stability (i.e., stable deformity). Indications for surgery include deformity that precludes intercourse and/or erectile dysfunction that precludes intercourse.

Surgical Correction of Peyronie's Disease

A number of surgical procedures have been used for the straightening of the deformity of Peyronie's disease. Pryor and Fitzpatrick (1979) described a procedure of excision and plicating closure of the aspect opposite the Peyronie's lesion. This procedure counteracted the effects of the inelastic lesion by shortening the opposite, more compliant aspect of the corpora cavernosa.

Lue performs a correction in which he omits the excision of the tunica albuginea and merely plicates the opposite aspect of the corpora cavernosa (Akkus et al, 1997; Gholami and Lue, 2002). Although this technique historically did not yield durable results in patients with congenital curvature, in the patient with Peyronie's disease, in whom accumulated intracavernosal pressures are probably less, it possibly can be expected to be more effective. Lue emphasizes the use of permanent suture that is "loosely tied" to correct the deformity. Although the techniques of both Pryor and Fitzpatrick (1979) and Lue are valid in some patients, many patients are already concerned by the shortening of their penis as a result of Peyronie's disease; thus, surgery that offers the suggestion of further shortening of the penis is unacceptable to them. The use of permanent suture as described by Lue is also not well accepted by some patients.

The procedure described by Yachia (1993) (see Chapter 36) represents a corporoplasty technique that can be effectively used for curvatures associated with Peyronie's disease. Plication and corporoplasty techniques seem to be useful especially for patients with associated erectile dysfunction, in whom grafting procedures could be expected to cause further deterioration of erectile function. The authors rely on this procedure for those patients with ventral curvature for reasons already discussed. The perceived shortening associated with these procedures in a number of studies, in properly selected patients, is not clinically significant

(Klevmark et al, 1994; Nooter et al, 1994; Sulaiman and Gingell, 1994; Kummerling and Schubert, 1995; Poulson and Kikeby, 1995; Ralph et al, 1995; Porst, 1997; Savoca et al, 2000; Chahal et al, 2001; Gholami and Lue, 2002; Van Drift et al, 2002; Lucas et al, 2004; Seipp and Schukfeh, 2004).

Gelbard (1989) described a surgical technique that involved incising the plaque of Peyronie's disease. He reported a series of patients in whom incisions were made in the plaque and grafts of temporalis fascia were used to fill the defects. His technique was based on the theory that by making a number of incisions, thus expanding the scar, and then filling them with compliant material, a smoother correction of curvature would result. He has reported good results with this procedure.

Das and Amar (1982) described a procedure in which the plaque is excised and the corporotomy defect is grafted with tunica vaginalis. They believed that the tunica vaginalis is an easy donor site for the urologist and that it gives the same results as the dermal graft. The authors' experience has been that tunica vaginalis is a suitable substitute for dermis in select patients with well-defined, small lesions. In patients in whom the corporotomy defect is large, however, the authors have not been pleased with the use of tunica vaginalis. A report has described tunica vaginalis double folded to limit the problem with larger corporotomy defects. In an observational series the authors reported acceptable results (Geavlete et al, 2004).

Lockhart has employed a procedure in which the plaque is excised and the corporotomy defect is closed with tunica vaginalis as an island based on a dartos fascial and cremasteric flap (cited in Helal et al, 1995). He found that his results were better with the improved vascularity of the tunica vaginalis transposed as a paddle on a flap.

Buncke (cited in Stefanovic et al, 1994) reported an experimental animal series in which the lesion is excised and the corporotomy defect is replaced with temporalis fascia transferred to the area of the penis as a microvascular free transfer flap. To date, this procedure has not been reported in humans.

El-Sakka and colleagues (1998b) have also described a procedure using incisions but patching the corporotomy defects with vein grafts. They initially believed that the excised deep dorsal vein provided an adequate donor site for the vein grafts. With time, however, it was found that the donor site offered inadequate amounts of donor tissue, and later the saphenous vein was harvested to design the vein graft patches. Lue believes that the intracorporeal space represents a large vessel and therefore a patch of vessel wall represents a physiologic procedure (Brock et al, 1993). He reports good results with this procedure. Montorsi and colleagues (2000b) reported a series of 50 men treated with plaque incision and vein grafting for Peyronie's disease. All patients were evaluated preoperatively with sexual history, examination, determination of penile length and degree of curvature, dynamic color power Doppler ultrasonography of the penile vessels, and three nights of nocturnal RigiScan. All were evaluated postoperatively with the same variables, including color duplex sonography and RigiScan. These researchers reported either complete or adequate straightening in 94% of patients. Penile rigidity was equal to that preoperatively in 94% of patients. Power Doppler imaging showed vascular impairment in 10% of patients, and RigiScan revealed significant decrease in nightly erections in 10% of patients. They concluded, thus, that plaque incision with vein grafting achieved satisfactory results in the majority of patients with severe and stable Peyronie's disease who have intact penile rigidity preoperatively. Akkus and colleagues (2001) quoted a series of 58 patients who were similarly evaluated with history, counseling, and duplex ultrasound examination. They reported complete or adequate straightening in 95% of patients and preservation of preoperative erectile function in 93%. They concluded that plaque incision with venous patch grafting is a satisfactory surgical method for the treatment of the curvature in Peyronie's disease.

Krishnamurti (1995) reported the use of de-epithelialized penile skin as a paddle carried on the dartos fascia. He cited increased dependability of flaps, not a fact that is totally validated in the literature. The authors have attempted to "de-epithelialize" penile skin with the dermabrader as described by Krishnamurti. However, histologic evaluation of these "de-epithelialized islands" actually shows many areas where the entire thickness of the skin has been removed. Thus, in the authors' minds, the precise histologic composition of Krishnamurti's de-epithelialized islands is not clear.

Hellstrom (1994) has reported the use of a number of nonautologous grafts. Hellstrom and Reddy (2000) reported the use of cadaver pericardium in a small series. Chun and associates (2001) compared the results of plaque incision or excision and grafting with either dermal or cadaveric pericardial graft techniques, and they suggest that the minimal preoperative preparation and decreased patient morbidity with cadaveric pericardium makes it a more efficacious and appropriate graft compared with dermis. They do not report that the graft provides clinical results superior to those of dermis. Levine and Estrada, in 2003, reported results of the use of human cadaveric pericardial graft for the surgical correction of Peyronie's disease in a retrospective evaluation of 40 men. Postoperatively, all patients reported sufficient rigid erection for coitus after the procedure; however, many required intracorporeal injection of papaverine. Thus, a 98% success with penile straightening and a 95% success with intercourse as previously described were reported; 70% of the patients had unaided full erections, and 30% required pharmacologic assistance. Palese and Burnett (2001) reported the use of pericardial allograft in patients requiring complex penile prosthetic surgery. Hellstrom thought that the pericardial graft essentially serves as an inert collagen matrix or scaffold for the adjoining tunica albuginea. As the graft is overgrown or ingrown and the new tissues are vascularized, the graft is enzymatically dissolved (Leungwattanakij et al, 2001). Egydio and colleagues (2002) reported the results of their series using plaque incision with bovine pericardial graft; they described 33 patients. It is unclear in the report how the patients were stratified preoperatively with regard to erectile function. They reported a good correction of deformity in 88% of cases with adequate correction in the rest of their series, and they stated that all recovered their ability to "penetrate with no difficulty." They thus think that the procedure is an effective one.

Knoll, in 2001, reported the use of a porcine small intestinal submucosal graft in the surgical management of Peyronie's disease. His initial report was of 12 patients, the majority of whom had adequate straightening and adequate preservation of erectile function. He later described 162 patients with curvatures of 60 degrees or more secondary to Peyronie's disease. Some patients were preoperatively stratified with color Doppler ultrasonography; the majority were evaluated with examination by intracavernous injection. Knoll reported successful correction of curvature in 91% of patients. Mean follow-up was 38 months. Preservation of erectile function is not clearly stated. Although results appear promising with a small intestinal submucosal graft (Knoll, 2003) there have been others who have not experienced the same success. Breyer and colleagues reported on 19 patients who underwent tunical grafting with a 1-ply small intestinal submucosal graft and found a recurrence of the curvature in 37% of patients and a recurrence of the Peyronie's plaque in 26%. Their complication rate was 37%,

with 26% of patients having a hematoma at the graft site and 5% developing graft infection. As the authors began to use this grafting procedure more and dermal grafts less, they were interested in comparing results. Fifty-eight patients were evaluated, and these patients all had an identical operation for their Peyronie's disease, but some had a small intestinal submucosal graft and some had a dermal graft. The patient ages were relatively matched, as was the mean degree of penile curvature. At the time of the analysis, 15 patients had the small intestinal submucosal graft and 45 had been treated with a dermal graft. The series was small, but dermal and small intestinal submucosal grafts in this analysis had equivalent success rates. Obviously the use of the small intestinal submucosal graft saved operative time and avoided donor site morbidity. Throughout the entire group, 91% were satisfied with the results of their surgery (Eltahawy, 2006). The authors believe that the small intestinal submucosal graft offers a good alternative, but larger and longer studies are needed. In the authors' experience foreign material "grafts" (e.g., Silastic, Gore-Tex, Dacron), in the absence of concomitant prosthetic implantation, inevitably yield poor results (Devine, 1997; Brannigan et al, 1998).

Devine and Horton (1974) described a procedure for correction of deformity of Peyronie's disease in which the plaque is excised and replaced with a dermal graft. This procedure continues to be used selectively in the authors' center. The use of dermal graft for corporoplasty has been variously applied. Austoni and coworkers (1995) reported a large series of 418 men. In this series, 17% required further surgery for curvature and 20% had troublesome postoperative erectile dysfunction. However, what one must realize is that Austoni and coworkers used an aggressive dissection of the penis, in many patients disassembling the glans from the tip of the corporeal bodies. Thus the results may not be a fair representation of the procedure of excision of Peyronie's plaque with dermal graft in general. The World Health Organization consensus (Lue et al, 2004) reports that the operation of excision of Peyronie's plaque with dermal graft is regarded as outmoded. The authors disagree. The procedure selectively still has use; however, there are many suitable alternatives.

In addition, the authors now have a relatively large series of patients who have been treated by incisions through the plaque and patching of the corporotomy defects with dermis. With the exception of those patients with severely calcified plaques, the authors have preferentially used the technique of incision with dermal grafting and more recently with porcine intestinal submucosal grafting. Early results indicate that the technique of plaque incision is at least as successful as the technique of plaque excision; however, it has not yet been determined whether there is a difference between the techniques with regard to preservation of erectile function or limitation of graft-induced veno-occlusive dysfunction. Likewise, early analysis, as described previously, of the porcine intestinal submucosal graft has been promising. The advantage of an off-the-shelf graft cannot be overemphasized.

The initial skin incision is dependent on the location of the lesion or the location of the proposed intervention; patients with ventral plaques or those who will have corporeal plication can be approached through a midline incision of the ventral aspect of the penis, and dorsal plaques are most effectively approached by a circumferential incision. In the patient who has been previously circumcised the incision should be placed through the original circumcision incision (Fig. 28–8). In many patients the circumcision scar may be displaced far down the shaft of the penis. The authors have not encountered any problems, however, with reapproaching the penis through the circumcising incision, even when this is the case.

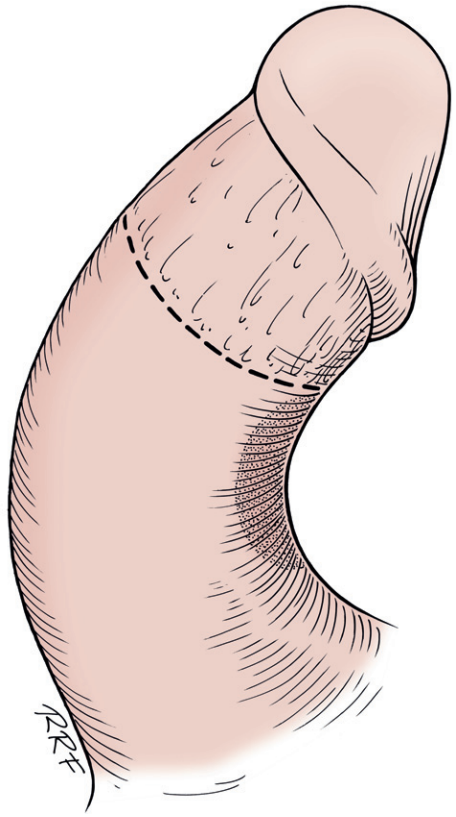

Figure 28–8. An erection demonstrates the dorsal curvature of the penis caused by the inelastic scar tissue in a dorsal plaque of Peyronie's disease. The incision to be made in the scar of the previous circumcision has been marked.

The shaft of the penis is then degloved to its base. This maneuver gives good exposure for midshaft and distal lesions. For proximal plaques or in patients who have relatively redundant foreskin, a second peripenile periscrotal incision is made. After the shaft of the penis is degloved it is delivered into the periscrotal incision; the shaft skin is laid aside and covered with a warm sponge. This protects the penile skin from trauma until the end of the procedure, when it is returned to the shaft. Optionally, a counterincision can be made at the penoscrotal junction in the scrotal raphe.

The dorsal neurovascular bundle is elevated in concert with the Buck fascia. This can be accomplished by several techniques. Incisions can be made just lateral to the corpus spongiosum, with the Buck fascia and the dorsal neurovascular bundle dissected off the lateral and dorsal aspects of the corpora cavernosa. Alternatively, the authors currently approach dorsal plaques by dissecting sharply through the bed of the deep dorsal vein and perform a modified vein dissection (Figs. 28–9 to 28–12). Initially this approach was used to investigate the potential effect of a modified vein dissection with regard to limitation of graft-induced veno-occlusive dysfunction. Although the beneficial effects of this are yet to be proved, approaching the dorsal plaque through the bed of the dorsal vein appears to be a superior approach technically.

In the past, if preoperative testing suggested veno-occlusive dysfunction, the authors proceeded with a formal vein dissection, ligation, and excision. More recent experience has shown, however, that vein dissection does not offer durable results in patients with Peyronie's disease, and it is currently believed that patients who demonstrate severe veno-occlusive dysfunction are better treated by a surgical approach or modeling to straighten the

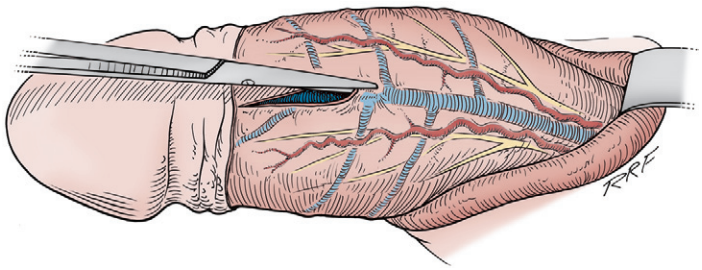

Figure 28–9. The skin has been degloved to the base of the penis by dissection in the layer immediately superficial to the Buck fascia. An incision in the dorsal midline of the Buck fascia exposes the deep dorsal vein. The coiled dorsal arteries and the circumflex veins are demonstrated.

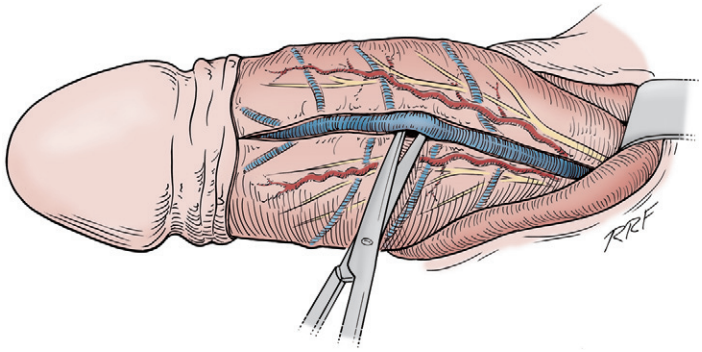

Figure 28–10. The deep dorsal vein is mobilized.

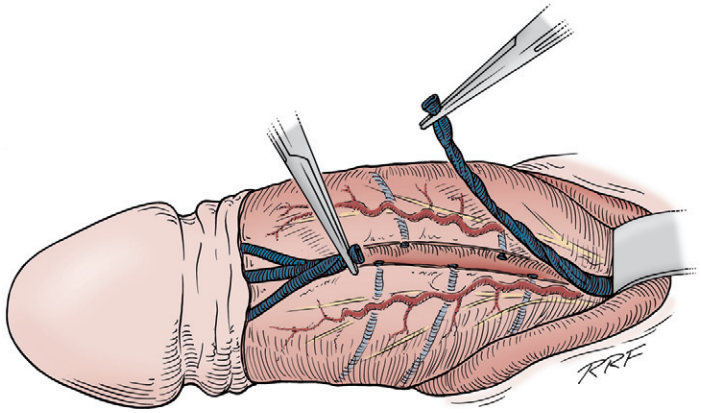

Figure 28–11. After the deep dorsal vein is divided it is dissected proximally; the emissary veins are divided and ligated. The subcoronal veins and the dorsal vein proximally are suture ligated.

penis and provided prosthetic implantation for their erectile dysfunction (Wilson and Delk, 1994). Some patients might do well with a plication or corporoplasty technique and then postoperatively undergo management of the erectile dysfunction pharmacologically.

After dorsal exposure of the tunica (see Fig. 28–12) the inelasticity of the plaque will be evident, and its extent can be delineated by feeling the surface of the tunica albuginea. An artificial erection accurately defines the curvature. Incisions are then planned either to incise or to excise the plaque. The authors place Prolene stay sutures in the midline, proximal and distal to the plaque, and mark the planned incisions. Depending on the technique selected, the plaque can be excised or incised. The use of a tourniquet for either control of bleeding or induction of an artificial erection is not advised because tourniquets can conceal proximal curvatures.

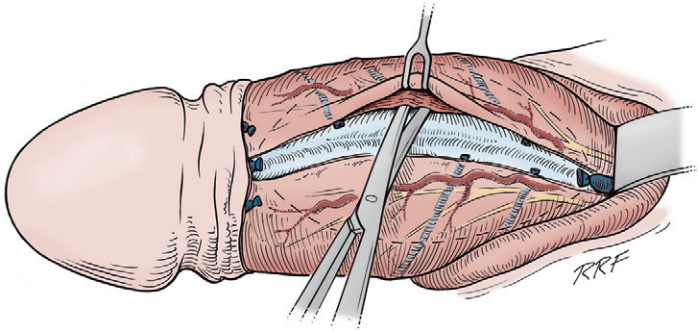

Figure 28–12. Buck fascia is elevated from the Peyronie's plaque. The area of dissection is outlined by the *dashed line*, continued far enough proximally, distally, and laterally to allow excision of the plaque without distraction or stretching of the nerves in the fascia.

Once the plaque has been excised or incisions have been made, the defect is measured, stretching the penis to ensure accurate coverage. The dermal graft, if that is what is being used, is then outlined on the donor site. The authors prefer to use the skin of the abdomen just above the iliac crest, lateral to the hairline, as the donor site for the dermal graft. The donor site is closed per primam by subcuticular sutures, with use of either a pull-out or the newer absorbable long-acting monofilament suture.

If a dermal graft is used it is carefully tailored to measure approximately 30% larger in all dimensions than the corporotomy defect and placed into either the incisional or the excisional defect. The graft, when it is released from the inherent tissue tension at the donor site, "contracts" about 30%. This should not be confused with graft contraction during "take." After completing the graft inlay with polydioxanone suture, another artificial erection is performed to demonstrate that the penis is straight and the suture lines are watertight. If there are leaks, they are oversewn. If the penis is not straight during surgery, it will not be straight postoperatively. If curvature persists, therefore, further modification by means of incisions and grafting or "touch-up" plications is necessary.

After completion of the dermal graft inlays the penis is closed. Buck fascia is reapposed with polydioxanone suture, and small suction drains are placed superficial to this fascia but deep to the dartos layer. The skin incisions are coapted with either chromic or small Vicryl sutures. If a ventral midline incision was made that crosses the penoscrotal junction, a Z-plasty should be used to prevent penoscrotal tethering.

Vein has also been used as a graft; however, the authors have never used or found the dorsal vein to be suitable but instead use the proximal saphenous vein. Use of this donor site has been criticized by some, the objection being the use of the donor site for a coronary artery graft. As an alternative, the distal vein can be used, beginning the dissection at the ankle. The vein must be turned into a "quilt," because the vein is rarely wide enough to adequately fill the corporotomy defect/defects even for incisions.

Beginning in 1998, in suitable patients, the authors further modified our technique of plaque incision. The technique of incision was described by Lue. In this technique the plaque is exposed as already illustrated and discussed. Artificial erection is used to identify the curvature and the point of maximal curvature. At that point, an H-shaped incision is made; the flaps are elevated, allowed to slide (Figs. 28–13 to 28–16), and sutured, leaving an

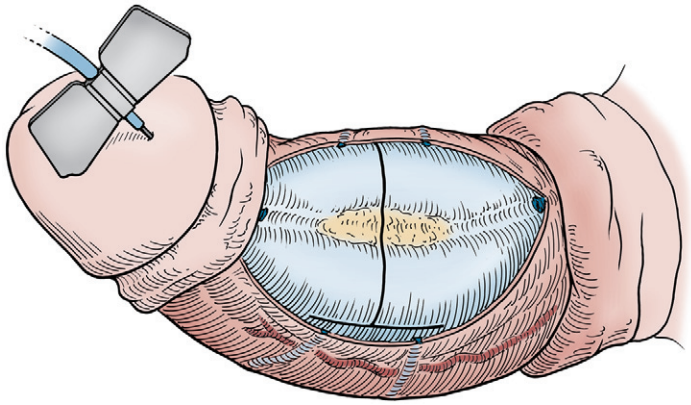

Figure 28–13. Illustration of "sliding H" technique of incision. The dorsal tunica and plaque are exposed as already described. An H-shaped incision is marked at the site of maximal curvature.

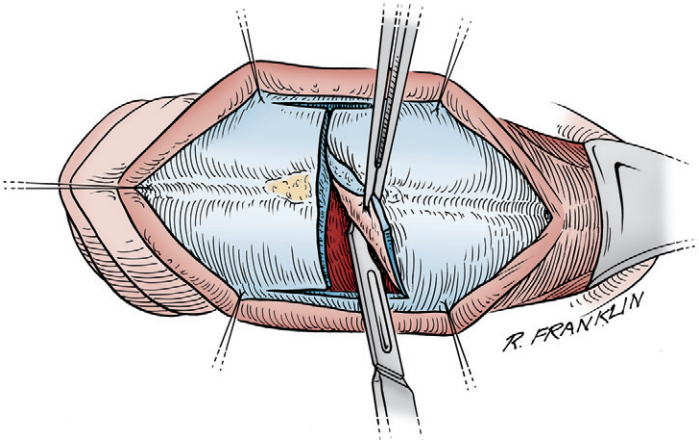

Figure 28–14. The flaps of the H are incised and elevated from the underlying erectile tissue. The septal fibers are divided. The septal fibers are detached back to the point of normal tunica albuginea both proximally and distally. This maneuver is extremely important in achieving straightening with this technique.

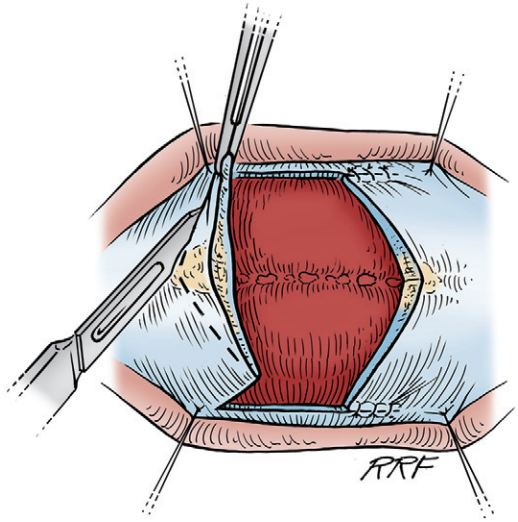

Figure 28–15. The flaps are elevated, and darting incisions are marked to allow some expansion of the defect circumferentially.

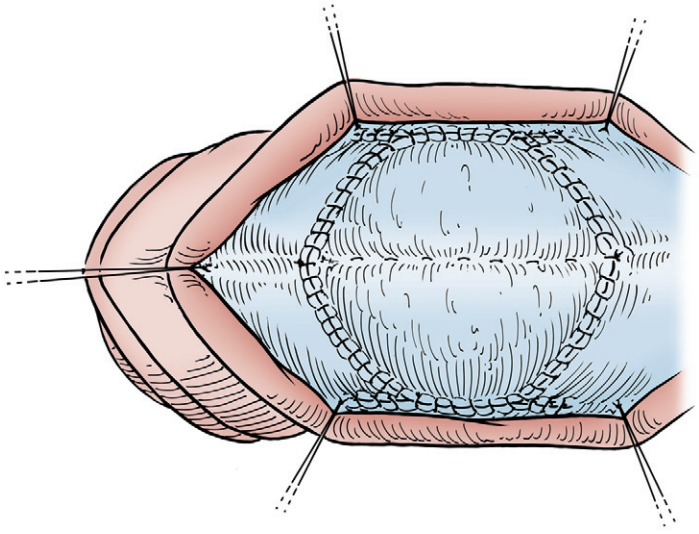

Figure 28–16. The flaps are sutured in place, creating a square corporotomy defect. Appearance with either dermis or small intestinal submucosa.

approximately square defect. Since 2001, the sliding-H incision has been modified. At the point of maximal curvature, which can be accurately identified during artificial erection, a stitch is placed and a strip of tunica albuginea is excised. This indeed does make a larger corporotomy defect; however, the corporotomy defect remains approximately square and the graft inlay can be placed without difficulty. After either H-shaped incision is made the sliding flaps are sutured. If there is indentation, the flaps are darted, allowing expansion. A graft is then sutured into the defect, and preferentially since 2003 the authors have used the small intestinal submucosal graft; however, dermis or vein can also be used (Fig. 28–17; see also Fig. 28–16). It is clear that the penis can be effectively straightened with this incision and graft technique alone in about 70% of patients. The addition of the small strip excision allows straightening in almost all patients. Only about 5% of patients will require touch-up plication, and generally that is for persistent tilt of the glans, as mentioned. Beginning about 2 years ago the modified sliding-H technique (excision of a small strip across the midline) has been used. With this technique touch-up plications are usually not required (Figs. 28–18 to 28–20). It is also clear that the sliding-H technique limits graft size, whether it is dermis, vein, or small intestinal submucosal graft. It is not clear whether this technique is more reliable or effective with regard to preservation of erectile function. It is the authors' distinct early impression that the small intestinal submucosal graft is clearly as efficacious as dermis or vein, and perhaps superior, and they continue to compare the small intestinal submucosal graft results to those of a series having an identical operation with the exception of the use of dermis versus small intestinal submucosa.

The penis is dressed with a Bioclusive dressing that is loosely applied and extending from the base of the penis to the level of the mid glans. A mildly compressing Kling dressing is wrapped over the Bioclusive dressing to limit edema and to allow better collapse of the surgical spaces around the suction drains. The Kling dressing is left in place for 4 hours, during which the glans is checked every 30 minutes. A No. 14-Fr Foley catheter is left until the patient ambulates on the morning after surgery. The suction drains are removed on the first postoperative day, and usually the patient is discharged on that day. Erections are suppressed with diazepam and amyl nitrite.

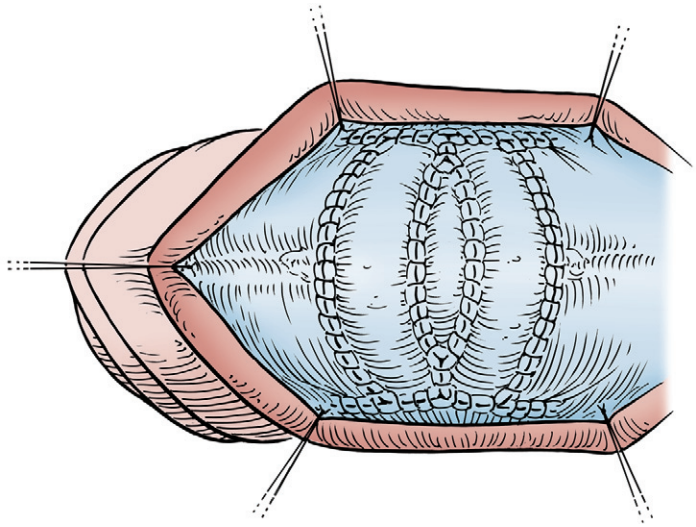

Figure 28–17. Alternatively, the corporotomy defect can be replaced with a vein graft. Notice that the vein graft is oriented so that the circumferential distensibility allows long axial lengthening.

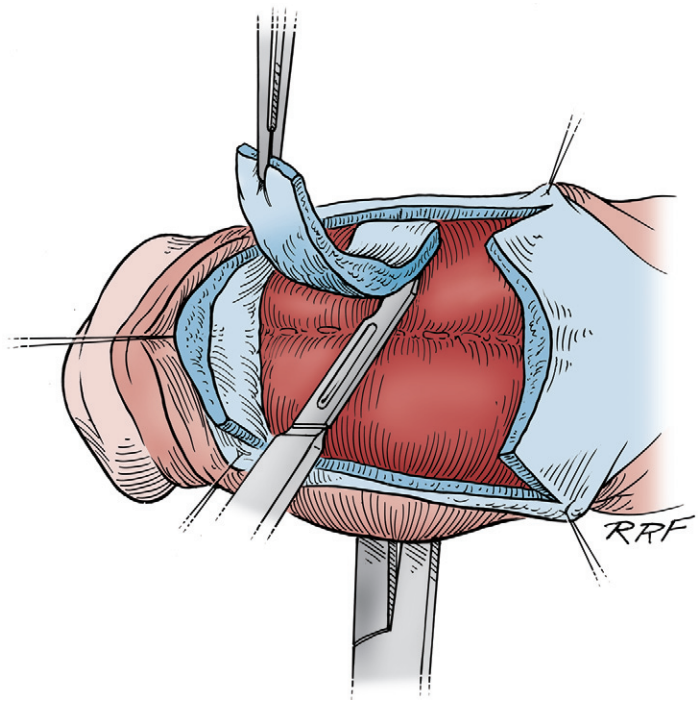

Figure 28–20. The transverse strip is excised; the H-shaped flaps are then sutured as discussed in Figure 28–15. The flap can be darted if lateral expansion is needed.

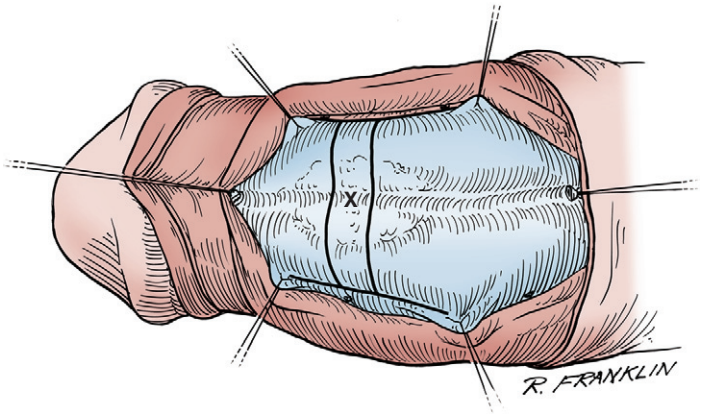

Figure 28–18. Modification of the "sliding H" technique, in which a small strip is excised at the point of maximal curvature. The stitch marks that point.

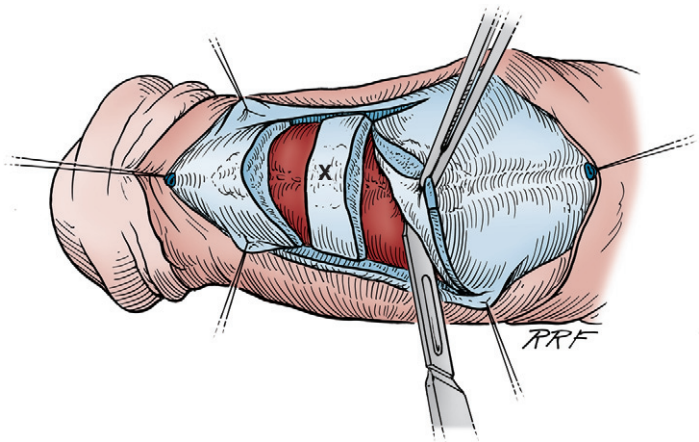

Figure 28–19. The incisions are made; the H-shaped flaps are elevated extensively as discussed in Figure 28–14. Note the expansion of the corporotomy defect.

Dermal grafts mature in the same manner as other grafts do: first nourished by imbibition of tissue fluids while inosculation occurs from adjacent blood vessels. Increased compliance is noted during the late phase of maturation, with the graft tending first to contract and then to become compliant. In the first 3 months the graft may contract enough to re-create some of the curvature, but as the graft softens, straightening occurs. This is seen less in patients who have had incisions as opposed to excisions. Patients should be forewarned of this sequence of events to avoid undue anxiety. With vein and also small intestinal submucosal grafts, this initial contraction can be seen, but seemingly less often and less severely.

After the first 2 weeks patients are encouraged to have erections but discouraged from intercourse. During this time, it is desirable for the penis to be manipulated so that the skin does not adhere to the deeper layers of the penis. In addition, erections stretch the graft and aid in the maturation phases of graft take. In some patients, the use of the vacuum erection device without the constriction ring is encouraged as a means of distending and stretching the graft.

Recently, the authors have placed Tisseel (Baxter Biosurgery, Deerfield, IL) beneath the small intestinal submucosal graft. Others have done this and believe that hematoma formation under the graft is less frequently encountered. The authors have not used this long enough or in a sufficient number of patients to say whether their current results are altered with this modification.

Penile Prosthesis in Peyronie's Disease

It is the consensus of the committee on Peyronie's disease at the World Health Organization Second International Consultation on Sexual Dysfunctions that the penile prosthesis is a reliable option for the older man with vascular impairment, erectile dysfunction, and acquired deformity of the penis (Lue et al, 2004). It is thus not the only treatment for Peyronie's disease but rather a prudent

Key Points: Surgical Correction

- For a patient to be a surgical candidate, his disease must be stable and mature. Most investigators consider curvature or erectile dysfunction that precludes intercourse the indication for surgery. The surgeon must consider all options of surgical therapy. Plication and corporoplasty techniques can be grouped under those operations that shorten the less involved side, and the application of those techniques is preferential in many patients. Procedures that incise or excise the plaque require the use of graft materials, and a number of graft materials have been successfully employed.
- Overall, plication or corporoplasty techniques seem to preserve the patient's erectile function more effectively; however, excellent results can be achieved with incision and grafting techniques. The use of a prosthesis for all Peyronie's disease patients is condemned.

treatment for the patient with significant erectile dysfunction in association with Peyronie's disease. In past years, semirigid devices have been preferred; however, with improvement in the three-piece hydraulic devices, these would appear to be preferable (Marzi et al, 1997; Ghanem, 1998). In 1993, Montorsi published a study that showed greater patient and partner dissatisfaction with semirigid devices when they were used for the treatment of erectile dysfunction combined with Peyronie's disease. Before 1994, correction of the curvature of Peyronie's disease, at the time of prosthesis placement, was accomplished by degloving of the penis and incision of the tunica albuginea in the area of curvature. In 1994, however, Wilson and Delk advised the modeling procedure. Since that report the modeling procedure has proved to be an excellent means for straightening the penis in the majority of patients. However, when the patient is to undergo this procedure, it is imperative to explain that urethral injury at the time of modeling is possible. This can occur with the extension of the modeling into the urethra at the point of maximal curvature, or the tips of the prosthesis can actually be forced through the tip of the corporeal bodies and into the urethra in some cases. If modeling does not work, one can resort to what was previously applied and that is incision with or without grafts as described earlier. In 1996, Montague and associates published a comparative study of the AMS CX cylinders versus the AMS Ultrex cylinders in Peyronie's disease. In that study it was found that the CX cylinders were superior. The message is that a controlled expansion cylinder provides better results; thus, the AMS 700CX or the Mentor Alpha I/Titan system would be preferable (Wilson and Delk, 1994; Montague et al, 1996). If incisions are required, the authors recommend closing the incisions with a synthetic patch. Gore-Tex was used in the past but now small intestinal submucosal graft is preferred. The AMS Ultrex cylinders have been redesigned to be controlled expansion cylinders. Milam reported favorable results in a series of about 35 patients with Peyronie's disease all treated with the AMS-LGX prosthesis with modeling (Whittam, 2009). To date, however, no comparative study of the AMS-LGX compared with the AMS 700CX prosthesis or the Coloplast Titan prosthesis has been undertaken.

The recent publications showing superiority of the antibiotic-coated prostheses or the hydrophilic-coated prosthesis with regard to infection rate suggest to the authors that in cases of Peyronie's disease, the antibiotic-coated devices should be used (Carson, 2004; Wolter and Hellstrom, 2004) unless there are concerns regarding antibiotic allergy. Wilson reported the use of the Ambicor prosthesis in Peyronie's patients. A series of 77 consecutive patients were studied. Primary implants were used in 32; of these patients, 20 had bothersome Peyronie's disease. Thirty-four were replacement devices for a malfunctioning AMS 700CX prosthesis, and many of these patients had Peyronie's disease. All of the Peyronie's patients had satisfactory straightening without another adjunctive procedure. There were no infections reported in the series. Thus, it was concluded that the Ambicor two-piece inflatable prosthesis has good patient satisfaction even when it is implanted for Peyronie's disease and in patients who have had previous three-piece devices (Scarzella and Wilson, 2004).

Key Points: Penile Prosthesis

- The consensus committee on Peyronie's disease at the World Health Organization Second International Consultation on Sexual Dysfunctions stated that the penile prosthesis is a reliable option for the older man with vascular impairment, erectile dysfunction, and acquired deformity of the penis.
- It is not the only treatment of Peyronie's disease but rather a prudent treatment for the patient with significant erectile dysfunction in association with Peyronie's disease. Hydraulic prostheses are preferred, and those prostheses that have true controlled expansion cylinders have been shown to provide better results.

CONCLUSION

Peyronie's disease is not the "terminal/no hope" diagnosis that many patients believe it is. These patients and their partners must be educated about what is happening and what might happen. They must be told that in the majority of cases their sexual relationship can be adequately restored. They must also understand that for most cases, all we have to offer will, at best, make their sex lives adequate. There is not one best operation or approach but rather a menu of options that for a given individual will have benefits and disadvantages. With counseling, they must match their "have to haves and can't stand to haves" to those advantages and disadvantages. This approach, in the authors' experience, will lead to the best management for most.

Androgen Deficiency in the Aging Male

Alvaro Morales, MD, FACS, FRCS

Definition
Historical Perspective
Epidemiology of Hypogonadism in Aging
Physiologic Principles
Diagnosis
Treatment of Testosterone Deficiency Syndrome
Recommendations and Guidelines

DEFINITION

Normal aging frequently results in a progressive functional dwindling of the hypothalamic-pituitary-gonadal axis (Liu et al, 2007). In men this process exhibits significant interindividual variability in the age at onset and speed and depth of the decline. The syndrome is variously known as andropause, androgen decline in the aging male (ADAM), late-onset hypogonadism (LOH), or, more accurately, testosterone deficiency syndrome (TDS). It is characterized by multiple clinical manifestations (Table 29–1) (Liu et al, 2004). Urologists often see the same presentation more acutely and dramatically in men subjected to medical or surgical castration for advanced prostate cancer (Shahani et al, 2008).

HISTORICAL PERSPECTIVE

Aging and Hormones: From Antiquity to the 21st Century

The importance of the gonads in the maintenance of homeostasis has been recognized since antiquity. The association of advancing age with hypogonadism has been widely acknowledged since the end of the 19th century with the report in the scientific literature by Brown-Séquard on his observations about the improvement in his own physical strength and intellectual capacity after administration of a *liquid testiculaire* prepared by him from animal gonads. These reports gave origin to a series of medical claims that exploited testicular extracts and heterologous transplants as effective treatments for the infirmities of aging. They were eventually exposed as hoaxes (Current Comment, 1927).

Concurrently with the pseudoscience at the turn of the last century, serious investigators were exploring the effects of substances produced and secreted by the testes, eventually resulting in the isolation of androsterone and testosterone by Laqueur (David et al, 1935). By 1935, almost simultaneously and independently, three research teams led by Adolf Butenandt, Kàroly Gyula, and Leopold Ruzicka, who were individually sponsored by three different corporations (Schering, Organon, and Ciba, respectively), synthesized the more powerful testicular hormone, ultimately named testosterone (T). **For this work, Butenandt and Ruzicka received the Nobel Prize for Chemistry in 1939.** After synthesis of the hormone, injectable preparations for human use were developed, and shortly before the onset of World War II clinical trials on T were under way. Interest grew in the use of T for a variety of ailments, ranging from sexual difficulties to the prevention of benign prostatic hyperplasia (Cuneo and Jomain, 1938). By the end of World War II the clinical picture of a syndrome named "male climacteric" associated with low T levels was fully recognized (Werner, 1946). T substitution became so widely used that warnings about the indiscriminate use and abuse of the hormone were already sounded by the 1940s (Thompson, 1946).

Key Point: Testosterone Deficiency Syndrome

- TDS is a clinical and biochemical syndrome frequently associated with advancing age and characterized by a deficiency in serum testosterone levels with or without changes in receptor sensitivity to androgens. It may affect the function of multiple organ systems and result in a significant detriment in the quality of life.

EPIDEMIOLOGY OF HYPOGONADISM IN AGING

The mean life span in Imperial Rome was about 20 years. United Nations estimates and projections of world population trends over a 75-year period showed that in the last decade of the 20th century the number of humans increased by 1 billion, and it will become close to 2 billion over the next 25 years. More importantly, life expectancy over this period will increase by more than 30 years (United Nations Secretariat, 2008). It follows that the prevalence of hormonal alterations in general and hypogonadism in particular is bound to rise significantly in the first half of this century.

The global prevalence of TDS is not accurately known, but it can be inferred from population projections that it is on the rise.

Table 29–1.

Clinical Manifestations of Late-Onset Hypogonadism and Their Anticipated Response to Treatment

SYSTEM/FUNCTION	AGING	RESPONSE TO TESTOSTERONE
Erectile function	↓	↑
Sexual desire	↓	↑
Mood/cognition	→/↓	↑*
Tiredness/lack of motivation	↓	↑
Sleep disturbances	→/↓	→
Spatial cognition	↓	↑*
Vasomotor (hot flashes)	↑	↓
Quality of life	↓	↑
Hematocrit	↓	↑
Leptin production	↑	↓
LDL and HDL cholesterol	→	↓
Fat mass	↑	↓
Muscle mass	↓	↑
Bone mass	↓	↑
Hair and skin changes	↓	→

↑ increases/improves; ↓ decreases/deteriorates; → no change; ↑* suspected/not proved.
HDL, high-density lipoprotein; LDL, low-density lipoprotein.

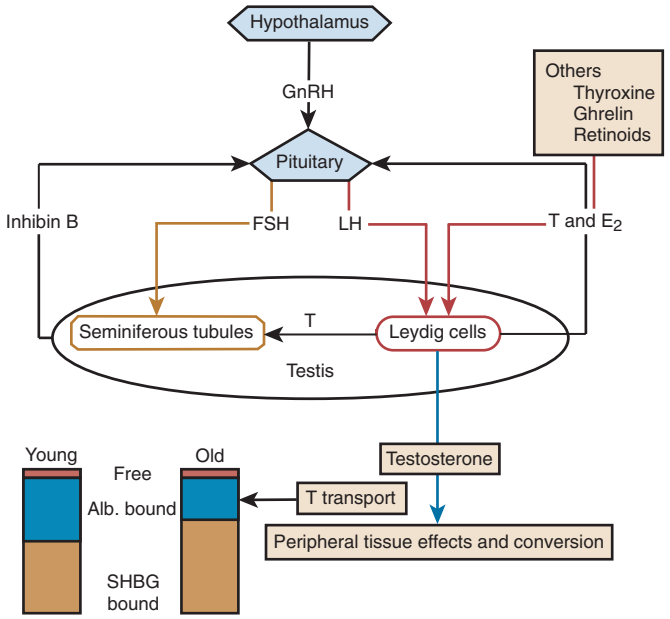

Figure 29–1. Effect of aging on the production, transport, and metabolism of testosterone (T). Luteinizing hormone (LH) is the major but not the only regulator of T production. Aging of the hypothalamus and the pituitary results in decreased production of gonadotropin-releasing hormone (GnRH) and LH, respectively. T circulates free (2%) or is bound to albumin or sex hormone–binding globulin (SHBG). Binding of T to SHBG renders it unavailable to most tissues. SHBG increases with aging. Bioavailable T (free and albumin-bound fractions) is metabolically active and can be converted to other hormones (dihydrotestosterone, dehydroepiandrosterone, estradiol [E_2]). FSH, follicle-stimulating hormone.

In an attempt to alleviate the scarcity of descriptive epidemiology of androgen deficiency, the Massachusetts Male Aging Study (MMAS) reported a crude incidence rate of 12.3 per 1000 person-years, leading to a prevalence of 481,000 new cases of TDS per year in American men 40 to 69 years old (Araujo et al, 2004). Further assessment with data from the Boston Area Community Health (BACH) survey documented a prevalence of symptomatic T deficiency in men 30 to 70 years of age of 5.6% (Araujo et al, 2007). These observations are further confirmed by an Australian study (Liu et al, 2007) and the European Male Aging Study with larger populations of very different geographic, cultural, and ethnic backgrounds (Wu et al, 2008).

PHYSIOLOGIC PRINCIPLES

Regulation of Testosterone Production—Central Mechanisms

Luteinizing hormone (LH) modulates T biosynthesis by Leydig cells and also controls their population (Habert et al, 2001). An example exists in aged animals, in which "hibernation" of Leydig cells develops after prolonged LH suppression (Chen and Zirkin, 1999). **In rodents, aging of the hypothalamus results in an apoptotic process leading to decreased production of gonadotropins** (Morales and Heaton, 2003). **Although not proved in humans, this process may explain a fundamental cause of TDS.** In the testis the local cellular environment has the potential for impact on regulation and function in a paracrine fashion, mostly in the form of T acting in seminiferous tubules (Fig. 29–1). Sertoli cells do not appear to have a major impact as long as LH control is active (Young et al, 2000). **Neural influences on Leydig cells have been demonstrated, independent of the pituitary, in the paraventricular nucleus of the hypothalamus** (Selvage and Rivier, 2003), and the peptide ghrelin actively regulates Leydig cell activity (Barreiro et al, 2004). These findings have implications for T production independent of central endocrine mechanisms.

Androgen Production in Aging—Peripheral Mechanisms

T and dihydrotestosterone (DHT) are the main androgens playing the key regulatory roles in determining and later supporting the male phenotype. Androgen effects require the delivery of androgens to the site of action, penetration into the cells, metabolic conversion where necessary, and action with the androgen receptor (AR) on the genome. T is the predominant circulating androgen; the adrenal cortex secretes 19-carbon steroids with weak androgenic activity that serve as precursors for estrogens and active androgens such as T. Very small amounts of steroids are produced in brain cells, but local production may be functionally important (King et al, 2002) and not be represented in serum-based measurements. **Leydig cells decrease in numbers in the testes of older men and these men have less T secreted per burst and a decline in secretory bursts in response to LH, suggesting partial desensitization of Leydig cells to LH with aging.** Taken together, these studies demonstrate that a component of the decline in T with aging in men is due to testicular failure.

Transport and Metabolism of Testosterone

T is exchanged readily through cellular membranes with the extracellular environment. The passive transfer of T through membranes means that serum concentrations reflect general tissue androgen levels except where local sources of production or conversion exist. Circulating T is 98% bound to proteins (sex

hormone–binding globulin [SHBG] and albumin (see Fig. 29–1), in which form it is relatively spared hepatic metabolism. The binding to SHBG and that to albumin have different affinities, providing the concept of bioavailable T; T bound to albumin is more readily unbound for use.

T levels are determined by the relative rates of production and metabolism. T can be aromatized to 17β-estradiol or reduced to 5α-DHT. Aromatization by cytochrome P450 arom and the supply of T substrate determine estrogen availability in estrogen-dependent cells such as those in the testis, fat, liver, hair follicles, and brain (de Ronde et al, 2003). There are two isoforms of 5α-reductase, and the cellular availability of 5α-DHT depends on T reduction and the rate of DHT metabolism. **The balance between T and DHT metabolic enzyme activity is more critical to the cells in which it is occurring than to the overall rate of T metabolism.** With aging, changes occur in enzyme functions that can potentially skew cellular activities in a way that is hidden from any systemic measures of androgen status. T catabolism takes place mostly in the liver, prostate, and skin, and catabolic products are largely excreted in the urine.

Androgen Receptor

T and DHT act through the androgen receptor (AR), which is a ligand-inducible transcription factor. The AR structure includes a COOH-terminal ligand binding domain, a DNA binding domain, a hinge region, a variable-length CAG repeat region, and an NH_2-terminal transactivation domain (Glass et al, 1997). Most of the transactivational activity is associated with the NH_2 terminus. The CAG repeat stretch is maximal in man (about 22 triplets) and decreases with evolutionary distance from man (Choong and Wilson, 1998). The hinge region is responsible for nuclear function after hormone binding. The ligand binding domain acts with the help of molecular chaperones, which increase the affinity for the hormone of the unbound AR.

T is transported through the cellular membrane, binds to the inactive AR complex, and is translocated to the nucleus. The binding of T to DNA activates the basal transcription machinery, thus regulating the transcription of target genes. Although the time frame for this genomic activity is 30 to 60 minutes there are nongenomic actions that take place too rapidly to follow this pathway. These rapid actions may be due to activation or possibly binding to undetermined membrane-bound receptors. **The AR may be activated without the presence of ligand, for example, by protein kinase C, a factor that has great importance in the androgen interaction with prostate cancer cells** (Culig, 2004).

CAG Repeat Polymorphism and Aging

The CAG repeat lengths of the AR vary from 6 to 39, depending on race (Valdehuis et al, 2005). In general, increased androgenic effect is seen at any level of T in men with shorter CAG repeat length. In older men, lower T is associated with fewer CAG repeats. The association of polymorphic AR with TDS manifestations showed that older men with more than 23 CAG repeats had less elevated LH, normal T, and less decreased potency but more depression, more anxiety, more deterioration of general well-being, and decreased beard growth (Harkonen et al, 2003; Lapauw et al, 2007). Changes in the AR can play a major role in the symptomatic response to T, potentially explaining some of the variability in clinical presentation in men with similar serum T. To complicate the picture, the AR CAG repeat length has been reported to correlate not only with serum T but also with estradiol in aging males (Huhtaniemi et al, 2009).

Androgen Actions

T actions on sexual function, spermatogenesis, and the prostate are discussed in other chapters. Action of T in other systems (i.e., musculoskeletal) is discussed later.

Testosterone and Glucose Metabolism

The metabolic syndrome is a complex association of several interrelated abnormalities that increase the risk for cardiovascular disease and progression to type 2 diabetes mellitus. Insulin resistance is the key factor for the clustering of risk factors (Grossman et al, 2008). Hypogonadism is seen frequently in association with the metabolic syndrome (Dandona et al, 2008), and several studies show that the fundamental cardiovascular risk parameters can be improved by the administration of T to these men. Hypogonadal men have increased leptin, obesity, and insulin levels that become normal with exogenous T treatment, which also reduces abdominal fat mass and improves insulin action (Zitzmann and Nieschlag, 2003). T administration to older men is associated with decreased visceral fat and glucose concentrations and increased insulin sensitivity (Bhasin, 2003). Hypogonadism correlates with high serum glucose, high triglycerides, high body mass, high waist-to-hip ratio, high total body fat mass, and high fasting insulin resistance index. Treatment with T improves the metabolic syndrome, especially in overweight older men (Schroeder et al, 2004).

Androgens and the Brain

A relationship between hypogonadism and depression has not been conclusively established. Although castration for the treatment of advanced cancer of the prostate has been shown to correlate with an increase in psychiatric illness, mostly depression (DiBlasio et al, 2008), there are studies showing improvements in measures of mood and well-being in aging men with hypogonadism (Almeida et al, 2008). There are well-researched gender differences in selected areas of cognition such as verbal skills and spatial tests that point to the developmental influence of T. Studies of hypogonadal men suggest that some cognitive skills can be improved with replacement therapy (Zitzmann, 2006), but this is not invariably seen because there are clearly many potential causes of impaired cognition.

DIAGNOSIS

Clinical Diagnosis

Clinical diagnosis of TDS is challenging because neither a low serum T level nor symptoms are truly diagnostic of the condition. The presence of symptoms, however, is a sine qua non for diagnosis and should be coupled with a low or borderline-low objective biochemical measure of T. In practice this ideal is not always achievable. Thus it was suggested that (Black et al, 2004) **in the presence of symptoms but without strong biochemical support that a therapeutic trial would be an acceptable diagnostic approach; it should be noted that a sustained placebo response can be observed for up to a year** (Haren et al, 2005). Morley (2007) **further advanced this notion by suggesting that the diagnosis of TDS requires the presence of symptoms, a low level of serum T, *and a positive response to treatment.* The concept was further supported by a recent set of multidisciplinary recommendations** (see Recommendation 4 later; Wang et al, 2009).

Table 29–2.

Spectrum and Severity of Late-Onset Hypogonadism Symptoms*

SYMPTOM (N = 52)	MINIMALLY TO MILDLY PROBLEMATIC	MODERATELY PROBLEMATIC	VERY PROBLEMATIC
Loss of energy	10 (19%)	17 (33%)	19 (36%)
Diminished libido	14 (27%)	10 (20%)	8 (15%)
Lack of motivation	9 (18%)	12 (23%)	8 (15%)
Irritability	4 (8%)	10 (20%)	11 (20%)
Sleepiness after meal	6 (12%)	5 (10%)	12 (23%)
Inability to concentrate	14 (26%)	4 (8%)	4 (8%)
Hot flashes	10 (20%)	2 (4%)	2 (4%)
Muscular aches	2 (4%)	0	6 (12%)

*Symptoms appearing after discontinuation of treatment with depot subdermal administration of testosterone (see text for details).

Table 29–3.

The Androgen Deficiency in Aging Male (ADAM) Questionnaire

Yes	No	1. *Do you have a decrease in libido (sex drive)?*
Yes	No	2. *Do you have a lack of energy?*
Yes	No	3. *Do you have a decrease in strength and/or endurance?*
Yes	No	4. *Have you lost height?*
Yes	No	5. *Have you noticed a decreased enjoyment of life?*
Yes	No	6. *Are you sad and/or grumpy?*
Yes	No	7. *Are your erections less strong?*
Yes	No	8. *Have you noticed a recent deterioration in your ability to play sports?*
Yes	No	9. *Are you falling asleep after dinner?*
Yes	No	10. *Has there been a recent deterioration in your work performance?*

If you answered Yes to questions 1 or 7 or any 3 other questions, you may be experiencing androgen deficiency (low testosterone level).

The clinical picture is well recognized (see Table 29–1). **Among the most prominent symptoms are tiredness, hypoactive sexual desire, and dysphoria.** Erectile dysfunction (ED) is, however, the most frequent reason for consultation. These manifestations generally correlate with the degree of T deficiency (Zitzmann et al, 2006) but need not all be present to identify the syndrome. In addition, the severity of one or more of them does not necessarily match the severity of the others, nor do we yet understand the uneven appearance of these manifestations. **TDS symptoms recur after discontinuation of therapy at highly reproducible intraindividual T levels, but the trigger level differs widely among individuals** (Table 29–2) (Kelleher et al, 2004). The increasingly recognized association of TDS and ED and cardiovascular disease (Billups et al, 2008) has brought to the forefront of clinical practice the need for a more in-depth assessment of men presenting with TDS-ED (Corona et al, 2009).

The **physical examination** suffers the same shortcomings as the history, mainly lack of specificity. Testicular atrophy may be present together with a decrease in pubic and facial hair. Sarcopenia and increase in visceral fat can also be part of the findings. The sequelae of osteoporosis become evident in long-standing cases. None of these is, alone or in combination, sufficient to make a definitive diagnosis, although the composite of history and findings on examination provides a strong case for a presumptive diagnosis of the syndrome.

Screening Questionnaires for TDS

Three questionnaires have been developed to detect hypogonadism in adult men: (1) St. Louis University's ADAM, (2) the Aging Male Survey (AMS), and (3) the MMAS. The first two are symptom questionnaires, and the last one represents a mixture of symptoms and epidemiologic findings. The ADAM questionnaire (Table 29–3) in the original validation had a sensitivity and specificity of 88% and 60%, respectively, against serum bioavailable T (BT) levels (Morley et al, 2000). In a follow-up study, BT and calculated free T (cFT) were lower in ADAM-positive men than in ADAM-negative men. The effectiveness of the ADAM questionnaire as a screening tool has been confirmed by most independent investigators (Tancredi et al, 2004). The AMS (Fig. 29–2) (Moore et al, 2004), in the author's hands, has sensitivity (83%) and specificity (39%) similar to those of the ADAM, but in a European study none of the three AMS domains correlated significantly with serum levels of total, bioavailable, or free T in men older than 70 (T'Sjoen et al, 2004). In contrast, the MMAS showed a sensitivity of 60% and a specificity of 59%. **These questionnaires are useful as screening tools but fall short of expectation for diagnostic purposes.** Their value as outcome measures after treatment with T remains undetermined (Morales et al, 2007).

Biochemical Diagnosis

T values decline while SHBG levels increase with aging. In young men, about 60% of circulating T is bound to SHBG, 38% is bound to albumin, and 1% to 2% is free (see Fig. 29–1). **The T that is free and bound to albumin is considered to be capable of entering tissues and to be responsible for the actions of T. SHBG-bound T is inaccessible to tissues and not active. In some tissues, such as the prostate, T bound to SHBG can activate SHBG receptors and produce effects within the cell** (Rosner et al, 1999). The active component (free plus albumin bound) is called bioavailable T (BT). Epidemiologic studies suggest that BT correlates better with symptoms associated with T deficiency than total T.

Assays for Testosterone

Establishing the presence of hypogonadism on a purely clinical basis is difficult. Only the most severe cases bring up clinical suspicion. The support of the biochemical evaluation is, therefore, fundamental in the diagnosis of the condition.

Although testosterone measurements should be restricted to morning hours at all ages (Brambilla et al, 2009), the importance of repeated measurements when the values are not conclusive cannot be emphasized enough. The biologic variation of repeated measurements of T is about 20%. **Values between 250 and 360 ng/dL (9 to 12 nmol/L) are considered "borderline." In the presence of a clear picture of TDS, a therapeutic trial of 3 months is justified** (see Fig. 29–3).

The urologist should become familiar with the range and quality of the T assays offered by the local laboratory as well as the intraindividual and interindividual variations in serum T levels. Assay techniques have

AMS Questionnaire

Which of the following symptoms apply to you at this time? Please mark the appropriate box for each symptom. For symptoms that do not apply, please mark "none."

Symptoms Score =	None 1	Mild 2	Moderate 3	Severe 4	Extremely severe 5
1. **Decline in your feeling of general well-being** (general state of health, subjective feeling)	☐	☐	☐	☐	☐
2. **Joint pain and muscular ache** (lower back pain, joint pain, pain in a limb, general back ache)	☐	☐	☐	☐	☐
3. **Excessive sweating** (unexpected/sudden episodes of sweating, hot flushes independent of strain)	☐	☐	☐	☐	☐
4. **Sleep problems** (difficulty in falling asleep, difficulty in sleeping through, waking up early and feeling tired, poor sleep, sleeplessness)	☐	☐	☐	☐	☐
5. **Increased need for sleep, often feeling tired**	☐	☐	☐	☐	☐
6. **Irritability** (feeling aggressive, easily upset about little things, moody)	☐	☐	☐	☐	☐
7. **Nervousness** (inner tension, restlessness, feeling fidgety)	☐	☐	☐	☐	☐
8. **Anxiety** (feeling panicky)	☐	☐	☐	☐	☐
9. **Physical exhaustion/lacking vitality** (general decrease in performance, reduced activity, lacking interest in leisure activities, feeling of getting less done, of achieving less, of having to force oneself to undertake activities)	☐	☐	☐	☐	☐
10. **Decrease in muscular strength** (feeling of weakness)	☐	☐	☐	☐	☐
11. **Depressive mood** (feeling down, sad, on the verge of tears, lack of drive, mood swings, feeling nothing is of any use)	☐	☐	☐	☐	☐
12. **Feeling that you have passed your peak**	☐	☐	☐	☐	☐
13. **Feeling burnt out, having hit rock-bottom**	☐	☐	☐	☐	☐
14. **Decrease in beard growth**	☐	☐	☐	☐	☐
15. **Decrease in ability/frequency to perform sexually**	☐	☐	☐	☐	☐
16. **Decrease in the number of morning erections**	☐	☐	☐	☐	☐
17. **Decrease in sexual desire/libido** (lacking pleasure in sex, lacking desire for sexual intercourse)	☐	☐	☐	☐	☐

Have you got any other major symptoms? Yes..... ☐ No..... ☐

If Yes, please describe: _____

_____

Thank you very much for your cooperation

Figure 29–2. The Aging Male Survey (AMS). This questionnaire has three domains: Psychological (questions 6, 7, 8, 11, 13); Somatovegetative (questions 1, 2, 3, 4, 5, 9, 10); and Sexual (questions 12, 14, 15, 16, 17). The minimum and maximum scores are 5 and 25, respectively, for the Psychological and Sexual domains and 7 and 35 for the Somatovegetative domain. The higher the score, the more severe are the symptoms.

improved greatly, but many laboratories have paid scant attention to the accuracy or the normal range of their assays. Three assays for measurement of total T are commonly used: (1) radioimmunoassay, (2) nonradioactive immunoassay kits, and (3) automated platform assays that use chemiluminescent detection. There is significant interassay variability: a value of 297 ng/dL (10.3 nmol) showed a variation from 160 to 508 ng/dL (5.5 to 17.6 nmol). In addition, the coefficients of variation ranged from 5.1% to 22.7%. Fortunately, most of the assay techniques had regression slopes close to 1 and correlation coefficients of 0.92 to 0.97 compared with liquid chromatography/tandem mass spectroscopy (Wang et al, 2004a).

In young men, but much less in older men, there is a substantial circadian rhythm, with higher values being obtained in the morning. In addition, in all men there is substantial variability (±20%) from week to week (Morley et al, 2002). **Thus, two samples obtained a week or two apart, ideally in the morning, would seem to be a minimal criterion. The assays that more closely reflect tissue available T are (1) free T only if measured by**

Key Point: Biochemistry

- In patients at risk for or suspected of having hypogonadism, the following investigations should be done: (1) T determination from blood taken between 7:00 and 11:00 AM. For screening purposes total T determination is usually sufficient. (2) If T levels are below or at the lower limit of the accepted normal values, it is prudent to confirm the results with a second determination together with assessment of gonadotropins (LH) and prolactin. (3) In the younger male, low levels of T (<12 nmol/L or <350 ng/dL) with chronically elevated gonadotropins make a clear diagnosis of primary hypogonadism. (4) In an older man the diagnostic lines are not as clearly defined and additional information may be needed (see Fig. 29–3).

ultracentrifugal ultrafiltration or dialysis techniques, (2) BT, generally measured by an ammonium sulfate precipitation technique, and (3) calculated free T or BT that can be obtained by measuring T and SHBG with or without an albumin level (see later).

Assays for BT and free T are cumbersome, costly, and not readily available. Vermeulen and colleagues (1999) provided a solution for situations in which the more reliable BT or free T determinations are not accessible: a calculation can be made from the values obtained for total T and the determination of SHBG. It has become known as calculated free T, or simply cFT. This method provides a good correlation with the values of nonbound T. (The formula is available at http://www.issam.ch.) Although this approach, in general, works well, there are pitfalls: (1) different SHBG levels varying up to twofold with different assays and (2) altered binding characteristics (either SHBG or serum) related to aging or illness. The relative advantages, drawbacks, and usefulness of the various assays are given in Table 29–4.

Because of the controversial nature of the biochemical assessment, when the biochemistry does not support a

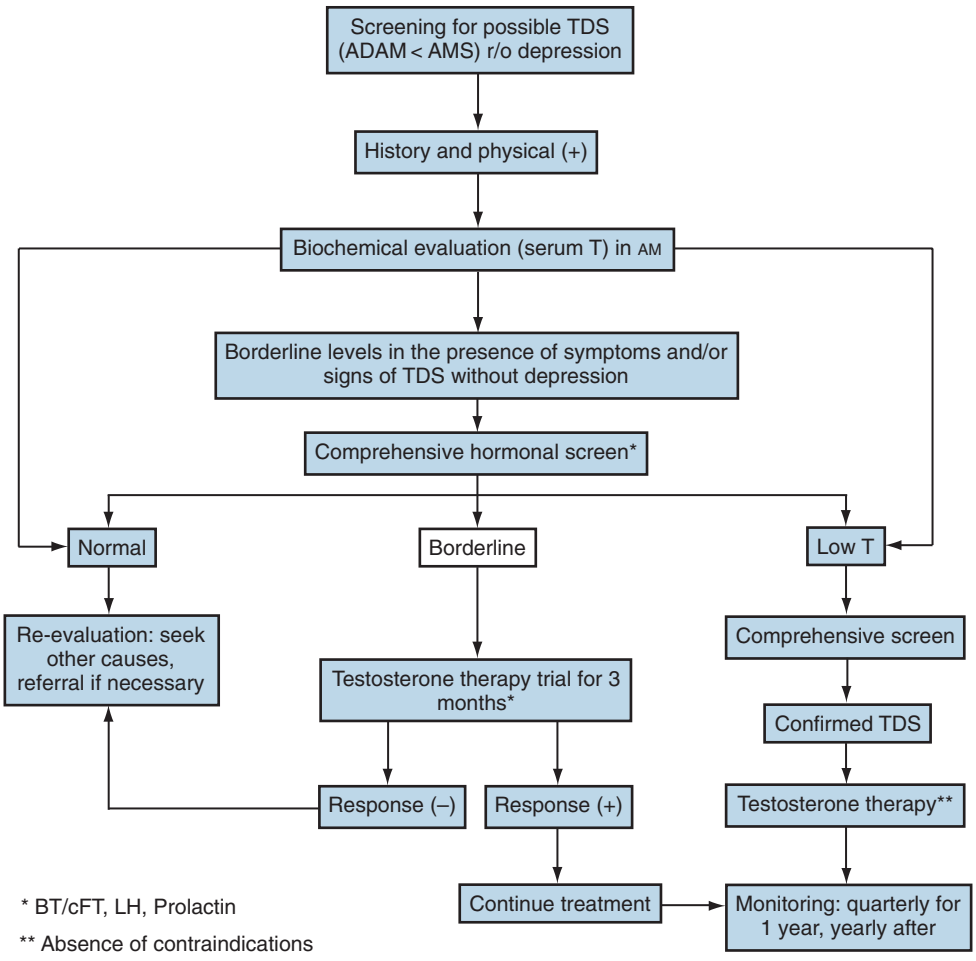

Figure 29–3. Diagnostic algorithm for testosterone deficiency syndrome (TDS). Screening questionnaires are appropriate for initial assessment. A comprehensive hormonal screen includes either a repeated measurement of total testosterone (T) or bioavailable or calculated free T (BT/cFT) to assess the non–sex hormone–binding globulin fraction. A basic evaluation of the pituitary (prolactin, luteinizing hormone) is indicated in the presence of low T levels. Evaluation of other hormones (dihydrotestosterone, dehydroepiandrosterone, growth hormone, melatonin) is not generally necessary. ADAM, Androgen Deficiency in Aging Male questionnaire; AMS, Aging Male Survey; r/o, rule out.

Key Point: Inappropriate Assay

- The assay that should not be used is commonly available and frequently ordered: direct radioimmunoassay of free T using a labeled T analog with low affinity for SHBG and albumin that binds to an immobilized antibody that is specific for T. This assay has poor accuracy and precision. It is most closely related to the measurement of total T. Clinicians are thus misled to believe that true "free T" is being measured.

Table 29–4.

Assays for Testosterone and Their Attributes

ASSAY	UTILITY	COMMENTS
Total testosterone	Low/intermediate	Variable normal ranges; below 200 ng/dL very likely to be hypogonadal; above 600 ng/dL unlikely to be hypogonadal
Free testosterone		
Dialysis	High	Difficult to do; requires ^{3}H-T
Ultrafiltration	High	
Analog	Poor	Commonly available in NA
Calculated free	Intermediate	Requires SHBG and T measurements
Bioavailable testosterone		
Ammonium sulfate	High	Easier to do than free T; excellent precipitation assay; good correlation with symptoms
Calculated bioavailable	Intermediate	Requires SHBG and T measurements
Free androgen index		
Testosterone/SHBG	Poor	Requires SHBG and T measurements
Salivary testosterone	Undetermined	Uncertain value

NA, North America; SHBG, sex hormone–binding globulin; T, testosterone.

strong clinical picture, other causes have been ruled out, and no contraindications exist, a 90-day therapeutic/diagnostic trial of T administration is justified (Black et al, 2004; Morley, 2007) (see Fig. 29–3).

Other Hormones

It is important to dispel the concept that endocrinopathies resulting from the normal process of aging in men are narrowly focused on sex steroids. Although hypotestosteronemia is most widely recognized, the production of several other hormones is also profoundly affected by age (Table 29–5).

Dehydroepiandrosterone (DHEA)

Production of DHEA reaches a peak in the second to third decade of life and decreases steadily afterward, to very low values (<30% of those in the young) by the age of 70 (Vermeulen, 1995). The finding of a putative specific DHEA receptor on the plasma membrane of bovine aortic endothelial cells (Liu and Dillon, 2002) changed our understanding of the role of DHEA in many functions, particularly in the vascular system. Kawano and colleagues (2003) and Simoncini and associates (2003) have documented an improvement in vascular endothelial function in middle-aged men with a variety of vascular problems with DHEA supplementation. These findings may have direct and significant implications for the mechanisms of sexual function. DHEA may have a dual role in sexual function: an indirect endocrinologic and a direct vascular role. The preponderance of the evidence, however, is that DHEA plays a minor, if any, role in improving quality of life (Nair et al, 2006) in men with DHEA deficiency but might be beneficial in those with Addison disease (Gurnell et al, 2008).

Table 29–5.

Hormones, Other Than Testosterone, Most Commonly Affected by the Aging Process*

HORMONE	PRODUCTION	FUNCTION AND REAL/PUTATIVE EFFECTS
DHEA	↓	Neurosteroid; regulation of vascular endothelium
Growth hormone	↓	Somatic growth; anabolic effects mediated by IGF-1 (protein synthesis and cell proliferation)
Melatonin	↓	Regulation of biorhythms and sleep patterns. Prevention of oxidative stress
Thyroxine	↓	
Leptin	↗	Regulation of appetite and fat distribution. Receptor expressed in prostate gland

*For most, their functions are not fully understood in most cases. It is known, however, that there is a great deal of cross talk among them in their production, function, and activity.

DHEA, dehydroepiandrosterone; IGF, insulin-like growth factor.

Growth Hormone (GH)

Production of GH also decreases with age, about 14% per decade. This reduction is associated with changes in lean muscle mass, bone density, hair distribution, and the pattern of obesity described also in hypogonadal states. **Administration of GH reverses these alterations** (Götherström et al, 2009) **and does it more efficiently in eugonadal men than in their hypogonadal counterparts.** Although the body of evidence favors the use of androgens in the treatment of some of the manifestations of TDS, more recent studies clearly indicate that elderly patients respond to GH administration alone (Gola et al, 2005) as well as those with other hormone deficiencies (Lo et al, 2008). Some of the concerns about androgen supplementation in elderly men (e.g., prostate health) also may be shared with GH administration. Although no changes in prostate-specific antigen (PSA) were found in adults receiving injectable GH (Colao et al, 2003), the simultaneous administration of GH and T may lead to significant increases in prostate size (Vance, 2003).

Melatonin

Melatonin production decreases with age. The pineal gland is involved in gonadal function and regulation of biorhythms.

However, the popular enthusiasm about the hormone has a precarious scientific basis. It is likely that administration of melatonin may improve sleep disorders, frequently seen in elderly persons, but profound hypogonadism is associated with alterations in melatonin production, making it difficult to attribute some symptoms exclusively to deficits of one or the other hormone. Evidence is emerging of a wide range of direct and indirect activities of melatonin on many human organ systems (Reiter and Tan, 2004), although its role in sleep disturbances in the aging population has been challenged (Tozawa et al, 2003).

Thyroxine, Prolactin, and Leptin

Changes occur with aging in the hypothalamic-pituitary-thyroid axis resulting in the development of hypothyroidism, which may reach an incidence of close to 20% in the elderly population (Leitolf et al, 2002). The production of prolactin, corticosteroids, and estradiol (E_2) in males remains fairly constant throughout life. **Hyperprolactinemia secondary to a pituitary adenoma should be ruled out in men with diminished sexual desire and/or hypogonadism. It may also be drug induced (metoclopramide).** Leptin is altered in hypotestosteronemia, which explains, in part, some of the changes in fat distribution observed in these men. Levels of leptin can be brought down by androgen supplementation (Luukkaa et al, 1998), which usually results in an improvement in obesity. **The linkage between obesity and prostate cancer is of interest. Obesity contributes to a higher risk for prostate cancer incidence and mortality as well as its aggressiveness and recurrence** (Ribeiro et al, 2004). It appears that the relationship is not simply due to the excess fats. The leptin receptor is expressed in prostatic tissue, leptin promotes prostate growth during puberty, and it might stimulate cancer development by a direct effect on the gland (Stattin et al, 2001). It has been shown that there exists an inverse correlation between plasma leptin and T levels in men with advanced prostate cancer. Equally relevant is the finding that leptin is capable of inducing proliferation of androgen-independent prostate cancer cells. The role of leptin in prostate cancer remains to be fully explored (Behre et al, 1997).

TREATMENT OF TESTOSTERONE DEFICIENCY SYNDROME

The clinical picture of TDS or LOH is not specific, and some manifestations can be effectively treated with methods other than sex hormone administration. Changes in lifestyle (smoking and alcohol abuse cessation) should be advised to all patients. Diet and exercise do decrease visceral obesity and improve muscle strength and sensation of well-being. Bisphosphonates are effective drugs for osteoporosis, and antidepressants and counseling work well for dysphoria. However, programs of lifestyle changes are characterized by a high dropout rate or only intermittent adherence. In most cases, in the presence of confirmed hypogonadism, the administration of T alone results in significant improvement in many of the signs and symptoms of the condition. That better results are achieved with lifestyle changes and additional nonhormonal medications is not debatable.

In clinical practice there are few valid and specific reasons to withhold T treatment in men with TDS. The case for treatment is compelling. It was suggested that hypogonadism did not influence life expectancy, as reported in a historical analysis of castration (n = 50) (Nieschlag et al, 2004). A retrospective study (Tomlinson et al, 2001) suggests a more realistic view: standardized mortality ratio is significantly higher in men with untreated gonadotropin deficiency compared with those treated with sex steroids and healthy control subjects. Hypogonadism was associated with increased mortality in males (Shores et al, 2006) and, more recently, TDS was found to be clearly associated with increased risk of death independently of multiple risk factors and preexisting conditions (Laughlin et al, 2008).

Options for Treatment with Testosterone

There is an ever-increasing selection of T delivery formulations available, of which the vast majority is safe and effective. Currently obtainable preparations of T are listed in Table 29–6.

Table 29–6.

Most Frequently Used Testosterone Preparations

	GENERIC NAME	TRADE NAME	DOSE	COMMENTS
Injectable	Testosterone cypionate	Depo-Testosterone cypionate	200-400 mg q 3-4 wk	Supraphysiologic levels Roller-coaster effect
	Testosterone enanthate	Delatestryl	200-400 mg q 4 wk	Same as cypionate
	Testosterone undecanoate*	Nebido	700-1000 mg q 12-14 wk*	Stable levels; unavailable in North America
Oral/buccal	Buccal tabs	Striant	30 mg bid	Inconvenient
	Methyltestosterone†	Metandren	10-30 mg/day	Liver toxicity
	Testosterone undecanoate	Andriol Testocaps	120-160 mg/day	Not available in United States
Transdermal	Testosterone patch	Androderm	5 mg/day	Skin reactions Visible
		Testoderm	10-15 mg/day	Skin reactions
	Testosterone gel	Androgel/Testim	5-10 g/day	Good tolerability. Reproduces circadian rhythm. Variable sites for application.
		Axiron (axillary application)	30-90 mg/day	
		Fortesta (thigh application)	40 mg/day	

*Requires a loading dose of 3 × 1000 mg every 6 weeks for naive patients or of 2 × 1000 mg every 8 weeks for those switching from a different testosterone formulation.
†As 17α-alkylated testosterone products, both fluoxymesterone and methyltestosterone are associated with potential for serious liver toxicity.

Intramuscular Injections

Intramuscular injections of T are long acting and reach a maximum concentration at about 72 hours. They do not provide normal circadian patterns of serum T. Levels of DHT are usually normal, but E_2 levels may become excessive in some men. In the first few days after injection, supraphysiologic serum T levels occur. These injections are commonly administered every 10 to 21 days to maintain normal average T levels; baseline values are reached at approximately 21 days. These T preparations are cost efficient and proven effective (Amory et al, 2004). Injectable T undecanoate (Nebido) is a newcomer. After a loading dose, administration of 750 to 1000 mg every 12 weeks resulted in stable serum levels within the normal range (Morales et al, 2006; Morgentaler et al, 2008). This product is not yet available in North America.

Oral Preparations

Oral agents include the alkylated preparations, which are generally associated with erratic androgenic effects, significant changes in lipid profile, and a risk of liver toxicity. They are not recommended. Although not available in the United States, oral T undecanoate (Andriol) is commonly used throughout the world. It is free of liver toxicity but may result in supraphysiologic levels of DHT (Gooren, 1994). It is taken daily with meals containing more than 20 g of fat for T to be absorbed. Cost considerations make it impractical to treat severe hypogonadism.

Buccal and Nasal Methods

A mucoadhesive delivery system (Striant) can be placed against the gum twice a day (30 mg). To diminish the incidence of local irritation (about 9%), the site of application should be alternated. It is somewhat inconvenient. The nasal route for T administration is being investigated with encouraging results (Mattern et al, 2008).

Transdermal Testosterone Therapy

Transdermal T therapy is available in patches and gels. Both result in normal serum T levels and reproduce the diurnal physiologic variations with normal E_2 and DHT levels. Drawbacks of the patches include their visibility and skin reactions (Jordan and Atkinson, 1998). **Transdermal T gel preparations are better tolerated (minimal skin irritation).** All require daily application to upper abdomen, chest, or upper arms, avoidance of showers or baths for 2 to 4 hours (residence required for absorption), as well as direct skin-to-skin contact with other persons to prevent transfer of T. They improve sexual function and mood and increase lean body mass and muscle strength and decrease fat mass (Wang et al, 2004b). The studies, however, are limited in the size of the sample, the age range of the participants, and the length of follow-up. A newer adhesive matrix patch formulation is available only in Europe. In the fourth quarter of 2010, two newer transdermal formulations were approved by the FDA: Axiron for axillary application and Fortesta for application on the thighs.

Dihydrotestosterone

The use of DHT as an alternative to T appears occasionally in the literature (Kunelius et al, 2002). **The main argument for the use of DHT is that it is not aromatizable and, as such, may prevent prostate enlargement (believed to require both androgens and estrogens).** The transdermal DHT preparation is easy to use, but long-term studies are still lacking and its use outside proper trials is not recommended (Wang and Swerdloff, 2002).

7α-Methyl-19-Nortestosterone

Effective androgens that spare the adverse effects of T are of interest. Among the drugs better recognized is 7α-methyl-19-nortestosterone (MENT). It has high biopotency per molecule (about 10 times more than T), does not undergo 5α reduction, but retains its capacity to be aromatized to E_2. It has antigonadotropic properties and anabolic effects on muscles, and its effects on the prostate are less pronounced than those of T (Kumar et al, 1999).

Selective Androgen Receptor Modulators

The therapeutic potential of selective estrogen receptor modulators (SERMs) in women has set the stage for the development of selective androgen receptor modulators (SARMs). The availability of these molecules with their diversity of ligands provides the opportunity to explore the utility and activities of SARMs (Negro-Vilar, 1999). Various SARMs are under active investigation.

Key Point: Choice of Preparation

- The choice among T preparations depends on **A**vailability, **S**afety, **T**olerability, **E**fficacy, and **P**reference (by patient and physician): **ASTEP.**

Objective Effects of Testosterone

Administration of T to hypogonadal men results in a variety of positive effects (see Table 29–1).

Body Composition and Strength

Studies consistently report changes in body composition with T therapy (Snyder et al, 1999). The magnitude of the fat mass changes in older men appeared similar to that seen with T replacement in young hypogonadal men, whereas the lean body mass changes produced were usually less dramatic. In terms of strength changes, the effects are more limited in older men. Most studies noted an increase in grip strength with T treatment (Vermeulen, 2002); **the effects are significant even when T is administered with finasteride, indicating that DHT is not necessary for these positive actions** (Page et al, 2005). The preservation of the anabolic effects of T while safeguarding prostate health by inhibition of conversion of T to DHT with the simultaneous use of T and finasteride is an important observation. It has been documented in animal studies (Borst et al, 2007) as well as human clinical trials (Page et al, 2005; Jacobsen et al, 2008).

Bone

A number of studies have evaluated the effects of T therapy on bone mineral density or biochemical parameters of bone turnover in older men. These studies have lasted from 3 to 36 months, with the shorter-term trials evaluating only bone turnover parameters. **T therapy was reported to slow the rate of bone degradation and significantly increase bone mineral density, especially in the lumbar spine** (Szulc et al, 2003). **No study has yet conclusively demonstrated the effect of T therapy in the prevention of osteoporotic fractures.**

Cardiovascular System

Most epidemiologic studies have shown that higher serum T levels correlate with lower, rather than higher, cardiovascular disease risk in men (Rosano et al, 2007). Cardiovascular disease risk factors that might be affected by sex steroids include serum lipoprotein profiles, vascular tone, platelet and red blood cell clotting parameters, and the direct process of atherogenesis commonly leading to ED (Corona et al, 2008). The effects on serum lipoprotein levels in older men are the one area in which T therapy has been more extensively evaluated (Jockenhovel et al, 1999). In general, **T therapy in older men leads to a decrease in total and low-density lipoprotein cholesterol levels with no change or a small decrease in high-density lipoprotein cholesterol levels. These lipoprotein changes are modest, and the ultimate impact on cardiovascular disease is unknown.**

Sexual Function

The efficacy of T administration to men with sexual dysfunction needs to be discussed in two different areas: sexual desire and erectile function.

Sexual Desire. Hypogonadal men frequently experience hypo active sexual desire disorder (HSDD). The threshold of serum androgen levels for adequate libido, however, exhibits large interindividual variability and is largely dependent on a number of intrapsychic and environmental factors (Morley, 2003). As monotherapy, T administration is successful in a majority of patients but it is difficult to assess outcomes of sexual interest and there is a need for large controlled studies in this area. It is, however, widely recognized that HSDD and low serum T levels clearly indicate a need for therapy (Zitzmann et al, 2006).

Erectile Dysfunction. An adequate amount of T is essential for the cascading of mechanisms driving the penile erectile response: production of nitric oxide synthase, release of nitric oxide, and augmentation of the synthesis of cyclic guanine monophosphate leading to arteriolar dilatation and relaxation of the corporeal smooth muscle. **When a critical low-androgen milieu is reached, this complex process is blunted or fails altogether.** The critical androgen level for adequate maintenance of the process remains to be determined, but, undoubtedly, it exhibits large interindividual (and possibly some intraindividual) inconsistency. For this reason, **in the presence of a combination of erectile insufficiency and hypotestosteronemia, a tr ial of supplemental androgen is justified. If no success is evident, other causes need to be explored** (Morales et al, 2004).

Synergism of Testosterone with Phosphodiesterase-5 Inhibitors

In cases of recalcitrant ED, a multipronged pharmacologic approach may be more effective than the single-agent management. Specifically in cases of ED and hypogonadism the available evidence is encouraging. Aversa and associates (2003) showed in a small, controlled, randomized study that hypogonadal patients in whom sildenafil failed could be rescued by the administration of T. The proposed mechanism of action in the study was vascular because increased arterial dilatation was documented by Doppler ultrasonography. These findings have been supported by the report of Shabsigh and coworkers (2004) that showed a significantly better response in the erectile function domains for the combination of T plus sildenafil compared with sildenafil alone in hypogonadal men. Kalinchenko and colleagues (2003) treated a group of type 2 diabetics with sildenafil. In the group of hypogonadal patients who had initially failed a trial of sildenafil alone, 70% responded to the combination of sildenafil and oral T undecanoate. Further exploration of class agents (i.e., phosphodiesterase-5 inhibitors, dopaminergic agonists) in combination with androgens should be pursued.

Adverse Effects of Testosterone Treatment

The presence of prostate or breast carcinoma is an absolute contraindication for T treatment. However, T administration can result in adverse effects that are particularly significant in elderly persons.

Fluid retention is rarely seen. In the chronically ill or frailer older man, fluid retention might pose a concern.

Liver toxicity is not a problem with modern T preparations.

Sleep apnea has been reported to be exacerbated by T therapy. A 36-month trial of T in older men found no effect on apneic or hypoapneic episodes (Luboshitzky et al, 2002).

Gynecomastia occurs rarely because of the relatively greater increase in serum E_2 levels. Often this side effect can be overcome with a downward adjustment of the T dose.

Prostate

The main concern about T supplementation relates to prostate safety. Both benign prostatic hyperplasia and prostate cancer are diseases common in older men and believed to be promoted by androgens, although endogenous levels do not correlate with prostatic cancer (Roddam et al, 2008). **Androgen deprivation therapy has been used for the treatment of both of these processes, but whether T therapy for an older man places him at increased risk for developing clinically significant prostate disease from a preexisting but subclinical condition is unknown.** There have been at least 22 T replacement trials, involving a total of 583 men aged 45 to 89 years, in which serum PSA levels were measured. Sixteen of the 22 studies showed no increase in PSA with T therapy. In the six studies showing a PSA rise with T, the average PSA change was 0.48 ng/mL and the average PSA velocity was 0.52 ng/mL/yr. Seven T replacement trials in older men have evaluated prostate size, maximum urine flow rates, and International Prostate Symptom Scores. None of them showed any change in these parameters with treatment (Morales, 2002). The data suggest that, in the short term (up to 3 years), T therapy in the older man has little effect on the prostate. **If T promotes prostate growth, how does one manage T deficiency in the presence of a normal PSA?** The evidence remains sparse, but two studies provide guidance in this regard. Morgentaler and colleagues (2006) showed an increased risk of prostate cancer in association with the severity of the hypogonadism in men with PSA levels of 4 ng/mL or less. Another study (Rhoden et al, 2008) showed that a low ratio of T to PSA is an independent predictor of prostate cancer in men with TDS; ratios of less than 1.8 were associated with greater than a threefold increase in cancer risk. **Taken together, these studies would suggest that a more aggressive approach to rule out prostate cancer is warranted in men with hypogonadism in the presence of a normal digital rectal examination and PSA test result. However, because both prostate cancer and benign prostatic hyperplasia are diseases with long natural histories and the observation time to date with T therapy in older men is limited to less than 900 man-years, it is possible that T therapy might have long-term effects on the prostates of older men.**

T supplementation after successful treatment of prostate cancer is now under investigation. Although the numbers are small, the limited evidence in cases of radical prostatectomy, brachytherapy, or external-beam radiation (Morales et al, 2008) is comforting. All studies have used standard PSA measurements as parameters to initiate therapy and to follow these patients. The ultrasensitive assay may permit early initiation of T supplementation after radical prostatectomy. After brachytherapy and external-beam radiotherapy the situation is more complex because in these situations the PSA may not reach undetectable levels. A stable nadir may prove to be acceptable.

Polycythemia

T therapy in older men can often result in a significant increase in red blood cell mass and hemoglobin levels. This may lead to termination of therapy, a decrease of dose, or a switch to a different formulation of T. The method of T replacement may affect the magnitude of the change in red blood cell mass.

RECOMMENDATIONS AND GUIDELINES

Despite the long time since the synthesis and initial use of T in clinical practice there is a scarcity of credible, well-designed trials to document its safety and efficacy. The completion of large studies on hormone replacement in postmenopausal women brought into sharp focus the inadequacy of limited trials (Writing Group for the Women's Health Initiative Investigators, 2002). **It is, however, unhelpful and misleading to assume that the results of the Women's Health Initiative on hormone replacement therapy (HRT: estrogen ± progesterone) in postmenopausal women apply equally to the men's situation; such an assumption does not take into consideration the large differences in the molecular structures and actions of the hormones themselves and the gender responses to them** (Goderie-Plomp et al, 2004). Although it is tempting to equate the possible effects of HRT in the development of breast cancer to androgen replacement therapy (ART) in prostate cancer, the biologic behavior and clinical management of the two tumors are markedly dissimilar. It is estimated (Bhasin et al, 2003) that some 5000 hypogonadal men receiving T supplementation for a period of 5 years are needed to have a study of the magnitude of the Women's Health Initiative. Alternatives to such a difficult and unrealistic study are currently under scrutiny.

The Institute of Medicine Report

In an extensive and comprehensive publication, a committee of the Institute of Medicine (IOM) analyzed the current status of androgen therapy in men. The report (available on the Internet at http://www.iom.edu or in hard copy) (Liverman et al, 2004) contains several recommendations (Table 29–7). The gist of the report is that initially the efficacy of T treatment should be assessed in a limited trial. Only if a positive response is found should the investigations proceed to the large studies designed to evaluate safety. **Although no one would question the need for and importance of these studies, it is also clear that reliable answers will not be available for at least 10 to 15 years after the completion of the efficacy studies and the subsequent safety trials.** For the practicing physician, it is not logical to wait that long until all conclusive evidence is complete. When indicated, action needs to be taken on the basis of the most reliable information at hand regarding the advantages and drawbacks of T treatment and guidelines and recommendations available from professional societies.

Table 29–7.

Summary of the Institute of Medicine Recommendations

Need for clinical trials exists.
Focus on populations most likely to benefit.
Use for treatment not for prevention.
Focus on clinical outcomes with preliminary evidence of benefit.
Begin with short-term efficacy trials.
Conduct longer-term studies if short-term efficacy is established.
Ensure safety of research participants.

Endocrine Society Guideline and the European Association of Urology Recommendations

The Endocrine Society Guideline is an important document that became the standard practice because of the reliability of the evidence-based criteria used and the high credibility of the sponsoring society. However, the document was "developed to be of assistance to endocrinologists…" (Bhasin et al, 2010) and does not contemplate several issues of importance for the urologist. For this reason, the Recommendations, jointly sponsored, among others, by the European Association of Urology, the International Society for the Study of the Aging Male and the International Society of Andrology (Wang et al, 2009) are included here, replacing the ones from the previous edition.

The recommendations that follow have been adapted (mostly because of space restrictions) from the ones published recently (Wang et al, 2009). They are categorized by the level of evidence and grade of recommendation according to the U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research (1992).

Recommendation 1: Definition

- TDS/LOH is a clinical *and* biochemical syndrome associated with advancing age and characterized by symptoms *and* a deficiency in serum T levels. It may result in significant detriment in the quality of life and adversely affect the function of multiple organ systems.

Recommendation 2: Clinical Diagnosis

- 2.1. The diagnosis of TDS requires symptoms and signs suggestive of T deficiency (level 3, grade A). Most common symptom is low libido (level 3, grade A). Others include ED, sarcopenia, osteopenia/osteoporosis, increased body fat, decreased vitality, and low mood. None of them is specific for T deficiency and must be corroborated with a low T level (level 3, grade A).
- 2.2. Questionnaires such as AMS and ADAM are not recommended for diagnosis of hypogonadism because of low specificity (level 3, grade B).

Recommendation 3: Laboratory Diagnosis

- 3.1. Patients suspected of TDS need a biochemical workup (level 4, grade A). Risk factors for hypogonadism in older men include chronic illnesses (diabetes, chronic

obstructive lung disease, and renal and HIV-related diseases), obesity, metabolic syndrome, and hemochromatosis (level 4, grade A).

- 3.2. A sample for T determination should be obtained between 7:00 and 11:00 AM (level 2a, A). The most widely accepted test is serum total T. Generally levels above 12 nmol/L (350 ng/dL) do not require substitution. Men with T levels below 8 nmol/L (230 ng/dL) usually benefit from T treatment. If the levels are between 8 to 12 nmol/L, repeating the measurement of total testosterone once or twice may be helpful.
- 3.3. Measurement of free or bioavailable T should be considered when the total T is not diagnostic, particularly in obese men.
- 3.4. Equilibrium dialysis is the gold standard for free T measurement. Free T assays based on immunoassays are widely available but do not give an accurate measurement of free T; thus they should not be used. Calculated free T correlates well with free T by equilibrium dialysis (level 2b, grade A).
- 3.5. Salivary T may be a reliable substitute for free T measurements but cannot yet be recommended because the methodology has not been standardized (level 3, grade B).

Recommendation 4: Assessment of Treatment Outcome and Decisions on Continued Therapy

- Improvement in TDS manifestations should be sought. Failure to benefit within a reasonable interval (3 months is adequate for sexual function, others require a longer interval) should result in discontinuation of treatment. Seeking other causes of symptoms is then mandatory (level 1b, grade A).

Recommendation 5: Body Composition

- T administration improves body composition in hypogonadal men (decrease fat mass, increase lean body mass) (level 1b, grade A).

Recommendation 6: Bone Density and Fracture Rate

- Osteopenia/osteoporosis and fracture prevalence rates are greater in hypogonadal men. Bone density in hypogonadal men increases under T treatment (level 1b, grade A).

Recommendation 7: Testosterone and Sexual Function

- 7.1. The initial assessment of all men with ED and/or diminished libido should include determination of serum T. These dysfunctions, with or without T deficiency might be related to comorbidities or medications (level 2a, grade A).
- 7.2. Men with ED and/or diminished libido and documented T deficiency are candidates for therapy (level 2a, grade A). An inadequate response to treatment requires reassessment of the causal mechanisms.
- 7.3. In the presence of a TDS picture and borderline serum T levels, a short (e.g., 3 months) therapeutic trial may be justified. An absence of response calls for discontinuation of T administration. A satisfactory response might be placebo generated so that continued assessment is advisable before long-term treatment is recommended (level 2a, grade B).
- 7.4. There is evidence suggesting therapeutic synergism with combined use of T and phosphodiesterase-5 inhibitors in hypogonadal men (level 1b, grade B). These observations require additional study. It is unclear whether men with hypogonadism and ED should be treated initially with phosphodiesterase-5 inhibitors, T, or the combination of the two.

Recommendation 8: Testosterone and Obesity, Metabolic Syndrome, and Type 2 Diabetes

- Several components of the metabolic syndrome are also present in hypogonadal men. Epidemiologic studies have established a close relationship between obesity and low T in healthy men. T should be measured in men with type 2 diabetes mellitus with manifestations of TDS (level 2b, grade A).

Recommendation 9: Carcinoma of the Prostate and Benign Prostatic Hyperplasia

- 9.1. There is no conclusive evidence that T therapy increases the risk or carcinoma of the prostate or benign prostatic hyperplasia. There is also no evidence that T treatment will convert subclinical prostate carcinoma to clinically detectable disease (level 4, grade C). However, there is unequivocal evidence that T can stimulate growth and aggravate symptoms in men with locally advanced and metastatic prostate carcinoma (level 2a, grade A). Adequately powered and optimally designed long-term prostate disease data are not available to determine whether there is any additional risk from T replacement. Patients should be counseled on the potential risks and benefits of T replacement before treatment and carefully monitored for prostate safety during treatment (level 3, grade A).
- 9.2. Prior to therapy with T, the risk of carcinoma of the prostate must be assessed using, as a minimum, direct rectal examination and PSA screening. Ultrasound examination or biopsies are not recommended as routine requirements.
- 9.3. During treatment, patients should be monitored for prostate disease at 3 to 6 months, 12 months, and at least annually thereafter (level 3, grade C). If the patient's risk of prostate carcinoma is high (changes in the direct rectal examination or PSA value) transrectal ultrasound-guided biopsies of the prostate are indicated (level 2b, grade A).
- 9.4. Severe lower urinary tract symptoms (>21 in IPSS) due to benign prostatic hyperplasia represent a temporary contraindication (level 3, grade C). After successful treatment of these symptoms this contraindication is lifted (level 4, grade C)
- 9.5. Men successfully treated for prostate carcinoma and suffering from confirmed TDS are potential candidates for T treatment after a prudent interval if there is no clinical or laboratory evidence of residual cancer. Because long-term outcome data are not available, clinicians must exercise good clinical judgment together with adequate knowledge of advantages and drawbacks of testosterone therapy in this situation (level 2b, grade C). The risks and benefits must be clearly discussed with and understood by the patient, and the follow-up must be particularly careful.

Recommendation 10: Treatment and Delivery Systems

- 10.1. Available intramuscular, subdermal, transdermal, oral and buccal preparations of testosterone are safe and effective (level 1b, grade A). The treating physician should have sufficient knowledge and adequate understanding of the pharmacokinetics as well as of the advantages and drawbacks of each preparation. The selection of the preparation

should be a joint decision of an informed patient and his physician.

- 10.2. Inadequate data are available to determine the optimal serum T level for efficacy and safety. Mid to lower young adult male levels seem appropriate as the therapeutic goal. No evidence exists for or against the need to maintain a circadian rhythm (level 3, grade B).
- 10.3. 17α-Alkylated preparations such as 17α-methyl-T should no longer be prescribed because of their potential liver toxicity (level 2b, grade A).

Recommendation 11: Adverse Effects and Monitoring

- 11.1. T treatment is contraindicated in men with prostate or breast cancer (level 3, grade A). T is relatively contraindicated in men at high risk of developing carcinoma of the prostate (family history).
- 11.2. Men with significant erythrocytosis (level 3, grade A), untreated obstructive sleep apnea (level 3, grade B), and untreated severe congestive heart failure should not be treated with T until resolution of the comorbid condition (level 3, grade B).
- 11.3. Erythrocytosis might develop during treatment, especially with injectable preparations. Periodic hematologic assessment is indicated. Dose adjustments and/or periodic phlebotomy may be necessary (level 3, grade A).

Recommendation 12: Age

- Age is not a contraindication to initiate testosterone treatment. Individual assessment of comorbidities and potential risks versus benefits of treatment is particularly important in elderly men (level 2a, grade A).

Diagnosis
Treatment
Conclusion

"I think sex is here to stay."

—*Groucho Marx*

Urologists are well versed in the diagnosis and treatment of male sexual dysfunction. However, what is less commonly recognized but demonstrated in several studies is that male erectile dysfunction negatively impacts female sexual function and sexual quality of life (Fisher et al, 2005; Rosen et al, 2007). It was not until recently that urologists actually began to consider female sexual function as relevant to their practice. Based on the National Health and Social Life Survey, sexual dysfunction is actually more prevalent in women (43%) than in men (31%). Other studies suggest female sexual dysfunction (FSD) affects 25% to 76% of women in the United States. In one study, 98% women seeking routine gynecologic care had sexual concerns (Nusbaum et al, 2000).

Despite the high prevalence of sexual problems among women, physicians and patients alike are hesitant to initiate conversations about female sexual health. In a study of 471 physicians, only 22% stated they always screen for FSD whereas 55% screen most of the time and 23% never or rarely screen their patients (Pauls et al, 2005). Physicians cited various reasons for their lack of screening for FSD, the most common being lack of time. The majority of respondents (69%) underestimated the prevalence of FSD in their patient population. Fifty percent believed that their training and ability to treat FSD was unsatisfactory. Bachmann (2006) conducted a similar survey among physicians and health care providers attending the annual meetings of four specialty societies. Of the 1946 participants 42% did not inquire about FSD, citing limitations in time and training, embarrassment, and the absence of effective treatments as obstacles to discussing FSD. Sixty percent of participants rated both their knowledge and comfort level with FSD as fair or poor, whereas 86% rated treatment options as fair or poor.

Over the past 5 years the urologic literature has shown that a significant number of women with female pelvic floor disorders also report FSD. The aim of this chapter is to characterize female sexual function and dysfunctions while making urologists aware of the magnitude of FSD and providing them with information to diagnose and treat FSD in patients suffering from urologic conditions.

FEMALE SEXUAL ANATOMY AND PHYSIOLOGY

Genital Anatomy

The organs of the female reproductive tract are classically divided into the external and the internal genitalia. The external genital organs include the mons pubis, clitoris, urethral meatus, labia majora, labia minora, vestibule, Bartholin glands, and Skene glands. The internal genital organs are located in the true pelvis and include the vagina, uterus, cervix, oviducts, ovaries, and surrounding supporting structures.

The *vulva* is a collective term for the female external genitalia. The vulva consists of the mons pubis, labia majora, labia minora, hymen, clitoris, vestibule, urethra, Skene glands, Bartholin glands, and vestibular bulbs. The boundaries of the vulva extend from the mons pubis anteriorly to the rectum posteriorly and laterally to the genitocrural folds.

The labia majora are two large, longitudinal, cutaneous folds of adipose and fibrous tissue that extend from the mons pubis to the posterior fourchette. The skin of the outer convex surface of the labia majora is pigmented and covered with hair follicles. The inner surface does not have hair follicles but has many sebaceous glands. Histologically the labia majora have both sweat and sebaceous glands. The labia majora are homologous to the scrotum in the male. The labia minora, which are homologous to the penile urethra, are two smaller folds located between the labia majora and the vaginal orifice. Anteriorly they divide at the clitoris to form the prepuce superiorly and the frenulum of the clitoris inferiorly. Histologically they are composed of dense connective tissue with erectile tissue and elastic fibers rather than adipose tissue. The skin of the labia minora is less cornified and has many sebaceous glands but no hair follicles or sweat glands (Katz et al, 2007). The labia minora surround a space called the vestibule, into which the orifices of the urethra, vagina, and Bartholin glands open.

Bartholin glands are vulvovaginal glands located on the posterolateral aspect of the vaginal orifice at the 4- and 8-o'clock positions. Bartholin ducts open into the groove between the hymen and the labia minora and are homologous to Cowper glands in the male.

Skene glands, or paraurethral glands, are tubular glands adjacent to the distal urethra. Skene ducts run parallel to the long axis of the urethra for approximately 1 cm before opening into the distal urethra (Katz et al, 2007). Skene glands are homologous to the prostate in the male.

Lying anteriorly to the urethra is the clitoris. The average length of the clitoris is 1.5 to 2 cm. The clitoris consists of the glans, the body, and two crura, which attach to the periosteum of the symphysis pubis. The glans is the visible external portion of the clitoris. The clitoral body has two cylindrical corpora cavernosa composed of thin-walled, vascular channels that function as erectile tissue. The clitoris is the female homologue of the penis in the male.

Deep to the labia, immediately below the bulbocavernous muscle, are two erectile bodies called the vestibular bulbs. Each bulb is attached to the inferior surface of the perineal membrane and covered by the bulbocavernosal muscle. During sexual arousal the bulbs become engorged, thereby narrowing the vaginal opening.

Central and Peripheral Nervous System

The innervation of the internal genitalia is primarily by the autonomic nervous system. The sympathetic portion of the autonomic nervous system originates in the thoracic and lumbar portions of the spinal cord, and sympathetic ganglia are located adjacent to the central nervous system. In contrast, the parasympathetic portion originates in cranial nerves and the middle three sacral segments of the cord and the ganglia are located near the visceral organs. As a broad generalization, sympathetic fibers in the female pelvis produce muscular contractions and vasoconstriction whereas parasympathetic fibers cause the opposite effect on muscles and vasodilation.

The pudendal nerve and its branches supply the majority of both motor and sensory fibers to the muscles and skin of the vulvar region. The pudendal nerve arises from the second, third, and fourth sacral roots. As the pudendal nerve reaches the urogenital diaphragm it divides into three branches: the inferior hemorrhoidal, the deep perineal, and the superficial perineal. The dorsal nerve of the clitoris is a terminal branch of the deep perineal nerve.

The skin of the anus, clitoris, and medial and inferior aspects of the vulva is supplied primarily by distal branches of the pudendal nerve. The vulvar region receives additional sensory fibers from three nerves. The anterior branch of the ilioinguinal nerve sends fibers to the mons pubis and the upper part of the labia majora. The genital femoral nerve supplies fibers to the labia majora, and the posterior femoral cutaneous nerve supplies fibers to the inferoposterior aspects of the vulva.

The female sexual response is mediated primarily via spinal cord reflexes that are under descending control from the brainstem. The nucleus paragigantocellaris, which projects directly to the pelvic efferent neurons and interneurons in the lumbosacral spinal cord, is believed to play a role in female orgasm (Meston, 2000; Meston and Frohlich, 2000). The pelvic efferent neurons and interneurons in the lumbosacral spinal cord contain the neurotransmitter serotonin (Walsh et al, 2002). Serotonin applied to the spinal cord inhibits spinal sexual reflexes and may explain selective serotonin reuptake inhibitor (SSRI)-induced anorgasmia (Meston, 2000). The raphe nuclei and pallidus, the magnus and parapyramidal region, and the locus ceruleus all project to the lumbosacral spinal cord and are believed to play a role in sexual function with the periaqueductal gray area acting as a relay center for sexual stimuli (Meston, 2000; Meston and Frohlich, 2000).

In males the hypothalamic medial preoptic area, which has widespread connections to the limbic system and brainstem, functions in the ability to recognize a sexual partner. In female animals, lesions to this area increase not only lordosis but also avoidance (Meston, 2000). During orgasm and arousal oxytocin is released from neurons in the paraventricular nucleus of the hypothalamus.

c-FOS staining during copulatory testing in animals has identified the medial amygdala and the red nucleus of the stria terminalis of the forebrain as playing a role in female sexual function. Stimulation of these areas results in subjective pleasurable responses in both males and females.

More recently functional magnetic resonance imaging (MRI) studies have been used to identify specific patterns of brain activation in the female sexual response. A study by Park and coworkers (2001) reported significant activation of the inferior frontal lobe, cingulate gyrus, insula, hypothalamus, caudate nucleus, globus pallidus, and inferior temporal lobe in women watching erotic films. In another study Jeong and associates (2005) compared brain activation in premenopausal and postmenopausal women watching erotic videos. Premenopausal women were found to have greater activity in whole brain and limbic, temporal, and parietal lobes whereas postmenopausal had greater activation in the superior frontal gyrus. A study by Arnow and associates (2009) compared functional MR images after erotic videos in women with and without a history of hypoactive sexual desire disorder (HSDD) and reported significantly greater activity in the entorhinal cortex in women with no history of sexual dysfunction and higher activation in the medial frontal gyrus and putamen in women with HSDD. These findings suggest that women with HSDD have a shift in attentional focus from erotic cues to a self-monitoring of sexual response and performance concerns, underscoring the neural correlates of heightened self-focus that clinically characterizes women with HSDD (Arnow et al, 2009).

ENDOCRINE FACTORS

Estrogen and Progesterone

Traditionally three sex steroids have been implicated in female sexual behavior: estrogens, progestins, and androgens. In premenopausal woman, with normal ovulation, estrogen and progesterone levels are maintained until menopause. In premenopausal women the primary source of estradiol production is from the ovaries, under the control of follicle-stimulating hormone and inhibin produced by the pituitary gland, with less contributed from the adrenal gland and ovarian androgen precursors (Simpson, 2000; Davis et al, 2004; Giraldi et al, 2004). During the late follicular phase and in the luteal phase of the menstrual cycle there is a rise in estradiol. During the luteal phase there is also a rise in progesterone. Estradiol and progesterone levels fall abruptly at the time of menopause when ovulation ceases (Simpson, 2000; Davis et al, 2004; Giraldi et al, 2004).

Recent research suggests that estrogen and progesterone have little direct influence on female desire. Schreiner-Engel and

coworkers (1989) found no significant difference in the estrogen levels of women with and without clinically diagnosed HSDD. Numerous studies have also shown no change in sexual desire with the administration of exogenous estrogen therapy alone in women (Furuhjelm et al, 1984; Nathorst-Boos et al, 1993a, 1993b). However, administration of both estrogen and androgen in natural and surgically menopausal woman has been shown to restore normal levels of sexual desire (Sherwin and Gelfand, 1985a). Although lack of estrogen may not directly impair female arousal and desire, it can indirectly impair sexual function by decreasing vasocongestion and lubrication and vaginal epithelial atrophy. Because estrogen plays a role in the regulation of vaginal and nitric oxide synthase expression, both naturally and surgically induced menopause result in decreased vaginal and nitric oxide synthase expression, resulting in apoptosis of the vaginal wall, smooth muscle, and epithelium. Treatment with estrogen therapy increases nitric oxide synthase expression, restores vaginal lubrication, and decreases dyspareunia, resulting in improved female sexual satisfaction.

In general, progestins do not have a direct impact on female sexual function. Although oral contraceptives that increase progesterone levels have been associated with decreased sexual desire and interest, treatment with progesterone alone has not been shown to improve sexual desire in either premenopausal or menopausal women (Persky, 1976; Schreiner-Engel et al, 1981; Leiblum et al, 1983; Sherwin and Gelfand, 1985b). Indirectly, progesterone may affect female sexual behavior by increasing depressive moods. It is believed that progesterone and estradiol compete for receptors in the central nervous system, and higher ratios of progesterone to estradiol correlate with unpleasant feelings and depressive moods (Persky et al, 1982).

Testosterone

Premenopausal women also produce 0.3 mg of testosterone daily. Unlike in men, 50% of testosterone production in women comes directly from the ovaries and the adrenal glands, with the remaining 50% produced by testosterone precursors such as androstenedione and dehydroepiandrosterone (DHEA) in peripheral tissues (Walsh et al, 2002). Only 2% of the total testosterone is free, whereas 98% is bound to albumin or sex hormone–binding globulin (SHBG). Fluctuations in SHBG alter the bioavailability of free testosterone. The administration of exogenous estrogens, such as oral contraceptives, increases hepatically synthesized SHBG, thereby reducing the bioavailability of free testosterone. Oral contraceptives also diminish follicle-stimulating hormone and luteinizing hormone levels, thereby suppressing ovulation and inhibiting androgen production. The combination of these two mechanisms may lead to very low circulating levels of free and bioavailable testosterone. Several studies have documented the negative effects of oral contraceptives on sexual function, including diminished sexual interest and arousal, suppression of female-initiated sexual activity, and decreased frequency of sexual intercourse and sexual enjoyment (Basson et al, 2004; Davis et al, 2004; Nappi et al, 2005). In premenopausal women with regular menstrual cycles, testosterone and androstenedione rise in the late follicular and luteal phases (Vierhapper et al, 1997). In premenopausal women there is also a diurnal variation in testosterone, with levels peaking in the morning (Vierhapper et al, 1997).

Unlike estrogen and progesterone levels, which fall abruptly with menopause, testosterone levels diminish gradually throughout life. Between the ages of 30 and 60, total and free testosterone levels decrease by 50% (Basson, 2008). In addition, adrenal precursors, DHEA and DHEA sulfate, decrease with increasing age (Baulieu, 1996; Baulieu et al, 2000). Decreased androgen levels associated with aging have been associated with decreased libido, arousal, orgasm, and genital sensations.

In addition to aging there are several clinical conditions in premenopausal women that are associated with low testosterone levels. Hyperprolactinemia and adrenal insufficiency can cause hypogonadotropic hypogonadism and loss of libido. Cushing disease or endogenous or exogenous glucocorticosteroid excess leads to adrenal suppression and androgen insufficiency and indirectly inhibits sexual function. Symptoms of androgen insufficiency include diminished sense of well-being or dysphoria; unexplained fatigue; decreased libido, sexual receptivity, and pleasure; and vasomotor instability or decreased vaginal lubrication despite adequate estrogen treatment. Bone loss, decreased muscle strength, and changes in memory or cognitive function are also possible as a result of diminished androgen production.

In studies of both naturally and surgically menopausal women the administration of testosterone alone, without estrogen replacement therapy, has been shown to improve desire, arousal, and sexual fantasies (Leiblum et al, 1983; McCoy and Davidson, 1985; Sherwin and Gelfand, 1985a). However, the effect of relationship between testosterone levels and desire in premenopausal women is less well defined. Several studies have failed to find differences in testosterone levels in premenopausal women with and without HSDD (Stuart et al, 1987; Schreiner-Engel et al, 1989). New data suggest that testosterone is beneficial in premenopausal women with HSDD who have low circulating testosterone levels (Schwenkhagen and Studd, 2009). Women placed on testosterone supplementation must be counseled regarding the potential risks and side effects of therapy, which include acne, hirsutism, male pattern baldness, clitoral hypertrophy, and increased triglyceride levels.

PHYSIOLOGY OF FEMALE SEXUAL RESPONSE CYCLE

Although detailed writings of female anatomy date back to medieval times it was not until the 1900s that female sexuality and the physiology of the female sexual response cycle were described. Prior to 1900 female sexuality was demonized and deemed inappropriate unless procreatory or tied to pleasuring one's husband. It was also widely believed that mental diseases in females resulted from abnormalities or excitation of the female external genitalia. It was not until 1953 when Arthur Kinsey published the controversial *Sexual Behaviour in the Human Female,* the first book to candidly report on female orgasm, masturbation, premarital sex, and infidelity, that the many myths surrounding female sexuality were dispelled.

Masters and Johnson were the first to study and report on sexual function and dysfunction. Published in 1966, the *Human Sexual Response* described the male and female sexual response cycle as four linear, successive phases: excitement, plateau, orgasm, and resolution. In females, the excitement phase begins with engorgement of the vaginal mucosa, thickening of the vaginal walls, and transudation of fluid into the vagina. There is engorgement of labia, clitoris, and vagina, with a resultant increase in vaginal and clitoral length. The breast become slightly enlarged from engorgement and the areolae become erect. Muscular tension, heart rate, and blood pressure rise slightly. In the plateau phase the labia become more engorged, the clitoris retracts, the outer one third of the vagina becomes more congested and narrow while the inner two thirds expand, and pelvic floor muscle tension builds. Orgasm

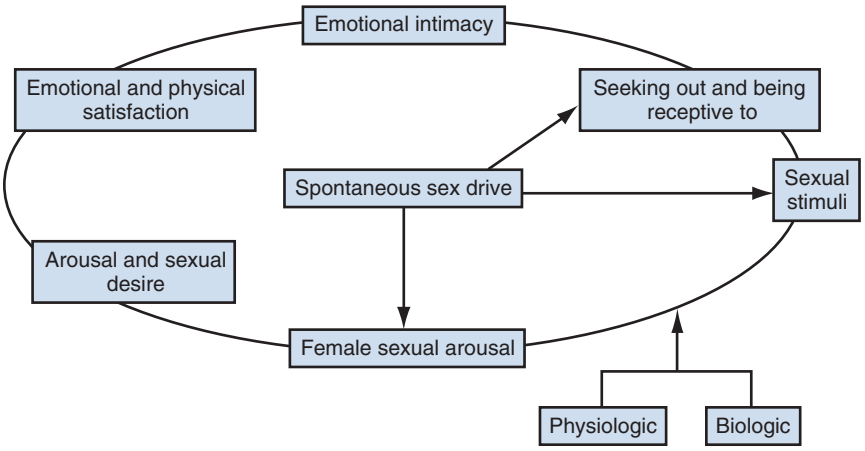

Figure 30–1. Female sexual response cycle.

is characterized by rhythmic contractions of levator ani, vagina, and uterus with massive release of muscular tension. During the resolution phase there is gradual diminishing of sexual muscular tension and detumescence of the labia, clitoris, and vagina.

In response to much criticism, Basson, in 2000, described a more contemporary nonlinear model of female sexual response, integrating emotional intimacy, sexual stimuli, and relationship satisfaction (Fig. 30–1). This model recognizes that female sexual functioning is more complex and is less linear than male sexual functioning. It also emphasizes that many women initially begin a sexual encounter from a point of sexual neutrality, with the decision to be sexual stemming from the conscious need for emotional closeness or as a result of seduction from a partner. As demonstrated by the model, arousal stems from intimacy and seduction and often precedes desire. This model emphasizes that women have many reasons for engaging in sexual activity other than spontaneous sexual drive. Sexual neutrality or being receptive to, rather than initiating sexual activity, is considered a normal variation of female sexual functioning.

CLASSIFICATION AND EPIDEMIOLOGY

Unlike male erectile dysfunction, female sexual disorders are more difficult to assess, diagnose, and treat. One of the initial barriers in the field of FSD was the lack of consensus of the definitions and criteria of these disorders. In 1998 the American Foundation of Urologic Disease Consensus convened to create a classification system and common terminology. It was at this conference that FSD was divided into four categories: sexual desire disorders, sexual arousal disorders, orgasmic disorders, and sexual pain disorders. In 2000 the panel reconvened and changed the classification schema to add "causing personal distress" as a criterion for diagnosis (Basson et al, 2000). This distinction is important because many studies on the prevalence of FSD have not qualified if the sexual symptoms reported caused "personal distress." In 2004 the Second International Consensus of Sexual Medicine, consisting of over 200 multidisciplinary experts from 60 countries, convened and revised the definitions for FSD (Table 30–1).

Estimates on the prevalence of FSD varies greatly depending on the definitions, the assessment tool used, and the demographics of the population (age, race, educational and marital status). Hayes and colleagues (2008) compared the difference in the prevalence of the types of FSD among 356 women using four different instruments and found that the prevalence varied substantially depending on the instrument used, leading to the conclusion that the instrument chosen to assess for FSD significantly affects prevalence estimates. U.S. population census data suggest that roughly 10 million American women aged 50 to 74 years self report complaints of diminished lubrication, pain during intercourse, decreased arousal, and difficulty achieving orgasm (Salonia et al, 2004).

Several studies have shown that the prevalence of FSD varies depending on age, with women older than age 45 years at an increased risk of having FSD (Shifren et al, 2008). Among women

Table 30–1.

Revised Definitions for Female Sexual Dysfunction from the Second International Consensus of Sexual Medicine

Hypoactive Sexual Desire Disorder: Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies, and a lack of responsive desire. Motivations for attempting to become sexually aroused are scarce or absent. The lack of interest is considered to be beyond the normal decrease experienced with increasing age and relationship duration.

Subjective Sexual Arousal Disorder: Absent or markedly diminished feelings of sexual arousal from any type of sexual stimulation. However, vaginal lubrication or other signs of physical response still occur.

Genital Sexual Arousal Disorder: Complaints of impaired genital sexual arousal, which may include minimal vulvar swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. However, subjective sexual excitement still occurs with nongenital sexual stimuli.

Combined Genital and Subjective Arousal Disorder: Absent or markedly diminished feelings of sexual arousal from any type of sexual stimulation plus complaints of absent or impaired genital sexual arousal.

Persistent Sexual Arousal Disorder: Spontaneous, intrusive, and unwanted genital arousal in the absence of sexual interest and desire. Arousal is unrelieved by orgasms and the feelings of arousal persist for hours or days.

Women's Orgasmic Disorder: Despite the self-report of high sexual arousal or excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation.

Dyspareunia: Persistent or recurrent pain with attempted or complete vaginal entry and/or penile-vaginal intercourse.

Vaginismus: Persistent or recurrent difficulties to allow vaginal entry of a penis, finger, or other object, despite the woman's desire to participate.

Sexual Aversion Disorder: Extreme anxiety or disgust at the anticipation of or attempt at any sexual activity.

aged 40 and older, the most common reported sexual problem was low desire (38.7% to 54%), difficulty with lubrication (21.5% to 39%), and inability to orgasm (20.5% to 34%) (Shifren et al, 2008).

Female pelvic floor disorders (incontinence, lower urinary tract symptoms, and pelvic organ prolapse) have also been shown to have a negative impact on female sexual function. Women with incontinence are up to three times more likely to experience decreased arousal, infrequent orgasms, and increased dyspareunia (Handa et al, 2004; Hansen, 2004; Laumann et al, 1999; Salonia et al, 2004). Several recent large studies have found a statistically significant improvement in sexual function scores among women who underwent successful surgery for incontinence and prolapse (Brubaker et al, 2009; Handa et al, 2007).

DIAGNOSIS

The first step in diagnosing FSD is to identify women with the problem. Plouffe (1985) and colleagues found three simple questions as effective at identifying sexual problems as a lengthy interview (Kammerer-Doak and Rogers, 2008).

1. Are you sexually active?
2. Are there any problems?
3. Do you have pain with intercourse?

Validated questionnaires are also valuable tools to help identify the presence or absence of a sexual problem. A list of questionnaires recommended by the 4th International Consultation on Incontinence for evaluation of sexual function and health in women with urinary symptoms by grade is shown in Table 30–2. For additional information regarding commonly used and validated sexual function assessment tools the reader is referred to the Baylor College of Medicine website (http://femalesexualdysfunctiononline.org/resources/) (Kingsberg and Janata, 2007).

After identifying patients at risk for FSD, the diagnosis of a problem relies on a careful clinical evaluation consisting of a detailed history, which includes sexual, medical, surgical, and

Key Points: Physiology

- Sex steroid hormones are critical for normal female sexual structure and function.
- Androgen sex steroid hormone values decline gradually in menopausal women whereas estrogen and progesterone decrease abruptly.
- Lack of estrogen may not directly impair female arousal and desire, but it can indirectly impair sexual function by decreasing vasocongestion and lubrication and vaginal epithelial atrophy.
- Progestins do not have a direct impact on female sexual function, but they may indirectly affect female sexual behavior by increasing depressive moods. Progesterone and estradiol compete for receptors in the central nervous system, and higher ratios of progesterone to estradiol correlate with unpleasant feelings and depressive moods.
- Decreased androgen levels associated with aging have been associated with decreased libido, arousal, orgasm, and genital sensations.
- Studies have also shown no change in sexual desire with the administration of exogenous estrogen therapy alone in women.
- The administration of testosterone alone, without estrogen replacement therapy, in both naturally and surgically menopausal women has been shown to improve desire, arousal, and sexual fantasies. However, the effect of relationship between testosterone levels and desire in premenopausal women is less well defined.
- Female pelvic floor disorders (incontinence, lower urinary tract symptoms, and pelvic organ prolapse) have also been shown to have a negative impact on female sexual function. Women with incontinence are up to three times more likely to experience decreased arousal, infrequent orgasms, and increased dyspareunia.

Table 30–2.

Questionnaires Recommended by the 4th International Consultation on Incontinence for Evaluation of Sexual Function and Health in Women with Urinary Symptoms

QUESTIONNAIRE	GRADE	NO. OF QUESTIONS	GOAL
Golombok-Rust Inventory of Sexual Satisfaction (GRISS)	A	28	Self-administered questionnaire assessing quality of heterosexual relationships and function in women currently in relationships
ICIQ-FLUTSsex (BFLUTS)	A	4	Self-administered questionnaire to assess affect of urinary symptoms on sexual function
Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ)	A	31	Self-administered questionnaire to assess sexual function in women with pelvic organ prolapse or incontinence
Brief Index of Sexual Function for Women (BISF-W)	B	22	Self-administered questionnaire to assess sexual function and satisfaction
Female Sexual Function Index (FSFI)	B	19	Self-administered questionnaire assessing six domains of sexual function
Sexual Quality of Life-Female (SQOL-F)	B	18	Self-administered questionnaire to assess impact of female sexual dysfunction on womens' quality of life
McCoy Female Sexuality Questionnaire (MFSQ)	C	19	Self-administered questionnaire to assess aspects of sexual function in postmenopausal women

Grade A: highly recommended indicating that the questionnaire is valid, reliable, and responsive to change following psychometric testing.
Grade B: valid and reliable.
Grade C: valid or reliable.

psychosocial history; medications (including over-the-counter medications and supplements); physical examination; and validated questionnaires. At times blood tests and specialized laboratory tests may be appropriate. Although FSD can be purely physiologic, many cases are multifactorial owing to a combination of physiologic and psychological/social factors. It is advised that women with sexual health concerns undergo a separate and concomitant psychological interview by a psychologically focused health care professional (Basson, 2000; Basson et al, 2003, 2004).

History

If a problem is elicited a detailed and more thorough sexual history is warranted and should include past and present assessment of physiologic sexual responses (desire, arousal, and orgasm) to determine the following:

- What the sexual problem is
- When it began
- How often it occurs
- If it occurs only with the current partner or also with previous partners
- If there were any precipitating events (physiologic or psychologic)
- If sex is associated with pain, whether the problem occurs both with a partner and with self-stimulation
- Whether the onset of the problem temporally coincides with starting a new medication or the diagnosis of any disease/condition
- If there are new significant life stressors
- Whether the patient's partner has any sexual problems
- Whether either the patient or her partner has received any treatment (medications, surgery, counseling)
- If there is any history of sexual or emotional abuse

The medical history should include focused questions on the patient's medical conditions, surgeries, and medication use. Current and medical history should focus on the following:

- Reproductive history: age of menarche and menses, use of chronic birth control, number of pregnancies, obstetric trauma, infertility, sexually transmitted diseases, sexual abuse
- Chronic medical conditions: diabetes, renal failure, congestive heart failure, hypertension, coronary artery disease, atherosclerosis, hyperlipidemia
- Neurologic conditions: multiple sclerosis, spinal cord injuries, spina bifida
- Endocrinologic illnesses: hypogonadism, thyroid disorders
- Pelvic/genital trauma: pelvic fractures, female mutilation
- Urologic history: incontinence, prolapse, interstitial cystitis, urinary tract infections, fecal incontinence, pelvic surgery
- Psychiatric history: anxiety, depression
- Medications that have been found to negatively affect sexual function (Table 30–3): hormones, prescription drugs, and over-the-counter and recreational drugs including alcohol, marijuana, cocaine, steroids, street drugs

See Tables 30–4 and 30–5 for the components of a complete patient history.

Table 30–3.

Medications with Known Sexual Side Effects

Amphetamines
Antidepressants and mood stabilizers
Selective serotonin reuptake inhibitors (SSRIs)
Serotonin-norepinephrine reuptake inhibitors (SNRIs)
Tricyclic antidepressants
Monoamine oxidase inhibitors (MAOIs)
Antipsychotics
Benzodiazepines
Anticonvulsants
Antiepileptics
Antihypertensives
β blockers
α blockers
Diuretics
Cardiovascular agents
Lipid-lowering agents
Digoxin
Histamine-2 receptor
Hormones
Oral contraceptive pills
Estrogens
Progestins
Gonadotropin-releasing hormone agonists
Narcotics
Psychotropic drugs
Recreational drugs
Cocaine
Alcohol
Marijuana
Steroids

Table 30–4.

Components of Comprehensive Sexual History

1. Establish the sexual difficulty in the patient's own words.
2. Are there problems with arousal, desire, or orgasm?
3. How long has the problem been present?
4. Was the onset acute or gradual?
5. Is the problem specific to a certain situation or partner or is it generalized?
6. Was there a precipitating event—physical or psychological?
7. Are there current life stressors that may be contributing to the sexual problem(s)?
8. Is the problem temporally related to starting a new medication?
9. Is intercourse associated with pain?
10. Is there any history of physical, emotional, or sexual abuse?
11. Does the partner have any sexual problems?
12. Have you received any previous treatment—medical or psychological for the problem?

Physical Examination

The goals of the physical examination in women with sexual concerns are to confirm normal anatomy, assess for abnormalities, and reproduce and/or localize pain or tenderness (if tolerable). Given the intimate nature of the physical examination it is recommended that it be conducted in the presence of a female chaperone.

Although the physical examination of a woman with sexual concerns should focus on the genital examination, the examination should also include vital signs, particularly blood pressure, peripheral pulses, and a neurologic evaluation, including a sensory assessment. For women with neurologic disorders, anal and vaginal tone, voluntary tightening of the anus, and bulbocavernosal reflexes should be evaluated.

The genital examination should begin with visual inspection. Atrophy, abnormal discharges, signs of vaginitis, vulvar skin

Table 30–5.

Components of Comprehensive Medical and Surgical History

1. Past medical history
   a. Endocrinologic diseases (diabetes, thyroid dysfunction)
   b. Neurologic diseases (multiple sclerosis, spinal cord injuries)
   c. Cardiovascular disease (hypertension, chronic obstructive pulmonary disease, atherosclerosis)
   d. Pelvic trauma
2. Past surgical history, with emphasis on urologic and gynecologic surgeries
3. Current health status
4. Reproductive history
   a. Age at menarche and menopause
   b. Number of pregnancies, miscarriages, abortions
   c. History of sexually transmitted diseases
   d. Infertility
   e. Birth control use
5. Psychiatric illnesses

abnormalities, Bartholin or Skene gland cysts, urethral diverticuli, and signs of former episiotomy scars should be noted. The clitoris should be exposed to inspect for adhesions.

The second portion of the physical examination is palpation. The levator ani muscles should be palpated to assess for vaginismus and levator ani myalgia. A bimanual examination should be done to assess for motion tenderness, adnexal masses, endometriosis, and fibroids. Finally, a speculum examination should be performed to evaluate for pelvic organ prolapse. Table 30–6 is a list of physical examination findings that may impair female sexual function.

Table 30–6.

Physical Examination Findings That May Impair Female Sexual Function

EXAMINATION	CONDITION	SEXUAL SYMPTOMS
Inspection of Genitalia		
Vaginal or labial atrophy	Low estrogen levels	Decreased arousal, dyspareunia
Sparse pubic hair	Low androgen levels	Decreased desire
Vulvar skin lesions	Lichen sclerosis, *Candida*, sexually transmitted infections	Dyspareunia
Vaginal discharge	Infection	Dyspareunia
Hypertonic muscle tone	Vaginismus, vestibulitis	Dyspareunia
Clitoral hood retraction	Adhesions	Anorgasmia
Vaginal wall cysts	Infected Bartholin or Skene gland	Dyspareunia
Manual Examination		
Urethral fullness	Urethral diverticulum	Dyspareunia
Levator tenderness	Levator ani myalgia	Vaginismus, deep dyspareunia
Fixed retroverted uterus	Endometriosis, masses	Deep dyspareunia
Narrowed vaginal canal	Stricture/stenosis	Dyspareunia
Speculum Examination		
Pelvic organ prolapse		Dyspareunia, decreased desire
Stress incontinence		Vaginitis, decreased desire

Data from from Kingsberg, 2007, and Frank, 2008.

Laboratory Testing

Vaginal pH

Vaginal pH should be measured in women with vaginal discharges, odors, or atrophic vaginitis. Normal vaginal pH in women is 3.5 to 4.5. An acidic pH rules out a bacterial vaginitis other than candidiasis. A pH of 4.5 or more is suggestive of vaginitis, vaginosis, and/or atrophic vaginitis.

Wet Mount Testing

During the speculum portion of the examination samples should be taken of any abnormal discharge for wet mount and culture. Normal vaginal secretions are odorless and are not associated with the clinical complaint of itching or irritation.

Clue cells on wet mount are suggestive of bacterial vaginosis. Women diagnosed with bacterial vaginosis should be treated with oral or vaginal administration of metronidazole (Flagyl). Partners do not require treatment. If a patient is diagnosed with bacterial vaginosis it is important to also screen for gonorrhea and chlamydia.

The observation of an increased white blood cell count on a wet mount, more than 1 white blood cell per epithelial cell, may occur under the following conditions: vaginitis secondary to *Trichomonas,* yeast, and/or atrophy; cervicitis secondary to gonorrhea, chlamydia, and/or herpes; and upper genital/reproductive tract disease such as endometritis and/or pelvic inflammatory disease (Haefner, 1999; Anderson et al, 2004).

Blood Testing

Currently there are no recommended routine laboratory tests for women with sexual concerns. Therefore laboratory testing should be tailored to the results of the history and physical examination.

There are 10 sex steroids, including 7 androgens and 3 estrogens. Measurement of multiple sex steroids may be of clinical relevance to gain a better understanding of the hormonal integrity in a woman with sexual health concerns. Certain clinical scenarios might suggest checking estrogen (estradiol and estrone) and androgen values (DHEA sulfate, androstenedione, total testosterone, free testosterone, SHBG, and dihydrotestosterone). For example, measuring SHBG values might be of value in a premenopausal woman on oral contraceptive therapy with sexual complaints or measuring dihydrotestosterone levels in a woman who develops acne or alopecia after treatment with testosterone.

There are multiple concerns and limitations in determining serum hormone levels in women with sexual health concerns (Södergård et al, 1982; Zumoff et al, 1995; Shifren et al, 2000; Basson et al, 2004; Davis et al, 2005; Davison et al, 2005). First, although two studies have suggested normative ranges of androgens in women, the Endocrine Society's Clinical Guidelines on Androgen Therapy in Women state that there are insufficient data to determine normal ranges of testosterone concentration values for women of different ages (Guay et al, 2004; Davison et al, 2005;

Wierman et al, 2006). Second, the accuracy, precision, and reliability of the assays used to measure testosterone levels in women are not uniformly sensitive or reliable to accurately measure the low serum concentrations typically found in women (Wierman et al, 2006). However, newer testosterone assays, using mass spectroscopy, have shown promise in measuring testosterone more accurately and precisely (Rosner et al, 2007). Free testosterone is more important than total testosterone in sexual function. Only 1% to 2% of testosterone is found in its free biologically available form, with the remainder bound to either SHBG or albumin (Shufelt and Braunstein, 2002). The gold standard for measuring free testosterone is equilibrium dialysis. DHEA is usually measured in the sulfated form because it is easier to measure and does not vary during the menstrual cycle. Several studies have shown a consistent, age-related decline in DHEA sulfate levels (Zumoff et al, 1995; Munarriz et al, 2002; Basson et al, 2004). If low levels of DHEA sulfate are found, a morning cortisol level should be drawn to rule out adrenal insufficiency.

Specialized Testing

Vascular Testing

The female sexual response cycle is a complex interplay of physiologic, hypothalamic and emotive factors that relies on an intact neurovascular system. During sexual arousal, engorgement of the clitoral, labial, and vaginal erectile tissues occurs as a result of increased blood flow through the iliohypogastric-pudendal arterial bed. Just as atherosclerosis can cause impotence in men it can also cause sexual dysfunction in women. Diminished genital blood flow to the iliohypogastric-pudendal arterial bed secondary to atherosclerosis resulting in clitoral and vaginal vascular insufficiency syndromes can lead to decreased engorgement and arousal (Goldstein and Berman, 1998). In return, diminished blood flow and atherosclerotic changes lead to clitoral fibrosis, which interferes with normal smooth muscle relaxation and dilation to sexual stimulation (Tarcan et al, 1999).

Therefore Doppler ultrasonography, vaginal and clitoral photoplethysmography, and selective pudendal arteriography have all been used to assess the integrity of the female pelvic vascular supply. However, none of these measures has been validated or standardized. In addition, no normative data for control subjects exist for comparison. Therefore the clinical relevance of diagnostic hemodynamic investigations in women with sexual dysfunction has not yet been established (Basson et al, 2004).

Indications for vascular testing include (1) women with sexual arousal disorders who have exposure to multiple vascular risk factors, (2) women who have suffered pelvic fractures, and (3) women with sexual arousal disorders unresponsive to other therapies.

Vaginal photoplethysmography, the most commonly used noninvasive vascular testing in women with FSD, measures vaginal blood flow and vaginal pulse amplitude, thereby providing quantitative data on the extent of vaginal engorgement (Pasqualotto et al, 2005). However, this test has many drawbacks, including movement artifact (not suitable for use during stimulation or orgasm), the fact that it provides arbitrary rather than absolute units of measure, and that it provides no anatomic information (Verit et al, 2006).

Duplex Doppler ultrasonography before and after stimulation—visual, vibratory, or after topical alprostadil—has been used to record vaginal, clitoral, and labial blood flow during arousal. It also can be used to obtain changes in peak systolic velocity that occur in the vaginal, clitoral, cavernosal, and labial arteries during sexual arousal as well as the changes in clitoral and labial diameter associated with sexual stimulation. Drawbacks include paucity of "control" of duplex Doppler ultrasound values in women without sexual dysfunction and lack of standardized technique (Akkus et al, 1995; Khalife et al, 2000; Bechara et al, 2003; Munarriz et al, 2003; Pasqualotto et al, 2005).

MRI is one of the newest technologies being used to assess sexual function and arousal in women. MRI provides noninvasive, unparalleled multiplanar high-resolution imaging of the female pelvic floor without ionizing radiation. It can also be used to obtain dynamic quantitative physiologic information regarding changes in tissue volume, regional blood flow changes, and regional metabolite composition. **MRI can be used to define the normal anatomic relationships of the female genital structures in vivo,** providing a more accurate picture and a better understanding of the functional anatomy of women compared with cadaveric studies (Deliganis et al, 2002; Maravilla et al, 2002; Suh et al, 2003, 2004). During arousal, MR images show characteristic engorgement that is most pronounced in the clitoris, especially in the crura and body of the clitoris. The vaginal mucosa does not show any increase in size and signal intensity because it is only a few cell layers thick, below the limit of resolution of the MRI technique (Suh et al, 2003).

Functional brain imaging or functional MRI represents the ability to observe anatomic sites of brain activation in response to a specific task performed by a subject using rapid dynamic MRI. This technique is an experimental tool for exploring brain function associated with emotional attraction, feelings of pleasure, and even sites of activation associated with sexual arousal. There have been a number of studies applying functional MRI techniques to the evaluation of sexual arousal or emotional response in women. Brain regions that activated with sexual arousal were related with visual association areas (posterior temporo-occipital cortices, paralimbic areas, anterior cingulate cortex) (Komisaruk and Whipple, 2005).

As discussed earlier, a study by Arnow and associates (2009), comparing functional MRI in women with HSDD with women without sexual dysfunction found greater activation in the bilateral entorhinal cortex in women without FSD but greater activation of the medial frontal gyrus, right inferior frontal gyrus, and bilateral putamen in women with HSDD, suggesting that women with HSDD shift focus from erotic cues to self-monitoring of sexual response and performance concerns.

TREATMENT

The treatment of FSD is complicated owing to the many causes for these disorders. Optimal female sexual health requires physical, emotional, and mental well-being, which often makes medical treatment alone insufficient. Therefore, treatment requires a multimodal approach, often involving a multidisciplinary team of urologists and a mental health specialist with expertise in sexual medicine/sex therapy. Known anatomic, metabolic, and infectious causes should be corrected first. After correcting medical causes, treatment should begin with patient education.

Women should be educated about average sexual behaviors and frequencies (Kammerer-Doak and Rogers, 2008). Often women are led to believe they have a sexual dysfunction based on misinformation about what is "normal." Behavioral changes such as changes in sexual practices and routine (e.g., initiating a sexual encounter in the morning instead of when exhausted at the end of a long day), smoking cessation, a healthy diet, and adequate

rest and exercise should be discussed. Psychological referrals should be made to those providers who specialize in sexual disorders.

Once these issues have been addressed the use of pharmacotherapy should be discussed when appropriate. It is important to inform patients that to date the only U.S. Food and Drug Administration (FDA)–approved pharmacologic treatment of any female sexual disorder is that of conjugated estrogens (Premarin Vaginal Cream) for moderate to severe dyspareunia.

Hypoactive Sexual Desire Disorder

HSDD is defined as the absence or diminution of sexual interest or desire, absence of sexual thoughts or fantasies, and a lack of responsive desire. This is the most common type of female sexual disorder, and the cause can be physiologic, psychological, or both (Laumann et al, 1999; Nicolosi et al, 2004).

Although desire disorders are the most common sexual disorder they are challenging for physicians to treat. Desire is a complex concept composed of three discrete yet interrelated components: drive, cognition, motivation (Althof et al, 1992; Kingsberg and Althof, 2009). It is imperative for physicians to determine which component or components are causative because the treatments for impaired sex drive are different from those of impaired motivation.

Drive, the biologic component of desire, is based on neuroendocrine function and manifested by spontaneous sexual interest: sexual fantasies, dreams, and thoughts. Cognition is the woman's sexual expectations, beliefs, and values. The third component of desire is motivation or the willingness to engage in sexual activity and is commonly related to psychosocial factors.

Treatment should begin with educating the patient that it is normal for drive to decline with increasing age, which reflects decreased androgen and testosterone production.

If desire is diminished secondary to psychosocial factors the patient should be referred to a sex therapist or psychologist to discuss lifestyle changes, stress management, or couples therapy.

If the cause appears to be related to drive, exogenous testosterone therapy with tibolone (a synthetic steroid with selective estrogenic, androgenic, and progesterogenic properties) may be an appropriate option, particularly for postmenopausal women. Centrally acting agents also are being investigated for the treatment of HSDD in both premenopausal and postmenopausal women.

Androgens for the Treatment of Desire Disorders

Despite testosterone being one of the most commonly prescribed drugs for desire disorders, its use is controversial and not FDA approved in women. Although testosterone is linked to sexual desire, studies have shown that low serum testosterone levels are not predictive of low desire nor do they correlate well with the likelihood of a therapeutic response (Davis et al, 2005).

In 2005 a Cochrane review of 23 trials with 1957 participants looking at the benefits of adding testosterone to hormonal therapy in perimenopausal and postmenopausal women concluded that although there was insufficient evidence in perimenopausal women, postmenopausal women did experience improved sexual function with the addition of testosterone to hormonal therapy (Somboonporn et al, 2005).

Several subsequent randomized controlled trials in postmenopausal women and surgically castrated women have shown that the addition of testosterone to hormonal therapy improved not only desire but also arousal and orgasm (Shifren et al, 2000, 2006; Braunstein et al, 2005; Davis et al, 2005).

The data regarding testosterone therapy in premenopausal women is lacking owing to a paucity of studies, but in two studies an improvement in sexual desire in premenopausal women with low libido treated with transdermal testosterone was suggested (Goldstat et al, 2003; Davis et al, 2005).

When prescribing testosterone therapy physicians must be aware of the potential adverse side effects and contraindications. Complications include acne, hirsutism, seborrhea, menstrual irregularities, virilization, hyperlipidemia, liver dysfunction, and male pattern baldness. Transdermal preparations may minimize adverse effects. Any patient on testosterone should be seen and have laboratory studies done routinely to avoid having levels reach superphysiologic levels.

Contraindications to testosterone therapy include androgenic alopecia, hirsutism, seborrhea or acne, polycystic ovary syndrome, liver dysfunction, and estrogen depletion (Basson et al, 2004).

For the androgen precursors DHEA and DHEA sulfate there are limited data regarding their effectiveness. One small retrospective study showed DHEA (50 mg/day) to improve desire, arousal, orgasm, and sexual satisfaction in both premenopausal and postmenopausal women (Munarriz et al, 2002).

Other Medication for the Treatment of Desire Disorders

Tibolone, a synthetic steroid, has been used in Europe for more than 20 years given its positive effects on sexual function. In one randomized control study of postmenopausal women with arousal and desires disorders, tibolone in combination with hormonal therapy was shown to significantly improve sexual function scores and increase clitoral circulation.

Arousal Disorders

Sexual arousal disorders can be treated, depending on the etiology, with counseling to change sexual practice patterns, medical therapy, or a combination of the two.

Estrogen replacement therapy has shown beneficial effects in women with postmenopausal arousal disorder by improving vaginal lubrication and blood flow.

Bupropion, an aminoketone antidepressant, has been shown to improve arousal in both premenopausal and postmenopausal women and both depressed and nondepressed women with arousal disorder (Modell et al, 2000; Segraves et al, 2001, 2004).

Alprostadil, a topically applied prostaglandin applied to the external genitalia, is currently under investigation for use in women given its beneficial effects on male arousal.

Arginmax, a nutritional supplement containing L-arginine, a precursor of nitric oxide, showed an increase in sexual arousal in both premenopausal and postmenopausal women in two small randomized control studies (Ito et al, 2001, 2006).

Zestra, botanical massage oil applied to the vulva, has been shown in one randomized control trial to significantly improve arousal in women with arousal disorders (Ferguson et al, 2003).

Phentolamine and yohimbine are α-androgenic antagonists that cause vasodilatation through smooth muscle relaxation. Although phentolamine has been shown to improve arousal and lubrication for menopausal women with arousal disorder, yohimbine failed to show any clinical improvement in arousal (Raina et al, 2007).

Sildenafil, a selective phosphodiesterase-5 inhibitor used to treat erectile dysfunction in men via smooth muscle relaxation, has also been used in women with arousal disorder with mixed results. Kaplan and colleagues (1999) reported no overall improvement in

33 postmenopausal women with arousal disorder treated with 50 mg of sildenafil despite improved vaginal lubrication and clitoral sensitivity. Basson and associates (2002) also reported no improvement in 781 premenopausal and postmenopausal women with arousal disorder with sildenafil. However, several studies have shown significant improvement in sexual arousal, orgasm, and overall satisfaction in women with arousal disorders treated with sildenafil (Caruso et al, 2001; Berman et al, 2003).

The EROS clitoral therapy device, an FDA-approved device that applies gentle suction to the clitoris, enhancing clitoral engorgement, has proven beneficial in women with arousal disorders (Wilson et al, 2001).

Orgasmic Disorders

Orgasmic disorders can be classified as primary or secondary. Primary orgasmic disorders are typically the result of sexual inexperience and are treated using cognitive behavioral therapy, directed masturbation, and sex education. Permission giving by the physician regarding sexual exploration and masturbation is hugely helpful to women with anorgasmia. Secondary anorgasmia, or acquired anorgasmia, is often the result of antidepressant medications. This can be treated by stopping the offending medication.

Dyspareunia and Vaginismus

The treatment of sexual pain disorders is often challenging, given the paucity of controlled trials as well as the multiple causes. Ideally, treatment should involve a multidisciplinary team that can address the physiologic, emotional, relational, and psychological factors. Pelvic floor physical therapy with biofeedback, pelvic floor electrical stimulation, perineal ultrasonography, and vaginal dilators have all been used with reported clinical benefit but without scientific evidence (Basson et al, 2004).

Pharmacotherapy for sexual pain disorders is routed in treating the underlying condition. Postmenopausal women with pain secondary to atrophic vaginitis should be treated with topical estrogen whereas women with vulvovaginitis should be treated with oral or transvaginal antifungal agents.

Tricyclic antidepressants, SSRIs, and corticosteroids have been used to treat vulvar vestibulitis, but data supporting their use are limited.

SSRI-Related Sexual Dysfunction

Selective phosphodiesterase-5 inhibitors have been used in therapy for SSRI-induced sexual function. In several studies, women with SSRI-induced sexual dysfunction reported significant improvements in overall sexual function and satisfaction on sildenafil (Nurnberg et al, 1999, 2008; Salerian et al, 2000; Basson et al, 2004). Some reports suggest that bupropion may be an effective antidote for SSRI-induced sexual dysfunction; however, the data on restoring normal sexual functioning in this patient population are mixed (Clayton et al, 2004; DeBattista et al, 2005).

Surgical Therapy

Sexual Pain Disorders

The role of surgery in the treatment of female sexual pain disorders should be considered only in patients who have failed conservative medical and psychological therapy.

Vulvar Vestibulectomy. Vulvar vestibulectomy has been used in women with refractory vulvar vestibulitis syndrome and in women with various conditions such as lichen sclerosis or posterior fourchette fissures that have destroyed the normal vulvar architecture. Since first described in 1981, the surgery has undergone several modifications and variations. A complete vulvar vestibulectomy involves anterior, posterior, and lateral vaginal mucosa with a posterior vaginal advancement flap. In a modified vulvar vestibulectomy, only the posterior vaginal mucosa is excised (Kehoe and Luesley, 1999).

It is imperative to map the painful vestibular areas preoperatively. With the patient under general anesthesia, the previously mapped areas are infiltrated with lidocaine and epinephrine (1:200,000 units) for hydrodissection. A No. 15 blade is then used to excise the vestibular mucosa. The defect is then closed using 3-0 or 4-0 Vicryl sutures. Attention should be paid to the location of the Bartholin gland, which should be avoided to prevent postoperative cyst formation (Kehoe and Luesley, 1999).

Postoperatively, patients should be instructed to avoid vaginal penetration and limit physical activity for a minimum of 4 weeks. At 4 weeks patients should begin a physical therapy regimen, which may include biofeedback and vaginal dilators.

In 2008 Landry and colleagues conducted a review of the treatment of vestibulodynia. Of the 38 studies reviewed only 5 were randomized controlled studies and the majority of the studies had several methodologic weaknesses, including absence of a control group, pretreatment pain evaluation, validated questionnaires assessing pain and sexual function, and standard surgical technique.

Yet based on these limited prospective studies and the randomized clinical trials, vestibulectomy was the most efficacious treatment to date, achieving a high rate of patient satisfaction and greater than 50% resolution of dyspareunia (Landry et al, 2008).

Drainage of Sebaceous Cysts or Infected Bartholin or Skene Gland Cysts. If conservative therapy fails, incision and drainage and, at times, marsupialization of the cyst is indicated.

Female Pelvic Floor Disorders

Although female pelvic organ prolapse, incontinence, and overactive bladder have all been shown to have a negative impact on female sexual function, surgical restoration of normal anatomy with alleviation of symptoms does not consistently improve female sexual outcomes.

Key Points: Diagnosis and Treatment

- A detailed history (including medical, sexual, and psychiatric history), medication list, and thorough physical examination are imperative to diagnosing female sexual dysfunction.
- Currently there are no recommended routine laboratory tests for women with sexual concerns. Therefore laboratory testing should be tailored to the results of the history and physical examination.
- In women with FSD, known anatomic, metabolic, and infectious causes should be corrected first.
- To date the only FDA-approved pharmacologic treatment of any female sexual disorder is conjugated estrogens (Premarin Vaginal Cream) for moderate to severe dyspareunia.

CONCLUSION

Despite our increasing knowledge base, female sexual disorders still remain a challenge to physicians and patients alike. Much of this is based on both physician and patient avoidance of the topic. Sexual health is as important to the quality of lives of women as it is to men, and female patients expect that their physicians will address their sexual concerns. The goal of this chapter was to equip the urologist with the tools to screen, diagnose, and collaborate with a multidisciplinary team to adequately address the complexity of female sexual disorders.

Neoplasms of the Testis

Andrew J. Stephenson, MD, FACS, FRCSC • Timothy D. Gilligan, MD, MS

Germ Cell Tumors

Non–Germ Cell Tumors

Tumors of the Testicular Adnexa

Neoplasms of the testis comprise a morphologically and clinically diverse group of tumors, **95% of which are germ cell tumors (GCTs). GCTs are broadly categorized as seminoma and nonseminoma (NSGCT) owing to differences in natural history and treatment. GCTs are relatively rare malignancies, accounting for 1% to 2% of cancers among men in the United States,** with an incidence of approximately 5 cases per 100,000. Approximately 90% of GCTs arise in the testis and 2% to 5% are extragonadal (the retroperitoneum and mediastinum are the most common sites). With the development of cisplatin-based chemotherapy and the integration of surgery, GCTs have become a model of a curable neoplasm and serve as a paradigm for the multidisciplinary treatment of cancer (Einhorn, 1981). Before therapy with cisplatin was introduced the cure rate for patients with advanced GCT was 5% to 10%. Currently the long-term survival for men with metastatic GCT is 80% to 90%. With the successful cure of patients (even those with advanced disease), an important treatment objective is minimizing treatment-related toxicity without compromising curability. Mortality from GCT is due to inherent resistance to platin chemotherapy and the failure to fully eradicate residual disease elements in the early course of therapy.

Non-GCTs of the testis are rare and include sex cord/stromal tumors, lymphoid and hematopoietic tumors, tumors of the collecting duct and rete testis, and tumors of the testicular adnexa. A classification of neoplasms of the testis is provided in Table 31–1.

GERM CELL TUMORS

Epidemiology

As of 2010 in the United States it was estimated that 8400 men would develop testicular cancer and 380 would die of this disease (Jemnal et al, 2010). **In the United States, testicular cancer is the most common malignancy among men aged 20 to 40 years and the second most common cancer after leukemia among males aged 15 to 19 years** (Horner et al, 2009). Testicular tumors have three age model peaks: infancy, ages 30 to 34 years, and approximately age 60. **The incidence of bilateral GCT is approximately 2%** (Fossa et al, 2005). **Testicular lymphoma is less common than GCT but accounts for the majority of testicular tumors in men older than 50 years of age** and is more likely to have a synchronous bilateral presentation.

The incidence of testicular cancer varies significantly according to geographic region: **rates are highest in Scandinavia, Germany, Switzerland, and New Zealand; intermediate in the United States and Great Britain; and lowest in Africa and Asia. The incidence of testicular cancer in the United States in non-Hispanic whites is five times higher than the incidence in African-Americans, four times higher than the incidence in Asians, and 78% higher than in Hispanics** (Horner et al, 2009).

The incidence of GCT appears to be increasing worldwide (McKiernan et al, 1999; McGlynn et al, 2005; Purdue et al, 2005). In the United States, the age-adjusted incidence rate for males aged 15 to 49 years increased from 2.9 per 100,000 in 1975 to 5.1 per 100,000 in 2004 (Holmes et al, 2008). Over this time period incidence rates have increased substantially more for seminoma than NSGCT (McGlynn et al, 2005; Powles et al, 2005). **A stage migration of GCT has been observed in several countries owing, in part, to increased awareness and earlier diagnosis.** Between 1973 and 2001 the percentage of tumors diagnosed at a localized stage increased from 55% to 73% in the United States among white males. The stage distribution for African-American males remained stable during this time (McGlynn et al, 2005). **Only 10% to 30% of men will present with distant metastatic disease.** In the United Kingdom the change in stage distribution over time is largely restricted to an increase in localized seminoma and a decrease in metastatic NSGCT; rates of localized NSGCT and metastatic seminoma are largely unchanged (McGlynn et al, 2005). **Currently, localized seminoma is the most common presentation of GCT, representing approximately 50% of all men with GCT** (Powles et al, 2005). Thus, contemporary testicular germ cell tumors have more favorable prognostic features on average compared with those diagnosed in the 1970s and 1980s.

Risk Factors

There are four well-established risk factors for testicular cancer: cryptorchidism, family history of testicular cancer, a personal history of testicular cancer, and intratubular germ cell neoplasia (ITGCN). Infertile men also have a higher incidence of testicular cancer. **Numerous studies have reported that recent increases in the incidence of testicular cancer can be largely attributed to birth-cohort effects, which implies that diet and/or other environmental factors play a major role in GCT carcinogenesis** (Liu et al, 1999; Huyghe et al, 2003; McGlynn et al, 2003; Richiardi et al, 2004; Bray et al, 2006; Verhoeven et al, 2008).

Males with cryptorchidism are four to six times more likely to be diagnosed with testicular cancer, but the relative risk (RR) falls to 2.0 to 3.0 if orchidopexy is

Table 31–1.

World Health Organization Classification of Testicular Tumors

Germ Cell Tumors

Precursor lesions—intratubular malignant germ cells (carcinoma in situ)
Tumors of one histologic type (pure forms)
- Seminoma
  - Variant—seminoma with syncytiotrophoblastic cells
- Spermatocytic seminoma
  - Variant—spermatocytic seminoma with sarcoma
- Embryonal carcinoma
- Yolk sac tumor
- Polyembryoma
- Trophoblastic tumors
  - Choriocarcinoma
  - Choriocarcinoma with other cell types
  - Placental site trophoblastic tumor
- Teratoma
  - Mature teratoma
  - Dermoid cyst
  - Immature teratoma
  - Teratoma with malignant areas

Tumors of more than one histologic type (mixed forms)—specify types and estimate percentage

Sex Cord/Gonadal Stromal Tumors

Pure forms
- Leydig cell tumor
- Sertoli cell tumor
  - Large-cell calcifying Sertoli cell tumor
  - Lipid-rich Sertoli cell tumor

Granulosa cell tumor
- Adult-type granulosa cell tumor
- Juvenile-type granulosa cell tumor

Tumors of thecoma/fibroma group
Incompletely differentiated sex cord/gonadal stromal tumors
Mixed forms

Unclassified Forms

Tumors Containing Both Germ Cell and Sex Cord/Gonadal Stromal Elements

Gonadoblastoma
Mixed germ cell–sex cord/gonadal stromal tumors, unclassified

Miscellaneous Tumors

Carcinoid tumor
Tumors of ovarian epithelial types

Lymphoid and Hematopoietic Tumors

Lymphoma
Plasmacytoma
Leukemia

Tumors of Collecting Ducts and Rete

Adenoma
Carcinoma

Tumors of the Tunica, Epididymis, Spermatic Cord, Supporting Structures, and Appendices

Adenomatoid tumor
Mesothelioma
- Benign
- Malignant

Adenoma
Carcinoma
Melanotic neuroectodermal
Desmoplastic small round cell tumor

Soft Tissue Tumors

Unclassified Tumors

Secondary Tumors

Tumor-like Lesions

Nodules of immature tubules
Testicular lesions of adrenogenital syndrome
Testicular lesions of androgen-insensitivity syndrome
Nodular precocious maturation
Specific orchitis
Nonspecific orchitis
Granulomatous orchitis
Malakoplakia
Adrenal cortical rest
Fibromatous peritonitis
Funiculitis
Residue of meconium peritonitis
Sperm granuloma
Vasitis nodosa
Sclerosing lipogranuloma
Gonadal splenic fusion
Mesonephric remnants
Endometriosis
Epidermal cyst
Cystic dysplasia
Mesolithial cyst
Others

Data from Vogelzang NJ, Scardino PT, Shipley WU, Coffey DS, editors. Genitourinary oncology. Philadelphia: Lippincott Williams & Wilkins; 1999.

performed before puberty (Dieckmann and Pichlmeier, 2004; Wood and Elder, 2009). Although most of the increased risk reflects an increased risk of cancer in the undescended testis, **a meta-analysis of cryptorchidism studies reported that the contralateral descended testis is also at slightly increased risk** (RR 1.74 [95% CI, 1.01 to 2.98]) (Akre et al, 2009). Men with a first-degree relative with testicular cancer have a substantially increased risk, and the median age at diagnosis in these men is 2 to 3 years younger than in the general population (Mai et al, 2009). An individual's RR for testicular cancer is 8.0 to 12.0 with an affected brother compared with 2.0 to 4.0 in those with an affected father (Westergaard et al, 1996; Sonneveld et al, 1999; Hemminki and Chen, 2006). Men with a history of testicular cancer are at a 12-fold increased risk of developing GCT in the contralateral testis, but the 15-year cumulative incidence is only 2%. The risk is higher in patients who are younger when testicular cancer is diagnosed and in men whose initial GCT is seminoma (Theodore et al, 2004; Fossa et al, 2005). A population-based study of contralateral testicular cancer reported that a man younger than the age of 30 with a testicular seminoma has a 3.1% risk of developing a contralateral testicular cancer (Fossa et al, 2005). The same study reported that 10-year overall survival after diagnosis with a second primary (i.e., contralateral) testicular cancer was 93%.

Most GCTs arise from a precursor lesion called intratubular germ cell neoplasia (ITGCN) (which is also referred to as carcinoma in situ). Men with ITGCN have a

significantly increased risk of developing invasive GCT. **ITGCN is present in adjacent testicular parenchyma in 80% to 90% cases of invasive GCT and is associated with a 50% risk of GCT within 5 years and a 70% risk within 7 years** (Skakkebaek et al, 1982; Dieckmann and Skakkebaek, 1999; Montironi, 2002). **Between 5% and 9% of patients with GCT have ITGCN within the unaffected contralateral testis, although the incidence of contralateral ITGCN increases to about 36% in men with testicular atrophy or cryptorchidism** (Dieckmann and Loy, 1996; Dieckmann and Skakkebaek, 1999). Gene expression profile analysis indicates that ITGCN develops before birth from an arrested gonocyte (Hussain et al, 2008; Sonne et al, 2009). In men with a history of GCT the finding of testicular microlithiasis on ultrasound evaluation of the contralateral testis is associated with an increased risk of ITGCN (Karellas et al, 2007). **However, the significance of microlithiasis in the general population is unclear;** a study of 1500 army volunteers found a 5.6% prevalence of microlithiasis, yet fewer than 2% of those with microlithiasis developed cancer within the subsequent 5 years (DeCastro et al, 2008).

Pathogenesis and Biology

The carcinogenesis of GCTs is poorly understood. As noted earlier, testicular GCTs develop from a precursor lesion, ITGCN, which, in turn, appears to develop from arrested primordial germ cells or gonocytes that failed to differentiate into prespermatogonia (Rajpert-de Meyts and Hoei-Hansen, 2007; Hussain et al, 2008). These cells are thought to then lie dormant until after puberty when they are stimulated by increased testosterone levels.

The increased incidence of testicular cancer that started in the first half of the 20th century has been accompanied by an increased incidence of other male reproductive disorders, such as hypospadias, cryptorchidism, and subfertility (Rajpert-de Meyts and Hoei-Hansen, 2007; Sonne et al, 2008). These findings led to the hypothesis that testicular cancer and these other disorders all resulted from a testicular dysgenesis syndrome, which in turn resulted from environmental and/or lifestyle factors and genetic susceptibility. The specific environmental or lifestyle factors have not been defined. Increased prenatal estrogen exposure has been hypothesized as a risk factor, but this is controversial (Martin et al, 2008). There is stronger evidence that reduction in androgen activity can result in features of testicular dysgenesis syndrome, including cryptorchidism, hypospadias, and impaired spermatogenesis, but a direct link between reduced androgen signaling and ITGCN or GCTs remains hypothetical (Sonne et al, 2008; Hu et al, 2009).

Evidence of environmental and lifestyle factors contributing to testicular cancer includes the rapid rise in its incidence as well as findings that the risk in second-generation immigrants is similar to that in their country of birth. In addition, mothers of children with testicular cancer (but not the testicular cancer patients themselves) have been found to have higher blood levels of certain organic pollutants compared with other mothers (Sonne et al, 2008). Evidence for genetic factors includes the clustering of testicular cancer in some families, the extreme difference in the rate of testicular cancer in black and white Americans, and the finding of susceptibility loci on chromosomes 5, 6, and 12 in case-control studies (Mai et al, 2009). In addition, specific polymorphisms of certain genes, including the gene encoding c-KIT ligand, have been associated with an increased risk of testicular cancer (Blomberg Jensen et al, 2008; Kanetsky et al, 2009). Gonocytes depend on c-KIT ligand for survival, and the gene for this protein is located on the short arm of chromosome 12. **Approximately 70% of GCTs have an extra copy of chromosome 12 in the form of an isochromosome 12p (i[12p])** (Bosl et al, 1989). Thus a connection between mutations or polymorphisms in this gene and GCT has biologic plausibility.

One of the most striking features of GCTs is their sensitivity to cisplatin-based chemotherapy, which enables cure in the vast majority of patients with widely metastatic disease. The specific biologic basis of this acute vulnerability to chemotherapy remains incompletely understood but is thought to derive from the close relationship between GCTs and embryonal stem cells and gonocytes, which have a low threshold for undergoing apoptosis in response to DNA damage (Mayer et al, 2003; Schmelz et al, 2010). GCTs have high intrinsic levels of wild-type TP53 protein (which plays a role in mediating cell cycle arrest and apoptosis), and *TP53* mutations in GCTs are rare, yet differences have not been consistently found in TP53 status when comparing chemosensitive and chemoresistant germ cell tumors (Burger et al, 1998; Houldsworth et al, 1998). Similarly, expression of the antiapoptotic protein BCL2 is low in germ cell tumors but BCL2 levels do not distinguish chemosensitive and chemoresistant cell lines (Mayer et al, 2003). Gene expression analysis has found an upregulation of numerous genes that facilitate apoptosis, including *FASLG, TNFSF10,* and *BAX,* whereas *BCL2* is downregulated (Schmelz et al, 2010). Expression patterns of genes controlling the G1/S-phase checkpoint in GCTs appear to promote induction of apoptosis (Schmelz et al, 2010). In addition, GCTs lack transporters to export cisplatin from the cell and have a reduced ability to repair cisplatin-induced DNA damage (Mayer et al, 2003). Nonetheless, a small fraction of GCTs are resistant to chemotherapy and the basis of that resistance remains obscure, although DNA mismatch repair deficiency, microsatellite instability, and *BRAF* mutations have been associated with treatment failure (Honecker et al, 2009).

Up to 10% of GCTs are extragonadal and develop in midline anatomic locations. There are two main competing theories regarding the pathogenesis of extragonadal GCTs. The first hypothesizes that they originate from germ cells that mismigrated along the genital ridge and were able to survive in an extragonadal environment. The second theory proposes a reverse migration from the testis to extragonadal locations (Chaganti and Houldsworth, 2000).

Primary mediastinal NSGCTs differ in several ways from those originating in the testis or retroperitoneum. First, they are less sensitive to chemotherapy and have a poor prognosis with a 5-year overall survival of about 45% (Bokemeyer et al, 2002b). Mediastinal NSGCTs are more likely to have yolk sac tumor components and thus to be associated with elevations in serum α-fetoprotein (AFP) (Kesler et al, 2008). They are also associated with Kleinfelter syndrome and with hematologic malignancies that carry extra copies of the short arm of chromosome 12, as seen in adult GCTs (Bokemeyer et al, 2002a; McKenney et al, 2007). **In contrast, mediastinal seminomas carry a similar prognosis to testicular seminomas. Primary retroperitoneal GCTs are indistinguishable biologically from testicular GCTs and carry the same prognosis.**

Histologic Classification

The histologic classification of GCT is outlined in Table 31–2 (Sobin and Wittekind, 2002). **GCTs are broadly classified as seminoma and NSGCT, and the relative distribution of each is 52% to 56% and 44% to 48%, respectively** (McGlynn et al, 2005; Powles et al, 2005). **NSGCTs include embryonal carcinoma (EC), yolk sac tumor, teratoma, and**

Table 31–2.

World Health Organization Classification of Germ Cell Tumors

Intratubular germ cell neoplasia
Tumors of one histologic type (pure forms):
Seminoma
Seminoma with syncytiotrophoblastic cells
Spermatocytic seminoma
Embryonal carcinoma
Yolk sac tumor
Trophoblastic tumors
Choriocarcinoma
Trophoblastic neoplasms other than choriocarcinoma
Monophasic choriocarcinoma
Placental site trophoblastic tumor
Teratoma
Dermoid cyst
Monodermal teratoma
Teratoma with somatic type malignancy (malignant transformation)
Tumors of more than one histologic subtype (mixed forms)

From Sobin LH, Wittekind CH. UICC: TNM classification of malignant tumors. 6th ed. New York: Wiley-Liss; 2002.

choriocarcinoma subtypes, either alone as pure forms or in combination as mixed GCT with or without seminoma (Ulbright, 2005). Most NSGCTs are mixed tumors that are composed of two or more GCT subtypes. GCTs that contain both NSGCT subtypes and seminoma are classified as NSGCT.

Intratubular Germ Cell Neoplasia. With the exception of spermatocytic seminoma, all adult invasive GCTs arise from ITGCN. ITGCN consists of undifferentiated germ cells that have the appearance of seminoma that are located basally within the seminiferous tubules. The tubule usually shows decreased or absent spermatogenesis, and normal constituents are replaced by ITGCN. The presence of ITGCN in an orchiectomy specimen in men with testicular cancer does not carry any prognostic implications with regard to the risk of relapse of the cancer (von Eyben et al, 2004). ITGCN is much less frequent in pediatric GCTs (Cheville, 1999).

Seminoma. Seminoma is the most common type of GCT. **On average, seminomas occur at an older average age than NSGCTs, with most cases diagnosed in the fourth or fifth decade of life** (Rayson et al, 1998). Grossly, seminoma is a soft tan to white diffuse or multinodular mass (Fig. 31–1A). Necrosis may be present but is usually focal and not as prominent as other GCTs. Seminomas consist of a sheetlike arrangement of cells with polygonal nuclei and clear cytoplasm, with the cells divided into nests by fibrovascular septa that contain lymphocytes (see Fig. 31–1B) (Ulbright, 2005). Syncytiotrophoblasts, which stain positive for human choriogonadotropin (hCG), can be identified in about 15% of cases of pure seminoma but are of no clear prognostic significance (Cheville, 1999). Lymphocytic infiltrates and granulomatous reactions are often seen and seminomas appear to be associated with an increased incidence of sarcoidosis (Rayson et al, 1998; Tjan-Heijnen et al, 1998). Seminomas may be confused with solid-pattern EC, yolk sac tumor, or Sertoli cell tumors (Ulbright and Young, 2008). Although immunohistochemical staining plays a limited role in diagnosing GCTs, seminomas are typically negative for CD30, positive for CD117, and strongly positive for placental alkaline phosphatase (PLAP). Anaplastic seminoma was a previously recognized subtype of seminoma, but this distinction is of no clear biologic or clinical significance and is no longer recognized. **Seminoma arises from ITGCN and is considered to be the common precursor for the other NSGCT subtypes** (Ulbright, 2004). This ability of seminoma to transform into NSGCT elements has important therapeutic implications for the management of seminoma (discussed later) (Ulbright, 2004).

Spermatocytic Seminoma. **Spermatocytic seminoma is rare and accounts for less than 1% of GCTs.** Although classified as a variant of seminoma it represents a distinct clinicopathologic entity from other GCTs. **Unlike other GCTs, spermatocytic seminoma does not arise from ITGCN, is not associated with a history of cryptorchidism or bilaterality, does not express PLAP or i(12p), and does not occur as part of mixed GCTs** (Ulbright, 2005). Histopathologically, it differs from seminoma in that the nuclei are round, minimal lymphocytic infiltration is present, and three distinct cell types are present, including small lymphocyte-like cells, medium-sized cells with dense eosinophilic cytoplasm and a round nucleus, and large mononucleated or multinucleated cells (Aggarwal and Parwani, 2009). The peak incidence is in the sixth decade of life (Eble, 1994; Chung et al, 2004a). **It is a benign tumor (only one documented case having metastasized) and is almost always cured with orchiectomy** (Chung et al, 2004a). An exception to this is the rare case of spermatocytic seminoma with sarcoma that exhibits elements of sarcomatous differentiation and is commonly associated with widely metastatic disease and poor prognosis.

Embryonal Carcinoma. EC consists of undifferentiated malignant cells resembling primitive epithelial cells from early-stage embryos with crowded pleomorphic nuclei (Ulbright, 2005). Grossly, EC is a tan to yellow neoplasm that often exhibits large areas of hemorrhage and necrosis. The microscopic appearance of these tumors varies considerably, and they may grow in solid sheets or in papillary, glandular-alveolar, or tubular patterns (see Fig. 31–1C). In some cases, syncytiotrophoblasts are identified. EC is an aggressive tumor associated with a high rate of metastasis, often in the context of normal serum tumor markers. **EC is the most undifferentiated cell type of NSGCT, with totipotential capacity to differentiate to other NSGCT cell types (including teratoma) within the primary tumor or at metastatic sites.** As discussed later, the presence and proportion of EC has been associated with an increased risk of occult metastases in clinical stage (CS) I NSGCT. EC typically stains for AE1/AE3, PLAP, and OCT3/4 and does not stain for c-KIT.

Choriocarcinoma. Choriocarcinoma is a rare and aggressive tumor that typically presents as elevated serum hCG levels and disseminated disease. **Choriocarcinoma commonly spreads by hematogenous routes,** and common sites of metastases include lungs and brain, but eye and skin metastases have also been reported (Tinkle et al, 2001; Osada et al, 2004). Microscopically the tumor is composed of syncytiotrophoblasts and cytotrophoblasts, and the former stain positively for hCG (see Fig. 31–1D) (Cheville, 1999). Seminoma and EC may also contain syncytiotrophoblasts. Areas of hemorrhage and necrosis are prominent. As in gestational trophoblastic disease, testicular choriocarcinoma is prone to hemorrhage, sometimes both spontaneously and immediately after chemotherapy is initiated, and such bleeding can be catastrophic, particularly when it occurs in the lungs or brain (Motzer et al, 1987).

Yolk Sac Tumor. Pure yolk sac tumors (sometimes called endodermal sinus tumors) represent a very small fraction of adult-type GCTs but are more common in mediastinal and pediatric GCTs. Mixed GCTs often include elements of yolk sac tumor, which

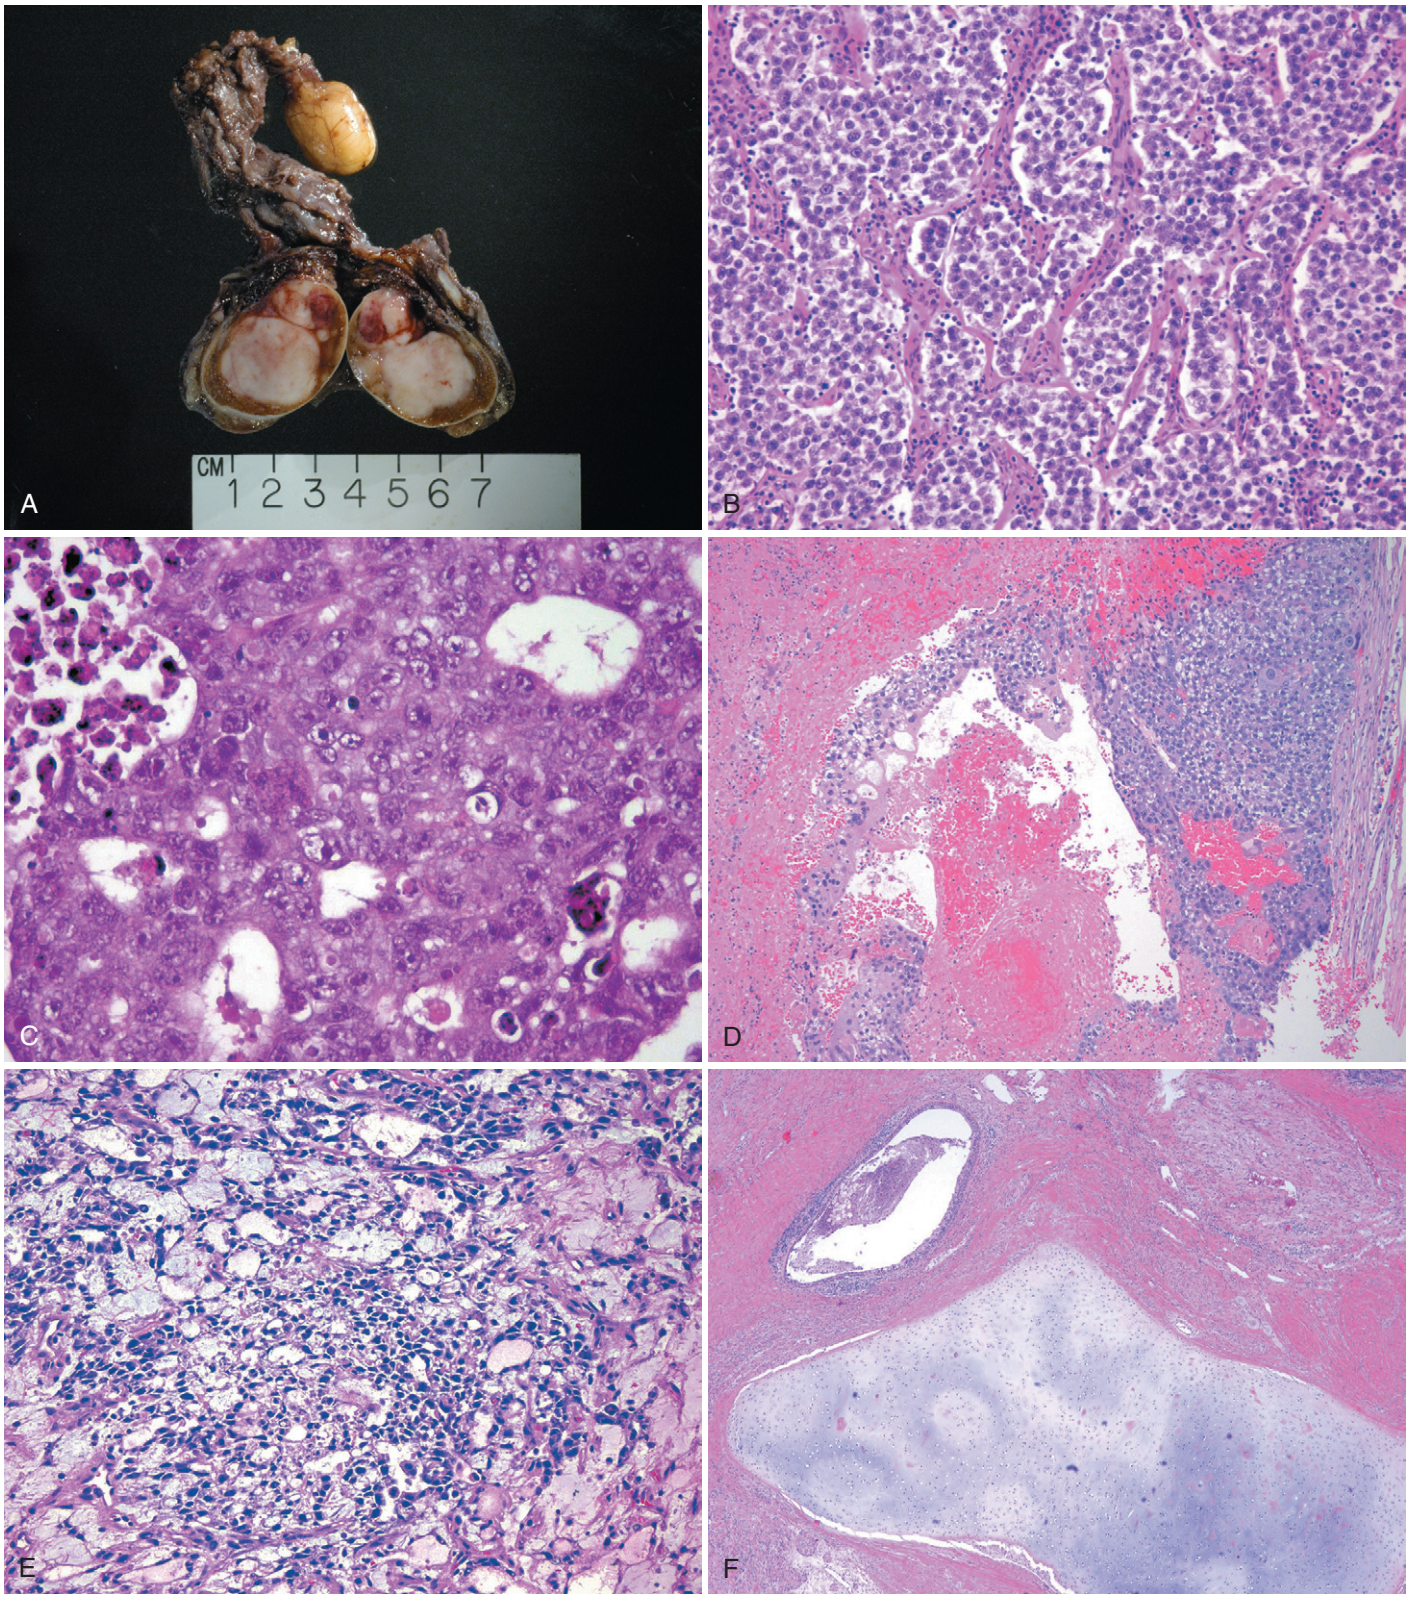

Figure 31–1. **A,** Gross section of testis containing seminoma. **B,** Seminoma (H&E stain). **C,** Embryonal carcinoma (H&E stain). **D,** Choriocarcinoma (H&E stain). **E,** Yolk sac tumor (H&E stain). **F,** Teratoma (H&E stain). (**A-F,** Courtesy of Donna E. Hansel, MD, PhD.)

consists of a reticular network of medium-sized cuboidal cells with cytoplasmic and extracytoplasmic eosinophilic, hyaline-like globules (Epstein, 2010). Hyaline globules are a characteristic feature and are present in up to 84% of cases. Yolk sac tumors may grow in a glandular, papillary, or microcystic pattern. A characteristic feature is the Schiller-Duval body, which resembles endodermal sinuses, and is seen in roughly half of cases (see Fig. 31–1E). **Yolk sac tumors almost always produce AFP but not hCG.** Among men with CS I NSGCT with normal serum tumor markers the presence of a yolk sac tumor is associated with a lower risk of

relapse, but this finding may simply be a result of serum tumor markers (i.e., AFP) having a higher sensitivity for detecting micrometastatic disease in this type of GCT (Read et al, 1992).

Teratoma. Teratomas are tumors that contain well-differentiated or incompletely differentiated elements of at least two of the three germ cell layers of endoderm, mesoderm, and ectoderm. Characteristically all components are intermixed. Well-differentiated tumors are labeled mature teratomas, whereas those that are incompletely differentiated (i.e., similar to fetal or embryonal tissue) are called immature teratomas. Mature teratomas may include elements of mature bone, cartilage, teeth, hair, and squamous epithelium, a fact that most likely explains the name teratoma, which roughly means "monster tumor," in Greek (see Fig. 31–1F). The gross appearance of teratoma depends largely on the elements within it, with most tumors having solid and cystic areas. **Teratomas are generally associated with normal serum tumor markers, but they may cause mildly elevated serum AFP levels.** Approximately 47% of adult mixed GCTs contain teratoma, but pure teratomas are uncommon. In contrast, pure teratomas comprise a sizeable fraction of pediatric GCTs (Epstein, 2010).

In adults, teratomas are histologically benign but are frequently found at metastatic sites in patients with advanced NSGCT. It is hypothesized that nonteratomatous elements (mostly EC) have the ability to mature into teratoma and that the metastases are derived from these elements before their differentiation. **Teratoma is resistant to chemotherapy.** Thus, given its frequent presence at metastatic sites in advanced NSGCT, patients with residual masses after chemotherapy require consolidative surgical resection because 40% to 50% will have residual teratoma. The inherent chemoresistance of teratoma is a limitation to treatment strategies for NSGCT that utilize chemotherapy alone.

Despite their benign histologic appearance, teratomas may contain genetic abnormalities frequently found in malignant GCT elements, including aneuploidy, i(12p), and widely variable proliferative capacity (Castedo et al, 1989; Sella et al, 1991). Studies have also shown that cystic fluid from teratoma frequently contains hCG and AFP, confirming the malignant potential of teratoma (Sella et al, 1991; Beck et al, 2004). The genetic instability of teratoma has important clinical implications. **Teratomas may grow uncontrollably, invade surrounding structures, and become unresectable (known as growing teratoma syndrome)** (Logothetis et al, 1982). **On rare occasions, teratoma may transform into a somatic malignancy such as rhabdomyosarcoma, adenocarcinoma, or primitive neuroectodermal tumor** (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998). These tumors are called "teratoma with somatic-type malignancy" or "teratoma with malignant transformation." They frequently have abnormalities of chromosome 12 or i(12p), indicating their origin from GCT. Malignant transformation is highly aggressive, resistant to conventional chemotherapy, and associated with a poor prognosis. Lastly, unresected teratoma in patients with advanced NSGCT may result in late relapse (Sheinfeld, 2003). All of these events may have lethal consequences.

Initial Presentation

Signs and Symptoms

The most common presentation of testicular cancer is a painless testicular mass. Acute testicular pain is less common and is caused by rapid expansion of the testis due to intratumor hemorrhage or infarction caused by rapid tumor growth. Pain is more commonly associated with NSGCT, because these tumors tend to be more vascular and exhibit more rapid growth compared with seminomas. Patients frequently report a history of testicular trauma, although incidental trauma is likely responsible for bringing the testicular mass to the patient's attention for the first time. Patients may also complain of vague scrotal discomfort or heaviness. **Regional or distant metastasis at diagnosis is present in approximately two thirds of NSGCTs and 15% of pure seminomas, and symptoms related to metastatic disease are the presenting complaint in 10% to 20% of patients.** Bulky retroperitoneal metastasis may cause a palpable mass, abdominal pain, flank pain due to ureteral obstruction, back pain due to involvement of the psoas muscle or nerve roots, lower extremity swelling due to compression of the inferior vena cava, or gastrointestinal symptoms. Pulmonary metastasis may present as dyspnea, chest pain, cough, or hemoptysis. Metastasis to supraclavicular lymph nodes may present as a neck mass. **Approximately 2% of men have gynecomastia,** resulting from either elevated serum hCG levels, decreased androgen production, or increased estrogen levels (most commonly seen in men with Leydig cell tumors). **Although approximately two thirds of men with GCT have diminished fertility, it is an uncommon initial presentation.**

Physical Examination

The physician should carefully examine the affected and the normal contralateral testes, noting their relative size and consistency and palpating for any testicular or extratesticular masses. Atrophy of the affected or contralateral testis is common, particularly in patients with a history of cryptorchidism. Any firm area within the testis is suggestive of malignancy and should prompt further investigations. A hydrocele may accompany a testicular cancer and impair the examiner's ability to evaluate the testis. In this case, scrotal ultrasonography to evaluate the testis is warranted. The patient should also be examined for any evidence of palpable abdominal mass or tenderness, inguinal lymphadenopathy (particularly if he has had prior inguinal or scrotal surgery), gynecomastia, and supraclavicular lymphadenopathy; and auscultation of the chest should be done in a search for intrathoracic disease.

Differential Diagnosis

The differential diagnosis of a testicular mass includes epididymo-orchitis, torsion, hematoma, or paratesticular neoplasm (benign or malignant). Other diagnostic possibilities include hernia, varicocele, or spermatocele, although these usually can be distinguished from a testicular mass by physical examination. **A firm intratesticular mass should be considered cancer until proven otherwise and should be evaluated further with scrotal ultrasonography. In patients with a presumptive diagnosis of epididymo-orchitis, patients should be reevaluated within 2 to 4 weeks of completion of an appropriate course of oral antibiotics.** A persistent mass or pain should be evaluated further with scrotal ultrasonography.

Diagnostic Delay

Although testicular cancer is the most common malignancy in young adult males, diagnostic delay is a well-recognized phenomenon of this disease, with patients and physicians contributing to this delay. Testicular cancer patients are typically young and may be less inclined to seek medical evaluation for symptoms due to denial, ignorance, or limited access. In cases of diagnostic delay,

the longest period of delay has been attributed to the physician in up to two thirds of cases. **Prior studies show that up to one third of testicular tumors are initially misdiagnosed as epididymitis or hydrocele** (Bosl et al, 1981). For patients who present with signs or symptoms from metastatic GCT, these may become the focus of the treating physician, resulting in the failure to diagnose GCT. These patients may be subjected to inappropriate treatment, diagnostic tests, and unnecessary surgery with subsequent delays in definitive therapy. Case reports describe patients undergoing exploratory laparotomy, neck dissection, or mastectomy for unsuspected metastatic GCT. The interval of delay is associated with advanced clinical stage, suboptimal response to chemotherapy, and diminished survival. Moul and colleagues (1990) reported a decrease in survival in GCT patients treated from 1970 to 1987 with a diagnostic delay greater than 16 weeks, although a significant survival difference was not observed among patients treated in the cisplatin era. Stephenson and associates (2004) reported a higher proportion of men requiring intensive chemotherapy (multiple regimens, high-dose, and salvage chemotherapy) among those with a treatment delay greater than 30 days due to unnecessary exploratory laparotomy.

Diagnostic delay can be avoided by efforts to improve patient and physician education. Physicians must consider the diagnosis of GCT in any male aged 15 to 50 years with a firm testicular mass, midline retroperitoneal mass, or mass in the left supraclavicular fossa. A thorough physical examination with appropriate serologic (serum AFP, hCG, lactate dehydrogenase [LDH]) and radiologic evaluations (testicular ultrasonography) should lead to the correct diagnosis.

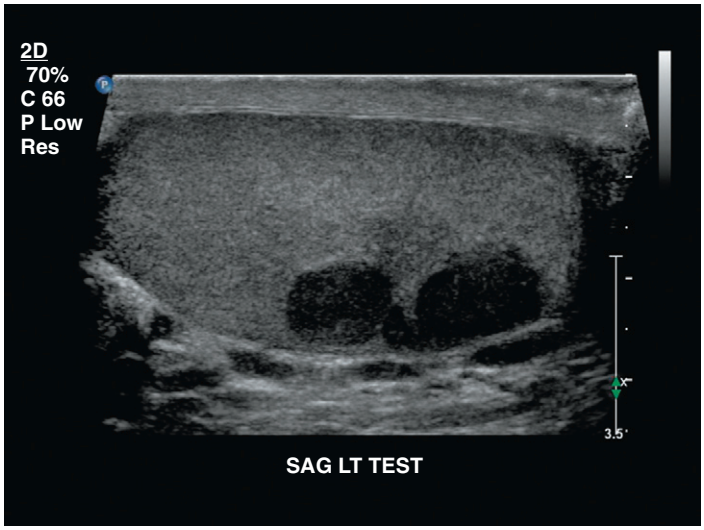

Figure 31–2. Sagittal view of left testis showing multinodular hypoechoic intratesticular lesion confirmed to be pure seminoma at orchiectomy.

Diagnostic Testing and Initial Management

Scrotal Ultrasonography

In men presenting with a testicular mass, hydrocele, or unexplained scrotal symptoms or signs, **scrotal ultrasonography should be considered an extension of the physical examination because it is widely available, inexpensive, and noninvasive.** With high-frequency transducers (5 to 10 MHz), intratesticular lesions as small as a few millimeters can be identified and readily distinguished from an extratesticular pathologic process. On ultrasonography the typical GCT is hypoechoic and two or more discrete lesions may be identified (Fig. 31–2). Heterogeneous echotexture within a lesion is more commonly associated with NSGCT, because seminomas usually have a homogeneous echotexture. The presence of increased flow within the lesion on color Doppler ultrasonography is suggestive of malignancy, although its absence does not exclude GCT. The association between testicular microlithiasis and GCT is not clearly defined, and this finding alone should not prompt further evaluation (DeCastro et al, 2008). **Given the 2% incidence of bilateral GCTs, both testes should be evaluated ultrasonographically, although bilateral tumors at diagnosis is rare (0.5% of all GCTs) and metachronous presentation is more common** (Fossa et al, 2005).

In men with advanced GCT and a normal testicular examination, scrotal ultrasonography should be performed to rule out the presence of a small, impalpable scar or calcification, indicating a "burned-out" primary testicular tumor. Radical orchiectomy should be performed in those patients with ultrasonographic evidence of intratesticular lesions. Men with advanced GCT with normal testes on physical examination and ultrasonographic evaluation are considered to have primary extragonadal GCT.

The presence of small (<10 mm), impalpable intratesticular lesions in the absence of disseminated GCT or elevated serum tumor markers represents a diagnostic dilemma. The majority of these lesions are benign (testicular cysts, small infarcts, Leydig cell nodules, or small Leydig cell or Sertoli cell tumors), although up to 20% to 40% may represent small GCTs (usually seminoma) (Hindley et al, 2003; Connolly et al, 2006; Muller et al, 2006). Management options include inguinal orchiectomy, inguinal exploration and excision (with frozen section analysis to rule out GCT), and close observation with serial ultrasonographic evaluation (with exploration of growing lesions). Intraoperative ultrasonography is useful during surgical exploration of the testis to locate the lesion. The risk of malignancy increases with the size of the lesion (Carmignani et al, 2005).

Serum Tumor Markers

Testicular cancer is one of the few malignancies associated with accurate serum tumor markers (LDH, AFP, and hCG), a finding that is essential in its diagnosis, prognosis, treatment, and monitoring. Serum tumor marker levels should be obtained at diagnosis, after orchiectomy, to monitor for response to chemotherapy, and to monitor for relapse in patients on surveillance and after completion of therapy.

At diagnosis, AFP levels are elevated in 50% to 70% of low-stage (CS I, IIA, IIB) NSGCT and 60% to 80% of advanced (CS IIC, III) NSGCT. EC and yolk sac tumors secrete AFP. Choriocarcinomas and seminomas do not produce AFP. Patients with pure seminoma in the primary tumor with an elevated serum AFP value are considered to have NSGCT. The half-life of AFP is 5 to 7 days. AFP levels may also be raised in patients with hepatocellular carcinoma and cancers of the stomach, pancreas, biliary tract, and lung. Patients with nonmalignant liver disease (infectious, drug-induced, alcohol-induced, autoimmune) may also have elevated AFP levels. Elevated serum AFP levels are also a feature of ataxic telangiectasia and hereditary tyrosinemia.

hCG levels are elevated in 20% to 40% of low-stage NSGCT and 40% to 60% of advanced NSGCT. Approximately 15% of seminomas secrete hCG. hCG is also secreted by choriocarcinoma and EC. Levels greater than 5000 IU/L are usually associated with NSGCT. The half-life of hCG is 24 to 36 hours. hCG levels may be elevated in cancers of the liver, biliary tract, pancreas, stomach, lung, breast, kidney, and bladder. The α subunit of hCG is common to several pituitary hormones, thus **immunoassays for hCG are directed at the β subunit. Cross-reactivity of the hCG assay with luteinizing hormone may cause false-positive hCG elevations in patients with primary hypogonadism.** Elevated serum hCG results caused by hypogonadism will normalize within 48 to 72 hours after the administration of testosterone, and this can be done to distinguish between true- and false-positive hCG results. Marijuana use may also cause false-positive hCG results.

LDH levels are elevated in approximately 20% of low-stage GCTs and 20% to 60% of advanced GCTs. LDH is expressed in smooth, cardiac, and skeletal muscle. Lymphoma may also cause elevated LDH levels. Of the five isoenzymes of LDH, LDH-1 is the most frequently elevated isoenzyme in GCT. LDH-1 levels are correlated with the chromosome arm 12p copy number, which is frequently amplified in GCT. The magnitude of LDH elevation correlates with the bulk of disease. As a nonspecific marker for GCT, its main use is in the prognostic assessment of GCT at diagnosis. The serum half-life of LDH is 24 hours.

Patients suspected of having a GCT should have blood drawn for serum AFP, hCG, and LDH evaluation before orchiectomy to aid in the diagnosis and to help interpret postorchiectomy tumor marker levels. For staging purposes it is relevant to know whether preorchiectomy serum tumor marker levels are declining after orchiectomy and, if so, how quickly. The results of serum tumor marker assays should not be used to guide decision making about whether to perform a radical orchiectomy, because AFP or hCG levels in the normal range do not rule out GCT. A significantly elevated serum AFP level can establish the diagnosis of NSGCT in a patient whose histopathologic diagnosis is pure seminoma because seminomas do not produce AFP. However, borderline-elevated values should be interpreted cautiously. **In rare patients who present with a testicular, retroperitoneal, or mediastinal primary tumor and whose disease burden has resulted in a need to start treatment very urgently, substantially elevated serum AFP and/or hCG levels may be considered sufficient for diagnosis of GCT.** For rare patients with medically unstable disease, treatment need not be delayed until histology results permit a tissue diagnosis. However, these patients should undergo radical orchiectomy after the completion of chemotherapy because the testis is a sanctuary site for malignant GCT owing to the blood-testis barrier and because the testis frequently contains residual invasive GCT, teratoma, and/or ITGCN (Geldart et al, 2002).

Radical Inguinal Orchiectomy

Patients suspected of having a testicular neoplasm should undergo a radical inguinal orchiectomy with removal of the tumor-bearing testis and spermatic cord to the level of the internal inguinal ring. **A transscrotal orchiectomy or biopsy is contraindicated because it leaves the inguinal portion of the spermatic cord intact and may alter the lymphatic drainage of the testis, increasing the risk of local recurrence and pelvic or inguinal lymph node metastasis.** Because of the rapid growth of GCT, orchiectomy should be performed in a timely manner and delays greater than 1 to 2 weeks should be avoided.

Radical orchiectomy establishes the histologic diagnosis and primary T stage, provides important prognostic information from the tumor histology, and is curative in 80% to 85% and 70% to 80% of CS I seminoma and CS I NSGCT, respectively.

Histopathologic examination of the testis should identify the histologic type of the tumor (see Table 31–2) (Sobin and Wittekind, 2002), tumor size, multifocality, local tumor invasion (rete testis, tunica albuginea, tunica vaginalis, epididymis, spermatic cord, scrotum), primary T stage (Table 31–3) (Sobin and Wittekind, 2002; Greene et al, 2002), presence of ITGCN, invasion of blood or lymphatic vessels (termed *lymphovascular invasion* [LVI]), and the surgical margin status. For patients with mixed GCT, each individual tumor subtype should be identified, including its relative proportion. Because of the relative rarity of GCT and the importance of primary tumor histology for treatment decision making, review of primary tumor specimens by experienced pathologists is recommended (Krege et al, 2008a). In a recent randomized, multicenter clinical trial, 5 of 382 NSGCT specimens (1.3%) were reclassified as seminomas by centralized pathologic review (Albers et al, 2008).

Testis-Sparing Surgery

Testis-sparing surgery (or partial orchiectomy) is highly controversial and has no role in the patient suspected of having a testicular neoplasm with a normal contralateral testis. However, it may be considered for organ-confined tumors of less than 2 cm in patients with synchronous bilateral tumors or tumor in a solitary testis with sufficient testicular androgen production. It may also be considered for suspected benign tumor or indeterminate lesion when serum AFP, hCG, and LDH values are normal. Testis-sparing surgery is seldom feasible for larger tumors (>2 cm) because a complete excision frequently leaves insufficient residual testicular parenchyma for preservation. **When testis-sparing surgery is performed, biopsies of the adjacent testicular parenchyma should be done to rule out the presence of ITGCN. ITGCN is present in adjacent testicular parenchyma in 80% to 90% cases of GCT and is associated with a 50% risk of GCT within 5 years and 70% within 7 years** (Skakkebaek et al, 1982; Dieckmann and Skakkebaek, 1999; Montironi, 2002). **Adjuvant radiotherapy to the residual testis using doses of 20 Gy or greater is usually sufficient to prevent the development of a GCT.** The German Testicular Cancer Study Group reported no cases of local recurrence over a median follow-up of 91 months in 46 patients with small, organ-confined tumors who underwent testis-sparing surgery and received adjuvant radiotherapy for ITGCN (Heidenreich et al, 2001).

Biopsy of the Contralateral Testis

Between 5% and 9% of patients with GCT have ITGCN in the normal contralateral testis (Dieckmann and Skakkebaek, 1999). In patients with an atrophic testis, history of cryptorchidism, or age younger than 40 years, the risk of ITGCN in the contralateral testis has been reported in up to 36% (Dieckmann and Loy, 1996). Thus an open inguinal biopsy of the contralateral testis may be considered in patients with risk factors for ITGCN or those with suspicious lesions on preoperative ultrasonography (Motzer et al, 2006).

Suspected Extragonadal GCT

Two to 5 percent of GCT are extragonadal origin (Bokemeyer et al, 2002b). Of the patients with metastatic GCT without a testicular

mass, only one third definitively has a primary extragonadal GCT, because one third has ITGCN in the testis and one third has ultrasonographic evidence of a "burned-out" primary tumor (Scholz et al, 2002). GCT should be considered in any young male with a midline mass. The presence of elevated serum AFP and/or hCG with a normal testicular evaluation is sufficient for the diagnosis of GCT, and histologic confirmation by biopsy is not necessary before starting treatment. When serum tumor markers are normal, then biopsy of the mass should be performed to confirm the diagnosis of GCT before beginning treatment. A biopsy specimen showing poorly differentiated carcinoma represents a diagnostic dilemma if a primary tumor site cannot be confirmed. In this scenario the diagnosis of extragonadal GCT with malignant transformation may be considered and supported by the expression of i(12p) in biopsy specimens.

Patients with suspected retroperitoneal extragonadal GCT should undergo inguinal orchiectomy at some point during their treatment course if the pattern of metastasis is consistent with a right- or left-sided testicular primary tumor or if there is ultrasonographic evidence of a "burned-out" primary tumor.

Table 31–3.

TNM Staging of Testicular Tumor: American Joint Committee on Cancer and Union Internationale Contre le Cancer

Primary Tumor (T)*	
The extent of primary tumor is usually classified after radical orchiectomy and, for this reason, a *pathologic* stage is assigned.	
pTx	Primary tumor cannot be assessed
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion; tumor may invade into the tunica albuginea but not the tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion, or tumor extending through the tunica albuginea with involvement of the tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion
Regional Lymph Nodes (N)	
CLINICAL (as determined by noninvasive staging)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension; or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass, more than 2 cm, but not more than 5 cm in greatest dimension; or multiple lymph nodes, any one mass greater than 2 cm but not more than 5 cm in greatest dimension
N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension
PATHOLOGIC (pN) (as determined by pathologic findings of RPLND without prior chemotherapy or radiotherapy)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and less than or equal to five nodes positive, none more than 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional nodal or pulmonary metastasis
M1b	Distant metastasis at site other than nonregional lymph nodes or lung
Serum Tumor Markers (S)	
SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH < 1.5 × N† *and* hCG (MIU/mL) <5000 *and* AFP (ng/mL) <1000
S2	LDH 1.5-10 × N *or* hCG (MIU/mL) 5000-50,000 *or* AFP (ng/mL) 1000-10,000
S3	LDH >10 × N *or* hcG (MIU/mL) >50,000 *or* AFP (ng/mL) >10,000

TNM Staging of Testicular Tumor: American Joint Committee on Cancer and Union Internationale Contre le Cancer—cont'd

Stage Grouping				
GROUP	T	N	M	S (SERUM TUMOR MARKERS)
Stage 0	pTis	N0	M0	S0
Stage I	pT1-4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2	N0	M0	S0
	pT3	N0	M0	S0
	pT4	N0	M0	S0
Stage IS	Any pT/Tx	N0	M0	S1-3
Stage II	Any pT/Tx	N 1-3	M0	SX
Stage IIA	Any pT/Tx	N1	M0	S0
	Any pT/Tx	N1	M0	S1
Stage IIB	Any pT/Tx	N2	M0	S0
	Any pT/Tx	N2	M0	S1
Stage IIC	Any pT/Tx	N3	M0	S0
	Any pT/Tx	N3	M0	S1
Stage III	Any pT/Tx	Any N	M1	SX
Stage IIIA	Any pT/Tx	Any N	M1a	S0
	Any pT/Tx	Any N	M1a	S1
Stage IIIB	Any pT/Tx	N1-3	M0	S2
	Any pT/Tx	Any N	M1a	S2
Stage IIIC	Any pT/Tx	N1-3	M0	S3
	Any pT/Tx	Any N	M1a	S3
	Any pT/Tx	Any N	M1b	Any S

*Except for pTis and pT4, extent of primary tumor is classified by radical orchiectomy. Tx may be used for other categories in the absence of radical orchiectomy.
†N indicates the upper limit of normal for the LDH assay.
AFP, α-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Key Points: Diagnosis and Initial Management

- A solid intratesticular mass in a postpubertal male should be considered a GCT until proven otherwise.
- With rare exceptions, inguinal orchiectomy with high ligation of the spermatic cord should be performed in men suspected of having GCT. Transscrotal orchiectomy or biopsy is to be condemned.
- Testis-sparing surgery for GCT is a consideration only in highly select patients who have a small tumor in either a solitary testis or synchronous bilateral testicular masses when preservation of the affected testis will provide the patient with sufficient testicular androgen production.
- Diagnostic delay is common in GCT, and approximately one third of cases are initially misdiagnosed.
- If elevated before orchiectomy, serum tumor marker levels should be measured after orchiectomy to determine if levels are declining, stable, or rising. Preorchiectomy serum tumor marker levels should not be used in management decisions.

Clinical Staging

The prognosis of GCT and initial management decisions are dictated by the clinical stage of the disease, which is based on the histopathologic findings and pathologic stage of the primary tumor, postorchiectomy serum tumor marker levels, and presence and extent of metastatic disease as determined by physical examination and staging imaging studies. In 1997 an international consensus classification for GCT was developed by the American Joint Committee on Cancer (AJCC) and Union Internationale Contre le Cancer (UICC) (see Table 31–3). The AJCC and UICC staging systems for GCT are unique because, for the first time, a serum tumor marker category (S) based on postorchiectomy AFP, hCG, and LDH levels is used to supplement the prognostic stages as defined by anatomic extent of disease. **The AJCC and UICC staging systems were updated in 2002 and the new systems consider the presence of LVI in the primary tumor as pT2 in an otherwise organ-confined tumor.** CS I is defined as disease clinically confined to the testis, CS II indicates the presence of regional (retroperitoneal) lymph node metastasis, and CS III represents nonregional lymph node and/or visceral metastasis.

Staging Imaging Studies

GCT follows a predictable pattern of metastatic spread that has contributed to its successful management. **With the exception of choriocarcinoma, the most common route of disease dissemination is via lymphatic channels from the primary tumor to the retroperitoneal lymph nodes and subsequently to distant sites. Choriocarcinoma has a propensity for hematogenous dissemination. The retroperitoneum is the initial site of metastatic spread in 70% to 80% of patients with GCT.** Detailed mapping studies from retroperitoneal lymph node dissection (RPLND) series have increased our understanding of the testicular lymphatic drainage

and identified the most likely sites of metastatic spread (Sheinfeld, 1994). **For right testicular tumors the primary drainage site is the interaortocaval lymph nodes inferior to the renal vessels, followed by the paracaval and para-aortic nodes. The primary "landing zone" for left testicular tumors is the para-aortic lymph nodes, followed by the interaortocaval nodes** (Donohue et al, 1982). The pattern of lymph drainage in the retroperitoneum is from right to left. Thus, contralateral spread from the primary "landing zone" is common with right-sided tumors but is rarely seen with left-sided tumors and usually is associated with bulky disease. **More caudal deposits of metastatic disease usually reflect retrograde spread to distal iliac and inguinal lymph nodes secondary to large volume disease and, more rarely, aberrant testicular lymphatic drainage. Retroperitoneal lymphatics drain into the cisterna chyli behind the right renal artery and right crus of the diaphragm.** Thus, retrocrural lymph node metastasis may be visible in patients with retroperitoneal disease. From there, lymphatic spread occurs via the thoracic duct to the posterior mediastinum and left supraclavicular fossa.

Clinical Staging of the Abdomen and Pelvis. All patients with GCT should undergo staging imaging studies of the abdomen and pelvis. Computed tomography (CT) after administration of oral and intravenous contrast agents is the most effective, noninvasive means of staging the retroperitoneum and pelvis. CT also provides a detailed anatomic assessment of the retroperitoneum to identify anatomic anomalies that may complicate subsequent RPLND, such as a circumaortic or retroaortic left renal vein, lower pole renal artery, or retrocaval right ureter. Magnetic resonance imaging (MRI) is an alternative to CT. Lymphangiography has no role where transaxial imaging is available.

Enlarged retroperitoneal lymph nodes are found on CT in 10% to 20% of seminomas and 60% to 70% of NSGCT. The retroperitoneum continues to be the most difficult area to accurately stage clinically. **A consistent 25% to 35% rate of pathologically involved retroperitoneal lymph nodes has been reported for CS I NSGCT in the presence of a "normal" CT scan despite the improvements in CT over the past 4 decades** (Fernandez et al, 1994). There is no consensus regarding size criteria for retroperitoneal lymph nodes that constitutes a "normal" CT scan. A size cutoff of 10 mm is frequently used to identify enlarged lymph nodes, but false-negative rates up to 63% have been reported when this size criterion is used. Among patients with CS IIA and IIB disease, clinical overstaging by CT (i.e., pathologically negative lymph nodes at RPLND despite enlarged lymph nodes on CT) is reported in 12% to 40% of patients.

An understanding of the primary drainage sites for left- and right-sided tumors has led to efforts to increase the sensitivity of abdominopelvic CT by decreasing the size criteria for clinically positive lymph nodes in the primary "landing zone," and a size criterion as small as 4 mm has been proposed. Leibovitch and colleagues (1995) showed that using a size cutoff of 4 mm in the primary landing zone and 10 mm outside this region was associated with a sensitivity and specificity for pathologic stage II disease of 91% and 50%, respectively. In a similar study, Hilton and associates (1997) reported a sensitivity and specificity of 93% and 58%, respectively, using a cutoff of 4 mm for lymph nodes in the primary "landing zone" that were anterior to a horizontal line bisecting the aorta. **Based on this evidence, retroperitoneal lymph nodes greater than 5 to 9 mm in the primary "landing zone," particularly if they are anterior to the great vessels on transaxial CT images, should be viewed with suspicion for regional lymph node metastasis** (Fig. 31–3). Because of the rapid growth of GCT, it is advisable to base the management decision on CT studies performed within 4 weeks of the initiation of treatment.

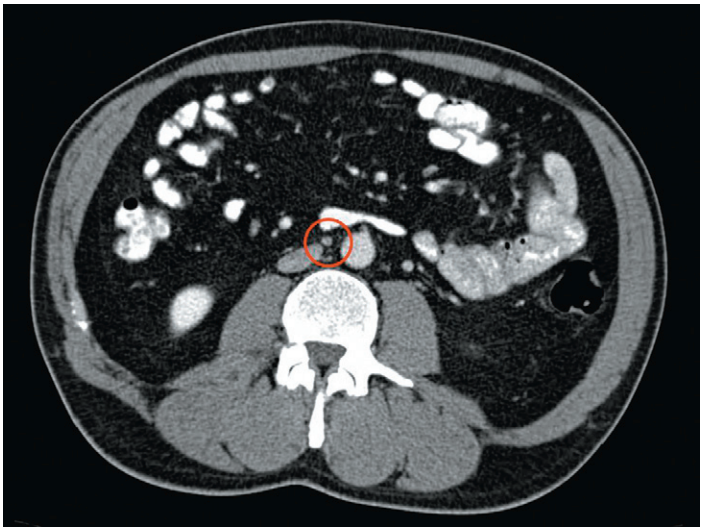

Figure 31–3. Postorchiectomy abdominopelvic CT scan in a patient with right testicular NSGCT showing a 7-mm lymph node in a primary landing zone. The lymph node was involved with teratoma at RPLND.

Malignant GCT accumulates fluorodeoxyglucose (FDG), and several studies have investigated FDG-labeled positron emission tomography (FDG-PET) in the staging of GCT at diagnosis and assessing response after chemotherapy. Several small pilot studies suggested that FDG-PET can identify retroperitoneal metastasis in low-stage seminoma and NSGCT more precisely than CT (Albers et al, 1999). In a prospective trial of centrally reviewed FDG-PET studies in 111 contemporary patients with CS I NSGCT on surveillance, relapse was observed in 33 of 87 patients who were PET negative, with an estimated relapse-free rate of 63% (Huddart et al, 2007). The investigators concluded that FDG-PET is not sufficiently sensitive to accurately stage CS I NSGCT. De Wit and associates (2008) also reported that FDG-PET yielded only slightly better results than CT as a primary staging tool for low-stage NSGCT. **Thus there is currently no role for FDG-PET in the routine evaluation of NSGCT and seminoma at the time of diagnosis.**

CS II disease is subclassified based on the size of regional lymph node(s) as determined by abdominopelvic imaging into IIA (enlarged retroperitoneal lymph nodes ≤2 cm), IIB (enlarged retroperitoneal lymph nodes >2 cm but ≤5 cm), and IIC (enlarged lymph nodes >5 cm).

Pathologic Staging of the Abdomen and Pelvis. In select centers European centers performing open RPLND and most laparoscopic RPLND series, RPLND is performed in patients with CS I or IIA NSGCT largely as a staging procedure without curative intent to identify the presence of regional lymph nodes and determine the need for subsequent chemotherapy (Nelson et al, 1999; Janetschek et al, 2000; Albers et al, 2003, 2008; Bhayani et al, 2003; Nielsen et al, 2007). Pathologic N stage differs from clinical N stage in that the former also considers the number of lymph nodes involved:

pN0: no regional lymph node metastasis
pN1: 5 or fewer lymph nodes involved, none larger than 2 cm
pN2: more than 5 lymph nodes involved and/or any lymph node of 2 to 5 cm
pN3: any lymph node larger than 5 cm

In patients with pathologic stage II disease (Any pT, pN1-3, M0), the risk of occult metastases (and relapse after RPLND) is closely related to the burden of regional lymph node metastasis (10% to 30% of pN1 vs. 50% to 80% for pN2-3). The pathologic N stage cannot be applied to RPLND specimens from patients who have received prior chemotherapy or radiotherapy.

Chest Imaging

All patients with GCT should undergo chest imaging before decisions regarding management are made. Thoracic metastasis in the absence of retroperitoneal disease and/or elevated serum tumor markers is uncommon, particularly for seminoma. Thus, routine chest CT may be associated with a high rate of false-positive findings, which may complicate subsequent therapy (Horan et al, 2007). Thus it is reasonable to perform obtain chest radiographs at the time of diagnosis as an initial staging study, and CT should be performed in patients with elevated postorchiectomy levels of serum tumor markers, evidence of metastatic disease by physical examination or abdominopelvic CT, or abnormal or equivocal findings on chest radiography. It may be reasonable to perform chest CT in patients with CS I NSGCT with evidence of LVI or EC predominance because some studies have reported a high rate of hematogenous metastasis to the lung in the setting of a negative CT for retroperitoneal metastasis (Hermans et al, 2000; Sweeney et al, 2000). Mediastinal or hilar lymphadenopathy in the absence of retroperitoneal disease should raise the index of suspicion of non-GCT etiology such as lymphoma or sarcoidosis, and histologic confirmation of GCT by mediastinoscopy and biopsy should be performed before initiating systemic therapy (Hunt et al, 2009).

Visceral metastasis to bone and brain is uncommon in GCT in the absence of symptoms or other clinical indicators of disease. As such there is no role for routine bone scintigraphy or brain CT at the time of diagnosis. A notable exception to this is brain CT for patients with a highly elevated hCG value (>10,000 IU/L) because these levels are often associated with metastati choriocarcinoma, which has a propensity for brain metastases.

Serum Tumor Markers

Postorchiectomy AFP, hCG, and LDH levels are important for staging, prognosis, and treatment selection. Thus, all patients should have blood drawn after orchiectomy to assess for appropriate decline in these markers according to half-life in those patients with elevated levels before orchiectomy. The presence of newly elevated and/or rising serum tumor marker levels after orchiectomy indicates metastatic disease, and these patients should receive induction chemotherapy as initial therapy. In the setting of a negative metastatic evaluation and slowly declining markers (i.e., not according to half-life), patients should be monitored closely and have levels checked periodically until levels normalize or begin to rise. Stable AFP or hCG levels slightly above the normal range should be interpreted cautiously, and other causes for serum tumor marker elevation should be ruled out before management decisions are made. As with staging imaging studies, management decisions should be based on serum tumor marker levels measured within 4 weeks of the initiation of treatment.

Prognostic Classification of Advanced GCT

An international, retrospective pooled analysis of 5202 patients with advanced NSGCT treated between 1975 and 1990 with platin-containing chemotherapy regimens (cisplatin or carboplatin) identified AFP, hCG, and LDH levels at the initiation of chemotherapy, the presence of nonpulmonary visceral metastasis, and primary mediastinal NSGCT as significant and independent prognostic factors for progression and survival. In 660 patients with advanced seminoma, only the presence of nonpulmonary visceral metastasis was an important predictor of progression and survival (International Germ Cell Consensus Classification, 1997).

Based on these analyses the International Germ Cell Cancer Collaborative Group (1997) **(IGCCCG) risk classification for advanced GCT was developed** (Table 31–4). **The**

Table 31–4.

International Germ Cell Cancer Collaborative Group Risk Classification for Advanced GCT

Good Prognosis	
NONSEMINOMA	SEMINOMA
Testicular/retroperitoneal primary *and* No nonpulmonary visceral metastases *and* Good markers—all of: AFP <1000 ng/mL *and* hCG <5000 IU/L (1000 ng/mL) *and* LDH <1.5 × *upper limit of normal*	Any primary site *and* No nonpulmonary visceral metastases *and* Normal AFP, any hCG, any LDH
56% of nonseminomas	90% of seminomas
5-year PFS 89%	5-year PFS 82%
5-year survival 92%	5-year survival 86%
Intermediate Prognosis	
NONSEMINOMA	SEMINOMA
Testicular/retroperitoneal primary *and* No nonpulmonary visceral metastases *and* Intermediate markers—any of: AFP ≥1000-10,000 ng/mL and ≤10,000 ng/mL *or* hCG ≥5000-50,000 IU/L and ≤50,000 IU/L *or* LDH ≥1.5 × N and ≤10 × N	Any primary site *and* Nonpulmonary visceral metastases *and* Normal AFP, any hCG, any LDH
28% of nonseminomas	10% of seminomas
5-year PFS 75%	5-year PFS 67%
5-year survival 80%	5-year survival 72%
Poor Prognosis	
NONSEMINOMA	SEMINOMA
Mediastinal primary *or* Nonpulmonary visceral metastases *or* Poor serum markers—any of: AFP >10,000 ng/mL *or* hCG >50,000 IU/L (10,000 ng/mL) *or* LDH >10 × *upper limit of normal*	No patients classified as poor prognosis
16% of nonseminomas	
5-year PFS 41%	
5-year survival 48%	

AFP, α-fetoprotein; GCT, germ cell tumor; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; PFS, progression-free survival; ULN, upper limit of normal.

From International Germ Cell Consensus Classification: a prognostic factor-based staging system for metastatic germ cell cancers. International Germ Cell Cancer Collaborative Group. J Clin Oncol 1997;15:594–603.

IGCCCG risk group should be determined for each patient with metastatic GCT and this should be used to guide treatment decision making on the choice of chemotherapy (discussed later). This classification applies only to patients with advanced GCT at the time of diagnosis and is not applicable to patients with relapsed GCT. It is also based on the postorchiectomy serum tumor marker levels at the start of chemotherapy not the preorchiectomy levels.

Approximately 56%, 28%, and 16% of patients with advanced NSGCT are classified as at good, intermediate, and poor risk by IGCCCG criteria; and the 5-year progression-free and overall survival rates for these patients are 89% and 92%, 75% and 80%, and 41% and 48%, respectively. There is no poor-risk category for seminoma. Approximately 90% and 10% of patients with advanced seminoma are classified as at good and intermediate risk, respectively, by IGCCCG criteria; and the 5-year progression-free and overall survival rates for these patients are 82% and 86% and 67% and 72%, respectively. Van Dijk and coworkers (2006) published a meta-analysis of 10 studies of 1775 NSGCT patients treated after 1989 and reported pooled 5-year survival estimates of 94%, 83% and 71% for good-, intermediate-, and poor-risk patients by IGCCCG criteria. These results represent a significantly improved survival compared with the original study (particularly for those classified as poor risk) and are attributed to more effective treatment strategies and more experience in treating NSGCT patients.

The TNM system does incorporate marker levels (S0-3) and nonpulmonary visceral metastasis in the staging of testicular cancer. However, this system does not consider the differences in prognosis between seminomas and NSGCT with nonpulmonary visceral metastasis. In the TNM system these would both be classified as stage IIIC, but IGCCCG would classify the former as intermediate risk and the latter as poor risk. As such, the IGCCCG system is preferentially used for prognostic assessment and the selection of chemotherapy.

Sperm Cryopreservation

Although infertility is an uncommon presentation for GCT, up to 52% of men have oligospermia at diagnosis and 10% are azoospermic (DH Williams et al, 2009). The germinal epithelium is exquisitely sensitive to platin-based chemotherapy and radiation therapy. **Virtually all patients will become azoospermic after chemotherapy, and 50% and 80% of patients with normal semen parameters at diagnosis will return to these levels within 2 and 5 years, respectively** (Bokemeyer et al, 1996a; Feldman et al, 2008). **Recovery of spermatogenesis after radiation therapy for seminoma may take 2 to 3 years or more** (Fossa et al, 1999b). RPLND may result in ejaculatory dysfunction in 80% or more of patients undergoing a full, bilateral template dissection without nerve sparing. **Given the impact of treatments for testicular cancer on fertility, men who are undecided or are planning future paternity are recommended to undergo sperm cryopreservation before treatment is initiated.** Sperm banking can be done before or after radical orchiectomy.

Treatment

Therapeutic Principles

The management of GCTs is governed by the potential for rapid growth and for cure in essentially all patients. **This translates into a need for rapid diagnosis and staging and expeditious application of appropriate treatment so as not to have patients die unnecessarily or suffer side effects from treatment that would not have been required with earlier diagnosis and proper management.** After orchiectomy, staging imaging studies, serum tumor marker status, and treatment plans should be performed/developed as rapidly as can be reasonably accomplished.

The probability of cure even in the presence of metastatic disease has also led to an aggressive approach with regard to the administration of chemotherapy and the performance of postchemotherapy surgery (PCS) to resect residual masses. Chemotherapy is generally administered regardless of low white blood cell counts or thrombocytopenia, and nephrotoxic chemotherapy (cisplatin) is often administered even in the presence of moderate-to-severe renal insufficiency (Williams, 1987a; Einhorn et al, 1989; Bajorin et al, 1993; Loehrer et al, 1995; Bokemeyer et al, 1996b; Nichols et al, 1998; de Wit et al, 2001). Similarly, an aggressive surgical approach is taken to resect all sites of residual disease after chemotherapy for NSGCT, even if this involves multiple anatomic sites. The young age and generally good health of GCT patients permits an aggressive treatment approach if needed.

Serum tumor markers strongly influence the management of GCTs, particularly NSGCT. As discussed, **elevated serum AFP or hCG after orchiectomy indicates the presence of metastatic disease and these patients are preferentially given chemotherapy as their initial therapy.** For patients receiving chemotherapy, rising serum tumor marker levels during or after therapy generally indicate refractory or relapsed disease, respectively. As discussed, serum AFP, hCG, and LDH levels at the initiation of chemotherapy are important prognostic factors and

Key Points: Clinical Staging

- Testicular GCT follows a predictable pattern of spread from the primary tumor to retroperitoneal lymph nodes and then to distant metastatic sites.
- The primary "landing zone" for left-sided tumors is the paraaortic and left renal hilar lymph nodes, and for right-sided tumors it is the interaortocaval and paracaval lymph nodes.
- CT is the optimal modality for staging the retroperitoneum, although false-negative results occur in 25% to 35% and 14% to 20% of patients with CS I NSGCT and seminoma, respectively, when a 1-cm cutoff is used.
- Chest radiography and CT are acceptable staging modalities in the absence of retroperitoneal lymphadenopathy or elevated serum tumor marker levels.
- Rising postorchiectomy serum tumor marker levels indicate the presence of metastatic GCT, and these patients should receive chemotherapy.
- The IGCCCG risk classification is used to evaluate the prognosis of patients with metastatic GCT and dictates the selection of chemotherapy. For NSGCT, IGCCCG risk is assigned based on the postorchiectomy serum tumor marker levels, mediastinal primary tumor, and the presence of nonpulmonary visceral metastases. For seminoma, IGCCCG risk is assigned based on the presence of nonpulmonary visceral metastases only.
- Sperm cryopreservation should be offered to all patients before RPLND, chemotherapy, or radiation therapy owing to the potential effects of these treatments on fertility.

influence the selection and duration of chemotherapy regimens (International Germ Cell Consensus Classification, 1997).

Testicular cancer is a relatively rare disease, and general urologists and general oncologists do not typically treat a large volume of GCT patients. In addition, the treatment algorithms are relatively complex and nuanced and the data supporting certain treatments, such as RPLND, are based on data from a relatively small number of surgeons who have performed a large number of these operations (Donohue et al, 1993, 1995; Heidenreich et al, 2003; Stephenson et al, 2005b; SB Williams et al, 2009). The majority of urology residents in the United States complete their training having performed two or fewer RPLND procedures (Lowrance et al, 2007). Several studies have reported improved survival when the treatment was provided at high-volume institutions (Aass, et al, 1991; Harding et al, 1993; Feuer et al, 1994; Collette et al, 1999; Joudi and Konety, 2005; Suzumura et al, 2008). Therefore, whenever possible, GCT patients should be treated at a high-volume centers and RPLND should be performed by surgeons who are experienced with this operation.

Contrasting Seminoma and NSGCT

For treatment purposes the distinction between seminoma and NSGCT holds great importance. Compared with NSGCT, seminoma has a relatively favorable natural history. In general, seminoma tends to be less aggressive, to be diagnosed at an earlier stage, and to spread predictably along lymphatic channels to the retroperitoneum before spreading hematogenously to the lungs or other organs. **At diagnosis the proportion of patients with CS I, II, and III disease is 85%, 10%, and 5%, respectively, for seminoma and approximately 33%, 33%, and 33% for NSGCT** (Powles et al, 2005). **Seminoma is also associated with a lower incidence of occult metastasis among patients with CS I (10% to 15% vs. 25% to 35% for NSGCT) and a lower risk of systemic relapse after treatment of the retroperitoneum (1% to 4% after radiotherapy for seminoma versus 10% after RPLND for NSGCT),** which has important implications for the use of chemotherapy. Seminoma is less likely to have elevated serum tumor markers, and they do not range as high as in NSGCT. Serum tumor markers are also not used in the IGCCCG risk classification of seminoma.

Compared with NSGCT, **seminoma is exquisitely sensitive to radiation therapy and platin-based chemotherapy.** Regarding the former aspect, substantially lower radiation doses are required to eradicate seminoma compared with other solid tumors. As such, **radiation therapy is a standard treatment option for CS I and IIA-B seminoma but has no role in NSGCT,** with the exception of treatment for brain metastases. Seminoma only accounts for 10% of advanced GCT cases despite the fact it accounts for 52% to 56% of all GCTs. A poor prognosis IGCCCG risk category does not exist for advanced seminoma, and over 90% of metastatic cases are classified as good risk (compared with 56% for NSGCT) (International Germ Cell Consensus Classification, 1997). **The risk of teratoma at metastatic sites is generally not a consideration for advanced seminoma, which has important implications for the management of residual masses after chemotherapy. However, the potential for seminoma to transform into NSGCT elements is an important consideration in the management of patients who fail to respond to chemotherapy or who experience relapse after radiation therapy. Of patients with metastatic seminoma who experience relapse after treatment, 10% to 15% have NSGCT elements at the site(s) of relapse. An autopsy study has shown that 30% of patients who die of seminoma have NSGCT elements at metastatic sites** (Bredael et al, 1982).

The risk of teratoma at metastatic sites has a substantial effect on treatment algorithms for NSGCT and necessitates the frequent use of PCS in patients with advanced disease. The risk of teratoma in the retroperitoneum in low-stage NSGCT has also influenced many clinicians to favor RPLND over chemotherapy in situations in which the risk of occult systemic disease is low. As discussed, teratoma is not sensitive to chemotherapy and the outcome of patients with metastatic teratoma is related to the completeness of surgical resection. Although histologically benign, teratoma has an unpredictable biology with a capacity to grow rapidly, undergo malignant transformation, or result in late relapse.

Because GCTs are almost always cured, numerous clinical trials have been conducted in an attempt to minimize treatment and avoid any unnecessary therapies in an effort to reduce short-term and particularly long-term side effects and toxicity. One such approach has been to limit the number of patients who receive two interventions ("double therapy"): either surgery or chemotherapy and not both. **However, because NSGCTs are usually mixed tumors and teratoma often exists at metastatic sites with other GCT elements, "cure" often requires chemotherapy to kill the chemosensitive components and surgery to remove teratomatous components.** It is widely accepted that the successful integration of systemic therapy and PCS is a major contributing factor to the improved cure rates for metastatic GCT seen over the past several decades. Although minimizing unnecessary treatment is an important goal, chemotherapy, radiation therapy, and CT imaging are associated with an increased lifetime risk of secondary malignant neoplasms and/or cardiovascular disease (Meinardi et al, 2000; Zagars et al, 2004; Brenner et al, 2007; van den Belt-Dusebout et al, 2007; Tarin et al, 2009). In contrast, RPLND is associated with a substantially more favorable long-term toxicity profile when performed by experienced surgeons.

Key Points: Contrasting Seminoma and NSGCT

- Compared with NSGCT, seminoma is associated with an indolent natural history with a lower incidence of metastatic disease and lower rates of occult retroperitoneal and distant metastases in patients with CS I and IIA-B disease, respectively.
- No poor-risk prognostic category exists for metastatic seminoma, and substantially more patients are classified as good risk by IGCCCG criteria compared with NSGCT.
- Seminoma is associated with increased sensitivity to radiation therapy and platin-based chemotherapy compared with NSGCT.
- Serum hCG is elevated in only 15% of patients with metastatic seminoma, and serum tumor marker levels are not used to guide treatment decisions.
- Teratoma at metastatic sites is less of a concern for seminoma compared with NSGCT but should be considered in patients whose disease fails to respond to conventional therapy.

Intratubular Germ Cell Neoplasia

ITGCN is diagnosed by testicular biopsy performed for the investigation of infertility, by biopsy of the contralateral testis in a patient with GCT, or by biopsy within the affected testis in a

patient undergoing testis-sparing surgery. The rationale for treatment of ITGCN is based on the high risk of developing invasive GCT (Skakkebaek et al, 1982; Dieckmann and Skakkebaek, 1999). Treatment options include orchiectomy, low-dose radiotherapy, and close observation. The choice of therapy should be individualized based on the patient's desire for future paternity, the presence or absence of a normal contralateral testis, and the patient's desire to avoid testosterone replacement therapy. **Radical orchiectomy is the most definitive, although low-dose radiotherapy (20 Gy) is associated with similar rates of local control with the prospect of preserving testicular endocrine function owing to the relative radioresistance of Leydig cells compared with germinal epithelium** (Heidenreich et al, 2001; Montironi, 2002; Dieckmann et al, 2003). **However, testosterone replacement therapy is ultimately required in 15% to 25% of patients and patients should be monitored after radiotherapy for adequate testicular androgen production** (Heidenreich et al, 2001). To preserve testicular endocrine function, dose reductions less than 20 Gy have been investigated but cases of recurrent ITGCN have been observed (Classen et al, 2003a; Dieckmann et al, 2003). For patients who do not desire future paternity, radiotherapy is the preferred option, although radical orchiectomy and testosterone replacement therapy is a reasonable alternative. For patients with a normal contralateral testis who desire future paternity, radical orchiectomy is preferred because scatter to the contralateral testis from radiotherapy may impair spermatogenesis. For patients with semen parameters that are abnormal but sufficient for assisted reproductive techniques, close surveillance with periodic ultrasound evaluation of the testis is a reasonable strategy with deferred therapy until successful pregnancy and/or GCT. Another option for these patients is exploration of the testis, sperm harvesting and cryopreservation for assisted reproductive techniques, and radical orchiectomy followed by testosterone replacement therapy.

Patients with ITGCN scheduled to receive cisplatin-based chemotherapy represent a unique circumstance because chemotherapy may reduce (but not eliminate) the risk of GCT. A recent study estimated the risk of testicular GCT after chemotherapy in a patient with ITGCN to be 21% and 45% at 5 and 10 years, respectively (Christensen et al, 1998). These patients may be treated by low-dose radiotherapy after completion of chemotherapy or they may undergo testicular biopsy 2 years or more after chemotherapy with therapy reserved for patients with evidence of ITGCN (Krege et al, 2008a).

Key Points: Intratubular Germ Cell Neoplasia

- ITGCN is a precursor lesion for GCT and is associated with a 50% risk of developing an invasive GCT within 5 years.
- Radical orchiectomy and low-dose (20 Gy) radiation therapy are effective treatment options for ITGCN.

NSGCT

Clinical Stage I NSGCT. Approximately one third of NSGCT patients have CS I with normal postorchiectomy levels of serum tumor markers. **The optimal management of these patients continues to generate controversy because the long-term survival associated with surveillance, RPLND, and primary chemotherapy approaches 100%.** Contributing to the controversy is the fact that occult metastases in the retroperitoneum or at distant sites are present in only 20% to 30% of patients overall. Thus, any intervention after orchiectomy, with the potential for short- and long-term morbidity, represents overtreatment for the 70% to 80% of patients with disease limited to the testis. Most centers employ a risk-adapted approach based on the probability of occult metastasis, although surveillance is the preferred approach at select centers, regardless of a man's risk.

Risk Assessment. Numerous studies have attempted to identify histopathologic factors within the primary tumor that predict for the presence of occult metastasis. **The most commonly identified risk factors for occult metastasis are LVI and a predominant component of EC.** The definition of EC predominance in the literature varies from 45% to 90%. **The reported rate of occult metastasis (based on observed relapses on surveillance or lymph node metastasis at RPLND) with LVI and EC predominance varies from 45% to 90% and 30% to 80%, respectively** (Heidenreich et al, 1998; Sogani et al, 1998; Hermans et al, 2000; Sweeney et al, 2000; Alexandre et al, 2001; Roeleveld et al, 2001; Vergouwe et al, 2003; Nicolai et al, 2004; Stephenson et al, 2005a; de Wit et al, 2008). **In the absence of these two risk factors the risk of occult metastasis is less than 20%.** Other identified risk factors include advanced pT stage, absence of mature teratoma, absence of yolk sac tumor, presence of EC (regardless of the percent composition), percentage of MIB-1 staining, tumor size, and patient age. In a pooled analysis of 23 studies assessing predictors of occult metastasis in CS I NSGCT, Vergouwe and coworkers (2003) identified LVI (odds ratio [OR] 5.2), MIB-1 staining greater than 70% (OR 4.7), and EC predominance (OR 2.8) as the strongest predictors, and these factors were present in 36%, 55%, and 51% of patients, respectively.

As discussed previously, the results of abdominopelvic CT should be considered when formulating treatment recommendations because a size cutoff of 1 cm is associated with a high false-negative rate. Retroperitoneal lymph nodes greater than 5 to 9 mm in the primary "landing zone" should be viewed with suspicion of regional lymph node metastasis.

Numerous risk groups and prognostic indices have been proposed based on the presence/absence of several of these risk factors, most commonly on the basis of LVI and EC predominance (Freedman et al, 1987; Read et al, 1992; Heidenreich et al, 1998; Sogani et al, 1998; Hermans et al, 2000; Alexandre et al, 2001; Albers et al, 2003; Nicolai et al, 2004; Stephenson et al, 2005a). **Patients classified as at low versus high risk based on LVI and EC predominance applies to the risk of occult metastatic disease in patients with CS I and should not be confused with the IGCCCG risk classification for metastatic NSGCT** (discussed previously). Only one of these prognostic models has been prospectively validated, and none has considered the results of staging CT (Freedman et al, 1987; Read et al, 1992). Three recent prospective studies suggest that LVI and EC predominance may be associated with a risk of metastasis between 35% and 45%, not 50% to 70% as has been reported in most older studies. A contemporary surveillance series from Princess Margaret Hospital reported a relapse rate of 39% among patients with LVI or pure EC (Duran et al, 2007). Likewise, a population-based surveillance study from Scandinavia reported a 42% relapse rate in patients with LVI (Tandstad et al, 2009). Lastly, only 18% of CS I NSGCT patients treated by RPLND in a randomized trial had retroperitoneal lymph node metastasis despite the fact that 42% had evidence of LVI in the primary tumor (Albers et al, 2008). This lower-than-expected rate of occult metastasis may be due to greater scrutiny of staging CT for abnormal lymph nodes and/or stage migration.

Table 31–5.

Surveillance Series for Clinical Stage I NSGCT

STUDY	NO. PATIENTS	RELAPSES (%)	MEDIAN FOLLOW-UP (mo)	MEDIAN TIME TO RELAPSE (mo)	% SYSTEMIC RELAPSE*	GCT DEATHS (%)
Read et al (1992)	373	100 (27)	60	3 (1.5-20)	39%	5 (1.3)
Daugaard et al (2003)	301	86 (29)	60	5 (1-171)	66%	0
Freedman et al (1987)	259	70 (32)	30	NR	61%	3 (1.2)

*Systemic relapse defined as relapse with elevated serum tumor markers and/or relapse in tissue other than retroperitoneal lymph nodes.
†Unpublished.
NR, not reported.

Surveillance. **The rationale for surveillance is based on the fact that 70% to 80% of patients with CS I NSGCT are cured by orchiectomy alone and the ability to salvage virtually all relapsing patients with chemotherapy based on the long-term cure rates achieved for chemotherapy for good-risk metastatic NSGCT** (International Germ Cell Consensus Classification, 1997). Surveillance offers the potential of reducing treatment-related toxicity by restricting treatment to those with a proven need for it. Surveillance series have reported overall and disease-specific survival rates indistinguishable from those seen with RPLND and primary chemotherapy. As a result, initial surveillance is regarded as a standard treatment option for CS I NSGCT. **The disadvantages of surveillance are that it is associated with the highest risk of relapse, the need for long-term (>5 years) surveillance, the potential for secondary malignant neoplasms due to intensive surveillance CT** (Brenner and Hall, 2007; Tarin et al, 2009), **and more intensive therapy required to treat patients at the time of relapse than if they had received treatment at diagnosis.**

Published surveillance series have reported results on more than 2500 men, with a mean relapse risk of 28% and a 1.2% cancer-specific mortality. The 10 largest series are summarized in Table 31–5 (Freedman et al, 1987; Read et al, 1992; Gels et al, 1995; Sogani et al, 1998; Colls et al, 1999; Sharir et al, 1999; Francis et al, 2000; Daugaard et al, 2003; Duran et al, 2007; Tandstad et al, 2009; Kollmannsberger et al, 2010b). **More than 90% of relapses occur within the first 2 years, but late relapses (>5 years) are found in up to 1% of patients (as many as 5% in some reports)** (Daugaard et al, 2003). In older surveillance series, relapse at systemic sites or with elevated serum tumor markers was common and only 30% to 40% of relapses were restricted to the retroperitoneum. In more contemporary series, 65% to 75% of relapses are contained in the retroperitoneum, with or without elevated serum tumor markers (Duran et al, 2007; Tandstad et al, 2009). **Induction chemotherapy is the most common treatment used for relapse because most patients will have bulky (>3 cm) retroperitoneal lymphadenopathy, elevated serum tumor marker levels, or distant metastasis. However, patients with normal serum tumor marker levels and relapses limited to nonbulky (<3 cm) retroperitoneal lymphadenopathy may be managed initially with RPLND** (Stephenson et al, 2007).

The surveillance schedule employed in published series is highly variable and no schedule has been demonstrated to be superior to another in terms of survival. Given that the vast majority of relapses will occur within the first 2 years, surveillance imaging and testing is intense in years 0 to 2, with less frequent testing in years 3 to 5. The risk of late relapse mandates surveillance beyond 5 years. The frequency of abdominopelvic CT varies across multiple series from 2 to 13 or more scans within the first 5 years of follow-up. A randomized trial of 2 versus 5 CT scans in years 1 and 2 reported no significant differences in survival, IGCCCG risk category at relapse, or clinical stage at relapse (Rustin et al, 2007). Noncompliance with the prescribed surveillance schedule has been reported in 35% to 80% of patients in published series (Howard et al, 1995; Hao et al, 1998). Although these patients are at risk for advanced NSGCT at relapse, excellent survival rates are achieved with surveillance despite issues with compliance.

Retroperitoneal Lymph Node Dissection. **The rationale for RPLND for CS I NSGCT is based on several factors:** (1) the retroperitoneum is the most common site of occult metastatic disease and the risk of associated systemic disease is low; (2) 15% to 25% incidence of retroperitoneal teratoma (which is resistant to chemotherapy) in those with occult metastasis; (3) low risk of abdominopelvic recurrence after full, bilateral template RPLND thereby obviating the need for routine surveillance CT; (4) high cure rates after RPLND alone for patients with low-volume (pN1) retroperitoneal malignancy and teratoma (pN1-3); (5) avoidance of chemotherapy in more than 75% or more of patients if adjuvant chemotherapy is restricted to those with extensive retroperitoneal malignancy (pN2-3); (6) high salvage rate of relapses with good-risk, induction chemotherapy; and (7) low short- and long-term morbidity when a nerve-sparing RPLND is performed by experienced surgeons. **In low-stage NSGCT the therapeutic focus is the retroperitoneum, for which RPLND provides most the effective control with the lowest rates of serious long-term morbidity. The disadvantages of RPLND are that all patients undergo major abdominal surgery, it requires the availability of experienced surgeons and thus may not be deliverable to all patients, and it is associated with the highest rate of double therapy.**

A summary of the seven largest RPLND series for CS I NSGCT is listed in Table 31–6 (Richie, 1990; Donohue et al, 1993; Hermans et al, 2000; Nicolai et al, 2004; Stephenson et al, 2005b; Albers et al, 2008; SB Williams et al, 2009). The rate of pathologic stage

PS, pathologic stage; NR, not reported.

II in these series ranges from 19% to 28%, and an estimated 66% to 81% of these patients were cured after RPLND alone (where adjuvant chemotherapy was not dictated by protocol) (Donohue et al, 1993; Hermans et al, 2000; Sweeney et al, 2000; Rabbani et al, 2001; Nicolai et al, 2004; Stephenson et al, 2005b). **The long-term cancer-specific survival with RPLND (± adjuvant chemotherapy) approaches 100%, and the risk of late relapse is negligible. Most RPLND series have reported retroperitoneal recurrences in less than 2% of patients, demonstrating its efficacy for control of the retroperitoneum** (Donohue et al, 1993; Hermans et al, 2000; Stephenson et al, 2005b).

A full, bilateral template dissection is associated with the lowest risk of abdominopelvic recurrence (<2%) and the highest rate of antegrade ejaculation (>90%) when nerve-sparing techniques are employed (Jewett, 1990; Donohue et al, 1998; Stephenson et al, 2005b; Eggener et al, 2007b; Subramanian et al, 2010). For this reason it is now considered by many to be the standard of care for primary RPLND (Stephenson and Foster, in press). A recent randomized trial of primary RPLND (+ adjuvant bleomycin-etoposide-cisplatin [BEP]×2 for pathologic stage II) versus BEP×1 chemotherapy for CS I NSGCT showed a significant improvement in 2-year progression-free survival with chemotherapy (99% vs. 92%), although no GCT deaths were observed in either arm (Albers et al, 2008). The local recurrence rate was 11% in patients with histologically negative retroperitoneal lymph nodes at RPLND, which was substantially higher than the local recurrence rate among patients treated at high-volume centers. It is noteworthy that the 191 patients undergoing RPLND in this trial were treated at 1 of 61 centers in Germany. Thus, the relative inexperience of surgeons and unilateral templates likely contributed to these poor results. **Thus, patients who opt for RPLND should have this procedure performed by an experienced surgeon with a full, bilateral template dissection. Otherwise, patients should go on surveillance or receive primary chemotherapy.**

RPLND is a curative procedure in 60% to 90% of patients with pN1 disease and up to 100% of patients with teratoma only (regardless of the extent of lymph node involvement) (Pizzocaro and Monfardini, 1984; Williams et al, 1987b; Richie and Kantoff, 1991; Rabbani et al, 2001; Sheinfeld et al, 2003; Stephenson et al, 2005b). The risk of relapse in patients with pN2-3 disease is greater than 50% (Vogelzang et al, 1983; Williams et al, 1987b; Socinski et al, 1988; Stephenson et al, 2005b). With two cycles of adjuvant chemotherapy (most commonly BEP×2 or EP×2), relapses are reduced to 1% or less (Behnia et al, 2000; Albers et al, 2003; Kondagunta et al, 2004). **A randomized trial of adjuvant chemotherapy versus observation after RPLND for pathologic stage II showed a significant reduction in the risk of relapse (6% vs. 49%) but no difference in overall survival** (Williams et al, 1987b). Adjuvant chemotherapy and observation are acceptable treatment options for patients with pathologic stage II disease, and patients should be informed of the risk of relapse after RPLND and the potential benefits and risks of these approaches.

Primary Chemotherapy. In distinction to adjuvant chemotherapy given for pathologic stage II disease after RPLND, primary chemotherapy refers to treatment administered to men with CS I NSGCT after orchiectomy. The goal of primary chemotherapy is to minimize the risk of relapse and to allow men to avoid RPLND and induction chemotherapy (for those who experience relapse on surveillance). The rationale for primary chemotherapy is based on the efficacy of two cycles of chemotherapy to eradicate micrometastatic disease when given as adjuvant therapy after RPLND and the 20% to 25% need for chemotherapy despite RPLND (either as adjuvant or for treatment of relapse) (Donohue et al, 1993; Hermans et al, 2000; Nicolai et al, 2004; Stephenson et al, 2005a). **Primary chemotherapy offers patients the greatest chance of being relapse free with any single treatment modality, and it can be delivered at community-based institutions** (Tandstad et al, 2009). **The disadvantages of primary chemotherapy are (1) it does not treat retroperitoneal teratoma and thus exposes patients to the potential for chemoresistant and/or late relapse (see later), (2) long-term surveillance CT of the retroperitoneum is required, and (3) all patients are exposed to chemotherapy and the potential risk of late toxicity (cardiovascular disease and secondary malignant neoplasms among others).** The risk of late toxicity from two cycles of chemotherapy is poorly defined, although there appears to be no safe lower limit.

Primary chemotherapy has been investigated in 11 published series, the majority of which have used BEP×2 (Table 31–7) (Abratt et al, 1994; Cullen et al, 1996; Pont et al, 1996; Ondrus et al, 1998; Bohlen et al, 1999; Amato et al, 2004; Chevreau et al, 2004; Oliver et al, 2004; Dearnaley et al, 2005; Albers et al, 2008; Tandstad et al, 2009). In men with LVI and/or EC predominance, it is possible to reduce the recurrence rate to 2% to 3% with BEP×2 chemotherapy. In 7 of the 11 series, no deaths from GCT have been observed over an average median follow-up of 5 years. In the other four studies totaling 406 patients, 13 relapses (3%) have been observed and 6 (46%) of these relapsing patients have died of GCT. **Thus, although primary chemotherapy is associated with the lowest risk of relapse, these relapses are less amenable to salvage therapy because they are chemoresistant. In contrast, patients who experience relapse after RPLND or on surveillance are chemotherapy naive**

Table 31–7.
Published Series of Primary Chemotherapy for Clinical Stage I NSGCT

	NO. PATIENTS	REGIMEN	MEDIAN FOLLOW-UP (mo)	RELAPSES	TIME TO RELAPSE (mo)	GCT DEATHS (%)
Abratt et al (1994)	20	BEP×2 (E: 360)	31	0		0
Cullen et al (1996)	114	BEP×2 (E: 360)	48	2	7, 18	2 (1.8)

E: 360, etoposide dose of 360 mg/m^2/cycle; E: 500, etoposide dose of 500 mg/m^2/cycle.

and are cured with chemotherapy in virtually all cases. Although relapses are uncommon with primary chemotherapy, virtually all occur in the retroperitoneum. This mandates the use of surveillance abdominopelvic CT in the follow-up of these patients. Many European institutions prefer BEP×2 to RPLND, because the RPLND is primarily used as a staging procedure and performed without curative intent (Krege et al, 2008a; Schmoll et al, 2009a).

A recent randomized trial and a population-based study have investigated the use of BEP×1 as primary chemotherapy for CS I NSGCT (Albers et al, 2008; Tandstad et al, 2009). Over a median follow-up of less than 5 years in both studies the risk of relapse after BEP×1 ranged from 1% to 3% and the cancer-specific survival approached 100% in both studies. BEP×1 needs to be compared with BEP×2 in a randomized trial to verify its safety and efficacy.

Treatment Selection for Clinical Stage I NSGCT. There are no randomized trials that compare the standard treatment approaches for CS I NSGCT. A recent phase III, randomized trial compared BEP×1 versus unilateral, modified-template RPLND (with BEP×2 for patients with pathologic stage II disease) (Albers et al, 2008). Although a statistically significantly reduced risk of relapse was reported with BEP×1, no cancer-specific deaths were reported in either arm. This trial has been criticized because it compared two nonstandard treatment approaches for CS I NSGCT (Sheinfeld and Motzer, 2008).

Given the excellent long-term survival with surveillance, RPLND, and primary chemotherapy, it is inappropriate to recommend any specific treatment option because there are relative advantages and disadvantages of each approach in terms of treatment-related toxicity, the need for subsequent treatment, and intensity of surveillance testing and imaging. Likewise, patient preferences may vary and should be considered. **Several clinical practice guidelines for CS I NSGCT have been published, and surveillance is generally recommended to low-risk patients and either surveillance, RPLND, or primary chemotherapy to those at high risk** (Albers et al, 2005; Motzer et al, 2006; Hotte et al, 2008; Krege et al, 2008a; Schmoll et al, 2009a; Stephenson et al, in press). Nguyen and associates (2010) have developed a decision-analysis model that considered cancer outcomes, treatment-related toxicity, and patient preferences for important post-treatment outcomes to define the optimal treatment for CS I NSGCT. Surveillance is associated with the highest quality-adjusted survival when the estimated risk of relapse is less than 33% to 37%, and active treatment (RPLND or primary chemotherapy) is favored when the risk of relapse is greater than 46% to 54%.

Clinical Stage IS NSGCT. CS IS is defined as the presence of elevated postorchiectomy serum tumor markers without clinical or radiographic evidence of metastatic disease. Studies of primary RPLND for CS IS NSGCT have reported that 37% to 100% of patients subsequently required chemotherapy for retroperitoneal metastasis, persistently elevated serum tumor markers, or relapse (Davis et al, 1994; Saxman et al, 1996). **There is consensus that these patients should be treated similar to those with CS IIC-III and receive induction chemotherapy.** The cancer-specific survival after chemotherapy for CS IS is greater than 90% (Culine et al, 1996; International Germ Cell Consensus Classification, 1997). Slightly elevated and stable serum tumor marker levels after orchiectomy in patients without clinical evidence of disease should be interpreted cautiously because they may represent false-positive results for disseminated NSGCT.

Clinical Stage IIA and IIB NSGCT. The optimal management of CS IIA-B NSGCT is controversial. **RPLND (± adjuvant chemotherapy) and induction chemotherapy (± postchemotherapy RPLND) are accepted treatment options, with survival rates exceeding 95%.** There are no randomized trials comparing these treatment approaches. In a prospective, multicenter, nonrandomized trial of RPLND and two cycles of adjuvant chemotherapy versus induction chemotherapy, no significant differences in recurrence (7% for RPLND vs. 11% for chemotherapy) or overall survival were observed (Weissbach et al, 2000). A single-institution, nonrandomized, retrospective comparison of RPLND (and two cycles of adjuvant chemotherapy for pathologic stage II) and induction chemotherapy reported a significant reduction in the risk of recurrence with induction chemotherapy (98% vs. 79%), but cancer-specific survival approached 100% with both modalities (100% vs. 98%), RPLND patients received fewer cycles of chemotherapy (mean 4.2 vs. 1.4), and 51% of RPLND patients avoided chemotherapy (Stephenson et al, 2007).

The arguments in favor of RPLND for CS IIA-B are (1) 13% to 35% of patients have pathologically negative lymph nodes and thus avoid chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007; (2) approximately 30% have retroperitoneal teratoma that is resistant to chemotherapy (Foster et al, 1996; Stephenson et al, 2007); (3) long-term cancer-specific survival is 98% to 100% with RPLND ± adjuvant chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007); (4) 10% to 52% avoid any chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007); and (5) ejaculatory function is preserved in 70% to 90% of patients (Richie and Kantoff, 1991; Donohue et al, 1995; Weissbach et al, 2000). **The disadvantages of RPLND are** (1) additional therapy is required in 48% or more of patients; (2) 13% to 15% have persistence of disease after RPLND and require a full induction chemotherapy regimen, and (3) high-quality RPLND may not be deliverable at all institutions (Weissbach et al, 2000; Stephenson et al, 2007).

The arguments in favor of induction chemotherapy are (1) 60% to 78% of patients achieve a complete response and avoid PCS; (2) treatment can be delivered at community-based institutions, and (3) cancer-specific survival is 96% to 100% (Peckham and Hendry, 1985; Logothetis et al, 1987; Socinski et al, 1988; Ondrus et al, 1992; Horwich et al, 1994; Lerner et al, 1995; Culine et al, 1997; Debono et al, 1997; Weissbach et al, 2000; Stephenson et al, 2007). **The disadvantages of chemotherapy are** (1) all patients are exposed to the risk of long-term toxicity of chemotherapy and (2) those who do not undergo post-chemotherapy RPNLD are at risk of relapse with chemorefractory GCT.

Given that 13% to 35% of patients with CS IIA NSGCT have pathologically negative lymph nodes (thus, a false-positive CT result), patients with indeterminate lesions on staging abdominopelvic CT who are at otherwise low risk for metastatic disease may be observed closely initially to clarify subsequent treatment decisions.

Treatment considerations for CS IIA-B NSGCT include the risk of occult systemic disease, risk of retroperitoneal teratoma, short- and long-term treatment-related morbidity, and need for double therapy. The last consideration is of least importance but has strongly influenced opinion regarding the optimal treatment of these patients. As discussed earlier, because metastatic NSGCT frequently exists as chemosensitive malignant GCT and chemoresistant teratoma, "cure" often requires the combination of chemotherapy and surgery.

Experience with primary RPLND in low-stage NSGCT for over the past 2 decades has identified parameters associated with systemic relapse. As with CS IS NSGCT, the presence of elevated postorchiectomy AFP and hCG are associated with an increased risk of systemic relapse after RPLND. Rabbani and associates (2001) reported relapses after RPLND in 4 of 5 patients (80%) with elevated postorchiectomy AFP or hCG compared with 7 of 45 (16%) patients with normal serum tumor markers. Stephenson and coworkers (2005b) identified the presence of elevated serum tumor markers (hazard ratio [HR] 5.6, $P < .001$) and retroperitoneal lymphadenopathy greater than 3 cm (hazard ratio [HR] 12.3, $P < .001$) as significant predictors of systemic relapse after RPLND in multivariable analysis adjusting for treatment year and the use of adjuvant chemotherapy. **Thus there is consensus that CS IIA-B NSGCT patients with elevated AFP or hCG or bulky lymph nodes (>3 cm) should receive induction chemotherapy.**

The presence of retroperitoneal teratoma is a limitation to any strategy for metastatic NSGCT that uses chemotherapy alone because it is resistant to chemotherapy. Overall, approximately 20% of CS IIA-B patients have retroperitoneal teratoma, and this increases to 30% to 35% in those with teratoma in the primary tumor (Donohue et al, 1995; Foster et al, 1996; Stephenson et al, 2005b). Residual microscopic teratoma may remain dormant and clinically silent throughout a patient's lifetime. It may also exhibit slow growth that can be detected on surveillance CT and is amenable to cure by surgical resection. However, growing teratoma syndrome, malignant transformation, and late relapse are the most serious (though rare) sequelae of unresected teratoma. **Thus RPLND is preferred as initial therapy in those patients at risk for retroperitoneal teratoma who are at otherwise low risk for systemic disease (normal serum tumor markers, lymphadenopathy <3 cm).**

Investigators at Memorial Sloan-Kettering reported the impact of these selection factors (primary chemotherapy for elevated serum tumor markers or bulky retroperitoneal lymphadenopathy and RPLND for all others) on the outcome of patients with CS IIA-B. Before these selection factors were applied, 62% of patients were treated by RPLND but 68% of patients received primary chemotherapy after these selection criteria were rigorously applied. The impact of these selection factors on outcome was a significantly improved 5-year progression-free survival (98% vs. 84%, $P = .004$) without a significant increase in the proportion of patients receiving any chemotherapy (79% vs. 70%, $P = .16$) (Stephenson et al, 2007).

Clinical Stage IIC and III NSGCT. Induction chemotherapy with cisplatin-based multiagent regimens is the initial approach used for the treatment of CS IIC and CS III NSGCT. As discussed previously, induction chemotherapy is also the preferred approach for CS IS and CS IIA-B with elevated postorchiectomy AFP and hCG. The specific regimen and number of cycles is based on the IGCCCG risk stratification (see Table 31–4) (International Germ Cell Consensus Classification, 1997).

The development of cisplatin-based chemotherapy represents the most important advancement in the treatment of GCT. Before the identification of cisplatin, complete responses to chemotherapy were achieved in 10% to 20% of patients and the cure rate was only 5% to 10% (Einhorn, 1990). Long-term cure is now anticipated in 80% to 90% of patients with metastatic GCT. Randomized trials have evaluated the efficacy and safety of various drug combinations to determine the optimal regimen based on the IGCCCG risk (International Germ Cell Consensus Classification, 1997).

The initial landmark study was conducted at Indiana University using cisplatin-vinblastine-bleomycin (PVB×4) in the 1970s and reported complete responses in 74% of patients and over 70% long-term survivors (Einhorn, 1990). When it was demonstrated that etoposide could cure some patients with relapse after PVB chemotherapy, PVB×4 was compared with bleomycin-etoposide-cisplatin (BEP×4) in a multicenter randomized trial. No significant difference in overall survival was seen between the two regimens (2-year survival 80%, $P = .11$), but BEP×4 was associated with less neuromuscular toxicity and was subsequently adopted as the standard regimen (Williams et al, 1987a).

Chemotherapy for Good-Risk NSGCT

After BEP×4 became the standard regimen for advanced GCT, subsequent trials focused on reducing toxicity for patients with good-risk features and improving outcomes for those with intermediate- and poor-risk disease. **For patients at good risk, two randomized trials have shown that BEP×3 is not inferior to BEP×4** (Einhorn et al, 1989; Saxman et al, 1998; de Wit et al,

2001). With 184 patients enrolled in the U.S. study, 92% of patients in each study arm were continuously disease free with a minimum follow-up of 1 year, and 4 deaths in each study arm at 10 years were reported (Einhorn et al, 1989). Similarly, an international European trial comparing BEP×3 versus BEP×4 in more than 800 IGCCG good-risk patients reported similar outcomes with respect to 2-year progression-free (90% vs. 89%) and overall survival (97% in each arm) (de Wit et al, 2001). With these studies, BEP×3 became the standard regimen for good-risk GCT.

To reduce toxicity, investigators have studied the effect of omitting bleomycin and substituting carboplatin for cisplatin. **All of the randomized trials in which a cisplatin regimen has been compared with a carboplatin regimen have reported superior outcomes with cisplatin** (Bajorin et al, 1993; Bokemeyer et al, 1996b, 2004; Horwich et al, 1997, 2000). **The issue of whether bleomycin can be safely omitted from cisplatin-based regimens in good-risk patients is much less clear and is one of the few remaining controversies in the management of advanced GCT.** The rationale for omitting bleomycin is based on the risk of pulmonary complications (including pulmonary fibrosis) and Raynaud phenomenon. All of these studies have shown a trend toward superiority for the bleomycin-containing regimen, although no significant survival advantage has been shown in any of the trials (Bosl et al, 1988; Levi et al, 1993). EP×3 is inferior to BEP×3 (Loehrer et al, 1995). A European randomized trial comparing BEP×4 to EP×4 (with reduced doses of etoposide) reported a significantly higher complete response rate (95% vs. 87%, $P = .008$) with BEP×3 but no difference in overall survival (de Wit et al, 1997). Most recently, a French randomized trial comparing BEP×3 with EP×4 (using conventional doses of etoposide) failed to show a statistically significant difference in the risk of relapse or survival between the two regimens (Culine et al, 2007). **Thus BEP×3 and EP×4 are both accepted regimens for advanced GCT patients with good-risk features by IGCCCG criteria, and the 5-year overall survival is 91% to 94%** (International Germ Cell Consensus Classification, 1997; van Dijk et al, 2006).

Chemotherapy for Intermediate- and Poor-Risk NSGCT. **BEP×4 has been the standard regimen for advanced GCT with intermediate- and poor-risk features since 1987, and the corresponding 5-year survival rate is 79% and 48%, respectively** (International Germ Cell Consensus Classification, 1997). Ifosfamide-based regimens using either etoposide-ifosfamide-cisplatin (VIP×4) and vinblastine-ifosfamide-cisplatin (VeIP×4) have been investigated in randomized trials compared with BEP×4 (de Wit et al, 1998; Nichols et al, 1998; Hinton et al, 2003). The multicenter U.S. trial reported results on nearly 300 men with advanced GCT, with 13%, 23%, and 64% classified as at good, intermediate, and poor risk by IGCCCG criteria, respectively (Nichols et al, 1998; Hinton et al, 2003). Comparing BEP×4 with VIP×4, the 2-year survival was 71% versus 74% and the 5-year survival was 57% versus 62%, neither of which was significantly different (Nichols et al, 1998). The European study closed prematurely because the results of the U.S. study became available. Nevertheless, with 84 patients enrolled and more than 7 years median follow-up there were 2 deaths in the BEP×4 arm and 1 in the VIP×4 arm, and overall survival at 5 years exceeded 80% (de Wit et al, 1998). Thus, in both BEP×4 versus VIP×4 trials there were more deaths with BEP×4 but the differences were not significantly different. **Because VIP×4 resulted in more high-grade hematologic and genitourinary toxicity, BEP×4 has remained the standard regimen for intermediate- and poor-risk GCT.** However, these studies showed that comparable cancer outcomes could be achieved when ifosfamide is substituted for bleomycin. **Thus, VIP×4 may be substituted for BEP×4 in patients with compromised pulmonary function and to patients in whom extensive chest surgery will likely be performed to remove residual disease after chemotherapy** (Kesler et al, 2008).

High-dose chemotherapy (HDCT) using carboplatin-etoposide–based regimens with autologous stem cell support (also termed *stem-cell rescue*) has been investigated as an alternative to BEP×4 in patients with poor prognosis GCT. The rationale for HDCT is the hypothesis that increasing dosage may overcome chemotherapy resistance. The most widely studied regimens have included carboplatin-etoposide alone or in combination with cyclophosphamide, ifosfamide, paclitaxel, or thiotepa (Beyer et al, 1996; Bokemeyer et al, 2002a; Einhorn et al, 2007; Kondagunta et al, 2007; Lorch et al, 2007; Kollmannsberger et al, 2009). Carboplatin is used in HDCT regimens because of dose-limiting nephrotoxicity and neuropathy with cisplatin. A randomized trial in 219 patients with intermediate- (21%) and poor-risk GCT (79%) randomized to BEP×4 versus BEP×2 followed by two cycles of high-dose carboplatin-etoposide-cyclophosphamide and autologous stem cell support showed no significant difference in the 1-year durable complete responses rate (48% vs. 52%, $P = .5$) or overall survival (Motzer et al, 2007). The 2-year and 5-year survival for patients in both arms was 83% and 71%, respectively. However, toxicity was more severe for patients receiving HDCT. A smaller randomized trial also failed to demonstrate an improved survival with HDCT compared with standard-dose regimens as first-line therapy for patients with poor-prognosis metastatic GCT (Droz et al, 2007). **As a result, BEP×4 remains the standard first-line regimen in patients with intermediate- and poor-risk disease.**

Although the standard chemotherapy for men with poor-risk disease has not changed in more than 20 years, the outcome of these men appears to have improved over time. In the original IGCCCG analysis, the 5-year overall survival for poor-risk patients was 48% whereas survival rates of 60% or better have been reported in subsequent multicenter randomized trials (Hinton et al, 2003; Droz et al, 2007; Culine et al, 2008). Moreover, a meta-analysis of 10 studies enrolling a total of 1775 disseminated NSGCT patients (including 456 poor-risk patients) reported that the pooled 5-year survival estimate for poor-risk patients was 71% (van Dijk et al, 2006). To what extent this improvement in reported outcomes reflects more effective treatment, prognostic-category migration due to improved staging tests, or patient selection bias is impossible to know.

Management of Postchemotherapy Residual Masses in NSGCT. To assess the response to first-line, cisplatin-based chemotherapy, patients are restaged with serum tumor markers and imaging studies of the chest-abdomen-pelvis (including other sites of disease if present before chemotherapy). **Patients are classified into the following categories based on their response to chemotherapy:** (1) complete response (CR), defined by normalization of serum tumor markers and resolution of radiographic disease (usually defined as residual masses ≤1 cm); (2) normalization of serum tumor markers with persistent radiographic tumor (partial remission–marker negative); (3) partial remission–marker positive; and (4) disease progression. **Five to 15 percent of patients fall into categories 3 and 4 and are typically managed with second-line (also termed *salvage*) chemotherapy** (Einhorn et al, 1989; Mead et al, 1992; Debono et al, 1997; de Wit et al, 1997). **There is clear consensus that patients with residual masses larger than 1 cm should undergo PCS** (Albers et al, 2005; Motzer et al, 2006; Krege et al,

2008b; Schmoll et al, 2009a). The management of patients with complete serologic and radiographic response is controversial, with some guidelines advocating close observation and others recommending PCS if prechemotherapy mass size is greater than 3 cm (Albers et al, 2005; Motzer et al, 2006; Krege et al, 2008b; Schmoll et al, 2009a).

The role of PCS for residual masses in metastatic NSGCT is well established and its rationale is based on several factors. **Multiple large series of patients undergoing PCS for residual masses after first-line chemotherapy have consistently reported evidence of persistent GCT elements in the resected specimens in 50% or more. On average, histology of resected specimens will demonstrate necrosis, teratoma, and viable malignancy (with or without teratoma) in 40%, 45%, and 15% of cases, respectively** (Table 31–8) (Toner et al, 1990; Gerl et al, 1995; Steyerberg et al, 1995, 1998; Debono et al, 1997; de Wit et al, 1997; Hartmann et al, 1997b; Sonneveld et al, 1998; Stenning et al, 1998; Hendry et al, 2002; Albers et al, 2004; Spiess et al, 2006b; Carver et al, 2007a). The 5-year overall survival of patients with complete resection of viable malignancy (with or without further chemotherapy postoperatively) ranges from 45% to 77% (Toner et al, 1990; Fox et al, 1993; Gerl et al, 1995; Hartmann et al, 1997b; Donohue et al, 1998; Stenning et al, 1998; Fizazi et al, 2001, 2008; Spiess et al, 2006a; Carver et al, 2007a). In contrast, if left unresected, residual viable malignancy is destined to relapse and only 25% to 35% of patients will achieve durable remissions to second-line chemotherapy.

As discussed earlier, teratoma is resistant to chemotherapy and is present at metastatic sites in 15% of more of patients with disseminated NSGCT. The presence of metastatic teratoma is a limitation to any strategy for NSGCT that utilizes chemotherapy alone and necessitates the integration of chemotherapy and PCS in the majority of patients with metastatic GCT. Unresected teratoma has the potential to exhibit rapid growth (growing teratoma syndrome), undergo malignant transformation, or cause late relapse, all of which may have lethal consequences. **The outcome of metastatic teratoma is related to the completeness of surgical resection, and long-term survival is reported in 75% to 90% of patients who undergo PCS for residual teratoma** (Toner et al, 1990; Hartmann et al, 1997b; Sonneveld et al, 1998; Stenning et al, 1998; Carver et al, 2007c). Lastly, infield retroperitoneal relapse occurs in fewer than 1% of patients after a full, bilateral template RPLND, largely eliminating the need for radiographic surveillance of the abdomen and pelvis (Carver et al, 2007b).

Six to 8 percent of PCS specimens will contain evidence of non-GCT malignancy, arising from malignant transformation of teratoma (Toner et al, 1990; Little et al, 1994; Carver et al, 2007c). The most common histology is rhabdomyosarcoma, and the presence of i(12p) or abnormalities of chromosome 12 in most specimens confirms its origin from GCT (Motzer et al, 1998). **As with teratoma, the outcome of patients with malignant transformation is related to the completeness of surgical resection because they are generally resistant to GCT-specific chemotherapy regimens.** With complete resection 50% to 66% of patients will survive, whereas the vast majority of patients with incomplete resection will experience rapid progression and death from GCT (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998; Lutke Holzik et al, 2003; Carver et al, 2007c). Chemotherapy specific to the transformed histology (e.g., sarcoma-specific regimen) has been investigated in two small series in select patients with measurable disease limited to one histology. Partial responses are observed in a total of 11 of 24 patients, 6 of whom are alive with PCS (Donadio et al, 2003; El Mesbahi et al, 2007).

Patients with necrosis only in the PCS specimens have a favorable prognosis, with relapse rates of 10% or less reported in most series (Toner et al, 1990; Hartmann et al, 1997b; Stenning et al, 1998; Carver et al, 2007a). However, PCS is a staging procedure only for these patients and they derive no therapeutic benefit. Investigators have sought to identify factors that reliably predict for a high probability of necrosis to obviate the need for PCS in all patients with residual masses. In an early study Donohue and colleagues (1987) reported that none of 15 patients without teratoma in the primary tumor and who achieved a 90% or greater reduction in the size of the residual mass with chemotherapy had any evidence of viable malignancy or teratoma at PCS. In contrast, 7 of 9 patients (78%) with teratoma in the primary tumor experiencing a similar reduction in the size of the metastasis with chemotherapy had evidence of viable malignancy and/or teratoma. **The absence of teratoma in the primary tumor, the percentage reduction in the retroperitoneal mass with chemotherapy, and the size of the residual mass have consistently been identified as predictors of necrosis in PCS specimens** (Toner et al, 1990; Stomper et al, 1991; Fossa

Table 31–8.

Histology of Postchemotherapy Residual Masses

	NO. PATIENTS	NECROSIS	VIABLE MALIGNANCY ± TERATOMA	TERATOMA ONLY
Steyerberg et al (1995)	556	45%	13%	42%
Carver et al (2007a)	504	49%	11%	39%
Hendry et al (2002)	330	25%	9%	66%
Debono et al (1997)	295	25%	7%	67%
Spiess et al (2006b)	236	41%	17%	42%
Albers et al (2004)	232	35%	31%	34%
Toner et al (1990)	185	47%	16%	37%
Steyerberg et al (1998)	172	45%	13%	42%
Stenning et al (1998)	153	29%	15%	55%
deWit et al (1997)	127	35%	9%	56%
Oechsle et al (2008)	121	45%	21%	34%
Sonneveld et al (1998)	113	46%	9%	45%
Gerl et al (1995)	111	47%	12%	41%
Hartmann et al (1997b)	109	52%	21%	27%

et al, 1992; Steyerberg et al, 1995, 1998; Albers et al, 2004). However, despite statistical modeling using these and other factors, a consistent false-negative rate for necrosis of 20% has been reported (Steyerberg et al, 1995, 1998; Vergouwe et al, 2001). **Thus, the presence of necrosis only in the retroperitoneum cannot be predicted with sufficient accuracy to safely obviate the need for PCS in patients with residual masses. An important concept is that the absence of teratoma in the primary tumor does not reliably exclude its presence in the retroperitoneum** (Toner et al, 1990; Beck et al, 2002). Investigators have also investigated the utility of FDG-PET in the prediction of the histology of residual masses after first-line chemotherapy. The utility of FDG-PET in the prediction of retroperitoneal histology for NSGCT is limited by the fact that teratoma is not FDG avid. In a prospective study of 121 patients with residual masses after induction chemotherapy, the predictive accuracy of FDG-PET (56%) for viable malignancy or teratoma was no better than that of CT (55%) or postchemotherapy serum tumor markers (56%) (Oechsle et al, 2008). **Thus FDG-PET has no role in the assessment of NSGCT patients with residual masses after chemotherapy.**

Twenty-six to 62 percent of patients will experience a serologic and radiographic complete response to first-line chemotherapy (Einhorn et al, 1989; Dearnaley et al, 1991; Mead et al, 1992; Debono et al, 1997; Stenning et al, 1998; Ehrlich et al, 2010; Kollmannsberger et al, 2010a). **The optimal management of these patients is controversial.** Advocates of PCS for these patients argue that residual mass size (or percentage reduction with chemotherapy) cannot be used to reliably exclude the presence of residual disease within the retroperitoneum. **Numerous studies have demonstrated that, on average, patients with residual masses 20 mm or smaller have a 30% and 6% incidence of teratoma and viable malignancy, respectively** (Table 31–9) (Fossa et al, 1989b, 1992; Toner et al, 1990; Stomper et al, 1991; Steyerberg et al, 1995; Beck et al, 2002; Oldenburg, et al, 2003; Stephenson et al, 2007). In an analysis of 295 patients with GCT managed at Indiana University where those with a complete serologic and radiographic response to chemotherapy (group A; 26%) and 90% or greater reduction in mass size without evidence of teratoma in the primary tumor (group B; 9%) were observed and those with residual masses (group C; 47%) underwent PCS, Debono and coworkers (1997) reported an improved survival for those patients in group C (94%) compared with those in group B (78%), despite the fact that the latter had a more favorable response to chemotherapy. This result highlights the therapeutic benefit of PCS for patients with residual masses. However, **Debono and colleagues** (1997) **reported a 92% survival for patients in group A, suggesting that patients who achieve a serologic and radiographic complete response can be observed. Patients in group A represented only 26% of the overall population, indicating that observation is a reasonable option for only a select group of patients.** Recently, two studies have confirmed the low risk of relapse (4% to 10%) and 97% to 100% cancer-specific survival in patients with residual masses less than 1 cm who were observed without PCS (Ehrlich et al, 2010; Kollmannsberger et al, 2010a). However, the majority of these patients were considered at good risk by IGCCCG criteria and did not have teratoma in the primary tumor, highlighting their select nature.

Approximately one third of patients will have residual masses at multiple anatomic sites (the retroperitoneum, chest, and left supraclavicular fossa are the most common), and these patients should undergo resection of all sites of measurable residual disease (Toner et al, 1990; Gerl et al, 1995; Hartmann et al, 1997a; McGuire et al, 2003). Although some centers have described performing simultaneous RPLND, thoracotomy, and/or neck dissection, the authors' practice is to perform infradiaphragmatic and supradiaphragmatic resections as separate procedures. **Discordant histology between anatomic sites is reported in 22% to 46% of cases, and different histologies in each lung have also been reported in patients undergoing bilateral thoracotomies for residual lung masses** (Toner et al, 1990). In general, the histology of PCS specimens from nonretroperitoneal sites is more likely to show necrosis (60%) and less likely to show viable malignancy (10%) and teratoma (30%) (Toner et al, 1990; Gerl et al, 1994; Hartmann et al, 1997a; Steyerberg et al, 1997). In addition to the size of residual masses and the number of anatomic sites, the presence of necrosis in postchemotherapy RPLND specimens is highly predictive of necrosis at other sites (Steyerberg et al, 1997). Of patients undergoing PCS for residual masses at different sites, only 19 of 159 (12%) who had necrosis in the RPLND specimen had either viable malignancy or teratoma at other sites (Tiffany et al, 1986; Gerl et al, 1994; Brenner et al, 1996; Steyerberg et al, 1997; Tognoni et al, 1998; McGuire et al, 2003). **Thus RPLND should be performed before PCS at other sites because the probability of residual disease in the retroperitoneum is highest and RPLND histology is a strong predictor of histology at other sites. Observation of small residual masses at other sites is a reasonable option if the histology of the RPLND specimen is necrosis.**

As mentioned, the 5-year survival for patients with viable malignancy in PCS specimens is 45% to 77%. The role of postoperative chemotherapy in this setting is controversial. Fox and colleagues (1993) reported that 14 of 27 patients (70%) undergoing PCS for viable malignancy were free of

Table 31–9.
Histology of Postchemotherapy Residual Masses Less Than 20 mm

	NO. PATIENTS	SIZE	NECROSIS	VIABLE MALIGNANCY ± TERATOMA	TERATOMA ONLY
Steyerberg et al (1995)	275	≤20 mm	65%	5%	30%
Steyerberg et al (1995)	162	≤10 mm	72%	4%	24%
Oldenburg et al (2003)	87	≤20 mm	67%	7%	26%
Fossa et al (1992)	78	<20 mm	68%	4%	29%
Fossa et al (1989a)	37	≤10 mm	67%	3%	30%
Stephenson et al (2007)	36	≤5 mm	69%	6%	25%
Toner et al (1990)	21	≤15 mm	81%	7%	12%
Stomper et al (1991)	14	≤20 mm	36%	14%	50%

recurrence with adjuvant chemotherapy versus none of 7 patients who were observed. In an international pooled analysis of 238 patients with viable malignancy in PCS specimens, Fizazi and associates (2001) identified prechemotherapy IGCCCG intermediate- and poor-risk disease, incomplete resection, and greater than 10% viable malignancy in PCS specimens as important prognostic factors. Patients with none, one, and two to three risk factors had a 5-year overall survival of 100%, 83%, and 51%, respectively. Overall, a significant improvement in 5-year relapse-free survival was observed with postoperative chemotherapy (73% vs. 64%, $P < .001$) but no difference in 5-year overall survival (74% vs. 70%, $P = .7$). In a subset analysis, patients with one risk factor had an improved 5-year survival with postoperative chemotherapy (88% vs. 56%, $P = .02$) but those with none (100% survival, with or without chemotherapy) and two to three risk factors (55% vs. 60%) did not. In a confirmatory study this prognostic index was validated for relapse-free and overall survival and no significant difference in these end points was observed among the patients who did and did not receive postoperative chemotherapy (Fizazi et al, 2008). **A complete resection of residual masses is the most critical determinant of outcome for patients with viable malignancy in PCS specimens after first-line chemotherapy. Immediate postoperative chemotherapy or surveillance may be reasonable options depending on the completeness of resection, IGCCCG risk group, and percent of viable cancer.** There is no consensus on the appropriate chemotherapy regimen and the number of cycles that should be used in this setting. The most common practice reported is two cycles of therapy using a second-line regimen. However, many centers favor using the same induction regimen (often omitting bleomycin) and up to four cycles of therapy are given.

The importance of PCS was highlighted in a randomized trial of BEP×3 versus EP×4 in 257 men with good-risk metastatic NSGCT (Culine et al, 2007). As part of this trial, PCS was not dictated by protocol and only 52% underwent PCS, which frequently involved resection of residual mass only. Overall, 14 of 20 (70%) patients with relapse of their disease and 7 of 14 (50%) of those who died of GCT either did not undergo PCS or experienced relapse in the retroperitoneum after an inadequate RPLND. **These results suggest a substantial proportion of deaths from GCT may be prevented by the appropriate integration of chemotherapy and surgery.**

Relapsing NSGCT. The treatment of relapsing NSGCTs depends on what treatment the patient has previously received and, in certain cases, the location of the relapse. Patients who have never received chemotherapy have a much more favorable prognosis than patients who have already been treated with chemotherapy for disseminated disease.

Chemotherapy-Naive NSGCT Relapse. Chemotherapy-naive relapses occur in men with CS I NSGCT managed with either surveillance or RPLND and in the men with CS IIA-B NSGCT treated with RPLND alone. Serum tumor markers are elevated 60% to 75% of the time in CS I NSGCT patients who experience relapse on surveillance (Read et al, 1992; Gels et al, 1995; Sharir et al, 1999; Alexandre et al, 2001). **In general these patients are treated with induction chemotherapy, with the specific regimen and duration of therapy determined by IGCCCG risk, and cure rates exceed 95%. Select CS I NSGCT patients on surveillance who experience relapse in the retroperitoneum with nonbulky (<3 cm) disease and normal serum tumor markers may be treated by induction chemotherapy or RPLND (particularly if teratoma was present in the primary tumor)** (Stephenson et al, 2007). The rationale for RPLND is to avoid or minimize the toxicity of chemotherapy, and long-term cure rates approach 100% with RPLND ± adjuvant chemotherapy (Stephenson et al, 2007). CS I, CS IIA, and CS IIB patients who experience relapse after RPLND will usually do so in the lungs or mediastinum. Virtually all of these patients are cured with first-line chemotherapy. The vast majority of relapses during surveillance or after RPLND occur within the first 2 years (Freedman et al, 1987; McLeod et al, 1991; Read et al, 1992; Albers et al, 1995; Gels et al, 1995; Sogani et al, 1998; Sharir et al, 1999; Colls et al, 1999; Francis et al, 2000; Daugaard et al, 2003; Stephenson et al, 2005b; Albers et al, 2008; SB Williams et al, 2009; Zuniga et al, 2009; Kollmannsberger et al, 2010a). For the rare patient experiencing relapse more than 2 years after orchiectomy or RPLND with normal tumor markers, biopsy or surgical resection should be strongly considered because of the likelihood of teratoma (Michael et al, 2000; Oldenburg et al, 2006). **Although the time to relapse is an important determinant of outcome in relapsing patients who have received prior chemotherapy, chemotherapy-naive patients who experience relapse more than 2 years after initial treatment have a similar prognosis to those who experience relapse earlier.**

Postchemotherapy NSGCT Relapse—Early. Men who experience relapse after previously receiving first-line chemotherapy are treated with second-line (also termed *salvage*) chemotherapy. **The majority of relapses will occur within 2 years of completing initial treatment, and these are classified as early relapse** (de Wit et al, 1997; Nichols et al, 1998; Michael et al, 2000; Culine et al, 2007; Motzer et al, 2007). **Relapses occurring more than 2 years after the completion of initial therapy are classified as late relapse and differ substantially in terms of prognosis and therapy** (discussed later). A subset of early relapsing patients who appear to have a particularly unfavorable prognosis are those who fail to achieve a complete response to first-line therapy or who experience relapse within 6 months of achieving a complete response; these patients are frequently termed *incomplete responders* (Fossa et al, 1999c). **In an international, pooled analysis of 1984 patients from 38 centers with relapse after first-line chemotherapy, incomplete response to induction chemotherapy (HR 1.4-1.9), primary mediastinal NSGCT (HR 3.0), nonpulmonary visceral metastasis (HR 1.3), and elevated AFP (HR 1.3-2.0) and hCG (HR 1.5) were associated with increased risk of progression with second-line chemotherapy. Overall, the 3-year progression-free and overall survival was 38% and 51%, respectively** (International Prognostic Factors Study Group et al, 2010). Second-line chemotherapy has not been investigated as extensively as first-line chemotherapy, but there is one randomized controlled trial and numerous single-arm studies that have defined current standards of care (McCaffrey et al, 1997; Loehrer et al, 1988, 1998; Mead et al, 2005; Einhorn et al, 2007; Kondagunta et al, 2005; Pico et al, 2005).

As discussed earlier, etoposide and ifosfamide were demonstrated to have substantial activity in patients with relapse after first-line chemotherapy and this led to the investigation of VIP×4 as a second-line regimen for relapse GCT after PVB×4 (Loehrer et al, 1986; Einhorn et al, 1990). VeIP×4 was also studied as a second-line regimen in men who had received prior etoposide from BEP regimens (Loehrer et al, 1988). Studies of VIP×4 and VeIP×4 reported long-term remission rates of 23% to 35% and overall survival rates of 32% to 53% (McCaffrey et al, 1997; Loehrer et al, 1998; Pico et al, 2005). Studies of paclitaxel in the early 1990s showed activity in relapsed GCT. This led to the

development of the paclitaxel, ifosfamide, and cisplatin (TIP) regimen, and relapse-free survival has been reported in 36% to 47% of patients (Kondagunta et al, 2005; Mardiak et al, 2005; Mead et al, 2005). **TIP×4, VIP×4, and VeIP×4 have never been compared in a randomized trial, and all are considered standard second-line regimens.**

HDCT has also been investigated as a second-line (and third-line) regimen in patients with GCT relapse, although its role as second-line therapy is controversial. Indiana University has amassed the largest, single-institution series involving 184 consecutive patients with metastatic GCT that progressed after first- (73%) or second-line chemotherapy (27%), 94% of whom received two or more courses of HDCT (Einhorn et al, 2007). Over a median follow-up of 4 years, 63% of patients were continuously disease free, including 70% and 45% of patients who received HDCT as second- and third-line therapy, respectively. Unfavorable prognostic variables on multivariate analysis included receiving HDCT as third-line therapy, cisplatin-refractory disease, and poor-risk disease at diagnosis by IGCCCG criteria. In an international matched-pair analysis comparing 74 patients treated at a single institution who received two to three cycles of VIP followed by one cycle of HDCT using carboplatin-etoposide-ifosfamide with 119 patients treated at multiple centers throughout Europe who received standard-dose, second-line chemotherapy using a variety of regimens, a 10% improvement was reported in event-free and overall survival with HDCT (Beyer et al, 2002). HDCT was compared to standard-dose, second-line chemotherapy in a randomized controlled trial enrolling 280 patients from 43 institutions. Patients in the standard-dose arm received VIP×4 or VeIP×4, depending on whether they received prior etoposide during first-line therapy. Patients in the HDCT study arm received VIP/VeIP×3 followed by one cycle of high-dose carboplatin-etoposide-cyclophosphamide (Pico et al, 2005). Over a median follow-up of 45 months there were no significant differences in complete and partial response rates (56% in both study arms) or the 3-year event-free (35% vs. 42%, $P = .16$) and overall survival (53% in both study arms).

There are several potential explanations for the lack of benefit of HDCT in the randomized trial despite the favorable results reported in the two nonrandomized studies. First, the results from single-arm trials may be subject to selection bias from differences in case mix. In addition, the results achieved at high-volume institutions with unique experience with HDCT may not be reproducible at other institutions. Alternatively, the treatment strategy employed in the randomized trial may have been suboptimal in that three cycles of standard-dose chemotherapy and only one cycle of HDCT were given. The treatment philosophy at Indiana University is to take patients to HDCT as quickly as possible, limit the number of cycles of standard-dose chemotherapy so patients are able to better tolerate HDCT, and to give 2 cycles of HDCT. In the randomized trial, only 73% of patients assigned HDCT were able to receive it and toxic deaths of patients in the HDCT study arm were twice as common as those in the standard-dose study arm (7% vs. 3%). In the Indiana University series 94% of patients were able to receive two cycles of HDCT and the treatment-related death rate was 2.7%. **Although HDCT as second-line therapy can cure a significant number of patients, the failure to demonstrate an improvement in survival compared with standard-dose regimens in three randomized trials (two as first-line therapy and one as second-line therapy) suggests it should not be considered a standard approach.** Currently, HDCT should only be offered at specialized centers with extensive experience.

Treatment options for high-risk patients with relapse (e.g., incomplete responders) include standard-dose, second-line chemotherapy or HDCT (if administered at a specialized, high-volume institution). Standard-dose, second-line chemotherapy is the preferred approach for patients who relapse more than 6 months after first-line chemotherapy. **Special mention is made of patients with declining or normalized serum tumor markers during first-line chemotherapy with enlarging (usually cystic) masses. These patients are considered to have growing teratoma syndrome. In these rare cases, chemotherapy is temporarily interrupted and patients are taken for surgical resection. With complete surgical resection the long-term prognosis for these patients is favorable** (Logothetis et al, 1982; Andre et al, 2000; Spiess et al, 2007).

Management of Post–Salvage Chemotherapy Residual Masses. **Patients with serologic complete response to second-line chemotherapy with residual masses should undergo post–salvage chemotherapy surgical resection (PSCS).** Patients undergoing PSCS differ from those undergoing PCS of residual masses after first-line chemotherapy in several ways. A complete resection of residual masses is feasible in only 56% to 72% of patients (compared with 85% or more after first-line therapy) (Fox et al, 1993; Debono et al, 1997; Hartmann et al, 1997b; Stenning et al, 1998; Eggener et al, 2007a). The histology of PSCS specimens is characterized by higher rates of viable malignancy (53%) and lower rates of necrosis (26%) and teratoma (21%) compared with those after first-line chemotherapy. The long-term survival of patients is also substantially poorer with 5-year survival rates of 44% to 61% in most series (Fox et al, 1993; Hartmann et al, 1997b; Donohue et al, 1998; Stenning et al, 1998). **Patients with viable malignancy in PCSC specimens have a particularly poor prognosis, and their survival is not improved with the use of postoperative chemotherapy.**

Desperation Surgery. The vast majority of patients with progressive disease despite first- and second-line chemotherapy have a dismal prognosis. **However, a highly select group of patients with rising serum tumor markers who are deemed to have resectable disease limited to a single site (usually the retroperitoneum) may be candidates for salvage surgery, commonly referred to as "desperation surgery."** Although published studies are limited to small, single-institution case series, 47% to 60% will have normalization of serum tumor marker levels postoperatively and long-term survival is reported in 33% to 57% of patients after desperation surgery ± postoperative chemotherapy (Wood et al, 1992; Murphy et al, 1993; Eastham et al, 1994; Albers et al, 2000; Beck et al, 2005).

Postchemotherapy NSGCT Relapse—Late. **Late relapse after chemotherapy is defined as that occurring more than 2 years after treatment.** Roughly 3% of NSGCT patients experience a late relapse (Ronnen et al, 2005; Oldenburg et al, 2006). Because late relapse is rare, a biopsy should be performed to confirm the diagnosis, particularly when serum AFP and hCG values are normal. **Late relapses can be divided into three histopathologic categories: viable malignancy (54% to 88%; yolk sac tumor most common), teratoma (12% to 28%), and malignant transformation (10% to 20%; adenocarcinoma most common)** (Baniel et al, 1995; Gerl et al, 1997; Michael et al, 2000; George et al, 2003; Sharp et al, 2008).

Risk factors for late relapse have not been definitively identified but a history of prior relapse and presence teratoma in PCS specimens (potentially for incomplete resection) are associated with an increased risk (Gerl et al,

1997; Sharp et al, 2008). Most men with a late relapse have only one site of disease. The majority of late relapses occur in the retroperitoneum (50% to 72%), 17% occur in the lungs, 9% in the mediastinum, 7% in the neck, and 4% in the pelvis (Baniel et al, 1995; Gerl et al, 1997; George et al, 2003; Dieckmann et al, 2005; Oldenberg et al, 2006; Sharp et al, 2008). **Thus failure to control the retroperitoneum in the initial treatment phase is a major risk factor for late relapse.** Serum AFP and hCG values are elevated in about 50% and 25% of late relapses (Oldenberg et al, 2006). Patients with elevated serum tumor marker levels as the only manifestation of late relapse should be monitored closely until there is measurable disease (George et al, 2003).

Until recently, late relapse has been associated with a worse prognosis than early relapses, although contemporary data suggest these patients may have a similar probability of cure. **In general, late relapse is resistant to chemotherapy and the outcome is related to the ability to render patients disease free by complete surgical resection** (Gerl et al, 1997; Shahidi et al, 2002; George et al, 2003; Dieckmann et al, 2005; Oldenberg et al, 2006; Sharp et al, 2008).

The importance of surgery is related to the fact that teratoma and malignant transformation are inherently chemoinsensitive and viable malignancy is usually present in the setting of prior chemotherapy (thereby, platin resistant). Of 32 patients with late relapse at Indiana University who received chemotherapy, only 6 (19%) achieved a complete response and 5 of these are in complete remission (3 of whom were chemotherapy naive). PCS successfully rendered 18 (69%) of the remaining 26 patients free of disease, 12 (46%) of whom remained in complete remission. Thus, 72% of patients treated with chemotherapy (± surgery) were rendered disease free and 53% are in complete remission. Of the 49 patients treated initially with surgery, 45 (92%) were rendered free of disease overall (22 [45%] by surgery alone) and 29 (59%) are in complete remission. Overall, 69 (85%) patients achieved a disease-free state and 58% are disease free over a median follow-up of 25 months (George et al, 2003). In the Memorial Sloan-Kettering experience, the 5-year cancer-specific survival was 60% and

Key Points: NSGCT

- The optimal management of CS I NSGCT is controversial. Surveillance, primary RPLND, and primary chemotherapy with BEP×2 are accepted treatment options, with long-term survival rates approaching 100% for each.
- A risk-adapted approach for CS I NSGCT based on the presence of LVI and EC predominance is recommended. Surveillance is recommended to patients without these risk factors and active treatment (RPLND or BEP×2) is recommended to those with LVI and/or EC predominance. A non–risk-adapted approach is employed at some centers, whereby surveillance is the recommended approach for all patients with CS I NSGCT.
- Surveillance is not recommended to patients who are anticipated to be poorly compliant with follow-up imaging and clinical evaluation. The standard treatment approach to patients who relapse on surveillance is induction chemotherapy based on the IGCCCG risk. However, select patients with normal serum tumor marker levels and nonbulky (<3 cm) retroperitoneal adenopathy may also be managed by RPLND.
- BEP×2 is the standard regimen used for patients with CS I NSGCT who choose to receive chemotherapy. There is insufficient evidence at this time to support BEP×1 as an acceptable alternative.
- A full, bilateral template with nerve sparing is the recommended approach for primary RPLND. Attempts at preserving ejaculatory function should not compromise oncologic efficacy. RPLND should be performed only by surgeons experienced with the procedure.
- Adjuvant chemotherapy after primary RPLND for pathologic stage II disease is associated with a reduced risk of relapse but no difference in long-term survival compared with an observational strategy with induction chemotherapy at the time of relapse. Adjuvant chemotherapy is usually recommended to patients with extensive retroperitoneal metastasis (pN2-3) and those anticipated to be noncompliant with postoperative cancer surveillance imaging and testing.
- Induction chemotherapy and primary RPLND are accepted treatment options for patients with CS IIA-B NSGCT, with long-term cure in 95% of more. Induction chemotherapy is favored in patients with a high risk of occult metastasis disease on the basis of elevated postorchiectomy serum tumor markers and/or bulky (>3 cm) retroperitoneal lymphadenopathy.
- The management of patients with CS IS, IIC, and III NSGCT is induction cisplatin-based chemotherapy. The specific regimen and number of cycles is dictated by IGCCCG risk criteria. Patients with good-risk disease should receive BEP×3 or EP×4, and those with intermediate- and poor-risk disease should receive BEP×4. With risk-appropriate chemotherapy and PCS, the survival of patients with good-, intermediate- and poor-risk disease is 89% to 94%, 75% to 83%, and 41% to 71%, respectively.
- Postchemotherapy resection of all residual masses is based on the incidence of residual cancer (either viable malignancy or teratoma) in 50% or more of patients.
- The use of adjuvant chemotherapy is controversial in patients with viable malignancy in residual masses after first-line chemotherapy. The outcome of patients with viable malignancy and/or teratoma in residual masses after chemotherapy is primarily influenced by the completeness of surgical resection.
- Neither the absence of teratoma in the primary tumor, size of the residual mass, nor percentage reduction in the size of the mass after first-line chemotherapy can be used to reliably exclude the presence of viable malignancy or teratoma in residual masses after first-line chemotherapy.
- The standard approach to patients who experience relapse within 2 years after first-line chemotherapy is conventional-dose, second-line chemotherapy with ifosfamide-containing regimens. HDCT should not be given outside of specialized centers. All patients with residual masses should undergo postchemotherapy resection given the 70% to 80% incidence of residual disease (viable malignancy and teratoma).
- The standard approach to patients with relapse 2 years or more after initial therapy is surgical resection of all sites of disease if feasible.

patients who had a complete surgical resection at the time of late relapse (60%) had a significantly improved survival compared with those without complete resection (40%) (79% vs. 36%, $P < .001$) (Sharp et al, 2008). The presence of symptoms and of multifocal disease at late relapse was associated with inferior survival. In a German study of 72 NSGCT patients with late relapse (51 [71%] of whom had received prior chemotherapy), 35 (49%) were in complete remission at last follow-up, most of whom were treated with a combination of chemotherapy and surgery (Dieckmann et al, 2005). The most favorable chemotherapy results for late relapse are with the TIP regimen. A study from Memorial Sloan-Kettering reported that 7 of 14 patients achieved a durable complete response to TIP plus surgical resection (Kondagunta et al, 2005). In the absence of data from randomized trials it is impossible to define optimal management, but an aggressive surgical approach to resect all disease is appropriate either as the primary treatment or, in the setting of unresectable disease, after chemotherapy. Given the rarity and complexity of these cases, referral to a specialized center is encouraged.

Seminoma

Clinical Stage I Seminoma. Approximately 80% of patients with seminoma have CS I disease, and this is the most common presentation of testicular cancer. **The management of these patients has undergone substantial changes over the past 2 decades, and surveillance, primary radiotherapy, and primary chemotherapy with single-agent carboplatin are now accepted treatment options.** Recent efforts have focused on reducing the therapeutic burden. **Platin-based chemotherapy and infradiaphragmatic radiotherapy are associated with an increased risk of late cardiovascular toxicity and secondary malignant neoplasms** (Zagars et al, 2004; Travis et al, 2005; van den Belt-Dusebout, 2007). Minimizing target volume and dose have been investigated to reduce the toxicity of radiotherapy. Carboplatin is associated with less neurotoxicity, ototoxicity, and nephrotoxicity compared with cisplatin, but the risks of cardiovascular disease and secondary malignant neoplasms are largely unknown. In many instances, the short-term efficacy and safety of these approaches has been validated by randomized trials. **The long-term cancer control with each of these modalities approaches 100%.**

Primary Radiotherapy. Until recently the mainstay of treatment for CS I seminoma for the past 4 decades had been primary radiotherapy to the retroperitoneum and ipsilateral pelvis, termed *dog-leg configuration*. Published series of radiotherapy for CS I are listed in Table 31–10 (Fossa et al, 1989a, 1999b; Warde et al, 1995, 2005; Classen et al, 2004; Jones et al, 2005; Oliver et al, 2005). **The optimal radiation dose has not been defined, and most centers use 25 to 35 Gy in 15 to 20 daily fractions** (Fossa et al, 1989a, 1999b; Warde et al, 1995). Long-term cancer-specific survival approaches 100%, and progression-free probability between 95% and 97% is reported (Fossa et al, 1989a, 1999b; Warde et al, 1995, 2005). **In-field recurrence after dog-leg radiotherapy is less than 1%,** obviating the need for routine surveillance abdominal-pelvic CT imaging. Inguinal metastases are uncommon in those without prior inguinal or scrotal surgery. **The most common sites of recurrence are the thorax and left supraclavicular fossa. Virtually all recurrences are cured with first-line chemotherapy.** Select patients with isolated inguinal relapse may be salvaged with radiotherapy or surgical resection. **The surveillance of patients after dog-leg radiotherapy consists of regular clinical assessment, chest radiography, and serum tumor markers.**

Most patients experience some acute side effects with adjuvant radiotherapy, which typically include transient nausea, vomiting, and diarrhea that are usually mild and self-limited. Acute grade II-IV hematologic toxicity occurs in 5% to 15% (Fossa et al, 1999b). Moderate and severe late gastrointestinal toxicity (usually chronic dyspepsia or peptic ulcer disease) is reported in 5% and less than 2% of patients, respectively. The testicular germinal epithelium is exquisitely sensitive to ionizing radiation, and scatter dose to the contralateral testis may be significant despite protective shielding. After dog-leg radiotherapy, persistent oligospermia is reported in 8% (Fossa et al, 1999b). The issue of late cardiac toxicity and secondary malignant neoplasms is particularly germane for these patients given the long anticipated life expectancy. **The actuarial risk of developing secondary malignant neoplasms is estimated to be 18% at 25 years after radiotherapy for seminoma** (Travis et al, 2005). Secondary leukemia is linked with radiotherapy and chemotherapy, whereas an excess of the upper gastrointestinal tract, bladder, and possibly pancreas cancers is associated with radiotherapy.

To reduce the toxicity of radiotherapy, efforts to minimize the target volume and dose have been evaluated in randomized trials. The Medical Research Council (MRC; United Kingdom) conducted a randomized trial of dog-leg versus para-aortic radiotherapy for CS I seminoma (Fossa et al, 1999b). The rationale for omitting radiotherapy to the ipsilateral pelvis is based on the low rate (1% to 3%) of pelvic lymph node involvement in patients without prior inguinal or scrotal surgery. Restricting radiotherapy to the para-aortic strip may reduce the risk of secondary malignant neoplasms and improve the recovery of spermatogenesis. The 3-year

Table 31–10.

Summary of Radiation Therapy Series for Clinical Stage I Seminoma

	NO. PATIENTS	MEDIAN FOLLOW-UP (mo)	TARGET VOLUME	MEDIAN DOSE (Gy)	GCT DEATHS (%)	RELAPSE (%)	IN-FIELD RELAPSE (%)	PELVIC RELAPSE (%)
Fossa et al (1989)	365	109	Dog leg	40	4 (1)	13 (4)	1 (0.3)	0
Warde et al (1995)	194	97	Dog leg	25	0	11 (6)	0	0

GCT, germ cell tumor.

relapse-free survival (96% vs. 97%) and overall survival (99% vs. 100%) in the para-aortic versus dog-leg study arms were similar, but patients receiving para-aortic radiotherapy had an improved short-term recovery of spermatogenesis (although no difference was seen at 3 years). However, those in the para-aortic study arm experienced a significant increase in the rate of pelvic recurrence (2% vs. 0%, $P = .04$). The small but significant risk of pelvic recurrence necessitates the use of routine surveillance pelvic CT with the associated increased cost and radiation exposure (Brenner and Hall, 2007).

The MRC and the European Organisation for the Research and Treatment of Cancer (EORTC) also conducted a randomized trial of 20-Gy versus 30-Gy PA radiotherapy for CS I seminoma (Jones et al, 2005). The 5-year relapse-free survival (96% vs. 97%) and overall survival (99.6% vs. 100%) were similar, but patients receiving 20 Gy experienced less acute gastrointestinal toxicity, leukopenia, and lethargy (although results were similar at 12 weeks). Further follow-up is necessary to assess the durability of these results.

Surveillance. Given the potential for late toxicity with dog-leg radiotherapy, the 80% to 85% cure rate after orchiectomy, and the more than 90% cure rates achieved with platin-based chemotherapy for advanced seminoma, surveillance has been evaluated at several centers. **Compared with NSGCT, surveillance for CS I seminoma is complicated by the limited utility of serum tumor markers to detect relapse and the need for long-term surveillance CT because 10% to 20% of relapses occur 4 years or more after diagnosis** (Chung et al, 2002).

The largest surveillance series for CS I seminoma are listed in Table 31–11 (Horwich et al, 1992; von der Maase et al, 1993; Warde et al, 1995, 2005; Aparicio et al, 2003, 2005; Choo et al, 2005; Daugaard et al, 2003). **The 5-year relapse-free survival ranges from 80% to 86%, and cancer-specific survival approaches 100%. Eighty-four to 100 percent of patients experience relapse in the retroperitoneum, and 18% to 24% of patients have bulky retroperitoneal disease and/or distant metastases at the time of recurrence** (Horwich et al, 1992; von der Maase et al, 1993; Warde et al, 1995; Aparicio et al, 2003). Dog-leg radiotherapy is employed for treatment of relapse in 73% to 88% of patients, and cure rates of 70% to 90% are reported. Virtually all patients who experience relapse of disease outside the retroperitoneum are cured with first-line chemotherapy.

To detect and treat recurrences at an early stage, patients on surveillance should be followed with clinical assessment, chest radiography, serum tumor marker evaluation, and abdominopelvic CT. Surveillance schedules employ assessments every 2 to 4 months in years 1 to 3, every 6 months in years 4 to 7, then annually thereafter. The necessary frequency of CT is poorly defined, and centers perform this every 4 to 6 months in years 1 to 3, every 6 months in years 4 to 7, then annually thereafter. A recent MRC trial suggested that the frequency of surveillance CT in low-risk CS I NSGCT in years 0 to 2 may be safely reduced from 5 to 2 without affecting survival or burden of therapy (Rustin et al, 2007). It is unclear whether these findings can be safely applied to surveillance for seminoma. Long-term follow-up is mandatory given the higher incidence of relapse after 5 years compared with NSGCT (Chung et al, 2002).

To better select patients for active treatment, investigators have endeavored to identify prognostic factors for occult metastasis. **In a pooled analysis of three large surveillance series from the 1980s, tumor size greater than 4 cm and invasion of the rete testis were significant predictors of relapse in multivariable analysis** (Warde et al, 2002). **Unlike NSGCT, LVI has not been identified as a significant predictor of relapse for CS I seminoma.** The 5-year relapse rate for patients with 0, 1, and 2 risk factors was 12%, 16%, and 32%, respectively. Twenty-one percent of patients in this cohort had both invasion of the rete testis and tumor size greater than 4 cm. Primary radiotherapy or carboplatin for all "high-risk" patients would still expose two thirds of CS I seminoma patients (who are cured by orchiectomy) to unnecessary therapy. However, prospective validation of these risk factors is currently lacking.

Primary Chemotherapy with Single-Agent Carboplatin. **Primary chemotherapy with one to two cycles of single-agent carboplatin** has also been investigated as an alternative to primary radiotherapy with the potential for reduced late toxicity. The rationale for single-agent carboplatin is based on the 65% to 90% reported complete response rates observed among patients with advanced seminoma (Horwich et al, 2000) and its reduced toxicity compared with cisplatin. Oliver and associates (1994) first described the use of one to two cycles of carboplatin in 78 patients and reported only two relapses and no deaths. The published studies of carboplatin in CS I seminoma are listed in Table 31–12 (Dieckmann et al, 2000; Reiter et al, 2001; Steiner et al, 2002; Aparicio et al, 2003, 2005; Oliver et al, 2005). No deaths from seminoma have been observed and 3- to 5-year relapse-free rates are 91% to 100%.

The MRC and EORTC conducted a randomized, phase III clinical trial of one cycle of carboplatin versus 20- to 30-Gy para-aortic radiotherapy in 1477 patients with CS I seminoma (Oliver et al,

Summary of Adjuvant Chemotherapy Series for Clinical Stage I Seminoma

	NO. PATIENTS	MEDIAN FOLLOW-UP (mo)	NO. CYCLES	GCT DEATHS (%)	RELAPSE (%)
Oliver et al (2005)	573	48	1	0	27 (5)
Steiner et al (2002)	108	60	2	0	2 (2)
Reiter et al (2001)	107	74	2	0	0
Dieckmann et al (2000)	93	48	1	0	8 (9)
Dieckmann et al (2000)	32	48	2	0	0
Oliver et al (1994)	78	51	2*	0	2 (2)
Aparacio et al (2003)	60	52	2	0	2 (3.3)
Aparacio et al (2005)	214	34	2	0	7 (4)

*33% of patients received 1 cycle of carboplatin.
GCT, germ cell tumor.

2005). Over a median follow-up of 4 years, the 3-year relapse-free survival was similar (96% vs. 95%) and only one death was observed in the para-aortic radiotherapy study arm. An update of this trial was recently presented in abstract form after a median follow-up of 6.5 years, and the 5-year relapse-free survival (95%) was the same in both arms of the trial (Oliver et al, 2008). The trial was designed as a noninferiority trial to exclude a risk of relapse greater than 3% with carboplatin, but the trial was only able to exclude a risk of relapse with 95% confidence greater than 3.6%; thus, the primary end point was not reached. In this trial, patients receiving carboplatin experienced less lethargy and time away from work than those receiving radiotherapy and acute grade III-IV hematologic toxicity was observed in 4% of patients.

A concern with one cycle of carboplatin is the potential for inadequate dosing, leading to an increased risk of relapse. A slightly higher relapse rate with one versus two cycles was reported in a phase 2 study, and a higher risk of relapse was reported among patients receiving an inadequate dose of carboplatin in the MRC/EORTC trial (Dieckmann et al, 2000; Oliver et al, 2008). The optimal dosing of carboplatin is calculated by the formula 7 × (glomerular filtration rate [GFR, mL/min] + 25) mg (Calvert et al, 2002). Estimated GFR using the serum creatinine level may underestimate the true GFR, leading to inadequate dosing of carboplatin. The MRC/EORTC trial calculated GFR using clearance of chromium-51–labeled ethylenediaminetetraacetic acid (EDTA) radioisotope renal scan, which is not licensed for this purpose in the United States. Available alternatives to calculate GFR include iodine-125–labeled iothalamate sodium radioisotope renal scan and 24-hour urine collection for creatinine clearance. **Carboplatin dosing should not be based on estimated GFR. Thus, it is recommended to base one cycle of carboplatin dosing on the results of radioisotope renal scans or administer two cycles of therapy.**

The equivalence of carboplatin to dog-leg radiotherapy has yet to be definitively proven, and several concerns about carboplatin approach limit its acceptance. Carboplatin is inferior to cisplatin in advanced GCT, and there is little evidence to support the notion that micrometastases will be more sensitive to carboplatin. This notion is supported by the higher risk of relapse after carboplatin for CS I seminoma (3% to 5% in most studies) compared with the 1% or less risk of relapse after two cycles of adjuvant cisplatin-based chemotherapy for pathologic stage II NSGCT after RPLND (a cohort with a substantially higher risk of relapse). Follow-up of patients treated with this approach is inadequate at this time to assess its long-term efficacy. It is also unclear whether carboplatin is associated with a substantially reduced risk of late toxicity compared with radiotherapy. Lastly, the pattern of recurrence after carboplatin is the same as that for surveillance, with the retroperitoneum being the most common (and often solitary) site of relapse (Mead et al, 2008). Thus, patients need to be followed with routine abdominopelvic CT.

Given the low overall risk of relapse with CS I seminoma, the lack of prospectively validated markers to identify a high-risk population, and the potential for late toxicity with radiotherapy and carboplatin, many clinical practice guidelines now recommend surveillance as the preferred approach (Krege et al, 2008a; Schmoll et al, 2009b). Surveillance enables 80% to 85% of patients to avoid treatment-related toxicity, and relapses are effectively salvaged with dog-leg radiotherapy in most cases. However, surveillance must be continued for more than 5 years and frequent CT imaging is required. **For noncompliant patients or those unwilling to accept surveillance, primary radiotherapy is recommended given the long-term efficacy and simplified follow-up.** The early results of single-agent carboplatin are encouraging but insufficient at this time to demonstrate equivalence with radiotherapy.

Clinical Stage IIA and IIB Seminoma. **Fifteen to 20 percent of seminoma patients have CS II disease, 70% of whom have CS IIA-B. Dog-leg radiotherapy using 25 to 30 Gy (including a 5- to 10-Gy boost to involved areas) is employed at most centers.** The higher radiation doses administered to CS IIA-B patients is generally well tolerated, with acute grade III-IV gastrointestinal toxicity reported in 8% to 10% (Classen et al, 2003b). Prophylactic radiation to the left supraclavicular fossa is no longer practiced because fewer than 3% of patients are likely to benefit (Zagars and Pollack, 2001; Chung et al, 2003). Long-term disease-free survival rates of 92% to 100% for CS IIA and 87% to 90% for CS IIB have been reported, with in-field recurrences reported in 0% to 2% and 0% to 7% of cases, respectively (Zagars and Pollack, 2001; Classen et al, 2003b; Chung et al, 2004b). **Relapses are cured in virtually all cases with first-line chemotherapy, and disease-specific survival approaches 100%. Routine surveillance CT is not necessary after complete resolution of disease.**

The Royal Marsden Hospital reported relapses in 15% and 30% of CS IIA and IIB patients, respectively with dog-leg radiotherapy alone, 87% of which occurred at distant sites (Patterson et al, 2001). To reduce the risk of relapse, the combination of single-agent carboplatin followed by 30-Gy dog-leg radiotherapy was investigated in 33 patients, and only two relapses (6%) were observed over a median follow-up of 48 months (Patterson et al,

2001). These early results are promising, but further data are required to assess the utility of this approach.

Induction chemotherapy using first-line regimens (BEP×3 or EP×4) is an accepted alternative to dog-leg radiotherapy. The Spanish Germ Cell Cancer Study Group recently reported on the use of BEP×3 or EP×4 in 72 patients with CS IIA-B seminoma (Garcia del Muro et al, 2008). Overall, 83% of patients achieved a serologic and radiographic complete response and only 1 (1.3%) had residual mass greater than 3 cm, and the 2 patients who underwent PCS for residual masses had necrosis only in the resected specimens. Overall, the 5-year relapse-free and overall survival was 90% and 95%, respectively. The rationale for chemotherapy in CS IIA-B seminoma is based on the risk of late toxicity due to dog-leg radiotherapy and the lower risk of relapse in patients with bulky retroperitoneal disease. **Induction chemotherapy is preferentially given to patients with bulky (>3 cm) and/or multiple retroperitoneal masses because the risk of relapse is lower than with dog-leg radiotherapy** (Patterson et al, 2001; Chung et al, 2004b; Garcia del Muro et al, 2008).

Clinical Stage IIC and III Seminoma. **As with NSGCT, patients with CS IIC and III seminoma are treated with induction chemotherapy, with the regimen and number of cycles determined by the IGCCCG risk. Ninety percent of patients with advanced seminoma are classified as good risk and should receive either BEP×3 or EP×4 chemotherapy.** Complete radiographic responses are reported in 70% to 90% of patients, and the 5-year overall survival is 91% (Loehrer et al, 1987; Mencel et al, 1994; International Germ Cell Consensus Classification, 1997; Gholam et al, 2003). Only 10% of advanced seminomas have nonpulmonary visceral metastasis (classified as intermediate risk by IGCCCG criteria). With BEP×4 chemotherapy, the 5-year overall and progression-free survival is 79% and 75%, respectively (International Germ Cell Consensus Classification, 1997). Single-agent carboplatin in advanced seminoma is associated with inferior survival compared with standard first-line regimens (Bokemeyer et al, 2004).

Management of Postchemotherapy Residual Masses. **After first-line chemotherapy, 58% to 80% of patients have radiologically detectable residual masses** (Motzer et al, 1987; Puc et al, 1996; Duchesne et al, 1997; Fossa et al, 1997; Herr et al, 1997; Flechon et al, 2002; De Santis et al, 2004). **Spontaneous resolution of these masses is reported in 50% to 60% of cases, and the median time to resolution is 13 to 18 months** (Flechon et al, 2002; De Santis et al, 2004). **The histology of residual masses is necrosis and viable malignancy in 90% and 10% of cases, respectively** (Puc et al, 1996; Herr et al, 1997; Ravi et al, 1999; Flechon et al, 2002; De Santis et al, 2004). **PCS for seminoma is technically difficult (and frequently not feasible) owing to the desmoplastic reaction that occurs after chemotherapy with resultant increased perioperative morbidity** (Mosharafa et al, 2003). Surgical complete resections in postchemotherapy seminoma are reported in only 58% to 74% of patients (compared with 85% or more after first-line chemotherapy for NSGCT) (Puc et al, 1996; Herr et al, 1997; Ravi et al, 1999; Flechon et al, 2002; De Santis et al, 2004). **Teratoma and malignant transformation are much less of a concern with advanced seminoma.** As such, the management of postchemotherapy residual masses differs substantially for seminoma compared with NSGCT.

Given the fact that the vast majority of postchemotherapy residual masses contain necrosis, investigators have endeavored to identify factors associated with a high risk of viable malignancy to justify PCS. **Postchemotherapy radiotherapy has no role in the management of residual masses** (Duchesne et al, 1997). **The size of residual masses is an important predictor of viable malignancy; 27% to 38% of discrete residual masses larger than 3 cm contain viable malignancy compared with 0% to 4% for masses less than 3 cm** (Puc et al, 1996; Herr et al, 1997; Flechon et al, 2002; De Santis et al, 2004). **Recently, FDG-PET has been found to be a useful adjunct to CT to select patients for PCS** (De Santis et al, 2004). FDG-PET has no role in the evaluation of residual masses in NSGCT owing to the poor uptake of FDG by teratoma; this is less of a concern with advanced seminoma. The specificity and sensitivity of a positive FDG-PET evaluation for masses greater than 3 cm were 100% and 80%, respectively. **Thus patients with discrete residual masses greater than 3 cm should be evaluated further with FDG-PET and those who are PET positive should undergo PCS. PET-negative residual masses greater than 3 cm and masses less than 3 cm should be observed.** Inflammation and residual nonviable malignancy may cause a false-positive PET result if patients are scanned too soon after completing chemotherapy. Thus FDG-PET should be delayed until at least 4 weeks after completion of chemotherapy.

Although a survival advantage associated with PCS for seminoma has yet to be definitively proven there is a therapeutic benefit because it enables an immediate assessment of tumor response and further chemotherapy can be administered in a timely fashion. PCS is also therapeutic for the rare advanced seminoma patient with teratoma at the metastatic site(s), which is reported to be present in up to one third of seminoma patients with residual masses larger than 3 cm after chemotherapy (Puc et al, 1996). In the study by Herr and colleagues (1997), all 6 patients who had complete resection of viable malignancy were disease free over a median follow-up of 45 months, including 2 patients with teratoma who were rendered disease free by resection alone. In contrast, 4 of 6 patients with unresected viable malignancy died of seminoma despite additional chemotherapy and/or radiotherapy. Although this suggests patients who undergo PCS with complete resection of residual masses have an improved survival, considering all 32 patients who had complete resection of residual masses and 72 patients with incomplete or no resection, no difference in overall survival was observed (91% vs. 93%).

Relapse Seminoma

Chemotherapy-Naive Seminoma Relapse. Chemotherapy-naïve relapse occurs in men with CS I seminoma on surveillance and in those with CS I-IIB seminoma treated with primary radiotherapy. **For the former, dog-leg radiotherapy is employed for treatment of relapse in 73% to 88% of patients and cure rates of 70% to 90% are reported. Patients with bulky (>3 cm) retroperitoneal masses and systemic relapse should receive first-line chemotherapy, and salvage rates approach 100%. First-line chemotherapy cures virtually all patients who experience relapse of their disease outside the retroperitoneum after primary radiotherapy.** Patients who experience relapse after therapy with single-agent carboplatin are considered to have a chemotherapy-naive relapse and should receive first-line cisplatin-based chemotherapy.

Postchemotherapy Seminoma Relapse—Early. **An estimated 15% to 20% of patients with advanced seminoma will experience relapse after induction chemotherapy, including 10% who achieve an initial complete response** (Loehrer

et al, 1987; Mencel et al, 1994; International Germ Cell Consensus Classification, 1997). In general, patients with an incomplete response to first-line chemotherapy or relapse after an initial major clinical response have a poor prognosis with long-term survival rates of 20% to 50% (Miller et al, 1997; Vuky et al, 2002; Gholam et al, 2003). The small number of patients with seminoma who require second-line chemotherapy has limited the evaluation of unique treatment strategies, and patients experiencing relapse of their disease are treated with regimens that were largely developed for NSGCT relapse. In two small studies the efficacy of VeIP×4 as second-line chemotherapy was evaluated in 36 patients with relapsed seminoma. Overall, 30 patients (83%) achieved a complete response to chemotherapy (with or without PCS) and 21 (53%) were continuously free of recurrence over a median follow-up of 72 to 84 months (Miller et al, 1997; Vuky et al, 2002). Vuky and colleagues (2002) also evaluated HDCT in 12 patients with advanced seminoma who had an incomplete response to first-line chemotherapy, and 6 patients (50%) achieving a complete response have remained free of recurrence. **An important consideration for patients with advanced seminoma who experience relapse after first-line chemotherapy is the potential for teratoma at the site of relapse. Thus patients with normal values of serum tumor markers should undergo biopsy before starting second-line chemotherapy.**

Postchemotherapy Seminoma Relapse—Late. In most published series, pure seminoma accounts for fewer than 8% of late relapse events (Baniel et al, 1995; George et al, 2003; Ronnen et al, 2005; Sharp et al, 2008). However, Dieckmann and coworkers (2005) reported a series of 122 patients with late relapse, of whom 50 (41%) had pure seminoma at diagnosis. Only 6 (12%) of these patients had received prior first-line chemotherapy, and the majority had received single-agent carboplatin or radiation therapy at diagnosis. Long-term cancer control was achieved in 88% of patients. **Thus late relapse of seminoma may have a favorable prognosis, particularly among patients without prior exposure to cisplatin.**

Brain Metastases

About 1% of men with disseminated GCT will have brain metastases detected before initiating chemotherapy, and between 0.4% and 3% will develop brain metastases after first-line chemotherapy (Raina et al, 1993; International Germ Cell Consensus Classification, 1997; Fossa et al, 1999a). **Brain metastases are associated with choriocarcinoma and should be suspected in any patient with a very high serum hCG level** (Fossa et al, 1999a; Kollmannsberger et al, 2000; Gremmer et al, 2008). **Choriocarcinomas are highly vascular and tend to hemorrhage during chemotherapy, and death rates of 4% to 10% due to intracranial hemorrhage have been reported** (Kollmannsberger et al, 2000; Nonomura et al, 2009). Management of these patients must consider this risk, and neurologic changes need to be evaluated expeditiously.

The 5-year overall survival in patients with brain metastases is 33% and 57% for those with disseminated NSGCT and seminoma, respectively (International Germ Cell Consensus Classification, 1997). **Men who relapse in the brain after achieving a complete response to chemotherapy appear to have a worse prognosis than those with brain involvement at diagnosis,** with overall survival rates of 39% to 44% for isolated brain metastases and 2% to 26% for those with brain metastases in association with other sites of disease (Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003; Salvati et al, 2006; Gremmer et al, 2008; Nonomura et al, 2009). Case studies and pooled analyses of GCT patients with brain metastases have reported outcomes with various treatment strategies, but there are no randomized trials to clearly define optimal management (Spears et al, 1992; Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003; Salvati et al, 2006; Gremmer et al, 2008; Nonomura et al, 2009). Treatment strategies have included chemotherapy, surgical resection, whole-brain radiation therapy, and stereotactic radiosurgery, with most patients receiving multimodal therapy. **Patients with brain metastases at diagnosis should receive BEP×4 chemotherapy followed by resection of residual masses.** The benefit of radiation therapy in this setting is unclear (Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003). At the authors' institution radiation therapy is

Key Points: Seminoma

- The optimal management of CS I seminoma is controversial. Surveillance, primary radiotherapy (20 to 30 Gy to the para-aortic region ± ipsilateral pelvis), and primary chemotherapy with carboplatin (one to two cycles) are accepted treatment options, with long-term survival rates approaching 100% for each.
- Prognostic factors for occult metastases in CS I seminoma are not as well developed as for NSGCT. Given the overall low-risk of occult metastases (15% to 20%), the inability to identify a high-risk population on the basis of histopathologic factors in the primary tumor and the potential for late toxicity with primary radiotherapy, surveillance has become the recommended treatment approach for CS I seminoma.
- Surveillance is not recommended to patients who are anticipated to be poorly compliant with follow-up imaging and clinical evaluation. The standard treatment approach to patients who relapse on surveillance is dog-leg radiotherapy (25 to 35 Gy), although patients with bulky retroperitoneal lymphadenopathy or distant metastases should receive IGCCCG risk-appropriate first-line chemotherapy.
- Primary radiotherapy and primary chemotherapy with single-agent carboplatin are associated with similar rates of cure and survival. Para-aortic radiotherapy and carboplatin both require periodic CT in the surveillance of recurrent disease after treatment; this is not required for dog-leg radiotherapy.
- Dog-leg radiotherapy (25 to 35 Gy) and first-line chemotherapy (BEP×3 or EP×4) are accepted treatment options for CS IIA-B seminoma patients with nonbulky (<3 cm) retroperitoneal lymph node metastasis. First-line chemotherapy (BEP×3 or EP×4) is recommended for bulky (>3 cm) and/or multifocal retroperitoneal metastases.
- The treatment of patients with CS IIC and III seminoma is first-line cisplatin-based chemotherapy, and the specific regimen and number of cycles is dictated by IGCCCG risk criteria. Patients with good-risk disease should receive BEP×3 or EP×4, and those with intermediate-risk disease should receive BEP×4.
- Patients with discrete, residual masses larger than 3 cm after first-line chemotherapy should undergo further evaluation with FDG-PET. Patients with PET-positive residual masses should undergo postchemotherapy surgical resection. Residual masses that are PET negative or less than 3 cm can be safely observed after chemotherapy.

only considered for patients with unresectable residual lesions not amenable to stereotactic radiosurgery owing to the concerns of radiation-induced neurotoxicity (Doyle et al, 2008). **Patients who experience relapse in the brain after first-line chemotherapy should be treated with second-line chemotherapy followed by resection and/or radiation therapy** (Fossa et al, 1999a; Hartmann et al, 2003). For men who experience relapse in the brain and at other anatomic sites the prognosis is particularly grim, particularly if it is not the first relapse.

Key Points: Brain Metastases

- Brain metastases are associated with choriocarcinoma and should be suspected in any patient with a very high serum hCG level.
- Choriocarcinomas are highly vascular and tend to hemorrhage during chemotherapy, causing intracranial hemorrhage.

Treatment-Related Sequelae

Testicular cancer treatment sequelae can be divided into late and early complications. Complications from orchiectomy and RPLND are discussed in Chapter 32 and will not be reviewed here except to note that the main issues after RPLND are midline scar, ejaculatory dysfunction, small bowel obstruction, and perioperative complications. It is also worth noting that there is an increased incidence of hypogonadism after orchiectomy for GCT.

Early Toxicity

Cisplatin-based chemotherapy is associated with numerous early complications and side effects, including fatigue, myelosuppression, infection, peripheral neuropathy, hearing loss, diminished renal function, and death. The toxic death rate has ranged from 0% to 2.4% during chemotherapy for good-risk disease and from 3.0% to 4.4% during standard first-line chemotherapy for intermediate- and poor-risk disease (Nichols et al, 1998; de Wit et al, 2001, 2008; Toner et al, 2001; Culine et al, 2007, 2008). The impact of chemotherapy and radiation therapy on spermatogenesis has been discussed previously. Most men are able to father children after treatment for GCT, but paternity rates are lower for men treated with radiation therapy and/or chemotherapy (Huyghe et al, 2004; Brydoy et al, 2005). Early complications of radiation therapy include fatigue, nausea and vomiting, leukopenia, and dyspepsia (Fossa et al, 1999b; Jones et al, 2005; Oliver et al, 2005).

Late Toxicity

Numerous long-term sequelae have been reported in GCT survivors, including peripheral neuropathy, Raynaud phenomenon, hearing loss, hypogonadism, infertility, secondary malignant neoplasms, and cardiovascular disease (Brydoy et al, 2005, 2009; Rossen et al, 2009). Symptoms of Raynaud phenomenon and peripheral neuropathy have been reported in 20% to 45% and 14% to 43%, respectively, and the risk appears to increase with increasing cumulative doses of cisplatin (Brydoy et al, 2009; Rossen et al, 2009). Significant hearing loss and/or tinnitus after cisplatin-based chemotherapy is reported in 20% to 40% of patients and can be documented via audiometry in 30% to 75%. Hypogonadism has been documented in 10% to 20% of patients treated with orchiectomy alone, 15% of patients treated with radiation therapy, and 20% to 25% of men treated with first-line chemotherapy regimens (Nord et al, 2003; Lackner et al, 2009).

Large population-based studies of GCT survivors have reported an increased risk of death from gastrointestinal and cardiovascular diseases after radiation therapy and an increased risk of death from infections and cardiovascular and pulmonary diseases after chemotherapy (Fossa et al, 2007). Patients treated with both radiation and chemotherapy have the highest risk of death from nonmalignant causes. The increased incidence and mortality of cardiovascular disease in GCT survivors is particularly well documented (van den Belt-Dusebout et al, 2007; Meinardi et al, 2000; Huddart et al, 2003; Fossa et al, 2007, 2009). The causes of these cardiovascular complications are not well understood, but putative contributing factors are radiation- or chemotherapy-induced vascular injury, as well as chemotherapy-induced cardiac injury and metabolic syndrome (Nuver et al, 2005; Altena et al, 2009).

The risk of second malignant neoplasms is a particular concern. The incidence of non–germ cell malignancies is 60% to 100% higher in GCT survivors treated with cisplatin-based chemotherapy or radiation therapy compared with the general population and 200% higher in patients who received both radiation and chemotherapy (Travis et al, 2005; Richiardi et al, 2007). The risk of death from non–germ cell malignancies in GCT survivors treated with radiation or chemotherapy is less well defined but appears to be doubled compared with the general population (Fossa et al, 2004). The frequent use of body CT in the surveillance of patients after therapy is another source of radiation that may increase the risk of secondary malignant neoplasms (Brenner and Hall, 2007; Chamie et al, 2008; Tarin et al, 2009).

Key Points: Treatment-Related Sequelae

- All treatments for GCT (surgery, radiotherapy, and chemotherapy) are associated with risks of early and late toxicity.
- The late complications of most concern are cardiovascular disease and secondary malignant neoplasms.
- With the successful cure of patients (even those with advanced disease), an important treatment objective is minimizing treatment-related toxicity without compromising curability.

NON–GERM CELL TUMORS

Sex Cord/Stromal Tumors

Sex cord/stromal tumors are rare, comprising approximately 4% of testicular neoplasms, and the term refers to neoplasms containing Leydig cells, Sertoli cells, granulosa cells, or thecal cells.

Leydig Cell Tumors

Leydig cell tumors are the most common of the sex cord/stromal tumors. There is no association with cryptorchidism. Most of these tumors occur in adult males between age 20 and 60 years, although approximately one fourth occur in children. In adults, the most common presentation is a painless testicular mass, frequently with feminizing characteristics (as a result of androgen excess and peripheral conversion to estrogen), including gynecomastia, impotence, and decreased libido. Children usually present with a

testicular mass and isosexual precocious puberty (prominent external genitalia, pubic hair growth, and masculine voice).

Radical inguinal orchiectomy is the initial treatment of choice. Ninety percent of these tumors are benign, and 10% are malignant. Benign lesions are usually small, yellow to brown, well circumscribed, and without areas of necrosis of hemorrhage. Histologically, the tumors consist of uniform polygonal cells with round nuclei. Reinke crystals are present in 25% to 40% of cases and appear as densely eosinophilic needle-like or rhomboid structures within the cytoplasm. These tumors must be distinguished from Leydig cell hyperplasia that occur in atrophic testes and adjacent to GCTs, in which Leydig cells infiltrate between seminiferous tubules without displacing or obliterating them. **Although large size, necrosis, nuclear pleomorphism, and increased mitotic activity may occur and suggest malignant Leydig cell tumor there are no consistently reliable histologic criteria for making this judgment.** The presence of metastatic disease is the only reliable criteria for making this distinction. Malignant behavior has not been reported in a prepubertal patient. Older patients are more likely to have malignant tumors. **The most frequent metastatic sites are the retroperitoneum and lung. If the pathologic features raise the suspicion for malignancy, abdominopelvic CT and chest radiography should be performed. RPLND is reasonable in select cases with adverse features.** Surveillance of men with Leydig cell tumors is not necessary in those without clinical or pathologic features suggestive of malignancy. **Metastatic Leydig cell tumors are resistant to chemotherapy and radiation therapy.** Mitotane (Lysodren), a potent inhibitor of steroidogenesis, may produce partial responses in metastatic patients with excess androgen production, but cure is not possible (Schwarzman et al, 1989).

Sertoli Cell Tumor

These tumors comprise less than 1% of testicular neoplasms. They can occur in any age group, including infants. There is no association with cryptorchidism. Gynecomastia is evident in one third of patients. Treatment is radical inguinal orchiectomy. The tumors are well circumscribed and yellow-white or tan, with uniform consistency. Microscopically the tumors contain epithelial elements resembling Sertoli cells with varying amounts of stroma organized into tubules. **Ninety percent of tumors are benign, and 10% are malignant. Because of its rarity there are no reliable histologic criteria associated with malignancy.** The presence of metastasis is the only reliable criterion. RPLND may be considered if the suspicion of malignancy is high or if retroperitoneal adenopathy exists. Radiation therapy and chemotherapy are ineffective. Surveillance of men with Sertoli cell tumors is not necessary in those without clinical or pathologic features suggestive of malignancy.

Granulosa Cell Tumors

Granulosa cell tumors of the testis are exceedingly rare and resemble adult-type granulosa cell tumors of the ovary. Gynecomastia and increased estrogen secretion are common. Radical inguinal orchiectomy is curative because these tumors appear to have limited metastatic potential.

Gonadoblastoma

Gonadoblastoma is a mixed germ cell/sex cord/stromal tumor composed of seminoma-like germ cells and sex cord cells showing Sertoli differentiation. They occur almost exclusively in patients with dysgenic gonads and intersex syndromes. Eighty percent of affected individuals are phenotypic females, usually presenting with primary amenorrhea. The remainder of patients are phenotypic males, almost always presenting with cryptorchidism (with the dysgenic gonad in the inguinal or abdominal location), hypospadias, and some form of female internal genitalia. One third of cases are bilateral (Scully, 1970). **These tumors should be considered an in-situ form of malignant GCT, because approximately 50% will develop an invasive GCT (usually seminoma, although yolk sac tumor and EC can occur)** (Ulbright, 2004). Gonadoblastomas do not metastasize, but the malignant GCT elements may. **Bilateral orchiectomy is required because of the risk of bilateral tumors.** For patients with malignant GCT, subsequent workup for metastatic disease ± treatment should be initiated.

Miscellaneous Testicular Neoplasms

Epidermoid Cyst

These rare benign neoplasms are thought to represent monodermally differentiated mature teratoma, because a case with adjacent ITGCN has been identified and association with cryptorchidism and bilaterality have been reported (Younger et al, 2003). Grossly they are well-circumscribed cystic masses filled with keratinized debris, similar to an epidermal inclusion cyst. They have a characteristic ultrasonographic appearance. **Enucleation or partial orchiectomy may be performed, although the lesion should be thoroughly sampled by a pathologist to rule out GCT or ITGCN.**

Adenocarcinoma of the Rete Testis

Adenocarcinoma of the rete testis is a rare but highly malignant neoplasm arising from the collecting system of the testis. The usual presentation is a painless testicular mass with hydrocele. More than 50% of patients present with metastatic disease, and the overall median survival is 1 year. RPLND may be curative in patients with limited retroperitoneal lymph node metastasis. Chemotherapy and radiation therapy are ineffective.

Secondary Tumors of the Testis

Lymphoma

Primary testicular non-Hodgkin lymphoma is a rare tumor and represents only 1% to 2% of all cases of lymphoma. Most commonly, lymphoma involves the testis through dissemination from extratesticular sites (Ulbright, 2004). Eighty-five percent of cases occur in men older than age 60. **Non-Hodgkin lymphoma is the most common testicular neoplasm in men older than age 50. Bilateral testicular involvement occurs in 35% of cases.** This tumor usually presents as a painless testicular mass in an older man. Approximately 25% of men have systemic symptoms (fever, night sweats, weight loss). Central nervous system involvement at diagnosis is reported in 10% of men. The initial treatment is radical inguinal orchiectomy. Men with testicular non-Hodgkin lymphoma should be referred to hematology-oncology for staging investigations and subsequent therapy. Most cases are associated with systemic disease, and the overall prognosis is poor.

Leukemic Infiltration

The testis is a frequent site of relapse in boys with acute lymphocytic leukemia. The majority of boys are in complete

remission at the time of testicular enlargement. **The diagnosis can usually be made by biopsy, and orchiectomy is unnecessary. Local control can be achieved with low-dose radiotherapy (20 Gy), and treatment should include the contralateral testis owing to the frequent risk of bilateral involvement.** Overall the prognosis is poor because most patients have associated systemic disease.

Metastases

Metastases to the testis are rare and usually associated with diffuse metastatic disease. Bilateral involvement occurs in 15% of patients. The most common primary lesions are prostate cancer, lung cancer, melanoma, colon cancer, and kidney cancer. Although treatment is largely dictated by the primary tumor, orchiectomy may be considered for palliative reasons.

Key Points: Non–Germ Cell Tumors

- Ninety percent of Leydig cell and Sertoli cell tumors are benign, and 10% are malignant.
- There are no reliable histologic criteria to identify malignancy.
- RPLND may be considered in patients with adverse histologic features (large size, necrosis, increased mitoses, nuclear pleomorphism) and/or evidence of retroperitoneal metastases.
- Malignant tumors are resistant to chemotherapy and radiation therapy.

TUMORS OF THE TESTICULAR ADNEXA

Adenomatoid Tumor

Adenomatoid tumor is the most common paratesticular tumor, most commonly involving the epididymis (although these tumors may also arise within the testicular tunics or the spermatic cord). The most common presentation is a small (0.5 to 5.0 cm), painless paratesticular mass detected on routine examination in a male in his third or fourth decade. **These tumors are benign and managed by inguinal exploration and surgical excision.** On microscopic examination these tumors are composed of epithelial-like cells that contain vacuoles and fibrous stroma.

Cystadenoma

Cystadenoma of the epididymis corresponds to benign epithelial hyperplasia. The lesions are usually multicystic, the walls of which are studded with nodules of epithelial cells arranged in a glandular or papillary configuration. **Approximately one third of cases occur in patients with von Hippel-Lindau syndrome.** The lesions are usually small and painless and are detected on routine examination in a young adult.

Mesothelioma

Paratesticular mesothelioma arises from the tunica vaginalis and usually presents as a painless scrotal mass in association with a hydrocele. These tumors most commonly occur in older adults but may be encountered in any age group. **Both benign and malignant mesothelioma have been described, with the distinction based on atypia, mitotic activity, and invasion** (Ulbright, 2004). Malignant cases may be associated with asbestos exposure. **Treatment is radical inguinal orchiectomy.** Unsuspected cases of paratesticular mesothelioma identified at the time of scrotal hydrocelectomy should be managed by inguinal orchiectomy. RPLND may be considered in patients with malignant tumors without widespread metastatic disease. The role of chemotherapy for these tumors is poorly defined.

Sarcoma

Sarcomas of the spermatic cord, epididymis, and testis are the most common genitourinary sarcomas in adults. **Liposarcoma is the most common histologic subtype in adults,** followed by rhabdomyosarcoma, leiomyoma, malignant fibrous histiocytoma, and fibrosarcoma (Coleman et al, 2003; Ulbright, 2004; Dotan et al, 2006). **Embryonal rhabdomyosarcoma is the most common histologic subtype in men younger than age 30. Sarcomas are most often in the intrascrotal region and primary mesenchymal tumors of the testis are uncommon.** These tumors usually present as a painless, palpable mass, and most are large (>5 cm) (Dotan et al, 2006). Ultrasonography will demonstrate a solid mass, although it cannot distinguish between benign and malignant pathology. **As such, any solid mass in the scrotum external to the tunica albuginea should be explored through an inguinal approach and biopsy performed. Liposarcomas of the spermatic cord in the inguinal canal may be mistaken for inguinal hernia or lipoma, and CT or MRI is helpful to distinguish between these entities.**

Sarcomas should be managed initially through an inguinal approach with wide excision of the spermatic cord and testis with high ligation. Patients with an initial incomplete resection should undergo repeat wide excision (Coleman et al, 2003). Additional therapy is dictated by the histologic subtype and the presence of regional or distant metastases. The vast majority of patients have localized disease at diagnosis. **Liposarcomas rarely metastasize but tend to recur locally** (Montgomery and Fisher, 2003). **Thus, postoperative radiation therapy may be considered for these tumors or in those in whom the adequacy of local excision is in doubt,** although the efficacy of this approach is debated (Fagundes et al, 1996; Coleman et al, 2003). Systemic chemotherapy should be given to patients with evidence of retroperitoneal or distant metastases. **In the presence of a normal metastatic evaluation, patients with sarcomas other than liposarcoma should undergo RPLND and postoperative chemotherapy should be given to patients with retroperitoneal lymph node metastasis.** The long-term survival

Key Points: Tumors of the Testicular Adnexa

- Adenomatoid tumor is the most common paratesticular tumor. These tumors are benign and managed by surgical excision.
- The paratesticular region is the most common location for genitourinary sarcomas. The most common histology in children and young adults is embryonal rhabdomyosarcoma, and liposarcoma is the most common histology in older adults.

of men with paratesticular sarcoma is approximately 50% (Coleman et al, 2003).

chapter 32

Surgery of Testicular Tumors

Joel Sheinfeld, MD ● George J. Bosl, MD

Management of the Primary Tumor
Retroperitoneum and Germ Cell Tumors
Retroperitoneal Lymph Node Dissection
Treatment Options for Low-Stage Germ Cell Tumors
Surgery for High-Stage Germ Cell Tumors

Each year, approximately 8000 new cases and almost 400 deaths due to testicular cancer are expected (Jemal et al, 2007). The incidence of germ cell tumors (GCTs), the most common solid tumor in men between the ages of 20 and 35 years, is rising both in the United States and Europe (Bergstrom et al, 1996; McKiernan et al, 1999).

Given the dramatic improvements in survival rates from 60% to 65% in the 1960s to more than 90% in the 1990s, the management of testicular cancer has come to represent a model in the successful multidisciplinary approach to solid tumors (Einhorn et al, 1981). Although testicular cancer is highly curable, it requires appropriate management at all stages (Bosl et al, 2000). Both the cure rate and the morbidity are highly sensitive to nuances of management. The clinician and, more importantly, the patient pay a high price for inappropriate management. Surgery remains an integral part of the management of patients with GCTs, but the advent of effective chemotherapy and improvements in clinical staging, including sophisticated imaging modalities and reliable serum tumor markers, have altered its role over the past 30 years (Sheinfeld and Herr, 1998).

In this chapter the principal indications and controversies of surgery in the management of testicular neoplasms are summarized, common surgical techniques and their associated complications are described, and established and investigational alternatives to surgery in both low- and high-stage GCTs are discussed.

MANAGEMENT OF THE PRIMARY TUMOR

Unfortunately, delays in the timely and accurate diagnosis of testicular cancer continue to be a significant problem. Moul (1994) noted a mean duration of symptoms of 26 weeks before diagnosis in a review of 4948 patients with testicular cancer, with both patient and physician factors contributing to this delay. Bosl and colleagues (1981) reported that the median interval of delay for patients with clinical stage I disease was 75 days compared with 101 and 134 days for patients with clinical stage II and III disease, respectively. Painless scrotal masses are often ignored, whereas testicular cancers presenting as scrotal pain are treated as epididymitis up to 18% to 30% of the time (Bosl et al, 1981; Prout et al, 1984). Almost 20% of patients present with signs or symptoms of metastatic disease, such as back or abdominal pain, weight loss, neck mass, and gynecomastia or breast tenderness (Bosl et al, 1981, 2000; Thornhill et al, 1987). Patients have undergone unnecessary mastectomy or laparotomy or prolonged therapy for back pain without considering the diagnosis of testicular cancer (Post and Belis, 1980; Moul and Moellman, 1992; Moul et al, 2000). Stephenson and associates (2004) reported on 40 patients with a midline retroperitoneal mass who underwent unnecessary laparotomy. At the time of laparotomy all patients had an abnormality on testicular examination or ultrasonography or an elevated serum tumor marker to suggest the diagnosis of GCT. The laparotomy contributed to therapeutic delay in a substantial number of patients and complicated their therapy.

A careful history and physical examination, as well as serum β-human chorionic gonadotropin (hCG), α-fetoprotein (AFP), and lactate dehydrogenase (LDH) levels are helpful in establishing a correct diagnosis. Scrotal ultrasonography is extremely accurate in identifying solid intratesticular lesions with greater than 95% sensitivity and specificity.

Radical Orchiectomy

A radical orchiectomy with high ligation of the spermatic cord at the level of the internal ring is the first step in the treatment of patients suspected of harboring a testicular neoplasm. This procedure provides histopathologic diagnosis and tumor (T) staging categorization, is associated with minimal morbidity and no mortality, and provides local control of the tumor in the vast majority of patients. The rare exceptions are usually due to tumor spillage, suboptimal orchiectomy, or transscrotal surgery (Whitmore et al, 1982).

The procedure is performed under general, spinal, or local anesthesia on an outpatient basis. The patient is placed in the supine position with the scrotum prepped in the sterile field. A 5- to 7-cm oblique incision is made in the inguinal area along Langerhans skin lines approximately 2 cm above the pubic tubercle. This incision can be extended onto the upper scrotum to facilitate removal of large tumors. Camper and Scarpa fascia are incised to the level of the external oblique aponeurosis, which is then incised in the direction of its fibers to the level of the internal ring (Fig. 32–1). The ilioinguinal nerve is identified, dissected free of the cord, and preserved. The spermatic cord is isolated and occluded with either a noncrushing clamp or a 0.5-inch Penrose tourniquet at the level of the internal ring. The testis and its investing tunics are delivered into a carefully draped off field as gubernacular attachments are divided in the avascular plane. **If a diagnostic biopsy or**

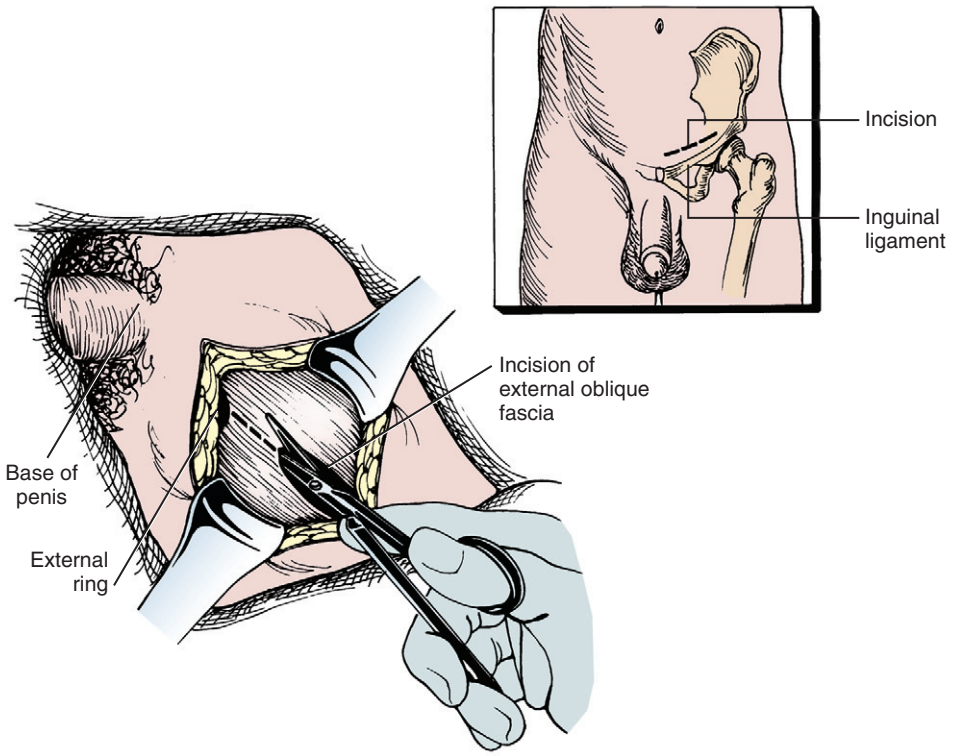

Figure 32–1. Approach for radical inguinal orchiectomy. The incision is shown in the inset. The external oblique fascia is divided in line with its fibers down to the external inguinal ring. (Adapted from Gottesman JE. In: Crawford ED, editor. Current genitourinary cancer surgery. Philadelphia: Lea & Febiger; 1990. p. 319.)

subtotal orchiectomy is planned, meticulous draping off is necessary before opening the tunica vaginalis and incising testicular parenchyma. Radical orchiectomy is completed by mobilizing the cord 1 to 2 cm inside the internal ring and individually ligating the vas deferens and the cord vessels between separate clamps (Fig. 32–2). The cord vessels are secured with silk ligatures, which can then be used to identify the stump if a retroperitoneal lymph node dissection (RPLND) is performed. The wound and scrotum are thoroughly irrigated and hemostasis is secured. A testicular prosthesis (soaked in antibiotic solution) can then be placed. The external oblique aponeurosis is closed with running 2-0 polypropylene suture. The Scarpa fascia is closed with absorbable sutures, and the skin is closed with either skin staples or a subcuticular suture. Compressive fluff dressings with a scrotal support minimize postoperative edema.

The most common complication of radical orchiectomy remains postoperative bleeding, which may occasionally result in either a scrotal or a retroperitoneal hematoma. Furthermore, significant retroperitoneal hematomas may delay further therapy or be misinterpreted as metastatic disease and result in unnecessary treatment (Bochner et al, 1995).

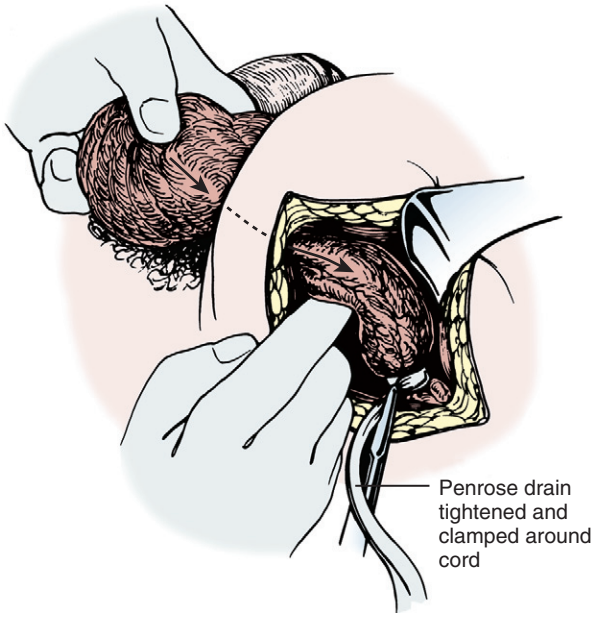

Figure 32–2. After the cord has been controlled with a tightened Penrose drain or rubber-shod clamp, the testis is mobilized out of the scrotum using blunt dissection. (Adapted form Gottesman JE. In: Crawford ED, editor. Current genitourinary cancer surgery. Philadelphia: Lea & Febiger; 1990. p 319.)

Scrotal Violation

Sayegh and associates (1966) reported that prior inguinal or scrotal surgery could alter the normal lymphatic drainage of the testis; consequently, many patients with scrotal violation have undergone extensive local surgery and/or adjuvant therapy to prevent an adverse outcome.

Suboptimal approaches to testicular neoplasms including scrotal orchiectomy, transscrotal biopsy, or fine-needle aspiration are reported from 4% to 17% of the time (Capelouto et al, 1995; Leibovitch et al, 1995a).

A recent meta-analysis of 206 cases of scrotal violation reported a local recurrence rate of 2.9% compared with 0.4% of patients treated by inguinal orchiectomy but no difference in systemic relapse or survival rates. There did not appear to be any advantage to adjuvant therapy (Capelouto et al, 1995). Others have reported an increased local recurrence rate in patients with scrotal

contamination (Giguere et al, 1988) and an 11% presence of tumor in hemiscrotectomy specimens of patients with scrotal violation. Therefore the following recommendations for patients with scrotal violation seem prudent:

1. **In patients with low stage seminoma the radiation portals should be extended to include the ipsilateral groin and scrotum.** This may result in an increased risk of azoospermia (Amelar et al, 1971).
2. **In patients with low-stage nonseminomatous GCT (NSGCT), the scrotal scar should be widely excised with the spermatic cord remnant at the time of RPLND.** Patients with clinical stage I NSGCT and scrotal violation are not good candidates for surveillance.
3. **Patients treated with full-dose platinum-based regimens should have the cord stump removed at the time of RPLND; however, given the relative absence of local relapse after systemic treatment, extensive groin dissection or hemiscrotectomy is not required.**

Partial Orchiectomy

A small subset of carefully selected patients with a solitary testis or bilateral testicular tumors, or a suspected benign lesion, may be candidates for "testis-sparing" surgery. The German Testicular Cancer Intergroup reported on 63 patients with median follow-up of 74 months and found only 4 local recurrences, all in patients with untreated intratubular germ cell neoplasia (Van der Schyff et al, 2000). Almost 90% of patients maintained normal testosterone levels. **Favorable selection criteria include organ-confined disease with a mass less than 20 mm, negative postresection biopsies of the tumor bed, and absence of intratubular germ cell neoplasia (ITGCN) in the remaining testicular parenchyma. The procedure is performed under conditions of cold ischemia with great care to avoid tumor spillage or contamination.** Biopsies of adjacent parenchyma are performed to identify ITGCN. The diagnosis of ITGCN on frozen section can be difficult due to artifact, and an experienced pathologist is particular helpful. The decision to perform completion orchiectomy in the presence of documented ITGCN is individualized based on preoperative discussion and the status of the contralateral testis. Patient compliance for rigorous follow-up must be assured, particularly because most patients with GCT have associated ITGCN.

Delayed Orchiectomy

A subset of patients with documented advanced germ cell cancer that includes histologic verification from a metastatic site undergo systemic chemotherapy without orchiectomy. Rarely, postoperative complications after orchiectomy have resulted in delays initiating chemotherapy. **The rationale for delayed orchiectomy after systemic chemotherapy is supported by data from a review of 160 patients in which 40 (25%) patients had viable cancer and 50 (31%) had teratoma in the resected testis** (Simmonds et al, 1995).

Staging

Staging evaluation must include thorough history and physical examination with particular attention to the contralateral testis. **Serum tumor markers should be repeated immediately before RPLND and should include hCG, LDH, and AFP. Computed tomography (CT) of the chest, abdomen, and pelvis is the most efficient and cost-effective means of detecting metastatic disease.** Magnetic resonance imaging (MRI) is usually reserved for the setting of major vascular involvement to assess patency of the inferior vena cava and renal vessels (Bosl et al, 2000).

In 1997 the American Joint Committee on Cancer (AJCC) and Union Internationale Contre le Cancer (UICC) adopted a comprehensive staging system that now includes serum tumor markers (TNMS). Stage I refers to disease confined to the testis, stage II implies retroperitoneal metastases, and stage III disease indicates supradiaphragmatic or visceral metastases. In the TNMS system vascular or lymphatic invasion in the primary tumor are classified in the T2 category and serum tumor markers are included because of their independent prognostic significance (AJCC, 1998). Staging systems for testicular cancer are discussed in Chapter 31.

Key Points: Demographics

- Testicular cancer is the most common solid tumor in men between the ages of 20 and 35 years.
- Approximately 8000 new cases and 400 deaths per year occur due to testicular cancer.
- Delay in diagnosis continues to be a significant problem.
- Careful history, physical examination, and serum tumor markers (hCG, AFP, and LDH) are helpful in establishing the correct diagnosis.
- Scrotal ultrasonography is extremely accurate in identifying solid intratesticular lesions, with greater than 95% sensitivity and specificity.

RETROPERITONEUM AND GERM CELL TUMORS

Natural History, Patterns of Metastasis, Anatomic Considerations

The natural history of testicular cancer provides the basis for its evaluation and management, and, in turn, is favorably influenced by effective treatment (Whitmore et al, 1982). GCTs share several features that have contributed significantly to their successful management. **These include (1) a germ cell origin, which is associated with responsiveness to irradiation (seminoma) and a number of chemotherapeutic agents, and with a potential for differentiation to histologically benign teratoma; (2) a rapid growth rate; (3) frequent production of specific tumor markers such as AFP and hCG; (4) usual occurrence in otherwise healthy young adults who can tolerate the necessary therapy; and (5) a predictable and systematic pattern of metastatic spread from the primary site to the retroperitoneal lymph nodes and subsequently to the lung and posterior mediastinum** (Whitmore et al, 1982; Richie, 1992; Sheinfeld, 1994).

Lymphatic spread is common to all forms of GCTs, although, in the case of choriocarcinoma, vascular dissemination is often a more common clinical feature. In 1899, Most was the first to accurately describe the lymphatic drainage of the testis (Most et al, 1899; Skinner and Leadbetter, 1971). Other anatomic studies in the early 20th century confirmed his findings and noted that the primary lymphatic drainage of the testis was to the area of its embryologic origin, that is, the retroperitoneal lymph nodes adjacent to the great vessels (Cuneo,

1901; Jamieson and Dobsin, 1910; Skinner and Leadbetter, 1971). **Right-sided testicular drainage included the interaortocaval lymph nodes, followed by the precaval and paracaval nodes, whereas left-sided drainage included the left para-aortic and preaortic lymph nodes** (Weinstein, 1999).

Further anatomic studies and detailed mapping studies of RPLNDs have increased our understanding of the testicular lymphatic drainage and sharpened the focus of clinical staging and treatment by identifying the most common sites of metastatic disease (Busch and Sayegh, 1963; Chiappa et al, 1966; Sheinfeld, 1994). There are four to eight lymphatic vessels that accompany the spermatic vessels through the internal ring into the retroperitoneum. Although the majority of lymphatic channels continue to accompany the spermatic vessels to the point where those vessels cross the ureter and to their origin, some may drain directly into a lymph node on the anterior surface of the proximal third of the external iliac artery. At the point where the spermatic vessels cross ventral to the ureter, lymph channels fan out medially in relation to the aorta and inferior vena cava and drain into the retroperitoneal lymph node chain extending from approximately L5 to T11 (Weinstein, 1999). Contralateral lymphatic flow is often seen, particularly for right-sided lymphatics (Weinstein, 1999).

Surgical mapping studies by Donohue and associates (1982), Weissbach and Boedefeld (1987), and Ray and colleagues (1974) divided the retroperitoneum into specific anatomic regions: right and left suprahilar, right paracaval, precaval, interaortocaval, preaortic, left para-aortic, right and left iliac, interiliac, and gonadal vessels (right or left) (Weinstein, 1999) (Fig. 32–3).

The first echelon of lymph nodes draining the right testis is located in the interaortocaval area, followed by the precaval and preaortic nodes. The primary "landing zone" for left-sided tumors includes the para-aortic and preaortic lymph nodes, followed by the interaortocaval nodes (Donohue et al, 1982). More caudal deposits of metastatic disease usually reflect retrograde spread secondary to large volume disease and, rarely, aberrant drainage. **Contralateral spread is more common with right-sided tumors, rare with left-sided tumors, and usually associated with large-volume disease** (Sogani, 1991; Richie et al, 1992).

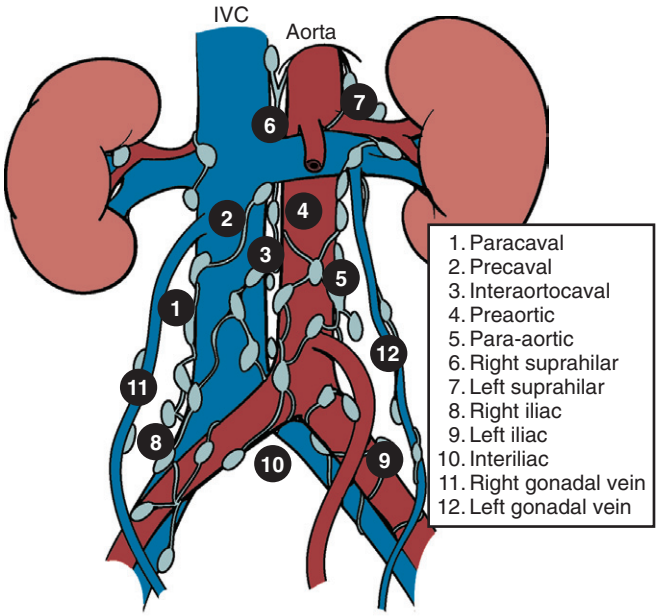

Figure 32–3. Anatomic regions of the retroperitoneum.

Testicular tumors have the capacity to spread by direct extension and involve the epididymis and/or scrotum. The lymphatic drainage of the epididymis is to the external iliac chain, whereas that of the scrotum is to the inguinal lymph nodes (Osler, 1907; Weinstein, 1999).

The rationale for treatment of the retroperitoneal lymph nodes in patients with testicular cancer is based on several factors. First, there is evidence that retroperitoneal lymph node spread is usually the first and often the only site of metastatic disease (Whitmore, 1979). This is supported by several clinical observations: (1) the survival rates in patients with retroperitoneal lymph node metastases treated by RPLND alone (Richie and Kantoff, 1991; Sheinfeld et al, 1999a; Stephenson et al, 2005); and (2) patients whose regional lymph nodes are found to be pathologically negative after adequate RPLND are usually cured by orchiectomy and the rare treatment failures in this group of patients are usually a result of pulmonary metastases and/or elevated serum tumor markers. Systemic relapse rates are declining and average approximately 10%, with disease-free survival rates ranging from 96% to 100% (Staubitz et al, 1973; Whitmore, 1979; Bredael et al, 1983; Stephenson et al, 2005).

Second, although clinical staging continues to improve through refinements of radiologic imaging such as CT (Hilton et al, 1997), in **15% to 40% of patients their disease is clinically understaged, particularly in the retroperitoneum. This is supported by the 20% to 30% incidence of pathologic stage II disease in patients with clinical stage I disease, the approximately 25% relapse rate in the retroperitoneum on surveillance protocols** (Lashley and Lowe, 1998), **and the 20% incidence of teratoma and/or viable carcinoma in resected specimens of patients with subcentimeter lymph nodes on CT after chemotherapy** (Fossa et al, 1989c; Toner et al, 1990; Sheinfeld and Bajorin, 1993; Oldenburg et al, 2003; Karellas et al, 2007).

Third, untreated retroperitoneal lymph node metastases are usually fatal (Whitmore, 1979). **Autopsy studies of patients dying with GCTs of the testis indicate that brain, liver, and bone metastases were late occurrences in the course of the disease and that most patients had concomitant and usually bulky retroperitoneal metastases** (Johnson et al, 1976; Bredael et al, 1982). Interestingly, autopsy data did not reveal any significant differences in the site or frequency of metastasis between those treated before and after introduction of cisplatin-based chemotherapy (Bredael et al, 1982). **Furthermore, the most common site of late recurrence of both teratoma and viable GCT is the retroperitoneum** (Baniel et al, 1995c; Sharp et al, 2008). **Late recurrences are usually chemorefractory, and survival rates are poor** (Borge et al, 1988; Baniel et al, 1995; George et al, 2003; Carver and Sheinfeld, 2005; Sharp et al, 2008).

RETROPERITONEAL LYMPH NODE DISSECTION

Evolution of Surgical Templates and Techniques

Although RPLND has been well established in the management of NSGCTs since 1948, both its role and the surgical template itself have undergone considerable change over the past 30 years.

Either a transabdominal or thoracoabdominal approach to the retroperitoneum for lymph node dissection may be used (Whitmore, 1962; Skinner and Leadbetter, 1971; Donohue, 1977). Initially, RPLND included bilateral suprahilar dissections as well as all the nodal tissue between both ureters down to the bifurcation of the common iliac arteries.

Given the significant limitations in clinical staging at the time, and the absence of other effective therapeutic modalities, emphasis was necessarily placed on extensive dissection of all lymph nodes. Although its therapeutic efficacy was confirmed (Skinner, 1976; Donohue, 1977; Donohue et al, 1993), extensive suprahilar dissection can result in increased pancreatic, lymphatic, and renovascular complications. **Several studies have confirmed that suprahilar metastases are rare in low-stage NSGCT, and, currently, suprahilar dissections are usually performed for residual hilar or suprahilar masses after cytoreductive chemotherapy for advanced-stage NSGCT** (Ray et al, 1974; Donohue et al, 1982). **In this setting the most common site of suprahilar disease is in the retrocrural space** (Schmeller et al, 1981).

In an effort to reduce surgical perioperative morbidity, bilateral infrahilar RPLND replaced the original suprahilar dissections (see Fig. 32–2) (Donohue et al, 1982, 1993). The procedure was associated with minimal morbidity and a mortality rate less than 1% (Baniel et al, 1994).

The most consistent long-term morbidity of a standard bilateral RPLND has been the loss of antegrade ejaculation and, consequently, potential infertility, owing to damage of sympathetic nerve fibers (Lange et al, 1983, 1984; Jewett et al, 1988). **Therefore patients are advised to complete sperm banking before the surgery.** Prior to development of nerve-sparing techniques the incidence of this complication was associated with the extent of the retroperitoneal dissection (Lange et al, 1984; Jewett et al, 1988).

The sympathetic chain, the paravertebral sympathetic ganglia, and postganglionic sympathetic fibers T2 to L4 and their convergence at the hypogastric plexus are most crucial in the preservation of antegrade ejaculation. Minimizing damage to these structures has resulted in higher rates of ejaculation (Lange et al, 1984; Sheinfeld and Herr, 1998). Two general approaches have been utilized to protect theses structures and include modified template RPLND and, more recently, nerve-sparing dissections, which can be applied to any template, including a bilateral template.

Modified Templates

Narayan and colleagues (1982) first reported that modification of surgical boundaries resulted in spontaneous return of ejaculation, with 25 of 55 patients recovering ejaculation at 3 years. Subsequently, a number of investigators have proposed a variety of modified RPLND templates for both right- and left-sided primary tumors with rates of return of ejaculation ranging from 51% to 88% (Fossa et al, 1984; Pizzocaro et al, 1985; Donohue et al, 1990; Richie, 1990).

Successful preservation of ejaculation is higher for right-sided dissections compared with left-sided ones. **In an effort to avoid disrupting the sympathetic nerves and the hypogastric plexus, all modified templates share several goals: (1) to thoroughly resect all ipsilateral lymph nodes between the level of the renal vessels and the bifurcation of the common iliac artery and (2) to minimize contralateral dissection, particularly below the level of the inferior mesenteric artery** (Sheinfeld and Herr, 1998).

These arbitrary changes were made on the basis of surgical mapping studies and overreliance of cisplatin-based chemotherapy. Initially, short-term and medium-term follow-up appeared to corroborate this approach, but long-term data (particularly late relapse and redo-RPLND studies) have since exposed some of its limitations.

Modified templates are based on mapping studies of retroperitoneal metastasis and aim to limit the extent of dissection in anatomic regions thought to be at decreased risk of metastatic spread. Unfortunately, mapping studies have several important limitations that contribute to an underestimation of the extent of retroperitoneal disease. Mapping studies often lack adequate postoperative follow-up, so the rate of recurrence outside the template region is unknown. Without appropriate follow-up, sample errors by the surgeon and/or the pathologist cannot be determined. For example, studies by Ray and associates (1974) and Donohue and coworkers (1982) did not report any follow-up data and the study by Weissbach and Boedefeld (1987) reported three retroperitoneal recurrences with a median follow-up of only 22 months in patients with pathologic stage I disease. This was a multicenter study that included 46 centers and 50 surgeons, thereby introducing significant surgical variability. Importantly, in the Weissbach and Boedefeld study it is not possible to accurately assess unresected metastatic sites in patients who subsequently received chemotherapy.

In a recent analysis of 500 patients with clinical stage I and IIA disease who underwent primary RPLND at Memorial Sloan-Kettering Cancer Center (MSKCC), Eggener and associates (2007b) reported that depending on the template applied, 3% to 23% of patients with positive nodes will have extratemplate disease, including up to 11% with low-volume retroperitoneal disease. Similarly, Carver and colleagues (2007b) reported that, of 532 patients who underwent postchemotherapy RPLND (PC-RPLND) at MSKCC, up to 32% would have had disease outside the template region, depending on the limits of the modified templates.

Both of these studies showed that the histology outside the template region was similar to that within the templates. This is an important observation, because chemoresistant teratomatous elements are present in approximately 30% of positive nodes in primary RPLND specimens and in approximately 40% of post-chemotherapy specimens. Teratoma and malignant transformation are clearly overrepresented in patients who have experienced late relapse and repeat retroperitoneal surgery and arise from unresected disease (McKiernan et al, 2003; Sheinfeld, 2007; Sharp et al, 2008). These catastrophic sequelae highlight the potential danger of a reduced surgical field and overreliance on chemotherapy.

Antegrade Ejaculation

Antegrade ejaculation requires the coordination of three separate events: (1) closure of the bladder neck, (2) seminal emission, and (3) ejaculation. The sympathetic fibers that mediate seminal emission originate primarily from the T12 to L3 levels of the thoracolumbar spinal cord. In the mid retroperitoneum after leaving the sympathetic trunk the fibers converge toward the midline and form the hypogastric plexus near the takeoff of the inferior mesenteric artery just above the aortic bifurcation. From the hypogastric plexus the sympathetic fibers travel via the pelvic plexus to innervate the seminal vesicles, vas deferens, prostate, and bladder neck (Fig. 32–4). Ejaculation is mediated by nerves originating at

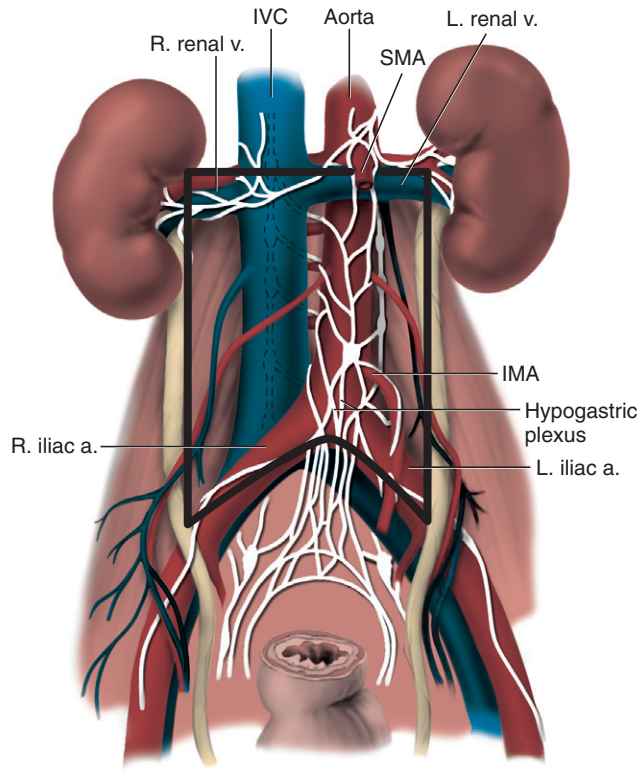

Figure 32–4. Surgical template for bilateral RPLND. IMA; inferior mesenteric artery; IVC, inferior vena cava; SMA, superior mesenteric artery.

the sacral and lumbar spinal cord levels. Sympathetic fibers tighten the bladder neck, whereas pudendal somatic innervation from S2 to S4 causes relaxation of the external urethral sphincter and rhythmic contractions of the bulbourethral and perineal muscles (Lange et al, 1983, 1984; Sheinfeld, 1994; Sogani, 1991).

Nerve-Sparing Techniques

The highest rates of preserved ejaculation are reported with nerve-sparing RPLND, in which the sympathetic chains, the postganglionic sympathetic fibers, and the hypogastric plexus are prospectively identified, meticulously dissected, and preserved (Jewett et al, 1988; Donohue et al, 1990). Nerve-sparing techniques can be utilized either in the primary or postchemotherapy setting and within standard bilateral or modified templates, depending on clinical and surgical circumstances; however, **margins of resection should never be compromised in an attempt to maintain ejaculatory function** (Bosl et al, 2000).

Surgical Technique

Strict adherence to basic surgical principles is critical to perform RPLND safely. First, it is imperative that the surgeon have an in-depth understanding of retroperitoneal anatomy and be able to recognize common variations and their potential implications. Second, excellent exposure of the retroperitoneum must be ensured to properly set up the RPLND; and, finally, a thorough lymphadenectomy using meticulous "split and roll" technique should be carried out.

Exposing the Retroperitoneum

Adequate exposure of the retroperitoneum can be accomplished with either a transabdominal or a thoracoabdominal approach.

Thoracoabdominal Approach. The extraperitoneal thoracoabdominal approach to RPLND was originally described by Cooper and later refined and popularized by Skinner and their associates (Cooper et al, 1950; Skinner et al, 1982). The main advantages of this approach are to allow easier visualization and dissection of the suprahilar lymphatic tissues and less risk of postoperative small bowel obstruction. In addition, simultaneous thoracic procedures can be performed through the same incision.

The patient is placed in the torqued position with the lower extremities and pelvis supine and the chest and upper extremities rotated medially. The operating table is hyperextended to allow exposure and retraction of the rib cage. The incision starts obliquely over the eighth or ninth rib and curves downward paramedian toward the pubic ramus. A subperiosteal rib resection is performed and the ipsilateral rectus muscle is divided. The peritoneum and contents are mobilized from the undersurface of the rectus sheath, and the diaphragm is divided and the pleural cavity is entered. The chest can be inspected and pulmonary or mediastinal procedures performed through the same incision. The retroperitoneum is exposed to the level of the contralateral ureter. Full bilateral RPLND can be performed as described for the transabdominal approach. In primary RPLND routine suprahilar dissection is not warranted, because the incidence of suprahilar or retrocrural disease is extremely low. In advanced disease, suprahilar dissection is directed by preoperative imaging studies and intraoperative palpation. The most common site of residual suprahilar disease is in the retrocrural space (Schmeller et al, 1981).

The wound is closed by reapproximation of the diaphragm with silk sutures and of the costal cartilage with polypropylene sutures. Chest tube drainage is established, and the flank is closed.

Complications specific to the thoracoabdominal approach are pulmonary, including atelectasis, prolonged chest tube drainage, and increased need for postoperative analgesia. In 1982 Skinner and colleagues described their complications with this technique in 149 patients both before and after chemotherapy. The overall operative mortality was 1.3% with both deaths due to hepatic failure. The overall complication rate was 13%, and major complications included small bowel obstruction, lymphocele, and wound dehiscence.

Transabdominal Approach. After successful induction of general endotracheal anesthesia and placement of the patient in the supine position, the skin of the chest wall, abdomen, pubis, genitalia, and upper thighs is prepared. A Foley catheter is placed and connected to closed drainage. A nasogastric tube is placed and connected to intermittent suction.

A midline incision is made from the xiphicostal junction to a point 2 cm above the symphysis pubis. It is carried down through the subcutaneous tissues, and the linea alba and peritoneum are opened. The falciform ligament is either divided between silk ligatures or excised en bloc with the preperitoneal fat. This prevents hepatic capsular tears and allows upward displacement of the liver as the wound edges are spread by two self-retaining Balfour retractors. Careful inspection of the abdomen, retroperitoneum, and pelvis is then carried out to assess resectability and the presence of metastatic disease. The greater omentum and the transverse colon are then displaced superiorly onto the chest between warm moist packs.

The small bowel is reflected to the right, and an incision is made in the posterior peritoneum medial to the inferior mesenteric vein

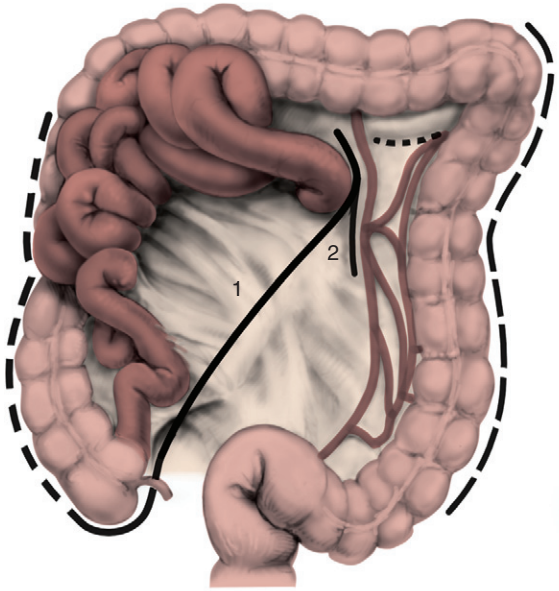

Figure 32–5. Incision of the posterior parietal peritoneum. The incision extends from the ligament of Treitz along the left side of the root of the small bowel mesentery to the ileocecal region (1). It may be extended superiorly and medially to the duodenojejunal flexure and inferolaterally around the cecum and ascending colon. The left leaf of the incised posterior peritoneum is defined (2).

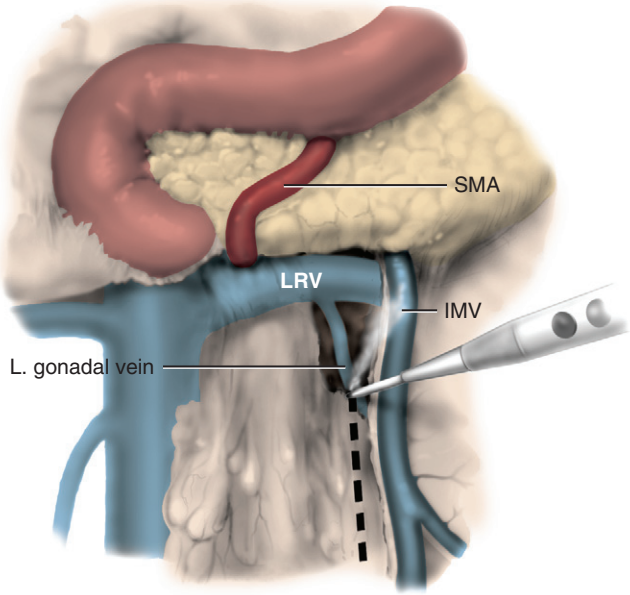

Figure 32–6. Development of the left leaf of the incised posterior peritoneum in the avascular plane between the inferior mesenteric vein (IMV) and the left gonadal vein. The colonic mesentery lies anteriorly and the para-aortic space and Gerota fascia posteriorly. SMA, superior mesenteric artery; LRV, left renal vein.

(Fig. 32–5). This incision is continued cephalad to the ligament of Treitz and is extended superiorly and medially to the duodenojejunal flexure, allowing for superior mobilization of the fourth portion of the duodenum and pancreas. The left leaf of the incised posterior peritoneum is further developed, with the colonic mesentery located anteriorly and the para-aortic retroperitoneal space posteriorly (Fig. 32–6). The proper plane of dissection is the avascular plane between the inferior mesenteric vein and the left gonadal vein. This maneuver further defines a thick condensation of fibrovascular tissue (ligament of Treitz) and several large lymphatic trunks, which should be divided between silk sutures, further mobilizing the tail of the pancreas. **Alternatively, to gain adequate exposure in the area of the left renal hilum, particularly with large postchemotherapy masses, the inferior mesenteric vein can be doubly ligated and divided.**

The incision in the posterior parietal peritoneum is continued inferiorly along the medial aspect of the small bowel mesentery, lateral to the right gonadal vein and its branches, and extended around the cecum and up the right paracolic gutter to the foramen of Winslow. The duodenum is then kocherized, allowing cephalad reflection and exteriorization of the small bowel, cecum, and right colon onto the chest wall where they can be either placed in a Lahey bag or protected by moist laparotomy pads (Fig. 32–7). To facilitate retraction of the exteriorized viscera and minimize traction when self-retaining Gallagher and large Deaver retractors are placed, careful and thorough division of attachments between the undersurface of the duodenum and pancreas and the anterior surface of the left renal vein is necessary (Fig. 32–8). It is also important to ligate or clip the numerous lymphatic vessels in this area to minimize postoperative lymphatic complications. In placing self-retaining retractors great care must be taken in identifying the superior mesenteric artery to avoid vascular compromise of the small bowel. Periodic inspection of small bowel color

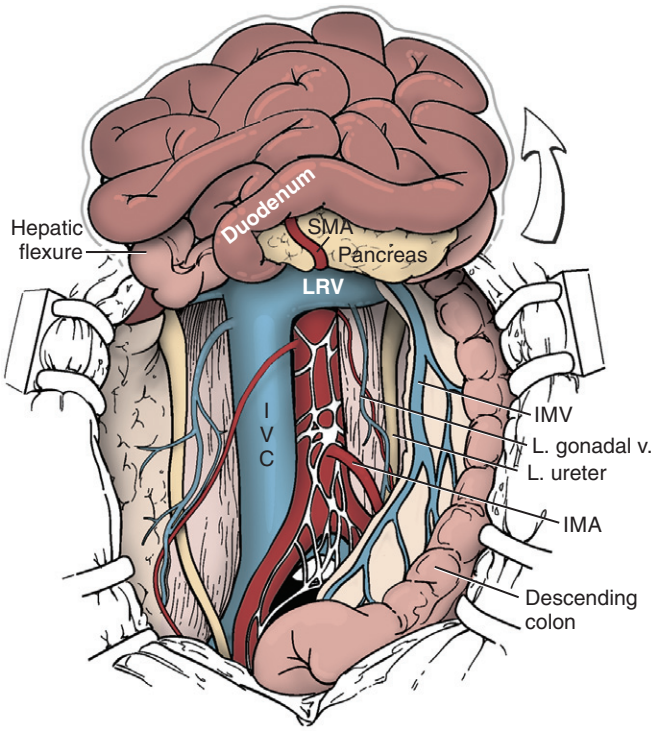

Figure 32–7. The retroperitoneal space has been exposed. The duodenum has been kocherized; its second, third, and fourth portions have been reflected superiorly along with the pancreas and superior mesenteric artery. The entire right colon has been mobilized and exteriorized. SMA, superior mesenteric artery; LRV, left renal vein; IMV, inferior mesenteric vein; IVC, inferior vena cava; IMA, inferior mesenteric artery.

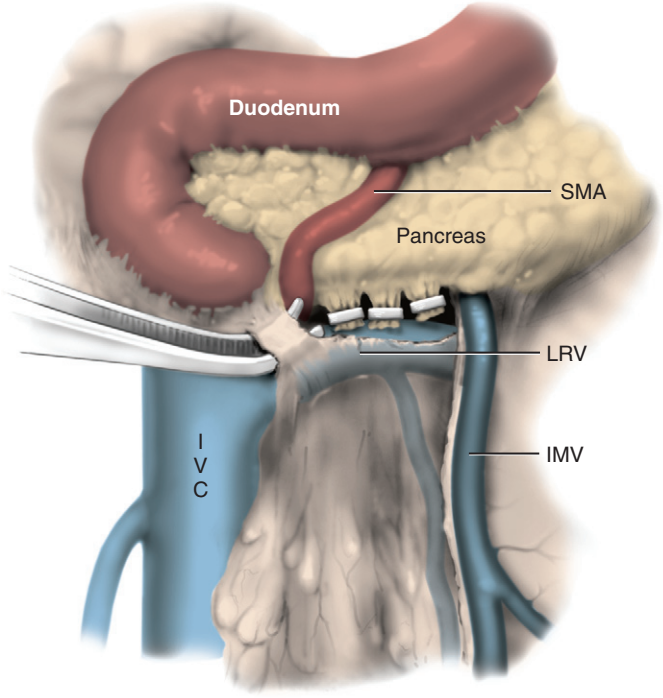

Figure 32–8. Division of attachments between undersurface of the duodenum and pancreas and the anterior surface of the left renal vein. It is important to clip or ligate the numerous lymphatic channels in this area. Prominent lacteals in the vicinity of superior mesenteric artery are often seen. SMA, superior mesenteric artery; IMV, inferior mesenteric vein; LRV, left renal vein; IVC, inferior vena cava.

or pulsation of the superior mesenteric artery is prudent. These maneuvers allow for excellent exposure of the retroperitoneal space from the level of the right and left suprahilar areas distally to the bifurcation of the right common iliac artery. **Additional exposure of the distal left para-aortic and left parailiac space can be accomplished by further extending the incision in the left leaf of the parietal peritoneum inferiorly and, if necessary, sacrificing the inferior mesenteric artery.** Alternatively, the left colon can be reflected medially by incising the left white line of Toldt and developing the plane between the colonic mesentery and the anterior surface of the Gerota fascia.

Setting Up the Dissection

Injury to important structures can be avoided by being aware of the following structures: the superior and inferior mesenteric arteries, the pancreas, the renal vessels, and the ureters. Up to 20% of patients will have accessory renal arteries and 2% to 3% of patients will have a retroaortic left renal vein. It is particularly important to recognize a retroaortic left renal vein because it may be inadvertently mistaken for a lumbar vein and ligated or, as the surgeon extends the cephalad dissection in search of the left renal vein, the pancreas and superior mesenteric artery may be injured. In the absence of a normally positioned left renal vein the attachments of the undersurface of the pancreas and duodenum may lie directly on the aorta.

Soft vessel loops are placed around the ureters as they are retracted laterally, and their medial aspect defines the lateral margins of resection. The ipsilateral gonadal vein is mobilized from its insertion in the inferior vena cava (right) or left renal vein (left) to the internal ring. It is important to encompass all the branches as well as the fibroalveolar and lymphatic tissue surrounding the gonadal vessels to avoid late paracolic recurrences from incomplete excision of the spermatic cord (Chang et al, 2002a).

Lymphadenectomy

Attention is initially directed to the left renal vein, and the renal perivascular lymphatic tissue is mobilized inferiorly. The anterior surface of the aorta is thus exposed. Then adrenal, spermatic, and lumbar branches are tied with 3-0 silk and divided. The dissection along the anterior surface of the left renal vein continues to the right until the anterior surface of the inferior vena cava is encountered and the first anterior "split" is then performed. The "split and roll" technique is illustrated in Figure 32–9. The right gonadal vein is ligated at the vena cava. Lymphatic tissue can then be rolled off the inferior vena cava laterally and medially as the dissection proceeds inferiorly. Lumbar veins are dissected, doubly ligated with 3-0 silk, and divided.

At this point, nerve-sparing techniques can be performed if clinically indicated (see later).

After control of the postganglionic sympathetic fibers has been secured with soft vessel loops as they course medially under the inferior vena cava to the anterior surface of the aorta, they are then retracted laterally. The anterior split on the surface of the aorta should then be carried inferiorly to the bifurcation of the common iliac arteries. The origin of the inferior mesenteric artery is identified. If necessary, this artery can be sacrificed without detrimental effects, provided that the marginal colonic artery is intact. The gonadal arteries should be ligated early to prevent the subadventitial hematoma that may result if they are avulsed. Following the anterior aortic split lymphatic tissue is retracted medially and laterally and lumbar arteries are dissected, doubly ligated with 3-0 silk, and divided. At this point the aorta and inferior vena cava have been separated from the retroperitoneal lymphatic tissue, which is attached to the posterior body wall and the renal arteries. The right and left renal arteries are skeletonized, and the lymphatic tissue is separated from the psoas fascia and anterior spinous ligament, which are the posterior limits of dissection. Great care should be taken to control lumbar vessels as they pass into the posterior body wall near the sympathetic chains to avoid possible injury to sympathetic innervation in attempting to control problematic bleeding.

Throughout the procedure it is important to ligate or clip the cut ends of lymphatic vessels, particularly in the region of the right renal artery and the diaphragmatic crus bilaterally, where large tributaries to the cisternae chyli are located.

Surgical margins should never be compromised in an effort to preserve ejaculation and, in the presence of documented or suspected metastatic disease in a primary RPLND, a full bilateral dissection remains the standard.

At the completion of a bilateral dissection the aorta, inferior vena cava, and renal vessels should be skeletonized and the anterior spinous ligament and psoas fascia should be visible, as should the stumps of the right and left gonadal vessels and inferior mesenteric artery.

The area of dissection is thoroughly irrigated with warm water, and lymphostasis and hemostasis must be ensured. The bowel and mesentery are inspected for injury, as are the kidneys and ureters. Intravenous indigo carmine may be given to rule out a urinary leak if ureteral integrity is in doubt. The posterior parietal

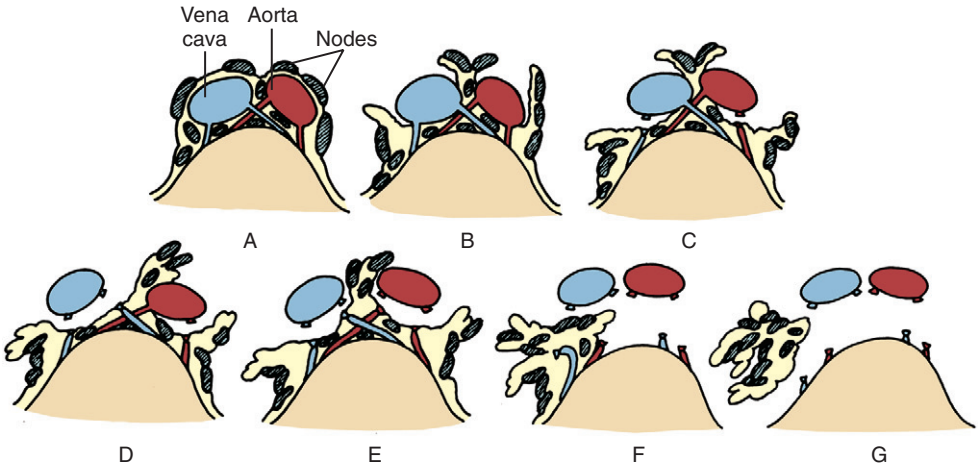

Figure 32–9. **A** to **G,** This diagram sequentially shows the "split and roll" technique that allows for en bloc removal of the nodal package. The lumbar vessels must be divided twice, first at the wall of the great vessels and again as they enter the foramina along side the vertebral bodies.

peritoneum is loosely approximated with interrupted 3-0 silk sutures to minimize the risk of small bowel obstruction and prevent direct adherence of bowel to the anterior surface of a great vessel. The abdomen is closed in a single layer with interrupted 1-0 polydioxanone suture.

Most patients can usually be extubated immediately after surgery and are managed with nasogastric tube drainage until ileus resolves. **Postoperative tachycardia is common owing to sympathetic discharge.** Fluid requirements are monitored closely and third space volume losses corrected as indicated. Diet is resumed when bowel activity returns, and volume status is monitored by pulmonary examination, net fluid balance, and daily weights. The remainder of the postoperative care is routine with average hospital stays of 5 to 7 days.

Prospective Nerve-Sparing Techniques

Appropriate candidates for nerve-sparing techniques include patients with clinical stage I and low-volume stage II NSGCT undergoing primary RPLND as well as a carefully selected subset of patients undergoing postchemotherapy lymphadenectomy (Pettus et al, 2009).

The most important aspect in performing nerve-sparing RPLND is the prospective identification and preservation of relevant sympathetic nerves, specifically (1) the sympathetic chains bilaterally, (2) the postganglionic sympathetic nerves arising from the sympathetic chains, and (3) the hypogastric plexus, which is the anastomosing network of nerve fibers anterior to the lower aorta (Fig. 32–10).

The sympathetic chains run parallel to the great vessels on either side of the spine. On the left side the sympathetic chain is lateral and posterior to the lateral border of the aorta (see Fig. 32–10) and postganglionic fibers leave at an oblique angle transversing lymphatic tissue posterolateral to the aorta as they join the hypogastric plexus (Klein, 1995). On the right side the sympathetic chain lies posterior to the inferior vena cava and the postganglionic fibers emerge from the medial edge of the vena cava and course at an oblique angle anterior to the aorta to join the hypogastric plexus. **Therefore it is important to note that an anterior "split" maneuver over the vena cava does not damage these fibers; however, dissection along the aorta before isolating and preserving these nerves individually results in their disruption** (Klein, 1995).

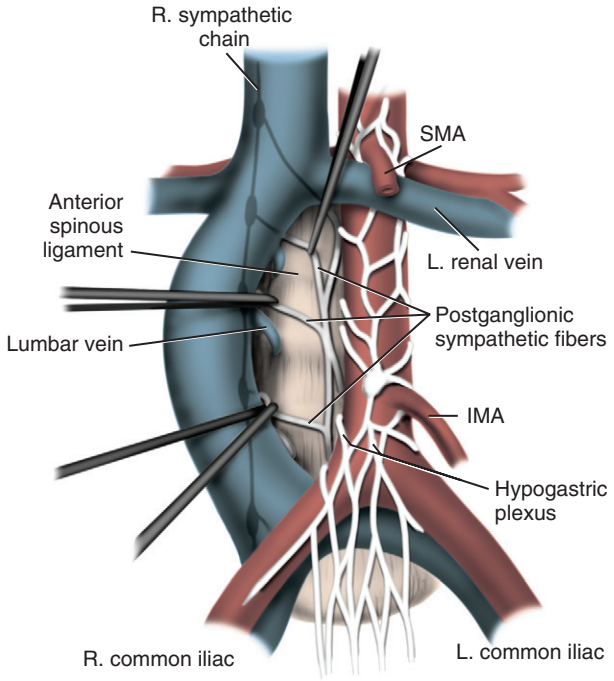

Figure 32–10. Nerve-sparing technique with soft vascular tapes around the right postganglionic branches of the sympathetic chains as they course in an oblique fashion toward the hypogastric plexus. Their relationship to the great vessels, lumbar veins, and root of the inferior mesenteric artery is shown. SMA, superior mesenteric artery; IMA, inferior mesenteric artery.

It appears that the most important nerves to preserve antegrade ejaculation are those arising from the L3 and L4 ganglia. It is often possible to preserve three or four separate nerve trunks. Nerve fibers often exit in close proximity to lumbar vessels, and great care must be taken in ligating them to avoid injury to these delicate nerve fibers.

These nerves are dissected free of surrounding fibrofatty and lymphatic tissue, encircled with soft vessel loops, and gently retracted out of harm's way. The lymphadenectomy then proceeds as described earlier within the appropriate template. Again, when performing nerve-sparing RPLND, dissection on the aorta should be done only after the nerve fibers have been isolated and

protected. Nerve-sparing techniques result in greater than 95% rates of antegrade ejaculation.

Intraoperative Neurostimulation

Several investigators have reported the use of intraoperative electrical stimulation of individual postganglionic sympathetic fibers to identify the most important nerves for antegrade emission (Recker and Tscholl, 1993; Kell and Jewett, 1999). Bladder neck closure and seminal emission can be documented endoscopically.

Laparoscopic Retroperitoneal Lymph Node Dissection

In an effort to reduce the perioperative associated with a primary RPLND, several investigators have evaluated the role of laparoscopic RPLND (L-RPLND) in the management of clinical stage I and IIA and low-volume residual disease after chemotherapy. L-RPLND has been shown to be technically feasible in the hands of dedicated experts, although it involves a steep learning curve. In addition to a faster convalescence and more favorable cosmetic results, postoperative morbidity, perioperative blood loss, and length of hospital stay appear to be reduced compared with open surgery (Janetschek et al, 1996; Nielsen et al, 2007; Rassweiler et al, 2008), although no direct comparative studies have been done and the morbidity, blood loss, and hospital stay in open RPLND have dropped significantly during the same time period (Beck et al, 2008).

However, the therapeutic efficacy of L-RPLND remains difficult to assess. First, the majority of patients with pathologic stage II disease receive chemotherapy after L-RPLND regardless of disease volume. A recent meta-analysis that included articles published since 2000 reported that 90% (126 of 140) of patients with positive nodes received postoperative chemotherapy. In spite of adjuvant chemotherapy the incidence of local and distant relapse rates were 1.4% (0.7 to 2.3) and 3.3% (1.8 to 4.6), respectively (Rassweiller et al, 2008).

Second, it remains unclear whether L-RPLND has been performed with therapeutic intent. One group reports that L-RPLND is used for diagnostic purposes only and "patients with positive nodes are definitively treated with adjuvant chemotherapy" (Janetschek et al, 2000). A second group reports that the "dissection was limited if grossly positive nodes were encountered" and the total number of nodes resected was significantly different if the nodes were positive or negative (14 ± 2 and 25 ± 3, respectively) (Nelson et al, 1999). Disappointingly, a follow-up study that combined selected data from four of the most experienced groups in the United States continued to show a higher node count in pathologic stage I disease (median 22) compared with pathologic stage II disease (median 15.5). It is counterintuitive and inappropriate to perform a more extensive and thorough dissection in the absence of disease and a more limited one in the presence of retroperitoneal metastasis (Carver and Sheinfeld, 2005). The node counts in three contemporary series appear low, with means reported of 14.4 (range 5 to 25) (Campero et al, 2009); 14 (IQR 11 to 20) (Nicolai et al, 2009); and 14 (IQR 10 to 18) (Castillo et al, 2007).

Third, there appear to be inconsistent and variable boundaries of dissection. Several laparoscopic surgeons recommend omitting dissection behind the great vessels and posterior to the lumbar vessels (Janetschek et al, 2000; Höltl et al, 2002) and advocate restricted templates even with pathologic stage II disease (Janetschek et al, 2000; Nielsen et al, 2007). The limitations of mapping studies and the incidence of extratemplate disease are discussed elsewhere in this chapter. Multifocality, contralateral, and extratemplate disease increase in pathologic stage II disease, and 20% to 30% will contain teratomatous elements, placing patients at risk for reoperative surgery, late relapse, and potentially inferior clinical outcomes (McKiernan et al, 2003; Eggener et al, 2007b). The indiscriminate use of chemotherapy is unnecessary in most cases of pN1 disease (Stephenson et al, 2005) and will not prevent relapse in cases of chemoresistant teratoma and a subset of viable cancer and increase long-term morbidity (Carver and Sheinfeld, 2005). Meinardi and colleagues (2000) reported a sevenfold increase in cardiovascular complications in men treated with cisplatin-based chemotherapy. On a positive note, a few highly specialized centers are now performing bilateral nerve-sparing RPLND, with preservation of antegrade ejaculation reported in 86% of patients. Follow-up is too short to evaluate the oncologic efficacy in pathologic stage II patients who did not receive chemotherapy (Steiner et al, 2008).

Most worrisome are patterns of relapse not seen with open RPLND. Pizzocaro and associates (2007) reported on eight patients with clinical stage IA disease, two of whom with relapsing liver disease making them at poor risk by International Germ Cell Cancer Collaborative Group (IGCCCG) criteria. Although both were salvaged, the burden of therapy is necessarily increased, as is the potential risk of subsequent failure. There have also been reports of patients with liver metastasis and diffuse abdominal and pelvic carcinomatosis after L-RPLND (Bosl, 2008; Castillo, 2008). The presumptive mechanism for this unusual pattern of metastasis is the pneumoperitoneum and positive intra-abdominal pressure required to perform L-RPLND.

Postchemotherapy Laparoscopic Retroperitoneal Lymph Node Dissection

The complication rate of L-RPLND after chemotherapy is higher than that of primary RPLND. Postchemotherapy desmoplastic reaction, as well as larger-volume residual disease requiring more extensive retroperitoneal dissection, increases the technical demands of the surgery. Nevertheless, investigators from Indiana University have reported a significant decrease in overall morbidity, major complications, and length of hospital stay (Mosharafa et al, 2004). Furthermore, for residual masses less than 2 cm, investigators from MSKCC reported a 4% major complication rate, including approximately a 2% incidence of bowel obstruction and a 1% to 2% incidence of chylous ascites (Patel et al, 2003).

In the postchemotherapy setting, with the exception of the Austrian group who report minimal morbidity in carefully selected patients with low-volume residual masses, the conversion rate to open surgery is high and very significant complications have been reported. Rassweiler and coworkers (1996) converted seven of nine (78%) postchemotherapy patients with stage II disease from L-RPLND to open RPLND, and Palese and associates (2002) reported that two (28.5%) of seven patients required open conversion. Furthermore, in the Johns Hopkins experience of seven postchemotherapy patients with L-RPLND for residual masses with a mean size of 1.9 cm, the overall complication rate was 57%. Major complications included transection of the external iliac artery requiring bypass graft in a patient with a 1.5-cm residual mass, renal artery hematoma in a patient with mild adenopathy requiring aortorenal bypass, and a 4.5-cm residual mass in a third patient who suffered renal artery thrombosis requiring nephrectomy, subsequent duodenal perforation, necrotizing fascitis, and a cerebrovascular event with neurologic sequelae (Palese et al, 2002).

The incidence of chylous ascites remains high (approximately 10%) after laparoscopic RPLND, in both the primary and the postchemotherapy setting (Wille et al, 2009). Consequently, in the postchemotherapy setting, L-RPLND cannot be endorsed as standard but rather as an operation to be evaluated in a formal prospective study by very experienced minimally invasive surgeons.

Key Points: RPLND

- Suprahilar metastasis are rare in low-stage NSGCT.
- Patients should be advised to complete sperm banking before RPLND.
- It is important to ligate or clip the cut end of lymphatic vessels.
- Surgical margins should never be compromised. In an effort to preserve ejaculation and in the presence of documented or suspected metastatic disease, bilateral RPLND remains the standard.
- Nerve-sparing techniques involve preservation of both sympathetic chains, the postganglionic sympathetic fibers, and the hypogastric plexus.
- Appropriate candidates for nerve-sparing techniques include patients with clinical stage I and low-volume stage II NSGCT undergoing primary RPLND as well as carefully selected patients undergoing PC-RPLND.
- The therapeutic impact of L-RPLND remains unknown.

TREATMENT OPTIONS FOR LOW-STAGE GERM CELL TUMORS

Clinical Stage I NSGCT

Retroperitoneal Lymph Node Dissection

In the United States and parts of Europe the conventional approach to patients with clinical stage I NSGCT has been bilateral RPLND, and it remains the standard against which all diagnostic and therapeutic alternatives must be judged (Whitmore, 1983; Hesketh et al, 1990; Chang and Sheinfeld, 2000). **As noted earlier, RPLND (1) provides the most accurate N categorization of the retroperitoneal lymph nodes that are the first site of metastatic spread in approximately 90% of GCT and (2) is curative in the majority of patients with pathologic stage I (pNO) and low-volume retroperitoneal disease (pN1) and avoids the persistence of chemorefractory teratoma in the retroperitoneum** (Sheinfeld et al, 2003). **Relapses in the retroperitoneum are rare in the hands of experienced surgeons after properly performed RPLND. Primary RPLND is associated with negligible mortality and minimal and declining morbidity rates** (Baniel et al, 1994; Stephenson and Sheinfeld, 2004; Stephenson et al, 2005; Beck et al, 2009).

Nerve-sparing techniques should be considered the operation of choice, with reported antegrade ejaculation rates greater than 95% (Donohue et al, 1990). Surgical margins should never be compromised in an attempt to preserve ejaculation, and if positive nodes are noted or suspected at the time of RPLND a bilateral dissection is warranted, particularly for right-sided primary tumors, because contralateral crossover is more common than for left-sided primary tumors.

Surveillance

The strategy of surveillance after orchiectomy was first reported by Peckham and colleagues in 1979. The rationale for surveillance protocols rests with the improved accuracy of clinical staging, the ability of cisplatin-based chemotherapy to cure early relapses, and the probability of surgical cure after radical orchiectomy alone and the possible infertility resulting from RPLND due to retrograde ejaculation (Sheinfeld, 1994; Bosl et al, 2000, 2005).

Approximately 25% of patients with T1N0M0 disease and normal serum tumor markers experience relapse while on surveillance protocols (Hoskin et al, 1986; Swanson, 1993; Lashley et al, 1998; Sogani et al, 1998). **The retroperitoneum is the most common site of relapse; the lungs or markers alone occur less frequently, and other visceral metastases are rare.** Survival rates after therapy for surveillance failures range from 96% to 100% (Hoskin et al, 1986; Swanson, 1993; Lashley et al, 1998; Sogani et al, 1998).

A number of factors predictive for retroperitoneal and/or systemic failure have been identified. The presence of lymphovascular invasion within the primary tumor (now included as T2), higher T stage (T2 to T4), that is, tumor involvement of the cord, capsule, or scrotum, and a high percentage of embryonal carcinoma are associated with a higher likelihood of relapse (Read et al, 1992; Gels et al, 1995; Nicolai et al, 1995; Heidenreich et al, 1998; Sogani et al, 1998). Approximately 50% of patients with T2 to T4 tumors experience relapse compared with 15% of patients with T1 tumors. One study from MSKCC noted that almost 80% of patients with clinical stage I and pure embryonal carcinoma who underwent RPLND had pathologic stage II disease (Pohar et al, 2003).

Patient compliance cannot be overemphasized, because strict adherence to periodic follow-up evaluations is critical. Most relapses occur within the first 2 years and are rare after 5 years (Bosl et al, 2005).

Of concern is the increased incidence of second malignancies reported in patients undergoing surveillance, presumably owing to the multiple CT scans required. Using the Surveillance Epidemiology and End Results (SEER) database, a retrospective study of, 334 patients demonstrated an odds ratio of 1.74 (1.02 to 2.95) for second malignancies associated with radiation exposure in patients on surveillance compared with those who underwent RPLND (Chamie et al, 2008). More recently, Tarin and colleagues (2009) calculated the risk of a second malignancy associated with image-related radiation during surveillance for clinical stage I NSGCT and using the National Comprehensive Cancer Network (NCCN) guidelines for CT they reported a relative risk of 15.2 compared with a single post-RPLND scan. The lifetime cancer risk ranged from 1 in 52 (1.9%) for an 18-year old to 1 in 63 (1.2%) for a 40-year old. This increases to 1 in 39 (2.6%) and 1 in 85 (1.6%), respectively, if CT of the chest is included (Tarin et al, 2009).

Chemotherapy

In an attempt to avoid the potential morbidity of an RPLND, several European groups have studied the role of two cycles of cisplatin-based adjuvant chemotherapy in high-risk clinical stage I NSGCT (Oliver et al, 1992; Cullen et al, 1995; Studer et al, 2000). More recently, investigators have examined the efficacy of one cycle of bleomycin-etoposide-cisplatin (BEP) for "high risk" clinical stage I NSGCT and reported encouraging short-term results (Albers et al, 2008; Tandstad et al, 2009). A detailed

discussion of these studies is beyond the scope of this chapter (see Chapter 31).

Although less than 5% of these patients relapse, they are exposed to both the short- and long-term toxicities of chemotherapy, such as myelosuppression, neuropathy, Raynaud phenomenon, ototoxicity, nephrotoxicity, and the risk of acute leukemia. Furthermore, given the paucity of long-term follow-up, the risk of late relapse secondary to unresected chemoresistant teratoma remains unknown.

Investigators at MSKCC reported a 21% incidence of teratoma in patients with pathologic stage II disease, including 6 of 64 (9%) with clinical stage I disease (Sheinfeld et al, 2003a). Although teratomatous elements in the orchiectomy specimen predict for teratoma in retroperitoneal metastasis, its absence in the primary tumor does not preclude its presence in the retroperitoneum (Toner et al, 1990; Foster and Donohue, 1998; Beck et al, 2002; Sheinfeld et al, 2003a).

Clinical Stage IS ("Marker Only" Disease)

Patients with persistently elevated serum tumor markers after radical orchiectomy but negative CT scans of the chest, abdomen, and pelvis should undergo primary cisplatin-based chemotherapy because systemic disease is usually present. Davis and associates (1994) reported that all 11 patients with "marker only" disease who underwent primary RPLND had persistently elevated markers postoperatively. Saxman and colleagues (1996) also reported a high rate of systemic failures in patients with "serologic disease" only after initial surgery. RPLND should be performed if there is radiographic evidence of retroperitoneal disease after chemotherapy. Dash and coworkers (2008) reported the MSKCC experience and noted that 6 of 14 (43%) patients who underwent PC-RPLND in this setting had teratoma ± viable cancer in the resected specimen.

Clinical Stage II Nonseminomatous Germ Cell Tumor

The decision to treat patients with clinical stage II NSGCT initially with either RPLND or cisplatin-based chemotherapy depends primarily on (1) extent of disease, (2) serum tumor marker status, and (3) presence or absence of tumor-related back pain (Bosl and Motzer, 1997).

Retroperitoneal Lymph Node Dissection

Patients best suited for RPLND are those with clinical stage IIA and rare, unifocal IIB tumors less than 3 cm with ipsilateral disease restricted to the primary landing zone and normal serum tumor marker levels (Bosl and Motzer, 1997; Bosl et al, 2005). **The presence of suprahilar, retrocrural, pelvic, or inguinal lymphadenopathy, contralateral or multifocal disease, or back pain implies either unresectable disease or metastases beyond the locoregional lymph nodes, and these patients should receive initial cisplatin-based chemotherapy** (Bosl et al, 2005).

Patients with clinical IIA or IIB disease and elevated serum tumor marker levels should be considered for primary cisplatin-based chemotherapy, because this usually reflects systemic disease (Sheinfeld and Motzer, 2004). Investigators at MSKCC reported that elevated serum tumor marker levels before RPLND were the most predictive factor for (1) systemic relapse in patients with low-volume (pN1) retroperitoneal disease treated without adjuvant chemotherapy and (2) for persistent NSGCT (usually persistent serum tumor marker elevation) despite complete resection of high-volume (pN2, pN3) retroperitoneal disease (Rabbani et al, 1999a, 1999b; Sheinfeld et al, 1999a, 1999b; Bosl et al, 2000; Stephenson et al, 2005, 2007).

A study of 453 patients who underwent primary RPLND at MSKCC showed that by excluding patients whose markers fail to normalize or are clinical stage IIB after 1999, the proportion of patients with pathologic stage II low-volume (pN1) retroperitoneal disease increased significantly (40% before vs. 64% after 1999, $P = .01$) without significantly affecting the rate of retroperitoneal teratoma (21% vs. 22%, $I = .89$) or pathologic stage I (56% vs. 67%, $P = .06$). For patients who did *not* receive chemotherapy, the 4-year progression-free probability improved significantly from 83% before 1999 to 96% after 1999. Consequently, for patients with normal serum tumor markers and clinical stage I to IIA the low rate of systemic progression and the 22% incidence of retroperitoneal teratoma supports the therapeutic role of RPLND (Stephenson et al, 2005).

After RPLND a meticulous pathologic assessment of the retroperitoneal lymph nodes is essential to assess prognosis and direct further therapy (Motzer and Bosl, 1993). With the exception of the Testicular Cancer Intergroup Study, most investigators have reported that the risk of relapse is related to the size and/or number of involved lymph nodes (Motzer and Bosl, 1993; Sheinfeld, 1994). Careful observation is preferred in compliant patients with fully resected low volume (pN1) disease, that is, five or fewer positive nodes *and* all nodes less than 2 cm with no evidence of extranodal extension, because these patients have a low risk of relapse (Pizzocaro et al, 1985; Richie and Kantoff, 1991; Rabbani et al, 1999a, 1999b; Stephenson et al, 2005). Three cycles of cisplatin-etoposide-bleomycin (PEB) or four cycles of etoposide-cisplatin (EP) will be necessary in the event of relapse.

Conversely, patients with high-volume nodal disease have a relapse rate or 50% to 90% (Fraley et al, 1985; Williams et al, 1987; Donohue et al, 1995); therefore patients with six or more positive nodes, any node greater than 2 cm, or any extranodal extension should be considered for two cycles of adjuvant cisplatin-based chemotherapy.

The randomized Testicular Cancer Intergroup Study showed that in patients with pathologic stage II NSGCT observation with standard treatment at relapse and two cycles of adjuvant chemotherapy resulted in equivalent survival rates (Williams et al, 1987). A number of cisplatin-based regimens have proven efficacy is preventing relapse after RPLND (Williams et al, 1987; Weissbach and Hartlapp, 1991). The PEB regimen is favored by the Indiana University group (Behnia et al, 2000); however, Kondagunta and coworkers (2004) have shown that an EP regimen was adequate in preventing relapse in patients with resected high volume disease.

Only patients who undergo complete resection and are clinically free of disease after RPLND are candidates for two cycles of cisplatin-based chemotherapy to prevent relapse. The management of patients with incompletely resected adenopathy or with any clinical evidence of disease (elevated hCG and/or AFP, lung nodule, retrocrural adenopathy) is the same as that for patients with systemic metastasis, that is, three or four cycles of cisplatin-based chemotherapy (Motzer and Bosl, 1993).

Fertility in Low-Stage Germ Cell Tumors

Up to 60% of patients diagnosed with testicular cancer have subnormal pretreatment semen analysis (Nijman et al, 1988). **When compared with healthy controls or males with lymphoma, testicular cancer patients were found to have lower total sperm counts and higher serum follicle-stimulating hormone levels. Similar findings have also been reported in patients with carcinoma in situ** (Petersen et al, 1999). These abnormal parameters before treatment suggest a primary germ cell defect in testicular cancer patients. After orchiectomy, improvement in sperm parameters is seen, implying a reversible defect in fertility that may be due to circulating hCG or psychological stress. Despite this high incidence of oligospermia at the time of diagnosis, while on surveillance 65% of men are able to achieve a pregnancy after orchiectomy (Herr et al, 1998).

Antegrade ejaculation can be preserved in 95% to 98% of patients with clinical stage I disease undergoing nerve-sparing RPLND. Paternity rates as high as 74% have been reported after RPLND for these patients (Foster et al, 1994).

Key Points: Treatment of Low-Stage NSCGT

- Patients whose tumor markers fail to normalize after radical orchiectomy should receive cisplatin-based induction chemotherapy regardless of radiographic findings.
- Bilateral RPLND is the standard template for patients with pathologic stage II NSGCT.
- Although teratoma is histologically benign, its biologic potential is unpredictable and it may grow or undergo somatic (malignant) transformation.
- Patients who have an incomplete resection with pathologic stage II NSGCT or those with any clinical evidence of disease (elevated hCG and/or AFP, lung nodules, retrocrural adenopathy) after primary RPLND require cisplatin-based induction chemotherapy.

SURGERY FOR HIGH-STAGE GERM CELL TUMORS

The initial treatment of patients with advanced GCTs is cisplatin-based combination chemotherapy (Sheinfeld, 1994; Bosl et al, 2000), and a number of effective regimens have been used over the past 30 years (Einhorn and Donohue, 1977; Bosl et al, 1988).

Preoperative Preparation and Timing of Surgery

The postchemotherapy patient mandates thorough reevaluation to assess response to therapy before surgical intervention. This must include repeat serum tumor marker evaluations, a complete blood cell count, and blood chemistries with attention directed to platelet, neutrophil, and white blood cell counts. Operative blood chemistries are checked with particular attention to serum creatinine value after cisplatin-based therapy. Repeat CT of the retroperitoneum and repeat imaging of any other site of prechemotherapy disease are done. Surgical intervention should be delayed until recovery of the white blood cell count (>3.5) and platelet count (>100,000/mm^3) into the normal range, which usually occurs 3 to 4 weeks after the final cycle of chemotherapy.

Preoperative evaluation should include pulmonary function testing in all patients treated with bleomycin. A restrictive pulmonary fibrosis due to alveolar edema and increased collagen deposition after bleomycin treatment can occur (Hay et al, 1991). **This pulmonary fibrosis is believed to increase susceptibility to alveolar edema when patients are exposed to high levels of inspired oxygen concentration and fluid overload** (Goldiner et al, 1978; Zwikler et al, 1994). Donat and Levy (1998) reviewed perioperative pulmonary complications of 77 patients treated with RPLND after bleomycin chemotherapy and found a 57% rate of pulmonary complications. Preoperative symptoms, pulmonary function testing, and history of acute bleomycin were not predictive of postoperative pulmonary complications. **The strongest risk factor for postoperative complications were overall fluid requirements and blood transfusions** (Donat and Levy, 1998). Meticulous management of intravenous fluid in the perioperative period is imperative in patients treated with bleomycin-containing chemotherapeutic regimens (Donat and Levy, 1998).

Histologic Findings and Management Controversies

Postchemotherapy surgery has evolved into an integral part of the management of patients with advanced GCTs; however, its role has undergone continued refinement over the past 2 decades (Sheinfeld et al, 1997). Prior to the development of cisplatin-based chemotherapy, surgical cytoreduction or "debulking" was followed by postoperative chemotherapy, resulting in high relapse rates, significant morbidity, and poor survival rates (Merrin et al, 1976; Donohue et al, 1980).

Improvements in staging techniques such as with CT and MRI, the reliability of serum tumor markers AFP and hCG, and the advent of effective cisplatin-based chemotherapy have led to the integration of surgery as an adjunct after cytoreductive chemotherapy (Donohue et al, 1982, 1998; Sheinfeld and Bajorin, 1993). This multidisciplinary approach has resulted in survival rates of 70% to 80% of patients with advanced GCT (Einhorn, 1981; Bosl et al, 1986, 2000).

Increased serum concentrations of AFP and hCG after primary cisplatin-based chemotherapy are often characterized by unresectable, viable GCT, and second-line "salvage" chemotherapy is usually recommended for these nonresponders (Sheinfeld and Bajorin, 1993; Bosl et al, 2000). A possible exception are patients with an increased serum AFP level, teratoma in the primary tumor, and a postchemotherapy cystic mass in the retroperitoneum. Investigators at MSKCC reported that fluid from cystic teratoma contained variably increased levels of hCG and AFP in all patients with these features and that complete resection resulted in postoperative normalization of serum AFP (Beck et al, 2004). On the other hand the recommendations for adjunctive surgery for patients who have undergone chemotherapy with appropriate normalization of serum tumor markers are variable and occasionally contradictory (Bajorin et al, 1992). Although most clinicians agree that surgical

exploration is indicated for patients with normal tumor marker levels and residual radiographic abnormalities, at the present time there are no standard guidelines for observation rather than adjunctive surgery (Bajorin et al, 1992; Sheinfeld et al, 1997, 2004). Reported variables for patients in whom surgery can be safely omitted include residual masses less than 1.5 cm (Stomper et al, 1985; Carter et al, 1987), "normal" postchemotherapy CT and absence of teratomatous elements in the primary tumor (Gelderman et al, 1988), and a greater than 90% volume reduction of the prechemotherapy mass, a residual mass less than 1.5 cm, and no teratoma in the primary tumor (Donohue et al, 1987).

Earlier published reports demonstrated that the pathologic findings at RPLND after cisplatin-based chemotherapy and normalization of serum tumor marker levels were necrosis/fibrosis, teratoma, or persistent viable carcinoma, each in approximately one third of cases (Donohue et al, 1980). More recently investigators have reported a decrease in the proportion of patients with viable GCT (Table 32–1). This is commonly attributed to stage migration and more effective chemotherapy regimens (Bosl et al, 1988; Carver et al, 2007a).

Current investigators note that, in the retroperitoneum, necrosis/fibrosis compromises 45% to 50% of pathologic findings after primary chemotherapy, teratoma another 40%, and viable GCT the remaining 10%, although variations in the various series probably reflect patient selection and stage migration (see Table 32–1). After second-line or "salvage" chemotherapy the distribution of histologic findings is markedly different, with viable GCT noted in approximately 50% of resected specimens, teratoma in 40%, and necrosis/fibrosis in only 10% of cases (Fox et al, 1993).

Table 32–1.

Postchemotherapy Pathologic Findings in Patients with High-Stage Germ Cell Tumors

AUTHOR	NO. OF PATIENTS	NECROSIS	TERATOMA	CARCINOMA
Donohue et al (1982)	51	16 (31%)	16 (31%)	19 (38%)
Bracken et al (1983)	23	9 (40%)	7 (30%)	7 (30%)
Tait et al (1984)	73	25 (34%)	32 (44%)	16 (22%)
Freiha et al (1984)	40	21 (53%)	18 (45%)	1 (2%)
Pizzocaro et al (1985)	36	16 (44%)	10 (28%)	10 (28%)
Donohue et al (1987)	80	35 (44%)	33 (41%)	12 (15%)
Gelderman et al (1988)	24	17 (71%)	7 (29%)	—
Harding et al (1989)	42	19 (45%)	14 (33%)	9 (22%)
Toner et al (1990)	122	57 (47%)	48 (39%)	17 (14%)
Mulders et al (1990)	55	31 (56%)	12 (22%)	12 (22%)
Aass et al (1991)	173	85 (49%)	50 (29%)	38 (22%)
Fossa et al (1992)	78	51 (65%)	22 (28%)	5 (7%)
Sonneveld et al (1998)*	110	49 (45%)	51 (46%)	10 (9%)
Stenning et al (1998)	153	45 (29%)	85 (56%)	23 (15%)

Steyerberg et al (1998)	172	77 (45%)	72 (42%)	23 (13%)
Carver et al (2008)	504	248 (49%)	199 (40%)	57 (11%)

*Three additional patients underwent exploratory laparotomy but no specimen was resected.

Viable Cancer

The patient's prognosis is related to serum marker level at the time of RPLND, prior treatment burden, and the pathologic findings of the resected specimen and completeness of resection (Donohue et al, 1998). The relapse rate of patients with necrosis/fibrosis or mature or immature teratoma is 5% to 10% after complete resection (Toner et al, 1990; Fossa et al, 1992; Donohue et al, 1998; Carver et al, 2007a); therefore additional chemotherapy is not required. However, if viable GCT is present at any site but all disease is completely resected, two additional cycles provide survival benefit in this subset of patients (Fox et al, 1993). Fox and colleagues (1993) reported that 19 of 27 (70%) patients with completely resected viable GCT after primary chemotherapy followed by two cycles of postoperative chemotherapy remained disease-free compared with none of 7 patients without additional chemotherapy. Similarly, Logothetis and Samuels (1984) and Geller and associates (1989) reported survival rates of 53% and 66%, respectively, in patients undergoing complete resection of viable GCT and additional postoperative chemotherapy. Fizazi and colleagues (2001) challenged the therapeutic benefit of additional chemotherapy in completely resected GCT after induction chemotherapy in a multicenter, retrospective analysis of 146 patients. Three independent prognostic variables for survival were identified: (1) complete resection; (2) good-risk IGCCCG classification; and (3) less than 10% viable malignant cells. Additional chemotherapy appeared to benefit only those with one risk factor but not those without risk factors or with two or more risk factors (Fizazi et al, 2001). The overall survival rates for patients with no, one, or two or three risk factors were 100%, 83%, and 51%, respectively (Fizazi et al, 2001). A follow-up study validated this prognostic index with 5-year overall survival rates of 90%, 86%, and 52% for patients with zero, one, and two or three risk factors. Again, the authors emphasized the need for a complete resection as the most important variable in achieving cure (Fizazi et al, 2008). Fox and associates (1993) reported that two additional cycles of chemotherapy did not have any therapeutic benefit after salvage chemotherapy.

Teratoma

Despite the benign histologic appearance of teratoma, its clinical behavior is unpredictable, suggesting benefit in early and complete resection.

First, teratoma may grow, obstruct or invade adjacent structures, and become either unresectable or increase the technical demands and/or morbidity of a subsequent procedure (Logothetis et al, 1982; Logothetis and Samuels, 1984; Sheinfeld and Bajorin, 1993; Carver et al, 2007c).

Second, there is the risk of somatic (malignant) transformation, that is, the development of non–germ cell malignant elements such as sarcoma or carcinoma (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998). At present there is no reliable way to predict this event; therefore, teratoma cannot be known a priori to be benign. The overall incidence is

6% to 8% but increases to almost 20% in the setting of late relapse or redo PC-RPLND (McKiernan et al, 2003; Sharp et al, 2008). The most common histologic subtypes include sarcoma, particularly rhabdomyosarcoma and carcinomas (Little et al, 1994; Motzer et al, 1998). Toner and coworkers (1990) reported that 3 of 48 (6%) patients with resected teratoma had non–germ cell elements, whereas Little and associates (1994) noted that 45 of 557 (8%) patients undergoing PC-RPLND had malignant transformation of resected teratoma. Thirteen of the 19 patients with sarcomatous elements and 10 of 18 with nonsarcomatous disease remain disease free after surgery (Little et al, 1994). Complete surgical resection is the treatment of choice for this group of chemoresistant tumors and offers patients the best chance for survival (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998).

Motzer and colleagues (1998) performed conventional cytogenetic or molecular genetic techniques on 12 patients diagnosed with teratoma with malignant transformation (TMT). The isochromosome 12p [i (12p)] was identified in 11 patients, confirming GCT clonality. Additionally, chromosomal abnormalities associated with the transformed histology are also noted.

Third, it has been shown that recurrence of teratoma is related to completeness of resection. Sonneveld and associates (2007) reported a fourfold increase in the relapse rate for patients whose tumor was incompletely resected. Loehrer and colleagues (1986) reported on 51 patients with resected teratoma after cisplatin-based chemotherapy. Twenty (39%) patients experienced relapse either with teratoma (10 patients) or visible GCT (10 patients). Predictors of relapse on univariate analysis included initial tumor burden, somatic transformation, and site of residual disease (mediastinum). In an updated series from the Indiana University group on resected teratoma greater than 10 cm 2- and 5-year disease-free survivals of 86% and 75% were reported with a mean follow-up of 42 months. The 2-year disease-free survival was 86% for patients with retroperitoneal disease only compared with 79% and 41% for patients with two to three sites and four sites, respectively ($P = .004$) (Beck et al, 2009).

A series from MKSCC on 210 patients with PC-RPLND teratoma reported a relapse rate of only 14% (30 patients), with half experiencing relapse with teratoma and 17% with somatic transformation and the remainder with viable GCT. Larger postchemotherapy size and intermediate or poor IGCCCG risk classification were independent predictors of relapse after complete resection (Carver et al, 2007c).

Given the potential for teratoma to recur adjacent to the resected specimen it is prudent that imaging with abdominal or pelvic CT should be part of the surveillance protocol for patients with resected teratomas larger that 2 cm (Einhorn, 2007).

Fourth, teratoma is associated with late recurrence (Loehrer et al, 1986; Gelderman et al, 1988; Gels et al, 1995). Loehrer and colleagues (1986) noted that 10 of 51 (19%) patients with teratoma developed late recurrence, with similar rates for mature teratoma (17%) and immature teratoma (23%). Roth and associates (1988) reported that all 7 patients with relapse after 24 months of achieving complete response had teratoma in the primary and/or retroperitoneal specimen. Furthermore, most recurrences developed locally, implying incomplete resection and foci of residual disease (Gelderman et al, 1988; Gerl et al, 1995; McKiernan et al, 2003).

Fibrosis

In an effort to reduce treatment-related morbidity, investigators have attempted to predict fibrosis and thus identify patients who could safely avoid postchemotherapy surgery. This approach is predicated on (1) the reliability of accurately predicting fibrosis; (2) comparable clinical outcomes with timely and appropriate treatment at relapse; and (3) the assumption that surgery for residual masses that yields only fibrosis is never therapeutic. Currently, fibrosis comprises 45% to 50% of resected retroperitoneal specimens after PC-RPLND.

Of 80 patients with sequential CT scans before and after chemotherapy reported from Indiana University, 15 were without teratoma in the primary tumor and at least a 90% decrease in the retroperitoneal tumor volume determined by the formula $v = 0.52d^2$ and none had viable GCT or teratoma (Donohue et al, 1987). However, in a subsequent analysis from the same institution, Debono and associates (1997) found that only 74% of patients with these same criteria who were observed were continuously free of disease and 4 of 6 experienced relapse with retroperitoneal disease. Nichols and coworkers (2008) reported on 56 patients with advanced NSGCT who were observed after a clinical complete response with induction chemotherapy: four (7%) patients experienced a relapse (median follow-up of 34 months) and were salvaged with further treatment, including PC-RPLND for retroperitoneal recurrences.

Observation has been recommended in patients whose tumor marker levels have normalized and in whom the postchemotherapy CT scan is "normal" (Debono et al, 1997; Foster and Donohue, 1998). The definition of a normal postchemotherapy CT scan varies and includes lymph node diameters of 10 mm or less (Fossa et al, 1989c) and 20 mm or less (Mead et al, 1992). A significant number of resected specimens will contain teratoma and/or viable GCT despite strict normal CT criteria (Sheinfeld et al, 1997). Fossa and associates (1989c) reported that 12 of 37 (30%) patients with normal postchemotherapy serum tumor marker levels and CT scan (≤10 mm) had teratoma and 1 patient had viable GCT. Toner and coworkers (1990) reported that 8 of 39 (21%) patients with residual masses less than 1.5 cm had residual teratoma or viable GCT. Oldenburg and colleagues (2003) reported that one third of retroperitoneal postchemotherapy masses less than 2 cm harbored either teratoma or viable GCT, including 20% in masses less than 5 mm. Debono and associates (1997) reported 5 patients (6%) with recurrence in a group of 78 patients with normal postchemotherapy CT scan who were observed.

Positron emission tomography (PET) has been studied in the evaluation of postchemotherapy residual masses in both seminoma and NSGCT (Stephens et al, 1996; Ganjoo et al, 1999). In NSGCT the major limitation is the inability to distinguish teratoma from necrosis (Stephens et al, 1996). In the nonseminoma setting, viable GCT was not reliably predicted and PET is therefore not recommended (Ganjoo et al, 1999).

Although teratoma in the primary tumor predicts the presence of teratoma and viable GCT in the postchemotherapy resection despite volume reduction of the original mass (Donohue et al, 1987; Toner et al, 1990; Fossa et al, 1992; Debono et al, 1997; Beck et al, 2002), **teratoma may be found in the retroperitoneum despite its absence in the orchiectomy specimen** (Toner et al, 1990; Beck et al, 2002). Toner and coworkers (1990) reported that of 75 patients without teratoma in orchiectomy specimen, 25 had resected teratoma after chemotherapy. Furthermore, of 17 patients with a residual mass less than 1.5 cm there was 90% or more shrinkage of the retroperitoneal mass and no evidence of teratoma in the primary specimen, 3 patients (18%) had teratoma, and 2 patients (12%) had viable GCT in the resected specimen. Beck and associates (2002) noted that 48% of patients with teratoma in the retroperitoneal specimen after

chemotherapy did not have teratomatous elements in the primary tumor.

Several logistic regression models have been developed to calculate the probability of necrosis (Toner et al, 1990; Steyerberg et al, 1995). In Steyerberg and colleagues' model, predictors of necrosis included the absence of teratoma in the primary tumor, normal prechemotherapy hCG and AFP levels, a small prechemotherapy or postchemotherapy mass, and a large volume reduction in the retroperitoneal mass.

Multiple studies show that approximately 20% of patients predicted to have fibrosis will harbor either teratoma or viable GCT (Toner et al, 1990; Steyerberg et al, 1995). **No single criterion or combination of criteria predict a negative pathology with sufficient accuracy to eliminate the risk of residual teratoma or viable GCT and thus obviate PC-RPLND** (Sheinfeld et al, 1997; Bosl et al, 2000; Carver et al, 2007c). **Therefore the decision to recommend postchemotherapy surgery depends on the frequency of viable GCT, the biologic potential of teratoma, and the morbidity of the RPLND** (Bosl et al, 2000). **If viable GCT is present, it is partially drug resistant and will progress if left unresected.** When these patients experience relapse, more intensive salvage high-dose or ifosfamide-based chemotherapy is required at the time of relapse (Motzer et al, 1992; Loehrer et al, 1988; Kondagunta et al, 2004; Einhorn, 2007). This therapy would possibly have been avoided had RPLND been performed, viable GCT identified, and two additional cycles of chemotherapy administered. The cure rate of recurrent GCT to ifosfamide-based salvage regimens is approximately 25% (Motzer et al, 1992; Loehrer et al, 1988). Conversely, if viable GCT is completely resected and two additional cycles of cisplatin-based chemotherapy are given, cure rates between 50% and 70% are likely (Toner et al, 1990; Fox et al, 1993). As noted earlier, unresected teratoma may grow rapidly ("growing teratoma syndrome"), invade or compromise local structures, become unresectable, or undergo malignant transformation (Logothetis and Samuels, 1984; Little et al, 1994; Sheinfeld and Bajorin, 1993; Motzer et al, 1998).

The data suggest that undertreatment of patients with advanced GCT after chemotherapy may result in inferior clinical outcomes compared with those who have immediate surgery. Prompt recognition and appropriate treatment of disease progression or relapse after chemotherapy do not appear to compare favorably with immediate postchemotherapy surgery. In a nonrandomized study comparing 330 patients who underwent salvage surgery after relapse, Hendry and coworkers (2002) reported lower rates of complete resection (72% vs. 87%), relapse-free survival (62% vs. 83%), and overall survival (56% vs. 89%) and higher rates of viable GCT (49% vs. 8%) and TMT (6% vs. 1%) in the salvage group. Debono and colleagues (1997) reported that 4 of 78 patients with a complete clinical response who were observed after chemotherapy subsequently died of disease and that only 78% of 27 patients with a teratoma-negative primary tumor, normal serum marker levels, and a 90% or greater radiographic response who were initially treated expectantly were free of disease. Conversely, of 140 patients with less favorable clinical parameters (less than 90% radiographic response with or without teratoma in primary tumor) who underwent immediate postchemotherapy surgery, 4 died of their disease and 94% were free of disease (Debono et al, 1997).

The concept that a pathologically negative surgical specimen (i.e., fibrosis) is of no therapeutic benefit needs to be reassessed. The cumulative experience of 187 patients who underwent PC-RPLND with elevated serum tumor marker levels showed normalization of markers in almost 90% of the 24 patients with necrosis, and they were rendered disease free (Wood et al, 1992b; Beck et al, 2005; Ong et al, 2008). This finding suggests that a subset of patients derive therapeutic benefit from surgery despite a negative pathology. Pathologic sample error may account for this observation, and step-sectioning might identify foci of previously undiagnosed disease.

Recently, investigators from Indiana University performed laser microdissection analysis and fluorescence in-situ hybridization for chromosome arm 12p in stromal cells from 27 patients whose retroperitoneal specimen revealed only fibrosis. Overall, 88% of the cases had genetic alterations as either loss of heterozygosity for genes implicated in germ cell transformation or chromosome arm 12 p abnormalities. The authors conclude that "benign-appearing fibrous lesions could represent a previously unrecognized germ cell tumor element rather than a reactive fibroproliferative response" (Cheng et al, 2007).

The debate over RPLND after chemotherapy is centered on whether residual disease less than 1 cm in diameter requires RPLND (frequently called a "complete remission," even if a small mass is visualized), particularly when there is no teratoma in the primary site. However, even in this most favorable setting, 15% to 20% of resected specimens will contain either teratoma or viable GCT. **Most authors recommend RPLND if residual retroperitoneal disease after chemotherapy measures more than 1 cm in greatest transverse diameter.** This rule of thumb should be followed in the case of these patients and patients referred to experienced urologists if necessary to minimize risk. **When metastatic disease did not initially involve the retroperitoneum, then RPLND may not be necessary after chemotherapy if imaging is normal.** Under any circumstance compliance with follow-up after chemotherapy, and surgery if required, is necessary to detect recurrent disease and minimize the risks associated with late relapse or other unfavorable settings.

Late Relapse

Finally, the data suggest that an uncontrolled retroperitoneum may be a predisposing factor for late relapse (Baniel et al, 1995a, 1995c; George et al, 2003; Carver and Sheinfeld, 2005; Sharp et al, 2008).

Late recurrence of GCT of the testis is defined as relapse after a disease-free interval of at least 2 years in the absence of a second primary testicular tumor. The reported incidence of late relapse of GCT is 2% to 4% and appears to be increasing (George et al, 2003; Carver and Sheinfeld, 2005). Almost 60% of late relapses occur beyond 10 years, emphasizing the need for prolonged follow-up. Approximately 50% of patients with late relapses will be symptomatic, and approximately 60% will have an elevated AFP level (Baniel et al, 1995a, 1995c; George et al, 2003; Carver and Sheinfeld, 2005; Dieckmann et al, 2005; Sharp et al, 2008).

Although late relapses of GCT have been reported in the chest, neck, liver, brain, and pelvis, **the most common site is the retroperitoneum,** regardless of initial stage, clinical presentation, or prior treatment. Fifty to 80 percent of late relapses occur in the retroperitoneum, which further underscores the need for initial complete surgical resection. Postoperative, cisplatin-based chemotherapy did not prevent late local recurrence in the retroperitoneum after suboptimal RPLND for initial low-stage disease (Baniel et al, 1995a, 1995c; Carver and Sheinfeld, 2005; Sharp

et al, 2008). More than 50% of patients with late relapse referred to MSKCC after induction chemotherapy for advanced disease had unresected retroperitoneal masses after chemotherapy, many with residual masses greater than 1 cm at the conclusion of chemotherapy (Sharp et al, 2008). Similarly, only 22 of 37 (59%) patients had undergone PC-RPLND in the Indiana series (Baniel et al, 1995a, 1995c). Late relapse is more common when teratoma is present in a metastatic site (Loehrer et al, 1986; Sonneveld et al, 1998).

Late relapses of GCT are usually chemorefractory, although Motzer and colleagues (2000) reported encouraging results with paclitaxel, cisplatin, and ifosfamide followed by surgery when disease is unresectable at the time of relapse presentation. **Survival rates range from 26% to 46%, and survival is rare without complete resection** (Baniel et al, 1995; George et al, 2003; Dieckmann et al, 2005; Sharp et al, 2008).

Postchemotherapy Surgery for High-Risk Patients with Nonseminomatous Germ Cell Tumors

In a review of 801 patients who underwent PC-RPLND at Indiana University between 1974 and 1994 after cisplatin-based chemotherapy, Donohue and associates (1998) identified several unfavorable subsets of patients characterized by higher relapse and lower survival rates. The overall relapse rate for all PC-RPLND (n = 801) was 27.8%. Whereas the favorable group of PC-RPLND patients (n = 414) had a relapse rate of 11.8%, 174 of 387 (45%) patients with one or more unfavorable risk factors experienced relapse and 29% died of GCT (Donohue et al, 1998).

The first high-risk group are patients undergoing PC-RPLND after salvage chemotherapy, that is, patients with advanced GCT who have a relapse or fail to achieve a complete response to standard cisplatin-based chemotherapy and receive either conventional-dose salvage therapy or high-dose chemotherapy regimens with bone marrow or stem cell support (Donohue et al, 1998). Surgery in this setting is characterized by lower rates of complete resection and a higher proportion of viable cancer (approximately 50%) (Fox et al, 1993). Recent data suggest that taxane-based salvage chemotherapeutic regimens appear to have reduced the rate of viable GCT at PC-RPLND (from 42% to 14%; $P = .01$) (Eggener et al, 2007a). Overall 5- and 10-year disease-specific survival rates were 74% (range 62% to 86%) and 70% (range 56% to 84%), respectively. Furthermore, in the salvage setting patients with resected fibrosis and teratoma had an 87% 5-year survival (Eggener et al, 2007a).

Additional standard-dose chemotherapy does not appear to benefit patients in this setting, compared with a clear benefit in the setting of complete resection of viable GCT after primary chemotherapy (Fox et al, 1993).

The second risk group comprises those with "desperation" PC-RPLND, that is, patients with an elevated serum level of a tumor marker (AFP or hCG) at the time of surgery. Historically, surgery has been avoided in patients with persistently elevated serum levels of tumor markers, because the disease is usually unresectable and thus incurable (Nijman et al, 1988). Recent studies have identified highly selected patients in this setting in whom surgery has curative potential (Wood et al, 1992b; Murphy et al, 1993; Eastham et al, 1994). Murphy and colleagues (1993) reported that 38 of 48 (79%) such patients were rendered free of disease, 29 (60%) normalized their serum tumor marker levels, and 10 (21%) remain disease free with a median follow-up of 46 months. Eastham and associates (1994) noted that 6 of 16 (31%) patients undergoing desperation PC-RPLND were cured, whereas Wood and coworkers (1992b) reported 7 of 15 (47%) patients were rendered disease free.

Beck and colleagues (2005) updated the Indiana University experience with desperation RPLND and reported a 54% survival rate. Unfavorable variables included the need for a redo PC-RPLND and viable cancer in the specimen. Ong and associates (2008) reported a 69% survival rate in patients with elevated tumor markers undergoing PC-RPLND. Favorable survival criteria included stable or declining serum levels of tumor markers, elevated AFP (vs. hCG or hCG and AFP) and complete resection. Dotan and coworkers (2005) reported the MKSCC experience and also noted that patients with rising levels of tumor markers and those with viable disease either in the retroperitoneum or in an extraretroperitoneal site fared worse.

The third high-risk group were patients whose disease was deemed to be unresectable. These patients did very poorly, with 17 of 19 (90%) patients experiencing relapse and only 4 (21%) survivors (Donohue et al, 1998).

The fourth high-risk group is the "redo" PC-RPLND, that is, patients who have undergone a prior attempt at PC-RPLND who present with recurrence in the surgical field (Donohue et al, 1998). **The importance of complete initial postchemotherapy surgery cannot be overemphasized. The data from Indiana University clearly demonstrate that patients who require repeat RPLND are severely disadvantaged, regardless of other risk factors** (Donohue et al, 1998). The relapse rates for primary versus redo PC-RPLND are 20.6% and 51.6%, and the survival rates are 55.3% for the redo group compared with 84.1% in the primary PC-RPLND group (Donohue et al, 1998).

Adjunctive procedures are sometimes necessary to ensure complete surgical resection of residual retroperitoneal masses. En-bloc nephrectomy is the most common adjunctive procedure, ranging from 5% to 20% of cases in the postchemotherapy setting (Nash et al, 1998; Stephenson et al, 2006). These are predominantly left-sided primary tumors with large volume residual disease densely adherent to the left renal vessels and/or hilum (Nash et al, 1998; Stephenson et al, 2006). The MSKCC group reported an 87% (range 69% to 100%) disease-specific survival in this group of patients (Stephenson et al, 2006). Although renal complications are rare, after adjunctive nephrectomy patients should be followed closely for evidence of microalbuminuria or a decline in the creatine clearance value. Vigilance and the early institution of appropriate preventative measures optimize long-term renal function in these patients after cisplatin-based chemotherapy (Stephenson et al, 2006).

Multiple investigators have reported en-bloc resection of a great vessel to achieve complete resection of densely adherent bulky retroperitoneal masses (Donohue et al, 1991; Kelly et al, 1995; Spitz et al, 1997; Beck et al, 1999). Long-term survivors are reported with both inferior vena cava and aortic resections (Kelly et al, 1995; Spitz et al, 1997). Of 65 patients who had a portion of the infrarenal inferior vena cava resected without reconstruction, Beck and associates (1999) reported no long-term sequelae in 75% with 7-year follow-up. However, significant morbidity with venous congestion of the lower extremities and persistent lymphatic drainage into the retroperitoneal space is possible (Waters et al, 2000). If necessary, venous reconstruction can be accomplished with synthetic graft material (Mullen et al, 1996; Spitz

et al, 1997). Similarly, aortic resection is occasionally necessary to achieve a complete resection; and, again, vascular continuity can be achieved with synthetic grafts (Kelly et al, 1995).

This aggressive surgical approach in a subset of appropriately selected patients is justified by the high proportion of teratoma or viable cancer in the resected specimen, the high survival rate of patients after complete resection, and acceptable morbidity when performed by experienced surgeons in tertiary centers (Donohue et al, 1991; Kelly et al, 1995; Spitz et al, 1997).

Postchemotherapy Retroperitoneal Lymph Node Dissection

Although many of the techniques previously described for primary RPLND are applicable in performing postchemotherapy lymphadenectomy, several important points should be emphasized. Large retroperitoneal tumors and severe desmoplastic reaction make PC-RPLND one of the most difficult and dangerous operations undertaken by urologists (Skinner and Skinner, 1992); therefore this operation should be performed by experienced surgeons in referral centers.

The choice of incision is based on tumor location and size. Large masses, located high in the retroperitoneum, may require a thoracoabdominal approach or costal extension of a midline incision. For large left-sided tumors, particularly those that cause lateral displacement of the left kidney with stretching of the renal vessels, massive suprahilar infradiaphragmatic extension is often seen. In this setting a "visceral roll" provides good exposure of the para-aortic area above the left renal artery. By incising (1) the peritoneum of the left lumbar gutter along the white line of Toldt, (2) the splenophrenic ligament, and (3) the parietal peritoneal attachments of the stomach, the descending colon, spleen, stomach, and tail of the pancreas can be reflected medially thus exposing the aorta to the level of the diaphragmatic hiatus (Whitmore and Morse, 1986).

The "split and roll" technique is used to perform the lymphadenectomy. Great care must be taken to avoid subadventitial dissection along the aorta while separating the fibrous wall of the tumor mass and lymph nodes from the great vessels. Aortic wall stripped of adventitia is not amenable to conventional suture repair and may result in delayed rupture. Direct invasion of the aorta or vena cava may require resection with graft interposition. Adjunctive procedures such as nephrectomy may be necessary to achieve complete resection particularly for left-sided tumors. Extensive violation of bowel serosa or enterotomies predispose patients to possible life-threatening fistulas, and omental interposition is advisable.

Tumor involvement of the superior mesenteric artery, celiac axis, or porta hepatis often precludes resection (Whitmore and Morse, 1986).

As noted previously, data from Indiana University and MSKCC clearly demonstrate that patients **who require repeat RPLND are at a significant disadvantage independent of other established risk factors,** and all investigators agree that the oncologic efficacy of an RPLND should not be compromised in an effort to preserve antegrade ejaculation. Importantly, in a recent study from MSKCC analyzing factors associated with the improved clinical outcome in recent years for men with advanced NSGCT, Carver and colleagues (2007a) noted that **complete RPLND superceded stage migration as the most significant variable responsible for the marked decrease in relapse rates. Furthermore, the total number of lymph nodes removed was an independent predictor for disease recurrence after PC-RPLND** (Carver et al, 2008). **Nevertheless, the extent of surgery remains highly controversial. The data suggest that resection of mass alone is inadequate and is not recommended** (Carver et al, 2007a, 2008; Kakiashvili et al, 2009). The role of modified templates in the postchemotherapy setting is less clear. In a highly select subset of 100 patients, representing less than 10% of the overall cohort of patients undergoing PC-RPLND during the study period, and with a median follow-up of 32 months, investigators from Indiana University report a 2- and 5-year disease-free survival of 95% with modified templates (Beck et al, 2009). Conversely, in a recent mapping study, investigators from MSKCC report extratemplate disease between 7% and 32%, depending on the limits of the modified template, and recommend a standard bilateral dissection as the oncologically prudent approach (Carver et al, 2007a). Recently, investigators from the Princess Margaret Hospital reported disease outside a lumpectomy or modified template in 21.4% and 4.7% of cases, respectively (Kakiashvili et al, 2009).

Appropriately selected patients are candidates for nerve-sparing PC-RPLND (Coogan et al, 1996; Pettus et al, 2009). Pettus and associates (2009) reported a single surgeon experience with nerve-sparing PC-RPLND and noted that almost 80% of carefully selected candidates had preserved antegrade ejaculation, including 4 of 9 (44%) with a mass greater than or equal to 5 cm. The 5-year relapse-free survival rate was 98%. The oncologic aspects of the procedure should not be compromised to preserve antegrade ejaculation.

Reoperative Retroperitoneal Surgery

Completeness of resection is an independent and consistent predictive variable of relapse-free survival for patients with NSGCT (Carver et al, 2007a). As noted earlier, Donohue and coworkers (1998) noted that patients undergoing "redo" PC-RPLND were significantly disadvantaged in terms of survival (55% vs. 84%) compared with those who did not require reoperation, despite controlling for marker status, histologic findings, and prior need for salvage chemotherapy. Similarly, McKiernan and associates (2003) reported the MSKCC reoperative experience and noted a 56% 5-year disease-specific survival rate in patients requiring reoperation after PC-RPLND compared with 86% in those without reoperation.

Investigators at MSKCC also showed that inadequate initial surgery in low-stage NSGCT cannot be reliably remedied by postoperative chemotherapy. Twenty (90%) of 22 patients who received cisplatin-based chemotherapy after incomplete initial RPLND and who underwent reoperative retroperitoneal surgery after primary RPLND experienced compromised survival, 86% versus 99.3% in patients not requiring reoperation (McKiernan et al, 2003). In the MSKCC series, 10 (45%) of 22 patients undergoing primary RPLND and 20 (59%) of 34 undergoing PC-RPLND had teratomatous elements present at initial surgery before local recurrence, underscoring the need for complete and meticulous resection of teratoma (McKiernan et al, 2003). Hence, tumors that are incompletely resected and require reoperative surgery after either primary or PC-RPLND result in compromised survival (Donohue et al, 1998; Sheinfeld, 2002a; McKiernan et al, 2003).

The left para-aortic region is the most common site of local recurrence prompting reoperation (McKiernan et al, 2003). This is due to the increased technical demands of obtaining adequate exposure in this area, including pancreatic mobilization and dissection of the renal vessels. Unfortunately, the preaortic and

para-aortic lymph nodes in modified templates for right-sided tumors are often not dissected (Carver et al, 2007b; Eggener et al, 2007b). Data from MSKCC and Indiana have shown that a significant subset of patients with right-sided primary NSGCT and pathologic stage II disease will have involved lymph nodes in the para-aortic area (Leibovitch et al, 1995a; Koppie et al, 2004; Carver et al, 2007; Eggener et al, 2007).

When necessary, reoperative retroperitoneal surgery is better performed with acceptable morbidity in dedicated tertiary centers with experienced surgeons (Donohue et al, 1998; McKiernan et al, 2003; Sexton et al, 2003).

Lung, Mediastinal, and Neck Resections

The indications and timing for postchemotherapy resection of residual masses in the chest are less controversial. Early investigators reported discordant histologic findings ranging from 29% to 46% between the retroperitoneum and the chest (Mandelbaum et al, 1983; Tiffany et al, 1986; Qvist et al, 1991).

Toner and associates (1990) reported on 39 patients who underwent 57 procedures for pulmonary nodules. Six of 14 patients with nodules 1 cm or smaller had either teratoma (5 patients) or viable cancer (1 patient), whereas 3 of 8 patients who underwent bilateral thoracotomies had different histologic findings in each lung.

Logistic regression analysis of multiple clinical parameters to estimate the probability of necrosis at thoracotomy found that necrosis in the retroperitoneum was the most predictive variable (Steyerberg et al, 1997). Other predictors included primary tumor histology, prechemotherapy tumor markers, change in size after chemotherapy, and the presence of a single mass (Steyerberg et al, 1997).

More recently, Tognini and coworkers (1998) reported that although retroperitoneal histology was most predictive of thoracic histology, only 31 of 40 (78%) patients with necrosis in the abdomen had necrosis in the chest. Further categorization of the RPLND as standard or complicated increased the predictive accuracy to 86%.

Finally, the recent MSKCC experience of 93 patients who had RPLND and thoracotomy revealed histologic discordance between RPLND and thoracotomy in 27 of 93 (29%) patients; 7 of 59 (14%) patients with fibrosis in the retroperitoneum had teratoma or viable cancer in the chest (McGuire et al, 2003).

Postchemotherapy thoracotomy yields important prognostic information and is therapeutic in most patients with resected teratoma and a subset of patients with viable cancer. Criteria predictive of necrosis are not sufficiently accurate to omit resection of postchemotherapy residual thoracic masses; therefore, all sites of disease should be resected regardless of size (McGuire et al, 2003). **Furthermore, investigators have demonstrated the feasibility of simultaneous RPLND and thoracic resection in experienced tertiary centers** (Brenner et al, 1996; Tognini et al, 1998; McGuire et al, 2003).

Mohseni and colleagues (2002) reported on 16 patients with a residual neck mass who underwent resection of 61 residual masses in multiple sites. Histologic discordance in different sites was seen in 7 of 16 (44%) patients, and 13 of 16 patients had teratoma (10 patients) or viable GCT (3 patients) in the neck. All 10 patients with teratoma in the residual neck mass and 1 of 3 patients with viable GCT have no evidence of disease after complete resection. There were no perioperative deaths, and no patient suffered relapse in the neck.

Key Points: High-Stage Germ Cell Tumor

- The initial treatment for patients with advanced GCT is cisplatin-based combination chemotherapy.
- Postchemotherapy pathologic findings in patients with advanced NSGCT after induction therapy is 45% to 50%; for teratoma, 40%; and for viable carcinoma, 10%.
- Variables and statistical models to predict necrosis in the retroperitoneum after induction therapy have approximately a 30% error.
- Teratomatous elements may be found in the retroperitoneum despite its absence in the orchiectomy specimen.
- Teratoma may grow and obstruct or invade local structures, undergo malignant transformation, and result in late relapse.
- Recurrence of teratoma is related to completeness of resection.
- Bilateral RPLND remains the standard template in the postchemotherapy NSGCT setting; resection of residual mass *alone* is an *unacceptable* alternative.
- Histologic discordance between different sites (e.g., retroperitoneum, thorax, neck) after postchemotherapy resection is found in approximately 30% of cases.
- Sixty percent of late relapses occur beyond 10 years, emphasizing the need for prolonged follow-up. The most common site is the retroperitoneum.
- Patients who require repeat RPLND are at a significant disadvantage independent of other risk factors.
- The para-aortic region is the most common site of local recurrence after RPLND.

Complications

The rate of complications for postchemotherapy surgery is higher than for primary RPLND (Subramanian et al, 2008). Baniel and associates (1995a, 1995b) reported 38 (8%) major complications in 478 patients who underwent primary RPLND compared with 106 (18%) in 603 patients after PC-RPLND. Furthermore, there were five deaths in the postchemotherapy group and none in the primary group. Large-volume residual disease, postchemotherapy desmoplastic reaction, prior exposure to bleomycin, and more extensive retroperitoneal resection increase the technical and perioperative demands of the procedure and result in higher morbidity rates. Fortunately, the morbidity appears to be decreasing with time. Mosharafa and associates (2004) reported that the rate of perioperative complications and length of hospital stay decreased from July 2000 to July 2002 compared with patients who underwent PC-RPLND from July 1990 to July 1992. Careful monitoring of perioperative oxygen concentrations, meticulous fluid management with strict replacement criteria, and an emphasis on colloid rather than crystalloid have reduced pulmonary toxicity. Knowledge of the retroperitoneal anatomy, careful technique, and improved perioperative management have resulted in lower morbidity when PC-RPLND is performed by experienced surgeons. Data from a retrospective analysis suggested a beneficial impact of clinical care pathways on the reduction of perioperative morbidity (Chang et al, 2002b).

Lymphatic Complications

The incidence of chylous ascites is 2% to 3%, and predisposing factors include resection of the vena cava, suprahilar dissection, or simultaneous hepatic resection.

Familiarity with retroperitoneal lymphovascular anatomy and meticulous lymphostasis with clips or ligatures will minimize this complication.

Patients with chylous ascites may present with abdominal distention, prolonged ileus, an abdominal fluid wave, a pleural effusion, or chylous leakage from the incision. Ultrasonography or CT with paracentesis is diagnostic and may provide symptomatic relief. Chylous fluid has a characteristic milky or turbid appearance with a fat content of 4 to 40 g/L and a total protein content greater than 30 g/L. Initial management is with diuretics and dietary manipulation (low-fat diet with medium-chain triglycerides) and/or total parenteral nutrition. Persistent drainage of chyle that is refractory to conservative measures may require peritoneovenous shunting (Baniel et al, 1995b, 1995d). Reoperation to repair lymphatic leakage is associated with a high failure rate and should be avoided.

Asymptomatic lymphoceles require no treatment; however, percutaneous drainage for infection, hydronephrosis, or bowel obstruction is necessary in 1% to 2% of cases. Persistent drainage may require treatment with a sclerosing agent.

Pulmonary Complications

Pulmonary complications include (1) atelectasis, which is treated by vigorous pulmonary physiotherapy; (2) pneumonia, which requires appropriate antibiotic therapy; and (3) acute respiratory distress syndrome, which often requires prolonged mechanical ventilation and corticosteroids and may be fatal. The signs and symptoms of acute respiratory distress syndrome include a dry nonproductive cough, dyspnea, rales, fever, and interstitial pneumonitis on the chest radiograph. **It is the authors' practice to judiciously monitor the perioperative fluid administered to bleomycin-treated patients and to avoid unnecessary exposure to high concentrations of inspired oxygen.**

Infectious Complications

Superficial wound infections comprise the majority of infectious problems whereas urinary tract infections account for less than 1%. *Clostridium difficile* infections require appropriate antibiotic therapy with metronidazole or vancomycin. Incidental appendectomy increases the risk of infection and is contraindicated (Leibovitch et al, 1995b).

Vascular Complications

Renovascular injury is seen in 2% to 3% of cases and can result in renovascular hypertension or require nephrectomy at the time of RPLND. Minor injury of the great vessels during dissection can be managed with 5-0 vascular sutures. Major vascular injury requiring unplanned grafting or prolonged cross-clamping are uncommon in experienced centers.

Neurologic Complications

Peripheral nerve injury due to neural compression secondary to positioning is rare and accounts for less than 1% of all complications, particularly in the transabdominal approach. Femoral and brachial neurapraxias have been reported (Baniel et al, 1995b). The more serious complication of spinal cord ischemia with aortic mobilization is encountered in less than 1% of all cases and has been associated with older age, simultaneous mediastinal and retroperitoneal dissections, previous radiotherapy, and intraoperative hypotension (Leibovitch et al, 1996). This complication can be minimized by selective preservation of lumbar arterial branches in suprahilar and thoracic dissections.

Gastrointestinal Complications

Prolonged paralytic ileus may be associated with mechanical obstruction or less commonly with retroperitoneal hematoma, pancreatitis, urinary extravasation, mesenteric hematoma, and bowel infarction (Whitmore and Morse, 1986). Small bowel obstruction is seen in 2% to 3% of all patients and can be managed conservatively with exploration being reserved for signs of toxicity or failure to respond to prolonged nasogastric tube decompression. Pancreatitis usually presents as prolonged ileus and hyperamylasemia and can be avoided by minimizing traction on the pancreas during RPLND. Therapy is usually conservative with nasogastric tube decompression and occasional need for hyperalimentation. Isolated hyperamylasemia may be seen in up to 40% of asymptomatic patients and is self-limiting (Baniel et al, 1995d). Gastrointestinal bleeding is rare and can be minimized by the use of perioperative H_2 antagonists. Sacrifice of the inferior mesenteric artery is common and is rarely associated with any lower gastrointestinal complication. Duodenal hematomas and laceration have been reported and are seen in the setting of high-volume disease behind the duodenum, making dissection in this area particularly demanding. In the past, routine appendectomy at the time of RPLND was performed; however, it has been found to be associated with an increased risk of infectious complications and therefore is no longer recommended (Leibovitch et al, 1995b).

Seminoma

The approach to the patient with pure seminoma and a residual mass after chemotherapy is controversial. **There are two important differences between seminoma and NSGCT in this setting. First, teratoma in the residual mass is very rare. Second, a complete RPLND is often not technically possible owing to obliteration of tissue planes secondary to the severe desmoplastic reaction of these tumors after chemotherapy** (Horwich et al, 1997; Sheinfeld and Herr, 1998; Bosl et al, 2000). **Consequently, perioperative morbidity is higher than for NSGCT** (Fossa et al, 1987; Ellison et al, 1988).

Several studies have evaluated the role of surgery for residual masses in seminoma patients (Fossa et al, 1987; Loehrer et al, 1987; Puc et al, 1996; Herr et al, 1997; Horwich et al, 1997). Loehrer and associates (1987) reported on 62 patients with advanced-stage seminoma who received cisplatin-based chemotherapy. Of the 13 patients who underwent attempted surgical resection, 3 (23%) had residual malignancy and the size of the residual mass was not predictive of histologic findings. Fossa and colleagues (1987) reported 39 patients with advanced-stage seminoma, 15 of whom had received prior radiation therapy; 3 of 12 patients (25%) who underwent surgical exploration had viable seminoma, and one postoperative death secondary to pulmonary toxicity was reported. Both groups concluded that observation was preferable in these patients given the significant surgical morbidity and the fact that the majority of postchemotherapy seminoma patients with residual radiographic abnormalities do not have persistent malignant disease (Fossa et al, 1987; Loehrer et al, 1987). Investigators at the Royal Marsden Hospital report only a 12% relapse rate in postchemotherapy seminoma patients with observation alone despite radiographic abnormalities in over 80% of patients (Peckham et al, 1985).

In a group of 104 postchemotherapy seminoma patients, investigators at MSKCC reported that 8 of 30 (27%) patients with a residual mass of 3 cm or larger experience relapse or had residual

seminoma whereas only 2 of 74 patients (3%) with tumors smaller than 3 cm in diameter had relapse at the site of residual disease. Of the 55 patients who underwent surgery, 32 (58%) had masses resected whereas 23 (42%) underwent multiple biopsies. There were no postoperative deaths (Puc et al, 1996; Herr et al, 1997).

Although there is general agreement that patients with residual masses less than 3 cm should be observed, management of the minority of patients with residual masses larger than 3 cm remains controversial. Investigators at MSKCC believe that resection or biopsy of residual masses larger than 3 cm is preferable to observation because it can identify residual disease and direct immediate therapy (Puc et al, 1996; Bosl et al, 2000). If viable seminoma is identified, additional chemotherapy is necessary (Puc et al, 1996). Alternatively, radiation therapy is possible; however, approximately 75% of patients will receive it unnecessarily and it did not appear to reduce the risk of relapse (Horwich et al, 1997; Bosl et al, 2000). Observation is a third option; however, ifosfamide-based salvage chemotherapy for patients who experience relapse had a low cure rate (Bosl et al, 2000).

Recently, a study of fluorodeoxyglucose (FDG)-labeled PET in 52 patients with residual masses after chemotherapy for bulky seminoma reported that all 8 positive scans and 42 of 44 negative scans correlated with clinical outcome (De Santis et al, 2004). Conversely, Daneshmand and associates (2008) reported a 50% false-positive rate in this setting.

In summary, **patients with residual masses smaller than 3 cm after chemotherapy may be observed. FDT-PET should be done for masses 3 cm or larger. A negative PET scan usually implies freedom from disease, whereas a positive PET scan is often associated with residual viable seminoma and additional therapy should be considered.** If surgical resection appears feasible, it should be done at centers with experienced surgeons (Bosl et al, 2005).

Fertility in Advanced-Stage Germ Cell Tumors

Subnormal pretreatment semen parameters in conjunction with cytotoxic chemotherapy and more extensive surgery RPLND make fertility less common in the postchemotherapy setting. Cytotoxic chemotherapy has been shown to have long-term deleterious effects on Leydig cell function (Brennemann et al, 1997; Howell et al, 1999). Platinum-based chemotherapy regimens cause both Leydig and Sertoli cell dysfunction. **After two or four cycles of platinum-based chemotherapy a nadir in spermatogenesis is reached in 10 to 14 months. The majority of patients with normal pretreatment spermatogenesis will return to baseline function by 3 years** (Brennemann et al, 1997). Overall fertility rates after chemotherapy are directly related to the total dose of platinum delivered during treatment (Pont and Albrecht, 1997). Patient age and pretreatment follicle-stimulating hormone levels are also predictive of long-term fertility after chemotherapy (Brennemann et al, 1997). Cryopreservation of sperm is now widely available and is recommended before chemotherapy for testicular cancer. However, many patients will recover adequate spermatogenesis and not require the use of cryopreserved sperm (Fossa et al, 1989a). **Despite defects in spermatogenesis and exposure to cytotoxic therapy, the incidence of birth defects is not increased in children conceived after treatment of testicular cancer** (Byrne, 1990; Hartmann et al, 1999).

Results and Current Status
Summary

Germ cell tumors (GCTs) are the most common malignancy in men between the ages of 15 and 35 (Carver and Sheinfeld, 2005). Fortunately, testicular cancer is also one of the most curable solid organ neoplasms, owing in large part to an excellent multimodal treatment paradigm that includes effective platinum-based chemotherapy and surgery (Einhorn, 1981). **Although contemporary survival rates for GCTs are more than 90%, it is critical to note that cure rates and patient morbidity depend on selection of the management options.** Retroperitoneal lymph node dissection (RPLND) plays a major role in the management of patients with GCTs. The role of surgery continues to evolve owing to advances in chemotherapy regimens, clinical staging modalities, and continued surgical innovation (Sheinfeld and Herr, 1998; Allaf et al, 2005; Albers et al, 2008).

Whereas primary chemotherapy is favored in Europe, traditionally RPLND has been the management strategy of choice in the United States for high-risk patients with clinical stage I nonseminomatous GCT (NSGCT). The reason for this is that RPLND can accurately stage the retroperitoneum and thus positively identify those patients harboring metastases. In addition, patients with pathologic stage I disease are spared the toxicity and morbidity of any additional therapy because 90% or more experience long-term disease-free survival with surgery alone. Patients with pathologic stage II disease can learn more about the extent of their disease and make informed decisions regarding further therapy after RPLND. For patients in this group who harbor small-volume retroperitoneal disease (pN1), a properly performed RPLND can be curative in approximately 70% of men; thus chemotherapy also can be avoided in this setting (Richie and Kantoff, 1991; Donohue et al, 1993; Rabbani et al, 2001). Because the retroperitoneum is the most frequent site of chemoresistant malignant GCT and teratoma, both of these processes are minimized with RPLND (Baniel et al, 1995). Some groups advocate RPLND as the treatment of choice for all men with clinical stage I NSGCT with teratoma in the orchiectomy specimen given the increased propensity of harboring teratoma in the retroperitoneum (Sheinfeld et al, 2003). RPLND eliminates these chemoresistant elements and maximizes therapeutic efficacy.

Traditionally RPLND for GCTs has been performed via an open transabdominal or thoracoabdominal approach. Over the past 2 decades minimally invasive approaches for the treatment of various malignancies have emerged and become popular. Since the early 1990s, retroperitoneal laparoscopic surgery has been utilized with proven benefits related to reducing perioperative morbidity, improving cosmesis, and shortening convalescence without compromising oncologic efficacy (Cadeddu et al, 1998; Allaf et al, 2004; Permpongkosol et al, 2005). Laparoscopic RPLND (L-RPLND) is a technically demanding procedure that is increasingly being performed by experienced laparoscopic surgeons aiming to minimize morbidity while duplicating the open technique. **Given that untreated retroperitoneal disease and late relapses in the retroperitoneum are fatal and can be chemorefractory, it is of paramount importance that, just like in open RPLND, a complete "clean out" of lymph nodes is performed** (Whitmore, 1979; Borge et al, 1988; Baniel et al, 1995; Carver et al, 2005).

In this chapter the evolution of L-RPLND is summarized. Included is a discussion of controversies surrounding its use, surgical techniques, outcomes, and associated complications. The focus is placed on the management of low-stage NSGCTs and the role of L-RPLND in the postchemotherapeutic setting.

RATIONALE AND EVOLUTION

In an effort to decrease the morbidity associated with open RPLND, shortly after the introduction of laparoscopic renal surgery in 1991 several reports emerged documenting the feasibility of L-RPLND

in the management of clinical stage I NSGCT (Rukstalis and Chodak, 1992; Stone et al, 1993; Klotz, 1994). Larger retrospective series followed suggesting decreased blood loss, shorter hospital stays, and faster return to normal activity when compared with open RPLND, with preservation of antegrade ejaculation in more than 95% of patients (Gerber et al, 1994; Janetschek et al, 1994, 1996). An early multi-institutional retrospective analysis demonstrated preservation of antegrade ejaculation in all patients, short hospital stays (<3 days), and return to normal activity at 2 to 3 weeks postoperatively (Gerber et al, 1994). **The abbreviated convalescence allows patients who are candidates to receive chemotherapy with minimal delay.** These attractive early results encouraged others to investigate L-RPLND as a viable treatment option for low-stage NSGCT.

STAGING L-RPLND AND CONTROVERSY

Of all laparoscopic applications to surgical urology, L-RPLND has raised the most controversy. This is due to the technical difficulty of RPLND in general, the limited number of cases, as well as lack of interest at traditional centers of excellence. Laparoscopy is an access technique with the internal procedure being performed the same as that with an open incision. As such, experience drives an equivalent dissection. In all early series and some contemporary studies, L-RPLND was used as a staging procedure (Bianchi et al, 1998; Janetschek et al, 2000). Patients not harboring occult metastases were identified and spared exposure to chemotherapy without undergoing open RPLND. In this form, L-RPLND was performed without retrocaval or retroaortic dissection and chemotherapy was given to all patients harboring metastatic disease (including patients with pN1 disease). The decision to omit dissection behind the great vessels was based on the belief of a lack of isolated positive lymph nodes in this area (Holtl et al, 2002). Within this paradigm, the procedure was routinely aborted if positive lymph nodes were encountered and chemotherapy was instituted in these cases (Bianchi et al, 1998; Nelson et al, 1999). **In contemporary series this approach has been abandoned and L-RPLND has evolved into a therapeutic procedure duplicating the open approach in its intent** (Allaf et al, 2005; Steiner et al, 2008).

The use of restrictive template boundaries coupled with the universal use of chemotherapy in men harboring pathologic stage II disease generated criticism of published L-RPLND series. The controversy regarding the use of "staging" L-RPLND hinges on mapping studies demonstrating increased multifocality and contralateral disease in the presence of positive retroperitoneal nodes (Ray et al, 1974; Donohue et al, 1982; Weissbach and Boedefeld, 1987; Eggener et al, 2007). Critics argue that the liberal use of chemotherapy will not necessarily prevent relapses and compensate for incomplete resection.

DUPLICATION OF OPEN RPLND

Currently at experienced centers an exact replication of the open template is performed on all patients with NSGCT undergoing L-RPLND with wide templates and complete excision of retroaortic and retrocaval tissue, thus rendering the procedure both a staging and a therapeutic operation. Some groups perform a bilateral dissection on all patients whereas others reserve it for patients with lymph node involvement (Allaf et al, 2005; Steiner et al, 2008).

SURGICAL TECHNIQUE

L-RPLND is a technically challenging procedure associated with a steep learning curve and thus should be undertaken by experienced laparoscopic surgeons who are comfortable and adept with advanced vascular techniques and open surgery in case of conversion. The indications for primary L-RPLND are identical to those of open RPLND and include clinical stage I or IIA disease, negative serum tumor markers, and the absence of comorbidities that would preclude safe surgery. In the postchemotherapeutic setting L-RPLND has been mainly limited to small-volume residual disease; however, with experience, bulky tumors have been excised. **The surgical template for the procedure is dictated by laterality and intraoperative findings. Surgical margins should not be compromised to minimize morbidity, to preserve ejaculation, or because of technical constraints. The extent of the node dissection can be expanded based on intraoperative findings.**

Preoperative Patient Preparation and Technical Considerations

All patients considered candidates for L-RPLND must be fully informed of all treatment options, including open RPLND, chemotherapy, and surveillance. All potential complications, including bleeding requiring blood transfusion, injury to adjacent organs (liver, bowel, gallbladder, kidney, ureter, pancreas, major vascular structures), and orthopedic, neurologic, or pulmonary complications, as well as conversion to open surgery due to complications or incomplete resection, should be discussed (Allaf et al, 2005; Winfield, 1998). Patients interested in future fertility are educated regarding preoperative sperm banking. Some surgeons advocate a low-fat diet 1 to 2 weeks before surgery to reduce the risk of chylous ascites, but data regarding this practice are not definitive. Patients undergo a mechanical bowel preparation the afternoon before surgery and take only clear liquids until midnight to decompress the bowels. Preoperative antibiotics are given before surgery, and antiembolism devices are placed on the lower extremities to minimize deep vein thrombosis.

Standard laparoscopic instruments are used throughout this procedure (e.g., atraumatic graspers, scissors, clip appliers, irrigation/suction device, and laparoscopic paddle retractor). Radiolucent polypropylene clips (Hem-o-Lok, Weck Closure Systems, Triangle Park, NC) may minimize artifact on postoperative imaging of the retroperitoneum. In addition, a needle driver loaded with suture and adjunct hemostatic agents such as gelatin matrix (FloSeal Matrix Hemostatic Sealant, Fusion Medical Technologies, Fremont, CA) or oxidized cellulose (Surgicel, Ethicon, Piscataway, NJ) should be readily available in case of vascular injury. Sealing devices such as ultrasonic shears and bipolar devices should be used with caution and can be unreliable in sealing large lymphatic channels. A laparoscopic retractor is particularly useful for medial retraction of the bowel and alleviates the need to position the patient in a modified flank position. A gauze sponge placed in the abdomen can be helpful in tamponading bleeding.

Approach

Although some surgeons utilize an extraperitoneal approach (Hsu et al, 2003; Hara et al, 2004) most prefer a transperitoneal approach owing to the larger and more familiar working space. **Additionally, a transperitoneal approach facilitates bilateral**

dissection when warranted by allowing access to all four quadrants.

Patient Positioning and Port Placement

After general anesthesia is induced, an orogastric tube and Foley catheter are inserted. The patient may be placed in the modified flank position (45 degrees) with the side of dissection elevated, but the authors prefer the supine position because it makes transitioning to a bilateral dissection less cumbersome and does not require patient repositioning (Fig. 33–1). Great care is taken to pad all pressure points to minimize the risk of nerve injury or rhabdomyolysis because these surgeries may require a longer time than their open counterpart. The patient must be secured to the operating table because tilt is needed to use gravity to help shift the bowel out of the operative field.

After intraperitoneal access is achieved (via a Veress needle or Hasson technique), four equally spaced 10/12-mm laparoscopic ports are placed in the midline beginning 1 cm below the xiphoid process (Fig. 33–2). As such, the umbilicus may not necessarily be incorporated as a port site. The large port size is essential to allow for the convenient introduction of larger (10/12-mm) instruments from varying angles. An additional 5-mm port may be placed in the midaxillary line midway between the iliac crest and ribs for additional retraction if needed. The bed is rotated maximally to allow optimal medialization of the bowel away from the operative field.

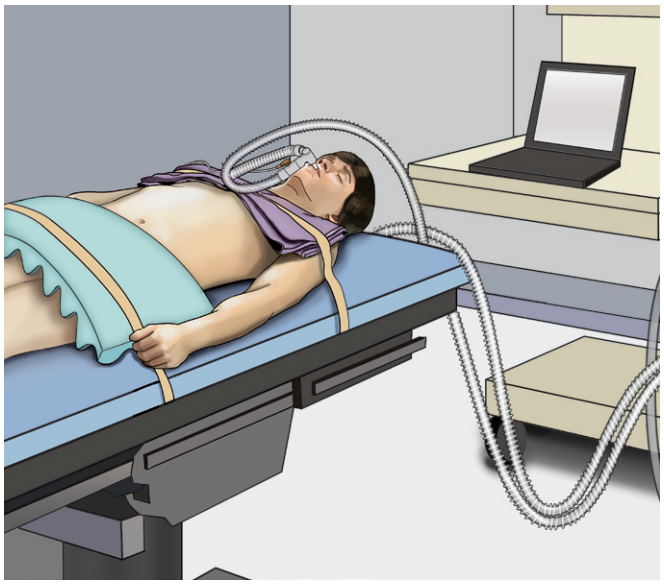

Figure 33–1. Patient positioning during laparoscopic retroperitoneal lymph node dissection. The arms are tucked, and the patient is padded and secured in a relatively supine position.

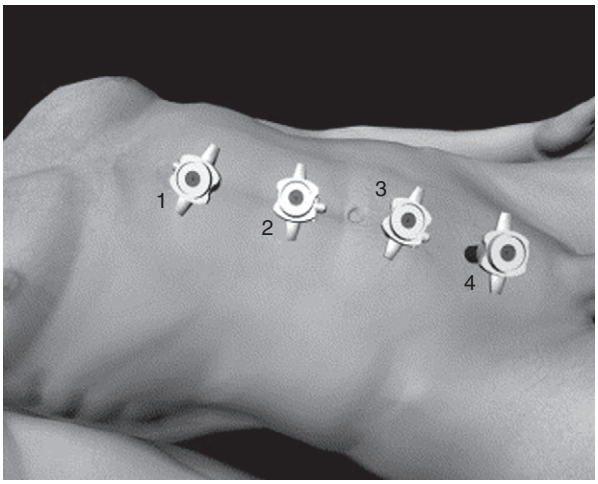

Figure 33–2. Port placement for laparoscopic retroperitoneal lymph node dissection. Four 10/12-mm equally spaced trocars are placed in the midline.

Right-Sided Dissection

The ascending colon is mobilized by incising the white line of Toldt from the pelvis and around the hepatic flexure. The second portion of the duodenum is identified and kocherized, providing exposure of the retroperitoneum including the medial para-aortic space on the left.

Spermatic Cord Dissection

The camera is moved to the second to the bottom trocar (trocar 3 in Fig. 33–2) to facilitate visualization during dissection of the spermatic cord stump. The peritoneum medial to the spermatic cord is incised, and the vas deferens is transected. The peritoneum is incised circumferentially around the inguinal ring (Fig. 33–3). With gentle traction on the cord, fibrous attachments and scar are incised until the suture on the spermatic cord is identified. The attachments are cut, and the cord is followed proximally along with surrounding nodal and fibroadipose tissue to the inferior vena cava (IVC). The ureter must be identified at all times to prevent inadvertent thermal injury. The spermatic vein and artery are both ligated proximally and transected. The specimen is placed in an endobag and dropped on the contralateral side of the abdomen.

Lymphadenectomy

Although templates should be individualized to each case, the authors advocate removal of the right common iliac, paracaval,

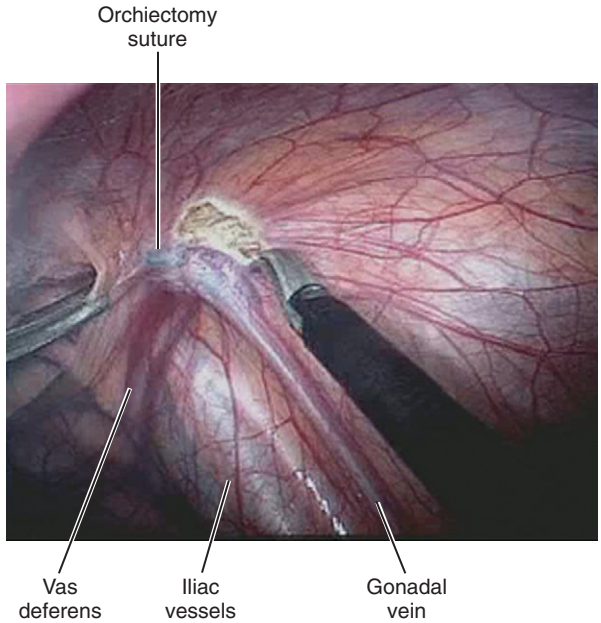

Figure 33–3. Incision of posterior peritoneum circumferentially about the inguinal ring.

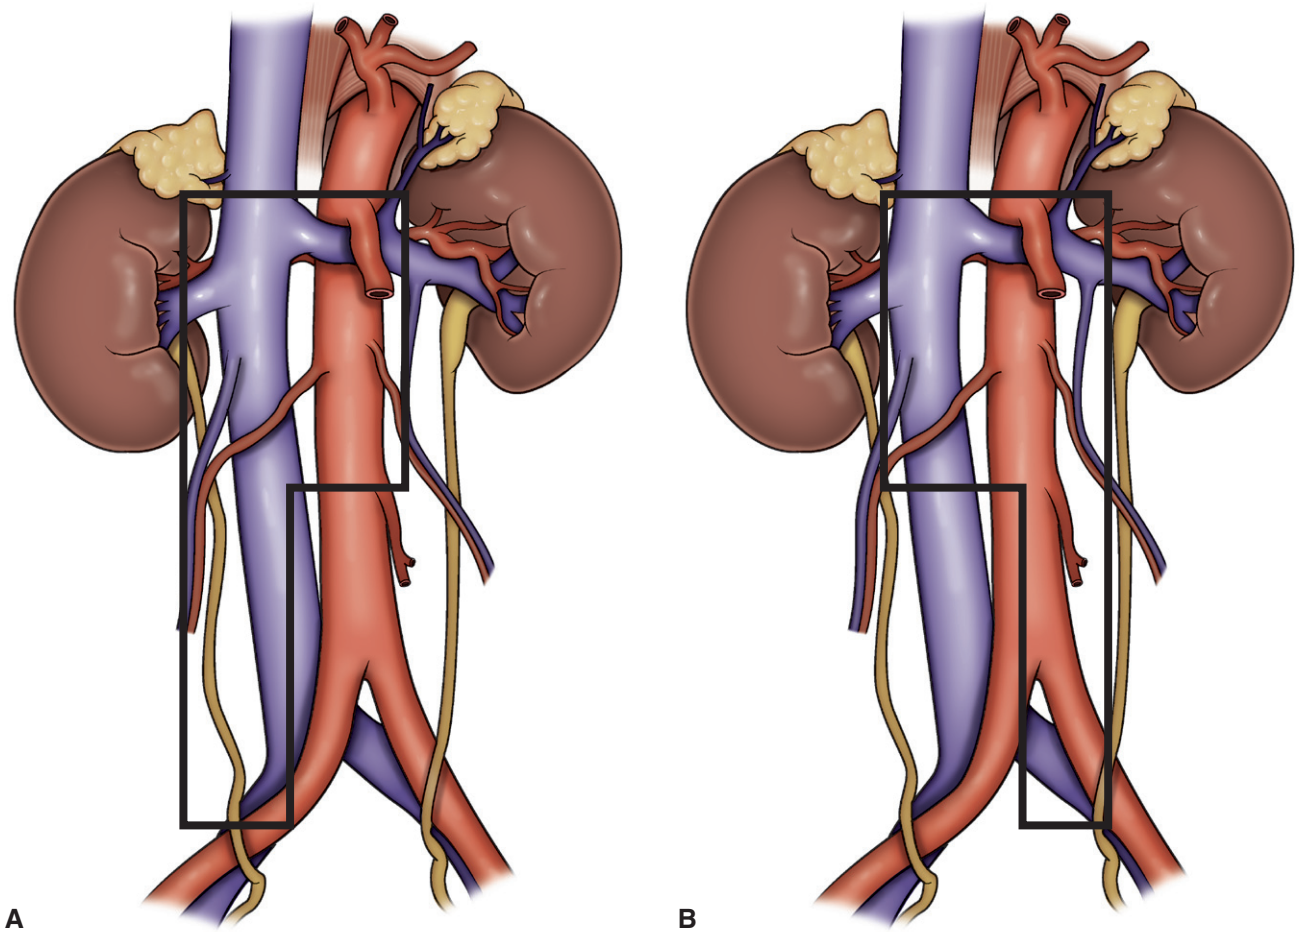

Figure 33–4. Suggested templates for right (**A**) and left (**B**) therapeutic laparoscopic retroperitoneal lymph node dissection. These templates can be expanded or contracted based on each patient's tumor.

interaortocaval, preaortic, and medial para-aortic nodes (Fig. 33–4). Occasionally in obese patients (or when performing a full bilateral dissection) the left-most border of the dissection must be performed after rotating the table contralaterally to optimize exposure. The camera should be moved to the port second from the top. A paddle retractor is placed in the lowest trocar to protect and sweep the bowel medially.

The testicular vein stump is identified and minimally manipulated to prevent pseudoaneurysm formation with subsequent rupture. The tissues overlying the IVC are gently lifted and carefully incised longitudinally (Fig. 33–5). It is swept off the IVC in a "split and roll" fashion. Blunt dissection aids in further separating these lymphatic tissues toward and overlying the common iliac vessels inferiorly and renal hilum superiorly. Care must be taken to avoid injury of lower pole renal arteries, which are present in approximately 20% of cases, and accessory vessels crossing anterior to the IVC. The renal hilum is then dissected to separate all fibroadipose tissue from the renal vein and artery as far under the IVC as possible. Next the ureter is traced to its crossing over the common iliac vessels, and thus the lymphatic packet is separated from both of these structures. The "split" tissue along the IVC is then "rolled" medially to expose the retrocaval space. Lumbar vessels are identified, clipped, and divided to allow splitting of the posterior lymphatic tissues (Fig. 33–6). Once this is accomplished the tissues are released from their attachment to the

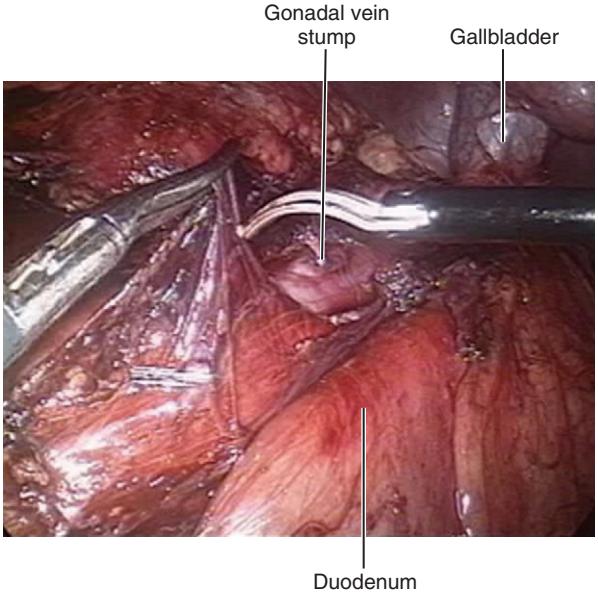

Figure 33–5. Fibrofatty tissue overlying the inferior vena cava being incised to initiate the "split and roll" technique. The duodenum has been reflected medially, and the spermatic vein stump has been clipped and divided.

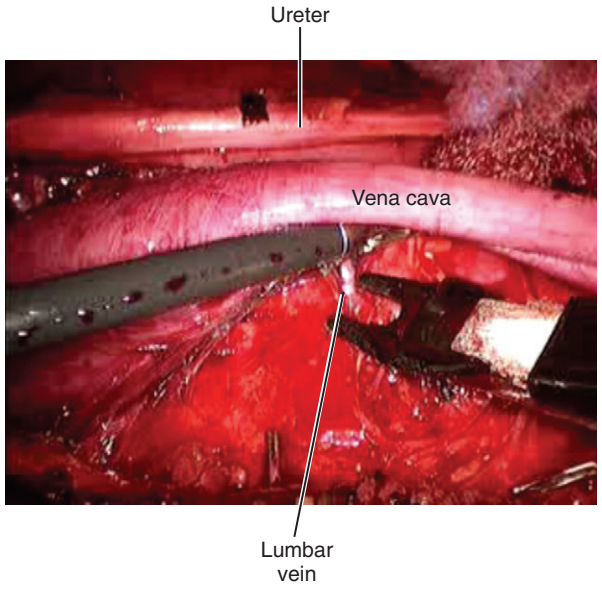

Figure 33–6. The inferior vena cava is retracted to allow for lumbar vein ligation. Paracaval and precaval lymph nodes have been cleared.

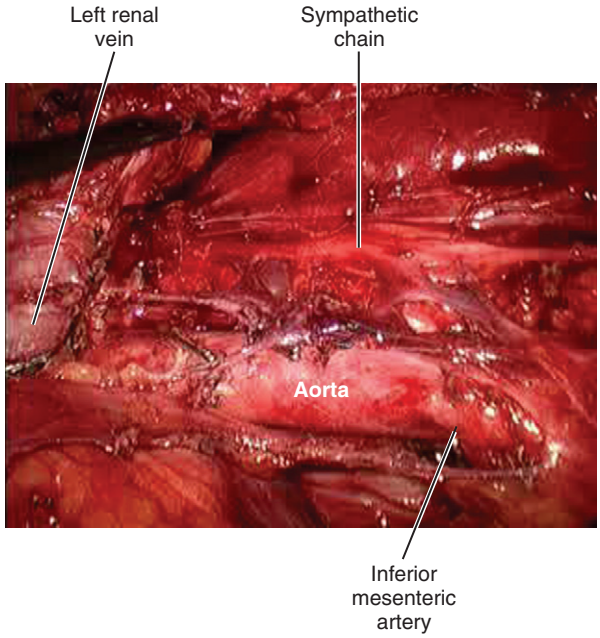

Figure 33–7. The sympathetic chain and efferent nerves are seen spared while para-aortic and preaortic lymph nodes have been removed.

spine and delivered laterally. Great care is taken to separate the lymph nodes from the sympathetic chain and postganglionic nerve fibers. Next the aorta is identified and the tissues overlying it are similarly split to the level of the inferior mesenteric artery and then rolled medially to enter the retroaortic space. The lumbar arteries may be controlled if additional mobility is needed to mobilize the interaortocaval packet posteriorly. The aorta can be medially retracted, thus facilitating para-aortic node excision with careful preservation of the sympathetic chain laterally. The interaortocaval nodes are then finally removed to complete the dissection.

An important technical point is to leave a long stump on the aorta/vena cava side when ligating lumbar vessels such that they can be grasped and controlled in the event a clip dislodges. Lumbar vessels that retract into the iliopsoas uncontrolled can usually be managed with pressure or a figure-of-eight suture placed deep into the muscle. Lacerations of the IVC and aorta may occur during this operation but in the vast majority of cases do not mandate open conversion. Direct pressure usually prevents excessive hemorrhage and can achieve hemostasis without the need for additional maneuvers. Adjunct hemostatic agents can also be used successfully in this circumstance. If the bleeding persists, or in the case of arterial bleeding, direct pressure can be used temporarily before definitive repair is undertaken with intracorporeal suturing.

Left-Sided Dissection

The peritoneum is incised lateral to the descending colon and along the splenic flexure. The colorenal ligaments are severed, and the bowel is bluntly dissected medially. The lateral attachments of the spleen are incised, and the tail of the pancreas is swept medially to ensure wide exposure of the retroperitoneum, including the medial paracaval space.

Spermatic Cord Dissection

Analogous to what is done on the right side, the spermatic cord stump suture is identified after circumscribing the peritoneum at the inguinal ring. The spermatic vein along with adjacent lymph nodes is traced proximally to the renal vein and the artery to the aorta where they are ligated and cut. The cord is then placed in an endobag for removal at the conclusion of the procedure.

Lymphadenectomy

The authors advocate removal of the left common iliac, para-aortic, preaortic, interaortocaval, and medial paracaval lymph nodes (see Fig. 33–4). The dissection can be expanded as needed. Lumbar veins draining into the renal vein are clipped and divided to allow full dissection of the renal hilum. The vein is cleaned off medially to the junction of the vena cava. A paddle retractor in the lowest trocar aids in dissection. The renal artery is completely freed of all lymphatic tissues. Again, generous use of clips is used to avoid postoperative leakage of lymph. The tissues overlying the aorta are split from the renal hilum to the level of the inferior mesenteric artery. Care should be taken to identify the right spermatic artery to avoid avulsion. In contrast to the tissues overlying the vena cava, the preaortic space may include postganglionic sympathetic nerves; thus care must be taken to separate the nodal tissue while preserving these nerves (Fig. 33–7). The ureter and common iliac vessels are separated from all fibroadipose tissue. The preaortic tissues are rolled medially down to the lumbar arteries. The lumbar vessels are controlled and cut, allowing excision of the retroaortic lymph nodes. The vena cava is identified, and using a "split and roll" approach the paracaval, precaval, and interaortocaval lymph nodes are removed in the same manner as for a right-sided dissection. Care should be taken to identify any right-sided renal arteries to avoid inadvertent ligation. In patients who have had chemotherapy it may be necessary to ligate and transect the inferior mesenteric artery. If suspect nodes are detected, the node dissection can be expanded to perform a complete bilateral dissection. This can be performed from the same side using retraction.

At the conclusion of the operation the lymph nodes are placed in an endobag and extracted. Each packet should be placed in a

separate sac during dissection to help increase yield of nodal evaluation and count. The retroperitoneum is irrigated with warm water, and lymphostasis and hemostasis are ensured. The bowel and adjacent organs (liver, gallbladder, kidneys, ureters, pancreas, and spleen) are carefully inspected for injury. The trocar sites are closed with fascial sutures using a Carter-Thomason device. A drain is not routinely used.

Bilateral L-RPLND

Bilateral dissections may be performed when necessary and can be usually undertaken without a change in patient positioning. When the side of primary tumor is completed with the templates described, a small amount of tissue is left just medial to the contralateral ureter and inferiorly toward the common iliac vessels. These tissues are dissected free, and a bilateral dissection is completed. It is easier to approach a bilateral dissection from the right side.

POSTOPERATIVE CARE

Patients are extubated and transferred to the recovery area without nasogastric tube drainage. The patient may ambulate and resume a liquid diet the night of surgery. **Postoperative tachycardia may occur due to sympathetic stimulation** (Bahnson et al, 1989). Most patients can be discharged on postoperative day 1. Some surgeons advocate consumption of a low-fat diet for 1 to 2 weeks postoperatively.

PROSPECTIVE NERVE-SPARING TECHNIQUES

As in open RPLND, nerve-sparing techniques involve prospectively identifying, dissecting, and preserving the sympathetic chains, hypogastric plexus, and postganglionic fibers. With experience these can be readily identified as more fibrous, compared with lymphatic, tissue. On the right side the postganglionic sympathetic fibers are most easily identified behind the IVC as they cross anterior to the aorta to insert in the hypogastric plexus. Their takeoff from the sympathetic chains is always near lumbar veins, so great care should be taken in clipping lumbar vessels. On the left side it is easiest to identify the postganglionic sympathetic nerves at the ganglia as they leave the sympathetic chain and then dissect them prospectively as they course anterior to the aorta before joining the hypogastric plexus. Care should be taken to avoid energy sources such as electrocautery when dissecting nerve fibers (Peschel et al, 2002; Bhayani et al, 2003; Abdel-Aziz et al, 2006; Steiner et al, 2008).

COMPLICATIONS

The most common reason for conversion to an open procedure is uncontrollable bleeding, and vascular injury is cited as the most common intraoperative complication (Bhayani et al, 2003; Abdel-Aziz et al, 2006; Neyer et al, 2007; Kenney and Tuerk, 2008). Although bleeding and open conversion occurred more frequently in older series, in more recent series this is less common. **In most contemporary series the open conversion rate is less than 5% but has been reported as high as 11.8%** (Rassweiler et al, 2000; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008). **Conversion to an open procedure should never be viewed as a failure, and surgeons should be familiar with open RPLND should it be required.** Injury to major abdominal viscera has also been reported but appears to be a rare event (Neyer et al, 2007; Kenney and Tuerk, 2008).

Postoperative complications have been reported at a rate of 9% to 25% in contemporary series (Albqami and Janetschek, 2005; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008). Reported complications include chylous ascites, ileus, lymphocele, nerve injury, pulmonary embolus, *Clostridium difficile* colitis, retroperitoneal hematoma, and ureteral injury (Kenney and Tuerk, 2008). Retrograde ejaculation is a potential long-term source of morbidity for patients undergoing both open RPLND and L-RPLND. **The rates of retrograde ejaculation have been consistently low with the laparoscopic approach and range from 0% to 14%** (Albqami and Janetschek, 2005; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008; Steiner et al, 2008). **With meticulous ligation of lymphatic channels the incidence of chylous ascites should be less than 2%.** A summary of the morbidity of L-RPLND in the management of clinical stage I NSGCT is provided in Table 33–1. Although it is difficult to compare these data retrospectively to published open RPLND series they appear to compare favorably. In one study of open primary RPLND a 6% transfusion rate with a mean length of stay of 6 days was reported (Subramanian et al, 2010). Similar to L-RPLND, vascular injury was the most common intraoperative complication (4.5% of cases) whereas 2 patients developed chylous ascites (1.8%) and 14 (12.5%) suffered from an ileus. Antegrade ejaculation in this group of patients was 80%, and 7 patients (6.3%) required reoperation (for small bowel obstruction [2 patients], incisional hernia repair [4 patients], and ureteral reconstruction [1 patient]). Interestingly, 2 patients required nephrectomy, 1 for a dysplastic kidney and the other for oncologic reasons.

The morbidity and open conversion rate of L-RPLND after chemotherapy is higher and seems to be experience dependent as well. Early series cited major complication rates of more than 50% (Palese et al, 2002) and high conversion rates (Rassweiler et al, 1996). However, similar to primary L-RPLND, more recent series from experienced centers show improvement in these parameters (Steiner et al, 2004; Permpongkosol et al, 2007). Steiner and colleagues (2004), for example, reported on 68 L-RPLND procedures performed after chemotherapy and reported no open conversions. In another more limited report including 17 patients who underwent L-RPLND after chemotherapy, the authors reported no complications, transfusions, or open conversions (Maldonado-Valadez et al, 2007). Recent studies report preservation of antegrade ejaculation with experience (LeBlanc et al, 2001; Albqami and Janetschek, 2005; Corvin et al, 2005).

RESULTS AND CURRENT STATUS

Unfortunately there are no randomized trials between open RPLND and L-RPLND. Retrospective assessments suggest that patients undergoing L-RPLND have a significantly shorter hospital stay, decreased blood loss, greater quality of life scores, and faster return to normal activities (Janetschek et al, 1996; Abdel-Aziz et al, 2006; Poulakis et al, 2006).

L-RPLND for Clinical Stage I Disease

Published reports of L-RPLND with long-term follow-up suggest that it is an effective treatment option for patients with low-stage NSGCTs (Table 33–2). The staging accuracy of

*Recurrences: PU, pulmonary; RP, retroperitoneal, outside of template; BC, isolated biochemical; PS, portsite.

L-RPLND has been documented and consistent with open series in that 25% to 30% of men with clinical stage I NSGCT are found to harbor occult nodal disease. **A recent study with a mean follow-up of 7 years included 87 patients with clinical stage I disease and revealed a 9% and 0% relapse rate for pN0 and pN+ patients, respectively, with all patients alive and free of disease at last follow-up** (Cresswell et al, 2008). The two retroperitoneal recurrences (2.5%) in this series occurred outside the dissection template, and all patients with pN+ disease were administered adjuvant chemotherapy. Examination of other large L-RPLND series confirms these findings, and recurrence rates and their patterns in this patient population are comparable to those of open RPLND series. The recurrence rate of those found to have negative lymph nodes at L-RPLND is reported between 0% and 10%, which compares favorably to open RPLND series (Hermans et al, 2000; Donohue et al, 1993).

Despite the favorable long-term outcomes the practice of universal chemotherapy in the adjuvant setting in patients with clinical stage I disease who are also harboring metastatic disease at L-RPLND has been the focus of critics who question the therapeutic efficacy of the technique. Interestingly, approximately 70% of men found to have pN1 disease and who undergo a properly performed RPLND are cured and can avoid chemotherapy (Richie and Kantoff, 1991; Donohue et al, 1993; Rabbani et al, 2001). However, patients found to have pN1 disease can opt to receive two cycles of chemotherapy in the adjuvant setting with excellent long-term results rather than risk receiving three or four cycles of chemotherapy should they experience relapse. Thus, the decision to administer chemotherapy to pN1 patients is a matter of preference and factors in the philosophy of the urologist and medical oncologist, as well as the patient.

A report of 120 patients undergoing L-RPLND at one of four institutions in the United States included 10 patients with pathologic stage II disease who underwent surveillance (Nielsen et al, 2007). At a mean follow-up of 34.8 months, none of the patients had experienced a retroperitoneal recurrence. **Additional recent**

reports omitting chemotherapy for patients with pN1 disease who underwent L-RPLND support its therapeutic efficacy, but further studies and follow-up are required (Skolarus et al, 2008; Steiner et al, 2008).

The adequacy of L-RPLND also can be evaluated by examining those patients found to have pathologic stage I disease. If L-RPLND was inadequate, then certain patients with pathologic stage II disease would be mislabeled as having pathologic stage I disease and a retroperitoneal recurrence would result. This supposition has not occurred, because no retroperitoneal recurrence has resulted in a series of therapeutic L-RPLND where a full dissection has been performed (Bhayani et al, 2003; Porter and Lange, 2003; Nielsen et al, 2007; Skolarus et al, 2008; Steiner et al, 2008). The therapeutic efficacy of L-RPLND will continue to be tested as more patients found to have pathologic stage II disease are choosing observation after this technique with good results.

L-RPLND for Clinical Stage II

Fewer reports exist examining the role of L-RPLND for patients with clinical stage II NSGCTs as a primary modality or in the postchemotherapeutic setting. There are limited data regarding the use of primary L-RPLND in patients with clinical stage IIA disease. Several authors have reported on the use of L-RPLND in the postchemotherapeutic setting (see Table 33–2). Albqami and Janetschek (2005) have reported their experience with 59 patients with stage IIB or IIC disease who have undergone postchemotherapy L-RPLND: of the 43 patients with preoperative stage IIB disease with a mean follow-up of 53 months, 1 experienced a recurrence 24 months postoperatively along the external iliac nodes, outside the original template. Another group (Maldonado-Valadez et al, 2007) reported on 17 patients and demonstrated the feasibility of L-RPLND after chemotherapy: viable tumor was found in 3 patients, 2 of whom experienced retroperitoneal recurrences. Full bilateral RPLND, which is typically recommended in this setting, was not performed in these series (Stephenson and Sheinfeld, 2004).

Keeping in line with the goals of open postchemotherapy RPLND, Steiner and associates (2008) have performed bilateral nerve-sparing L-RPLND on 19 postchemotherapy patients with stage IIB disease. The authors found teratoma, necrosis/fibrosis, and active tumor in 4, 14, and 1 patient, respectively. This study included 2 patients with clinical stage IIA disease who underwent L-RPLND without adjuvant chemotherapy. No retroperitoneal recurrences were noted in either group at 17 months follow-up. Longer follow-up and larger series are required to evaluate the efficacy of L-RPLND in the postchemotherapeutic setting.

SUMMARY

L-RPLND has been demonstrated to be a feasible, safe, and effective treatment option for men with clinical stage I NSGCT at large-volume institutions with experienced laparoscopic surgeons. L-RPLND has evolved into a therapeutic operation duplicating the open procedure, with reports demonstrating efficacy and minimal morbidity. Data regarding L-RPLND for clinical stage II disease and for patients who have received chemotherapy are limited and associated with a longer learning curve.

Tumors of the Penis

Curtis A. Pettaway, MD ● Raymond S. Lance, MD ● John W. Davis, MD

Squamous Cell Carcinoma
Surgical Management of the Primary Tumor
Treatment of the Inguinal Nodes
Radiation Therapy
Chemotherapy
Nonsquamous Penile Malignant Neoplasms

Cancers of the penis are uncommon tumors that are often devastating for the patient and frequently diagnostically and therapeutically challenging for the urologist. Although rare in North America and Europe, penile malignant neoplasms constitute a substantial health concern in many African, South American, and Asian countries.

Any discussion of penile cancers must begin by addressing both benign and malignant tumors of the penis. **Some penile lesions are strictly benign, whereas others have the potential to evolve into malignant neoplasms.** A description of these lesions serves to establish their anatomic, etiologic, and histologic relationship to squamous cell carcinoma, which is the most common malignant tumor of the penis, as well as to other malignant neoplasms that involve the penis. Developments in the etiology of various benign, premalignant, and malignant penile tumors are reviewed in this chapter.

A detailed discussion of surgical management of penile cancer is undertaken in Chapter 35. Here we review the epidemiology, etiology, and natural history of squamous carcinoma and its contemporary management. **Reports have confirmed the importance of pathologic stage and histologic features of the primary tumor as well as the presence and extent of lymph node metastasis in determining prognosis and treatment planning of penile squamous carcinoma** (Ravi, 1993b; McDougal, 1995; Theodorescu et al, 1996; Pizzocaro et al, 1997; Slaton et al, 2001). In addition, developments in staging of the disease, including novel imaging modalities and the use of lymphatic mapping, and modified surgical approaches to improve staging accuracy and reduce potential morbidities are presented. The selection of patients for organ-preserving surgical strategies is discussed.

The role of radiation therapy as both a primary treatment and a palliative measure is reviewed. Contemporary developments in chemotherapy as well as in combination therapy with multiple therapeutic modalities are also discussed. A contemporary scheme for the management of the inguinal region, based on histologic and clinical features, is presented.

Finally, the various nonsquamous malignant neoplasms that may involve the penis are reviewed and discussed.

Please see the Expert Consult website for a discussion of benign lesions, premalignant cutaneous lesions (including Figure 34–1), and virus-related dermatologic lesions.

SQUAMOUS CELL CARCINOMA

Carcinoma in Situ

Carcinoma in situ (Tis) of the penis is called erythroplasia of Queyrat by urologists and dermatologists if it involves the glans penis and prepuce or Bowen disease if it involves the penile shaft or the remainder of the genitalia or perineal region. This nomenclature has served to separate carcinoma in situ from the mainstream of thinking and reporting of penile carcinoma. However, the epidemiology and natural history of this lesion parallel those of early carcinoma of the penis, and carcinoma in situ can progress to invasive carcinoma.

The erythroplasia originally described by Queyrat in 1911 consists of a red, velvety, well-marginated lesion of the glans penis or, less frequently, the prepuce of the uncircumcised man (Aragona et al, 1985). It may ulcerate and may be associated with discharge and pain. On histologic examination the normal mucosa is replaced by atypical hyperplastic cells characterized by disorientation, vacuolation, multiple hyperchromatic nuclei, and mitotic figures at all levels. The epithelial rete extends into the submucosa and appears elongated, broadened, and bulbous. The submucosa shows capillary proliferation and ectasia with a surrounding inflammatory infiltrate that is usually rich in plasma cells. These microscopic features distinguish erythroplasia of Queyrat from chronic localized balanitis. Human papillomavirus (HPV) has been identified in penile carcinoma in situ (Pfister and Haneke, 1984). Progression to invasive carcinoma can occur in 10% to 33% of cases (Buechner, 2002; Bleeker et al, 2009).

In 1912 Bowen described an intraepithelial neoplasm of the skin associated with a high occurrence of subsequent internal malignant disease as a distinct entity. Bowen disease and erythroplasia of Queyrat are histologically similar (Graham and Helwig, 1973) (see Fig. 34–1C on the Expert Consult website). Both tumors are characterized by the noninvasive changes of carcinoma in situ. **Visceral malignant disease is not associated with erythroplasia of Queyrat, and subsequent case-control studies have shown no association of Bowen disease with internal malignant tumors** (Anderson et al, 1973). Thus penile carcinoma in situ does not in itself warrant a specific search for

internal malignant tumors. **Bowen disease is characterized by sharply defined plaques of scaly erythema on the penile shaft. Crusted or ulcerated variants can occur. The appearance can be confused with bowenoid papulosis, nummular eczema, psoriasis, and superficial basal cell carcinoma. If it is not treated then invasive carcinoma may arise in about 5% of cases** (Buechner, 2002). **When all cases of carcinoma in situ are considered, metastasis is extremely rare but has been reported** (Eng et al, 1995).

Treatment is based on proper histopathologic confirmation of malignancy with multiple biopsies of adequate depth to rule out invasion. When lesions are located on the foreskin, circumcision or excision with a 5-mm margin is adequate for local control (Bissada, 1992). In this regard, lesions on the glans penis are difficult to treat by excisional strategies while maintaining normal penile anatomy. Alternative strategies include topical 5-fluorouracil cream (Lewis and Bendl, 1971; Graham and Helwig, 1973; Goette, 1974), 5% imiquimod cream (Danielson et al, 2003), and ablation with the neodymium:yttrium-aluminum-garnet (Nd:YAG) (Landthaler et al, 1986; Frimberger et al, 2002a), potassium titanyl phosphate (KTP) 532-nm, or carbon dioxide lasers (Rosemberg and Fuller, 1980; Tietjen and Malek, 1998; van Bezooijen et al, 2001). Such strategies have been shown to produce excellent cosmetic and functional results. Radiation therapy can be used to treat tumors that are resistant to topical treatment, especially among patients who are not surgical candidates (Kelley et al, 1974; Grabstald and Kelley, 1980).

Key Points: Carcinoma in Situ

- Carcinoma in situ (Tis) is an intraepithelial malignant process.
- Progression to invasive carcinoma may occur in 5% to 33% of cases if it is not treated.
- Metastasis has rarely occurred.
- Cancer eradication with organ-preserving strategies is the goal of therapy.

Invasive Carcinoma

Penile carcinoma accounts for 0.4% to 0.6% of all malignant neoplasms among men in the United States and Europe; it may represent up to 10% of malignant neoplasms in men in some Asian, African, and South American countries (Gloeckler-Ries et al, 1990; Vatanasapt et al, 1995). **However, reports suggest that the incidence of penile cancer is decreasing in many countries, including Finland, the United States, India, and other Asian countries** (Maiche et al, 1992; Frisch et al, 1995; Vatanasapt et al, 1995; Yeole and Jussawalla, 1997). The reasons are unclear but may be related in part to increased attention to personal hygiene.

Penile cancer is a disease of older men, with an abrupt increase in incidence in the sixth decade of life (Persky, 1977). In two studies the mean age was 58 years (Gursel et al, 1973) and 55 years (Derrick et al, 1973). The tumor is not unusual in younger men; in one large series, 22% of patients were younger than 40 years and 7% were younger than 30 years (Dean, 1935); the disease has also been reported in children (Kini, 1944; Narasimharao et al, 1985). The Surveillance, Epidemiology and End Results (SEER) database reveals no racial difference in incidence of penile cancer between black and white men in the United States (incidence for white men, 0.8 of 100,000; for black men, 0.7 of 100,000) (Vatanasapt et al, 1995).

However, a study using SEER data suggested that race is associated with outcome. Rippentrop and colleagues (2004) noted there were 1605 patients diagnosed with penile cancer from 1973 to 1998, with 22.4% (360) dying of the disease. They found factors independently predictive of worsened survival to be higher stage at diagnosis, age older than 65 years, African-American ethnicity, and disease within lymph nodes. These researchers demonstrated a statistically significant disease-specific risk of death that was 2.2-fold higher in African-American patients than in white patients. Although the reason for this disparity is likely to be multifactorial, possibilities include differences in cancer biology, in health care access, or in treatment. These provocative findings clearly deserve further study.

Etiology

The incidence of carcinoma of the penis varies according to circumcision practice, hygienic standard, phimosis, number of sexual partners, HPV infection, exposure to tobacco products, and other factors (Barrasso et al, 1987; Maiche, 1992; Maden et al, 1993; Misra et al, 2004).

Neonatal circumcision has been well established as a prophylactic measure that virtually eliminates the occurrence of penile carcinoma because it eliminates the closed preputial environment where penile carcinoma develops. The chronic irritative effects of smegma, a byproduct of bacterial action on desquamated cells that are within the preputial sac, have been proposed as an etiologic agent. Although definitive evidence that human smegma itself is a carcinogen has not been established (Reddy and Baruah, 1963), its relationship to the development of penile carcinoma has been widely observed. Improper hygiene can lead to buildup of smegma beneath the preputial foreskin, with resulting inflammation. Healing by fibrosis leads to phimosis of the preputial skin, which tends to perpetuate the cycle. Phimosis is found in 25% to 75% of patients described in most large series. Reddy and associates (1984) studied the foreskins of 26 men undergoing circumcision because of phimosis and found epithelial atypia in one third of the specimens.

Carcinoma of the penis is rare among the Jewish population, for whom neonatal circumcision is a universal practice (Licklider, 1961). Similarly, in the United States, where neonatal circumcision is widely practiced, penile cancer represents less than 1% of male malignant neoplasms. Among uncircumcised tribes of Africa and within uncircumcised Asian cultures, penile cancer may amount to 10% to 20% of all male malignant neoplasms (Dodge, 1965; Narayana et al, 1982). Data from most large series show that penile cancer is rare among neonatally circumcised individuals but more frequent when circumcision is delayed until puberty (Frew et al, 1967; Gursel et al, 1973; Johnson et al, 1973). Adult circumcision appears to offer little or no protection from subsequent development of the disease (Maden et al, 1993). **These data suggest that the critical period of exposure to certain etiologic agents may have already occurred at puberty and certainly by adulthood, rendering later circumcision relatively ineffective as a prophylactic tool for penile cancer.**

Recent population-based data reveal that although neonatal circumcision is highly protective for invasive penile cancer it does not afford the same level of protection for carcinoma in situ. Schoen and colleagues (2000) evaluated the incidence of invasive penile cancer or carcinoma in situ during a 10-year period and found only 2 cases of 89 (2.3%)

occurring among neonatally circumcised men, whereas of 118 men with carcinoma in situ, 16 cases were noted in men circumcised at birth (15.7%). Considering that the protective effects of circumcision on invasive penile cancer are likely to be mediated by avoidance of phimosis, it is noteworthy that another study associated phimosis with the development of invasive penile cancer but not carcinoma in situ (Hung-fu et al, 2001).

Male circumcision has also been shown to be effective against HIV-1 infection. This effect was shown to be specific by Reynolds and colleagues (2004). There was no protective effect of circumcision for other sexually transmitted diseases, such as herpes simplex virus type 2 infection, syphilis, or gonorrhea.

HPV infection and exposure to tobacco products appear to be associated with development of penile cancer. Epidemiologic data provided the first clues to a relationship between a sexually transmitted agent and cancer by demonstrating that the wives or ex-wives of men with penile cancer had a threefold higher risk of cervical carcinoma (Graham et al, 1979). Further investigation revealed that the male partners of women with cervical intraepithelial neoplasia had a significantly higher incidence of penile intraepithelial neoplasia (Barrasso et al, 1987). These same male patients were also found to have a greater incidence of HPV infection.

Advanced molecular biologic techniques such as polymerase chain reaction and in-situ hybridization have provided increased evidence for an etiologic role of HPV by identifying specific DNA sequences from different HPV types in primary penile lesions (malignant and benign) but not in normal foreskins (Varma et al, 1991; Iwasawa et al, 1993). More than 25 types of HPV infect genital sites. HPV types 6 and 11 are most commonly associated with nondysplastic lesions such as genital warts, but these are also noted in nonmetastatic verrucous carcinomas. In contrast, HPV types 16, 18, 31, and 33 are associated with in-situ and invasive carcinomas (Wiener and Walther, 1995). **HPV-16 appears to be the most frequently detected type in primary carcinomas and has also been detected in metastatic lesions** (Varma et al, 1991; Iwasawa et al, 1993; Wiener and Walther, 1995). As noted previously, the HPV genome encodes oncoprotein E6, which complexes with the tumor suppressor protein TP53, and oncoprotein E7, which binds the retinoblastoma (RB) protein, thus affecting cell cycle regulation (Munger et al, 1989; zur Hausen, 1996; Levi et al, 1998; Griffiths and Mellon, 1999) via the $P14^{ARF}$/MDM2/p53 and $p15^{INK4a}$/cyclin D/Rb pathways (Bleeker et al, 2009). **Maden and colleagues** (1993) **found that the incidence of HPV infection directly correlated with the number of lifetime sexual partners, which was also related to risk of penile cancer.** Furthermore, Castellsague and colleagues (1997) noted a direct correlation between the number of sexual partners, HPV-infected men, and incidence of cervical neoplasia among their female partners. Thus, for both cervical and penile cancer, HPV infection represents a preventable etiology.

Poblet and coworkers (1999) reported on two cases of coexisting HIV-1 and HPV infection and postulated that HIV-1 could synergize with HPV to increase the progression of HPV penile lesions into penile carcinoma. Although there is evidence supporting this effect in cervical and anal neoplasia, definitive proof for penile cancer awaits further study (Northfelt, 1994).

Although HPV infection is probably an important factor in the development of penile cancer, its presence is not invariable (31% to 63% of patients with penile carcinoma test positive) (Wiener and Walther, 1995), **indicating that additional factors may be involved in the development of the disease or its subtypes.** Additional evidence for Rubin and associates (2001), who performed a sensitive polymerase chain reaction assay, provided this hypothesis-based essay on penile cancer specimens from the United States and Paraguay. Overall, 42% of penile carcinomas were HPV positive. However, only 34.9% and 33.3% of keratinizing and verrucous carcinomas, respectively, were positive, whereas 80% and 100% of basaloid and warty tumor subtypes, respectively, exhibited HPV DNA. Other non–HPV-dependent molecular events leading to penile carcinogenesis have been described, including silencing of the CDK2NA locus via promoter hypermethylation, the expression of genes that target the INK4a/ARF locus, other gene mutations affecting TP53, and $P14^{ARF}$ as well as MDM2 overexpression (reviewed in Ferreux et al, 2003; Bleeker et al, 2009).

Four studies have shown a significant association between exposure to cigarette smoke and development of penile cancer (Hellberg et al, 1987; Daling et al, 1992; Maden et al, 1993; Harish and Ravi, 1995). Hellberg and colleagues (1987) studied the smoking history of 244 men with penile cancer and matched controls. They found a significantly increased odds ratio for penile cancer based on whether an individual had smoked, and the risk increased with the number of cigarettes smoked. This observation held even when the presence of phimosis was controlled. **Harish and Ravi** (1995) **extended these observations by showing that all forms of tobacco products, including cigarettes, chewing tobacco, and snuff, were significantly and independently related to the incidence of penile cancer subsequent to multivariate regression analysis.** It has been hypothesized that tobacco products can act in the presence of HPV infection or bacteria associated with chronic inflammation to promote malignant transformation. These same risk factors are also common to other anogenital carcinomas (Daling et al, 1992; Maden et al, 1993).

Penile trauma may be another risk factor for penile cancer. The development of carcinoma in the scarred penile shaft after mutilating circumcision has been reported as a distinct entity (Bissada et al, 1986). Furthermore, Maden and colleagues (1993) found a greater than threefold risk of penile cancer in men with penile tears and rashes. A case-control study also revealed an odds ratio of 18:1 for the development of penile cancer for those men reporting a penile injury 2 years before the onset of the disease (Hung-fu et al, 2001).

Genital ultraviolet radiation, alone and combined with 8-methoxypsoralen, increases the risk of squamous carcinoma at genital sites. A 12-year follow-up study reported that the risk of penile and scrotal cancer was increased 286 times that of the general population for those exposed to ultraviolet A photochemotherapy and 8-methoxysoralen (PUVA) (Stern et al, 1990). The risk was dose related. For those treated with ultraviolet B exposure, the risk was 4.6-fold enhanced. Another long-term follow-up study of PUVA-associated malignant neoplasia from Sweden revealed a 30-fold increased risk for skin cancer (but not for penile cancer) among males. In this study, PUVA was also associated with respiratory and pancreatic cancers (Lindelof et al, 1991). Lichen sclerosus (also known as balanitis xerotica obliterans) is a risk factor for the development of penile cancer. **Studies have shown the incidence of subsequent cancer with long-term follow-up to be between 3% and 9% of men with lichen sclerosus** (Depasquale et al, 2000; Micali et al, 2001). Velazquez and Cubilla (2003) studied lichen sclerosus occurring in association with penile cancer and noted its presence distinctly among the subset of penile carcinomas that were not associated with HPV.

Larger studies performed in areas where the disease is endemic, incorporating the many risk factors for penile cancer into a multivariate analysis, are clearly needed to define which factors independently confer risk. Thus far, no convincing evidence has been found linking penile cancer to other factors such as occupation, other venereal diseases (gonorrhea, syphilis, and herpes), marijuana use, or alcohol intake (Maden et al, 1993).

Prevention

The role of routine neonatal circumcision as a preventive strategy for penile cancer has been, to say the least, a controversial topic. The position of the American Academy of Pediatrics has changed from one of denial of any medical benefits (Schoen et al, 1989) to the more moderate recent position stating, **"There are potential medical benefits of newborn circumcision; however, these data are not sufficient to recommend routine neonatal circumcision. In such situations where the procedure is not essential to the child's well being, parents should determine what is in the best interest of the child subsequent to being presented unbiased information"** (Shapiro, 1999).

Any argument against circumcision must consider that penile carcinoma represents the only neoplasm for which there exists a predictable and simple means of prophylaxis to spare the organ at risk (Dagher et al, 1973). Although circumcision can obviate the disease, especially where facilities for daily hygiene may be lacking, it may not be as important in countries where good hygiene is practiced. Frisch and colleagues (1995) reported a falling incidence of penile cancer (from 1.15 of 100,000 men to 0.82 of 100,000 men) in the Danish population, which has a circumcision rate of only 1.6%. They attributed this trend to improved hygiene because the incidence of dwellings having a bath facility increased from 35% in the 1940s to 90% in the 1990s. Thus, considering the benefits of circumcision (including the prevention of infections, HIV infection and its transmission, and penile and cervical cancer), enhanced education about the potential benefits of circumcision, especially in developing countries, seems rational (Schoen et al, 1989; Reynolds et al, 2004; Kinkade et al, 2005).

Although neonatal circumcision and good hygiene to prevent the occurrence of phimosis represent important prevention strategies, additional efforts to prevent malignant transformation include avoidance of HPV infection potentially through condom use, of ultraviolet light exposure, and of tobacco products. Thus, modifiable behaviors can potentially prevent penile cancer (Munger et al, 1989; Maden et al, 1993; Harish and Ravi, 1995; Levi et al, 1998; Griffiths and Mellon, 1999; Bleeker et al, 2009).

HPV vaccination could play an emerging role in the future with respect to preventing transmission of HPV between males and females and potentially penile cancer. To date two prophylactic HPV vaccines are available (HPV 16/18 vaccine Cervarix [GlaxoSmithKline] and the quadrivalent HPV 16/18/6/11 vaccine Gardasil [Sanofi Pasteur, Merck Sharpe & Dome]. The efficacy of preventing HPV infection among HPV negative women has been demonstrated (Harper et al, 2004; Villa et al, 2005). To date the safety and immunogenicity of the vaccines has also been established among adolescent boys. However, efficacy in prevention of HPV infection in such populations awaits the results of ongoing studies (Block et al, 2006; Bleeker et al, 2009).

Key Points: Epidemiology, Etiology, and Prevention

- Penile cancer is rare in developed countries and varies worldwide with age, circumcision, and hygiene practices.
- Recent epidemiologic data from the United States suggest a disparity in outcome, with African-Americans exhibiting poorer survival.
- Risk factors for development of penile cancer include lack of neonatal circumcision, phimosis, HPV infection, exposure to tobacco products, penile lichen sclerosus, and potentially penile trauma and exposure to PUVA.
- Histologic subtypes of penile cancer are correlated with HPV infection.
- Penile cancer represents a preventable disease in most cases via neonatal circumcision and/or behavior modification.

Natural History

Carcinoma of the penis usually begins with a small lesion that gradually extends to involve the entire glans, shaft, and corpora. The lesion may be papillary and exophytic or flat and ulcerative; if it is untreated, penile autoamputation may occur as a late result. The rates of growth of the papillary and ulcerative lesions are similar, but the flat, ulcerative tumor has a tendency toward earlier nodal metastasis and is associated with poorer 5-year survival rates (Dean, 1935; Marcial et al, 1962; Ornellas et al, 1994). Lesions larger than 5 cm (Beggs and Spratt, 1964) and those extending over 75% of the shaft (Staubitz et al, 1955) are also associated with an increased incidence of metastases and a decreased survival rate. However, others have not found a consistent relationship between lesion sizes, presence of metastases, and decreased survival (Ekstrom and Edsmyr, 1958; Puras et al, 1978).

Buck fascia acts as a temporary natural barrier to local extension of the tumor, protecting the corporeal bodies from invasion. Penetration of Buck fascia and the tunica albuginea permits invasion of the vascular corpora and establishes the potential for vascular dissemination. Urethral and bladder involvement are rare (Riveros and Gorostiaga, 1962; Thomas and Small, 1968).

The earliest route of dissemination from penile carcinoma is metastasis to the regional femoral and iliac nodes. A detailed description of lymphatic drainage of the penis is found elsewhere in this text and is well documented in the literature (Dewire and Lepor, 1992). Briefly, the lymphatics of the prepuce form a connecting network that joins with the lymphatics from the skin of the shaft. These tributaries drain into the superficial inguinal nodes (the nodes external to the fascia lata). The lymphatics of the glans join the lymphatics draining the corporeal bodies, and they form a collar of connecting channels at the base of the penis that drain by way of the superficial nodes. The superficial nodes drain to the deep inguinal nodes (those deep to the fascia lata). From there, drainage is to the pelvic nodes (external iliac, internal iliac, and obturator). Penile lymphangiographic studies demonstrate a consistent pattern of drainage that proceeds from superficial inguinal to deep inguinal to pelvic node sites without evidence of ipsilateral drainage (Cabanas, 1977, 1992). Multiple cross-connections exist at all levels of drainage, so that penile lymphatic drainage is bilateral to both inguinal areas.

Metastatic enlargement of the regional nodes eventually leads to skin necrosis, chronic infection, and death from inanition, sepsis, or hemorrhage secondary to erosion into the femoral vessels. Clinically detectable distant metastatic lesions to the lung, liver, bone, or brain are uncommon and are reported to occur in

1% to 10% of cases in most large series (Staubitz et al, 1955; Riveros and Gorostiaga, 1962; Beggs and Spratt, 1964; Derrick et al, 1973; Johnson et al, 1973; Kossow et al, 1973; Puras et al, 1978). Such metastases usually occur late in the course of the disease after the local lesion has been treated. Distant metastases in the absence of regional node metastases are unusual.

Carcinoma of the penis is characterized by a relentless progressive course, causing death for the majority of untreated patients within 2 years (Beggs and Spratt, 1964; Skinner et al, 1972; Derrick et al, 1973). Rarely, long-term survival occurs, even with advanced local disease and regional node metastases (Furlong and Uhle, 1953; Beggs and Spratt, 1964). No report of spontaneous remission of carcinoma of the penis is known. Five to 15 percent of patients have been reported to develop a second primary neoplasm (Buddington et al, 1963; Beggs and Spratt, 1964; Gursel et al, 1973), and one series reported secondary carcinoma in 17% of patients (Hubbell et al, 1988).

Modes of Presentation

Signs

It is the penile lesion itself that usually alerts the patient to the presence of penile cancer. The presentation ranges from a relatively subtle induration or small excrescence to a small papule, pustule, warty growth, or more luxuriant exophytic lesion. It may appear as a shallow erosion or as a deeply excavated ulcer with elevated or rolled-in edges. Phimosis may obscure a lesion and allow a tumor to progress silently. Eventually, erosion through the prepuce, foul preputial odor, and discharge with or without bleeding call attention to the disease.

Penile tumors may present anywhere on the penis but occur most commonly on the glans (48%) and prepuce (21%). Other tumors involve the glans and prepuce (9%), the coronal sulcus (6%), or the shaft (<2%) (Sufrin and Huben, 1991). This distribution of lesions may be due to constant exposure of the glans, coronal sulcus, and interior prepuce to irritants (e.g., smegma, HPV infection) within the preputial sac, whereas the shaft is relatively spared.

Rarely, a mass, ulceration, suppuration, or hemorrhage in the inguinal area may be due to nodal metastases from a lesion concealed within a phimotic foreskin. Urinary retention or urethral fistula due to local corporeal involvement is a rare presenting sign.

Symptoms

Pain does not develop in proportion to the extent of the local destructive process and usually is not a presenting complaint. Weakness, weight loss, fatigue, and systemic malaise occur secondary to chronic suppuration. On occasion, significant blood loss from the penile lesion, the nodal lesion, or both may occur. Because local disease and regional disease are usually far advanced by the time distant metastases occur, presenting symptoms referable to such metastases are rare.

Diagnosis

Delay

Patients with cancer of the penis, more than patients with other types of cancer, seem to delay seeking medical attention (Lynch and Krush, 1969). In large series, 15% to 50% of patients delayed medical care for more than a year (Dean, 1935; Buddington et al, 1963; Hardner et al, 1972; Gursel et al, 1973). Explanations include embarrassment, guilt, fear, ignorance, and personal neglect. This level of denial is substantial, given that the penis is observed and handled on a daily basis.

Delay on the part of the physician in initiating both diagnosis and treatment may also be considerable. In some instances patients have been given prolonged courses of antibiotics or topical antifungal preparations before being referred for biopsy. Although some studies show that the difference in survival rates between patients who present early and those who present later is negligible (Ekstrom and Edsmyr, 1958; Johnson et al, 1973), other series show decreased survival with longer delay (Hardner et al, 1972). It appears logical that earlier diagnosis and treatment should improve outcome.

Examination

At presentation most lesions are confined to the penis (Skinner et al, 1972; Derrick et al, 1973; Johnson et al, 1973). The penile lesion is assessed with regard to size, location, fixation, and involvement of the corporeal bodies. Inspection of the base of the penis and scrotum is necessary to rule out extension into these areas. Rectal and bimanual examination provides information about perineal body involvement and presence of a pelvic mass. Careful bilateral palpation of the inguinal area for adenopathy is extremely important.

Key Points: Natural History and Presentation

- Penile cancer often begins on the surface of the glans penis or in the preputial area, where it progressively enlarges.
- Delay in seeking medical attention and then subsequent definitive biopsy is common.
- Examination of both the penile primary tumor and the inguinal region is critical to treatment planning.
- Metastasis occurs by embolization of tumor deposits from the penile tumor through penile lymphatics to the inguinal lymph nodes.
- Distant metastases occur late in the history of the disease.

Biopsy

Confirmation of the diagnosis of carcinoma of the penis and assessment of the depth of invasion, the presence of vascular invasion, and the histologic grade of the lesion by microscopic examination of a biopsy specimen are mandatory before the initiation of any therapy. This provides insight into the therapeutic options for treatment of the primary lesion as well as the likelihood of nodal metastases in patients with no palpable adenopathy (McDougal, 1995; Lopes et al, 1996; Theodorescu et al, 1996).

Biopsy may be a separate procedure from definitive surgical treatment. A dorsal slit is frequently necessary to gain adequate exposure of the lesion for satisfactory biopsy. An alternative approach to treatment is biopsy with frozen-section confirmation followed by partial or total penectomy. Full informed consent must be obtained before the procedure. Velazquez and colleagues (2004) demonstrated the shortcomings of superficial diagnostic biopsies in a study evaluating specimens from 57 patients. There was difficulty in delineating the extent of depth in 91% of patients, discordance with the histologic grade in 30% of patients (specifically with verrucous and mixed histologic patterns), and failure to

detect any cancer in 3.5% of patients with well-differentiated cancers. The importance of obtaining an adequate biopsy specimen cannot be overemphasized.

Histologic Features

Most tumors of the penis are squamous cell carcinomas demonstrating keratinization, epithelial pearl formation, and various degrees of mitotic activity. The normal rete pegs are disrupted. Invasive lesions penetrate the basement membrane and the surrounding structures. Cubilla and associates (1993) originally divided penile cancers by growth pattern into superficially spreading squamous carcinoma, vertical growth carcinoma, verrucous carcinoma, and multicentric carcinoma. The superficially spreading carcinoma occurred most frequently, and inguinal lymph node metastases were found in 42% of patients. However, lymph node metastases were noted in 82% of patients with a vertical growth pattern, in none of those with a verrucous pattern, and in 33% of those with multicentric carcinomas. Subsequent to review of 61 cases from Memorial Sloan-Kettering Cancer Center, Cubilla and colleagues (2001) classified the histologic types as follows: usual type, 59% of cases; papillary, 15%; basaloid, 10%; warty (condylomatous), 10%; verrucous, 3%; and sarcomatoid, 3%. Of note, both the basaloid and sarcomatous types were associated with aggressive behavior; 5 of 7 patients with these histologic patterns exhibited metastasis, and 5 of 8 (63%) died. In contrast, the verruciform histologic patterns were more favorable (1 patient with metastasis and no deaths). The typical squamous histologic type was intermediate in biologic potential; 14 of 26 patients exhibited metastases, and 13 of 36 (36%) died.

The basaloid variant, in addition to its aggressive behavior as noted previously, is associated with HPV expression in approximately 80% of cases (Gregoire et al, 1995; Cubilla et al, 1998, 2001; Rubin et al, 2001).

Squamous cell carcinomas have classically been graded using the Broders classification to define the level of differentiation on the basis of keratinization, nuclear pleomorphism, number of mitoses, and several other features (Broders, 1921; Lucia and Miller, 1992). This grading system was originally designed for squamous carcinoma of the skin and has been adapted by pathologists for penile squamous carcinoma. Four grades were originally described, but it is common for authors to modify this to a three-grade system by combining grades (Maiche et al, 1991). Low-grade lesions (grade 1 and grade 2) constitute 70% to 80% of the reported cases at diagnosis, whether a three- or four-grade system is used (Maiche et al, 1991). These well-differentiated lesions show cords of atypical squamous cells projecting downward from a hyperkeratotic epidermis. The lower-grade carcinomas typically demonstrate keratin, prominent intercellular bridges, and keratin pearls, characteristics that are absent in high-grade tumors. Almost half the tumors originating in the shaft are poorly differentiated (grade 3 and grade 4, depending on scale), whereas only 10% of tumors located in the prepuce are high-grade tumors (Maiche et al, 1991). Thus, grade and stage are often correlated.

Several studies have emphasized the association of high-grade disease with regional nodal metastases (Fraley et al, 1989; Ravi, 1993b; McDougal, 1995; Theodorescu et al, 1996; Heyns et al, 1997). Overall there is a significant body of agreement as to the histologic features that characterize high tumor grade (grade 3 and grade 4) and its correlation with nodal metastasis. However, as noted previously, most tumors are of lower grades. Histologic features that would better stratify the prognosis for patients with invasive, low- to intermediate-grade penile cancers would be of value for management of patients.

Slaton and colleagues (2001) found that describing the percentage of poorly differentiated cancer in the primary penile tumor specimen correlated with lymph node metastasis. In this study, a semiquantitative system that estimated the amount of high-grade cancer (i.e., ≤50% vs. >50%) was significantly associated with nodal metastases and was more predictive than the Broders three-grade system in stratifying those with or without nodal metastasis.

Recently, however, Chaux and colleagues (2009 grade citation) questioned these findings as they examined 117 specimens among patients undergoing primary tumor therapy and lymph node dissection. Over 50% of the tumors were actually heterogeneous with respect to grade, and among these tumors any proportion of grade 3 cancer was associated with lymph node metastasis. These disparate findings point to at least three problems with respect to grading and prognosis, including (1) lack of a uniform system, (2) reproducibility of interpretation, and (3) intratumoral heterogeneity of tumor components.

Vascular invasion by tumor cells has significant prognostic importance but may not be specifically mentioned in pathology reports. When vascular invasion is present it provides valuable information. Four studies have assessed its presence or absence, and it was an important predictor of nodal metastasis in all the reports (Fraley et al, 1989; Lopes et al, 1996; Heyns et al, 1997; Slaton et al, 2001). **Thus the pathologist should specifically comment on the presence or absence of vascular invasion in the surgical specimen.**

Perineural invasion was recently found to be present in 36% of cases analyzed in a multi-institutional data set of 134 patients and was a strong predictor of lymph node metastasis (Velazquez et al, 2008).

Laboratory Studies

The results of laboratory tests in patients with penile cancer are often normal. Anemia, leukocytosis, and hypoalbuminemia may be present in patients with chronic illness, malnutrition, and extensive suppuration at the area of the primary and inguinal metastatic sites. Azotemia may develop secondary to urethral or ureteral obstruction.

Key Points: Biopsy and Histologic Features

- Adequate tumor biopsy is essential to diagnosis and treatment planning.
- Squamous carcinoma histologic subtypes include usual type, papillary, basaloid, warty, verrucous, and sarcomatoid. They vary with respect to metastatic potential.
- Pathologic description of anatomic structures invaded (i.e., stage), grade, and the status of vascular and perineural invasion provide important information to assess the risk of metastasis.

Hypercalcemia without detectable osseous metastases has been associated with penile cancer (Anderson and Glenn, 1965; Rudd et al, 1972). In a review from Memorial Sloan-Kettering Cancer Center (Sklaroff and Yagoda, 1982), 17 of 81 patients (20.9%) were hypercalcemic. Hypercalcemia seems to be largely a function of the bulk of the disease. It is often associated with inguinal metastases and may resolve after excision of involved inguinal nodes (Block et al, 1973). **Parathyroid hormone and**

related substances may be produced by both tumor and metastases that activate osteoclastic bone resorption (Malakoff and Schmidt, 1975). Medical treatment of hypercalcemia includes aggressive saline hydration to restore the extracellular fluid volume and to promote both sodium and calcium excretion. The administration of diuretics is performed if volume overload is suspected. Bisphosphonates (e.g., pamidronate, etidronate and zoledronic acid) have become first-line therapy because they possess demonstrated efficacy as antiresorptive agents and are relatively safer than mithramycin, an older agent (Videtic et al, 1997; Morton and Lipton, 2000). For severe hypercalcemia associated with neurologic manifestations, the antiresorptive bisphosphonates can be combined with an agent that produces calciuria, such as calcitonin, to rapidly lower serum calcium levels.

Radiologic Studies

Primary Penile Tumor. **In patients with penile cancer both the primary tumor and the inguinal lymph nodes are readily assessed by palpation.** However, Horenblas and associates (1991) found that physical examination incorrectly established the actual pathologic stage in 26% of cases, with understaging in 10% and overstaging in 16%. It is clear that more accurate means of staging for penile tumors is needed.

Penile ultrasonography was performed on 16 patients referred for primary therapy by Horenblas and colleagues (1994). With use of a 7.5-MHz linear array small parts transducer they found that the ultrasound appearance of cancer was invariably hypoechoic. However, ultrasound examination often underestimated the thickness of tumors and could not delineate invasion into the subepithelial connective tissue of the glans penis from corpus spongiosum involvement (i.e., glanular stage T1 vs. glanular stage T2). However, the tunica albuginea separating the corpus cavernosum from the glans was easily identified in all patients and the sensitivity for detecting corpus cavernosum invasion was 100%. This study confirmed the value of ultrasonography in assessing the primary tumor, as reported by others (Yamashita and Ogawa, 1989; Dorak et al, 1992).

Several studies have assessed the role of magnetic resonance imaging (MRI) in evaluating both the normal penis and its involvement by cancer. Vapnek and associates (1992) described the MRI appearance of the normal corpus cavernosum, corpus spongiosum, tunica albuginea, and Buck fascia. Of six patients with urethral cancer, the disease was accurately staged in five (83%). de Kerviler and colleagues (1995) used gadolinium contrast-enhanced MRI to compare both clinical and MRI findings with tumor pathologic stage. Clinical examination correctly staged six of nine tumors: MRI was correct in seven of nine cases but was not useful for clinical T1 lesions. Compared with MRI and ultrasonography, computed tomography (CT) has poor soft tissue resolution and has not been useful for imaging the extent of the primary tumor (Vapnek et al, 1992).

Lont and associates (2003) directly compared physical examination with ultrasonography and MRI to assess their ability to determine the tumor stage. They evaluated 33 patients with penile squamous cell carcinoma, all of whom underwent ultrasound examination, MRI, and physical examination of the primary tumor. Findings were correlated with histologic evaluation of the specimens obtained at surgery with a focus on determining the invasion of the corpus cavernosum. The respective positive predictive value, sensitivity, and specificity for the study were as follows—physical examination: 100%, 86%, 100%; ultrasound examination: 67%, 57%, 91%; and MRI: 75%, 100%, 91%. This comparative study concluded that physical examination is reliable in determining corporeal invasion and that additional tests are mainly of value when physical examination cannot be properly performed.

The technique of artificial erection (by intracorporeal injection of prostaglandin E_1) may augment the use of contrast-enhanced MRI in staging of the primary tumor. A study by the European Institute of Oncology evaluated nine patients to compare clinical, pathologic, and MRI staging (Scardino et al, 2004). MRI aided by artificial erection and contrast enhancement was shown to be of value as it correlated with pathologic stage in eight of nine cases, whereas physical examination correlated with only five of nine cases. These data suggest that this novel MRI approach could be beneficial in staging of glanular tumors, specifically when physical examination findings are equivocal. **Thus, for small-volume glanular lesions, imaging studies add virtually no additional information to palpation in most cases. However, for lesions thought to invade the corpus cavernosum, contrast-enhanced MRI (perhaps augmented with artificial erection) may provide unique information, especially when physical examination findings are equivocal and organ-sparing techniques are being considered.**

Inguinal/Pelvic Region. The ability to noninvasively determine the presence or absence of inguinal and pelvic metastases in patients with penile cancer remains problematic because physical examination exhibits varying reliability based on the grade and stage of the primary tumor. Historically, lymphangiography was used as an adjunct to physical examination in the identification of microscopic inguinal and pelvic nodal metastases and to direct needle biopsy (Vapnek et al, 1992). The technical difficulty of the procedure, combined with the availability of CT and MRI, has made lymphangiography obsolete in staging of this disease. Both CT and MRI techniques depend solely on lymph node enlargement for detection of metastases but are unable to define the internal architecture of normal-sized nodes. Because CT and MRI have similar accuracy in determining lymphadenopathy in other cancers, CT has often been the imaging modality chosen in penile cancer to examine the inguinal and pelvic areas as well as to rule out more distant metastases.

Horenblas and associates (1991) compared the ability of physical examination, CT, and lymphangiography to assess the inguinal region in patients who were surgically staged or had prolonged follow-up. In 102 patients with a 39% prevalence of positive nodes, the sensitivity and specificity of physical examination were 82% and 79%, respectively. Of note, both CT and lymphangiography were performed in patients who were thought to have metastases. The sensitivity of lymphangiography was only 31%, but there were no false-positive results. Similarly, the sensitivity and specificity of CT were 36% and 100%, respectively. The combination of CT and lymphangiography performed simultaneously demonstrated equally poor sensitivity. Only one fifth of patients had positive nodes detected with either test. **On the basis of these data the authors concluded that CT and lymphangiography offer no useful additional information over physical examination, especially in patients with no palpable adenopathy.** An important caveat is that CT may have a role in examination of the inguinal region in obese patients or in those who have had prior inguinal surgery, for whom the physical examination may be unreliable. In addition, in patients with known inguinal metastases, CT-guided biopsy of enlarged pelvic nodes may provide important information for consideration of neoadjuvant chemotherapeutic strategies.

Recent insights in the field of nanoparticle technology are being applied to imaging of genitourinary malignant neoplasms to

enhance detection of microscopic metastases. Ferumoxtran-10 particles (size = 35 nm), administered at a dose of 2.6 mg of iron per kilogram of body weight intravenously combined with MRI are now capable of imaging microscopic metastasis in lymph nodes that are by size criteria normal (1 cm). Tabatabaei and colleagues (2005) evaluated lymphotropic nanoparticle-enhanced MRI (LNMRI) in seven patients with penile cancer who subsequently underwent groin dissection. Five of seven patients had no palpable adenopathy. LNMRI was highly sensitive and detected positive nodes in all five of these patients. Of note the size range of the metastases was less than 1 cm in four patients.

Recently, squamous carcinoma was shown to take up the radiopharmaceutical fluorodeoxyglucose (FDG) and be amenable to detection utilizing combination positron emission tomography (PET) and CT. Scher and associates (2005) evaluated PET/CT among 13 patients with penile cancer injected FDG. Five of 13 patients had metastatic disease, and FDG-PET/CT detected it in 4 of them (80% sensitivity). Thus both LNMRI and PET/CT hold promise in the detection of microscopic inguinal disease in penile cancer but these promising initial reports will require validation among larger data sets.

In general, distant metastases occur late in the course of the disease, usually in patients with recognized significant inguinal and pelvic adenopathy. The most common metastatic sites are the lung, bone, and liver. In addition to abdominal and pelvic CT, radionuclide bone scintigraphy and chest radiography may be indicated to stage the extent of disease in patients thought to have widespread metastases (Vapnek et al, 1992).

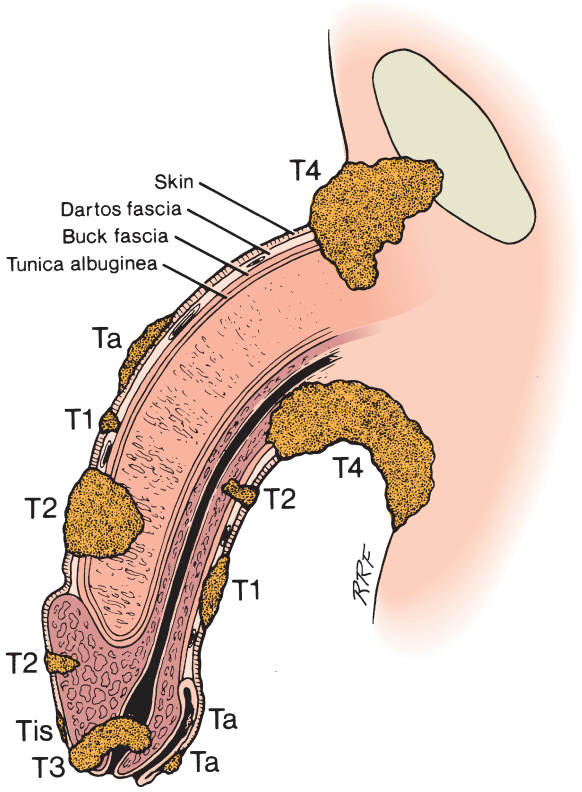

Figure 34–2. Because treatment decisions for inguinal node dissections are based on the characteristics of the primary lesion (see section on treatment of inguinal nodes), a careful assessment of the depth of invasion of the primary tumor is required. This diagram illustrates the importance of depth of invasion in assigning tumor (T) stage.

Key Points: Radiologic Studies

- Soft tissue detail of penile tumors is best imaged by ultrasonography or MRI.
- Physical examination provides the most reliable staging information for small distal lesions.
- Penile MRI performed in combination with artificial erection may provide unique staging information when physical examination findings are equivocal.
- Physical examination of the inguinal region remains the clinical gold standard for evaluating the presence of metastasis.
- CT or MRI can be useful in evaluating the inguinal region of obese patients and in those having prior inguinal surgery.
- Nanoparticle and PET/CT of the inguinal region have shown promising results in the detection of minimal inguinal metastases but validation in larger series is required.

Penile Cancer Staging

Sixth Edition TMN System. The unified Union Internationale Contre le Cancer (UICC, 1989) and American Joint Committee on Cancer (AJCC) TNM system (sixth edition) is most commonly used in contemporary series for staging penile cancer (Harmer, 1978; Fleming et al, 1997; Greene et al, 2006).

The primary tumor is staged according to histologic features and the precise anatomic structure invaded (Fig. 34–2). Experience documented in prior series has supported this system. Considering those patients with no palpable adenopathy, it is clear that patients with Tis and Ta lesions have a prognosis different from that of patients exhibiting T1 and T2 lesions (Johnson et al, 1985; Solsona et al, 1992; Gerber, 1994; Villavicencio et al, 1997). Because these histologic features are directly related to the risk of lymph node metastasis, such a staging arrangement is practical and informative with respect to surgical decision-making and prognosis.

The sixth edition TNM version also recognizes the importance of the extent of nodal involvement as a prognostic factor in survival, in that separate categories are used for patients with a single positive node (N1) versus those with bilateral nodes (N2) and deep inguinal or pelvic involvement (i.e., Cloquet or iliac nodes).

Challenges and Modifications. Horenblas and colleagues (1994) among others have challenged the utility and prognostic value of the sixth edition TMN system (Leijte et al, 2008a) based on data from several series including their own. With respect to primary tumor staging they recommended differentiating corpus spongiosum (CS) and cavernosum (CC) as separate T categories (i.e., T2 and T3, respectively) based on significant differences in both 5-year disease-specific survival (CS = 77.7% vs. CC = 52.6%) and percent of node-negative disease in the original TMN classification versus their proposed categories (current T category pT2 = 57.5%, pT3 = 57.9%; proposed T category pT2 = 65.7%, pT3 = 42.7%) (Leijte et al, 2008). Using this rationale they and others have also questioned the scientific basis for classifying isolated urethral involvement as stage T3 (Leijte et al, 2008a; Cubilla, 2009). Patients with isolated distal urethral involvement without corpus cavernosum involvement are often good candidates for organ preservation. Invasion of the prostate currently designated as stage T3 is rare, and most would concur that prostatic invasion is more

appropriately designated as pT4 related to invasion of adjacent structures rather than pT3 (i.e., same as urethral involvement in the current system).

With respect to nodal staging it is difficult to assign nodal status before definitive therapy using the sixth edition TMN "N" definitions owing to the potential for false-positive and false-negative inguinal examinations by palpation and fine-needle aspiration. In reality the current TNM staging system represents a pathologic staging system in which nodal histology must be assessed (i.e., aspiration, biopsy, lymphadenectomy). Leijte and coworkers (2008b) have proposed a clinical staging system for penile cancer based on their experience in more than 500 patients treated at the Netherlands Cancer Institute. Factors important in stratifying patient survival before definitive therapy included the presence (N+) or absence of palpable lymph nodes (N0), unilateral (N1) versus bilateral mobile nodes (N2), and a fixed inguinal mass or radiologic evidence of pelvic adenopathy (N3). The 5-year disease-specific survival (DSS) provided significantly different prognostic information for all three node positive categories (N1, N2, N3 = 77%, 54%, and 11%, respectively). Using the current N definition they could not demonstrate a significant survival difference between N1 and N2 categories (70.2% vs. 58.3%, $P = 0.176$). The proposed system if validated could represent an improvement in staging that may be more readily adapted universally (Leijte et al, 2008b).

Seventh Edition TMN Penile Staging System. A modified AJCC-UICC staging sytem has been published that addresses several inadequacies of the sixth edition TMN (Table 34–1). With respect to the primary tumor, because grade and the presence of vascular invasion are established prognostic markers in predicting the risk of subsequent inguinal metastasis the seventh edition TMN stratifies pT1 stage by their presence (i.e., high-grade tumors, vascular invasion present = pT1b) or absence (= pT1b) (Slaton et al, 2001; Solsona et al, 2004; Ficarra et al, 2005). In addition, prostatic invasion (a rare finding) is now included in the pT4 designation.

Of considerable importance is that the seventh edition has both clinical and pathologic nodal staging descriptors to facilitate both clinical and pathologic staging to better predict prognosis before definitive therapy. As pointed out by Leijte and colleagues (2008b) the prognosis worsens for patients exhibiting greater degrees of palpable adenopathy (i.e., unilateral vs. bilateral vs. a fixed mass) or positive nodes on imaging versus those with clinically negative inguinal lymph nodes. Considering pathologic nodal factors further, the seventh edition stratifies patients with a single positive node from those with multiple or bilateral nodes and further recognizes the ominous prognosis (5% to 18% 5-year survival) associated with extranodal extension of cancer (Srinivas et al, 1987; Ravi, 1993b; Lont et al, 2007).

Considering that the pathologic status of inguinal nodes is the driving factor determining survival, stage groupings (i.e., stage 0 to stage IV [see Table 34–1]) in the seventh edition TMN utilize the extent of nodal involvement as the major consideration. Thus the strength of the unified AJCC-UICC seventh edition TNM system (2009) is that it provides not only an accurate assessment of the primary tumor based on clinical staging (examination, biopsy) but also clinical and improved pathologic descriptors of lymph node status in order to predict outcome. This new TMN version, however, awaits validation using contemporary data sets.

In the 2009 AJCC-UICC TNM staging system the primary tumor stage is assigned by biopsy (or even more reliably by complete resection) and additional prognostic factors within the primary tumor now included in the TNM system (i.e., tumor grade and the presence of vascular invasion). In most cases the presence of

Table 34–2.

Minimal Diagnostic Criteria for Carcinoma of the Penis

Primary Tumor (T)
Clinical examination
Incisional-excisional biopsy of lesion (or complete resection) and histologic examination for grade, anatomic structure invaded, and presence of vascular invasion
Regional and Juxtaregional Lymph Nodes (N)
Clinical examination
Computed tomography, if inguinal adenopathy is palpable*
Superficial inguinal node dissection (as indicated for high grade, vascular invasion, or invasive histologic pattern)
Aspiration cytology (as indicated)
Distant Metastases (M)
Clinical examination
Chest radiography
Biochemical determinations (liver functions, calcium)
Magnetic resonance imaging, bone scintigraphy (as indicated)

*Computed tomography should also be performed in obese patients and those having prior inguinal surgery, whose physical examination findings may be unreliable.

palpable adenopathy, along with the histologic features of the primary tumor, determines the need for additional imaging studies. Positive fine-needle aspiration of palpably enlarged inguinal nodes or fine-needle biopsy of pelvic adenopathy identified by CT can assist in assigning nodal stage before therapy. In those patients requiring surgical staging (palpable lymph nodes or those with adverse primary tumor histologic features), pathologic nodal status assigned according to seventh edition TNM stage provides valuable prognostic information. The suggested diagnostic criteria for current TNM staging are listed in Table 34–2.

Key Points: Staging

- The sixth edition unified TNM staging system was a pathologic system that reflected the importance of describing penile structures invaded by tumor but lacked several important descriptors of primary tumor histology and lymph node extent in determining outcome.
- Both clinical and pathologic factors related to the presence and extent of lymph node involvement determine survival and should be recorded.
- The current seventh edition unified TMN staging system represents a consensus document that includes both clinical and pathologic descriptors that provide important prognostic information. Its prognostic utility awaits further independent validation.

Differential Diagnosis

A number of penile lesions must be considered in the differential diagnosis of penile carcinoma. They include condyloma acuminatum, Buschke-Löwenstein tumor, and balanitis xerotica obliterans as well as a number of infectious lesions (e.g., chancre, chancroid, herpes, lymphopathia venereum, granuloma inguinale, and tuberculosis). These diseases can be identified by appropriate skin tests, tissue studies, serologic examinations, cultures, or specialized staining techniques.

SURGICAL MANAGEMENT OF THE PRIMARY TUMOR

Organ Preservation

Surgical amputation of the primary tumor remains the oncologic gold standard for rapid definitive treatment of the penile primary tumor; local recurrence rates range from 0% to 8% (de Kernion et al, 1973; McDougal et al, 1986; Horenblas et al, 1992). Whereas amputation is often necessary for bulky stage T2-T4 tumors, it has been shown to decrease sexual quality of life (Opjordsmoen and Fossa, 1994). This is relevant because approximately 55% of penile cancer patients are 60 years of age or younger and 30% are 55 years of age or younger (Narayana et al, 1982).

It is generally accepted that patients with penile primary tumors exhibiting favorable histologic features (stages Tis, Ta, T1; grade 1 and grade 2 tumors) are at a lower risk for metastases. These patients are also best suited for organ-sparing or glans-sparing procedures (Solsona et al, 2004). The goal of treatment is to preserve glans sensation where possible or at least to maximize penile shaft length. Such approaches include topical treatments (5-fluorouracil or imiquimod cream for Tis only), radiation therapy, Mohs surgery, limited excision strategies, and laser ablation (Sanchez-Ortiz and Pettaway, 2003; Solsona et al, 2004; Minhas et al, 2005; Crook et al, 2009). This section focuses on novel insights into surgical strategies to achieve organ preservation. Radiation-based strategies are discussed later in the section Radiation Therapy for the Primary Lesion.

Circumcision and Limited Excision Strategies

Circumcision, limited excisions of the glans, and glans removal with sparing of the penile shaft represent surgical strategies to maintain function and penile length. Historically, data on circumcision and limited excision of glanular lesions have been associated with recurrence rates from 11% to 50% (Hanash et al, 1970; Skinner et al, 1972; McDougal et al, 1986). However, the grade, size, and exact location of the lesion and the status of surgical margins were often unavailable in such reports.

Recent reports have suggested that conservative surgery may be performed safely in well-selected patients with discrete tumors by intraoperative frozen-section analysis (Davis et al, 1999; Bissada et al, 2003; Pietrzak et al, 2004; Minhas et al, 2005). **In addition, several studies have challenged the dictum establishing that a 2-cm surgical margin is required for all patients undergoing partial penectomy** (Hoffman et al, 1999; Agrawal et al, 2000). After performing a prospective histologic analysis of 64 penectomy specimens, Agrawal and associates (2000) concluded that tumor grade highly correlated with microscopic tumor spread. The maximum proximal histologic extent was 5 mm for grade 1 and grade 2 tumors and 10 mm for grade 3 tumors. Furthermore, "skip" lesions were not encountered. After performing a retrospective pathologic review of 12 penectomy specimens, Hoffman and colleagues (1999) also found 7 patients with disease of pathologic stage T1 or greater with microscopic margins measuring less than 10 mm. None of these patients had disease recurrence at a mean follow-up of 32.4 months. Pietrzak and colleagues (2004) documented the use of various techniques in a series of 39 patients to excise the

tumor and to reconstruct or graft the glans and distal penis. With a mean follow-up of 16 months, only 1 patient (2.5%) who underwent a partial glans resection had a local recurrence. There were two early complications with grafts and two late complications with graft overgrowth intruding on the urethral meatus. Minhas and associates (2005) similarly performed either wide local excision or glans penis removal in 51 patients with margins of 0 to 10 mm in 48% and less than 2 cm in 98% of patients. With a median follow-up of 26 months a local recurrence rate of 4% to 6% was noted. Limitations of this approach include proximal and distal deeply invasive tumors, high-grade tumors, and patients with poor health status who would not be candidates for salvage procedures if they experienced recurrence. Although these results seem to suggest that a 2-cm margin may not be necessary for small tumors of lower grade in the presence of a negative frozen section, these findings should be interpreted with caution owing to the relatively short follow-up of most series. Patients managed with limited excision techniques should be considered to be at a higher risk for local recurrence until longer-term follow-up of current series is available.

Mohs Micrographic Surgery

Mohs microsurgery has historically had a positive impact on the management of penile carcinoma in situ and small superficially invasive tumors. As originally described by Mohs and colleagues (1985), it involves layer-by-layer complete excision of the penile lesion in multiple sessions (fixed tissue technique), with microscopic examination of the undersurface of each layer. Its sequential microscopic guidance offers improved precision and control of the negative margin while maximizing organ preservation. In a series of 29 consecutive cases of penile squamous cell carcinoma, the primary tumor was eradicated in 23 (92%) of 25 patients available for follow-up. Local recurrences were highly associated with tumor size (3 cm), advanced stage, and failure of previous definitive therapy (Mohs et al, 1992). These excellent results using a fixed tissue technique have not been reproduced using the currently utilized frozen section methodology. Shindel and associates (2007) treated 33 patients with stage Tis (26 patients), T1 (4 patients), T2 (7 patients), and T3 (4 patients) penile cancer. Five procedures were terminated with positive margins. Of 25 patients with mean follow-up of 58 months 8 (32%) developed recurrence. However, 7 of 8 were re-treated successfully with Mohs surgery. One patient who had progression of his disease died from it. **Thus Mohs microsurgery, as currently performed, may offer no additional benefit over surgical excision with intraoperative frozen section assessment of margin status.**

Laser Ablation

The four most widely used laser energy sources are the CO_2, argon, Nd:YAG, and KTP lasers (Carpiniello et al, 1987; Malloy et al, 1988; von Eschenbach et al, 1991). Although the CO_2 laser has been widely used previously, the superficial depth of penetration (limited to 0.1 mm) makes it less than optimal for the treatment of penile carcinoma in situ or small T1 tumors. When the CO_2 laser is used, local recurrence rates have been shown to be as high as 50% (Bandieramonte et al, 1988; van Bezooijen et al, 2001). Conversely, the Nd:YAG laser results in protein denaturation at a depth of up to 6 mm by emitting at a wavelength of 1060 nm. Overall recurrence rates after laser ablation have been reported at 7.7% for penile carcinoma in situ and have ranged from 10% to 25% for T1 lesions (Malloy et al, 1988; Windahl et al, 1995; Tietjen and Malek, 1998), but results from more contemporary series using the Nd:YAG laser exclusively have been more encouraging. **Frimberger and colleagues** (2002a) **treated 29 men with carcinoma in situ and stage T1 tumors, combining Nd:YAG laser ablation with tumor base biopsies to ensure negative surgical margins. Only two recurrences (6.9%) were reported at a mean follow-up of 46.7 months, which is comparable to recurrence rates after partial penectomy.** In an effort to reduce the incidence of positive surgical margins, Frimberger and associates (2002b) have proposed the use of autofluorescence and 5-aminolevulinic acid–induced fluorescence for targeting of frozen-section biopsy specimens.

Laser ablation is feasible and may achieve results equivalent to those of extirpative surgery, especially when it is performed in well-selected patients in conjunction with frozen-section biopsies. In addition, laser ablation has been associated with high rates of resumption of sexual activity (75%) and overall satisfaction (78%) (Windahl et al, 2004). However, until additional long-term studies become available, laser ablation should be performed with the understanding that local recurrences may develop and that close surveillance and patient self-examination are necessary for early detection. Although well-selected patients who develop small recurrent lesions may be candidates for repeated laser ablation, recurrences are best treated with wide local excision or partial amputation.

Contemporary Penile Amputation

Penile amputation remains the standard therapy for patients with deeply invasive or high-grade cancers. **Partial or total penectomy should be considered in patients exhibiting adverse features for cure by organ preservation strategies. These are consistently associated with tumors of size 4 cm or more, grade 3 lesions, and those invading deeply into the glans urethra or corpora cavernosa** (Mohs et al, 1992; Gotsadze et al, 2000; Kiltie et al, 2000). Because recurrence rates are higher with organ-preserving strategies, compliance with follow-up is also a consideration in recommending organ preservation versus amputation. Fortunately most patients with recurrences that are detected and treated early are not adversely affected with respect to survival (Lont et al, 2006). On the basis of contemporary results, organ preservation strategies should be discussed with patients exhibiting optimal tumor characteristics (stages Tis, Ta, T1; grade 1 and grade 2 tumors) to assist them in making an informed decisions about therapy.

Key Points: Surgical Treatment of the Primary Tumor

- Patients with small lesions of low grade and stage (Tis, Ta, T1; grade 1 and grade 2) are the optimal candidates for organ preservation to maintain sexual quality of life.
- The goals of organ preservation are to maintain glanular tissue for sensory purposes when possible and/or to maintain penile length when glans penis preservation is not possible.
- Surgical modalities include limited excision strategies, Mohs surgery, and laser ablation.
- Local recurrence rates overall after organ preservation are higher than with traditional amputation; however, when local recurrences are detected and treated, early survival may not be adversely impacted.
- Amputation remains the standard for large or deeply invasive lesions to gain rapid tumor control.

TREATMENT OF THE INGUINAL NODES

The presence and the extent of metastasis to the inguinal region are the most important prognostic factors for survival in patients with squamous penile cancer. These findings affect the prognosis of the disease more than do tumor grade, gross appearance, and morphologic or microscopic patterns of the primary tumor.

Unlike with many other genitourinary tumors, which mandate systemic therapeutic strategies once metastasis has occurred, lymphadenectomy alone can be curative and should be performed. The biology of squamous penile cancer is such that it exhibits a prolonged locoregional phase before distant dissemination, providing a rationale for the therapeutic value of lymphadenectomy.

However, owing to the morbidity of traditional lymphadenectomy especially among those patients with clinically negative groins, contemporary controversial issues include (1) the selection of patients for lymphadenectomy versus careful observation; (2) the types of procedures to correctly stage the inguinal region with low morbidity; and (3) multimodal strategies to improve survival among patients with bulky inguinal metastases.

In this rare disease, prospective randomized trials have not been performed to answer many of these questions. However, with the use of retrospective and prospective clinicopathologic data from several centers treatment strategies are presented using the available data.

Contemporary Indications for Inguinal Lymphadenectomy

Prognostic Significance of the Presence and Extent of Metastatic Disease

Table 34–3 reveals data collected from 24 surgical series during a 37-year period. Patients proved to have no evidence of inguinal metastases on the basis of histologic examination of the inguinal nodes or repeated normal examination findings over time; the average 5-year survival rate was 73% (46% to 100%). In patients with resected inguinal metastases the 5-year survival averaged 60% (0% to 86%), but this varied widely and was directly attributable to the extent of nodal metastasis (Table 34–4). This point is illustrated in several series shown in Tables 34–2 and 34–3. Patients with minimal nodal metastases (generally fewer than two) exhibited an average 5-year survival of 77% (89 of 115 patients), compared with only a 25% survival (26 of 102 patients) when a greater degree of nodal involvement was present.

The extent of cancer in a lymph node was also of prognostic significance. Ravi (1993b) noted extranodal extension of cancer in lymph nodes 4 cm in size, and only 1 of 17 patients (6%) undergoing lymphadenectomy survived 5 years. Finally, pelvic lymph node involvement has been a particularly ominous finding with respect to long-term survival; the combined results of several small series reveal an average 5-year survival of 15% when pelvic nodal metastases are present (Table 34–5). **Taken together, these data suggest that the pathologic criteria associated with long-term survival after attempted curative surgical resection of inguinal metastases (i.e., 80% 5-year survival) include minimal nodal disease (up to two involved nodes in most series), unilateral involvement, no evidence of extranodal extension of cancer, and absence of pelvic nodal metastases.**

Presence of Palpable Adenopathy as a Selection Factor for Inguinal Dissection

One can conclude from these data that it is advantageous to find and to treat nodal metastasis at the earliest possible opportunity. Data in Table 34–3 suggest that the presence of palpable adenopathy is associated with proven nodal metastasis in about 43% of cases on average (range 8% to 64%). In the remainder, lymph node enlargement is secondary to inflammation. Persistent adenopathy after treatment of the primary lesion and 4 to 6 weeks of antibiotic therapy is most often the consequence of metastatic disease. Similarly, the development of new adenopathy during follow-up is much more likely to be due to tumor than inflammatory response. Thus historically a course of antibiotics was recommended for patients with suspicious nodes to potentially discern metastasis from cancer (Srinivas et al, 1987). However, several authors have raised the issue that this causes a significant delay and could impact survival especially among patients who are likely to be truly positive by virtue of the stage/grade of the primary tumor (Kroon et al, 2005b; Pettaway et al, 2007). An alternative approach for such patients is to perform fine-needle aspiration cytology of palpable nodes either at the time of or immediately after treatment of the primary tumor. In the case of a positive result, definite therapy can be planned without a 4- to 6-week delay. Saisorn and associates reported a 93% sensitivity and a 91% specificity in 16 patients with palpable adenopathy (mean size 1.47 cm) undergoing fine-needle aspiration before lymphadenectomy. The recommendation for this procedure among patients with palpable nodes was also incorporated in the European Association of Urology (EAU) Penile Cancer Guidelines. **Thus, although treatment of the primary tumor and a period of antibiotics is useful to help sterilize the inguinal region, this practice is no longer advocated as a tool to select patients who either should or should not undergo lymphadenectomy.** Should the fine-needle aspiration result be negative depending on clinical suspicion, close observation, repeat aspiration, or excisional biopsy is performed because the false-negative rate of fine-needle aspiration cytology was 20% to 30% in two other older series (Scappini et al, 1986; Horenblas et al, 1991).

Evolving Indications for Lymphadenectomy in Patients without Palpable Adenopathy

Immediate versus Delayed Surgery

Considering the value of early detection and treatment of metastasis, **should inguinal lymphadenectomy be routinely performed in patients with clinically normal groin examination findings at the time of presentation of the primary lesion?** This has been the most controversial issue in the management of patients with squamous penile cancer; however, the pendulum has moved toward earlier lymphadenectomy in selected patients with penile cancer. As noted, the cure rate with inguinal lymphadenectomy when nodes are positive for malignancy may be as high as 80%. A cure rate of this magnitude with surgery in the face of regional nodal metastases parallels the urologist's experience with testicular cancer, in which retroperitoneal lymphadenectomy provides cure in many patients with minimal nodal metastasis. In contrast, for other common genitourinary malignant neoplasms—bladder, prostate, and kidney—surgical cure in the presence of regional nodal metastases is rare.

*On histologic or repeated physical examination.
†On histologic examination of adenectomy specimen.
[a]Majority of patients received prophylactic or preoperative radiation therapy to inguinal area.
[b]Histologic classification based on node biopsy, not node dissection.
[c]Corrected 5-year survival (i.e., patients dying before 5 years without evidence of disease are excluded).
[d]Patients dying free of cancer before 5 years are considered surgical cures.
[e]Three-year survival.
[f]Omitted.
[g]Positive findings in inguinofemoral nodes.
[h]Positive findings in inguinofemoral and pelvic nodes.
[i]Single inguinal node with positive findings.
[j]More than one inguinal node with positive findings.
[k]Three-year survival with positive findings in inguinal and pelvic nodes.
[l]N1-2.
[m]N3.
[n]After antibiotic therapy.
[o]One node positive.
[p]One to six nodes positive.
[q]More than six nodes positive.
[r]Bilateral nodes positive.
[s]Adjunctive adenectomy.
[t]Immediate therapeutic adenectomy.
[u]Delayed therapeutic adenectomy.
[v]One to three positive nodes.
[w]More than three positive nodes.
[x]Unilateral.
[y]Some lymph node dissection done without antibiotic pretreatment.

Given that node dissection can cure metastatic penile cancer, why is there debate about whether the procedure should be performed, especially given that regional node dissections are often advocated in other malignant neoplasms when evidence of their efficacy is marginal at best?

Morbidity versus Benefit

The reluctance to advocate automatic ilioinguinal lymphadenectomy in all patients with penile cancer stems from the substantial morbidity the procedure can produce, as opposed to the relatively limited postoperative morbidity of pelvic or retroperitoneal

lymphadenectomies. Early complications of phlebitis, pulmonary embolism, wound infection, flap necrosis, and permanent and disabling lymphedema of the scrotum and lower limbs were frequent after both inguinal and ilioinguinal node dissections (Fig. 34–3) (Skinner et al, 1972; Johnson and Lo, 1984b; McDougal et al, 1986; Fraley et al, 1989). **Postoperative complications have been reduced by improved preoperative and postoperative care; advances in surgical technique; plastic surgical consultation for myocutaneous flap coverage; and preservation of the dermis, Scarpa fascia, and saphenous vein, as well as modification of the extent of the dissection** (Catalona, 1988; Colberg et al, 1997; Bevan-Thomas et al, 2002; Coblentz and Theodorescu, 2002; Nelson et al, 2004) (Fig. 34–4). In the University of Texas M. D. Anderson Cancer Center experience both the incidence and severity of lymphedema and skin edge necrosis were significantly decreased (Table 34–6) (Bevan-Thomas et al, 2002).

Furthermore, experience has suggested that lymphadenectomy in the setting of microscopic disease may be less likely to produce complications than node dissection in the presence of bulky nodal metastases (Fraley et al, 1989; Ornellas et al, 1994; Coblentz and Theodorescu, 2002). This is presumably due to the reduced amount of lymphatic tissue removed, preservation of venous drainage, and blood supply compromised. Together these factors affect the viability of skin flaps and lymphatic flow.

Figure 34–3. Extensive lymphedema and cutaneous changes secondary to recurrent lymphangitis and thrombophlebitis 2 years after a classic groin dissection.

‡Incidence among 85 lymphadenectomies performed by Gibson-type incision.
From Bevan-Thomas R, Slaton JW, Pettaway CA. Contemporary morbidity from lymphadenectomy for penile squamous cell carcinoma: the M.D. Anderson Cancer Center experience. J Urol 2002;167:1638–42.

Mortality after inguinal lymphadenectomy has been reported in association with surgery performed concomitantly with penectomy and after palliative inguinal dissection. In both scenarios it was related to sepsis (Bevan-Thomas et al, 2002). An operative mortality of 3.3% was reported in earlier series (Beggs and Spratt, 1964). However, Johnson and Lo (1984b) and others (Ravi, 1993a;

Figure 34–4. Postoperative appearance after contemporary lymphadenectomy. The patient's status is post left ilioinguinal lymphadenectomy and right superficial inguinal dissection for stage T2N1M0 squamous penile cancer. Trace edema is visible on the left 18 months after surgery.

Ornellas et al, 1994; Coblentz and Theodorescu, 2002; Nelson et al, 2004) have reported no mortality in more recent series. Appropriate selection of patients along with routine preoperative antibiotic therapy and wound care to avoid septic complications has minimized this event.

Clearly, lymphadenectomy is not a trivial concern even though morbidity appears to be decreasing. If a policy of routine lymphadenectomy were adopted in all patients with clinically negative lymph nodes, the average risk of a false-negative examination (metastasis is actually present) would be approximately 29%, with wide-ranging variation (see Table 34–3). Stated another way, an average of 70% of patients could be subjected to the morbidity of inguinal lymphadenectomy with no benefit. Potential reasons for false-negative examinations include obesity, preexisting edema, and changes from prior therapy (radiation, inguinal surgery).

One alternative to immediate lymphadenectomy for all patients has been to observe patients with normal findings on inguinal examination. Lymphadenectomy is subsequently reserved for those patients who develop palpable lymph nodes. **The relevant question then becomes, can a delayed therapeutic dissection effectively salvage patients who have inguinal recurrence?**

Several studies have analyzed the survival of men undergoing early versus delayed lymphadenectomy according to pathologic evaluation of nodal status. McDougal and coworkers (1986) reported a series of 23 patients with invasive primary lesions and nonpalpable nodes; 9 patients were treated with immediate adjunctive lymph node dissection (6 had positive findings), and 14 were treated with surveillance and delayed lymph node dissection. The 5-year survival in the node-positive immediate adjunctive lymphadenectomy group was 83% (5 of 6 patients), whereas in the surveillance group the 5-year survival was 36% (5 of 14 patients). However, only 1 patient in the surveillance group had a node dissection. Presumably, the other 9 patients had progressed to inoperable local tumor or distant disease before presentation, emphasizing the role of careful, frequent follow-up and the difficulty of enforcing it. A third subset in this series had palpable nodes at presentation and had immediate therapeutic lymph node dissection, with 10 of 15 patients (66%) surviving 5 years (McDougal et al, 1986). The best results were from immediate adjunctive lymph node dissection (83%), with the next best from immediate therapeutic lymphadenectomy (66%). The worst results were from the surveillance and delayed lymphadenectomy group (36%), in whom dissection was delayed until palpable nodes developed. The interval of opportunity for cure in this third group appears to have been lost.

Similarly, Fraley and associates (1989) reported that immediate adjunctive lymphadenectomy resulted in a 5-year disease-free survival in 6 of 8 node-positive patients (75%) compared with 1 of 12 patients (8%) who had been observed and then treated by delayed lymphadenectomy when nodal enlargement occurred. Six other patients in that series also presented with unresectable adenopathy after initial surveillance, and all died of their disease. Although only 2 of 6 patients who had immediate lymphadenectomy had more than two positive nodes, all the patients treated by delayed lymph node dissection had three or more positive nodes.

Three other series suggest that early lymphadenectomy for varying degrees of "suspicious" or clinically positive nodes improves survival compared with the "surveillance" or delayed intervention approach in patients presenting with clinically negative nodes (Johnson and Lo, 1984a; Ornellas et al, 1994; Kroon et al, 2005b). A series from the University of Texas M. D. Anderson Cancer Center compared 5-year disease-free survival of 14 patients undergoing early lymphadenectomy for clinically suspicious and histologically node-positive disease with that of 8 patients who were observed and later underwent lymphadenectomy when clinical nodal enlargement was undisputed (Johnson and Lo, 1984a). The primary tumors were of similar stage. The 5-year disease-free survival was 57% for early lymphadenectomy compared with 13% for delayed node dissection. Of note, the number of involved nodes in the immediate lymphadenectomy group (median, two) was half that of the delayed lymphadenectomy group (median, four), and no patient with more than two positive nodes survived more than 5 years.

Kroon and associates (2005b) from the Netherlands Cancer Institute compared survival of 20 patients found to have positive lymph nodes subsequent to prophylactic dynamic sentinel node biopsy (DSNB) with that of 20 patients who underwent delayed inguinal dissection after proven nodal metastasis. The 3-year survival for those patients detected during close surveillance was only 35% compared with 84% ($P = .0017$) for those undergoing early dissection. Pathologic evaluation of involved lymph nodes revealed extranodal extension of cancer among 19 of 20 patients in the delayed group versus only 4 of 20 patients ($P = .001$) in the early group. Thus, despite careful follow-up, survival was adversely affected by the extent of cancer in involved lymph nodes.

A single large study from India disputes the magnitude of the value of early prophylactic dissection. Ravi (1993a) performed early prophylactic dissection in 113 patients with invasive penile cancer and compared the 5-year survival with that of 258 similarly staged patients who were initially observed. In the "early" group,

20 patients (18%) were found to have metastases, and all patients survived 5 years. The recurrence rate in the observed group was only 8% (21 patients). However, the 5-year survival in the patients who experienced recurrence was only 76% (compared with 100% in the early lymphadenectomy group). The enhanced survival of patients undergoing surveillance in India compared with other countries is probably attributable to patient selection factors, strict adherence to follow-up schedules, and aggressive treatment approach for recurrent disease (a combination of radiation and surgical resection) (Ravi, 1993b).

Thus, six series reveal an improvement in survival for patients undergoing early therapeutic versus delayed therapeutic dissection. Further, five of the six series show that delayed therapeutic dissection can rarely salvage patients who experience recurrence. Taken together, these data suggest that a policy of immediate adjunctive or early lymphadenectomy gives greater assurance that surgical intervention will occur when tumor volume is small (see Table 34–4) (Johnson and Lo, 1984b; Fossa et al, 1987; Srinivas et al, 1987; Fraley et al, 1989; Ravi, 1993a; Kroon et al, 2005b).

Impact of Primary Tumor Histologic Features on Predicting Occult Nodal Metastasis

Although early lymphadenectomy improves survival in patients with inguinal metastases, the challenge remains to identify those patients who are truly lymph node negative to avoid the morbidity of traditional lymphadenectomy. **Data gained from analysis of a variety of histopathologic variables within the primary penile tumor allow the classification of patients into higher and lower risk groups for lymph node metastasis** (McDougal, 1995; Lopes et al, 1996; Theodorescu et al, 1996; Solsona et al, 2001; Ficarra et al 2006).

Patients with primary tumors exhibiting carcinoma in situ or verrucous carcinoma have little or no risk for metastasis. Only two cases of metastasis in association with carcinoma in situ have been reported, and none of 47 cases of penile verrucous carcinoma has been shown to metastasize (Avrach and Christensen, 1976; Johnson et al, 1985; Seixas et al, 1994; Eng et al, 1995). Thus patients with both Tis and Ta penile cancer are included in the low-risk group for inguinal metastases (Solsona et al, 2001, 2004).

In contrast, patients with corporeal invasion (stage pT2) in the penile tumor exhibit a high risk for metastasis. The average risk for inguinal metastasis among 225 patients in seven different series was 59% (Table 34–7). **The risk for metastasis among patients exhibiting corporeal invasion was similar irrespective of whether palpable adenopathy was present.**

Stage T1 penile cancers exhibit involvement of the subepithelial connective tissue only and lack involvement of the corpus spongiosum, corpora cavernosa, or urethra (Fleming et al, 1997). Similarly staged tumors historically have been associated with a 4% to 14% incidence of nodal metastasis (Solsona et al, 1992; Villavicencio et al, 1997; Hall et al, 1998). Theodorescu and colleagues (1996) noted one exception to this relatively low rate of metastatic disease; 58% of patients (14 of 24) with pT1 primary tumors and initially negative nodes on clinical assessment subsequently developed inguinal nodal metastases. These data suggest that other variables present within the penile cancers of the cohort of patients studied (i.e., tumor grade and presence of vascular invasion) may have modified the effect of tumor stage on metastasis.

Several authors have evaluated the risk of nodal metastasis for stage T1 lesions according to tumor grade (Table 34–8). Among 73 patients with T1 grade 1 or grade 2 primary tumors, metastasis occurred in only 5 patients (7%). Recent data from Naumann and coworkers (2008), however, suggested that among T1 grade 2 tumors specifically the risk of metastases could be higher than previously described. Among three series reporting specifically on the T1 grade 2 subset, in 24 initially node-negative patients metastases occurred in 9 (38%). However, 5 patients in this subset also exhibited either lymphatic or venous invasion (an adverse prognostic feature, see later). Ficarra and colleagues (2006) developed the first penile cancer nomogram utilizing data from 175 patients. Based on tumor thickness and growth pattern, patients with T1 grade 2 tumors exhibited metastatic rates between 5% and 20%. Thus grade 2 tumors represent a heterogeneous group in which the histologic criteria used to describe grade 2 and the presence or absence of other poor prognostic features ultimately determine prognosis (Cubilla, 2009). In this regard the EAU guidelines assigned patients with T1 grade 2 tumors to the intermediate-risk category in which the risk of lymph node metastasis is greater than 16% (low risk) and less than 68% (high risk) (Solsona et al, 2004).

The presence of vascular invasion as a prognostic indicator of inguinal lymph node metastasis in squamous penile cancer is now evident (Fraley et al, 1989; Lopes et al, 1996; Heyns et al, 1997; Slaton et al, 2001; Ficarra et al, 2005). Lopes and colleagues (1996) studied the prognostic value of lymphatic invasion in 146 patients with penile cancer. In a univariate analysis, clinical nodal stage, tumor thickness, lymphatic and

Five tumors in node-positive group had lymphatic or venous invasion.

venous embolization, and urethral infiltration were all associated with lymph node metastasis. However, subsequent to multivariate analysis, only venous and lymphatic invasion remained significant predictors for positive lymph nodes. Data from the University of Texas M. D. Anderson Cancer Center revealed that vascular invasion was absent in all patients with T1 tumors (Slaton et al, 2001). These patients were also lymph node negative at surgery. In contrast, patients with stage pT2 primary tumors exhibited nodal metastasis in 75% of cases (15 of 20) when vascular invasion was present but in only 25% of cases (3 of 12) when it was absent.

Ficarra and colleagues (2005) described prognostic factors for lymph node metastasis in 175 patients undergoing surgery for penile cancer in a multicenter study from the Northeast Uro-Oncological Group from Italy. Subsequent to multivariate statistical analysis, the presence of venous or lymphatic invasion and pathologic invasion of the corpus spongiosum or urethra were the only independent risk factors for lymph node metastasis among patients who were clinically lymph node negative. Taking this a step further and including the variables of tumor thickness, growth pattern, grade, venous/lymphatic invasion, corpus spongiosum or cavernosum involvement, urethral involvement, and palpable lymph nodes Ficarra and colleagues (2006) developed a nomogram predicting inguinal lymph node involvement. The most important variables were venous/lymphatic invasion and the presence of palpable nodes in multivariate analysis. The concordance index of the nomogram was very good at 0.876. However, external validation of the nomogram is pending at this time.

The presence of perineural invasion (Velazquez et al, 2008) and the microscopic front pattern of invasion (Guimares et al, 2006) have also been shown in recent studies to provide independent information with which to stratify a patient's risk of lymph node metastasis.

Molecular Prognostic Markers

Analysis of gene expression in penile cancer may have future implications with respect to the prediction of lymph node metastasis or survival. A review by Muneer and colleagues (2009) describes the current status of several genes evaluated in tissue or serum that could have future prognostic implications with respect to predicting lymph node status or survival (Table 34–9). Presently, standardization of methodologies for assessment of gene expression and the lack of large tissue banks with well annotated clinical data for validation studies hamper efforts to rigorously evaluate the potential utility of such biomarkers. Prospective multi-institutional studies analyzing both pathologic and molecular features are needed to further validate which pathologic and molecular variables best stratify a patient's risk for metastasis and survival.

Contemporary Evolving Indications for Expectant Management of the Inguinal Region

Data reviewed in the preceding paragraphs along with consensus guidelines demonstrate that patients with primary tumors exhibiting carcinoma in situ (Tis), verrucous carcinoma (Ta), and stage T1, grade 1 tumors exhibit less than a 10% incidence of positive lymph nodes overall and are optimal candidates for watchful waiting strategies (Solsona et al, 2004). **Recommendations for management of patients with T1 grade 2 tumors vary based on quoted rates of subsequent metastases. The current EAU guideline (while classifying such patients in the intermediate risk group) recommends observation for T1 grade 2 tumors that lack vascular invasion and exhibit a superficial growth pattern (i.e., absence of any other adverse features)** (Solsona et al, 2004). Table 34–10 provides guidelines for the follow-up of such patients.

Table 34–10.

Penile Carcinoma: Suggested Follow-Up for Patients with No Evidence of Inguinal Adenopathy Who Do Not Undergo Initial Lymphadenectomy

	Interval	
YEAR	Low-Risk Group*	High-Risk Group†
1-2	3 months	2 months
3	4 months	3 months
4	6 months	6 months
5+	Annually	Annually

*Tis, Ta, and T1, grade 1 or grade 2; no vascular invasion with superficial growth pattern.

†T1, grade 2 with nodular growth or stage T2 or higher, grade 3, with vascular invasion.

Prognostic Molecular Markers of Lymph Node Status and Survival in Penile Cancer: Current Status

MARKER	ROLE	LYMPH NODE STATUS	SURVIVAL
Human papillomavirus (HPV)	High-risk types affect TP53 and RB function	Contradictory studies	Most studies show no correlation
TP53	Altered/mutated expression increased proliferation, altered Apoptosis, dedifferentiation	Preliminary data correlated with increased metastasis	Correlated with survival in T1 penile cancers only
CDKN2A	Inhibits RB function enhancing proliferation	Not established	Not established
Squamous cell carcinoma antigen (TA-4)	Serum marker function unknown	Correlates with grossly evident metastases	No role
Ki-67	Nuclear protein associated with cycling cells	Predicts increased risk	No role
E-Cadherin	Epithelial cell adhesion molecule lost in progression	Low expression associated with nodal metastasis	Low expression predicts worse survival
MMP-9	Matrix metalloproteinase family facilities invasion	No role	High expression predicts recurrence

Modified from Muneer A, Kayes O, Ahmed HU, et al. Molecular prognostic factors in penile cancer. World J Urol 2009;27:161–7.

Alternatively, all other fit patients with stage pT2 or greater or grade 3 tumors and those exhibiting vascular invasion have a greater than 50% incidence of metastasis, so prophylactic lymphadenectomy appears warranted. Although not in this high-risk group, patients with T1 grade 2 tumors with other high-risk features (tumor thickness, vertical growth) should also be considered for surgical staging owing to an intermediate risk of metastatic disease (Solsona et al, 2004). Additionally, noncompliant patients with invasive primary tumors should be offered an inguinal staging procedure versus observation. Table 34–10 provides a guideline for more intensive follow-up of high-risk patients, especially within the first 2 years. **It is imperative for both the patient and the physician to adhere to such follow-up agreements and be willing to intervene immediately if initial inguinal parameters change. Leijte and colleagues** (2008b) **have documented that only a third of patients who were initially node negative but subsequently develop an inguinal recurrence survive 5 years.**

Indications for Modified and Traditional Inguinal Procedures

Modified Procedures

In patients with no evidence of palpable adenopathy who are selected to undergo inguinal procedures by virtue of adverse prognostic factors within the primary tumor the goal is to define if metastases exist with minimal morbidity for the patient. A variety of treatment options for this purpose have been reported and include fine-needle aspiration cytology, node biopsy, sentinel lymph node biopsy, extended sentinel lymph node dissection, intraoperative lymphatic mapping, superficial dissection, and modified complete dissection. The technical aspects of many of these procedures are beyond the scope of this chapter but may be found in Chapter 35 and in the references Horenblas and colleagues (2000) and Spiess and coworkers (2009).

Fine-Needle Aspiration Cytology. The experience with aspiration of clinically negative inguinal nodes guided by either lymphangiography or ultrasonography is limited. Scappini and associates (1986) performed fine-needle aspiration cytology under pedal or penile lymphangiography for nodal localization in 29 patients. Of 20 patients who had lymphadenectomy for histologic confirmation there was complete agreement between aspiration cytology and histologic results. However, 2 of 9 patients whose cytologic analysis was negative subsequently died of metastatic disease, a presumptive 20% false-negative result. A series from Horenblas and colleagues (1991) also found that the sensitivity of fine-needle aspiration cytology was approximately 71% in 18 patients with clinically negative lymph nodes. This finding and the technical difficulty with lymphangiography make aspiration less practical as a staging technique for patients with no palpable lymph nodes. Kroon et al (2005a) described fine-needle aspiration cytology guided by ultrasonography as a preliminary study to surgical staging with DSNB. Thirty-four groins in 27 patients with clinically negative groins were found to have suspicious nodes by ultrasound examination and were aspirated. However, the sensitivity of the technique was only 39% subsequent to surgical staging. **Thus, at present, fine-needle aspiration cytology of clinically negative groins does not exhibit the sensitivity for it to be relied on as a staging modality.** However, direct aspiration of palpable inguinal nodes is easily performed, exhibited a sensitivity of 93% in a recent study, and, if positive, provides immediate information with which to advise patients about further treatment (Saisorn et al, 2006).

Sentinel Lymph Node Biopsy, Extended Sentinel Lymph Node Dissection, and Node Biopsy. The concept of sentinel lymph node biopsy as described by Cabanas (1977) is predicated on detailed penile lymphangiographic studies that have demonstrated consistent drainage of the penile lymphatics into a sentinel node or group of nodes located superomedial to the junction of the saphenous and femoral veins in the area of the superficial epigastric vein. In this series, when this sentinel node was negative for tumor, metastases to other ilioinguinal lymph nodes did not occur. Metastases to this node indicated the need for a complete superficial and deep inguinal dissection.

The accuracy of the sentinel node histology to identify inguinal node metastases was, however, questioned by a number of reports (Perinetti et al, 1980; Fowler, 1984; Wespes et al, 1986). Because nodal metastases became palpable within 1 year of sentinel node biopsy with normal findings in some patients in these series, a false-negative biopsy result must be presumed. In one large series, 5 of 41 patients (12%) with normal findings on sentinel node biopsy subsequently developed inguinal node metastases (Fossa et al, 1987). In Cabanas' series (1992), 3 of 31 patients with negative sentinel nodes died of disease, suggesting a false-negative rate for identifying metastases of 10%. McDougal and associates (1986) reported a 50% false-negative rate with inguinal node biopsy. A report by Pettaway and colleagues (1995), in which additional nodes around the sentinel node area were also removed, revealed that even this extended dissection was associated with a false-negative rate of 25%. The authors hypothesized that false-negative inguinal node biopsies were the result of anatomic variation in the position of the sentinel node within the inguinal field. **Thus, biopsies directed to a specific anatomic area can be unreliable in identifying microscopic metastasis and are no longer recommended.**

Dynamic Sentinel Node Biopsy. DSNB offers the potential for precise localization of the sentinel node with the lowest morbidity of any surgical staging technique (Kroon et al, 2005c). The goal of DSNB is to define where in the inguinal lymph node field the sentinel lymph node resides utilizing a combination of visual (vital blue dyes) or gamma emission (hand-held gamma probe) techniques at the time of surgery.

The technique has been studied in patients with malignant melanoma and breast and vulvar carcinomas who required evaluation of the regional lymph nodes (Morton et al, 1992; Levenback et al, 1994; Albertini et al, 1996; Gershenwald et al, 1999). The technique involves intradermal injection of a vital blue dye (isosulfan blue or patent blue dyes) or technetium-labeled colloid adjacent to the lesion. The dye (or radioactive tracer) is transported by the afferent lymphatics to a specific node in the regional nodal basin. This node is designated the sentinel lymph node. In Morton's series of 237 patients with melanoma, the sentinel lymph node was identified in 194 patients. These patients then underwent full regional lymphadenectomy, with a false-negative sentinel node in only 1% of cases.

Several studies evaluating the results of DSNB as a staging tool in penile cancer are now available. Kroon and associates (2004) updated the Netherlands Cancer Institute experience, describing their experience using the combination of preoperative lymphoscintigraphy and intraoperative intradermally injected blue dye in 123 patients with penile cancer. They identified a sentinel node in 98% of patients, for a sensitivity rate of 82% and a false-negative rate of 18% (6 patients). Four of the 6 patients subsequently died of disease progression. Spiess and associates (2007)

also noted a false-negative rate of 25% among 31 patients undergoing DSNB. The Netherlands Cancer Institute group subsequently instituted several changes, including (1) routine serial sectioning of the involved lymph nodes along with cytokeratin immunohistochemistry, (2) routine exploration of groins with low or no signal subsequent to preoperative or intraoperative studies, and (3) inguinal ultrasonography with fine-needle aspiration to detect subtle architectural changes (nonpalpable) in positive lymph nodes that could result in the redistribution of lymphatic flow (Kroon et al, 2005a).

In a multicenter update that included patients assessed with the modified DSNB protocol from two high-volume centers (the Netherlands Cancer Institute and St. George's Hospital in London) the false-negative rate was 7% (6 patients) among 323 patients (Leijte et al, 2009). Three of 6 patients with recurrence (50%) either died or developed distant metastases. **Thus DSNB when performed at high-volume centers using a standardized protocol has an acceptable sensitivity but deaths from penile cancer among initially node-negative patients still occurred.** This limits the applicability of this strategy to larger centers with experienced surgeons and nuclear medicine specialists.

Superficial and Modified Complete Inguinal Dissection. Both superficial inguinal and modified complete dissections have been proposed as staging tools for the patient without palpable inguinal lymphadenopathy. Superficial node dissection involves removal of those nodes superficial to the fascia lata. A complete ilioinguinal lymphadenectomy (removal of those nodes deep to the fascia lata contained within the femoral triangle as well as the pelvic nodes) is then performed if the superficial nodes are positive at surgery by frozen-section analysis. The rationale for superficial dissection is that two series have shown no positive nodes deep to the fascia lata unless superficial nodes were also positive (Pompeo et al, 1995; Puras-Baez et al, 1995). Furthermore, Spiess and colleagues (2007) showed that among the lymph node–negative cohort of patients undergoing DSNB with completion superficial dissection no patient with a negative superficial dissection recurred with more than 3-year follow-up. A complete modified inguinal dissection was originally proposed by Catalona (1988) and involves smaller skin incision, limited field of inguinal dissection, preservation of the saphenous vein, and thicker skin flaps. This technique also avoids having to transpose the sartorius muscle to cover exposed femoral vessels. Unlike in superficial dissection, deep nodes within the fossa ovalis are also removed. Two reports involving 21 patients have confirmed the value of this technique, when it is properly performed, for identifying microscopic metastases with minimal morbidity (Parra, 1996; Colberg et al, 1997).

Thus, either superficial or complete modified inguinal dissection should adequately identify microscopic metastases in patients with clinically normal inguinal examination findings, without the need for a pelvic dissection if the inguinal nodes are negative. The disadvantage of the modified dissections is the higher overall complication rate (12% to 35%) when compared with DSNB (5% to 7%) (Kroon et al, 2005c; Spiess et al, 2009).

Limited dissections have the following advantages: more information is provided than by biopsy of a single node or group of nodes; the possibility of not identifying the sentinel node is limited by removal of all potential first-echelon nodes; morbidity is minimal compared with standard lymphadenectomy; and the dissection is readily performed by any surgeon experienced in inguinal surgery without the need for specialized equipment.

Laparoscopic Inguinal Lymphadenectomy

The laparoscopic approach to the inguinal region offers the potential of removing all the inguinal lymph nodes at risk for disease while minimizing complications. The technical details of the contemporary procedure and early results have been described by two groups from South America (Sotelo et al, 2007; Tobias-Machado et al, 2007). To date among highly selected small series of patients inguinal lymph nodes removed have been comparable to open series, only a single recurrence has been reported with a 12- to 33-month follow-up, and minor complications have occurred in about 20% of patients (Sotelo et al, 2009; Spiess et al, 2009). Thus this approach, although promising, will require further validation with larger patient numbers and longer follow-up.

Traditional Inguinal and Ilioinguinal Lymphadenectomy

In patients with resectable metastatic adenopathy the potential therapeutic value of lymphadenectomy justifies the morbidity of treatment. The goals are to eradicate all obvious cancer, to provide coverage for exposed vasculature, and to provide rapid wound healing (primary closure or myocutaneous flap coverage). Several issues remain with respect to surgical decision-making.

Should inguinal lymphadenectomy be bilateral rather than unilateral for patients presenting with unilateral adenopathy at initial presentation of the primary tumor? The answer to this question is yes. The anatomic crossover of penile lymphatics is well established, and bilateral drainage is the rule. In 43 of 54 patients (79%) undergoing intraoperative lymph node mapping at the Netherlands Cancer Institute, lymphatic drainage from the penis was bilateral (Horenblas et al, 2000). The contralateral node dissection may be limited to the area superficial to the fascia lata if no histologic evidence of positive superficial nodes is found at surgery by frozen-section analysis. Clinical support for a bilateral procedure is based on the finding of contralateral metastases in more than 50% of patients so treated, even if the contralateral nodal region was normal to palpation (Ekstrom and Edsmyr, 1958).

Should bilateral inguinal lymphadenectomy be performed in patients who present with unilateral lymphadenopathy some time after the initial presentation and treatment of the primary tumor? It is generally believed that bilateral node dissection in this setting is not necessary. The recommendation of unilateral rather than bilateral node dissection with delayed presentation of unilateral lymphadenopathy is supported by the elapsed disease-free interval of observation on the normal side. If one assumes that nodal metastases will enlarge at the same rate, the clinical palpation of nodal metastases, if present in both groins, should appear at approximately the same time. The absence of clinical adenopathy on one side despite prolonged observation suggests freedom from disease on that side (Ekstrom and Edsmyr, 1958). However, this concept may not apply to all patients with delayed recurrence. Horenblas and colleagues (2000) noted that in patients with two or more unilateral metastases contralateral occult metastases were noted in 30% of cases. Thus, in patients with a bulky unilateral recurrence, a contralateral inguinal staging procedure should be considered. Considering the current treatment recommendations for bilateral inguinal staging procedures in men at high risk for metastasis and the definition of low-risk groups for metastasis by use of available prognostic markers, this scenario should rarely occur.

Should pelvic lymphadenectomy be performed in all patients with inguinal metastases considering its

potential for added morbidity and relatively low therapeutic value? This issue remains controversial. Patients with inguinal nodal metastases are at increased risk for spread to the pelvic nodes. Ravi (1993a) found no pelvic nodal metastases when inguinal nodes were negative but found positive pelvic nodes in 17 of 75 patients (22%) with one to three positive inguinal nodes and in 13 of 23 patients (57%) with more than three positive inguinal nodes. Srinivas and associates (1987) also found a similar correlation. Horenblas and colleagues (1993) showed that among patients with a single inguinal lymph node involved without extracapsular extension the incidence of pelvic metastases was rare and recommended avoiding pelvic dissection among such patients. Zhu and coworkers (2008) found that the sensitivity of CT for pelvic lymph node metastasis was only 37.5%. Defining the status of the Cloquet node in predicting a positive pelvic node was only about 30% sensitive as well. Important predictors were the number of positive nodes as well as lymph node size. Two contemporary studies addressing this issue have found a 0% to 12% incidence of pelvic lymph node metastasis when patients exhibited only one to two positive inguinal nodes especially when extracapsular extension was absent and/or size was less than 3.5 cm (Lont et al, 2007; Zhu et al, 2008). Additional factors noted in these studies included the grade of the nodal metastasis and its TP53 status. Thus patients with only a single small lymph node metastasis discovered at the time of a inguinal dissection (i.e., no extracapsular extension, not high grade) may be at very low risk for pelvic metastasis and are potentially the optimal candidates in whom pelvic lymphadenectomy can be avoided.

With respect to efficacy the 5-year survival for patients with positive pelvic nodes averages around 14% (see Table 34–5). However, data from some of the smaller series suggested that in selected instances 5-year survival can occur in patients treated with surgery alone. In the series reported by Ravi (1993a), however, even patients with a single positive pelvic node failed to survive 5 years (0 of 8 patients). The difficulty in determining the potential independent value of pelvic lymphadenectomy as a therapeutic procedure is related to the small numbers of patients reported, the coexisting extensive inguinal adenopathy in patients with resectable pelvic nodes, and the failure to specify sites of relapse in patients undergoing ilioinguinal lymphadenectomy (i.e., inguinal versus pelvic versus distant site). Although unproved, it is conceivable that patients with minimal inguinal disease who exhibit focal involvement of a pelvic node could benefit from pelvic dissection. The series reported from Lopes and coworkers (2000) provides support for this concept. Among 13 patients with pathologically proven lymph nodes, 5 of 13 (38%) were alive without disease with follow-up for more than 90 months in 4 of 5 survivors. This series is unique in that 4 of 5 survivors exhibited only a single iliac nodal metastasis and one inguinal lymph node metastasis; in fact, 1 patient with iliac metastases had no inguinal disease. This series is clearly the exception but reveals that selected patients with minimal inguinal and pelvic disease may be cured with surgery alone.

Thus in patients undergoing inguinal lymphadenectomy for curative intent (i.e., in whom preoperative studies reveal no pelvic adenopathy), pelvic lymphadenectomy should be considered in most patients with positive nodes because it can serve as an effective staging tool for identifying those patients who should receive adjuvant combination chemotherapy or radiation (Pizzocaro et al, 1997; Lont et al, 2007). It also adds to locoregional control and provides little additional morbidity to the simultaneous inguinal procedure being performed. Alternatively, if pelvic nodal metastases are proven before lymphadenectomy, consideration should be given to neoadjuvant chemotherapeutic strategies followed by surgery in those patients who respond (Pizzocaro et al, 1997; Corral et al, 1998; Bermejo et al, 2007).

Key Points: Treatment of the Inguinal Nodes

- The presence and extent of inguinal metastases determine survival in penile cancer.
- Patients with persistent palpable inguinal adenopathy should undergo an inguinal staging procedure.
- On the basis of the histologic features of the primary tumor, risk of lymph node metastases can be assessed in patients with no palpable adenopathy and lymphadenectomy or close follow-up can be recommended.
- Factors associated with cure in surgically treated patients include no more than two inguinal metastases, unilateral involvement, no extranodal extension of cancer, and absence of pelvic metastases.
- Morbidity of lymphadenectomy is decreasing in contemporary series.
- Superficial and modified inguinal dissections remain the standard dissection techniques to reliably determine the presence of microscopic inguinal metastases.
- Dynamic sentinel lymph node biopsy techniques to determine microscopic inguinal disease exhibit low morbidity, have been validated externally, and can be used in experienced centers.
- Laparoscopic lymphadenectomy is an investigational tool at this time.

Risk-Based Management of the Inguinal Region

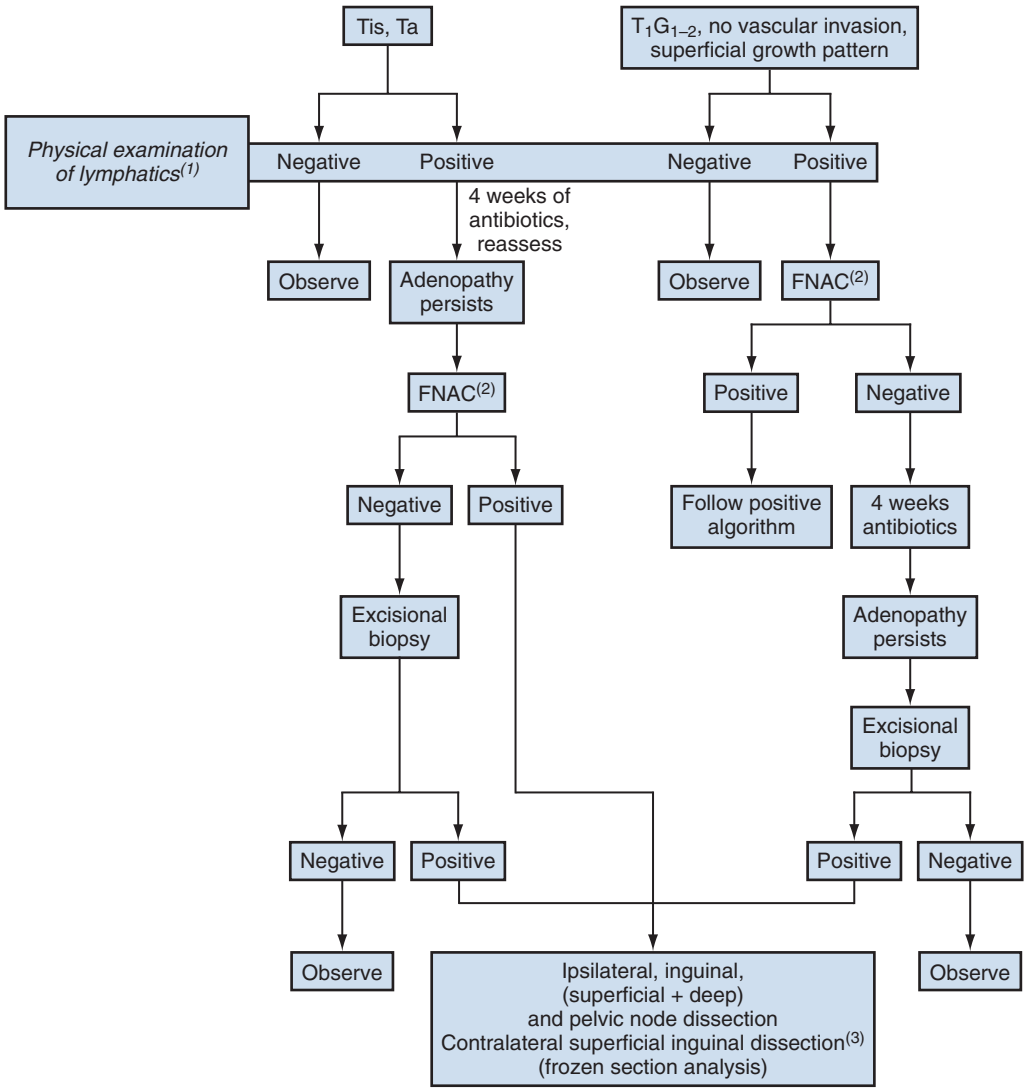
A contemporary schema for management of the inguinal region is presented in Figure 34–5. Assumptions for these guidelines are that the primary tumor has been adequately controlled, that the pathologic stage of the primary tumor is available, and that an inguinal examination has been performed. CT of the abdomen and pelvis as well as chest radiography or other imaging studies should also be performed as clinically indicated.

Very Low-Risk Patients

Because the incidence of inguinal metastasis is anecdotal at best for patients with stage Tis or Ta primary tumors, observation is reasonable for those patients with normal inguinal examination findings (see Fig. 34–5A, left). For patients with palpable adenopathy, a course of antibiotics should reveal those whose adenopathy is related to infection versus metastasis. A persistently palpable node should undergo fine-needle aspiration cytology; if the result is negative, an excisional biopsy is recommended. If the biopsy finding is abnormal, ipsilateral ilioinguinal dissection with contralateral superficial or modified complete dissection is performed.

Low- to Intermediate-Risk Patients

Several series have combined patients with stage T1 grade 1 and grade 2 tumors and have found them to exhibit less than a 10% incidence of inguinal metastasis (see Fig. 34–5A, right; see also



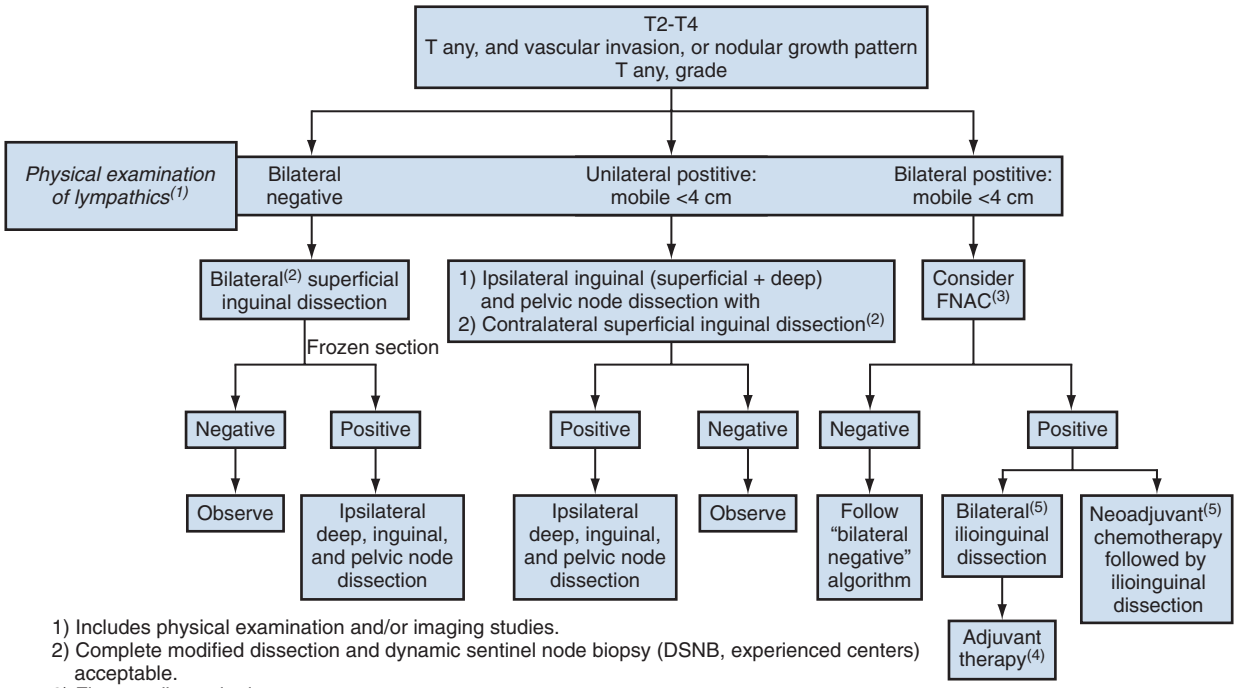


Figure 34–5. Management of regional disease. **A,** Low-risk patients. *Continued*

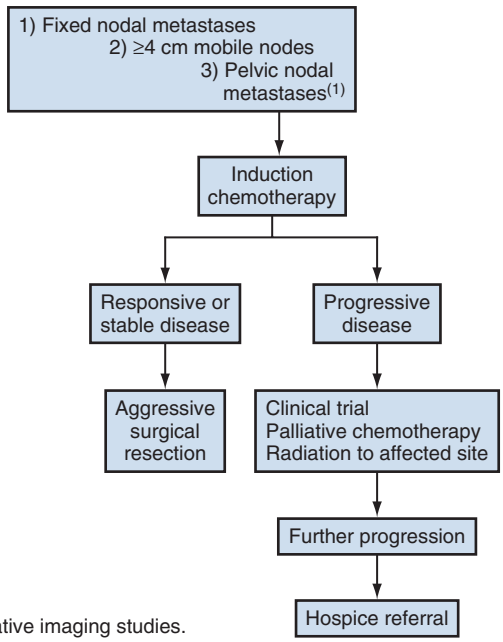
Table 34–8). However, the incidence of metastasis among strictly T1 grade 2 tumors (25% to 44%) may be higher and variable recommendations have been made. The recent EAU guidelines suggest that compliant patients with clinically negative lymph nodes that exhibit superficial growth and are vascular invasion negative can be observed (Solsona et al, 2004). However, similar patients with palpable nodes on initial presentation should undergo fine needle aspiration cytology. If the nodes are positive, the patients then undergo lymphadenectomy, as in Figure 34–5A. If they are negative, then a 4-week period of antibiotic therapy is reasonable. If adenopathy does not resolve, then either excisional biopsy and/or planned lymphadenectomy are reasonable options. Close follow-up is indicated for patients whose nodes resolve after antibiotic therapy, although the overall risk in this group remains low.



High-Risk Patients

For the high-risk cohort, the incidence of inguinal metastasis ranges from 50% to 70% (see Fig. 34–5B). According to the recent EAU guidelines, patients with T1 grade 2 tumors exhibiting a nodular growth pattern or vascular invasion are managed according to this stratification (Solsona et al, 2004). The surgical approach is designed to maximize detection and treatment for those with proven nodal metastasis while limiting the morbidity of those with negative lymph nodes at surgery. Thus surgical staging is indicated even in those patients with clinically normal inguinal examination findings. **In this setting, antibiotic use minimizes the risk of inguinal wound infections or septic complications after control of an infected primary tumor, rather than influencing the decision for surgical staging.**

Patients with normal inguinal examination findings are offered bilateral superficial dissection, complete modified dissection, or DSNB (with the last offered in experienced centers). If frozen-section results reveal no metastasis, the procedure is concluded. For DSNB the results are based on permanent sections; thus further therapy is planned at a second setting if needed. If either side is positive, an ipsilateral ilioinguinal dissection is performed.

1) Includes physical examination and/or imaging studies.
2) Complete modified dissection and dynamic sentinel node biopsy (DSNB, experienced centers) acceptable.
3) Fine needle aspiration.
4) Consider if >2 positive lymph nodes, or bilateral metastases, extranodal extension of cancer, or positive pelvic lymph nodes.
B 5) Either approach is acceptable.

C (1) Subsequent to preoperative imaging studies.

Figure 34–5, cont'd. **B,** High-risk patients. **C,** Metastatic disease. FNAC, fine-needle aspiration cytology.

Patients with unilateral resectable adenopathy that is strongly suggestive of metastasis should undergo an ipsilateral ilioinguinal dissection and a contralateral superficial or complete modified dissection. Frozen-section analysis then determines if deep inguinal or pelvic nodes should be excised. DSNB is another option in managing the contralateral node-negative side. Palpable adenopathy of less than 4 cm was arbitrarily selected as a cutoff point for surgery as monotherapy because nodal metastases larger than 4 cm are associated with extranodal extension of cancer (Ravi, 1993b).

For patients who present with bilateral palpable nodes that are strongly suggestive of metastasis, preoperative fine-needle aspiration cytology can be helpful for counseling of the patient as to the likelihood of the extent of surgery. For patients with negative results of fine-needle aspiration cytology, a staged surgical approach starting with superficial dissection is performed. Subsequent procedures in this setting depend on the results of frozen-section analysis. For patients requiring ilioinguinal lymphadenectomy because of metastases, adjuvant chemotherapy should be considered for those exhibiting more than two positive

lymph nodes, extranodal extension of cancer, or pelvic nodal metastasis.

Bulky Adenopathy and Fixed Nodal Metastasis

Survival in this cohort of patients is related to complete eradication of extensive disease (see Fig. 34–5C). **This task is difficult to achieve with surgery, chemotherapy, or radiation therapy alone. The combination of surgery and chemotherapy has shown some benefit in advanced penile carcinoma** (Pizzocaro et al, 1997; Corral et al, 1998; Bermejo et al, 2007; Leijte et al, 2007). The optimal integration and timing of such therapy are unknown. A reasonable approach in this cohort of patients is to use neoadjuvant chemotherapy followed by an aggressive surgical resection for patients demonstrating either response to therapy or stable disease. This potentially improves surgical resectability and avoids long delays in the administration of chemotherapy resulting from delays in postoperative healing. The prognosis is poor in patients exhibiting progression while they are receiving chemotherapy. Palliative groin dissection is a consideration but rarely provides significant palliation (Leijte et al, 2007). Hemipelvectomy in patients without distant metastases has been reported (Block et al, 1973). Endoluminal vascular stents have also been reported to have transient success in preventing vascular erosion by tumor (Link et al, 2004). Clinical trials of novel systemic strategies and radiation therapy to affected areas provide the next level of care. With further progression, supportive care provided by hospice services can provide valuable daily support to patients with end-stage disease.

RADIATION THERAPY

Radiation Therapy for the Primary Lesion

Primary radiation therapy has significant curative potential and may permit relative preservation of penile form and function. If local control is not achieved, salvage surgery may still be curative; thus in a subset of men with penile cancer radiation as an initial strategy represents a reasonable treatment strategy. Both external-beam radiation therapy and interstitial brachytherapy are currently utilized in treating the primary penile tumor. Before radiation therapy is performed circumcision is necessary to expose the lesion, to allow resolution of any surface infection, and to prevent maceration and preputial edema.

External-Beam Radiation Therapy

External-beam radiation therapy has several advantages: it is widely available, delivers a homogeneous dose, and does not require the same expertise with respect to technical skills required for delivery of effective brachytherapy. In their review Crook and colleagues (2009) described contemporary doses and fractions as ranging from 60 Gy in 25 fractions delivered over 5 weeks to 74 Gy in 37 fractions delivered over 7.5 weeks. This contrasts to lower doses of 50 to 55 Gy cited in older series (Neave et al, 1993; McLean et al, 1993). One of the challenges of external radiation therapy is immobilizing the penis to achieve consistent targeting of the tumor as treatment progresses. Both wax blocks along with a "see through" variant Perspex have been used for this purpose in addition to treating the patient in a prone position with the penis suspended in a small waterbath container (McLean et al, 1993; Zouhair et al, 2001; Vujovic et al, 2001).

Table 34–11 is adapted from the work of Crook and colleagues (2009) and describes the efficacy of both external-beam radiation therapy and interstitial brachytherapy with respect to local control, cause-specific survival, complications, and penile preservation. The data represent retrospective reviews of single institution series collected over many years.

Five-year local control rates among patients treated using a variety of techniques ranged from 44% to 69.7% with penile preservation rates of 50% to 65%. Thus the ability of primary external-beam radiation therapy to control the primary tumor was inferior to that of traditional surgical techniques. However, further local control in most cases was achieved by partial or total amputation. Cause-specific survival ranged from 58% to 86% depending on primary tumor stage and lymph node status.

Prognostic factors for response among patients treated with external-beam radiation therapy include dose less than 60 Gy, protracted treatment time greater than 45 days or daily fraction less than 2 Gy in addition to stage T3 disease, size greater than 4 cm, and high-grade tumors (Sarin et al, 1997; Gotsadze, et al 2000; Crook et al, 2009).

Brachytherapy

As an alternative to external-beam radiation therapy, interstitial brachytherapy with a variety of radioisotopes (radium-226, iridium-192, cesium-137) have been used. Gerbaulet and Lambin (1992), using percutaneously placed interstitial iridium-192 implants, reported successful local control in 82% of 109 patients, with long-term survivals of 75% to 80% in patients with tumor-free regional lymph nodes. Rozan and associates (1995) reviewed 259 patients from multiple centers, with 5- and 10-year disease-free survival rates of 78% and 67%, respectively. Twenty-two percent of patients also had surgery ranging from circumcision to total penectomy. Late side effects occurred in 53% of the group. Alternatively, iridium-192 wires are placed in a plastic mold worn in close apposition to the penile shaft for 12 hours or so daily for a period of 7 to 10 days for a total tumor dose of 60 Gy (El-Demiry et al, 1984; Akimoto et al, 1997).

Crook and associates (2002) initially reported a cohort (1989-2000) of 30 men with cT1-cT3 squamous cell carcinoma treated with iridium-192 delivered by 17- to 19.5-gauge steel needles held in a three-dimensional array by predrilled acrylic plastic templates. With a median of six needles, dosages of 55 to 65 Gy were delivered during an average of 93 hours. With a median 34 months of follow-up there were four local failures and four regional failures and one patient required partial penectomy for radionecrosis. The 2-year actuarial local failure-free rate was 85%, and successful penile conservation was 83%. Obviously, tumors could only be clinically staged and the authors stated that clinical distinction between cT1 and cT2 is subjective. Failure related to tumor grade but not tumor size. Kiltie and associates (2000), however, found local failures in 60% of tumors larger than 4 cm compared with 14% of tumors smaller than 4 cm. Mazeron and colleagues (1984) and Soria and coworkers (1997) both demonstrated more local failure as the tumor invaded the corpora and with tumor size larger than 4 cm. In the initial Crook series, prophylactic lymph node dissections were not routinely performed and, as one would expect, 50% of moderately or poorly differentiated tumors recurred regionally or distally. Therefore, selection of patients for prophylactic lymph node dissection should be the same as selection of patients having surgical removal of the primary tumor.

Table 34–11.

Selected Series of Studies Reporting Local Control (LC) of Disease, Cancer-Specific Survival (CSS), Complications, and Penile Preservation for Men Treated with External-Beam Radiation Therapy (XRT) or Brachytherapy (BT) as Primary Treatment for Penile Cancer

STUDY	NO. PATIENTS	TYPE OF RT	DOSE (Gy)	F/U (mo) median (range)	LC BY RT AT 5 YEARS	CSS AT 5 YEARS	COMPLICATIONS	PENILE PRESERVATION

Soria et al, 1997	102	BT	61-70	111	77%	72%		72% (6 years)
Chaudhary et al, 1999	23	BT	50	21 (4-117)	70% (8 years)		0 necrosis 9% stenosis	70% (8 years)
Kiltie et al, 2000	31	BT	63.5	61.5	81%	85%	8 necrosis 44% stenosis	75%
Crook et al, 2009	67	BT	60	48 (4-194)	87.5%	83.6%	12% necrosis 9% stenosis	88% 5 years 67% 10 years

The Crook series was updated in 2009 to 67 patients with a median follow-up of 4 years (range 0.2 to 16.2). At 10 years the actuarial cause-specific survival was 83.6% and three late failures were observed (42, 64, 90 months). Penectomy was performed for 8 recurrences and 2 necroses for 5- and 10-year penile preservation rates of 88% and 67%, respectively. Inguinal lymph nodes in the most recent patients were managed with the same indications as for patients undergoing primary surgery but using only biopsy information. The dominant predictor of local failure was needle spacing—an increase in spacing decreased recurrences due to the wider lateral margin achieved. **Overall local control** (see Table 34–11) **provided by interstitial brachytherapy appeared superior to that provided by external-beam radiation therapy with 5-year local control rates from 70% to 87%. Penile preservation rates are highest at 5 years (74% to 88%) with some decrease at 8 to 10 years (67% to 70%)** (Crook et al, 2009).

Adverse Effects Associated with Radiation Therapy

There are significant disadvantages to radiation therapy. Squamous cell carcinoma is characteristically radioresistant, and the dosage required to sterilize the tumor (i.e., 60 Gy) may cause urethral fistula, stricture, or stenosis, with or without penile necrosis, pain, and edema (Kelley et al, 1974). **In some instances secondary penectomy may be required** (Duncan and Jackson, 1972). Penile necrosis was seen in 0% to 23% of patients treated with external-beam or interstitial radiation therapy but appeared more common with brachytherapy (see Table 34–11). In the case of necrosis a diagnostic dilemma exists in determining whether recurrent cancer is present and biopsy may be indicated. Close follow-up and treatment with antibiotics, vitamin E, corticosteroid creams, and hyperbaric oxygen have been recommended (Crook et al, 2009). Urethral stenosis was noted in 10% to 45% of patients and may be related to increased dose per fraction in those treated with external-beam radiation therapy or needle spacing among those treated with brachytherapy. Urethral strictures often occur late and based upon severity may be managed with repeated dilation or in some cases urethroplasty.

The benefits of avoiding a mutilating surgical procedure are obvious, and although sexual function is generally reported to be preserved the side effects of radiation on sexual quality of life have not been studied with validated instruments (Crook et al, 2009). In addition, patients and physicians must carefully consider the unique acute and long-term side effects of radiation therapy. Radiation therapy is usually administered for a period of 3 to 6 weeks and is followed by several months of morbidity. This may pose a formidable burden in elderly patients. By contrast, partial penectomy offers a prompt and effective treatment, with relatively few side effects limiting activity in the postoperative period.

The organ-sparing benefits of radiation must be compared with surgical choices such as laser therapy, Mohs micrographic surgery, and reconstructive surgery, all of which can provide a surgical treatment while minimizing functional loss and potentially avoiding the long-term risks of recurrence, necrosis, and urethral stenosis that may occur after radiation therapy. Age and comorbidities may also direct treatment, with surgery as a possible solution for

the elderly patient in whom preservation of the penis is secondary, whereas radiation may be the only solution for a patient with significant comorbidities.

Finally, it must be accepted that should radiation therapy fail, prompt penectomy must be done to avoid jeopardizing survival. Careful long-term follow-up is essential to detect recurrence promptly, and it must be recognized that recurrence may develop relatively late. In one series, 7 of 11 recurrences were detected after 2 years (63%) and 2 (18%) after 5 years (Mazeron et al, 1984). In terms of salvage surgery, Crook and colleagues (2009) note that external-beam radiation therapy generally treats the entire penile shaft whereas brachytherapy tends to be best for focal disease. Therefore salvage options after brachytherapy may more likely result in a partial penectomy versus total penectomy.

Close follow-up may be difficult in a group of patients whose reliability is often poor and who have often neglected a markedly symptomatic primary lesion for an extended time before seeking treatment. Furthermore, distinguishing postirradiation ulcer, scar, and fibrosis from possible recurrent carcinoma is often impossible, and repeated biopsies of the lesions may be required.

In summary, small superficial tumors will respond well to radiation therapy and, with careful planning, complications can be minimized. Brachytherapy for tumors smaller than 4 cm may offer acceptable local control rates with faster dose delivery. The treatment of larger, invasive malignant neoplasms is less successful, may be associated with severe local complications, and theoretically may provide an interval during which metastatic dissemination may occur. For the patient who is an appropriate candidate for a radiation-based approach, the selection of external beam versus brachytherapy may depend on the skill and experience of the radiation therapist involved, with the former more widely available. Crook and colleagues' series and review (2009) would suggest that the brachytherapy technique should be expanded and studied further in a multi-institutional fashion.

Radiation Therapy for the Inguinal Areas

Assessment of the treatment of the inguinal area by primary radiation therapy is hampered by the uncertainty arising from the inaccuracy of clinical staging and the frequent lack of histologic confirmation of nodal metastases. Other objections to the treatment of inguinal node metastases are that the inguinal areas tolerate radiation poorly and are subject to skin maceration and ulceration.

Both the therapeutic and adjunctive use of radiation in the treatment of the regional nodes has fallen out of favor with little contemporary data available for review. Even if metastases were documented by node biopsy, the efficacy of subsequent radiation is impossible to judge because all tumors may have been removed by the biopsy. In one series, 70% of nodal metastases involved a single node, and survival in this group was 70% (Cabanas, 1977). Radiation therapy for inguinal metastases documented by histologic examination has been compared with surgery for the node-positive groin. A 50% 5-year survival rate was observed among the surgically treated group, and a 25% 5-year survival rate was observed among the irradiated group (Staubitz et al, 1955). Other series report that radiation to the inguinal areas has not proved therapeutically effective (Murrell and Williams, 1965; Jensen, 1977; Kulkarni et al, 1994).

Prophylactic radiation therapy to the inguinal lymph nodes in penile cancer has to date not shown benefit. In a series of 130 patients initially having clinically impalpable nodes but treated with adjuvant radiation therapy, 18 subsequently developed palpable nodal disease requiring lymphadenectomy and another 11 patients had metastases but no surgery. Therefore 29 of 130 men (22%) who received prophylactic groin irradiation subsequently developed inguinal metastases (Ekstrom and Edsmyr, 1958).

Murrell and Williams (1965) found that 3 of 11 patients (25%) who received radiation therapy to the inguinal area without initially palpable nodes subsequently developed inguinal metastases. These percentages closely approximate the incidence of subclinical metastases that are encountered if node dissection is performed when the clinical examination is normal (see Table 34–3), and they suggest that radiation therapy did not alter the course of the disease. Furthermore, because of tissue changes that follow radiation to the groin, clinical evaluation of the groin is difficult and the complications encountered with groin dissection after irradiation can be significant.

One of the largest series demonstrating a benefit of radiation therapy for lymph node metastases and/or distant metastases from penile cancer was published by Ravi and associates in 1994. One hundred and twenty patients with lymph node metastases and 9 with distant metastases were managed by radiation therapy alone (palliative) or in the preoperative or postoperative setting. Pertinent to the advanced disease presentation setting, 33 patients were treated with preoperative radiation therapy at 40 GY over 4 weeks and subsequently had inguinal lymphadenectomy. Of note, after radiation therapy and surgery only 8% had evidence of extranodal extension and 3% experienced recurrence of the disease within the groin. This is relevant because in a prior report within a contemporary time frame (Ravi, 1993b) the incidence of extranodal extension was 33% among patients treated with surgery alone and groin recurrence was noted in 19%. The difference for both extranodal extension and local recurrence were both statistically lower ($P = < .01$ and .03, respectively). The data are suggestive but not definitive that preoperative radiation therapy for nodes 4 cm or larger without skin fixation improved local control. The 5-year survival among the latter group was 70% (Ravi et al, 1994). These data are consistent with the beneficial effects seen when radiation therapy is used together with surgery or chemotherapy in management of other squamous malignancies such vulvar, cervical, or anal carcinomas (UKCCCR Anal Cancer Trial Working Party, 1996; Montana et al, 2000; Green et al, 2001). Such approaches should be further explored in the treatment of locally advanced penile cancer.

In the series by Ravi and colleagues (1994), palliative radiation therapy ameliorated symptoms in 56% of patients with fixed groin nodes, in 5 of 5 patients with painful bony metastases, and in 1 of 2 patients with spinal cord compression and paraplegia. However, pelvic and/or para-aortic radiation therapy was ineffective in patients with pelvic node metastases. Thus radiation therapy may be considered in patients presenting with inoperable fixed and ulcerative inguinal lymph nodes who are not candidates for chemotherapy. On occasion, radiation to these areas is well tolerated, may result in significant palliation, and may postpone local complications for prolonged periods (Furlong and Uhle, 1953; Staubitz et al, 1955; Vaeth et al, 1970).

An alternative use of radiation would be as adjuvant therapy for surgically treated, pN patients. In a small retrospective study from Taiwan, Chen and colleagues (2004) reported regional failure rates after positive inguinal lymph node dissections in 11% (1 of

9) versus 60% (3 of 5) with and without adjuvant inguinal radiation therapy.

In summary, radiation therapy to the inguinal area is not as effective therapeutically as lymph node dissection, but it may be useful for palliation in the situation of inoperable nodes. Based on studies in other squamous malignancies, radiation as a part of a multimodal approach with chemotherapy and surgery among patients with advanced penile cancer should be further evaluated.

Key Points: Radiation Therapy

- Primary radiation therapy for the penis may be successfully applied to select patients with T1 and T2 squamous cell carcinomas smaller than 4 cm with either external-beam or brachytherapy techniques.
- Salvage penectomy may be required after external-beam radiation therapy or brachytherapy for persistent or recurrent disease or radiation necrosis. Lifelong careful follow-up is required.
- For patients selected for radiation therapy for the primary tumor, surgical management of inguinal lymph nodes should be recommended by the same criteria as for patients selected for surgical management of the primary tumor.
- Radiation to the inguinal area is not as effective as surgery for treatment of the inguinal nodes.
- Prophylactic radiation therapy has not been shown to alter the natural history of inguinal metastases and is not recommended.
- Integration of radiation therapy with surgery and chemotherapy in advanced disease requires further study.
- Palliative radiation therapy among patients with inoperable inguinal nodes may provide some benefit.

CHEMOTHERAPY

Advanced penile cancer presenting as either bulky or unresectable regional disease or visceral metastases at initial presentation or disease recurrence is highly lethal because it is incurable in most cases with either surgery or radiation therapy alone (Ornellas et al, 1994; Ravi et al, 1994; Hegarty et al, 2006). Experience with single- or multiple-agent chemotherapy in this setting is limited because there are few phase 2 clinical trials and no randomized clinical trials. Several regimens have produced clinically meaningful responses that have occasionally resulted in clearance of disease or facilitated surgical resection.

Single-Agent Chemotherapy

Gagliano and associates (1989) from the Southwest Oncology Group treated 26 patients, 12 of whom had prior radiation, with low-dose (50 mg/m^2) cisplatin and observed a 15% response rate of 1 to 3 months' duration and a median overall survival of 4.7 months. In a study from Memorial Sloan-Kettering Cancer Center, 13 patients with extensive disease and either prior radiation therapy or chemotherapy were treated with cisplatin 70 to 120 mg/m^2 every 21 days. Three of 12 evaluable patients (25%) demonstrated responses (one complete and two partial; duration = 2 to 8 months; Ahmed et al, 1984).

Initial favorable reports from Japan suggested that bleomycin appeared to be effective in the treatment of penile and scrotal cancer. Ichikawa and associates (1969, 1977) reported a 50% response in 24 previously untreated patients with squamous cell carcinoma of the penis. A similar report from Uganda documented partial or complete tumor regression in 45% of treated patients (Kyalwazi et al, 1974). A review of 90 patients from the world literature demonstrated similar responses (Eisenberger, 1992). In the study by Ahmed and colleagues (1984) 14 patients were evaluable for response to single-agent bleomycin. There was one complete response but the patient died of bleomycin pulmonary toxicity. There were also two partial responses for an objective response rate of 21%. The median response duration was only 3 months (range 2 to 4 months).

Methotrexate produced responses in 8 of 13 patients (61%) treated at Memorial Sloan-Kettering Cancer Center (Ahmed et al, 1984), with one complete response. However, median response duration even with the high response rate was 3 months (2 to 31 months) and 1 patient died of treatment-related sepsis. Methotrexate had been shown to be active in other reports (Mills, 1972; Garnick et al, 1979). Based on the Ahmed and colleagues' study in which cisplatin (P), bleomycin (B), and methotrexate (M) were given sequentially there did not appear to be any obvious cross-resistance to the three agents. Subsequently a three-drug trial using PMB was developed.

Combination Chemotherapy

The Southwest Oncology Group reported a phase 2 study using a modified regimen that reduced the total dose of PMB. Haas and associates (1999) employed combination cisplatin, methotrexate, and bleomycin in 45 patients with locally advanced or metastatic penile cancer accrued from 31 different institutions. There were five complete and eight partial responses among 40 evaluable patients (32.5% response rate). The median duration of response was 16 weeks, with an overall survival of 28 weeks (Haas et al, 1999). Although the response rate appeared encouraging it was still within the 95% confidence intervals for single-agent cisplatin and there were five treatment-related deaths on the study (one from infection and four from pulmonary complications) (Ahmed et al, 1984; Gagliano et al, 1989; Haas et al, 1999). Thus this study failed to confirm the initial high response rate of single-agent methotrexate, which was not significantly higher than that of single-agent cisplatin; and bleomycin pulmonary toxicity was significant (Haas et al, 1999).

Two additional more contemporary trials both containing cisplatin reveal significant activity while omitting the significant toxicity associated with bleomycin and methotrexate. Theodore and coworkers (2008) reported the results of a European Organization for Research in Cancer Therapy phase 2 study in which 28 patients with stage T3/T4, N1-3, or M1 disease received combination cisplatin and irinotecan. Patients were treated in either the neoadjuvant setting for four cycles before surgery (T3N1-2) or up to eight cycles (T4N3M1 disease). Toxicity was acceptable with no treatment-related deaths. Eight responses were noted (two complete, six partial), for an objective response rate of 30.8% (80% confidence interval = 18.8% to 45%). Of note, 3 patients who underwent surgery in the neoadjuvant setting were found to have no evidence of residual disease. The authors reported the trial as negative however because it was powered to show a response rate greater than 30%.

A phase 2 clinical trial of neoadjuvant paclitaxel, ifosfamide, and cisplatin chemotherapy (TIP) is in progress at the University

Table 34–12.

Safety and Efficacy of Multidrug Penile Cancer Regimens without Bleomycin

	CHEMOTHERAPEUTIC REGIMEN	RESPONSE RATE	TREATMENT-RELATED DEATH	MEDIAN OVERALL SURVIVAL
Shammas et al, 1992	Fluorouracil, 1000 mg/m^2/day, days 1-5 (continuous infusion) Cisplatin, 100 mg/m^2, day 1; cycle every 3-4 weeks	25%	0/8	11.5
Pagliaro and Crook, 2009	Paclitaxel, 175 mg/m^2, day 1 Ifosfamide, 1200 mg/m^2, days 1-3 Cisplatin, 25 mg/m^2, days 1-3; cycle every 3 weeks	55%	0/20	11
Theodore et al, 2008	Irinotecan, 60 mg/m^2, days 1, 8, 15 Cisplatin, 80 mg/m^2, day 1; cycle every 4 weeks	30.8%	0/28	4.7

of Texas M. D. Anderson Cancer Center. Preliminary experience was recently published (Pagliaro and Crook, 2009). Eligible patients exhibited stage TxN2-N3 lymph node metastases, no evidence of distant metastases (M0), and no prior chemotherapy. Treatment consisted of four courses of chemotherapy followed by bilateral inguinal lymph node dissections, unilateral or bilateral pelvic lymph node dissections, and surgical control of the primary tumor when appropriate. Preliminary analysis of data from the first 20 patients revealed an objective response rate of 55% and pathologic complete responses in 10% (2 patients). Sixteen patients had residual disease at surgery, and 2 did not undergo surgery. Four patients (20%) were alive and free of disease at 23, 24, 31, and 32 months. Fifteen deaths occurred as a result of progressive disease, and one occurred from unknown causes. Toxicity was acceptable, and no treatment-related deaths occurred (Pagliaro and Crook, 2009). Thus the preliminary data using the TIP regimen suggest a response rate that may be significantly higher than that with single-agent cisplatin that is better tolerated than prior bleomycin- or methotrexate-containing regimens. However, patients treated thus far with the TIP regimen have in general had lower-stage disease and the final trial results have yet to be reported. Table 34–12 provides safety and efficacy data of cisplatin-containing chemotherapy regimens reported thus far. Treatment-related pulmonary toxicity and death were avoided with the absence of bleomycin.

Data from the just discussed two contemporary trials suggest that selected patients with advanced, unresectable primary tumors or bulky regional lymph node metastases appeared to benefit from postchemotherapy lymphadenectomy. Negative pathology in lymph nodes was seen after neoadjuvant treatment with TIP (2/20 patients) and irinotecan/cisplatin (3/7 patients). For patients with unresectable primary tumors or bulky regional lymph node metastases, neoadjuvant treatment with a cisplatin-containing regimen may be effective and may allow curative resection. The optimal chemotherapy regimen has yet to be determined.

Adjuvant Chemotherapy

Historically, combination vincristine, bleomycin, and methotrexate therapy was administered in 12 weekly courses to 17 patients in the postoperative setting (12 patients) or neoadjuvant setting (5 patients) at the Milan National Tumor Institute. The patients treated were at high risk for recurrence with surgery alone; 9 showed extranodal tumor growth, 5 had pelvic nodal involvement, and 5 had bilateral metastases. At follow-up ranging between 18 and 102 months, only one relapse had occurred (Pizzocaro and Piva, 1988). Later reports from this center further confirmed the value of adjuvant chemotherapy. Of 56 node-positive patients, 82% of the 25 patients receiving adjuvant vincristine, bleomycin, and methotrexate therapy survived 5 years, compared with 37% of 31 patients treated with surgery alone (Pizzocaro et al, 1995, 1997). In the neoadjuvant treatment group, partial responses were noted in 3 of 5 patients with extremely large (6 to 11 cm) nodal metastases. These 3 patients subsequently were underwent complete resection and were free of tumor at intervals ranging from 20 to 72 months. These data have yet to be confirmed and will probably not be further studied given the potential toxicities of bleomycin and methotrexate.

Postchemotherapy Surgical Consolidation

Shammas and coworkers (1992) reported on 8 patients treated with the combination of cisplatin and 5-fluorouracil. Seven of the patients had Jackson stage III or IV disease, and 2 in this group had either pleural or lung metastases. One of the 7 with stage III or IV disease (14%) had a partial response with disappearance of lung metastases and postsurgical consolidation and lived 32+ months; he received five cycles of therapy. Three patients with stable disease received only one to two cycles and survived 2+ to 11 months. Of note, 2 of 3 patients who ultimately had disease progression received three to four cycles of therapy and underwent surgical consolidation with survivals of 12 and 28 months after chemotherapy. Thus, 2 of 7 patients (28%) who survived 28 and 32+ months received significant palliation or cure from the combination.

Corral and colleagues (1998) reported on the long-term follow-up of a prospective group of patients treated with bleomycin, methotrexate, and cisplatin. Among the cohort, 21 patients had penile carcinoma with 10 of the 21 (48%) having either N3 or M1 disease. The remainder had either N1 or N2 nodal metastases. Objective responses were noted in 12 (57%), including 2 of 5 patients with distant metastases. Six patients in the group (28.5%) achieved disease-free status with either chemotherapy alone (2 patients) or surgery (3 patients) or radiation therapy (1 patient) with a median survival of 27.8 months. This was significantly longer than that of those not achieving disease-free status (6.7 months, $P = .004$). Thus, this prospective study showed that a multidisciplinary approach to achieve disease-free status could prolong survival. Subsequently Leijte and associates (2007) from the Netherlands Cancer Institute reviewed their experience with neoadjuvant chemotherapy in patients with initially "unresectable" penile cancer. The series included 20 patients treated with five different regimens, including (1) single-agent bleomycin; (2) bleomycin, vincristine, and methotrexate; (3) cisplatin and

5-fluorouracil; (4) bleomycin, cisplatin, and methotrexate; and (5) cisplatin and irinotecan. The objective responses were evaluable in 19 (1 patient died of bleomycin toxicity after 2 weeks) with 12 responses (63%, 2 complete, 10 partial). Surgical procedures included treatment of the primary tumor as well as inguinal and pelvic dissections. Additional soft tissue resection including bone was sometimes required. Vascularized tissue flaps were used for inguinal reconstruction. Among 12 responders only 9 went to surgery, because 2 died of bleomycin-related complications while the third was deemed unfit for surgery. Eight of 9 responding patients taken to surgery (2 were pT0) were free of disease with a median follow-up of 20.4 months. This is in contrast to 3 nonresponders who went to surgery for palliative intent: all 3 died within 4 to 8 months due to locoregional recurrence. The implications from this study indicate that response to chemotherapy together with an aggressive surgical procedure provides the optimal scenario for significant palliation or potential cure.

In a separate study Bermejo and colleagues (2007) described the surgical considerations and complications among 10 patients who had either a response or stable disease after combination chemotherapy. The regimens utilized included (1) cisplatin, methotrexate, and bleomycin (PMB); (2) paclitaxel, ifosfamide, and cisplatin (TIP); or (3) paclitaxel and carboplatin. This cohort of patients exhibited bulky inguinal or pelvic metastases, with the only exclusions being patients with fixed pelvic masses or complete encasement of the femoral vessels. In addition to ilioinguinal lymphadenectomy, resection of the inguinal ligament, the inferior aspect of the rectus abdominis or external and internal oblique muscles, the spermatic cord and ipsilateral testis, and segments of the femoral artery and vein (with subsequent patch or bypass grafting) were performed to achieve negative margins. Plastic surgery consultation was obtained for wound coverage, including the insertion of monofilament polypropylene mesh for abdominal wall defects and myocutaneous flaps of the sartorius, rectus abdominis, serratus anterior, and latissimus dorsi muscles. Of 5 patients exhibiting an objective response 3 were alive and free of disease at 48, 50, and 73 months. Two other patients died (1 of disease at 30 months, another of unknown causes at 21 months). Among the 5 remaining patients with stable disease 3 were dead of disease within 7 months and 1 patient treated with bleomycin died of "failure to thrive" at 8 months. However, another patient treated with paclitaxel and carboplatin achieving only stable disease was alive and free of disease at 84 months. These data appear to reinforce the concept that response to systemic chemotherapy before surgery enhances the chance for long-term survival among those undergoing surgical resection. Related to systemic therapy the authors reported that the TIP regimen was well tolerated and all three pT0 responses at surgery were among patients treated with TIP. This provided the rationale for the prospective phase 2 study discussed previously (Pagliaro and Crook, 2009).

Providing additional rationale to consider a taxine-based regimen in patients with advanced penile cancer as part of a multimodal strategy, Pizzocaro and associates (2009) reported on 6 patients (5 of 6 with N3 metastatic nodes) who were treated with paclitaxel (1 patient received docetaxel), cisplatin, and 5-fluorouracil. Post surgery, 3 patients exhibited a pathologic complete response. Two of the 3 received five to seven cycles of therapy and showed no evidence of disease at 25 to 27 months. The third patient tolerated only two cycles of therapy; and although he was pT0 at surgery he experienced relapse at 11 months and died. Another patient with a pathologic partial response (>90% necrosis in specimen) also received only two cycles of therapy but was without evidence of disease at 46 months. A patient with a clinical complete response refused surgical consolidation and experienced relapse and died at 6 months, as did the only remaining patient with no response to therapy (4 months survival). Taken together these data provide evidence that response to chemotherapy improves resectability and survival. Surgery among patients who do not respond to therapy may occasionally be associated with long-term survival but is more often associated with death due to either rapidly occurring locoregional recurrence or distant metastases (Bermejo et al, 2007; Leijte et al, 2007).

Key Points: Chemotherapy

- Treatment with a cisplatin-containing regimen in advanced metastatic penile cancer should be considered, because responses do occur and this may facilitate curative resection. The optimal chemotherapy regimen has yet to be determined.
- The use of bleomycin in the treatment of men with penile cancer was associated with an unacceptable level of toxicity and is discouraged as first-line therapy.
- Surgical consolidation to achieve disease-free status or palliation should be considered in fit patients with a proven objective response to systemic chemotherapy among patients who progress through chemotherapy is not recommended.

NONSQUAMOUS PENILE MALIGNANT NEOPLASMS

Nonsquamous penile malignant neoplasms are extremely rare. Pathologic descriptions and local/regional treatment options are available; however, outcomes and comparisons are limited to case reports and small retrospective series. Most reports establish the following features: (1) incidence of disease, (2) distinguishing pathologic features, (3) treatment recommendations, and (4) parallels (or lack thereof) to the same carcinoma in nongenital locations.

Basal Cell Carcinoma

Although basal cell carcinoma is frequently encountered on other sun-exposed cutaneous surfaces it is rare on the penis (Fig. 34–6A). Fewer than 30 cases have been well documented (Goldminz et al, 1989; Ladocsi et al, 1998; Nguyen, 2006). The lesion can be seen anywhere on the penis but is commonly on the penile shaft. It is slow growing, and delay in diagnosis in one series ranged from 2 months to 50 years (Kim et al, 1994). **Treatment is by local excision, which is virtually always curative** (Hall et al, 1968; Goldminz et al, 1989). Only one case report describes what the authors believe to be the only reported case of metastatic penile basal cell carcinoma (Jones, 2000). Nguyen and colleagues (2006) reported two cases of basal cell carcinoma treated by Mohs surgery.

A benign variant of basal cell carcinoma, the premalignant fibroepithelioma of Pinkus, has been reported to occur on the penile shaft (Heymann et al, 1983). Diagnosis is made at excisional biopsy. Excision has been uniformly curative.

Melanoma and basal cell carcinoma rarely occur on the penis, presumably because the organ's skin is protected from exposure

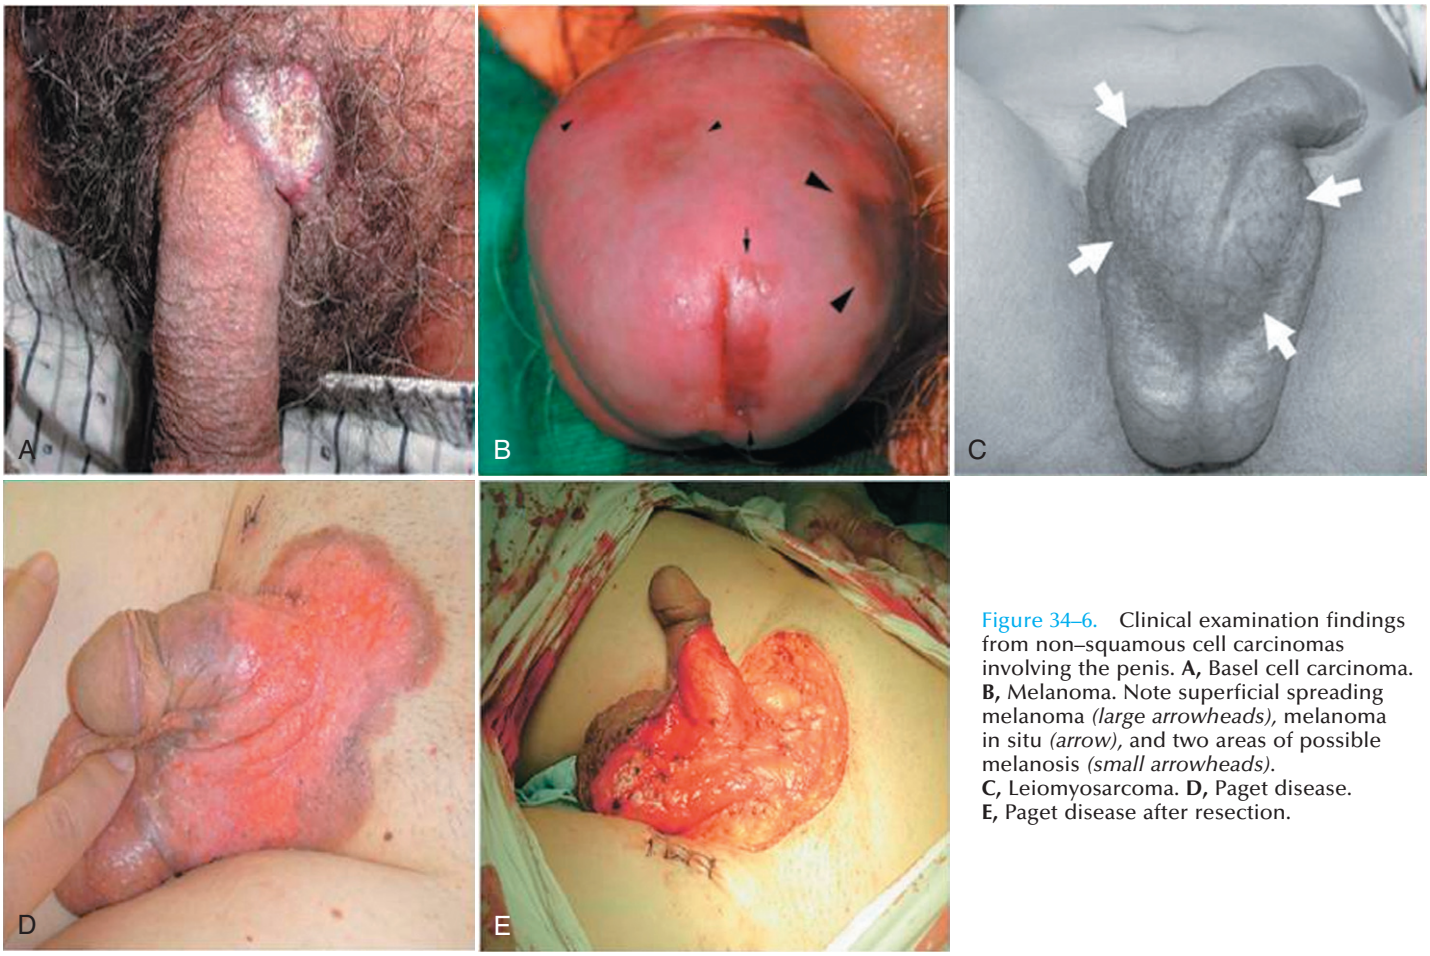

Figure 34–6. Clinical examination findings from non–squamous cell carcinomas involving the penis. **A,** Basel cell carcinoma. **B,** Melanoma. Note superficial spreading melanoma *(large arrowheads),* melanoma in situ *(arrow),* and two areas of possible melanosis *(small arrowheads).* **C,** Leiomyosarcoma. **D,** Paget disease. **E,** Paget disease after resection.

to the sun. Malignant neoplasms arising from the supporting structures of the penis are also rare and include any combination of tumors of smooth or striated muscle or of fibrous, fatty, or vascular tissue. Information about appropriate treatment of these malignant neoplasms is derived from the review of single case reports and small series (Belville and Cohen, 1992).

Melanoma

More than 150 cases of melanoma of the penis have been reported (see Fig. 34–6B). Of 1200 melanomas treated at Memorial Sloan-Kettering Cancer Center, only 2 were of penile origin (Das Gupta and Grabstald, 1965). At the University of Texas M. D. Anderson Cancer Center, less than 1% of all primary penile cancers were malignant melanomas (Johnson and Ayala, 1973; de Bree et al, 1997).

Melanoma presents as a blue-black or reddish brown pigmented papule, plaque, or ulceration on the glans penis. It occurs on the prepuce less frequently. Diagnosis is made by histologic examination of biopsy specimens, which demonstrate atypical junctional cell activity with displacement of pigmented cells into the dermis.

Prognostic characteristics that have been found significant for melanoma in other sites, such as depth of invasion (Clark staging) and thickness of the tumor (Breslow classification), have not been prospectively applied to penile lesions because experience with these lesions is limited. Sanchez-Ortiz and colleagues (2005) used the American Joint Committee on Cancer system for classifying cutaneous melanomas (Fleming et al, 1997) in the largest report to date on melanoma of the penis. This system incorporates elements of the Clark and Breslow staging systems. When this information is favorable, local excision is feasible. Distant metastatic spread has been found in 60% of patients studied (Abeshouse, 1958; Johnson et al, 1973; de Bree et al, 1997) in older series. However, Sanchez-Ortiz found that patients with early-stage melanomas had excellent outcomes if primary tumors were of low stage and regional lymph nodes were negative. Hematogenous metastases occur by means of the vascular structures of the corporeal bodies; lymphatic spread to the regional inguinal and pelvic nodes occurs by lymphatic permeation.

Surgery is the primary mode of treatment; radiation therapy and chemotherapy are of only adjunctive or palliative benefit. For stage I melanoma (localized lesion without metastases) and stage II melanoma (metastases confined to one regional area), adequate excision of the primary tumor by partial or total penile amputation together with en bloc bilateral ilioinguinal node dissection has historically been advocated (Johnson et al, 1973; Bracken and Diokno, 1974; Manivel and Fraley, 1988). In reviewing the University of Texas M. D. Anderson Cancer Center experience plus the literature to date, Sanchez-Ortiz and colleagues (2005) proposed a treatment algorithm for management of the primary tumor and inguinal lymph nodes. For tumors of the foreskin, circumcision may be adequate. For glans tumors, a partial penectomy was recommended; and for glans-shaft

tumors, a partial or total penectomy can be performed. The authors recommend bilateral modified inguinal lymph node dissections in all patients with lesions that are Breslow depth 1 mm or greater, with ulceration, or with Clark level IV or V involvement. Although sentinel lymph node biopsy techniques are increasingly utilized in more common sites of melanoma, its use in penile melanoma is unproven, and a learning curve of over 25 cases with this rare malignancy may be a barrier (Sanchez-Ortiz et al, 2006).

The prognosis for patients with penile melanoma is clearly dependent on stage of the primary tumor and the presence or absence of inguinal metastases. Contemporary staging and prognostic factors are reviewed by Sanchez-Ortiz and coworkers (2005). A report from the Netherlands (van Geel et al, 2007) focused on the concept of mucosal site penile melanomas—glans, meatus, fossa navicularis, and distal urethral. These lesions may appear more aggressive than cutaneous lesions, but greater delay in diagnosis may be a factor. In a pooled, retrospective analysis of 66 cases, the recurrence outcomes were similar for cutaneous melanomas of comparable tumor thickness.

Sarcomas

Primary mesenchymal tumors of the penis are rare. A thorough review of 46 such tumors from the Armed Forces Institute of Pathology revealed an equal number of benign and malignant lesions (Dehner and Smith, 1970). The patients ranged in age from newborn to the eighth decade of life. The presenting signs and symptoms of subcutaneous mass, penile pain and enlargement, priapism, and urinary obstruction were the same for both benign and malignant lesions. A sarcoma has been reported to masquerade as a Peyronie plaque (Moore et al, 1975).

Malignant lesions were found more frequently on the proximal shaft (see Fig. 34–6C); **benign lesions were more often located distally. The most common malignant lesions were those of vascular origin (hemangioepithelioma), followed in frequency by those of neural, myogenic, and fibrous origin** (Ashley and Edwards, 1957). Single case reports of sarcomatous lesions have been published, for example, malignant fibrous histiocytoma (Parsons and Fox, 1988), angiosarcoma (Rasbridge and Parry, 1989), leiomyosarcoma (Planz et al, 1998), epithelioid sarcoma (Leviav et al, 1988), hemangioendothelioma (Kamat et al, 2004), and osteosarcoma (Sacker et al, 1994).

Sarcomas have been classified as superficial when they arise from the integumentary supporting structures and as deep when they develop from the corporeal body supporting structures (Pratt and Ross, 1969). Wide, local surface excision and partial penile amputation for the superficial tumors have been suggested and used successfully in isolated case reports (Pak et al, 1986; Dalkin and Zaontz, 1989). Total penile amputation has been reserved for tumors of deep corporeal origin. **However, local recurrences are characteristic of sarcomas** (Dehner and Smith, 1970). Fetsch and colleagues (2004), from the Armed Forces Institute of Pathology, have updated their series of 14 cases of leiomyosarcoma with review of the literature. They concluded that small, less than 2-cm lesions were best managed with local resection whereas deeper-seated tumor often requires partial or total amputation. Deep lesions at the base of the penis have the worst prognosis.

Regional metastases are rare. Unless adenopathy is palpable, node dissections are not recommended (Hutcheson et al, 1969). Distant metastases have also been unusual (Dehner and Smith, 1970). This supports aggressive local treatment in anticipation of cure. Radiation therapy and chemotherapy have not been used extensively enough for comment on their efficacy (Fetsch, 2004)

Kaposi sarcoma, which is usually a cutaneous manifestation of a generalized lymphoreticular disorder, may produce genital lesions but is now most frequently associated with human immunodeficiency virus infection.

Extramammary Paget Disease

Extramammary Paget disease of the penis is rare with fewer than 30 cases reported (Mitsudo et al, 1981; Macedo et al, 1997) up to the late 1990s. However, more recently several larger series have been reported from China and Korea (Yang, 2005; Wang, 2008). It appears grossly as an erythematous, eczematoid, well-demarcated area that cannot be clinically distinguished from erythroplasia of Queyrat, Bowen disease, or carcinoma in situ of the penis. Clinical presentation includes local discomfort, pruritus, and occasionally a serosanguineous discharge involving the penis, scrotum or even the perianal area (see Fig. 34–6D and E). On microscopic examination, identification is clearly made by the presence of large, round or oval, clear-staining hydropic cells with hypochromatic nuclei (i.e., Paget cells). The cells often stain positively for cytokeratin 7 in addition to carcinoembryonic antigen and show gross cystic fluid protein but are S-100 protein negative (O'Connor et al, 2003). The tumor behaves as a slow-growing intraepithelial adenocarcinoma with cells derived from apocrine glands. With time the cells may become invasive with dermal tumor deposits metastasizing to regional lymph nodes via dermal lymphatics (Park et al, 2001). Of note, penoscrotal extramammary Paget disease may be associated with other malignancies of the genitourinary tract, such as prostate, bladder, and renal malignancies (Chanda, 1985; Ojeda et al, 1987; Koh, 1995; Allan et al, 1998), and should be evaluated for their presence.

Two reports from the Far East have added to the case series in the literature: 130 cases of penoscrotal Paget disease from China (Wang, 2008) and 36 from South Korea (Yang et al, 2005). In most cases only the skin and dermis must be resected with a gross margin of up to 3 cm. Positive margins may still occur, and frozen sections are recommended to guide the extent of resection. Local skin or scrotal flaps (Wang et al, 2008) can be used to cover the defects. Patients with a positive surgical margin are at a higher risk for recurrence, and additional resection is advised.

In a minority of cases, the tumor may invade deeper structures requiring more extensive resection and reconstruction, as reported in case series (Hatoko, 2002; Fujisawa, 2008). If inguinal adenopathy is present, radical node dissection is advised (Hagan et al, 1975) but prognosis is poor (Yang et al, 2005).

Adenosquamous Carcinoma

This is a rare tumor characterized by both glandular and squamous histologic elements that are independent of the urethral glands. It presents as a large (5 to 9 cm), firm, and grayish white granular exophytic mass involving the distal shaft or glans. On microscopic examination the glands contain mucin and are positive for carcinoembryonic antigen. In one reported case tumor was metastatic to a single inguinal node. This patient was managed with local excision of the primary tumor and a limited inguinal node dissection and lived 9 years after treatment. Other tumors were managed with local excision and surveillance (Cubilla et al, 1996). In only the seventh reported case (Romero, 2006), a patient with a bulky primary mass and inguinal lymph nodes underwent total

penectomy and delayed inguinal and pelvic lymphadenectomy with a final pathologic stage pT2N3M0 and free of disease at 5-year follow-up.

Lymphoreticular Malignant Neoplasm

Primary lymphoreticular malignant neoplasm rarely occurs on the penis (Dehner and Smith, 1970). **Leukemia may infiltrate the corpora, resulting in priapism** (Pochedly et al, 1974). **A thorough search for systemic disease is necessary when lymphomatous infiltration of the penis is diagnosed.** If the penile lesion is indeed a primary tumor, systemic chemotherapy may be administered. It is the most effective therapy for local disease, for potential occult deposits that may exist elsewhere, and for preservation of form and function (Marks et al, 1988). Local low-dose radiation therapy has also been reported to be successful (Stewart et al, 1985).

Metastases

Metastatic lesions to the penis are unusual with fewer than 300 cases reported in the literature (Belville and Cohen, 1992) until the early 1990s. Their infrequency is somewhat puzzling when one considers the rich blood and lymphatic supply to the organ and its proximity to the bladder, prostate, and rectum areas frequently involved with neoplasm. It is from these three organs that the majority of metastatic penile lesions originate (Abeshouse, 1961). The most likely routes of spread are by direct extension, retrograde venous and lymphatic transport, and arterial embolism. Other sources of penile metastases emanate from the gastrointestinal tract, testis, and kidney (Bellville and Cohen, 1992).

The most frequent sign of penile metastasis is priapism; penile swelling, nodularity, and ulceration have also been reported (McCrea and Tobias, 1958; Abeshouse and Abeshouse, 1961; Weitzner, 1971). Urinary obstruction and hematuria may occur. The most common histologic feature of penile invasion by metastatic lesions is the replacement of one or both corpora cavernosa, which explains the frequent occurrence of priapism. Solitary cutaneous, preputial, and glandular deposits are less common.

The differential diagnosis includes idiopathic priapism; venereal or other infectious ulcerations; tuberculosis; Peyronie plaque; and primary, benign, or malignant tumors.

Penile metastases represent an advanced form of virulent disease and usually appear rather rapidly after recognition and treatment of the primary lesion (Abeshouse and Abeshouse, 1961; Hayes and Young, 1967; Mukamel et al, 1987). On rare occasions a long period may elapse between the treatment of the primary lesion and the appearance of penile metastases (Abeshouse and Abeshouse, 1961) or the penile lesion may occur as the initial and only site of metastasis.

Because of the association of a penile metastatic lesion with advanced disease, survival after its presentation is limited, and the majority of patients die within 1 year (Robey and Schellhammer, 1984; Mukamel et al, 1987; Fischer and Patrick, 1999). Successful treatment may occasionally be possible in the case of solitary nodules or localized distal penile involvement if complete excision by partial amputation succeeds in removing the entire area of malignant infiltration (Spaulding and Whitmore, 1978). The prospect for surgical cure is minimal if proximal corporeal invasion is present. Penectomy is occasionally indicated after failure of other modalities to palliate intractable pain (Mukamel et al, 1987). Pain can also be managed by dorsal nerve section (Hill and Khalid, 1988). Radiation therapy has generally been unsuccessful, and chemotherapy has not been employed in a sufficient number of cases to warrant definitive recommendations.

Key Points: Nonsquamous Malignant Neoplasms

- Basal cell carcinoma represents a highly curable variant with low metastatic potential.
- Sarcomas are prone to local recurrence; regional and distant metastases are rare. Superficial lesions can be treated with less radical procedures.
- Melanoma is an aggressive form of cancer but can be cured if diagnosed and treated with the appropriate surgical procedure at an early stage.
- Extramammary Paget disease disseminates by intraepidermal spread. Wide local excision to achieve negative margins is the therapy of choice.
- Penile metastases most often represent spread from a clinically obvious existing primary tumor. Prognosis is poor, and therapy should be directed toward the primary tumor's histology or local palliation is advised.

Surgery of Penile and Urethral Carcinoma

David S. Sharp, MD ● Kenneth W. Angermeier, MD

Penile Cancer

Male Urethral Cancer

Female Urethral Cancer

PENILE CANCER

Despite ongoing clinical experience, treatment of squamous cell carcinoma of the penis remains primarily surgical. Early meticulous surgical management with close follow-up generally provides the best opportunity for cure. A thorough understanding of the various operative procedures for treatment of the primary tumor and regional lymph nodes is therefore critical in the successful management of this condition.

Primary Tumor

Penile Biopsy

The majority of penile squamous cell carcinomas initially involve the glans penis, coronal sulcus, or inner preputial skin (Ekstrom and Edsmyr, 1958; Burgers et al, 1992). **When a suspicious lesion is identified, a biopsy is required to provide histologic confirmation of the diagnosis. It is important to include some adjacent normal tissue with the specimen to allow optimal evaluation of the depth of invasion of the cancer.** Biopsy may take the form of a punch biopsy, excisional biopsy of a relatively small tumor of the glans or foreskin, or incisional biopsy of a larger lesion that cannot be completely excised. A dorsal slit may be required to gain adequate exposure of the preputial cavity. If a lesion involves the urethral meatus, urethroscopy is indicated to evaluate the urethra, and directed biopsies are performed if any suspicious areas are noted.

Laser Therapy

Laser therapy has been extensively evaluated as a form of conservative treatment of penile squamous cell carcinoma. It is attractive because it has the potential advantage of eliminating the primary tumor with preservation of surrounding tissues and penile function. The lasers most commonly reported for this purpose are the carbon dioxide (CO_2), neodymium:yttrium-aluminum-garnet (Nd:YAG), and potassium titanyl phosphate (KTP). Circumcision is generally recommended at the time of laser therapy, if it has not already been done.

The CO_2 laser has a wavelength of 10,600 nm. The laser energy is absorbed by intracellular water, resulting in vaporization to a skin depth of 0.01 mm. Blood vessels up to 0.5 mm in size can be coagulated. For these reasons, it has been most often used as monotherapy for treatment of dysplastic lesions and squamous cell carcinoma in situ (Greenbaum et al, 1989; Tietjen and Malek, 1998; van Bezooijen et al, 2001). It remains unclear whether the CO_2 laser represents optimal therapy for carcinoma in situ; however, a local recurrence rate of up to 33% has been reported (van Bezooijen et al, 2001).

Because of its cutting properties, the CO_2 laser has been shown to be technically capable of excising small superficial lesions of the penis (Bandieramonte et al, 1987). In this study, surgical specimens were adequate for pathologic examination in 87% of cases, and three patients underwent a repeated laser procedure for a positive margin. The mean distance between the resected lesion and the incision borders was 0.6 mm. A similar technique was used to completely resect the entire surface of the glans penis in a series of patients with diffuse glanular disease: 3 with carcinoma in situ and 11 with superficially invasive squamous cell carcinoma (Bandieramonte et al, 1988). Healing time varied from 5 to 8 weeks, and cosmetic appearance was good in all cases. Following these procedures, the authors recently reported an overall 10-year tumor recurrence rate of 17.5% for patients with stage Tis and T1 penile carcinoma. Most of the recurrences were readily treated, and the penile amputation rate was 5.5% (Bandieramonte et al, 2008). The laser most commonly reported in the treatment of squamous cell carcinoma has been the Nd:YAG laser (Rothenberger, 1986; Boon, 1988; Malloy et al, 1988; von Eschenbach et al, 1991; Horenblas et al, 1992; Frimberger et al, 2002a; Windahl and Andersson, 2003). It has a depth of penetration of 3 to 6 mm and therefore is considered to potentially be more appropriate for treating small superficial penile lesions. The application of iced saline to the treatment area during laser coagulation may prevent carbonization of the surface and promote deeper penetration of the laser energy when desired. When the Nd:YAG laser is used alone for carcinoma in situ and T1 squamous cell carcinoma, the local recurrence rate has been approximately 20% (Malloy et al, 1988; von Eschenbach et al, 1991). The Nd:YAG laser has also been used in combination with surgical excision, with the hope of improving treatment efficacy. The tumor is excised initially, followed by laser coagulation of the base and margins of the defect (Rothenberger, 1986; Boon, 1988; Horenblas et al, 1992; Windahl and Andersson, 2003). With this technique, the local recurrence has been reported to be 18% to 20%.

The KTP (532-nm wavelength) laser has also been used successfully in the treatment of superficial penile carcinoma (Tietjen and

Malek, 1998). It has an intermediate depth of penetration relative to the CO_2 and Nd:YAG lasers, and better hemostasis than the CO_2 laser.

Most reports of laser therapy for penile cancer have described treatment of the lesion with a margin of 3 to 5 mm, which may underestimate the extent of the lesion in some cases. In an attempt to decrease the recurrence rate, preparation of the genital skin with 5% acetic acid has been proposed along with the use of mapping biopsies and surgical excision during the procedure (Tietjen and Malek, 1998; Frimberger et al, 2002a). The acetic acid is applied for approximately 20 minutes before the procedure, and human papillomavirus–induced areas then appear whitened. In one study, the aceto-white staining was most prominent in the periphery of the grossly visible lesions (Tietjen and Malek, 1998). Laser therapy was then carried out with elimination of all abnormal areas, with a local recurrence rate of 7% to 11%. A more recent technique intended to decrease recurrences has been described by photodynamic diagnosis with 5-aminolevulinic acid and autofluorescence to visually direct frozen-section biopsies for assessment of margin status at the time of Nd:YAG tumor ablation (Frimberger et al, 2002b).

In general, laser therapy seems to be reasonable for patients with Tis and small T1 squamous cell carcinoma of the penis, and for patients with manageable T2 tumors who refuse more aggressive surgical treatment. Disadvantages include difficulty in determining the exact depth of laser coagulation; inability to treat larger lesions; and potentially difficult healing in patients who are obese, immunocompromised, or receiving anticoagulation therapy (Tietjen and Malek, 1998). Postoperative healing generally requires 8 to 12 weeks for the Nd:YAG and KTP lasers, but overall cosmetic results are generally good. Erectile function after combined CO_2 and Nd:YAG laser treatment of penile squamous cell carcinoma was unaltered in 72% of patients in one study (Windahl et al, 2004). As with any form of conservative treatment, careful long-term surveillance is essential because of the remaining tissues of the preputial cavity that are at risk for carcinogenesis (Horenblas and Newling, 1993).

Mohs Micrographic Surgery

Mohs micrographic surgery is a technique allowing removal of penile cancer by excision of tissue in thin layers (Mohs et al, 1985). This was originally described as a fixed tissue technique, but a fresh tissue technique has increasingly been used as a result of treating smaller lesions and its shorter procedural time (Brown et al, 1988; Cottel et al, 1988; Mohs et al, 1992). Color coding of the excised layers with tissue dyes allows accurate orientation of the specimen and the creation of a tissue map. Frozen sections to evaluate the surgical margin are cut horizontally from the undersurface of the tissue specimens rather than vertically, allowing microscopic examination of the entire deep and peripheral margin. Any remaining tumor is marked on the tumor map. This is continued until the lesion is completely excised. Mohs micrographic surgery allows excellent local control rates while maximizing organ preservation. Mohs reported a cure rate of 81% for tumors on the glans or prepuce. For all tumor stages, 5-year cure rates were 100% for lesions smaller than 1 cm, 83% for lesions 1 to 2 cm, 75% for lesions 2 to 3 cm, and 50% for lesions larger than 3 cm (Mohs et al, 1985). With extended follow-up, the local control rate was 94% (Mohs et al, 1992), and this has been duplicated by others (Mikhail, 1976; Brown et al, 1988). In addition to tumor size, local recurrence has been associated with advanced stage and failure of previous definitive therapy.

Mohs micrographic surgery would seem to be best suited for patients with carcinoma in situ or small superficially invasive tumors, with cure rates comparable to partial penectomy. However, these results may be variable and dependent on the technique used and the experience of the surgeon (Cottel et al, 1988; Mohs et al, 1992). It should not be used in patients with higher-stage or large lesions. Complications of Mohs micrographic surgery may include meatal stenosis and glans disfigurement.

Conservative Surgical Excision

Conservative surgical excision is another form of tissue-sparing therapy for low-stage penile cancer. **It may be attractive in some instances when the surgeon is inexperienced regarding lasers or Mohs micrographic surgery, or when these modalities are unavailable. In addition, compared with laser therapy, excision has the advantage of providing tissue for tumor grading and assessment of margins, and it does not require the technical support necessary for Mohs micrographic surgery.** Support for a conservative approach in selected patients has been provided by studies suggesting that the traditional 2-cm surgical margin may not always be necessary for cure. Pathologic analysis of 14 patients undergoing partial or total penectomy for squamous cell carcinoma revealed a mean surgical margin of approximately 14.5 mm; seven patients had a margin of 10 mm or less. No patient in this series had a local recurrence (Hoffman et al, 1999). Microscopic extent of penile carcinoma has also been shown to be dependent on tumor grade; grade 1 and grade 2 tumors demonstrated a maximum histologic extent of 5 mm in an analysis of 64 penectomy specimens (Agrawal et al, 2000). In addition, these authors were unable to identify any tumors with a pattern of discontinuous spread. The simplest form of conservative surgical excision is circumcision. Distal preputial tumors may be effectively treated in this fashion when a surgical margin of 2 cm can be achieved (Skinner et al, 1972; McDougal et al, 1986). If the cancer is more proximal and close to the coronal sulcus; however, recurrence rates may be as high as 50% (Narayana et al, 1982), and therefore excision of additional adjacent tissue is needed to ensure an adequate surgical margin.

Local excision of glanular tumors is more difficult because of the requirement of a surgical margin that may not preserve enough tissue to allow an adequate remaining glans penis. This is most often done in the form of excisional biopsy of a lesion with negative surgical margins. In some cases, the surgical defect is small and can be closed primarily. If the defect is larger and primary closure is not possible, the area can be covered with an outer preputial skin flap (Ubrig et al, 2001) (Fig. 35–1). Alternatively, a full-thickness graft of penile skin or extragenital split-thickness skin graft may be used to reconstruct the area (Pietrzak et al, 2004) (Fig. 35–2). Local recurrence rates after conservative penile surgery have varied. Two early publications reported recurrence in 32% and 40% of patients (Hanash et al, 1970; McDougal et al, 1986). In 1999, Ficarra and colleagues noted local recurrence after conservative penile surgery in three of eight patients with Tis and T1 disease. More recent data have been a bit more favorable, with reported local recurrence rates of 8% to 11% (Banon Perez et al, 2000; Bissada et al, 2003; Pietrzak et al, 2004).

Total glansectomy for penile malignant lesions was initially described in 1996 (Austoni et al, 1996). Since that time, excellent local tumor eradication has been described in a small number of patients with verrucous carcinoma and nonsquamous penile

Figure 35–1. malignant neoplasms. Adequate voiding and erectile function was preserved in the majority of cases (Davis et al, 1999; Hatzichristou et al, 2001). In comparison, standard partial penectomy may be associated with significant impairment of sexual function (Opjordsmoen et al, 1994) and, in our experience, often results in the inability to void in a standing position with long-term follow-up. On the basis of this experience, a subsequent report described six patients with superficial, well to moderately differentiated squamous cell carcinoma limited to the glans penis who underwent glansectomy as primary therapy. With follow-up of 6 to 18 months, there were no local recurrences, and all patients

Figure 35–2. Finely meshed extragenital split-thickness skin graft quilted to glans defect after superficial tumor excision.

maintained adequate sexual function (da Fonseca et al, 2003). The procedure begins with a distal circumferential skin incision to the level of the Buck fascia. The plane under the Buck fascia is developed proximal to the corona of the glans. Laterally, there are usually only a few small vessels within the Buck fascia that may be controlled with electrocautery. Dorsally, the neurovascular structures are divided between surgical ties. Ventrally, a plane is developed under the urethra, but it is not yet divided. Dorsal dissection is commenced in the plane between the glans penis and the tunica albuginea of the corpora cavernosa, and this is continued until the glans is attached by the urethra alone. The urethra is then divided, completing the excision. Frozen-section biopsy specimens are obtained from the tips of the corpora or any other suspicious area. Reconstruction is accomplished by fixing the remaining neurovascular bundle to the tunica albuginea dorsally and the urethra ventrally if needed. The urethra is spatulated, and the penile skin is then approximated in the midline and around the neomeatus. A urethral catheter is left indwelling for 3 to 7 days.

Pietrzak and colleagues (2004) have reported the results of glansectomy or glansectomy and distal corporectomy in 29 men with primarily stage T1 and T2 squamous cell carcinoma of the glans, prepuce, and coronal sulcus. Patients undergoing glansectomy had circumcision and glans excision as described before, followed by mobilization of the urethra to allow formation of a urethrostomy near the tip of the penis. Frozen-section biopsy specimens are taken from the distal tunica albuginea and the urethral margin. The shaft skin is sutured in place approximately 2 cm from the end of the penis, leaving the corporeal tips exposed. A split-thickness skin graft is harvested and quilted to the corpora, and a urethral catheter is placed. The patient is maintained at bed rest for 5 days. If the findings on frozen-section biopsy are abnormal, distal corporectomy is performed until the margins are negative, and the corpora are reconstructed as in partial penectomy. A distal split-thickness skin graft is then used to cover the corpora and to form the neoglans. Early results were encouraging; there were no local recurrences in this initial group of patients at a mean follow-up of 16 months. These data were recently updated in a review of 72 patients treated with glansectomy and split-thickness skin graft reconstruction for stage T1 and T2 tumors limited to the glans penis. Clinical efficacy was very good with two patients requiring early repeat excision for a positive surgical margin and clinical tumor recurrence, and only three late local recurrences (4%) at a mean follow-up of 27 months (Smith et al, 2007).

Figure 35–4. Penile stump after partial penectomy.

Partial Penectomy

Partial penectomy remains the most common surgical procedure for treatment of the primary tumor in patients with invasive squamous cell carcinoma. Successful local control is accomplished in the majority of patients by amputation of the penis at least 2 cm proximal to the tumor. Additional goals of the procedure are to preserve the ability to void in a standing position and possibly to allow sexual function. The lesion is initially excluded from the surgical field by a small towel or surgical glove (Fig. 35–3). Some authors have recommended the use of a tourniquet at the base of the penis, but we have not found this to be necessary. The skin and underlying dartos fascia at the proposed line of amputation are incised circumferentially to the level of the Buck fascia. The Buck fascia is incised laterally, and a plane is dissected between the tunica albuginea and the neurovascular structures dorsally. The dorsal penile vessels are sequentially ligated and divided. The corpora cavernosa are sharply divided, leaving the specimen attached only by the urethra. The urethra is dissected for a distance of 1 to 1.5 cm distal to the proximal corpora and then transected. The corpora are closed transversely with interrupted horizontal mattress sutures of 2-0 polydioxanone. The penile skin is closed in the midline over the corporeal ends with interrupted 3-0 or 4-0 chromic suture material. A ventral urethrostomy is constructed by approximating the urethra to the adjacent penile skin with interrupted 4-0 chromic sutures (Fig. 35–4). An indwelling urethral catheter is left in place for 3 to 5 days. If additional stump length is needed to increase the probability of adequate voiding function, the suspensory ligament of the penis may be divided. The proximal corpora may subsequently be dissected off of the pubic arch for a short distance as well. Scrotal flaps are used to help with skin coverage as needed, and the skin is attached to the pubic arch to preserve the dissected penile length. Division of the penoscrotal fold with a Z-plasty at the penoscrotal junction ventrally may contribute to better definition of the remaining penile stump (Parkash et al, 1986). In selected patients, glans reconstruction may be considered by covering the distal corpora with a split-thickness skin graft (de Souza, 1976) or a two-stage pedicled flap of scrotal skin (Mazza and Cheliz, 2001).

The reported local recurrence rate after partial or total penectomy has ranged from 0% to 8% (Hardner et al, 1972; de Kernion et al, 1973; McDougal et al, 1986; Horenblas et al, 1992). Two studies have suggested that recurrence rates are dependent on tumor stage, reporting a recurrence rate of 0% for patients with T1 tumors and 18% to 21% for T2 lesions (Lindegaard et al, 1996; Brkovic et al, 1997). Although one of the accepted goals of partial penectomy is to allow upright voiding, the percentage of patients able to do this after surgery has not been well documented. A 6% incidence of urethral meatal stenosis has been reported (Horenblas et al, 1992). In our experience, a significant number of men sit to void in the long term because of spraying of the urinary stream. In terms of sexual function, most published reports have indicated that approximately 20% of patients describe adequate sexual function postoperatively (Opjordsmoen et al, 1994; Ficarra et al, 1999; Mazza and Cheliz, 2001).

Total Penectomy

Total penectomy is a bit of a misnomer, because the penis is amputated at or near the level of the suspensory ligament of the penis without removal of the corpora cavernosa more proximally. **It is indicated for penile tumors whose size or location would not allow excision with an adequate surgical margin and preservation of a remnant sufficient for upright voiding.** The primary tumor is draped and an elliptical incision made around the base of the penis (Fig. 35–5). Dissection is commenced in the plane between the tunica albuginea and Buck fascia dorsolaterally, and the dorsal vessels are ligated and divided. The corporeal bodies are sharply transected, and the urethra is divided at the same level. The corpora are then closed with interrupted horizontal mattress sutures of 2-0 polydioxanone.

A perineal urethrostomy is then constructed by one of two techniques. The most commonly described method is to mobilize the urethra from the surrounding bulbospongiosus muscle and dorsally from the corporeal bodies to near the departure of the urethra from the bulb (Fig. 35–6). A small U-shaped incision is made in the perineum. The mobilized urethra is transposed through the perineal opening without angulation. The urethra is spatulated dorsally, and the skin is sutured to the full-thickness urethra with 3-0 polyglactin sutures. Alternatively, a flap inlay urethrostomy may be constructed without mobilization of the urethra. A modified lambda incision, with a short vertical limb, is made in the perineum (Fig. 35–7). The soft tissues overlying the urethra are incised, and the bulbospongiosus muscle is divided in the midline to expose the corpus spongiosum of the bulbous urethra. A 3- to 4-cm ventral urethrotomy incision is made and carried proximally to a point just distal to the bulbomembranous junction (Fig. 35–8). The lateral aspects of the corpus spongiosum in the region of the urethrotomy are fixed to the adjacent corporeal bodies with a few interrupted sutures of 4-0 polydioxanone to splay the opened urethra. The perineal skin flap is sutured to the full-thickness urethra with 3-0 polyglactin starting in the midline and working laterally as far as the flap will easily reach (Fig. 35–9). The urethrostomy is completed by approximation of the scrotal skin to the urethra dorsolaterally, and the resulting short lateral skin incisions are closed in standard fashion (Fig. 35–10).

After completion of the perineal urethrostomy, the primary skin incision is closed transversely, and a small Penrose or suction drain is placed. A urethral catheter is left indwelling for 7 to 10 days.

Radical Penectomy

Although it is not commonly done, radical penectomy with excision of the corporeal bodies in their entirety may on occasion be necessary. We have had experience with this procedure in three patients, one with epithelioid sarcoma of the penis involving multiple sites within the corpora cavernosa (Ormsby et al, 2000), and for palliation in two patients with extensive metastatic disease within the corporeal bodies related to transitional cell carcinoma of the bladder and adenocarcinoma of the rectum.

The patient is placed into lithotomy position with adjustable stirrups so that the level of the legs can be altered during the procedure as needed. The procedure begins with a peripenile incision as for total penectomy, and the corpora are mobilized off of the ischiopubic rami proximally to the point at which the dorsal vein may be seen coursing under the pubis, where it is ligated and divided (Fig. 35–11). A modified lambda incision is then made in the perineum, and the penis is maneuvered through this incision

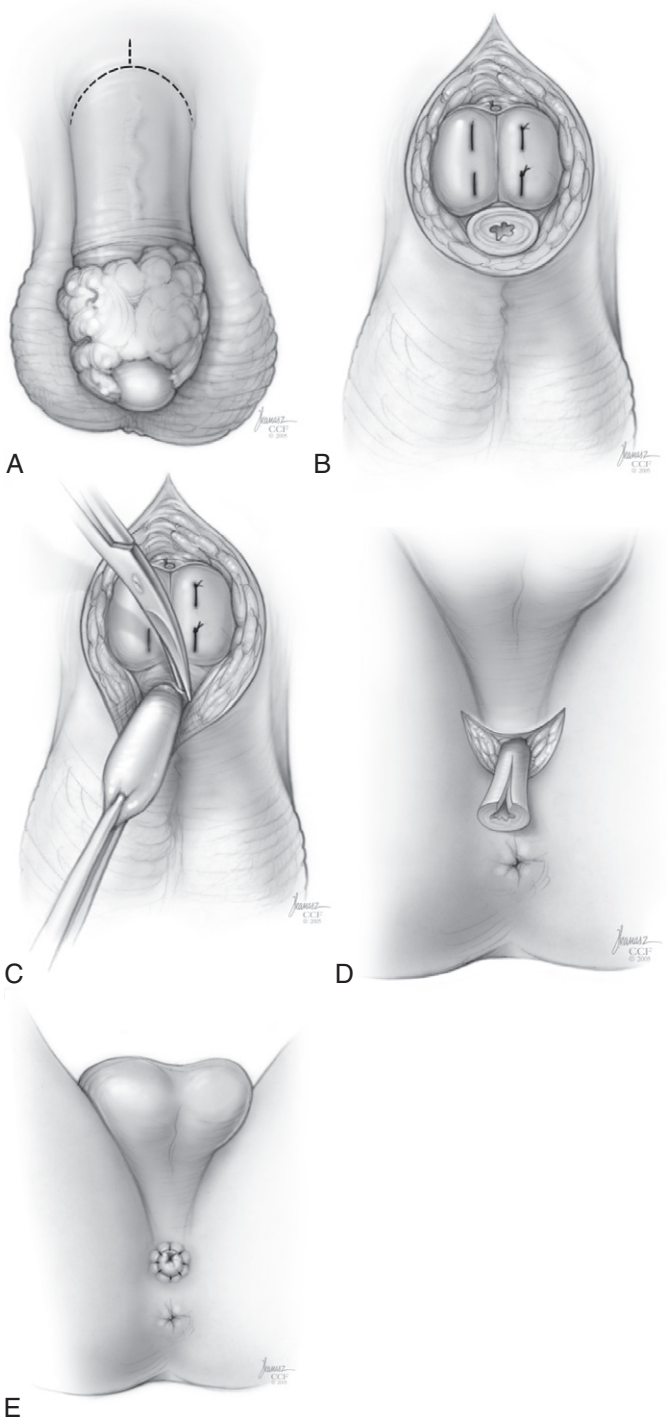

Figure 35–5. Total penectomy. **A,** Incision. **B,** Transection of the corpora near the level of the pubis. **C,** Mobilization of the remaining urethra off of the proximal corporeal bodies. **D,** Transposition of the urethra through a curvilinear perineal incision. **E,** Completion of perineal urethrostomy. (Fig. 35–12). Dissection of the corporeal bodies continues to the tips of the crura, which are completely excised. Suture ligatures are used to control the dorsal penile and cavernosal vasculature near the dorsal aspect of the crura, and in the penile hilum. A plane is developed between the proximal urethra and the corpora,

and the urethra is then transected, leaving 2 to 3 cm of urethra to form a perineal urethrostomy (Fig. 35–13). A standard flap perineal urethrostomy is then constructed. A small suction drain is placed, and the peripenile incision is closed transversely.

Regional Lymph Nodes

Squamous cell carcinoma of the penis spreads initially to regional lymph nodes before the occurrence of distant metastatic disease. Lymphatic spread occurs in a systematic

Figure 35–12. Penis transposed through the perineal incision.

fashion along the normal route of penile lymphatic drainage. Lymphatic vessels draining the prepuce and skin of the penile shaft converge dorsally and then divide at the base of the penis to drain into the right and left superficial inguinal nodes. Drainage from the glans penis is toward the frenulum, where large trunks are formed and encircle the corona to unite with those from the other side on the dorsum. They traverse the penis to the base within the Buck fascia, draining through presymphyseal lymphatics into the superficial inguinal nodes and the deep inguinal nodes of the femoral triangle. It is not uncommon for the tumor to metastasize to the contralateral inguinal nodes. Drainage proceeds from the inguinal nodes to the ipsilateral pelvic lymph nodes. Although some anatomic texts have stated that penile lymphatics may drain directly to the external iliac nodes, we are not aware of any patients or reports in the literature in which this has occurred clinically. **Although penile carcinoma metastatic to the inguinal lymph nodes confers a poorer prognosis overall, aggressive lymphadenectomy is associated with improved long-term survival and potential cure in 30% to 60% of patients** (McDougal et al, 1986; Horenblas and van Tinteren, 1994). In addition, immediate resection of clinically occult lymph node metastases is associated with improved survival when compared with delayed resection of involved nodes at the time of clinical detection (Kroon et al, 2005). If the tumor has spread to the pelvic nodes, long-term survival is less than 10%.

Inguinal Anatomy

See Figs. 35–14 and 35–15 on the Expert Consult website.

Sentinel Node Biopsy

The concept of sentinel node biopsy in patients with invasive squamous cell carcinoma of the penis and clinically negative inguinal regions was proposed by Cabanas (1977) after extensive study of lymphangiograms and anatomic dissections. The impetus for a conservative approach to evaluate this group of patients arose from the realization that surgical treatment of inguinal metastases is desirable, and because of the significant morbidity associated with conventional inguinofemoral lymphadenectomy. A 5-cm incision is made parallel to the inguinal crease and centered two fingerbreadths lateral and inferior to the pubic tubercle. By insertion of the finger under the upper flap toward the pubic tubercle, the sentinel lymph node is encountered and excised (Fig. 35–16).

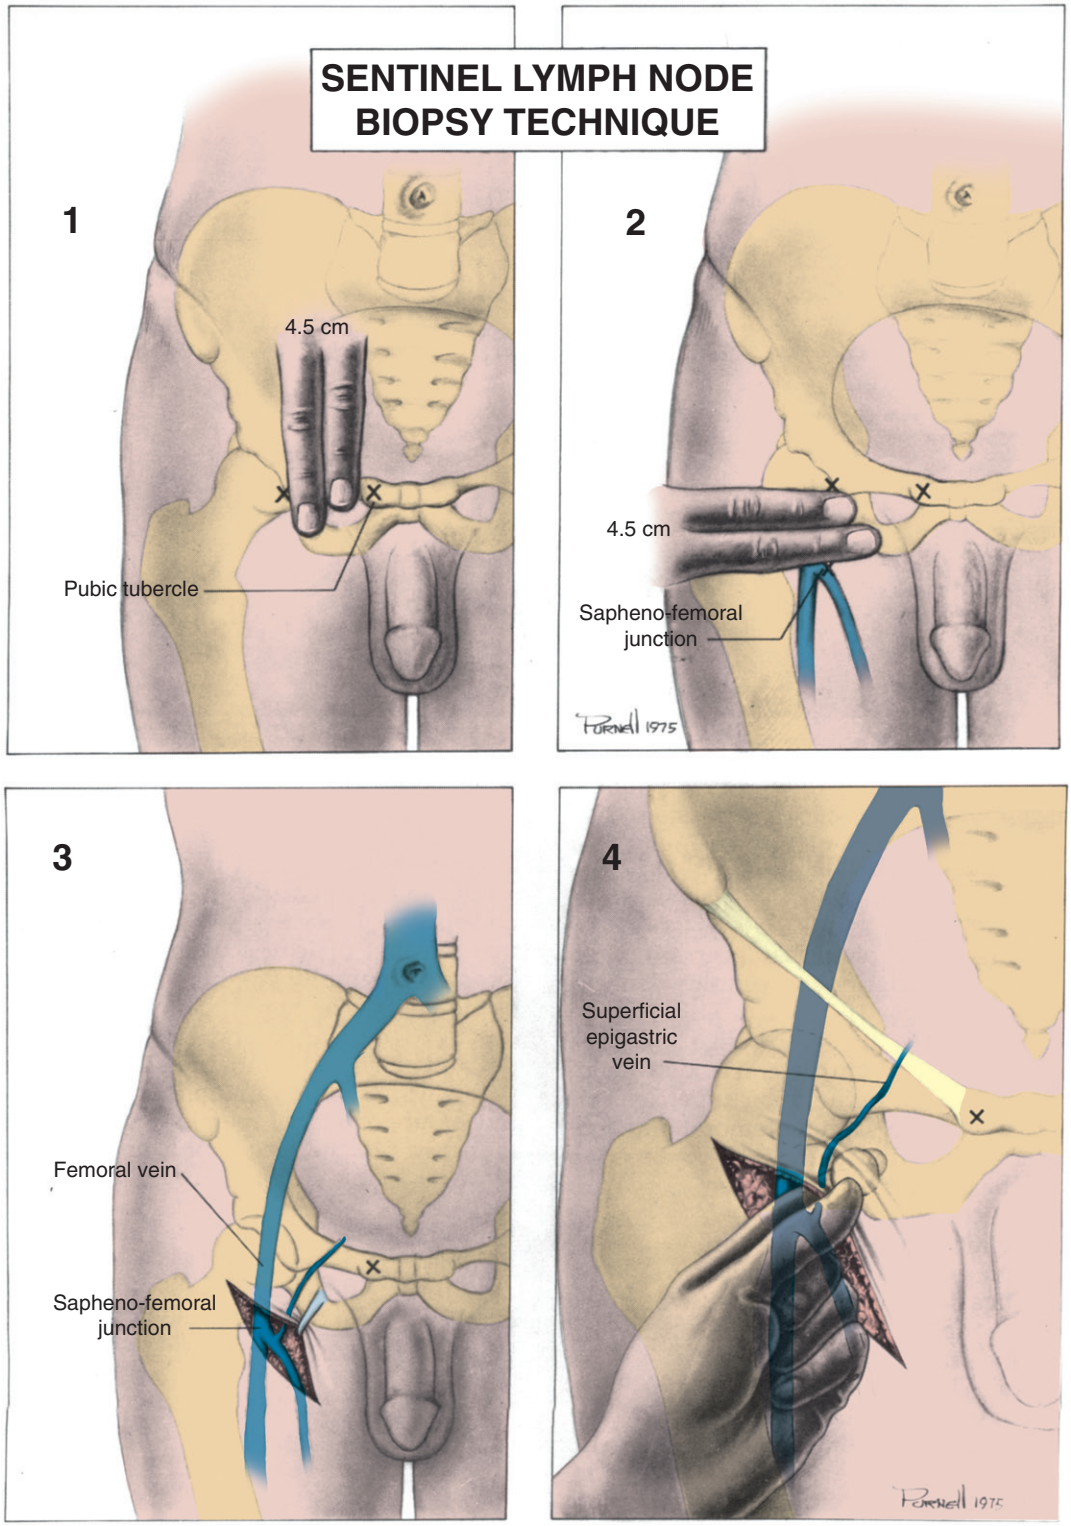

Figure 35–16. Sentinel lymph node biopsy technique as described by Cabanas. (From Cabanas RM. An approach for the treatment of penile carcinoma. Cancer 1977;39:456–66.)

Although Cabanas reported 90% survival in patients with normal findings on sentinel node biopsy, subsequent authors found the results to be less satisfactory, with reports of development of extensive regional metastases after a biopsy with normal findings (Perinetti et al, 1980; Wespes et al, 1986). As an alternative, Pettaway and colleagues (1995) evaluated extended sentinel node biopsy, during which all of the lymph nodes between the inguinal ligament and the superficial external pudendal vein were removed. This approach has also been abandoned, because it resulted in a false-negative rate of 15% to 25% (Ravi, 1993; Pettaway et al, 1995).

Efforts have been made to improve the accuracy of sentinel node biopsy. Dynamic sentinel node biopsy with lymphoscintigraphic imaging has been described on the basis of experience in other tumors (Horenblas et al, 2000). The technique starts the day before surgery with the intradermal injection of technetium Tc 99m nanocolloid at three or four sites around the primary tumor. Dynamic anterior lymphoscintigraphy is subsequently performed at defined intervals. The location of the sentinel node is marked on the skin. Shortly before surgery, 1 mL of patent blue dye is injected around the tumor in a similar fashion. The sentinel node is harvested after dissection of blue lymphatic vessels and intraoperative detection of radioactivity by use of a gamma-ray detection probe. Detection of positive nodes has also been aided by preoperative inguinal ultrasonography with fine-needle aspiration of any abnormal-appearing lymph nodes. A false-negative rate of 18% was initially reported with this approach (Kroon et al, 2004). More recently, the authors have amended their algorithm with the addition of routine inguinal exploration in the absence of radiotracer visualization, intraoperative palpation of the wound for abnormal nodes, and extended pathologic analysis of excised nodes as means of decreasing the number of false-negative biopsy results. These additional maneuvers have decreased the false-negative rate to 5% while maintaining a low risk of complications (Leijte et al, 2007).

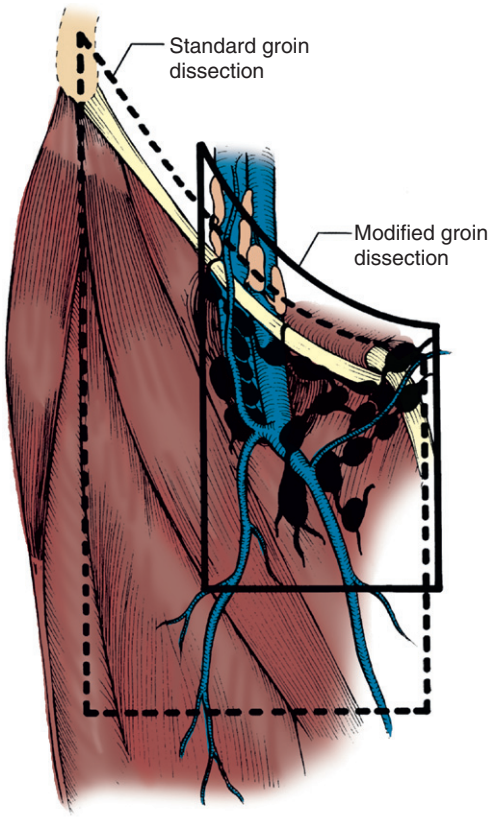

Figure 35–17. Limits of standard and modified groin dissection. (From Colberg JW, Andriole GL, Catalona WJ. Long-term follow-up of men undergoing modified inguinal lymphadenectomy for carcinoma of the penis. Br J Urol 1997;79:54–7.)

Modified Inguinal Lymphadenectomy

In 1988, Catalona proposed a technique of modified inguinofemoral lymphadenectomy designed to provide staging information and therapeutic benefit similar to standard extended lymphadenectomy with less morbidity (Fig. 35–17). **Key aspects of the procedure are (1) shorter skin incision, (2) limitation of the dissection by excluding the area lateral to the femoral artery and caudal to the fossa ovalis, (3) preservation of the saphenous vein, and (4) elimination of the need to transpose the sartorius muscle.** All of the superficial lymph nodes within the described area are removed, as are the deep inguinal nodes that are located primarily medial to the femoral vein to the level of the inguinal ligament.

The procedure begins by placing the patient into a frog-legged position. A 10-cm skin incision is made approximately 1.5 to 2 cm below the inguinal crease. Skin flaps are developed in the plane just beneath the Scarpa fascia for a distance of 8 cm superiorly and 6 cm inferiorly. The superior dissection is carried to the level of the external oblique fascia with exposure of the spermatic cord. A funiculus of lymphofatty tissue, extending from the base of the penis to the superomedial portion of the lymph node packet, is ligated and divided. Dissection commences in a caudad direction with removal of the superficial and deep inguinal nodes, with the boundaries consisting of the adductor longus muscle medially and the femoral artery laterally. The saphenous vein is identified and preserved, although a number of branches draining into it will need to be sacrificed. The nodal packet is dissected caudad to the level of the skin flap dissection (Fig. 35–18), at which point the lymphatics are carefully ligated and the specimen is delivered from the operative field (Fig. 35–19). A closed-suction drain is placed, and the incision is closed in standard fashion.

Morbidity after modified inguinal lymphadenectomy consists primarily of minor complications including seroma (25% to 27%), lymphorrhea (9% to 10%), and wound infection or skin necrosis (0% to 9%). These have been self-limited in the majority of cases (Parra, 1996; Coblentz and Theodorescu, 2002; Jacobellis, 2003; Bouchot et al, 2004; d'Ancona et al, 2004). Temporary lower extremity edema has been reported in approximately 20% of patients, and persistent edema is uncommon. Major complications are rare.

Although it is not universally accepted, the literature suggests that the primary use of modified inguinal lymphadenectomy currently is in patients with a primary tumor that places them at increased risk for inguinal metastasis and clinically negative groins on examination (stage T2 or greater, presence of vascular/lymphatic invasion, or high grade). If nodal metastasis is detected on frozen-section examination of the specimen, the procedure is converted to a standard extended lymphadenectomy. The false-negative rate for this procedure, in terms of detecting inguinal metastatic disease, ranges from 0% to 5.5% in the majority of published reports (Parra, 1996; Colberg et al, 1997; Coblentz and Theodorescu, 2002; Bouchot et al, 2004; d'Ancona et al, 2004).

Radical Ilioinguinal Lymphadenectomy

Radical ilioinguinal lymphadenectomy is indicated in patients with resectable metastatic adenopathy and may be curative when the disease is limited to the inguinal nodes. We have also favored its use as a palliative procedure in patients with documented inguinal metastasis who are fit for surgery. If left unchecked, cancer-bearing inguinal nodes may lead to significant complications, such as infection or abscess with chronic foul-smelling drainage or life-threatening femoral hemorrhage (Fig. 35–20). The procedure is carried out 4 to 6 weeks after surgical treatment of the primary tumor. Antibiotics are administered during this time to reduce the inflammatory component of the regional adenopathy. The patient is positioned with the involved thigh slightly abducted and externally rotated with cushioned support under the flexed knee.

The inguinofemoral dissection is designed to cover an area outlined superiorly by a line drawn from the superior margin of the external ring to the anterior superior iliac spine, laterally by a line drawn from the anterior superior iliac spine extending 20 cm inferiorly, and medially by a line drawn from the pubic tubercle 15 cm down the medial thigh. In most situations, the procedure is carried out through an oblique incision approximately 3 cm below and parallel to the inguinal ligament and extending from the lateral to the medial limit of the dissection (Fig. 35–21). If an area of the skin overlying the cancer-bearing nodes is invaded or adherent and requires excision, an elliptical incision is made around the involved skin and then extended medially and laterally. In this setting, the incision may alternatively be extended superiorly from the lateral border of the ellipse and inferiorly from the medial border to make a single S-shaped incision for the iliac and inguinofemoral dissections (Fig. 35–22).

Superior and inferior skin flaps are developed in the plane just below the Scarpa fascia. The superior flap is elevated cephalad to a point 4 cm above the inguinal ligament, and the inferior flap to the limit of the dissection. The fat and areolar tissues are dissected

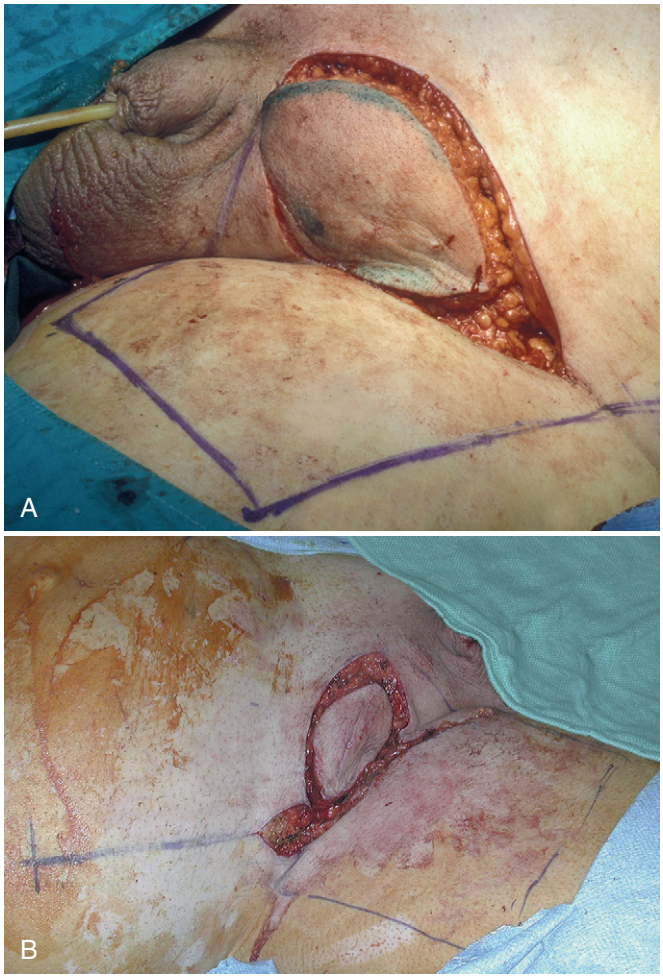

Figure 35–22. **A,** Incision and area of dissection for left inguinofemoral lymph node dissection with excision of adherent skin overlying nodal mass. **B,** Single-incision approach and area of dissection for right ilioinguinal lymph node dissection with excision of overlying skin.

from the external oblique aponeurosis and the spermatic cord to the inferior border of the inguinal ligament, forming the superior boundary of the lymph node packet (Fig. 35–23). The inferior angle of the inguinofemoral exposure is at the apex of the femoral triangle, where the long saphenous vein is identified and divided. In patients with minimal metastatic disease, it may be feasible and beneficial to spare the saphenous vein, and this should be considered (Fig. 35–24). Dissection is deepened through the fascia lata overlying the sartorius muscle laterally and the thinner fascia covering the adductor longus muscle medially. At the apex of the femoral triangle, the femoral artery and vein are identified, and dissection is continued superiorly along the femoral vessels. Superficial cutaneous perforating arteries are ligated as they are encountered on the surface of the femoral artery. The saphenous vein is divided at the saphenofemoral junction, and the dissection is continued superiorly to include the deep inguinal nodes medial and lateral to the femoral vein until continuity with the pelvic dissection is attained at the femoral canal (Fig. 35–25). The anterior aspects of the femoral vessels are dissected, but the femoral vessels are not skeletonized, and the lateral surface of the femoral artery is not exposed. This avoids injury to the femoral nerve and the profunda femoris artery, and the femoral nerve is usually not visible as it runs beneath the iliacus fascia.

After the femoral triangle is dissected (Fig. 35–26), the sartorius muscle is mobilized from its origin at the anterior superior iliac spine and either transposed or rolled 180 degrees medially to cover the femoral vessels. The muscle is sutured to the inguinal ligament superiorly, and its margins are sutured to the muscles of the thigh immediately adjacent to the femoral vessels (Fig. 35–27). The femoral canal is closed, if necessary, by suturing the shelving edge of the Poupart ligament to the Cooper ligament, being careful not to compromise the lumen of the external iliac vein or to injure the inferior epigastric vessels in the process. Primary closure of the inguinofemoral dissection is usually possible with minimal or no further mobilization of the excision margins. When circumstances demand a large area of inguinal soft tissue sacrifice, primary closure may be obtained by scrotal skin rotation flaps (Skinner, 1974), an abdominal wall advancement flap (Tabatabaei and McDougal, 2003), or a myocutaneous flap based on the rectus abdominis or tensor fascia lata (Airhart et al, 1982) for more extensive defects.

Laparoscopic inguinal lymphadenectomy has recently been shown to be technically feasible and may decrease postoperative morbidity (Sotelo et al, 2007). In one study, patients underwent

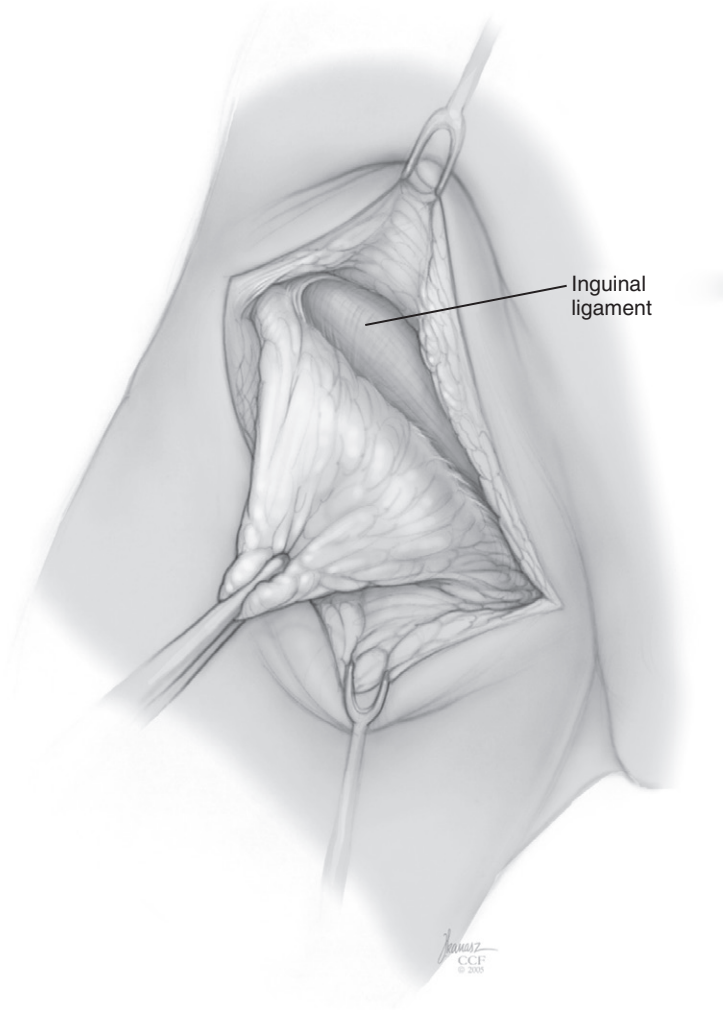

Figure 35–23. Initial dissection for radical inguinofemoral lymph node dissection with exposure of superior border defined by the external oblique fascia. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2003-2010. All Rights Reserved.)

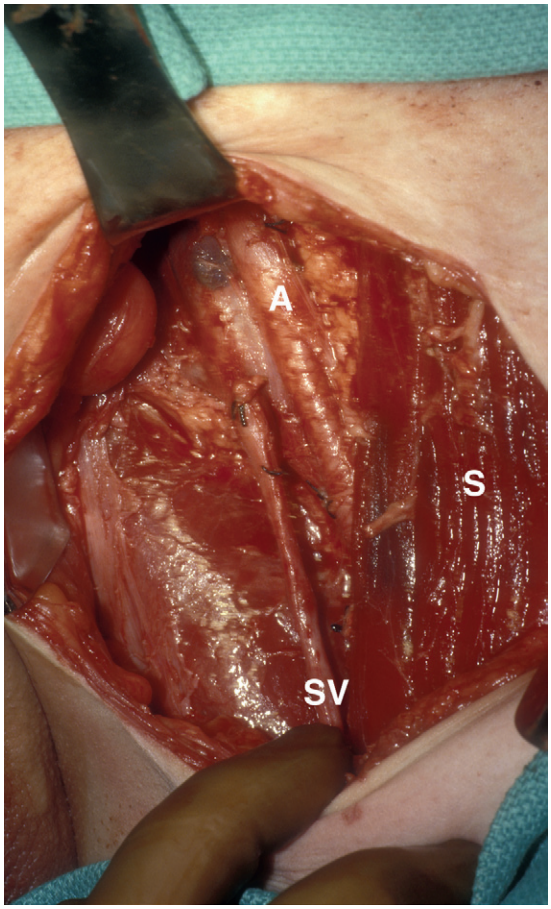

Figure 35–24. Intraoperative photograph after saphenous-sparing, radical, left inguinofemoral lymph node dissection. A, femoral artery; S, sartorius muscle; SV, saphenous vein.

open radical inguinal lymphadenectomy on one side and video endoscopic lymphadenectomy contralaterally. A similar number of lymph nodes were excised on both sides, and there were no recurrences or disease progression at a mean follow-up of 18 months (Tobias-Machado et al, 2007).

Bilateral pelvic lymphadenectomy is best accomplished by an extraperitoneal approach through a lower midline incision. If a unilateral dissection is indicated, we favor a modified Gibson incision or an S-shaped ilioinguinal incision (see Figs. 35–21 and 35–22). **Pelvic lymphadenectomy should include the distal common iliac, external iliac, and obturator nodes. No further benefit is gained from proximal iliac or para-aortic dissection.**

Closed-suction drains are placed under the subcutaneous tissue and brought out inferiorly. During closure, the skin flaps are sutured to the surface of the exposed musculature to decrease dead space. The skin is closed with absorbable subcutaneous sutures and staples. The patient is maintained at bed rest for 2 or 3 days, and pneumatic compression stockings are used. The drains are removed after 5 to 7 days, when drainage is less than 30 to 40 mL/day. Compression stockings are recommended postoperatively. We maintain the patient on a suppressive dose of a cephalosporin for

Key Points: Penile Cancer

- Early meticulous surgical management with close follow-up generally provides the best opportunity for cure of penile squamous cell carcinoma.
- In performing a penile biopsy, it is important to include some adjacent normal tissue with the specimen to allow optimal evaluation of the depth of invasion of the cancer.
- Conservative surgical approaches may be reasonable for patients with stage Tis and small T1 squamous cell carcinoma of the penis, and for patients with manageable T2 tumors who refuse more aggressive surgical treatment.
- Partial penectomy with a 2-cm surgical margin remains the most common surgical procedure for treatment of the primary tumor in patients with invasive squamous cell carcinoma and affords excellent local control in most instances.
- In patients at risk for the development of inguinal metastatic disease and with no palpable adenopathy, modified inguinal lymphadenectomy provides excellent assessment of the regional nodes and may be converted to a full lymphadenectomy if metastatic disease is detected.
- Penile cancer metastases to the pelvic lymph nodes do not occur in the setting of negative ipsilateral inguinal nodes.

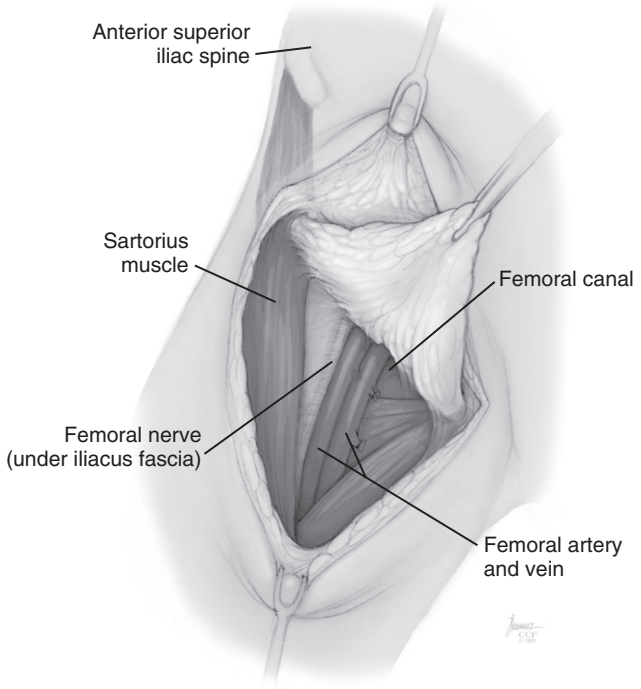

Figure 35–25. Inferior dissection during radical inguinofemoral lymph node dissection with removal of lymph node packet from the inferior border of the femoral triangle. After further lateral and medial dissection, the packet will remain in continuity with the pelvic dissection in the area of the femoral canal. 2 months to decrease the incidence of erythema and cellulitis, and this seems to improve overall wound healing.

In the past, complications related to radical ilioinguinal lymphadenectomy have been significant. In contemporary series, early minor complications have been reported in 40% to 54% of dissections (Bevan-Thomas et al, 2002; Bouchot et al, 2004; Nelson et al, 2004). These consist primarily of lymphocele, wound infection or necrosis, and lymphedema. Major complications, such as

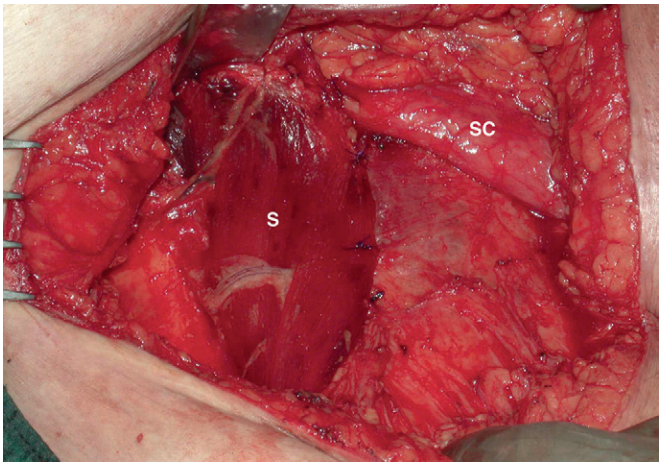

Figure 35–27. Sartorius muscle after detachment from the anterior superior iliac spine and 180-degree rotation medially, with suture fixation to the fascia of the inguinal ligament and the adductor longus. S, sartorius muscle; SC, spermatic cord.

debilitating lymphedema, flap necrosis, and lymphocele requiring intervention, occur in 5% to 21% of cases (Bevan-Thomas et al, 2002; Nelson et al, 2004). Efforts to minimize lower extremity lymphedema include the use of elastic stockings and sequential compression devices. The trend seems to be toward earlier ambulation, with the avoidance of prophylactic low-dose heparin therapy because of the possibility of an increased risk of lymphocele formation (Tomic et al, 1994).

MALE URETHRAL CANCER

General Considerations

Carcinoma of the male urethra is rare and usually presents in the fifth decade of life (Dalbagni et al, 1999). **Etiologic factors include chronic inflammation due to a history of frequent sexually transmitted diseases, urethritis, and urethral stricture, and there is likely to be a causal role for human papillomavirus 16 in squamous cell carcinoma of the urethra** (Weiner et al, 1992; Cupp et al, 1996). The onset of malignant change in a patient with chronic urethral stricture disease may be insidious, and a high index of clinical suspicion is required to diagnose these tumors expediently. More than 50% of patients have a history of urethral stricture disease, almost 25% have a history of sexually transmitted disease, and 96% are symptomatic at presentation (Dalbagni et al, 1999). The most common presenting symptoms are urethral bleeding, a palpable urethral mass, and obstructive voiding symptoms.

Pathology

Tumors of the male urethra are categorized according to location and histologic features of the cells lining the urethra (Mostofi et al, 1992) (Fig. 35–28). The bulbomembranous urethra is involved most frequently, accounting for 60% of tumors, followed by the penile urethra (30%) and the prostatic urethra (10%). Overall, 80% of male urethral cancers are squamous cell carcinoma; 15% are transitional cell carcinoma; and 5% are adenocarcinoma, melanoma, lymphoma, paraganglioma, sarcoma, or an undifferentiated tumor. The histologic subtype of urethral cancer also varies by anatomic location. Carcinomas of the prostatic urethra are of transitional cell origin in 90% and of squamous cell origin in 10%;

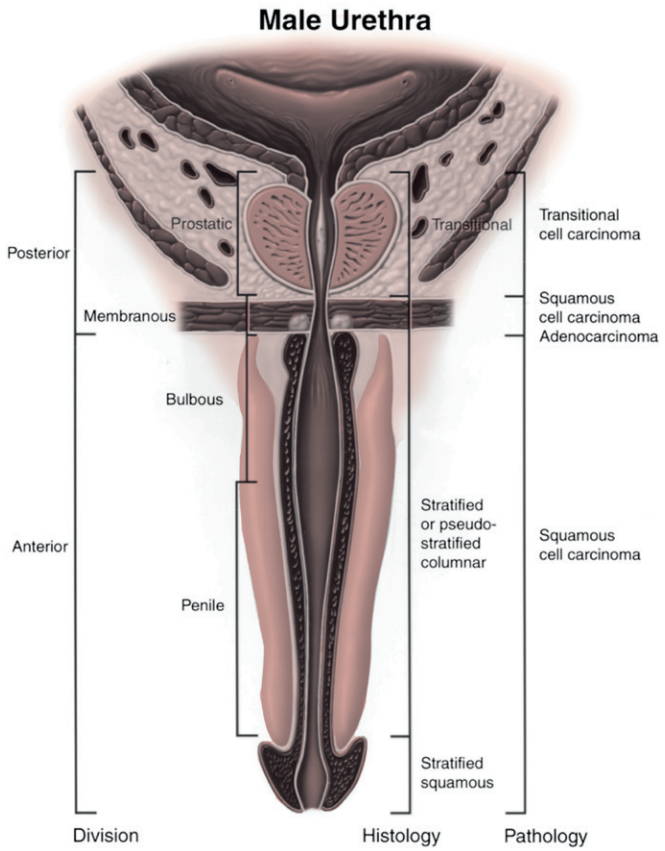

Figure 35–28. Anatomic regions of the male urethra and corresponding histology and histopathology.

carcinomas of the penile urethra are of squamous cell origin in 90% and of transitional cell origin in 10%; and carcinomas of the bulbomembranous urethra are of squamous cell origin in 80%, of transitional cell origin in 10%, and adenocarcinoma or undifferentiated in 10% (Grigsby and Herr, 2000).

Male urethral carcinoma can spread by direct extension to adjacent structures, usually involving the vascular spaces of the corpus spongiosum and the periurethral tissues, or it can metastasize through lymphatic embolization to regional lymph nodes. The lymphatics from the anterior urethra drain into the superficial and deep inguinal lymph nodes and occasionally into the external iliac lymph nodes. Tumors of the posterior urethra most commonly spread to the pelvic lymph nodes. Palpable inguinal lymph nodes occur in about 20% of cases and almost always represent metastatic disease, in contrast to penile cancer, in which a large percentage of palpable nodes may be inflammatory. Hematogenous dissemination is uncommon except in advanced disease.

Evaluation and Staging

The tumor, nodes, metastasis (TNM) staging classification is based on depth of invasion of the primary tumor and presence or absence of regional lymph node involvement and distant metastasis (Table 35–1). Examination under anesthesia, consisting of cystoscopy and bimanual palpation of the external genitalia, urethra, rectum, and perineum, aids in evaluating the extent of local involvement by tumor. Transurethral or needle biopsy of the lesion is also performed. Cytologic studies of voided urine do not seem to be a reliable method for diagnosis of primary urethral carcinoma. In one study, sensitivity was greatest in men with transitional cell carcinoma (80%) and in those with tumors involving the pendulous urethra (73%) (Touijer and Dalbagni, 2004). If rectal involvement is suspected on bimanual examination or by the patient's symptoms, an evaluation of the lower colon by barium enema study and flexible sigmoidoscopy is recommended to assist with surgical planning. Local soft tissue involvement, lymph node involvement, and bone extension are best evaluated by a computed tomographic scan of the abdomen and pelvis or by magnetic resonance imaging. Magnetic resonance imaging may be helpful for detecting invasion of the corpora cavernosa and is a useful staging modality (Vapnek et al, 1992).

Table 35–1.

Urethral Cancer TNM Staging System

Primary Tumor (T) (Male and Female)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades any of the following: corpus spongiosum, prostate, periurethral muscle
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck
T4	Tumor invades other adjacent organs
Transitional Cell Carcinoma of the Prostate	
Tis-pu	Carcinoma in situ, involvement of the prostatic urethra
Tis-pd	Carcinoma in situ, involvement of the prostatic ducts
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension)
T4	Tumor invades other adjacent organs (invasion of the bladder)
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but less than 5 cm in greatest dimension; or in multiple nodes, none greater than 5 cm
N3	Metastasis in a lymph node greater than 5 cm in greatest dimension
Distant metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Treatment

As in penile carcinoma, the primary form of treatment for men with urethral carcinoma is surgical excision. **In general, anterior urethral carcinoma is more amenable to surgical control, and the prognosis is better than that of posterior urethral carcinoma, which is often associated with extensive local invasion and distant metastasis** (Zeidman et al, 1992). A large series reported overall survival rates of 83% for low-stage tumors, 36% for high-stage tumors, 69% for anterior tumors, and 26% for those in the posterior urethra (Dalbagni et al, 1999).

Carcinoma of the Penile Urethra

Transurethral resection, local excision, or distal urethrectomy and perineal urethrostomy may be acceptable treatment in selected patients with superficial, papillary, or low-grade tumors. Long-term disease-free survival has been reported in this setting (Mandler and Pool, 1966; Konnak, 1980; Gheiler et al, 1998; Hakenberg et al, 2001). Squamous cell carcinoma in situ of the perimeatal glans may extend into the distal urethra (Fig. 35–29) and has been successfully treated with partial glansectomy and distal urethrectomy with simultaneous urethral reconstruction (Nash et al, 1996) or penile urethrostomy (Fig. 35–30). **Partial penectomy with a 2-cm negative margin is the treatment of choice for tumors infiltrating the corpus spongiosum and localized to the distal half of the penis. Excellent local control after this procedure has been documented** (Kaplan et al, 1967; Ray et al, 1977; Anderson and McAninch, 1984; Hopkins et al, 1984; Dinney et al, 1994; Gheiler et al, 1998). If invasive disease extends to or involves the proximal penile urethra, total penectomy is required to obtain an adequate margin of excision (Fig. 35–31). In the largest series to date, a local recurrence rate of 13% was reported after this procedure (Kaplan et al, 1967).

Accurate staging is important to avoid underestimation of the proximal extent of the tumor. Review of previous data would suggest that radical penectomy is an insufficient operation for bulbous urethral tumors (Zeidman et al, 1992). There have been limited reports of urethrectomy alone with perineal urethrostomy for infiltrating tumors confined to the corpus spongiosum (Hakenberg et al, 2001). The benefits of this more conservative approach need to be weighed against the probability of local relapse or dissemination of disease. **Ilioinguinal lymphadenectomy is indicated in the presence of palpable inguinal lymph nodes without evidence of metastatic disease. Benefit from prophylactic inguinal lymph node dissection has not been demonstrated in urethral cancer.**

Carcinoma of the Bulbomembranous Urethra

Early lesions of the bulbomembranous urethra have been treated successfully by transurethral resection or by segmental excision of the involved urethral segment with an end-to-end anastomosis. Unfortunately, cases appropriate for limited resection are rare. **Poor survival figures have been recorded for all forms of treatment, but it appears that radical excision offers the best opportunity for long-term disease control and the lowest incidence of local recurrence.** Radical cystoprostatectomy, pelvic lymphadenectomy, and total penectomy are usually required. Extending the operation to include in-continuity resection of the pubic rami and the adjacent urogenital diaphragm may improve the margin of resection and local control (Mackenzie and Whitmore, 1968; Shuttleworth and Lloyd-Davies, 1969; Bracken, 1982; Klein et al, 1983; Dinney et al, 1994).

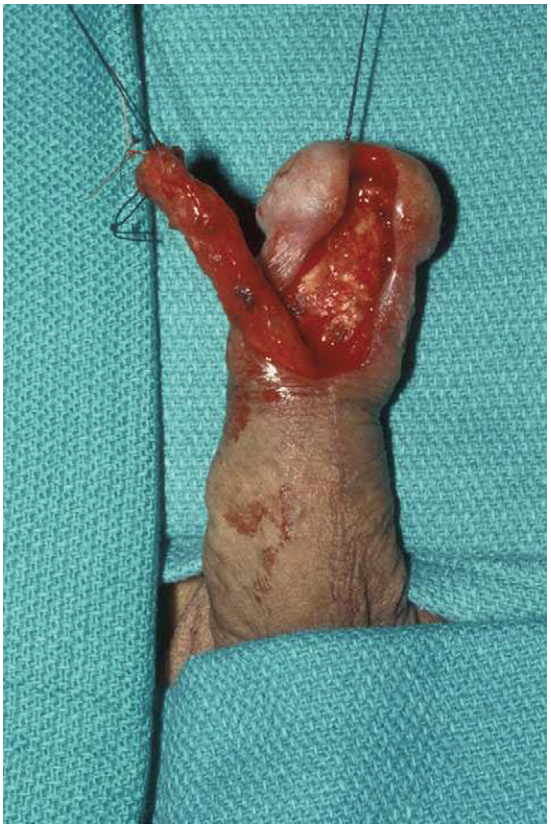

Figure 35–30. Partial glansectomy and distal urethrectomy (same patient as in Figure 35–29). After negative margins were ensured, penile urethrostomy completed the procedure.

Figure 35–29. Squamous cell carcinoma in situ (erythroplasia of Queyrat) of the glans penis surrounding the urethral meatus. The patient also had significant extension of disease into the distal urethra.

Figure 35–31. Large penile mass in a patient with transitional cell carcinoma of the penile urethra.

With the patient in low lithotomy position to allow perineal access, the standard abdominal mobilization of the bladder is completed, except for preservation of the endopelvic fascia and the anterior pubic attachments. A modified lambda or inverted U-shaped perineal incision is performed, based just medial to the ischial tuberosities, with the apex in the midperineum. The ischiorectal fossae are developed as in perineal prostatectomy, and a tunnel is bluntly dissected just anterior to the rectum, extending from one fossa to the other. The inferior skin flap is mobilized by sharply dividing the intervening subcutaneous tissue and rectourethral muscle. The superior flap is mobilized by sharply incising the subcutaneous tissue to the superficial Colles fascia and then continuing bilaterally to the adductor musculature at the inferior pubic rami. Circumferential incision of the skin and dartos fascia at the penoscrotal junction is performed, and the corporeal bodies are mobilized for a short distance proximally from the superior aspect of the symphysis pubis to allow subsequent inferior pubectomy. Care must be taken not to carry this dissection too far proximally to avoid breaching the anterior aspect of a locally advanced tumor. The penis is passed downward through the perineal incision. Wider exposure may be gained by dividing the scrotum in the midline if necessary. The scrotum can usually be preserved; however, bulky tumors may necessitate sacrifice of portions of the scrotum or perineal skin. In this setting, the testicles may be preserved in thigh pouches.

To complete the pubic arch resection, the adductor musculature is sharply divided bilaterally from the length of the inferior pubic ramus along the medial margin of the obturator foramen. A Gigli saw is passed along the inferior ramus just posterior to the origins of the transverse perineal musculature. An inferiorly beveled transection is made bilaterally to simplify perineal delivery of the specimen. Alternatively, an osteotome may be used for this purpose. The entire symphysis may be resected for bulky urethral lesions involving the presymphyseal tissues. This is accomplished by division of the superior rami at their junction with the symphysis. For most lesions, however, the bulk of the symphysis can be preserved with resection of the subsymphyseal arch. This procedure is preferred, when possible, to preserve stability of the pelvic girdle, and it results in a much smaller pelvic floor defect. A Gigli saw passed through the obturator foramina, or an osteotome is used to incise the symphysis transversely, joining the foramina (Fig. 35–32). The specimen is delivered en bloc (Fig. 35–33). After hemostasis is secure, the omentum is mobilized to cover the bowel. Large pelvic floor defects, such as occurring after total pubectomy, may be managed with a rectus abdominis muscle flap placed as a pelvic sling. Myocutaneous flaps can be fashioned to close large full-thickness perineal defects (Larson and Bracken, 1982).

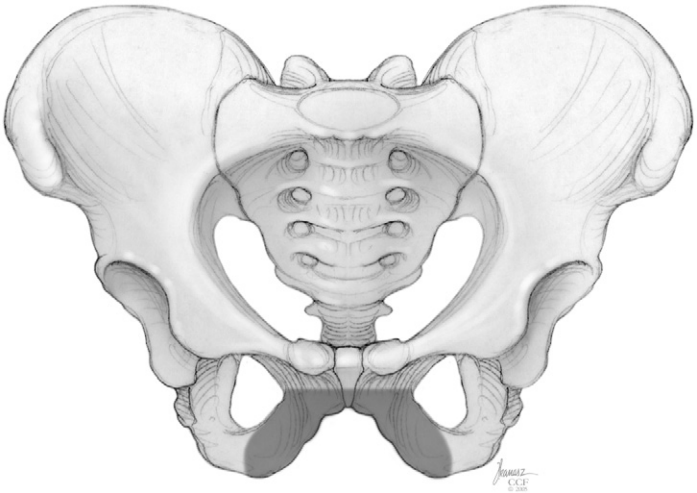

Figure 35–32. Shaded area outlines the portions of the ischiopubic rami excised at the time of inferior pubectomy during radical excision of bulbomembranous urethral cancer. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2003-2010. All Rights Reserved.)

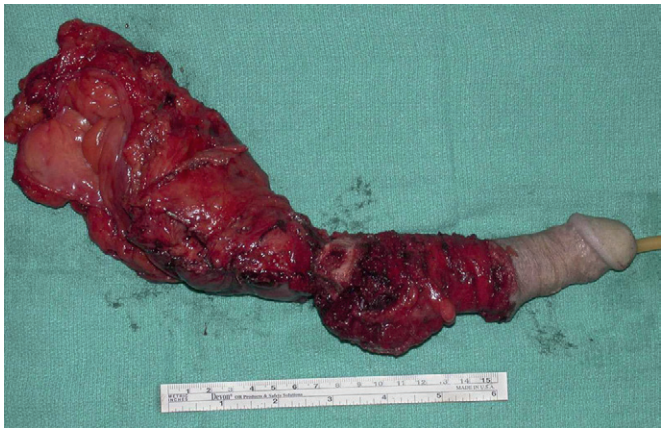

Figure 35–33. Surgical specimen after radical cystoprostatectomy, urethrectomy, penectomy, and inferior pubectomy for a large bulbomembranous squamous cell carcinoma.

Radiation Therapy and Chemotherapy

Although some instances of tumor control by irradiation have been reported, in general, radiation therapy has been reserved for patients with early-stage lesions of the anterior urethra who refuse surgery. The most commonly used technique consists of parallel opposed fields with the penis suspended vertically by a urethral catheter (Heysek et al, 1985). Radiation therapy has the advantage of preserving the penis, but it may result in skin ulceration or necrosis, urethral stricture, or chronic edema, and it does not prevent new tumor occurrence. The long-term results of radiotherapy are difficult to evaluate because few reports are available of patients treated with this modality (Raghavaiah, 1978; Forman and Lichter, 1992).

A small number of studies have reported the results of neoadjuvant and adjuvant combination chemotherapy in patients with advanced-stage or metastatic disease. A regimen including methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC) has been noted to have activity against transitional cell carcinoma but was ineffective against other tumor histologic types (Scher et al, 1988). Dinney and colleagues (1994) reported long-term survival in four of eight patients who presented with metastatic urethral carcinoma and were treated with cisplatin-based chemotherapy and surgical excision. On the basis of this experience, their favored regimen consisted of cisplatin, bleomycin, and methotrexate for squamous cell carcinoma and M-VAC for transitional cell carcinoma.

The combination of chemotherapy and radiation therapy has shown some success in a small number of patients with localized and metastatic urethral cancer (Licht et al, 1995; Oberfield et al, 1996). More commonly, these forms of treatment are combined with surgery in a multimodal approach in patients with advanced stage or metastatic disease (Johnson et al, 1989; Gheiler et al, 1998; Grigsby and Herr, 2000).

Management of the Urethra after Cystectomy

General Considerations

Contemporary series have demonstrated the incidence of urethral cancer recurrence that follows cystoprostatectomy to range from 2.1% to 11.1% after cutaneous diversion (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004) and 0.5% to 4% after construction of an orthotopic neobladder (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004; Varol et al, 2004). Early studies indicated that transitional cell carcinoma involving the prostatic urethra, particularly with stromal invasion, significantly increased the probability of postoperative urethral recurrence (Hardeman and Soloway, 1990; Freeman et al, 1996). **However, the low incidence of urethral recurrence after orthotopic bladder replacement has led most surgeons to feel comfortable proceeding with this form of diversion, as long as the findings on frozen-section biopsy of the distal prostatic urethral margin are normal at the time of cystoprostatectomy** (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004).

Approximately 40% of urethral recurrences are diagnosed within 1 year after cystoprostatectomy, with a median time to diagnosis of 18 months (Clark et al, 2004). However, a number of cases of late urethral recurrence have been reported, indicating the need for prolonged surveillance in these patients (Schellhammer and Whitmore, 1976; Freeman et al, 1996). Urethral wash cytology has traditionally been recommended for urethral monitoring after cutaneous diversion and leads to earlier diagnosis of urethral recurrence than when evaluation is delayed until symptoms occur. However, the presumed survival benefit afforded by surveillance with urethral wash cytology over symptomatic presentation has been called into question (Lin et al, 2003). Voided urine cytology is part of standard surveillance in patients who have undergone orthotopic diversion. Patients with positive results of urine or urethral wash cytology or symptoms of urethral bleeding, discharge, or palpable mass are evaluated with cystoscopy and biopsy. Pelvic computed tomography or magnetic resonance imaging may be necessary to aid in assessment of the local extent of larger invasive tumors and to assess for metastatic disease. Patients who develop urethral carcinoma in situ after orthotopic diversion may respond to urethral perfusion with bacillus Calmette-Guérin, but this treatment is ineffective for those with papillary or invasive disease (Varol et al, 2004).

Total Urethrectomy after Cutaneous Diversion

The high or exaggerated lithotomy position provides optimal exposure for total urethrectomy, with the hips and knees gently flexed and the lower limbs abducted in boot-type stirrups. A modified lambda or midline perineal incision (Fig. 35–34) is made, and the subcutaneous tissue and bulbospongiosus muscle are then divided in the midline and retracted to expose the corpus spongiosum. The corpus spongiosum is mobilized circumferentially near the level of the mid-bulbous urethra, and traction is applied to facilitate sharp dissection of the urethra distally, thus separating the corpus spongiosum from the adjacent corpora cavernosa. As dissection proceeds distally, the penis becomes inverted, the corpora cavernosa become bowed, and the glans recedes into the phallus. The penis is essentially turned inside out onto the perineum, and the dissection is completed to the base of the glans. To excise the meatus and glandular urethra, the penis is replaced in its anatomic position, and an incision is made around the meatus and extended on each side down the ventral aspect of the glans. The distal urethra is then freed from its investments within the glans, and the isolated pendulous urethra is delivered onto the perineum. The deep spongiosum of the glans penis is reapproximated with 4-0 polydioxanone sutures in a horizontal mattress fashion; the surface layer is closed with interrupted 4-0 chromic.

Proximal sharp dissection of the urethral bulb is carried out posteriorly and laterally, staying close to the bulb but avoiding entry, if possible, because bothersome bleeding will result. The urethra is detached from the corporeal bodies anteriorly to the level of the departure of the urethra from the bulb, leaving the specimen attached only by the membranous urethra itself. The bulbar arteries are usually identified at the 4-o'clock and 8-o'clock positions just inferior to the perineal membrane after they are transected during the posterior bulb dissection. They are controlled with electrocautery or suture ligature, or they can be ligated if they are identified before transection. **Care must be exercised in completing the proximal dissection, in view of the possible postcystectomy adherence of intestine to the superior surface of the urogenital diaphragm.** This should be done under direct vision, and exposure can be aided by separating the crura of the corporeal bodies in the midline to open the intracrural space. All that remains of the membranous urethra proximally is an ill-defined fibrotic band, and it should be completely excised. Frozen-section analysis of this region adds some assurance that a negative proximal margin has been attained. A small suction drain is placed in the urethral bed and brought out through the perineum. Closure of the bulbospongiosus muscle, subcutaneous tissue, and skin with interrupted absorbable sutures completes the procedure, and a light pressure dressing is applied. Superficial hematoma, edema along the penile shaft, and infection are uncommon complications.

Total Urethrectomy after Orthotopic Diversion

Total urethrectomy after orthotopic urinary diversion is performed through an abdominoperineal approach. The patient is placed in

Key Points: Male Urethral Cancer

- Eighty percent of male urethral cancers are squamous cell carcinoma, and the region most commonly involved is the bulbomembranous urethra.
- In general, anterior urethral carcinoma is more amenable to surgical control, and the prognosis is better than that of posterior urethral carcinoma, which is often associated with extensive local invasion and distant metastasis.
- As opposed to penile carcinoma, benefit from prophylactic inguinal lymph node dissection has not been demonstrated in urethral cancer.
- The low incidence of urethral recurrence after orthotopic bladder replacement has led most authors to feel comfortable proceeding with this form of diversion, as long as the findings on frozen-section biopsy of the distal prostatic urethral margin are normal at the time of cystoprostatectomy.
- In converting a patient to cutaneous conduit urinary diversion, bowel from the existing orthotopic neobladder can often be reconfigured with its blood supply intact and used for this purpose.

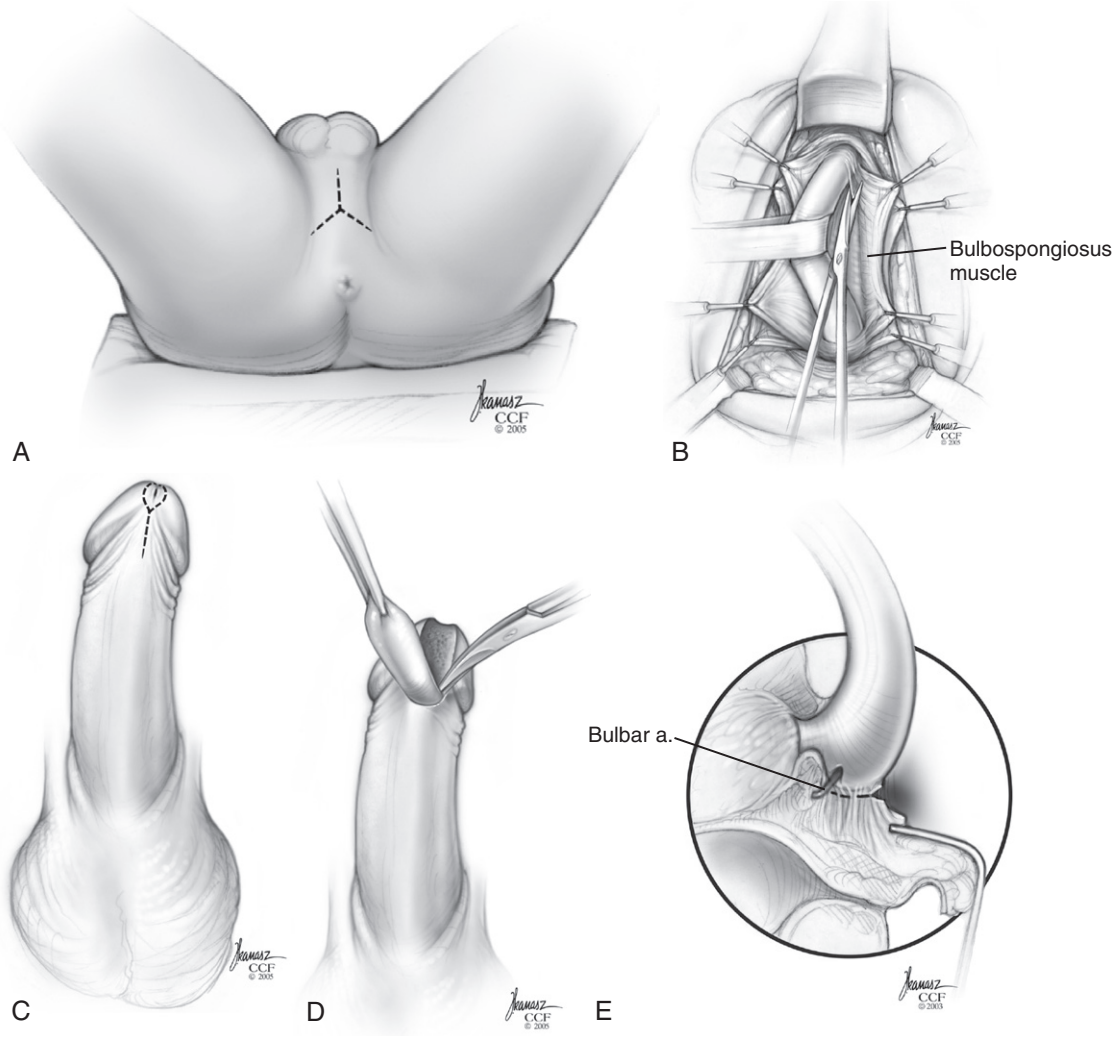

Figure 35–34. Secondary urethrectomy after previous cystoprostatectomy. **A,** Perineal incision. **B,** Division of bulbospongiosus muscle to expose the bulb of the corpus spongiosum and initial dissection of the urethra off of the corporeal bodies. **C,** Distal incision circumscribing the urethral meatus. **D,** Distal urethral dissection, which then connects to the proximal dissection at the level of the distal shaft. **E,** Sagittal view demonstrating posterior bulb dissection and location of the bulbar artery. lithotomy position with boot-type stirrups that can be adjusted during the procedure. Urethrectomy is carried out to the level of the membranous urethra. Abdominal exploration with lysis of adhesions and mobilization of the orthotopic neobladder is done to the level of the urethral anastomosis. Working with careful palpation from above and below, the area of the membranous urethra and the anastomosis are dissected free in their entirety. A circular area of the pouch adjacent to the anastomosis is excised to ensure an adequate surgical margin, and the specimen is delivered through the perineum. Bleeding from the musculature within the tunnel developed during excision of the membranous urethra can be bothersome and is best controlled with suture ligatures.

In most situations, urinary diversion is accomplished with an ileal conduit. **This can often be carried out with use of bowel from the orthotopic neobladder, which may be reconfigured when necessary, with care taken to incise the bowel along visible lines of previous closure with preservation of the mesenteric blood supply.** The remaining portions of the pouch are excised. If the existing diversion has an afferent limb (Studer pouch, for example), this segment can be used to construct the conduit without the need for manipulation of the ureters (Bissada et al, 2004). Conversion to a continent cutaneous diversion may also be possible in selected patients, depending on intra-abdominal anatomy and the motivation of the patient (Bartoletti et al, 1999).

FEMALE URETHRAL CANCER

Epidemiology, Etiology, and Clinical Presentation

Female urethral carcinoma is rare and accounts for approximately 0.02% of all female cancers (Fagan and Hertig, 1955) and less than 1% of cancers in the female genitourinary tract (Srinivas and Khan, 1987). More than 1200 cases are reported in the literature, most diagnosed in the fifth and sixth decades of life (Srinivas and Khan, 1987). Incidence appears to increase with age regardless of histologic subtype. Previous literature had suggested that despite the female urethra being much shorter than in the male, primary cancers of the urethra were more common than in men (Narayan

and Konety, 1992). However, a more recent study has called this into question. Swartz and colleagues studied the incidence of primary urethral carcinoma in the United States and found that based on information from the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database that 1615 cases were identified between 1973 and 2002, including 1075 men and 540 women (Swartz et al, 2006). Therefore the SEER data suggests that there is a 2:1 male to female predominance. In addition, it had previously been noted that approximately 85% of urethral carcinomas occur in white women (Terry et al, 1997). However, analysis of the SEER data revealed an overall annual incidence of 1.5 cases per million women, including 4.3 cases per million African-American women and 1.3 per million white women (Swartz et al, 2006). Although it is possible that misclassification of the site of origin of tumors within the SEER database has lead to some inaccuracy in the above findings, previous studies may also be biased by the tertiary referral center populations from which they originate.

Although the cause of urethral carcinoma in women has not been identified, several factors have been implicated. **Etiologic factors associated with the development of urethral carcinoma include leukoplakia, chronic irritation, caruncles, polyps, parturition, and human papillomavirus infection or other viral infections** (Mevorach et al, 1990; Grigsby and Herr, 2000). Female urethral diverticula may also predispose the patient to malignant change, with perhaps 5% of female urethral carcinomas arising within a diverticulum (Rajan et al, 1993).

Ninety-five percent to 98% of patients are symptomatic at presentation. Many patients will present with obstructive symptoms, dysuria, urethral bleeding, urinary frequency, and often a palpable urethral mass or induration. A suspicion of a urethral tumor should be raised in any otherwise healthy middle-aged woman without prior urologic history who presents in urinary retention. Patients may also present with a small lesion prolapsing through the urethral meatus or with a small submucosal lesion on the anterior wall off the vagina. Tumors spread typically by local extension and may ulcerate as the tumor progresses to the skin and vulvar region. Proximal lesions may extend posteriorly into the vagina or proximally into the bladder. Lymphatic spread is uncommon at early stages, but clinically palpable nodes may be present in up to one third of patients at presentation and half of patients with advanced and proximal tumors (Grabstald et al, 1966). Hematogenous spread may occur to the lung, liver, bone, and brain, in order of frequency (Forman and Lichter, 1992).

Anatomy and Pathology

See Fig. 35–35 on the Expert Consult website.

Diagnosis and Staging

The evaluation of women with suspected urethral carcinoma includes cystourethroscopy, examination under anesthesia, computed tomography of the abdomen and pelvis, and chest radiography. Magnetic resonance imaging has been used to evaluate pelvic lesions and may help determine local extension. Serum prostate-specific antigen has been found to be elevated in a small number of case reports of females with adenocarcinoma, and it appears only a minority of female patients with primary adenocarcinoma of the urethra have this elevated tumor marker (Dodson et al, 1994; Pongtippan et al, 2004). TNM staging for female urethral cancer is identical to that for male urethral cancer (see Table 35–1). Clinically palpable inguinal nodes are found in 30% of patients overall, and these are confirmed to be malignant in approximately 90% of cases. Up to 50% of patients with proximal or advanced urethral cancers may have palpable nodes. Pelvic nodal metastases are also not uncommon, affecting 20% of cases. Metastasis outside of the pelvis at presentation is rare, however. During follow-up, another 15% of patients will develop metastatic nodal disease (Grigsby and Herr, 2000).

Treatment and Prognosis

Because of the rarity of this tumor and heterogeneity of disease, insufficient experience at any single institution within a reasonable period has precluded attempts to effectively define the natural history of the disease, recommendations for therapy, and follow-up of these patients (Grigsby and Herr, 2000). **Although it is conceivable that different histologic subtypes may affect prognosis and the propensity for route of disease spread, most studies have failed to detect any differences in survival based on histologic subtype** (Foens et al, 1991; Dimarco et al, 2004). Consequently, lesions of varying histologic type are often treated in a similar fashion.

Treatment recommendations are primarily dependent on tumor location and clinical stage. Local excision, which should lead to excellent functional results, may be sufficient for the relatively uncommon small, superficial, distal urethral tumors. For more proximal and advanced urethral tumors, a more aggressive approach is warranted. **Compared with proximal urethral cancers, distal lesions are associated with improved survival.** Five-year disease-specific survival is reported at 71% for distal lesions, 48% for proximal lesions, and 24% for lesions that involve the majority of the urethra (Dalbagni et al, 1998). Surgical and radiotherapy series reflect overall 5-year survival rates of 30% to 40%. Unfortunately, little improvement has been made in treatment of this disease, and survival rates have remained statistically unchanged for the last 50 years (Bracken et al, 1976; Prempree et al, 1984; Foens et al, 1991; Dalbagni et al, 1998; Dimarco et al, 2004). Options for treatment of female urethral carcinoma include surgery, radiation therapy, and chemotherapy, alone or in combination. Treatment has trended toward a multimodality approach in recent years. As representative of a heterogeneous group of studies, with varying treatment techniques and follow-up, and based on primary treatment modalities, Tables 35–2 and 35–3 summarize results for early and advanced disease, respectively, taken from study series having more than two patients.

Distal Female Urethral Carcinoma

Small, exophytic, superficial tumors arising from the urethral meatus or anterior urethra may be surgically treated with circumferential excision of the distal urethra and inclusion of a portion of the anterior vaginal wall. The distal third of the urethra may be excised while urinary continence is maintained. Frozen-section specimens of the proximal urethra should be obtained to ensure an adequate margin (Narayan and Konety, 1992). Laser coagulation of small distal tumors has been described (Staehler et al, 1985; Dann et al, 1989). In select patients with T2 or T3 cancer, bladder-sparing strategies have also been employed, if the tumor is more anterior, while an attempt is made to maintain a thorough resection. Dimarco and colleagues (2004) describe radical urethrectomy in the female patient, including excision up to the level of the bladder neck with wide resection of periurethral tissues and anterior vaginal wall. Urinary diversion is then accomplished with a catheterizable stoma (ileovesicostomy or appendicovesicostomy) to the native bladder. **Tumors in the distal urethra tend to**

[6]No evidence of disease at 6 months and 4 years.
[7]No evidence of disease at 1.5 and 4 years.

be low stage, and cure rates of 70% to 90% have been achieved with local excision alone. However, in a study by Dimarco and colleagues (2004), 21% of patients with stage T2 tumors, or less, treated with partial urethrectomy had local recurrence. Other studies of partial urethrectomy, with or without radiation therapy, for lower-stage lesions have recurrence rates of 0% to 50% (Hahn et al, 1991; Gheiler et al, 1998). Meatal stenosis is a common complication, and incidence may be decreased by spatulation of the urethra. Approximation of the anterior vaginal wall and labia may help prevent urinary incontinence, although a sling procedure or other procedure to treat urinary incontinence may need to be subsequently performed. Many authors report minimal complications and rare incontinence from partial urethrectomy, but one series noted de novo or worsening stress urinary incontinence in 42% of patients (Dimarco et al, 2004).

Radiation therapy, as well as surgery, has proved effective for the treatment of low-stage distal urethral carcinomas. An overall 5-year actuarial survival rate of 41% was reported by Garden and colleagues (1993) in a series of 84 patients. This was subdivided into 5-year survival of 74% if only part of the urethra was involved, and 55% if the entire urethra was involved. Survival appeared to be associated with clinical stage of the tumor (Garden et al, 1993). Radiation may be delivered as external beam, brachytherapy, or combined therapy. In a series of 42 patients treated at the University of Iowa, radiotherapy delivered with combined interstitial and external beam radiation provided fewer local failures (14%) than all radiation-treated patients (36%) or those treated by surgery alone (60%). However, 5-year survival rates for irradiated and surgically treated groups are similar (Foens et al, 1991). Although doses may vary widely, a dose of between 55 and 70 Gy is reported in most series. Complication rates, now decreasing, have ranged from 20% to 40%, including urinary incontinence, urethral strictures, necrosis, fistula formation, cystitis, vulvar abscess, and cellulitis (Forman and Lichter, 1992).

Significant morbidity has been noted with ilioinguinal lymphadenectomy. In addition, female urethral carcinoma often spreads systemically without regional lymph node involvement. Although studies are small, there has been no evidence for improved survival after pelvic or inguinal lymphadenectomy (Grabstald et al, 1966; Levine, 1980; Dimarco et al, 2004). These findings, as well as the inability to prognosticate likelihood for micrometastatic lymph node involvement, have led to the recommendation against prophylactic or diagnostic lymphadenectomy. **Acknowledging that few objective data exist for making definitive decisions, recommendations for performing groin dissection have been made only for patients who present with positive inguinal or pelvic lymphadenopathy without distant metastasis, or patients who develop regional adenopathy during surveillance.** Late inguinal lymph node recurrences up to 7 years have been noted. The technique of ilioinguinal lymphadenectomy is identical to the dissection performed in men for penile cancer (Narayan and Konety, 1992; Grigsby and Herr, 2000).

In patients with recurrent or radioresistant tumors, neoadjuvant irradiation followed by local excision has resulted in a survival advantage over radiotherapy alone (Grabstald et al, 1966; Peterson et al, 1973; Allen and Nelson, 1978). Despite early and aggressive therapy for anterior lesions, local recurrence rates and mortality

remain high. Further studies are necessary to evaluate the potential role of multimodality therapy in these patients.

Proximal Female Urethral Carcinoma

Proximal female urethral carcinomas are more likely to be high stage and may extend into the bladder and vagina. Results with anterior exenteration alone resulted in a 10% to 17% 5-year survival rate and a local recurrence rate of 67% (Bracken et al, 1976; Klein et al, 1983). The poor disease-specific survival and high local recurrence rates observed with single-modality treatment of advanced female urethral carcinoma have led to the recommendation of combination therapy (Dalbagni et al, 1998, 2001; Gheiler et al, 1998). Advanced female urethral carcinoma includes tumors in a proximal location, a lesion that encompasses the entire urethra, or a locally invasive lesion that involves external genitalia, vagina, or bladder. Anterior exenteration (cystourethrectomy), pelvic lymph node dissection, and wide vaginal or complete vaginal excision are often required to obtain negative surgical margins. If the lesion extends into the external genitalia, partial vulvectomy or labial excision may be necessary. Anterior exenteration is performed as for bladder cancer in a female patient, with a more extensive perineal portion of the procedure to provide wide margins around the urethra. The margins of the lymphadenectomy should include the Cloquet node distally and otherwise retain limits identical to the dissection encouraged for lymphadenectomy in bladder cancer. Anterior exenteration includes the en bloc removal of the entire urethra and bladder, the uterus and adnexa, and the anterior and lateral vaginal walls. On occasion, the entire vagina may need to be resected. The perineal portion is initiated by completing an inverted U-shaped incision to encircle widely around the urethral meatus. It has been suggested that this incision be extended onto the posterior vaginal wall to the labia minora and continued anteriorly to beyond and including the clitoris (Narayan and Konety, 1992). En bloc resection of the pubic symphysis and inferior pubic rami may be necessary if the lesion encroaches anteriorly at the pubis, although the necessity of bone resection has been questioned in ensuring durable local control when intraoperative irradiation is added in suspect cases (Dalbagni et al, 2001).

Radiotherapy alone for proximal invasive urethral carcinoma has yielded poor local control, and 5-year survival rates of 0% to 57% are reported (Grabstald et al, 1966; Johnson and O'Connell, 1983; Prempree et al, 1984; Narayan and Konety, 1992). An improved mean survival rate of 54% at 5 years has resulted from the combination of radiation therapy and surgery for high-stage disease (Moinuddin Ali et al, 1988; Terry et al, 1997).

A combination of chemotherapy, radiation therapy, and surgery has been recommended for optimal local and distant disease control in advanced female urethral cancer. Patients whose treatment fails are thought likely to harbor micrometastatic disease at the time of primary treatment. For patients with squamous cell carcinoma, in part because of its effectiveness against anal cancers, 5-fluorouracil plus mitomycin C has been the most common empirically chosen regimen (Kalra et al, 1985). For transitional cell cancers, either M-VAC (methotrexate, vinblastine, doxorubicin, and cisplatin) or a gemcitabine regimen is recommended (Grigsby and Herr, 2000). Chemotherapy given concomitantly with radiation therapy has been shown to interfere with cell repair and thus act as a radiosensitizer. It is hoped that this rationale may serve to decrease local recurrence and improve survival by eliminating micrometastatic disease and preventing progression of local failures to systemic failures. The group at Memorial Sloan-Kettering has shown early results based on six patients with advanced proximal urethral tumors treated with a multimodality approach. The authors suggest that anterior exenteration with high-dose intraoperative brachytherapy followed by external beam radiation seems to improve local control. Studies must evaluate whether combined modality therapy proves to decrease distant metastasis and improve survival (Dalbagni et al, 1998, 2001).

Urethral Recurrence after Cystectomy in Women

Orthotopic neobladder construction in women is now an established form of urinary diversion after radical cystectomy for transitional cell carcinoma. **The incidence of carcinoma involving the urethra in female patients undergoing cystectomy for bladder cancer ranges from 1% to 13%** (Coloby et al, 1994; Stein et al, 1995, 1998; Stenzl et al, 1995). There is still debate whether involvement of the bladder neck is a contraindication to orthotopic diversion; a prospective study has revealed that although all patients with urethral transitional cell carcinoma on final pathologic analysis of the cystectomy specimen had involvement of the bladder neck, more than 60% of women with bladder neck involvement had no evidence of urethral transitional cell carcinoma (Stein et al, 1998). Intraoperative frozen-section analysis of the urethral stump has been subsequently espoused by some authors to determine the feasibility of urethra-sparing cystectomy and orthotopic diversion (Stein et al, 1998).

Despite the reported incidence of urethral involvement in cystectomy patients and the increased use of orthotopic diversion in women, there are few reported cases of subsequent urethral malignant neoplasms in patients who have undergone this procedure. A review of 1054 patients undergoing radical cystectomy at a single center with a median follow-up of 10 years included 211 women, 44 of whom had an orthotopic urinary diversion. None of the 44 women developed a urethral recurrence (Clark et al, 2004). More recently, the group from the University of Southern California reported their first case of primary urethral recurrence in their series of female patients undergoing orthotopic urinary diversion. The patient remained without evidence of disease at 4 years of follow-up after total urethrectomy, resection of neobladder neck, and conversion of the orthotopic reservoir to a continent cutaneous urinary diversion (Stein et al, 2008). In a study by Ali-el-Dein and colleagues (2004), 145 women underwent orthotopic urinary diversion, 61% for squamous cell carcinoma and 21% for transitional cell carcinoma. At a median follow-up of 56 months, two patients (1.4%) developed an isolated urethral recurrence. One patient was reportedly not a surgical candidate, and the other patient underwent urethrectomy and conversion to a continent cutaneous reservoir but died 8 months later (Ali-el-Dein et al, 2004). One additional report described urethral transitional cell carcinoma in a woman after orthotopic diversion. This patient had a high-grade lesion of the bladder base with evidence of nodal metastasis. The patient was treated initially with chemotherapy, followed by urethral resection and conversion to a continent cutaneous diversion. The patient died 5 months later with visceral metastases (Jones et al, 2000). Limited experience to date precludes the ability to make definitive treatment recommendations for women with urethral cancer recurrence after orthotopic diversion. Urethrectomy and surgical resection of the area of the urethra-pouch anastomosis with conversion to a continent cutaneous urinary diversion seem feasible and reasonable in the absence of metastatic disease. Conversion to a cutaneous urinary conduit with use of reconfigured bowel from the existing orthotopic diversion is another option (Bissada et al, 2004).

Key Points: Female Urethral Cancer

- Squamous cell carcinoma is the most common histologic type of urethral cancer in women, accounting for 50% to 70% of all cases.
- Most studies have failed to detect any differences in survival based on histologic subtype.
- Compared with proximal urethral cancers, distal lesions are associated with improved survival.
- Tumors in the distal urethra tend to be low stage, and cure rates of 70% to 90% have been achieved with local excision alone.
- Proximal female urethral carcinomas are more likely to be high stage and may extend into the bladder and vagina.
- A combination of chemotherapy, radiation therapy, and surgery has been recommended for optimal local and distant disease control in advanced female urethral cancer.
- In appropriately selected women undergoing orthotopic diversion for bladder cancer, recurrence of cancer in the retained urethra is a rare event.

Vesicourethral Distraction Defects
Complex Fistulas of the Posterior Urethra
Curvatures of the Penis
Total Penile Reconstruction
Female-to-Male Transsexualism

Improvements in microsurgery, tissue transfer techniques, and tissue handling have expanded the repertoire of the urologic surgeon and the genitourinary reconstructive surgeon in particular. Urologists are now able to reconstruct congenital, and acquired genitourinary abnormalities with greater facility. Microvascular and microneurosurgical techniques have made it possible to construct a phallus that allows a patient to void while standing and to enjoy erotic sensibility. Because the phallus has both erotic sensibility and protective sensation, the patient can eventually have a prosthetic implantation that allows an acceptable sexual life. This chapter discusses the general principles of male genital reconstructive surgery; specifics include male urethral surgery, surgery for congenital and traumatic penile lesions, and complex fistula and obliterative issues associated with the posterior urethra.

PRINCIPLES OF RECONSTRUCTIVE SURGERY

Many techniques in reconstructive surgery require the transfer of tissue. Skin is one of those tissues, and **its properties vary from individual to individual and from place to place on the same individual.** Variable characteristics such as color, texture, thickness, extensibility, innate skin tension, and blood supply can be useful in various situations.

The term *tissue transfer* implies the movement of tissue for purposes of reconstruction. Unlike extirpative surgery, **the transfer of tissue for reconstruction requires an intimate knowledge of the anatomy of both the donor and the recipient sites, as well as of the principles that will allow that tissue to survive once it is transferred.**

The skin can be used as a model. The superficial layer of the skin is termed the epidermis (thickness, 0.8 to 1 mm). The deep layer of the skin is termed the dermis. The dermis has two layers: a superficial layer, the adventitial dermis (also called the papillary or periadnexal dermis, depending on the anatomy), and a deep layer, the reticular dermis. For genitourinary reconstruction, skin without adnexal structures is often used; thus, the papillary dermis is synonymous with the adventitial dermis. Other tissues commonly transferred for genitourinary reconstruction include bladder and oral mucosa. The bladder epithelium is the superficial layer of the bladder; the deep layer of the bladder is termed the lamina propria, with superficial and deep layers. The oral mucosa is the superficial layer of much of the oral cavity, which also has a deeper layer termed the lamina propria, again with superficial and deep layers.

All tissue has physical characteristics: extensibility, inherent tension, and the viscoelastic properties of stress relaxation and creep. The physical characteristics of a transferred unit are primarily a function of the helical arrangement of collagen along with the elastin cross-linkages. The collagen-elastin structure is suspended in a mucopolysaccharide matrix that influences the viscoelastic properties.

Tissue can be transferred as a graft (Fig. 36–1A and B). **The term *graft* implies that tissue has been excised and transferred to a graft host bed, where a new blood supply develops by a process termed take. Take requires approximately 96 hours and occurs in two phases. The initial phase, imbibition, requires about 48 hours.** During that phase, the graft survives by "drinking" nutrients from the adjacent graft host bed, and the temperature of the graft is less than the core body temperature. **The second phase, inosculation, also requires about 48 hours and is the phase in which true microcirculation is reestablished in the graft.** During that phase, the temperature of the graft rises to core body temperature. The process of take is influenced by both the nature of the grafted tissue and the conditions of the graft host bed. Processes that interfere with the vascularity of the graft host bed thus interfere with graft take.

The epidermal, or epithelial layer, is a covering, the barrier to the "outside," and is adjacent to the superficial dermis, or superficial lamina. At approximately that interface is the superficial plexus. In the case of skin, the plexus is the intradermal plexus. There are some lymphatics in the superficial dermal or tunica layer. On the undersurface of the deep dermal layer or deep lamina is the deep plexus. In the case of skin, this is the subdermal plexus. The deep dermis contains most of the lymphatics and greater collagen content than found in the superficial dermal

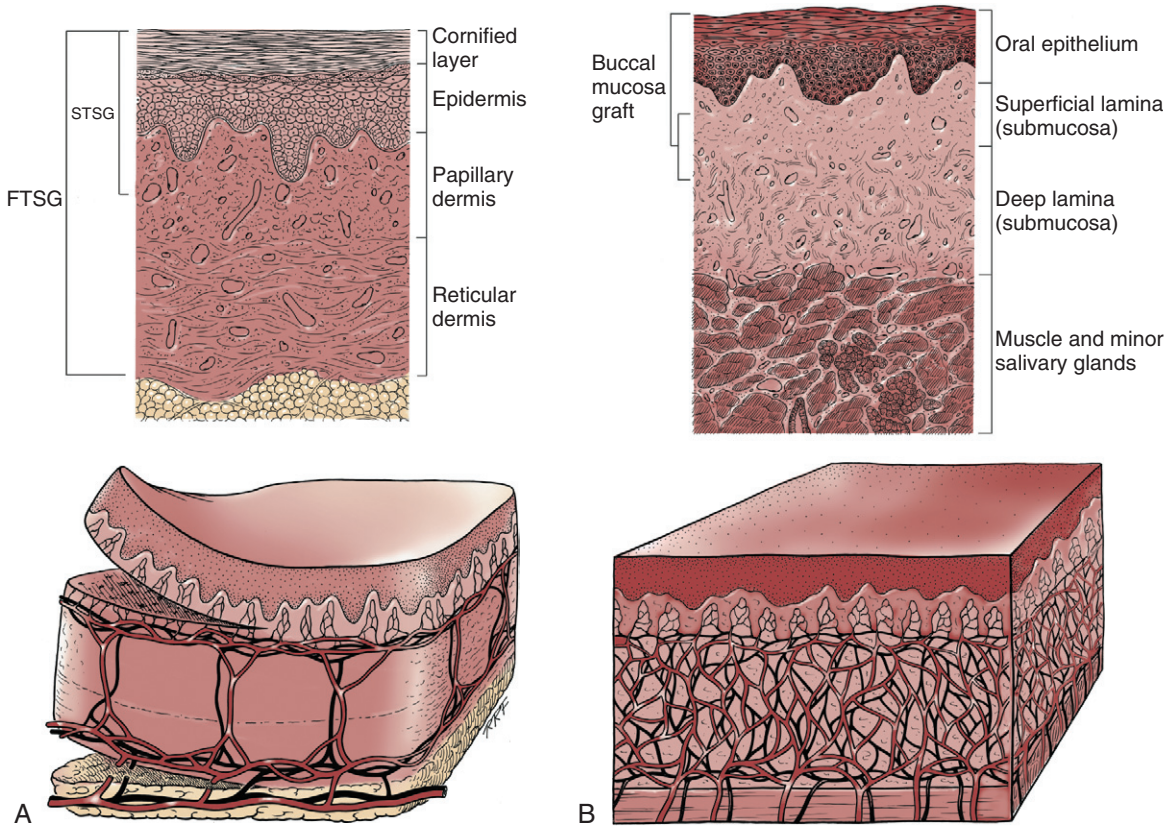

Figure 36–1. Cross-sectional diagrams (histologic appearance above, microvasculature below) of the skin. **A,** Cross-sectional diagrams of skin. **B,** Cross-sectional diagrams of oral mucosa. (From Jordan GH, Schlossberg SM. Using tissue transfer for urethral reconstruction. Contemp Urol 1993;13:23.)

layer. The deep or reticular dermis is generally thought to account for the physical characteristics of the tissue.

Thus **if a graft is a split-thickness unit, that graft carries the epidermis or the covering. That graft also exposes the superficial dermal (intradermal or intralaminar) plexus.** In most grafts, that superficial plexus is composed of small but numerous vessels. **This thus conveys favorable vascular characteristics to a split-thickness unit.** The unit has few lymphatics, and **the physical characteristics are not carried, which accounts for the tendency of split-thickness units to be brittle and less durable.** The reticular dermis is not carried with the split-thickness unit (Jordan, 1993).

The mesh graft is usually an application of the split-thickness graft. After the harvest of a sheet graft, the sheet is placed on a carrier that cuts systematically placed slits in the graft. These slits can expand the graft by various ratios (i.e., 1.5:1, 2:1, 3:1). For most genital reconstructive surgery, the slits are not for expansion but rather to allow subgraft collections to escape; in some cases, the slits allow the graft to conform better to irregular graft host beds (e.g., the testes in split-thickness skin graft scrotal construction). It has also been proposed that mesh grafts take readily because of increased levels of growth factors, possibly as a function of the slits. In general, full-thickness skin grafts are not meshed (Schreiter and Koncz, 1983; Jordan, 1993).

If a graft is a full-thickness unit, it carries the covering and the superficial dermis or lamina with all the characteristics attributable to that layer. It also, however, carries the deep dermis or deep lamina. In skin, the subdermal plexus is exposed. In most cases, **that plexus is composed of larger vessels that are more sparsely distributed. The graft is thus fastidious in its vascular characteristics.** A full-thickness unit carries most of the lymphatics, and the physical characteristics are likewise carried with the transferred tissue (Devine et al, 1976; Jordan, 1993; Wessels and McAninch, 1996). An off-the-shelf substance called Integra is currently available. Integra (Integra LifesSciences Corporation, Plainsboro, NJ 08536, 1-877-444-1122) is used to "prepare" graft recipient sites. After a period, the Integra material becomes infiltrated with granulation tissue and after about 10 days to 2 weeks can be grafted with split-thickness skin. The resultant graft is said to have both a dermal layer as well as the graft covering. We have limited experience with the material at this time.

When the grafts that are most commonly used in genitourinary reconstructive surgery are examined, **the split-thickness skin graft has favorable vascular characteristics but tends to contract** and be brittle when mature. **The full-thickness skin graft tends to have more fastidious vascular characteristics, but it does not contract as much and is more durable when mature** (see Fig. 36–1A). There is a difference between genital full-thickness skin (penile and preputial skin grafts) and extragenital full-thickness skin. This is probably a reflection of the increased mass of the graft in extragenital skin grafts. This increased mass makes the graft more fastidious, and the poor results reported with urethral reconstruction with extragenital full-thickness skin grafts are probably due to poor or ischemic take (Webster et al, 1984; Webster, 1987; Jordan, 1993). The posterior auricular graft (Wolfe graft) is an exception to the rule concerning extragenital skin. The postauricular skin is thin and overlies the temporalis fascia and is thought to be carried on

numerous perforators. The subdermal plexus of this graft thus mimics the characteristics of the intradermal plexus, and the total mass of the graft is more like that of the split-thickness unit. In the bladder epithelial graft, there is a superficial and a deep plexus; however, the plexuses are connected by many more perforators. Thus **bladder epithelial grafts tend to have more favorable vascular characteristics.** In the case of the oral **mucosal grafts, there is a panlaminar plexus.** Thus **the oral mucosal graft can be thinned somewhat, provided a sufficient amount of deep lamina is carried to preserve the physical characteristics** (see Fig. 36–1B). **The oral mucosal grafts are thought to have optimal vascular characteristics** (Humby, 1941; Memmelaar, 1947). The thinned graft diminishes the total graft mass while preserving the physical characteristics and not adversely affecting the vascular characteristics. The enthusiasm for the buccal mucosal graft thus seems well founded. The fact that the graft has a "wet epithelial" surface is likewise thought to be a favorable characteristic for many cases of urethral reconstructive surgery. The lingual, labial, and buccal grafts all vary in thickness and somewhat in substance. Because the labial mucosal grafts are thin, many surgeons prefer that donor site for reconstruction of the fossa navicularis (Jordan, 1993).

A series reporting the use of "buccal mucosal" onlay grafts with mid- and long-term results seems to suggest durability for these grafts. In that series (Fichtner et al, 2004), 67 patients were described, all with follow-up exceeding 5 years and some with 10 years of follow-up. All failures occurred within 12 months of the original procedure.

The dermal graft has been used for years to augment the tunica albuginea of the corpora cavernosa. When it is harvested, the graft exposes both the intradermal plexus and the deep dermal plexus. The dermal graft thus takes readily (is not fastidious) and has the physical characteristics normal to skin. When it is properly prepared, the tunica vaginalis graft is essentially peritoneum. The tendency of peritoneum to take readily is well documented both in the literature that examines adhesion formation and in the urology literature concerning the application of peritoneal grafts for reconstruction of the urinary tract. The literature fails to accurately define what the surgeon can expect regarding physical characteristics (Jordan, 1993). **Tunica vaginalis grafts have proved useful for small defects of the tunica albuginea of the corpora cavernosa, but there is a tendency to aneurysmal dilation when they are used for larger defects. Tunica vaginalis grafts have been tried for urethral reconstruction with uniformly poor results.**

As described in the urologic literature, vein grafts are perhaps not true grafts according to the terminology used in this chapter. Vein patches are widely used in vascular surgery. The premise is that the vein survives by endothelial direct perfusion and reestablishment of vein wall blood flow by perfusion of the vasa vasorum. The vascular literature is at odds with this concept. The intima is the endothelial layer; it is thin and easily injured during the process of vein harvest and preparation, with areas of endothelial sloughing noted. Inflammatory cells and fibrin adhere to the exposed basement membrane. However, the endothelium does regenerate in the first 6 weeks. The media is a combination of smooth muscle and interlaced collagen. After graft harvest, smooth muscle injury is prominently noted and is thought to be related to warm ischemia. In more mature grafts, much of the smooth muscle is replaced by a process of fibrous transformation with collagen deposition. The adventitia is a loose collagenous network interspersed with vasa vasorum. Mature vein grafts show evidence of take to the vasa vasorum. However, the adventitia becomes incorporated by periadventitial connective tissues. Thrombosis in the vasa vasorum, early in the process of take, is not an unusual phenomenon. When vein grafts are exposed to arterial pressure and shear stress forces, the process colloquially described as "arterialization" occurs and is associated with changes of the vessel wall elastic properties, and the graft becomes rigid with low compliance. Once these changes are noted, at least when veins are used for vessel replacement, the graft remains noncompliant throughout the remaining life of the graft (Szilagyi et al, 1973; Fuchs et al, 1978; Tolhurst and Haeseker, 1982). Vein "grafts" are currently being widely used for replacement of defects of the tunica albuginea of the corpora cavernosa. The pertinent points with regard to the transfer of vein patches to the corpora cavernosa and their long-term behavior, however, have been inferred from the current vascular literature. Dermal grafts have been tried for urethral reconstruction, also with poor results in general. **Rectal mucosal grafts have also been proposed for urethral reconstruction but little is known about their graft take. In general, the vascularity of the bowel mucosa is based on the vascularity of the underlying muscle, with the mucosa carried on perforators. Little is found in the literature regarding the process of take of these grafts.**

Tissue can be transferred as a flap. **The term *flap* implies that the tissue is excised and transferred with the blood supply either preserved or surgically reestablished at the recipient site. Flaps can be classified by a number of criteria. We can classify flaps on the basis of their vascularity and thus characterize flaps as either random flaps** (Fig. 36–2) **or axial flaps** (Fig. 36–3). **A *random flap* is a flap without a defined cuticular vascular territory.** The flap is carried on the dermal or laminar plexuses; the dimensions of random flaps can vary widely from individual to individual and from body site to body site. **The term *axial flap* means that there is a defined vessel in the base of the flap. There are three types of axial flaps. The direct cuticular axial flap is a flap based on a vessel superficial to the superficial layer of the deep body wall fascia** (see Fig. 36–3A). The classic example of a direct cuticular flap is the groin flap. **A musculocutaneous flap** (Fig. 36–4A), **on the other hand, is based on the vascularity to the muscle. The overlying skin paddle**

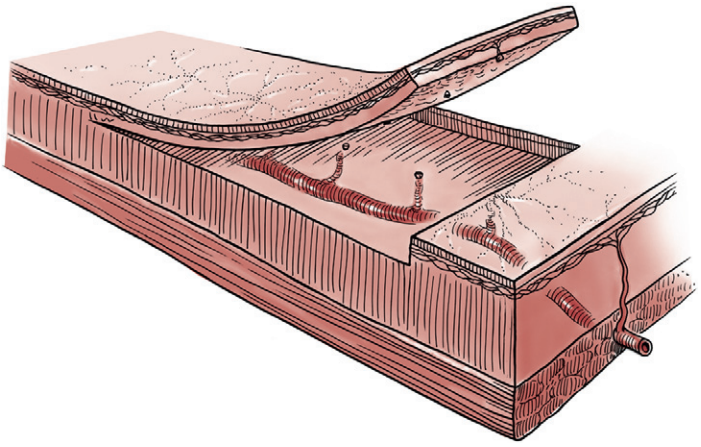

Figure 36–2. Random flap. The arterial perforators have been interrupted, and flap survival depends on the intradermal and subdermal plexuses.

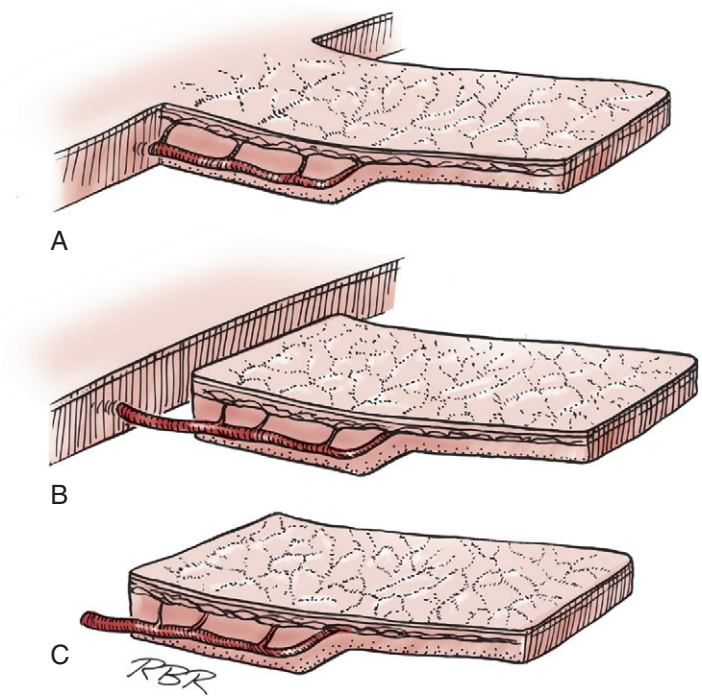

Figure 36–3. Axial flaps. Large vessels enter the base of the flaps. Survival depends on these vessels and on the random distal vascularity. **A,** Peninsula flap. The vascular continuity and the cutaneous continuity in the flap base are intact. **B,** Island flap. The vascular pedicle is intact; the cuticular continuity has been divided. These axial vessels are unsupported (dangling). **C,** Microvascular free-transfer flap. The free-flap cuticular and vascular connections are interrupted at the base of the flap. Vascular continuity is reconstituted in the recipient area by a microsurgical anastomosis. (**A** to **C,** From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary reconstructive surgery. AUA Update Series 1988;7:lesson 10.)

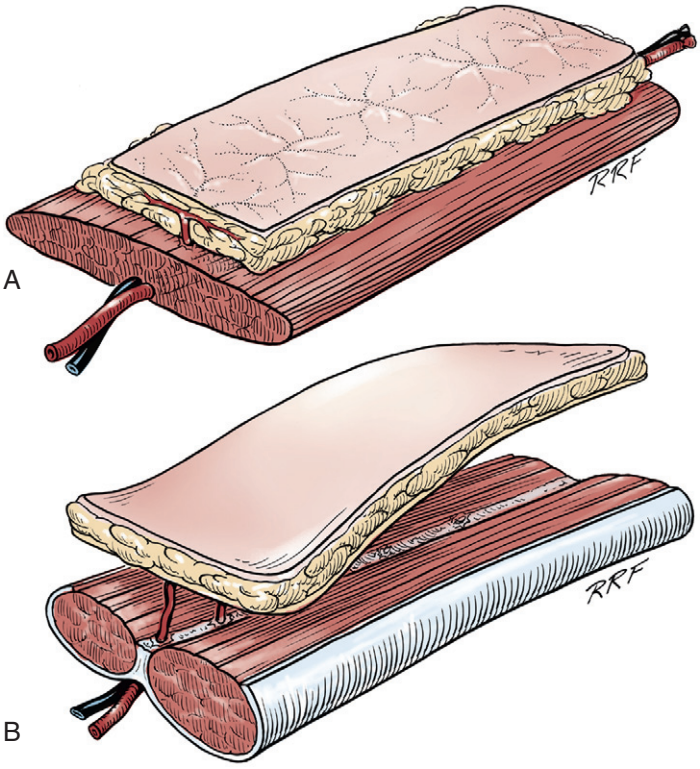

Figure 36–4. **A,** Musculocutaneous flap. Musculocutaneous perforators from the artery to a muscle vascularize the skin and overlying subcutaneous fat. They may be transferred as free flaps but are usually transferred locally, left attached to the vascular pedicle. **B,** Fasciocutaneous flap. Perforating blood vessels from rich plexuses on the superficial and deep aspects of the fascia connect to perforator vessels that communicate with the microvasculature of the overlying paddle. In genital reconstruction, these flaps are based on the dartos fascia of the penis or are free flaps from the forearm. (**A** and **B,** From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary reconstructive surgery. AUA Update Series 1988;7:lesson 10.)

is carried on perforators. If the muscle alone is carried as a flap, the overlying skin survives as a random unit. **The fasciocutaneous system of vascularity** (Fig. 36–4B) **is similar to the musculocutaneous system.** However, the deep blood supply is carried on the fascia (both deep and superficial layers), and the overlying skin paddle is based again on perforators. Thus one can transfer a fascial flap based on the deep blood supply associated with the flap; the overlying skin, if it is not carried with the flap, remains as a random unit (Ponten, 1981; Tolhurst and Haeseker, 1982; Cormack and Lamberty, 1984). It has been argued that fascia is relatively avascular and hence cannot serve as "the blood supply" to the fasciocutaneous unit. Indeed, the fascial layer, in reality, acts as a trellis—thus the vessels are carried much like the limbs of a vine (Jordan, 1993).

A flap can also be classified by the elevation technique. A peninsular flap is a flap in which the vascular continuity and the cutaneous continuity of the flap base are left intact (see Figs. 36–2 and 36–3A). **An island flap** (see Fig. 36–3B) **is a flap in which the vascular continuity is maintained; however, the cuticular continuity is divided. Thus a true island flap is elevated on dangling vessels. The microvascular free transfer flap (free flap)** (see Fig. 36–3C) **has both the vascular continuity and the cuticular continuity interrupted. The vascular continuity is then reestablished at the recipient site.**

Again, there is confusion in terminology. In genitourinary reconstructive surgical procedures, we tend to use the term *island flap*. As already mentioned, a true island flap is elevated on dangling vessels. The usual case, however, is that a skin island or paddle is elevated either on the muscle, as in the gracilis musculocutaneous flap, or on the fascia, as in local genital skin flaps. The term *island flap* is not synonymous with the terms *skin island* and *skin paddle*. The usefulness of these flaps and grafts is illustrated in the discussion of the surgical techniques in this chapter. There is continued interest in the use of tissue-cultured grafts or "manufactured" grafts. The likelihood of someday, soon, being able to successfully use off-the-shelf grafts or sheets of cultured material is right around the corner (Chen et al, 1999; Atala, 2002; Rotariu et al, 2002; El-Kassaby et al, 2003; Bhargava et al, 2004).

Anatomy of the Penis and Male Perineum

See Figs. 36–5 to 36–13 on the Expert Consult website.

Generalities of Reconstructive Surgical Techniques

With any surgical procedure, there are basic rules and surgeons' biases as to the best way to perform a certain operation. Certainly,

Key Points: Principles of Reconstructive Surgery

- Many of the techniques in reconstructive surgery require the transfer of tissue. Tissue transfer implies the movement of tissue for purposes of reconstruction. All tissue has extensibility, inherent tension, and the viscoelastic properties of stress relaxation and creep. These physical characteristics are important in predicting the behavior of transferred tissue.
- A graft is tissue that has been excised and transferred to a graft host bed, where a new blood supply develops by a process termed take. A flap is tissue that has been excised and transferred with the blood supply preserved or surgically reestablished at the recipient site. The grafts that have been successfully used for primary urethral reconstruction are the full-thickness skin graft, the bladder epithelial graft, the oral mucosal graft, and the rectal mucosal graft. Little is known about the characteristics of the rectal mucosal graft. The bladder epithelial graft and the oral mucosal graft have a number of vascular properties that make them desirable for urethral reconstruction. The issue of desiccation and hypertrophic growth, in the case of the bladder epithelial graft, has limited its use in the distal urethra.
- Full-thickness skin and split-thickness skin have been used for penile reconstruction. The results with split-thickness skin are so good that full-thickness grafts are rarely used for coverage of the penis. In complex cases, microvascular free-transfer technology has become a mainstay. For urethral reconstruction, skin islands based on the dartos fascia or tunica dartos have been effectively used. The dermal graft has been used for years to augment the tunica albuginea of the corpora cavernosa.
- The behavior of almost all forms of transfer can be predicted by examinating histologic features and recognizing which layers provide which characteristics to the tissue.

this is true for reconstructive procedures of the external genitalia. In this section, the differences are highlighted.

Reconstructive surgery is performed with all efforts aimed at minimizing tissue injury and promoting healing. Adequate visualization is essential. Surgical loupes are used by almost all surgeons performing both adult and pediatric reconstructive genital surgery. A headlight or suction with attached light often adds to visualization, especially in deep perineal surgery. **In penile cases such as reconstruction of the fossa navicularis or correction of penile curvature, bipolar cautery is used exclusively.** With cautery, the electric charge is grounded either to a pad (monopolar) or to the opposite tong of the forceps (bipolar). It is easy to see that in most instances, the field effects of the electricity are more confined with bipolar cautery. Because electricity is dissipated by conductors (in the case of human tissue, vessels and nerves), there is a possibility of damage to these delicate structures. In other cases, monopolar cautery can be used in the superficial structures, but bipolar cautery is better during dissection around the corpus spongiosum, elevation of penile and scrotal flaps, division of the perineal intracorporeal space, and dissection of the dorsal neurovascular structures.

Appropriate instruments for genitourinary reconstructive surgery can commonly be found in a plastic surgery tray or on the peripheral vascular tray in the typical operating room. Some examples are fine tenotomy scissors, fine forceps, a variety of skin hooks, and delicate needle holders. Sharp scissors that cut with minimal collateral trauma are essential. These instruments minimize tissue injury from manipulation and permit more precise dissection. For urethral surgery, a set of bougie à boule sizers is essential to check the caliber of the urethral lumen. McCrea urethral sounds are a nice addition to the typical van Buren sounds available in the usual operating room. For calibration, sounds do not replace the need for bougie à boule calibrators. For posterior urethral reconstruction, a sound to pass through the cystostomy tract and prostate to find the proximal end for the reconstruction is often helpful. We find that a Haygrove staff serves this role nicely. Some centers use the cystoscope for this purpose, and often it suffices well, whereas at other times it is not as effective as the Haygrove-style sound. The choice of suture material clearly evolves on the basis of the surgeon's experience and bias. However, there are some common principles with which most surgeons would agree. First, in urethral surgery, absorbable suture is the rule. Typical choices for most surgeons are braided absorbable sutures or the family of monofilament absorbable sutures. Chromic suture is rarely used now because the choices of other absorbable sutures seem superior in virtually all cases. Thus, in the case of tension-free closures, very small sutures can be used. In some cases, tying the suture can be awkward, and thus a larger suture may be warranted, even though the anastomosis is tension free. The caliber of suture should be the smallest possible to line up the tissue, which is typically not under tension. There is no reason to use suture that is stronger than the tissues that are being sutured. Fine suture such as 5-0 and 6-0 chromic or polyglactin can be used to suture the epithelium to the adventitia of the corpus spongiosum to control bleeding. For a flap or graft repair, 4-0 to 6-0 suture is usually adequate. For primary anastomosis of the corpus spongiosum or for a posterior urethral reconstruction, 3-0 suture may be appropriate because of tying concerns. The needle should be tapered if possible except when, as in urethroplasty, for example, severe spongiofibrosis or scarring is present. Some of the typical choices are taper needles, such as RB-1, TF, and SH-1, and cutting needles, such as P-3 and PC-3. The UR-6 half-circle taper needle that is often used in radical prostatectomy can be helpful for deep perineal anastomosis of the urethra.

Surgical position and retraction are critical to attaining good results. If possible, procedures are done with the patient supine or prone. Many procedures that previously were done with the patient in the lithotomy position can be done with the patient in the frog-leg or split-leg position. For penile surgery, a Scott retractor with stay hooks,* the Jordan-Bookwalter perineal retractor set,† or the Omni-Tract perineal retractor‡ are helpful. Lithotomy or exaggerated lithotomy positions are used only for the minimal time necessary. With appropriate padding for the foot and positioning without pressure on the back of the leg, the complications in the low lithotomy position are minimal. When the patient is in the supine, split-leg, and low lithotomy positions, venous compression stockings can be used. The controversy in positioning revolves around the use of the exaggerated lithotomy position. It is our preference to use this position for all bulbar and posterior urethral reconstructions. Other surgeons use a lower lithotomy position. We find the more exaggerated position to be safe and

‡Omni-Tract Surgical, Division of Minnesota Scientific Inc., 4849 White Bear Parkway, St. Paul, MN 55110; 800-367-8657.

believe that it provides unequaled access to the deep perineal structures (Angermeier and Jordan, 1994). Details of positioning, as we do it, are covered later. To minimize the patient's time in the exaggerated position, all graft harvesting or flap elevation is done with the patient in the flat supine position.

In addition to proper diagnosis and planning, the surgical technique is important for the overall success of reconstructive surgery. Unlike the results of extirpative surgery, the results of reconstructive surgery depend on methods that minimize tissue damage and maximize wound healing. The key ingredients are adequate visualization, appropriate choice of suture, delicate tissue handling, appropriate positioning, and adequate retraction.

Key Points: Reconstructive Surgical Techniques

- Reconstructive surgery is performed with all efforts aimed at minimizing tissue injury and promoting healing. Loupe magnification is used by almost all surgeons performing adult and pediatric reconstructive surgery. For deep exposure, a headlight or lighted suction is advantageous. Instruments must be delicate because reconstructive surgery uses small sutures and small needles.
- The choice of suture material clearly evolves on the basis of the surgeon's experience. However, the caliber of sutures should be the smallest possible to align the tissue, which is not typically under tension. There is no reason to use suture that is stronger than the tissues being sutured.
- The choice of surgical positioning is clearly left to the surgeon's preference.
- Proper diagnosis and planning of the surgical technique are important for the success of reconstructive surgery.

SELECTED PROCESSES

Urethral Hemangioma

Although **urethral hemangioma is a rare condition, it is usually persistent** and offers a challenge to the surgeon when excision is deemed necessary. Patients typically present with hematuria or a bloody urethral discharge and, occasionally, with obstructive symptoms. The lesions may be either single or multiple, and the urethral meatus is a common location. Although diagnosis is often made at cystoscopy, which readily visualizes the dilated blood vessels, the lesion often extends beyond the point at which it is seen with cystoscopy.

Because all reported cases of urethral hemangioma have been benign, management depends on the size and location of the lesion. Asymptomatic lesions do not require treatment and should be observed, because hemangiomas can regress spontaneously. Symptomatic lesions that require treatment must be completely excised to prevent recurrence.

Although electrofulguration has been reported as a possible treatment of urethral hemangioma, it should be used only to control an acute episode. For smaller lesions, laser treatment has been successful and produces less scarring. Lasers that are used for this purpose include argon, potassium titanyl phosphate (KTP) (532 nm), and neodymium:yttrium-aluminum-garnet (Nd:YAG). The preferred treatment of larger lesions is open excision and urethral reconstruction. This, in some cases, means circumferential reconstruction. It is clear that tubed graft reconstruction should be avoided; tubed flap reconstruction or tubed construction with mixed tissue transfer could be considered, although staged reconstruction is probably preferable. In addition, good initial success has been reported with polidocanol as a sclerosing agent for extensive urethral hemangiomas.

Reiter Syndrome

Reiter syndrome is characterized by a classic triad of arthritis, conjunctivitis, and urethritis. In addition, **some patients have had an episode of diarrhea that preceded the development of arthritis.** In most cases, however, the classic triad is not present, and patients present with only arthritis affecting the knees, ankles, and feet in an asymmetrical distribution. The history of urethritis is obtained on detailed questioning.

Urethral involvement is usually mild, self-limited, and a minor portion of the disease. In approximately 10% to 20% of patients, a glanular lesion is present. Referred to as **circinate balanitis,** this lesion **is diagnostic of Reiter syndrome** and typically appears as a shallow, painless ulcer with gray borders. On occasion, the lesion appears as small, red macules, 1 to 2 mm in diameter. When the urethritis is mild and self-limited, no treatment is necessary.

In rare cases, urethritis causes severe inflammation with necrosis of the mucosa, producing uncompromising stricture disease. We have not been successful in excision and replacement of the urethra in these cases. Alternatively, we perform a perineal urethrostomy and excise the entire distal urethra. This approach may decrease the rheumatic manifestations associated with Reiter syndrome.

Lichen Sclerosus (Balanitis Xerotica Obliterans)

Lichen sclerosus (LS) is the preferred term for what was previously known as balanitis xerotica obliterans (BXO). Lichen sclerosus is a **chronic inflammatory disorder of the skin of uknown origin.** No specific mechanism of disease has been elucidated. There are several acquired scarring disorders of the skin associated with pathology of the basement membrane, such as mucous membrane pemphigoid, that may be shown as related (Bernard et al, 1992; Akporiaye et al, 1997). The reported incidence of LS in the western population is 1 in 300; however, the worldwide prevalence may be substantially different (Wallace, 1971; Dogliotti et al, 1974; Jacyk and Isaac, 1979; Datta et al, 1993). The peak ages of recognition in women are bimodal, with many cases noted before puberty but with another peak presenting in postmenopausal women (Tasker and Wojnarowska, 2003). In men, LS seems to peak between the ages of 30 to 50; however, incidences of LS have been described in people of all ages, from infants to the elderly (Tasker and Wojnarowska, 2003). LS is commonly found at the time of circumcision when performed beyond the neonatal period (McKay et al, 1975; Rickwood et al, 1980; Garat et al, 1986; Ledwig and Weigland, 1989; Meuli et al, 1994). **The most common cause of meatal stenosis, LS appears as a whitish plaque that may involve the prepuce, glans penis, urethral meatus, and fossa navicularis. If only the foreskin is involved, circumcision may be curative** (Akporiaye et al, 1997). In the authors' experience, LS usually begins as a meatal or perimeatal process in the circumcised patient, but it may involve other areas of the preputial space in the uncircumcised patient. In uncircumcised men, the prepuce becomes edematous and thickened, and often may be adherent to the glans (Bainbridge et al, 1971).

Diagnosis is made through biopsy. Several reports have suggested the association with chronic infection by a spirochete, *Borrelia burgdorferi* (Tuffanelli, 1987; Dillon and Ghassan, 1995; Shelley et al, 1999).

The term BXO was first applied by Stühmer in 1928. Freeman and Laymon showed that BXO and LS were probably the same process (Freeman and Laymon, 1941; Laymon and Freeman, 1944). The first report of what was probably LS was published by Weir in 1875. He described a case of vulvar and oral "ichthyosis" (Weir, 1875). In 1976, the International Society for the Study of Vulvar Disease unified the nomenclature devising a new classification system and proposed the term lichen sclerosus (Friedrich, 1976). As mentioned previously, the cause of LS has not been defined. A number of mechanisms have been proposed. Koebner phenomenon relates the development of LS to trauma to an affected area (Lee and Phillips, 1994). The etiology has also been suggested to be an autoimmune disease (Goolamali et al, 1974; Marren et al, 1995). Sander hypothesized that reactive oxidative stress contributed to the sclerotic, immunologic, and carcinogenic process in LS (Sander et al, 2004). As mentioned, the infectious cause has also been implicated (Tuffanelli, 1987; Ross et al, 1990). That has been called into question because the organism has not been uniformly demonstrated in the lesions. It has also been proposed that LS has a genetic origin, based on the observation of a familial distribution of cases (Marren et al, 1995). There have been reports of concomitant existence of the disease in identical twins (Fallic et al, 1997; Thomas and Kennedy, 1986) and nonidentical twins (Cox et al, 1986), with coexistence of dermatosis. The disease has also been seen in mothers and daughters (Shirer and Ray, 1987). Studies on the human leukocyte antigen (HLA) have suggested a genetic component in patients afflicted with LS (Marren et al, 1995). The combination of topical steroids and antibiotics may help stabilize the inflammatory process. Conservative therapy may be warranted in patients whose meatus can easily be maintained at 14 to 16 French (Staff, 1970). In these cases, intermittent catheterization with lubrication of the catheter and meatal dilator with 0.05% clobetasol (brand name Temovate) may be adequate treatment. Long-term antibiotic therapy may also be helpful to improve the inflammation, because secondary infection of the inflamed tissue may occur. We have typically used tetracycline, but a trial of long-term penicillin or advanced-generation erythromycin therapy may be warranted (Shelley et al, 1999). This nonsurgical approach to treatment is used in patients who are not good surgical candidates for other medical reasons or in older patients, and in younger patients who demonstrate stable disease. Secrest has proposed a link between hypogonadism and LS in male patients. He has consistently shown diminished testosterone levels in patients afflicted with LS and has a study underway analyzing whether replacement androgen therapy may be helpful (Secrest et al, 2008).

In young patients with severe meatal stenosis, surgery is indicated. Because patients with long-standing meatal stenosis often have severe proximal urethral stricture disease, retrograde urethrography should be performed before the initiation of therapy. The etiology of stricture disease associated with LS is unclear. Possible causes include iatrogenic stricture resulting from repeated instrumentation and pressure voiding associated with meatal stenosis causing secondary intravasation of urine into the glans Littre (Fig. 36–14). In cases of early LS with only meatal involvement resulting in stenosis of the fossa navicularis, prompt reconstruction seems to be successful in the long term and seems to avoid the sequelae of panurethral stricture disease. Most surgeons now believe that because LS is a disease of genital skin, better tissue for reconstruction is the oral mucosa, and techniques are discussed later (Mundy, 1994; Bracka, 1999). Long-standing cases with a long length of urethral stricture are amenable to techniques of reconstruction but are very challenging. It is becoming clear that except in the case of urethral stricture disease confined only to the meatus and fossa navicularis, staged oral graft reconstruction, at least in the short to mid term, seems to provide superior durable results. This may also be the case in cases confined to the meatus and fossa navicularis, because a recent analysis of patients reconstructed with the ventral transverse skin island technique showed a 50% recurrence rate even in those patients. The weakness of that analysis, is that the data did not include biopsy proof that all patients had LS (Virasoro et al, 2007). We also are seeing more and more patients who present with a buried penis. This phenomenon occurs when the skin of the penile shaft has been lost because of severe inflammation, and the penis is trapped in the penopubic and scrotal area. These

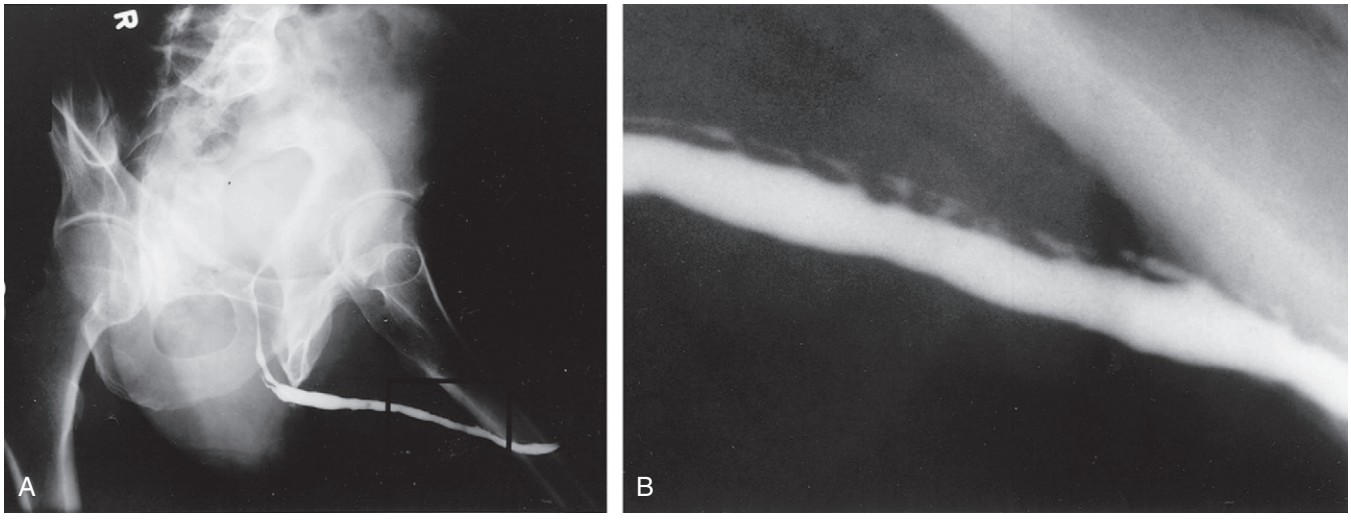

Figure 36–14. **A** and **B,** Urethrogram in a patient with urethral stricture disease associated with lichen sclerosus–balanitis xerotica obliterans. It illustrates the intravasation of contrast material into the dilated glands of Littre during voiding. (From Jordan GH. Management of membranous urethral strictures via the perineal approach. In: McAninch J, Carroll P, Jordan GH, editors. Traumatic and reconstructive urology. Philadelphia: WB Saunders; 1996.)

patients are often profoundly overweight, and many are diabetic; they have often had prior surgical procedures. Their management is complex and ultimately determined by their desire and need for functional reconstruction. In some patients with severe urethral stricture disease, we have completely reconstructed the urethra; in others, we have simply performed a perineal urethrostomy. Perineal urethrostomy is usually technically straightforward, because the rule in most patients with lichen sclerosus is to spare the proximal anterior urethra. We have proposed that, in many cases, the sparing of the proximal anterior urethra demonstrates the distribution of the glands of Littre for a given patient. Younger patients have requested mobilization and release of the penis with placement of a split-thickness skin graft. However, because the inflammation involves the glans penis (which is not removed), the secondary inflammation may also involve the skin graft. Therefore lifelong monitoring of these patients for the secondary effects of inflammation is necessary.

Several reports have suggested the development of squamous cell carcinoma in patients with a long history of lichen sclerosus (Doré et al, 1990; Pride et al, 1993).

Amyloidosis

Although a rare disease, amyloidosis of the urethra should be considered in the evaluation of any patient with a urethral mass. Patients may present with hematuria, dysuria, or urethral obstruction. Because the differential diagnosis includes urethral neoplasm, cystoscopy with transurethral biopsy is indicated. Once the diagnosis is made, treatment should be based only on symptoms. Most patients can be observed expectantly and not require aggressive treatment. Some will require treatment for urethral stricture. Progression and recurrence are rare (Walzer et al, 1983; Dounis et al, 1985; Crook et al, 2002).

Urethrocutaneous Fistula

A urethrocutaneous fistula is a tract lined with epithelium that leads from the urethra to the skin. The size of a fistula can vary from pinpoint to large. **Urethral fistulas may be a complication of urethral surgery or develop secondary to periurethral infection associated with inflammatory strictures or treatment of a urethral growth** (condyloma or papillary tumor). **Treatment of a urethral fistula must be directed not only to the defect but also to the underlying process that led to its development.** Treatment therefore varies according to the cause of the fistula. In cases of urethral reconstruction, especially reconstruction for hypospadias, fistula often occurs or recurs because of distal obstruction and high-pressure voiding. Additionally, in some cases where multiple attempts at fistula closure have been attempted and failed, the condition of the tissue adjacent to the fistula are so scarred that staged reconstruction is needed to import "better tissue."

After urethral surgery, fistulas can develop immediately or as delayed complications. An early fistula is the result of poor local healing, possibly secondary to hematoma, infection, or tension with closure. In addition, a mere breakdown of the urethral or overlying skin closure, or both, could occur. Very occasionally, with aggressive local care and continued urinary diversion, the fistula closes spontaneously.

Several techniques are used for fistula closure. Endoscopic and radiographic evaluation of the urethra must be performed before the repair in all cases. If the fistula is small and closure of the hole will not decrease the lumen of the urethra, a button of skin is removed from around the fistula, and its edges are cut flush with the urethral wall. The urethra is closed with small (6-0 or 7-0) absorbable suture, inverting the epithelial edge, and the repair is tested to ensure that it is watertight. The authors prefer either polyglycolic acid (Vicryl) or polydioxanone suture. Subsequent layers are designed and closed to avoid superimposed suture lines. Without question, the safest diversion is a suprapubic catheter. However, in many cases, a silicone stent that reduces pressure during voiding for 7 to 14 days suffices. The operating microscope can be useful for the closure of small fistulas, allowing the use of 8-0 polyglycolic acid suture and limiting the size of the associated skin incision.

If the fistula is so large that simple closure will compromise the lumen of the urethra, then often local flaps will be required. However, if the adjacent tissues are thin and poorly visualized, then closure of the fistula may become a staged urethral reconstruction as mentioned above. For larger fistulas, a suprapubic tube for diversion is probably prudent. The mobilization of flaps, such as the tunica dartos flap, may be necessary to secure adequate tissue interposition and avoidance of superimposed suture lines.

Fistulas associated with inflammatory strictures occur as periurethral tracts and develop secondary to high-pressure voiding of infected urine. As multiple tracts develop, this problem becomes what is known as a "watering pot perineum." Repair requires suprapubic drainage, and treatment of the infection requires incision and drainage of any abscesses present. We widely excise the fistula tracts and associated inflammatory tissue and wait 4 to 6 months before repairing the underlying stricture. Flap reconstruction, if donor tissues are available, may be used. However, a staged graft procedure (discussed later) is also an excellent choice. One must be cautious in the patient with urethral fistulas but without a chronic history of obstructive voiding symptoms. In many cases, fistula or periurethral abscess may be the hallmark symptom of urethral carcinoma.

Urethral Diverticulum

A congenital diverticulum is a transitional cell epithelium-lined pouch that is the result of either a distention of a segment of the urethra or the attachment of a structure to the urethra by a narrow neck (i.e., a müllerian remnant). **In males, a congenital anterior urethral diverticulum may result from incomplete development of the urethra,** with a defect in only the ventral wall and subsequent distention of this segment by the hydraulic force of the voiding stream (Valdivia et al, 1986; Bedos and Cibert, 1989; Ozgok et al, 1994). Furthermore, the downstream lip of the defect may serve as a valvular obstruction, increasing the pressure in the lumen and subsequently the diverticulum enlarges. **Another possible etiology is injury of the urethra that may cause an intraspongiosal hematoma.** This could create a paraurethral space and subsequent diverticulum or defects (fistula or diverticulum). These can also be associated with urethral strictures (Bryden and Gough, 1999). It has also been suggested that congenital diverticula may represent giant cystic dilation of Cowper ducts (Gil-Vernet, 1977; Jiminez Cruz and Rioja Sanz, 1993). We do not favor this proposed suggested etiology because the diverticula seem to be slightly more distal than the expected location of Cowper ducts, and in our experience with reconstruction of a considerable number of these diverticula, no proximal limb of the ducts seems to exist in them. In many cases, endoscopic unroofing

of the diverticulum remedies the voiding symptoms; although, after unroofing it is not uncommon for the patient to note postvoid dribbling. Open repair essentially excises the redundancy of the urethra associated with the diverticulum. If the lumen is comprised, then dorsal onlay by either graft or flap can be useful.

A congenital diverticulum in the prostatic urethra may be a large remnant of the müllerian duct associated with defects of diminished virilization. However, it often occurs in proximal hypospadias and represents an enlarged utricle (Devine et al, 1980). **These diverticula may not be demonstrated with voiding urethrography but are demonstrated with cystoscopy or retrograde urethrography.** The tip of a urethral catheter tends to catch in this opening, necessitating the use of something to direct the catheter tip toward the true lumen. Other than necessitating caution during evaluation, they do not usually cause problems or require treatment unless they are very large.

Large utricles can accumulate urine with voiding and then decompress after voiding. If they are large enough, the stasis of urine can be associated with recurrent urinary tract infection or difficult-to-manage "incontinence." A surgical approach to small lesions can be through a suprapubic incision, possibly opening the bladder to go through the center of the trigone. However, large diverticula can be approached trans-sacrally (Peña and Devries, 1982). Although this is a complex procedure, it seems to be associated with much less morbidity than an abdominal or a perineal approach and provides superior exposure. We excise the diverticulum after exposing and dissecting its communication with the urethra. After ensuring that there is no distal obstruction to interfere with healing, we close the urethra.

Diverticula of the female urethra are covered in Chapter 78.

Paraphimosis, Balanitis, and Phimosis

Paraphimosis, or painful swelling of the foreskin distal to a phimotic ring, occurs if the foreskin remains retracted for a prolonged time. Swelling is sufficient to make reduction of the foreskin over the glans difficult. **In the very young child, paraphimosis is often seen after the foreskin has been traumatically reduced during an examination, or sometimes by overzealous parental attempts at hygiene.** It serves to say that traumatic, sudden reduction of a tight foreskin should be avoided in all ages and circumstances. To reduce a paraphimosis, gentle steady pressure must be applied to the foreskin to decrease the swelling. Especially with a child, this is best accomplished in a quiet room by a parent squeezing it in the hand. Elastic wrap may be helpful in some cases. Putting an ice pack on the area for a short time before gentle compression helps, not with the swelling but as an analgesic. When the swelling has been reduced, the surgeon can push against the glans with the thumbs, pulling on the foreskin with the fingers. Because paraphimosis tends to recur, a dorsal slit at a minimum or a circumcision should be carried out as an elective procedure at a later date. An occasional patient presents with acute paraphimosis that has been present for many hours to days. This is typically seen in an adolescent who is reluctant to reveal the problem to his parents. In these cases, reduction may be impossible and should be dealt with by emergency dorsal slit or circumcision. Considerable postoperative edema is the rule in these cases.

Balanitis, or inflammation of the glans, can occur as a result of poor hygiene, from failure to retract and clean under the foreskin. The subsequent swelling makes cleaning more difficult, but the inflammation usually responds to local care and antibiotic ointment. Oral antibiotic therapy may occasionally be necessary. Balanoposthitis is a severe balanitis and occurs when the phimotic band is tight enough to retain inflammatory secretions, creating what amounts to a preputial cavity abscess. On occasion, an emergent dorsal slit is required.

Phimosis, or the inability to retract the foreskin, can result from repeated episodes of balanitis. In older patients, balanitis may be a presenting sign of diabetes**.** In these cases, circumcision may be warranted.

Urethral Meatal Stenosis

A small urethral meatus in the newborn will probably not be called to a urologist's attention unless the stenosis is associated with other congenital deformities (e.g., hypospadias) or causes voiding difficulties or urinary tract infection (Allen and Summers, 1974). If the urethral meatus of a boy appears exceptionally narrow and there are associated symptoms, a meatotomy should be considered. For this decision to be made, voiding should be observed to note that the meatus opens as a full, forceful stream is passed. If the stream is narrow and excessively forceful, stenosis is probably present. The occluding skin is generally a thin layer that can sometimes be seen to pouch out, with the meatus opening at the dorsal lip as the child voids. **Meatal stenosis in a boy appears to be a consequence of circumcision that then allows subsequent ammoniacal meatitis.** If the child is seen with ammoniacal meatitis, we usually start meatal dilation with 0.05% clobetasol cream. Within a week, the process seems to settle down. Anecdotally, the fusion of the ventral-meatal skin that causes meatal stenosis can be avoided. Parents must be counseled about the cause, that is, a wet diaper pressing for prolonged periods against the tip of the glans.

A ventral urethral meatotomy can at times be accomplished with the use of local anesthesia. In the young child, general anesthesia is the preferred approach, avoiding trauma to the child, the parents, and the urologist. It is important to insert the anesthetic needle into the skin fold from the underside, so that the tip of the needle can be observed and controlled. If insertion is done from the outside, the needle will pass through both layers of the fold, and a wheal cannot be raised because of leakage of the anesthetic solution. After the meatotomy, the edges of the cut will seal together unless they are kept open. The tip of a meatal dilator is the best instrument for this purpose. The child's parents are instructed to gently separate the edges with the tip of the dilator three times a day for 7 to 10 days. The surgeon should observe the parents carry out this procedure. Pediatric meatal dilators (see the later product reference) are available; however, the tip of an ophthalmic antibiotic tube also works well, and the antibiotic ointment can be used as the lubricant.

Meatal stenosis occurs in adults after inflammation, specific or nonspecific urethral infection, and trauma (especially in association with indwelling catheters, urethral instrumentation, or radical prostatectomy in some cases). It may also be the result of the failure of a previous hypospadias repair. To perform a ventral meatotomy in a normally developed penis in adolescents and adults, it is often necessary to place sutures to approximate the urethral mucosal edge to control bleeding. This step usually requires three sutures: one at the apex and one on either side. We have found a dilator made by Cook Urological* to be helpful in

*Cook Urological, PO Box 227, Spencer, IN 47460; 800-457-4448. Catalog No. 073406, adult 6 to 34 French; No. 073403, pediatric 6 to 10 French.

keeping the meatus open. In some cases, it may be necessary to perform a dorsal rather than a ventral meatotomy. This can be accomplished as a Y-V-plasty after the excision of any scarred ridge of neourethra. Dorsal meatotomy, although effective in opening the meatus, often creates a cosmetically less-than-optimal shape of the meatus. In the adult, it is unusual for the meatal stenosis to be an isolated finding. The stricture process usually involves the fossa navicularis to some extent as well.

Circumcision

Controversy continues about whether neonatal circumcision should or should not be performed (Poland, 1990; Schoen, 1990). Much attention has been focused on this issue, but despite this, many little boys in the United States are circumcised. Ritual circumcision will continue; however, in ritual circumcision, it is not necessary to remove the skin but only to draw blood. **It is important not to circumcise any boy with a penile abnormality (e.g., hypospadias, chordee) that may require the foreskin during repair. An indication for circumcision in the young boy presents when the child has had recurrent urinary tract infections thought to be associated with the redundant preputial skin.**

Most circumcisions performed just after birth are done with the Gomco clamp or one of the plastic disposable devices made for this purpose. Care should be taken to free the foreskin from the glans completely and to apply appropriate tension when the foreskin is pulled into the clamp. To prevent either a too generous or an inadequate circumcision, we find it useful to carefully mark the foreskin so that the correct level is ascertained. At this center, we do neonatal circumcision with a penile block for anesthesia.

The most common complication is bleeding due to inadequate control with vascular compression. Application of an epinephrine-soaked sponge may help in controlling a minimal ooze. Infection can also occur and responds to local care. Any resulting skin separation should be repaired after the inflammation resolves. Sometimes, too much skin is removed, or the urethra is included in the clamp, resulting in a fistula. In many if not most cases in which excess skin is removed, closure can still be accomplished with aggressive frenuloplasty along with remaining skin closure by transposition of the remaining skin. If the entire penis is "scalped," it may be best managed with a split-thickness skin graft or with reapplication of the excised foreskin, after it is prepared properly as a graft. In complicated cases, burying the penis in the scrotum and repairing it at a later date may be prudent. **Monopolar electrocautery should be avoided in a neonatal circumcision, because penile loss from the field distribution of the current can occur. The use of monopolar cautery with a Gomco or similar clamping device must be avoided, because devastating loss of tissue can occur.**

At present, whether a newborn who has lost his penis because of a circumcision mishap should be gender reassigned is under review by the North American Task Force on Intersexuality (Oesterling et al, 1987; Gearhart and Rock, 1989). Our experience with phallic construction now includes a number of children and youths who had been converted to a female after a circumcision accident. As they passed through puberty, they realized that this sexual assignment was wrong. We believe that with the present knowledge of reconstructive techniques, the matter is not clear, one way or the other. However, most of these boys could undergo reconstruction in such a manner as to preserve reproductive function.

In adults, circumcision can be done with local anesthesia, by blocking the dorsal nerves at the base of the penis and circumferentially infiltrating the superficial layers of the penile base. In men and older boys, we favor a sleeve circumcision. With the foreskin in its retracted position, a marking pen outlines an incision, leaving a small preputial cuff. This mark should go straight across the base of the frenulum. This incision is made and carried through the dartos fascia to the superficial lamina of the Buck fascia. The foreskin is reduced, and a second incision is marked, following the outlines of the coronal margin and the V of the frenulum on the ventral side. The frenulum usually retracts into a V. In some cases, the frenulum can be lengthened by closing the edges of the V in a longitudinal orientation for a short length (frenuloplasty). If frenuloplasty is done, the proximal incision does not need to follow the V of the retracted frenulum because the ventral skin is straight. We make the skin incision and fulgurate bleeding vessels with bipolar cautery as the incision is deepened and the skin edge mobilized. In older boys and adults, the vessels are more substantial and not easily sealed by compression, no matter how vigorous. Thus circumcision clamps can be ineffective and are not recommended even though larger sizes are available. After the sleeve of preputial skin has been removed, hemostasis is obtained and the skin edges are reapproximated.

In smaller boys, some may consider this sleeve procedure to be tedious and difficult. If this is the case, after the skin is marked, a dorsal slit is made through both layers of the prepuce back to the level of the corona. Following the marks, the two layers of the preputial skin are incised. Bleeders are controlled, and the skin edges are reapproximated.

Complications should be uncommon. Most patients develop some hyperesthesia of the glans, which resolves. A hematoma is probably the most common immediate complication. Some patients notice minor cosmetic imperfections that are functionally insignificant. One of the most distressing problems we see, however, is a patient who complains that the surgeon has removed too much skin. To avoid this unfortunate occurrence, a circumcision should be done precisely, and, whatever the procedure to be carried out, the incisions should first be marked with the skin lying undistorted on the shaft. Adults requesting circumcision must be carefully evaluated from a psychosexual standpoint because many of these patients, who are the most persistent in requesting circumcision, become the most dissatisfied after the surgery.

Circumcision has been shown now in numerous studies to provide protection for men in areas where HIV is very prevalent (Tobian et al, 2009).

Failed Hypospadias Repair

In treating a patient in whom hypospadias repair has failed, it is important to obtain all available records to help determine what may have contributed to his complications. **A hypospadias repair may fail because of an inadequate correction of chordee or an inadequate urethra, with a stricture, fistula, or diverticulum** (Winslow et al, 1986). **Many times, it is readily apparent from the records that not all aspects of the hypospadias deformity** (i.e., ventrally displaced meatus, ventral chordee, and some expression of inadequacy of ventral tissue fusion) **were addressed in the previous repairs.** Adults with urethral strictures are often seen who have had hypospadias surgery as children. Depending on the age of the patient and the preference of the treating urologist, a variety of

different techniques may have been used to repair the original hypospadias. Many of these patients have persistent chordee and a subcoronal meatus. Adults have also been seen who have had long-standing evidence of urethral fistula. In addition, some patients may have clinical findings not related to hypospadias that should have been recognized previously, especially when hypospadias is part of an overlying intersex problem. In years past, problems associated with previous failures have been caused by errors in design, technique, or postoperative care (Devine et al, 1978). **With more modern techniques available and with most hypospadias treated by surgeons with considerable experience, failures seem to be associated with perioperative infections or other factors that adversely affect wound healing.** Complex hypospadias repair failures are currently encountered with much less frequency, and most that are encountered are in patients who had previous procedures more than 15 to 20 years ago. Truly, their complications resulted not from poorly designed surgery at the time but rather from the "state of the art" at the time.

Evaluation of a failed hypospadias repair includes retrograde urethrography, voiding cystourethrography, and cystoscopy. In an older patient, a reliable preoperative assessment of residual chordee can be made on the basis of the history and photographs taken at home. In younger patients, complete evaluation of more complex situations with use of anesthesia may be necessary.

In the adult patient, a detailed discussion must occur regarding the positive and negative aspects of the various approaches. Patients who were initially operated on before the late 1970s probably underwent either a graft or some form of repair using almost exclusively ventral tissue. Some of these patients still have the remnants of a dorsal hood or enough dorsal skin for a dorsal transverse penile skin island type of reconstruction to be performed.

We believe that surgical correction of complex cases requires an aggressive approach by the surgeon (Secrest et al, 1993). However, with the advent and very common usage of the tubed incised plate repair, initially described by Snodgrass (1999), the nature of failures is different and the approaches also remarkably different. It is the authors' observation that the number of failed surgeries is less, the nature of graft salvage techniques is remarkably different, and the method of addressing residual curvature is also different. It is possible to reincise the "urethral plate" and tabularize it if the plate is not scarred, possible to graft the plate dorsally if it is, and, if the tissues are badly scarred, then the tendency to revert to staged reconstruction has now been adopted by many surgeons (Snodgrass et al, 2009). Certainly, the use of flaps has a place in corrective procedures, and the excision of scarred tissues causing residual curvature, likewise its place. However, the procedure of plication or corporoplasty techniques for correction of residual curvature has, for the most part, become the standard of care. Certainly graft techniques for correction of curvature are used, but with far less frequency than in years past.

Residual Genital Abnormality in Patients with Closed or Diverted Exstrophy

General

Residual genital defects in men who have had exstrophy repaired as children can cause functional, aesthetic, and psychologic problems. The effects of these problems are compounded in men who have undergone urinary diversion and who must wear stomal appliances, although with the improvement of continent diversions, this is less of a factor. Except in the most severe forms of bladder exstrophy or cloacal exstrophy—when the penis or the halves of the bifid penis are truly inadequate—successful reconstruction is possible. Even then, if normal testes are present, the success of newer techniques of phallic construction (see subsequent discussion) should lend support to considerating the option of raising such a child as a boy, possibly preserving his reproductive potential through puberty. In these very difficult cases, we think that the parents must be presented with both options, gender reassignment versus eventual phalloplasty. Remarkable progress has been made in the treatment of difficult cases (Johnston, 1975; Hendren, 1979; Jeffs, 1979; Snyder, 1990; Perovic et al, 1992; Gearhart et al, 1994; Mitchell and Bagli, 1996), as well as in techniques of primary closure. However, many patients need further genital surgery, because they experience the hypertrophic growth spurt of the penis associated with puberty.

The goals of reconstructive surgery in male patients with exstrophy or epispadias are to produce a dangling penis with erectile bodies of satisfactory length and shape to allow sexual function and to construct a urethra that serves as a conduit for the passage of urine and ejaculate. However, experience has shown that in the diverted exstrophy patient with only a bladder remnant, construction of a urethra that is essentially defunctionalized is difficult. These urethras all eventually seem to fibrose and stenose. The bladder neck remnant thus becomes a cyst that is often colonized. Bouts of virulent epididymitis or the formation of what is really a bladder neck remnant abscess begin to occur. We have now seen two patients who developed carcinoma of the prostate in a bladder neck remnant. The diagnosis in these patients was difficult and the resultant surgery even more difficult. Neither patient did well from the standpoint of treatment of the carcinoma. Both were seen before the aggressive use and better understanding of prostate-specific antigen.

Many patients who have undergone surgery as children do not present for correction of inadequacies of the external genitalia until after they have completed puberty and realize that their situation has not improved and is not likely to improve. Some have been in sexual situations and have encountered problems. We employ a systematic approach to accomplishing the reconstruction necessary to correct the anatomic defects in these patients (Devine et al, 1980; Winslow et al, 1988). Surgery is undertaken in a sequential fashion beginning with the simplest procedure that will achieve the desired functional result.

Lower abdominal wall scarring can be corrected or defects can be closed by fashioning peripenile flaps that are shaped like a W (see Fig. 36–19). In many patients, there may be wide diastasis recti that is really a ventral hernia. Anchoring of meshes or Gore-Tex can be difficult, and in several cases we have resorted to a fibular bone microvascular free transfer to reconstruct the continuity of the pubis, allowing effective closure of the abdominal hernia.

Surgical Technique

The adult reconstructive surgeon's place, now, with the more effective primary closures, is in the correction of hernia as mentioned above or in the patient who has an inadequate penis either due to the deformity, scarring from multiple surgeries, or has had prior gender reassignment yet recognizes and chooses their male gender.

Key Points: Selected Processes

- Urethral hemangioma is a rare condition and usually persistent. It can offer a significant challenge to the surgeon. All reported cases of urethral hemangioma have been benign, and management depends on the size and location of the lesion.
- Reiter syndrome is characterized by a classic triad of arthritis, conjunctivitis, and urethritis. Urethral involvement is usually mild, self-limited, and a minor portion of the disease.
- Lichen sclerosus was referred to in the past as balanitis xerotica obliterans. Diagnosis is made through biopsy. Lichen sclerosus is thought to be possibly premalignant for the development of squamous cell carcinoma of the glans. It is the most common cause of meatal stenosis. Management of patients with lichen sclerosus–related stricture is complex, and results to date are less than optimal. The management is determined by the desire of the patient and the need for functional reconstruction.
- Amyloidosis is a rare disease of the urethra and should be considered in the evaluation of any patient with a urethral mass. Patients present with hematuria, dysuria, or urethral obstruction.
- A urethrocutaneous fistula is a tract lined with epithelium that leads from the urethra to the skin. It may be a complication of urethral surgery or develop secondary to periurethral infection associated with inflammatory strictures or treatment of a urethral growth. Treatment of the urethral fistula must be directed not only to the defect but also to the underlying process that led to its development.
- A congenital urethral diverticulum is a transitional cell epithelium-lined pouch that is the result of either a distention of a segment of the urethra or the attachment of a structure to the urethra by a narrow neck. In males, "congenital" anterior urethral diverticulum may result from incomplete development of the urethra or may possibly be the result of straddle trauma that led to an intracorporeal spongiosal hematoma. Congenital diverticulum in the prostatic urethra is a remnant of the müllerian duct.
- Paraphimosis is a painful swelling of the foreskin distal to a phimotic ring. It occurs when the foreskin has been retracted and not reduced. Edema then forms in the distal skin.
- Urethral meatal stenosis in the young boy appears to be a consequence of circumcision. The circumcision allows the development of ammoniacal meatitis, which then can heal with a membrane across the ventral portion of the meatus. Controversy continues about whether neonatal circumcision should or should not be performed. If it is going to be performed, an adequate circumcision needs to be done. The most common complication of neonatal circumcision, in the authors' opinion, is the fact that it is inadequately done.
- A patient with failed hypospadias repair can be complex. Many are victims of the technology of the time when they had their initial reconstruction. When the urethra is involved, all should be evaluated as if they have urethral stricture disease.
- Advanced techniques for the reconstruction of exstrophy-epispadias complex have led to much better functional results and less need for secondary exstrophy reconstruction. Secondary exstrophy reconstruction is aimed at the area of the escutcheon, the dorsal base of the penis, the penile shaft, the urethra, and the penoscrotal junction.

TRAUMA TO THE GENITALIA

This topic is primarily covered in Chapter 88, but an additional description is also included in the electronic version of this chapter. Please see the Expert Consult website for this section, as well as Fig. 36–15.

URETHRAL STRICTURE DISEASE

The term *urethral stricture* refers to anterior urethral disease, or a scarring process involving the spongy erectile tissue of the corpus spongiosum (spongiofibrosis) (Fig. 36–16). The spongy erectile tissue of the corpus spongiosum underlies the urethral epithelium, and, in some cases, the scarring process extends through the tissues of the corpus spongiosum and into adjacent tissues. **Contraction of this scar reduces the urethral lumen.** For example, if a normal urethra measures 30 French, its diameter is 10 mm and the area of the lumen is approximately 78 mm^2. If scarring has resulted in a urethra that measures 15 French, the lumen is only 55 mm^2, or 29% reduced. It is therefore evident that scar contraction caused by anterior urethral stricture disease can, for a while, be asymptomatic, but because the lumen is further reduced can be associated with marked voiding symptoms.

In contrast, posterior urethral "strictures" are not included in the common definition of urethral stricture. Posterior urethral stricture is an obliterative process in the posterior urethra that has resulted in fibrosis and is generally the effect of distraction in that area caused by either trauma or radical prostatectomy. Although the distraction defect can be lengthy in some cases, the actual process involving the tissues of the urethra is usually confined. By consensus of the World Health Organization conference, the term *stricture* is limited to the anterior urethra. Distraction defects are those processes of the membranous urethra associated with pelvic fracture. Other narrowings of the posterior urethra are termed urethral contractures or stenoses (Bhargava et al, 2004).

Urethral Anatomy

Although urethral anatomy is described in the earlier section on anatomy, it is useful to re-emphasize key anatomic points. **The bulbous urethra is eccentrically placed in relation to the corpus spongiosum and is much closer to the dorsum of the penile structures** (see Fig. 36–6). As one moves distally, the pendulous or penile urethra becomes more centrally placed within the corpus spongiosum.

The genital skin has a dual (proximal and distal) and bilateral blood supply, forming a fasciocutaneous system (see Fig. 36–10). **The corpus spongiosum receives blood from the common penile artery, the terminal branch of the internal pudendal artery** (see Fig. 36–12). **The corpus spongiosum also has a dual blood supply—a proximal blood supply and a retrograde blood supply through the dorsal arteries as they arborize in the glans penis.**

Etiology

Any process that injures the urethral epithelium or the underlying corpus spongiosum to the point that healing results in a scar can cause an anterior urethral stricture. Today, most urethral strictures are the result of trauma (usually straddle trauma). This trauma to the urethra often goes

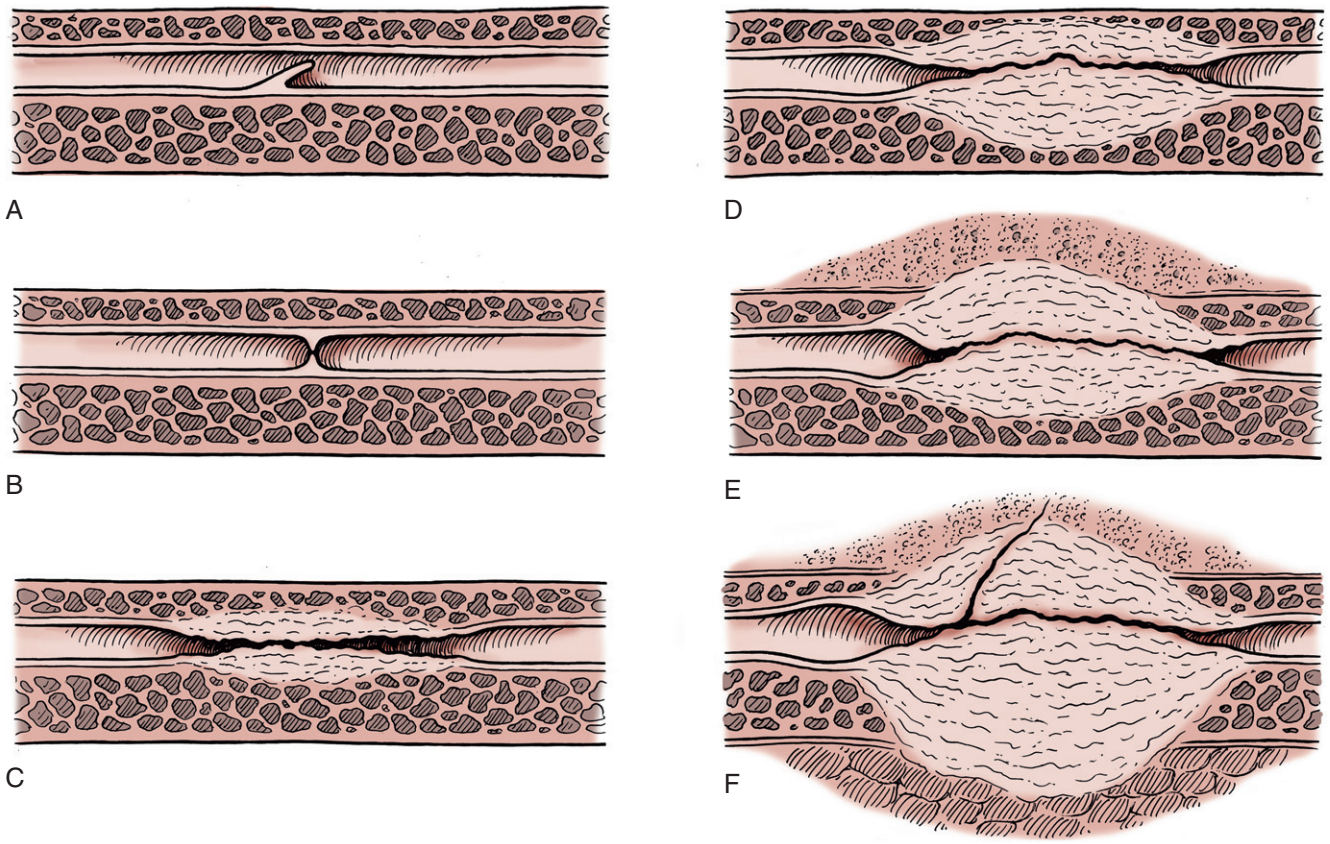

Figure 36–16. The anatomy of anterior urethral strictures includes, in most cases, underlying spongiofibrosis. **A,** Mucosal fold. **B,** Iris constriction. **C,** Full-thickness involvement with minimal fibrosis in the spongy tissue. **D,** Full-thickness spongiofibrosis. **E,** Inflammation and fibrosis involving tissues outside the corpus spongiosum. **F,** Complex stricture complicated by a fistula. This can proceed to the formation of an abscess, or the fistula may open to the skin or the rectum. (**A** to **F,** From Jordan GH. Management of anterior urethral stricture disease. Probl Urol 1987;1:199–225.)

unrecognized until the patient presents with voiding symptoms resulting from the obstruction of the stricture or scar. In most straddle trauma, the injury to the bulbous urethra is readily reconstructable (Park and McAninch, 2004). Unfortunately, iatrogenic trauma to the urethra still exists, but with the development of small endoscopes and the limitation of indications for cystoscopy in boys, we see fewer iatrogenic strictures today than in the past. The place of idiopathic urethrorrhagia with regard to strictures in children is not clear; some question whether it may be a cause of strictures in young boys irrespective of the child's having undergone an endoscopic procedure (Rourke et al, 2003). To date, no specific inciting factor has been identified as causing idiopathic urethrorrhagia. We appear to have histologic results from a patient with resolving urethrorrhagia that shows portions of tissues covered in part by squamous epithelium; other parts are covered by transitional epithelium; there are several areas of denuded epithelium with acute hemorrhage and neutrophilic infiltration; a few foci of microcalcification were shown; several mucus glands were found within the submucosal connective tissue and a few collections of amorphous material, likely mucin. These areas stain negatively, however, with a special stain for amyloid. There is no evidence of viral cytopathic effect or malignancy. Thus, what is not seen is evidence of bacterial infection, viral inclusions, and so on. We are, however, seeing an increase in strictures associated with lichen sclerosus, and those strictures clearly behave much more like inflammatory strictures than traumatically induced isolated scars. Finally, posterior urethral injuries, traumatic by definition, result in obliterative or near-obliterative defects that are associated with extensive fibrosis interposed between the distracted ends of the urethra.

On the other hand, inflammatory strictures associated with gonorrhea were the most commonly seen in the past and are less common now. With the advent of prompt and effective antibiotic treatment, gonococcal urethritis now progresses less often to gonococcal urethral strictures. The place of *Chlamydia* and *Ureaplasma urealyticum* (i.e., nonspecific urethritis) in the development of anterior urethral strictures is not clear. To date, no clear association between nonspecific urethritis and the development of anterior urethral stricture has been established.

There is, as mentioned earlier, a definite association between the development of an inflammatory stricture and lichen sclerosus–balanitis xerotica obliterans (LS-BXO). LS-BXO usually begins with inflammation of the glans and inevitably causes meatal stenosis, if not a true stricture of the fossa navicularis. The cause of this distal penile skin and urethral inflammation is not known. Literature suggests the possibility that bacterial infection is the cause of the resultant skin changes. There is some evidence to suggest that the progression of the stricture eventually to involve the anterior urethra extensively may be due to high-pressure voiding that causes intravasation of urine into the glands of Littre, inflammation of these glands, and, perhaps, microabscesses and deep spongiofibrosis. Whether the urethral changes and eventual fibrosis are also related to bacterial injury has not, to our knowledge, been well defined. Although the use of antibiotics seems, in these

patients, to limit obstructive voiding symptoms, to our knowledge the literature does not show resolution of the stricture process with the use of antibiotics.

What is known as a congenital stricture is an entity that is difficult to understand. If, in embryologic development, a stricture is found at a natural place where a fusion of structures occurs (i.e., the posterior and anterior urethra), a congenital stricture might be a reasonable assumption**.** However, the term *congenital stricture* is used by some to define a stricture for which there is no identifiable cause. We propose, however, that it is reasonable to define a stricture as congenital only if it is not an inflammatory stricture, it is a short-length stricture, and it is not associated with a history of or potential for urethral trauma. This then limits the term *congenital stricture* to strictures of the anterior urethra found in infants before they attempt erect ambulation. So defined, congenital strictures will clearly be the rarest encountered.

Diagnosis and Evaluation

Patients who have urethral strictures most often present with obstructive voiding symptoms or urinary tract infections such as prostatitis and epididymitis. Some patients also present with urinary retention. However, on close inquiry, most of these patients are found to have tolerated notable voiding obstructive symptoms for a long time before progressing to complete obstruction.

Not uncommonly, when a patient cannot void, an attempt is made to pass a urethral catheter. If the catheter does not pass, the nature of the obstruction is determined by dynamic retrograde urethrography. Thus, most cases are managed with acute dilation, and clearly there are many instances in which this is not the best course for the patient. When there is doubt, we determine the nature of the stricture when possible, and selectively place a suprapubic cystostomy catheter to treat the acute situation and allow time for a more appropriate treatment plan to be devised. The practice of blind passage of filiforms and blind dilation without knowledge of the anatomy of the urethral stricture is condemned. Although detailed imaging is not always available, flexible endoscopy is almost universally available in the United States. At the least, the stricture can be visualized and attempted guide wire placement under direct vision is attempted.

For an appropriate treatment plan to be devised, it is important to determine the location, length, depth, and density of the stricture (spongiofibrosis). The length and location of the stricture can be determined with radiography, urethroscopy, and ultrasonography. The depth and density of the scar in the spongy tissue can be deduced from the physical examination, the appearance of the urethra in contrast-enhanced studies, and the amount of elasticity noted on urethroscopy. The depth and density of fibrosis are difficult to determine objectively. The absolute length of spongiofibrosis may not be evident on ultrasound evaluation. **Ultrasound examination clearly can augment contrast-enhanced studies and is accurate in determining the length of narrow-caliber annularity** (Morey and McAninch, 1996a). Contrast studies of the urethra are best carried out by or under the direct supervision of the surgeon responsible for treatment of the patient.

In 1979, McCallum and Colapinto described the use of dynamic radiographic studies and emphasized the need for these studies to be dynamic as opposed to static (Fig. 36–17) (McCallum and Colapinto, 1979a, 1979b). At our center, imaging includes dynamic studies that are accomplished during retrograde injection of contrast material and while the patient is voiding. Even with gentle technique, extravasation during retrograde urethrography is possible in patients in whom the urethra is markedly inflamed. For this reason, contrast studies should be carried out with contrast material that is suitable for intravenous injection and used either directly from the bottle or diluted according to the manufacturers' guidelines. Contrast materials that have been thickened with lubricating jelly or anesthetic gels can be a source of problems, and offer little with regard to enhancement of radiographic studies, nor do they make the studies more comfortable. Real-time ultrasound evaluation of the urethra after it has been filled with a lubricating jelly or saline has been described by Morey and McAninch (1996a, 1996b). It is a misconception, however, that ultrasonography always directly visualizes the spongiofibrosis. However, Morey and McAninch (1996a, 1996b) believe that ultrasonography of the bulbous urethra possibly more accurately determines the length of the stricture, which could be important in considering an anastomotic repair. If the patient is not in steep lateral oblique position for retrograde urethrography, the length of the stricture will be underestimated. Finally, it should be understood that during contrast-enhanced urethrography, more than one projection may be necessary to visualize the stricture. Magnetic resonance is also being explored as an adjunct to the evaluation of urethral stricture, as well as pelvic fracture urethral injuries. In our experience, the use of magnetic resonance for routine strictures or pelvic fracture urethral distraction defects is not routinely beneficial. In the case of urethral tumors, we have found magnetic resonance to be invaluable. The experience of others is commensurate with ours (Pavlica et al, 2003). In the occasional pelvic fracture urethral distraction defect, the alignment of the two urethral ends can be nicely defined.

Endoscopic examination may be necessary after the contrast studies. The flexible cystoscope has simplified this evaluation, and when local anesthesia is used, there is little discomfort associated with it. The scope can be passed to the stricture, and many times it is not necessary to pass it beyond that level. In addition, it is not always necessary, and usually not beneficial, to dilate the stricture at the time of the initial endoscopic evaluation. Pediatric endoscopic equipment has proved to be extremely valuable for examination of the urethra proximal to a narrow-caliber area without the need to dilate the narrowest area. In the patient who cannot void and has a suprapubic tube, combined contrast studies with endoscopy are helpful in defining the stricture anatomy (Fig. 36–18).

It is imperative, however, to completely evaluate the urethra proximal and distal to the stricture with endoscopy and bougienage during surgery to ensure that all the involved urethra is included in the reconstruction. Whereas hydraulic pressure generated by voiding may keep segments proximal to the stricture patent, unless these segments are included in the repair, they are at risk for contraction after obstruction of the narrow-caliber segment is relieved with reconstruction. For this reason, any abnormal areas of the urethra that are proximal to a narrow-caliber segment of the stricture must be treated with suspicion. If the lumen does not appear to demonstrate evidence of diminished compliance, we presume that area to be uninvolved in active stricture disease. However, coning down of the urethra suggests its involvement in the scar.

In some patients, the urethra proximal to a narrow area may remain confusing with regard to its potential for continued constriction after reconstruction. In select patients, we have found it useful to place a suprapubic tube to defunctionalize the urethra. After 6 to 8 weeks, if there is to be

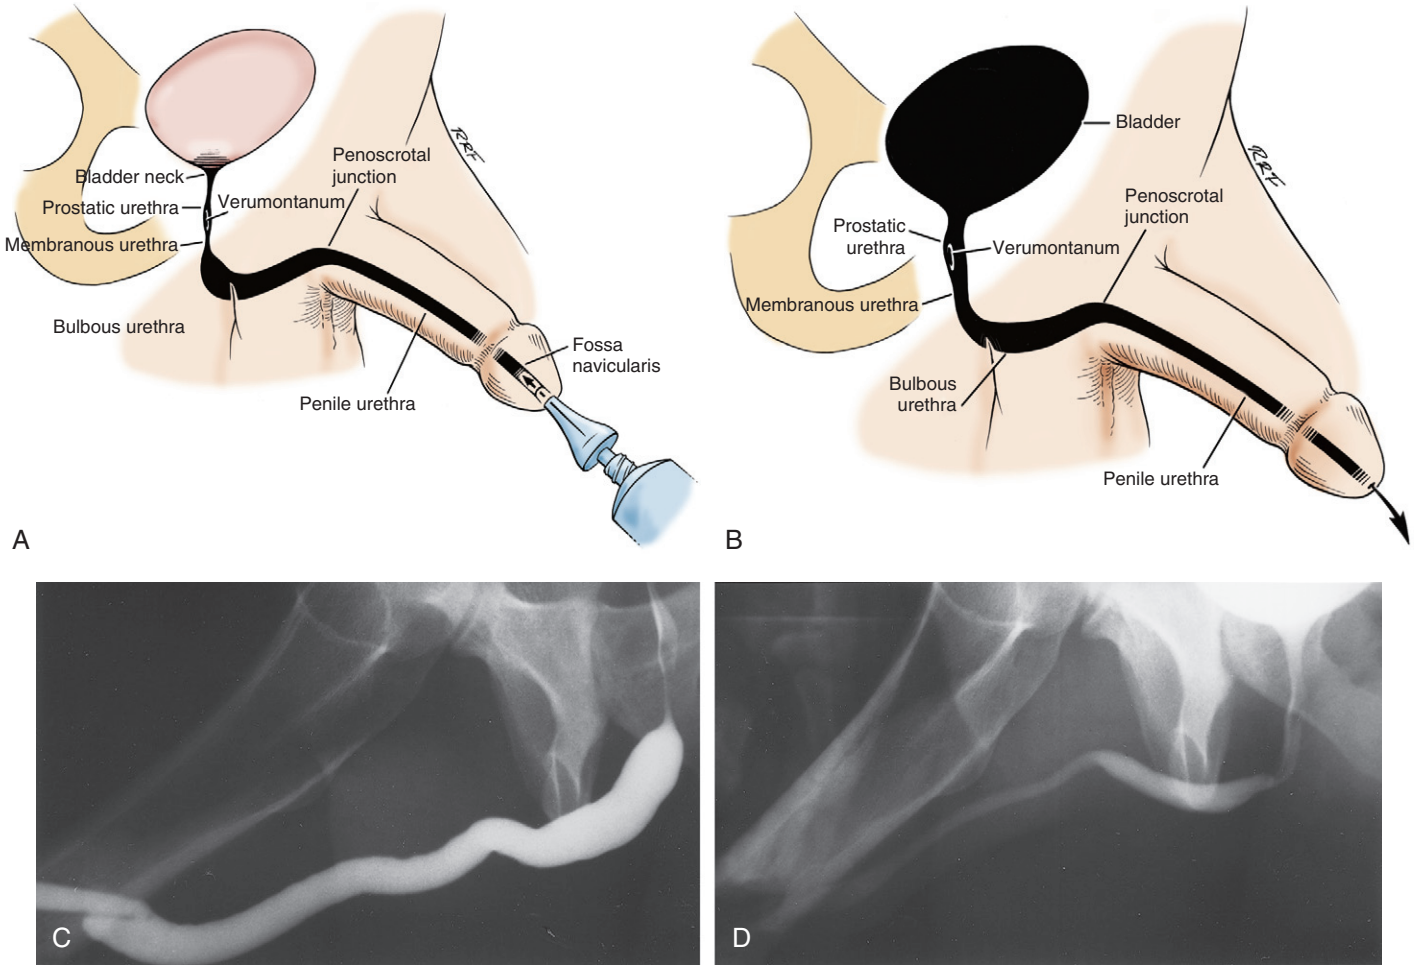

Figure 36–17. **A,** Representation of a dynamic retrograde urethrogram with the criteria of McCallum illustrated. **B,** Representation of a dynamic voiding urethrogram with the criteria of McCallum illustrated. **C,** A normal retrograde urethrogram. **D,** A normal voiding urethrogram. constriction of an area that was hydrodilated with voiding, the tendency for that constriction to occur should become apparent.

Key Points: Urethral Stricture

- The term *urethral stricture* refers to anterior urethral disease and is a scarring process that involves the epithelium as well as the spongy erectile tissue of the corpus spongiosum. Contraction of the scar reduces the urethral lumen. In contrast, posterior urethral strictures are more correctly referred to as pelvic fracture urethral injuries; strictures of the prostatic urethra or bladder neck are properly referred to as contractures or stenoses.
- The anterior urethra is invested by the corpus spongiosum and as it proceeds proximally is eccentrically placed in relation to the corpus spongiosum. The genital skin has a dual and bilateral blood supply, forming a fasciocutaneous vascular system. The vascularity of the corpus spongiosum is based on the common penile artery.
- In general, most anterior urethral strictures are the result of trauma. Inflammatory strictures associated with gonorrhea are rarely seen; however, strictures associated with lichen sclerosus clearly behave like inflammatory strictures.
- Patients who have urethral strictures most often present with obstructive voiding symptoms or urinary tract infections such as prostatitis and epididymitis. Those patients who present with urinary retention, on close inquiry, have tolerated notable voiding obstructive symptoms for a long time.
- For an appropriate treatment plan to be devised, it is important to determine the length, location, depth, and density of the spongiofibrosis. This can be done with a combination of contrast-enhanced studies, endoscopy, and selective ultrasonography. It is imperative to completely evaluate the urethra proximal and distal to the stricture with endoscopy. A pediatric cystoscope is useful.

Treatment

Although the treatment of urethral stricture disease dates to the foundations of our specialty, significant progress made during the last 50 years allows many of the most complex strictures to be reliably reconstructed in one stage. In the past, a concept known as the reconstructive ladder was used as a treatment guideline for urethral strictures. That concept was based on the principle that the simplest procedure should always be attempted first, and sometimes repeated after failure, before moving on to more complex approaches. This approach is considered archaic in modern urethral reconstruction.

Both the patient and the physician must have a good understanding of the goal of treatment before the treatment choice is made. To this end, treatment options should be discussed with the patient, with care taken to emphasize the anticipated outcome with regard to potential cure. Some patients may prefer stricture management and choose to have periodic dilations in the office, at home, or in the hospital rather than undergo technically detailed open surgery. Others may have cure as a goal and choose surgical management. Many surgical procedures today have short- and midterm results approaching long-term success rates of more than 90% to 95% for many strictures.

Dilation

Urethral dilation is the oldest and simplest treatment of urethral stricture disease, and for the patient with an epithelial stricture without spongiofibrosis, it may be curative. **The goal of this treatment, a concept that is frequently forgotten, is to stretch the scar without producing more scarring.** If bleeding occurs during dilation, the stricture has been torn rather than stretched, possibly further injuring the involved area.

The least traumatic method to stretch the urethra is to use soft techniques over multiple treatment sessions. We believe that the safest method of urethral dilation currently available involves the use of urethral balloon-dilating catheters. These catheters may be attached to a filiform tip or passed over a guide wire or may come with an integral coudé tip. For initial dilation, we favor the use of balloons placed over wires that have been passed through the stricture under endoscopic control.

Dilation can be curative, and, in the literature, in correctly selected patients, has short and midterm efficacy rates equal to internal urethrotomy. Selection criteria will be discussed in the following section that discusses internal urethrotomy. The literature does not compare internal urethrotomy and dilation in randomized selection, thus we do not have a true comparison but rather comparison by retrospective analysis (Steenkamp et al, 1997).

Internal Urethrotomy

Internal urethrotomy refers to any procedure that opens the stricture by incising it transurethrally. The urethrotomy procedure involves incision through the scar to healthy tissue to allow the scar to expand (release of scar contracture) **and the lumen to heal enlarged.** The goal is for the resultant larger luminal caliber to be maintained after healing.

With epithelial apposition, wound healing occurs by primary intention. Internal urethrotomy does not provide an epithelial approximation but, rather, aims to separate the scarred epithelium so that the healing occurs by secondary intention. In healing by secondary intention, epithelialization progresses from the wound edges. As it progresses from the wound edge, epithelialization slows. In an effort to aid epithelialization, nature invokes the forces of wound contraction, not to be confused with scar contraction. Wound contraction closes the wound defect and limits the size of the area that requires epithelialization, hastening the healing of the surface defect. In the case of internal urethrotomy, however, wound contraction merely tries to reapproximate the edges of the scar, putting a race into effect. If epithelialization progresses completely before wound contraction significantly narrows the lumen, the internal urethrotomy may be a success. If wound contraction significantly narrows the lumen before completion of epithelialization, the stricture has recurred. The study by Dubey and colleagues (2005) shows the extent of luminal narrowing to be a predictor of success with internal urethrotomy: the narrower the percent of narrowing, the worse the outcome, with a cutoff of 74% narrowing.

Many surgeons have learned to perform internal urethrotomy by making a single incision at the 12-o'clock position. This location might be questioned, however, on the basis of the location of the urethra within the corpus spongiosum (see Fig. 36–25). On examination of a cross section of the corpus spongiosum, it can be seen that the thinnest portion of the anterior aspect is from 10-o'clock to 2-o'clock. The distance between the anterior wall of the urethra and the corpora cavernosa is likewise short in the bulbous urethra, and a single 12-o'clock cut could rapidly

penetrate the corpus spongiosum and extend into the triangular ligament; although it might not enter the corpora cavernosa, a deep cut could enter the intracrural space. Distally, although the anterior aspect of the corpus spongiosum is thicker, on the other hand, a deep incision in the more distal aspects of the anterior urethra will certainly enter the corpora cavernosa, and these incisions have been associated with erectile dysfunction thought to be due to local cavernosal veno-occlusive dysfunction. Vigorous incisions at 10-o'clock and 2-o'clock in the bulbous urethra risk the same problem. If deep spongiofibrosis is present, stricture cure is impossible by internal urethrotomy, and these deep incisions are therefore unnecessary.

The most common complication of internal urethrotomy is recurrence of stricture. Less commonly noted complications of internal urethrotomy include bleeding (almost always associated with erections immediately after the procedure) and extravasation of irrigation fluid into the perispongiosal tissues. These complications are rare today, however, because of the less frequent use of aggressive internal urethrotomy as a treatment modality for urethral strictures. Normal saline should be used as the irrigant when direct visual internal urethrotomy is performed. Additionally with the use of deep urethrotomy incisions, another complication can be creation of a fistula between the corpus spongiosum and the corpora cavernosa, and thus cavernosal veno-occlusive dysfunction.

A major problem with assessing the success rates of internal urethrotomy is that the nature of the strictures that have been treated with internal urethrotomy has been poorly reported. In addition, the literature is not clear regarding the goal of internal urethrotomy. For many, an internal urethrotomy is successful if it offers temporary relief. Therefore, in many cases, internal urethrotomy has been reported as successful despite the fact that it has been associated with eventual stricture recurrence. A report published by Santucci and McAninch (2001) (Rosen et al, 1994) using actuarial techniques shows the curative success rate of internal urethrotomy to be approximately 20%. Evaluations by Pansadoro and Emiliozzi (1996) and others show the curative success rate of direct visual internal urethrotomy to be approximately 30% to 35%. Their analysis also shows that there is virtually no increase in success rate with a second internal urethrotomy. **The data show that strictures at the bulbous urethra that are less than 1.5 cm in length and not associated with dense, deep spongiofibrosis (i.e., straddle injuries) can be managed with internal urethrotomy, with a 74% moderately long-term success rate.** Pansadoro's study did not have any long-term successes for treated strictures outside the bulbous urethra. The variables associated with success of internal urethrotomy have been verified by other studies (Heyns et al, 1998). A number of studies now show that the success of reconstruction is diminished by multiple prior urethral dilations and internal urethrotomy (Stone et al, 1983; Albers et al, 1996; Heyns et al, 1998; Boccon-Gibod, 2005). Success rates with internal urethrotomy are not equal to those of open urethral reconstruction (Mandhani et al, 2005). A number of analyses have sought to compare the cost effectiveness of the practice of internal urethrotomy initially prior to consideration of open reconstruction. The analyses all differ in method, and thus not surprisingly differ in findings (Rourke and Jordan, 2005; Wright et al, 2006; Wessells, 2009).

Several techniques have been employed to oppose the process of wound contraction and to prevent stricture recurrence. One method is to leave an indwelling Foley catheter for as long as 6 weeks after urethrotomy, in the hope that the urethra will mold around the catheter as it heals. Studies have shown, however, that the failure rate of long-term catheterization after internal urethrotomy is similar to that seen with 3 to 7 days of catheterization, and even 6 weeks is not sufficient time to oppose the forces of wound contraction.

Another technique used to oppose the forces of wound contraction after internal urethrotomy is home self-catheterization or home urethral obturation. After internal urethrotomy, patients generally have an indwelling catheter placed for a period of 3 to 5 days. When the catheter is removed, the patient is started on a urethral obturation regimen. Most regimens require more frequent catheterizations early in the recovery period, with a tapering schedule during the next 3 to 6 months. Anecdotally, many have reported an improved cure rate with self-catheterization in combination with internal urethrotomy. It has been our experience, however, that the stricture inevitably recurs when the patient stops self-obturation, regardless of how long it has been used. That being understood, this can effectively manage the problems when it is combined with a urethral dilating regimen in the properly motivated patient. Colchicine, because it binds tubulin, has been used along with internal urethrotomy (Carney et al, 2007). Initial findings in a nonrandomized study also suggest that, perhaps by pharmacologically blocking tubulin and thus possibly wound contracture, the results of internal urethrotomy may be better.

Urethral stents (removable or permanently implantable) are another modality used in opposing the forces of wound contraction after internal urethrotomy or dilation. Removable urethral stents are designed to prevent the process of epithelialization from incorporating the stent into the urethral wall and are left in place for as long as 6 months to 1 year before they are removed. The greatest experience with these removable stents comes from Israel (Yachia and Beyar, 1991), and centers there report good success in small series. The Memokath stent is currently being used in studies in the United States. It is a removable stent made of nitinol.

The majority of experience with permanently implantable stents comes from Europe and the United Kingdom. Milroy (1993) has reported a success rate of 84% at 4.5 years with use of the permanently implantable UroLume (Rousseau et al, 1987; Sigwart et al, 1987; Milroy et al, 1988, 1989; Sarramon et al, 1990; Ashken et al, 1991; Krah et al, 1992; Sneller and Bosch, 1992; Verhamme et al, 1993; Badlani et al, 1995; Milroy and Allen, 1996; Jordan, 1997; Tillem et al, 1997; Brandes and McAninch, 1998; Shah et al, 2003). The UroLume, made of an alloy, is designed to be incorporated into the wall of the urethra and corpus spongiosum. Available data show that the stent is best employed for relatively short strictures of the bulbous urethra associated with minimal spongiofibrosis. However, these are the strictures that are most successfully reconstructed with open techniques that offer better long-term success rates. The North American Study Group 11-year data have been published (Shah et al, 2003). Of 179 patients originally enrolled in the North American Study, 24 patients completed 11 years of follow-up. The overall success rate for all patients enrolled at 11 years is less than 30% (Shah et al, 2003). A 10-year follow-up study from the Netherlands (De Vocht et al, 2003) reported results thought to "weaken the optimistic early results"; of 15 patients implanted, only 2 were satisfied with their stent at 10 years.

Permanently implantable stents are associated with some unique complications. The stents must be **placed only in the bulbous urethra,** and when they are placed beyond the area of the scrotal urethra, placement has been associated with

pain on sitting and intercourse. Some patients (particularly young patients) **complain of perineal pain,** often with vigorous activity, even after implantation of the stent in the deep bulbous urethra. In addition, **longer, bulbous strictures require two stents that are overlapped.** These **stents can migrate** away from each other, leaving a gap between them where recurrence of stricture is inevitable. When this occurs, the stricture recurrence is excised and a third stent is placed to span the gap.

There are also **specific contraindications to the use of the UroLume.** Patients who have undergone **prior substitution urethral reconstruction,** particularly where skin has been incorporated into the urethra, have been shown to be poor candidates for implantation with the UroLume stent because contact of the stent with the skin is associated with a virulent hypertrophic reaction. These patients experience postvoid dribbling, and the hypertrophic reaction can be so severe in some cases that functional recurrence of the stricture results. Another subset of patients shown to be **poor candidates for the UroLume is those with strictures associated with deep spongiofibrosis.** Patients who fall into this category are **those who have had urethral distraction injuries and straddle injuries associated with deep fibrosis.** As of this writing, the UroLume is approved by the U.S. Food and Drug Administration. The product insert clearly contraindicates use of the UroLume in patients with pelvic fracture urethral distraction defects. Many greeted the arrival of the UroLume as a panacea. Experience is accumulating not only with use of the UroLume but also with misuse of the device, and its use should therefore be approached with the utmost caution. Some centers in Europe are now advocating use of the UroLume only in patients who are older than 50 years, or who have other significant medical problems that make the option of lengthy open urethral reconstruction less appealing. At our center, we have seen teenagers implanted, many patients implanted for pelvic fracture urethral distraction, patients with stents palpable on the shaft of the penis, and patients with both prostatic stents and urethral stents—all absolute contraindications. We have seen patients with as many as six stents in place, and although the maximal number of stents is not absolutely defined, if the first stent does not work, it is probably wise to refer the patient for reconstruction, which is possible with acceptable results (86% with mean follow-up of 25 months) (Barbagli et al, 1999). Placement of more stents, except when two stents were originally placed and then migrated from each other, is probably futile. However, in carefully selected elderly patients, the UroLume can be life changing for the patients, with minimal morbidity associated with the implantation procedure, in a situation where early and midterm success is adequate. The place of permanently implanted stents seems to be challenged as newer temporary/removable urethral stents are introduced.

Lasers

Types of lasers that have been used for the treatment of urethral stricture disease include carbon dioxide, argon, KTP, Nd:YAG, holmium:YAG, and excimer lasers. The ideal laser for use in the treatment of urethral stricture disease is one that totally vaporizes tissue, exhibits negligible peripheral tissue destruction, is not absorbed by water, and is easily propagated along a fiber. Although the carbon dioxide laser appears to be ideally suited, it must be used with a gas cystoscope, which carries the potential threat of a carbon dioxide embolus.

For both the argon and the Nd:YAG lasers, the predominant mode of action is thermal necrosis, which leads to a significant potential for peripheral tissue injury, rather than vaporization. The Nd:YAG laser has also been used with a bare fiber in the contact mode. A bare fiber carries with it a risk of forward scatter. When it is used in the contact mode, the YAG energy is transferred to a sapphire tip. Advocates of the use of a contact laser suggest that it obliterates the scar by vaporization; however, results with use of these fibers are no better than those with direct cold-knife visual internal urethrotomy.

A KTP laser is essentially an Nd:YAG laser that has passed through a KTP crystal, resulting in a reduced depth of penetration. A KTP laser urethrotomy is accomplished by passing the fiber over the scar tissue to make urethrotomy cuts. The holmium:YAG laser has properties similar to the KTP laser, and like the KTP laser, it provides both direct contact cutting and vaporization with minimal forward scatter. Experience with the holmium:YAG laser is accumulating; anecdotally, it may have a place in the management of some strictures, in particular strictures that are relatively isolated and short.

The excimer laser is a true vaporizing laser that has little forward scatter or peripheral tissue necrosis associated with it. Little experience with this laser has been reported, but future investigation is clearly warranted.

To date, the results of laser urethrotomy are mixed. With the advent of new lasers and experience with them, however, future data may show better results.

Open Reconstruction

Excision and Reanastomosis. **It has now been demonstrated with certainty that the most dependable technique of anterior urethral reconstruction is the complete excision of the area of fibrosis, with a primary reanastomosis of the normal ends of the anterior urethra** (Fig. 36–19) (Russell, 1914). The best results are achieved when **the following technical points are observed: the area of fibrosis is totally excised; the urethral anastomosis is widely spatulated, creating a large ovoid anastomosis; and the anastomosis is tension free.**

The **success of this procedure relies on vigorous mobilization of the corpus spongiosum.** With vigorous mobilization, dissection of Buck fascia to improve compliance, development of the intracrural space, and detachment of the bulbospongiosus from the perineal body, significant lengths of stricture can be excised and reanastomosed. Strictures of 1 to 2 cm are generally easily excised with reanastomosis. In some cases, strictures as long as 3 to 5 cm can be totally excised and a primary reanastomosis of the anterior urethra performed. For very proximal short-length bulbous strictures, tension-free anastomosis can be facilitated by the dissection of the membranous urethra (Fig. 36–20). As a rule, the closer the stricture is to the membranous urethra, the longer it can be and still be reconstructed with anastomotic techniques. For many proximal strictures, a single-layer anastomosis is preferable. When the length of stricture precludes total excision of fibrosis with primary anastomosis, tissue transfer is required. Morey published a series of patients who had stricture excision with anastomosis for strictures up to 5 cm. He makes the point that the younger patient has more compliant tissue, thus allowing the limits to be stretched (Morey and Kizer, 2006).

Morey also reported an interesting variant of excision with anastomosis for anterior stricture. In that case report, a patient had two independent areas of stricture apparently separated by totally normal urethra and corpus spongiosum. The authors excised both areas of stricture independently with respective anastomosis of

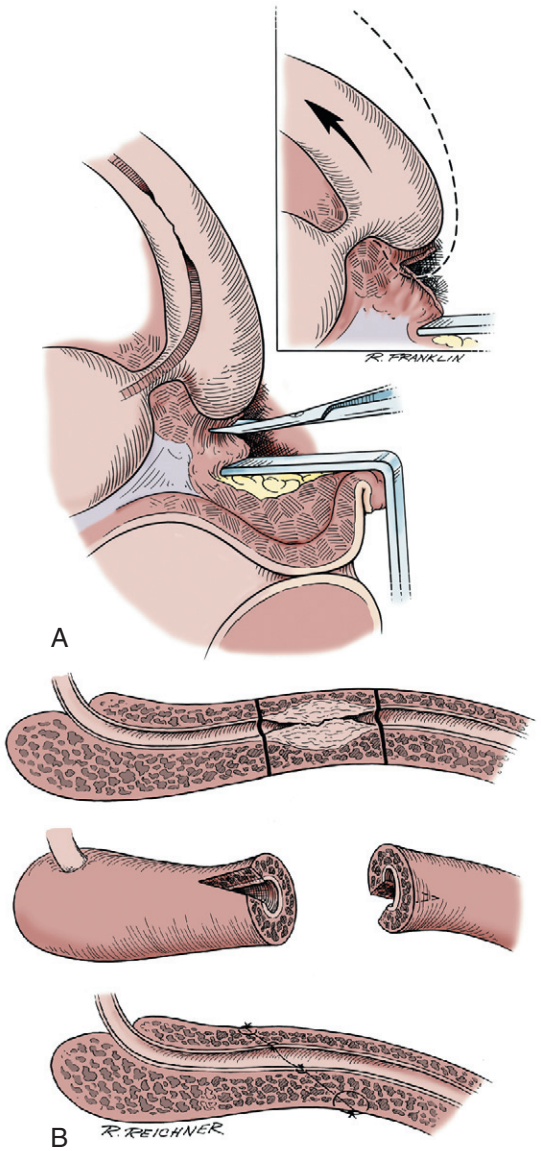

Figure 36–19. Techniques for excision and primary reanastomosis of anterior urethral stricture. **A,** The bulbospongiosus is released from its attachment to the perineal body. The arteries to the bulb are not divided. This technique allows the urethra to be mobilized distally. This technique combined with development of the intracrural space can shorten the path of the urethra by approximately 1 to 1.5 cm. **B,** Technique of a primary spatulated anastomosis after excision of an anterior urethral stricture. (**A** and **B,** From Jordan GH. Principles of plastic surgery. In: Droller MJ, editor. Surgical management of urologic disease: an anatomic approach. Philadelphia: Mosby–Year Book; 1992. p. 1218–37.)

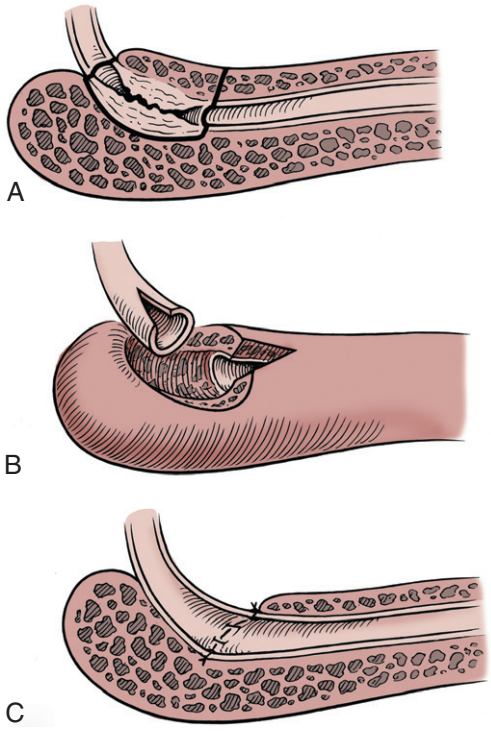

Figure 36–20. Technique of excision of very proximal bulbous urethral stricture with reanastomosis. This technique is facilitated by dissection of the membranous urethra. **A,** The area of the stricture is defined for excision. **B,** The stricture is excised and both ends of the urethra are spatulated on the dorsal aspect. **C,** The anastomosis is complete.

each site. Although this case was successful, we think that the authors' considerable experience allowed them to achieve a successful result, and a safer reconstruction with use of onlay or augmented onlay might have been better (DeCastro et al, 2002).

Jordan reported the use of a vessel-sparing excision and reanastomosis of the bulbar urethra. The dissection is similar to the standard excision and reanastomosis (Fig. 36–21), except once the triangular ligament is divided and the intracrural space developed, the space between the membranous urethra and the proximal vasculature is developed and these vessels are preserved (Fig 36–22). The urethra is then divided with the stenotic segment excised, the ends are spatulated, and then the reanastomosis is done. Advantages of preserving the proximal blood supply to the bulbar urethra include those patients whose distal blood supply is compromised by trauma, previous surgery, or hypospadias. Another theoretical advantage would be a decrease in the risk of erectile dysfunction. Further studies need to be done to confirm our initial excellent results and the above advantages (Jordan, et al 2007; Gur and Jordan, 2008).

Four grafts that have been successfully used for primary urethral reconstruction are the full-thickness skin graft, the bladder epithelial graft, the oral mucosal graft and the rectal mucosal graft. Oral mucosal grafts as mentioned can be taken from the cheek (buccal), the lip (labial), and the undersurface of the tongue (lingual). Split-thickness skin grafts have been used for staged anterior urethral reconstruction (Humby, 1941; Memmelaar, 1947; Pressman and Greenfield, 1953; Devine et al, 1976; Hendren and Crooks, 1980; Schreiter and Koncz, 1983; Webster et al, 1984; Hendren and Reda, 1986; Ransley et al, 1987; Burger et al, 1992; Jordan, 1993; El-Kassaby et al, 1996; Wessels and McAninch, 1996). The characteristics and microvascularity of some of those grafts are discussed earlier in this chapter in the section Principles of Reconstructive Surgery.

In years past, graft reconstruction of the urethra was almost abandoned in favor of flap reconstruction techniques. However, since the late 1990s, there has been a resurgence of interest in the use of grafts (Wessells and McAninch, 1996) and, specifically, the use of buccal mucosal grafts (Hellstrom et al, 1996; Weinberg et al, 2002; Barbagli et al, 2003; Elliott et al, 2003; Bhargava and Chapple, 2004; Kellner et al, 2004; Xu et al, 2004; Dubey et al,

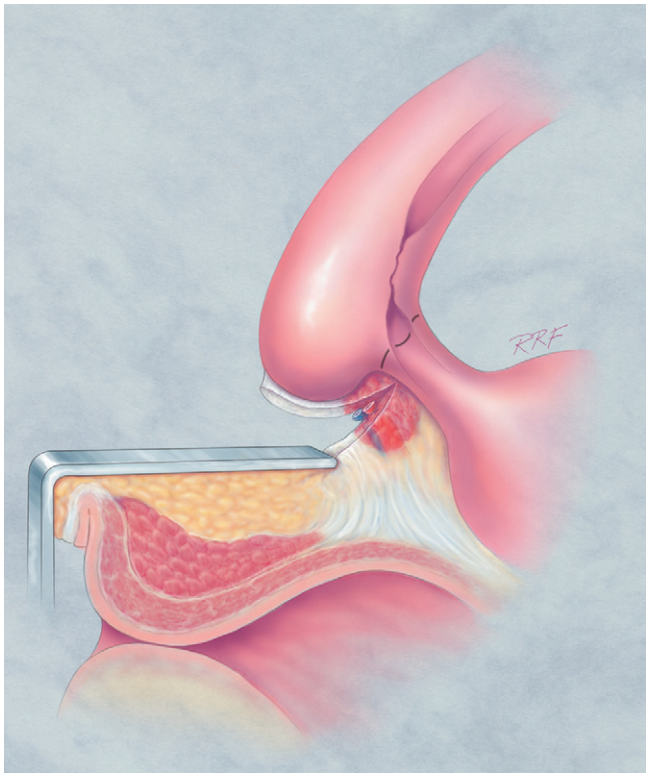

Figure 36–21. Diagrammatic representation of the dissection of the proximal corpus spongiosum, bulbospongiosum, and the membranous urethra. Illustrated is the customary technique for dividing the urethra through the juncture of the membranous urethra with the proximal bulbous urethra—to perform an excision of stricture with a primary anastomosis. In this illustration, the proximal vasculature has been ligated and divided. The urethra can then be divided at the distal most limits of the membranous urethra.

2005). **Grafts have been most successfully employed in the area of the bulbous urethra, where the urethra is invested by the bulk of the ischiocavernosus muscles. However, the use of grafts, other than in the area of the bulbous urethra, and, in some cases, the use of tubed reconstruction is reported in increasing numbers.** The grafts can be applied to the ventrum of the urethra; however, a ventral urethrotomy seems to be advantageous only if the use of the spongioplasty maneuver is contemplated (Fig. 36–23). The spongioplasty procedure requires that the corpus spongiosum adjacent to the area of the stricture be relatively normal and free of fibrosis. There are data to support the superiority of results with the dorsal onlay technique and other reports showing no difference in success. In the past, we preferred to use lateral graft onlay (see Fig. 36–23) or dorsal graft onlay (see Fig. 36–23). Placement of the urethrostomy laterally allows exposure of the urethra while cutting through the corpus spongiosum, where it is relatively thinner, thus limiting bleeding and maximizing exposure. In addition, in the bulbous urethra, the graft can be sutured to the underlying muscle bed in the hope of improving graft host bed immobilization and approximation.

The Monseur (1980) urethral reconstruction was applied in only a few select centers. In this technique, the urethrostomy was made through the stricture on the dorsal wall. The edges of the stricture were then sutured open to the underlying triangular ligament or corpora cavernosa, or both. Barbagli and associates (1995) have modified the Monseur technique (Fig. 36–24). In that modification, the urethrostomy is performed through the stricture on the dorsal wall. In the area of the urethrostomy, a graft is then applied and spread fixed to the triangular ligament or corpora cavernosa, or to both. In turn, the edges of the stricturotomy are then sutured to the edges of the graft as well as to the adjacent structures. The results of this technique are excellent. The ventral and dorsal graft onlay techniques can both be used with stricture excision and strip anastomosis (augmented anastomotic procedure) (Fig.

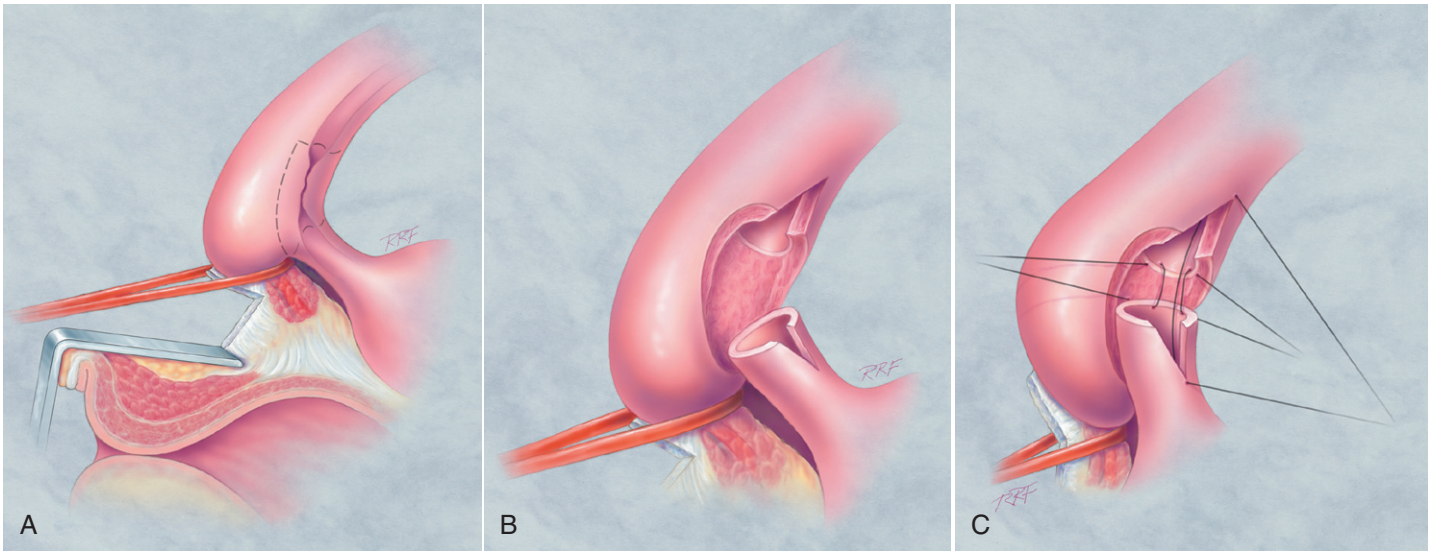

Figure 36–22. Illustrated is the technique of vessel-sparing excision with primary anastomosis. The proximal corpus spongiosum, bulbospongiosum, and area of the proximal vessels and membranous urethra have been dissected. **A,** Illustrated is the dissection of the space between the proximal vasculature and the membranous urethra. In this technique, the arteries to the bulb can be preserved, and the membranous urethra can be divided at its juncture with the bulbous urethra. The area of proximal stricture can be excised. **B,** The illustration of the stricture having been excised prior to placement of the anastomotic sutures. **C**, Anastomotic sutures are placed to effect the spatulated anastomosis. At this center, customarily we alternate polydioxanone sutures with Monocryl; however, any acceptable absorbable suture can be used. Note the membranous urethra is spatulated on the dorsum as is the proximal bulbous urethra.

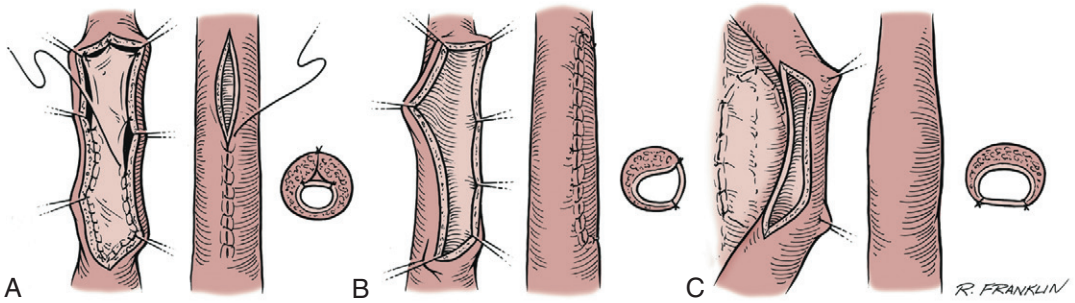

Figure 36–23. Diagram of various techniques of graft onlay. **A,** Ventral onlay with spongioplasty. **B,** Lateral onlay with quilting to the ischiocavernosus muscle. **C,** Dorsal onlay with spread fixation of the graft.

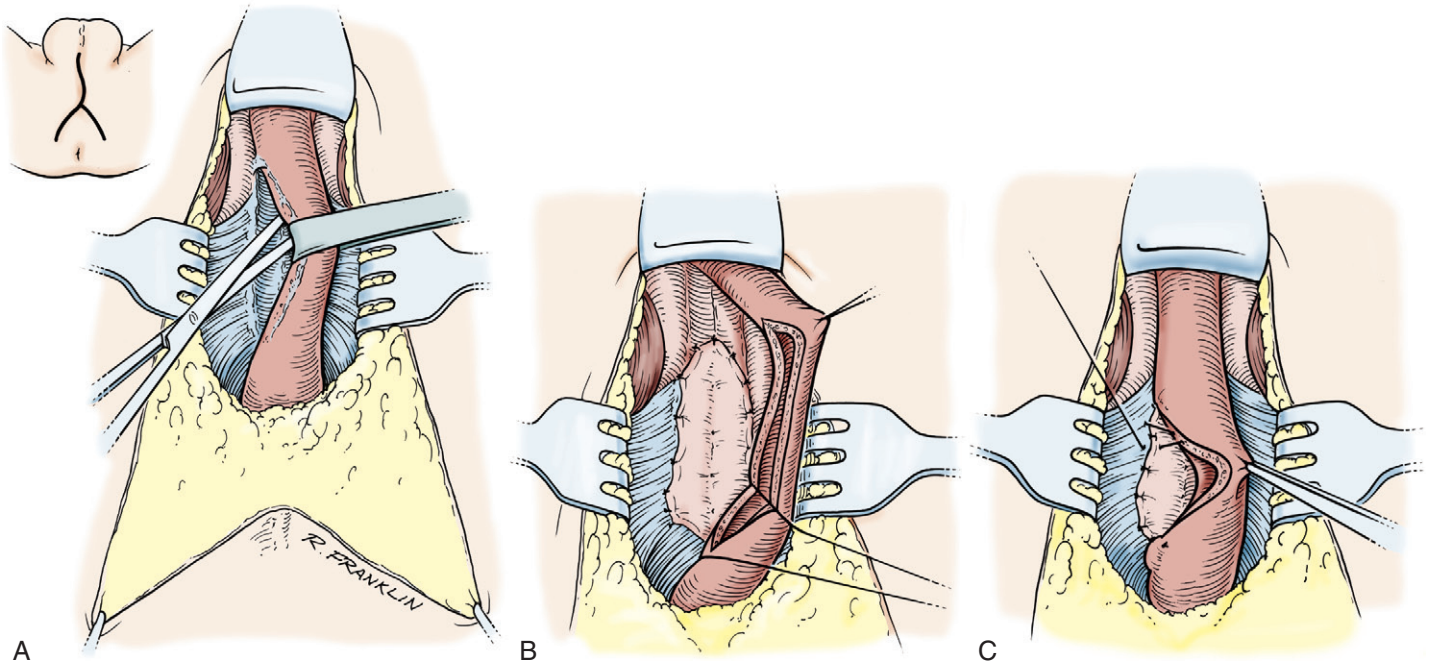

Figure 36–24. Technique of dorsal graft onlay popularized by Barbagli. **A,** The corpus spongiosum is detached from the triangular ligament and corpora cavernosa. **B,** A dorsal urethrostomy is performed. The graft is spread fixed to the corpora cavernosa. Note the pie-crusting incision. **C,** The edges of the stricturotomy are then sutured to the graft as well as to the corpora cavernosa.

36–25). For proximal strictures, the vessel-sparing technique of augmented anastomosis depends on the surgeon's ability to excise the scarred epithelium and underlying corpus spongiosum tissue without the need to completely divide the corpus spongiosum.

Another option is the two-staged application of a mesh split-thickness skin graft, buccal mucosal graft, or posterior auricular full-thickness skin graft. In the first stage of the staged graft procedure, a medium-thickness split-thickness skin graft, a buccal mucosal graft, or a Wolfe graft is placed over the dartos fascia. If the graft is placed immediately onto the tunica albuginea or corpora cavernosa, the inability to mobilize the graft makes second-stage tubularization difficult. However, there is an advantage to having at least a midline strip of the graft adherent to the corpora cavernosa. At a later date, second-stage surgery is performed to tubularize the graft. Whereas Schreiter and Noll (1989), who first described the procedure of mesh split-thickness skin graft, often proceeded to the second stage within 3 to 4 months, we wait 12 months between the first- and second-stage surgeries if a split-thickness skin graft is used. This procedure has been found useful for select cases in both the United States and Europe. In the United States, its use has mostly been confined to the most difficult cases, however, with single-stage reconstruction still applied to the majority. As already mentioned, staged graft techniques have been effectively used in the complicated hypospadias patient. Staged buccal graft operations have been successfully employed in the LS-BXO patients with midterm follow-up. In addition, in the complicated hypospadias patient, staged buccal grafts and posterior auricular skin grafts have been successfully employed (Fig. 36–26).

A number of applications of genital skin islands, mobilized on either the dartos fascia of the penis or the tunica dartos of the scrotum, have been proposed for the repair of urethral stricture disease. In the past, these "flap operations" were considered separate procedures. We suggest that all these procedures are really different applications of a single concept, as proposed by the microinjection studies of Quartey (1983). Skin islands can be viewed as passengers on fascial flaps, and the design of flaps for urethral reconstruction can be paralleled to the design of flaps for reconstruction in general.

There are **three important considerations for the use of flaps in urethral reconstruction: the nature of the flap**

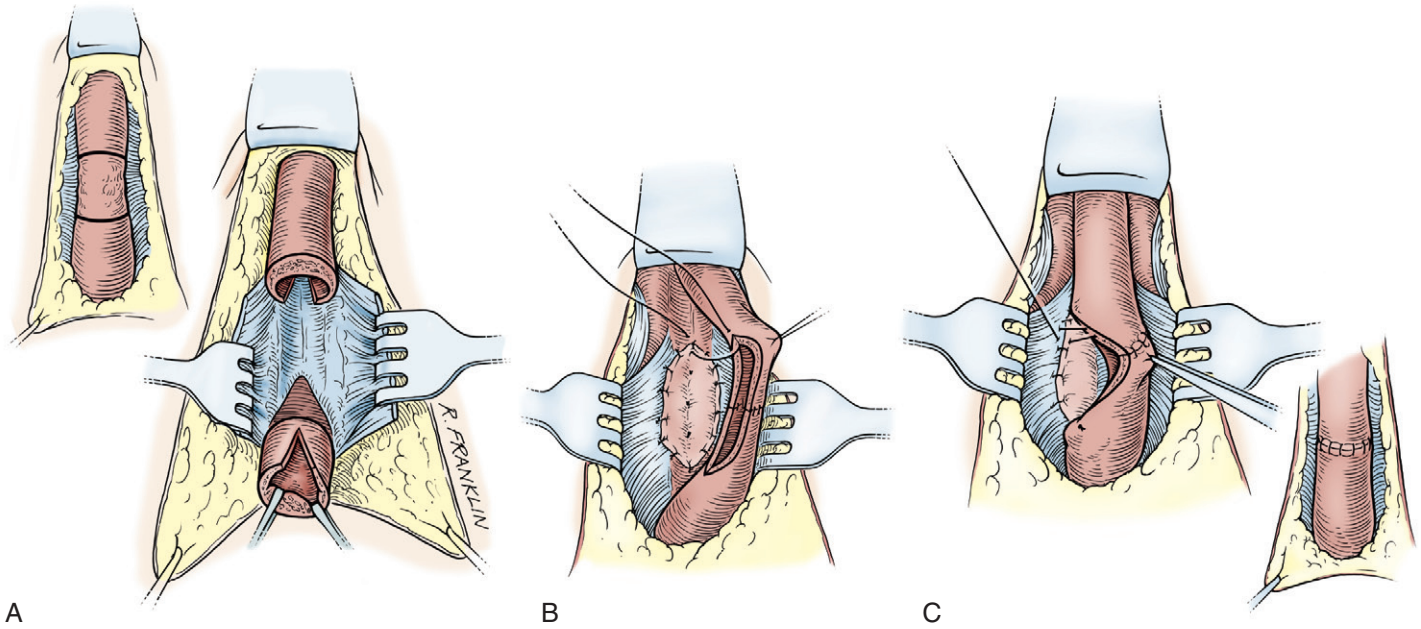

Figure 36–25. Technique of augmented anastomosis with graft onlay. **A,** The corpus spongiosum is detached from the triangular ligament and the corpora cavernosa. The area of spongiofibrosis is identified and marked, and the area of narrowest caliber stricture is excised. The urethral ends are then spatulated on the dorsum. **B,** A two-layer floor strip anastomosis is performed and the graft is spread fixed to the corpora cavernosa. Note the pie-crusting incisions and the mattress sutures. **C,** The edges of the stricturotomy are then sutured to the graft as well as to the corpora cavernosa.

tissue, the vasculature of the flap, and the mechanics of flap transfer. The skin must be nonhirsute for urethral reconstruction. **In addition, for donor site consideration, it is most convenient to use the areas of redundant nonhirsute genital skin.**

If the redundancy is dorsal, the skin island can be oriented transversely and mobilized on the dorsal dartos fascia after the techniques described by Duckett and Standoli in 1984 (Fig. 36–27) (Duckett, 1986, 1992; El-Kassaby et al, 1986; Duckett et al, 1993). If there is redundancy of the ventral skin, the skin island can be mobilized as a ventral longitudinal island. These islands can be either vigorously mobilized on a ventrolaterally oriented dartos fascial flap for transposition to the perineum or less vigorously mobilized and transposed and inverted into a pendulous urethral stricture defect (Fig. 36–28) (Orandi, 1972). Ventral islands can be oriented transversely (Fig. 36–29) as well as longitudinally. Longer skin islands can be mobilized by orienting the island both ventrally and transversely at the distal extent. This "hockey stick" orientation allows islands as long as 7 to 9 cm (Fig. 36–30). For distal strictures of the anterior urethra, including the fossa and meatus as well as the pendulous urethra, the islands can be advanced to reconstruct to the level of the meatus by either developing glans wings or elevating the ventral glans.

Where there is general redundancy to the penile skin, the islands can be oriented circumferentially. These "circular skin islands" are mobilized on the entire penile dartos fascia, and the mechanics of transposition suggest that they are most efficient when they are ventrally based, with the pedicle split dorsally. In some cases, circular skin islands as long as 15 cm can be obtained (El-Kassaby et al, 1986; McAninch, 1993; Miller and McAninch, 1993). The so-called Q flap circular island design can provide even longer islands, sometimes necessary for complex long-length anterior urethral reconstruction (Morey et al, 2000).

Many times, it is beneficial to combine the excision of the stricture with a skin island onlay (Fig. 36–31) **or a graft onlay** (see Fig. 36–25, augmented anastomosis). We have found that **segments of very narrow caliber (nearly or totally obliterating) are difficult to deal with.** These segments can often be completely excised; a roof or floor strip anastomosis of the urethra is performed, and the remaining urethrotomy defect is filled with either a graft or a skin island onlay. In some patients, there are relatively large nonhirsute areas of the scrotal skin that can be elevated on the tunica dartos of the scrotum. This flap has, in the past, been maligned in the literature. However, we and others have extensive experience with these flaps and, in select cases, have had very good results. The fascial flap must be based laterally, and so oriented, these flaps have been shown to be extremely reliable. Because the tunica dartos has a significant muscle component, the skin island must be carefully tailored. If these skin islands are correctly tailored at the outset, they are not attended with diverticular development as some have believed they were in the past. We now have used these flaps in more than 80 patients with excellent results and good long-term follow-up (>12 years at this writing). Scrotal skin islands are not our first choice; however, for difficult cases, they remain a reasonable option.

These procedures using skin islands oriented on the penile dartos fascia have also been useful for reconstruction of the fossa navicularis (Cohney, 1963; Blandy and Tresidder, 1967; Brannen, 1976; De Sy, 1984; Jordan, 1987; Armenakas et al, 1998). In the past, meatal strictures and strictures of the fossa navicularis were managed with repeated dilations or sequential meatotomies. Because these meatotomies were seldom successful in the long term, techniques were developed that allowed the spatulation of random penile skin flaps into the meatotomy defects. These procedures functionally improved the results; however, the cosmetic

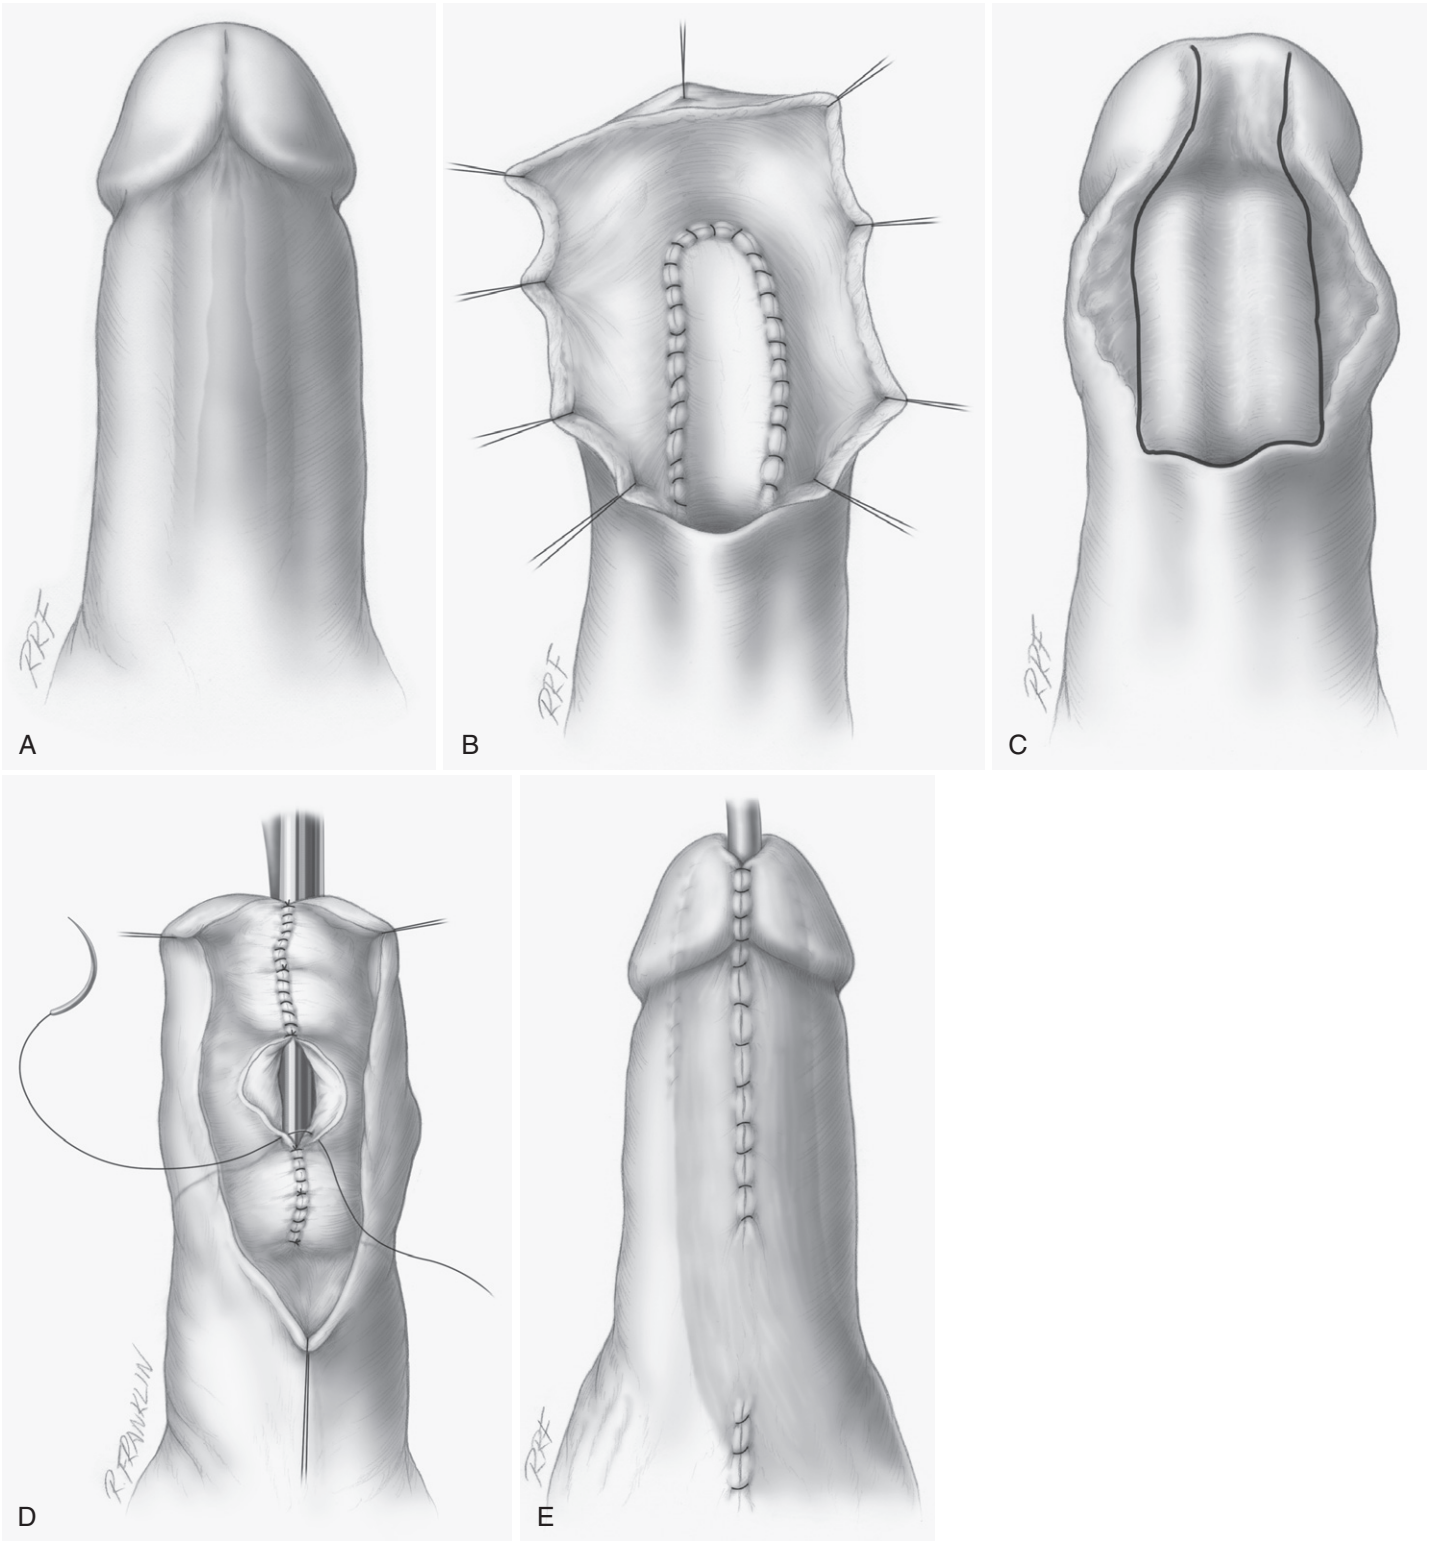

Figure 36–26. Staged reconstruction of a distal anterior urethral stricture. **A,** The appearance of the penis with the urethra (shaded area shows the location of a tight stenosis of the fossa navicularis that extends into the distal pendulous urethra). **B,** The distal narrow stricture of the fossa navicularis has been excised and stricturotomy performed into the normal urethra proximal to the excised tissue. A buccal graft has been applied to the defect, but the bolster dressing has not yet been applied. **C**, After 6 months, the graft is mature. The illustration shows a Tiersch tube ready for closure. **D**, The Tiersch tube is closed with a watertight suture line. The distal urethra is usually calibrated to create a urethral lumen of approximately 28 Fr. **E,** Glans reconstruction and closure of the distal shaft has been performed (the shaded area shows the tunica dartos flap that carries a parietal tunica vaginalis island). The flap is mobilized in this case from left hemiscrotum, and transposed to cover the entire area of the urethral reconstruction.

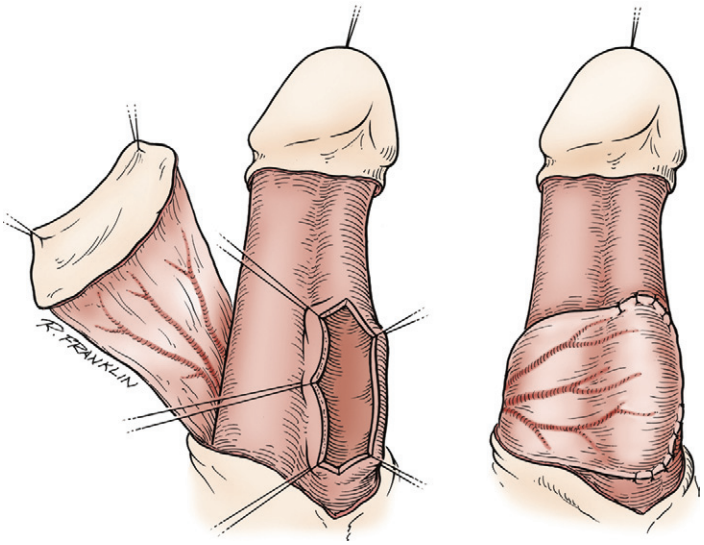

Figure 36–27. A dorsal transverse island of penile skin applied to a stricture of the urethra. The flap has been elevated on the dartos fascia, and a lateral incision has been made into the urethra. The flap is secured in place *(right)*. (From Jordan GH. Management of anterior urethral stricture disease. In: Webster GD, editor. Problems in urology. Philadelphia: JB Lippincott; 1987. p. 217.)

appearance of the penis was less than optimal. With the use of skin islands elevated on the dartos fascia, excellent functional as well as cosmetic results became the norm. Again, the design of these islands must take into consideration the location of hair on the shaft of the penis, as well as the mechanics of flap transfer (i.e., transposition versus advancement) (Figs. 36–32 and 36–33). In addition, full-thickness skin has been used to reconstruct the fossa navicularis, but when they can be avoided, skin grafts are not thought appropriate for reconstruction in cases of LS-BXO. As already mentioned, there is question about the use of skin islands in general in patients with LS-BXO.

The literature is clear that onlay procedures (graft or flap) are attended with a higher success rate than tubularized grafts or tubularized skin islands (Hendren and Crooks, 1980). **Tubularized grafts and skin islands should therefore be avoided, if possible. When tubularized segments cannot be avoided, the length of these segments can be limited by combining aggressive mobilization and excision. Without question, tubularized flaps provide better results than tubularized grafts.** Where extremely long segments of the anterior urethra require reconstruction, a flap can be used distally and augmented by graft onlay proximally (Wessells et al, 1997). Where tubed reconstruction is required, the combination of a graft spread fixed to reestablish the "urethral plate" with flap onlay, in a small series with only short follow-up, seems perhaps to be better than tubed flap reconstruction, even when it is employed in the onlay-tube-onlay configuration (Morey, 2001).

A flap procedure that can be used as an alternative to the split-thickness skin grafts when nonhirsute skin is unavailable is the epilated midline genital skin island. Like the split-thickness skin graft, this procedure must be viewed as a staged procedure, with the epilations being the initial stage or stages. Epilation can be accomplished with either a narrow-gauge needle and monopolar cautery or epilation needles and machines. The interval between the epilations must be 6 to 8 weeks, and urethral reconstruction cannot be accomplished until 10 to 12 weeks after the last

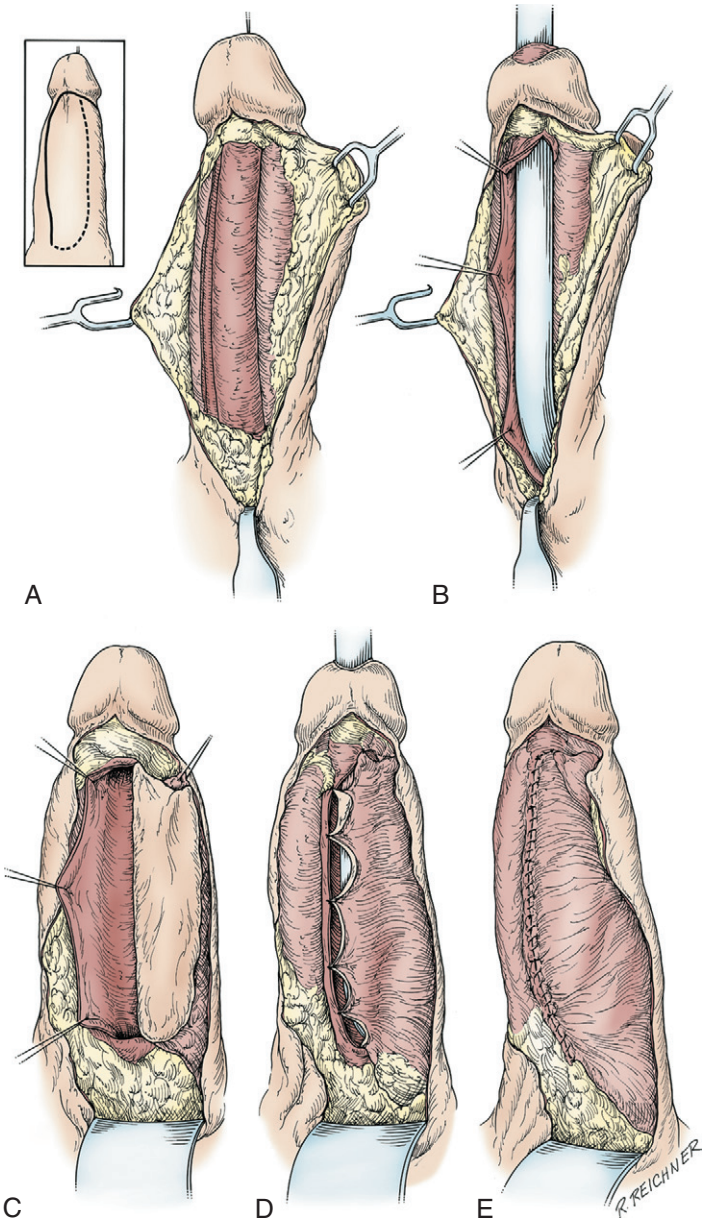

Figure 36–28. Penile longitudinal skin island. The incisions to be made to mobilize the flap are demonstrated in the inset. The heavy line is the primary incision made full thickness through the dartos fascia and superficial Buck fascia lateral to the corpus spongiosum. **A,** Dissection elevates the dartos fascial flap well past the corpus spongiosum in the midline. **B,** A lateral urethrostomy placed to face the flap has opened the entire length of the stricture. **C,** The skin paddle of the flap has been developed by making the incision outlined by the dotted line *(inset)* and undermining the skin lateral to it. The medial edge of the flap has been fixed to the edge of the stricturotomy. **D,** The flap is inverted into the defect. **E,** A watertight subepithelial suture line has been completed with a running absorbable monofilament suture. The skin will be closed with subcutaneous sutures and interrupted cutaneous sutures. (**A** to **E,** From Jordan GH. Management of anterior urethral stricture disease. In: Webster GD, editor. Problems in urology. Philadelphia: JB Lippincott; 1987. p. 214.)

epilation. The actual stricture repair involves elevation of the midline skin island, based on both the dartos fascia of the penis and the tunica dartos of the scrotum. As with nonhirsute scrotal skin islands in general, the importance of meticulous tailoring of the scrotal portion of the island cannot be overemphasized.

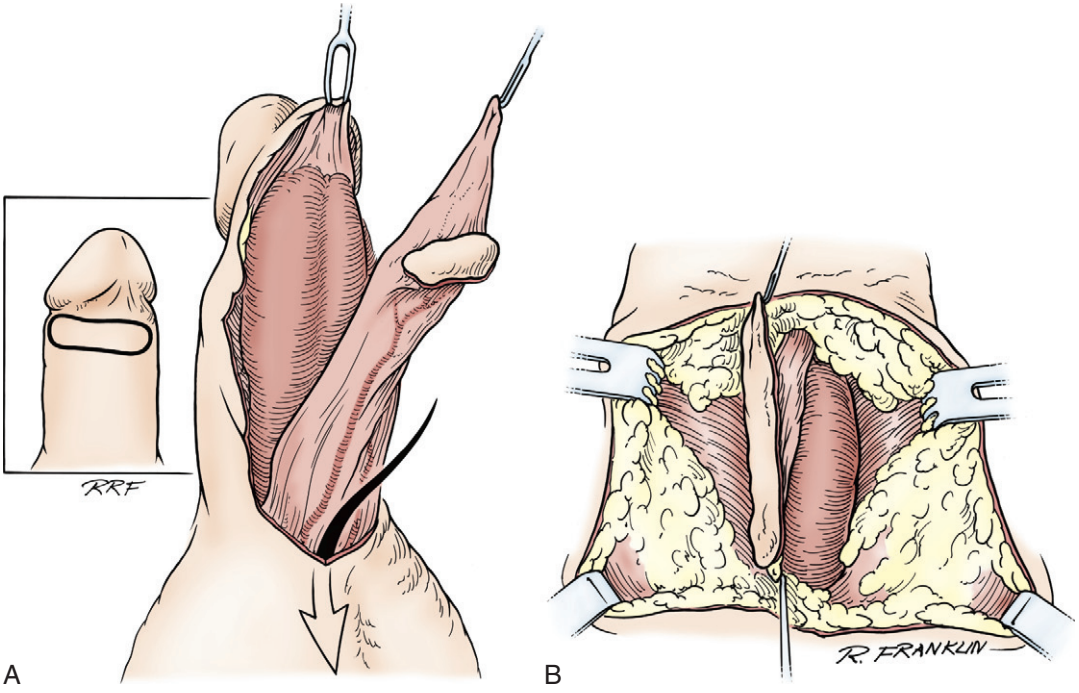

Figure 36–29. A ventral transverse skin island is elevated on the penile dartos fascia, inverted to the area of the perineum where flap onlay is accomplished. **A,** The skin island is elevated on the dartos fascia. **B,** The appearance of the flap transposed to the area of the perineum for onlay in a proximal bulbous urethral stricture.

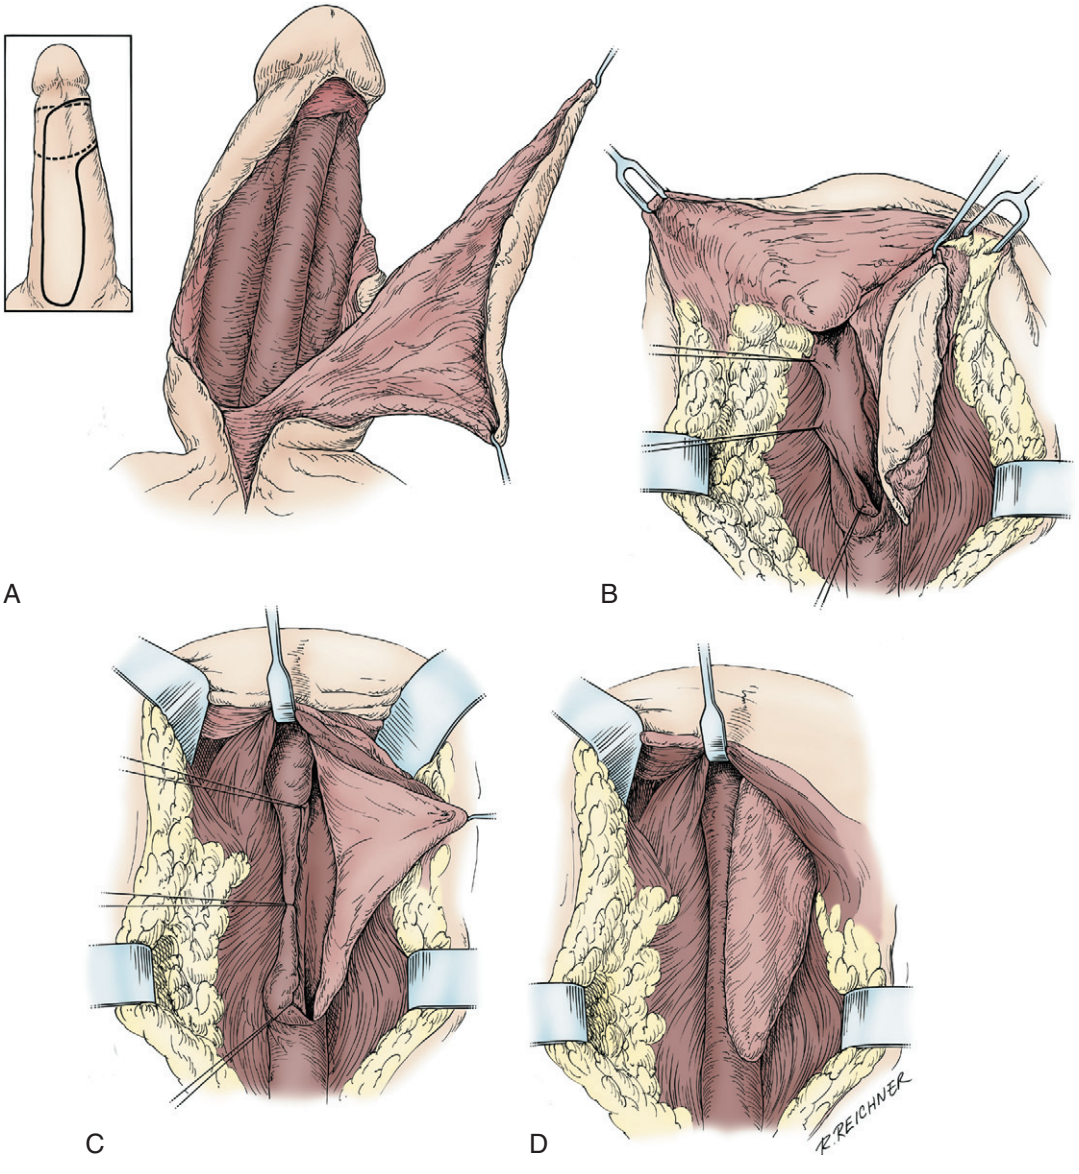

Figure 36–30. Ventral skin island for long bulbous stricture. The skin paddle of the flap is developed on the ventral midline of the penis and can be extended around the penile shaft at its distal end. **A,** The paddle of the flap has been incised and its pedicle elevated. This pedicle includes Buck fascia and dartos fascia, denuding the tunica of the corpus spongiosum and the corpora cavernosa. The pedicle (the dartos fascia bilaterally) is based on the superficial external pudendal vessels and the internal pudendal vessels in the scrotum. Development of this pedicle allows the flap to be moved to any area of the urethra. **B,** The flap has been passed through a tunnel beneath the scrotum developed by dissection along the corpus spongiosum. A laterally placed urethrostomy has opened the urethral stricture. **C,** The deep edge of the flap is secured by the suture techniques previously described. **D,** Anastomosis of the flap has been completed. The pedicle can be seen extending beneath the scrotum. (**A** to **D,** From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary surgery, part III. AUA Update Series 1988;7:lesson 11.)

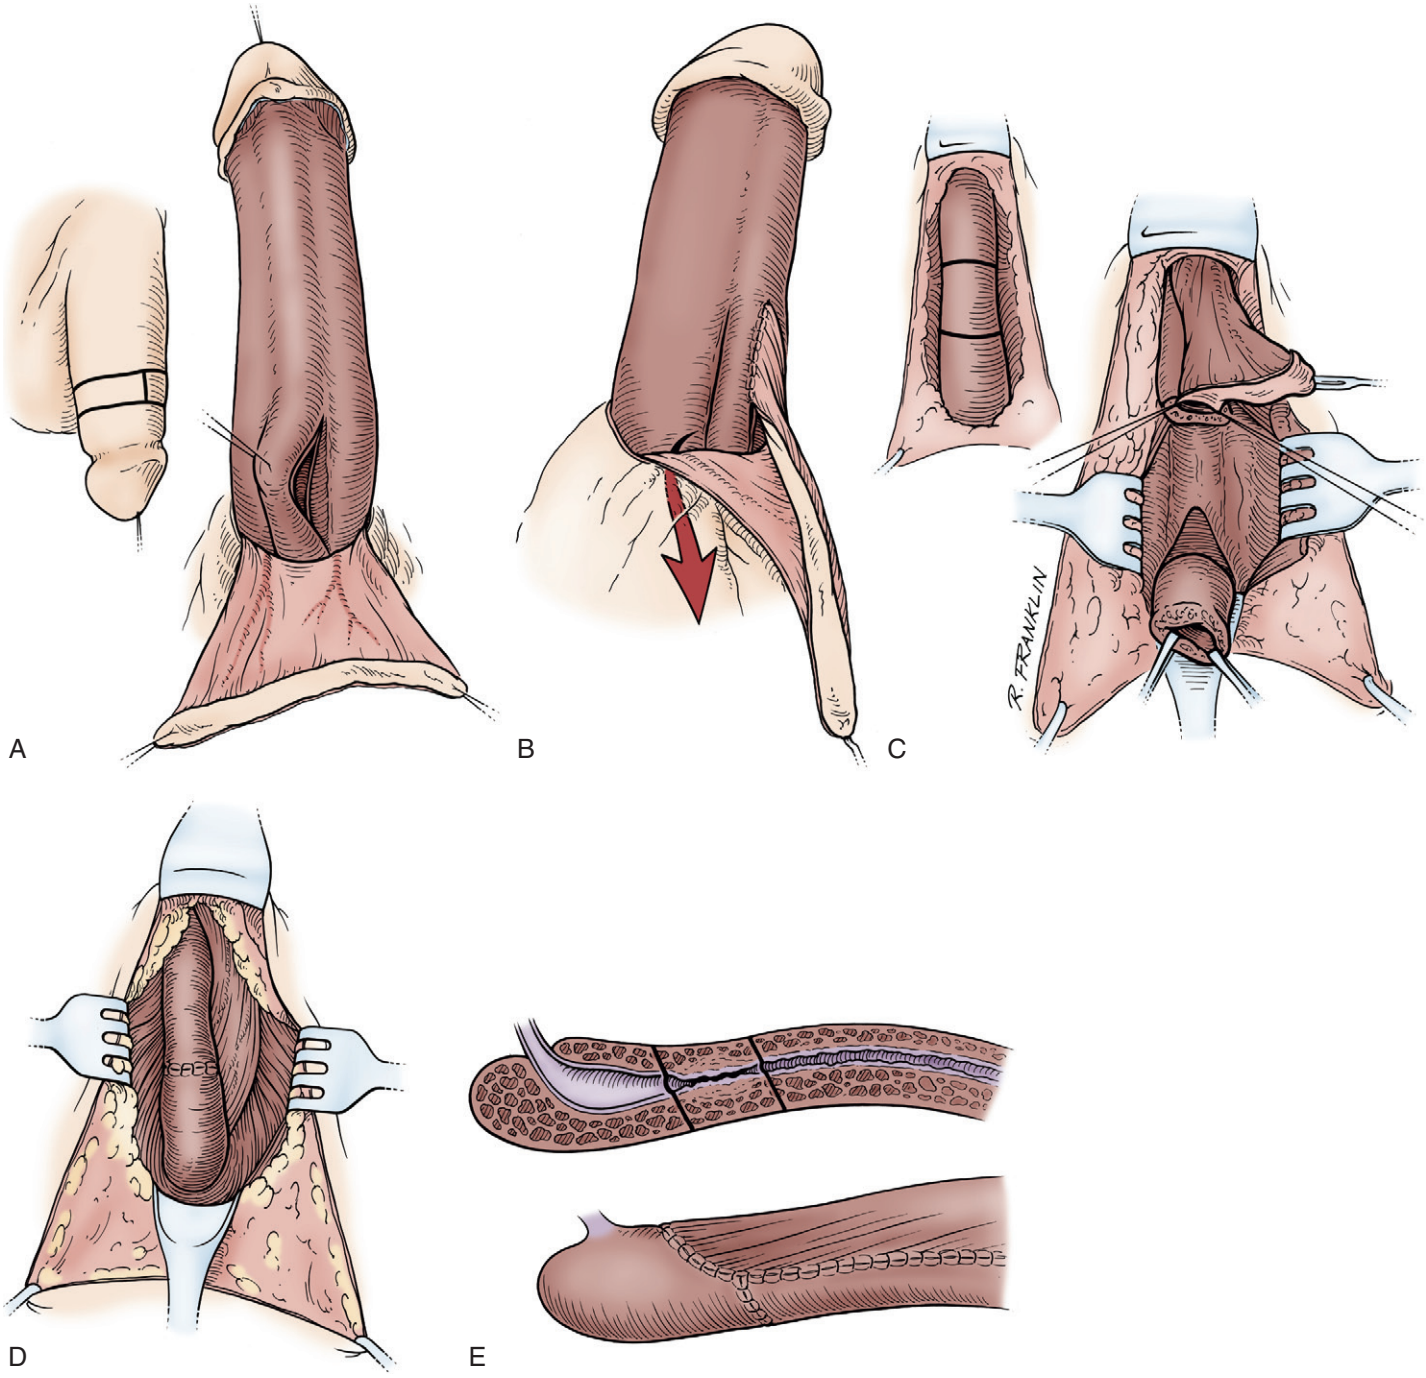

Figure 36–31. Illustration of reconstruction in a patient with a long anterior urethral stricture with a relatively short narrow-caliber section (technique of augmented anastomosis with circular skin island). **A,** A circular skin island is elevated on the dartos fascia. The patient is positioned flat on the table. **B,** The skin island onlay is begun, the rest of the flap is placed into the perineal dissection, and the penis is closed; the patient is then repositioned in the lithotomy position. **C,** The flap is retrieved through the perineal dissection. The narrow-caliber section is excised, and the urethra is spatulated on the dorsum. **D,** The onlay is completed, and the floor strip anastomosis is closed. **E,** Schematic of the surgery. (**A** to **E,** From Stack RS, Schlossberg SM, Jordan GH. Reconstruction of anterior urethral strictures by the technique of excision and primary anastomosis. Atlas Urol Clin North Am 1997;5:11–21.)

Mundy (1994) **analyzed a large series of urethral reconstructions. His data show that when follow-up is limited to 1 year, the success rate with tissue transfer clusters is about 95%. With longer follow-up, however, there is deterioration over time. With excision and primary anastomosis, the success seen at 1 year seems to be more durable, however, and does not appear to deteriorate at the same rate with time.** We have reported our long-term data for excision and primary anastomosis with anterior urethral stenosis in 220 patients with a mean follow-up of 44 months; three recurrences were noted, two within the first 6 months and a third at 4 years. The rate of postoperative erectile dysfunction is 2%, with the severe straddle population being at increased risk. Wessells and McAninch (1998), **in a meta-analysis of graft onlay procedures compared with flap procedures, showed equivalent results for graft operations and flap**

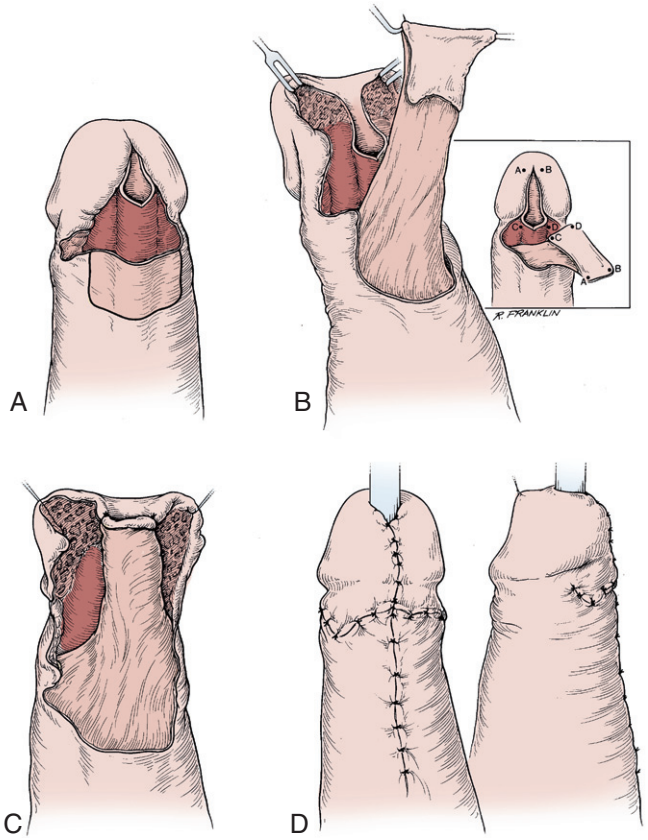

Figure 36–32. Technique of reconstruction of the fossa navicularis after Jordan. **A,** The ventral corpus spongiosum is exposed and the urethra opened ventrally through the area of stenosis. A transverse ventral skin island is outlined on the distal penile skin. **B,** The skin island is elevated on the ventral dartos fascia. **C,** The skin island is transposed and inverted into the meatotomy defect *(inset)*. **D,** The appearance of the penis closed after the procedure. (**A** to **C,** From Jordan GH. Reconstruction of the fossa navicularis. J Urol 1987;138:1210; **D,** from Jordan GH. Reconstruction of the meatus–fossa navicularis using flap techniques. In: Schreiter F, editor. Plastic-reconstructive surgery in urology. Stuttgart: Georg Thieme; 1999. p. 338–44.)

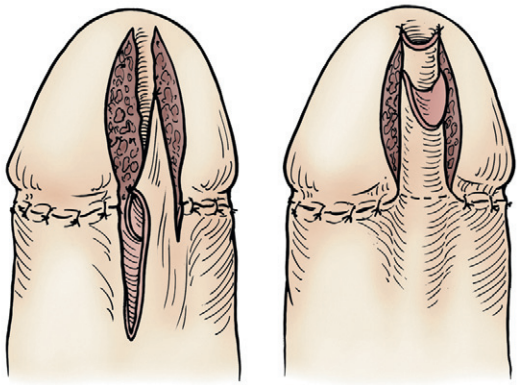

Figure 36–33. Technique after De Sy, in which a ventral longitudinal skin island is advanced into the meatotomy defect. The skin island is developed by deepithelialization of a portion of the longitudinal flap. (From Jordan GH. Management of anterior urethral stricture disease. Probl Urol 1987;1:199–225.)

procedures, and graft onlay procedures are technically far easier to perform. There clearly are some cases where flap reconstruction would be expected to provide superior results (i.e., radiation strictures, patients with multiple operations, pendulous strictures). However, with the increased knowledge gained by the enthusiastic application of graft reconstruction, there is currently a redefined paradigm for anterior reconstruction. Whereas grafts have been used successfully for all segments of the anterior urethra, many think that flaps are best suited for distal reconstruction and grafts for proximal reconstruction, all other variables equivalent (Greenwell et al, 1999).

Key Points: Treatment of Urethral Stricture

- In the treatment of urethral stricture disease, both the patient and the physician must have a good understanding of the goals of treatment before the treatment choice is made.
- Urethral dilation is the oldest and simplest treatment of urethral stricture disease. However, the goal of dilation is to stretch the scar atraumatically. Dilation is seldom used curatively.
- Internal urethrotomy refers to any procedure that opens the stricture by incising it transurethrally. The factors that contribute to success of internal urethrotomy have been defined as follows: internal urethrotomy should be reserved for strictures of the bulbous urethra; the stricture should be less than 1.5 cm in length; and the stricture should not be associated with dense deep spongiofibrosis. Repeated dilation and internal urethrotomies have been shown in a number of studies to diminish the success rate of eventual open urethral reconstruction.
- Urethral stents can be either removable or permanently implantable. The UroLume is the Food and Drug Administration–approved permanently implantable stent. The long-term data have not held up to the original enthusiasm for use of the UroLume. The greatest experience with explantable urethral stents comes from Europe. The concept of these stents is different in that they are designed to prevent epithelial incorporation.
- A number of lasers have been used for anterior urethral strictures. To date, the results of laser urethrotomy are mixed.
- Excision with primary anastomosis has proved to be the "gold standard" form of repair for anterior urethral strictures. In years past, excision with primary anastomosis was thought to be a relatively limited procedure and applicable only for strictures less than 1.5 to 2 cm. However, with better understanding of the anatomy, longer and longer strictures have been successfully addressed with excision and primary anastomosis.
- Admittedly, there are strictures that require tissue transfer, and grafts and flaps have been successfully employed. A meta-analysis by Wessells has shown that the results of graft reconstruction and flap reconstruction are equivalent. Clearly, the complexity of flap procedures is greater than that of graft procedures. The concept of augmented anastomosis can be used with both graft and flap onlay and is thought, in many cases, to provide better results than just pure onlay. When flaps are employed for urethral reconstruction, conceptually all become one operation with multidimensional application.

The issue of postoperative erectile dysfunction must be discussed. Our rates for anterior urethral anastomotic reconstruction are quoted earlier. **In an analysis by Coursey, 200 urethroplasty patients were studied. Overall, the rate of erectile dysfunction after urethroplasty was approximately equal to that with circumcision. However, longer-segment reconstructions did have a higher risk of postoperative erectile dysfunction, although in many, over time, the patient's erectile function improved** (Coursey et al, 2001).

Special mention must be made regarding reconstruction for strictures associated with LS-BXO**.** With the advent of flap techniques, many centers embraced these techniques for these strictures. However, analysis of results from these patients treated at several large centers has shown a very high recurrence rate. Consequently, these centers adjusted the techniques by applying staged graft techniques (see Fig. 36–26). Interestingly, staged graft techniques using skin grafts again had a very high recurrence rate in a number of analyses. **Theoretically, because LS-BXO is a skin condition, the use of skin as a flap, single-stage graft, or staged graft does not preclude involvement of the skin with the inflammatory process** (Lee and Phillips, 1994; Akporiaye et al, 1997). **Thus surgeons at a number of centers believe that staged oral graft techniques should be employed for reconstruction of strictures associated with LS-BXO.** Short follow-up suggests better success with this approach. Long-term follow-up is not available. In a review of our experience in patients with a fossa navicularis stricture and LS-BXO, we noted a 50% recurrence in the stricture with a ventral transverse skin island (Virasoro et al, 2007).

PELVIC FRACTURE URETHRAL INJURIES

Pelvic fracture urethral injuries are the result of blunt pelvic trauma and accompany about 10% of pelvic fracture injuries. Although it is possible to totally disrupt the urethra with a straddle injury, these injuries most commonly involve only the bulbous urethra. However, the ensuing spongiofibrosis can be associated with complete obliteration of the urethra. **Distraction injuries are for all intents unique to the membranous urethra.** Pelvic fracture distraction injuries of the membranous urethra have been compared with plucking an apple (prostate) off its stem (the membranous urethra). This analogy implies that the injury most frequently occurs at the apex of the prostate. Experience shows that this is not the case, however, and the most frequent point of distraction is at the departure of the bulbous urethra from the membranous urethra (Andrich and Mundy, 2001; Mouraviev and Santucci, 2005). The distraction can, however, involve all or any portion of the membranous urethra between the departure of the bulbous urethra and the apex of the prostate. In the postpubescent male, the injury seldom involves the prostatic urethra. In the prepubescent male, in whom the prostatic urethra is more fragile, the injury can extend into that area.

Many injuries appear not to totally distract the entire circumference of the urethra. Instead, a strip of epithelium is left intact. In these patients, the placement of an aligning catheter may allow the urethra to heal virtually unscarred or with an easily managed stenosis. Because of flexible endoscopy equipment, the placement of an aligning catheter is relatively straightforward. If distraction is complete, the catheter then serves to align the obliterated urethral ends, and reconstruction is facilitated. Because of the ready availability of flexible cystoscopes, some centers are now acutely evaluating these injuries only with endoscopy. Those enthusiastic for this approach believe that not only can the injury be completely evaluated but the entire process, including the placement of an aligning catheter, is expedited (Kielb et al, 2001). **Aligning catheters are just what the name implies—a guide, not a mechanism for placing traction on the bladder and prostate.** Aligning catheters also seem to act as a drain as the pelvic hematoma liquefies, and perhaps the presence of the catheter may allow more rapid and complete resolution of the process (Cohen et al, 1991; Herschorn et al, 1992; Rehman et al, 1998; Mouraviev et al, 2005).

Evaluation

As with the repair of any stricture or stenosis, it is important to define the precise anatomy of the pelvic fracture injury before treatment is undertaken (McCallum and Colapinto, 1979a, 1979b); **this includes the depth, density, length, and location. In pelvic fracture urethral distraction defects, the depth and density of fibrosis are predictable. Although the location of the distraction injury has been demonstrated to be an important factor in continence after reconstruction, this information should be a factor only in counseling of patients before the reconstruction and not in the treatment approach. The length of the defect is an important consideration and must be determined as precisely as possible.**

Contrast studies are a first-line tool for the evaluation of pelvic fracture urethral injury. A cystogram outlines the bladder and provides information about rostral displacement of the proximal urethra. A lack of contrast material in the posterior urethra gives some information, albeit inconclusive, about the integrity of the bladder neck.

When the patient is successful in relaxing to void and the cystogram outlines the posterior urethra, a simultaneous retrograde urethrogram nicely outlines the length of the injury defect. However, this situation is the exception rather than the rule, and retrograde urethrography is most useful for determining whether the anterior urethra is normal. If the anterior urethra is normal, **it has been our experience, as well as that of others, that a successful anastomotic repair is ensured.** In fact, a primary anastomosis has been shown to be possible even with some involvement of the anterior urethra. Even in cases of prior failed posterior urethral reconstruction, primary anastomotic repair is often feasible, although the failure rate is slightly higher in these cases (Chapple and Pang, 1999; Flynn et al, 2003; Koraitim, 2003; Shenfeld et al, 2004). **Thus primary anastomosis is unquestionably the goal in all these patients until it is proved impossible to perform.**

When the proximal urethra is not visualized on a simultaneous cystogram with urethrogram, endoscopy through the suprapubic tract in combination with retrograde urethrography can be used to outline the defect. After the endoscopic appearance of the bladder neck is assessed, the flexible endoscope can be advanced through the bladder neck and into the posterior urethra to the level of the obstruction. **The appearance of the bladder neck on contrast studies or on antegrade endoscopy does not accurately predict the ultimate function of the bladder neck after urethral reconstruction** (Iselin and Webster, 1999). A simultaneous retrograde urethrogram will then outline the anterior urethra, with the space not visualized representing the injury defect.

Some have also advocated magnetic resonance imaging for the evaluation of patients with pelvic fracture urethral injuries. We have had little experience with this modality for that purpose; however, we have found the information obtained on the few studies that we have done to be useful. In these cases, there was the question of bone interposition into the injury defect, and magnetic resonance imaging nicely outlined that. We evaluated a case in which the prostatic urethra appeared obliterated. On magnetic resonance imaging, one could easily see that the prostate was not only distracted from the membranous urethra but also distracted from the bladder. This information was essential to planning of subsequent reconstruction in this case. It would seem intuitively obvious that knowing the length of distraction would be helpful in determining the precise approach and steps necessary for reconstruction. However, the literature is not clear on this matter (Andrich et al, 2003; Koraitim, 2004), and it is our experience that the surgeon must be prepared to exercise all options of reconstruction in virtually all such cases (McCallum and Colapinto, 1979a, 1979b).

Repair

The timetable for the reconstruction of pelvic fracture urethral injuries is determined by the type and extent of associated injuries. If possible, it is desirable to proceed within 4 to 6 months after trauma. However, orthopedic injuries of the lower extremities often necessitate a delay in proceeding with urethral reconstruction (Mundy, 1991; Follis et al, 1992; Brandes and Borrelli, 2001). Most pelvic fracture patients have inferior venal caval filters placed, because of the risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) at the time of trauma. It is our practice to start all of these patients on low-dose anticoagulation and to continue it for about 10 days to 2 weeks after surgery.

In the majority of cases, pelvic fracture urethral injuries are not long, and the resultant obliteration is amenable to a technically straightforward mobilization of the corpus spongiosum with a primary anastomotic technique. The classic reconstruction consists of a spatulated anastomosis of the proximal anterior urethra to the apical prostatic urethra. Experience has demonstrated, however, that anastomosis of the proximal anterior urethra to any segment of the posterior urethra (apical, prostatic, or below) **can be successfully accomplished by a widely spatulated anastomosis in which optimal epithelial apposition is achieved.** About 10% of pelvic fracture urethral injuries are associated with more complex injuries and can be associated with fistulas (most commonly urethral rectal fistulas). Reconstruction of these injuries is technically more demanding.

Several series support the concept that the bulk of pelvic fracture urethral injuries, even the most difficult cases, can be managed by the perineal approach (Webster et al, 1983, 1990; Webster and Sihelnik, 1985; Koraitim, 1985, 1997; Morey et al, 1996; Flynn et al, 2003). In fact, a transpubic or an abdominal-perineal approach, as pioneered by Waterhouse and colleagues (1973), in our experience, is not necessary for the reconstruction of distraction injuries. In addition, pubectomy can be associated with long-term sequelae that include shortening of the penis, destabilization of erection, and destabilization of the pelvis, resulting in a chronic pain syndrome with exercise. However, there are surgeons who continue to rely heavily on the transpubic approach (Koraitim, 1997; Das et al, 2004).

Alternatively, the above-and-below approach does have merit when concomitant surgery is planned in the region of the bladder neck. We have found, and Iselin and Webster (1999) have reported that the competence of the bladder neck is difficult to assess accurately before the reestablishment of urethral continuity. In the past, great reliance was placed on whether the bladder neck was closed or open on cystography. We now know, however, that contrast material can opacify the prostatic urethra when the bladder neck is more than adequately competent for continence. Similarly, confidence has been placed in the appearance of the bladder neck on endoscopic examination through the suprapubic tube. Again, even when an obvious scar is noted to involve the bladder neck, follow-up of these patients after the urethral reconstruction establishes continuity of the urethra and finds many patients with more than adequate continence. Still other patients are believed to have incontinence due to scar incarceration of the bladder neck, caused by the extensive fibrosis left behind by resolution of the hematoma. In our experience, however, this is an infrequent occurrence, and the appearance of the bladder neck by any modality available is not predictive of continence. Therefore, it is currently our practice to reestablish the continuity of the urethra and, when there are concerns about continence, forewarn the patient before the urethral reconstruction. If these patients find that they experience less-than-adequate continence postoperatively, the problem is addressed in a subsequent procedure (Bhargava et al, 2004).

At the time of reconstruction, before the patient is placed in the lithotomy position, endoscopy is performed through the meatus and again through the suprapubic tube sinus. Endoscopy on the table is designed to ensure that there is no concomitant vesicolithiasis. This endoscopy is performed with a rigid endoscope, which is manipulated through the suprapubic tube sinus and the bladder neck and positioned against the area of total obliteration. On gentle manipulation of the endoscope, if the impulse of the endoscope tip is felt on the patient's perineum, the impulse will be palpable when the perineum is opened and an instrument is manipulated through the bladder neck during reconstruction. If the impulse is not palpable perineally at this time, it may not be palpable during dissection, and in those cases, we create a temporary vesicostomy. This allows us to position an instrument reliably through the bladder neck, because the vesicostomy allows the surgeon to palpably identify the bladder neck before instrumentation of the posterior urethra. This maneuver has eliminated the occurrence of false passages with use of a sound such as the Haygrove staff through the suprapubic site, and also has eliminated the occurrence of misanastomosis of the anterior urethra to sites other than the apical proximal urethra.

We prefer the use of the exaggerated lithotomy position for the perineal approach (Fig. 36–34). This position is safe and provides optimal exposure to the area of the membranous and apical prostatic urethra (Angermeier and Jordan, 1994; Miller et al, submitted). A custom Skytron table, modified to allow the exaggerated lithotomy position, and a Stille-Scandia table, designed to place patients in the lithotomy position, are our preferences. The legs are carefully positioned in the Allen- or Guardian-style stirrups. Care is taken to avoid pressure on the lateral aspects of the lower extremities and calf muscles. The patient's hips are elevated into position by raising the buttocks portion of the operating table. The boots are positioned to avoid stretch injuries of the common peroneal nerves (see Fig. 36–34).

After the patient is correctly positioned, the perineal approach to reconstruction begins with an incision and dissection anterior to the transverse perinei musculature (anterior perineal triangle).

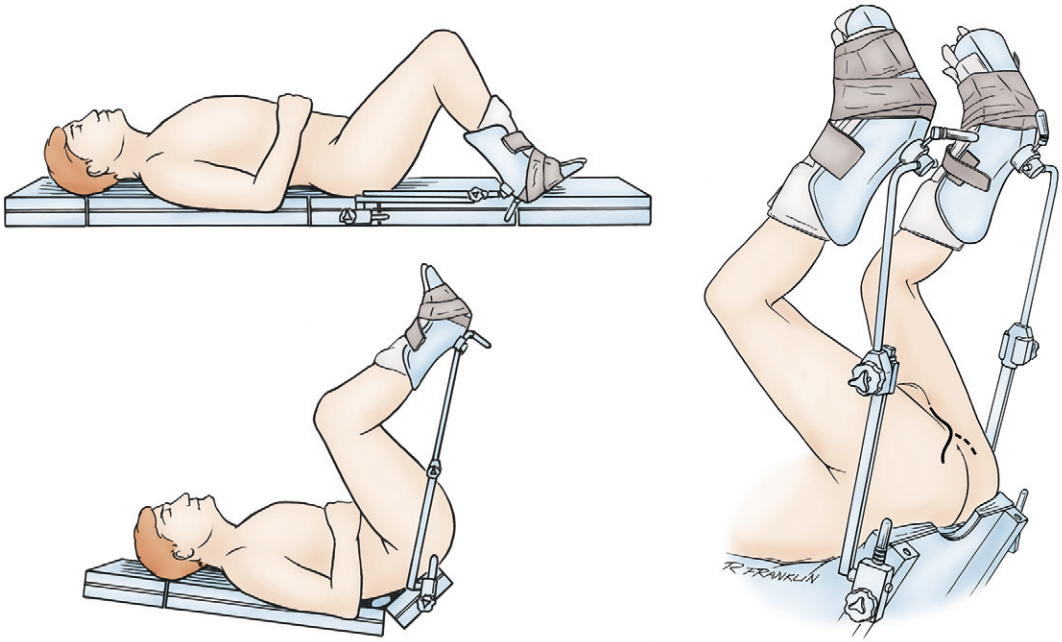

Figure 36–34. Patient placed in an exaggerated lithotomy position. The hips have been rotated into position by elevation of the buttocks portion of a specially modified table. The legs are suspended from boot-style stirrups with as little flexion of the hips and knees as allowed by the design of the stirrups. (From Angermeier KW, Jordan GH. Complications of the exaggerated lithotomy position: a review of 177 cases. J Urol 1994;151:866–8.)

This is in contrast to the approach posterior to the transverse perinei musculature (posterior anal triangle), which is useful for perineal prostatectomy. We use a λ-shaped incision (Fig. 36–35) that is carried sharply down to the midline fusion of the ischiocavernosus musculature (see Fig. 36–35A), then beneath the scrotum, to expose the uninvested portion of the corpus spongiosum. We then place a self-retaining ring retractor.

The fusion of the ischiocavernosus musculature is divided, and the musculature is cleanly dissected from the corpus spongiosum and bulbospongiosum (see Fig. 36–35B to D). The corpus spongiosum is detached from the triangular ligament and corpora cavernosa (see Fig. 36–35E), the bulbospongiosum is detached from the perineal body, and the dissection is carried farther down to the infrapubic space. Posterior detachment of the bulbospongiosum is carried anteriorly, and the dissection is eventually carried through the area of fibrosis (see Fig. 36–35F).

In some cases, the proximal blood supply is encountered and must be controlled. We have found that these arteries are easily controlled with a sharp tip hemostat and monopolar cautery. Suture ligature should be avoided in the case of the arteries to the bulbospongiosum because of their proximity to the nerves as they are coursing into the corpora cavernosa.

We then divide the triangular ligament and vigorously develop the intracrural space down to the pubis (Fig. 36–36). If the dorsal vein is encountered, it is ligated and divided. It is important to make sure that the arteries were not rolled into the intracrural space if the tissues were dislocated during trauma. It is not uncommon to see the penetration of the cavernosal arteries or the dorsal arteries, or both, into this space. If there is doubt about the nature of the vessels encountered, Doppler sonography should be used. When the pubis is exposed, the periosteal elevator can be gently introduced onto the retropubic surface, releasing and allowing the descent of the tissues from beneath the pubis.

We then introduce a Haygrove staff into the suprapubic sinus and through the bladder neck to the distal limits of the posterior urethra (see Fig. 36–35G and H). The impulse is palpated, and the fibrosis is resected until normal tissue planes are encountered. The tissue is submitted for histologic examination. The tip of the Haygrove staff is eventually concealed only by the normal urethral epithelium, at which point we open the epithelium and control it with either a skin hook or a stitch. We then perform endoscopy to ensure that the urethrotomy is at the distal limits of the posterior urethra. If a tension-free anastomosis is not thought possible, we mobilize the corpus spongiosum beneath the scrotum from its attachment to the corpora cavernosa. Aggressive mobilization of the corpus spongiosum is the last maneuver undertaken, because it is thought to have possible ill effects on the retrograde blood supply, which in the pelvic fracture patient may be tenuous. Meticulous detachment of the investment of Buck fascia from the corpus spongiosum increases the compliance of the corpus and limits the need for aggressive mobilization.

It is important to try to avoid the creation of chordee during the repair of a distraction injury. To prevent chordee, the attachment cannot be carried beyond the area of the penoscrotal attachment. It is warranted in some cases, however, to preoperatively counsel patients that they may have some chordee after aggressive mobilization that results in a primary anastomotic repair. Primary anastomotic repairs carry success rates in the high 90% range. If a technique of tissue transfer is needed, the long-term cure rates may eventually only be in the mid 80% range. Most of these patients are young. Successful, durable reconstruction is of paramount importance. If chordee results, it is most often mild and not disabling sexually; in our and other surgeons' minds, it is probably a fair trade for optimizing the urethral reconstruction. Development of the intracrural space—mobilization of the corpus spongiosum, infrapubectomy, and, if needed, rerouting of the

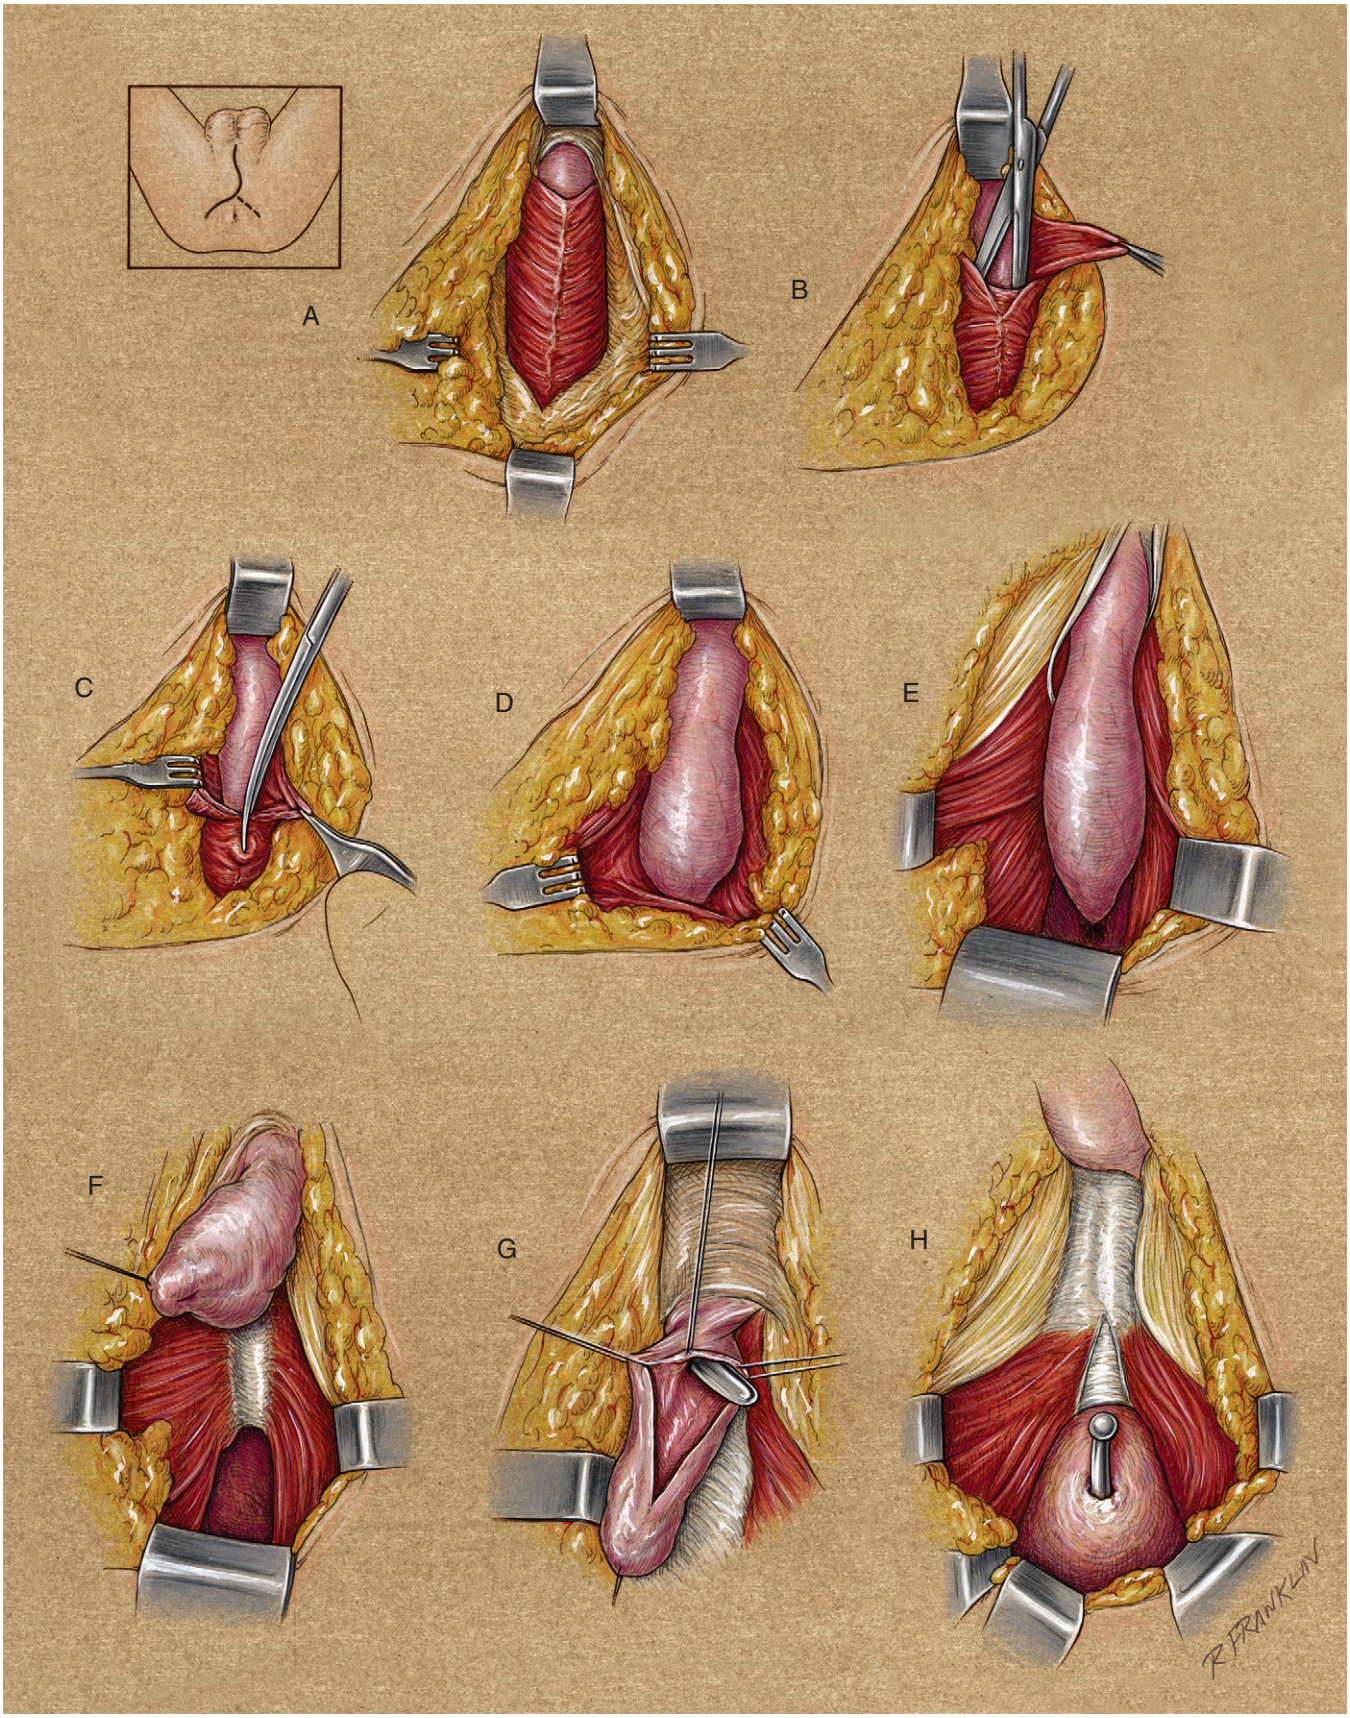

Figure 36–35. Diagram of a perineal repair of a membranous urethral stricture. A λ incision extends from the midline of the scrotum to the ischial tuberosities. **A,** Colles fascia has been opened to expose the midline fusion of the ischiocavernosus muscles and the tunica of the corpus spongiosum distal to the edge of the muscles. **B,** The scissors are introduced to develop the space between the muscle and the bulb of the urethra. **C,** An incision is made in the midline with the scissors, exposing the length of the bulb. **D,** The ischiocavernosus muscle is retracted to expose the full length of the bulb. **E,** The self-retaining retractor is placed to expose the inferior fascia of the genitourinary diaphragm. The bulb of the corpus spongiosum (bulbospongiosum) can now be mobilized to gain access to the fibrosed area of the urethra. **F,** The fibrosed urethra is incised, freeing the bulb. **G,** The anterior urethra is opened to make an adequate lumen. **H,** The Haygrove staff has been passed through the suprapubic cystostomy. Resection of the fibrotic distraction defect has allowed it to pass into the perineum.

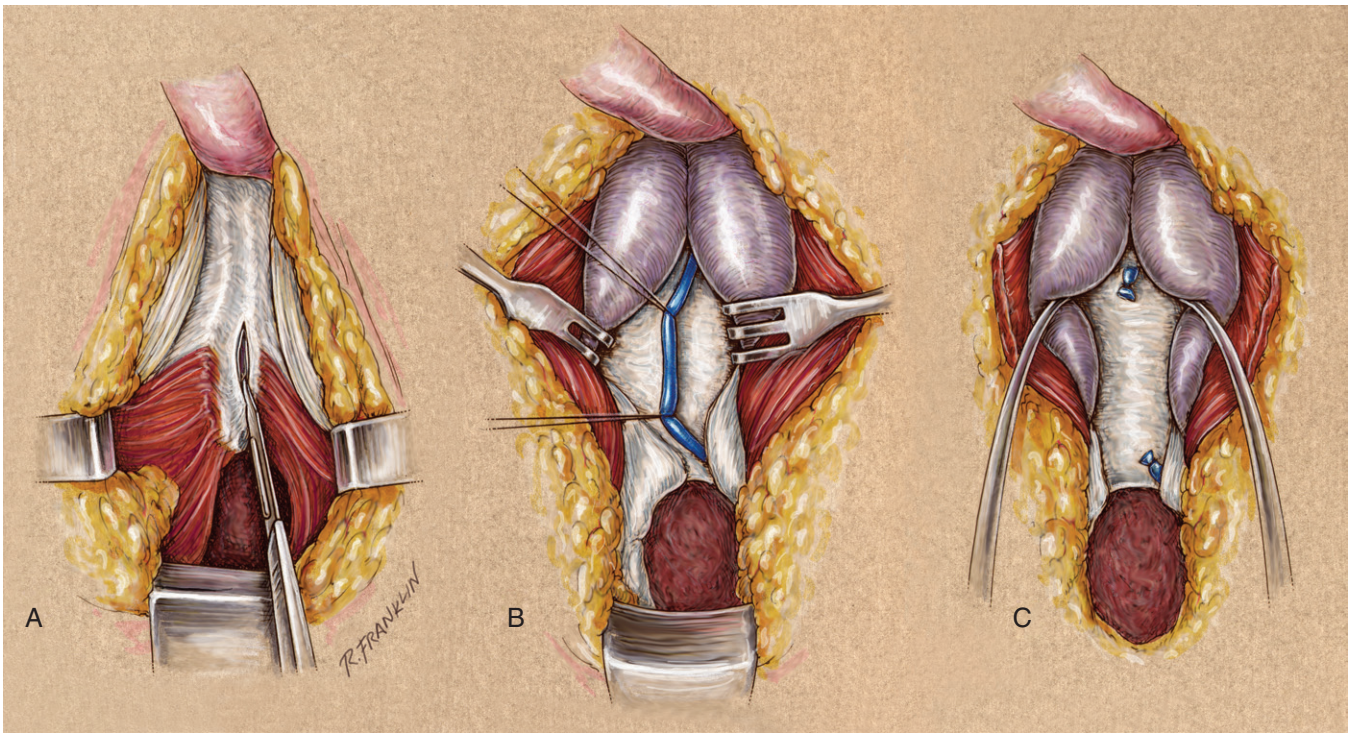

Figure 36–36. Division of the triangular ligament and development of the intracrural space. **A,** When the prostatic urethra is displaced, and the arc that the urethra must traverse needs to be shortened, that length can be shortened by incision of the triangular ligament. **B,** Incision and mobilization of the perichondrium and periosteum of the symphysis pubis to allow placement of retractors without trauma to the erectile bodies. Lateral displacement of the crura will expose the dorsal vein of the penis; after careful identification, the vein can be ligated and divided. **C,** Completion of the dissection affords additional exposure for resection of the fibrosis that surrounds the apex of the prostate and the proximal end of the disrupted urethra. (**A** to **C,** From Jordan GH. Reconstruction of the meatus–fossa navicularis using flap techniques. In: Schreiter F, editor. Plastic-reconstructive surgery in urology. Stuttgart: Georg Thieme; 1999. p. 338–44.)

corpus spongiosum—shortens the course that the corpus spongiosum must traverse and allows reconstruction without attendant chordee.

The proximal urethrotomy is spatulated so that it accepts at least a 32 French bougie à boule, and 10 to 12 anastomotic sutures are placed and tagged to allow identification of their position in the proximal anastomosis. We have used a combination of 3-0 Monocryl and 3-0 polydioxanone sutures for this purpose. No special needles are required for the placement of these sutures. However, a Heaney needle driver and a Ravitch needle driver can be useful in difficult cases. A lighted sucker is also beneficial at this point in the procedure. We recently have used a posterior retractor blade with integral light bundle and have found it very helpful with visualization.

After spatulation of the proximal urethrotomy and placement of the sutures, we spatulate the proximal portion of the anterior urethra. The spatulation is continued until the urethrotomy accepts a 30 to 32 French bougie à boule, and the anastomotic sutures are placed in their respective locations. Before seating the anastomosis, we introduce a soft silicone (Silastic) ribbed urethral stenting catheter through the anastomosis under direct vision. The wound is then copiously irrigated to reduce the clot around the area of the anastomosis, and the anastomosis is seated.

Next, we reattach the corpus spongiosum to the corpora cavernosa and the bulbospongiosum to the perineal body. We then place a small suction drain deep to the closure of the ischiocavernosus musculature and Colles fascia, and a second one superficial to that closure and beneath the subcutaneous closure.

In those cases in which the proximal urethra is significantly distracted in a rostral direction, the surgeon must be prepared to perform infrapubectomy (Fig. 36–37) or corporeal rerouting, or both (Fig. 36–38). The performance of the infrapubectomy, along with the development of the intercrural space, allows exposure of the apical prostatic urethra. When the prostatic urethra remains rostrally displaced, the impulse of the sound or instrument placed through the cystostomy tract into the bladder neck is often not readily apparent. In these situations, it is comforting to be able to palpate the bladder neck and the properly placed sound before embarking on a dissection beneath the pubis. In addition, if the rostral distraction is significant, the path of the anterior urethra over the hilum of the penis into the infrapubectomy often does not allow a tension-free anastomosis, and the infrapubectomy can be continued beneath one side of the corpora cavernosa, allowing rerouting of the corpus spongiosum (see Fig. 36–38).

Postoperative Management

We use a small soft silicone (Silastic) stenting catheter. Urine is diverted by way of the suprapubic cystostomy, and the urethral catheter is plugged and serves as a stent only. After the reconstruction, patients are initially kept at bed rest for 24 to 48 hours and then ambulated and discharged with the suprapubic catheter and stenting urethral catheter in place. They are also discharged on a regimen of oxybutynin and a suppressive antibiotic. The drains are removed as drainage allows.

A voiding trial with contrast material is performed between 21 and 28 days postoperatively. Patients are directed to stop taking oxybutynin 24 hours before the voiding trial. In anastomoses that are technically straightforward, the trial is performed at 21 days, and in those cases with more rostral distraction of the proximal

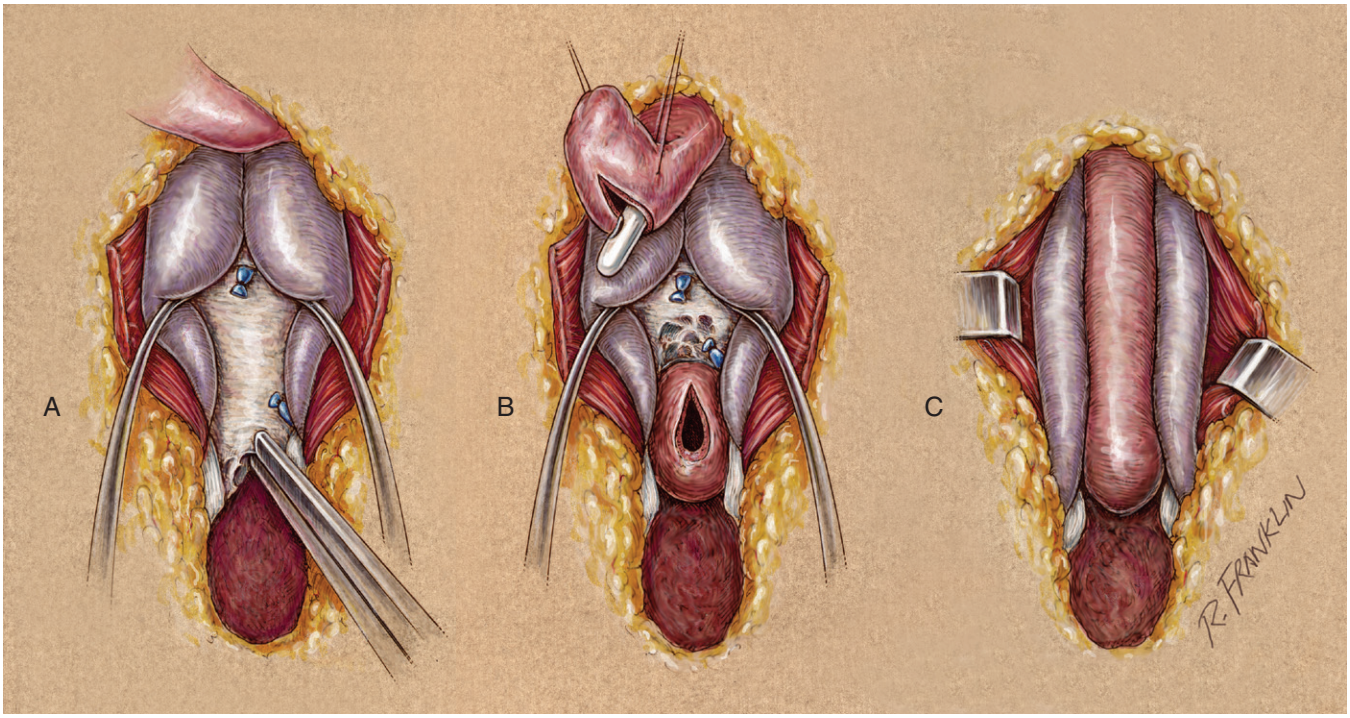

Figure 36–37. Infrapubectomy. If the prostate is elevated behind the symphysis pubis **(A)**, the inferior aspect of the symphysis is resected with a Kerrison rongeur. As much of the bone can be removed as necessary **(B)**, to afford a simple approximation of the ends of the urethra **(C)**.

urethra, the trial is delayed for 3 to 5 days longer. The trial involves removing the urethral catheter, filling the patient's bladder with contrast material, and instructing him to void. We do not use pericatheter retrograde urethrography for the evaluation of patients who have undergone urethral reconstruction. The voiding film is examined to ensure that there is not extravasation and that the reanastomosis appears widely patent. A urine culture specimen is also obtained, and the suprapubic catheter is plugged. The patient is allowed to void through the urethra for 5 to 7 days, and the suprapubic catheter is then removed. Patients remain on the suppressive antibiotic regimen until they are tube free, and a culture and a sensitivity test are performed. At that time, they are prescribed a short regimen of culture-specific antibiotic.

Approximately 6 months postoperatively, and again 1 year later, the patients are evaluated with flexible endoscopy. At that time, we consider the reconstruction to be mature, and it should be widely patent. Absent the reappearance of symptoms, we refer further follow-ups to the referring urologist.

We have almost completely replaced postoperative retrograde studies with flexible endoscopy. We have not found flow studies to be valuable in observing these patients and, in many cases (anterior urethral reconstruction), have found that retrograde urethrography is more confusing than helpful.

With the use of the techniques discussed or similar techniques, curative rates for reconstruction of posterior pelvic fracture urethral injuries are in the high 90% range. In large centers, failures are not due to technical problems (i.e., anastomotic restenosis). In general, failures are indicative of ischemia of the proximal corpus spongiosum with ensuing stenosis of the mobilized corpus spongiosum. This occurs because, with mobilization, the corpus spongiosum, in essence, becomes a flap with the vascular pedicle being the retrograde vascularity from the arborization of the dorsal arteries through the glans (Fig. 36–39).

We have studied this phenomenon in our trauma patients and have now arrived at conclusions that we believe allow us to predict the patients at risk for this ischemic atrophy phenomenon. Initially, we used pudendal angiography to study all our trauma patients who seemed to be at risk for bilateral deep internal pudendal artery injury at the time of trauma. These were patients who had evidence of injury to the dorsal penile nerves, patients in whom reconstruction had failed at other centers, patients with lateral impact pelvic fractures, and patients whose pelvic fractures were of the "windswept" variety (Brandes and Borrelli, 2001). We found that many patients had evidence of either unilateral or bilateral pudendal artery lesions but that most had evidence of vascular reconstitution. **Patients with an intact pudendal artery on one side often were potent and were reliably cured with reconstruction. Patients with only reconstituted vessels, either unilateral or bilateral, never were potent but were reliably reconstructed.** We found that these patients were optimal candidates for penile arterial revascularization to improve potency. Because we noted this relationship to potency, we began looking at our patients with duplex ultrasonography. We found that patients with normal pudendal arteries, either unilateral or bilateral, demonstrated normal arterial parameters on duplex evaluation. Those with only reconstituted arteries, either bilateral or unilateral, never had normal arterial parameters on duplex ultrasonography.

This now allows us to proceed to pudendal angiography only in those patients with abnormal arterial parameters on duplex ultrasonography; the patients with normal findings on ultrasonography predictably do well with reconstruction. Our data also show that patients do well with reconstruction if they have at least one side that is reconstituted, and those patients at risk for ischemic stenosis are only those with bilateral complete obstruction of the internal pudendal vessels. In such a patient, we now perform penile arterial

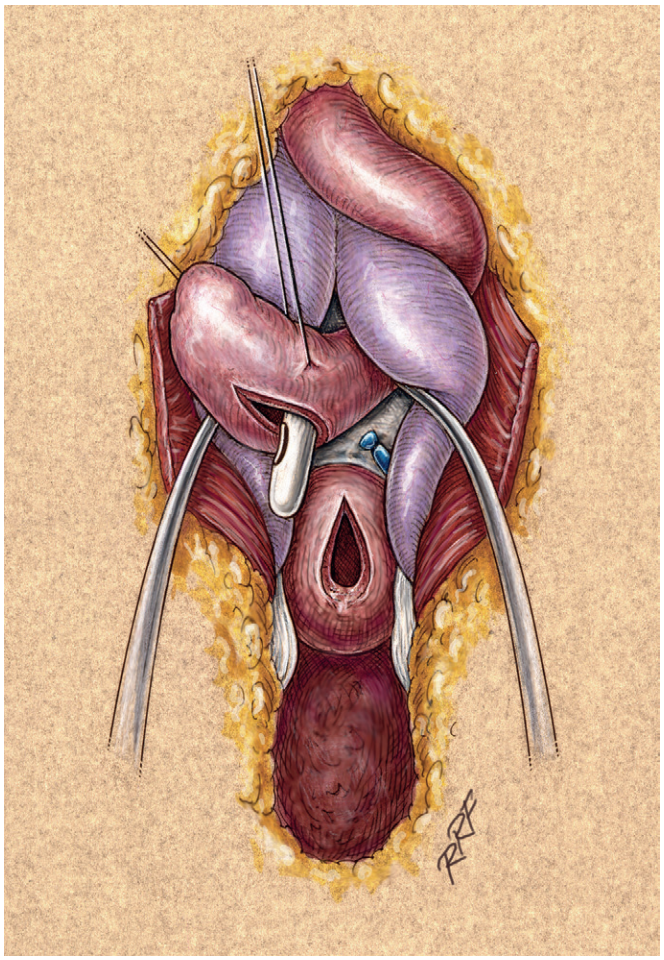

Figure 36–38. Resection of the pubis and rerouting of the urethra around the crus. When the prostate is markedly displaced, it may be necessary to expand the infrapubectomy. Sometimes, despite separation of the crura to the full extent possible, the two ends of the urethra do not meet when they are brought directly through the crus. It is necessary to bring the urethra lateral to one of the crura to make up this length.

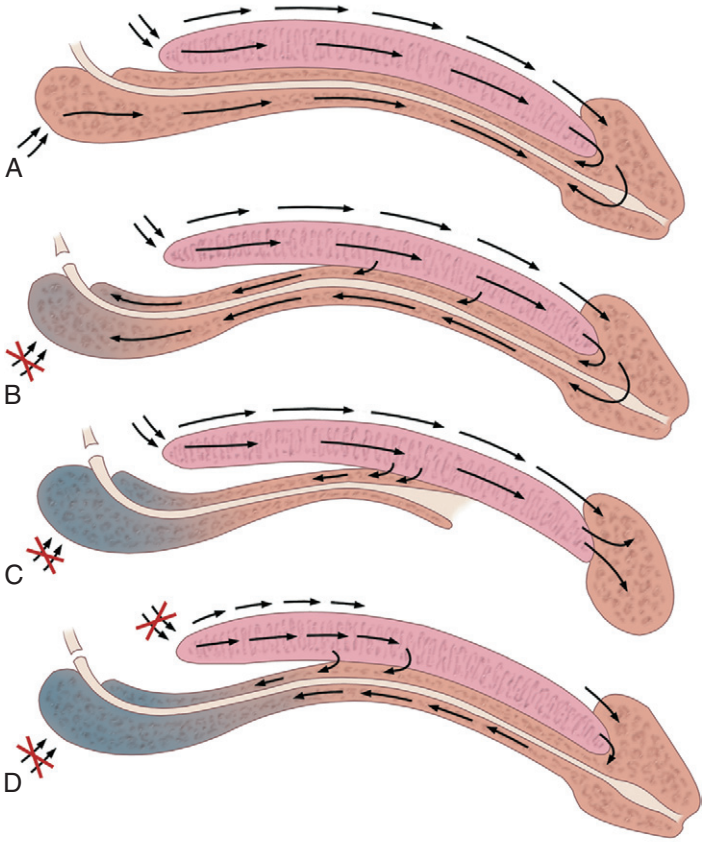

Figure 36–39. Diagrammatic representation of the deep vasculature of the penis. **A**, In the normal situation, through the common penile artery, flow is directed to the tip of the penis with arborization into the spongy erectile tissue of the glans penis. This provides retrograde flow into the corpus spongiosum. If the arteries of the bulb are intact, there is also antegrade arterial flow to the corpus spongiosum. **B**, With interruption of the arteries to the bulb and mobilization of the corpus spongiosum, all flow to the corpus spongiosum is retrograde through the common penile arterial system. **C**, In the case of hypospadias, in which the distal corpus spongiosum may have been interrupted, with proximal mobilization of the corpus spongiosum and therefore division of the arteries to the bulb. Even if the common penile circulation is intact to the tip of the penis, it may not adequately provide retrograde vascularity to the corpus spongiosum; hence, ischemic stenosis can ensue. **D**, In the case of injury to the common penile artery, with elevation of the proximal corpus spongiosum and division of the arteries to the bulb, blood flow to the proximal corpus spongiosum may not be adequate, leading to ischemic necrosis or ischemic stenosis.

revascularization to augment the vascularity and, with that accomplished, then proceed to urethral reconstruction (Jordan, 2005; Davies et al, 2009). We are currently evaluating new technology to see if we can get the same information regarding the deep vasculature without need for either duplex ultrasonography or angiography in many patients. The SPY Imaging System (Novadaq, Bonita Springs, FL) is a novel noninvasive technique of evaluating vasculature. It uses indocinen green (ICG) dye, which is a fluorescent compound injected intravenously. It binds to plasma proteins and consequently remains intravascular, making it ideal for imaging the arterial supply. A laser is used to excite the ICG dye and make it fluoresce. The filtered fluorescent images are captured by a charge-coupled device video camera demonstrating the vasculature. In many cases of pelvic fracture urethral distraction defects, erectile dysfunction is a consequence of the injury, although clearly in some patients, erectile dysfunction results from the reconstructive surgery. We think that the incidence of injury to the pudendal arteries is drastically underreported and underrecognized. Thus, we, along with others, believe that in many of these cases, the cause of erectile dysfunction is vascular (Brandes and Borrelli, 2001). However, others think that in most, the cause is neurologic (Shenfeld et al, 2003).

Summary

Using the maneuvers outlined, we have found that virtually all distraction injuries can be reconstructed through a perineal approach with an anastomotic technique. Although the above-and-below approach is used when concomitant bladder neck surgery is performed, the inability to accurately identify those patients has led us to perform bladder neck surgery at a second setting. We have therefore abandoned a transpubic approach as applied to posterior urethral distraction injuries.

Although we favor primary reconstruction of posterior urethral distraction injuries, others choose to manage these injuries endoscopically (Barry, 1989). We have found that the endoscopic management of pelvic fracture urethral injuries is not a simple procedure and must be undertaken only by a skilled and experienced surgeon. Many of these procedures can be categorized as a

"cut-for-light" procedure. Although there are surgeons who report success, the majority of cut-for-light procedures are not done with sufficient precision to allow adequate realignment of the urethra. We have seen many disasters that have resulted from these procedures and in most cases condemn the use of these modalities. In addition, no cut-for-light series compares favorably, with regard to long-term success rates, with series from large centers that use primary anastomotic techniques (Levine and Wessells, 2001).

In 1989, Marshall described his method of using stereotactic techniques for endoscopic alignment of the ends of the urethra. He emphasized the length of time it takes to obtain precise alignment before undertaking the endoscopic portion of the procedure. In his procedure, he passes a wire through the aligned ends of the urethra, minimally dilating the channel, and widening it with transurethral resection. The scar is stabilized by a period of self-catheterization. A communication with Marshall has determined that he has limited the applications of this procedure and does not advocate it as a primary modality. Patients whose medical condition, age, or concomitant orthopedic injury prevents them from being placed in the exaggerated lithotomy position, or reconstructed using a transpubic approach, may be managed with this technique.

In children, the goals of surgery are the same as in adults. In our experience, most children can be reconstructed by the same perineal exposure as in adults. Exposure is clearly more difficult, but nonetheless perineal anastomosis can be done (Hafez et al, 2005). However, the posterior, sagittal trans-sphincteric approach has been proposed as a better approach in children (Mathews et al, 1998; Peña and Hong, 2004). We agree that the posterior approach is an elegant method of exposure; however, our observation is that with this approach, surgeons tend to resort to techniques of substitution reconstruction where primary anastomosis could be done and, in our opinion, is superior. With our experience accumulating using the vessel-sparing approach to anterior urethral reconstruction—both primary anastomosis and augmented anastomosis—we have extended the technique to select patients with pelvic fracture urethral reconstruction and have found the approach feasible with good results in a small number of patients. The advantage however has not been proven.

Key Points: Distraction Injuries of the Urethra

- Urethral distraction injuries are the result of blunt pelvic trauma and accompany about 10% of pelvic fracture injuries. Many injuries appear to not totally distract the entire circumference of the urethra; instead, a strip of epithelium may be left behind.
- The use of aligning catheters acutely is somewhat controversial, but most would agree that the aligning catheter, at the very worst, facilitates subsequent reconstruction and, at best, often leaves the patient with an endoscopically manageable stenosis.
- As with any stricture, it is important to define the precise anatomy. The combination of contrast-enhanced studies with endoscopy and selective magnetic resonance imaging is useful. The appearance of the bladder neck on contrast-enhanced studies or on antegrade endoscopy is not predictive of ultimate function of the bladder neck. Hence, simultaneous reconstruction of the bladder neck and the posterior urethra is, for the most part, not currently undertaken.

VESICOURETHRAL DISTRACTION DEFECTS

Enthusiastic use of radical prostatectomy has unfortunately led to increasing experience with patients who have had total obliteration of their vesicourethral anastomosis. In some patients, there is distraction of the vesicourethral anastomosis with either a totally obliterating distraction defect or severe anastomotic stenosis. In addition, with the proposal that bladder tube interposition might enhance continence, a new entity, the stenotic or obliterated vesicourethral anastomosis due to ischemia of the bladder tube, is now encountered.

As with other defects, it is important to accurately determine the length of the defect. This can be accomplished by simultaneous cystography with retrograde urethrography, simultaneous retrograde urethrography and antegrade endoscopy through the suprapubic tube, or both.

There are a number of options for the management of these complex patients. Many have other medical problems, and it has been our observation that many have thick and small bladders, possibly contributing to the difficulty with the initial surgery. The ever-present issue of body habitus also must be considered and, in our opinion, contributes to problems with the initial anastomosis. An indwelling suprapubic tube must always be considered an option. In the individual who is significantly overweight, the results of aggressive reconstruction have not been good. The place for endoscopic techniques is covered later in this section; however, in the case of short-length distractions, we have had good success with aggressive incisions at the 3-o'clock and 9-o'clock positions followed in approximately 3 weeks with repeated incisions. Whether the holmium laser is better than the cold knife can be debated; the hot knife is not necessary. If one must "core through" to establish continuity, in our opinion endoscopic procedures have no place except as discussed later.

In some cases, a continent catheterizable bladder augmentation may indeed be a better operation than aggressive functional reconstruction; however, the very heavy patient makes construction of a functional catheter channel difficult. Diversion must also be entertained, and in patients in whom functional reconstruction is not an obvious choice, it then becomes a primary option.

If functional reconstruction is deemed possible, we think it is a reasonable choice and our technique is as follows. We place the patients in a low lithotomy position and use an abdominal-perineal combined approach. We make a lower midline incision, exposing the bladder and dissecting it from the lateral sidewall and further mobilizing the anterior bladder from beneath the pubis as aggressively as can be safely undertaken from above. We then open the peritoneum and develop the retrovesical space, again taking care to complete the dissection as safely as can be accomplished from above.

A second surgeon then begins the perineal dissection by a curvilinear perineal incision similar to that used for a radical perineal prostatectomy. The dissection is posterior to the transverse perinei musculature (posterior anal triangle) and carried along the anterior rectal wall to the area where fibrosis is encountered from the prior radical prostatectomy dissection. The impulse of the perineal surgeon's digits can usually be felt adjacent and lateral to the area of fibrosis and distraction at this point. In addition, the abdominal surgeon places a finger at the limits of the retrovesical dissection from above to provide another palpable landmark and to ensure a safe dissection anterior to the rectal wall and posterior to the

bladder and trigone. The perineal dissection is then joined to the abdominal dissection, and the rectal wall is completely peeled off the area of fibrosis associated with the distraction defect. We then place drains between the rectum and the distraction defect, encircling the area of fibrosis.

The dissection beneath the pubis is made easier by the excision of an ellipse of the rim of the superior pubic ramus. Total pubectomy is not required. The partial pubectomy can be performed with the reciprocating attachment of the Aesculap surgical drilling device (Aesculap, Tuttlingen, Germany); this makes placement of the sutures technically straightforward and improves the exposure for the dissection and resection of the distraction fibrosis.

At this point, the bladder is opened and the area of the bladder neck is determined. A sound is placed and advanced to the area of obliteration. This allows us to completely resect the well-defined area of fibrosis. The urethral stump is exposed and opened, and the site of the neobladder neck, having been identified, is opened. We marsupialize the bladder epithelium as described by Eggleston and Walsh (1985), place anastomotic sutures in the urethral stump, and pass a stenting catheter.

Before the vesicourethral anastomosis is seated, the omentum is mobilized and placed between the posterior wall of the anastomosis and the anterior rectal wall. We then seat the anastomosis and wrap the omentum around the area of anastomosis, tagging it into place. The lateral vesical spaces are drained with closed-suction drains, and a suprapubic tube is left in place when the vesicostomy is closed.

Postoperative care is the same as for a radical prostatectomy. The patients are discharged when their drainage and ambulation allow and their diet has been resumed. We evaluate the patients 4 to 6 weeks postoperatively, with the stenting urethral catheter removed and the bladder filled by way of the suprapubic tube.

Because one attempt has failed in these patients, we generally are conservative with the timing of a voiding trial. In some cases, voiding trials are being done at 2 to 3 weeks.

Our series continues to grow, and we continue to have excellent success in reconstruction. We have some patients who deem their continence adequate for their lifestyle; in the others, we have been successful with the placement of an artificial sphincter.

Others have proposed a different approach to these very difficult cases. In patients for whom multiple attempts at dilation or incision of these vesicourethral anastomotic stenoses have failed, Elliott and Boone (2001) proposed making an incision with placement of the UroLume endoprosthesis, followed at an interval by the placement of an artificial sphincter. They initially described nine men treated with this approach; seven of the men were satisfied with the results of their treatment at 17.5 months mean follow-up. Others (Mark et al, 1993; Kaplan, 2004; Anger et al, 2005) have proposed slight modifications of this approach and are also reporting adequate patency and continence in these patients. Additionally, there are centers accumulating experience with either a pure perineal or a pure abdominal approach with good success rates (Herschorn, 2007; Fisch, 2009).

COMPLEX FISTULAS OF THE POSTERIOR URETHRA

The increase in the performance of radical prostatectomy has also led to an increased incidence of vesicorectal or vesicourethrorectal fistulas. In most cases, these are small and managed by a transperineal, transanal–trans-sphincteric, or posterior approach. However, some cases are complex, with the fistulas associated with large granulated cavities. The problem is magnified when radiation (brachytherapy, external beam therapy, or both) is part of the equation. With radiation fistulas, a number of centers have gone to diversion with ileal conduit or bowel pouch as opposed to functional reconstruction. These cases have also been managed with the approach described earlier for vesicourethral distraction problems. The omentum, however, serves an even more important purpose in these cases. In addition, with the increasing application of "minimally invasive" modalities for carcinoma of the prostate (i.e., brachytherapy, combined brachytherapy with external beam irradiation, higher dose external beam irradiation, and cryotherapy), the magnitude of complexity of these problems of prostatic urethral fistulas, granulated cavities, and severe rectal injury continues to increase. We have tried to approach these problems aggressively, with preservation of function, where possible.

In many of these cases, salvage prostatectomy can be combined with rectosigmoid resection. In some cases, we have successfully reanastomosed the bladder to the membranous urethra. Preservation of continence has been mixed. Where vesicourethral anastomosis is not possible, a urachal-peritoneal flap combined with a rectus abdominis muscle flap is used to bolster the closed bladder neck and to keep the closed bladder neck from sticking to the back of the pubis. The bladder is augmented, and a continent catheterizable channel is developed. In some cases, the continuity of the colon cannot be reestablished, and a colostomy is performed as distally on the descending portion of the colon as possible. Whenever continuity of the colon can be reestablished, a J-pouch coloanal anastomosis is done. Omentum is used to envelop the rectal closure or to separate the rectal closure from the vesicourethral anastomosis. The combined abdominal-perineal approach that was previously described provides excellent safe exposure for management of these complex situations. The morbidity of this approach has been acceptable.

One must be careful in addressing the irradiated bowel. We had a patient who did well with his surgery for continent catheterizable augmentation and bowel closure, but when his colostomy was reversed, he developed an overwhelming colitis and a refistula, with an eventual septic death. Another patient had a breakdown of his bladder neck closure and to date remains with a large vesicoabdominal fistula. Thus it cannot be overemphasized that these cases must be individualized. When they go well, they go wonderfully well; when they do not, they become a disaster for the patient, the patient's family, and the surgeons involved.

Zinman recently reported a 10-year experience with the management of rectourethral fistula. That series had 33 patients who had fistulas and who had not been irradiated, and 33 more who had been irradiated. Mean follow-up for the entire series was about 20 months. The review was a retrospective review taken from office records and hospital records. All fistulas were repaired by an anterior transperineal approach using gracilis muscle interposition flaps, and in some cases with a buccal graft. In this series, 100% of the nonirradiated fistulas were successfully closed with a mean follow-up of 20 months, 85% of the irradiated fistulas were closed in a single stage, and 12% required an additional procedure, with an ultimate closure rate of about 97%. In the nonirradiated group, there were no urethral strictures noted with long-term follow-up; 5 recurrent strictures were noted in the irradiated group. In the nonirradiated group, 91% of the patients had their bowel undiverted. In the irradiated group, 39% had long-term bowel diversion. Zinman believes that the use of muscle interposition flaps are integral to achieving good results, and their use of buccal

mucosal grafts, where needed to augment the closure of the urinary tract, were also believed to be invaluable (Vanni et al, 2009). Clearly, both an estimation of ultimate urinary and bowel function are integral to the determination of the plan for reconstruction and/or diversion. Also, it must be recognized that the surgical approach chosen both facilitates and limits options (i.e., of the bowel, the urethra, and/or tissue interposition) (Lane et al, 2006).

Key Points: Vesicourethral Distraction Defects and Complex Fistulas of the Posterior Urethra

- Vesicourethral distraction defects are an unfortunate complication of radical prostatectomy.
- There are a number of options for management of these complex patients. An indwelling suprapubic tube must always be considered an option, long term. Likewise, in some cases, a continent catheterizable bladder augmentation may indeed be a better operation than aggressive functional reconstruction. If functional reconstruction is deemed reasonable, we have employed an above-and-below technique, in which laparotomy is combined with a posterior perineal triangle dissection.
- The interposition of omentum has been used both for distraction defects and for complex fistulas. This approach allows safe mobilization of the rectum from the area of the distraction scar or from the fistula site.
- When radiation is added to the equation, the complexity of reconstruction is magnified. The effects of radiation must be allowed to settle; tissue interposition is the rule, and in many cases functional reconstruction is not possible. Some think that diversion, in the case of the irradiated patient, is the safest and best option.
- Careful consideration of ultimate urinary and bowel function are integral to proper planning of surgery.

CURVATURES OF THE PENIS

Normal elasticity and compliance of all tissue layers of the penis are critical for erectile function, tumescence, and rigidity. Tissues must expand in all dimensions as the penis engorges with blood; eventually, the tissues of the tunica albuginea and the septal fibers of the corpora cavernosa are stretched to the limits of their compliance, and tumescence is converted to rigidity. In the normal penis, the tissues are symmetrically elastic and the erection is straight. In curvature of the penis, there is relative asymmetry of one aspect of the erect penis. In some cases, this arises from diminished compliance of one aspect of the tunica albuginea or outright foreshortening of one aspect of the erectile bodies.

The term *chordee* means curvature, but it is commonly used as if it refers to the tissues causing the curvature. This misuse of the term is seen in the statement "the chordee was resected"; properly phrased, "the chordee can be corrected by resecting the inelastic tissues that are causing the chordee."

Curvatures of the penis can be congenital or acquired. Some confusion also exists in common usage of the term *congenital curvature of the penis*. The terms *congenital curvature of the penis* and *chordee without hypospadias* have often been used interchangeably. We prefer to reserve the term *chordee without hypospadias* for those patients in whom the meatus is properly located on the tip of the glans penis, yet a ventral curvature is associated with abnormalities of the ventral fascial tissues or corpus spongiosum, or both. It has long been recognized that hypospadias is a condition that is associated in some males with either a diminutive penis or a micropenis. Although a small penis is not diagnostic of hypospadias, it is highly unusual for a patient with hypospadias to have an exceptionally large erect penis. In contrast, other congenital curvatures of the penis (ventral, lateral, or dorsal) are inevitably associated with the finding of a large erect penis. Because **the trauma that results in acquired curvature is virtually always associated with intercourse, the occurrence of acquired curvature is nil before the onset of puberty.** We have seen some patients in whom there was a history of trauma during vigorous masturbation, but these patients are the exception. Like congenital curvatures of the penis, acquired curvatures may be dorsal, lateral, ventral, or complex.

Types of Congenital Curvature of the Penis

The urethra begins as an epithelial groove in the midline of the ventral surface of the developing penis. As the groove extends, it deepens, with the edges eventually meeting to fuse into a tube. Fusion begins proximally and progresses distally. During normal development, the fusion of the urethral tube eventually reaches the tip of the glans penis. Proliferating mesenchyma surrounds the tube, separating it from the skin, and differentiates to form the corpus spongiosum, Buck fascia, dartos fascia, and overlying ventral skin of the penis. Fetal development of the penis is regulated by testosterone, produced by the fetal testis, which is converted by 5α-reductase to dihydrotestosterone. Dihydrotestosterone acts directly on cells with androgen receptors and on all layers of the male external genitalia. This embryologic process explains the development of the anterior urethra that is unique to males.

Maturation of these tissues into normal structures depends on the same growth factors that control the formation of the urethra. Even though urethral development has progressed normally, mesenchymal tissue development in the penis may be deficient or abnormal and result in dysgenetic and inelastic fascial layers. In unpublished data, Galloway and associates (El-Galley et al, 1997) have shown that at least in hypospadias, there is a deficiency of growth factors in the ventral penile skin. To our knowledge, to date there are no data that show the same growth factor deficiencies for the deeper tissues.

In 1973, Devine and Horton proposed a typing classification for the various congenital curvatures. In type I congenital curvature, the urethral meatus is at the tip of the glans. None of the surrounding layers are normally formed, however, and the epithelial urethra is associated with malfusion of the corpus spongiosum and all the tissues superficial to the urethra. Skin coverage of the epithelial tube is present. In type II, a dysgenetic band of fibrous tissue thought to be derived from the mesenchyma, which would have produced the Buck fascia and the dartos fascia, lies beneath and lateral to the urethra. However, the urethra is contained within a normally developed and fused corpus spongiosum.

In type III, the urethra, corpus spongiosum, and Buck fascia are all normally developed and ventrally fused. However, there is a short area of inelastic tissue in the dartos layer of the penis that causes a relatively sharp bend. Abnormal development of the dartos fascia is frequently associated with complex curvatures. With extensive involvement, the inelastic dartos can be sufficient

to restrain the penis and conceal the penile shaft. In many of these cases, there appears to be abnormal prominence of the mons fat pad. These stigmata are thought to be associated with an abnormality in the proper progression of virilization during fetal development.

In type IV, although the urethra, corpus spongiosum, and fascial layers are normally developed, there is relative shortness or inelasticity of one aspect of the tunica albuginea of the corpora cavernosa. Experience has shown that most patients whose congenital curvature is type IV seem to actually demonstrate evidence of a hypercompliance of the tunica albuginea. In these patients, the flaccid penis is normal in size and not necessarily impressively large, whereas the erect penis is large. The tunica albuginea of the corpora cavernosa is required to expand through a wide range, and if there is asymmetry in the compliance of the tunica, curvature occurs. It is not uncommon for patients with type IV curvature to have noticed curvature before puberty; but as they traverse puberty, an increase in the curvature is noted because of the penile hypertrophic growth spurt that occurs during this time.

Type V congenital curvature is also known as the congenital short urethra. This implies that there has been correct fusion of all elements of the penis (i.e., tunica albuginea, urethral epithelium, corpus spongiosum, Buck fascia, dartos fascia, and ventral skin). However, during erection, the correctly fused urethra and corpus spongiosum are not long or compliant enough to match the compliance of the other ventral tissue layers.

If type V congenital curvature exists at all, it occurs so rarely that when it is encountered, one should doubt the findings. Whereas discussion of the condition in the past has centered on the best location to "cut the urethra" during the repair, on the rare occasions when this condition is encountered, it is our belief that it should be diagnosed and treated only by the most experienced surgeons. In general, if the urethral meatus has developed to the tip of the glans, the urethra should not be divided to correct ventral curvature of the penis. Although there will obviously be extremely rare exceptions to this bold statement, if those exceptions are encountered, their existence should still be questioned.

The congenital curvature types I, II, and III represent forms of the hypospadias anomaly, and we prefer to refer to them collectively under the term *chordee without hypospadias*. This term implies that although the meatus is not improperly placed, curvature is due to inappropriate fetal development of the ventral penile structures. We prefer to refer to the type IV anomaly as congenital curvature of the penis. If a patient has findings of hypercompliance of the corpora cavernosa and a ventral curvature, the patient is diagnosed as having congenital ventral curvature of the penis; and if the hypercompliance causes a lateral curvature, it is referred to as congenital lateral curvature of the penis (left or right). Although, as mentioned, **the type V anomaly is so rarely encountered that it deserves its own diagnosis, we believe its correction is best discussed with types I, II, and III, under the category of chordee without hypospadias.**

Chordee without Hypospadias in Young Men

Patients with chordee without hypospadias usually present with either ventral curvature or ventral curvature associated with torsion (complex curvature). These young men do not typically have a greater than average stretched penile length (13.1 cm) (Schonfeld and Beebe, 1942) and will have noted curvature throughout life. If prepubescent, they have obvious curvature with erection; if postpubescent, they may offer a history of increasing curvature as they pass through puberty.

In many cases, there are abnormalities of the ventral penile skin. These might consist of either an element of hooded preputial skin or a high insertion of the penoscrotal junction. Although the patients have fusion of the preputial skin, there is also often a wrinkled appearance dorsally that we now recognize to be a form of the classic hooded preputial skin. In addition, in many cases, the tissues on the ventrum of the penis seem inelastic as the patient's penis is examined on stretch. This palpable inelasticity on the ventral penis consists of dysgenetic tissue, which can replace the Buck and dartos fascia layers; and in some cases, there is an element of inelasticity of the tunica itself.

During surgical exploration, Devine and Pepe obtained tissue from these patients for evaluation of 5α-reductase levels. Those data suggested a deficiency of the enzyme in the ventral dysgenetic tissue. The values were inconclusive at the time and the study was discontinued. El-Galley and colleagues (1997) also looked for growth factor deficiency in tissues of males with hypospadias and found a correlation. To our knowledge, however, a growth factor analysis has not been undertaken in patients with chordee without hypospadias.

An important part of the preoperative evaluation is the submission of instant or digital photographs of the erect penis, taken by the patient, documenting the curvature. The photographs are especially helpful in differentiating between the patients we refer to as having chordee without hypospadias and those with congenital curvatures of the penis. In a patient who has chordee without hypospadias, the photograph reveals an erect penis commensurate with the size of the detumesced penis, whereas in the congenital curvature patient, the erect penis is noticeably large. It is important to address the psychologic aspects of the condition as an integral part of the treatment, and many of our patients will see a psychologist preoperatively. Corrective surgery for chordee without hypospadias is highly successful, and, in almost all cases, an effective correction can be accomplished with a single operation (Devine et al, 1991). In some cases, the penis has been straightened by excision of all the dysgenetic tissues from the ventral side of the penis and wide mobilization of the corpus spongiosum from the glans penis into the perineum.

Even in patients with obvious abnormalities of the corpus spongiosum (i.e., poor ventral fusion or frank bifid corpus spongiosum), wide mobilization usually reveals that it is not the corpus spongiosum that remains as the ventral limiting factor. In most patients, the penis remains curved because of the inelasticity of the ventral aspect of the corpora cavernosa themselves. Furthermore, in an occasional patient, the corpus spongiosum becomes atretic distal on the shaft, and the urethra itself is only an epithelium-lined tube. Even in these patients, with wide mobilization of the epithelial distal portion and elevation of the proximal corpus spongiosum, it is unusual to find the corpus spongiosum or the epithelial tube limiting the ventral erection. If the epithelial tube has served as an adequate urethra (i.e., it is not stenotic), the morbidity of urethral division and subsequent need for urethral reconstruction must be considered before such a procedure is undertaken. Because the evolution of hypospadias repairs accomplished by wide mobilization of the corpus spongiosum and epithelial and corpus spongiosal elements distal to the meatus has allowed onlay procedures, the morbidities of urethral division must be strongly considered and, we believe, usually avoided.

In children, after mobilization and excision of the dysgenetic tissues, the residual chordee can usually be corrected by making a longitudinal incision, with a sharp blade, in the ventral midline of the corpora cavernosa while an artificial erection is maintained. The incision (midline ventral septotomy) can often be extended between the corporeal bodies for a significant distance, allowing the edges of the ventral tunica to move laterally. The penis will noticeably straighten with erection.

If this maneuver is not sufficient, the dorsal neurovascular structures can be mobilized in concert with Buck fascia, and a small ellipse or ellipses of dorsal tunica albuginea can be excised and closed with watertight plicating sutures. Caution is important, however, when the dorsal neurovascular structures are mobilized; with poor development of the ventral structures, which occurs in some patients, the arborization of the dorsal arteries provides the dominant vascularity to the glans.

Congenital Curvatures of the Penis

Patients with congenital curvature of the penis can have ventral, lateral (which is most often to the left), or, unusually, dorsal curvature. Photographs of the erect penis demonstrate a smooth curvature that generally involves the entire pendulous portion of the penile shaft.

Patients usually present as otherwise healthy young men between the ages of 18 and 30 years. Many of these patients have noticed curvature before passing through puberty but have presumed it to be normal. With puberty, however, they discover that the curvature is not normal, or they become sexually active and discover that the curvature impedes their efforts, or they notice increasing curvature as they pass through puberty, and this, in their minds, clearly would preclude sexual intercourse. On occasion, a patient waits until he is older than 30 years to deal with the anomaly, and, even less often, there is a younger adolescent, who is able to discuss his genitalia with his parents.

In circumcised patients, we make an incision through the circumcision scar, which in many cases is displaced well down on the penile shaft. Even with relatively significant displacement of the circumcision scar on the shaft of the penis, however, the reincision should be through the circumcision scar. The penis is then degloved by dissection of the layer immediately superficial to the superficial lamina of Buck fascia.

An artificial erection is obtained with normal saline while others use pharmacologic agents. We do not routinely recommend a tourniquet device, because constricting devices can conceal the proximal limits of the curvature. This is of most significance in cases of ventral curvatures, which frequently extend proximally. On occasion, some element of perineal pressure is initially required, but these are patients with normal erectile function, and their venous occlusive function is normal. The artificial erection demonstrates the character of the curvature and the location of maximal curvature. In patients with ventral curvature, there may be some illusion of thickening of the dartos and Buck fascia, and in those patients, the fibrous tissue is mobilized and completely excised. The corpus spongiosum is detached from the corpora cavernosa and mobilized from the glans to the penoscrotal junction.

After these tissues are excised, the artificial erection is repeated, and an occasional patient is found to have been completely straightened. Most patients, however, suffer from a differential elasticity between the dorsal and the ventral aspects of the corporeal bodies, and although the curvature may have been lessened, it persists unless further procedures are done to straighten the penis.

In the adult patient with persistent curvature, there are two options for surgical correction: (1) to lengthen the ventral aspect of the penis by making transverse incisions in the ventral tunica and placing an autologous tissue graft (we currently use the small intestinal submucosal graft at our institution), and (2) to shorten the dorsal aspect of the penis by elevating the neurovascular bundle, excising an ellipse or ellipses from the dorsum of the tunica albuginea, and closing the defects in watertight fashion (Nesbit [1965] procedure). **Because the size of the erect penis is usually not a problem in these cases of congenital curvature, we have chosen the second option and are strenuously against ventral grafting.** The recovery period after this procedure is much shorter, and the variabilities of graft take do not have to be considered. In addition, when a graft is used, there is always the possibility, although uncommon, of the development of graft-induced veno-occlusive dysfunction. **In a 2000 consensus conference sanctioned by the World Health Organization, the committee on Peyronie disease and congenital curvature of the penis agreed that the majority of, if not all, cases in men with the classic finding of congenital curvature of the penis were best managed with a plication or corporoplasty techniques but not grafting techniques** (Jardin et al, 2000; Lue, 2004). This consensus was reiterated at the next World Health Organization conference. It is therefore preferable to shorten the longer aspect of the penis in patients with congenital curvature. However, **if the patient falls into the category of chordee without hypospadias and shortness of the penis is an issue, we selectively use incisions with grafts to correct the curvature** (Devine and Horton, 1975).

After the decision has been made to proceed with excisions of ellipses of dorsal tunica, the Buck fascia can be elevated, in concert with the dorsal neurovascular structures, by beginning just lateral to the corpus spongiosum and carrying the dissection dorsally across the midline. Alternatively, the tunica can be exposed by excising the deep dorsal vein of the penis and opening the inner lamina of the Buck fascia. Elevation of the neurovascular structures is done by dissecting from the dorsal midline laterally around to the corpus spongiosum and from the coronal margin to the penopubic junction, thus limiting the effects of stretching the dorsal structures with exposure of the dorsum of the penis.

An artificial erection is obtained to plan the proposed ellipse excisions. We prefer to use several small ellipses rather than try to correct the curvature with one large ellipse. The first ellipse is usually positioned at the point of maximal concavity. The edges of the planned ellipse are then apposed with a Prolene suture. The artificial erection is repeated to assess the effects of that excision. If there is good straightening in that area of the shaft, the incisions are again well marked, the plicating sutures are removed, and the ellipses of tunica are made with a sharp scalpel blade. By dissection in the space of Smith and removal of only an ellipse of tunica, the ellipses are carefully excised to avoid damage to the underlying erectile tissue or can be merely closed under the reapproximated edge of the defect in the tunica albuginea. The edge of the ellipse is reapproximated with a combination of interrupted 4-0 polydioxanone sutures and a watertight running 4-0 polydioxanone suture.

After closure, we repeat the artificial erection to assess the results of the first ellipse with the others. A final artificial erection should demonstrate the penis to be perfectly straight. In cases of ventral curvature, or when complex curvatures are associated with an element of ventral curvature, a minimal degree of dorsal curvature after correction is acceptable. In most cases, as the sutures dissolve,

the penis either remains minimally dorsiflexed or becomes perfectly straight.

The Buck fascia is closed. Two small suction drains are placed superficial to the Buck fascia but deep to the dartos fascia. We then replace the skin sleeve, with its edges apposed with interrupted small Vicryl or Monocryl sutures. In all patients, we place a small Foley catheter, which is removed on the first postoperative day. The two small suction drains are also removed at 12 to 24 hours. Depending on the amount of edema and drainage, patients are discharged from the hospital on the evening of the first or early the second postoperative day.

A congenital lateral curvature of the penis is often associated with some complexity of curvature; patients frequently notice lateral curvature in association with a ventral or, less commonly, a dorsal curvature. However, some patients present with only lateral curvature, with the right side larger than the left, and curvature to the left.

In some cases, a repair of the lateral curvature can be approached through a small incision at the point of maximal curvature. Laterally placed incisions on the penile shaft are not cosmetically optimal. We prefer, however, a degloving incision after exposure of the deep penile structures; the point of maximal concavity is then marked. Prolene sutures are placed, and an artificial erection is again performed. The size of the ellipse is then assessed, and the ellipse is excised and closed as discussed earlier.

As mentioned, however, most cases of lateral curvature are associated with complex curvatures. In these patients, the correction of the curvature is similar to that described for patients with ventral curvature, by a circumcising incision with the skin reflected. In contrast to a ventral curvature, however, with a lateral curvature, the entire dorsal neurovascular bundle does not need to be reflected; therefore, it is seldom required, nor is it considered beneficial, to excise the deep dorsal vein in approaching the dorsum of the penis. The postoperative care is the same as described for a ventral curvature.

For the uncommon patient with a congenital dorsal curvature of the penis, the repair is best accomplished by mobilizing the lateral aspect of the corpus spongiosum to allow small ellipses lateral to the midline to be positioned on the ventrum of the penis, by the technique described before. Again, postoperative care is as described for a ventral curvature.

Although described as a method for plication for curvature associated with Peyronie disease, corporoplasty, the procedure described by Yachia (1993), is also useful for the correction of congenital curvatures. The procedure essentially consists of longitudinal incisions in the tunica albuginea with transverse closure. Thus the "long side" is plicated without the need for excision; however, the plication is durable in that the tunica is opened and closed with a resulting scar, rather than reliance only on the strength of sutures as originally described by Nesbit (1965). With this technique, closure is done with absorbable monofilament suture.

Acquired Curvatures of the Penis

Acquired curvatures of the penis inevitably follow trauma to the penis. Many of these cases are associated with Peyronie disease, also believed to be associated with trauma to the penis during intercourse (Bella et al, 2007). An occasional patient also presents who has had vigorous internal urethrotomy, with the incision extended outside the urethra and corpus spongiosum, and involving the tunica of the corporeal bodies, causing scarring that is significant enough to be associated with curvature.

Acquired Curvatures of the Penis That Are Not Peyronie Disease

When a young man presents with an acquired curvature of the penis, one must always consider Peyronie disease. However, many will not have true Peyronie disease. These patients, on close questioning, reveal a history of minimal lateral curvature of the penis and a clear memory of a lateral buckling injury that occurred during intercourse. In some cases, the patient remembers hearing a "snap" and notices immediate detumescence and significant ecchymosis of the penis. These patients are often referred with a diagnosis of Peyronie disease, but a diagnosis of curvature secondary to penile fracture is more accurate. Because of the noticeable events associated with fracture of the penis, many patients present acutely, and reconstruction can be accomplished at that time.

On occasion, however, a patient or his initial-care physician ignores the stigmata of the trauma (often described as "minimal" by patients), and the patient presents with a noticeable lateral scar that causes both indentation of the lateral aspect of the penis and, in some cases, curvature. Patients who had preexisting lateral curvature may actually notice that their penis has been straightened by the trauma, but they are disturbed by the concavity caused by the scar. In others, the small linear scar causes a significant lateral curvature.

Another group of patients presents after a similar buckling trauma to the penis but without associated detumescence or ecchymosis. These patients report noticing that their erections were painful for a period after the trauma, and then a nodule developed in the lateral aspect of the penis. Eventually, they present with a lateral linear scar that has led to curvature and indentation at the site. We refer to this injury as a subclinical fracture of the penis.

The lesion of a subclinical fracture of the penis is believed to be due to the disruption of the outer longitudinal layer of the tunica albuginea during the buckling trauma. The inner, circular layer is not disrupted, however, and maintains the blood-tight continuity of the corpus spongiosum. Another possible scenario is that both layers of the tunica albuginea are disrupted but the overlying Buck fascia maintains its integrity. There are also patients who notice a pop with intercourse and a period of pain with erections, followed by curvature of the penis—usually dorsal. These patients probably tear the septal insertion completely. These patients clearly behave more like Peyronie disease patients.

Patients usually have normal erectile function after subclinical or clinical fracture of the penis; there appears not to be an association with concomitant global cavernosal veno-occlusive dysfunction. However, the association of cavernosal veno-occlusive dysfunction and trauma of the penis continues to be seen, and some patients have significant problems with erectile dysfunction after fracture-type injuries of the penis. These injuries are not associated with shortening of the penis. In most cases, it is the lack of erectile dysfunction and penile shortening that help distinguish these patients from Peyronie disease patients. If a detailed history leads one to suspect blighted erectile function, an evaluation of erectile function should be accomplished before proceeding with surgery. At our institution, we evaluate these patients with duplex ultrasonography and selectively with dynamic infusion cavernosometry and cavernosography.

Although foreshortening of the penis is not a characteristic of either the injury itself or the resulting scar in either of these injuries, these patients are not thought to be best treated by approaching the opposite aspect of the scar and excising an ellipse of the tunica. This would result in bilateral scars, which would cause bilateral indentations of the penis, and although the penis would have been straightened by the correction, most patients are upset by the cosmetic and functional result of a near-circumferential indentation of the penis. Instead, we excise the scar and place a graft to replace the corporotomy defect caused by the scar excision. Because these scars are on the lateral aspect of the penis, minimal mobilization of Buck fascia, associated dorsal neurovascular structures, and corpus spongiosum is required at the site.

The results of the surgical correction described have been extremely effective. All such patients treated at the authors' institution have been successfully corrected with a single operation.

Key Points: Curvatures of the Penis

- Curvatures of the penis can be acquired or congenital. Congenital curvatures of the penis can be categorized as chordee without hypospadias or congenital curvature of the penis.
- In general, chordee without hypospadias is really a forme fruste of hypospadias. Although the meatus may not be abnormally placed, these patients usually have findings suggestive of hypospadias (i.e., malformation of the ventral structures of the penis). These patients are not characterized by large erect penises. In contrast, patients with congenital curvature of the penis seem to have exceptionally large erect penises.
- The entity of congenital curvature of the penis seems to be related to nonsymmetrical expansion of the erectile bodies, which must expand significantly during tumescence. In general, these patients are best reconstructed by excision with plicating closure or pure plication techniques. The use of grafts is not recommended because of the unusual but real occurrence of graft-induced veno-occlusive dysfunction in certain of these patients.

TOTAL PENILE RECONSTRUCTION

General

The principal techniques of penile reconstruction were originally developed for treatment of trauma patients, and, in many cases, these patients were victims of war injuries. In 1936, Bogaraz described a technique for phallic construction in a series of war-injured patients, and in 1944, Frumkin followed with a series from the Soviet Union. Aware of the work in the Soviet Union, Gillies and Harrison (1948) reported on a series of patients in whom they had accomplished penile reconstruction while stationed at a major hospital in the outskirts of London during World War II. In this series, there were a number of patients with a complete absence of the penis.

Initially, all procedures for phallic construction involved delayed formation and transfer of tubed abdominal flaps. These tubes were produced from random flaps of skin and because of their size were based on a tenuous blood supply. To allow new vascular patterns to become established in the transferred tissue, they were formed in stages, with a "delay" between the stages. In the "tube-within-a-tube" design, the inner tube allowed the placement of a baculum during intercourse, and the outer tube provided skin coverage. Patients voided through a proximal urethrostomy. This continued to be the "state-of-the-art" phallic construction and penile reconstruction until 1972, when Orticochea described total reconstruction of the penis using the gracilis musculocutaneous flap. In 1978, Puckett and Montie reported a series in which they constructed the penis with a tubed groin flap. In the early cases in this series, the flap was transferred in delayed fashion to the area of the penile stump. Later in the series, a microvascular free-transfer technique was employed.

In 1984, Chang and Hwang popularized the forearm flap, based on the radial artery, for phallic construction. Biemer (1988) reported a modification of the forearm flap, which was also based on the radial artery; and, in 1990, Farrow and colleagues reported their "cricket bat" modification of the radial forearm flap. **Today, forearm flaps are the most commonly employed method for total phallic construction and penile reconstruction.**

The forearm flap is usually harvested from the nondominant forearm. Preoperatively, the Allen test is used to screen patients carefully for arterial insufficiency. This test involves palpation of the radial and ulnar arteries in the wrist, with the patient making a tight fist to express blood from his hand. As he opens his hand, the fingers are pale, but if palmar circulation is normal and both arteries are patent, the fingers turn pink when one of the arteries is released. If, on the basis of either the Allen test or the patient's history, there is any doubt about the integrity of the radial and ulnar arteries or the palmar arch, upper extremity angiography is performed.

As described, the forearm flap is a fasciocutaneous flap vascularized by the radial artery; however, the ulnar artery also vascularizes the forearm fascia and most of the forearm skin. The radial artery arises as a continuation of the brachial artery and proximally lies beneath the belly of the brachioradialis muscle, becoming more superficial at the wrist. The ulnar artery is also a continuation of the brachial artery and vascularizes a similar area of skin and underlying adipose tissue. The vascularity of the overlying skin is achieved by way of the underlying (antebrachial) fascia, which is the superficial fascia investing the musculature of the forearm.

The forearm flap can be elevated and transferred on the superficial fascia. The lateral and medial antebrachial cutaneous nerves appear proximally beneath the fascia. The cephalic, basilic, and medial antebrachial veins are also included in the flap and constitute a portion of the venous drainage. In some patients, the vena comitans is the dominant venous drainage system. At the time of flap transfer, it is imperative to assess both the venous comitans and the superficial veins to determine which is the dominant system in the individual patient.

The various modifications of the forearm flap do not represent changes in the technique of flap elevation; rather, they are modifications in the design of the skin island and the relative position of the urethral paddle in relation to the skin that will eventually become shaft coverage. Each of these modifications has advantages in different situations.

In the forearm flap as described by Chang and Hwang (1984), the shaft is covered with the radial aspect of the skin paddle. A de-epithelialized strip is made, and a second skin island, on the ulnar aspect of the skin paddle, is tubed to form the urethra. The urethral tube is then rolled within the tube of skin to form a

tube-within-a-tube design. In the white population, this flap has demonstrated a tendency to lead to ischemic stenosis of the lateral paddle, where the urethra is constructed.

In the cricket bat modification, the urethral tube extends distally, closely overlying either the radial or the ulnar artery. We have experience with elevation of the cricket bat modification on both arteries. Proximal to the urethral strip, a broader portion of the skin paddle provides coverage of the shaft. The urethral portion is tubed and transposed by inverting it into the center of the shaft portion of the skin paddle. The advantage of this modification lies in centering the urethral portion over the respective artery, in contrast to the Chinese design, in which the ulnar aspect is far distal from the radial artery, with the potential for ischemic stenosis or loss of that portion. The cricket bat modification has been useful in trauma patients, particularly in those who have a significant stump of erectile bodies and urethra left after the injury.

The modification by Biemer (1988) also centers the urethral portion of the flap over the artery. As described by Biemer, the flap is elevated on the radial artery and includes a vascularized piece of the radial bone intended to provide rigidity to the new penis. The inclusion of cartilage and bone has not been universally successful, however, and rigidity in these flaps is obtainable by the use of either an externally applied or internally implanted prosthesis. If the bone is not elevated, the Biemer flap design can be elevated on either the radial or the ulnar artery. At our center, we most often elevate the flap on the ulnar artery, in a modification of the Biemer design.

Modifications of the Biemer design also include the glans construction technique that was originally described by Puckett and Montie (1978). In the original Biemer design, a central strip becomes the urethra, and lateral to that strip, two de-epithelialized portions and two lateral islands (lateral aspects of that skin paddle) are fused dorsally and ventrally to cover the shaft. With the modification of Puckett and colleagues (1982), a large island is left distally and flared back over the tip of the tubed flaps, creating the illusion of a glans penis. The Biemer design, especially when it is combined with Puckett's design for glanular construction, offers the best cosmetic results (Fig. 36–40).

There are several disadvantages to the use of a forearm flap for phallic construction. The major disadvantage of forearm flaps is the obvious donor site deformity. We have reconstructed the donor site with full-thickness skin grafts taken from the area of the inguinal crease, and the cosmetic result is far superior to that obtained when the donor site is reconstructed with split-thickness skin (even thick split-thickness skin). A second disadvantage lies in the **possibility of the development of cold intolerance in the hand of the donor side.** Early in our experience with the forearm flap, we reconstructed the radial artery with an interposition vein graft. We have since abandoned this procedure in the majority of our series and have not seen cold intolerance in our patients. Another disadvantage occurs in both male and virilized transgender patients **when the forearm skin is hirsute, because the hair can be problematic** if it is included in the portion of the flap used for urethral construction. In such patients, we try to identify the potential for the problem and refer them for epilation before surgery.

McRoberts and Sadove (2002) proposed the use of the fibular osteocutaneous flap for phallic construction. The fibula is elevated on the periosteal vessel along with the overlying skin paddle. As they described, urethral reconstruction is by tubed graft techniques, and their procedure had a 100% urethral complication rate. The center from Munich has proposed use of this flap with a prefabricated urethra. They place a tubed graft initially in the center of the paddle while it is still on the leg, then elevate the flap later and attach the urethra. We do not agree with the presumption that these tubed grafted urethras would behave differently; however, the surgeons in Munich propose the technique as a better one. For patients who only need vascularized tissue to cover the shaft of the penis, we have used the upper lateral arm flap. This is a fasciocutaneous flap, and its cutaneous vascular territory is centered on the radial collateral artery. The skin of the lateral upper arm is thin, with little subcutaneous adiposity. To mark the location of the lateral intramuscular septum and the course of the superior radial collateral artery, we draw a line joining the insertion of the deltoid with the lateral epicondyle. We begin the dissection posteriorly, elevating the superficial fascia until the posterior lateral portion of the intramuscular septum has been identified. A potential disadvantage of this flap lies in the fact that the entire venous drainage is dependent on the vena comitans, and although superficial veins do traverse the flap, none of them seems to provide significant venous drainage. Although this is disquieting, we have found the flap to be completely reliable thus far, with no losses due to venous insufficiency.

This flap has also been used for total phallic construction. For this purpose, the flap is expanded by tissue expander and elevated across the elbow, and the distal flap is elevated on the recurrent radial artery. As with the forearm flap, the donor site of an upper lateral arm flap can be disfiguring. However, because the scar is on the upper arm, it is more easily concealed beneath a shirtsleeve than a scar in the forearm. All the flaps described allow microneurosurgical coaptation of the flap cutaneous nerves with recipient nerves. With total phallic construction, the cutaneous nerves can be attached either to the dorsal nerves of the penis or to the dorsal nerves of the clitoris in the transsexual patient. When these nerves are not available, the nerves can be coapted to the pudendal nerve, which in most patients requires an interposition graft. These nerves are thought to provide the best restoration of erogenous cutaneous sensibility. We have also coapted the flap's cutaneous nerves to the ilioinguinal nerves, which provides sensation to the inner aspect of the thigh and the lateral aspect of the scrotum, and have achieved a reasonable degree of erogenous sensibility.

In most patients, the deep inferior epigastric vessels are the recipient vasculature for flap transfer. These vessels are medial branches of the iliac system and lie on the dorsal (deep) aspect of the rectus abdominis muscle. The artery usually remains deep to the muscle, although an early penetration of the artery into the muscle can be observed in some patients. The artery classically bifurcates at the level of the umbilicus and is generally accompanied by two or more venae comitantes. These vessels have been elevated by several methods, and Lund and colleagues (1995) described their elevation for penile revascularization with laparoscopic techniques. When the deep inferior epigastric vessels are used, it is often necessary to also include a saphenous vein for further venous runoff.

In some patients, however, these vessels are not available, and we have used a saphenous interposition graft to the superficial femoral artery. With use of this technique, we mobilize the saphenous vein well down the upper aspect of the thigh and then attach the vein to the femoral artery, making a temporary arteriovenous fistula. The fistula is divided, with the saphenous vein becoming the venous runoff and the interposition graft providing the arterial inflow. This system of recipient vessels is greatly inferior to a direct arterial anastomosis. Because of this, in a few patients we have divided the profunda femoris vessel and vigorously dissected it from its other branches. We have then done an end-to-end

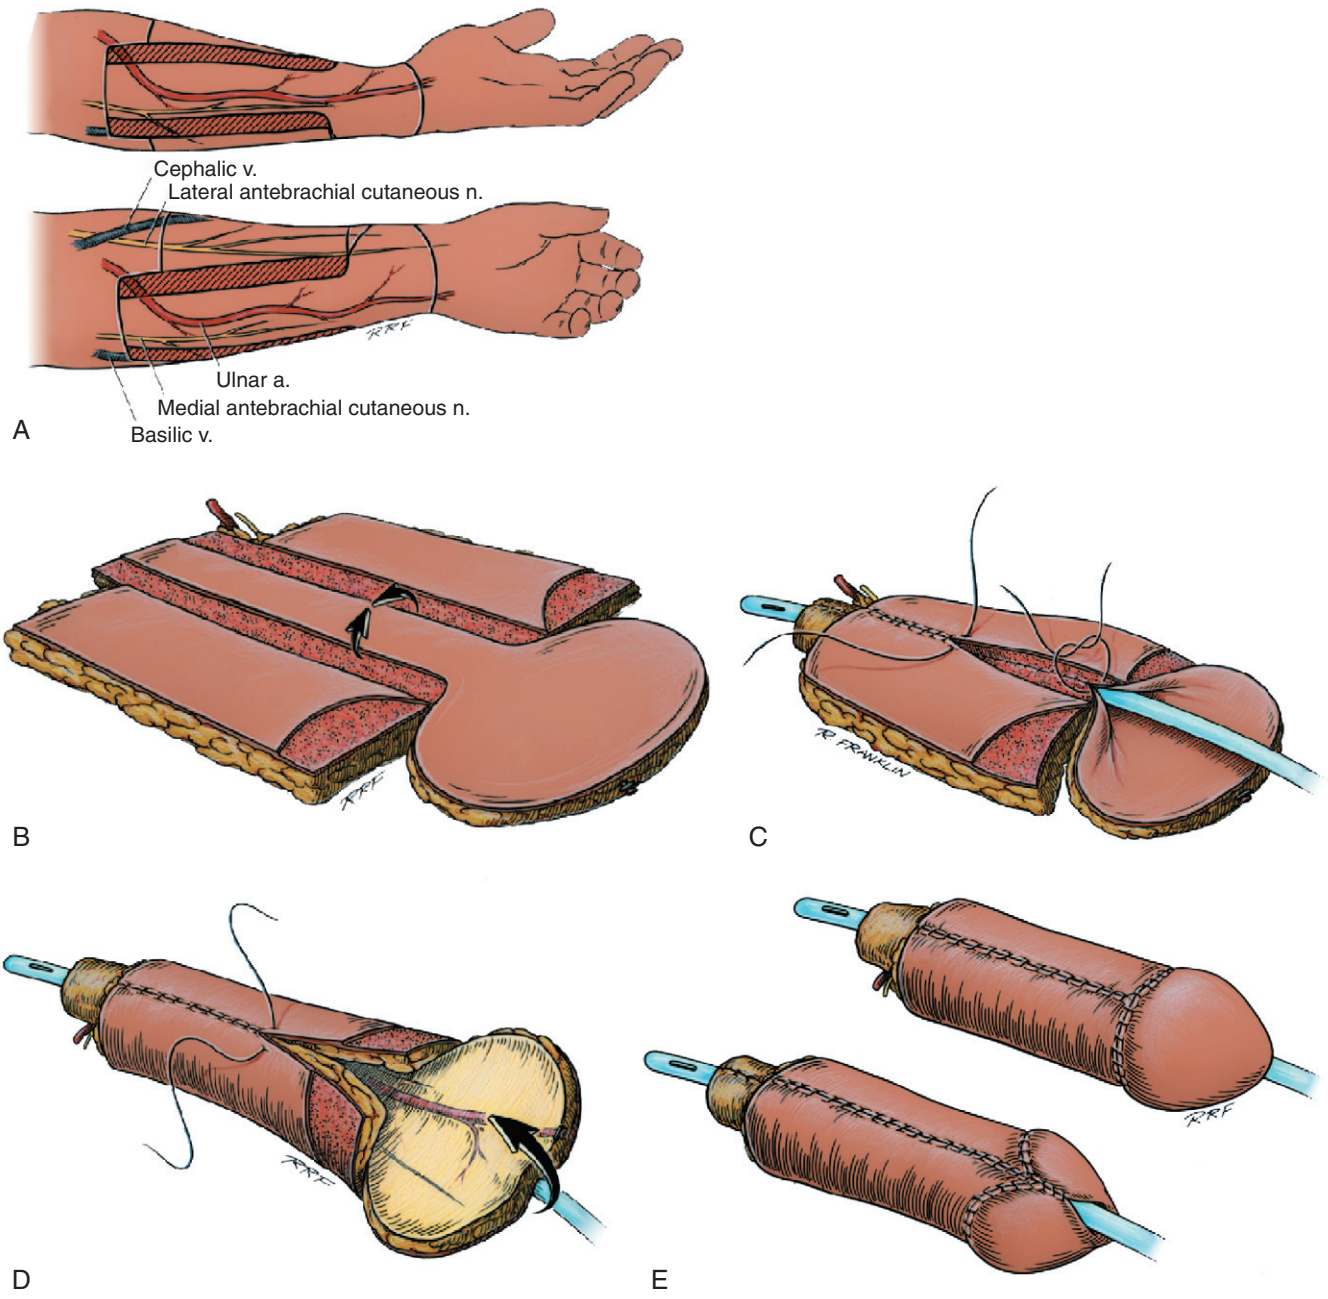

Figure 36–40. **A**, Schematic diagram of an ulnar forearm flap, modified Biemer design, on the patient's left (usually nondominant) forearm. **B**, Schematic of the elevated flap. Notice the flap has been divided into skin islands by de-epithelializing the strips. Laterally are the shaft skin islands, medially is the urethral skin island, and distally is the intergral glans, after the design of Puckett. **C**, Schematic of the configuration of the flap. Notice the urethral skin island has been tabularized to the level of the neomeatus. The lateral shaft skin islands are now in the process of being tabularized over the tabularized urethra. **D**, Schematic of the phallic flap as it is further configured, this view is of the dorsum. Notice the venral skin island has been closed over the urethra, the dorsal skin islands are being collected. The integral glans will then be reflected over the dorsum of the flap. **E,** The drawing of the appearance of the phallus after it is totally configured and transposed to the area of the "penis."

(artery-to-artery) anastomosis of the ulnar artery to the profunda femoris. However, the long-term consequences to the patient of dividing the profunda femoris are not clear. Immediate reconstruction of the profunda does not appear to be advantageous, as the dissection required to mobilize the profunda femoris to become a recipient vessel requires the division of a number of proximal branches, and these would not be reconstructed with an immediate reconstruction of the profunda femoris. Mention of this as a potential means of "creating" recipient vessels is not to recommend the procedure, because the procedure may yet have unacceptable long-term consequences. Another option in extreme cases is to use the superficial femoral, which could be reconstructed with a vein interposition. When the "classic" recipient vessels are not available, these other methods may be acceptable. However, we strenuously caution concerning their use, because the long-term consequences are not known. We currently believe

that division of the superficial femoral artery with immediate reconstruction is the better of these choices.

In the latter part of our series, we included the routine transfer of gracilis muscle to cover the area of the urethral anastomosis, increasing the vascularity to that area and significantly altering the incidence of anastomotic fistula and stricture formation. We have also elevated a bipedicled flap from the area of the penile shaft base, which is transposed beneath the phallic flap. This flap provides increased bulk and some modicum of scrotal construction, and when it is combined with the gracilis muscle, its thickness provides excellent coverage for the juncture of the flap with the base of the neoscrotum. Mobilization of a tunica dartos flap with tunica vaginalis pedicle, or a Martius flap in the transgender patient, may obviate the necessity to elevate and transpose a gracilis muscle flap.

During the phallic construction procedure, urine is diverted by means of a suprapubic cystostomy tube, and the urethra is stented with a No. 14 soft silicone (Silastic) catheter. A voiding study is usually performed between the third and fourth postoperative week.

Rigidity for intercourse in the patient with phallic construction is usually achieved by either an externally applied or a permanently implanted prosthesis. Prosthetic implantation is never undertaken until 1 year after phallic construction, because protective sensibility must be demonstrated in the flap. When the flap is transferred, it is, by definition, rendered insensate. At about 3 to 4 months after reconstruction, however, as nerve regeneration occurs, sensation becomes noticeable. In addition, before prosthetic implantation is undertaken, the urethra must be patent and proved to be durable.

At our center, we now have a large series of patients with internally implanted devices. We have implanted both hydraulic and articulated prostheses encased in Gore-Tex neocorpora. These devices are anchored to the ischial tuberosity and the pubis by anchoring the neocorpora to these bone structures. In most patients, we implant two cylinders or rods. Early in our series, we had problems with hematoma and seroma formation and subsequent infection. However, since modifying our antibiotic regimen and including the routine use of suction drains with the implant procedure, we have had excellent success with implantation. We currently place the antibiotic-coated (Inhibizone) AMS 700CXR.* The Titan prosthesis with hydrophilic coating and narrow base has also been used.

We also have implanted testicular prostheses in a number of patients. In patients in whom we have used a hydraulic device, we have implanted the pump in one neohemiscrotum and a testicular prosthesis in the opposite one.

Reconstruction after Trauma

In many ways, the problems of trauma patients are more challenging to solve than are those of patients who require total phallic construction. We have treated a large number of patients who have had devastating injuries to the penis after complicated prosthetic surgery or surgery to correct penile curvatures of Peyronie disease. The goal in these patients is to preserve the penile structures and function as much as possible, yet correct the deficiencies that are imposed on the patient by the trauma.

Acutely, urine must be diverted, necrotic tissue must be carefully debrided, and any foreign bodies that may have been implanted must be removed. Vigorous acute wound management stabilizes the wounds and allows active granulation to progress. In all trauma patients, an attempt should be made to save as many of the penile structures as possible.

Approximately 3 to 6 weeks after trauma, primary reconstruction can be undertaken, although we have elected to wait 4 to 6 months in some patients, depending on the situation. When significant adjacent tissue loss has occurred, the adjacent areas must be well reconstructed before proceeding with either phallic construction or penile reconstruction.

In the trauma patient, it is imperative that well-vascularized tissues be eventually transposed to the adjacent area, and reconstruction of these areas can be accomplished with a number of flaps. For groin reconstruction, the tensor fascia lata flap has been useful. The rectus femoris flap, characteristically long and large, can be transposed to the area of the lower abdomen and has been an extremely useful flap for inguinal and lower abdominal reconstruction. The gracilis muscle is an excellent flap for reconstruction of the perineum and the groin. Alternatively, the posterior thigh flap can be used for reconstruction of the groin and perineum and, in some cases, transposed to the lowermost portion of the lower abdomen. The rectus abdominis flap is a useful flap and can be elevated with a vertical or transverse skin paddle. In addition, the flap can be transposed to either the ipsilateral or contralateral side. Care must be taken in the patient who has had lower abdominal external beam irradiation.

Variations of the flap designs described for complete phallic construction have been successfully applied in select patients for penile reconstruction. An example is seen in one patient who suffered an injury to his penis from a shotgun blast. The blast injured a large portion of the patient's right corpus cavernosum, and the majority of the penile skin was either destroyed or used for urethral reconstruction. In this patient, a flap based on the Chinese design was elevated. However, because the urethral reconstruction was accomplished with a penile skin island, the ulnar portion of the flap was not needed for that purpose. Therefore the ulnar portion was de-epithelialized and tubularized to form bulk and a new right corporeal body. This patient is now sexually active, and the bulk of the tube's dermal section gives adequate support to his penis for intercourse.

Another patient required only distal urethral construction and glans reconstruction. For this patient, we based a flap on the Biemer design to construct a glans. The proximal portions of the flap were de-epithelialized, allowing fixation of the neoglans on the tips of the corporeal bodies, and an excellent functional and cosmetic result was achieved for this patient. The versatility of free-flap technology allows the solution of complex issues with reasonably acceptable functional and cosmetic results.

FEMALE-TO-MALE TRANSSEXUALISM

Female-to-male transsexual patients present a unique challenge, and no patient should be considered for definitive reassignment surgery without having undergone complex screening and evaluation by a team consisting of mental health professionals, as well as surgeons who are skilled in undertaking transgender surgery. It is imperative that an ongoing, stable, therapeutic relationship be established between the patient and a mental health professional at the time of definitive gender reassignment surgery. At our institution, the Harry Benjamin criteria (Ramsey, 1996) are strictly

*American Medical Systems, Inc., 10700 Bren Road West, Minnetonka, MN 55343; 952-930-6000.

adhered to, and surgery is accomplished by a team of urologists, plastic surgeons, and gynecologists.

In most patients, the first stage of female-to-male transsexual surgery consists of bilateral salpingo-oophorectomy, hysterectomy, vaginectomy, and urethral lengthening with colpocleisis. Even in the virginal patient, our surgeons have become skilled at accomplishing a hysterectomy and bilateral salpingo-oophorectomy by way of transvaginal surgery. We perform a vaginectomy at the same operation, leaving the anterior vaginal wall to be transposed as a random flap to lengthen the female urethra and allow colpocleisis. Lengthening of the female urethra brings the base of the native urethra up to what will be the base of the phallic flap; along with the transfer of gracilis muscle, it has significantly altered our surgical results with regard to urethral anastomotic fistula and stricture. Urine is diverted with a suprapubic tube, and a voiding trial is performed in approximately 21 days. Patients are generally in the hospital for 2 to 3 days and return 3 to 4 months later for phallic construction.

For phallic construction in the transsexual patient, we elevate a bipedicled flap of skin, as already described, from the area where the phallic structure will be implanted and transpose it to the undersurface of the neopenis. The patient is generally in the hospital for a period of 10 to 14 days after total phallic construction, and a voiding trial with contrast material is done at about 28 days postoperatively. After 1 year, when erogenous sensibility is demonstrated and the urethra is proved to be durable, prosthetic implantation is considered.

Key Points: Total Penile Reconstruction

- The principal techniques of penile reconstruction were originally developed for treatment of victims of war injuries. Initially, all of the procedures involved delayed tissue transfer. In 1978, Puckett and Montie reported a series of phallic reconstructions in which a groin flap was transferred by microvascular free-transfer techniques to the area of the penis. The phallus was insensible, but that represented the first free-flap reconstruction for phallic construction. In 1984, Chang and Hwang popularized use of the forearm flap. That flap has been modified by a number of individuals.
- Our preference is to use an ulnar forearm flap with a combined Puckett modification of the flap and Biemer modification of the glans. These flaps allow sensible phallic construction that lets the patient stand to void and permits eventual prosthetic implantation as the phallus has both protective and erogenous sensibility.
- The techniques employed in the transsexual patient are not different from those in the trauma patient. Often, the shapes of the skin paddles must be tailored to the individual patient.

SURGICAL ANATOMY OF THE SCROTUM

The scrotum is a unique body component because the superficial anatomic location of the scrotum and scrotal contents facilitates physical examination, imaging, and surgical access. It is crucial to understand the blood supply to the organs within the scrotum when surgical intervention is indicated. This is summarized in Table 37–1.

The availability of multiple blood supplies to the testis allows continued testicular viability when one or two of the arteries are compromised by injury or ligation.

Scrotal anatomy allows easy access for surgical procedures, including surgery of the scrotal wall, vasectomy, spermatocelectomy, surgery of the epididymis, hydrocelectomy, and surgical treatment of orchitis.

Spread of Scrotal Infections and Postoperative Fluids Based on Scrotal Anatomy

There is a predictable pathway for the spread of scrotal infections and postoperative fluids based on scrotal anatomy. This defined anatomy for the spread of infection is demonstrated in patients with Fournier gangrene (necrotizing fasciitis of the scrotum). **Anatomic barriers to the spread of necrotizing fasciitis include the dartos fascia of the penis and scrotum, Colles fascia of the perineum, and Scarpa fascia of the anterior abdominal wall. The testes and epididymes tend to be spared from necrotizing fasciitis of the scrotum** (Figs. 37–1 and 37–2) (Gupta et al, 2007).

PREOPERATIVE PREPARATION

Anesthetic Technique for Scrotal Surgery

Effective anesthetic techniques for scrotal surgery range from local injection with or without sedation to spinal to general anesthesia. The use of a spermatic cord block with local infiltration of 0.5% xylocaine without epinephrine is a simple, cost-effective anesthetic technique that can be implemented by the surgeon for outpatient scrotal surgical procedures. Regional cord block can typically be performed without premedication with satisfactory patient analgesia (Magoha, 1998; Wakefield and Elewa, 1994). Spermatic cord block can be used in patients with large hydroceles for anesthesia by initially percutaneously draining the hydrocele, performing the block, followed by hydrocelectomy (Reale et al, 1998). Outpatient scrotal surgery performed with midazolam sedation and a local block, with sedation reversal at the end of the procedure has a very high patient satisfaction rate (Birch and Miller, 1994).

Preoperative Preparation and the Use of Antibiotics in Scrotal Surgery

The overall infection rate with scrotal surgery is relatively low, ranging from zero to ten percent. There is no difference in the incidence of postoperative wound infections or complications in patients undergoing hydrocelectomy or spermatocelectomy when comparing iodine-based versus chlorhexidine antiseptic preparations. Scrotal cases are considered as class II (clean-contaminated surgeries), which makes it reasonable to use preoperative antibiotics (Kiddoo et al, 2004). The American Urological Association (AUA) best practice policy statement on urologic surgery antimicrobial prophylaxis recommends a single dose of preoperative antibiotics if the patient has risk factors for infection, including advanced age, anatomic anomalies of the urinary tract, poor nutritional status, smoking, chronic corticosteroid use, immunodeficiency, externalized catheters, colonized endogenous/exogenous material, a distant coexistent infection, or prolonged hospitalization. The recommended antibiotic prophylaxis is a dose of a first generation cephalosporin, or clindamycin as an alternative antimicrobial (Wolf et al, 2008). **Patients who underwent preoperative clipping for hair removal the morning of surgery had a significantly lower wound infection rate**

than those who underwent shaving or clipping the night before surgery (Alexander et al, 1983).

SURGERY OF THE SCROTAL WALL

Cyst Excision

Patients with multiple scrotal cysts can be managed with surgical excision with excellent cosmetic results and low recurrence rates (Noël et al, 2006).

The classical management of scrotal sebaceous cysts is surgical excision with excellent outcomes and minimal morbidity with good cosmetic results. Less invasive techniques, such as Nd:YAG photocoagulation, have been performed successfully but are not considered standard management (Franco de Castro et al, 2002).

Partial/Total Scrotectomy

Partial scrotectomy is an uncommon procedure. Partial scrotectomy is most commonly performed with infectious processes such as Fournier gangrene. **Partial scrotectomy has been advocated after trans-scrotal exploration, orchiectomy, biopsy, or when aspiration has been performed for a scrotal mass and the pathology has revealed a nonseminomatous germ cell tumor of the testis.** Prompt and aggressive management has resulted in no local recurrences due to scrotal tumor contamination, even when a tumor was found in the scrotectomy specimen (Johnson and Babaian, 1980; Boileau and Steers, 1984; Leibovitch et al, 1995). In a small group that underwent aggressive local surgical resection and did not receive adjuvant chemotherapy, there was no increase in the local or distant recurrence (Giguere, 1988).

Total scrotectomy is less commonly performed than partial scrotectomy. Total scrotectomy is often necessary when there is extensive involvement of the scrotum with Fournier gangrene. Total scrotectomy has also been described for radical oncologic procedures, concomitantly with cystoprostatectomy, penectomy, or pelvic exenteration with aggressive cases of squamous cell carcinoma of the prostate (Sarma et al, 1991).

Debridement of the Scrotal Wall in Fournier Gangrene

Treatment of Fournier gangrene should include emergent radical surgical debridement and intravenous broad-spectrum antibiotics. When culture results are available the antibiotics can be tailored to the organisms based on sensitivities. Treatment should be performed expeditiously and aggressively, because Fournier gangrene is a life-threatening process. All nonviable and necrotic tissue must be aggressively excised (Fig. 37–3). **An empirical broad-spectrum antibiotic regimen for the initial treatment of Fournier gangrene includes a third-generation cephalosporin, an aminoglycoside (if the creatinine clearance is acceptable), and metronidazole.** Aggressive fluid resuscitation is required,

Figure 37–3. Aggressive debridement of Fournier gangrene. (From Kavoussi PK, Costabile RA. Disorders of scrotal contents: orhcitis, epididymitis, testicular torsion, torsion of the appendages, and Fournier's gangrene. In: Chapple CR, Steers WD, editors. Practical urology: essential principles and practice. London: Springer-Verlag; 2011.)

including the use of blood and blood products when needed. After debridement, adequate nutrition with early enteral feeding, when possible, is crucial for wound healing. Repeat debridement should be performed two days after the initial exploration to excise any remaining nonviable tissue. Multiple resections may be necessary. If the source of the infection is anorectal or the wound is contaminated, a colostomy may need to be performed to divert fecal flow (Ghnnam, 2008). Similarly, patients may require cystostomies for urinary diversion when there is a urinary source exacerbating the necrotizing fasciitis.

Once the patient has been initially treated and resuscitated and all necrotic tissue has been excised, most wounds can be closed secondarily. **Large wounds will often require skin grafts for coverage. Fasciocutaneous rotational thigh flaps may be used for coverage with good cosmetic results** (Bhatnagar et al, 2008). **Wound closure is performed as soon as there is no evidence of infection or remaining necrotic tissue, and there is a viable bed that will allow reapproximation or grafting** (Ghnnam, 2008). Patients with less than 50% scrotal skin loss can almost always be closed primarily without major difficulty. **The testes may be placed in thigh pouches until the time of definitive reconstruction in cases with major scrotal skin loss** (Gudaviciene and Milonas, 2008). **Vacuum-assisted closure devices (Wound V.A.C.) have been used to help these complex wounds heal after wide excision and debridement.** This technique has been shown to be as effective as conventional wound care in healing wounds. These patients require fewer dressing changes, have less pain, fewer skipped meals, and greater mobility (Ozturk et al, 2009). The use of a small intestinal submucosa graft and fibrin sealant is an option for closure of scrotal defects after excision for Fournier gangrene when standard grafting is not possible (Kavoussi and Bird, 2007).

A severity index has been created and validated to identify prognostic factors in patients suffering from Fournier gangrene. Parameters associated with mortality include abnormalities in heart rate, respiratory rate, serum creatinine, serum bicarbonate, serum lactate, and serum calcium. There is a 46% mortality rate in patients with a severity index score of nine or greater, and a 96% survival rate in patients with a severity index score of less than nine. Necrotizing fasciitis involving the abdominal wall or the lower extremities is associated with increased mortality (Corcoran et al, 2008).

VASECTOMY

Vasectomy is a highly effective and safe form of contraception (Schwingl and Guess, 2000). Vasectomy was first described by Sir Ashley Cooper in the United Kingdom when he did experiments to vasectomize dogs (Cooper, 1827). **Approximately 526,501 men undergo vasectomy annually in the United States, which makes vasectomy the most commonly performed urologic surgical procedure.** 0.01% of men between the ages of 25 and 49 undergo vasectomy annually (Barone et al, 2006). This comprises 11% of all married couples.

Anesthetic Techniques for Vasectomy

Vasectomy can be performed under sedation, spinal, or general anesthesia, although most surgeons perform vasectomy under local anesthesia because the majority of patients tolerate this method well and it minimizes anesthetic complications and morbidity.

The choice of local anesthetic is based on surgeon preference. Options for local anesthesia include the use of 1% or 2% lidocaine without epinephrine or a 50/50 mixture of lidocaine and bupivacaine. The vas deferens is isolated through the scrotal skin and grasped tightly between the thumb and the middle finger of the nondominant hand in a superficial position just beneath the scrotal skin. A 25-gauge needle is used to inject the local anesthetic subcutaneously to raise a small wheel over the vas deferens. Once superficial anesthesia is achieved, the needle is carefully advanced into the vasal sheath, and a small amount of anesthetic is injected. Great care should be taken to use as few punctures as possible and as little needle movement as possible to minimize the risk of hematoma formation.

EMLA (emulsion of lidocaine and prilocaine) cream applied as topical anesthesia on the scrotal skin one hour prior to injection of 1% lidocaine followed by vasectomy does not decrease the pain associated with vasectomy compared with the use of injectable anesthesia alone (Thomas et al, 2008).

The no-needle jet anesthetic technique has been described to eliminate the needle for anesthetic injection. This technique uses the MadaJet medical injector (MADA Medical Products, Carlstadt, NJ) to deliver lidocaine without epinephrine by means of a high-pressure injector through a tiny head to beneath the skin to diffuse a mist of anesthetic around the vas (Weiss and Li, 2005).

Conventional Technique

Vasectomy should be performed in a warm room with warm preparation solution to allow scrotal relaxation, regardless of the technique employed. Shaving should be

performed prior to the procedure to minimize the risk of infection. There is no difference in the rate of postvasectomy infection in men randomized to prophylactic antibiotics versus no antibiotics; therefore antibiotic prophylaxis is not recommended (Khan, 1978). In any chosen technique, the use of a single incision or bilateral scrotal incisions is based on surgeon preference. Many surgeons advocate bilateral scrotal incisions to minimize the risk of dividing the same side twice and to allow performing the vasectomy at a position in the midportion of the vas deferens. After induction of adequate local anesthesia, an incision is made over the isolated vas deferens, which is grasped tightly between the thumb and middle fingers. The vasal sheath is sharply divided down to the vas. The vas is delivered through the incision; the deferential artery, nerves, veins, and adjacent tissue are separated from the vas, and the vas is divided. Some surgeons remove a small segment of vas deferens, although most urologists who perform vasectomy reversals prefer not to, which allows easier future reversal. The AUA Policy Statement (American Urological Association, 2007) states that removal of a segment of vas deferens for histologic confirmation is not required or recommended. Most surgeons occlude both the testicular and abdominal ends of the vas with suture ligation, hemoclips, intraluminal fulguration with electrocautery, or fascial interposition. These techniques are further discussed below. The same procedure is repeated on the contralateral vas deferens.

"No-Scalpel" Technique

The no-scalpel vasectomy was initially described in China in 1974 (Li, 1976).

Routine antibiotic use is not needed for vasectomy patients undergoing no-scalpel vasectomy with sterile technique (Seenu and Hafiz, 2005). **The no-scalpel technique significantly decreases the rate of hematomas, infections, and pain during the procedure.** Patients who undergo the no-scalpel technique also resume sexual activity sooner after surgery and have a shorter operative time than occurs with the conventional technique (Sokal et al, 1999, Cook et al, 2007a).

There are several variations to the technique of the no-scalpel vasectomy. One technique involves firmly securing the vas through the skin with a ring-tipped vas deferens fixation clamp (Fig. 37–4) after local anesthesia has been administered as described above (Fig. 37–5). A modified, sharpened tipped curved hemostat (Fig. 37–6) is used to puncture the skin and the vas sheath, and the hemostat is spread to stretch the hole that is made. Then the vas deferens is lifted out, divided, the occlusion technique of choice is employed, inspection is done for hemostasis, and the vas deferens is replaced in the scrotum. The same procedure is performed

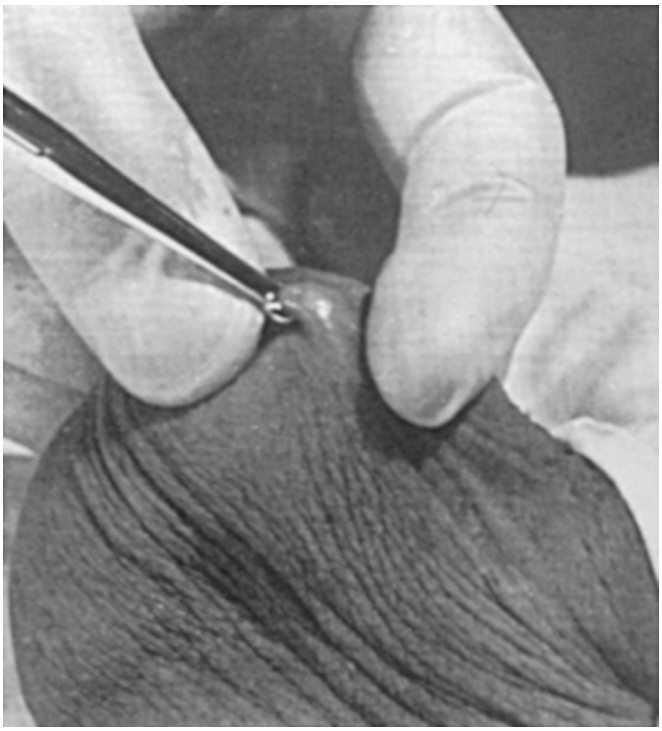

Figure 37–5. Vas fixed in the ring clamp. The scrotal skin is tightly stretched over the most prominent portion of the vas. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145:341–4.)

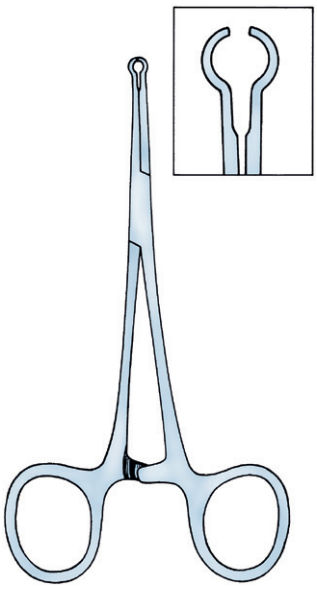

Figure 37–4. Ring-tipped vas deferens fixation clamp. Cantilevered design prevents injury. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145:341–4.)

Figure 37–6. Sharp, curved mosquito hemostat. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145:341–4.)

on the contralateral vas deferens (Huber, 1988). The perforation in the skin can be closed with an absorbable suture, but can also be left open, and will heal well without closure.

A variation of this technique employs local anesthesia; fixes the vas through the scrotal skin with the ring-tipped vas deferens fixation clamp; and pierces the scrotal skin, vas sheath, and vas deferens in the midline with a sharpened tipped curved hemostat held at 45 degrees from horizontal (Fig. 37–7). To prepare the vas deferens for division, the clamp is then rotated 180 degrees relative to the pierced vas deferens. The remainder of the procedure is performed in the same manner as described above, and this is done bilaterally (Schlegel and Goldstein, 1992).

Another technique for performing no-scalpel vasectomy is to isolate the vas deferens after induction of adequate local anesthesia, grasping it tightly between the thumb and middle finger, and puncture the skin overlying the vas deferens with a sharpened tipped curved hemostat. The curved hemostat is used to spread the skin to enlarge the vertical slit in the skin just large enough to allow the ring-tipped vas deferens fixation clamp to fit through to grasp the vas deferens. The vas deferens is grasped and brought up through the puncture, and the vasal fascia and vessels can be spread off the vas deferens to expose the bare vas deferens by spreading the sharp-tipped curved hemostat onto the vasal fascia to open the vasal fascia (Figs. 37–8 and 37–9). The remainder of the vasectomy is performed as described above for bilateral procedure (Li et al, 1991). **This modification of making the puncture prior to grasping the vas deferens with the ring-tipped vas deferens fixation clamp was found to significantly decrease the operative time and showed no difference in incision length, postoperative pain, or time to return to work in a randomized prospective evaluation** (Chen et al, 2005).

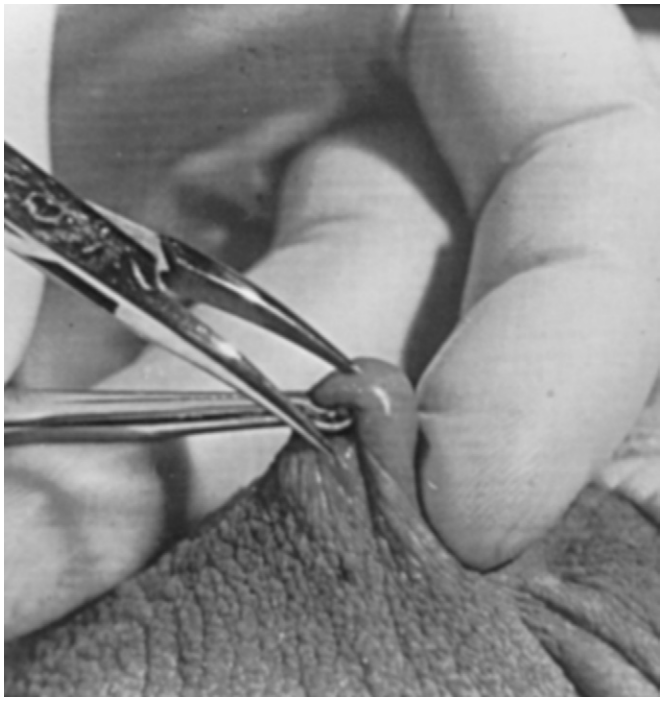

Figure 37–7. Puncture of the skin, vas sheath, and wall into the lumen. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145:341–4.)

Methods of Vasal Obstruction/Male Sterilization

There are a number of vasectomy occlusion techniques currently employed, including excision and ligation, thermal occlusion with intraluminal electrocautery, mechanical occlusion with hemoclips, fascial interposition, and chemical occlusion with percutaneous techniques.

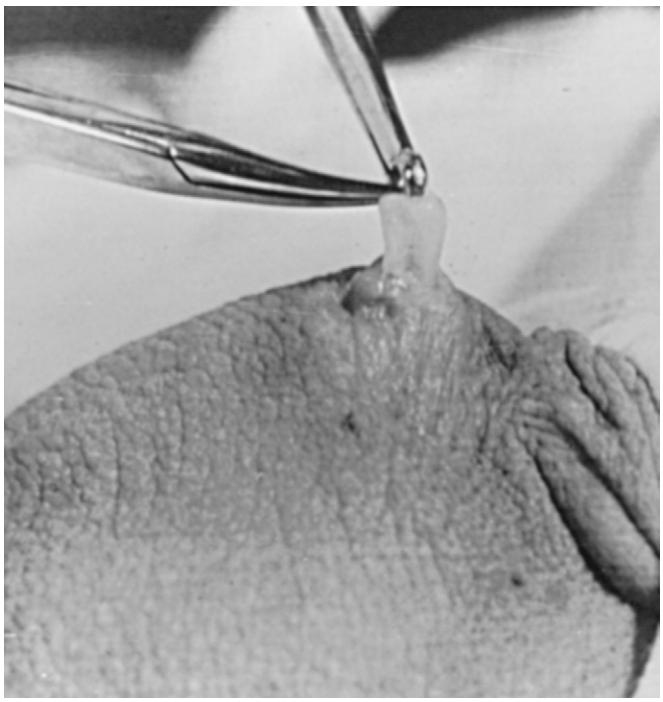

Figure 37–8. Delivery of the clean vas. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145: 341–4.)

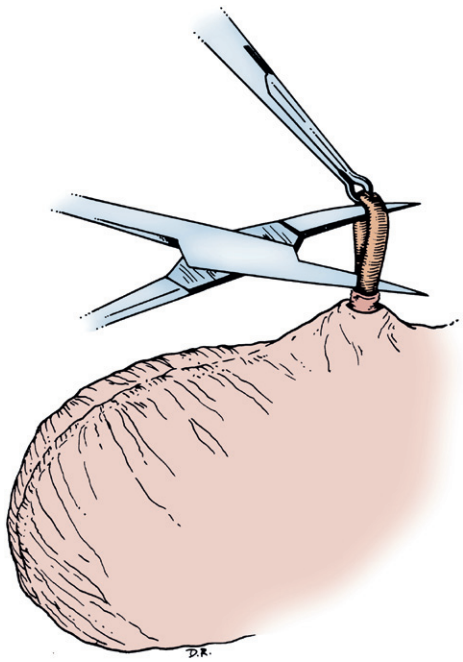

Figure 37–9. Segment cleaned. (From Li S, Goldstein M, Zhu J, Huber D. The no-scalpel vasectomy. J Urol 1991;145:341–4.)

There have been concerns about the risk of vasal necrosis and sloughing distal to the ligated end when suture ligation is performed, theoretically increasing the risk of recanalization. **Low-voltage thermal occlusion with intraluminal electrocautery in the abdominal and testicular ends of the divided vas deferens reduces recanalization rates to less than 0.5%** (Schmidt, 1987; Barone et al, 2004). **Vasectomy failure rates have been reported to be less than 1% when both the testicular and abdominal ends of the divided vas deferens are occluded with hemoclips** (Moss, 1974; Bennett, 1976). **Interposition of dartos fascia between the divided ends of the vas deferens is another technique for occlusion. This method has been reported to reduce the recanalization rate even further, nearly to zero** (Esho and Cass, 1978; Sokal et al, 2004).

Percutaneous vasectomy has been performed on over 500,000 men in China. This technique employs chemical occlusion by fixing the vas deferens up to the scrotal skin tightly, puncturing the lumen of the vas deferens with a 22-gauge needle, and then cannulating the lumen of the vas deferens with a 24-gauge blunt needle. For confirmation of vas deferens cannulation, Congo red is injected into the lumen of the abdominal end of the right vas deferens, and methylene blue is injected into the lumen of the left vas deferens prior to chemical occlusion by injection of 20 µl of two parts phenol to one part *N*-butyl-2-cyanoacrylate mixture. Following chemical occlusion the patient should void. If the urine is red, the left side was not cannulated, if it is blue, the right side was not cannulated, and if it is brown, that indicates bilateral successful cannulation (Ban, 1980; Li, 1980). Although these chemicals are not approved for use in the United States by the Food and Drug Administration, they appear to be safe by toxicologic testing and experience in China.

Fascial interposition is the technique that has been found to decrease vasectomy recanalization rates the most significantly. Randomized controlled trials examining the other techniques are not available. Several trials have been performed using irrigation of the abdominal ends of the vas deferens with saline, but there was no difference in time to azoospermia (Cook et al, 2007b).

Open-ended vasectomy, where the testicular portion of the vas deferens remains patent, is another technique that has been evaluated with the aim of decreasing epididymal pressure by performing intraluminal cautery or another method of occlusion on the abdominal end, while leaving the testicular end unoccluded. Ninety-seven percent of patients undergoing open-ended vasectomy develop sperm granulomas. This reduces pressure-induced damage to the epididymis, but increases the vasectomy failure rate to as high as 7% to 50% (Shapiro and Silber, 1979; Goldstein, 1983). **There is a significant decrease in the failure rate with open-ended vasectomy when fascial interposition is performed, decreasing the failure rate by approximately 7%** (Li et al, 1994).

Performing Vasectomy to Make Microscopic Vasectomy Reversal Easier

Technical aspects of performing vasectomy can affect the ease of microsurgical vasectomy reversal in the future if needed (Mammen et al, 2008). One procedural aspect is that excising a lengthy (>1 cm) segment of vas deferens is associated with the need for a higher scrotal incision, possibly up to the lower inguinal region, with the potential for anastomotic tension with microscopic vasectomy reversal. **Vasectomy reversal can be far more difficult when a lengthy portion of the vas deferens has been excised, with concomitant increases in operative time, length of incision, and postoperative pain** (Practice Committee of the American Society for Reproductive Medicine, 2006).

Another procedural aspect is the location along the length of the vas deferens where the vasectomy is performed. Experts in microsurgery agree that the anastomosis is least problematic when the lumen of the vas deferens is largest and most concentric, as opposed to the lumen in the epididymis or the convoluted vas (Mammen et al, 2008). Prospective studies show that the length of the testicular vas deferens present at the time of reversal has a direct correlation with the presence of seminal fluid containing intact sperm at the time of microscopic vasectomy reversal. A testicular length of vas deferens less than 2.7 cm correlates with seminal fluid without intact sperm 85% of the time, and testicular length over 2.7 cm is associated with intact sperm in seminal fluid 94% of the time. For each centimeter increase in testicular remnant length, the probability of whole sperm being present increases fourfold (Witt et al, 1994). **Division of the vas deferens should be performed approximately 3 cm distal to the cauda of the epididymis in the straight portion of the vas deferens at the time of vasectomy.**

The other technical aspect to consider is the occlusion technique employed. **All occlusive modalities for vasectomy carry a similarly high efficacy in terms of postprocedure azoospermia.** To date, no specific studies on occlusion technique as a predictor of reversal success have been performed. **Simple transection of the vas deferens followed by low-voltage intraluminal cautery occlusion followed by fascial interposition provides successful vasectomy and may result in minimal inflammatory reaction.** It would stand to reason that minimizing inflammation near the vas deferens would provide the optimum condition for microscopic vasectomy reversal in the future (Mammen et al, 2008).

Postoperative Care and Follow-up Semen Analysis

Routine postoperative care practices vary, but typically include the use of ice packs on the scrotum intermittently for the first 48 hours, limited heavy or strenuous activity for one week, and the use of nonsteroidal anti-inflammatory drugs, as needed, for pain, if the patient does not have any contraindications to these medications.

There is no vasectomy technique that is 100% effective, and a definitive standard to declare a patient sterile has not been agreed upon. Time to reach azoospermia is variable, although over 80% of patients achieve azoospermia by three months and after twenty ejaculations. Persistent nonmotile sperm are present in 1.4% of postvasectomy patients. **This data points to obtaining a semen analysis at three months and twenty ejaculations after vasectomy to reveal azoospermia.** If the semen analysis does not show azoospermia, periodic semen analyses can be obtained until azoospermia is achieved. Patients who have small numbers of persistent nonmotile sperm can be advised to cautiously discontinue contraception (Griffin et al, 2005). There is evidence that these men will ultimately reach azoospermia. **Vasectomy should be repeated if any motile sperm are found in the ejaculate three months after the initial vasectomy** (Aradhya et al, 2005).

An immunodiagnostic test, the SpermCheck Vasectomy (ContraVac, Charlottesville, VA), has been developed to allow patients to test themselves for severe oligospermia or azoospermia at home following vasectomy. This was developed to increase compliance with postvasectomy evaluation of semen parameters. The SpermCheck Vasectomy test was 96% accurate at predicting whether sperm counts were greater or less than a threshold of 250,000 sperm per milliliter (Klotz et al, 2008).

Complications: Local/Postoperative

Local complications of vasectomy include hematoma, infection, Fournier gangrene, chronic scrotal pain, and traumatic fistula/scrotal sinus (Awsare et al, 2005). **Surgeon volume and experience is the most important predictor of postoperative complications** (Kendrick et al, 1987).

Hematoma is the most common complication of vasectomy. The rate of hematoma formation after vasectomy ranges between 0.09% and 29%, with a mean incidence of 2% (Kendrick et al, 1987). The no-scalpel technique has decreased the hematoma rate to a 0.5% incidence (Pant et al, 2007).

The rate of infection from vasectomy with the conventional technique was reported between 12% and 38%, but decreased to 0.4% with the no-scalpel technique (Appell and Evans, 1980; Pant et al, 2007). Although it is an exceedingly rare complication, Fournier gangrene has been reported as a complication in men undergoing vasectomy (de Diego Rodríguez et al, 2000; Romero Pérez et al, 2004).

Up to 30% of men have short-term scrotal pain lasting a few weeks**. However, postvasectomy pain syndrome, or long-term scrotal pain after vasectomy, occurs in approximately one in 1000 vasectomies, although some report the incidence to be as high as 15%** (McConaghy et al, 1996; Awsare et al, 2005; Tandon and Sabanegh, 2008). Postvasectomy pain syndrome has no association with immediate postoperative complications such as hematoma or infection. There are several theories about the cause of postvasectomy pain syndrome. One is that dilation of the epididymal duct with obstruction of the testicular end of the vas deferens produces interstitial fibrosis. Another theory is that extravasation of spermatozoa, with epididymal duct rupture forming a sperm granuloma at the site where the vas deferens is transected, results in perineural fibrosis and inflammation, because sperm are highly antigenic (McMahon et al, 1992). This contradicts the previous belief that sperm granulomas are protective against postvasectomy pain syndrome by relieving pressure, although most sperm granulomas are asymptomatic (Tandon and Sebanegh, 2008). Interestingly, there are markedly increased pressures in the epididymis and the testicular end of the vas deferens after vasectomy, but these pressures were not found to be transmitted to the seminiferous tubules in human micropuncture studies (Johnson and Howards, 1975). It is unclear why some patients would develop long-term symptoms and others transient ones. Factors such as age, socioeconomic status, race, environmental, or vasectomy technique have not identified patients at risk for postvasectomy pain syndrome (Tandon and Sebanegh, 2008).

Conservative therapy should be the first line of therapy. This includes scrotal elevation and support, heat or ice (as needed for comfort), and nonsteroidal anti-inflammatory drugs. Empiric antibiotic therapy is not recommended without evidence of infection (Selikowitz and Schned, 1985). **Conservative therapy should be employed for at least three months for postvasectomy pain. Spermatic cord blocks should be considered after failure of conservative therapy.**

Surgical therapy might be considered if the above methods fail. **When pain is clearly localized to a sperm granuloma, excision of the granuloma and intraluminal cautery occlusion of the vas deferens may relieve the pain and prevent recurrence** (Schmidt, 1979). Epididymectomy has been performed in patients who had point tenderness to the epididymis, and epididymal dilation after vasectomy and failed conservative therapy. Predictors of poor outcomes with epididymectomy are atypical symptoms, concomitant erectile dysfunction, and a normal-appearing epididymis on scrotal ultrasound (West et al, 2000). **Up to 50% of patients who were properly selected for epididymectomy were cured of postvasectomy pain syndrome** (Chen and Ball, 1991). The patient must consider that vasectomy reversal will no longer be feasible after epididymectomy. **Vasectomy reversal rendered 69% of patients with postvasectomy pain syndrome pain free** (Nangia et al, 2000). **Although it has only been evaluated in a small number of patients, microscopic denervation of the spermatic cord in patients who had temporary relief with a spermatic cord block resulted in complete pain relief in 76% and improvement in pain in 9% of these men** (Levine and Matkov, 2001). The last resort consideration after failure of conservative and more invasive interventions have failed, is orchiectomy for severe intractable pain after vasectomy. **In this group, pain relief was reported in 73% of men who underwent inguinal orchiectomy versus 55% in those who underwent scrotal orchiectomy for postvasectomy pain syndrome** (Davis et al, 1990).

There is a report of 0.3% rate of scrotal sinus/vasocutaneous fistula after no-scalpel vasectomy (Pant et al, 2007).

Association of Vasectomy with Long-Term Systemic Disease

Previous studies found an increased risk of prostate cancer in men who underwent vasectomy (Giovannucci et al, 1993). Detection bias is thought to be the source of this association of prostate cancer with vasectomy (Millard, 1999). **Recent investigations have found that there is no association between vasectomy and prostate cancer** (Schuman et al, 1993; Holt et al, 2008). There is no association between vasectomy and prostate cancer in developing countries in which there are low incidences of prostate cancer in the general population as well (Schwingl et al, 2009). **Screening recommendations for prostate cancer should be no different in men who have undergone vasectomy than those who have not undergone vasectomy** (Healy, 1993).

Vasectomy does not place the patient at an increased long-term risk for cardiovascular disease or atherosclerosis (Coady et al, 2002; Goldacre et al, 2005).

Previous studies suggested that vasectomy may be a risk factor for patients with primary progressive aphasia, a dementia syndrome with aphasia as the presenting symptom (Weintraub et al, 2006). There are no longitudinal studies confirming this, and there have been many large, epidemiological studies comparing vasectomized and nonvasectomized men without any increased risk of dementia. There is no evidence that vasectomy adversely affects psychological health status (Thonneau and D'Isle, 1990).

Antisperm Antibodies

There is a disruption of the blood-testis barrier when vasectomy is performed. **Of men who undergo vasectomy, 60% to 80%**

of them have detectable levels of antisperm antibodies in the serum (Fuchs and Alexander, 1983). **After vasectomy, 50% to 60% of men develop sperm agglutinating antibodies, and 20% to 30% develop sperm immobilizing antibodies** (Kovacs and Frances, 1983). Although some studies suggest that antisperm antibodies persist, others suggest that they diminish in two or more years after vasectomy, but neither immune complex deposition nor circulation are increased in vasectomized men (Witkin et al, 1982).

Key Points: Vasectomy

- There is no vasectomy technique that is 100% effective, and a definitive standard for when to declare a patient sterile has not been agreed upon.
- The no-scalpel technique significantly decreases the rate of hematomas, infections, and pain during the procedure.
- Fascial interposition is the occlusion technique that has been found to decrease vasectomy failure rates the most significantly.
- Technical aspects of performing vasectomy can affect the ease of microsurgical vasectomy reversal in the future if needed.
- There is no association between vasectomy and prostate cancer or cardiovascular disease.

SPERMATOCELECTOMY/SURGERY OF THE EPIDIDYMIS

Surgical Indications

A spermatocele is a cystic dilation of an epididymal tubule, which is benign in nature. **Spermatoceles are very common, occurring incidentally in 30% of men on high-resolution ultrasound, and they are typically asymptomatic and do not cause epididymal obstruction, and therefore rarely require intervention.** Men typically seek surgical treatment when the spermatocele has reached the approximate size of the testis and is causing pain with point tenderness (Walsh et al, 2007).

Surgical treatment for chronic epididymitis is poorly studied in clinical trials with no level 1 evidence to support the use of a specific surgical procedure. In one study, ten patients with chronic epididymitis (defined as epididymal pain lasting greater than 3 months), underwent epididymectomy for intractable symptoms. Only one of these patients had significant improvement in pain (Davis et al, 1990). Other authors have reported much higher success rates, such as six out of seven patients (86%) having significant improvement in pain after epididymectomy (Chen and Ball, 1991). **Chronic or recurrent epididymitis and persistent epididymalgia with point tenderness to the epididymis may be reasonable indications for epididymectomy** (Padmore et al, 1996).

Surgical treatment for chronic epididymitis should only be considered after failure of extensive conservative therapy and after appropriate counseling, with the understanding that the symptoms may not improve after surgery, or may indeed worsen. A retrospective review of men who underwent epididymectomy for chronic epididymitis showed that outcomes were best when the patient had a palpable epididymal abnormality on physical examination. Men in this study without a palpable abnormality, but with sonographic changes, had slightly worse outcomes, and those with neither a palpable abnormality nor a demonstrable ultrasound abnormality did not improve with epididymectomy (Calleary et al, 2009).

Purulent epididymitis diagnosed by a combination of physical examination, ultrasound evaluation, and, occasionally, needle aspiration of the epididymis is an absolute indication for epididymectomy (Arbuliev et al, 2008). This is also the treatment of choice for epididymal abscesses and chronic infectious epididymitis that is unresponsive to antibiotic treatment**. Diagnostic epididymal puncture and aspiration should not be performed in men with interest in future fertility, because this will result in epididymal obstruction.**

Total epididymectomy may relieve chronic persistent pain localized to the epididymis after vasectomy.

Epididymal malignancies are extremely rare, and 73% of nontransilluminating, solid epididymal masses are benign adenomatoid tumors (Beccia et al, 1976). Surgical extirpation should be considered for adenomatoid tumors, especially if there is any suspicion for malignancy (Alvarez et al, 2009).

Partial/Total Epididymectomy

Any patient undergoing epididymal surgery should be extensively counseled that the surgery may impair his fertility, or even cause sterility if bilateral epididymal surgery is required, because the distal epididymis consists of a single tubule.

Partial/total epididymectomy can be approached scrotally through a median raphe or a unilateral transverse scrotal incision to deliver the testis. The vas deferens is identified, isolated, ligated, and divided. The testicular end of the vas deferens is then followed to the vasoepididymal junction. The tunica vaginalis is opened, and the plane of dissection between the epididymis and the testis is found in order to divide the epididymis from the testis. Great care should be taken to avoid injury to the spermatic cord and testicular artery. The efferent ducts superior to the testicular vasculature are ligated with an absorbable suture to complete the epididymectomy. The edges of the tunica vaginalis where the epididymis was excised are approximated with a running absorbable suture, which helps with hemostasis. The dartos fascia and skin are closed in layers with absorbable suture. In the case of partial epididymectomy, ligations are performed between the testis and epididymis with absorbable suture to excise the affected portion of the epididymis, while leaving the remainder attached to the testis with its vascular supply intact (Figs. 37–10 and 37–11).

Spermatocelectomy/Excision of Epididymal Cysts

Spermatocelectomy can be approached scrotally through a median raphe or a unilateral transverse scrotal incision to deliver the testis. The tunica vaginalis is opened, and the spermatocele is identified and dissected free from the epididymis. The epididymal–spermatocele attachment is ligated and divided to complete the spermatocelectomy. The tunica vaginalis is closed, and the dartos fascia and scrotal skin are reapproximated in layers.

Excision of Epididymal Tumors

As discussed above, the majority of epididymal nontransilluminating masses are benign adenomatoid tumors. Fine needle aspiration

of solid epididymal masses has been evaluated and found to be very accurate when compared with surgical pathology (Gupta et al, 2006). **When malignancy is suspected, an inguinal approach should be used with clamping of the spermatic cord and delivery of the testis.** The addition of testicular hypothermia by adding ice slush to the Chevassu maneuver (of clamping the vessels) was employed and found to salvage three out of five testicles with benign processes after clamping and parenchymal biopsy (Goldstein and Waterhouse, 1983). When malignancy is ruled out, the epididymal mass may be excised as for a spermatocelectomy.

Complications

Complications of epididymectomy, spermatocelectomy, and excision of epididymal masses are rare. Complications include bleeding, infection, damage to the testicular artery with resultant testicular atrophy, and recurrence in cases of spermatocelectomy (Kiddoo et al, 2004; Zahalsky et al, 2004). **Complications also include impairment of fertility with obstruction of the epididymal tubules and possible sterility in bilateral cases, necessitating counseling and recommending sperm cryopreservation in men who undergo bilateral procedures and have an interest in fertility.** Approximately 17% of patients undergoing spermatocelectomy will have resultant epididymal injury (Zahalsky et al, 2004). The overall complication rate has been reported to be as high as 20%, with the most common complications being persistent scrotal pain and infection. **Leaving a scrotal drain did not decrease complication rates** (Kiddoo et al, 2004).

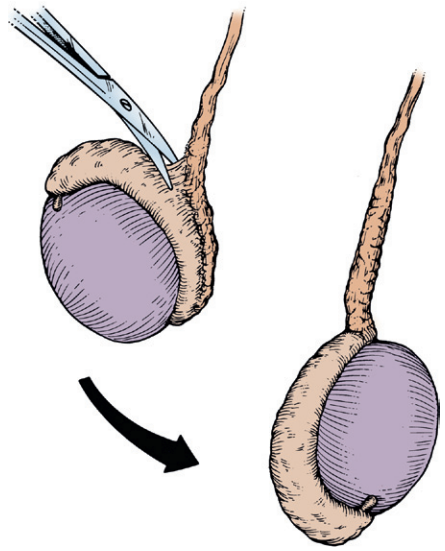

Figure 37–10. Convuluted vas dissected off the epididymal tunica.

HYDROCELECTOMY

The adult hydrocele is caused by excessive fluid secretion by the visceral tunica albuginea without adequate reabsorption of this fluid by the parietal peritoneum around the testis.

Inguinal Surgical Approach

Men diagnosed with hydroceles, where there is suspicion for concomitant malignancy, should undergo high-resolution scrotal ultrasound. If malignancy is suspected, an inguinal approach should be used to allow control of the spermatic cord in preparation for radical orchiectomy. If this approach is taken and no malignancy is encountered, the testis can be spared and the hydrocele can be repaired by one of the techniques described below.

Scrotal Surgical Approaches

When there is no evidence of malignancy on physical examination and high-resolution ultrasound, hydroceles may be approached scrotally through a median raphe or a transverse unilateral incision. In all techniques, the hydrocele is dissected and delivered intact to allow the easiest dissection. Once it is delivered, an opening in the sac is made away from the testis, epididymis, and cord structures, and the fluid is suctioned out. The hydrocele sac is then opened further to expose the sac for the elected repair. **The overall single-treatment success rates for surgical hydrocelectomy range between 90% and 100%** (Rodriquez et al, 1981).

Excisional techniques are the least likely to result in recurrence of a hydrocele. Excising the hydrocele is recommended for long-standing, thick-walled, loculated hydroceles. The hydrocele sac is opened, taking great care not to injure the spermatic cord, and the sac is simply excised, leaving room to oversew the edge of the excised sac without endangering

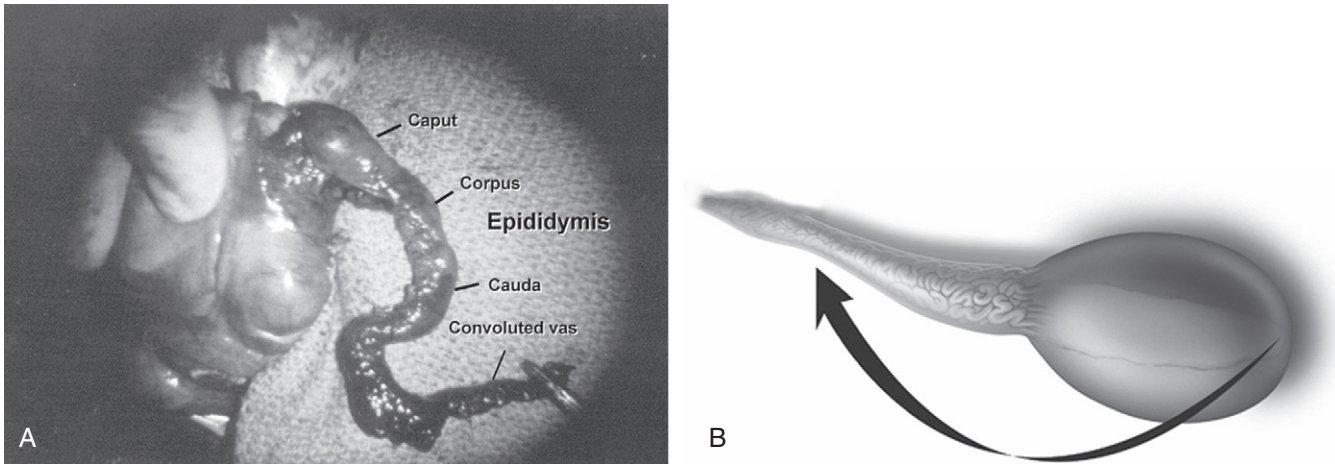

Figure 37–11. **A** and **B,** Entire vasoepididymal complex is dissected to the caput.

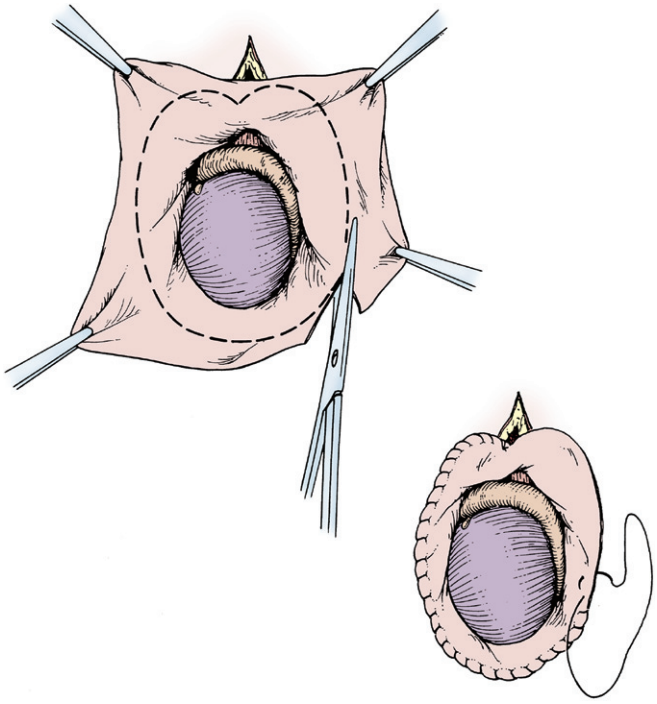

Figure 37–12. Simple excision of the thick-walled hydrocele sac and oversewn edges.

the cord or the epididymis. A 3-0 chromic suture can be used in a baseball stitch manner to oversew the edge of the sac (Fig. 37–12).

The Jaboulay bottleneck technique is a useful method for large, floppy, thin hydrocele sacs. This is performed by excising the sac as described above, but a larger margin of excision should be left between the edge of the sac and the testis and epididymis, to allow for sewing the edges of the sac together behind the cord, without compressing the cord (Fig. 37–13) (Jaboulay, 1902).

If there appears to be a risk for hematoma after excision and oversewing with either technique, a Penrose drain can be left in the dependent portion of the scrotum and fixed in place to the scrotum. The dartos fascia and skin are then closed in layers. Fluffs and a scrotal support are used for the dressing.

Plication techniques are suitable for thin-walled hydroceles but should not be used in large, long-standing, thick-walled, multiloculated hydroceles because this leaves a large bundle of plicated tissue in the scrotum. The Lord plication technique (1964) is performed by opening the hydrocele as described above, delivering the testis, cauterizing or oversewing the cut edges of the sac, and using interrupted, radially placed chromic sutures to plicate the sac. Closure is then performed as described above. Drains are not necessary with plications (Fig. 37–14).

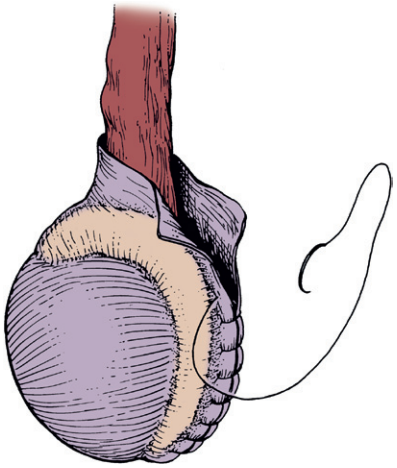

Figure 37–13. Jaboulay bottleneck technique for excision of thin, floppy sacs.

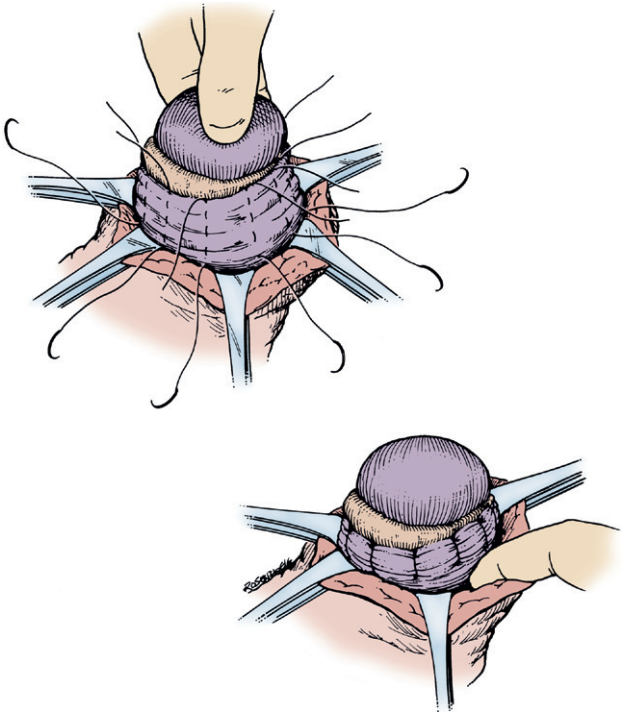

Figure 37–14. Lord placation technique.

Sclerotherapy

Sclerotherapy is another treatment option with a single-treatment success rate ranging from 33% to 75% (Levine and Dewolf, 1988). This may be a good choice for patients who cannot tolerate anesthesia or who refuse surgical treatment. **The common steps of the procedure include needle aspiration of the hydrocele fluid, followed by injection of local anesthesia, and ultimately instillation of the sclerosing agent.** The most commonly used sclerosing agent is tetracycline (500 mg), although 2.5% phenol solutions, 95% alcohol, and ethanolamine oleate have also been used effectively (Nash, 1984; Hellström et al, 1986; Miskowiak and Christensen, 1988). One study showed no statistically significant improvement in patients who underwent aspiration of hydrocele fluid alone versus aspiration plus instillation of tetracycline as a sclerosing agent, with a higher complication rate in the sclerotherapy group (Breda et al, 1992). When sclerotherapy was compared to hydrocelectomy, the success rate was higher in hydrocelectomy, although the hydrocelectomy group had a higher complication rate. Nonetheless, the patients who underwent hydrocelectomy had higher satisfaction rates (Beiko et al, 2003).

Table 37–2.
Hydrocelectomy Techniques and Risks

	RECURRENCE	HEMATOMA
Excision	Decreased	Increased
Plication	Increased	Decreased

Complications

The most common complication after hydrocelectomy is hematoma (Table 37–2). **The overall complication rate in hydrocelectomy is approximately 19%, including hematoma, infection, persistent swelling, recurrence, injury to spermatic vessels, and chronic pain.** Although the use of a drain in selected patients is recommended, it has not been proven to decrease complication rates thus far (Kiddoo et al, 2004). When repairing large hydroceles, great care must be taken to not injure the epididymis and spermatic vessels, because they may be splayed within the hydrocele layers. Injury to the epididymis or vas deferens can put the patient's future fertility at risk (Zahalsky et al, 2004).

Sclerotherapy complications include scrotal pain in 29% to 55% of patients (Rencken et al, 1990; Ovrebø and Vaage, 1991), recurrence, hematoma, and infection; febrile chemical epididymo-orchitis has also been reported with sclerotherapy (López Laur, 1989; Beiko et al, 2003). **Sclerotherapy can have an adverse effect on fertility and should be avoided in patients with interest in fertility potential** (Sigurdsson et al, 1994).

SURGICAL TREATMENT OF ORCHITIS AND CHRONIC SCROTAL PAIN

Orchitis is defined as inflammation of the testicle (Delavierre, 2003). The typical symptoms of orchitis include scrotal pain, swelling, tenderness, and skin fixation over the testicle. The Prehn sign has been described in orchitis and epididymitis when there is relief of pain with elevation of the testicle over the symphysis pubis (Noske et al, 1998). The Prehn sign is nonspecific and nondiagnostic and does not necessarily distinguish epididymo-orchitis from spermatic cord torsion. **Orchitis can cause an irreversible affect on spermatogenesis, impacting the quality and number of spermatozoa.** Lymphocytic infiltration and seminiferous tubule damage is seen on testicular biopsies of subfertile men with a history of chronic orchitis (Schuppe et al, 2008).

Chronic orchitis is defined as constant or intermittent scrotal pain lasting at least 3 months or longer, and of unclear cause (Costabile et al, 1991). **In patients with clinical orchitis, a scrotal ultrasonograph should be obtained because testicular malignancy has been reported to masquerade as orchitis** (Vaidyanathan et al, 2008). At least 10% of men with testicular malignancy will initially be incorrectly diagnosed as having an acute inflammatory process or spermatic cord torsion (Cook and Dewbury, 2000). High-frequency transducer sonography (7.5 to 10 MHz) is considered the best modality for evaluation of scrotal pathology including orchitis (Lee and Bhatt, 2008).

Although there is no level 1 evidence for the optimal treatment of chronic orchitis or epididymitis, local supportive therapy, including heat, nerve blocks, analgesics, tricyclic antidepressants, anticonvulsants (such as gabapentin), and anti-inflammatory drugs are common practice and may offer some relief (Davis and Noble, 1992). Other treatment options implemented for chronic epididymitis include phytotherapy, anxiolytics, narcotics, acupuncture, and steroid injection therapy (Nickel et al, 2002). Despite evidence that up to 75% of patients do not have an identifiable bacterial urinary tract infection concomitantly with their clinical epididymitis, antibiotics are routinely given. Empirical antibiotic administration in the absence of positive urine cultures has been steadily increasing, from 75% to 95% between the years of 1965 and 2005. **Antibiotic administration does not decrease the length of symptoms or the return to full activity in men without an identifiable bacterial pathogen** (Mittemeyer et al, 1966).

Orchiectomy

Surgical treatment for chronic orchitis is poorly studied in clinical trials, with no level 1 evidence to support the use of a specific surgical procedure. Fewer than 250 patients with chronic scrotal pain have been treated with differing surgical therapies in the available literature, despite the common nature of chronic scrotal pain. There is no level 1 evidence that orchiectomy is effective for the treatment of chronic orchalgia. If orchiectomy is recommended, the patient should previously have failed conservative therapy and must be apprised of the risks, benefits, and options of orchiectomy. Because many patients will continue to have pain or have pain recur after orchiectomy, the surgeon should be aware of the medical legal aspects of this action. **If orchiectomy is performed, it should be performed through an inguinal incision, because this approach has been shown to have a better outcome than the scrotal approach for orchalgia** (Davis and Noble, 1992).

Microsurgical Denervation of the Spermatic Cord

Some surgeons have attempted microsurgical denervation of the spermatic cord for symptomatic relief of chronic scrotal pain. **Microsurgical denervation of the spermatic cord was performed in 79 men on 95 testicular units for chronic orchalgia over a mean duration of 62 months. There was complete relief of pain in 71% of the patients, partial relief in 17%, and there was no change from the preoperative status in 12%, with no patients experiencing worsened postoperative pain.** The mean follow-up was 20.3 months (Strom and Levine, 2008). **Microscopic denervation should only be considered if the patient has temporary relief of orchalgia with a spermatic cord block with 10 ml of 0.5% bupivacaine** (Levine et al, 1996).

To mobilize the spermatic cord, microsurgical denervation is performed by the same approach as microscopic subinguinal ligation of the spermatic veins for varicocele repair. Microscopic transection of all branches of the genitofemoral nerve along the spermatic cord is performed while preserving the testicular artery, the vas deferens, the vasal vessels, and some of the lymphatics (Fig. 37–15). This procedure can also be performed laparoscopically (Cadeddu et al, 1999). If fertility is not an issue of concern, it is recommended to divide the vas deferens as well to eliminate the sympathetic innervation, which may contribute to orchalgia by a sympathetic dystrophy component (Levine et al, 1996).

Large, clinically palpable varicoceles can cause orchalgia. The pain typically improves with the patient in the supine position, as the varicocele decompresses. **In a small series of men who underwent microscopic varicocelectomy for clinically palpable varicoceles with concomitant orchalgia, just**

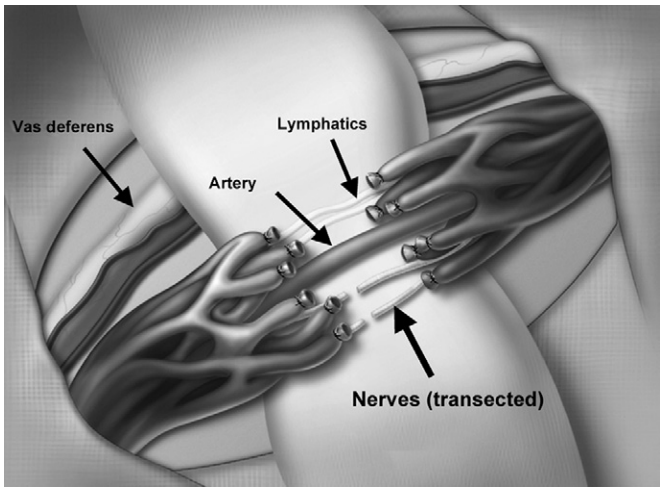

Figure 37–15. Microsurgical denervation. The goal is to transect all branches of the genitofemoral nerve while preserving the vas deferens, vasal vessels, testicular artery, and lymphatics.

over 50% had resolution of pain and 90% had improvement (Chawla et al, 2005). Higher success rates were reported in a previous, larger-powered, retrospective study (Peterson et al, 1998). Smaller, nonclinical varicoceles are unlikely to cause orchalgia and should be managed conservatively.

Retractile testes are another source of scrotal pain in the adult male. A careful history must be elicited to make this diagnosis, as the patient may not demonstrate a retractile testis on examination. The history is consistent with orchalgia only when the testis retracts up toward the external inguinal ring. This is typically seen in younger men with hyperactive cremasteric reflexes. Orchiopexy can be performed in these patients as it would in patients with intermittent torsion (Forte et al, 2003). **When orchiopexy is offered, it should be performed by a dartos pouch technique to prevent retraction, as is recommended for testicular torsion** (Redman and Barthold, 1995).

The other surgical treatment for orchalgia secondary to the retractile testis is to perform microscopic release of the cremasteric muscle. This is performed in a similar manner to microscopic subinguinal varicocelectomy. The spermatic cord is mobilized and isolated and the cremasteric muscle is divided circumferentially while preserving the vasculature of the spermatic cord and the vas deferens. This effectively releases the spermatic cord, thus not allowing retraction of the testis with hypercontraction of the cremasteric muscles.

Key Points: Surgery of the Scrotal Contents

- Patients undergoing epididymal surgery should be counseled that the surgery may impair their fertility, or even cause sterility if bilateral epididymal surgery is required.
- Sclerotherapy as treatment for a hydrocele can have an adverse effect on fertility and should be avoided in patients with an interest in fertility potential.
- Antibiotics should not be given for epididymitis or orchitis without evidence of infection.
- All patients with chronic orchalgia should undergo a scrotal ultrasound.
- When a clinically palpable varicocele is encountered in a patient with orchalgia, varicocelectomy will resolve the pain 50% of the time.

SURGERY OF THE SEMINAL VESICLES

In 1561, Gabriele Fallopius, a renowned Italian anatomist and physician, first described the seminal vesicles as paired male organs. He was considered an authority in the field of sexuality and advocated the use of condoms to decrease the transmission of syphilis. There was a great deal of interest in the seminal vesicles in the late 19th century due to their discovered involvement with inflammatory diseases (Brewster, 1985).

Seminal vesicle secretions contribute 50% to 80% of the volume of the ejaculate. The pH of the secreted fluid is neutral to slightly alkaline, and the mean volume is approximately 2.5 mL. The secreted fluid contains fructose and other carbohydrates necessary for sperm motility. It also contains a coagulation factor and prostaglandins A, B, E, and F (Tauber et al, 1975).

Primary disease processes of the seminal vesicles are very rare, although secondary processes are seen more commonly. Diagnosis of such entities has improved over the years with advanced imaging. Surgical access and management of seminal vesicle pathology can be difficult for the urologist due to the anatomic location.

Anatomy

The seminal vesicles are paired male organs with no equivalent in the female. It is useful to understand the developmental anatomy of the seminal vesicles to gain a full understanding of the anatomy in the adult patient. **The seminal vesicles begin as bilateral dorsolateral bulbous dilations of the distal mesonephric ducts between 12 and 12½ weeks of gestation.** By 13 weeks, these dilations have enlarged and the ejaculatory ducts are beginning to form in the developing prostate (Brewster, 1985). The seminal vesicle and the ampulla of the vas deferens join posterior and superior to the prostate to form the ejaculatory duct (Nguyen et al, 1996). By the early portion of the seventh month, the seminal vesicle has multiple outpouchings and a widened main central lumen (Fig. 37–16) (Brewster, 1985).

The adult seminal vesicle measures 5 to 6 cm in length and 3 to 5 cm in diameter with a volume capacity of 13 cm, although they decrease in size as men age (Redman, 1987). At the terminal portion of the vas deferens within the prostate, the major lumen of the seminal vesicle empties into the ejaculatory duct. The ejaculatory duct is in continuity with the seminal vesicle but does not share the thick muscular wall of the seminal vesicle (Fig. 37–17) (Nguyen et al, 1996). **The arterial supply to the seminal vesicle is from the vesiculodeferential artery, branching off from the umbilical artery** (Braithwaite, 1952). Venous drainage of the seminal vesicle follows the arterial supply draining through the vesiculodeferential veins and the inferior vesicle plexus. **Innervation of the seminal vesicles is by the hypogastric nerve (adrenergic and cholinergic) and the pelvic nerve. Lymphatic drainage of the seminal vesicles is through the internal iliac nodes** (Mawhinney and Tarry, 1991).

Congenital Anatomic Anomalies of the Seminal Vesicles

The incidence of unilateral seminal vesicle agenesis is 0.6% to 1%. **Unilateral seminal vesicle agenesis may be associated with ipsilateral renal anomalies and unilateral absence**

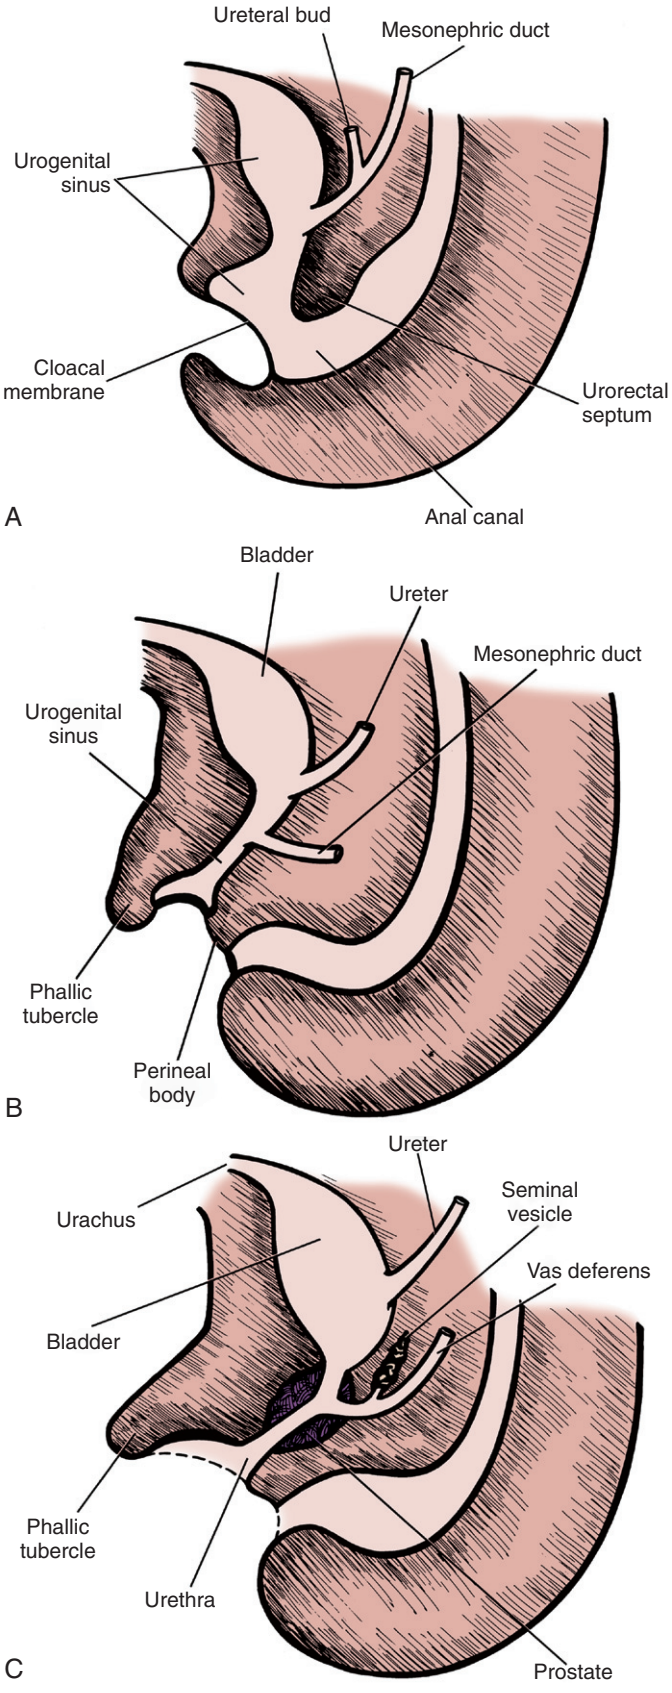

Figure 37–16. Intrauterine (fetal) development of the seminal vesicles. **A,** Fifth week. **B,** Eighth week. **C,** Thirteenth week. (Redrawn from Langman J. Medical embryology. 4th ed. Baltimore: Williams & Wilkins; 1981. p. 242–3.)

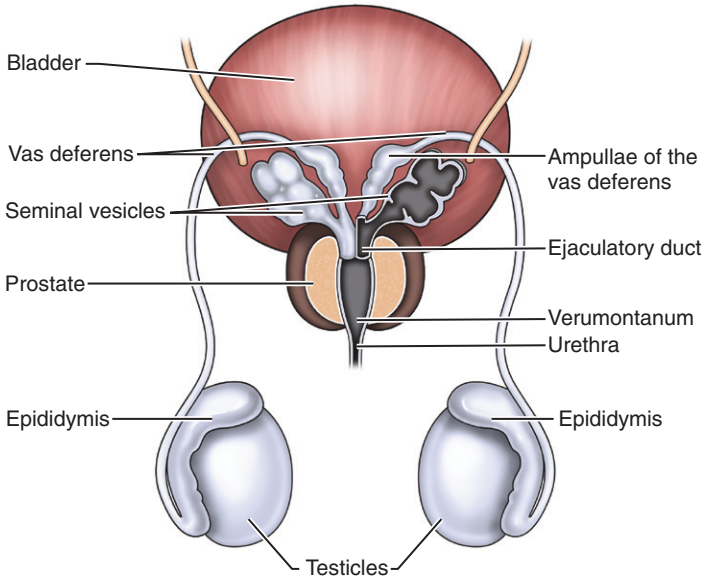

Figure 37–17. Posterior view of seminal vesicle anatomy in relation to the lower genitourinary tract (*bivalved areas in dark gray*).

of the vas deferens. This is thought to be secondary to an embryological insult at the seventh week of gestation prior to the separation of the ureteral bud from the mesonephric duct. If this insult occurs after the seventh week, it is unlikely that renal agenesis would be associated with the seminal vesicle agenesis (Hall and Oates, 1993). It is common to find bilateral absence of the seminal vesicles along with congenital bilateral absence of the vas deferens, which is typically associated with a cystic fibrosis transmembrane receptor mutation. Of these men, 70% to 80% carry the genetic mutation associated with cystic fibrosis (Anguiano et al, 1994; Chillon et al, 1995). Treatment is only necessary when fertility becomes an issue.

Infectious Processes of the Seminal Vesicles

Infection of the seminal vesicles is seen in underdeveloped countries more frequently than in the United States. The causative agents are *Mycobacterium tuberculosis* and *Schistosoma haematobium*. The diagnosis of bacterial seminal vesiculitis can be made by transrectal or perineal needle aspiration. Surgery is not usually indicated, and culture-specific systemic antibiotics are the treatment of choice (Gutierrez et al, 1994). Very rarely, seminal vesiculectomy is necessary to prevent recurrent bacteremia or to eliminate persistent symptoms (Indudhara et al, 1991). Seminal vesicle abscesses are rare, but have been associated with diabetes mellitus, chronic indwelling catheters, and endoscopic instrumentation (Gutierrez et al, 1994). Management of seminal vesicle abscesses is discussed below along with management of seminal vesicle cysts**. Infection, obstruction, or the combination of the two can result in calculi formation in the seminal vesicles.** Patients with seminal vesicle calculi present with hematospermia, perineal pain, painful ejaculation, and infertility. These stones can be managed through an open or laparoscopic vesiculectomy, or the stone can be retrieved endoscopically using a small-caliber ureteroscope (Ozgök et al, 2005; Cuda et al, 2006; Han et al, 2008).

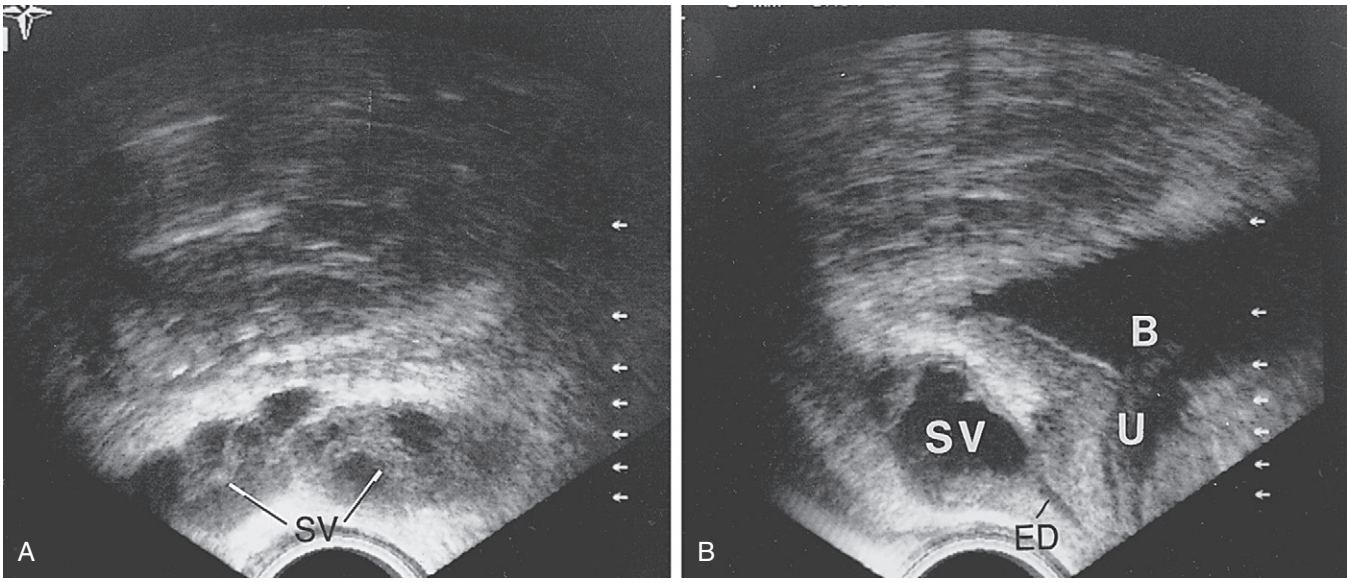

Figure 37–18. Transrectal ultrasound examination of normal seminal vesicles. **A,** Transverse view. **B,** Sagittal view. B, bladder; ED, ejaculatory duct; SV, seminal vesicle; U, urethra.

Evaluation of Abnormalities of the Seminal Vesicles

Normal seminal vesicles are not palpable on digital rectal examination. When a seminal vesicle cyst is present, the area immediately above the prostate may be compressible on digital rectal examination. This same area may feel firm or solid when a seminal vesicle tumor is present.

Semen analysis revealing a low seminal volume and a lack of liquefaction and fructose may indicate ejaculatory duct obstruction or absence of seminal vesicles (Goldstein and Schlossberg, 1988).

High-resolution transrectal ultrasonography (TRUS) has become the mainstay of imaging for the diagnostic evaluation of seminal vesicle pathology, because it is a reliable and inexpensive imaging modality. On TRUS, the seminal vesicles can be found just superior to the prostate, between the bladder and the rectum, and can be well visualized in the anteroposterior and sagittal views. The normal seminal vesicles should appear as flat, elongated, paired structures in the above described positions (Fig. 37–18). Along with the seminal vesicles, the ampullae of the vas deferens, the ejaculatory ducts within the prostate, and the verumontanum can be imaged and evaluated by TRUS. Abnormalities such as seminal vesicle obstruction, aplasia, atrophy, and cyst formation can be identified by TRUS (Carter et al, 1989).

Seminal vesicle obstruction may result in seminal vesicle dilation identifiable by TRUS with the following characteristics: anteroposterior diameter of greater than 15 mm, length greater than 35 mm, and large anechoic areas, which contain sperm when aspirated (Jarow, 1996; Colpi et al, 1997). Asymptomatic cystic dilation of the seminal vesicle was incidentally found in 5% of men undergoing TRUS for prostate cancer screening (Wessels et al, 1992).

TRUS revealing hyperechoic solid masses in the seminal vesicles (isoechoic to the prostate) are concerning for tumor. If there is a unilateral solid mass in the seminal vesicle, it is more likely to be a primary tumor, whereas if it is present in bilateral seminal vesicles, it is more likely to be a secondary tumor from a primary prostate, rectal, or bladder malignancy. TRUS-guided biopsy or aspiration is necessary to assist in the diagnosis.

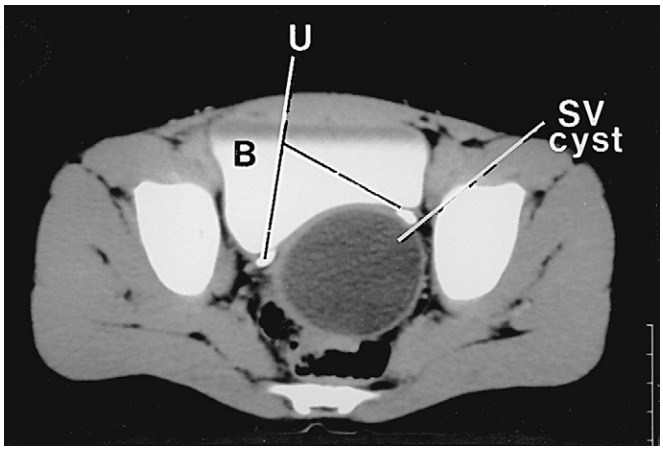

Figure 37–19. CT scan of seminal vesicle cyst (SV cyst). B, bladder; U, ureters.

Computed tomography (CT) has also been used to evaluate the seminal vesicles. **The normal appearance of the seminal vesicles on CT is that of paired structures just below the bladder with medium contrast similar to muscle** (Goldstein and Schlossberg, 1988)**.** A seminal vesicle cyst imaged by CT scan appears as a well-defined retrovesicular fluid density with the attenuation of water, from 0 to 10 Hounsfield units, cephalad to the prostate gland (Fig. 37–19). CT accurately images seminal vesicle anomalies, and is a good modality to allow for imaging of the ipsilateral kidney concomitantly (Arora et al, 2007).

In cases of primary seminal vesicle malignancy, CT scan may be useful to further characterize the lesion prior to intervention. A tumor within the seminal vesicle on CT has a higher attenuation than the normal seminal vesicle, but the tumor may appear cystic secondary to tumor necrosis (King et al, 1989). It is not possible to differentiate malignant tumors from benign ones on CT scan alone, although secondary tumors from the bladder, rectum, or prostate may have a more contiguous appearance (Sussman et al,

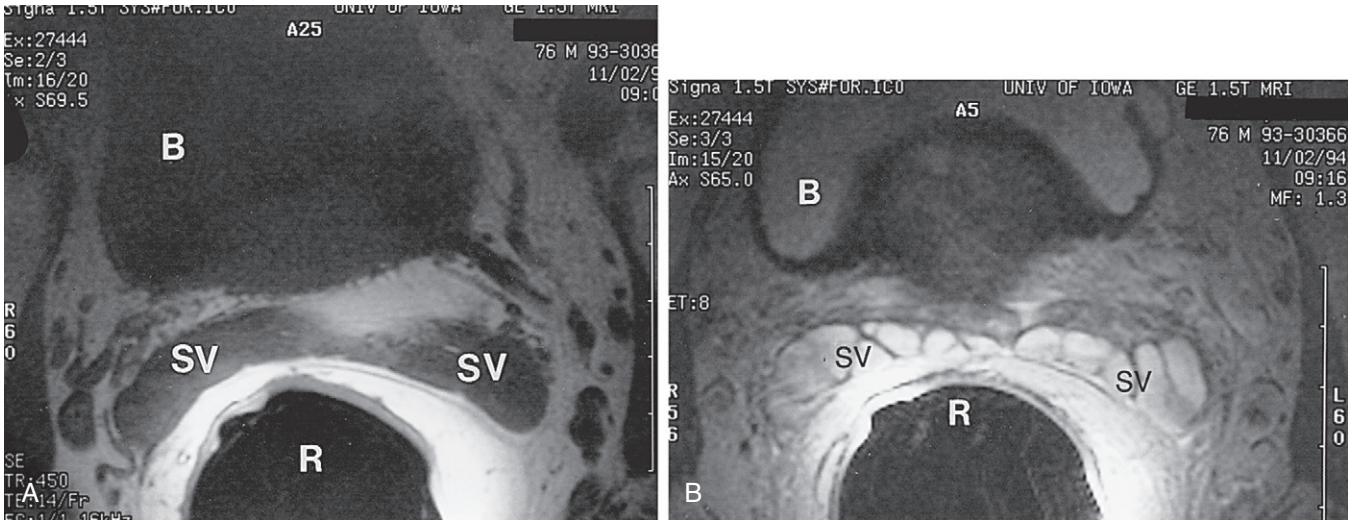

Figure 37–20. Transaxial MRI of normal seminal vesicles (SV) with endorectal coli. **A,** T1-weighted image. **B,** T2-weighted image. B, bladder; R, rectum.

1986). The CT findings of a leiomyosarcoma of the seminal vesicle are described as an irregular mass, resulting in enlargement of the seminal vesicle with displacement of the prostate gland (Upreti et al, 2003). CT, as well as magnetic resonance imaging (MRI), allows metastatic evaluation when seminal vesicle neoplasms are further characterized (Dahms et al, 1999).

MRI is another useful imaging modality for the seminal vesicles, which gives more anatomic detail than CT. On T2-weighted images, the ampulla of the vas deferens is visible approximately 71% of the time and exhibits low signal intensity. The seminal vesicles exhibit high signal intensity 79% of the time, low signal intensity 19% of the time, and a heterogeneous signal intensity 2% of the time on T2-weighted images (Roy et al, 1993). On T2-weighted images, the seminal vesicles generally have similar or higher intensity than fat in patients less than 70 years of age, and typically have signal intensity lower than that of fat in patients greater than 70 years of age. The convolutions of the seminal vesicles can be seen on T1-weighted imaging with contrast (Fig. 37–20) (Secaf et al, 1991).

On MRI, seminal vesicle agenesis is best exemplified on T1-weighted axial images (Fig. 37–21). Care must be taken to not mistake the vesicoprostatic venous plexus for small glands. Arteriovenous malformations appear as large ectatic vessels adjacent to the lateral edge of the seminal vesicle. After androgen ablation, seminal vesicles demonstrate low signal intensity on T2-weighted images and appear small in size (Secaf et al, 1991). The appearance of seminal vesicles after pelvic radiation reveals a decrease in size in a third of the patients. The seminal vesicles have a normal MRI appearance in 63% of the patients after pelvic radiation, 21% had normal signal intensity but had fewer tubules, 8% had diffuse loss of signal intensity appearing hypointense to fat, and 8% were hypointense to fat on T2-weighted images (Chan and Kressel, 1991). A seminal vesicle cyst may have variable signal intensities on T1-weighted images but typically demonstrates fluid signal intensities on T2-weighted images and does not enhance with the administration of intravenous gadolinium. Increased T1-weighted intensity represents increased proteinaceous concentration within the cyst or hemorrhage (Arora et al, 2007). Hemorrhagic seminal vesicle cysts have high signal intensity on T1- and T2-weighted images (Sue et al, 1989). A benign primary mass of the seminal vesicle appears as a sharply marginated mass arising from the seminal vesicle. The most common form of malignancy affecting

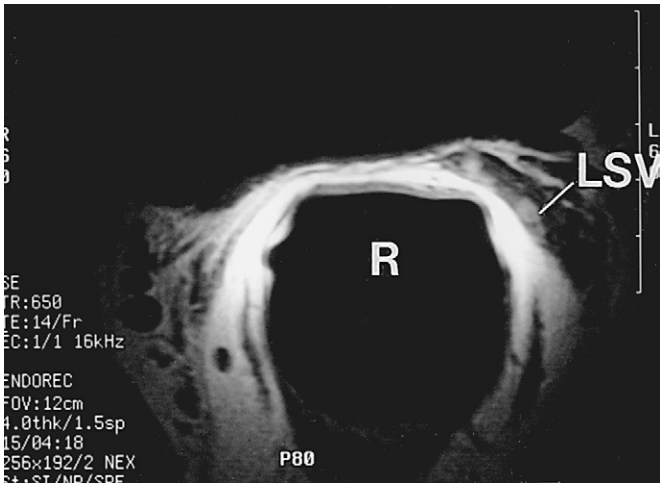

Figure 37–21. Transaxial T1-weighted endorectal magnetic resonance image of absent right seminal vesicle. LSV, left seminal vesicle; R, rectum.

the seminal vesicle is invasion of prostate cancer directly into the seminal vesicle. This can make the seminal vesicle appear large but does not always do so, and the seminal vesicle has low signal intensity on T2-weighted images (Secaf et al, 1991). **MRI is not necessary to make the diagnosis in cases with a seminal vesicle abnormality. If there is a palpable seminal vesicle abnormality, TRUS should be performed with biopsy if there is suspicion for malignancy. MRI is helpful with hemorrhagic lesions, and body imaging is useful for staging.**

Surgical Approaches to the Seminal Vesicles

The surgical approach to the seminal vesicles is mainly dependent on the expertise and comfort of the surgeon, although the characteristics of the lesion may impact the decision on the approach.

Preoperative preparation for seminal vesicle surgery should include a bowel preparation the evening before surgery, in case of

the uncommon occurrence of a bowel injury; GoLYTELY is recommended. A prophylactic systemic antibiotic is administered preoperatively, and two doses are given postoperatively. The use of intermittent compression stockings to prevent deep vein thrombosis during surgery is recommended.

Anterior Surgical Approaches to the Seminal Vesicles

The anterior surgical approach to the seminal vesicles has been well established and is a good open approach for patients with large benign masses or cysts, and for patients with an ectopic ureter draining into a seminal vesicle cyst, so the kidney, ureter, and seminal vesicle can all be approached concomitantly.

A popular open anterior approach is the transvesicle approach, which has been well described (Walker and Bowles, 1968; Politano et al, 1975). A lower midline infraumbilical incision is made sharply, and the rectus muscles are divided in the midline. The space of Retzius is developed. The anterior bladder is exposed, and a self-retaining retractor is placed. A longitudinal incision, about 7 to 10 cm long, is made in the anterior bladder wall, taking care to stay at least 3 to 4 cm proximal to the bladder neck. Moist sponges are placed in the bladder dome, and a bladder blade for the retractor is used to gently offer exposure. The ureteral orifices should be identified, and 8-Fr feeding tubes can be passed gently up the ureters to help with identification of the intramural ureters. A 5-cm longitudinal incision is made in the midline of the trigone with electrocautery on cutting current. Once the incision goes through the posterior bladder muscle, the ampullae of the vas deferens should be visible just below the bladder neck. The seminal vesicles should be identified just lateral to the ampullae of the vas deferens on the prostatic base. The seminal vesicles should be dissected free completely. Metal clips are placed on the vascular pedicle. A clip is placed on the proximal end of the vas deferens. A 2-0 chromic tie is used to ligate the end of the seminal vesicle at the prostate. The seminal vesicle is resected and removed. Care must be taken not dissect too deep through Denonvilliers fascia posteriorly, to not endanger the rectum. The posterior bladder wall is closed in two layers with a 2-0 absorbable suture in the muscle and a 4-0 absorbable suture in the mucosa. The sponges and ureteral catheters are removed, a 20-Fr urethral catheter is placed, and the anterior bladder wall is closed in the same fashion as the posterior bladder wall. A suction drain is placed in the perivesicle space, not overlying the suture line, and is brought out through a separate stab incision (Fig. 37–22). This drain can be removed when the output is less than 50 ml per day, typically in 2 to 3 days. The urethral catheter can be removed in 5 to 7 days. This approach has a lower rectal injury rate, although it places the ureters at a higher risk for injury and is more prone to blood loss.

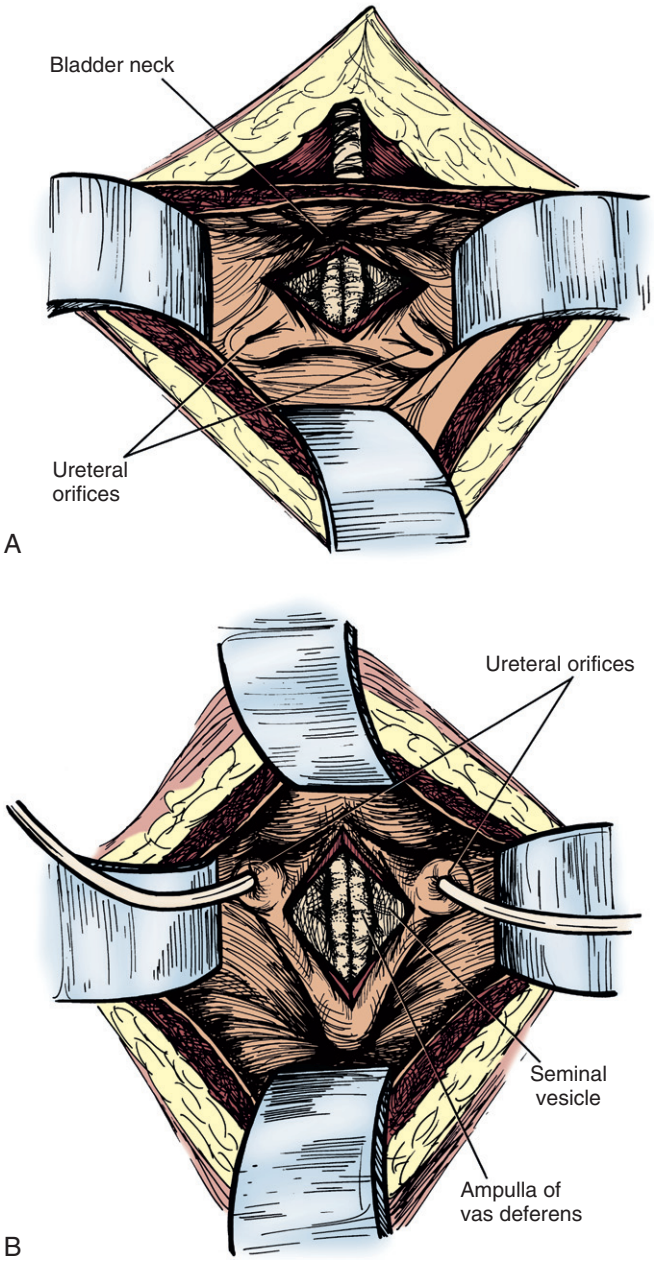

Figure 37–22. Transvesical approach to seminal vesiculectomy. **A,** Vertical incision between the ureteral orifices. **B,** Transverse incision 2 cm superior to the bladder neck below the ureteral orifices. (Redrawn from Hinman F Jr. Atlas of urologic surgery. Philadelphia: WB Saunders; 1989. p. 382.)

The perivesicle approach is useful in pediatric patients with a large seminal vesicle cyst, so that nephroureterectomy can be performed along with seminal vesiculectomy. A midline or Pfannenstiel incision will offer adequate exposure for this approach. Finger dissection is used to dissect the bladder from the lateral pelvic sidewall on the side with the cyst. The seminal vesicle cyst should be readily identifiable, the seminal vesicle should be dissected free in its entirety, and a 1-0 chromic can be placed through the cyst as a traction suture to assist with dissection. The ureter must be identified crossing the vas deferens to prevent ureteral injury. The superior, and possibly the inferior, vesicle arteries may be sacrificed to offer exposure to the base of the seminal vesicle. The cyst should be dissected away from the bladder, and any seminal vesicle vessels can be clipped and divided. When the base of the seminal vesicle is accessed at the prostate–seminal vesicle junction, it can be ligated with a 2-0 absorbable suture. Dissection of the proximal portion of the seminal vesicle must be done carefully by hugging the cyst, so not to injure the neurovascular bundle, which is directly lateral to the seminal vesicle. A clip is then placed just distal to the previously placed suture, and the seminal vesicle is resected. A suction drain is placed adjacent to the seminal vesicle bed and is brought out through a separate stab incision. The drain and urethral catheter may both be removed in 24 hours, as long as there is not excessive drainage through the drain.

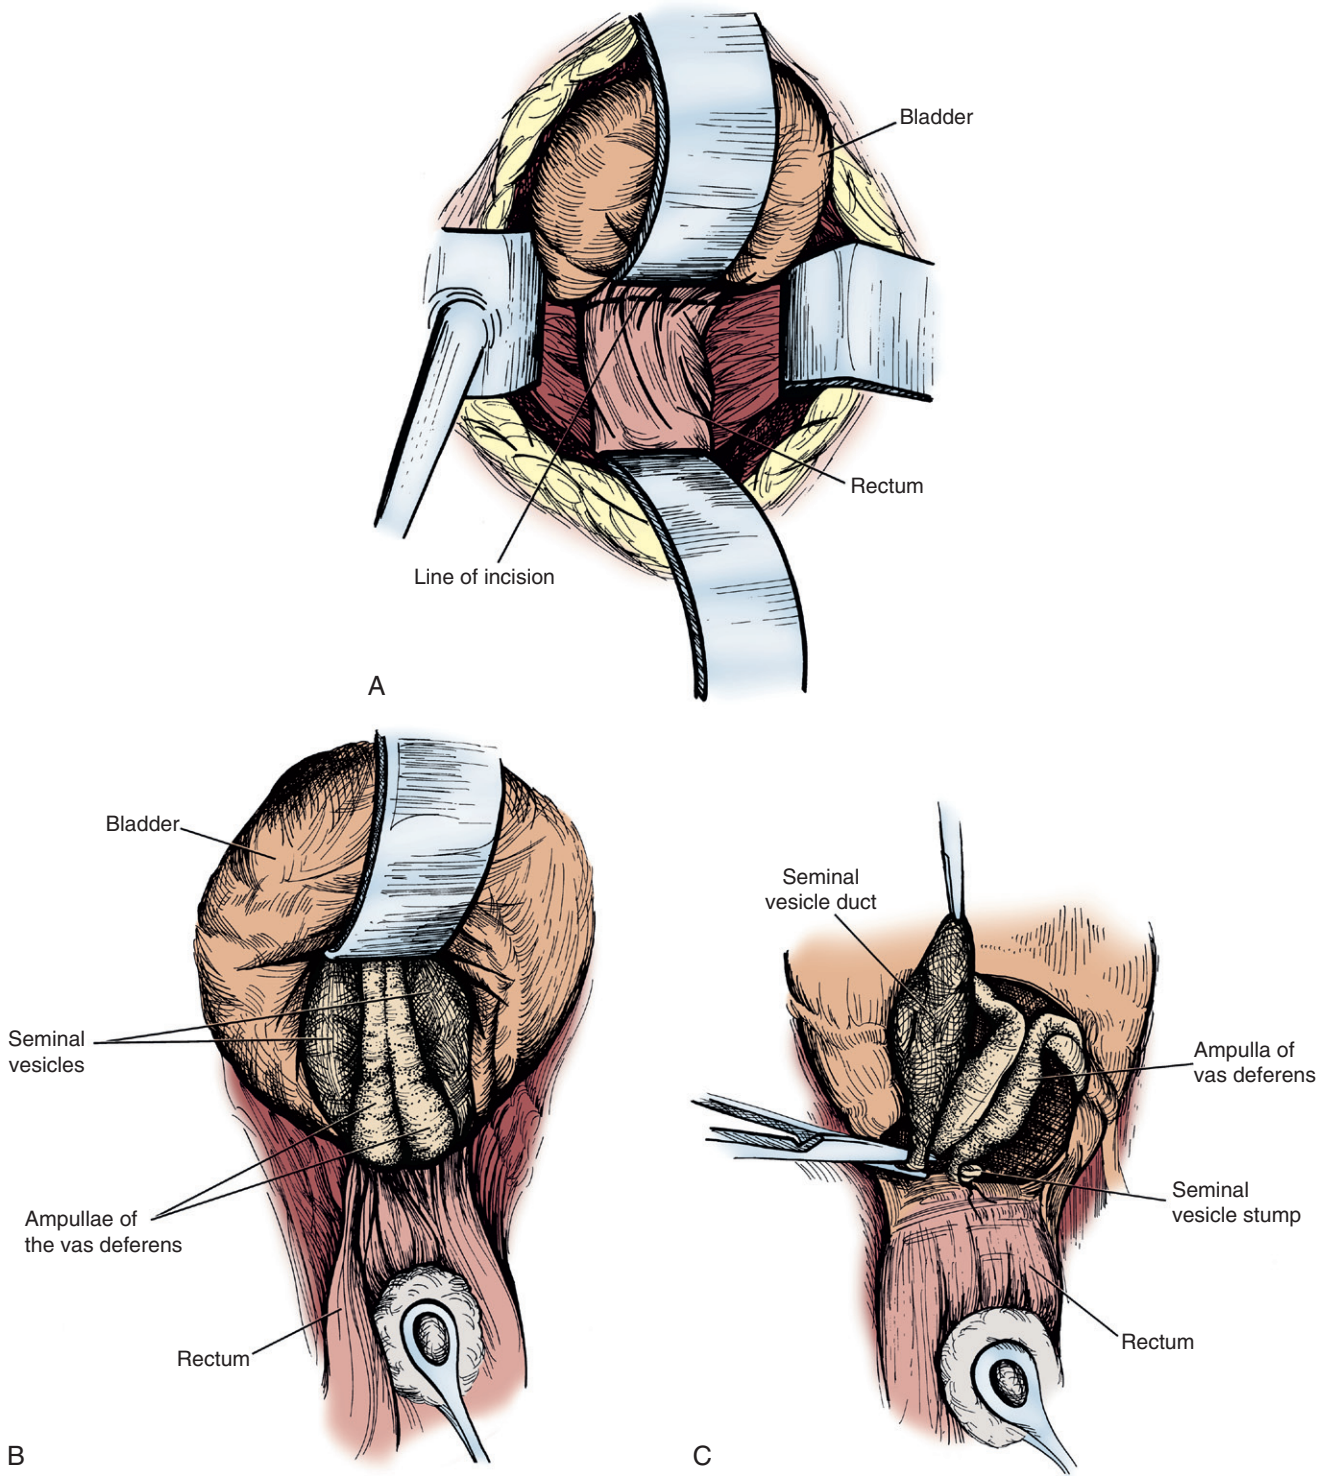

Figure 37–23. Retrovesical approach to seminal vesiculectomy. **A,** Incision line between base of bladder and peritoneal reflection over the rectum. **B,** Caudal dissection reveals the ampullae of the vas deferens on the midline and seminal vesicles immediately lateral to them. **C,** The duct of the seminal vesicle is ligated and transected. (Redrawn from Hinman F Jr. Atlas of urologic surgery. Philadelphia: WB Saunders; 1989. p. 379–80.)

A third anterior approach to the seminal vesicles is the retrovesicle approach and is useful for bilateral seminal vesiculectomies for bilateral small cysts or benign masses (de Assis, 1952). A urethral catheter should be placed, a midline incision is made, and the peritoneum is entered. A transverse incision is made in the peritoneal reflection over the rectum at the posterior bladder wall, taking great care to not enter the rectum. The posterior bladder is sharply dissected off the anterior rectal wall until the ampullae of the vas deferens and the tips of the seminal vesicles are visible. The seminal vesicles are dissected free to the base at the prostate–seminal vesicle junctions and are ligated and resected. A suction drain is placed at the posterior bladder and brought out through a separate stab incision. The incision is closed (Fig. 37–23).

Transperineal Surgical Approach to the Seminal Vesicles

The patient should be positioned as they would be for perineal prostatectomy. The same incision is made as would be for perineal prostatectomy, but the rectum needs to be dissected free high on the base of the prostate. A transverse incision is then made in Denonvilliers fascia above the base of the prostate–seminal vesicle junctions. This incision can be made longitudinally to allow better preservation of the neurovascular bundles for potency (Weldon and Tavel, 1988). A Lowsley retractor can be placed through the urethra into the bladder to elevate the prostate to provide traction to allow for easier dissection of the base of the seminal vesicle. Just below Denonvilliers fascia and above the prostate, the ampulla of the vas deferens can be dissected. If the surgery is being done for benign pathology, dissection can be carried laterally to the seminal vesicle. If it is being done for malignancy or recurrent infection, the ampulla of the vas deferens should be included in the specimen with a wider resection. The seminal vesicle should be dissected completely free, and the base should be ligated at the prostate–seminal vesicle junction with a 2-0 suture. A second tie or clip should be placed on the distal seminal vesicle, and the seminal vesicle should be divided. The divided end of the seminal vesicle is then grasped with an Allis clamp, and the Metzenbaum scissors are used in a spreading motion to free the rest of the seminal vesicle from surrounding tissue while using the Allis for traction. Metal clips are placed on the vascular pedicle and it is divided, typically within 1 cm of the distal tip of the seminal vesicle. The seminal vesicle is removed, a Penrose drain is left in the seminal vesicle bed, and the incision is closed in layers. The drain can be removed in 24 hours if there is minimal drainage. **The transperineal approach offers minimal blood loss, minimal pain, and early ambulation** (Fig. 37–24).

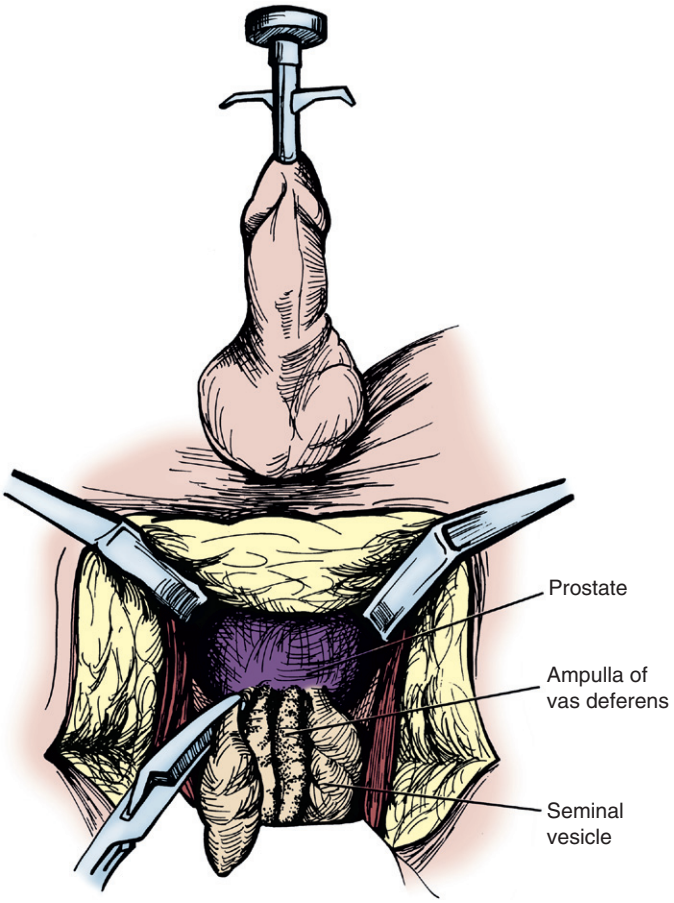

Figure 37–24. Transperineal approach to seminal vesiculectomy. (Redrawn from Hinman F Jr. Atlas of urologic surgery. Philadelphia: WB Saunders; 1989. p. 381.)

Posterior Surgical Approach to the Seminal Vesicles

Although the transcoccygeal approach is the least familiar to most urologists, it may be useful for patients who have had previous suprapubic or perineal surgeries. The patient is positioned in a prone, jackknife position (Kreager and Jordan, 1965). An L-shaped hockey stick incision is made from midway on the sacrum, 10 cm from the tip of the coccyx, and angled at the tip of the coccyx down the gluteal cleft stopping 3 cm from the anus. The lateral side of the coccyx is carefully divided free from the rectum and removed. The layers of the gluteus maximus are swept aside until the rectosigmoid is reached, and then it is carefully dissected from the underside of the sacrum. The lateral rectal wall is divided free medially from the levator ani muscle until the prostate is encountered on the side of the seminal vesicle pathology. Dissection is carried superior to the base of the prostate in the midline until the ampulla of the vas deferens is identified with the seminal vesicle just lateral to the ampulla. The seminal vesicle should be dissected and resected as previously described in the above approaches. A Penrose drain should be placed at the bed of the seminal vesicle and brought out through a separate stab incision from the closure. The drain can be removed in two to three days if there is no drainage (Fig. 37–25).

Laparoscopic/Robot-Assisted Surgical Approach to the Seminal Vesicles

Laparoscopic surgery on the seminal vesicles is most commonly performed concomitantly with prostate surgery. The technique for laparoscopic approach to the seminal vesicles was first described in 1993 (Kavoussi et al, 1993). Laparoscopy has also been applied to seminal vesiculectomy without prostatectomy and has been reported in a case of amyloid of the seminal vesicle (Vandwalle et al, 2007). Robot-assisted laparoscopy has also been used to excise seminal vesicle cysts (Moore et al, 2007; Selli et al, 2008). Patients are positioned in the supine position with careful padding of all pressure points, and the arms are tucked and padded. A split-leg table is necessary for the robot-assisted technique. Wide cloth tape is used across the chest and hips to secure the patient to the table, and the table is placed in steep Trendelenburg position. Prior to gaining access, a urethral catheter and an orogastric tube should be placed to decompress the bladder and stomach for subsequent trochar placement. To gain access, the Varess needle is placed periumbilically and a pneumoperitoneum is achieved, not exceeding pressures of 15 mm Hg. After an adequate pneumoperitoneum is achieved, the laparoscopic ports can be placed, placing the first one with an optical trocar for the camera port, and the following ones under direct laparoscopic visualization. The ports can be placed in either a horseshoe or a diamond

Figure 37–25. arrangement for pure laparoscopy and can be placed in the same position as would be for prostatectomy for robot assistance (Fig. 37–26) (Menon et al, 2003; Lee et al, 2004). The peritoneum is then incised between the two obliterated umbilical ligaments just anterior to the rectum in the pouch of Douglas. The seminal vesicles can then be visualized and should be dissected carefully to avoid injury to the neurovascular bundles or the surrounding viscera. Monopolar energy should not be used in order to minimize injury to surrounding structures, and much of this dissection can safely be performed sharply. The seminal vesicle arterial pedicle can be managed with a clip or with bipolar cautery. The seminal vesicle should be dissected toward its junction with the ampulla of the vas deferens, and both can be clipped together at the base. The specimen can then be placed in an extraction bag and can be removed through one of the laparoscopic ports. The ports are then closed under visualization.

The extraperitoneal laparoscopic approach to the seminal vesicles was first described in 1997, and was performed concomitantly with radical prostatectomy (Raboy et al, 1997). In the following years, this approach gained more popularity (Bollens et al, 2001; Stolzenburg et al, 2003). A 1.5-cm periumbilical incision is made, and the preperitoneal space is entered. A balloon trocar is

introduced into the preperitoneal space, and insufflation is performed under direct vision. The details of the technique are further described in detail in Chapter 103.

Surgical Treatment of Seminal Vesicle Cysts

Seminal vesicle cysts are thought to be secondary to ejaculatory duct obstruction and can be congenital or acquired (Heaney et al, 1987; King et al, 1991; Conn et al, 1992). **Seminal vesicle cysts are associated with ipsilateral renal agenesis or dysplasia in two thirds of patients; the cysts are secondary to maldevelopment of the distal mesonephric duct and are an error in ureteral budding** (Beeby, 1974). Seminal vesicle cysts have also been associated with polycystic kidney disease. In one report, seminal vesicle cysts were identified in 60% of patients with polycystic kidney disease, and some authors recommend that all patients with seminal vesicle cysts undergo renal imaging (Alpern et al, 1991; Hihara et al, 1993; Danaci et al, 1998). **Seminal vesicle cysts should only be treated if they are symptomatic or result in ejaculatory duct obstruction and affect fertility** (Surya et al, 1988).

Seminal vesicle cysts can be drained by a number of techniques. **TRUS-guided aspirations or transperineal aspirations**

can be performed on small seminal vesicle cysts that are symptomatic or obstructing the ejaculatory ducts. If the cyst reaccumulates fluid, resulting in recurrent symptoms or obstruction, it may be aspirated again with the injection of a sclerosing agent such as tetracycline. A small abscess in the seminal vesicle can be managed similarly with drainage (Frye and Loughlin, 1988; Shabsigh et al, 1989; Gutierrez et al, 1994). If the seminal vesicle cyst is proximal, adjacent to the prostate, transurethral resection can be performed to unroof the cyst at the 5-o'clock and 7-o'clock positions just distal to the bladder neck (Frye and Loughlin, 1988; de Lichtenberg and Hvidt, 1989). The same outcome has been reported by incising the seminal vesicle cyst to drain it cystoscopically with the use of a Collin knife (Gonzalez and Dalton, 1998). Seminal vesicle abscesses can be managed in a similar fashion. Some groups have reported using semirigid ureteroscopes to treat seminal vesicle cysts and abscesses (Razvi and Denstedt, 1995; Shimada and Yoshida, 1996; Okubo et al, 1998). If the above techniques for drainage of seminal vesicle cysts are unsuccessful, open or laparoscopic excision can be performed (Moudouni et al, 2006). Seminal vesiculectomy, along with nephroureterectomy should be performed in cases with an ectopic ureter. If the above techniques for seminal vesicle abscess fail, open drainage is required (Kore et al, 1994).

Surgical Treatment of Tumors of the Seminal Vesicles

Benign tumors of the seminal vesicle that occur more commonly than malignant ones include fibromas, leiomyomas, cystadenomas, schwannomas, and papillary adenomas (Mostofi and Price, 1973; Lundhus et al, 1984; Narayana, 1985; Mazur et al, 1987; Bullock, 1988; Gentile et al, 1994; Latchamsetty et al, 2002; Lee et al, 2006). Primary papillary adenomas and cystadenomas of the seminal vesicle typically occur in middle-aged men and are almost never bilateral, and they appear as simple cysts on imaging; therefore, the diagnosis is typically one made on final pathology after excision (Mazur et al, 1987). Amyloid localized to the seminal vesicles has also been reported (Jun et al, 2003). Twenty percent of men over the age of 76 have subepithelial deposits of amyloid in the seminal vesicles, and the reported incidence in male autopsies is 4% to 17% (Pitkanen et al, 1983; Ramchandani et al, 1993). Patients should only be treated if they are symptomatic and the diagnosis of amyloid of the seminal vesicle is made. Hydatid cysts of the seminal vesicle have also been reported (Kuyumcuoglu et al, 1991; Papathanasiou et al, 2006).

Seminal vesicle malignancies are extremely rare and are difficult to diagnose, because patients are typically asymptomatic until late in the course of the disease process. Primary malignancies of the seminal vesicles are extremely rare, and serum PSA and tissue biopsies can help differentiate primary malignancies from extension/metastasis of lymphoma, prostate, bladder, or rectal cancer. It is thought that the seminal vesicles low proliferative activity accounts for the low incidence of primary malignancies of the seminal vesicle (Meyer et al, 1982). **Primary adenocarcinoma of the seminal vesicle occurs in patients greater than 50 years old.** Serum PSA is normal and serum carcinoembryonic antigen is elevated (Mostofi and Price, 1973; Benson et al, 1984; Tanaka et al, 1987; Chinoy and Kulkarni, 1993; Thiel and Effert, 2002). **Primary sarcoma of the seminal vesicle is an extremely rare malignancy, which is diagnosed by biopsy, and is usually discovered late in the course of the disease process** (Benson et al, 1984; Chiou et al, 1985; Schned et al, 1986; Tanaka et al, 1987; Davis et al, 1988; Kawahara et al, 1988). All sarcoma types of the seminal vesicle, including leiomyosarcoma, rhabdomyosarcoma, angiosarcoma, and müllerian adenosarcoma-like tumor, behave very aggressively, and radical extirpation has varying outcomes (Amirkhan et al, 1994; Lamont et al, 1991; Laurila et al, 1992; Berger et al, 2002). Cystosarcoma phylloides and seminoma have also been reported as primary malignancies of the seminal vesicles (Fain et al, 1993; Adachi et al, 1991). Primary squamous cell carcinoma of the seminal vesicle has been reported and treated with surgical extirpation followed by adjuvant radiation therapy with success with short-term follow-up (Tabata et al, 2002).

Solid seminal vesicle masses that are benign on biopsy and show no evidence of local spread should be treated with seminal vesiculectomy only if they are symptomatic, which is a very rare occurrence. Solid masses of the seminal vesicles that are proven to be malignant by biopsy or with a high suspicion for malignancy should be surgically treated, although the optimal treatment is still debated because there have been so few primary seminal vesicle malignancies treated at any institution. Large primary malignancies of the seminal vesicles have been treated with radical pelvic surgery: cystoprostatectomy with pelvic lymphadenectomy or pelvic exenteration. Adjuvant therapy has not proven to be effective, although the only survivors in the literature underwent radical surgery followed by pelvic radiation and/or androgen ablation.

Complications of Seminal Vesicle Surgery

Complications of seminal vesicle surgery are minimized by the surgeon selecting the approach that he or she is most comfortable and facile performing. The surgeon must be aware of the following seminal vesiculectomy specific complications. Rectal injury can occur with the perineal approach to the seminal vesicles. If a preoperative bowel preparation was administered and there is no gross fecal contamination, a two-layer closure of the rectum may be performed closing the mucosal layer with a running 3-0 absorbable suture, and the submucosal layer with interrupted 4-0 silks. The anus should also be dilated prior to the end of the case. A temporary colostomy should be considered with a large rectal injury or gross fecal contamination. The bladder may also be injured during the perineal approach. The bladder should be closed in two layers, leaving a urethral catheter in place for 7 to 10 days postoperatively. During the perineal approach, the ureter may be injured. If this occurs, the injury should be repaired, or a double-J ureteral stent may be placed and left in place for 10 to 14 days postoperatively. Hemorrhage is least likely in the perineal approach, and the transvesicle approach is more prone to blood loss.

Complications of the laparoscopic approach include general laparoscopic complications, such as trocar injury to the bowel or great vessels, extraperitoneal insufflation, abdominal wall bleeding, and gas embolism. Bladder and rectal injuries may be repaired laparoscopically, as long as there is not gross fecal contamination with rectal injuries. The distal ureter is close to the tip of the seminal vesicle, and, if the ureter is injured it may be repaired laparoscopically, although a ureteral reimplant may be necessary, and performed open or laparoscopically, depending on the

experience of the surgeon. It is recommended that a ureteral stent and a pelvic drain be left in such cases. The neurovascular bundle runs just lateral to the tips of the seminal vesicles; therefore, injury to the neurovascular bundle can result in erectile dysfunction, regardless of the surgical approach. Potential complications of endoscopic management of the seminal vesicles include postvoid dribbling due to urinary reflux and infection (Goluboff et al, 1995).

Key Points: Surgery of the Seminal Vesicles

- Seminal vesicle secretions contribute 50% to 80% of the volume of the ejaculate.
- Unilateral seminal vesicle agenesis may be associated with ipsilateral renal anomalies and unilateral absence of the vas deferens.
- Normal seminal vesicles are not palpable on digital rectal examination.
- If there is a palpable seminal vesicle abnormality, TRUS should be performed with biopsy if there is suspicion for malignancy.
- The surgical approach to the seminal vesicles is mainly dependent on the expertise and comfort of the surgeon, although the characteristics of the lesion may impact the decision on the approach.
- Benign and malignant tumors of the seminal vesicles are very rare.

chapter 38

Renal Physiology and Pathophysiology

Daniel A. Shoskes, MD, MSc, FRCSC • Alan W. McMahon, MD

Renal Physiology

Renal Pathophysiology

Renal physiology impacts the urological care of patients in numerous ways. These can include the pathophysiology of surgical disease (renal tubular acidosis, malignant paraneoplastic syndromes), the modification of surgical technique (ischemia reperfusion injury and intrarenal surgery), or iatrogenic complications of surgery (hyponatremia, metabolic complications of urinary diversions). The purpose of this chapter is not to turn urologists into nephrologists, but rather to provide a firm fundamental knowledge of renal physiology and pathophysiology to provide the foundation for urologic specific conditions and therapies.

RENAL PHYSIOLOGY

Vascular (Renal Blood Flow and Glomerular Flow Rate)

Renal Blood Flow (RBF)

RBF is regulated by changes in vascular resistance of all the arteries up to and including the efferent arteriole, which in turn is regulated by a variety of neurohormonal signals (see below).

Blood enters the kidney through the renal arteries and divides into progressively smaller arteries (interlobar, arcuate, and interlobular arteries) until it enters the glomerular capillary through the afferent arteriole. A portion of the plasma that enters the glomerulus is filtered across the glomerular membrane; this is called the *filtration fraction*. The rest of the blood exits the glomerular capillary through the efferent arteriole. In nephrons located in the renal cortex, these capillaries travel in close proximity to the tubules and modulate solute and water reabsorption. In juxtamedullary nephrons (located deeper in the medulla), the efferent arterioles branch out to form vasa recta, which participate in the countercurrent mechanism through which urine is highly concentrated and body water conserved (see later discussion).

Under normal resting conditions, RBF is 20% of total cardiac output. Total blood flow is different for men and women, averaging 982 ± 184 mL/min in women and 1209 ± 256 mL/min in men (Dworkin and Brenner, 2004). Renal plasma flow (RPF) is slightly less, averaging 592 mL/min in women and 659 mL/min in men, and varies with hematocrit (RPF = RBF × [1–Hct]). RBF is not evenly distributed to all parts of the kidney. Flow to the outer cortex is 2 to 3 times greater than that to the inner cortex, which in turn is two to four times greater than that to the medulla (Dworkin and Brenner, 2004).

Determinants of Glomerular Filtration

The most important function of the kidney is the process of glomerular filtration. Through the passive ultrafiltration of plasma across the glomerular membrane, the kidney is able to regulate total body salt and water content, electrolyte composition, and eliminate waste products of protein metabolism.

The process of filtration is analogous to fluid movement across any capillary wall, and is governed by Starling forces. The glomerular filtration rate (GFR) is thus determined by both hydraulic and oncotic pressure differences between the glomerular capillary and the Bowman space, as well as by the permeability of the glomerular membrane:

$$GFR = LpS \times (\Delta \text{hydrostatic pressure} - \Delta \text{oncotic pressure})$$

where Lp = glomerular permeability and S = glomerular surface area.

The rate at which filtration occurs within an individual nephron is termed the "single nephron GFR" (SN-GFR). A more relevant measurement is that of total GFR, which is the sum of all SN-GFR and is expressed in milliliters per minute. **GFR is thus a reflection of overall renal function.** Alterations in GFR can occur either with alterations in any aspect of Starling forces, or through a change in renal plasma flow (RPF).

1. *Transglomerular (hydraulic) pressure (TGP)*—the most significant determinant of GFR is the TGP. Although systemic arterial pressures impact on TGP, the glomerular capillary is unique in that it is interposed between two arterioles (the afferent and efferent arterioles) and thus can regulate intraglomerular capillary pressure (IGP) independent of systemic pressures through changes in afferent and efferent arteriolar tone. Under normal circumstances, the pressure within the Bowman space is essentially zero, and only in conditions of urinary obstruction does the pressure increase to clinically significant levels. Thus the TGP = IGP.
2. *Renal plasma flow*—increases in RPF lead to increases in GFR. Although the filtration fraction cannot exceed 20% under normal circumstances, an increase in RPF will lead to an increase in absolute GFR.
3. *Glomerular permeability*—generally, an increase in permeability does not lead to an increase in GFR, because the

glomerulus is already at maximal permeability for water and other relevant solutes. It may, however, lead to increased filtration of larger molecules not normally filtered, such as albumin. Reductions in permeability, or in glomerular surface area, can lead to reductions in GFR.

4. *Oncotic pressure*—the least relevant of all the variables. Under normal circumstances, plasma proteins are not filtered across the glomerular membrane and so oncotic pressure within the Bowman space is essentially zero.

Regulation of Glomerular Filtration Rate

Under normal circumstances, GFR is tightly maintained at a relatively constant level, despite large fluctuations in systemic arterial pressures and renal blood flow. This is accomplished through the processes of autoregulation and tubuloglomerular feedback.

1. *Autoregulation*—with increases in mean arterial pressure (MAP), afferent arteriolar tone increases to minimize increases in IGP. Similarly, with reductions in MAP, afferent arteriolar tone decreases to allow increased flow into the glomerulus to maintain IGP, thus maintaining GFR. Autoregulation of IGP is effective to a MAP of about 70 mm Hg; below that, reductions in MAP lead to similar reductions in GFR, and below a MAP of 40 mm Hg, filtration ceases. The mechanism(s) by which autoregulation is achieved is not well understood. It is likely mediated through myogenic stretch receptors in the afferent arteriole wall, possibly mediated by adenosine triphosphate (ATP) (Schnermann and Levine, 2003), but angiotensin II is also involved with more severe fluctuations.
2. *Tubuloglomerular feedback (TGF)*—tubular ultrafiltrate flow rates are monitored by cells in the macula densa. If SN-GFR increases, delivery of sodium cations (Na^+) and chloride anions (Cl^-) to the distal tubule also increases. This increased Cl^- delivery triggers a response by the macula densa, which ultimately leads to an increase in afferent arteriolar tone and subsequent decrease in RPF, thus returning SN-GFR (and tubular flow) back to baseline (Schnermann et al, 1998). Thus TGF can be thought of as a mechanism to minimize salt and water losses through regulation of GFR. The mediators of this response are not well understood, but it seems that angiotensin II plays a permissive role in TGF. Both adenosine and thromboxane can cause afferent arteriolar vasoconstriction and have been implicated in TGF. Nitric oxide (Schnermann and Levine, 2003) is also believed to be important, particularly in minimizing TGF in the setting of increased NaCl intake.

Under abnormal conditions however, neurohumoral responses become more important. With significant reductions in effective circulating volume (ECV), both norepinephrine and angiotensin II play an important role in maintaining GFR through arteriolar vasoconstriction, often at the expense of reduced RPF. Notably, renal prostaglandins (PGs) and nitric oxide offset afferent arteriolar vasoconstriction; so, arteriolar tone is a balance between the vasoconstrictive and vasodilatory effects of the above-mentioned hormones. Inhibition of PG synthesis (due to administration of nonsteroidal anti-inflammatory drugs), particularly in states of high angiotensin II production, can lead to severe vasoconstriction and acute reduction in GFR. In contrast, norepinephrine and angiotensin II levels are diminished in states of volume expansion, while dopamine and atrial natriuretic peptide levels are increased to facilitate an increase in RPF (dopamine) and natriuresis (atrial natriuretic peptide [ANP]), thus returning volume status back to normal.

Clinical Assessment of Glomerular Filtration Rate

Unfortunately, GFR cannot be measured directly. It can, however, be estimated by a variety of methods, some more accurate (but usually more cumbersome) than others.

Renal Clearance. **The best estimate of GFR can be obtained by measuring the rate of clearance of a given substance from the plasma.** However, in order to be accurate, the substance to be measured must meet certain criteria. It must:

- Be able to achieve a stable plasma concentration,
- Be freely filtered across the glomerulus,
- Not be secreted, reabsorbed, synthesized, or otherwise metabolized by the renal tubules, and
- Not be impacted by any other means of removal from the plasma.

If all these criteria are met, then:

$$\text{Filtered X} = \text{excreted X}$$

and since

$$\text{Filtered X} = \text{GFR} \times \text{plasma [X]}$$

and since

$$\text{Excreted X} = \text{urine [X]} \times \text{urine volume (in mL/unit time)}$$

we can now see that

$$\text{GFR} \times \text{P[X]} = \text{U[X]} \times \text{urine volume}$$

$$\text{GFR} = \text{U[X]} \times \text{urine volume/P[X]}$$

This is called the *clearance* of a substance and reflects the amount of plasma that is completely cleared of the substance per unit time. There are a number of substances that have been used clinically to estimate GFR.

1. *Inulin*—is a fructose polysaccharide that meets the necessary requirements, and inulin clearance is felt to be the best measure of GFR. However, it is not clinically useful because it is difficult to administer (requires an intravenous infusion of inulin), and difficult to measure.
2. *Radiolabelled compounds*—such as iothalamate or diethylenetriaminepentaacetic acid (DTPA). These clearances are also very accurate, but are again limited in clinical use by their cost and availability (Perrone et al, 1990).
3. *Creatinine*—**the most widely used estimate of GFR is the 24-hour creatinine clearance (CrCl)** (Levey, 1990). It uses endogenous creatinine, which is produced at a constant rate. The rate of production varies from individual to individual, but for a single individual daily variability is less than 10%. It has the advantage of being easy to perform (no intravenous [IV] infusion), is relatively cheap, and readily available. However, it is less accurate than inulin clearance, because some creatinine is cleared from plasma through proximal tubular secretion; thus a CrCl overestimates true GFR, on average, by 10% to 20%. This becomes even more important as GFR declines, because tubular secretion increases in response to increasing serum creatinine levels and may contribute up to 35% of all creatinine removal at GFR levels of 40 to 80 mL/min (Shemesh et al, 1985). **At best, then, the CrCl should be considered the "upper limit" of the true GFR.**

Plasma Markers. An even simpler method to estimate GFR is with the use of plasma levels of substances that can be used as surrogate markers of GFR. To be useful, the substance must fulfill the criteria outlined above. Three such substances have been used:

1. *Plasma creatinine (PCr)*—**the most widely used plasma marker of GFR.** While creatinine production is constant within an individual from day to day, there is marked variation in production rates between individuals. The absolute rate depends upon muscle mass, which in turn is influenced by age, sex, and body mass. Thus **there is no single "normal" PCr that reflects a "normal" GFR; it must be individualized for every person.** This can be accomplished through mathematical manipulation (see below). However, the relationship of PCr to GFR is relatively constant (Fig. 38–1), and thus changes in PCr can be used to predict corresponding changes in GFR. As a general rule of thumb, every 50% reduction in GFR results in a doubling of PCr. There are limitations to the use of the PCr that should be noted:
   - As GFR falls, tubular secretion of creatinine increases; so, PCr may not change noticeably until there has been a significant drop in GFR (Shemesh et al, 1985).
   - Creatinine production may increase in states of increased muscle breakdown (e.g., rhabdomyolysis) or with increased dietary protein intake or supplementation, leading to an underestimation of true GFR.
   - Creatinine production may decrease with liver cirrhosis, leading to an overestimation of true GFR.
2. *Plasma urea*—another widely used plasma marker. Urea production and excretion is highly variable, influenced, for instance by dehydration, high-protein diets, and increased tissue breakdown. As a result, it is a much less reliable marker of GFR than is the PCr and should not be used as the sole determinant.
3. *Plasma cystatin C*—is an endogenous protein found in all nucleated cells. It has a constant rate of production unaffected by diet, and clearance is not influenced by tubular functions (Filler et al, 2005). This test is not widely available at present, but likely will replace PCr as the standard test in GFR assessment.

Mathematical Correction. **There are a number of mathematical formulas that have been developed to improve the accuracy of the PCr estimation of GFR** (National Kidney Foundation, 2002). The two most widely used are the Cockcroft-Gault and "modification of diet in renal disease" (MDRD) formulas.

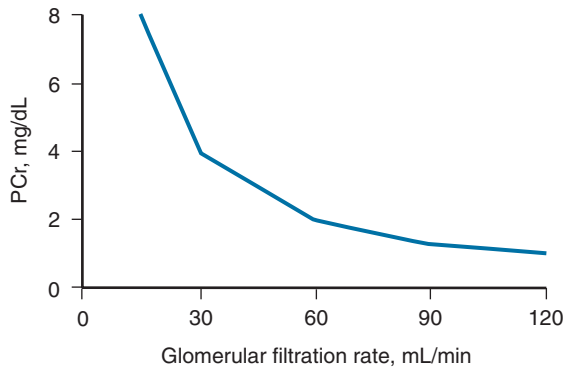

Figure 38–1. Relationship between serum creatinine and creatinine clearance. PCr, plasma creatinine.

1. *Cockcroft-Gault*—originally developed from data collected from individuals with normal renal function; it is a simple formula to estimate CrCl (not GFR) that corrects for age, sex, and body mass (Cockcroft and Gault, 1976). The formula is

$$\text{CrCl} = \frac{\{(140 - \text{age}) \times (\text{IBW in kg})}{[\text{PCr (mg/dL)} \times 72]\}} \times 0.85 \text{ (women)}$$

   It has the advantage of being very simple, but is not as accurate as other methods when renal function is impaired.
2. *MDRD formulas*—a series of formulas derived from data collected in patients with severe renal impairment; they are more complex but more accurate than the Cockcroft-Gault. The simplest estimate of GFR is the four-variable equation (PCr, age, sex, and ethnicity) (Manjunath et al, 2001):

$$\text{GFR (mL/min/1.73 m}^2) = 186 \times (\text{PCr [mg/dL]})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \times (1.210 \text{ if African American})$$

In summary, the GFR is analogous to renal function. Total GFR is a summation of all SN-GFR, which in turn are determined primarily by TGP and glomerular permeability of the individual nephrons, and it is usually tightly regulated. **A GFR estimate should be obtained in all patients with renal impairment (rather than a PCr alone), and the recommended method is through the use of the four-variable MDRD formula or Cockcroft-Gault formula**.

Key Points: Renal Blood Flow and Glomerular Filtration Rate

- GFR reflects total renal function.
- GFR can be approximated by creatinine clearance.
- Formulas based on patient's age, weight, and serum creatinine can best estimate GFR.

Hormonal

Control of Renal Vascular Tone

Vascular tone of the renal vessels, the net balance of vasoconstrictive and vasodilatory forces, is crucial to the maintenance of renal blood flow, GFR, tubular renal function, and systemic blood pressure. **There is a complex network of hormones and vasoactive substances with both direct and indirect effects, resulting in a system that is pleiotropic and redundant.** Although much has been learned from animal models about the function of individual molecules, the complexity of the total system can lead to unexpected outcomes when individual pathways are manipulated pharmacologically. A summary of substances known to impact vascular tone is given in Table 38–1.

Vasoconstrictors

Angiotensin II. Angiotensin II is a potent vasoconstrictor. In the kidney, there is a more pronounced constrictive effect on the efferent than the afferent arteriole, due to inhibition of angiotensin II actions in the afferent arteriole by nitric oxide and prostaglandin (Arima, 2003). Elevated levels of angiotensin II are important for maintaining GFR in pathologic conditions that reduce RBF (e.g., renal artery stenosis, dietary sodium restriction). The classical effects of angiotensin II (vasoconstriction, aldosterone release, sodium retention) are mediated by the AT1 receptor (Kaschina and

Unger, 2003). The AT2 receptor, however, may cause intrarenal dilation and be protective against renal ischemic injury (Carey, 2005).

Norepinephrine. Norepinephrine vasoconstricts all the major vascular beds in the kidney, mediated through the α_1 receptor. In patients who receive norepinephrine as a pressor agent in the face of systemic vasodilation, renal function is preserved and may actually improve (Albanese et al, 2004).

Endothelin. **Endothelin is the most potent vasoconstrictor yet identified.** There are three isoforms, with ET-1 being the most fully described. An endothelin precursor (big ET-1; 39 amino acids) is cleaved to ET-1 (21 amino acids) by an endothelin converting enzyme found on the endothelial cell membrane. The endothelin receptors are subclassified into ET (A), which are purely vasoconstrictive, and ET (B). The ET (B) receptors may cause either vasodilation by stimulating the release of nitric oxide from endothelial cells, or vasoconstriction of vascular smooth muscle cells (Fellner and Arendshorst, 2004). ET-1 release is stimulated by angiotensin II, antidiuretic hormone, thrombin, cytokines, reactive oxygen species, and shearing forces acting on the vascular endothelium. ET-1 release is inhibited by nitric oxide, as well as by prostacyclin and atrial natriuretic peptide. Blockade of the ET (A) receptor can reduce renal vasoconstriction seen in such ischemic conditions as ureteral obstruction (Bhangdia et al, 2003).

ET-1 has a number of other actions besides vasoconstriction. ET-1 stimulates aldosterone secretion, produces positive inotropy and chronotropy in the heart, decreases renal blood flow and GFR, and releases atrial natriuretic peptide. **Despite reduction in RBF, sodium excretion is increased,** suggesting that ET may be responsible for maintaining sodium balance when the renin-angiotensin system is depressed (Perez del Villar et al, 2005). Medullary blood flow is preserved in the face of endothelin induced vasoconstriction, which may explain the relative stimulation of tubular functions (Evans et al, 2004).

Table 38–1.

Vasoactive Substances That Control Renal Artery Tone

Vasoconstriction
Angiotensin II
Norepinephrine
Vasopressin
Endothelin
Atrial natriuretic peptide
Vasodilation
Nitric oxide
Carbon monoxide
Prostaglandin E_2
Acetylcholine
Serotonin/bradykinin
Glucocorticoids

Vasopressin. Vasopressin acts directly on blood vessels through the vasopressin V1 receptor but does not directly change RBF at low doses (Malay et al, 2004). Vasopressin does potentiate the vasoconstrictive effects of norepinephrine (Segarra et al, 2002) and can induce renal ischemia at high doses**. At the low doses typically employed in the management of septic shock, renal function is preserved** (Holmes et al, 2001).

Atrial Natriuretic Peptide. Atrial natriuretic peptide (ANP) is a vasoactive hormone synthesized primarily by the atria in response to stretching, as occurs during physiologic levels of volume expansion (Fig. 38–2). **The primary actions of ANP on the kidney are increased GFR and natriuresis.** ANP can increase GFR without a change in renal blood flow (Sward et al, 2005) by the combination of afferent arteriolar vasodilatation and efferent arteriolar vasoconstriction. In addition, ANP dilates vessels that have been preconstricted by norepinephrine, angiotensin II, or vasopressin. ANP production increases during bilateral obstructive uropathy, which may be one mechanism of preserving GFR (Kim et al, 2002).

ANP increases natriuresis mainly through inhibition of sodium reabsorption in the medullary collecting duct (Zeidel et al, 1988); decreased renin and decreased aldosterone production may also play a role (Laragh, 1985). Clinically, however, infusion of low-dose ANP during surgery increases water and electrolyte excretion without measured systemic changes in cortisol, angiotensin II, or aldosterone (Koda et al, 2005). This approach has also been used to prevent ischemic renal damage in high-risk cardiac surgery (Sward et al, 2004).

Vasodilators

Nitric Oxide. Nitric oxide (NO) is a highly reactive gas that participates in multiple physiologic and pathophysiologic reactions in the body. **NO is synthesized from the reaction between arginine, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and oxygen to produce citrulline, NADP, water, and NO.** This reaction is catalyzed by a family of enzymes called nitric oxide synthase (NOS).

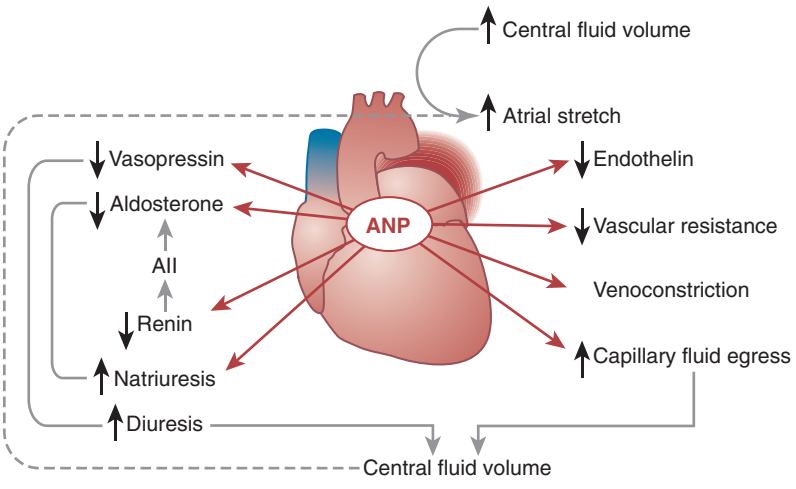

Figure 38–2. Schematic representation of the fundamental biologic processes of atrial natriuretic peptide (ANP). AII, angiotensin II.

Although all NOS enzymes catalyze the same reaction, they differ in distribution, expression, and stimuli. Neuronal (nNOS, NOS-1) and endothelial (eNOS, NOS-3) are constitutively expressed, and iNOS (NOS-2) is inducible. **eNOS is found in the vascular endothelium, and the NO produced there plays a key role in vasodilation and vascular remodeling** (Rudic et al, 1998). eNOS expression is stimulated by shear stress by activation of the tyrosine kinase c-SRC (Davis et al, 2004), by heat shock protein 90 (Harris et al, 2003), by oxidant stress (Cai et al, 2001), and by vascular mediators such as bradykinin, serotonin, adenosine, ADP/ATP, histamine, and thrombin (Arnal et al, 1999).

After its formation by vascular endothelial cells, NO diffuses to vascular smooth muscle cells where it activates soluble guanylyl cyclase (sGC), producing 3′,5′-cyclic guanosine monophosphate (cGMP). Subsequently, cGMP activates both cGMP- and 3′,5′-cyclic adenosine monophosphate (cAMP)-dependent protein kinases (PKG and PKA, respectively) leading to smooth muscle relaxation. eNOS blockade increases renal vascular resistance and decreases the glomerular ultrafiltration coefficient (Gabbai, 2001). NO also helps maintain vascular integrity, with increased expression being linked to decreased neointimal formation and medial thickening (Kawashima et al, 2001). Indeed, the degenerative changes seen in chronic allograft nephropathy related to cyclosporine use can be mitigated by increased nitric oxide expression (Chander et al, 2005). Increased eNOS activity is also associated with protection from renal ischemia-reperfusion injury (Shoskes et al, 1997).

Although raised local levels of NO from eNOS can be beneficial to renal function, induction of iNOS and overproduction of NO from inflammatory cells can be deleterious. In the face of free oxygen radicals at the site of inflammation, NO can interact with reactive oxygen species to form peroxynitrite, which induces protein damage by formation of nitrotyrosine. Increased iNOS has been related to damage from nitrotyrosine in glomerular disease (Trachtman, 2004), lupus nephritis (Takeda et al, 2004), and transplant rejection (Albrecht et al, 2002). Increased iNOS activity has direct renal effects as well, including upregulation of sodium and bicarbonate tubular transport (Wang, 2002).

Carbon Monoxide. Carbon monoxide (CO) gas is another reactive diffusible mediator with multiple effects throughout the body, especially in the kidney. **Heme oxygenase (HO), an essential enzyme in heme catabolism, catalyzes the rate-limiting step in heme degradation, resulting in the formation of iron, carbon monoxide, and biliverdin** (Hill-Kapturczak et al, 2002). Biliverdin is subsequently converted to bilirubin by biliverdin reductase. HO is expressed in two forms, constitutive HO-2 and inducible HO-1. Increased CO production produces vasodilation in the kidney and can counteract catecholamine induced vasoconstriction (Mustafa and Johns, 2001). In particular, both HO-1 and HO-2 are highly expressed in the medulla and help maintain renal medullary blood flow (Zou et al, 2000). In cirrhosis, decreased renal expression of HO-1 is linked to renal dysfunction (Miyazono et al, 2002). CO also regulates sodium transport in the loop of Henle, with HO-2 blockade inhibiting sodium excretion (Wang et al, 2003) and stimulation increasing natriuresis and diuresis (Rodriguez et al, 2003).

The other primary effect of CO in the kidney is renoprotection from oxidant injury. CO has documented anti-inflammatory, antioxidant, and cytoprotective actions (Sikorski et al, 2004). Indeed, a patient with a genetic HO-1 deficiency had significant tubular and vascular endothelial injury (Ohta et al, 2000). Increased CO is protective against ischemia-reperfusion injury in native and transplant kidneys (Nakao et al, 2005). Induction of HO-1 through agents such as bioflavonoids protects against tubular damage and improves renal transplant function (Shoskes et al, 2003).

Key Points: Hormonal

- Multiple chemical mediators act on renal vascular tone, which controls renal blood flow.
- Endothelin is the most potent vasoconstrictor.
- Nitric oxide and carbon monoxide are potent vasodilators.

Erythropoiesis

Red blood cell (RBC) production is a tightly regulated process. Basal RBC production is roughly 10 RBCs/hr, but this rate can be greatly increased during times of anemia or hypoxia. The kidney is the major organ involved in this process, and is responsible for monitoring RBC levels and increasing RBC output through the production of the hormone erythropoietin.

Erythroid Progenitor Cells. Mature RBCs are produced from a small pool of multipotent progenitor cells (Suda et al, 1984), which in turn are derived from the fetal liver. The earliest committed cell is the erythroid burst-forming unit (BFU-E), which, under appropriate stimulation, divides to produce erythroid colony-forming units (CFU-E). Further differentiation leads to the production of proerythroblasts, reticulocytes, and, ultimately (after extrusion of the nucleus), mature RBCs. The entire process requires about 2 weeks.

Erythropoietin. Maturation of the BFU-E and CFU-E depends on the appropriate growth factors. The most important of these factors is erythropoietin (EPO). The kidney is responsible for the majority of EPO production (90%), while the liver may contribute a smaller amount (10%). Kidney-derived EPO is produced by a subpopulation of interstitial fibroblasts, and possibly proximal tubular cells, in response to decreased O_2 tension.

EPO-deficient mice die in utero with a marked reduction in erythropoiesis (Munugalavadla and Kapur, 2005). Additional growth factors such as interleukin-3, GM-CSF, stem cell factor, activin, insulin-like growth factor (IGF-I), and, possibly, hepatic growth factor act synergistically with EPO to reduce apoptosis and thus promote proliferation of erythroid cells (Muta and Krantz, 1993).

EPO has also been shown to have effects outside of the bone marrow. EPO receptors have been demonstrated in kidney, brain, retina, heart, skeletal muscle, and endothelial cells (Juul et al, 1998). In the kidney, pretreatment with high-dose EPO has been shown to reduce ischemia-reperfusion injury in animal models, due to decreased apoptosis (Patel et al, 2004).

Regulation of EPO Production and Erythropoiesis. Production of EPO, and hence erythropoiesis, is closely associated with circulating O_2 tension. Under hypoxic conditions, the alpha subunit of the regulatory protein hypoxia-inducible factor-1 (HIF-1) is exposed (Wang et al, 1995). Binding of HIF-1 alpha with HIF-1 beta, hepatic nuclear factor-4 (HNF-4), and p300 turns on erythropoietin transcription (Arany et al, 1996). Once the hypoxia has been corrected, HIF-1 alpha is ubiquinated and rapidly degraded by proteosomes, thus shutting down erythropoietin production. There is also in-vitro evidence that hypoxia itself may directly increase erythropoiesis through HIF-1–mediated increases in autocrine motility factor (AMF) production and subsequent decrease in apoptosis (Mikami et al, 2005).

In states of chronic inflammation, erythropoiesis is decreased. Apoptosis of erythroid progenitor cells occurs in the presence of

the tumor-associated antigen RCAS1, which is also produced by macrophages under inflammatory conditions (Suehiro et al, 2005).

In certain malignancies, such as renal cell carcinoma, erythropoiesis is enhanced due to a mutation in the von Hippel-Lindau (VHL) gene. As a result, there are constitutively increased levels of HIF-1 and polycythemia (Wiesener et al, 2002).

Erythropoiesis is also decreased in most forms of chronic renal failure, and subsequently anemia is common in the later stages of the disease. This is due to decreased EPO levels as a result of a reduction in the number of functional EPO-producing cells within the kidney. Recombinant human erythropoietin (rHuEPO) has been shown to be an effective treatment for this type of anemia.

rHuEPO has also been used to treat anemia associated with malignancy but must be used with caution in these conditions because its use may be associated with an increased risk of venous thromboembolism and higher mortality (Bennett et al, 2008).

Bone Mineral Regulation

Normal regulation of bone mineralization, through maintenance of serum calcium and phosphorus levels, is achieved through the actions of vitamin D and parathyroid hormone (PTH). The actions of both hormones are exerted largely through the kidney (Fig. 38–3).

Vitamin D Regulation. **The kidney plays an important role in the regulation of vitamin D activity**. The major source of vitamin D is through dermal synthesis of the precursor compound cholecalciferol (vitamin D_3), or through dietary intake of vitamin D_3–fortified foods. Vitamin D_3 has minimal biological activity and requires two hydroxylations to become active. The first occurs in the liver through the action of 25-hydroxylase to form 25-hydroxycholecalciferol (calcidiol). The calcidiol molecule is bound to vitamin D binding protein and transported to the kidney, where it is filtered and reabsorbed by renal tubular cells. A second hydroxylation occurs within the tubular cell. Because these cells contain both 1α-hydroxylase and 24α-hydroxylase, hydroxylation will produce either inactive 24,25-dihydroxycholecalciferol or 1,25-dihydroxycholecalciferol (calcitriol), the biologically active form that is one hundred times more potent than calcidiol. Calcitriol production is regulated by calcidiol levels as well as the 1α-hydroxylase levels. These are, in turn, determined by PTH and plasma phosphate levels (increased enzyme activity) and serum calcitriol levels (decreased enzyme activity) (Portale et al, 1989). However, unregulated calcitriol synthesis can occur in macrophages in granulomatous conditions such as sarcoidosis and tuberculosis, and in prostate epithelial and cancer cells (Young et al, 2004).

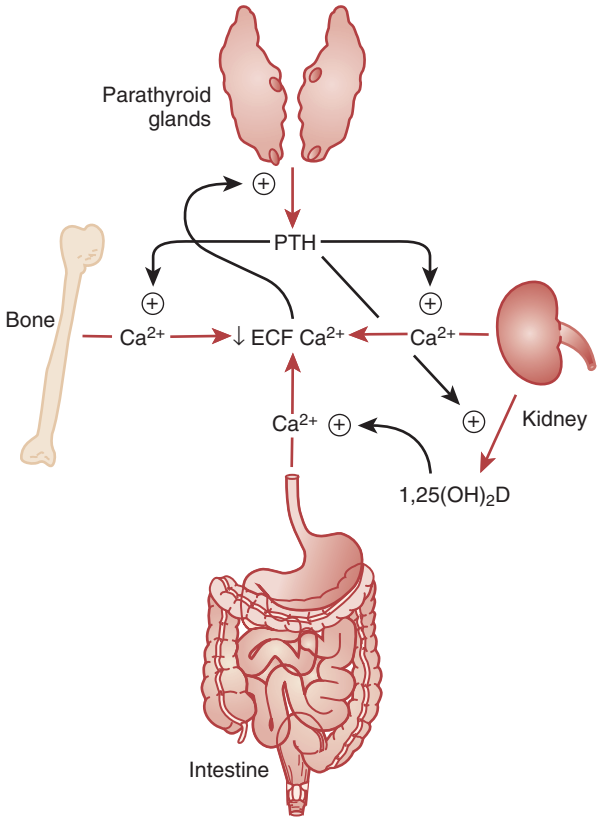

Figure 38–3. Effects of vitamin D and parathyroid hormone (PTH) on calcium homeostasis. ECF, extracellular fluid. (From Yu SLY. Renal transport of calcium, magnesium, and phosphate. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 536.)

Vitamin D Activity. Calcitriol functions through a single intracellular vitamin D receptor (VDR) to regulate gene transcription (Lowe et al, 1992). Its primary function is the maintenance of serum calcium and phosphorus levels. The four main target organs are the intestine (increases intestinal absorption of calcium, and to a lesser extent, phosphorus), the bones (regulates osteoblast activity, and in combination with PTH, allows for osteoclast activation and bone resorption), the kidney (increases reabsorption of calcium) and the parathyroid gland (suppresses PTH release). Recent evidence suggests that both calcidiol and calcitriol may also function as antiproliferative agents. Prostate epithelial and cancer cells demonstrate VDR, and vitamin D may suppress the growth of these cells, especially in combination with androgens (Tuohimaa et al, 2005).

In summary, vitamin D contributes to normal bone mineralization by maintaining normal serum calcium and phosphorus levels through increased intestinal absorption of calcium and phosphorus and increased renal reabsorption of calcium.

Parathyroid Hormone Regulation. Synthesis, secretion, and degradation of PTH are influenced directly by serum calcium levels through calcium sensing receptors located on parathyroid cells. During periods of hypocalcemia, PTH synthesis and secretion are increased while degradation is decreased. The opposite occurs during hypercalcemia. In addition, calcitriol has a suppressive effect on PTH synthesis and parathyroid cell proliferation, mediated through vitamin D receptors located on the surface of parathyroid cells. Hyperphosphatemia also directly stimulates PTH release, primarily in advanced renal insufficiency. Finally, other cations such as magnesium and aluminum have slight stimulatory effects, likely mediated through the calcium sensing receptors.

Parathyroid Hormone Activity. PTH exerts its activity through PTH/PTHrP receptors, which are localized primarily in the kidneys and bone.

Bone. Its effect on bone metabolism depends upon its administration; if given continuously, it stimulates bone resorption and increases serum calcium and phosphorus levels. Given intermittently, it leads to increased bone formation and mineral density.

Kidney. The renal effects of PTH are threefold. First, it increases active calcium reabsorption at the level of the distal tubule (Friedman and Gesek, 1993). Second, it decreases phosphate reabsorption in the proximal convoluted tubule (and the distal tubule, to a lesser degree) through its action on the sodium phosphorus cotransporter (Pfister et al, 1997). Third, it stimulates calcitriol production by increasing 1α-hydoxylase levels while decreasing 24α-hydroxylase levels (Broadus et al, 1980).

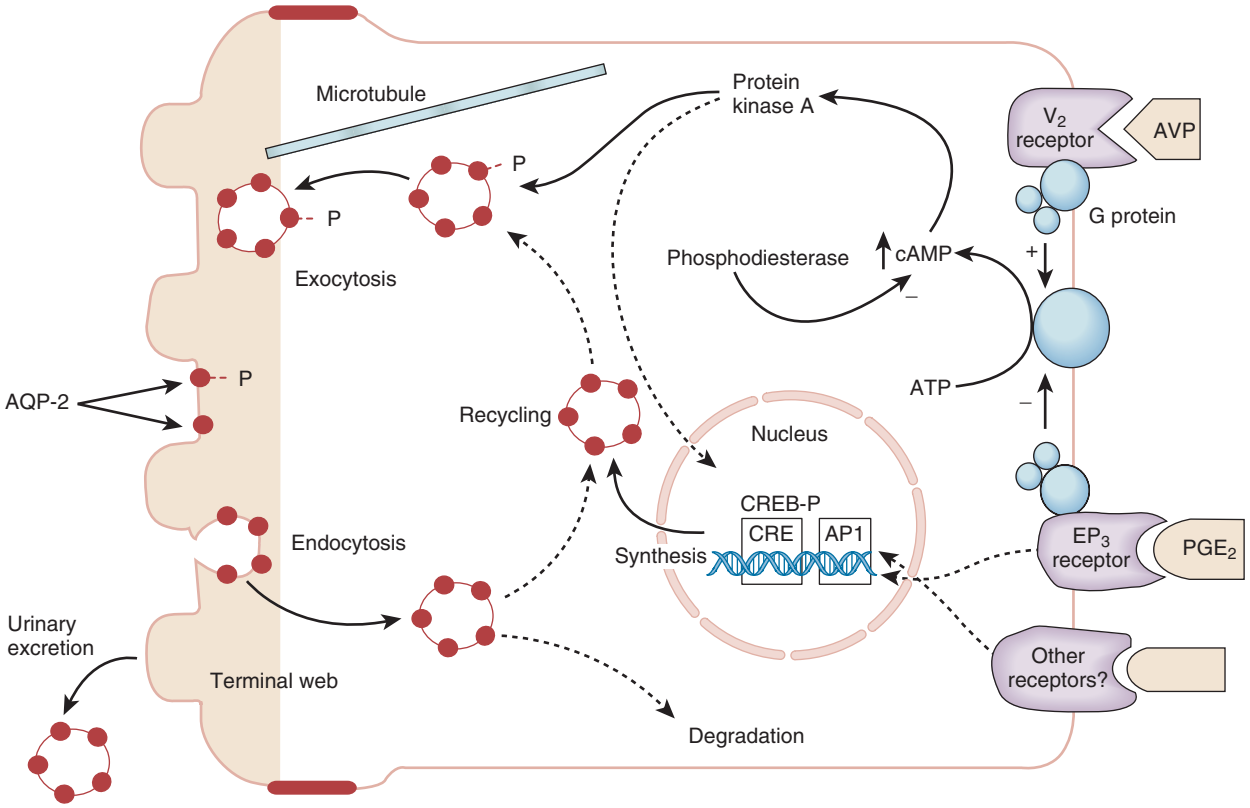

Figure 38–4. Action of antidiuretic hormone on aquaporin (AQP) transport. AC, adenylate cyclase; AP1, transcription factor; AVP, arginine vasopressin; cAMP, cyclic adenosine monophosphate; CRE, cAMP response element; CREB-P, CRE binding protein; EP_3, prostaglandin receptor; PGE_2, prostaglandin E_2. (From Brown D, Nielsen S. The cell biology of vasopressin action. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 574.)

In summary, PTH functions to maintain normal serum calcium and phosphorus levels by increasing bone resorption, increasing renal reabsorption of calcium and excretion of phosphorus, and stimulating production of calcitriol.

Antidiuretic Hormone

Antidiuretic hormone (ADH), or arginine vasopressin as it is called in humans, is a polypeptide secreted by the posterior pituitary gland. It functions to maintain serum osmolality and volume through the regulation of free-water excretion in the kidney.

ADH Actions. **ADH increases the passive reabsorption of water at the level of the collecting duct.** Through interaction with the V2 receptor, it facilitates the insertion of preformed water channels, known as aquaporin-2 (AQP-2), into the luminal membrane of the principal cells (Agre et al, 2002). This allows luminal water to enter the cell and then diffuse back into the systemic circulation through the basolateral membrane of the cell (Fig. 38–4). ADH increases urea reabsorption in the medullary collecting tubule through specific urea transporters, which helps maintain the high interstitial osmolality required for water reabsorption. ADH also increases systemic vascular resistance through interaction with the V1 receptor; this is of minor physiologic importance. Other effects of ADH include increased sodium reabsorption and potassium excretion, increased prostaglandin synthesis, increased ACTH secretion (through V3 receptors), and release of both factor VIII and von Willebrand factor from vascular endothelium.

Control of ADH Secretion. There are two major stimuli for ADH release, hyperosmolality and decreased effective circulating volume (ECV), as well as a number of less common factors (Table 38–2).

Table 38–2.
Physiologic and Pathologic Factors Affecting the Release of Antidiuretic Hormone

STIMULI	INHIBITORS
Hyperosmolality	Hypo-osmolality
Hypovolemia	Hypervolemia
Stress (e.g., pain)	Ethanol
Nausea	Phenytoin
Pregnancy	
Hypoglycemia	
Nicotine	
Morphine	
Other drugs	

Hyperosmolality. The major extracellular osmole is sodium; so, for practical purposes ADH release is governed by changes in serum sodium concentrations. Serum osmolality is monitored by osmoreceptors in the hypothalamus, and changes as little as one percent are enough to affect ADH release (Robertson, 1987).

Decreased ECV. Circulating volume is monitored by pressure (baro-) receptors in the carotid sinus, which stimulate ADH release in response to reductions in ECV. These receptors are much less sensitive than the osmoreceptors, and, as such, ADH release is not affected until there is a noticeable drop in mean arterial pressures (usually around 10% to 15% blood volume loss) and after other

vasoconstrictive hormones, such as renin and norepinephrine, have been activated.

Other Stimuli. There are a number of other factors that can increase ADH secretion (see Table 38–2). Nausea and pain are probably the most clinically relevant, and, as a result, postsurgical hyponatremia due to excessive ADH release is a potentially life-threatening problem.

When both decreased ECV and hyponatremia coexist, the pressure receptors usually override the osmoreceptors and prevent the inhibition of ADH secretion that is usually seen with hyponatremia (Baylis, 1987). This is clinically relevant in conditions of decreased ECV and hyponatremia, such as congestive heart failure where ADH secretion persists despite significant hyponatremia.

Renal Tubular Function

Basic Functions

The renal tubule has two basic functions: *reabsorption* (transport of substances from lumen to blood) and *secretion* (transport of substances from blood to lumen). Transport can involve one of two pathways: either *transcellular* (across the luminal and basolateral membrane) or *paracellular* (between cells) (Fig. 38–5). **Each section of the tubule** (Fig. 38–6) **is specialized to facilitate absorption and secretion of certain substances through a variety of transport mechanisms.**

Proximal Convoluted Tubule (PCT)

The PCT is responsible for reabsorption of 60% of the glomerular filtrate. Under normal circumstances it reabsorbs 65% of the filtered sodium, potassium, and calcium; 80% of filtered phosphate, water, and bicarbonate; and 100% of the filtered glucose and amino acids (Moe et al, 2004). The PCT is able to increase or decrease reabsorption in response to changes in GFR to maintain constant reabsorptive fractions through the process of *glomerulotubular balance*. This is accomplished mainly by the early (S1 and S2) segments of the PCT. The later (S3) segment is responsible for secretion of numerous drugs and toxins that are too large, or protein bound, to be filtered. As well, the PCT is responsible for the generation of ammonia from glutamine, which is necessary for urinary acidification.

Sodium. The majority of sodium reabsorption occurs in the PCT, and occurs through both secondary active and passive mechanisms (Fig. 38–7).

1. *Secondary active reabsorption*—luminal Na^+ moves passively into tubular cells; this movement, though, is driven by osmotic and electrochemical gradients between the luminal and intracellular environments established by the energy-requiring Na-K ATPase located in the basolateral cell membrane. There is an active exchange of three intracellular Na^+ for two extracellular K^+ ions, which keeps the intracellular sodium concentration low and the cell interior negative with respect to the lumen. This is called *secondary passive reabsorption*. Na^+ then enters the cell through coupled transport with other solutes (see below) or in exchange for H^+ through a Na^+/H^+ antiporter. The activity of this transporter is under neurohormonal regulation, and can be influenced by angiotensin II, norepinephrine, and dopamine to either increase or decrease Na^+ reabsorption in response to changes in effective circulating volume.

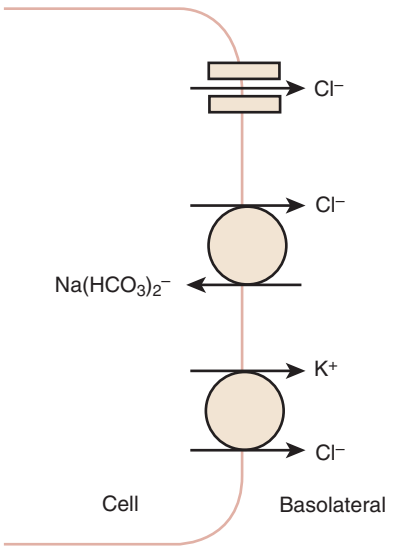

Figure 38–5. Example of transcellular transport between the tubule cell and the basolateral membrane. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 425.)

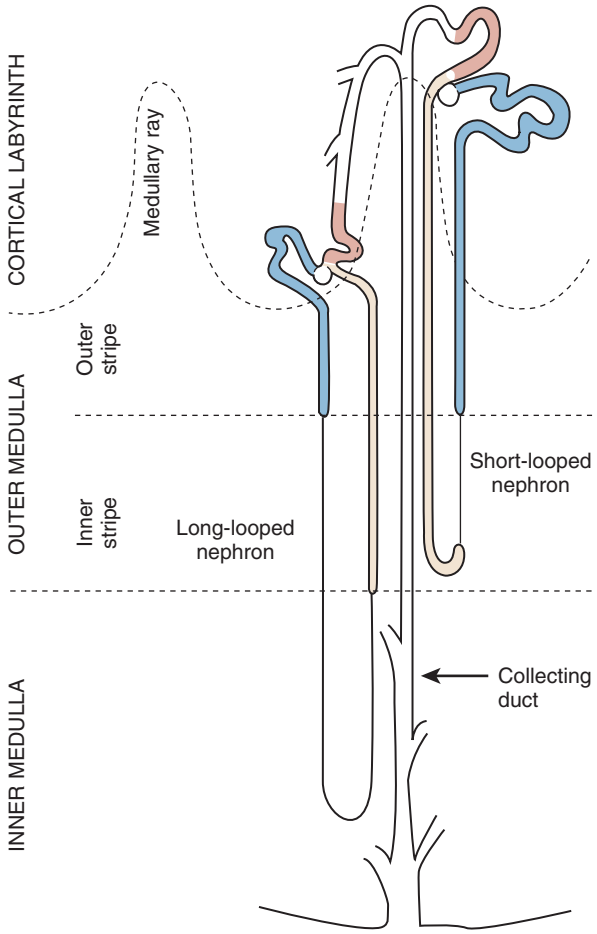

Figure 38–6. Organization of the renal tubule. (From Knepper MA, Gamba F. Urine concentration and dilution. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 601.)

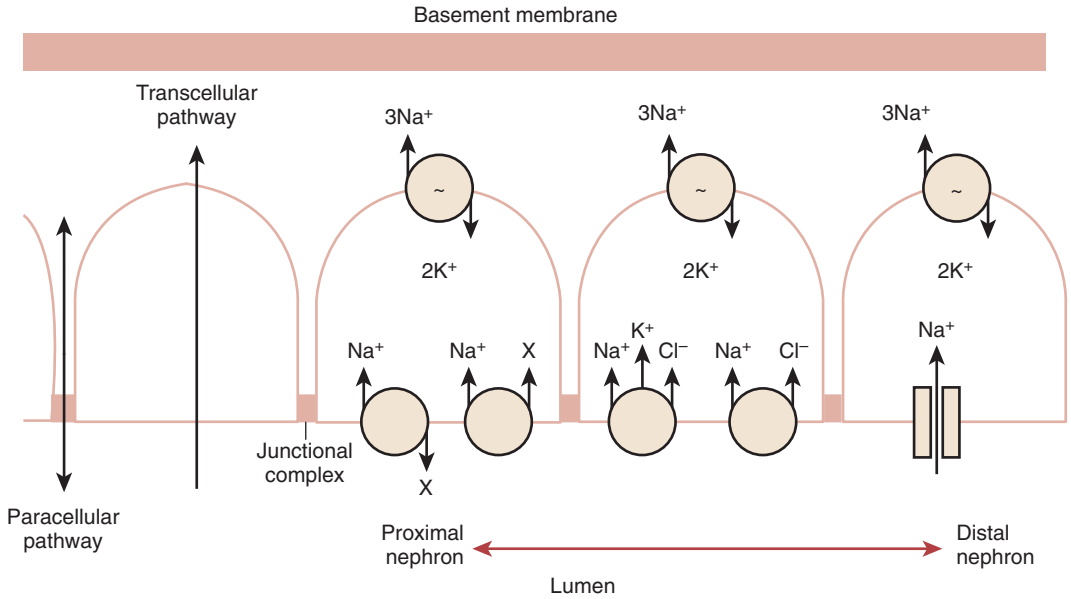

Figure 38–7. Mechanisms of sodium reabsorption in the proximal tubule. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 414.)

2. *Passive reabsorption*—this occurs when Na^+ moves paracellularly into the intercellular space. It is meditated through Cl^- transport across the paracellular pathway, which creates an electrochemical gradient favoring Na^+ movement out of the lumen into the intercellular space.

In summary then, sodium is the most significant solute for the PCT for three reasons:

- It is the only solute that is actively reabsorbed (through the basolaterally located Na-K ATPase pump).
- All other solutes are passively reabsorbed through Na^+ coupled transport.
- Early reabsorption of Na^+ (as well as other solutes) creates an osmotic gradient that facilitate passive reabsorption of water.

Potassium. The majority of potassium reabsorption occurs by the paracellular route. It is largely dependent on sodium and fluid movement, as potassium reabsorption parallels that of water and sodium.

Bicarbonate. **The majority of filtered bicarbonate (90%) is reclaimed in the PCT.** There is no upper limit to bicarbonate reabsorption; in states of volume depletion and increased proximal reabsorption of Na^+, bicarbonate reabsorption continues even in the presence of significant alkalemia (Moe et al, 2004). Bicarbonate is not transported across PCT cells; its reabsorption is dependent upon H^+ secretion by the Na^+/H^+ antiporter. Within the lumen, bicarbonate combines with H^+ to form H_2O and CO_2, which can diffuse intracellularly and be converted back to H^+ and bicarbonate and subsequently secreted through the basolateral membrane by a Na^+-coupled transporter and returned to the circulation. Both these reactions are catalyzed by carbonic anhydrase (Fig. 38–8).

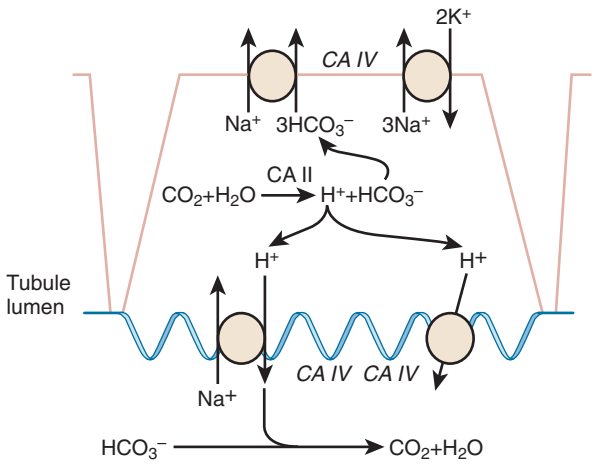

Figure 38–8. Reabsorption of bicarbonate in the renal tubule. CA, carbonic anhydrase. (From Hamm LL. Renal acidification mechanisms. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 500.)

Water. **Water reabsorption in the PCT is a passive process, driven by the reabsorption of other solutes and the subsequent osmotic gradient that develops between the lumen and intercellular space.** The majority of water reabsorption occurs in the late PCT. As with Na^+ movement, water can also move either transcellularly or paracellularly. Transcellular movement accounts for 80% of water reabsorption, and occurs through the specialized water channel aquaporin-1 (AQP-1) (Agre et al, 2002). Paracellular movement accounts for only 20% of water reabsorption and occurs across the tight junctions between cells.

Glucose. Glucose reabsorption is driven by passive Na^+ reabsorption. In the early (S1 and S2) PCT, this occurs through a high-capacity, low-affinity Na^+/glucose transporter called SGLT-2 (Moe et al, 2004). In the later (S3) segment of the PCT, reabsorption occurs through a low-capacity, high-affinity $2Na^+$/glucose transporter (also found in intestine) called SGLT-1. Intracellular glucose is then transported out of the cell through the basolateral membrane by the facilitative transporter GLUT-2. Under normal plasma glucose levels, all filtered glucose is reabsorbed. **However, if plasma levels exceed 200 mg%, then the filtered load will exceed the reabsorptive threshold and urinary glucose will be detected** (Fig. 38–9).

Proteins and Amino Acids. Amino acid transport is very complex. Generally, there are separate transporters for the basic, acidic, and neutral amino acids, and most are Na^+ dependent. There are a few amino acids that have specialized transporters, and some are Na independent. Larger proteins are usually catabolized by brush border peptidases and reabsorbed as amino acids; some, however, enter the cell through carrier-mediated endocytosis.

Phosphate. About 85% to 90% of filtered phosphate is reabsorbed, primarily in the PCT. Phosphate reabsorption occurs through a Na^+-phosphate cotransporter. The activity of this transporter is regulated by both plasma phosphate levels and parathyroid hormone levels (Fig. 38–10).

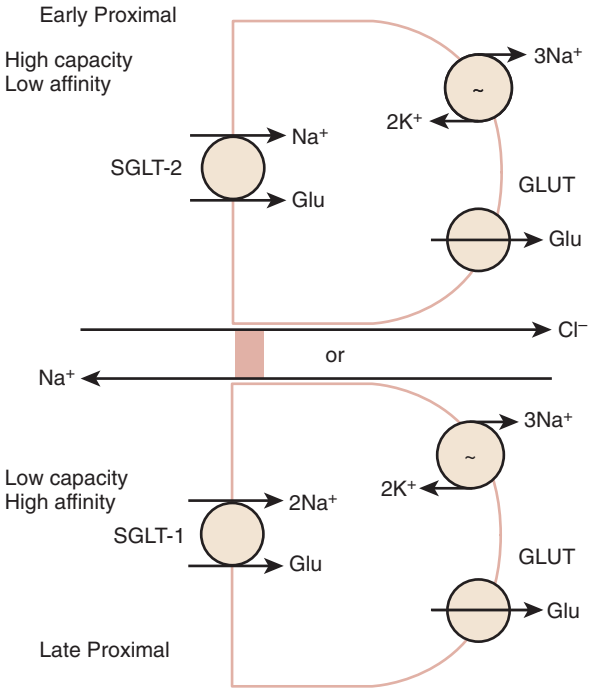

Figure 38–9. Absorption of glucose by the renal tubule. GLUT, glucose transporter; SGLT, sodium glucose-linked transporter. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 417.)

Calcium. Most calcium reabsorption occurs in the late S2 segment and early S3 segment of the PCT. It is a passive process, driven by the lumen (+) potential difference (PD). Calcium movement occurs by the paracellular route, through the specific calcium channel claudin-2 (Amasheh et al, 2002), located in the tight junctions. It is also possible that there is a small amount of active calcium reabsorption in the late S3 segment, but this is poorly characterized (Fig. 38–11).

Magnesium. About 15% of filtered magnesium is reabsorbed in the PCT, but the mechanism is poorly understood (Konrad et al, 2004).

Loop of Henle

The loop of Henle consists of four segments; the thin descending limb (DLH), the thin ascending limb (ALH), the medullary thick ascending limb (mTALH), and the cortical thick ascending limb (cTALH). It receives the 40% of ultrafiltrate not reabsorbed by the PCT. **Each segment of the loop of Henle has specific functions related to fluid, electrolyte, and acid-base balance, but the major function of the loop, as a whole, is to reabsorb 25% to 30% of the filtered Na^+ and to reabsorb**

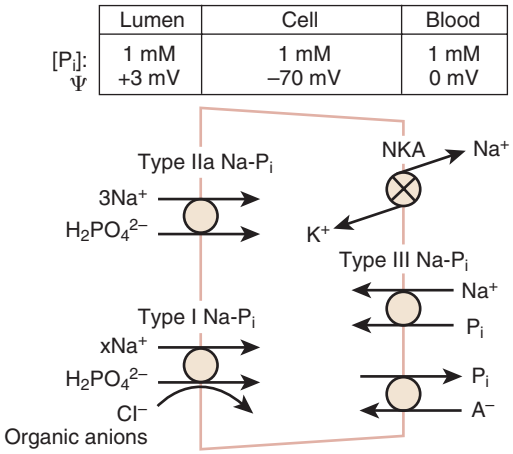

Figure 38–10. Absorption of phosphate by the renal tubule. (From Yu SLY. Renal transport of calcium, magnesium, and phosphate. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 555.)

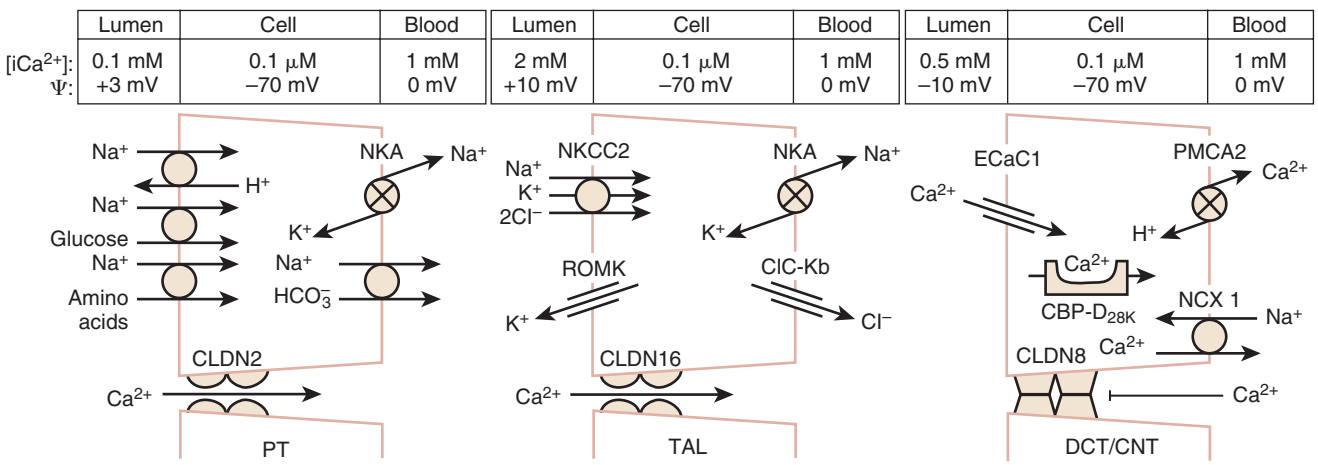

Figure 38–11. Absorption of calcium by the renal tubule. CNT, connecting tubule; DCT, distal convoluted tubule; PT, proximal tubule; TAL, thick ascending limb. (From Yu SLY. Renal transport of calcium, magnesium, and phosphate. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 538.)

NaCl in excess of water to establish an extremely concentrated medullary interstitium, which is necessary for the excretion of a concentrated final urine. The loop of Henle, like the PCT, is also controlled by glomerulotubular balance, which maintains a consistent ultrafiltrate delivered to the collecting ducts (Fig. 38–12).

Thin Descending Limb. The DLH consists of the segment of the nephron between the end of the PCT (S3 segment) and the bottom of the loop. Cortical nephrons, in general, have short DLH while juxtamedullary nephrons have longer DLH. There is very little active transport of any kind within the DLH, but it has very high water permeability due to abundant expression of AQP-1 (Agre et al, 2002).

Thin Ascending Limb. The ALH begins at the loop and continues up to the thick ascending limb. The AHL is of variable length; cortical nephrons may have very little ALH. Similar to the DLH, there is no active transport of solutes. However, unlike the DLH, the AHL is water impermeable. There is high permeability for NaCl as well as urea; so, reabsorption of these solutes occurs passively along an osmotic gradient, because the luminal concentrations of these solutes is quite high due to water removal during transit through the DLH.

Thick Ascending Limb. The TALH is far more active in terms of solute reabsorption than either thin limbs. Water reabsorption, however, is negligible because this segment of the loop is entirely impermeable to water due to the lack of aquaporins.

Sodium, Potassium, and Chloride. The TALH reabsorbs 25% to 30% of the sodium filtered across the glomerulus. This is primarily through the secondary active process driven by basolateral Na-K ATPase pumps that keep intracellular sodium concentration low. Na^+ is transported transcellularly by a $Na^+/K^+/2Cl^-$ (NKCC2) transporter located in the apical membrane. Once inside the cell, Cl^- is pumped out across the basolateral membrane by a Cl^-/K^+ cotransporter, which helps keep intracellular chloride concentration low. K^+, however, preferentially exits the cell back through the apical membrane K channel ROMK and reenters the tubular lumen, where it can interact once again with the NKCC2 transporter. **This K^+ recycling is important; without it, sodium reabsorption would be limited by the luminal potassium concentration, which is much lower than either sodium or chloride concentrations.** By recycling K^+, the tubule is able to reabsorb sodium independent of potassium. A secondary benefit of this process is to help establish a lumen (+) PD, which helps facilitate paracellular transport of a variety of cations, including sodium (Fig. 38–13).

The NKCC2 transporter is the site of action of loop diuretics. These drugs bind to the Cl^- receptor and interfere with normal transporter action, resulting in decreased NaCl reabsorption and subsequent diuresis.

Sodium reabsorption along the TAHL, in the absence of water reabsorption, is critical to the formation of the interstitial concentration gradient. This gradient is essential to subsequent urinary concentrating ability in the collecting duct. It also creates a progressively more hypotonic ultrafiltrate, which is important for water diuresis to occur (see below).

Calcium and Magnesium. About 15% of the filtered calcium is reabsorbed in the TALH. Reabsorption is passively driven by the lumen (+) PD by the paracellular route, facilitated by the calcium channel paracellin-1 (also known as claudin-16). Magnesium reabsorption (60% to 70%) also occurs in the TALH in a similar manner (Konrad et al, 2004). Inhibition of the NKCC2 transporter with loop diuretics induces renal calcium and magnesium wasting due to dissipation of the lumen (+) PD.

Bicarbonate. The TALH also reabsorbs 10% to 20% of the filtered bicarbonate, mainly through H^+ secretion by using the Na^+/H^+ exchanger. Water reabsorption occurring in the DLH increases bicarbonate reabsorption by increasing luminal bicarbonate concentrations.

Countercurrent Mechanism. A critical function of the kidney is the preservation of body water; this is accomplished through the osmotic reabsorption of solute-free water in the collecting tubule

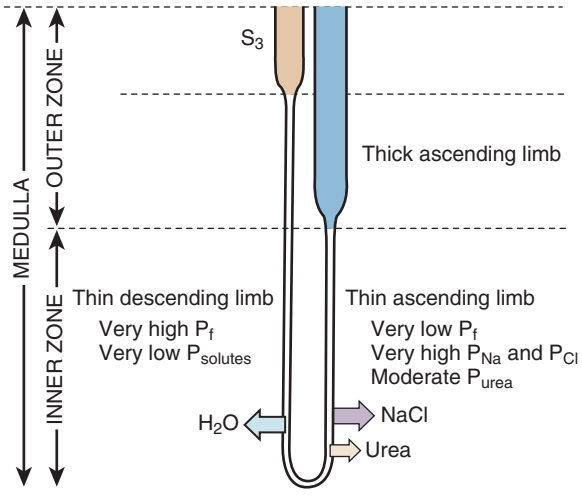

Figure 38–12. Anatomy of the loop of Henle. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 431.)

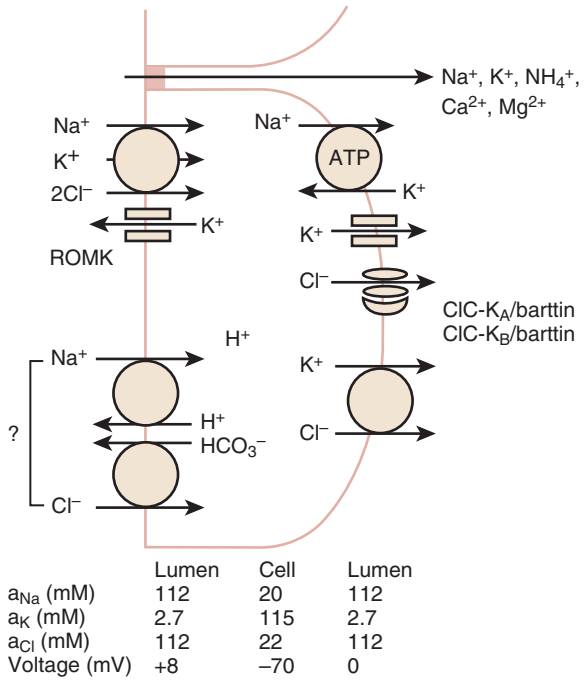

Figure 38–13. Paracellular transport of cations in the thick ascending limb. ROMK, renal outer medullary potassium channel. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 433.)

(see later) and the excretion of urine that is hyperosmolar with respect to plasma. Human kidneys can produce a urine concentration up to 1200 mOsm/kg. **To achieve this degree of urinary concentration, the kidney must be able to generate an interstitial osmotic gradient of similar degree.** Through the process of *countercurrent multiplication*, the loop of Henle is able to produce an interstitial osmotic gradient ranging from 285 mOsm/kg (isosmotic with plasma) in the outer medulla to 1200 mOsm/kg in the inner medulla. The basic steps of countercurrent multiplication are as follows:

1. Medullary interstitium is made hyperosmolar by the reabsorption of NaCl (in the absence of water reabsorption) in the ascending limbs of the loop of Henle.
2. Due to the hairpin (*countercurrent*) configuration of the loop, the concentration of the luminal fluid can be progressively increased *(multiplied)* to as much as 1200 mOsm/kg (Fig. 38–14). This allows the interstitial osmolarity to increase to similar levels.
3. In the presence of ADH, urea diffuses from the medullary collecting tubule into the interstitium, increasing the interstitial osmolarity even further (Yang and Bankir, 2005). This has a secondary benefit of increasing water reabsorption in the DLH, thus increasing luminal sodium and chloride concentrations in the ascending limbs and making step 1 even more efficient (Fig. 38–15).
4. Due to the high interstitial osmolality, water is passively reabsorbed in the medullary collecting tubule (in the presence of ADH). This could potentially lead to dilution of the interstitium. To minimize this effect, the volume of ultrafiltrate is minimized through water reabsorption in the cortical collecting tubule. Also, the vasa recta are arranged in a similar hairpin loop that allows water removal but minimizes removal of interstitial solutes (Pallone et al, 2003).

The osmotic gradient can be disturbed in certain clinical conditions. Increased medullary blood flow (as seen with osmotic diuresis) increases removal of interstitial solutes through the vasa recta and leads to a lower interstitial osmolality. As well, prolonged use of loop diuretics will prevent the transport of NaCl in the ascending limb of the loop of Henle, necessary for the ongoing maintenance of the interstitial hyperosmolality; hence, prolonged water diuresis may be seen after discontinuation of the drug, until the gradient can be reestablished.

Tamm-Horsfall Mucoprotein. The TALH is also the site of secretion of Tamm-Horsfall mucoprotein, or uromodulin. It is clinically important, because it forms the matrix of all urinary casts. Recently, it has been shown to be important in the prevention of urinary tract infections (Bates et al, 2004). It has also been implicated in the pathogenesis of cast nephropathy, medullary cystic renal disease, and familial juvenile hyperuricemic nephropathy.

Distal Tubule

The distal tubule is primarily involved in sodium and calcium reabsorption. There may be some capacity for H^+ and K^+ secretion, but the importance of this is unknown. The distal tubule can be subdivided into two sections, the distal convoluted tubule (DCT), and the connecting tubule (CNT).

Sodium and Chloride. The DCT reabsorbs another 5% to 10% of the sodium filtered through the glomerulus. As in the TAHL, it is a secondary active process, driven by basolateral Na-K ATPase pumps, that occurs in the absence of water reabsorption. Na^+ is reabsorbed electroneutrally with Cl^- by a Na^+/Cl^- (NCC) cotransporter that can be inhibited with the thiazide diuretics. Additionally, there may be some Na^+ reabsorption by the Na^+/H^+ exchange transporter in the luminal membrane. Notably, Na^+ reabsorption in the DCT is regulated by luminal sodium concentration but not by hormonal influences. **Hence, anything that increases delivery of Na^+ to the DCT will lead to increased Na^+ reabsorption in the section of the tubule.** One clinical example would be the use of loop diuretics. By inhibiting the NKCC2 transporter in the TAHL, Na^+ delivery increases to the DCT. In response, there is usually a marked increase in Na^+ reabsorption,

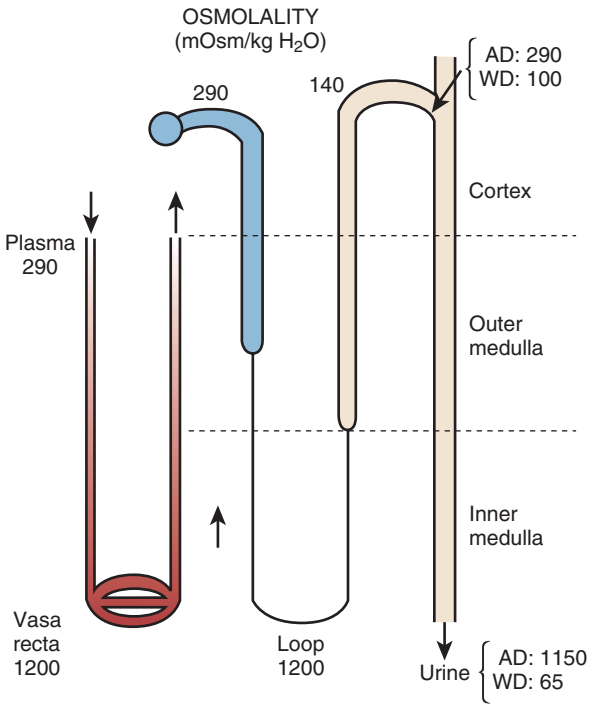

Figure 38–14. Countercurrent mechanism in the renal tubule. AD, antidiuresis; WD, water diuresis. (From Knepper MA, Gamba F. Urine concentration and dilution. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 604.)

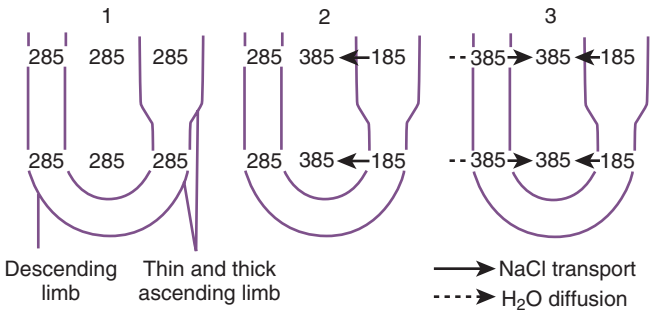

Figure 38–15. Role of active NaCl transport in initiating countercurrent multiplication. In step 1, at time zero, the fluid in the descending and ascending limbs and the interstitium is isosmotic to plasma. In step 2, NaCl is transported out of the ascending limb into the interstitium to a gradient of 200 mOsm/kg. In step 3, the fluid in the descending limb equilibrates osmotically with the hyperosmotic interstitium, primarily by water movement out of the tubule. Dilution of the interstitium by this water movement is prevented by continued NaCl transport out of the ascending limb. The result is the creation of an osmotic gradient between the ascending limb and the relatively hyperosmotic descending limb and interstitium.

which may significantly diminish the diuretic response achieved with the loop diuretic. Such a response may be minimized by concomitant use of a thiazide diuretic.

The connecting segment can also reabsorb sodium, but does so under the influence of aldosterone similar what occurs in the principal cells of the cortical collecting tubule.

Calcium. The DCT accounts for 10% to 15% of calcium reabsorption. Unlike either the PCT or loop of Henle, calcium reabsorption in the DCT is independent of Na^+ reabsorption. Calcium enters the cell through the luminal calcium channel $ECaC_1$ and binds to the intracellular binding protein calbindin D_{28} (Loffing, 2003). By doing so, free intracellular calcium concentration is kept low, thus facilitating inward movement of calcium. Extrusion from the cell occurs through the basolateral membrane using either a Ca^{2+}/H^+ (PMCA) or Na^+/Ca^{2+} (NCX) exchanger (Loffing and Kaissling, 2003). In contrast to the PCT or loop of Henle, movement of calcium by the paracellular route is inhibited due to the presence of the protein claudin-8, which markedly decreases calcium permeability through tight junctions.

Calcium reabsorption is regulated in this region by the actions of PTH and, to a lesser degree, calcitriol (vitamin D). PTH increases calcium reabsorption, possibly through alterations in intracellular voltage as a result of increased Cl^- flux through the basolateral membrane. Calcitriol is thought to increase the number of $ECaC_1$ channels and increase calbindin production, both of which would increase calcium reabsorption.

Magnesium. Five percent to 10% of filtered magnesium is actively reabsorbed in the DT by the transcellular route. This likely occurs through the luminal magnesium channel TRPM6 (Voets et al, 2004), and is driven by a basolateral Na-Mg pump that generates a Mg gradient favoring inward flow of Mg.

Collecting Tubule

The collecting tubule consists of two parts; the cortical collecting tubule (CCT) and the medullary collecting tubule (MCT). While the more proximal portions of the nephron are designed for bulk reabsorption of ultrafiltrate, the collecting tubules are responsible for the final qualitative changes in ultrafiltrate composition in response to dietary intake.

Cortical Collecting Tubule

The CCT consists of two distinct cell types, each with distinct functions. Principal cells (65%) are generally involved in NaCl reabsorption while intercalated cells (35%) are mostly involved with acid secretion. Both are also involved in K regulation.

Principal Cells

Sodium, Potassium, and Chloride. Sodium reabsorption occurs passively through the luminal Na channel $ENaC_1$ rather than through a cotransporter system (Loffing and Kaissling, 2003). Basolateral Na-K ATPase pumps keep intracellular sodium concentration low, facilitating inward movement of sodium. Movement of sodium intracellularly, without an accompanying anion, creates a lumen (–) PD that results in either passive paracellular movement of Cl out of the lumen, or secretion of intracellular K into the lumen to restore electroneutrality. Sodium reabsorption is regulated in the CCT primarily by aldosterone, which increases the number of open $ENaC_1$. Blockade of the Na channel by the diuretic amiloride leads to reduced Na reabsorption as well as K secretion, as the electrochemical gradient is eliminated, and thus the driving force for K secretion is abolished (Fig. 38–16). Prostaglandin E_2 also seems to inhibit Na reabsorption, and reduction of PGE_2 by nonsteroidal anti-inflammatory drugs leads to sodium retention.

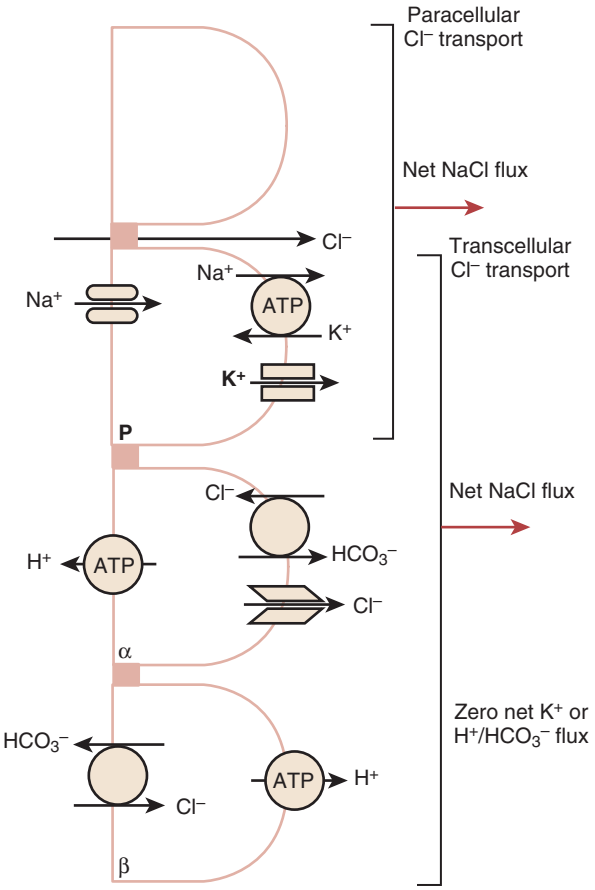

Figure 38–16. Effect of blockade of the Na channel by the diuretic amiloride. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: WB Saunders; 2004. p. 439.)

K secretion in the CCT depends not only upon aldosterone sensitive inward Na movement, but also luminal flow rates. When flow decreases in the tubular lumen, local intraluminal potassium concentration increases and minimizes the favorable potassium gradient, thus minimizing secretion. This can be partially offset by the actions of ADH, which increase potassium secretion, possibly by the insertion of new K channels in the luminal membrane or by increased Na reabsorption (Wang, 1995). **Thus any condition that leads to decreased luminal flow rates, or increased aldosterone production, can lead to reduced potassium excretion.**

Water. The water permeability of the CCT is low in the basal state. However, it can be greatly increased in the presence of ADH. This is due to the insertion of preformed AQP-2 water channels into the luminal membrane (Agre et al, 2002), which allows water to be passively reabsorbed and equilibrate with the cortical interstitium through basolateral AQP-3 and AQP-4 channels. This is important for the development of highly concentrated final urine, because it decreases the volume of ultrafiltrate delivered to the MCT, where most of the final concentration of urine occurs (Knepper et al, 1994) (Fig. 38–17).

Intercalated Cells. There are two different types of intercalated cells, with different functions: type A intercalated cells, involved mostly with H^+ secretion; and type B intercalated cells, involved mostly with bicarbonate secretion.

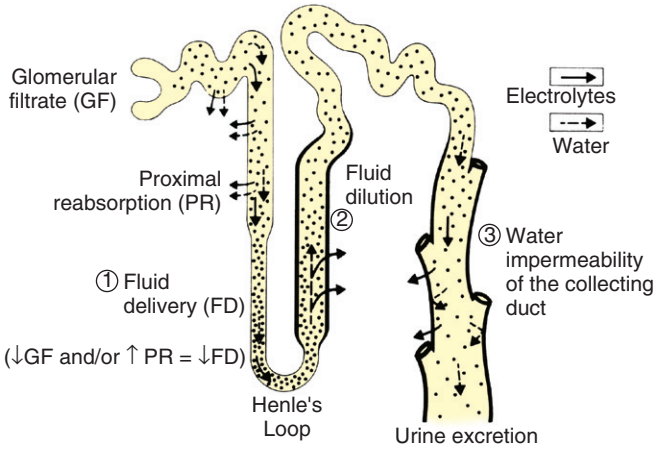

Figure 38–17. The components of the normal urine dilution mechanisms. (Redrawn from Berl T, Schrier RW. Water metabolism and the hypo-osmolar syndrome. In: Brenner BM, Stein JH, editors. Sodium and water homeostasis. New York: Churchill Livingstone; 1978. p. 1–23.)

Hydrogen and Bicarbonate. **In both cell types, intracellular H_2O, under the influence of carbonic anhydrase, is combined with CO_2 to produce H^+ and HCO_3^-.** As well, in both cell types, H^+ and HCO_3^- are secreted from the cell by similar transporters. However, what differs is the location of the transporters.

Type A intercalated cells have both H^+ ATPase and H^+-K^+ ATPase pumps located on the luminal membrane, which facilitate H^+ secretion into the tubular lumen. Bicarbonate is transported back to the systemic circulation by a HCO_3^-/Cl^- transporter on the basolateral side of the cell. The net effect is acidification of the urine and subsequent increase in extracellular pH. As expected, this process is stimulated under conditions of acidemia. Aldosterone seems to have a permissive effect on this, probably through actions on the H^+ ATPase pump, because increased urine H^+ loss and subsequent systemic alkalosis is seen in conditions of hyperaldosteronism.

Type B intercalated cells have similar transporters, but they have reversed polarity. That is, the H^+ATPase pumps are located on the basolateral side of the cell, while the HCO_3^-/Cl^- transporters are localized to the luminal membrane. The result is a net loss of bicarbonate and a decrease in systemic pH. This result is necessary in states of alkalemia and thus functions to lower systemic bicarbonate.

Potassium. Although there is normally a net secretion of potassium in the CCT, there is the potential for potassium reabsorption through the H^+-K^+ ATPase. This becomes more relevant in states of potassium depletion, when the activity of these pumps is increased. **Although this may serve to help correct systemic hypokalemia, it is often at the expense of increased H^+ secretion and resultant systemic alkalosis**.

Medullary Collecting Tubule

The MCT is divided into the outer MCT (oMCT) and inner MCT (iMCT). Both segments contain cells similar to the principal cells and intercalated cells found in the CCT; hence, the handling of sodium, potassium, hydrogen ion, and bicarbonate is very similar. The main functional difference lies with the MCT's water and urea permeabilities, and thus its ability to concentrate the urine to levels far greater than that of plasma.

Water and Urea. The MCT is relatively impermeable to water in the basal state, but under the influence of ADH, permeability increases in both the iMCT and oMCT by the insertion of AQP-2 water channels. This allows water to move out of the tubule into the hyperosmolar interstitium, and urine concentration occurs. Equally important to this process is urea. The oMCT is relatively impermeable to urea, both in the basal state and under ADH stimulation. In contrast, the iMCT has a high basal permeability for urea, due largely to specific urea transporters (UT-A1 and UT-A3) located on the basolateral cell membrane, and, also to a lesser extent, the luminal membrane. Short-term regulation is under the influence of ADH, which can increase urea permeability as much as fourfold through an increased number of urea transporters. Longer-term regulation can be affected by protein intake. **This allows a high concentration of urea to develop in the interstitium, thus sustaining the osmotic gradient that is responsible for water reabsorption and ultimately urinary concentration** (Yang and Bankir, 2005).

Key Points: Renal Tubular Function

- The nephron has different functional segments that control homeostasis.
- Most resorption of bicarbonate and ions occurs in the proximal tubule.
- The architecture of the loop of Henle allows a highly hypertonic interstitium to develop, which is crucial to maximal urinary concentration.

Sodium. As mentioned earlier, Na reabsorption in the MCT is similar to that occurring within principal cells in the CCT. However, it has been shown that Na reabsorption is diminished in the MCT under conditions of volume expansion. This is due, in part, to the actions of ANP, which decreases Na reabsorption in the iMCT but not the oMCT. This effect seems to be due to a reduction in the number of open Na channels in the luminal membrane.

RENAL PATHOPHYSIOLOGY

Sodium and Water Imbalances

Imbalances of sodium and water are often poorly managed and understood by clinicians, despite the mechanisms and appropriate therapy being quite well documented. **The most consistent clinical misconception is that sodium concentration reflects total body sodium content.** Because sodium is primarily extracellular, the serum concentration reflects water balance. Therefore hyponatremia can occur in the face of total body sodium excess, and hypernatremia can occur with sodium deficits. For an imbalance to occur, there has to be an imbalance between sodium and water not handled by the normal mechanisms of response. **Therefore the way to approach serum sodium abnormalities is to determine the water status of the patient and then to determine why the normal compensatory mechanisms have failed** (Fig. 38–18).

Hyponatremia

By definition, hyponatremia exists if there is a water excess relative to extracellular sodium that has not been handled by the normal compensatory mechanisms of thirst suppression and decreased

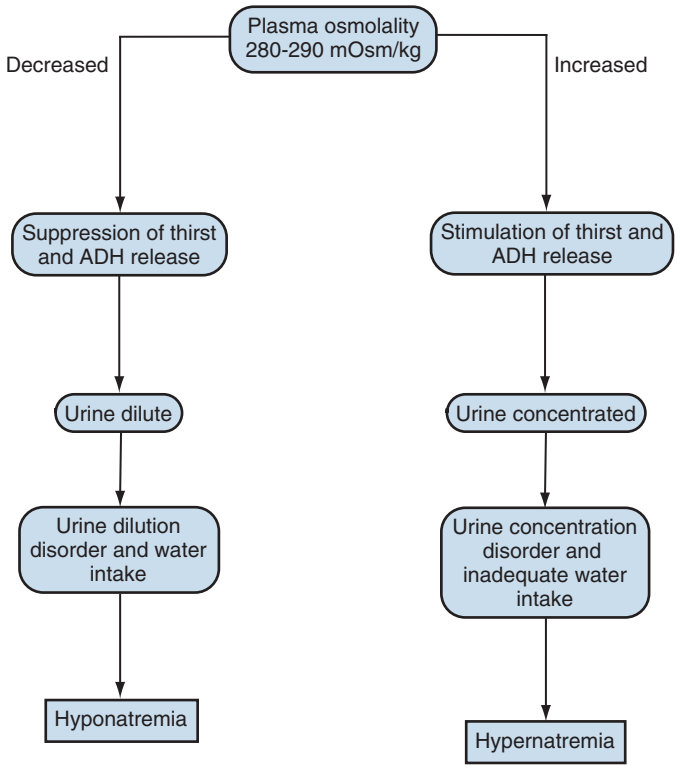

Figure 38–18. Flowchart illustrating the development of disorders of water metabolism. ADH, antidiuretic hormone.

Table 38–3.

Disorders Associated with the Syndrome of Inappropriate Antidiuretic Hormone Secretion

CARCINOMAS	PULMONARY DISORDERS	CENTRAL NERVOUS SYSTEM DISORDERS
Bronchogenic	Pneumonia (viral, bacterial)	Encephalitis (bacterial, viral)
Duodenum	Pulmonary abscess	Meningitis (viral, bacterial, tubercular, fungal)
Pancreas	Tuberculosis	Head trauma
Thymoma	Aspergillosis	Guillain-Barré syndrome
Ureter	Positive pressure breathing	Subarachnoid hemorrhage
Lymphomas	Asthma	Subdural hematoma
Ewing sarcoma	Pneumothorax	Cerebellar or cerebral atrophy
Mesothelioma	Cystic fibrosis	Cavernous sinus thrombosis
Bladder		Hydrocephalus
Prostatic		Shy-Drager syndrome
		Rocky Mountain spotted fever
		Delirium tremens
		Olfactory neuroblastoma
		Hypothalamic sarcoidosis
		Multiple sclerosis

ADH release, leading to a serum sodium less than 135 mEq/L. Hyponatremia is seldom symptomatic unless severe (<120 mEq/L), but when severe and/or of sudden onset can produce seizures, altered mental state, coma and death. Most commonly hyponatremia occurs because the kidney is unable to excrete solute-free urine (Mallie et al, 1997). **To calculate the amount of water excreted or retained by the kidney, it is useful to consider that urine has two components: one that contains all of the solute in an isotonic solution (termed C_{osm}, or osmolar clearance) and another that contains only solute-free water (termed C_{H_2O} or free-water clearance).** The total urine volume (V) (e.g., liters per day) is the sum of C_{osm} and C_{H_2O}:

$$V = C_{osm} + C_{H_2O}$$

where P_{osm} = plasma osmolality and U_{osm} = urine osmolality.

When the urine is hypo-osmotic to plasma, C_{H_2O} is a positive value. **Hyponatremia occurs when one or more of these requirements are not fulfilled, such as when GFR is reduced, when diuretics impair NaCl reabsorption, or when vasopressin is in excess (e.g., SIADH).** If water intake exceeds the kidney's capacity to form solute-free water (>10 to 20 L/day), hyponatremia also occurs. This abnormality in solute-free water clearance in hyponatremic patients is reflected by the failure to excrete maximally dilute urine (U_{osm} = 100 mOsm/kg).

The diagnosis of hyponatremia is made by measurement of serum electrolytes. There are, however, several conditions in which a low serum sodium level is misleading. The reported lab value is usually in terms of sodium per volume of plasma, rather than water. If large molecules, such as lipids or protein, are present in large quantities, they decrease the amount of water in a given volume of plasma, but these molecules contribute little to plasma osmolality. **What is truly important is the amount of osmotically active solute per volume of water.** Pseudohyponatremia is most commonly seen with abnormal elevations of serum lipids or glucose. For every 1 g/dL increase in triglycerides, measured sodium is decreased by 2 mEq/L, and for every 100 mg/dL of glucose, measured sodium is decreased by 1.6 mEq/L.

Therefore the approach to a patient with true hyponatremia begins with an assessment of volume status (Fig. 38–19). Clinical features such as skin turgor, orthostatic hypotension, jugular venous distension, ascites, and respiratory crackles can all be helpful in this decision. Patients who are clinically hypovolemic by definition will have a sodium deficit greater than their water deficit. The appropriate renal response would be to excrete urine that is hypo-osmotic with a high C_{H_2O}. Therefore, if the urine is not hypo-osmotic, then the etiology is related to the kidney. Measuring the urinary sodium (U_{Na}) is a useful surrogate for urinary osmolality. Therefore a hypovolemic patient with an appropriately low U_{Na} (<20) has extrarenal sodium losses, such as from trauma, vomiting, diarrhea, burns, or third spacing. In a hypovolemic patient with an inappropriately high U_{Na} (>20), a renal source should be suspected, such as diuretic excess, osmotic diuresis, renal tubular acidosis, or mineralocorticoid deficiency. If the hyponatremic patient is hypervolemic, total body sodium can be low, normal, or high. A high U_{Na} of greater than 20 would point to renal failure. A low U_{Na} of less than 20 would suggest heart failure, cirrhosis, or nephrotic syndrome.

A patient who is euvolemic would have low or normal total body sodium. The differential diagnosis would include glucocorticoid deficiency, hypothyroidism, stress, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). **SIADH is a syndrome triggered by release of ADH by a mechanism other than low blood volume or high plasma osmolality, one associated with increased aquaporin expression in the kidney** (Kwon et al, 2001). The most common causes of SIADH are brain infections, surgery, neoplasm, and drug side effects (Table 38–3). Pharmacologic antagonists that can be used to treat patients with SIADH include lithium and demeclocycline.

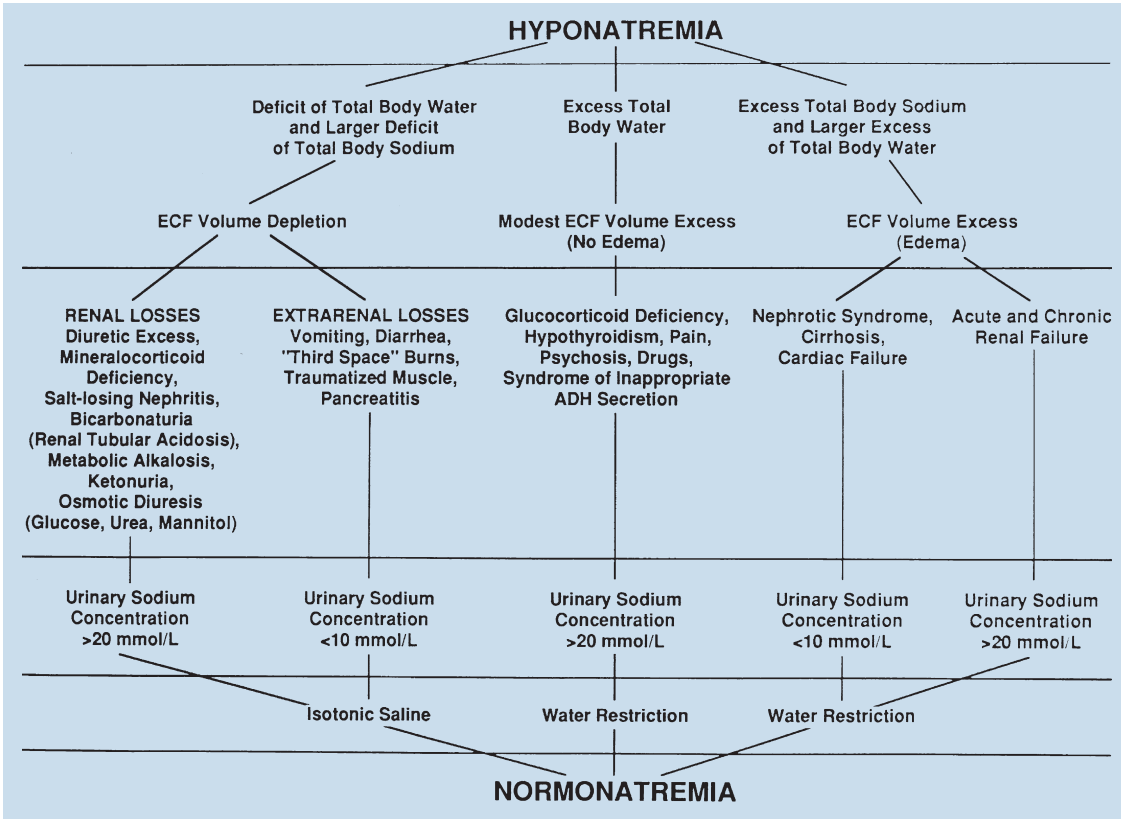

Figure 38–19. Clinical approach to patient with hyponatremia. ADH, antidiuretic hormone; ECF, extracellular fluid. (From Berl T, Anderson RJ, McDonald KM, Schrier RW: Clinical disorders of water metabolism. Kidney Int 1976;10:117–32.)

Lithium inhibits vasopressin action both proximal and distal to cAMP formation in the collecting duct (Miller, 1994). Demeclocycline, in doses ranging from 600 to 1200 mg/day, induces vasopressin-resistant diabetes insipidus that corrects the serum sodium within 1 to 2 weeks (Goh, 2004).

Therapy of hyponatremia is directed both at the cause of the condition and the water imbalance itself (Fig. 38–20). Patients with acute severe hyponatremia symptomatic with confusion, convulsions, or coma, should undergo fluid restriction plus administration of hypertonic (3%) saline (about 1 cc/kg/hr). Fluid overload is unlikely as long as fluid intake is restricted, but may be further reduced by simultaneous administration of a loop diuretic such as furosemide, which causes excretion of hypotonic fluid equivalent to half-normal saline. The serum sodium concentration should be raised to no more than 25 mEq/L in the first 48 hours, at a rate of no more than 2 mEq/L per hour, and the target goal should be 120 to 125 mEq/L. Total sodium deficit to reach this point can be calculated as

$$(\text{Volume of distribution}) \times \text{body weight (kg)} \times (125 - \text{plasma [Na]})$$

where volume of distribution is 0.5 for men and 0.6 for women. If the hyponatremia is severe but chronic, the rate of correction should not exceed 8 to 12 mmol/L/day, otherwise a cerebral demyelination syndrome may occur (Martin, 2004). Therefore the rate of correction should be slower (0.5 to 1 mEq/L/hr). During acute intervention for severe hyponatremia, frequent electrolyte measurements and patient reassessment are required. Aggressive therapy should be discontinued when the serum sodium concentration is raised 10% or symptoms subside. At that point, water restriction and reversal of underlying causes should suffice. This is also the best approach for therapy of asymptomatic hyponatremia. Obviously, patients with associated hypovolemia should have this corrected with the appropriate volume of normal saline.

Hypernatremia

The underlying problem of hypernatremia is a disorder of urine concentration with inadequate water intake (Adrogue and Madias, 2000). **Again, in hypernatremia it is the water balance that matters, and total body sodium can be high, normal, or even low.** Symptoms are nonspecific and overlap with those seen in hyponatremia, with the early occurrence of restlessness, nausea, and vomiting, which can progress to tremor, lethargy, and coma. Indeed, mortality is higher with hypernatremia than with most other electrolyte disorders. **Most patients with an intact thirst mechanism and free access to water can prevent hypernatremia** and, as such, the condition is more common at the extremes of age.

Again, the approach to a patient with hypernatremia begins with an assessment of fluid status (Fig. 38–21). Hypovolemia is common and may be due to renal conditions that fail to adequately concentrate the urine (loop diuretics, postobstructive diuresis), or to conditions of extrarenal water loss, such as seen with burns, diarrhea, or fistulas. Patients with hypervolemia will have a metabolic or iatrogenic reason for high sodium in excess of the elevated total body water. Causes include Cushing syndrome, primary hyperaldosteronism, and excessive exogenous sodium (orally or IV). Patients who are euvolemic may have renal or extrarenal losses and may be caused by diabetes insipidus, an impairment in renal concentrating ability due to lack of central production (neurogenic), or impaired renal response (nephrogenic).

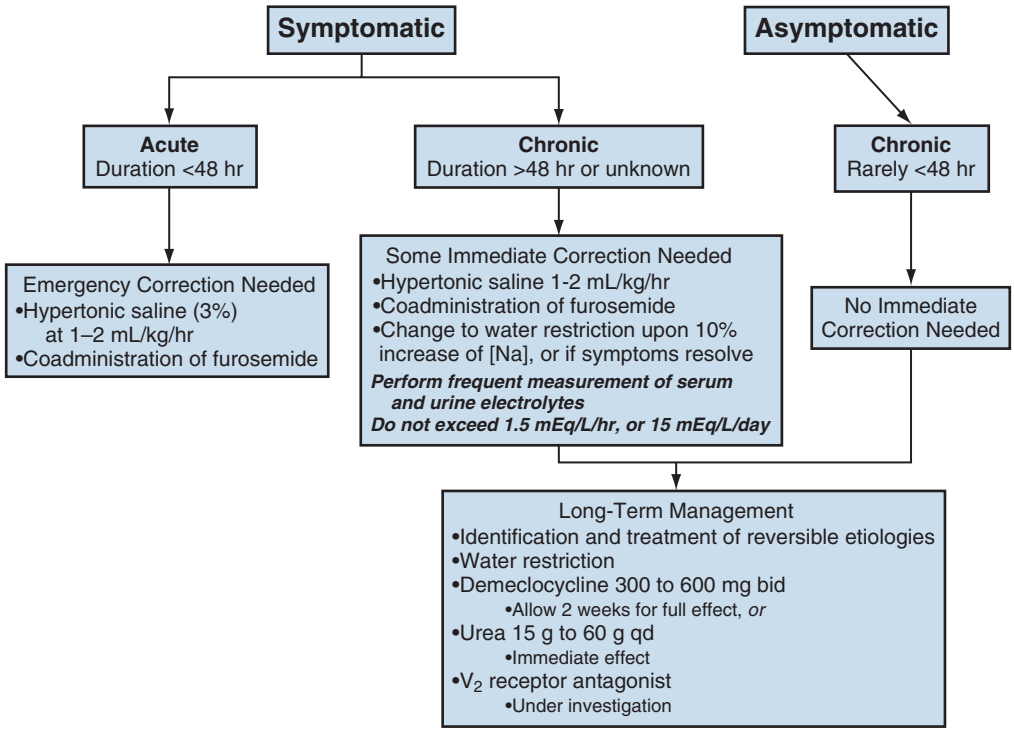

Figure 38–20. Therapy of hyponatremia. (From Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady H, Wilcox C, editors. Therapy in nephrology and hypertension. Philadelphia: WB Saunders; 1999. p. 261.)

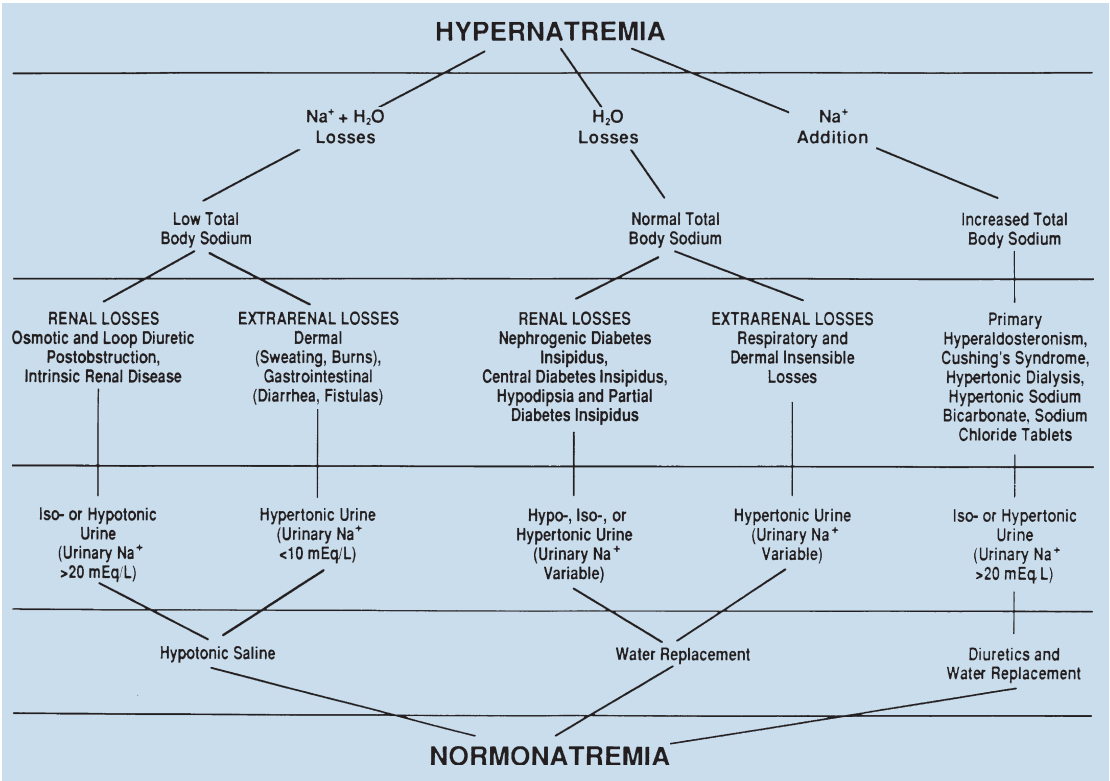

Figure 38–21. Clinical approach to patient with hypernatremia. (From Berl T, Anderson RJ, McDonald KM, Schrier RW. Clinical disorders of water metabolism. Kidney Int 1976;10:117–32.)

In neurogenic diabetes insipidus, vasopressin deficiency is most commonly caused by destruction of the neurohypophysis. To produce symptomatic polyuria, 80% to 90% of the neurosecretory neurons must be destroyed at or above the level of the infundibulum. Because of the reduced vasopressin level, the kidney excretes a high volume of dilute urine. This leads to a reduction in total body water, a rise in total-body osmolality, and thus hypernatremia. The related cellular dehydration stimulates thirst. Compensatory water intake decreases plasma osmolality (and Na^+ concentration) toward normal, but they stabilize at the threshold level for thirst, which is slightly above normal. **As in all forms of diabetes insipidus, the ability of the kidney to maximally concentrate the urine in response to vasopressin is also impaired in neurogenic diabetes insipidus. This abnormality occurs because the medullary osmotic gradient is reduced by the high urine flow.** In nephrogenic diabetes insipidus, secretion of vasopressin by the neurohypophysis is normal, but renal responsiveness to the hormone is attenuated or absent, and urinary concentrating ability is impaired (Sasaki, 2004). Several different mutations of the aquaporin gene have been identified, which contribute to the pathogenesis of this disorder (Leung et al, 2005).

Therapy of hypernatremia is directed at fluid deficit, water replacement, and reversal of underlying causes. Hypovolemia should be initially corrected with half-normal saline. If the patient is awake and not symptomatic, oral hydration with water is sufficient. Otherwise, intravenous (IV) therapy should be started with the goal of slowly lowering plasma osmolality to no more than 2 mOsm/L/hr to avoid cerebral edema. The water deficit can be calculated as

$$(\text{Volume of distribution}) \times \text{body weight (kg)} \times (\text{plasma [Na]}/140 - 1)$$

where, again, volume of distribution is 0.5 for men and 0.6 for women. For patients with central diabetes insipidus, desmopressin (a synthetic exogenous vasopressin) can be given intranasally. For nephrogenic diabetes insipidus, the underlying cause (lithium, hypercalcemia) should be treated. If polyuria persists while the kidney recovers, therapy includes modest sodium restriction, thiazide diuretics, and nonsteroidal anti-inflammatory drugs (Pattaragarn and Alon, 2003).

Key Points: Sodium and Water Imbalances

- Serum sodium represents sodium concentration, *not* total body sodium.
- The best tools to determine the cause of a sodium disorder are the history, volume status, and urinary sodium.
- Severe sodium deficit or excess must be corrected slowly.

Potassium Imbalances

Potassium is primarily an intracellular ion, and serum levels do not represent total body content in disease states. Because neuromuscular excitability is closely linked to serum potassium levels, extremes of low or high values can lead to cardiac arrhythmias and death. The body responds to changes in potassium intake and levels by controlling urinary excretion and by changing the balance between intra- and extracellular stores. **Urinary excretion can be increased in the kidney through increased aldosterone, a high sodium load in the distal tubule, and by acidosis. Potassium is driven into the cells by insulin, bicarbonate, and β-agonists.**

Hypokalemia

The most common causes of hypokalemia are increased losses through the gastrointestinal (GI) tract or urine, and increased intracellular shift of potassium in response to alkylosis (mnemonic: aLKylosis = low K^+). The most common iatrogenic causes are diuretics, laxatives, amphotericin, theophylline, and postobstructive diuresis. Metabolic causes include conditions associated with elevated aldosterone, such as adrenal adenoma, Cushing syndrome, and adrenal carcinoma. The patient may have no symptoms or present with signs and symptoms of their underlying condition (e.g., hypertension). Severe hypokalemia may produce tachycardia, heart block, and ST depression. Therapy is directed at correction of the underlying cause and oral or parenteral potassium supplementation. In general, intravenous potassium replacement should not exceed 40 mEq/hr.

Hyperkalemia

Hyperkalemia usually reflects decreased renal excretion of potassium or a shift out of cells into the extracellular space (usually by acidosis). A compromised excretory capacity can be further exacerbated by a GI bleed or hemolysis. The most common causes (Table 38–4) are renal failure, drugs (potassium-sparing diuretics, lithium, digoxin, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs]), chronic acidosis (e.g., renal tubular acidosis type 4), and hypoaldosteronism. Hemolysis of the drawn blood sample can falsely elevate serum potassium. Therefore when a patient has no symptoms, risk factors, or electrocardiogram (ECG) changes, but has an unexpectedly high value, the sample should be redrawn pending aggressive therapy. The classical ECG changes include a short QT interval, peaked T waves, and ultimately ventricular arrhythmias. Need for therapy is driven by the degree of elevation of potassium, the acuteness of elevation, and the presence of ECG changes. Mild hyperkalemia without ECG changes only requires dietary restriction and reversal of underlying causes. ECG changes require emergency therapy: intravenous calcium gluconate (to protect the heart) and a cocktail of drugs to drive the potassium into the cell, including sodium bicarbonate, insulin (given with glucose to avoid hypoglycemia), and nebulized albuterol (especially if there is a delay in gaining intravenous access). Therapy to increase intracellular potassium must be coupled with a therapy to remove potassium stores, or the hyperkalemia will recur once infusions stop. Potassium-binding exchange resins (kayexalate, calcium resonium) can be used for this purpose orally or by enema. Finally, hemodialysis can remove extracellular potassium the most quickly and completely.

Key Points: Potassium Imbalances

- Potassium is primarily intracellular.
- Serum potassium levels reflect total body potassium, as well as the equilibrium between intra- and extracellular potassium.
- Alkalosis produces low serum potassium.

Acid-Base Metabolism

Although the hydrogen ion (H^+) is present in miniscule concentrations in the extracellular fluid, compared with other common ions in the body, its primary importance is reflected by the multiple

Table 38–4.

Etiology of Hyperkalemia

Factitious
Laboratory error
Pseudohyperkalemia: in vitro hemolysis, thrombocytosis, leukocytosis
Increased Input
Exogenous: diet, salt substitutes
Endogenous: hemolysis, GI bleeding, catabolic states, crush injury, tumor lysis
Renal Failure
Acute: especially tubulointerstitial disease
Chronic: GFR < 15–20 mL/min
Impaired Renin-Aldosterone Axis
Addison disease
Congenital adrenal enzyme deficiencies (e.g., corticosterone methyl oxidase deficiency)
Drug induced: heparin, prostaglandin inhibitors, ACE inhibitors, pentamidine, β blockers
Hyporeninemic hypoaldosteronism
Primary hypoaldosteronism (normal renin)
Primary Renal Tubular Potassium Secretory Defect
Sickle-cell disease
Systemic lupus erythematosus
Postrenal transplantation
Obstructive uropathy
Tubulointerstitial renal disease
Pseudohypoaldosteronism
Hyperkalemic distal renal tubular acidosis
Inhibitors of Tubular Secretion
Diuretics: amiloride, spironolactone, triamterene
Cyclosporine
Lithium
Digitalis
Abnormal Potassium Distribution
Metabolic acidosis
Insulin deficiency
Hypertonicity (e.g., hyperglycemia)
Aldosterone deficiency
β-Adrenergic receptor blockade
α-Adrenergic receptor agonist
Exercise
Periodic paralysis

Adapted from Rastegar A, DeFronzo RA. Disorders of potassium metabolism associated with renal disease. In: Schrier RW, Gottschalk CW, editors. Diseases of the kidney. 5th ed. Boston: Little, Brown; 1992. p. 1645–2661.

mechanisms that exist to control its concentration within a tight range. The reason is that small alterations in H^+ concentration has large effects on the relative concentrations of every other conjugate base and acid of all the weak electrolytes. At neutral body pH, most biologically active molecules are in their charged state and can more effectively be trapped within cells to perform their functions. Furthermore, pH determines the net charge of proteins, which influences protein conformation and enzyme binding characteristics. Outside normal blood pH (7.35 to 7.46), severe metabolic problems occur.

To maintain pH, the body has to deal with the daily production of acid. There is a large production of acid by the metabolism of carbohydrates and fats, largely in the form of carbon dioxide, at approximately 15,000 mmol per day. CO_2 is not an acid in the classical sense of the Brønsted-Lowry theory (Kildeberg, 1983), because it is not capable of donating a H^+ to a base. CO_2 can be considered a "volatile acid" because it is easily converted into H_2CO_3, carbonic acid:

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

Each molecule of CO_2 excreted by the lungs results from the reaction of one molecule of bicarbonate with one molecule of H^+. The H^+ remains in the body as H_2O. The catabolism of ingested proteins to amino acids is another source of acid production, estimated at between 50 and 100 meq of H^+ per day (sulphate from the three sulphur-containing amino acids; phosphate from phosphoproteins). Because these acids cannot be excreted by the lungs, they are considered "fixed" and must be excreted by the kidneys.

Therefore the body has three primary mechanisms to handle physiologic and pathophysiologic acid loads: buffers in the blood, CO_2 excretion by the lungs, and H^+ excretion by HCO_3 metabolism in the kidneys (Vasuvattakul et al, 1992). The immediate response to an acid load is buffering. A buffer is simply a mixture of a weak acid and its conjugate base, or a weak base and its conjugate acid, that resists changes in pH when another acid or base is added. The key buffers in the blood are HCO_3 for metabolic acids and hemoglobin for CO_2. Within the cell, proteins and phosphates, which are found in higher concentrations than in the blood, become important as well. In the extracellular fluid, HCO_3 is responsible for about 80% of buffering. Changes in pH are governed by the Henderson-Hasselbach equation, which generally is

$$pH = pKa + \log \text{base/acid}$$

When specifically formulated for the bicarbonate system it becomes

$$pH = 6.1 + \log HCO_3^-/0.03 \times pCO_2$$

In general, optimal buffering occurs within 1.0 pH unit of the pKa. Therefore the pKa = 6.1 of bicarbonate buffer does not appear to be the most efficient for maintaining pH 7.4 that is required for normal homeostasis. **The bicarbonate buffer system is effective despite having a low pKa, because the body also controls pCO_2.**

Excretion of CO_2 by the lungs can occur rapidly and change both blood and intracellular pH. Elevated pCO_2 is detected by central and peripheral chemoreceptors that increase respiratory rate leading to increased alveolar ventilation. Respiratory compensation in response to a pure metabolic acidosis cannot reduce CO_2 to below 10 mm Hg and is therefore unable to maintain pH in the setting of a large acid load.

Although most of the daily acid production is volatile, and therefore excreted by the lungs, the kidneys must excrete the fixed acid, and, in doing so, also reabsorb most of the filtered bicarbonate so that efficient extracellular buffering can be maintained. A normal individual, with a GFR of 180 L/day and plasma [HCO_3^-] of 24 mEq/L, filters 4300 mEq of HCO_3^- daily from the glomerulus into the proximal tubule. Of this filtered load, less than 0.1% normally appears in the urine. **The bulk of the filtered bicarbonate is reclaimed in the proximal nephron, with approximately 80% of the filtered HCO_3^- reabsorbed within the proximal convoluted tubule.** In the tubular urine, H^+ and HCO_3^- are formed from CO_2 and H_2O in a reaction catalyzed by carbonic anhydrase (Kaunisto et al, 2002). The H^+ is returned to the tubular urine by two mechanisms: a Na^+-H^+ pump ("antiporter") and a direct H^+-ATPase proton pump. The net result

is the reabsorption of $NaHCO_3$ into the interstitial fluid and the secretion of H^+ into the proximal collecting duct urine. Note that the use of a carbonic anhydrase inhibitor, such as acetazolamide, reduces HCO_3 reabsorption and increases excretion of Na^+ and water, resulting in a weak diuretic effect (Puscas et al, 1999). The reabsorption of HCO_3 does not result in a net excretion of H^+ from the body; however, the proximal tubular reabsorption of HCO_3 is essential to preserving acid-base balance. The primary factors that increase HCO_3 reabsorption are arterial pCO_2, HCO_3 concentration in the lumen, luminal flow rate, and angiotensin II (de Mello-Aires and Malnic, 2002).

The remainder of the filtered bicarbonate is reabsorbed in the distal nephron by a mechanism independent of carbonic anhydrase. In the distal tubule, further H^+ is secreted through the production of "titratable acid," usually by buffering with phosphate. The term *titratable acidity* refers to the quantity of NaOH required to titrate urine back to a pH of 7.40, which is similar to that of blood. Other buffers, such as uric acid (pKa 5.75) and creatinine (pKa 4.97) contribute to the titratable acidity, but only to a minor extent. H^+ is also secreted through the production of ammonium ion (NH_4^+). NH_4 is produced from glutamine, primarily by proximal tubular cells (Michoudet et al, 1994). Because of its high pKa (about 9.2), it is present almost exclusively as the NH_4^+ ion. Ammonium excretion can increase significantly during systemic acidosis (Nagami, 2004), which is the key mechanism for secreting excess H^+, because at very low urinary pH, titratable acid cannot increase much (unless other ions, such as keto-anions, are being produced).

Regulation of H^+ secretion occurs through multiple biochemical and hormonal actions upon the above system. **Volume depletion** leads to Na retention and enhanced HCO_3 absorption, with a net loss of H^+. **Elevated pCO_2,** as seen in chronic respiratory acidosis (see below), will lead to a renal response of increased H^+ secretion. **Reduced GFR** will reduce the amount of filtered HCO_3, leading to increased H^+ excretion. **High aldosterone levels** indirectly increase H^+ excretion by increasing Na^+ absorption. **Low potassium and low chloride** increase HCO_3 reabsorption and can maintain chronic metabolic alkalosis.

Acid-Base Disorders

Those of us outside the fields of nephrology and anesthesia encounter acid-base disorders less commonly and are often intimidated by the process of working through the appropriate diagnosis. Nevertheless, once the terminology and basic equations are understood, the process is simple and, in many ways, mechanical (Corey, 2005). Common misconceptions begin with definition of terms. **The actual pH disturbance is an "emia," and the disease causing it is an "osis." Acidemia** refers strictly to a low arterial blood pH of less than 7.36. **Alkalemia** is a blood pH of greater than 7.44. **Acidosis** is an abnormal condition or process that would lower arterial pH if no other condition existed, and **alkalosis** is a condition that would raise pH. **The basic information required to diagnose an acid-base disturbance is a history, physical, serum electrolytes, and arterial blood gas.** If the acid-base disorder is caused by a respiratory problem, the pCO_2 will move in the opposite direction of the pH (Madias and Adrogue, 2003). If caused by a metabolic (renal) disorder, the HCO_3 will move in the same direction as the pH. In every disorder, there should be an attempt by the other acid-handling mechanism to compensate for the change. For instance, chronic loss of bicarbonate from the kidney causing a metabolic acidosis (low pH and low HCO_3) should lead to increased ventilation to try to excrete the excess acid by the lung, leading to a lower pCO_2 (respiratory compensation). In **simple** acid-base disorders, there is one mechanism causing the acid disturbance with an appropriate compensation. In **mixed** disorders, the clue to multiple mechanisms comes from significant under- or overcompensation. Although formulas have been developed to predict appropriate compensation for each disorder, visual nomograms are more practically used at the bedside.

Metabolic Acidosis

In metabolic acidosis, loss of bicarbonate leads to systemic acidemia, which produces a low arterial pH and low serum HCO_3. The appropriate compensation is increased respiration leading to a reduced pCO_2. In general, the expected degree of pCO_2 reduction is calculated as

$$\text{Expected } pCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$$

This bicarbonate loss can be direct, or from secondary effects of other ions. The presence of active ions that are not measured in routine blood chemistry can be detected by the anion gap. The anion gap is defined as the difference between the levels of routinely measured cations (Na^+) and anions (Cl^- and CO_2) in blood:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) = 140 - (105 + 24) = 11$$

The normal range is 9 to 14 mEq/L. The predominant unmeasured anions include albumin, and phosphate. The major unmeasured cations include calcium, magnesium, and gamma globulins. If the anion gap is elevated in a patient with metabolic acidosis, the condition occurs because acids that do not contain chloride are present in the blood. The most common are ketones (diabetic ketoacidosis), lactate (lactic acidosis), and drug intoxication (methanol, aspirin) (Levraut and Grimaud, 2003).

Metabolic acidosis with a normal anion gap is caused by direct bicarbonate loss through the gut or kidney, or by the addition of exogenous acid that is buffered by bicarbonate (Table 38–5). The

patient history can give major clues to the diagnosis, either because of GI loss (vomiting, diarrhea, fistula), drug use (acetazolamide), or previous surgery (ileal conduit). Serum potassium can be a further clue to etiology. Low potassium is associated with loss through the GI tract or renal tubular acidosis because renin is stimulated from the volume contraction. In acidosis associated with severe renal dysfunction, potassium will often be elevated.

Renal Tubular Acidosis

Renal tubular acidosis (RTA) is a family of syndromes of metabolic acidosis from defects in tubular H secretion and urinary acidification. They are classified according to the mechanism of defect, and each type has different clinical manifestations.

RTA type I is the most common form and the most clinically significant to the urologist. It has also been called "classic" RTA and distal RTA. The old classification of RTA type III is now recognized as a type 1 variant. The underlying problem is failure of H^+ secretion in the distal nephron, which can be congenital or acquired. Associated disorders include autoimmune diseases (thyroiditis), toxic nephropathy, and chronic ureteral obstruction. **The hallmark is a hyperchloremic metabolic acidosis with a high urinary pH (>5.5) in the face of persistently low serum HCO_3.** If no metabolic acidosis is present but the condition is still suspected, then acid loading with ammonium chloride will drop the serum HCO_3 while maintaining a high urine pH. Volume contraction from sodium loss is common, which leads to secondary hyperaldosteronism and hypokalemia. These patients often develop recurrent renal stones, composed of calcium phosphate. The most likely contributing factor is low urinary citrate, coupled with a high urinary pH and hypercalciuria. Treatment with sodium bicarbonate can alkalinize the urine, correct the sodium defect, lower aldosterone and raise the potassium. Potassium citrate can augment the urinary citrate levels and inhibit stone formation (Domrongkitchaiporn et al, 2002).

Type II RTA, also called proximal, is caused by failure of bicarbonate reabsorption in the proximal tubule (Igarashi et al, 2002). The mechanisms of H^+ secretion in the distal tubular are overwhelmed, resulting in HCO_3 loss in the urine. The bicarbonate is replaced in the circulation by Cl^- resulting in hyperchloremia. Increased sodium delivery to the distal tubule increases aldosterone secretion resulting in hypokalemia. Ultimately, a new steady state is reached in which serum HCO_3^- is decreased, and hence, the filtered load, distal delivery, and urinary excretion of HCO_3^- are all reduced. **The acidosis is self-limited, because acid production and excretion are equivalent at this reduced pH; the plasma HCO_3^-** remains at 15 to 20 mEq/L. Because urinary citrate levels are not reduced, stone formation does not occur, despite increased urinary calcium. Because this condition is more common in children, it can lead to growth retardation and metabolic bone disease (Roth and Chan, 2001). Oral supplementation with $NaHCO_3$ can correct the condition but can lead to further hypokalemia, so potassium supplements may also be required. As an interesting aside (and possible memory aid), it was suggested that Dickens' character of Tiny Tim was based on a child with type II RTA (growth retardation, osteomalacia) that was reversed when Mr. Scrooge paid for his therapy (sodium bicarbonate).

Type IV RTA is due to impairment of cation exchange in the distal tubule, with reduced secretion of both H^+ and K^+. It is due to aldosterone deficiency or resistance. **The unique feature compared with other RTAs is hyperkalemia.** Patients often have associated azotemia and hypertension. The distal tubule H^+ pump functions normally, so patients are able to decrease urine pH to less than 5.5 in response to the acidosis. Urinary citrate may be normal or low, but renal dysfunction reduces secretion of calcium and uric acid, so stones do not form (Uribarri et al, 1994). Type IV RTA is occasionally seen in obstructive uropathy. Therapy is typically directed at controlling the hyperkalemia.

Metabolic Alkalosis

In metabolic alkalosis, the pH will be high (alkalemia) and the HCO_3 high (mirrors pH in primary metabolic disorder) (Khanna and Kurtzman, 2001). The appropriate respiratory compensation is reduced ventilation with increased pCO_2. The expected degree of respiratory compensation can be estimated by

$$\text{Expected } pCO_2 = 6 \text{ mm Hg per } 10 \text{ mEq/L increase in } HCO_3$$

An exogenous alkali load is usually rapidly excreted into the urine by the kidney, so other mechanisms are required to maintain the disorder. Maintenance of the alkalosis requires a process that greatly impairs the kidney's ability to excrete bicarbonate and prevent the return of the elevated plasma level to normal. Chloride deficiency leads to the kidney reabsorbing more bicarbonate anion than usual because there is not sufficient chloride anion present to maintain electroneutrality. This condition is reversed with fluid and chloride. Consequently, metabolic alkalosis is most conveniently classified as chloride responsive and chloride resistant.

The most common chloride responsive conditions are GI loss (vomiting, nasogastric drainage, laxative abuse) and kidney loss (diuretics). These make up over 90% of clinical cases of metabolic alkalosis (Table 38–6). Volume contraction in these conditions stimulates aldosterone production and distal secretion of H^+ and K^+. **Thus there may be a paradoxical aciduria, which will persist until volume is replaced.** Chloride-resistant metabolic alkalosis is associated with potassium loss from mineralocorticoid excess. They are associated with volume expansion and high urinary chloride levels, which can aid in the diagnosis. Common

Table 38–6.

Differential Diagnosis of Metabolic Alkalosis

MEASUREMENT	SALINE RESPONSIVE	NORMOTENSIVE: SALINE UNRESPONSIVE	HYPERTENSIVE: SALINE UNRESPONSIVE
Urinary [Cl^-]	<15 mEq/L	>15 mEq/L	>15 mEq/L
Blood pressure	Normal	Normal	Increased
Differential diagnosis	Vomiting Nasogastric suction	Diuretics Bartter magnesium deficiency	Primary mineralocorticoid excess

Adapted from Alpern RJ, Emmett M, Seldin DW. Metabolic alkalosis. In: Seldin DW, Giebisch G, editors. The kidney: physiology and pathophysiology. 2nd ed. New York: Raven; 1992. p. 2733–58.

causes are hyperaldosteronism (primary or secondary), Cushing syndrome, diuretics, and congenital conditions such as Bartter syndrome (hyperplasia of the juxtaglomerular apparatus).

Respiratory Acidosis

In respiratory acidosis, pH is low (acidemia) and pCO_2 is high, due to inadequate respiration (Epstein and Singh, 2001). The anticipated compensatory response is increased HCO_3:

Acute: Expected HCO_3 = 1 mEq/L for each 10 mm Hg pCO_2

Chronic: Expected HCO_3 = 3.5 mEq/L for each 10 mm Hg pCO_2

Elevated pCO_2 can be caused by increased production of CO_2, decreased ventilation, and increased CO_2 in the inspired air. Because increased production is usually handled quickly by increased respiration, and CO_2 does not vary except in ventilated patients, the most common cause is decreased ventilation. This can be due to central depression of respiration (e.g., opiates, trauma, cervical cord trauma), chest cavity problems (e.g., pneumothorax, pulmonary edema), upper airway obstruction, or iatrogenic causes (insufficient ventilation). Because CO_2 readily diffuses across all cellular membranes, marked elevation can severely interfere with intracellular metabolism. Clinical effects of elevated pCO_2, which are separate from acidosis per se, include elevated intracranial pressure, tachycardia, central depression, and eventually coma and death.

Respiratory Alkalosis

In respiratory alklalosis, pH is high (alkalemia) due to a low pCO_2. This is due to hyperventilation (Foster et al, 2001). The appropriate compensatory response is a lowering of HCO_3 by the following expected amounts:

Acute: Expected HCO_3 = 2 mEq/L for each 10 mm Hg pCO_2

Chronic: Expected HCO_3 = 5 mEq/L for each 10 mm Hg pCO_2

Common causes of hyperventilation that can lead to respiratory alkalosis are fever, pain, anxiety, septicemia, head trauma, pulmonary embolism, and iatrogenic (excessive mechanical ventilation). Neurological symptoms such as paresthesia and tetany may occur. Therapy is directed at improving oxygenation and ventilation.

Key Points: Acid-Base

- Physiologic chemical reactions require a narrow range of serum pH.
- Acid is excreted through the lungs and the kidney.
- Type 1 RTA (distal) is the only type associated with renal stones.
- In acid-base disorders, first determine whether the kidney (HCO_3) or lungs (pCO_2) are responsible for the primary disorder; then determine whether the compensatory response is appropriate.

HISTORICAL BACKGROUND

Richard Bright, Physician Extraordinary to the Queen of England, was the first to associate proteinuria, fullness and hardness of the pulse, and dropsy with "hardening of the kidneys" (Bright, 1827). In 1856, Traube, from an analysis of pulse tracings, suggested that the abnormality might be high blood pressure, and Mohomed (1874) demonstrated "high tension in the arterial system" in association with renal disease.

The critical experimental work was the discovery of renin by Tigerstedt and Bergemann (1898), who noted an increase in arterial blood pressure in rabbits injected with a saline renal extract. They reasoned that the renal extract contained a pressor substance and coined the term *renin*. However, the significance of their work was not recognized until the critical experiments by Goldblatt and colleagues (1934), who produced diastolic hypertension in dogs by clamping the main renal arteries and corrected the hypertension by clamp removal.

Soon thereafter, Butler (1937) reported the first reversal of hypertension after nephrectomy in a patient with a small "pyelonephritic kidney"; 1 year later, Leadbetter and Burkland (1938) reported another cure of hypertension in a child with pathologic signs of a renal arterial lesion.

These clinical observations were paralleled by laboratory investigation, and in 1940, Page and Helmer, and Braun-Menendez and associates, independently reported that renin itself was not a pressor substance but acted as an enzyme to release a pressor peptide, now called *angiotensin*, from a circulating plasma globulin. Goormaghtigh and Grimson (1939), who had previously described the juxtaglomerular cells, described increased granularity of these cells in both animals and humans with renal hypertension and postulated that these cells were secreting excessive amounts of renin.

There followed an aggressive but disappointing clinical experience with nephrectomy for cure of hypertension in patients with unilateral renal disease. This experience led to the search for a way of proving that a renal lesion was actually causing the hypertension. Smith (1948), reviewing the literature, reported relief of hypertension in only 19% of 200 patients whose elevated blood pressure was thought to result from unilateral renal disease. Thus it became apparent that even if pressor mechanisms did underlie some forms of renal hypertension, there were no ways to measure them.

This challenge led to studies of the effect of renal artery constriction on renal function. **In dogs, renal artery constriction resulted in a marked decrease in sodium and water excretion from the affected kidney** (Blake et al, 1950; Pitts and Duggan, 1950). In 1964, Howard and Connor used these observations to develop a differential renal function test based on bilateral ureteral catheterization to identify the "ischemic kidney." Another major advance was the development of translumbar aortography and the demonstration of its value in visualizing renal

arterial lesions (Smith et al, 1952). By 1957, the first large series of studies of patients with renal arterial lesions was reported (Poutasse and Dustan, 1957).

In addition, interest in what would become known as the *renin-angiotensin-aldosterone system* (RAAS) was also emerging as new discoveries were made. Accordingly, it was determined that there were two forms of angiotensin (Skeggs et al, 1954), and angiotensin was sequenced and synthesized (Bumpus et al, 1957). These critical advancements led to an accurate radioimmunoassay for angiotensin, the development of angiotensin analogues, and angiotensin-converting enzyme (ACE) inhibitors, all major tools now used to identify the patient with renovascular hypertension (RVH). More recently, the presence of a family of angiotensin receptors has been clarified (Kang et al, 1994; Goodfriend et al, 1996), and specific blockers of the angiotensin receptor have been used clinically for treatment of hypertension.

It is now recognized that the RAAS is a critical integrated system regulating not only blood pressure, sodium balance, and potassium balance but also regional blood flow and, in particular, the glomerular filtration rate (GFR) (Gunning et al, 1996; Laragh and Blumenfeld, 1996). Moreover, there is an expanding body of literature implicating angiotensin II in cell proliferation and interstitial fibrosis (Mai et al, 1993; Eng et al, 1994; Stoll et al, 1995; Egido, 1996; Gunning et al, 1996).

DEFINITIONS

Hypertension

As strange as it may seem, it has been difficult to establish a precise definition of *hypertension*. The problem was best stated by Sir George Pickering, who wrote that "there is no dividing line. The relationship between arterial blood pressure and mortality is quantitative; the higher the pressure the worse the prognosis" (Pickering and Pickering, 1995; Pickering et al, 1996). Indeed, cumulative data obtained from insurance companies have validated this point! **Untreated blood pressure in excess of 140/90 mm Hg is associated with excess mortality, and diastolic pressures below 70 mm Hg are optimal** (Lew, 1973). For operational purposes, the World Health Organization has defined hypertension in adults as a systolic pressure greater than 160 mm Hg or a diastolic pressure greater than 95 mm Hg or both. In addition, consistent elevation of blood pressure should be established with repeated readings before evaluation is instituted. In children, there is a rise in blood pressure with age; an upper normal limit of 130/80 mm Hg is reached by 12 to 15 years of age.

Renal Arterial Disease versus Renovascular Hypertension

The development of arteriography provided an accurate means of identifying renal arterial disease and heralded the advent of renal arterial vascular repair (Freeman et al, 1954), which renewed enthusiasm for surgical management of the disease. However, it soon became apparent that normotensive patients undergoing arteriography for other reasons often had renal arterial disease (Eyler et al, 1962), especially those with arteriosclerotic disease (Wilms et al, 1990), and autopsy figures supported the radiologic findings (Holley et al, 1964). Accordingly, **the finding of renal arterial disease alone is not sufficient justification to warrant correction in a hypertensive patient. The lesion must be functionally significant** (i.e., it must reduce blood flow by an amount sufficient to activate renin release, initiating RVH). Hence, **a practical definition of RVH is hypertension resulting from a renal arterial lesion that is relieved by correction of the offending lesion or removal of the kidney.**

PATHOLOGY AND NATURAL HISTORY

The two major pathologic entities that cause renal arterial disease are atherosclerosis obliterans (ASO) and fibrous dysplasia (FD). The Cleveland Clinic group has emphasized the importance of the various distinct histologic patterns, identifiable by angiographic techniques, that have predictable natural histories (Schreiber et al, 1984, 1989; Novick et al, 1994). Their classification is shown in Table 39–1.

Atherosclerosis

Approximately 70% of all renovascular lesions are caused by atherosclerosis (Novick et al, 1996). This disease may be limited to the renal artery but more commonly is a manifestation of generalized atherosclerosis, involving the abdominal aorta and coronary, cerebral, and lower extremity vessels. Atherosclerotic stenosis usually occurs in the proximal 2 cm of the renal artery, and distal arterial or branch involvement is distinctly uncommon. Owing to the proximal location of these lesions, oblique aortic views are often needed to adequately visualize the area of stenosis. The lesion involves the intima of the artery and, in two thirds of the cases, presents as an eccentric plaque (Fig. 39–1); in the

Table 39–1.

Classification and Natural History of Renovascular Disease

Atherosclerosis: Proximal intimal plaques. Seen predominantly in males and usually in older age groups. Progressive in about 40% of patients; may dissect or thrombose. May involve renal arteries only or may involve carotid and coronary arteries, aorta, and other vessels.

Intimal fibroplasia: Collagenous disease involving intima; seen in children and young adults. Progressive; may dissect. May involve other vessels.

True fibromuscular hyperplasia: Diffusely involves media. Seen in children and young adults. Progressive. Radiographically indistinguishable from intimal fibroplasia. Very rare.

Medial fibroplasia: Series of collagenous rings involving media of main renal artery, often extending into branches. Usually seen in women in their 30s and 40s. Produces typical "string of beads" pattern in angiography. Does not dissect, thrombose, or rupture, and seldom progresses after 40 years of age. May involve other vessels.

Perimedial (subadventitial) fibroplasia: Dense collagenous collar involving media, just beneath adventitia of vessel. Tightly stenotic, with extensive collateral circulation on angiography. Seen mostly in women ("girlie disease"). Progressive. Involves renal arteries only.

Miscellaneous: Renal artery aneurysms, middle aortic syndrome, periarterial fibrosis, and post-traumatic intimal or medial disease. Variable in location and obstruction; occurs in diverse clinical settings.

remainder, the vessel is circumferentially involved, with narrowing of the lumen and destruction of the intima. Dissecting hematomas frequently complicate this disease, sometimes resulting in thrombosis of the entire vessel.

The natural history of atherosclerotic renal artery disease (RAD) has been studied by obtaining sequential abdominal aortography or duplex ultrasound scanning in patients with documented renal artery lesions who have been treated medically (Table 39–2). The largest of these studies have shown that **progressive arterial obstruction occurs in 42% to 53% of patients with atherosclerotic renal artery disease, often within the first 2 years of radiographic follow-up. The incidence of progression to complete renal artery occlusion in these studies has ranged from 9% to 16%, and this has occurred more often in arteries that initially showed high degrees of stenosis.**

Schreiber and colleagues (1984) reviewed the natural history of atherosclerotic renal artery stenosis (ARAS) in 85 patients who were followed with sequential renal angiograms obtained 3 to 172 months after an initial diagnostic angiogram. Progressive obstruction of the renal artery due to atherosclerosis occurred in 37 patients (44%), including 14 (16%) in whom such progression eventuated in complete occlusion of the involved renal artery. In patients in whom progressive disease developed, it occurred primarily within the first 2 years of angiographic follow-up. The rate of progression of ARAS correlated directly with the degree of stenosis on the initial angiogram. The majority of renal arteries with mild (50%) or moderate (50% to 75%) stenosis on the initial angiogram were unchanged on follow-up angiograms. In contrast, 39% of renal arteries with more than 75% stenosis on the initial angiogram progressed to complete occlusion. Other studies have since validated this observation that **progression to 100% occlusion occurs more often and more rapidly in renal arteries that are initially involved with a high degree** (>75%) of stenosis (Tollefson and Ernst, 1991; Zierler et al, 1994).

Clinical follow-up of patients in the same study (Schreiber et al, 1984) also revealed that significantly more patients with progressive disease developed deterioration of overall renal function compared with patients with stable disease. Interestingly, **serial blood pressure control** was equivalent in these two groups, indicating that blood pressure is not a useful clinical marker for progressive ARAS.

These natural history data clearly show that **atherosclerotic renal artery disease progresses in many patients, and that loss of functioning renal parenchyma is a common sequela of such progression.** Such loss of renal function due to progressive atherosclerotic renal artery obstruction can result in end-stage renal disease (ESRD). In this setting, ESRD occurs in older patients with generalized atherosclerosis who are not suitable candidates for transplantation and whose prognosis on chronic dialysis is poor in terms of both the quality of life and longevity. An early study identified 25 patients in whom ESRD was clearly a consequence of advanced atherosclerotic renal artery disease (Novick, 1994b). Seventeen of these patients were maintained on chronic dialysis, and, of these, 13 died within 1 year (mean survival 8.7 months). The causes of death on dialysis were myocardial infarction (6), infection (2), gastrointestinal bleeding (1), ruptured aortic aneurysm (1), mesenteric infarct (1), cardiogenic shock (1), and cerebrovascular accident (1). In a subsequent study, Mailloux and colleagues (1988) analyzed the survival of patients started on dialysis from 1970 to 1985 according to the primary renal diagnosis. Patients with renovascular disease as the cause of ESRD had the poorest survival, with a 27-month median survival time and a 12% 5-year survival rate. In another study, in which 51 patients with bilateral ARAS were followed for 52 months, 12% of the patients progressed to ESRD, and an average rate of decline of GFR of 4 mL/min/yr was noted (Baboolal et al, 1998). A crude mortality rate of 45% was reported. These data further highlight that ESRD from atherosclerotic renal artery disease does not respond well to renal replacement therapy.

The exact incidence of ESRD caused by atherosclerotic renal artery disease in the United States is not known. Fatica and colleagues (2001) reported an increase in incidence of renal vascular disease (RVD) as a cause for ESRD in patients starting dialysis treatment. This increase was from 1.4% to 2.1%, with an annual increase of 12%. This information was derived from the recorded diagnosis of these patients in the U.S. Renal Data System database, and the disease was not specifically searched for. No increase in mortality on dialysis was found in these patients when compared with other etiologies of ESRD.

When investigating the use of CT angiography, van Ampting and coworkers (2003) reported a 27% incidence of significant renal artery stenosis (RAS) in 49 patients over 45 years of age starting dialysis.

Uzu and coworkers (2002) reported a higher (50%) incidence in 44 patients with ESRD who were studied by magnetic resonance angiography when additional vascular disease (cerebral, coronary, or peripheral) was also diagnosed.

In a report from England, Scoble and colleagues (1989) prospectively performed renal arteriography in all new patients with ESRD during an 18-month period. Atherosclerotic renal artery disease was the cause of ESRD in 6% of all patients, and in 14% of patients older than 50 years. Approximately 300,000 patients in the United States are currently being maintained on chronic dialysis. Their median age is older than 60 years, and a majority show evidence of generalized atherosclerosis obliterans. **Although the exact number of patients with ESRD caused by atherosclerotic renal artery disease is not known, based on the data previously described, there appear to be several thousand patients in this category**.

Fibrous (Fibromuscular) Dysplasia

Fibrous dysplasia (FD) is a nonatherosclerotic noninflammatory vascular disorder with multiple subtypes depending upon the portion of the vessel wall that is primarily involved. The vast majority of cases affect the media (medial fibroplasia); less common is perimedial fibroplasia, intimal fibroplasia, and fibromuscular hyperplasia.

Intimal Fibroplasia

Primary intimal fibroplasia occurs in children and in young adults and constitutes approximately 10% of the total number of fibrous lesions. This lesion is characterized by a circumferential accumulation of collagen inside the internal elastic lamina (Fig. 39–2). Disruption and duplication of the elastica interna occur more often in younger patients, with dissecting hematomas as a complication in many patients. The possibility of atherosclerosis as a cause of renal artery disease in this group can be excluded histologically by the absence of lipid demonstrable with special staining techniques. Intimal fibroplasia with complicating medial dissection is characterized pathologically by large dissecting channels in the outer half of the media. These lesions are thought to develop because of defects in the internal elastica with resultant medial dissection and aneurysmal dilatation.

Angiography in primary intimal fibroplasia reveals a smooth, fairly focal stenosis, usually involving the proximal or midportion of the vessel or its branches (Fig. 39–3). Dissecting hematomas may distort the area of the stenosis. With nonoperative management, progressive renal artery obstruction and ischemic atrophy of the involved kidney invariably occur. Severe intimal fibroplasia may subsequently develop de novo in the contralateral renal artery. Although primary intimal fibroplasia most commonly affects the renal arteries, it may also occur as a generalized disorder with concomitant involvement of carotid, upper and lower extremity, and mesenteric vessels.

Medial Fibroplasia

Medial fibroplasia is the most common of the fibrous lesions, constituting 75% to 80% of the total number. It tends to occur in women between the ages of 25 and 50 years and often involves both renal arteries. It may involve other vessels in the body, most notably the carotid, mesenteric, and iliac arteries. Microscopically, the internal elastic membrane is focally and variably thinned and lost. Within the alternating thickened areas, much of the muscle is replaced by collagen, hence the term *medial fibroplasia*. In other areas, thinning of the media occurs to the point of complete loss, and microaneurysms can be seen as saccules lined by only the external elastica. In extreme cases, giant aneurysms may be found in association with medial fibroplasia.

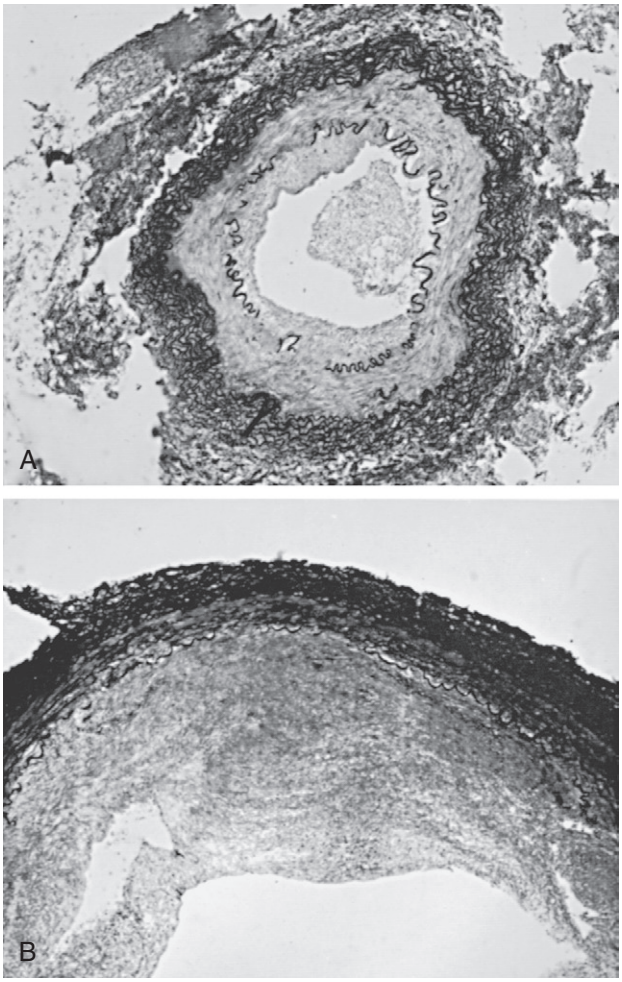

Figure 39–2. **A,** Photomicrograph of a cross section demonstrates intimal fibroplasia with focal fragmentation and partial absence of the elastica interna. **B,** Photomicrograph of cross section demonstrates severe renal arterial intimal fibroplasia with a dense cuff of intimal collagen apposed to the luminal surface of a partially disrupted elastica interna. A small recannulized channel is noted in the lower left. (From Novick AC. Renal vascular hypertension in children. In: Kelalis PP, King LR, Belman AB, editors. Clinical pediatric urology. Philadelphia: WB Saunders; 1984.)

Angiographically, medial fibroplasia demonstrates a typical "string of beads" appearance involving the distal two thirds of the main renal artery and branches (Fig. 39–4). The areas of stenosis are often overshadowed by contrast medium in the microaneurysms, making the degree of actual stenosis difficult to assess. The aneurysms themselves are greater in diameter than the normal renal artery proximal to the disease, and extreme collateral circulation is absent. These are important features in differentiating the lesion from perimedial fibroplasia.

Figure 39–3. Aortogram of a 6-year-old boy demonstrates proximal left renal artery stenosis *(arrow)* from intimal fibroplasia. (From Novick AC. Renal vascular hypertension in children. In: Kelalis PP, King LR, Belman AB, editors. Clinical pediatric urology. Philadelphia: WB Saunders; 1984.)

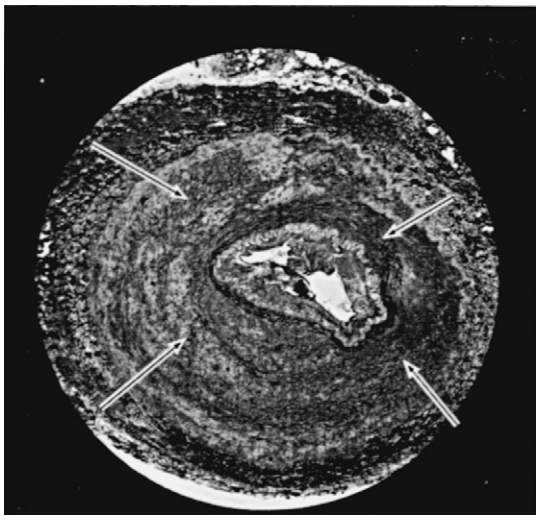

Figure 39–5. Cross section of the main renal artery in a girl with perimedial fibroplasia demonstrates a dense collagenous collar *(arrows)* involving the outer media of the vessel, which causes a severe progressive stenosis. (From Novick AC. Renal vascular hypertension in children. In: Kelalis PP, King LR, Belman AB, editors. Clinical pediatric urology. Philadelphia: WB Saunders; 1984.)

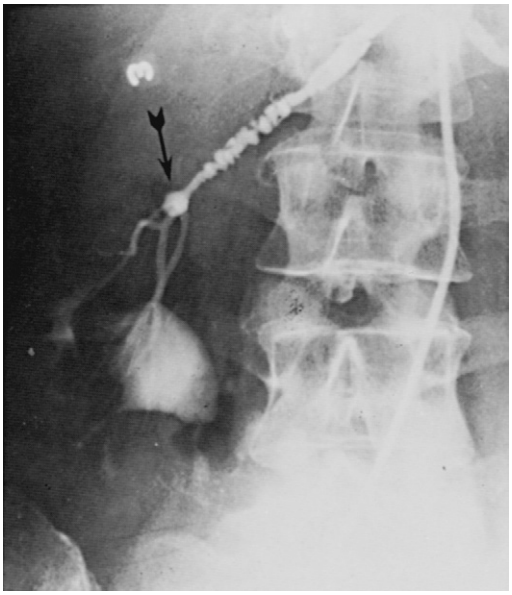

Figure 39–4. Selective right renal arteriogram reveals medial fibroplasia involving the main renal artery with typical "string of beads" appearance. (From Novick AC. Renal vascular hypertension in children. In: Kelalis PP, King LR, Belman AB, editors. Clinical pediatric urology. Philadelphia: WB Saunders; 1984.)

Schreiber and colleagues (1984) studied the natural history of renal artery disease due to medial fibroplasia in 66 patients who were followed with serial angiography. Progressive renal artery stenosis (RAS) occurred in 22 patients (33%), and, contrary to an earlier report, this occurrence was no different whether patients were older or younger than 40 years. Significantly, there were no cases of progression to total arterial occlusion in this group. Also, clinical follow-up revealed that serial decreases in either overall renal function or the size of the involved kidney seldom occurred in patients with progressive medial fibroplasia, suggesting that the risk of losing renal function is relatively small in patients with this disease who are managed medically.

Perimedial Fibroplasia

Perimedial fibroplasia occurs predominantly in young women between the ages of 15 and 30 years and has therefore been referred to, rather crudely, as *girlie disease*. It constitutes about 10% to 15% of the total number of fibrous lesions and occurs only in the renal artery. This is a tightly stenotic lesion that, pathologically, consists of a collar of dense collagen enveloping the renal artery for variable lengths and thicknesses. The collagen is deposited in the outer border of the media, usually replaces a considerable portion of the media, and may replace it completely in some areas (Fig. 39–5). Islands of smooth muscle are occasionally seen trapped within the collagenous ring. Special stains show that the lesion is confined within the external elastic lamina and contained in all cases by intact adventitial connective tissue. The arterial lumen may be further compromised by a process of secondary intimal fibroplasia. It has been suggested that this secondary thickening of the intima is related to slowing of blood flow through a narrowed arterial segment, with resultant platelet and fibrin deposition and subsequent fibrous organization.

The arteriogram in perimedial fibroplasia may give the appearance of arterial beading, but careful observation shows that the caliber of the normal segment of the vessel is not exceeded by the "bead" (Fig. 39–6). This fact, along with the frequent occurrence of extensive collateral circulation, differentiates this lesion angiographically from that of medial fibroplasia. Perimedial fibroplasia produces severe stenosis, and, although complicating thrombosis or dissection is relatively uncommon, progressive obstruction with ischemic renal atrophy occurs in almost all patients managed nonoperatively.

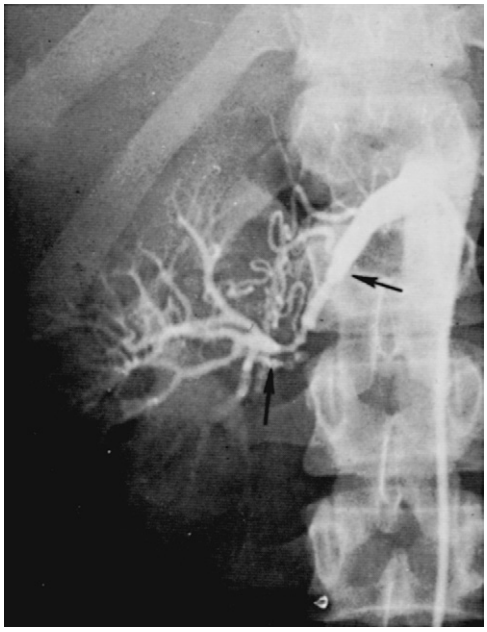

Figure 39–6. Renal arteriogram in a patient with perimedial fibroplasia shows slightly irregular, yet severe, stenosis of the midrenal artery *(arrows)* associated with extensive collateral circulation to the kidney. The small size of the arterial irregularities and the presence of collateral circulation distinguishes this lesion radiographically from medial fibroplasia. (From Novick AC. Renal vascular hypertension in children. In: Kelalis PP, King LR, Belman AB, editors. Clinical pediatric urology. Philadelphia: WB Saunders; 1984.)

Fibromuscular Hyperplasia

Fibromuscular hyperplasia is an extremely rare disease, constituting only 2% to 3% of fibrous lesions, and tends to occur in children and young adults. This is the only renal arterial disease in which true hyperplasia of the smooth muscle cells is present. The renal artery shows a concentric thickening of its wall with a mixture of proliferating smooth muscle and fibrous tissue in variable quantity. Angiographically, fibromuscular hyperplasia presents as a smooth stenosis of the renal artery or its branches and, from a radiographic standpoint, may be indistinguishable from intimal fibroplasia. Most patients with this disease have developed progressive vascular obstruction when followed with serial angiographic studies.

Key Points: Pathology of Renal Artery Stenosis

- The finding of anatomical stenosis does not denote arterial hypertension; renal artery stenosis has to be functionally significant to produce renovascular hypertension.
- The vast majority of cases of renovascular hypertension are caused by two entities: fibromuscular disease (generally younger patients) and atherosclerosis (generally older patients).
- Atherosclerosis of the renal artery is usually a component of generalized atherosclerosis, and can often be progressive, usually with associated loss of kidney function.
- Medial fibroplasia is the most common type of fibromuscular disease, and is rarely associated with progression to occlusion of the renal artery or renal function deterioration.

PHYSIOLOGY OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The RAAS plays a fundamental role in maintaining arterial blood pressure as well as extracellular volume. The system is composed of a series of proteins and peptides that react in a cascade, ultimately resulting in a widespread series of actions. Local renin-angiotensin systems are widely present in several organ systems and exert numerous local actions. **The main components of the system are angiotensinogen, renin, ACE, and various angiotensins, the most important being angiotensin II (AII). AII is a powerful vasoconstrictor that increases peripheral vascular resistance to raise blood pressure. In addition, AII stimulates sodium reabsorption directly and through stimulation of aldosterone synthesis. The primary role of the RAAS is to maintain tissue perfusion, especially in cases of hypovolemia.**

The basic cascade involves conversion of angiotensinogen to angiotensin I (AI) through the action of renin. This is the rate-limiting step for the entire system, and, accordingly, control of renin release regulates the activity of the whole system. ACE then acts on AI to produce AII, which exerts a wide variety of immediate and delayed actions on the vascular system and kidneys, as well as stimulates production of aldosterone from the adrenal cortex. In healthy subjects with normal dietary sodium intake, the RAAS probably plays a minor role in day-to-day blood pressure control. Several disease states, however, activate the RAAS. True hypovolemia or hypotension is the physiologic stimulus for AII secretion. Inappropriate activation of the RAAS occurs in cases of perceived hypovolemia, such as renal artery stenosis, congestive heart failure, or advanced hepatic disease, and leads to hypertension, inappropriate salt and fluid retention, or both.

Angiotensinogen

Angiotensinogen is a 452–amino acid protein and is the source of all angiotensins (Kageyama et al, 1984). It is formed as preangiotensinogen and loses the signal peptide as it becomes secreted from the cell as angiotensinogen. It functions as a serine protease inhibitor (serpin) similar to α_1-antitrypsin and antithrombin III, with which it shares some structural homology (Carrell et al, 1987). It is present in plasma in two forms, a smaller (52- to 60-kD) predominant molecule and a larger (450- to 500-kD) molecule that increases in pregnancy and after estrogen treatment (Tewksbury and Dart, 1982). The larger form is probably composed of the smaller molecule bound to other plasma proteins. Renin acts on the smaller form of angiotensinogen preferentially, cleaving AI off the larger molecule. Renin reacts with much less affinity with the larger form, also forming AI.

The liver is the primary site of synthesis of angiotensinogen, which is not stored but secreted directly after production. Angiotensinogen mRNA is widely present in several tissues that are regulated by local renin-angiotensin systems, including the central nervous system (CNS), kidney, adrenal, heart, and leukocytes (Dzau et al, 1987). Several hormones stimulate angiotensinogen synthesis by the liver, including estrogens and glucocorticoids. Stressful stimuli, such as infection or tissue injury, also increase plasma angiotensinogen levels (Hoj Nielsen and Knudsen, 1987). Feedback control through the RAAS is also present, with AII increasing and renin decreasing plasma levels of angiotensinogen.

Renin

Renin is a single–polypeptide chain aspartyl protease that is secreted from the juxtaglomerular cells of the afferent arteriole. **The kidney is the major site of renin production,** although renin mRNA is found in several other tissues where a local renin-angiotensin system functions. It is produced as pre-prorenin, and both active renin and prorenin are secreted (Atlas et al, 1980). The function of circulating prorenin is not clear, and it does not appear that prorenin is transformed to active renin in the circulation (Sealey et al, 1977). The action of renin is very specific, restricted to cleavage of a single bond, separating AI from angiotensinogen. Because renin controls the rate-limiting step of the RAAS, control of renin secretion regulates the activity of the RAAS. Several mechanisms affect the secretion of renin, as described in the following sections.

As the first and rate-limiting step for production of angiotensin II, targeting renin is an attractive option for inhibiting the RAAS. Recently a new class of orally effective medications targeting renin has been developed and approved for treatment of hypertension, direct renin inhibitors (DRI). The first of these medications is aliskiren, is a competitive analog and specific inhibitor of human renin, with therapeutic potential similar to other available antagonists of the RAAS (ACE inhibitors, angiotensin receptor blockers) (Nussberger et al, 2002).

Macula Densa Mechanism

The macula densa region of the thick ascending loop of Henle comes in close proximity to the juxtaglomerular cells and influences renin release. **Reduction of distal tubule salt delivery stimulates renin secretion, and vice versa.** Although sodium was initially thought to be responsible for this action, it now appears that the signal for macula densa–controlled renin release is the alteration of tubular chloride concentration (Lorenz et al, 1990).

Baroreceptor Mechanism

The juxtaglomerular cells of the afferent arteriole act as their own baroreceptors by responding directly to stretch of the afferent arteriole (Tobian et al, 1959). **Diminished cell stretch, as a result of renal hypoperfusion, hyperpolarizes the juxtaglomerular cells, resulting in decreased intracellular calcium and increased renin release.**

Neural Mechanism

The juxtaglomerular cells are richly innervated by β-adrenergic sympathetic nerve fibers. Stimulation of these β-adrenergic nerves leads to increased renin secretion (Keeton and Campbell, 1980). Dopamine is also stimulatory to renin release, although the limited number of dopaminergic nerve endings results in a much smaller role (Mizoguchi et al, 1983). Renal nerve stimulation is the mechanism through which renin release is increased as a result of exercise and tilting.

Endocrine and Paracrine Mechanisms

Several local and systemic hormones affect the rate of renin secretion. Foremost among these are prostaglandins. **Prostaglandin E_2** and **I_2** (prostacyclin), as well as exogenously administrated arachidonic acid, stimulate renin secretion (Franco-Saenz et al, 1980; Whorton et al, 1980). This prostaglandin effect is independent of the other mechanisms controlling renin release. AII inhibits renin release as a feedback mechanism. Other inhibitors of renin release include endothelin, vasopressin, and atrial natriuretic peptide.

Intracellular Mechanisms

Agents that increase adenylate cyclase activity increase the secretion of renin, including β-adrenergic agonists, prostaglandin E_2, prostaglandin I_2, dopamine, histamine, and parathyroid hormone. This is because cyclic adenosine monophosphate (cAMP) is an important second messenger in renin release. Intracellular calcium concentrations are also important in controlling renin release. AII, vasopressin, and adenosine increase intracellular calcium levels and inhibit renin secretion through their effect on intracellular calcium levels.

Angiotensin-Converting Enzyme

ACE is a zinc-containing single-chain glycoprotein enzyme. It is also known as *kininase II* and is a dipeptidyl carboxypeptidase (Ehlers and Riordan, 1989). It splits two amino acids off the carboxy terminus of AI to form AII and, at the same time, functions in the kallikrein-kinin system by inactivating bradykinin. ACE is found in a wide variety of organs, where it is primarily expressed on endothelial, epithelial, and neuroepithelial cells. A high concentration of ACE is found in the kidney, ileum, duodenum, and uterus (Lieberman and Sastre, 1983). **Although pulmonary endothelial ACE was presumed to be the major site of ACE activity for the systemic RAAS, it is now believed that peripheral sites might play an equal role.** The majority of circulating ACE originates from endothelial cells and macrophages.

ACE is expressed in several tissues where local renin-angiotensin systems function. Renal ACE is localized to the glomerular endothelial cells and the proximal tubule brush border, where it might play a role in cleaving filtered protein for reabsorption (Danilov et al, 1987). Within the CNS, ACE is found in several locations, where it functions in the local renin-angiotensin system. This local CNS renin-angiotensin system is thought to have dipsogenic and hypertensive effects as well as to stimulate vasopressin secretion (Strittmatter and Snyder, 1987). Adrenal ACE is found predominantly in the medulla, where it is thought to stimulate catecholamine secretion (Peach et al, 1971). ACE is found abundantly in the testes and prostate, in the Leydig cells, and also in cytoplasmic droplets in sperm (Pandey et al, 1984; Yotsumoto et al, 1984). In the female reproductive tract, ACE is found in follicular and fallopian tube oocytes (Brentjens et al, 1986). The precise role of ACE in the reproductive system has not been elucidated. Several hormones and disease states affect the level and activity of ACE. Corticosteroids, as well as thyroid hormones, stimulate ACE activity (Friedland et al, 1978; Smallridge et al, 1983). The serum ACE level is increased in silicosis, primary biliary cirrhosis, and sarcoidosis (Studdy et al, 1983). As mentioned previously, **ACE is not the rate-limiting step in the RAAS cascade; so, changes in serum ACE levels do not directly affect the activity of the systemic RAAS (circulating AII levels)**.

In addition to ACE, several angiotensinases act in the RAAS to lesser degrees. The physiologic contribution of these enzymes to the function of the RAAS is not clear. Most of these enzymes are present in body tissues such as the kidney. Among these are aminopeptidase A and angiotensinase A, B, and C. Nonspecific

angiotensinases hydrolyze AII and angiotensin III (AIII), inactivating them rapidly.

Angiotensin II

The role of the RAAS in the control of blood pressure and extracellular volume is carried out through the integration of a variety of actions performed by AII. Vasoconstriction and the release of aldosterone occur immediately and are of short duration, supporting the role of AII in maintaining tissue perfusion in hypovolemia. Other actions such as vascular growth and ventricular hypertrophy are slower in onset and longer in duration, lasting for several days or weeks.

Effect of Angiotensin II on Glomerular Circulation

One of the most important actions of AII is the autoregulation of the GFR in response to changes in renal perfusion. These are affected through changes in vascular resistance as well as mesangial cell tone. AII causes a marked increase in efferent arteriolar resistance in cases of renal hypoperfusion but does not affect afferent arteriolar resistance unless there is an increase in renal perfusion pressure. The result of this disproportionate increase in efferent over afferent resistance is an increase in capillary hydraulic pressure, and subsequently in filtration pressure, maintaining the GFR in the face of decreased renal perfusion (Hall et al, 1977). It is through inhibition of this action that ACE inhibitors result in a decrease in GFR in cases of renal artery stenosis. This effect of AII on the glomerular circulation is thought to be mediated through differential induction of vasodilatory prostaglandins from the afferent and efferent vessels (Hura and Kunau, 1988).

In addition to its effects on the glomerular vessels, AII directly results in mesangial cell contraction, leading to a decrease in the filtration coefficient of the glomerulus (Blantz et al, 1976).

Tubular Effects of Angiotensin II

AII-induced increases in the filtration fraction lead to an increase in the oncotic pressure in the postglomerular vessels. This leads to an increase in fluid reabsorption in the proximal tubules. AII receptors are also present on the proximal tubule brush border and basolateral sides, and AII is produced in large amounts locally within the proximal tubules. AII is present within the proximal renal tubule in much higher concentration than in the plasma (Seikaly et al, 1990). **The effect of AII on sodium reabsorption is bimodal; physiologic concentrations of AII stimulate sodium reabsorption in the proximal tubule, whereas higher concentrations inhibit sodium transport** (Harris and Young, 1977).

Medullary Effects

AII decreases medullary blood flow, leading to increased medullary hypertonicity and concentration of urine (Arendshorst and Finn, 1977).

Vascular Effects

AII raises blood pressure by increasing peripheral vascular resistance through a direct effect on vascular smooth muscle cells, causing them to contract. Medium-sized and small arteries are more responsive to AII than large vessels. Contraction occurs mainly in the vessels of the kidney, skin, mesentery, coronary arteries, and brain. Vessels of the lung and skeletal muscle are less responsive to AII. In addition to vasoconstriction, AII stimulates vascular smooth muscle cell growth, leading to a hypertrophic response (Geisterfer et al, 1988). Such smooth muscle proliferation results in left ventricular hypertrophy in cases of chronic stimulation of the RAS. AII is also involved in inflammatory processes including atherosclerosis. This cascade of cardiovascular events including hypertension, ventricular hypertophy, and atherosclerosis is felt to be central to the development of heart failure. With this mechanism in mind, interruption of the RAAS through multiple pharmacologic channels has become a major objective in lowering cardiac mortality associated with hypertension and heart failure.

Adrenal Effects

AII acts directly on the adrenal glomerulosa cells to stimulate aldosterone secretion. This is accomplished through increased desmolase activity and increased conversion of corticosterone to aldosterone (Aguilera, 1993). This augments the salt reabsorptive actions of AII to conserve sodium.

CNS Renin-Angiotensin-Aldosterone System

The CNS is affected mainly by the local renin-angiotensin system, but high circulating levels of AII may also affect CNS function. Central AII results in an increase in blood pressure as well as increased drinking and salt appetite (Sweet et al, 1971; Fitzsimons, 1980). Central AII also leads to increased secretion of corticotropin, prolactin, luteinizing hormone, oxytocin, and vasopressin (Unger et al, 1988).

Gonadal Renin-Angiotensin-Aldosterone System

Gonadal RAAS is present in both the testis and the ovary. The function of testicular RAAS is not clear; in the ovary, RAAS may play a role in oocyte maturation.

Angiotensin II Receptor Subtypes

Nonpeptide receptor antagonists have provided definite proof of at least two major angiotensin receptor subtypes, named AT1 and AT2. Both receptors are polypeptides containing 360 amino acids spanning the cell membrane several times. They are functionally distinct with a sequence homology of 30%. The gene for the AT1 receptor is located on chromosome 3, and the gene for the AT2 receptor is located on the X chromosome (Goodfriend et al, 1996). AT1 receptors are blocked by DuP 753 (losartan), and AT2 receptors are blocked by tetrahydroimidazopyridines such as PD 123177. AT1 receptors have a higher affinity for AII than AIII, but AT2 receptors bind both AII and AIII equally. AT1 receptors have been further subtyped into two isoforms, AT1A and AT1B, although the function of the subtypes is not clear.

The AT1A receptor is expressed in the liver, kidney, aorta, uterus, adrenals, ovary, spleen, and lung as well as in the hypothalamus.

The AT1B receptor is expressed in the pituitary, adrenals, kidney, uterus, and liver and is absent in the heart, brain, and spleen. In fetal life, the AT2 receptor is widely present in the adrenals, kidney, liver, skin, tongue, and brain. In the adult, this distribution becomes restricted to the adrenals, uterus, ovary, heart, and some nuclei in the brain.

In the kidneys, AT1 receptors are located predominantly in the glomeruli and tubulointerstitium, whereas AT2 receptors are located in the large cortical blood vessels (Goldfarb et al, 1994).

Almost all the vascular effects of AII, including vasoconstriction, aldosterone release, and β-adrenergic stimulation, are mediated by the AT1 receptor (Timmermans et al, 1992). The development of AT1 receptor antagonists (e.g., losartan) has produced a new class of drugs, as well as an effective tool for blocking the RAAS in a variety of disease states, including hypertension. Further, these new drugs modulate cardiac and renal injury responses to disease.

The function of the AT2 receptor has not been fully defined; however, it may act in a manner antagonistic to the AT1 receptor, especially in the cardiovascular system, where it exerts antiproliferative, antihypertrophic, and proapoptotic functions (Horiuchi et al, 1999). AT2 receptors are thus thought to mediate protective actions that counterbalance the potentially harmful actions mediated through the AT1 receptors. AT2 receptors are also believed to play a crucial role during gestational growth and development, mainly due to the widespread distribution of these receptors in most body tissues during fetal life. Reexpression of these receptors in adult life occurs as a response to vascular injury or inflammation (Horiuchi et al, 1999).

The signal transduction mechanism initiated by binding of AII to the AT1 receptor has been well described; however, the signal transduction mechanism for the AT2 receptor is not yet known. Binding of AII to the AT1 receptor leads to the dissociation of subunits of a guanine nucleotide–binding protein, which activates phospholipase C to generate diacylglycerol and inositol triphosphate. Inositol triphosphate releases calcium from the endoplasmic reticulum, and AII also increases calcium entry through the cell membrane. The intracellular calcium, as well as diacylglycerol, activates protein kinase C and other enzymes that phosphorylate protein and ultimately regulates the specific cellular function induced by AII (Goodfriend et al, 1996).

Other Angiotensins

The parent peptide of the angiotensin family is the decapeptide AI. Several other peptides are formed within the RAAS, some of which have weak activity compared with AII, and some of which have undetermined activity. As previously mentioned, AII (also called angiotensin 1-8) is the major active peptide in the system; it is an octapeptide formed by the removal of terminal histidine and leucine from the carboxy terminus of AI. AIII (or angiotensin 2-8) is similar to AII but lacks the aspartyl amino acid at the amino terminus of the polypeptide chain. It can be formed from AII or directly from AI. Angiotensin 1-7 lacks the three amino acids at the carboxy terminus of AI and has undetermined receptor activity. AIV is a hexapeptide lacking the two terminal amino acids at both ends of the AI polypeptide chain (Goodfriend et al, 1996).

The actions of angiotensin 1-7 have been defined. It appears to be formed from AI directly by a different enzyme than ACE, called neprilysin. ACE inhibitors thus increase the levels of circulating angiotensin 1-7. It acts in an opposing fashion to AII, producing vasodilatation and natriuresis, and also has antiproliferative effects on vascular smooth muscle (Chappell and Ferrario, 1999).

Key Points: Angiotensin II

- Angiotensin II is the major active component of the renin angiotensin aldosterone system; its main action is to raise blood pressure to maintain tissue perfusion.
- Angiotensin II directly stimulates aldosterone secretion from the adrenal gland.
- The kidney is the major site of renin production, which is the rate-limiting step in aldosterone II production. Renin production is stimulated by mainly by renal hypoperfusion.

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

The classic experiments on RVH were performed by Goldblatt and colleagues (1934), who demonstrated that hypertension could be produced by constricting the renal artery in the dog. Two models of experimental Goldblatt hypertension are described: the two-kidney, one-clip (2K,1C) model, in which one renal artery is clipped and the contralateral kidney is in place and normal; and the one-kidney, one-clip (1K,1C) model, in which one renal artery is clipped and the contralateral kidney is removed. RVH results in both models, but the evolution and the pathophysiologic mechanisms are different. These models provide the basis for understanding the mechanism and evolution of RVH in humans.

Two-Kidney, One-Clip Model

In the two-kidney, one-clip model, the renal artery to one kidney is clipped, resulting in ischemia of the clipped kidney. The RAAS is activated as a result of renal hypoperfusion, resulting in generalized vasoconstriction and systemic hypertension. The adrenal cortex is also stimulated, resulting in secondary hyperaldosteronism and promoting sodium retention by the stenotic kidney. This is the early phase of RVH and is totally mediated by high circulating levels of AII. The normal contralateral kidney is subjected to higher-than-normal perfusion pressure and reacts by suppression of renin secretion as well as "pressure" natriuresis, excreting higher-than-normal levels of sodium and water. Renal vein renin (RVR) from the normal kidney is equal to the arterial value, indicating no secretion by the kidney. In this manner, both kidneys work against each other, with the normal kidney preventing the systemic blood pressure and sodium content from reaching levels high enough to suppress renin release from the stenotic kidney.

Briefly, the two-kidney, one-clip model is characterized by the unilateral release of renin from the ischemic kidney accompanied by contralateral suppression of renin release from the normal kidney, sodium retention by the stenotic kidney, and excretion by the contralateral kidney; euvolemia; and hypertension dependent on AII-induced vasoconstriction. Accordingly, unclipping of the ischemic kidney, ACE inhibitors, or AII antagonists result in a marked decrease in blood pressure.

One-Kidney, One-Clip Model

In the one-kidney, one-clip model, one renal artery is clipped and the contralateral kidney is removed. The solitary ischemic kidney secretes renin, activating the RAAS and resulting in systemic

Table 39–3.
Phases of Experimental Renovascular Hypertension

Chronic Phase
Volume expansion
Suppressed renin secretion
Systemic vasoconstriction
Increased sensitivity to angiotensin II
Increased vasopressin secretion
Increased sympathetic activity
Structural vessel wall changes
Development of contralateral nephrosclerosis

hypertension. Owing to the absence of the normal contralateral kidney, pressure natriuresis does not occur, and the stenotic kidney avidly conserves sodium and fluid, producing volume expansion. The elevation of blood pressure, sodium retention, and volume expansion gradually suppress renin release from the ischemic kidney. Accordingly, although the *generating* mechanism of hypertension is similar in both models, **hypertension in the one-kidney, one-clip model is largely *maintained*** by volume and sodium excess, in the face of normal circulating AII levels. ACE inhibitors or AII antagonists do not result in marked decrease of blood pressure. Under conditions of sodium depletion, hypertension once again becomes dependent on AII, with a marked response to ACE inhibition.

In addition, both models do not remain static but, rather, pass through an acute phase, a transitional phase, and then a final chronic phase (Table 39–3). In cases of two-kidney, one-clip hypertension, after several days or weeks a chronic phase is eventually reached in which unclipping of the stenotic kidney fails to normalize blood pressure. In this chronic phase, the elevated perfusion pressure, as well as high levels of AII, results in widespread arteriolar damage to the contralateral kidney. The excretory function (natriuresis) of the contralateral kidney declines, resulting in extracellular volume expansion, a decrease in circulating AII levels, and the gradual development of a "volume-dependent" type of hypertension. ACE inhibition or removal of the stenotic kidney fails to cure the hypertension in this phase of the disease unless sodium depletion is instituted. Systemic vasoconstriction continues to play a role in maintaining hypertension in the chronic phase, with increased sensitivity to AII, increased vasopressin secretion, and increased sympathetic nervous system activity.

HUMAN CORRELATES OF EXPERIMENTAL RENOVASCULAR HYPERTENSION

The situation in cases of human RVH is not as simple as the experimental models, but **in most cases human unilateral RAS resembles the two-kidney, one-clip model.** A similar sequence of events ensues, with activation of the RAAS resulting in hypertension and secondary hyperaldosteronism, sometimes resulting in hypokalemia. Relief of the stenotic lesion by revascularization or nephrectomy carries a higher chance of amelioration of hypertension if carried out before the development of a chronic phase in which parenchymal damage in the contralateral kidney maintains the blood pressure elevation.

Bilateral renal artery stenosis in humans does not clearly follow either experimental model but rather is a mixed picture with some characteristics of each. In this respect, a beneficial blood pressure response is seen with ACE inhibition, indicating overactivity of the RAAS, and there is also evidence of volume expansion with frequent pulmonary edema, as well as diuresis after revascularization. Different reasons for this mixed picture are possible, mainly owing to the asymmetrical development of renal artery stenosis, starting with unilateral disease and progressing to bilateral disease. Undetermined renal parenchymal damage may occur to the contralateral normal kidney before the onset of bilateral disease as well. Volume overload would then be exacerbated by the development of bilateral disease.

The one-kidney, one-clip model clinically resembles cases of stenosis to a solitary functioning kidney, unilateral renal artery stenosis with parenchymal damage to the contralateral kidney (nephrosclerosis or atheroembolism), and transplant renal artery stenosis.

PATHOPHYSIOLOGY OF ISCHEMIC NEPHROPATHY

In addition to RVH, a second, equally important phenomenon resulting from renal artery stenosis is deterioration of renal function, termed *ischemic nephropathy* (IN). This is a clinical syndrome that occurs through different pathophysiologic mechanisms, is distinct from RVH, and can occur in the absence of elevated blood pressure.

IN is the result of chronic hypoperfusion of the total functioning renal mass. This occurs in the setting of bilateral severe stenosis or stenosis to a functionally or anatomically solitary kidney. The pathophysiology of renal injury as a result of chronic ischemia is poorly understood. This injury is not simply cell death due to a lack of oxygen and nutrients, because the oxygen demand of the kidney never exceeds the supply. Experiments studying the effects of acute renal ischemia do not lend themselves to the explanation of chronic ischemic injury. For ischemic injury to occur, the reduction in renal blood flow needs to exceed the compensatory ability of the kidneys. Renal autoregulation fails to maintain the GFR when renal perfusion decreases below 70 to 80 mm Hg. This occurs when the luminal diameter of the renal artery is stenosed by more than 70% of the original size. At this point, the stenosis becomes hemodynamically significant, resulting in a gradual deterioration of the GFR with an accompanying rise in the serum creatinine level (Fig. 39–7).

Critical reduction of renal blood flow results in IN without affecting renal viability, because renal blood flow is severalfold higher than blood flow to other organs such as the liver or heart. This flow rate far exceeds the needs of the kidney for oxygenation but is necessary to drive glomerular filtration. It is estimated that the kidney needs only about 10% of its blood flow to maintain its oxygen requirement. Under conditions of chronic ischemia, collateral circulation to the kidney develops from the adrenal, lumbar, and ureteric vascular

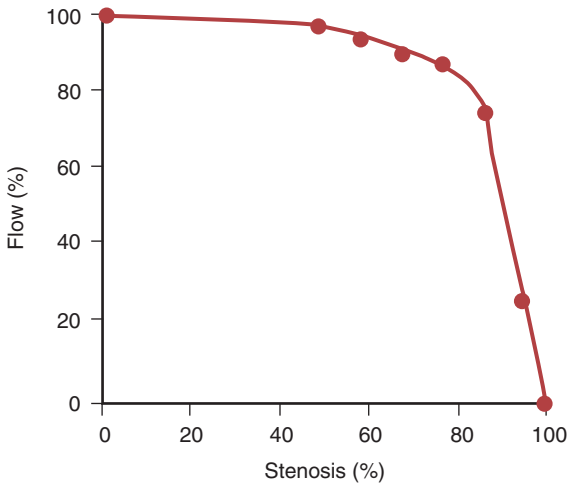

Figure 39–7. Relationship between renal artery stenosis and renal blood flow.

beds and can sustain renal viability even in cases of complete occlusion of the renal artery.

Reduction of renal blood flow activates the RAAS to produce angiotensin II, which maintains glomerular capillary hydrostatic pressure (and GFR) through efferent arteriolar vasoconstriction. Reduction of renal blood flow also leads to redistribution of blood within the kidney and diminished cortical blood flow to prevent medullary anoxia.

The cellular mechanisms by which a decrease in renal size and IN develop are not well understood. Several mechanisms play a role, including vascular mediators (endothelin, thromboxane, prostacyclin, and nitric oxide); calcium accumulation in or adenosine triphosphate (ATP) depletion of the ischemic cells; production of oxygen free radicals; or disruption of cellular membrane polarity (Textor, 1994). The exact role played by each of these mechanisms is not well defined. The action of repetitive cycles of hypoperfusion may allow renal injury to continue before repair is complete, whereas a disturbance in cellular repair processes may hinder recovery between these episodes (Textor, 1996). The point at (or mechanism through) which these changes become irreversible after relief of renal ischemia is even more poorly understood.

Although the exact mechanisms through which chronic ischemic injury of the kidneys occur are not clear, the resulting structural changes within the chronically ischemic kidney have been well identified. Tubular changes are usually most prominent, in the form of patchy tubular necrosis and atrophy. Glomeruli decrease in size, with wrinkling of the glomerular tuft and thickening of the Bowman capsule. Localized or global glomerular sclerosis is also seen. Hypercellularity of the juxtaglomerular apparatus is commonly seen. Blood vessels show the effects of comorbid conditions, such as essential hypertension, diabetes, and hyperlipidemia, with arteriolar thickening and hyalinosis.

Atheroembolism (Cholesterol Embolism)

Renal cholesterol embolism occurs most commonly in older hypertensive patients, with severe abdominal aortic ASO as the most common associated underlying cause, and contributes significantly to renal dysfunction in cases of IN (Vidt et al, 1989). Atheroembolism can occur spontaneously but more commonly follows manipulation of the atherosclerotic aorta by surgery, angiography, or the use of thrombolytic agents. In a review of 221 cases of cholesterol embolism, 69% were spontaneous, and an inciting event precipitated embolism in 31%. Renal manifestations were present in 50% of cases, and the mortality rate was 81% (Fine et al, 1987).

Atheromatous fragments lodged in blood vessels are highly thrombogenic, leading to occlusion of the vessels in which they lodge, and, at the same time, an inflammatory reaction and fibrosis are incited. Cholesterol crystals can remain histologically detectable in blood vessels for up to 9 months after the event. Diagnosis of atheroembolism is made by examination of biopsy samples from the affected tissue, most commonly skin, muscle, or kidney. Cholesterol microemboli are seen within the renal vasculature (needle-shaped cholesterol crystals, which appear birefringent on frozen section and are dissolved by the solvents used in permanent sections, leaving empty cholesterol clefts) and generally portend a poorer prognosis. In a study of 44 patients from the Cleveland Clinic, findings reflective of atheroembolism were identified on intraoperative biopsy of 16 patients (36%) at the time of open surgical renal revascularization. Patients with atheroembolism had a significantly decreased 5-year survival (54% versus 85%), compared with patients who did not exhibit histologic evidence of atheroembolism. Patients with atheroembolism had a significantly higher incidence of postoperative atherosclerotic complications as well as renal and renovascular complications (Krishnamurthi et al, 1999).

The organs most commonly affected by atheroembolism are the kidney, spleen, pancreas, and gastrointestinal tract. Virtually all organs can be affected, however, leading to multisystem organ disease. Cutaneous manifestations are the most common extrarenal manifestation, in the form of livedo reticularis (lacy bluish discoloration affecting the lower extremities), digital cyanosis or gangrene, ulceration, or subcutaneous nodules. Retinal emboli (Hollenhorst plaques) can occur, leading to visual symptoms, or can be silent.

Renal affection takes the form of deteriorating renal function, usually after a precipitating event. Decline of renal function can vary in severity from mild to rapid acute renal failure. Gradual improvement in renal function occurs after the event, but recurrent episodes lead to progressive loss of renal function with time (Siemons et al, 1987). Symptoms of renal involvement are usually absent, but new-onset hypertension or worsening of preexisting hypertension may occur.

A preventive approach to atheroembolism entails avoiding unnecessary or rough manipulation of atherosclerotic vessels, as well as avoiding prolonged anticoagulation in patients at risk for

Key Points: Ischemic Nephropathy

- Pathophysiologic aspects of renovascular hypertension differ according to the presence or absence of a normal contralateral kidney, from a euvolemic angiotensin II–dependent hypertension to a volume-expanded hypertension with a normal angiotensin II level.
- Ischemic nephropathy is the deterioration of kidney function secondary to renal artery stenosis, and follows separate and distinct pathophysiology from renovascular hypertension.
- Ischemic nephropathy occurs in the setting of bilateral significant renal artery stenosis or significant stenosis of the artery of a solitary kidney.

developing atheroemboli. **Management of cholesterol embolism is supportive, with removal of the inciting trauma if present, cessation of anticoagulation, control of hypertension, and institution of renal replacement therapy as needed.** Increased awareness of this condition has led to early diagnosis and institution of aggressive supportive care, resulting in a decline in mortality from the disease. A 1999 study of intensive multiorgan support for 67 patients reported a mortality rate of only 16%, with 32% of the survivors requiring long-term dialysis therapy (Belenfant et al, 1999).

CLINICAL FEATURES OF RENOVASCULAR HYPERTENSION

Although RVH is the most common correctable cause of secondary hypertension (with the exception of hypertension due to oral contraceptive use), the prevalence of RVH is probably less than 1% for patients with mild or moderate hypertension (Lewin et al, 1985). For this reason, before subjecting patients to numerous diagnostic procedures that are potentially invasive and costly, enough clinical suspicion needs to be generated to prevent unnecessary investigations of the patient with essential hypertension. Patients with RAS may also present with renal impairment (IN) in the presence or absence of RVH.

Clinical Clues

Symptoms suggestive of RVH are rare, with the exception of flank pain due to segmental infarction or arterial dissection, and generalized nonspecific symptoms in cases of Takayasu arteritis. The clinical course of hypertension, however, may be suggestive of a renovascular cause.

The age at presentation is a clue. The onset of hypertension before the age of 30 years or after the age of 55 years is more commonly associated with renovascular disease, typically FD in young patients and ASO in those older than 55 years. In the Cooperative Study for Renovascular Hypertension, the average age at the onset of essential hypertension was 35 years; for hypertension secondary to FD, the average age of onset was 33 years; and for atherosclerotic renal artery stenosis (ASO-RAS), the average age of onset was 46 years (Maxwell et al, 1972).

A family history of hypertension suggests essential hypertension, although there are reports of familial fibromuscular disease of the renal arteries, especially in females (Major et al, 1977; Pannier-Moreau et al, 1997).

Sudden onset and shorter duration of hypertension is usually associated with RVH; it may also be associated with a better chance of cure after treatment.

Hypertension that is difficult to control on two or three medications is more likely to be associated with renovascular disease. A sudden increase in severity or difficulty of control of previous mild or well-controlled hypertension is also suggestive of the development of RVH on top of preexisting essential hypertension.

Accelerated, malignant hypertension, or hypertensive crises are more frequently associated with RVH than essential hypertension (Simon et al, 1972).

Hypertension associated with episodes of pulmonary edema, evidence of generalized atherosclerotic disease, or gradual impairment of renal function is also suggestive of RVH.

Smoking is a risk factor for developing atherosclerotic disease. In a retrospective study comparing patients having documented RVH with patients having essential hypertension, 88% of patients with ASO-RAS were smokers, compared with 42% of patients with essential hypertension. Patients with FD also showed a higher incidence of smoking (71%) (Nicholson et al, 1983).

On physical examination, clues suggestive of RVH include severe hypertension, the presence of an upper abdominal or epigastric bruit (with both systolic and diastolic components), severe hypertensive retinopathy (grade III or IV), and evidence of generalized atherosclerosis.

Laboratory Investigations

The presence of mild *proteinuria* is not uncommon in RVH; however, nephrotic-range proteinuria has also been described with RVH (Kumar and Shapiro, 1980; Chen et al, 1995) and has been reversed by renal revascularization (Zimbler et al, 1987). Apart from renal artery disease, proteinuria may be the result of coexisting disease such as diabetes or glomerulosclerosis.

Azotemia in the presence of generalized atherosclerosis, with or without the presence of hypertension, is strongly suggestive of a renal arterial cause.

Hypokalemia (serum potassium level 3.4 mEq/L) especially in the absence of diuretic use is strongly suggestive of RVH resulting in secondary hyperaldosteronism. In the Cooperative Study for Renovascular Hypertension, 16% of patients with RVH were found to have hypokalemia (Maxwell et al, 1972).

CLINICAL FEATURES OF ISCHEMIC NEPHROPATHY

Epidemiologic Considerations

Epidemiologic studies indicate that atherosclerotic renal artery disease is quite common in patients with generalized atherosclerosis obliterans, regardless of whether or not RVH is present. These studies have involved renal angiography in patients with a documented abdominal aortic aneurysm, aorto-occlusive disease, or lower extremity occlusive disease. In such patients, the overall incidence of ARAS has ranged from 31% to 61%, with significant (>50%) ARAS present in 14% to 42% of patients (Table 39–4). In a detailed study by Olin and colleagues (1990), significant ARAS was present in 41 of 108 patients (38%) with an abdominal aortic aneurysm, 7 of 21 patients (33%) with

Table 39–4.

Prevalence of Atherosclerotic Renal Artery Stenosis (ARAS) in Patients with Peripheral Vascular Disease

STUDY	PATIENTS (*N*)	NO. WITH 50% ARAS	NO. WITH >50% ARAS
Choudhri et al, 1990	100	17 (17%)	42 (42%)
Wilms et al, 1990	100	NA	22 (22%)
Olin et al, 1990	318	71 (22%)	122 (38%)

NA, not available.

aorto-occlusive disease, and 74 of 189 patients (39%) with lower-extremity occlusive disease.

Other studies have evaluated the prevalence of atherosclerotic renal artery disease in patients with coronary artery disease by obtaining abdominal aortography at the time of coronary angiography. Vetrovec and colleagues (1989) noted significant (>50%) ARAS in 22 of 76 patients (29%) with coronary artery disease. In a much larger study, Harding and colleagues (1992) found significant (>50%) ARAS in 164 of 817 patients (20%) with coronary artery disease. In the latter study, the prevalence of significant ARAS was greater in patients with more severe coronary artery disease; significant ARAS was present in 29% of patients with three-vessel disease and in 39% of patients with left-main disease. More recently, the Mayo Clinic group (Rihal et al, 2002) reported a 19% incidence of greater than 50% stenosis, 7% with greater than 70% stenosis, and 3.7% with bilateral stenosis in 297 hypertensive patients undergoing coronary angiography. Similar results are reported by Aqel and colleagues (2003) in a smaller group of 90 veterans with hypertension. A 16% incidence of severe stenosis and 6% incidence of bilateral disease were reported in this study. None of these studies reported an increase in complications related to the addition of abdominal angiography to coronary angiography. This would present a logical rationale for screening the renal arteries in patients with risk factors such as peripheral vascular disease, renal insufficiency, and hypertension.

In a large population-based study of nonselected subjects, Hansen and colleagues (2002) screened 870 patients for renal artery stenosis using duplex ultrasonography. An overall prevalence of 6.8% was noted, with 12% having bilateral disease, and stenosis was associated with hypertension, advancing age, and elevated LDL.

Another study has shown an increased prevalence of ARAS in patients with diabetes mellitus. Sawicki and colleagues (1991) evaluated 5194 consecutive autopsy protocols from patients who died between 1980 and 1988. Significant (>50%) ARAS was present in 4.3% of all patients but in 8.3% of all diabetic patients; all but one of the latter had type II diabetes mellitus. Bilateral ARAS was found in 30% of the nondiabetic patients with ARAS but in 43% of diabetic patients with ARAS. These data suggest that the presence of type II diabetes increases the risk of ARAS and that the latter is more likely to involve both kidneys.

These studies show that **ARAS is commonly present in patients with generalized atherosclerosis, particularly those with peripheral vascular disease or coronary artery disease. Although hypertension is also commonly present in such older patients with ARAS, it is far more likely to be idiopathic (essential) than renovascular in origin. Therefore, the prevalence of anatomic ARAS is much greater than that of atherosclerotic RVH.**

Screening and Diagnosis

The screening of patients for atherosclerotic renal artery disease is based, in part, on an early study by Gifford and associates (1965). These investigators found that in 53 of 75 older patients (71%) with unilateral renal atrophy, the renal atrophy was caused by stenosing atherosclerotic renal artery disease. Of equal importance was the finding that 22 of these 53 patients (42%) also had unsuspected atherosclerotic renal artery disease involving the opposite, normal-sized kidney. Subsequently, Lawrie and associates (1980) reviewed 40 patients with renal atrophy caused by total arterial occlusion and noted contralateral ARAS in 31 patients (78%). **These observations underscore the high incidence of renal artery disease, often bilateral, in patients with generalized atherosclerosis and diminished renal size. The additional finding of even mild azotemia in this setting further enhances the likelihood that underlying large vessel occlusive disease is present.**

Harding and associates (1992) evaluated clinical variables associated with ARAS in a study of 1235 patients undergoing simultaneous cardiac catheterization and abdominal aortography. **A multivariate logistic-regression analysis identified the following five risk factors as strongly predictive of significant ARAS: higher age, coronary artery disease, a history of congestive heart failure, female gender, and peripheral vascular disease. An elevated serum creatinine level was also predictive of ARAS** by univariate logistic-regression analysis. Hypertension was not helpful in identifying patients with ARAS.

Another important clinical clue to the presence of significant ARAS is the development of progressive azotemia after medical control of the blood pressure in patients with significant hypertension. This problem strongly suggests the presence of perfusion-dependent renal function due to significant underlying renal artery obstruction (Textor et al, 1983). In addition to reducing flow across a stenotic renal artery by lowering the systemic blood pressure, antihypertensive medications can impair renal function in such patients through other mechanisms as well. β-Adrenergic blockers produce a fall in cardiac output, which may occasionally diminish effective renal plasma flow and the GFR. ACE inhibitors can lead to deterioration of renal function through loss of efferent arteriolar vasoconstrictor tone in the kidney (Hricik et al, 1983).

Finally, **atherosclerotic renal artery disease should also be suspected in older patients with renal insufficiency and no obvious cause for the latter.** Corradi and associates (1993) obtained renal angiography in 51 consecutive patients with the following criteria: age older than 60 years, creatinine clearance less than 50 mL/min, no analgesic abuse, proteinuria less than 1 g/day, clinical signs of generalized atherosclerosis, and no biochemical or radiographic findings indicative of glomerulopathy, diabetic nephropathy, polycystic disease, obstructive nephropathy, or pyelonephritis. Angiographic studies revealed significant renal artery stenosis in 29 patients (56.8%); renal artery stenosis was present bilaterally in 10 patients (19.6%) and unilaterally in 19 patients (37.2%).

The studies described indicate that clinical screening for atherosclerotic renal artery disease is appropriate in older patients with most or all of the following features: (1) evidence of generalized atherosclerosis; (2) a decrease in the size of one or both kidneys; (3) renal insufficiency, even of a mild extent, particularly in patients with no obvious underlying cause; (4) the development of progressive azotemia after restoration of normotension with medical antihypertensive therapy; (5) coronary artery disease; (6) a history of congestive heart failure; and (7) peripheral vascular disease. It should be emphasized that **patients with atherosclerotic renal artery disease may or may not have significant hypertension, and this should not influence the decision to investigate the patient for this disease.**

DIAGNOSTIC EVALUATION

Several noninvasive studies are available to diagnose renal artery stenosis. Most of these studies are intended for hypertensive patients, aiming to identify those patients with a renovascular

cause of hypertension. Among these studies are rapid-sequence intravenous urography, ultrasonography, peripheral renin activity assays, captopril testing, and radionuclide renal scanning (with and without ACE inhibition). A variety of modern noninvasive tests have become available and have largely superseded the previously mentioned tests; these are duplex ultrasonography (DUS), magnetic resonance angiography (MRA), and CT angiography (CTA). These tests offer anatomic information only, with no functional information. **The definitive diagnosis of RAS, however, is documented by angiographic study of the aorta and renal vessels, which remains the "gold standard" against which all other diagnostic modalities are compared.**

Diagnostic evaluation for patients presenting with suspected RVH differs from that of patients presenting with suspected IN. **For patients with suspected RVH, a number of tests are available for functional diagnosis of RVH. These tests (plasma renin activity [PRA], captopril test, captopril renography, and RVR assays) diagnose hyperactivity of the RAAS but provide no anatomic information regarding the offending arterial lesion.** Captopril renography and RVR assays can localize the ischemic kidney as well. Anatomic delineation of the arterial lesion guides the treatment decisions and is obtained by intra-arterial angiography. A variety of noninvasive anatomic studies (DUS, MRA, and spiral CTA) can be used before angiography in cases in which clinical suspicion of RVH is not confirmed by functional tests.

The pathophysiology of RVH is different and distinct from that of IN. **The diagnostic evaluation of patients with suspected IN is hampered by the lack of functional tests** and the inability to determine conclusively that an anatomic lesion in the renal artery is responsible for impairment of renal function. Noninvasive anatomic testing is used to confirm a clinical suspicion of renal artery stenosis, which is definitively diagnosed by intra-arterial angiography. Stabilization or improvement of renal function after revascularization remains the final proof of the cause, provided that ischemic damage to the kidney has not become irreversible.

Intravenous Urogram

Until better methods were developed, a modification of the standard intravenous urogram, called the hypertensive, rapid-sequence, or minute-sequence urogram was used as a screening test for RVH. Several findings are suggestive of RVH, including a delayed appearance of contrast material in the calyces of the affected kidney (most important), disparity of renal size of more than 1.5 cm (most common finding), delayed hyperconcentration of contrast material within the affected collecting system, retention of contrast material in a nonobstructed collecting system, and notching of the pelvicalyceal system by collateral vessels.

The **poor sensitivity and specificity of the rapid-sequence urogram, as well as the development of multiple other more sensitive diagnostic tests, have led to the discontinuation of its use for diagnosing renovascular disease.**

Peripheral Plasma Renin Activity

Measurement of peripheral PRA is a functional test designed to diagnose overactivity of the RAAS. Originally intended as a screening test for RVH, it provides no anatomic information and has no value for diagnosing IN. In order to obtain meaningful results from this test, all antihypertensive medications should be discontinued for 2 weeks, and the PRA should be indexed to the sodium intake. Blood should be collected at noon after 4 hours of patient ambulation. When the test is standardized as mentioned, a sensitivity and specificity of 80% and 84%, respectively, can be expected (Pickering et al, 1984).

Important limitations to this test have restricted its general use. Sixteen percent of patients with essential hypertension have elevated PRA, whereas up to 20% of patients with RVH have normal PRA (Brunner et al, 1972). In addition, discontinuation of all antihypertensive medication in a population of patients with severe, sometimes life-threatening hypertension is not generally feasible.

Captopril Test

Measurement of peripheral PRA before and after an oral dose of captopril is called the *captopril test*. This is a functional test of RVH that does not provide anatomic information. The test is based on the observation that after the administration of ACE inhibitors, patients with RVH show a higher reactionary rise of PRA than patients with essential hypertension (Case and Laragh, 1979). Patients may continue to take β blockers, but all diuretics and ACE inhibitors need to be discontinued for at least 1 week before the test. A normal- or high-salt diet is needed. Blood should be drawn with the patient in the same position before and after captopril administration, after measurements of blood pressure are stable. An oral dose of 25 mg of captopril is used, and blood is drawn again 1 hour after the dose.

Criteria for a positive test are the presence of all the following: postcaptopril PRA greater than 12 ng/ml/hr, an absolute increase in PRA greater than 10 ng/ml/hr, and a 400% increase in baseline PRA (150% increase if the baseline PRA was more than 3 ng/ml/hr) (Muller et al, 1986). The test is generally safe, with the main risk being an excessive fall of blood pressure in hyper-reninemic patients who are also volume depleted. Overall sensitivity is about 74% and specificity is around 89% (Pickering et al, 1996). **The test is not reliable in patients who are azotemic, nor is it sufficiently accurate for use in children** (Gauthier et al, 1991).

The low sensitivity of the captopril test makes it unsuitable for use as a general screening test for RVH. The major strength of the captopril test is its accuracy in excluding RVH, especially in patients with low clinical suspicion. The high negative predictive value (approximately 95%) of captopril testing has been confirmed in several studies (Gosse et al, 1989; Svetkey et al, 1989; Frederickson et al, 1990).

Renal Vein Renins

The primary criterion for the functional diagnosis of RVH is hypersecretion of renin from the ischemic kidney combined with contralateral suppression of renin secretion. Calculation of net renin secretion from any kidney is performed by subtracting the renin value in the arterial blood to the kidney (inflow) from the renin value in the venous blood from the kidney (outflow). Because renin values in both the aorta and the inferior vena cava (IVC) are the same, IVC renin is used instead of aortic renin (Sealey et al, 1973). RVR assays are useful for localizing the ischemic kidney in unilateral renal artery stenosis, as well as the more ischemic kidney in bilateral cases. A moderate sodium intake should be maintained at the time of the sampling, which is usually performed with the patient in the

supine position. Blood samples from both renal veins as well as from the IVC are obtained.

Hypersecretion of renin from the ischemic kidney (>50% of PRA) confirms the diagnosis of RVH. Contralateral suppression of renin secretion (renal vein – IVC renin = 0) indicates an appropriate response of the normal contralateral kidney to the elevated blood pressure and predicts a cure of hypertension after revascularization. Increasing severity of stenosis reduces blood flow to the ischemic kidney, resulting in an increased RVR increment (after subtracting IVC renin) higher than 50% of the total peripheral PRA (Vaughan et al, 1973). In patients with high PRA and RVR failing to show an increment above 50% from both kidneys, sampling from segmental renal veins may be performed to localize the segment of kidney responsible for hypersecretion of renin (Schambelan et al, 1974). Administration of captopril results in accentuation of renin secretion from the ischemic kidney (similar to the captopril test), which increases accuracy in diagnosing RVH (Simon and Coleman, 1994). This is particularly useful when RVR values are equivocal, in cases of branch stenosis, and in cases of coexisting hypertension or renal disease.

Captopril Renography

Radionuclide renography without ACE inhibition has limited use for the functional or anatomic diagnosis of renovascular disease. The physiologic principle of captopril renography is the loss of preferential vasoconstriction of the efferent arteriole that is mediated by AII and maintains the glomerular pressure gradient in cases of RAS. This loss of postglomerular pressure results in a decreased GFR of the kidney distal to the stenosis, which is measured noninvasively by radionuclide renography.

The study is performed in well-hydrated patients on liberal salt intake. ACE inhibitors are discontinued for 3 to 5 days before the study, but other antihypertensives may be continued (Setaro et al, 1991). Oral hydration is continued on the day of the procedure. Oral captopril (25 to 50 mg) is usually used, although IV enalapril (0.04 mg/kg) can be used as well (Sfakianakis and Sfakianakis, 1988). The captopril renogram is obtained 1 hour after the captopril dose. The use of furosemide has also been suggested to improve the accuracy of ACE renography (Erbsloh-Moller et al, 1991).

Considerable debate continues around the optimal radionuclide agent to use for captopril renography. The most commonly used agents are technetium 99m (^{99m}Tc)–diethylenetriaminepentaacetic acid (DTPA) and iodine 131 (^{131}I)–orthoiodohippurate (OIH), with the recent addition of ^{99m}Tc-mercaptoacetyltriglycine (MAG3). The imaging characteristics of ^{99m}Tc compounds are better than that of ^{131}I compounds. On the other hand, OIH and MAG3 are excreted by both glomerular filtration and tubular secretion, whereas DTPA is excreted by glomerular filtration only, making it less optimal for patients with renal dysfunction. To date, ^{99m}Tc-MAG3 has shown the best results for captopril renography, especially in patients with impaired renal function (Dondi, 1991). Studies have shown that ^{99m}Tc-ethylenedicysteine (EC) can be used as an imaging agent for captopril renography to diagnose RVH and predict the outcome of revascularization (Ugur et al, 1999).

Captopril renographic diagnostic criteria have not been well standardized. The following are the criteria suggested by the Consensus Panel on Captopril Renography (Nally et al, 1991). Two categories of information are used: asymmetry of renal size and function as suggested by the scintigraphic images, and specific captopril-induced changes in the renogram. These changes on the postcaptopril renogram include a delayed time to maximal activity (>11 minutes), significant asymmetry of peak activity of each kidney, marked cortical retention of radionuclide, and a marked decrease in the GFR of the ipsilateral kidney. For radionuclides with tubular excretion (^{131}I-OIH and ^{99m}Tc-MAG3), the ratio of 20-minute counts to peak counts can also be used. Normally less than 0.3, a 0.15 change is considered significant. A small poorly functioning (30%) kidney that shows no change after ACE inhibition, as well as bilateral symmetrical change after ACE inhibition, is considered to be moderately indicative of RVH (Taylor et al, 1998).

The use of AT1 receptor antagonists for hypertension does not preclude the use of captopril renography as a diagnostic test. In a study comparing captopril renography in patients using AT1 receptor antagonists to hypertensive controls, Picciotto and colleagues (2003) found equally accurate results in both groups.

Overall, the sensitivity of captopril renography appears to be approximately 90% to 93%, and the specificity approximately 93% to 98% (if the test is used in patients with a strong clinical suspicion). More importantly, captopril renography is predictive of a cure or improvement in blood pressure after revascularization in 80% to 90% of cases (Nally, 1996). The presence of bilateral renal artery stenosis, renal artery stenosis to a solitary kidney, or impaired renal function (serum creatinine level > 2.5 to 3 mg/dL) decreases the accuracy of captopril renography.

Duplex Ultrasonography

DUS of the renal arteries is a noninvasive anatomic study that has shown an excellent ability to diagnose renal artery stenosis. It combines the use of real-time B-mode renal ultrasonography with color-coded pulsed Doppler to obtain blood flow velocities within the major abdominal vessels. Flow velocity at the renal hilum and inside the renal parenchyma can be measured as well. **The basis for diagnosing renal artery stenosis is the altered flow pattern distal to the stenosis, with a turbulent jet during systole and a decrease in diastolic flow**. Measurements are obtained at the proximal main renal artery using a standardized angle of incidence, and several indices as well as waveform analysis are used to diagnose stenosis. More than 180 cm/sec **peak systolic velocity (PSV) in the renal artery** is indicative of RAS (normal renal PSV averages 100 ± 25 cm/sec). PSV has been found to be the most important single indicator of RAS (Miralles et al, 1996). The ratio of the renal PSV to the aortic PSV (renal PSV/aortic PSV) is called the *renal aortic ratio* (RAR). A ratio of 3.5 or more indicates severe (>60%) stenosis. The use of the RAR is not possible in cases of aortic occlusive or aneurysmal disease because of the abnormal aortic flow patterns in these situations. Measurement of the flow patterns within the distal hilar renal artery branches, as well as within the parenchyma, can be analyzed to provide indices indicative of arterial stenosis or increased renovascular resistance (Nazzal et al, 1997; Riehl et al, 1997). These indices (acceleration time, acceleration index, resistive index) have not proved as universally reliable as the aforementioned (PSV, RAR) measurements. Intraluminal ultrasonography has also been used to measure flow rate directly within the renal artery (van der Hulst et al, 1996; Chavan et al, 1998), and this has been useful to evaluate the flow rate before and after angioplasty (Savader et al, 1998).

Diagnostic categories obtained by DUS include normal, mild stenosis (60%), severe stenosis (>60%), and technically unsatisfactory study (unable to visualize the renal arteries). Renal artery occlusion is indirectly diagnosed by the

findings of a small kidney and the inability to detect a renal artery flow pattern.

DUS offers significant advantages as a diagnostic tool for RAS. It is noninvasive, uses portable equipment that is relatively inexpensive and widely available, does not use iodinated contrast material, and has no effect on renal function. Azotemia does not affect the results of the study, and no discontinuation of antihypertensive medications is required. Repeated evaluations can be performed, which is particularly useful for postintervention and follow-up examinations.

The main disadvantage of DUS is its dependence on operator skill, with less reliable results obtained from less experienced vascular laboratories. In obese patients and patients with a lot of bowel gas, the renal arteries may be difficult to visualize. Accessory renal arteries are difficult to visualize, and occluded renal arteries cannot be diagnosed with certainty. Finally, DUS offers anatomic data with no indication of the functional significance of the lesion.

In a prospective study comparing DUS with angiography in 102 patients, DUS was found to have a sensitivity and specificity of 98%, correctly identifying the lesions in 182 of 187 arteries with different degrees of stenosis (Olin et al, 1995). In another prospective study in 41 patients, DUS (compared with angiography) revealed a sensitivity of 95% and a specificity of 90% (Strandness, 1994). In a more recent prospective study evaluating 53 patients with both DUS and angiography, a DUS sensitivity of only 75% was reported, with 103 (of 112) arteries and 12 (of 16) stenoses detected by DUS. Specificity for detecting RAS was 100% (Mollo et al, 1997).

In a study using slightly different diagnostic criteria (PSV > 210 cm/sec) and evaluating 46 patients, the sensitivity and specificity of DUS were 89.5% and 90.7%, respectively. Notably, in the same study, only 23 patients were hypertensive, and captopril renography was positive in only 5 cases (Miralles et al, 1993). The superior utility of DUS over captopril renography reported in this study was not validated in a more recent study prospectively comparing both DUS and captopril renography to angiography in 28 patients. After 11 (of 45) renal arteries were excluded from the study because no Doppler signal could be obtained, the accuracy of both diagnostic modalities was comparable, with a sensitivity and specificity for DUS and captopril renography of 78% and 81%, and 83% and 81%, respectively (Kaplan-Pavlovcic and Nadja, 1998).

Continuous developments in equipment and techniques of DUS are occurring and promise an increased accuracy and utility. Among these developments are the use of power Doppler imaging, three-dimensional imaging, harmonic imaging, and ultrasonic contrast agents. Power Doppler imaging is more sensitive, especially in the detection of low flow rates (Murphy et al, 1997). Three-dimensional imaging uses computer technology to produce a three-dimensional image of the region of interest. Harmonic imaging also improves the imaging of structures that might be moving, like the proximal renal arteries. The use of biodegradable microbubbles in the circulation increases the echogenicity and enhances the visualization of the renal vessels (Missouris et al, 1996).

Magnetic Resonance Angiography

MRA is a modern noninvasive anatomic diagnostic modality that has become available for diagnosing RAS. The techniques used for MRA are time of flight or phase contrast. Gadolinium DTPA enhances the blood signal, resulting in improved images of the aorta and the proximal renal arteries. **MRA has the advantage of being noninvasive, not using radiation, having a low technical failure rate, and not using iodinated contrast material, the latter factor making the technique suitable for use in patients with renal insufficiency** (Ghantous et al, 1999). Multiple projections can be obtained, and the morphology of the kidney can be evaluated as well. Functional information, including individual renal blood flow and GFR, can also be obtained (Grist, 1994).

The emergence of nephrogenic systemic fibrosis (NSF) with the use of gadolinium MRI contrast agents in patients with renal impairment has received much attention lately and has severely limited contrast MRI use in these patients. This is a rare but potentially life-threatening condition that results from dissociation of gadolinium from its parent compound and chelation with endogenous cations, thus liberating toxic free gadolinium. Affected patients develop multisystem fibrosis affecting primarily the skin, with devastating consequences. Most of the reported cases occurred in patients on dialysis; some studies report that the condition is more likely to occur in patients with acidosis (Broome et al, 2007).

MRA provides an image quality that is inferior compared with angiographic images. Only the proximal parts of the main renal arteries are visualized, without the ability to image the distal arterial tree. MRA is contraindicated in patients with magnetic implants and claustrophobia, and it uses sophisticated expensive equipment that might not be widely available.

MRA was compared with intra-arterial angiography in 103 patients, all of whom had both studies performed. When MRA was used, all main renal arteries and 31 of 33 accessory renal arteries were visualized, and 61 of 65 stenoses were diagnosed and graded correctly. The overall sensitivity was 93% and the specificity was 90% (Hany et al, 1998). Another study evaluated 62 patients with both MRA and angiography (Thornton et al, 1999). MRA had a sensitivity of 88% and a specificity of 98% and visualized 93% of all the arteries seen on angiography. The reproducibility of interpretation and interobserver variability of MRA were found to be comparable with those of conventional angiography in 54 patients who underwent both diagnostic procedures (Gilfeather et al, 1999).

A prospective study compared gadolinium-enhanced MRA to color DUS in 45 patients, and the results of both examinations were referenced to angiography in all cases (De Cobelli et al, 2000). Out of 13 accessory renal arteries detected by digital subtraction angiography (DSA), 12 were detected by MRA and only 3 were detected by DUS. The sensitivity and specificity of MRA were 94% and 91% for diagnosing all degrees of stenosis, whereas the sensitivity and specificity of DUS were 71% and 76%. For the detection of stenoses of more than 50%, the corresponding values were 93% and 95% for MRA, compared with 93% and 89% for DUS. Another group (Leung et al, 1999) compared the two modalities (and referenced results to DSA studies) and reported similar results, with slightly better sensitivity and specificity for MRA (90% and 86%) compared with DUS (81% and 87%). This study also confirmed the superior ability of MRA over DUS in detecting accessory renal arteries (96% vs. 5%). MRA was more sensitive in detecting RAS due to ASO than in detecting RAS due to FD, according to this study; this could be related to the more distal nature of most FD lesions. MRA can also diagnose renal artery aneurysms, and is useful for following the size of renal artery aneurysms over time, although aneurysms distal to the primary

branches of the renal artery are not well visualized on MRA (Browne et al, 2004).

Improved techniques and increased experience with MRA continue to increase its accuracy and utility. The use of time-resolved imaging to decrease artifacts, decrease venous overlap, and improve spatial resolution and contrast enhancement has been reported (Van Hoe et al, 2000). Gadolinium has been administered intra-arterially in vitro in an attempt to improve visualization of blood vessels (Omary et al, 1999). Multiecho gradient echo technique for three-dimensional MRA has been reported to produce high vessel-to-background contrast with decreased bowel-related artifact (Papachristopoulos et al, 1999). Although the recognition of nephrogenic systemic fibrosis (NSF), a serious complication of using gadolinium-based contrast agents for MRI in patients with renal insufficiency, has hampered the use of MRI in many patients with renal artery stenosis, several precautions have been recommended that may allow MRI contrast agents to be used with minimal risk. Cyclic gadolinium–based contrast agents have less chance of causing NSF if using smaller doses of contrast, and if avoiding gadolinium agents altogether in patients with estimated GFR of less than 30 mL/min or in patients with metabolic acidosis (Boyd et al, 2007; Othersen et al, 2007).

MRI has the potential to provide other important information, in addition to anatomical depiction of the arterial stenosis. Gadolinium clearance can be used to measure single-kidney glomerular filtration rate, and renal volume can be measured and followed to evaluate recovery after revascularization. Loss of corticomedullary differentiation and increased cortical-medullary transit time can also indicate renal ischemia, and reversal of these findings may indicate successful revascularization (Chrysochou et al, 2008).

Computed Tomography Angiography

The availability of spiral CT technology with rapid acquisition time has made possible imaging of the renal arteries. Scanning through the area of the renal arteries using thin (2-mm) slices during the arterial phase of contrast material injection is performed while the patient holds a single breath. Three-dimensional reconstruction of the axial image is then carried out, showing the abdominal aorta with its main branches. Atherosclerotic disease affecting the aorta and the renal arteries can be visualized, as well as renal morphology and parenchymal lesions. **Spiral CTA lacks the ability to define disease distal to the main stem renal artery, and a relatively large volume of intravenous (IV) iodinated contrast material is required to perform the study;** however, CTA might offer the advantages over MRA of cost, convenience, and widespread availability (Prokop et al, 1998).

Comparison between CTA and DSA in 82 patients revealed a sensitivity and specificity of 96% and 99%, respectively, for hemodynamically significant stenosis, with only 1 stenosis (of 34) missed on CTA. Thirty-three accessory renal arteries were visualized in this study, as well as 5 adrenal masses (Wittenberg et al, 1999). In another study evaluating 50 patients with suspected RAS, CTA showed a sensitivity of 90% and a specificity of 97% and demonstrated 27 of 28 accessory renal arteries (Kim et al, 1998). Modern CT technology can also be used to perform virtual endoscopy, which can be helpful for evaluating renal artery stenoses and positioning arterial stents (Neri et al, 2000). Multiple detector–row CT angiography is a new method of CT angiography that also promises more accurate depiction of the renal and other visceral arteries (Fleischmann, 2003; Pannu et al, 2002).

In order to clarify the various limitations of noninvasive imaging modalities in respect to accessory renal arteries as well as proximal branches of the renal artery, a study compared DUS, CTA, and MRA to angiography. The points of comparison were the ability to evaluate accessory renal arteries and proximal branches. Fifty-six patients underwent angiography; of those patients, 45 underwent DUS, 52 underwent CTA, and 28 underwent MRA. When angiography was used, 28 accessory renal arteries as well as 21 proximal (>2 cm from the aorta) renal artery branches were visualized. DUS depicted 21% of the accessory arteries and 0% of the proximal branches. MRA depicted 73% of the accessory arteries (and four additional arteries not seen on angiography), and 0% of the proximal branches. CTA depicted 92% of the accessory arteries and 76% of the proximal branches. Although experience with modalities differs among institutions, this study offers an interesting comparison of the limitations of these techniques (Halpern et al, 1999).

In a more recent study comparing MRA against CTA with intra-arterial DSA as the reference standard, there was no significant difference in the accuracy of both MRA and CTA, with sensitivity around 92% and specificity around 99% for both modalities. Patient acceptance was also measured, and estimated to be best for CTA, although the time consumed for reconstruction of the images was most in CTA (Willmann et al, 2003).

Contrast Arteriography

Intra-arterial angiography remains the gold standard for diagnosing renal artery disease, and it is the test against which the results of other tests are compared. The availability of modern interventional techniques (angioplasty and arterial stents) has allowed angiography to become a combined diagnostic and therapeutic procedure. However, for several reasons, angiography is not suitable for use as a preliminary screening tool for all patients suspected of having renal artery stenosis. It is an expensive test that cannot be done on an outpatient basis. It is also an invasive test using ionizing radiation and requiring arterial puncture, manipulation of arterial catheters, and injection of iodinated contrast material.

Complications of arterial puncture and manipulation include bleeding, hematoma, dissection, thrombosis, and distal embolization of atherosclerotic plaque, as well as cholesterol embolization. The use of iodinated contrast material carries the risk of allergic reaction and volume overload. The contrast load also leads to a transient impairment of renal function, especially in patients with preexisting renal insufficiency and in diabetic patients. Several advancements in the field of angiography have been directed at decreasing side effects from iodinated contrast material. These advancements include decreasing the contrast load through digital postprocessing, as well as the use of contrast agents with decreased nephrotoxicity, such as carbon dioxide or gadodiamide (Spinosa et al, 1999). The advent of digital subtraction angiography (DSA) has allowed reduction of the contrast load with a concomitant reduction in catheter size. Although the spatial resolution of DSA is lower than that of conventional angiography, the contrast resolution of DSA is superior. The ability to subtract bone and soft tissue with DSA is an important advantage, making conventional cut film angiography obsolete, and DSA the most commonly used technique today.

Early in the development of digital techniques, it was suggested that IV studies (IV-DSA) would be accurate and supersede the arterial approach (Wilms et al, 1986). The attraction of visualizing the renal arteries angiographically with an outpatient procedure was not realized, however. Several disadvantages led to the gradual abandonment of IV-DSA in favor of intra-arterial studies. These

disadvantages include the need for a large contrast material volume, the frequent need for central venous catheters to deliver this large volume, poor image quality owing to overlying visceral arteries, frequent uninterpretable studies, and poor opacification, especially in elderly patients or those with cardiac dysfunction (Buonocore et al, 1981; Smith et al, 1982).

Carbon dioxide has been introduced as a contrast agent for intra-arterial injection in an effort to reduce contrast nephrotoxicity from iodinated contrast material. An injected bolus of carbon dioxide displaces blood from the vessels to be imaged and provides sufficient contrast for adequate imaging using DSA technology and postprocessing enhancement. The injected carbon dioxide is cleared by the lungs without deleterious effects. Carbon dioxide has no effect on renal function, making it an ideal agent for use in patients with renal insufficiency. It is nonallergenic, cheap, and presents no problems with fluid overload. Smaller softer arterial catheters can be used for injection, minimizing trauma to the arterial walls. This technique can also provide information that is not visualized using standard iodinated contrast material, including small arteriovenous shunts, small tumor vessels, and minute amounts of arterial bleeding (Hawkins et al, 1994).

In a prospective study comparing carbon dioxide angiography with standard contrast arteriography in 100 patients, the overall accuracy of carbon dioxide DSA was 97% (Schreier et al, 1996). Carbon dioxide DSA was successfully used for guiding angioplasty and renal artery stenting in 17 patients in another study, with only one transient rise in the serum creatinine level (Caridi et al, 1999). Similarly, no cases of contrast nephropathy were reported in a study employing carbon dioxide DSA as the main imaging technique for patients with renal impairment (Fitridge et al, 1999). Carbon dioxide renal angiography has been used safely in children (Kriss et al, 1997). Although carbon dioxide is generally regarded as a benign contrast medium, a case of fatal complications (rhabdomyolysis and intestinal infarction) after carbon dioxide angiography has been reported (Rundback et al, 1997).

Ailawadi and colleagues (2003) evaluated the use of gadolinium as a contrast agent for intra-arterial angiography in patients with renal insufficiency and found it to be safe and adequate for imaging the renal arteries as well as first- and second-order branches. No comparison with conventional contrast angiography was performed, but this might be an option to decrease nephrotoxic side effects of angiography. Significant concern about NSF in patients with renal insufficiency will undoubtedly limit the use of gadolinium-based contrast agents in patients with renal impairment.

COST-EFFECTIVE APPROACH FOR DIAGNOSIS

The diagnostic approach for patients with renal artery stenosis should be tailored according to the predominant clinical picture, that is, patients with IN should be worked up differently from patients with hypertension as the presenting clinical problem. As mentioned previously, **patients with IN constitute the majority of patients presenting for treatment today, may not have hypertension as part of the clinical picture, and cannot be diagnosed by functional testing. In these patients, an anatomic diagnosis is pursued directly.** Patients with a strong suspicion of renal arterial disease should probably undergo intra-arterial angiography (iodinated contrast material or carbon dioxide) directly. Patients with mild or moderate suspicion of having renal artery stenosis should undergo a noninvasive anatomic test (DUS, MRA, or CTA). The choice of diagnostic procedure depends on patient's level of renal function (azotemic patients more suitable for DUS than CTA), as well as the experience with the various modalities at different centers. Positive findings on noninvasive testing should lead to definitive confirmation of the lesion and therapeutic planning through intra-arterial angiography. Negative findings on these tests should be interpreted with understanding of the limitations of each technique and should lead to further noninvasive testing if technical factors are suspected, or to no further testing if a technically perfect study is clearly negative in a patient with minimal clinical suspicion.

Patients with suspected RVH present a different diagnostic challenge. Functional evaluation of the RAAS is possible and is usually performed as a first step in the diagnosis before anatomic diagnosis. The steps used to screen and select patients for further study differ according to different centers and have changed over the last years, mainly owing to the introduction of reliable noninvasive anatomic imaging techniques.

Patients should be ranked according to the clinical findings suspicious for RVH into patients with low, moderate, and high suspicion. Like patients with IN, patients with a high suspicion for RVH are probably best served by performing angiography directly. Negative findings on other studies would not prevent these patients from progressing to angiography in any case. In bilateral cases, RVR assays can be used to localize the more ischemic side.

Patients with low or moderate suspicion of RVH are more problematic. In these cases, it is probably reasonable to perform captopril renography as a preliminary test. A positive test should be followed by further testing, preferably definitive diagnosis through angiography. Patients with low clinical suspicion and a technically satisfactory negative study should not be subjected to further testing. Technically unsatisfactory studies should probably be followed by a noninvasive test of a different type (e.g., DUS). These tests (DUS, MRA, or CTA) will provide no functional information or prediction of cure after intervention. To date, anatomic confirmation of the disease and treatment planning still require intra-arterial angiography.

The role of renin assays has decreased significantly since the 1980s. Few centers use the captopril test to exclude patients from having RVH, because of its consistently high negative predictive value. RVR assays are rarely used to diagnose RVH before a noninvasive test indicates the anatomic presence of stenosis; their role has focused on localizing the more ischemic kidney in bilateral cases.

Key Points: Diagnostic Evaluation

- In patients with clinical features of renovascular hypertension, the diagnosis is confirmed by contrast angiography.
- Noninvasive testing with CT angiography, MR angiography, and duplex ultrasonography is often used in suspicious cases before proceeding to contrast angiography.
- Except in rare circumstances, functional testing for renovascular hypertension has been largely superseded by anatomical testing for renal artery stenosis.
- There is no functional testing currently available to evaluate patients with ischemic nephropathy.

RENOVASCULAR DISEASE IN CHILDREN

Renovascular disease is estimated to cause 5% to 10% of childhood hypertension (Wyszyńska et al, 1992). The causes of renovascular hypertension in children are more variable than adults, and diagnosis is usually more difficult, particularly in young children and infants. Blood pressure measurement in children requires consideration of the child's age, sex and height. Inaccurate cuff size and positioning will result in inaccurate measurements, and blood pressure should be taken in a relaxed environment and in all four limbs. Causes of renovascular hypertension in children include fibromuscular dysplasia, vasculitis (Takayasu disease, Kawasaki disease, polyarteritis nodosa), syndromes such as neurofibromatosis, and extrinsic compression from tumors such as Wilms tumor or neuroblastoma. As in adults, intra-arterial digital subtraction angiography remains the definitive diagnostic procedure in children. In smaller children, general anesthesia will be required, and small-caliber coronary angiography catheters can be used. In general, life-long medical treatment is avoided in children with renovascular hypertension, and most children will be referred for surgical or endovascular revascularization. Medical management is useful in emergency control of blood pressure, optimization of blood pressure control in preparation for revascularization, and rare cases of widespread distal arterial disease not amenable to surgical or endovascular intervention.

MANAGEMENT OF PATIENTS WITH RENAL ARTERY DISEASE

Management options for patients with renal artery disease resulting in renovascular hypertension or ischemic nephropathy includes medical management, surgical revascularization (or nephrectomy), and endovascular treatment.

Medical Management

Medical treatment of renovascular hypertension is often the preferred treatment for patients with well-controlled mild hypertension in the absence of a threat to kidney function (from ischemic nephropathy or progressive arterial disease). Medical treatment is also reasonable in patients with advanced age and multiple comorbidities that place them at high risk for surgical or endovascular intervention. Some patients with ischemic nephropathy and hypertension who have poor potential for recovery of renal function (see later), are also managed medically. New classes of antihypertensive medications, including newer ACE inhibitors and angiotensin receptor antagonists (and potentially renin inhibitors), provide specific blockade of RAAS overactivity and adequate control of blood pressure.

Optimal medical therapy aims to reduce overall risk of cardiovascular disease in addition to lowering blood pressure, particularly in patients with atherosclerotic renal artery disease. This approach is important because patients with renal artery ASO usually have a large burden of systemic arterial disease and multiple risk factors for cardiovascular mortality. Strict blood pressure control is essential to a target blood pressure below 140/90, or below 130/80 in diabetics and patients with renal disease and proteinuria (Chobanian et al, 2003). Use of angiotensin receptor antagonists or ACE inhibitors as first-line therapy is attractive and usually effective in controlling blood pressure, although renal function has to be carefully monitored during use. Combination treatment with diuretics, calcium channel blockers, β or α blockers, and vasodilators is based on clinical results and patient comorbidities. In addition to blood pressure control, a complete treatment regimen includes treatment of dyslipidemia (to low-density lipoprotein cholesterol <100), strict management of diabetes (tight glucose control, medical nutrition, foot and eye care, physical activity), antiplatelet agents (aspirin, clopidogrel, or ticlopidine), smoking cessation, and management of complications of renal insufficiency (anemia, hyperparathyroidism, etc.), which are frequently present in patients with renal impairment.

SELECTION OF PATIENTS FOR SURGICAL OR ENDOVASCULAR THERAPY

Renovascular Hypertension

In patients with RVH secondary to FD, the decision for intervention (surgery or angioplasty) is guided by the specific type of disease as determined by angiographic findings and the associated natural history (Novick et al, 1996). **Medical management of hypertension is the preferred initial treatment for patients with medial fibroplasia, because loss of renal function from progressive obstruction is uncommon with this disease. Interventive treatment** in the latter category is reserved for patients whose blood pressure is difficult to control with multiple drugs. Conversely, renal artery stenosis secondary to intimal or perimedial fibroplasia generally progresses and often eventuates in ischemic renal atrophy. Furthermore, these lesions tend to occur in younger patients and to cause hypertension that is extremely difficult to control. Early interventional therapy in these patients is therefore indicated both to preserve renal function and to minimize the need for long-term antihypertensive medication.

In selecting patients with FD for surgical renal revascularization, the efficacy of percutaneous transluminal angioplasty (PTA) must also be considered. **The results of angioplasty for FD of the main renal artery have been excellent** and equal to those obtained with surgical revascularization; therefore, angioplasty is the initial treatment of choice in such cases. However, as many as 30% of patients with FD have branch renal arterial involvement, which increases the technical difficulty of, and often precludes, angioplasty. Therefore surgical renal revascularization is the primary interventional treatment in this category.

In patients with atherosclerotic RVH, more vigorous attempts at medical management are warranted, because these patients are older and often have extrarenal vascular disease. Therefore multiple-drug regimens that control the blood pressure are often the preferred approach. Indeed, the advent of new β-blocking agents and converting enzyme inhibitors has enhanced the efficacy of medical antihypertensive therapy. Intervention with surgery or endovascular therapy is best reserved for patients whose hypertension cannot be adequately controlled or when renal function is threatened by advanced vascular disease (Novick et al, 1996).

Ischemic Nephropathy

Anatomic Severity and Extent of Renal Artery Disease

After angiographic diagnosis of ARAS, and with knowledge of the natural history of this disease, one can identify those

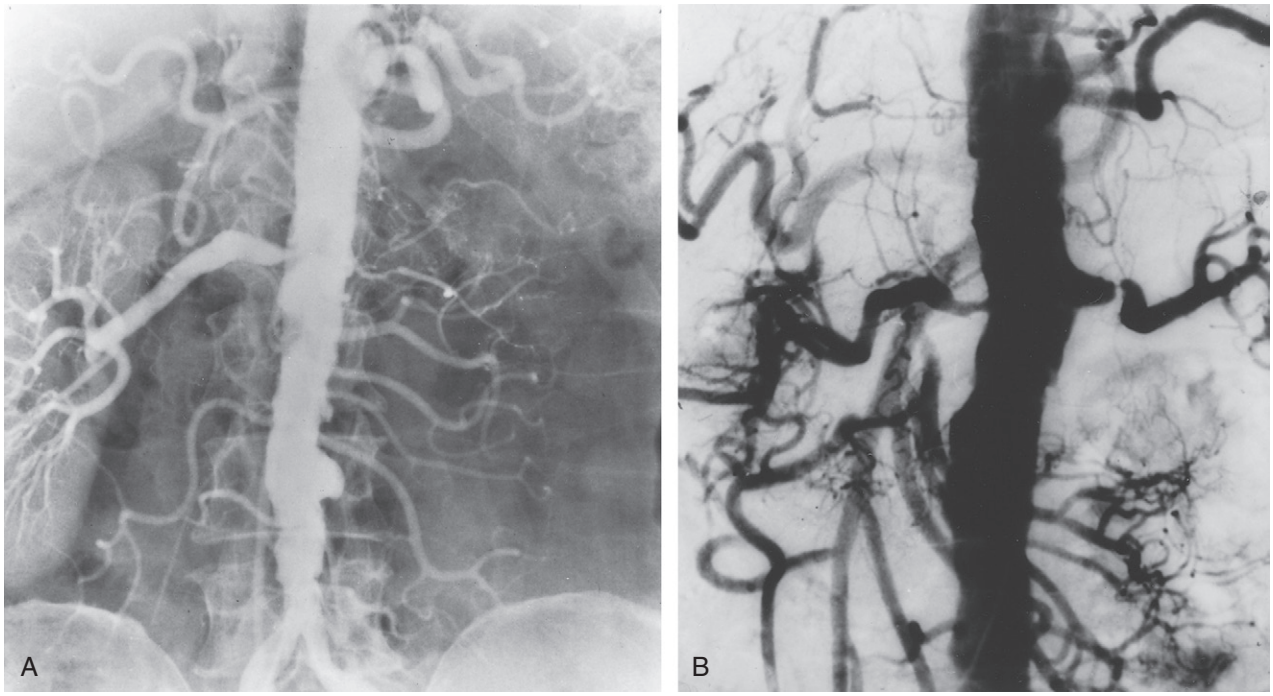

Figure 39–8. Atherosclerotic renal artery disease poses the greatest threat to overall renal function in patients with high-grade arterial stenosis to a solitary (right) kidney **(A),** and bilateral high-grade renal artery stenosis **(B),** as demonstrated on these abdominal aortograms.

patients in whom such disease poses a significant threat to overall renal function. This designation applies to patients with high-grade (>75%) arterial stenosis affecting their entire renal mass, namely, where such stenosis is present bilaterally or involves a solitary kidney (Fig. 39–8). In these patients, the risk of complete renal arterial occlusion is significant, and, if this occurs, the clinical outcome is a critical decrease in functioning renal mass with resulting renal failure. Intervention to restore normal renal arterial blood flow is indicated in such patients for the purpose of preserving renal function. In a study from the Cleveland Clinic (Novick et al, 1987), surgical revascularization for preservation of renal function was performed in 161 patients with ARAS bilaterally or in a solitary kidney. Postoperatively, renal function was improved in 93 patients (58%), stable in 50 patients (31%), and deteriorated in only 18 patients (11%).

The benefit of undertaking revascularization for the preservation of renal function in patients with unilateral ARAS and an unobstructed contralateral renal artery is not established. If the contralateral kidney is anatomically and functionally normal, revascularization for this purpose is clearly not warranted. If the opposite kidney is functioning but involved with some type of parenchymal disorder, revascularization of the ischemic kidney may benefit some patients, but specific indications for this approach are not well defined. Dean and associates (1991) reviewed the renal functional outcome after surgical revascularization in 53 patients with IN. The postoperative estimated GFR was improved significantly in 41 patients treated for bilateral ARAS but was unaltered in 12 patients with unilateral ARAS.

Complete occlusion of the renal artery most often eventuates in irreversible ischemic damage of the involved kidney. However, in some patients with gradual arterial occlusion, the viability of the kidney can be maintained through the development of collateral arterial supply (Morris, 1956; Zinman and Libertino, 1977; Schefft et al, 1980). Helpful clinical clues suggesting renal salvability in such cases include (1) angiographic demonstration of retrograde filling of the distal renal arterial tree by collateral vessels on the side of total arterial occlusion (Fig. 39–9), (2) a renal biopsy showing well-preserved glomeruli, (3) kidney size greater than 9 cm, and (4) function of the involved kidney on isotope renography or intravenous pyelography. When such criteria are present, restoration of normal renal arterial flow can lead to recovery of renal function.

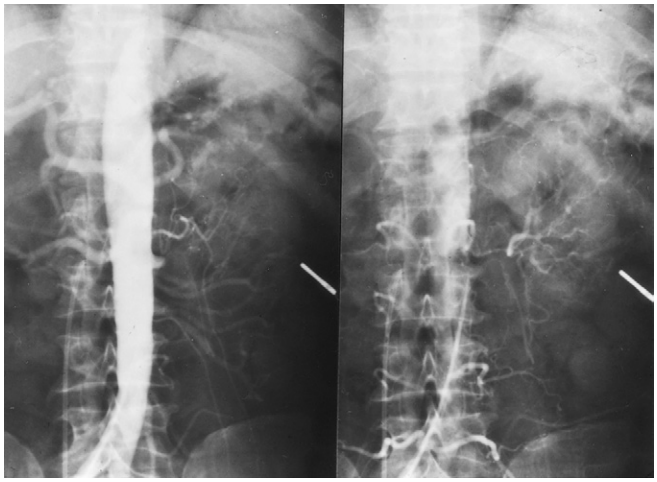

Figure 39–9. Abdominal aortograms reveal complete occlusion of the left renal artery *(left)* with filling of the distal renal artery branches from an extensive collateral supply on delayed film *(right)*.

Level of Renal Function

In general, revascularization to preserve renal function in patients with ARAS is most likely to be beneficial in those who have not yet sustained severe, permanent impairment of overall renal function. In a study from the

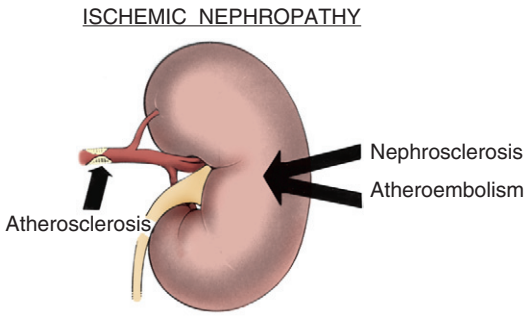

Figure 39–10. Patients with atherosclerotic renal artery disease often have renal parenchymal involvement with varied degrees of nephrosclerosis or atheroembolic disease.

Cleveland Clinic (Bedoya et al, 1989), we evaluated the effect of baseline renal function on the outcome of surgical revascularization in elderly patients with ARAS. The majority of these patients had preoperative serum creatinine levels of less than 3 mg/dL; postoperative renal function was stable or improved in 89% of patients in this category.

Revascularization to preserve renal function is generally not worthwhile in patients with severe azotemia (serum creatinine level >4 mg/dL), because advanced underlying renal parenchymal disease is inevitably present and obviates improvement in renal function with restored perfusion. This observation has been recorded by several groups including our own (Mercier et al, 1990; Chaikof et al, 1994). Severe nephrosclerosis is the most common form of renal parenchymal disease in such patients; however, renal cholesterol embolization may be an additional complicating feature (Fig. 39–10) (Vidt et al, 1989). In patients with atherosclerotic ischemic renal disease and a serum creatinine level greater than 4 mg/dL, our policy is to perform a renal biopsy to evaluate the severity of renal parenchymal involvement from one or both of these disorders.

Some patients present with severe impairment of overall renal function that has developed acutely after the initiation of medical antihypertensive therapy (Hricik et al, 1983; Textor and Novick, 1983). Such rapidly progressive renal insufficiency may be a manifestation of perfusion-dependent renal function due to underlying ARAS. If this problem is detected promptly, renal function often improves after discontinuation of the offending antihypertensive medications. Intervention to relieve renal arterial obstruction can prevent permanent renal damage in patients with this type of severe acute renal insufficiency.

In addition to the absolute level of renal function, the rate of decline in overall renal function is an important determinant of the outcome after intervention in atherosclerotic ischemic renal disease. In a study by Dean and associates (1991), patients with a rapid rate of deterioration in estimated GFR during the 6 months preceding surgical revascularization achieved the greatest benefit in terms of postoperative improvement of estimated GFR. Unfortunately, their data precluded definition of a critical rate of decline in estimated GFR that would predict retrieval of renal function by revascularization. Nevertheless, rapid deterioration of overall renal function in association with ARAS suggests a strong possibility of retrieval of function by intervention to restore normal renal arterial flow.

Occasional patients with ESRD from IN have had salvable renal function on revascularization (Wasser et al, 1981; Kaylor et al, 1989). The basis for this has been the presence of chronic bilateral total renal arterial occlusion in which, fortuitously, the viability of one or both kidneys has been maintained through collateral vascular supply. In such cases, revascularization can yield dramatic recovery of renal function (Fig. 39–11). Unfortunately, this clinical presentation is rare, and a less favorable outcome of bilateral arterial occlusion on renal viability is far more common.

We reported nine patients with ESRD, caused by atherosclerotic renal artery occlusion, who underwent surgical revascularization with subsequent recovery of renal function (Kaylor et al, 1989). The duration of dialysis preoperatively ranged from 1 to 13 months. In all cases, renal viability was being maintained by collateral vascular supply. Postoperatively, renal function improved immediately, and no patient required subsequent dialysis. Excellent overall rehabilitation was achieved in all patients. Six patients were alive at a mean interval of 4 years postoperatively and with satisfactory renal function (mean serum creatinine level of 2.7 mg/dL). Three patients died at a mean interval of 6.8 years postoperatively, and they all maintained satisfactory renal function (mean serum creatinine level of 3 mg/dL) until death. Although some patients with ESRD caused by atherosclerotic arterial occlusion can be salvaged in this manner, in most such cases irreversible loss of renal function has occurred. Therefore the most effective approach is to relieve arterial obstruction before ESRD develops.

Finally, it is important to emphasize that **patients with ESRD and ARAS without complete occlusion are not appropriate candidates for revascularization to restore function.** In such cases, main renal arterial blood flow is preserved, albeit at a reduced level, yet the supplied renal parenchyma is without function. The basis for this is the presence of severe unalterable parenchymal damage that precludes recovery of renal function with improved perfusion.

Renal Histopathology

Evaluation of renal histopathology can help to determine the presence of salvable renal function in selected patients with atherosclerotic renal ischemic disease. **In patients with ARAS and severe existing impairment of overall renal function (serum creatinine level >4 mg/dL),** renal biopsy findings can help to predict whether revascularization is likely to forestall further progressive renal insufficiency. In patients with atherosclerotic renal artery occlusion, renal biopsy findings can indicate whether the involved kidney is viable and functionally salvable on the basis of collateral vascular supply. The two predominant morphologic lesions in such patients are arteriolar nephrosclerosis and atheroembolic renal disease, with the former more often encountered. Both these diagnoses can be established on a frozen-section histopathologic examination, and, therefore the renal biopsy can be done at the same time as surgical revascularization, if the biopsy findings are favorable. In patients with arteriolar nephrosclerosis, the most important favorable criterion is histologic evidence that a majority of examined glomeruli are intact and viable (Zinman et al, 1977; Schefft et al, 1980). The presence of tubular atrophy, interstitial fibrosis, and arteriolar sclerosis are of lesser importance and do not necessarily preclude recovery of renal function; these findings may merely reflect the histologic changes of chronic reversible renal ischemia. However, the finding of widespread glomerular hyalinization indicates irreversible ischemic renal injury that obviates any benefit from relief of renal arterial obstruction (Fig. 39–12A). The finding of extensive atheroembolic disease would also preclude renal revascularization (Fig. 39–12B). Regarding the technique for renal biopsy in such patients, a more representative specimen of renal tissue is obtained with an open surgical (or laparoscopic) wedge biopsy than with a closed needle biopsy.

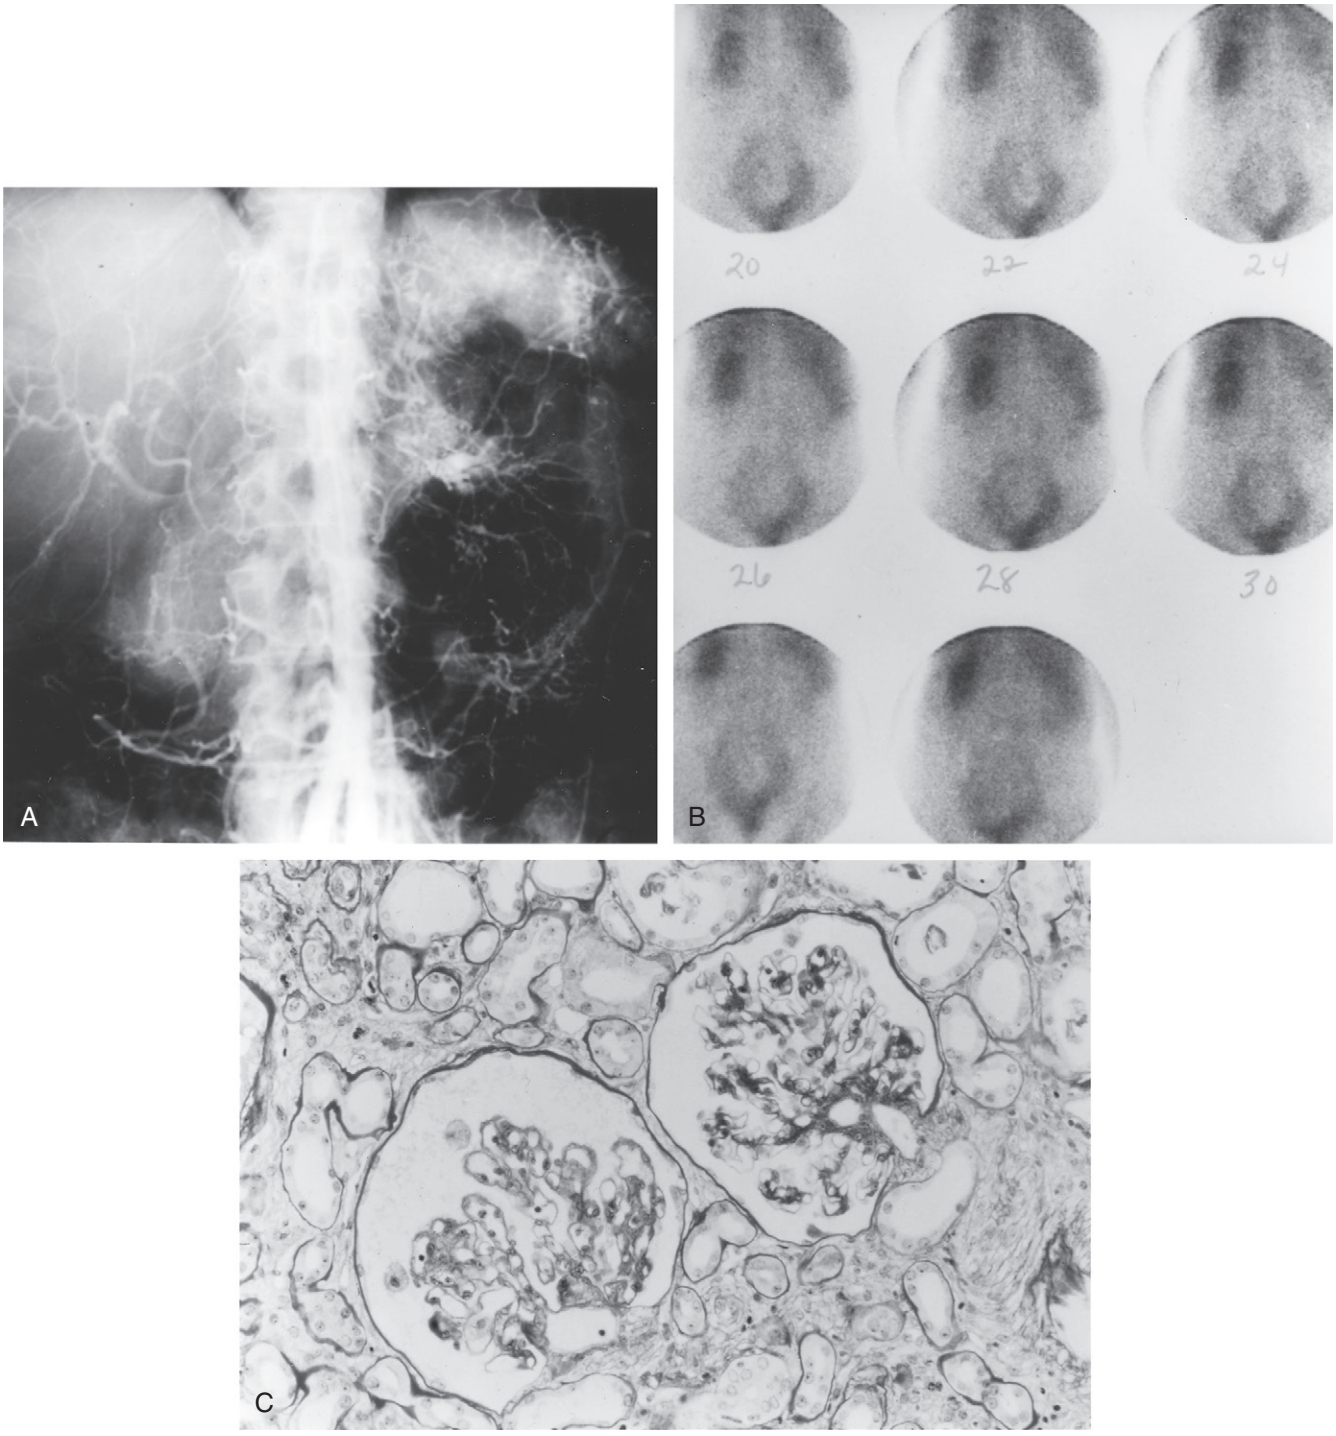

Figure 39–11. **A,** This abdominal aortogram was obtained in a 60-year-old woman who had been undergoing chronic dialysis for 9 months with no urine output. The aortogram shows complete bilateral renal artery occlusion with evidence of collateral vascular supply to the left kidney. **B,** Technetium renal scan confirms blood flow to the left kidney from collateral supply. **C,** Left renal biopsy shows hypoperfused but viable glomerular tissue, indicating a salvageable kidney. Left renal revascularization led to recovery of renal function and discontinuation of dialysis in this patient.

SURGICAL REVASCULARIZATION

Although repair of renal artery disease by revascularization is usually the main goal of surgical intervention, ablative surgery (nephrectomy) is occasionally more appropriate. The original surgery for renovascular hypertension, nephrectomy is a suitable alternative in hypertensive patients with a unilateral small kidney and markedly decreased ipsilateral function. Renal vein renin evaluation can confirm the kidney as the cause of hypertension, and laparoscopic nephrectomy can provide an attractive minimally invasive alternative to open nephrectomy in such cases (Fig. 39–13).

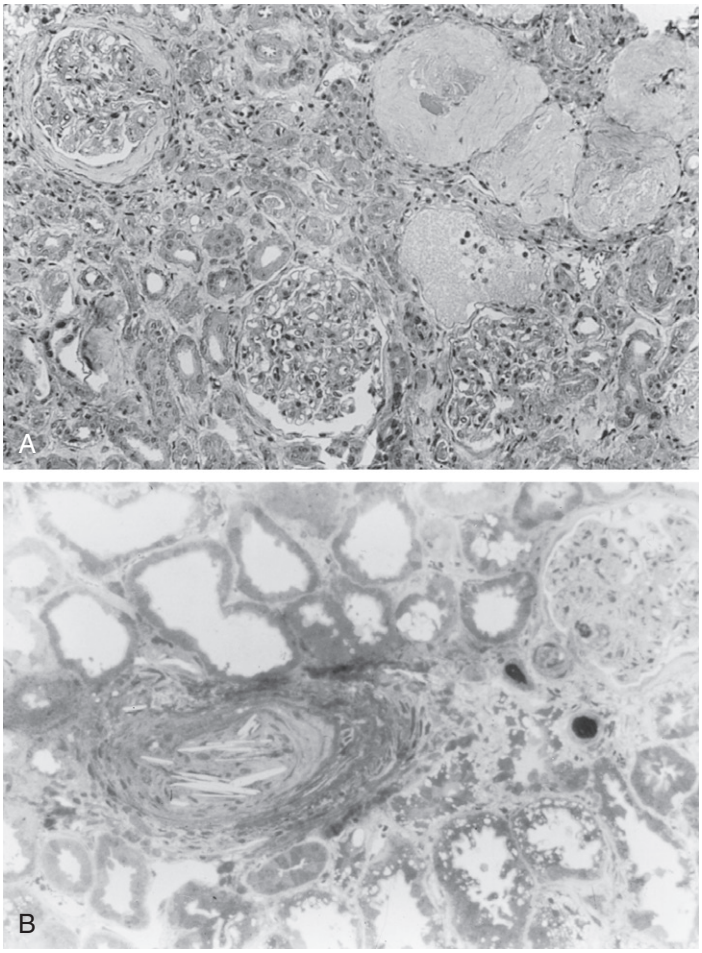

Figure 39–12. **A,** Light microscopic findings on biopsy of a kidney with total arterial occlusion demonstrate extensive glomerular hyalinization, which precludes any benefit from revascularization. **B,** Biopsy of a kidney in another patient demonstrates atheroembolic disease.

Preoperative Preparation

When surgical revascularization is indicated for renal artery disease, it is important to accurately define the general medical condition of the patient, because this will determine the risk of undertaking a major vascular operation. Most patients with renal arterial FD are young and otherwise healthy, and the operative risk is minimal in this group (Novick, 1994a). **In patients with atherosclerotic renovascular disease, the preoperative evaluation should include a thorough search for coronary artery disease, because this has been the leading cause of operative death after surgical revascularization.** In our program, in addition to a careful history, a physical examination, and an ECG, a thallium cardiac stress test is done on all operative candidates in this category. If any of these assessments suggest the presence of coronary artery disease, our policy is to perform coronary cineangiography and left-sided ventriculography. Myocardial revascularization is recommended for patients with significant correctable coronary artery disease before renal revascularization (Novick et al, 1981).

Cerebrovascular accident has also been a significant cause of death after renal revascularization in patients with atherosclerosis, albeit a less common complication than myocardial infarction. The approach to patients whose history or examination suggests extracranial cerebrovascular disease is analogous to that employed for patients with suspected coronary artery disease. In such patients, carotid arteriography is obtained preoperatively, and if significant occlusive disease is found, endarterectomy is recommended before renal revascularization (Novick et al, 1981).

In patients with generalized atherosclerosis and renal artery disease, cardiac function is often compromised to various degrees. In these patients, hypertension increases the workload on the left ventricle, which decreases cardiac reserve and renders the heart less efficient. In addition to having an impaired myocardium, these patients also often have a decreased intravascular volume because of prior treatment with diuretic agents. These patients can

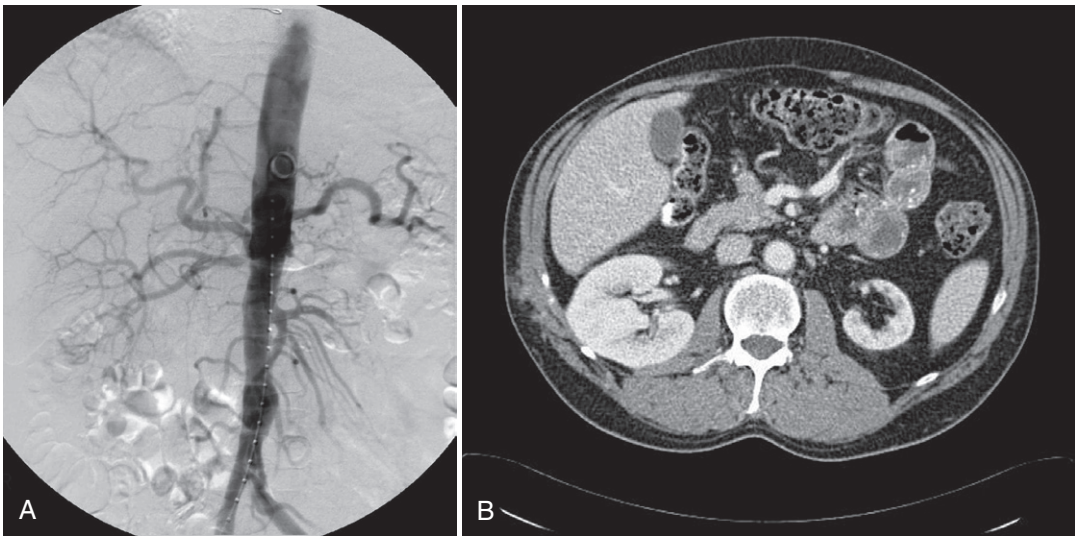

Figure 39–13. A 47-year-old male with poorly controlled hypertension (215/115) on four medications. CT scan shows a small left kidney **(A),** and angiography confirms an occluded left renal artery with minimal right renal artery stenosis **(B).** Renin evaluations from the infrarenal inferior vena cava, right and left renal veins were 15.4, 14.9, and 91.5 µg/L/hr, respectively. After laparoscopic left nephrectomy, blood pressure improved to 145/85 on one medication.

benefit from a careful hemodynamic assessment in an intensive care unit for 12 to 24 hours before surgical revascularization. In the intensive care unit, Swan-Ganz arterial and urethral catheters are placed for measurement of blood pressure, pulmonary capillary wedge pressure, pulmonary artery pressure, cardiac output, total peripheral resistance, and urinary output. While these parameters are being monitored, intravenous vasodilators can be administered to control the blood pressure and decrease the cardiac afterload, while the intravascular space is carefully expanded with isotonic fluid. Afterload reduction and fluid repletion, in this manner, optimize perioperative cardiac function by increasing cardiac output and decreasing cardiac work. This approach can enhance the safety of surgical renal revascularization in patients with generalized atherosclerosis.

Operative Techniques

Advances in both surgical renovascular reconstruction and medical antihypertensive therapy have limited the role of total or partial nephrectomy in the management of patients with renal artery disease. These operations are only occasionally indicated in patients with severe arteriolar nephrosclerosis, severe renal atrophy, uncorrectable renovascular lesions, and renal infarction.

A variety of surgical revascularization techniques are available for treating patients with significant renal artery disease. **Aortorenal bypass with a free graft of autogenous hypogastric artery or saphenous vein remains a popular method in patients with a healthy** abdominal aorta. Polytetrafluoroethylene aortorenal bypass grafts have been successfully employed by some authors, usually when an autogenous graft is not available. Renal endarterectomy also continues to be used occasionally to treat atherosclerotic renal artery disease. Patients with complex branch renal artery lesions are managed with extracorporeal microvascular reconstruction and autotransplantation.

In older patients, severe atherosclerosis of the abdominal aorta may render an aortorenal bypass or endarterectomy technically difficult and potentially hazardous to perform. In such cases, several authors prefer alternative surgical approaches that allow renal revascularization to be safely and effectively accomplished while avoiding operation on a badly diseased aorta. The most effective alternate bypass techniques have been a splenorenal bypass for left renal revascularization and a hepatorenal bypass for right renal revascularization. The absence of occlusive disease involving the origin of the celiac artery is an important prerequisite for these operations. A 1995 study indicated the presence of significant celiac artery stenosis in 50% or more of patients with ARAS (Fergany et al, 1995). This information underscores the importance of obtaining preoperative lateral aortography to evaluate the celiac artery origin in patients who are being considered for hepatorenal or splenorenal bypass.

Use of the supraceliac or lower thoracic aorta for renal revascularization is a more recent surgical alternative in patients with significant atherosclerosis of the abdominal aorta and its major visceral branches. The supraceliac aorta is often relatively disease-free in such patients and can be used to achieve renovascular reconstruction with an interposition saphenous vein graft. Simultaneous aortic replacement and renal revascularization have been associated with an increased risk of operative mortality, and this approach is best reserved for patients with a fixed indication for aortic replacement, such as a significant aortic aneurysm or symptomatic aortoiliac occlusive disease.

Results

Reports from several centers indicate that the techniques described previously for surgical renovascular reconstruction can be safely performed with a high technical success rate. **Patients with FD are usually otherwise healthy, and operative morbidity and mortality after revascularization in this group have been minimal** (Novick et al, 1987; Hansen et al, 1992). Operative mortality rates of 2.1% (Novick et al, 1987), 3.1% (Hansen et al, 1992), 3.4% (Bredenberg et al, 1992), and 6.1% (Libertino et al, 1992) have been reported after surgical revascularization in patients with atherosclerotic renal artery disease. An increased risk of operative mortality has been observed with bilateral simultaneous renal revascularization (Hallett et al, 1987), or when renal revascularization is performed in conjunction with another major vascular operation such as aortic replacement (Lawrie et al, 1989). Most studies have indicated a high technical success rate for surgical vascular reconstruction with postoperative thrombosis or stenosis rates of less than 10% (Novick et al, 1987; Van Bockel et al, 1987; Libertino et al, 1992).

In a retrospective study from the Cleveland Clinic, Tsoukas and colleagues (2001), evaluated the results of simultaneous aortic and renal revascularization and reported a 13% postoperative mortality rate for bilateral renal revascularization versus 7% for patients with unilateral renal revascularization, when both were performed simultaneously with aortic replacement. The 5-year survival rate for patients with preoperative serum creatinine more than 2 mg/dL was 53% compared with 85% for patients with lower creatinine. The authors recommend adjunctive use of endovascular techniques to decrease the magnitude of the surgical procedure for patients with concomitant aortic and bilateral renal artery atherosclerotic disease.

In evaluating the results of surgical revascularization for RVH, most studies have considered patients to be cured if the blood pressure is 140/90 mm Hg, or less, postoperatively. Patients have been considered to be improved if they have either shown a reduction in diastolic pressure of 10 to 15 mm Hg, or more, or become normotensive on medication. Failures have been those who have not qualified for either of the aforementioned categories. The results of surgical treatment for RVH vary according to the underlying pathologic diagnosis. In patients with FD, 50% to 60% are cured, 30% to 40% are improved, and the failure rate is less than 10% (Novick et al, 1987; Hansen et al, 1992). In patients undergoing revascularization for atherosclerotic RVH (Table 39–5), the failure rate is approximately the same; however, fewer patients are cured and more patients are improved postoperatively. The explanation for this is that RVH is often superimposed on existing essential hypertension in older patients. A study by Van Bockel and colleagues (1987) highlighted the excellent long-term results after reconstructive surgery for atherosclerotic RVH, with a mean

Table 39–5.

follow-up of 8.9 years; postoperative hypertension was cured or improved in 83 of 105 patients (79%).

During the past 15 years, **more centers have been performing surgical revascularization to preserve renal function in patients with high-grade atherosclerotic arterial occlusive disease affecting both kidneys or a solitary kidney.** These are generally older patients with diffuse atherosclerosis, ostial renal artery lesions, and varied degrees of renal functional impairment. Studies from several centers (Table 39–6) have indicated improvement or stabilization of renal function postoperatively in 75% to 89% of patients. Considering the significant risks of progressive occlusive disease and renal failure that have been associated with medical management of such patients, these results demonstrate a favorable influence of revascularization on the natural history of untreated atherosclerotic renal artery disease.

We have reviewed the contemporary experience at the Cleveland Clinic, between 1980 and 1992, with surgical renal revascularization employing an extra-anatomic bypass operation (Fergany et al, 1995). A total of 175 operations were done, including hepatorenal bypass (n = 59), splenorenal bypass (n = 54), iliorenal bypass (n = 37), thoracic aortorenal bypass (n = 23), renal autotransplantation (n = 1), and superior mesenterorenal bypass (n = 1). There were five operative deaths (2.9%) and seven cases of postoperative graft thrombosis (4%). All patients with poorly controlled hypertension were cured or improved postoperatively. Among patients with IN, postoperative renal function improved in 35%, remained stable in 47%, and deteriorated in 18%. These extra-anatomic techniques have become an important component of the surgical armamentarium for ARAS.

In another study, we analyzed long-term clinical outcomes and survival after surgical revascularization for ARAS in 222 patients treated from 1974 to 1987 at the Cleveland Clinic (Steinbach et al, 1997). The indications for surgical revascularization were treatment of hypertension in 60 patients, preservation of renal function in 12 patients, and both control of hypertension and preservation of renal function in 148 patients. The mean postoperative follow-up interval was 7.4 years.

In this study, there were five operative deaths (2.2%), and postoperative thrombosis or stenosis of the repaired renal artery occurred in 16 patients (7.3%). Long-term improvement or stabilization of renal function was achieved in 71.3% of patients. Actuarial 5- and 10-year survival for the entire series from the time of revascularization was 81% and 53%, respectively. The expected 5- and 10-year survival for a comparable healthy population is 89% and 77%, respectively. Using a multivariate analysis, factors correlating with diminished long-term survival were age greater than 60 years (P = .002), coronary artery disease (P = .031), and previous vascular operations (P = .001). These data support the long-term therapeutic efficacy of surgical revascularization in patients with ARAS. The merits of newer forms of therapy, such as PTA and endovascular stenting, must ultimately be weighed against these results.

Cherr and colleagues (2002), reported on the results of surgical revascularization in 500 patients with atherosclerotic renal artery disease from 87 to 99. Unilateral surgery was performed in 40%, bilateral in 60%, and combined aortic and renal surgery in 41%. Mortality rate was 4.6% overall. Hypertension was cured, improved and unchanged in 12%, 73%, and 15%, respectively. Renal function was improved in 43%, unchanged in 47% and deteriorated in 10%.

The results of renal autotransplantation for renal artery stenosis due to various pathologies (fibromuscular disease [FMD], ASO, and Takayasu arteritis) were reported by Chiche and colleagues (2003). Results of surgery were better in the FMD patients with early or delayed nephrectomy performed in five of eight patients with ASO. Hypertension was cured or improved in 96% of patients with FMD, and 89% of patients with Takayasu disease.

Secondary Renal Revascularization

Relatively few reports have addressed the management of patients with recurrent renal artery stenosis after failed surgical revascularization or PTA. For patients in the latter category, repeat PTA may be attempted; however, ultimately, many of these patients will require surgical revascularization. **There has been controversy concerning whether the prior performance of PTA increases the technical difficulty or compromises the outcome of surgical renal revascularization.** A report by Dean and associates (1987) indicated that the task of arterial reconstruction may be rendered more complicated by a perivascular inflammatory response induced by PTA. Reports from McCann and colleagues (1988) and Martinez and coworkers (1990) found that surgical revascularization is not more technically difficult after PTA than when done primarily, and that the same satisfactory results can be achieved. The latter study comprised 53 patients treated surgically after failed PTA for renal artery stenosis. Three patients underwent nephrectomy because a nonviable kidney was found at operation. Successful surgical revascularization was achieved in all the remaining 50 patients. The authors noted no significant fibrosis or inflammation around the previously dilated renal artery. PTA necessitated performing a more complicated revascularization operation in only 1 patient. These data indicate that if the kidney is viable at operation, prior performance of PTA does not increase the technical difficulty of surgical renovascular reconstruction.

Recurrent renal artery stenosis after surgical revascularization is typically a late complication occurring weeks, months, or even years postoperatively. If the involved kidney is functionally salvable, then another attempt to restore normal renal arterial flow is indicated. There has been scant experience with PTA or stenting in this setting; however, this is an appropriate initial approach for focal stenotic lesions. Secondary surgical revascularization has constituted the predominant reported approach, and this may be technically

complicated (Stanley et al, 1985; Erturk et al, 1989). Reoperation often entails dissection in a surgical field obliterated by fibrous scar tissue, and it is most efficacious to employ a secondary reconstructive technique that avoids the site of previous surgery. In patients with recurrent renal artery stenosis after an abdominal aortorenal bypass, alternate approaches that may be used for secondary revascularization include hepatorenal bypass, splenorenal bypass, thoracic aortorenal bypass, iliorenal bypass, and renal autotransplantation.

PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Percutaneous dilatation of arterial stenoses (angioplasty) was originally introduced by Dotter and Judkins in 1964; however, their technique of using coaxial catheters of increasing diameter was limited to the femoral and popliteal arteries and did not gain wide acceptance. It was the development of the balloon catheter by Gruntzig and colleagues in 1978 that permitted the widespread use of angioplasty for dilatation of the renal, coronary, and almost all other visceral arteries. Numerous modifications have been made to the original technique since its introduction, and there are currently several approaches to performing renal PTA.

Technique

All angioplasty techniques require a high-quality angiogram before dilatation to accurately delineate the lesion and allow assessment of proper equipment needs and approach. A proper-sized balloon should be selected to correspond to the original diameter of the renal artery as measured on the angiogram. Because there is 15% to 20% magnification on the angiogram, the result is the intentional overdilatation of the renal artery by 1 mm. Progress of angioplasty is monitored as the balloon inflates, and a postdilatation angiogram is obtained to assess the results and diagnose complications. PTA should be performed only when a skilled vascular surgeon is immediately available in case inadvertent occlusion or disruption of the renal artery creates a surgical emergency.

The original Gruntzig coaxial technique uses an 8- or 9-Fr renal guiding catheter through which a 4.3- or 4.5-Fr balloon catheter is passed over a guidewire traversing the stenotic segment through a femoral arterial puncture. In selected circumstances, an axillary approach may be used. Modification of the original technique and balloon catheters have allowed the use of a 5-Fr femoral artery puncture through which a 5-Fr diagnostic catheter is passed to the renal artery using the Seldinger technique. After the lesion is negotiated with an appropriate guidewire, the diagnostic catheter is exchanged with a 5-Fr balloon catheter and the angioplasty is performed (Tegtmeyer et al, 1980).

Mechanism

The principal mechanism through which the increase in arterial diameter after PTA occurs in cases of ASO is fracture of the atherosclerotic plaque. Stretching of the arterial wall with tearing of the media and adventitia also occurs but contributes to a smaller degree in cases of ASO than in FD. This stretching effect probably occurs after the atherosclerotic plaque is fractured and becomes more pronounced with increasing plaque circumference and a decrease in the uninvolved area of the vessel wall.

Complications

Renal angioplasty is a complex and technically demanding procedure that should be performed only by skilled interventional radiologists to prevent the occurrence of potentially serious complications. The complications of PTA include those of standard angiography (complications related to arterial puncture and to the use of iodinated contrast material), as well as specific complications related to manipulation of the renal arteries. **Transient deterioration of renal function is the most frequently occurring complication and is related to the contrast load delivered during the procedure.** Adequate hydration, minimizing the volume of contrast material, separating the diagnostic procedure from the PTA (by several days), and possibly the use of carbon dioxide or non-nephrotoxic contrast agents may decrease the incidence of this complication.

Technical mishaps during PTA may lead to an intimal dissection or even thrombosis of the renal artery. A small intimal flap is usually inconsequential, healing without sequelae. A larger flap compromising blood flow is usually managed by placing an arterial stent across the dissection. Thrombosis of the renal artery can be managed by injecting a thrombolytic agent through the renal artery or by emergency surgery. Rupture of the renal artery, a rare complication, is also managed by emergency surgery after reinflation of the balloon catheter to control retroperitoneal hemorrhage. Overall, the complication rate can be expected to be 5% to 10%.

Fibrous Dysplasia

Several studies have reported the results of PTA on blood pressure in cases of FD. Cure of hypertension is usually defined as a diastolic blood pressure of 90 mm Hg, or less, with no antihypertensive medication. Improvement of hypertension is usually defined as either a decrease in diastolic pressure of 15 mm Hg or a diastolic pressure of 90, or less, with a decrease in the antihypertensive medication needed to maintain normal blood pressure. Standardization of the results of these studies is difficult for several reasons. Several definitions are not uniform, including *significant stenosis* (varying from >50% to >80% of the original lumen) and technical success (defined as no stenosis or insignificant residual stenosis). Measures of success are also variable, with most studies relying on clinical parameters (blood pressure response) as the measure of success. Follow-up angiographic studies are rarely available. In addition, most studies combine ASO and FD patients, and sometimes results or complication rates are not referred specifically to one of the disease groups. Further complicating the interpretation of results is the reporting of results per patient in some studies and per lesion in others. The results of these studies are summarized in Table 39–7. Data per patient are used, and represent primary procedures only.

Overall, PTA is usually performed in cases of FD without stent placement and has become the primary modality of treatment for these lesions. With the use of modern equipment and increasing experience with the technique, technical success has been more than 90% in most modern studies. A beneficial blood pressure response, that is, cure of hypertension or improvement in blood pressure control, can be expected in more than 80%, and up to 100% of cases (Fig. 39–14). The incidence of major complications (when reported for FD patients alone) was 6% or less. At short to moderate follow-up intervals, restenosis of the treated artery was reported in up to one third of cases; however, most of these cases have been successfully

redilated. Rare reports describe the use of renal artery stents for resistant fibrous lesions (Joffre et al, 1992; Imamura et al, 1998); however, these are usually not needed for this form of RAS.

Atherosclerotic Renal Artery Stenosis

The pattern of arterial disease in cases of ASO is different from that in FD. **Renal artery stenosis in cases of ASO is usually bilateral and ostial, or very proximal in the main renal artery. In most ostial cases, this represents encroachment of the atherosclerotic plaque in the abdominal aorta on the origin of the renal artery rather than primary renal artery disease.** The patients affected by atherosclerotic RAS are also different from patients with FD of the renal arteries. Patients with ASO are generally older and have a number of comorbid medical conditions, as well as generalized atherosclerosis affecting the coronary or carotid arteries or the peripheral vascular tree. Associated essential hypertension and nephrosclerosis are usually present. All the previously mentioned factors, as well as the propensity for atheroembolism in patients with generalized ASO, make PTA for ASO-RAS less successful and associated with higher morbidity (and some mortality) than in cases of FD.

The presence of renal insufficiency or borderline renal function in a significant percentage of patients leads to an increased incidence of contrast nephrotoxicity as well.

The results of PTA on blood pressure in cases of RVH secondary to ASO are summarized in Table 39–8. Because of the previous factors, **the cure rate is lower than that for FD, commonly around 15%, and less in cases with bilateral PTA.** Failure to improve the blood pressure occurs in 15% to 85% in the reported series. Technical success at the time of angioplasty varies from 57% to 92% (Fig. 39–15), and is lower in cases in which separate results for ostial stenosis are reported (62% to 72%). Restenosis rates of 8% to 22%, and as high as 68% in some earlier series, are reported. Restenosis of ostial lesions is higher, reaching 35%, although more recent studies of ostial angioplasty show improved results (Eldrup-Jorgensen et al, 1995; Hoffman et al, 1998). Major complications requiring surgical intervention are reported in 5% to 24% of cases, and a mortality rate of 1% to 2% is also generally reported. More recent reports tend to show higher rates of technical success and lower complication rates (Martin et al, 1986), reflecting improved equipment and increasing expertise (Table 39–9); however, major complications and mortality rates reflect the fact that PTA is a serious procedure with significant attendant risks in this patient population. Renal artery stents are an adjunct to renal PTA that has been developed to improve the results obtained in ASO patients (see later).

With the advent of newer, more potent antihypertensive medications, as well as the increasing awareness of IN as a cause of renal failure, renal revascularization in patients with ASO is increasingly being performed with the intent of preserving or improving renal function, rather than the intent of curing RVH. **Several studies have reported the results of PTA on renal function in patients with ASO-RAS** (Table 39–10). Clinical benefit is defined as an improvement in renal function or a stabilization of renal function, in view of the steadily progressive decline in renal function associated with IN. With technically successful angioplasty, improvement can be expected in 15% to 43% of cases, and stabilization of renal function in 26% to 50% of cases. The remaining cases continue to suffer a decline in renal function. Although a mean follow-up of more than 100 months was achieved in one of these studies (Paulsen et al, 1999), follow-up for the rest of the studies is generally short to intermediate, ranging from 1 to 3 years. Percutaneous revascularization has also

been reported to be successful in improving blood pressure control and renal function in a diabetic subset of ASO patients (Zuccala et al, 1998).

Inflammatory Renal Artery Stenosis

Takayasu arteritis is one of the causes of RAS in children and accounts for a majority of cases of RAS in South and East Asian countries. In the absence of active disease or inflammation, angioplasty has been performed to relieve RVH as well as to prevent renal loss. In a series of 24 patients aged 5 to 16 years, all with inactive disease, technically successful dilatation was achieved in 92%, with a restenosis rate of 20% after a mean of 33 months of follow-up, and these were successfully redilated. Half the children in this study were cured of hypertension, and the other half improved. No complications were specifically reported in this study (Sharma et al, 1996). In a slightly larger group of 31 children (age range 5 to 14 years) in which less importance was given to the presence of active disease, technical success was possible in 87% of cases, with a restenosis rate of 26% at a mean follow-up of 23 months. Thirty-one percent of the patients were cured, 61% improved, and 8% failed clinically. One acute occlusion of the renal artery was reported; it was successfully redilated (Tyagi et al, 1997).

These excellent results were not duplicated in a smaller Canadian study of six patients in which only one patient obtained clinical benefit and the remaining five patients proceeded to surgical autotransplantation (D'Souza et al, 1998). All these studies were in agreement that long stenoses starting at the ostium of the renal artery were much less likely to have a successful result with PTA.

Management of RAS secondary to Takayasu disease in adults with PTA has also been successful (Dong et al, 1987; Deyu et al, 1998; Sharma et al, 1998). Technical success was obtained in more than 80% of patients in these studies, with overall clinical benefit in the range of 85%.

Children

RAS in children is caused by a variety of arterial diseases, including FD, middle aortic syndrome, and neurofibromatosis. In Asian countries, a significant proportion of RAS in children is also caused by aortoarteritis (Takayasu disease). The main limitation to performing PTA in children was the lack of suitably small-sized equipment. With modern angiographic techniques and digital imaging, PTA has been reported in several studies and is becoming a primary mode of management for children with RVH. The largest series reporting on PTA for treatment of FD in children comprises 16 children, 12 of whom were

diagnosed with FD. Three patients required a secondary PTA. Overall, 9 patients were cured and 2 were improved; in 5 patients, the treatment failed, and 4 of these were treated surgically. The PTA failed in all 3 patients with multiple stenoses in this study (none had FD). There were no reports of complications in this study (Courtel et al, 1998).

Reports of smaller studies of PTA in children with FD also demonstrate the technical success and beneficial blood pressure response obtained with this treatment modality (Lund et al, 1984; Millan et al, 1985; Chevalier et al, 1987; Simunic et al, 1990). Angioplasty has been successfully used in very young children, with reports of 18-, 15-, and even 9-month-old children being treated using small coronary angioplasty equipment (Hofbeck et al, 1998; Lee et al, 1999; Liang et al, 1999).

ENDOVASCULAR STENTING

With increasing experience with PTA, limitations of the technique, especially in regard to atherosclerotic lesions, have become well recognized. These limitations involve mainly ostial lesions that represent engulfment of the renal ostium in aortic plaque. These cases represent a significant percentage of ASO-RAS cases, and elastic recoil of the plaque leads to poor initial results and frequent restenosis. **Renal artery stents are an adjunct to PTA that was introduced in an effort to oppose this recoil force and provide better results for angioplasty, especially in ostial lesions. Almost all renal artery stents in the literature have been placed to treat ASO of the renal arteries** (estimated at 97%), with many fewer stents placed in cases of FD, transplant renal arteries, and other miscellaneous renal arterial abnormalities (Rees, 1999).

Arterial stents are radiopaque, expandable metallic wire mesh tubes that have been widely used in the peripheral vascular system. Experience in other parts of the vascular as well as the biliary tree has led to the use of stents in the renal artery, although none are specifically approved by the U.S. Food and Drug Administration for use in the renal artery. Different stents are currently available and include the Palmaz, Strecker, Wallstent, and Nitinol stents. Stent expansion either is spontaneous on extrusion from a delivery catheter (self-expandable) or occurs on inflation of a balloon on which the stent is preloaded (balloon expandable).

Technique

Several techniques for stent placement in the renal artery have been developed. It is essential in all cases to obtain a high-quality angiographic study (immediately before stent placement at the same sitting or separately) in order to precisely delineate the lesion and assess balloon and stent length and diameter. The stent used should be long enough to traverse the entire lesion, taking into consideration shortening of the stent with expansion. Excessive length beyond the lesion is undesirable because the presence of the stent may excite an intimal hyperplastic reaction, placing healthy segments of the vessel at risk. This might also obstruct a site suitable for later bypass surgery. In cases of ostial lesions, the stent should be placed to protrude 1 to 2 mm into the aortic lumen to prevent restenosis due to recoil of the aortic plaque.

Indications

Current indications for stent placement are poor immediate results during PTA as well as restenosis after PTA. Stents are also used to treat angioplasty complications (artery dissection and intimal flaps) and thus have markedly reduced the incidence of emergency surgery for these complications. **"Primary" stent placement is becoming increasingly popular in cases of RAS in which PTA alone is unlikely to be successful (ostial lesions).**

Results

The results of several studies reporting on endovascular stent placement in the renal arteries are summarized in Tables 39–11 and 39–12. Most of the published experience in the renal arteries has been described using the Palmaz stent. With the exception of two of the earliest studies using Strecker and Wallstents, **the reported technical success for stent placement has consistently been above 95%**, and in most studies has been 99% or 100% (Fig. 39–16). With short to moderate follow-up intervals, restenosis of the renal artery after stent placement has ranged from 6% to 38%. A single early study (Wilms et al, 1991) reported a 71% restenosis rate; however, most larger contemporary series average a restenosis rate of 15% to 20%. Restenosis commonly

occurs within the stent owing to a hyperplastic intimal reaction. In other cases, an intimal lining about 1 mm thick covers the luminal surface of the stent. Renal arteries that are dilated and stented to a luminal diameter of less than 6 mm are more prone to develop restenosis.

The blood pressure response to renal revascularization by PTA and stenting is shown in Table 39–11. The low cure rates (31% at most) reflect the pathophysiologic nature of atherosclerotic renal artery disease in which anatomic stenosis is frequently associated with concomitant essential hypertension and renal parenchymal damage, precluding a simple pathologic explanation for hypertension. Revascularization for preservation of renal function has become the focus of intervention in cases of ASO-RAS. The result of renal artery stent placement (for renal function preservation or improvement) in various studies is shown in Table 39–12. Because of the progressive nature of renal dysfunction due to ASO, a clinical benefit is defined as improvement or stabilization (halt of decline) of renal function after revascularization. Improvement in renal function was achieved in 13% to 60% of cases, and stabilization was achieved in 24% to 75% of cases, with the remaining cases continuing to have progressive dysfunction.

Perhaps the clearest situation of IN is RAS to a solitary kidney, and it is on these patients that the effect of revascularization on renal function can be most clearly identified. In a study of 21 such patients, an improvement in the serum creatinine level was obtained after stent placement in 42% of cases, and stabilization in 29% of cases. Within the group of improved patients were 4 who were relieved of dialysis dependence. These results were associated with a major complication rate of 19% including a single early (and another late) procedure-related mortality (Shannon et al, 1998).

In the only prospective study comparing PTA alone versus PTA with stenting in ostial atherosclerosis, a total of 85 patients were randomized to either treatment group. Technical success was higher in the stented group (88% vs. 57%), and patency at 6 months was 75% for patients in the stent group versus 29% for PTA alone. In patients with successful primary procedures, restenosis occurred in 14% of the patients with stents and in 48% of patients with PTA alone. Stenting for immediate or late failure of PTA was required in 12 (of 42) patients in the PTA group. **This study reflects the overall higher success of PTA with stenting in treating ostial ASO when compared with PTA alone, and probably also justifies the increasing trend to perform primary stenting in these cases to avoid exposing patients to a secondary procedure** (Van de Ven et al, 1999).

Several studies addressed the factors affecting outcome after stenting and recommended selecting patients for interventional treatment based on their findings; Kennedy and colleagues (2003) and Zeller and colleagues (2003) both report that baseline renal insufficiency correlates with decreased survival and increased adverse events after renal artery stenting. In Zeller's study, the 5-year survival rate was 30% for patients with creatinine more than 2.5 mg/dL versus 95% in patients with creatinine less than 1.2 mg/dL. Major causes of death were cardiac events, cerebral events, and malignancy.

Perkovic and colleagues (2002) studied several parameters for patients undergoing renal artery stenting and reported baseline renal impairment, older age (>70), and diabetes as predictors of poor outcome. ACE inhibitor therapy after stenting appeared to improve outcome in this series.

Complications

Complications of renal artery stent placement are similar to those of renal PTA, with the added complications of stent delivery. The incidence of access site complications is higher because of the larger arterial puncture needed. The incidence of intimal injury and dissection is lower than that of PTA, because stent placement itself is a treatment for these complications. A higher incidence of contrast nephrotoxicity owing to a larger contrast load is noted, but the increasing use of carbon dioxide as a contrast agent may decrease the incidence of this

†Procedure-related mortality only.

complication. The literature has rare reports of endovascular infection from renal artery stents, resolving after conservative therapy with IV antibiotics (Gordon et al, 1996), or progressing to form mycotic aneurysm of the aorta and renal artery necessitating major excision and vascular reconstructive surgery (Deitch et al, 1998).

Major complications (including death) are reported in 0% to 20% of cases (Table 39–13). Minor complications are reported in 0% to 40% of cases. Mortality directly related to the procedure is reported in almost all large series in the range of 3%. This attests to the fact that PTA with stent placement is not a benign procedure and is associated with definite risk. In a review of complications of stent placement in 50 patients, a complication rate of 20% was noted, 10% of patients suffered major complications, and a 10% rate of cholesterol embolism was reported (Beek et al, 1997).

In a meta-analysis of renal artery intervention studies earlier than 1998, including more than 1300 patients, initial technical success of stent placement was 98%, with major complications occurring in 11%. The overall cure rate for hypertension was 20%, whereas hypertension was improved in 49%. Renal function improved in 30% and stabilized in 38% of patients. The restenosis rate at follow-up of 6 to 29 months was 17%. Stent placement had a higher technical success rate and a lower restenosis rate than did renal PTA (98% versus 77% and 17% versus 26%, respectively; $P < .001$). The complication rate was not different between the two treatments (Leertouwer et al, 2000).

Proper patient selection for endovascular intervention in cases of ASO-RAD should be a careful process that takes into account the patient's chances of a successful outcome. This process should be as rigorous as patient selection for open surgery to minimize morbidity and poor outcomes from endovascular intervention. Recent studies have suggested that renal artery intervention (with or without stenting) may not improve overall patient outcomes compared with optimal medical treatment alone (van Jaarsveld et al, 2000), and a large prospective randomized multicenter study (CORAL [Cardiovascular Outcomes in Renal Atherosclerotic Lesions]) is currently underway attempting to provide informed clinical decisions regarding patient outcomes.

Complications of PTA with stenting were not found to be significantly different from those of PTA alone in a prospective study comparing both procedures. Specifically, bleeding-related complications were 19% in both groups; cholesterol embolism was 10% in both groups; and access site pseudoaneurysm and renal artery injury were slightly higher with stent placement (7% vs. 5%). Transient deterioration of renal function from contrast nephrotoxicity was noted in 24% of patients undergoing PTA and 21% of patients undergoing PTA with stent placement (Van de Ven et al, 1999).

Recent advances in renal artery intervention include the use of distal protection devices (DPD), and the use of drug-eluting stents (DES) to minimize restenosis. Distal protection devices include filters, baskets, nets, and balloons, most primarily intended for use in carotid artery stenting, and are intended to prevent distal embolization during manipulation of the renal artery. Although clinically apparent distal embolization is uncommon, such atheroemboli may be associated with decreased survival (Krishnamurthi et al, 1999). Experience with DPD has been promising but is still preliminary, with studies reporting retrieval of debris in 60% to 100% of cases (Holden et al 2006, Henry et al, 2001). Difficulty in deploying the devices in the distal renal artery due to early bifurcation or tortuosity may be encountered, resulting in successful use of such a device in three of five cases (Hagspiel et al, 2005). Future device innovations tailored to the renal artery and increasing experience with DPD will further clarify their role in renal artery interventions.

Drug-eluting stents have been used increasingly in coronary interventions, with the intention of decreasing in-stent restenosis, particularly of smaller vessels. Drug-eluting stents have been studied prospectively in the renal artery in 105 patients (Zähringer et al, 2007). Although both Sirolimus and Paclitaxel are used for stent coating, this study used Sirolimus-coated stents only. There was no significant difference in results between the bare stent group and the DES group after 2 years of follow-up, with clinical patency at 88.5% for the bare metal stent group and 98% for the DES group. Blood pressure–lowering effects did not differ significantly between the two groups either. Based on the results of this study, it may seem that DES do not offer an additional advantage in renal artery intervention over bare metal stents, but this may be due to the larger size of the renal arteries (about 6 to 7 mm) compared with the coronary arteries (5 mm or less), where restenosis may be more common. In the future, DES may prove useful in smaller renal arteries or branch disease.

OTHER RENAL ARTERY DISEASES

Renal Arterial Aneurysms

A renal arterial aneurysm is a localized dilatation of the main renal artery or its branches or both caused by weakening of the elastic tissue and media of the arterial wall. The estimated incidence of such lesions in the general population ranges from 0.09% to 0.3%. Renal arterial aneurysms may be clinically significant because of a causative relation to hypertension, associated local symptoms, or the risk of catastrophic rupture in certain situations (Novick, 1982). According to the classification of Poutasse (1975), there are four basic types of renal artery aneurysms: saccular, fusiform, dissecting, and intrarenal (Fig. 39–17).

Saccular aneurysms are the most common type and constitute about 75% of renal artery aneurysms. They generally occur at the bifurcation of the renal artery, perhaps owing to an inherent weakness in the wall of the artery at this point. Because of this

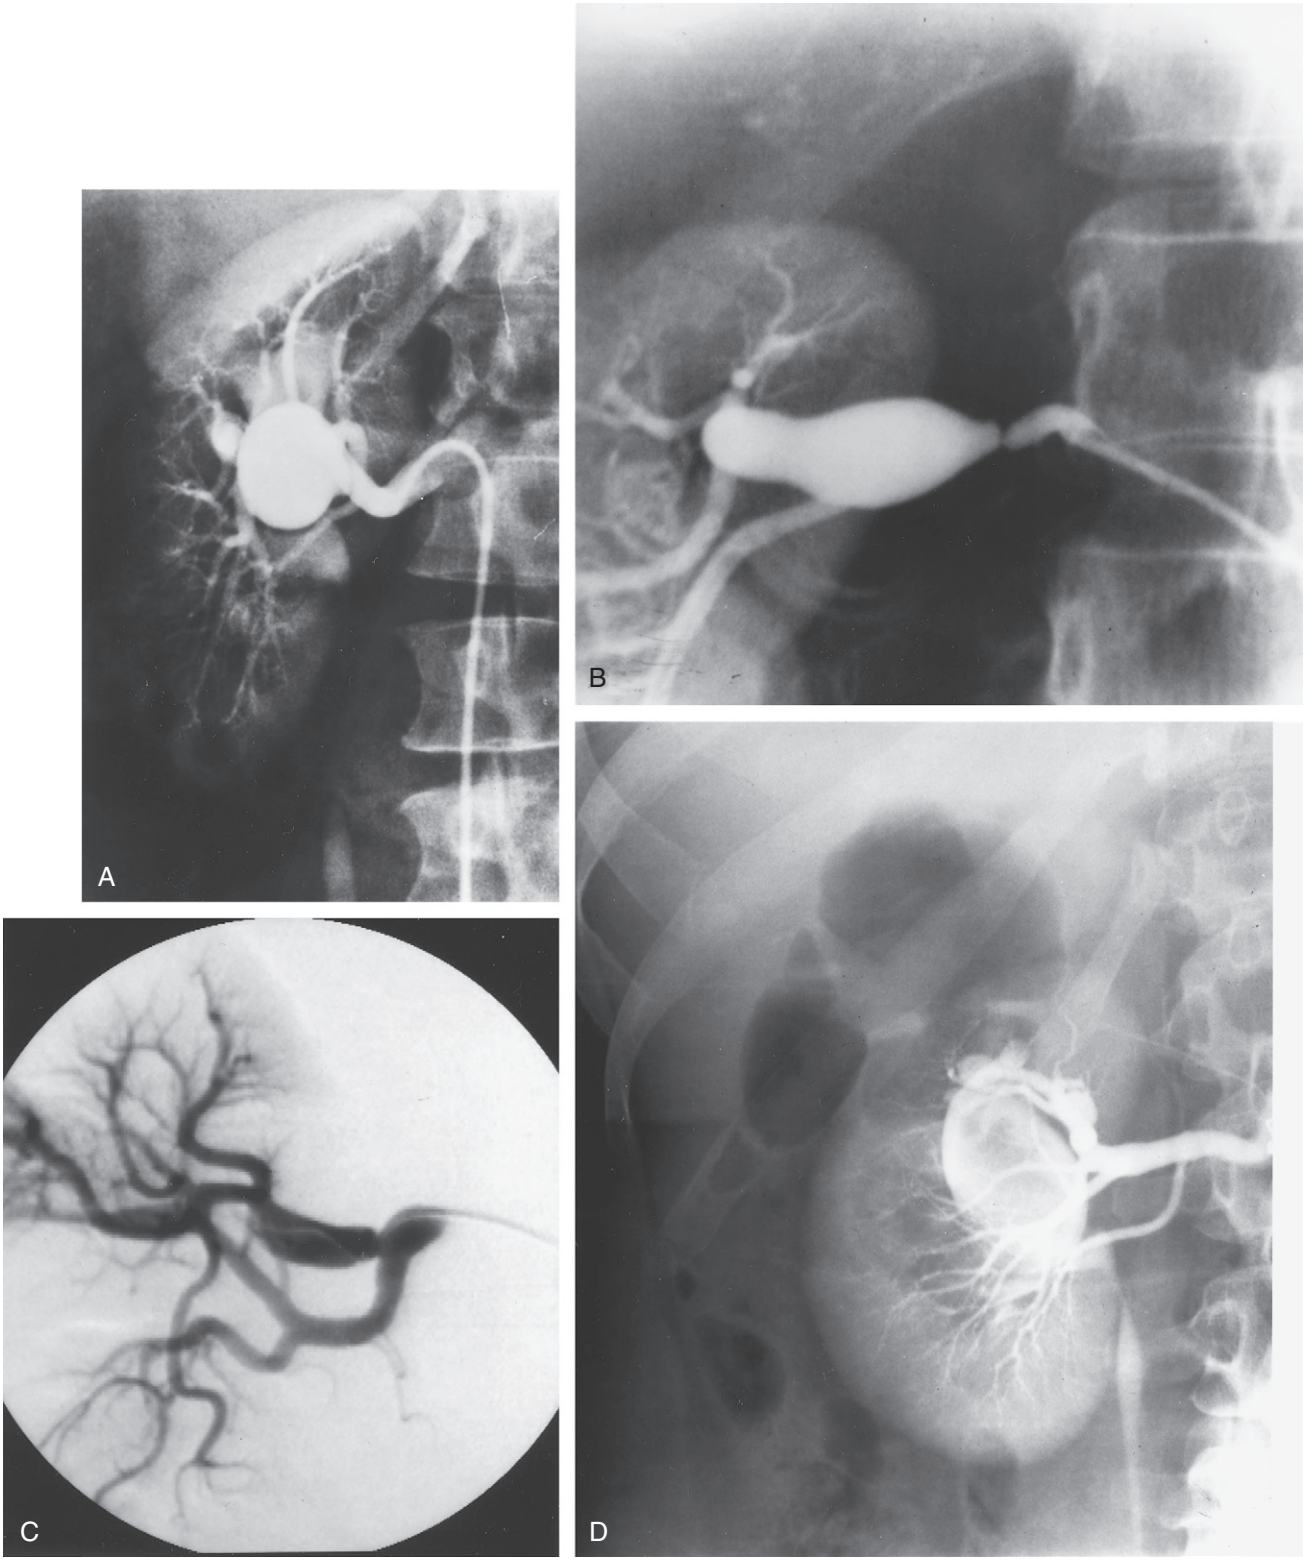

Figure 39–17. Selective renal arteriograms demonstrate the four types of renal artery aneurysms. **A,** Saccular aneurysm located at the bifurcation of the main renal artery. **B,** Fusiform aneurysm distal to a stenotic lesion of the main renal artery. **C,** Dissecting aneurysm involving a renal artery branch. **D,** Intrarenal aneurysm.

location, branch arterial involvement is common. The incidence of bilateral or multiple aneurysms or both is approximately 25%. These aneurysms may become involved with secondary atherosclerotic degeneration or intramural calcification or both. Incompletely calcified aneurysms may become soft, thin, and ulcerated between zones of calcification, thus predisposing to rupture. In addition to rupturing spontaneously, saccular aneurysms may erode into the renal vein or into the renal pelvis. Mural thrombus formation may also occur within saccular aneurysms, occasionally leading to peripheral renal embolization.

Fusiform aneurysms occur as a uniform dilatation of an entire segment of the renal artery to as much as three to four times its normal diameter. These aneurysms range in length from 1 to 3 cm and are generally not calcified. They are typically found in young hypertensive patients with stenosing fibrous renal arterial disease. The fusiform aneurysm is actually a poststenotic dilatation and can involve either the main renal artery or its branches. The major complication of this lesion is thrombosis of the involved arterial segment from progressive proximal stenosing vascular disease.

A dissecting aneurysm results from a tear in the internal elastic membrane of the renal artery, and as blood flows through the opening, the intima is separated from the remainder of the arterial wall. In some patients, the dissection may reenter the lumen distally to preserve renal function. In other cases, arterial thrombosis with renal infarction or rupture with hemorrhage may occur. Dissecting aneurysms are most often complications of renal arterial involvement with atherosclerosis, intimal fibroplasia, or perimedial fibroplasia. Less commonly, such an aneurysm may occur as an extension of a dissecting aortic aneurysm.

Intrarenal arterial aneurysms are of mixed origin and may be congenital, post-traumatic, iatrogenic, neoplastic, or associated with polyarteritis nodosa. They are usually saccular or fusiform and may or may not be calcified. Intrarenal aneurysms constitute approximately 17% of all renal arterial aneurysms, and they do have the propensity for rupture. Intrarenal aneurysms that occur after blunt trauma or closed renal biopsy occasionally resolve spontaneously with expectant management.

In general, the diagnosis of renal arterial aneurysm should be considered when ringlike calcification in or near the renal hilum is found on a plain abdominal radiograph. These calcifications occur in about 50% of cases. **The majority of renal arterial aneurysms are small and asymptomatic.** The most common clinical manifestations are hypertension, subcostal or flank pain, hematuria, an abdominal bruit, and, rarely, a palpable pulsating mass. RVH is reported to occur in 15% to 75% of patients and may be due to turbulent flow within an aneurysm, associated arterial stenosis, dissection, arteriovenous fistula formation, thromboembolism, or compression of adjacent arterial branches by a large aneurysm. Complications of renal arterial aneurysms include peripheral dissection, arterial thrombosis with renal infarction, emboli arising from mural thrombus within an aneurysm, obstructive uropathy, erosion into a vein with formation of an arteriovenous fistula, and spontaneous rupture with hemorrhage. Factors that appear to predispose to aneurysmal rupture include absent or incomplete calcification, aneurysmal size greater than 2 cm in diameter, coexisting hypertension, and pregnancy.

A small (2-cm) well-calcified renal arterial aneurysm in an asymptomatic normotensive patient does not require operative intervention. These aneurysms can be followed with serial plain abdominal radiographs to detect any change in size. Surgical removal is indicated for renal arterial aneurysms, regardless of size, in (1) aneurysm causing renal ischemia and hypertension, (2) dissecting aneurysm, (3) aneurysm associated with local symptoms such as flank pain or hematuria, (4) aneurysm occurring in a woman of child-bearing age who is likely to conceive, (5) aneurysm occurring with functionally significant renal arterial stenosis, (6) aneurysm with radiographic evidence of expansion on serial radiographs, or (7) aneurysm containing a thrombus detectable on angiography with evidence of distal embolization.

When none of these criteria are present, small (2-cm) asymptomatic noncalcified or incompletely calcified aneurysms can be managed nonoperatively. Such patients should be followed periodically with serial CT or MRI studies to document the size of the aneurysm. It is not possible to rigidly define indications for operative intervention in asymptomatic patients with aneurysms greater than 2 cm in diameter and with none of the previous criteria. The available data would seem to support surgical excision, if these aneurysms are not calcified throughout or are intrarenal because of the increased tendency to rupture in these settings.

In the largest series of renal artery surgery reported in the recent literature (Henke et al, 2001), a total of 121 patients underwent surgical repair. Eight unplanned nephrectomies were necessary resulting in the need for permanent dialysis in one patient, no perioperative mortality was encountered, and all but two reconstructions remained patent at follow-up.

In a retrospective review of surgical repair of renal artery aneurysms in 94 patients, Pfeiffer and colleagues (2003) encountered one postoperative mortality (in an emergency repair secondary to aneurysm rupture), overall morbidity of 17%, and a primary success rate of 97%.

English and colleagues (2004) reported their results of surgical repair of 72 renal artery aneurysms of varying etiology over a 16-year period. Only one aneurysm was deemed not reconstructable, and nephrectomy was performed. One operative mortality was encountered, and 12% of patients had significant perioperative morbidity, with 96% of repairs maintaining patency at 48 months.

A significant body of literature (almost all case reports) has accumulated over the last few years reporting successful endovascular management of renal artery aneurysms as well as dissection of the renal artery. In the case of renal artery aneurysms, two methods of endovascular treatment are reported. The first involves embolization of the aneurysm (usually with coils) to occlude it without disrupting the renal blood flow (Halloul et al, 2000; Karkos et al, 2000; Mounayer et al, 2000; Tshomba et al, 2002; Lupattelli et al, 2003). The second method involves placing an arterial stent in the renal artery or the branch where the aneurysm originates, thereby maintaining flow through the stent and effectively excluding the aneurysm (Tan et al, 2001; Bruce and Kuan, 2002; Pershad and Heuser, 2004). Stenting the renal artery across an aneurysm has also been described as a successful and rapid method of dealing with ruptured renal artery aneurysm (Schneidereit et al, 2003). Dissection of the renal artery also can be managed endovascularly by placing a renal artery stent through the area of dissection to keep the lumen patent and keep the dissected intima immobilized against the outer layers of the artery (Bilge et al, 2003).

Renal Arteriovenous Fistula

Renal arteriovenous fistulas are relatively uncommon lesions that are generally discovered during the course of angiographic evaluation for suspected renal or renovascular disease. There are three categories of renal arteriovenous fistulas: congenital, idiopathic, and acquired (Tynes et al, 1970; Novick, 1982).

Congenital fistulas have a cirsoid or angiomatous configuration with multiple communications between arteries and veins. They are usually supplied by a renal arterial branch of normal caliber. The angiographic appearance is one of multiple, small, interconnecting arterial and venous channels with impaired distal renal parenchymal vascularity and early filling of the renal vein. They constitute 22% to 25% of all renal arteriovenous fistulas, occur equally in both sexes, and generally do not become manifest until adult life.

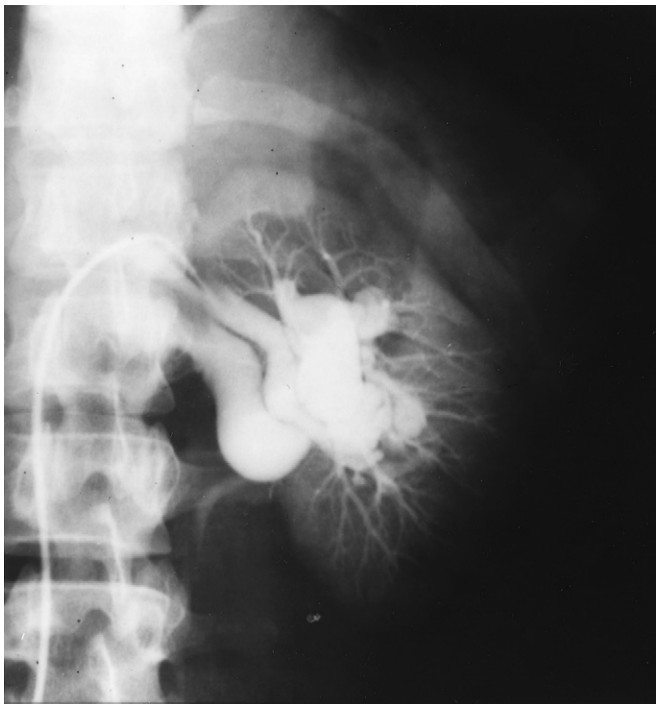

Figure 39–18. Left renal arteriogram shows renal arteriovenous fistula with early filling of the renal vein. This patient had previously undergone needle biopsy of the left kidney.

Table 39–14.

Causes of Renal Arterial Thrombosis and Embolism

Renal Artery Thrombosis
Blunt or penetrating trauma
Aortic or renal artery angiography
Atherosclerosis of aorta or renal artery
Fibrous dysplasia of renal artery
Polycythemia vera
Umbilical artery catheterization in neonates
Inflammation of renal artery
Syphilis
Polyarteritis
Thromboangiitis obliterans
Renal Artery Embolism
Bacterial endocarditis
Aseptic cardiac valvular vegetations
Open heart surgery
Atrial fibrillation
Saccular renal artery aneurysm
Cardiac tumor
Acute myocardial infarction
Ventricular aneurysm
"Paradoxical" embolism

Idiopathic fistulas are single, are not cirsoid, and have no apparent cause. They constitute only 3% to 5% of all renal arteriovenous fistulas. These lesions are called *idiopathic* because their angiographic appearance is similar to that of acquired arteriovenous fistulas, but their origin is unclear.

Acquired fistulas are the most common type, accounting for 70% to 75% of all renal arteriovenous fistulas. On angiography, they appear as solitary communications between an artery and a vein. By far the most common cause is iatrogenic trauma resulting from needle biopsy of the kidney (Fig. 39–18). Other causes include renal carcinoma, blunt or penetrating renal trauma, inflammation, and renal surgery such as nephrectomy, partial nephrectomy, or nephrolithotomy.

The clinical manifestations of a renal arteriovenous fistula depend on the size of the fistula. **Approximately 75% of patients have an abdominal bruit,** which is usually loud, high pitched, and continuous with systolic accentuation. Congestive heart failure, cardiomegaly, and diastolic hypertension are observed in 50% of patients. Hematuria is present in about one third of cases, tachycardia is occasionally found, and a palpable flank mass from spontaneous rupture is rarely encountered.

The management of a patient with a renal arteriovenous fistula depends on the cause of the fistula and the associated clinical manifestations. For patients with renal carcinoma, immediate nephrectomy is obviously indicated. **Approximately 70% of fistulas occurring after needle biopsy of the kidney close spontaneously within 18 months.** A smaller number of fistulas diagnosed immediately after renal trauma have also resolved spontaneously. Therefore in the absence of significant related symptoms, expectant management is appropriate initially in these cases.

Treatment of renal arteriovenous fistulas is indicated for patients who have hypertension, heart failure, severe hematuria, serial angiographic evidence of an expanding lesion, rupture, or progressive renal failure. When specific therapy of these lesions is indicated, renal-sparing procedures should be employed whenever possible.

Transcatheter angiographic occlusion is a nonsurgical therapeutic alternative that has been employed primarily in treating patients with postbiopsy fistulas, in which the arteriovenous connecting vessels are usually small. More recently, transcatheter occlusion of congenital or idiopathic fistulas with a stainless steel coil has also been performed.

Various operations have been employed in the surgical treatment of renal arteriovenous fistulas. **Most congenital or cirsoid fistulas have been managed with total or partial nephrectomy,** because of the difficulty of completely excising the many small communicating vessels. In patients with idiopathic or acquired fistulas, a single communication between the artery and the vein is characteristically present, and surgical obliteration of the fistula with preservation of the involved kidney is more often possible.

Renal Artery Thrombosis or Embolism

Thromboembolic disorders of the renal artery can present as fulminant clinical syndromes that threaten life or may be entirely asymptomatic and detected only at postmortem examination (Hoxie and Coggins, 1940; Schoenbaum et al, 1971). The various causes of acute renal artery thrombosis or embolism are listed in Table 39–14. The term *paradoxical embolism* refers to a clot originating in the venous circulation that gains entrance to the systemic arterial circulation through an intracardiac septal defect.

Renal arterial thrombosis commonly involves the proximal or middle third of the main renal artery, whereas renal arterial embolization generally involves peripheral arterial branches. Acute arterial occlusion is more common on the left side because of the more acute angle between the left renal artery and the aorta. Post-traumatic renal arterial occlusion is also more common on the left side, presumably because of the acute angulation of the shorter left

renal artery at its aortic junction, which predisposes to intimal disruption with deceleration of the mobile kidney.

The clinical symptomatology in these disorders is extremely varied. Bilateral acute renal arterial occlusion presents with rapidly progressing oliguric renal failure, whereas chronic occlusion of a single renal artery may be unnoticed because of the development of collateral circulation. The most common symptoms, when present, are dull, aching abdominal or flank pain often associated with nausea, vomiting, and fever. Other findings include hypertension, albuminuria, microscopic hematuria, leukocytosis, and elevation of serum lactate dehydrogenase levels.

Patients with unilateral renal arterial embolic occlusion generally have serious underlying extrarenal disease and are best managed nonoperatively with systemic anticoagulation or by percutaneous transcatheter thromboembolectomy (Millan et al, 1978; Hamilton, 1996). Patients with unilateral traumatic renal arterial thrombosis also often have severe associated injuries, and the results of vascular reconstruction are generally unsatisfactory unless this is undertaken within several hours of the time of injury. Surgical treatment in these cases is generally ill advised when a normal contralateral kidney is present. Percutaneous intra-arterial infusion of a fibrinolytic agent, such as streptokinase, now offers a nonoperative approach to the management of acute renal arterial thrombosis (Hamilton, 1996).

Renovascular reconstruction is generally indicated when renal artery thrombosis or embolism occurs bilaterally or in a solitary kidney. Alternatively, if angiographic and isotopic studies in such cases demonstrate an extensive collateral vascular supply maintaining renal viability, an initial therapeutic trial with one of the previously mentioned nonoperative approaches may be worthwhile.

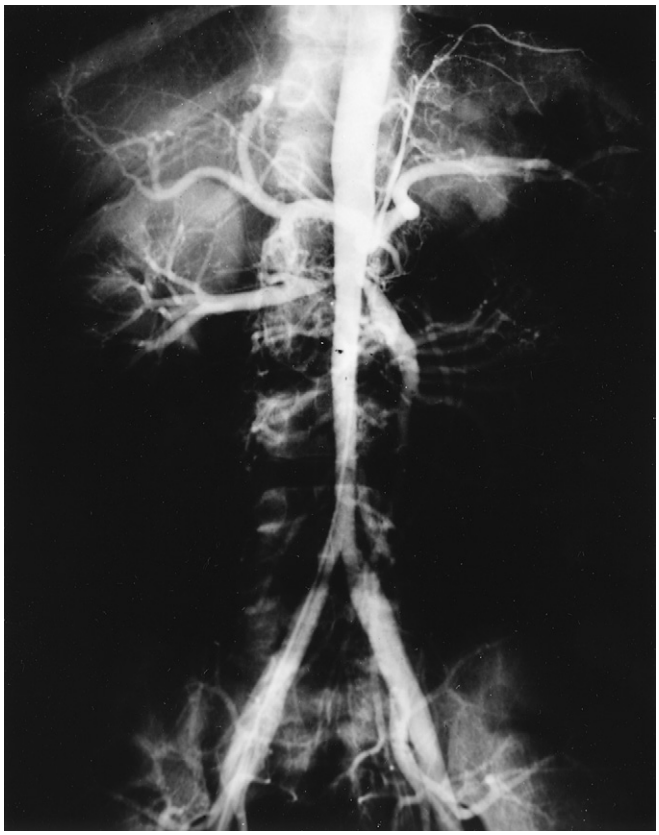

Figure 39–19. Aortography in a child with the middle aortic syndrome shows hypoplasia of the abdominal aorta and right renal artery stenosis.

Neurofibromatosis

Neurofibromatosis affecting the renal arteries is a congenital hereditary disorder characterized by café-au-lait cutaneous pigmentation, cutaneous neurofibromas, tumors of the CNS, skeletal disorders, and occasional gigantism (Grad and Rance, 1972; Tilford and Kelsch, 1973). Hypertension in patients with neurofibromatosis is most often due to renal artery stenosis; less commonly, this may be the result of an associated pheochromocytoma or aortic coarctation. Vascular abnormality occurs in the kidneys, heart, and gastrointestinal tract and consists of fibrosis and thickening of the intima, proliferation of neural tissue within the arterial wall, perivascular nodular proliferations, and occasional aneurysmal dilatation. In the kidney, arterial stenosis usually occurs at the origin or in the proximal third of the main renal artery, and the angiographic appearance may be indistinguishable from that of intimal fibroplasia. Considering the young age of these patients, renal revascularization is generally the treatment of choice for associated RVH.

Middle Aortic Syndrome

The middle aortic syndrome is a rare disorder, occurring in children or young adults, characterized by nonspecific stenosing arteritis affecting the aorta and its major branches, including the renal arteries (Fig. 39–19). This is thought to be a form of Takayasu disease, and an autoimmune pathogenesis is suspected (Kaufman, 1973). This disease can extensively involve the subdiaphragmatic aorta or, in some cases, may spare the aorta and involve primarily the renal or splanchnic vessels. The natural history is not well understood because most cases are diagnosed when the disease has already resulted in significant renal arterial stenosis in young good-risk patients, thus necessitating early revascularization. Because the inflammatory process generally does not extend to involve the iliac arteries, renal autotransplantation is the surgical treatment of choice.

Extrinsic Obstruction

Extrinsic obstruction of the renal artery has been observed but is extremely rare (Silver and Clements, 1976). Neural tissue, musculocutaneous fibers, and diaphragmatic crura have been suggested as etiologic factors contributing to this process. Other possible causes of extrinsic perivascular fibrosis include inflammation, trauma, tumor, or prior radiation.

The Page Kidney

In 1934, Page (1939) produced a renin-dependent model of hypertension by wrapping a dog kidney in cellophane. Hypertension could be reversed by removing the cellophane wrap or the kidney. **The clinical equivalent of this hypertensive model is the kidney compressed by a subcapsular or perirenal process causing renal ischemia, inducing unilateral hypersecretion of renin and contralateral suppression.** Causes of the perinephric process include blunt trauma, closed renal biopsy, anticoagulation, or hemorrhage from a tumor.

The diagnosis of the Page kidney depends on the presence of either a surrounding hematoma or an encasing fibrous

pseudocapsule. Imaging with ultrasonography, CT, or MRI localizes the hematoma or fibrous capsule.

The treatment of the Page kidney aims to preserve renal function and cure hypertension. Medical antihypertensive therapy plus observation, percutaneous evacuation of the perirenal hematoma, open drainage of the hematoma, and nephrectomy have all been used (Suffrin, 1975).

Some cases of the acute Page kidney with new-onset hypertension have spontaneously resolved. A hematoma may reabsorb, relieving the parenchymal compression without forming an adhesive fibrotic pseudocapsule. Treatment with medical antihypertensive therapy can control the blood pressure until the hematoma resolves. If the hematoma does not resolve, it may be drained percutaneously or surgically.

Renal Parenchymal Disease

Renin-mediated hypertension may be secondary to a variety of renal parenchymal diseases. The incidence of hypertension in patients with chronic pyelonephritis is approximately 5% to 10%. The mechanism of renin-mediated hypertension in such kidneys with segmental scars is ischemia of the relatively normal renal cortex in proximity to areas of interstitial fibrosis, within which are small vessels with intimal thickening. Other renal disorders that may cause hypertension include hydronephrosis, congenital hypoplasia or dysplasia, segmental hypoplasia (Ask-Upmark kidney), vesicoureteral reflux, renal cell carcinoma, benign cyst, Wilms tumor, radiation nephritis, or juxtaglomerular cell tumor.

Key Points: Management of Patients with Renal Artery Disease

- Medical management of renovascular hypertension is preferred in patients with mild hypertension or significant comorbidity.
- Medical therapy should aim to reduce overall risk of cardiovascular morbidity, not just lower blood pressure.
- Minimally invasive treatment by renal balloon angioplasty, with or without arterial stenting, has become the preferred method of treating patients with severe hypertension or ischemic nephropathy.
- Percutaneous angioplasty alone is usually successful for treating fibromuscular dysplasia; atherosclerotic disease generally requires arterial stenting in addition to angioplasty.
- Endovascular techniques have been successfully used to treat inflammatory diseases of the renal arteries, renal artery dissections, and renal artery aneurysm.
- Blood pressure results of revascularization (percutaneous or surgical) are significantly better in patients with fibromuscular disease due to the absence of intrinsic renal disease and less medical comorbidity.
- Selection of patients for endovascular or surgical revascularization should be carefully followed, to maximize chances of success and minimize patient morbidity.
- Surgical revascularization is currently employed in a minority of patients who have failed interventional treatment, or whose disease precludes interventional treatment.
- Surgical techniques that avoid operating on a badly diseased aorta (extra-anatomical bypass) can minimize patient morbidity, particularly when compared to combined aortic and renal revascularization.

chapter 40

Pathophysiology of Urinary Tract Obstruction

Iqbal Singh, MCh (Urology), DNB (Genitourinary Surgery), MS, DNB ● Jack W. Strandhoy, PhD ● Dean G. Assimos, MD

Prevalence of the Problem
Global Renal Functional Changes
Pathologic Changes of Obstruction
General Issues in Management of Patients
Selected Extrinsic Causes of Ureteral Obstruction

Obstruction of the urinary tract can occur during fetal development, childhood, or adulthood. The point of obstruction can be as proximal as the calyces and as distal as the urethral meatus. The cause of obstruction may be congenital or acquired and benign or malignant. The impact of the obstruction is influenced by the extent or degree of obstruction (partial or compete, unilateral or bilateral), its chronicity (acute or chronic), the baseline condition of the kidneys, the potential for recovery, and the presence of other mitigating factors such as urinary infection. These may ultimately lead to permanent renal damage, which may result in limiting the excretion of metabolic wastes and altering water and electrolyte balance.

Certain terms used in this chapter as descriptors of this process need to be defined from the outset. *Hydronephrosis* is the dilation of the renal pelvis or calyces. It may be associated with obstruction but may be present in the absence of obstruction. *Obstructive uropathy* refers to the functional or anatomic obstruction of urinary flow at any level of the urinary tract. *Obstructive nephropathy* is present when the obstruction causes functional or anatomic renal damage.

PREVALENCE OF THE PROBLEM

The prevalence of urinary tract obstruction is best estimated from autopsy series. In a series of 59,064 autopsies performed on individuals ranging from neonates to geriatric subjects, hydronephrosis was reported in 3.1% (Bell, 1950). There were no gender differences in this series until the age of 20 years. However, hydronephrosis was more prevalent in women in the 20- to 60-year interval. The latter was attributed to pregnancy and development of gynecologic malignancies. It was more prevalent in males after age 60 years, because of prostatic diseases. Hydronephrosis has been reported to be present in 2% to 2.5% of children subjected to autopsy (Campbell, 1970; Tan et al, 1994). It is somewhat more prevalent in boys, and the majority of cases were in subjects younger than 1 year. The aforementioned prevalences are most likely an underestimate of obstructive events, because temporary bouts of obstruction such as those induced by prior pregnancy or stone episodes were not captured.

There are no new data regarding the prevalence and incidence of obstructive uropathy. However, there are new data on ureteropelvic junction obstruction and ureterocele that may permit certain inferences. Based on the United States published and coded data on ureteropelvic junction obstruction generated by the Healthcare Cost and Utilization Project (HCUP) and Kids' Inpatient Database (KID), the number of inpatient hospitalizations for ureteropelvic junction have decreased from 1.1 per 100,000 in 1994 to 0.8 per 100,000 in 2000. Although this may be influenced by a shift to more outpatient procedures or observational management, it could also be due to a decreasing incidence of this problem (Schulam et al, 2007). However, this has not been demonstrated for those afflicted with ureterocele where the rates have been stable over this interval (Pohl et al, 2007).

The pathophysiology of obstructive nephropathy is discussed in detail in the beginning of this chapter to provide a platform for understanding the clinical ramifications of this process, some of which are detailed in later sections that focus on unique causes of this problem. The mechanisms of obstructive nephropathy are unveiled at genetic, molecular, cellular, glomerular, renal tubular, whole kidney, and systemic levels. The impact of obstruction on the fetal and developing kidney is not emphasized because this is covered in other sections of this book. A list of possible causes of obstructive nephropathy is provided in Table 40–1.

GLOBAL RENAL FUNCTIONAL CHANGES

Glomerular Filtration, Renal Blood Flow, Collecting System Pressure

There are many functional changes in the kidney associated with obstructive nephropathy that affect renal hemodynamic variables and glomerular filtration. These are influenced by the extent and severity of obstruction, whether the obstruction is unilateral or bilateral, and whether the obstruction currently persists or has been relieved. A brief discussion of the determinants of glomerular filtration is in order to understand the interrelationships between changes in renal hemodynamics and alterations in the glomerular filtration rate (GFR) during and after obstruction. Factors influencing GFR are expressed in the following equation:

$$GFR = K_f(P_{GC} - P_T - \pi_{GC})$$

Table 40–1.
Possible Causes of Obstructive Nephropathy

Renal

	Neurogenic bladder
	Urethral stricture

K_f is a glomerular ultrafiltration coefficient related to the surface area and permeability of the capillary membrane. P_{GC} is the glomerular capillary pressure, which is influenced by renal plasma flow and the resistances of the afferent and efferent arterioles. The hydraulic pressure driving fluid into Bowman space is resisted by the hydraulic pressure of fluid in the tubule (P_T), and also the increasing oncotic pressure (π) of the proteins remaining at higher concentrations in the late glomerular capillary and efferent arteriolar blood. Although filtered fluid is not completely free of small proteins, for practical purposes, its oncotic pressure is negligible. The net pressure determining glomerular filtration is referred to as the ultrafiltration pressure (P_{UF}) and is derived from ($P_{GC} - P_T - \pi_{GC}$). P_{GC} is also influenced by renal plasma flow (RPF). RPF depends upon the renal perfusion pressure and intrarenal resistance to flow, the latter primarily mediated by the resistances in the afferent and efferent arterioles. The aforementioned relationships are depicted in the following equation:

$$\text{RPF} = \frac{\text{aortic pressure} - \text{renal venous pressure}}{\text{renal vascular resistance}}$$

Thus constriction of the afferent or efferent arteriole or both would reduce RPF. Constriction of the afferent arteriole results in a decrease of P_{GC} and GFR, whereas an increase in efferent arteriolar resistance increases P_{GC}. Whole kidney GFR depends upon factors regulating perfusion of each glomerulus and also upon the percentage of glomeruli actually filtering. For each glomerulus, the single-nephron glomerular filtration rate (SNGFR) is determined by the previously mentioned GFR equation. Obstruction can transiently or permanently alter GFR and some or all of the determinants of GFR.

The results of animal experiments are used here to profile the hemodynamic, renal, and systemic responses of renal obstruction. The limitations of animal models including the potential for a species-specific response must be taken into consideration when making analogies or comparisons with humans.

Hemodynamic Changes with Unilateral Ureteral Occlusion

There are differences between unilateral ureteral obstruction (UUO) and bilateral obstruction (BUO) that have been characterized in animal models. These include hemodynamic patterns and other factors that influence GFR. Renal blood flow (RBF) was assessed in the classical studies characterizing hemodynamic differences. In some, RBF was measured directly with various types of flow probes, and in others it was determined indirectly by measuring RPF using secretory markers and indexing this to the hematocrit. A number of vasoactive substances are thought to play a role in the changes in RBF and GFR occurring with both models of obstruction. The timing of changes in intrarenal concentrations of vasoconstrictors and vasodilators during the course of obstruction and the release of obstruction is poorly understood. The varying hemodynamic patterns during the time course of obstruction may be due to a combination of vasoactive hormones synthesized and released at different rates, physical damage to glomerular and tubular units, and extrarenal compensatory mechanisms.

Animal experiments have demonstrated a triphasic pattern of RBF and ureteral pressure changes in UUO that differs from BUO or unilateral obstruction of a solitary kidney (Fig. 40–1). With UUO, RBF increases during the first 1 to 2 hours and is accompanied by a high P_T and collecting system pressure because of the obstruction. In a second phase lasting 3 to 4 hours, these pressure parameters remain elevated but RBF begins to decline. A third phase beginning about 5 hours after obstruction is characterized by a further decline in RBF, now paralleled by a decrease in P_T and collecting system pressure. These changes are explained by physical alterations in flow dynamics within the

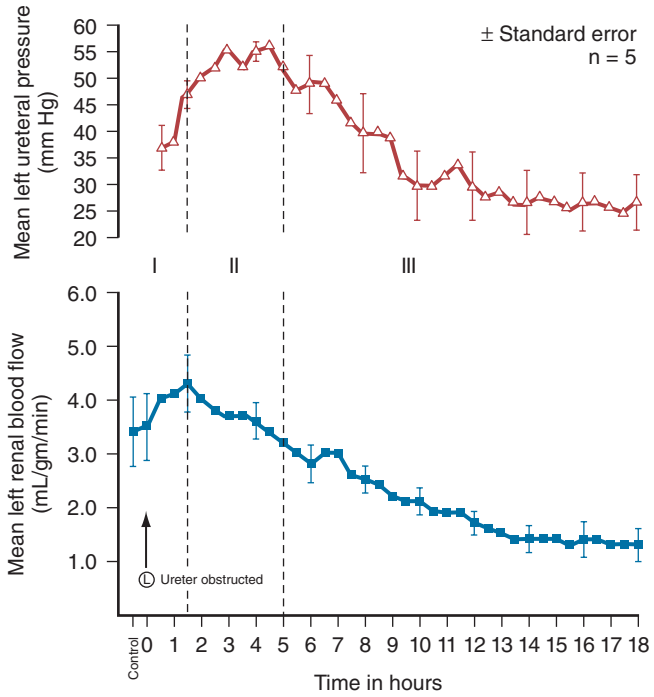

Figure 40–1. Triphasic relationship between ipsilateral renal blood flow and left ureteral pressure during 18 hours of left-sided occlusion. The three phases are designated by roman numerals and separated by vertical dashed lines. In phase I, renal blood flow and ureteral pressure rise together. In phase II, the left renal blood flow begins to decline and ureteral pressure remains elevated and, in fact, continues to rise. In phase III, the left renal blood flow and ureteral pressure decline together. (From Moody TE, Vaughn ED Jr, Gillenwater JY. Relationship between renal blood flow and ureteral pressure during 18 hours of total unilateral ureteral occlusion. Implications for changing sites of increased renal resistance. Invest Urol 1975;13:246–51.)

kidney and are modified by changes in the biochemical and hormonal milieu regulating renal resistance.

In the first phase of UUO, the increase in P_T would logically be expected to reduce GFR greatly. However, this is counterbalanced by an increase in RBF related to afferent arteriolar vasodilation (Vaughan et al, 1970), which limits the fall in GFR because P_{GC} rises. This hyperemic response has been attributed to stimulation of the tubuloglomerular feedback mechanism that relaxes the afferent arterioles as a consequence of decreased sodium delivery to the macula densa (Wright and Briggs, 1979), changes in interstitial pressure within the kidney (Vaughan et al, 1971; Francisco et al, 1980), or the release of vasodilators such as prostanoids like prostaglandin E_2 (PGE_2) (Allen et al, 1978). There are various lines of evidence supporting the role of prostaglandin involvement. Frøkiær and Sørensen (1995) demonstrated an increase in PGE_2 excretion in the urine from the contralateral kidney after UUO. In addition, studies have shown that the increase in PGE_2 and the vasodilation of the obstructed kidney could be blocked by indomethacin, a prostaglandin synthesis inhibitor (Allen et al, 1978; Blackshear and Wathen, 1978; Gaudio et al, 1980). Nitric oxide (NO) may also contribute to the early renal vasodilation in UUO. The kidney contains nitric oxide synthases (NOS) that are both constitutive (endothelial and neuronal isoforms) and inducible (iNOS). In obstructed kidneys from rabbits and rodents, iNOS increases (Salvemini et al, 1994; Miyajima et al, 2001). Furthermore, Lanzone and colleagues (1995) showed that administration of the NOS inhibitor N^G-monomethyl-L-arginine (L-NMMA) before UUO attenuated the early rise in RBF, and that the renal vasodilation returned when L-NMMA was discontinued. **Thus it is likely that both PGE_2 and NO contribute to the net renal vasodilation that occurs early following UUO.**

After this initial phase of several hours, GFR and RBF progressively decline in UUO (Jaenike, 1972; Harris and Yarger, 1974; Dal Canton et al, 1980). In contrast to the early rise in P_T in the initial phases of UUO, this parameter and RBF both decline 12 to 24 hours after obstruction. This is best explained by an increase in afferent arteriolar resistance (R_{aff}) that occurs. At this time, there are also shifts in regional blood flow in the kidney, with large portions of the cortical vascular bed not perfused or underperfused (Harris and Yarger, 1974; Gaudio et al, 1980). A shift in RBF from the outer cortex to more juxtamedullary regions was reported by Yarger and Griffith (1974) in dogs with UUO. **Thus reduced whole kidney GFR at this stage of obstruction is due not only to reduced perfusion of individual glomeruli, related to afferent vasoconstriction and reduced P_{GC}, but also to global reduction in filtration related to no perfusion or underperfusion of many glomeruli** (Arendshorst et al, 1974).

Vasoconstrictors appear to play a role in the reduction in RBF after UUO. There is evidence that the renin-angiotensin system is activated during UUO, that is, during the first phase of UUO renal vein renin levels increase (Moody et al, 1975; Yarger et al, 1980) even though there is a net renal vasodilation at this time**. Infusion of the angiotensin-converting enzyme (ACE) inhibitor captopril attenuates the declines in RBF and GFR in UUO, suggesting that angiotensin II is an important mediator of the preglomerular vasoconstriction occurring during the second and third phases of UUO** (Ichikawa et al, 1985).

Other vasoconstrictors also appear to be involved in the reduction of RBF with UUO. Thromboxane A_2 (TXA_2) is also thought to be an influential postobstructive vasoconstrictor that contributes to the continued reduction in GFR and RBF. Administration of TXA_2 synthesis inhibitors to the obstructed kidney limits the reduction in RBF and GFR (Klotman et al, 1986; Loo et al, 1987; Purkerson and Klahr, 1989). TXA_2 may be generated in the kidney itself, perhaps in glomeruli (Yanagisawa et al, 1990), but synthesis from macrophages migrating to the kidney during obstruction is another potential source of this vasoconstrictor (Schreiner et al, 1988; Harris et al, 1989).

Endothelin is another endogenous vasoconstrictor thought to participate in these events, although perhaps later in the established phase of UUO and after release of the obstruction. Administration of endothelin antagonists limits the reduction of RBF and GFR in rats during and after release of UUO (Bhangdia et al, 1998; Syed et al, 1998; Colon et al, 2000). Furthermore, endothelin excretion is increased in the targeted kidney after release of UUO in swine but not in the contralateral renal unit (Kelleher et al, 1992).

The kidney's response to the release of UUO depends on the duration and extent of obstruction and is also species specific. Many models of UUO use complete obstruction of the ureter for 24 hours before release. After release of 24-hour UUO, the GFR is initially 50% of normal in dogs and less than 25% of normal in rats, accompanied by greatly reduced RBF. There are also regional differences within the kidney. Harris and Yarger (1974) showed a

marked decrease in perfusion of the superficial cortex accompanied by an increase in juxtamedullary glomerular perfusion after release of 24 hours of UUO in rats. Tubuloglomerular feedback may play a role in these responses (Tanner, 1985). Some of the mediators of the hemodynamic changes in the kidney following release of the obstruction may be different from those involved in the earlier phases.

Hemodynamic Changes with Bilateral Ureteral Occlusion

The changes with BUO or obstruction of a solitary kidney are different. **In contrast to the early robust renal vasodilation with UUO, there is a modest increase in RBF with BUO that lasts approximately 90 minutes, followed by a prolonged and profound decrease in RBF that is greater than found with UUO** (Gulmi et al, 1995). Reyes and Klahr (1992) found that an NO synthesis antagonist caused a further decline in RBF and GFR compared with control values, suggesting that NO helps maintain renal hemodynamics in early BUO. Other potential vasodilators, such as platelet-activating factor (PAF), have been postulated to contribute to renal hemodynamic changes with BUO. Reyes and Klahr (1991) showed, in rats, that when vasoconstrictors such as TXA_2 were blocked, endogenous or exogenous intrarenal PAF-mediated vasodilation contributed to the preservation of RBF and GFR. The earlier and more profound decrease in RBF with BUO may be contributed to by increased renal nerve stimulation that initiates vasoconstriction related to increased renorenal reflex activity (Francisco et al, 1980; Ma et al, 2002). Endothelin may also contribute to these responses in BUO. The administration of an endothelin antibody to rats with BUO was reported to attenuate the decreases in GFR and RPF (Reyes and Klahr, 1992). Angiotensin II and TXA_2 are also probably involved in the changes occurring with BUO. The administration of inhibitors of either of these vasoconstrictors to rats, prior to BUO, resulted in improved postobstructive GFR and RPF compared with their administration at the time of release of obstruction (Purkerson and Klahr, 1989).

The intrarenal distribution of blood flow is quite different with BUO than with models of UUO. Jaenike (1972) used microspheres to show that 55% of the RBF perfused the cortical nephrons, while the innermost zones received only 14% of the flow in rats after BUO. Similarly, Solez and associates (1976) showed a 92% decrease in inner medullary plasma flow with 18 hours of BUO in rats**. Thus the shift seen with UUO of blood flow from outer to inner cortex is the opposite of that with BUO.**

Ureteral pressure is higher with BUO than with UUO. Although in both cases ureteral and tubular pressures are increased for the first 4 to 5 hours, the ureteral pressure remains elevated for at least 24 hours with BUO, whereas it begins to decline and approaches preocclusion pressures by 24 hours with UUO. The prolonged elevation in intratubular pressure contributes to the profound decrease in SNGFR and whole kidney GFR. Micropuncture studies (Yarger et al, 1972; Dal Canton et al, 1980) in which intratubular pressure is measured directly have demonstrated that it remains elevated in rats after 24 hours of BUO in comparison with pressure normalization in animals after 24 hours of UUO. Ureteral pressure remains high because BUO passes through a phase of preglomerular vasodilation and then a prolonged postglomerular vasoconstriction. This explains the persistent elevation in ureteral pressure in spite of a decrease in RBF and increase in renal resistance. In contrast, in UUO the initial preglomerular dilation and short-lived postglomerular vasoconstriction are followed by a more prolonged preglomerular vasoconstriction that tempers elevations in P_{GC} and hence in P_T. **This difference between the two pathophysiologic conditions has been hypothesized to be due to an accumulation of vasoactive substances in BUO that could contribute to preglomerular vasodilation and postglomerular vasoconstriction. Such substances would not accumulate in UUO because they would be excreted by the contralateral kidney. Atrial natriuretic peptide (ANP) appears to be one of these substances** (Purkerson et al, 1989). With excretory ability abrogated, BUO increases intravascular volume, as evidenced by an increase in pulmonary capillary wedge pressure and body weight, which serves as the stimulus for secretion of ANP. ANP increases afferent arteriolar dilation and efferent arteriolar vasoconstriction, thus increasing P_{GC}. It also decreases the sensitivity of tubuloglomerular feedback, inhibits release of renin, and increases K_f (Fried et al, 1987; Brenner et al, 1990; Cogan, 1990). In addition, changes within the renal unit may contribute to elevated pelvic pressure. In both rats and humans, ureteral obstruction increases COX-2 in the proximal dilated ureter but not in the distal nondilated ureter. When the obstruction was released, the urinary concentration of PGE_2 was elevated. Furthermore, a COX-2 selective inhibitor reduced pelvic pressure. Thus intrarenal PGE_2 acting on ureteral smooth muscle may contribute directly to increased pelvic pressure after obstruction (Nørregaard et al, 2006). Glomerular filtration and RBF remain depressed after release of BUO. This is due to persistent vasoconstriction of the afferent arteriole (Jaenike, 1972; Moody et al, 1977). The decrease in RBF in the renal medulla remains more prominent than in the cortex (Solez et al, 1976). Tubuloglomerular feedback does not appear to contribute to this response as it does with UUO (Tanner, 1985). Urine flow and sodium excretion are increased after release of BUO. ANP appears to play a prominent role in this response based on its natriuretic properties and those previously reviewed. It may also have a protective effect. Ryndin and associates (2005) reported that the administration of ANP or phosphoramidon, an inhibitor of ANP degradation, to rats with BUO resulted in improved GFR and a more brisk diuresis and natriuresis after release of obstruction.

In summary, both UUO and BUO involve increases in renal vascular resistances and increases in ureteral pressures. However, the timing and regulation of these changes differ (Fig. 40–2). With UUO, early renal vasodilation primarily mediated by prostaglandins and NO is followed by prolonged vasoconstriction and normalization of intratubular-ureteral pressure as the contralateral kidney contributes to fluid balance. With BUO, little early vasodilation is seen, and vasoconstriction is more profound. When the obstruction is released, the postobstructive diuresis is much greater with BUO because volume expansion, urea and other osmolytes, and secreted ANP contribute to a profound diuresis and natriuresis.

Partial Ureteral Occlusion

Although most models of urinary tract obstruction study complete obstruction over a fixed time interval, such as 24 hours, many clinical conditions involve partial obstruction over varying times. Partial obstruction models often involve perinatal obstruction where renal growth and differentiation may be affected, as well as hemodynamics and excretion. In many cases, the changes in renal hemodynamics and in tubular function are similar to those induced by more acute, complete models of obstruction but develop more slowly. In other cases, such as perinatal models of

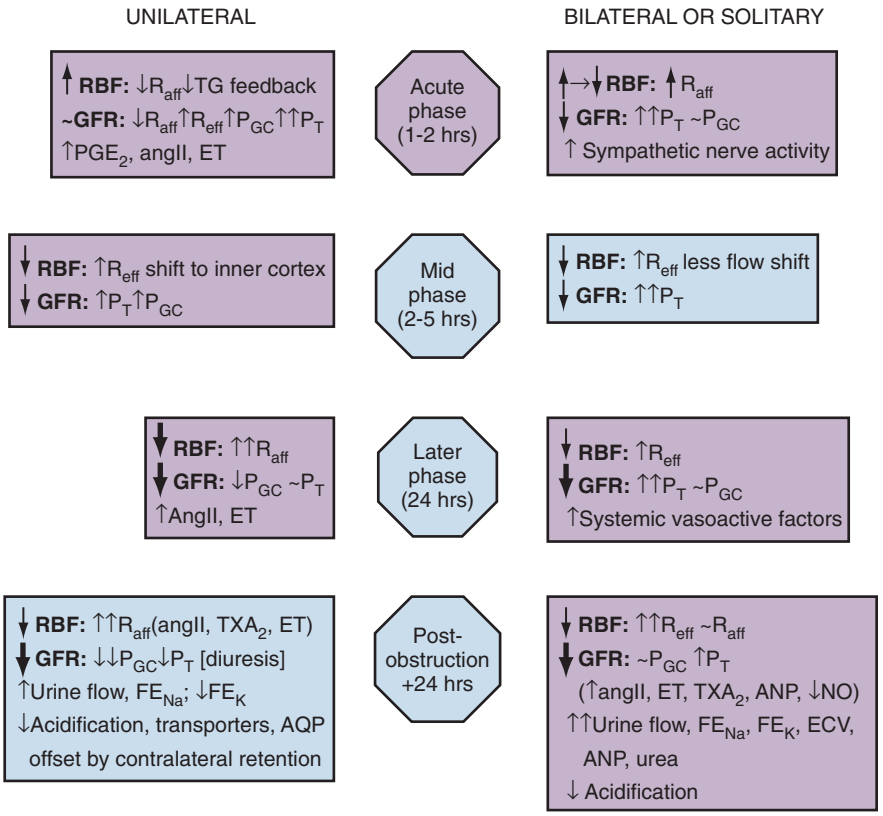

Figure 40–2. Summary of the functional changes during and following ureteral obstruction. obstruction either before or shortly after birth, an animal such as a rat is still in a period of nephrogenesis. **Consequently, formation of glomeruli and tubules may be compromised so that irreversible changes occur without total loss of kidney function.**

Recovery of renal function in adult animals with partial obstruction has been studied as a potential guideline for clinical treatment. Leahy and coworkers (1989) studied dogs in which partial UUO with stents was studied for up to 60 days. Reversibility of renal function was estimated by creatinine clearance. Renal function became normal in dogs partially obstructed for 14 days. Animals partially obstructed for 28 days recovered 31% of function, and those partially obstructed for 60 days recovered only 8% of function. Casts of the microvasculature showed arteriolar constriction, supporting the concept that postobstructive renal dysfunction is influenced by vascular responses.

Much less is known about the roles of vasoactive or inflammatory mediators in the partial ureteral obstruction model. As with acute occlusive models, administration of indomethacin or meclofenamate, both prostaglandin synthetase inhibitors, decreases GFR and increases arteriolar resistance (Ichikawa and Brenner, 1979) so that changes in eicosanoids are implicated in partial obstruction responses. Several investigators have shown that the renin-angiotensin-aldosterone axis is activated with partial obstruction, including studies in the fetus. Gobet and colleagues (1999) studied fetal sheep in utero and showed that partial obstruction of the bladder outlet increased renin messenger RNA (mRNA) after 2 weeks and increased the expression of renal AT2 receptors as well as the mRNA for transforming growth factor beta (TGF-β), a mediator of fibrosis.

One could hypothesize that changes in angiotensin II may be responsible for much of the hemodynamic, fibrotic, and apoptotic changes in neonatal animals with partial obstruction, as has been shown in more acute models. Beharrie and coworkers (2004) examined weanling male rats that had been subjected to a partial UUO. The partial obstruction led to proteinuria, hyperuricemia, and increased solute excretion primarily from the unaffected contralateral kidney. A parallel group of rats treated with the ACE inhibitor enalapril was protected from these changes. This suggests that angiotensin is involved with functional tubular changes as well. Eskild-Jensen and colleagues (2002) examined partial UUO for up to 24 weeks in young, postnatal pigs. The number of glomeruli was 28% less in the obstructed kidney, yet function was just transiently reduced by the occlusion. **Thus partial neonatal obstruction can impair nephrogenesis independently of renal functional decline, and these changes may depend upon species, stage of renal development, or degree of occlusion.** More work is needed to define the variables.

Various methods have been used to create partial obstruction. The models for preparing partial ureteral occlusions fall into three main categories. Intraluminal stents or catheters of varying sizes have been placed in the ureters of sheep (Abu-Zidan et al, 1999) and in dogs (Ryan and Fitzpatrick, 1987; Leahy et al, 1989) to restrict flow. In rats, or in growing animals, many investigators have used the technique of Ulm and Miller (1962), which involves splitting the psoas muscle longitudinally to form a groove into which the ureter is placed. This method has a potential advantage of increased constriction in proportion to the growth of the animal. Beharrie and colleagues (2004) used such a technique in young male weanling rats. A major problem with studies involving partial obstruction is the inability to determine reproducibly and accurately the degree of obstruction induced with these techniques. Thornhill and associates (2005) devised a method in neonatal rat pups of ligating a ureter along with a wire of a calibrated

diameter that was then removed to make a partial and graded constriction of one ureter. When ureteral diameter was reduced by 70% to 75%, renal growth and number of glomeruli were reduced and fibrosis and pelvic dilation were proportionately increased. GFR was reduced by 80% after 28 days of partial UUO. Such models may offer new opportunities to model the clinical condition reproducibly.

Egress of Urine from the Kidney

Although the normal flow of urine from the kidney through the urinary tract is compromised with obstruction, urine may still egress from the kidney. An example of this is extravasation at the calyceal fornix (pyelosinus) that occurs with acute obstruction, typically ureteral stones (Stenberg et al, 1988). Extravasation of urine into the venous (pyelovenous) and lymphatic system (pyelolymphatic) may also occur in this setting. In chronic obstruction, fluid is thought to exit into the renal venous system.

Effects of Obstruction on Tubular Function

Obstruction of one or both kidneys can have profound effects on sodium, potassium, and hydrogen excretion and mechanisms of urinary concentration and dilution. In the case of UUO, relatively normal function of the nonobstructed kidney partially offsets the reduced ability of the postobstructive kidney to reabsorb solutes and water. **Postobstructive diuresis, something that is commonly encountered after reversal of BUO, occurs uncommonly after release of UUO, probably as a consequence of the contralateral renal unit's functional capacities that are enhanced by an upregulation of ion transporters (Li et al, 2007).** The eventual correction of abnormal renal excretory function depends upon the degree and duration of obstruction.

Changes in tubule function after correction of UUO related to ureteropelvic junction or ureteral obstruction were characterized in 10 patients by Gillenwater and colleagues (1975). The mean period of obstruction in these cases was 12 months, and the range was from days to years. Functions of the normal and obstructed kidney were evaluated 1 week after relief of the obstruction. The GFR in the obstructed kidney was significantly less than that in the non-obstructed kidney (24 vs. 60 mL/min), and the urine osmolality and osmolar clearance were all significantly less in the postobstructed kidney. The similar osmolar clearances (volume of urine required to excrete urinary solute isosmotically) relative to GFR of the previously obstructed and unobstructed kidneys indicate that there is a true concentrating defect in the obstructed kidneys 1 week after relief of obstruction.

Urinary Concentrating Ability

Normal urine concentrating ability requires a hypertonic medullary interstitial gradient because of active salt reabsorption from the thick ascending limb of Henle, urea back flux from the inner medullary collecting duct, and water permeability of the collecting duct mediated by vasopressin and aquaporin water channels. Obstructive nephropathy can disrupt some or all of these mechanisms and lead to deficits in urinary concentration. A brief review of the normal concentrating mechanisms is provided to facilitate understanding the effects of obstruction.

In normal physiology, arginine vasopressin (AVP) is secreted into the bloodstream from the posterior pituitary gland in response to increased serum osmolality or a reduction in effective circulating volume. AVP binds to the V2 vasopressin receptor located on the basolateral surfaces of the collecting duct cells. This promotes G protein signaling, resulting in generation of cyclic adenosine monophosphate (cAMP). Generation of cAMP in turn activates protein kinase A, which stimulates the fusion of cytoplasmic vesicles containing aquaporin 2 (AQP2) with the apical membranes of the collecting duct cells. The fusion causes the normally watertight membrane to become water permeable. This promotes transcellular absorption of water through the AQP2 channels, which is transported through aquaporin 3 (AQP3) and aquaporin 4 (AQP4) channels located in the basolateral cell membrane into the interstitium. This sequence of events is driven by the osmotic gradient of sodium (Knoers, 2005). Another aquaporin, aquaporin 1 (AQP1), is abundant in renal proximal tubules, the thin descending limb of Henle, and the descending vasa recta in the kidney. It promotes urinary concentration through the countercurrent multiplier by facilitating water transport from the descending limb of Henle into the interstitium (King et al, 2001).

The onset of concentration defects may develop soon after obstruction. Jaenike and Bray (1960) demonstrated a concentrating defect in the unilaterally obstructed kidney after only 6 minutes of ureteral obstruction. Development of vasopressin resistance has been hypothesized as a mechanism of this occurrence. However, various studies have demonstrated conflicting results concerning whether vasopressin resistance is present. Vascular changes may play a role. Even after only 18 hours of UUO, Solez and colleagues (1976) found a decrease in inner medullary plasma flow that increased when the occlusion was released. Necrosis of both the inner and outer medullae was present, indicating that ischemia may contribute to the development of a concentrating defect.

Evidence from Li and coworkers (2001) demonstrated that the polyuria following the release of BUO correlates with a decreased expression of the aquaporin water channels AQP1, AQP2, and AQP3 in rats. Release of obstruction resulted in polyuria that gradually decreased over a 30-day period, even though urinary concentrating capacity remained significantly impaired. Expression of AQP2 and AQP3 became normal by 30 days after release, but the expression of AQP1 remained decreased.

Jensen and coworkers (2006) examined changes in water channels after bilateral ureteral obstruction in rats. As expected, postobstructive polyuria with reduced urine osmolality was accompanied by decreased expressions of AQP1, AQP2, and AQP3 compared with control rats. The AT1 antagonist candesartan attenuated reductions in GFR, urine output, and AQP suppression, as well as COX-2 induction in the inner medulla. These findings suggest that angiotensin II influences, directly or indirectly, the postobstructive diuresis of BUO.

Thus dysregulation of aquaporin water channels in the proximal tubule, thin descending loop, and collecting duct may contribute to the long-term polyuria and impaired concentrating capacity caused by obstructive nephropathy. Increases in angiotensin II may be a mediator of these changes.

Sodium Transport

A decrease in sodium transport in the nephron appears to play an additional prominent role in the decreased ability of the postobstructed kidney to concentrate urine. When UUO is released after an occlusion period of 24 hours, total urine excretion is normal

to modestly increased despite increased fractional excretion of sodium (FE_{Na}) in the previously obstructed kidney. This is attributed to the contralateral kidney compensating for the sodium losses of its mate. However, with BUO, sodium and water excretions may be quite robust after release of obstruction. The FE_{Na} may be increased to as much as 20 times normal in this setting (Zeidel and Pirtskhalaishvili, 2004). **Although ANP appears to play a role in sodium diuresis after release of BUO, it is unlikely to affect sodium transport defects associated with UUO.** The latter is most likely due to selective cell membrane changes in the nephron that reduce the number and effectiveness of sodium transporters. Such changes may also occur with BUO.

In spite of differential quantitative responses between UUO and BUO after release of the obstruction, the reabsorption defects in segmental nephron Na^+ transport are similar. Micropuncture studies of kidneys from animals have been undertaken to assess these responses. These studies demonstrate normal to modestly enhanced isotonic volume flux (J_v) in superficial proximal convoluted tubules after release of UUO or BUO. On the other hand, sodium delivery to the loop of Henle in juxtamedullary nephrons, and to the first accessible portion of the inner medullary collecting duct, is substantially increased after release of both UUO and BUO, indicative of reduced sodium transport. Sonnenberg and Wilson (1976) even found evidence for net influx of sodium throughout the medullary collecting duct, which further contributed to an increased FE_{Na}. However, this was more prominent with BUO in their rat model.

Studies in isolated perfused nephron segments have also provided knowledge about the impact of obstruction at the level of the nephron. They have shown normal isotonic reabsorption in the superficial proximal convoluted tubules from animals with either UUO or BUO, whereas J_v in proximal straight tubules from juxtamedullary nephrons was demonstrated to be impaired (Hanley and Davidson, 1982). Similarly, chloride reabsorption and transport-dependent oxygen consumption (QO_2) from the medullary thick ascending limb of the Henle loop (MTAL) were severely impaired (Hanley and Davidson, 1982; Hwang et al, 1993b).

Cell suspensions from nephron segments have been used to assess the effects of obstruction at a cellular level. Active transport of Na^+ across cell membranes requires apical entry through selective Na^+ transporters or channels and basolateral exit driven by sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase). Furthermore, adequate adenosine triphosphate (ATP) must be generated to drive these primary transport steps. Hwang and associates showed that the amount and activity of the apical Na^+,K^+,$2Cl^-$ cotransporter and bumetanide binding sites were reduced in cells isolated from the MTAL derived from obstructed rabbit kidneys. Basolateral transport is also affected in that ouabain-sensitive oxygen consumption, an index of Na^+,K^+-ATPase activity, has been shown to be reduced in cell suspensions from obstructed kidneys (Hwang et al, 1993a). A marked decrease in amiloride-sensitive oxygen consumption and Na^+ entry in isolated cells from the inner medullary collecting ducts of obstructed rabbit kidneys reflects reduced activity of the apical Na channel (ENaC). In addition, ouabain-sensitive transport as measured by oxygen consumption and ATPase activity was shown to be reduced in cells from this portion of the nephron harvested from obstructed kidneys (Hwang et al, 1993a). Because cell suspension studies indicate that ATP generation is not the rate-limiting step underlying sodium transport dysfunction in this setting, the evidence points to downregulation of sodium transporters. This may be due to translational factors (reduction in mRNA for transporter synthesis) or post-translational processing of receptor proteins (Hwang et al, 1993a).

The signals responsible for downregulation of transporter activity with obstruction have not been clearly defined, but a number have been hypothesized. Stasis of tubular fluid flow may be one of the signals. When urine flow is obstructed, upstream Na^+ delivery to apical cell membranes slows so that the transmembrane gradient is reduced. This could then serve as the signal for the downregulation of transporter activity or expression resulting in reduced active Na^+ transport across the basolateral cell membrane (Zeidel, 1993). Several studies indicate that this is a feasible mechanism. For example, ouabain-sensitive Na^+,K^+-ATPase activity is reduced in MTAL and collecting duct cells when mineralocorticoid activity is controlled and chronic furosemide or amiloride is given to reduce Na^+ entry into tubule cells (Petty et al, 1981; Grossman and Hebert, 1988). Additional studies have explored this concept in established cell lines. When A6 cells, an established line of collecting duct cells, are grown on a permeable substrate, Na^+ influx across the apical membrane through the ENaC Na^+ channel occurs. When Na^+ entry was blocked, this induced a decreased expression of β-subunit of the epithelial sodium channel in the apical membrane (Rokaw et al, 1996). Ischemia has also been proposed as a signal in this setting, where ischemia that accompanies the reduced perfusion of the kidney with obstruction can also be a mediator of reduced transporter expression. The reduction in major renal sodium transporters reported with ischemic models of renal failure supports this concept (Kwon et al, 2000). Other proposed downstream signals include changes in renal interstitial pressure and local generation of natriuretic substances. **Thus substrate delivery may be a regulatory step in the expression of sodium and possibly other transporters.**

Intrarenal and extrarenal substances and hormones can also modulate sodium transport. The milieu of influential hormones may be substantially different between UUO and BUO. A number of investigators have shown that obstruction markedly increases the endogenous production of PGE_2 in the renal medulla. Furthermore, supraphysiologic concentrations of PGE_2 are well known to produce natriuresis (Strandhoy et al, 1974), and studies in isolated tubules and cell suspensions show that PGE_2 inhibits Na reabsorption in the MTAL and throughout the collecting duct (CD). One mechanism of this natriuretic response may be that PGE_2 reduces the amount of Na^+,K^+-ATPase at the basolateral membrane (Marver and Bernabe, 1992). PGE_2 can also inhibit the tubular effects of vasopressin (Zook and Strandhoy, 1980), thereby contributing to the free water loss from the post-UUO kidney. The influence of other substances and hormones in the postobstructed UUO kidney is counterbalanced or minimized by the contralateral renal unit.

Li and coworkers (2007) found that BUO caused a persistent decrease in the alpha and beta subunits of the epithelial Na channel (ENaC) three days after relief of obstruction. Similar changes in ENaC occurred following UUO but only in the obstructed kidney. The contralateral control kidney showed no changes in ENaC expression. Furthermore, Jensen and coworkers (2006) showed in rats that at 2 days following BUO there was reduced expressions of the Na phosphate cotransporter (NaPi-2), the loop Na^+,K,$2Cl^-$ cotransporter (NKCC2) and the Na^+/H^+ exchanger (NHE3). These decreases in Na transporters were consistent with the postobstructive natriuresis. Candesartan partially reduced these changes and attenuated the natriuresis.

Extracellular fluid volume may be greatly expanded with BUO. When the BUO is relieved, both intrarenal and extrarenal factors greatly enhance salt and water excretion so that a postobstructive diuresis is often seen. The normal physiologic consequences

of extracellular fluid volume expansion ensue. These include a downregulation of sympathetic tone and the secretion of aldosterone and manifestation of the effects of ANP and probably other natriuretic factors. Levels of ANP are significantly elevated following BUO but not UUO (Purkerson and Klahr, 1989). The direct and indirect consequences of increased ANP levels include partial support of glomerular filtration, reduction of renin secretion and effects of angiotensin on transport, reduced aldosterone secretion, and direct inhibition of Na transport in the collecting duct (Brenner et al, 1990). Furthermore, BUO results in the accumulation of osmotic substances such as urea that can contribute to salt and water loss when the obstruction is relieved (Harris and Yarger, 1975, 1977). **The FE_{Na} following relief of BUO is typically greater than that after UUO because BUO causes retention of Na, water, urea nitrogen, and other osmolar substances and increased production of ANP, all of which stimulate a profound natriuresis. Although Na transporters are similarly downregulated in the affected kidney in UUO, the contralateral kidney adequately compensates to maintain Na balance.**

Potassium Transport

Obstruction has a complex impact on renal potassium handling, depending upon the type of obstruction. Harris and Yarger (1975) reported that there is a decrease in K^+ excretion, in proportion to the decrease in GFR, after release of a 24-hour period of UUO. This may be partially due to reduced delivery of Na^+ to the distal nephron and a low volume flow rate that would minimize the transmembrane gradient for K^+ secretion. Other investigations indicate that there is also an intrinsic defect in K^+ secretion after relief of UUO (Thirakomen et al, 1976). In contrast, K^+ excretion increases in parallel with Na^+ excretion with the relief of BUO. Micropuncture studies in rats showed that proximal reabsorption of K^+ remains unchanged, whereas secretion in the collecting duct is increased following release of BUO. This may be due to the massive increases in Na^+ and water delivery to the collecting duct acting as stimuli to secretion and also to the presence of high levels of ANP that can stimulate K^+ secretion in the distal nephron (Sonnenberg and Wilson, 1976).

Hydrogen Ion Transport and Urinary Acidification

Obstruction causes a deficit in urinary acidification that has been demonstrated in human subjects as well as animal models. The cumulative evidence indicates that the major acidification defect is in the distal nephron. Release of obstruction does not result in increased bicarbonate excretion, indicating that bicarbonate reclamation in the proximal tubule remains intact. In contrast, urinary pH does not decrease after an acid load, which is indicative of a distal nephron acidification defect, most likely related to defective H^+ transport in the collecting duct. A number of causes for the lack of acidification have been proposed, including defects in H^+-ATPase or H^+,K^+-ATPase, Cl^-/HCO_3^- exchange, a back leak of protons into the renal interstitium, or failure to generate a satisfactory transluminal electrical gradient. Obstruction has been demonstrated to decrease the expression of H^+-ATPase in the apical membrane of the intercalated cells of the collecting duct. However, the extent of this apical transporter decrease was too small to explain the significant acidification defects that develop. Therefore other mechanisms are also likely to play a role in the development of this acidification defect (Purcell et al, 1991). Valles and Manucha (2000) showed that the decrease in H^+-ATPase with UUO depends upon an increase in iNOS, which, in turn, appears to be regulated by angiotensin II. Thus recovery of H^+-ATPase activity in the inner medullary collecting duct of obstructed kidneys by losartan treatment may be related to a decrease in angiotensin-stimulated iNOS activity.

Wang and colleagues (2008b) showed that the urinary acidification defect and metabolic acidosis after release of BUO correlated with reduced expression of the Na^+/H^+ exchanger (NHE3) in the cortex, reduced electrogenic Na^+/HCO_3^- cotransporter (NBC1), the electroneutral Na^+/HCO_3^- cotransporter (NBCn1) and the anion exchanger, pendrin. These findings support alterations in both proton secretion and bicarbonate/anion transport in the acid-base defects found after the release of obstruction.

In the proximal tubule, glutamine uptake and oxidation and ammonia generation are diminished after release of obstruction. This has an impact on acid elimination in that a greater proportion of H^+ is buffered as titratable acid. Because phosphate excretion may be compromised, and binding of protons to phosphate has a limited capacity, the net result may be a lower urinary pH related to unbuffered protons, in spite of a net decrease in total H^+ secretion.

Effects of Obstruction on Anion and Other Cation Transport

The effects on phosphate reabsorption after the release of obstruction vary depending upon whether it was bilateral or unilateral. When BUO is released, accumulated phosphate is rapidly excreted in proportion to sodium (Beck, 1979). Conversely, a decrease in phosphate excretion and a net retention occur with release of UUO. Weinreb and colleagues (1982) showed that the decrease in the fractional excretion of phosphate following release of UUO in dogs produced no change in the transport of phosphate across brush border membrane vesicles. A reduced filtered load in the previously obstructed renal unit may stimulate increased phosphate reabsorption. Westenfelder and coauthors (1998) reported findings supporting the latter. They demonstrated that the increased reabsorption of phosphate after release of UUO in rats is due to a generalized increase in proximal tubular sodium reabsorption, a process linked to a reduction in GFR. They noted that this was linked to increased cotransport of phosphate and glucose with sodium.

Excretion of other cations is also induced by obstruction. **Magnesium excretion is markedly increased after the release of either UUO or BUO.** The increase most likely results from compromised transport in the thick limb of the Henle loop, which is related to ischemia. This causes decreased influx of Na^+, K^+, and Cl^- by the cotransporter and reduced back flux of K^+ across the apical membrane. It attenuates the positive luminal transepithelial voltage that normally drives the paracellular flux of both magnesium and calcium from lumen to basolateral membrane. The result is reduced passive reabsorption of Mg^{2+} and Ca^{2+} from the loop of Henle. However, calcium excretion may be increased or decreased, depending to a degree on the type of obstruction and the species. Although Mg^{2+} and Ca^{2+} are handled similarly in the thick limb of the Henle loop, calcium handling in the early distal tubule differs. Beaumont and coworkers (1989) demonstrated that the

thiazide-inhibitable sodium chloride cotransporter is rapidly downregulated during ischemia, such as may accompany ureteral occlusion. Blocking influx of Na^+ and Cl^- through this transporter hyperpolarizes the cells in the distal nephron, thereby increasing calcium reabsorption (Gesek and Friedman, 1992). Thus disruption of transport in areas of the nephron where Ca^{2+} and Mg^{2+} are differentially transported may account for varying effects of obstruction on their net transport and excretion.

Organic anions and cations are transported by the renal tubules as substrates of metabolism and as a mechanism of drug elimination. In rats, BUO decreases the renal clearance of *p*-aminohippurate (PAH), a prototypical substrate for the organic anion transporter 1 (OAT-1). Although secretion of PAH was reduced, the reduction did not correlate with a decrease in OAT-1 abundance or with cortical blood flow. It is postulated that decreased Na^+,K^+-ATPase activity, which provides the primary active transport to which OAT-1 is coupled, explains the decrease in PAH transport. In addition to the implications for drug transport and excretion with obstruction, this indicates that PAH clearance without measurement of extraction is an inaccurate index of RPF in postobstructed kidneys (Villar et al, 2004).

Effect of Obstruction on the Excretion of Peptides and Proteins

Some peptides and small proteins are normally filtered by the glomerulus and readily absorbed in the nephron. Some enzymes and proteins, such as Tamm-Horsfall protein and aquaporins, may normally be secreted into the tubular fluid. Obstruction can exaggerate or disrupt the excretion of these proteins and peptides. Some changes simply represent alterations in transport, whereas others are due to tubular damage and remodeling.

Monocyte chemoattractant protein 1 is a mediator of the inflammatory process accompanying obstruction in the kidney. Its excretion in the urine after UUO increases (Stephan et al, 2002) and has been considered an index of tubular damage. Conversely, epidermal growth factor (EGF) excretion, the renal cortical and outer medullary concentration of pre-pro-EGF, and excretion of Tamm-Horsfall protein (Storch et al, 1992) all decrease with obstruction. Urinary enzymes thought to be derived from the proximal tubule, such as alkaline phosphatase, γ-glutamyltransferase, *N*-acetyl-β-D-glucosaminidase, and leucine aminopeptidase have been reported to be elevated in patients with obstructed kidneys (Carr et al, 1994). However, such increases in enzymuria have been reported to be either biphasic, occurring only in the early stages of obstruction, or absent in animal models of partial or total ureteral obstruction (Everaert et al, 1998).

In summary, major changes occur with the ability of the kidney to concentrate the urine because of the downregulation of transporters and aquaporin water channels. These defects are enduring and correct slowly with time. Sodium excretion is greater after relief of BUO because extracellular volume is expanded and ANP directly affects transport and glomerular filtration. Potassium and phosphate excretions follow changes in sodium; they are decreased with UUO because of altered transporters and postobstructive retention and increased transiently with BUO in parallel with the massive natriuresis. Obstruction causes a deficit in urinary acidification that has been demonstrated both in humans and in animals. Magnesium excretion is increased in both models, but calcium handling is more complex. Changes in peptide excretion reflect mediators and markers of renal damage.

Metabolic Determinants of Ion Transport

An overview of the normal metabolic processes linked to ion transport provides a foundation for the understanding of changes that occur with obstruction. The myriad of transporters involved in maintaining cellular homeostasis and electrolyte balance is integrated longitudinally and vertically within the nephron. Families of ion-translocating ATPases mediate primary and secondary transport and are fueled by the availability and synthesis of ATP. In addition to providing energy for ion pumps, the adenine nucleotides can directly influence ATP-sensitive K^+ channels that link the activity of the sodium pump with the leak of potassium in some of the nephron segments, such as the thick ascending limb of the Henle loop and the collecting duct.

Although there is considerable variability between nephron segments, and even between species in the normal physiologic substrate for ATP generation in nephron segments, a few generalizations can be made. Aerobic glycolysis in several cell types, including renal tubules, links ATP generation to increased activity of Na^+,K^+-ATPase, QO_2, cAMP, and primary active transport of ions. In normal physiology, the renal cortex has a high rate of aerobic metabolism indicative of fatty acid oxidation and a low content of glycogen. Proximal tubules have relatively little glycolytic capacity and depend upon aerobic mitochondrial metabolism for ATP synthesis from substrates such as ketone bodies, fatty acids, glutamine, and lactate (Uchida and Endou, 1988; Ruegg and Mandel, 1990). Metabolism even varies along the length of the proximal tubule. For example, the proximal convoluted tubule cannot use glucose to support oxidative metabolism, but the proximal straight tubules can.

The medullary and cortical regions of the thick ascending limb of the Henle loop possess abundant mitochondria and high QO_2. Substantial energy reserves allow increased transport associated with glomerulotubular balance. This nephron segment and those downstream have the capability of aerobic and anaerobic glycolysis, which results in lactate accumulation and increased glycogen content (Abodeely and Lee, 1971; Cohen, 1979; Bagnasco et al, 1985). Compared with the proximal tubule, the medullary thick ascending loop of Henle has a greater capacity for anaerobic glycolysis but still requires ATP production from mitochondrial oxidative phosphorylation to maintain active Na^+ transport.

In addition to its role as a fuel for metabolism and transport, ATP and its metabolites can serve as regulators of solute transport, such as the ATP-sensitive K^+ channels previously mentioned, and activation of purinergic P_2 receptors within the kidney that modulate solute transport (Schwiebert and Kishore, 2001).

Although substrate availability for energy production related to transport is not generally rate limiting under physiologic conditions (Guder and Schmidt, 1976), some parts of the kidney, such as the thick ascending limb of the Henle loop, are located in areas where there is a tenuous balance between oxygen supply and demand. Consequently, these parts of the nephron are more susceptible to hypoxic injury and associated transport dysfunction. Therefore in addition to downregulation of the transport proteins themselves, with obstruction, the energy sources for transport function are at risk.

Renal obstruction provokes a number of changes in the metabolic cascade. There is a shift from oxidative metabolism to anaerobic respiration. This shift results in a reduction of renal ATP levels, an increase in amounts

of adenosine diphosphate (ADP) and adenosine monophosphate (AMP), and an increase in the renal lactate-to-pyruvate ratio (Stecker et al, 1971; Middleton et al, 1977; Nito et al, 1978; Klahr et al, 1986).

Cellular and Molecular Mechanisms Leading to Tubular Cell Death through Apoptosis

Renal obstruction produces tubular atrophy and cell death. The major mechanism by which tubular cells die is apoptosis, a process that is normally involved in postnatal development and tissue renewal in adults. The process can be triggered by both intrinsic and extrinsic factors and results in degradation and condensation of the nucleus. The cells are further degraded into apoptotic bodies, which are eventually phagocytized by healthy cells, usually without inducing inflammation. When rat kidneys are obstructed, renal tubular cell apoptosis begins in about 4 days and peaks after 15 days, with interstitial cell apoptosis continuing for the duration of obstruction (Choi et al, 2000). Glomerular cells appear to be resistant to obstruction-induced apoptosis. Pathological apoptosis of tubule cells from obstruction may secondarily trigger inflammatory responses from the release of cytokines and recruitment of leukocytes (Canbay et al, 2004).

Cysteinyl aspartate-specific proteinases (caspases) are known to mediate apoptotic cell death in obstructed kidneys (Hengartner, 2000; Truong et al, 2001). This family of 12 enzymes can be categorized into three main groups: initiators, effectors, and cytokine processors. Two distinct pathways of caspase activity are involved. One pathway involves activation of membrane death receptors by extrinsic binding of tumor necrosis factor alpha (TNF-α) to its receptor. A second pathway involves intrinsic stress signals that result in mitochondrial release of proapoptotic proteins such as cytochrome *c*. The two pathways converge to activate effector caspases, which cleave nuclear and cytoplasmic components, resulting in condensation of nuclear material and cell death. Truong and colleagues (2001) showed that all of the caspases increased with renal obstruction and that their levels paralleled renal cell apoptosis. Caspases 3 and 8 best correlated with renal cell apoptosis and appear to be central to this process (Choi et al, 2000; Truong et al, 2001).

In contrast to the defined role of angiotensin II in obstruction-induced renal fibrosis, its involvement in renal cell apoptosis is less clear. In mice with a knockout deletion of the AT2 receptor, there is a decreased degree of obstruction-induced apoptosis. However, these receptors are normally downregulated in the adult kidney, and their role in normal function and pathophysiologic responses is uncertain in the mature kidney. Angiotensin blockade or ACE inhibition has been shown by some investigators to reduce apoptosis in the early phases of renal obstruction (Truong et al, 1998; Eskild-Jensen et al, 2007), but others have reported conflicting results.

TNF-α can be a directly cytotoxic cytokine that can induce apoptosis in addition to its role in renal inflammation. When TNF-α binds to its receptor, TNFR1, an associated death domain (TRADD) binds to the TNFR1 and activates several signaling pathways. When coupled to a Fas-associated death domain, it triggers caspase 8 activation, which is pivotal to apoptosis. Alternatively, the TNFR1-TRADD complex can activate nuclear factor–κB (NFκB), which can have both pro- and antiapoptotic activity depending upon the cellular milieu. Increased amounts of TNF-α and its receptors have been demonstrated in rat models of obstruction (Tartaglia et al, 1991; Kaneto et al, 1996; Choi et al, 2000), along with other components of this cascade. These findings suggest an important role for TNF-α in apoptosis after obstruction.

Although the processes leading to renal apoptosis, inflammation, and fibrosis have many distinct pathways and mediators, they may also be intimately linked. Apoptosis is a primary cellular event leading to many toxic and ischemic insults. Although it is usually thought of as programmed cell death without inflammation, extensive damage to many cells may rupture and release cell contents and activate transcription factors, such as NFκB, to stimulate production of proinflammatory cytokines. Clearance of apoptotic debris through phagocytosis may directly stimulate fibrogenesis in many tissues, and fibrosis accompanying tissue injury may reciprocally induce pro-apoptotic gene expression such as the Fas/FasL pathway (Canbay et al, 2004).

Cellular and Molecular Changes Leading to Fibrosis

Urinary tract obstruction leads to progressive and, eventually, permanent changes in the structure of the kidney, including the development of tubulointerstitial fibrosis, tubular atrophy and apoptosis, and interstitial inflammation. A number of cytokines and growth factors have been shown to play roles in these events, among which the most prominent include transforming growth factor beta TGF-β, angiotensin II, NFκB, and TNF-α. Some are produced directly from the renal tubular and interstitial cells; others are generated from infiltrating macrophages.

Tubulointerstitial fibrosis develops as a consequence of extracellular matrix being synthesized and deposited at a greater rate than it is degraded, as well as to a relative increase in matrix due to collapse of parenchymal volume as nephrons are destroyed (Hewitson, 2009). A family of enzymes known as matrix metalloproteinases (MMPs), which includes collagenase, normally cleaves and degrades the collagenous and noncollagenous components of the extracellular matrix. **Obstruction increases the synthesis of tissue inhibitors of metalloproteinases (TIMPs) that reduce MMP activity, resulting in the accumulation of extracellular matrix.** Infiltrating macrophages stimulate TGF-β synthesis, and this growth factor increases TIMP production, thus reducing collagen turnover. Macrophages also produce other cytokines and growth factors, such as interleukin 2, interleukin 6, fibroblast growth factor, and platelet-derived growth factor (PDGF), that appear to contribute to this inflammatory and fibrotic process. Active TGF-β binds directly to its type 2 receptor, which subsequently activates and phosphorylates the type 1 TGF-β receptor. Both of these receptors have been shown to be upregulated in rats with UUO, in both the obstructed and contralateral renal units. This may be a factor in the hypertrophic response sometimes seen in the nonobstructed kidney (Sutaria et al, 1998). The activated type 1 TGF-β receptor subsequently phosphorylates SMAD (mobile transcription factors with a name derived from related genes in *Caenorhabditis elegans* [Sma] and *Drosophila* [Mad]) proteins. A heteromeric complex of SMAD proteins translocates to the nucleus, where it interacts with transcription factors to regulate gene transcription (Wamsley-Davis et al, 2004) and stimulates tubulointerstitial fibrosis (Fukasawa et al, 2004). Stimulation of TGF-β furthermore stimulates the JNK1 (c-JUN N-terminal protein kinase 1) pathway, which targets the activation of c-Jun and activates transcription factor 2, which are

critical components in activating fibronectin production. Increased mRNA expression of TGF-β is seen as early as 10 hours after obstruction and increases for 4 days (Walton et al, 1992; Diamond et al, 1994). The increase occurs primarily in medullary tubules and the interstitium and is less prominent in cortical tubules or glomeruli. Furthermore, TGF-β interacts with other profibrotic growth factors such as EGF and angiotensin II (Kaneto et al, 1993; Ishidoya et al, 1995; Chevalier et al, 1998).

Angiotensin II upregulates the expression of TGF-β1 in UUO, whereas ACE inhibitors or angiotensin receptor blockers diminish TGF-β1 expression and reduce tubulointerstitial fibrosis. This effect, and increases in TNF-α and NFκB promoted by activation of the renin-angiotensin axis, underscore the importance of this system in the obstructive process. Angiotensin II exerts its biologic effect through both AT1 and AT2 receptors, although in adult mammals, the AT1 receptors predominate and account for most of the known effects of the peptide. With UUO, a significant rise in both renal angiotensin II content and AT1 receptor expression is found (Misseri et al, 2004). Nephron angiotensin receptors are found in areas of the kidney where the peptide is known to have its greatest biologic effect: the proximal tubule, the thick ascending limb of the Henle loop, and the glomerulus (Sechi et al, 1992; Meister et al, 1993). The importance of this pathway has been shown in a murine AT1α receptor knockout model in which the mice have significantly less collagen expression and deposition, interstitial volume, and extent of obstruction-induced renal fibrosis (Morrissey and Klahr, 1998a). Angiotensin II stimulates cytosolic and mitochondrial oxidant production, which eventually leads to mitochondrial dysfunction. Activation of integrin signaling, release of TGF-β1 and transcription factor NFκB leads to a cell-type transition from epithelium to mesenchymal myofibroblasts that synthesize extracellular matrix (de Cavanagh et al, 2009). Angiotensin II activates the transcription factor NFκB, which, in turn, increases the expression of several chemokines and cytokines involved with the fibrotic process. The NFκB also upregulates the expression of the angiotensinogen gene and thereby provides a positive feedback for further angiotensin II production (Morrissey and Klahr, 1998b). The intimate link between angiotensin and NFκB was demonstrated in a study in which enalapril, an ACE inhibitor, reduced the levels of NFκB and fibrosis in a model of renal obstruction (Morrissey and Klahr, 1997).

The release of TNF-α, a potent inflammatory cytokine, is also stimulated by angiotensin, especially in the first few hours of renal obstruction. It can upregulate its own expression as well as that of other inflammatory mediators such as interleukin 1, PAF, NO, eicosanoids, and cell adhesion molecules. Although macrophages are a major source of TNF-α, renal tubular cells are also capable of producing it and become the predominant source of TNF-α after renal injury. Its role in renal inflammation and fibrosis is supported by studies in mice with knockout deletions of the two types of TNF receptors having less fibrosis.

Although the events leading to fibrosis are thought to be initiated by increased angiotensin II, other profibrotic factors appear to play a significant role because inhibition of angiotensin synthesis by ACE inhibitors or antagonism of the AT1 receptors blunts but does not completely abolish the fibrotic process (Kaneto et al, 1993; Ishidoya et al, 1995; Pimental et al, 1995).

In summary, obstruction of normal urine outflow results in biochemical, immunologic, hemodynamic, and functional changes. It stimulates a cascade in which elevated levels of angiotensin II, cytokines, and growth factors lead to tubular cell apoptosis and cellular inflammation, increased net matrix formation, and tubulointerstitial fibrosis. Many of the mediators are intrinsic to the renal tubular cells, whereas others are contributed by fibroblasts and by migrating macrophages (Fig. 40–3).

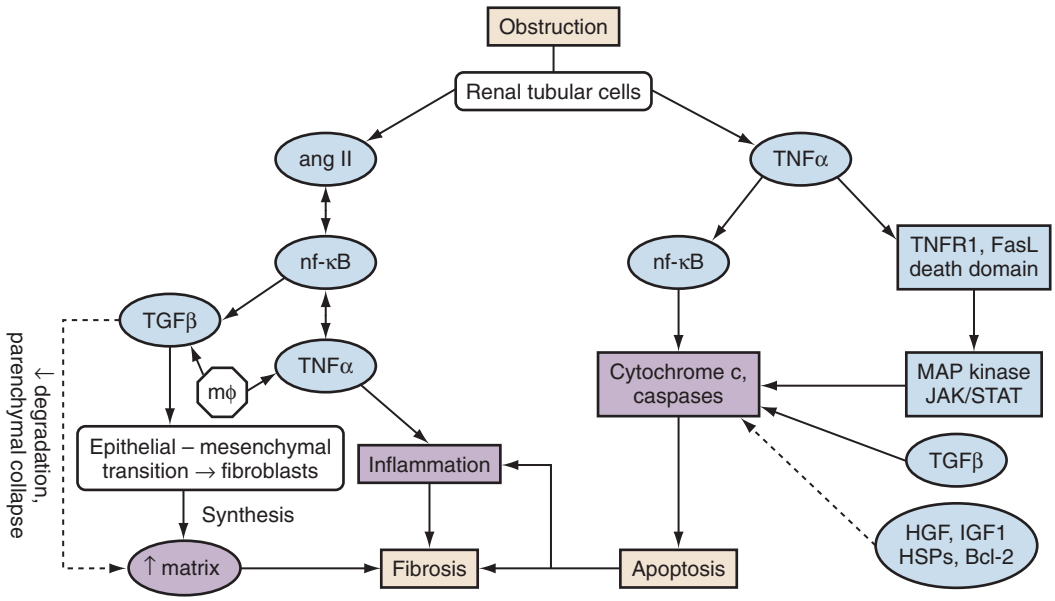

Figure 40–3. Summary of major pathways leading to tubulointerstitial fibrosis and tubular apoptosis as a consequence of ureteral obstruction. Membrane proteins and regulators are discussed in the text. ang II, angiotensin II; HGF, human growth factor; HSPs, heat shock proteins; IGF, insulin-like growth factor; JAK/STAT, Janus kinase/signal transducers and activators of transcription; mϕ, macrophages; MAP, mitogen-activated protein; NF-κB, nuclear factor κB; TGF, transforming growth factor; TNF, tumor necrosis factor; TNFR1, tumor necrosis factor receptor 1.

Experimental Treatment Approaches to Attenuate Renal Fibrosis and Functional Impairment

The aforementioned cascade of events points to many possible avenues to attenuate renal damage associated with obstruction. Experimental strategies to attenuate these noxious responses are reviewed.

Angiotensin antagonism is the best-studied therapeutic approach due to the clear link between angiotensin and renal injury and the clinical availability of ACE inhibitors and angiotensin receptor blockers (ARBs). Wamsley-Davis and colleagues (2004) administered the ACE inhibitor enalapril, the AT1 antagonists losartan or candesartan, or vehicle for up to 52 days to male rats with UUO. Candesartan inhibited the rise in JNK1 activity, losartan attenuated it, and enalapril did not affect it. Candesartan also reduced SMAD2 protein activation while attenuating the chronic tubulointerstitial fibrotic injury in obstructed kidneys and preserved renal mass. The apparent differences between candesartan, losartan, and enalapril may be dose- or delivery-related in that the AT1 antagonists were continuously infused by mini-pumps, whereas enalapril was added to the drinking water, and dose-response relationships were not examined. Manucha and colleagues (2005) showed, in rats, that losartan attenuated fibrosis in unilaterally obstructed kidneys by reducing oxidative stress as measured by lowered hydroxyl and oxygen radicals and increased superoxide dismutase and heat shock protein 70 levels.

In addition to the clear importance of angiotensin II in the processes leading to fibrosis and possibly apoptosis, other peptides in this family may be involved. Ureteral obstruction not only increases angiotensin-converting enzyme (ACE) and angiotensin II, but also decreases ACE-2, the enzyme most responsible for production of angiotensin-(1-7) (Bae et al, 2007). Angiotensin II stimulates many kinases probably involved in the profibrotic process, while angiotensin-(1-7) stimulates phosphatases that antagonize these effects (Gallagher et al, 2006). Inhibiting ACE shunts peptide production from angiotensin II towards more synthesis of angiotensin-(1-7). Thus the beneficial effects of ACE inhibitors and angiotensin receptor blockers may reside both in the synthesis and effect of less angiotensin II and the increased effect of angiotensin-(1-7). If so, the use of the latter as a drug could be explored, or there may be other means to modulate intrarenal kinases and phosphatases.

Manucha and colleagues (2004) showed that losartan prevented the development of renal fibrosis and kept interstitial volume and TGF-β mRNA expression to near control levels. Furthermore, these investigators implicated the well-known interactions between angiotensin II and activation of NOS isoforms and cyclooxygenase 2 (COX-2) in the inflammatory process. Whereas UUO increased iNOS in the obstructed renal medulla and increased neuronal NOS (nNOS) and endothelial NOS (eNOS) in the cortex, losartan treatment downregulated iNOS and nNOS with unchanged levels of eNOS. In addition, obstruction increased COX-2 expression in the obstructed renal cortex. It, too, was decreased by losartan treatment. **These studies suggest an important role of angiotensin-mediated profibrotic and apoptotic events occurring with renal obstruction that can be reduced with currently available inhibitors of angiotensin synthesis or receptor blockade.**

The known association of aldosterone and cardiac fibrosis prompted investigators to assess whether the administration of an aldosterone antagonist could attenuate the renal fibrosis generated with obstruction. Trachtman and coworkers (2004) examined this in a rat model of UUO. Whereas 1 week of obstruction produced minimal parenchymal damage, 2 weeks of obstruction produced renal fibrosis, which was significantly reduced by administration of the aldosterone antagonist spironolactone, without raising serum potassium or aldosterone concentrations.

Nitric oxide synthases are known to be double-edged swords in the processes of tissue perfusion and tissue inflammation. Obstruction increases inducible, neuronal, and endothelial NOS and high concentrations of NO can result in peroxynitrite production. Administration of L-arginine by infusion, or even by oral administration, prevents the upregulation of iNOS, blunts the increase in renal interstitial volume, and attenuates the infiltration of the renal parenchyma by macrophages in rats with obstructed kidneys (Ito et al, 2004c; Klahr and Morrissey, 2004). Gene therapy may be another approach. Ito and colleagues (2004b) showed that the gene for iNOS could be packaged in liposomes and delivered by intraureteral administration. Transfection and NO synthesis resulted in reduced fibrosis from ureteral obstruction.

Klahr and Morrissey (2003) showed that bone morphogenic protein (BMP) 7, a structural relative of TGF-β, was effective in preventing the tubulointerstitial changes and accelerating the return of renal function in a rat model of obstruction. They demonstrated that this agent inhibited apoptosis. This group also reported that the administration of hepatocyte growth factor has similar beneficial effects and proposed that it works by suppressing expression of TGF-β and PDGF. On the other hand, BMPs have been shown to also induce the epithelial-to-mesenchymal cell transition (Hu et al, 2009), which leads to fibrosis; so, the applicability of BMPs as drug candidates is not yet settled. Pirfenidone, a drug that purportedly inhibits collagen synthesis, downregulates production of multiple cytokines, and blocks fibroblast proliferation, may be another candidate to attenuate obstruction-induced renal injury and facilitate renal remodeling (Lasky, 2004).

The pathways of apoptosis, inflammation, and fibrosis all depend upon NFκB as a common mediator. Tamada and colleagues (2006) showed that kremezin, an oral adsorbant of indoxyl sulfate, lowers activation of NFκB and reduces inflammation and fibrosis. Curcumin, an ingredient of the spice turmeric, also appears to inhibit NFκB activity and interstitial inflammation and fibrosis (Kuwabara et al, 2006). This pathway appears important in drug-induced nephrotoxicity, as well as in obstructive nephropathy.

Heme oxygenase-1 (HO-1) exerts cytoprotection from a variety of kidney injuries. One of its endogenous products is carbon monoxide (CO). Wang and colleagues (2008c) found that low-dose CO protected against the fibrosis of UUO, probably by inhibiting TGF-β1 and other mediators of fibrosis. Similarly, Iwai and colleagues (2008) showed that induction of HO-1 with prophylactic cobalt protoporphyrin protected against renal fibrosis from UUO. Thus increasing HO-1 or its products may be a fruitful approach to treating obstructive nephropathy.

Although the results of the preliminary studies are encouraging, these agents should not be prescribed to patients for this purpose at this time. Their safety and efficacy first need to be established through carefully designed and controlled clinical studies.

Compensatory Renal Growth

Compensatory renal growth (CRG) of the unobstructed kidney was first described by Hinman (1943). This phenomenon has been subsequently demonstrated in a number of other animal models of UUO (Taki et al, 1983; Peters et al, 1993). There is evidence that

it occurs in the human fetus. An increase in contralateral renal volume has been detected ultrasonographically when contralateral hydronephrosis or unilateral renal agenesis is present (Mandell et al, 1993).

The mechanisms and nature of this growth are influenced by several factors including age, and degree and duration of obstruction. Both hyperplastic and hypertrophic CRG have been demonstrated (Dicker and Shirley, 1973; Castle and McDougal, 1984; Peters et al, 1993). CRG was demonstrated to decrease progressively with increasing age at which the obstruction occurred in animal models (Taki et al, 1983). **Studies of humans subjected to nephrectomy, a functional surrogate for obstruction, have demonstrated that a reduction in CRG occurs with increasing age** (Edgren et al, 1976). Animal experiments have also demonstrated that compensatory growth is directly proportional to the duration of obstruction (Chevalier et al, 1999). Compensatory growth is less prominent with partial than with total UUO (Chevalier and Kaiser, 1984; Eskild-Jensen et al, 2001). **While the kidney enlarges, an increase in the number of nephrons or glomeruli does not occur** (Peters et al, 1993). However, an increase in the length of the proximal tubule has been described, which may be due to an increase in cell size (Moller, 1988). In addition, there is augmented extracellular matrix synthesis and growth of mesangial cells (Kasinath et al, 2006; Sinuani et al, 2006). Insulin-like growth factor I (IGF-I), a mitogenic and anabolic peptide, may play a role in compensatory renal growth after obstruction. There is both animal and clinical evidence for its role. In rats, mean renal IGF-I is significantly elevated in the normal kidney compared with the contralateral 7-day obstructed kidney (Serel et al, 2000). Inferences can also be made from nephrectomy performed in animals and humans. Renal IGF-I mRNA levels are increased in immature rats previously subjected to nephrectomy (Mulroney et al, 1991). Significant increases in serum IGF-I have been demonstrated in humans after donor nephrectomy and peak 6 months after the procedure. Serum IGF-I was positively correlated with increases in renal volume demonstrated on serial postoperative imaging (Nam and Chang, 1999). It has also been demonstrated that the expression of IGF-I may be age dependent. Although renal IGF-I mRNA levels were found to be elevated after nephrectomy in immature rats, this did not occur in adult rats (Mulroney et al, 1991). Exogenous IGF-1 can attenuate renal injury from obstruction (Chevalier et al, 2000). Other growth factors, cytokines, and enzymes may be involved in regulating CRG, including IGF binding protein–3 (IGFBP-3), vascular endothelial growth factor (VEGF), matrix metalloproteinase–9 (MMP-9), interleukin-10 (IL-10), and TGF-β (Yildiz et al, 2008). Experimental studies suggest that CRG may be influenced by mitochondrial respiration (Tucci et al, 2008). The presence of compensatory growth in infants has been considered by some as an indicator that contralateral hydronephrosis is functionally significant (Koff and Peller, 1995). However, this approach has been challenged by others (Brandel et al, 1996). In addition, it was demonstrated that functional deterioration occurred in a rat model of partial UUO before compensatory growth developed in the contralateral renal unit. This implies that there may be a risk for functional renal loss if one uses only compensatory growth as an indication of correction of obstruction (Wen et al, 1999). Studies in children with unilateral renal tumors have shown that partial nephrectomy is associated with a greater degree of CRG versus nephrectomy, as assessed by ultrasonography (US) (Cozzi et al, 2007). The cause for this differential response is unknown but may be due the generation of more CRG factors in this setting.

Renal Recovery after Obstruction

The duration of obstruction has a significant influence on renal functional recovery. **When acute, complete ureteral obstruction is promptly relieved, full recovery of global GFR can occur.** In the rat model, after 3 days of UUO, GFR, and RBF were reduced to less than 10% of their baseline values. Both returned to their baseline within 14 days of relief of obstruction (Ito et al, 2004a). Bander and colleagues (1985) also noted complete return of GFR by 14 days after 24 hours of acute UUO, although they noted that the recovery was heterogeneous at the nephron level. Studying SNGFR, they found that approximately 15% of superficial and juxtamedullary nephrons were permanently lost, but hyperfiltration of the remaining nephrons allowed maintenance of whole kidney GFR. **Longer periods of complete ureteral obstruction are associated with diminished return of GFR.** Kerr (1954) reported that in dogs with complete UUO for 7 days, GFR 1 hour after relief of obstruction was 25% of the preligation GFR. GFR was then followed to assess the degree and time course of renal recovery. Maximal recovery was 58% of baseline, and this occurred within 57 days. Similar studies were conducted by Vaughan and Gillenwater (1971), who demonstrated that there was full functional renal recovery at 2 weeks after a 7-day period of UUO in dogs. This result declined to 70% recovery of GFR after 14 days of UUO, 30% after 4 weeks of UUO, and no recovery after 6 weeks of UUO.

The fate of the human kidney after prolonged periods of obstruction is less well defined and may be unpredictable. Functional recovery has been reported after a 150-day period of UUO (Shapiro and Bennett, 1976). Permanent reductions in GFR may occur after UUO or BUO in humans. However, there may be a differential pattern of recovery after BUO in adults. Jones and associates (1988) described two phases of functional improvement: an initial phase during the first 2 weeks after relief of obstruction, when tubular function improved, and a later phase occurring over the next 10 weeks, when GFR gradually improved. Patients with BUO or obstruction of a solitary kidney may also be at risk for unique sequelae such as chronic urinary acidification and concentrating defects (Berlyne, 1961).

Histopathological findings may predict recovery of renal function. The presence of increased collagen and elastin in renal parenchyma at the time of pyeloplasty has been shown to have a negative impact on recovery of renal function (Kim et al, 2005; Kiratli et al, 2008).

Renal parenchymal thickness based on computed tomography (CT) measurements has been used to estimate the renal function of chronically obstructed kidneys. One group compared renal surface areas in both kidneys calculated by multiplying the thickness (average of upper and lower pole values) by the renal length. They divided the surface area of one kidney by the sum of the surface areas of both and reported a strong correlation with differential renal function measured by nuclear medicine techniques (Feder et al, 2008). Another group measured the renal thickness at three discrete levels in the kidney and averaged these values. They reported that if the ratio of this measurement in the obstructed versus the unobstructed renal unit was less than 0.68, this correlated with a differential renal function of less than 20% (Kaplon et al, 2009). **Further studies are needed to corroborate these results before this approach is used in clinical practice.** Other factors influence functional return. Factors that have a positive influence on functional recovery include a smaller degree of obstruction, greater compliance of the collecting system, and presence of pyelolymphatic backflow (Shokeir et al, 2002).

Conversely, older age and decreased renal cortical thickness are predictors of diminished recovery of renal function (Lutaif et al, 2003).

Nuclear renography may help predict functional recovery. An assessment of functioning cortex with such imaging is the best predictor. For example, **dimercaptosuccinic acid (DMSA), a cortical agent, has been shown to be superior to tubular selective agents, such as diethylenetriaminepentaacetic acid (DTPA) or mercaptoacetyltriglycine (MAG3), for the prediction of renal recovery.** This was demonstrated in a prospective study in children undergoing pyeloplasty or ureteral reimplantation for ureterovesical junction obstruction (Thompson and Gough, 2001). It was postulated that DMSA better defines the functional cortex and is less affected by the dilated collecting system and dilution by undrained urine. Similarly, when the tubular agent *ortho*-iodohippurate was used, whole kidney activity was less predictive than the cortical phase (Kalika et al, 1981).

Renal recovery after relief of obstruction is affected by the duration of obstruction, degree of obstruction, patient's age, and baseline renal function. Cortical phase nuclear renograms may offer accurate prediction of the capacity of the kidney to recover after reversal of the obstruction.

PATHOLOGIC CHANGES OF OBSTRUCTION

Distinct gross and microscopic pathologic changes may occur with obstruction of the upper urinary tract. These may be affected by the presence of infection, duration of obstruction, and intra- versus extrarenal localization of the renal pelvis.

Gross Pathologic Findings

The gross pathologic changes occurring in the kidney have been characterized in animal models and parallel those in humans. Hodson (1969) and colleagues performed unilateral ureteral ligation in a porcine model and described pathologic changes in both kidneys over several time points. Dilation of the pelvis and ureter and blunting of the papillary tips were present in the obstructed kidney at 42 hours after obstruction, and the weight of this renal unit was heavier. Pelviureteric dilation and weight further increased and the parenchyma became edematous in the obstructed kidney at 7 days. The cortex remained slightly enlarged, and there was increased calyceal dilatation at 12 days in this renal unit; at 21 and 28 days, the external renal dimensions of both kidneys were similar. However, the cortex and medullary tissue in the obstructed kidney were diffusely thinned. Ladefoged and Djurhuus (1976) evaluated partial and complete obstruction in a porcine model. **They found that totally obstructed kidneys were enlarged, had a cystic appearance, and weighed less than the contralateral renal unit 6 weeks after obstruction. However, such gross differences in appearance were not present at this interval in the partially obstructed kidneys.**

Microscopic Pathologic Findings

Light microscopic changes reported in the aforementioned porcine model at 42 hours after obstruction included lymphatic dilation, interstitial edema, and tubular and glomerular preservation. Collecting duct and tubular dilatation was prominent by 7 days. In addition, further interstitial edema, widening of Bowman space, tubular basement membrane thickening, cell flattening, and cytoplasmic hyalinization were demonstrated. Papillary tip necrosis, regional tubular destruction, and inflammatory cell response were noted at 12 days (Hodson et al, 1969). Interstitial fibrosis and thickening of the tubular basement membranes were reported at 16 days after obstruction in a mouse model (Sharma et al, 1993). The inner cortex demonstrated severe tubular loss, proliferation of fibroblasts, and collagen deposition 3 weeks after obstruction in the porcine kidney. Cortical thinning and development of glomerular crescents were present at the 3- to 4-week interval in this model (Hodson et al, 1969). **Widespread glomerular collapse and tubular atrophy, interstitial fibrosis, and proliferation of connective tissue in the collecting system were reported at 5 to 6 weeks after obstruction in the porcine model** (Ladefoged and Djurhuus, 1976). Similar findings are noted in the chronically obstructed human kidney (Figs. 40–4 to 40–6).

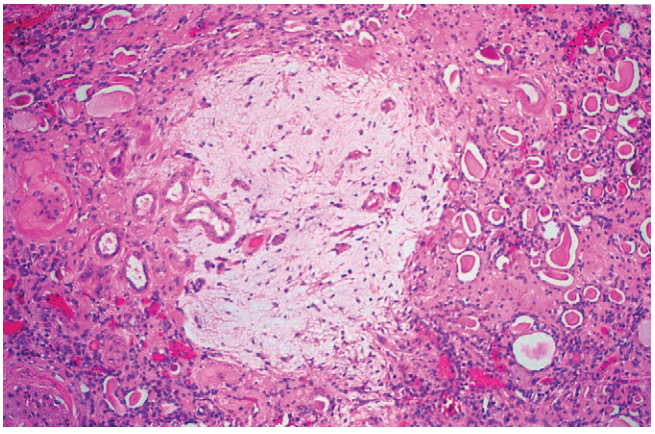

Figure 40–5. Sections of deep cortex and outer medulla from a patient with chronic obstructive uropathy. Obsolescent glomerulus *(left edge)* and pool of extravasated Tamm-Horsfall protein *(center)* are seen. Hematoxylin and eosin stain; original magnification, ×25. (Courtesy of Dr. Sami Iskandar.)

This is believed to be a result of interplay of several cellular and molecular mechanisms that collectively lead to the subtle development of tubular atrophy, macrophage infiltration/proliferation in the renal interstitial tissue, interstitial fibrosis and progressive loss of nephrons (Chevalier, 2006; Moon et al, 2006). These processes are also reviewed earlier in this chapter.

Electron Microscopic Pathologic Findings

Electron microscopic (EM) studies have confirmed the aforementioned light microscopic findings, including the presence of tubular atrophy, glomerular collapse, and renal pelvic smooth muscle atrophy at 5 to 6 weeks after obstruction (Fig. 40–7). Electron microscopic studies have also demonstrated other changes including the development of a cell-poor stroma composed of elastic and collagen fibers in the renal interstitium and obstructed portions of the collecting system (Ladefoged and Djurhuus, 1976). Collagen and elastin are normal components of the collecting system but are more prominent and have structural changes with obstruction (Gosling and Dixon, 1978; Murakumo et al, 1997).

GENERAL ISSUES IN MANAGEMENT OF PATIENTS

Diagnostic Imaging

As the clinical signs and symptoms of obstructive uropathy are so widely variable, prompt and accurate diagnosis is dependent upon appropriate imaging. The practicing urologist should be well versed in the diagnostic imaging modalities currently available, as well as their relative advantages, limitations, and appropriate modifications. An overview of current imaging techniques, with an emphasis on recent modifications, is presented here. Diagnostic tests used in the evaluation of upper urinary tract obstruction include ultrasonography, excretory urography (EXU), retrograde pyelography, antegrade pyelography, isotopic renography, computed tomography (helical), magnetic resonance imaging, and pressure flow study (Whitaker test).

Ultrasonography

Renal ultrasonography is a mainstay in the evaluation of suspected urinary tract obstruction. Although it is primarily an anatomic study, Doppler modifications may add a functional component. **There is no associated ionizing radiation, and it is thus considered safe in pediatric and pregnant patients. Because there is no need for iodinated contrast material, ultrasonography can be used in those with azotemia or contrast allergy.** Because it remains relatively inexpensive and widely available, ultrasonography is often a first-line investigational imaging modality to demonstrate dilatation, and it is also considered the best initial imaging modality for evaluating and following hydronephrosis (Watkin et al, 2007).

Renal parenchymal thickness can be measured readily, and cortical thinning may be indicative of chronic obstruction. The renal pelvis and calyces can be imaged, and dilatation is readily identifiable. **Caution in interpretation must be exercised, however, in that hydronephrosis is an anatomic as opposed to a functional diagnosis. Specifically, caliectasis and pelviectasis both may exist in an unobstructed system.** Functional inferences cannot be presumed from static images. For instance, the hydronephrosis of vesicoureteral reflux is not typically obstructive. In addition, renal sinus cysts can be misinterpreted as hydronephrosis. Conversely, early in acute obstruction, hydronephrosis may not be prominent, and the

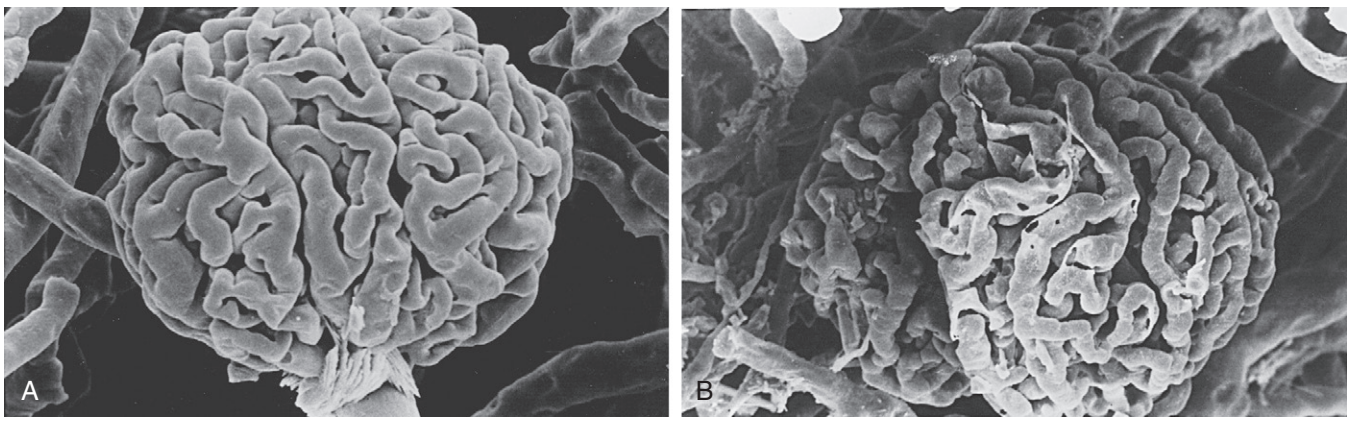

Figure 40–7. **A,** Scanning electron microscopic appearance of a normal glomerular cast (×390). **B,** Appearance of a glomerular microvascular cast after obstruction shows capillary collapse and irregularity (×390). (**A** and **B,** From Leahy AL, Ryan PC, McEntee GM, et al. Renal injury and recovery in partial ureteric obstruction. J Urol 1989;142:199–203.)

presence of an intrarenal collecting system or dehydration may lead to false-negative interpretations. **A prospective study of ultrasonography in obstruction by** Laing and colleagues (1985) **revealed a 35% false-negative rate in acute obstruction, underscoring the need to correlate the clinical picture carefully with the radiologic findings.**

Doppler ultrasonography allows measurement of the renal resistive index (RI), which has been used to assess for obstruction. The RI is defined as peak systolic velocity (PSV) minus the end-diastolic velocity (EDV) divided by the PSV. Several groups have assessed its ability to diagnose obstruction, but its utility has yet to be fully established. Platt and coworkers (1991) have suggested 0.7 as the upper limit of normal, with values greater than 0.7 reflecting elevated resistance to blood flow and thus suggesting obstructive uropathy. They subsequently reported their experience using this modality in 23 patients with acute unilateral obstruction. Three patients had false-negative studies, two of whom had pyelosinus extravasation and one of whom had been obstructed for less than 5 hours. They concluded that Doppler determination of RI was a valuable adjunct to routine sonographic evaluation of urinary tract obstruction (Platt et al, 1993). Conversely, others have found the sensitivity inadequate for the detection of obstruction. Tublin and associates (1994) reported that of 32 patients with colic, 12 of 19 patients with obstruction had normal RI, and 5 of 13 without obstruction had abnormal RIs.

One factor that may account for the dichotomy between such studies is the degree of obstruction. Chen and colleagues (1993) evaluated 27 patients with suspected obstruction by both Doppler ultrasonography and EXU. Overall, using an RI of 0.7 as the critical value, the sensitivity was only 52%. However, when correlated with degree of obstruction on EXU, RI was shown to differentiate the kidneys with mild obstruction from those with severe obstruction. In those with mild obstruction, the mean RI was only 0.64, whereas in those with severe obstruction the mean RI was 0.74, and the sensitivity of an RI greater than 0.70 for significant obstruction was 93.3%. Fung and coauthors (1994) also assessed this modality for evaluating obstruction. They measured RI in nine patients undergoing Whitaker testing for grade 3 or 4 hydronephrosis and reported that RI directly correlated with renal pelvic pressure. They determined that when renal perfusion pressures were normal, RI was less than 0.82. Major pitfalls in many of the studies assessing this modality have been the inconsistent definition of obstruction and degree of obstruction. **Although the presence of hydronephrosis associated with an abnormally elevated RI may be indicative of the severity of obstruction, it is important to recognize these limitations and use other clinical information and renal functional assessment for treatment planning.**

Crossing vessels are associated with ureteropelvic junction obstruction (UPJO), and their presence may influence treatment. Ultrasonographic techniques can be used to demonstrate their presence. Mearini and colleagues (2003), in a study of 21 patients with suspected UPJO, demonstrated the utility of color Doppler ultrasound scanning (CDUS) to correctly identify aberrant crossing vessels with an accuracy of 90.4%. Endoluminal sonography (EUS) is another useful means to evaluate a UPJO for a crossing aberrant vessel (Hendrikx et al, 2006). EUS uses a catheter-based sonographic probe, inserted under endoscopic and fluoroscopic control, that delivers a 360-degree cross-sectional view for assessing the ureter and periureteral structures. Recently, three-dimensional (3D) reconstruction of the two-dimensional (2D) endoluminal sonographic image has been shown to augment the diagnostic accuracy of this modality for comprehensive elucidation and assessment of the vascular morphology of the crossing vessel (Lin et al, 2008). Contrast-enhanced color Doppler imaging (CECDI) is another relatively new promising technique that is currently under evaluation. It has been compared with CT and magnetic resonance imaging (MRI) for the detection of crossing vessels in suspected ureteropelvic junction obstruction (UPJO). The CECDI technique uses galactose-based, echo-enhancing microbubble contrast agents that are administered intravenously, either as a single injection or as a fractionated, slow, continuous infusion. This is followed by color Doppler amplitude/frequency/pulsed-wave spectral imaging, which differentiates between arterial and venous flow signals. This permits identifying the presence of a crossing artery, vein, or both. Recently, Mitterberger and colleagues compared CECDI, MRI, and CT in correctly identifying the crossing vessels detected in patients with UPJO being subjected to laparoscopic pyeloplasty. The reported accuracies for CECDI, MRI, and CT were 100%, 100%, and 93%, respectively (Mitterberger et al, 2008).

Excretory Urography

Long considered the "gold standard" for the evaluation of the upper urinary tract, EXU has been supplanted by other modalities for many of its prior indications. Nevertheless, it provides both anatomic and functional information. **Acute urinary obstruction may be inferred from the *functional* abnormality of a delayed nephrogram and pyelogram on the affected side or sides. Delayed images may then ultimately reveal the *anatomic* level of obstruction and perhaps causation.** In addition, other signs may be present that may indicate chronicity of obstruction such as parenchymal thinning, extreme calyceal blunting, and ureteral tortuosity.

As the imaging is dependent upon glomerular filtration and renal concentration of the contrast medium, the utility of EXU is limited in those with renal insufficiency. Furthermore, the risk of contrast nephropathy increases with increasing serum creatinine. EXU, therefore, should not be performed in subjects with renal insufficiency, those who are at higher risk for developing contrast-induced nephropathy, or those with history of contrast allergy. Radiation exposure limits its utility in pregnancy, although abbreviated protocols have been established (Zagoria and Tung, 1997).

Retrograde Pyelography

Retrograde pyelography accurately defines ureteral and collecting system anatomy, including the location of an obstructive lesion and its extent. It should be considered in those who have renal insufficiency or have other risks for receiving intravenous iodinated contrast material. It may also be used in cases in which anatomy is not sufficiently defined with other imaging studies. In essence, a loopogram is another form of retrograde pyelography and may be useful in evaluating patients with cutaneous urinary diversion when obstruction is suspected.

Antegrade Pyelography

This technique may be helpful when other imaging studies do not adequately define collecting system or ureteral anatomy and when retrograde pyelography is not technically feasible.

Whitaker Test

First described by Whitaker in 1973**, this study involves measurement of renal pelvic pressure during infusion of**

either saline or contrast material into the collecting system through a percutaneous needle or nephrostomy at a fixed rate of 10 mL/min. A catheter is placed in the bladder to monitor intravesical pressure, which is subtracted from the measured collecting system pressures to calculate the "true pressure" within the pelvis. **A true intrapelvic pressure of less than 15 cm H_2O is considered normal, greater than 22 cm H_2O indicative of obstruction, and between 15 and 22 cm H_2O indeterminate.** Although its reliability to detect obstruction and differentiate degree of obstruction has been established in animal models (Ryan et al, 1989), the clinical utility of this test has been advocated by some and questioned by others. For example, one group reported that it was a valid test to confirm ureteral obstruction after renal transplantation (Kashi et al, 1993). However, others have reported a sensitivity and specificity of only 79% and 50% in this setting (Sperling et al, 2000).

Other concerns regarding potential shortcomings of the Whitaker test have been noted. Mortensen and colleagues (1983) reported wide variation in pelvic pressures in a normal porcine model, questioning the definition of a "normal" study. It has also been noted that a small, noncompliant obstructed system may give rise to a more rapid increase in pressure than a large, dilated obstructed system (Wahlin et al, 2001). Modifications have been suggested to overcome this pitfall. Individualized infusion rates based on maximum physiologic urine output have been advocated by some (Fung et al, 1995). Wahlin and colleagues (2001) proposed measuring flow as a function of pressure over a range of physiologic pressures. Resistance was then calculated and used to categorize responses as nonobstructed, indeterminate, or obstructed. They found that the major benefit of this modification was that it allowed identification of obstruction in some patients categorized as indeterminate with the standard Whitaker test. **These noted discordant results and the invasiveness of the study reflect the Whitaker test's limited applicability in contemporary clinical practice.**

Nuclear Renography

Nuclear renography is a useful, noninvasive test for evaluating patients with suspected obstruction. **It provides a functional assessment without exposure to iodinated contrast material.** Radiopharmaceuticals for renography are selected on the basis of the function to be studied. The glomerular agent technetium (Tc) 99m DTPA and the tubular agent ^{99m}Tc-MAG3 are most commonly used in the evaluation of obstruction. ^{99m}Tc-MAG3 has a high renal extraction rate, associated with rapid clearance, lower radiation dose, and tubular secretion. ^{99m}Tc-MAG3 has a 55% renal uptake in contrast with a 20% renal uptake associated with ^{99m}Tc-DTPA (Tremel et al, 1996). All radiopharmaceutical tracers are administered intravenously, and their uptake and subsequent clearance can then be evaluated and quantitated scintigraphically. From these data, relative renal function can be calculated. Obstruction can be assessed by measuring the clearance curves, either from a visual assessment of the pattern or from calculation of the half-time (time at which 50% of the radiopharmaceutical is eliminated from the collecting system). **By convention, a half-time less than 10 minutes is considered normal, greater than 20 minutes is considered obstructed, and between 10 and 20 minutes is equivocal.** Tracer clearance can be spuriously delayed because of renal insufficiency and the presence of vesicoureteral reflux, and some have suggested that renal immaturity in neonates may generate false-positive studies (Karam et al, 2003).

In order to detect obstruction, a high-flow state may be necessary. Therefore patients should be well hydrated to prevent misinterpretation related to low-flow states. Theoretically, bladder catheterization should be performed to maintain low intravesical pressure. However, in clinical practice this is used only in certain cases, such as suspected lower urinary tract obstruction, vesicoureteral reflux, neurogenic or noncompliant bladder, or low-lying, pelvic kidneys from which the renal signal may be obscured by intravesical radiopharmaceutical (Karam et al, 2003). The diuretic renogram is a modification designed to maximize flow and potentially distinguish truly obstructed collecting systems from those that are dilated but unobstructed. Because a given patient's response to the diuretic may be affected by the patient's baseline renal function, adjustments may need to be made on the basis of creatinine clearance (Upsdell et al, 1988).

In diuretic renography, as classically described, the diuretic, typically furosemide (F), is administered 20 minutes after the tracer to induce a brisk diuresis (F+20 study). Others have suggested alteration of diuretic timing to coincide with tracer administration (F+0) or precede it by 15 minutes (F–15). English and colleagues (1987) recognized that some patients with a partial obstruction may eliminate the tracer in the 20 minutes before the induction of diuresis using the standard F+20 sequence. To address this, they advocated administration of diuretic 15 minutes before injection of the radiopharmaceutical (F–15) so that initial tracer clearance could be studied during the period of maximal diuresis. Thirty-five renal units with hydronephrosis having equivocal or normal standard (F+20) diuretic renograms were evaluated by English and colleagues using the F–15 sequence. Using contralateral normal kidneys for comparison, they selected a clearance half-time of less than 5 minutes as normal, greater than 10 minutes as obstructed, and between 5 and 10 minutes as equivocal. With these criteria, 13 of the kidneys were demonstrated to be obstructed, and 18 were shown to be unobstructed. Only four kidneys remained in the equivocal range, underscoring the utility of this modified approach. This has also been confirmed in a crossover designed study demonstrating that **although an F+20 study is reliable when obstruction is demonstrated, both the F–15 and F+0 sequences can induce obstructed patterns in previously equivocal cases** (Turkolmez et al, 2004). A study by Tripathi and colleagues (2004), who evaluated the outcome of (F+0 renography) while investigating children with hydronephrosis, demonstrated that the sensitivity, specificity, and accuracy were 100%, 78%, and 83%, respectively. Liu and colleagues (2005) showed that the F+0 protocol had the advantage of a shorter time lag between the administration of furosemide and conclusion of the study, with earlier bladder filling than the F–15 protocol. **With the emergence of such techniques in isotopic renography, the differential renal function and drainage can be estimated with greater precision** (Frøkiaer et al, 2007).

Computed Tomography and Magnetic Resonance Imaging

Cross-sectional imaging, provided by CT and magnetic resonance urography (MRU), generates greater anatomic definition of abdominal and retroperitoneal anatomy than EXU or ultrasonography. **Both CT and MRU provide superior imaging of the obstructed upper urinary tract as compared to EXU** (Kemper et al, 2006). Unenhanced CT is the most sensitive method of detecting urinary tract stones and is currently the preferred imaging modality for evaluating most patients with suspected renal colic. Other advantages include its speed, reproducibility, and ability to detect other pathologic entities (Ulahannan et al, 2008). EXU currently has limited role, because noncontrast CT has

been shown to consistently outperform it for detecting renal/ureteral stones (Shine et al, 2008; Stacul et al, 2008).

Noncontrast CT directly demonstrates calculi classically considered radiolucent when evaluated by plain radiography, including uric acid, xanthine, dihydroxyadenine, and many drug-induced stones. Exceptions, however, are calculi composed of protease inhibitors, which are not visualized by noncontrast CT (Gentle et al, 1997). Secondary CT signs of obstruction such as ureteral dilatation, nephromegaly, decreased parenchymal density of the involved kidney as compared with the contralateral renal unit, perinephric stranding, or fluid can facilitate the diagnosis of acute obstruction. These signs have been reported to have a positive predictive value of 99% and negative predictive value of 95% for identification of acute ureteral obstruction (Smith et al, 1996). This is also an excellent technique for evaluating patients suspected of having chronic obstruction who have renal insufficiency or other contrast risks.

Contrast-enhanced CT has also been advocated for the evaluation of patients with chronic obstructive uropathy and normal serum creatinine. In addition to the aforementioned anatomic details afforded by noncontrast CT, functional evaluation including calculation of differential GFR is possible. Abou El-Ghar and colleagues (2004) compared contrast-enhanced CT with EXU and nuclear renography in 65 patients. **CT had significantly improved sensitivity for identification of the cause of obstruction compared with EXU.** Furthermore, they reported an excellent correlation between isotope and CT-estimated GFR. Multiphasic helical CT has also been shown to be useful in surgical planning for ureteropelvic junction obstruction, with sensitivity for detection of crossing vessel of 97%, specificity of 92%, and with an overall accuracy of 96% (El-Nahas et al, 2004).

A number of advances in MRI technology have facilitated the evaluation of patients with obstruction of the urinary tract. There are a number of different techniques used to generate MRI images. Comprehensive MRI includes static imaging (MRU), dynamic imaging (dy-MRI), and MR angiography (MRA). Magnetic resonance urography (MRU) can be executed essentially with two different imaging techniques: (1) static-fluid MRU that relies heavily on the T2-weighted turbo spin echo (TSE) sequences, and (2) gadolinium-enhanced excretory MRU, a dynamic sequence that relies on the administration of gadolinium with or without a diuretic. The image quality of an excretory gadolinium-enhanced MRU can be considerably improved by using intravenous hydration and diuretics (Ergen et al, 2007). Recent advances and emergence of newer techniques of MRU, such as fast spin echo (FSE) and postprocessing maximum-intensity projection (MIP), have advantages over the previously employed single-shot MRU approach. The accuracy of the former for identifying noncalculous obstruction was reported to be 93% as compared with 89% for the latter (Abou El-Ghar et al, 2008a). T2-weighted MRU is an excellent imaging modality for demonstrating an obstructed renal unit (Nolte-Ernsting et al, 2003). In this approach, gadolinium contrast (Gd-MRI), intravenous fluids, and furosemide are administered. MRU has been compared to EXU, and the former has been found to be superior in most cases. A prospective study compared it with EXU in patients with ureteral obstruction (Karabacakoglu et al, 2004). The accuracy of diuretic MRU for detection of obstruction was demonstrated to be 93% in those with obstructing stones and 100% in those with obstruction related to strictures or congenital anomalies, whereas the accuracy of EXU was 96% and 55%, respectively. A study by Khanna and colleagues (2005), comparing the diagnostic utility and accuracy of MRU versus EXU in 48 patients with obstructive uropathy, concluded that MRU was superior to EXU in patients with moderate to severe dilatation, staghorn and ureteral calculi, impaired renal function, extrinsic ureteric, and UPJ obstruction. However, they also found that EXU was better in depicting small calculi and mild hydronephrosis (Khanna et al, 2005) (Figs. 40–8 and 40–9).

MRU may be used to assess renal function. It has been demonstrated to have an excellent correlation with the renal isotope GFR

Figure 40–8. T2 magnetic resonance urography image showing right ureteral obstruction.

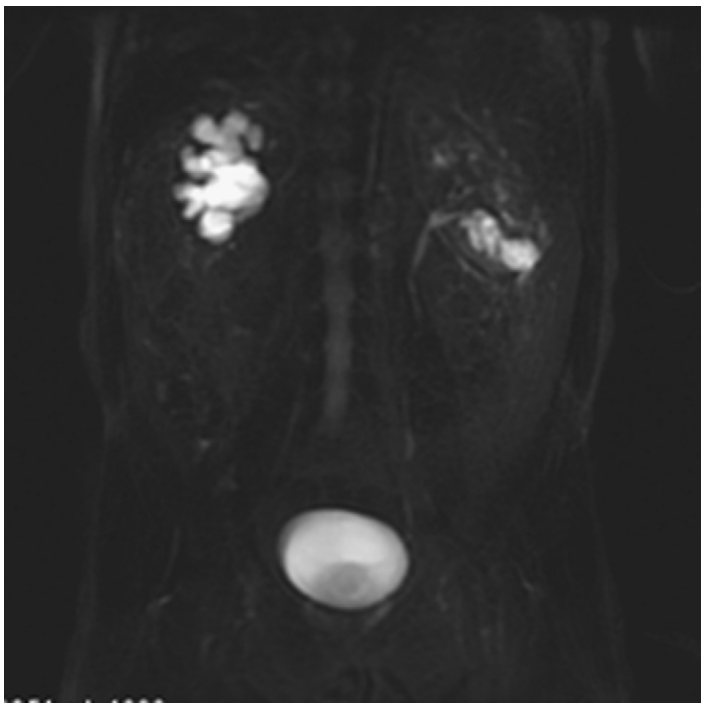

Figure 40–9. Magnetic resonance urography image showing right ureteropelvic junction obstruction.

in the adult (Abo El-Ghar et al, 2008b) and pediatric patients (Jones et al, 2008) with obstructed kidneys. The incorporation of intravenous administration of gadopentetate-DTPA has allowed a dynamic, functional assessment of the collecting system that correlates well with diuretic renal scintigraphy, yet provides far greater anatomic detail than nuclear studies. Differential GFR can be assessed with postimaging processing, and contrast washout can be measured to calculate renal clearance, differentiating dilated systems from obstructed systems (Rohrschneider et al, 2002; Chu et al, 2004). MRU with the contrast agent gadopenteate dimeglumine can be used to estimate renal function because it is filtered by glomeruli and is neither secreted nor reabsorbed by the renal tubules. Studies indicate the possibility of estimating single-kidney function with this technique (Hackstein et al, 2004; Krishnamurthi et al, 2005; O'Dell-Anderson et al, 2006).

Comprehensive MRI, including the incorporation of magnetic resonance angiography (MRA), is a useful modality for the evaluation of patients with UPJO. The sensitivity, specificity, and accuracy of this approach for identification of crossing vessels has been reported to be 95%, 94%, and 94%, respectively (El-Nahas et al, 2007). Cost, availability, time for acquisition of images, and need for sedation in pediatric patients have all been cited as possible limitations of this technique, but the superior anatomic detail, functional assessment, elimination of risk of contrast-induced nephropathy, and lack of ionizing radiation make this an attractive option. **The risk of nephrogenic systemic fibrosis associated with the use of some gadolinium agents (especially gadodiamide) in patients with renal insufficiency (GFR < 30 mL/min), limits the utility of using contrast MRI in such patients** (Broome et al, 2007; Frøkiaer and Zeidel, 2007; Sadowski et al, 2007; Abou El-Ghar et al, 2008b). **The absence of ionizing radiation has allowed its use in the assessment of children, women of child-bearing age, and pregnant patients** (Jorgensen et al, 2006) **with flank pain and hydronephrosis, which is further explored in the discussion of hydronephrosis of pregnancy later in this chapter. In children MRU has the potential to replace conventional uroradiological diagnostic tests in the near future. The present level of evidence does not suggest that MRI is clearly superior to combined ultrasonography (US) and CT imaging for the routine diagnosis and evaluation of obstructive uropathy.**

On the whole, both MRU and CT have critical roles in evaluating select patients with urinary tract obstruction. Although these studies can estimate renal function (He and Fischman, 2008), **nuclear renography remains the current gold standard.**

Hypertension

Hypertension can be precipitated by ureteral obstruction and is a well-recognized sequela of BUO or obstruction of a solitary kidney. Vaughan and Gillenwater (1973) noted hypertension in 17 of 22 patients with BUO, which resolved in 15 subjects upon relief of BUO. This response has also been demonstrated in pregnant patients with BUO (Satin et al, 1993). Patients with BUO are typically volume overloaded. Gulmi and colleagues (1989) measured ANP and plasma renin activity (PRA) in nine patients with BUO before and after relief of obstruction and compared them with those of age-matched control subjects. ANP was significantly increased in the BUO group prior to relief, and progressively returned to normal after drainage. Conversely, PRA was depressed prior to relief of BUO. These findings are suggestive of a volume-mediated mechanism for hypertension in BUO. Hypertension is significantly less common, however, with UUO (Vaughan and Sosa, 1995). In contrast to the BUO model, in UUO the contralateral, unobstructed kidney compensates and eliminates excess volume and solutes. Renin activation and resultant angiotensin II generation have been demonstrated in animal models of UUO and may be the mechanism by which new-onset hypertension occurs in this setting. Pain may be another contributing factor (el-Dahr et al, 1993). **In summary, there is a good chance of reversal of new-onset hypertension with relief of BUO, but this is less likely with UUO.**

Renal Drainage

Ureteral obstruction that is symptomatic, accompanied by fever, complicated by an undrained infection, or determined to be high grade, bilateral, or inducing renal failure warrants immediate drainage of the affected renal unit(s).

Minimally invasive endourologic and interventional radiologic techniques allow prompt drainage of the obstructed kidney. These measures may allow temporary drainage until a definitive procedure is performed or, in some circumstances, may be a permanent form of management. Urine specimens for urinalysis and culture should be obtained from the obstructed renal unit at the time of relief of obstruction when infection is suspected. Antibiotic therapy is started if these tests are indicative of infection or there are clinical signs and symptoms of infection.

The relative merits of indwelling ureteral stents and percutaneous nephrostomy tubes have been evaluated by several groups. Indwelling stents obviate the need for external collection devices but are associated with bothersome voiding symptoms. In spite of this, prospective studies have demonstrated that there is no statistically significant difference in health-related quality of life (Joshi et al, 2001; Mokhmalji et al, 2001). The choice of drainage ultimately depends on the clinical setting. If the patient has an uncorrectable coagulopathy or platelet abnormality, ureteral stenting is indicated. There does not appear to be a significant advantage of either approach in those requiring drainage for stone-related problems (Pearle et al, 1998; Mokhmalji et al, 2001). Compared with percutaneous nephrostomy placement, stent insertion may require greater x-ray exposure (Mokhmalji et al, 2001). This may be of concern in pregnant patients, particularly early in gestation when the fetus is most sensitive to radiation effects (McAleer and Loughlin, 2004). Ultrasound-guided ureteral stent placement is an option in this setting (Jarrard et al, 1993). Nephrostomy tube drainage is also an option for pregnant patients, and radiation exposure can be limited with the use of ultrasound guidance (Denstedt and Razvi, 1992; Agostini et al 2003). Percutaneous nephrostomy should be strongly considered if pyonephrosis is suspected. However, if it is not suspected and thick, purulent fluid is obtained from the kidney at ureteral stenting, placement of a large-diameter stent is recommended. If this does not provide satisfactory drainage, percutaneous nephrostomy should be performed. Percutaneous nephrostomy also allows estimation of differential renal function that can be used in making decisions regarding renal salvage (Al-Hunayan et al, 2008). Percutaneous nephrostomy is also a bailout procedure when retrograde stenting fails or is not feasible.

Ureteral stenting may not be as effective for treating patients with extrinsic ureteral obstruction. Docimo and Dewolf (1989) reported a mean 43% failure rate in ureteral stents placed for extrinsic ureteral obstruction, the majority related to malignancy. This was subsequently confirmed in a prospective

study evaluating success rates for retrograde ureteral stenting (Yossepowitch et al, 2001). Initial retrograde access failed in 27% of patients with extrinsic ureteral obstruction, compared with only 6% of those with intrinsic obstruction. At 3-month follow-up, 56.4% of stents placed for ureteral obstruction had failed. Of note, on multivariate analysis, stent diameter did not predict risk of stent failure. Chung and colleagues (2004) similarly identified an overall 42% rate of stent failure in patients with extrinsic obstruction of the ureter and additionally noted that 43% of those failures occurred within 6 days of the initial placement. **A diagnosis of cancer, metastatic disease requiring chemotherapy or radiation, and renal insufficiency were predictors of stent failure in this series.** Some have advocated the placement of two parallel ureteral stents to provide better drainage as an alternative to percutaneous nephrostomy (Liu and Hrebinko, 1998). **Closer monitoring for stent failure should thus be considered in patients with extrinsic ureteral obstruction** (Ku et al, 2004). Rosevear and colleagues (2007) reviewed their 9-year experience of managing extrinsic ureteral obstruction with retrograde stenting and found an overall success rate of 84%. They also found that a higher serum creatinine value was the only factor that was significantly associated with stent failure (Rosevear et al, 2007). The association of stent failure and poor renal function has also been reported by others (McCullough et al, 2008). The presence of extrinsic ureteral obstruction due to bladder or prostatic pathology, especially advanced malignancies, is another risk factor for stent failure (Danilovic et al, 2005). Encrustation is one of the causes of stent failure. This occurs commonly in pregnant patients, which may be due to increased calcium excretion during pregnancy (Goldfarb et al, 1989). Other reported risk factors for encrustation include urinary tract infection (UTI), stasis, dehydration, renal insufficiency, prolonged dwell time, and history of nephrolithiasis (Singh et al, 2001). A positive correlation between composition of the respective stones and stent encrustations has been reported (Rouprêt et al, 2005).

Choice of Surgical Intervention

After the acute obstruction has been addressed, definitive management is based upon the cause of the obstruction, the functional recovery of the affected kidney, and the condition of its counterpart, and the patient's age and medical status. Endoscopic, open, or laparoscopic ablative and reconstructive procedures may all be used. Indications and pertinent preoperative, intraoperative, and postoperative considerations are discussed elsewhere in this text. The decision to remove a kidney should be made only after the affected kidney has been adequately drained for a sufficient period of time, 6 to 8 weeks based on the results of animal experimentation (Kerr, 1954). Split renal function (SRF) can be assessed by measuring creatinine or inulin clearance (both surrogates of glomerular filtration) directly from bilateral nephrostomy tubes or a nephrostomy tube, and an indwelling urethral catheter when there is complete UUO and the other renal unit is not obstructed. However, nuclear imaging techniques are more commonly used to assess renal function in this setting.

A less-than-10% contribution to global renal function has been proposed as the threshold for nephrectomy, although others have used higher values (Thompson and Gough, 2001). Another criterion has been the ability of the affected renal unit to provide sufficient function to prevent dialysis dependence if the contralateral kidney were removed. These criteria were not generated by prospective study but by clinical inference from functional reconstructive outcomes. There is conflicting evidence in children regarding this threshold. One group reported that renal units with less-than-10% renogram-derived differential function in children have been shown to derive no benefit from reconstruction (Dhillon, 1998). Another group found that in children with moderate hydronephrosis (initial SRF <10%) significant improvement of SRF occurred one year following pyeloplasty (Wagner, 2008). In adults, a GFR of less than 10 mL/min/1.73 m^2 in the affected kidney successfully predicted renal function that did not stabilize or improve after surgical correction of obstruction (Khalaf et al, 2004). Another conflicting study showed that the renal function improvement following pyeloplasty in adult obstructed kidneys may not occur if the initial SRF was less than 30% (Ortapamuk et al, 2003). The decision to proceed with nephrectomy in a patient with significant global renal insufficiency, however, should not be based solely on the aforementioned criteria because this could hasten dialysis dependence and dramatically affect quality of life. The patient may prefer life with a stent or percutaneous nephrostomy, or an attempt at surgical reconstruction.

Pain Management

Five classes of drugs are used to treat pain associated with acute renal colic, namely, nonsteroidal anti-inflammatory drugs (NSAIDs), narcotic analgesics, calcium channel blockers, corticosteroids, and α_1 blockers (Micali et al, 2006). NSAIDs and narcotic analgesics are now most commonly used (Davenport et al, 2005; Holdgate and Oh, 2005; Holdgate and Pollock, 2006). Cochrane meta-analysis studies have demonstrated the effectiveness of both agents but suggest that NSAIDs are preferred (Holdgate and Pollock, 2004, 2005; Das et al, 2006). Other investigators have demonstrated the superiority of NSAIDs (Lee et al, 2005; Engeler et al, 2008). **The present level of evidence supports the role of NSAIDs as first-line drugs for the management of renal colic presenting to the emergency department, with narcotics being reserved as second-line drugs.**

Both classes of medications may be administered parenterally, orally, or as a rectal suppository. NSAIDs are nonopioid analgesics that, unlike narcotics, target the inflammatory basis of pain. Prostaglandins, generated from arachidonic acid metabolism mediated by both *iso* forms of cyclooxygenase, potentiate pain receptors. Therefore inhibition of prostaglandin synthesis prevents this potentiation of nociceptors (Mense, 1983). Narcotic analgesics have a rapid onset but may promote nausea, emesis, constipation, urinary retention, hypotension, respiratory depression, excessive sedation and have a potential for addiction (Lasoye et al, 2004; Holdgate and Pollock, 2006).

Increases in collecting system pressure and ureteral wall tension are proposed mechanisms of renal colic (Holmlund, 1983). Primate models reveal that distention-mediated activation of renal pelvis mechanoreceptors results in spinothalamic (pain pathway) C fiber excitation. The mean threshold pressure to elicit this primate response was 32 mm Hg. This is similar to the 30-mm Hg proposed threshold for evoking pain in humans (Ammons, 1992). Interventions that reduce collecting system pressure should theoretically reduce pain.

NSAIDs have been demonstrated to reduce collecting system pressure. Pretreatment with indomethacin significantly blunted the rise in pelvic pressure and RBF in pigs with UUO (Frøkiaer et al, 1993). Indomethacin administered 30 minutes after UUO reduced an already elevated renal pelvic pressure by approximately 30% in rats (Sjodin et al, 1982). A study of four different NSAIDs in dogs with acute obstruction showed 25% to 58% reductions in renal pelvic pressure after administration of these drugs, which

were most pronounced after the first dose (Gasparich and Mayo, 1986). A concomitant reduction in RBF induced by NSAIDs is thought to be one of the mechanisms for decreasing collecting system pressure. This has been demonstrated in a canine model of UUO in which the administration of ketorolac, an NSAID, induced prompt reduction in both RBF and intrapelvic pressure (Perlmutter et al, 1993). A second potential mechanism involves regulation of aquaporin water channels. COX-2 expression is upregulated in the obstructed ureter (Nakada et al, 2002). There is also a downregulation of AQP2 water channels associated with this COX-2 induction, and this promotes diuresis after obstruction is relieved. Rats treated with a COX-2 inhibitor during obstruction had only a 28% reduction of AQP2, attenuating the diuresis occurring after release of UUO (Cheng et al, 2004).

The choice of pain management should be based on the patient's clinical profile. **NSAIDs should not be used in patients with renal insufficiency, because this could be exacerbated by the induced reduction in RBF.** COX-1 inhibitors should not be administered to patients at risk for gastrointestinal bleeding or when optimal platelet function is needed. Although COX-2 inhibitors are attractive on a pathophysiologic basis, the market withdrawal of some COX-2 inhibitors, related to increased risk of cardiac morbidity, underscores the need for prospective trials to assess their long-term safety in managing patients with renal colic.

The administration of α_1 blockers, calcium channel blockers, and corticosteroids have been used for medical expulsive therapy. Studies have demonstrated the utility of the first two medications to facilitate stone passage, while the benefit of the latter one is questioned. The use of α_1 blockers for this purpose has also been shown to reduce the requirement for analgesics (Micali et al, 2007; Singh et al, 2007; Sterrett et al, 2008; Wang et al, 2008a). Anticholinergic agents have been used in the setting of colic but their benefits have not been established (Holdgate and Oh, 2005; Prcić et al, 2006).

Patients may be fluid depleted as a result of anorexia and emesis, and therefore should receive intravenous hydration. However, there is no evidence that intravenous hydration facilitates stone passage (Springhart et al, 2006; Worster and Richards, 2005).

Postobstructive Diuresis

Mechanisms

Following the relief of urinary tract obstruction, postobstructive diuresis—a period of significant polyuria—may ensue. Urine outputs of 200 mL/hr or greater may be encountered. Although this occurs mainly after relief of BUO or obstruction of a solitary kidney, it can rarely occur when there is a normal, contralateral kidney (Schlossberg and Vaughan, 1984). The diuresis is typically a normal physiologic response to the volume expansion and solute accumulation occurring during obstruction. Sodium, urea, and free water are eliminated, and the diuresis subsides after solute and fluid homeostasis is achieved. With the return of homeostasis, the period of diuresis ends (Loo and Vaughan, 1985).

However, a "pathologic" postobstructive diuresis may ensue, characterized by inappropriate renal handling of water or solutes, or both. It is due to a number of mechanisms previously reviewed in this chapter, including a derangement of the medullary solute gradient and a number of altered signaling and transport pathways. Downregulation of sodium transporters with subsequent impaired sodium reabsorption in the thick ascending limb of the Henle loop prevents maintenance of the medullary interstitial solute gradient, promoting a continued diuresis (Rokaw et al, 1996). The increased endogenous production and altered regulation of ANP induce a saline diuresis (Kim et al, 2001b). In addition, other natriuretic peptides, such as the *Dendroaspis* natriuretic peptide, may play a role (Kim et al, 2002). Pathologic postobstructive diuresis is also marked by poor responsiveness of the collecting duct to antidiuretic hormone (ADH). This is thought to be due to a downregulation of aquaporin water channels in this segment of the nephron and perhaps in the proximal tubule, which has been demonstrated in experimental models of UUO and BUO (Nielsen and Agre, 1995; Frøkiaer et al, 1996; Kim et al, 2001a; Li et al, 2003).

Various reasons have been proposed for the rare occurrence of postobstructive diuresis with release of UUO and a normal contralateral kidney. GFR may be atypically preserved in the setting of distal tubular damage such that the kidney filters a normal volume but there is limited free water reabsorption. Alternatively, a pronounced aquaporin channel defect may be present, causing diminished free water absorption in this setting (Schlossberg and Vaughan, 1984; Li et al, 2003). An experimental study by Nørregaard and colleagues (2007) concluded that decreased Na^+,K^+,$2Cl^-$ cotransporter type 2, collapse of the inner medulla osmotic gradient, and suppressed phosphorylated renal aquaporins (AQP2) may be responsible for the impaired urine-concentrating capacity in the chronic postobstructive phase following release of ureteral obstruction. The rarity of this condition has been ascribed to compensatory retention of salt and water by the contralateral renal unit (Frøkiaer et al, 2007).

Clinical Management of Postobstructive Diuresis

The majority of patients do not demonstrate a clinically significant postobstructive diuresis following relief of urinary tract obstruction. Those who are susceptible to this phenomenon typically have signs of fluid overload including edema, congestive heart failure, or hypertension (Loo and Vaughan, 1985). The most common clinical setting is release of urinary retention. A catheter should be placed to drain the bladder rapidly in those with urinary retention. There is no role for gradual bladder decompression, because this has not been demonstrated to limit hematuria or the risk of postobstructive diuresis (Nyman et al, 1997).

Subjects in whom BUO or UUO in a solitary kidney is relieved should be monitored for a postobstructive diuresis. Serum electrolytes, magnesium, blood urea nitrogen (BUN), and creatinine should be checked. The intensity of monitoring depends on presence of risk factors for postobstructive diuresis and the subject's mental status, renal function, and electrolyte status. Those with normal renal function and electrolytes, no evidence of fluid overload, and who are mentally alert should have their vital signs and urine output monitored. They are allowed free access to oral fluids, and if they do not manifest signs of a postobstructive diuresis they can be discharged and return later for further urologic evaluation and care. If they show signs of a postobstructive diuresis but are alert, able to consume fluids, and have normal vital signs, observation is continued and the patients may consume fluids as desired. **This is a physiologic diuresis that, in the majority of cases, resolves when free water and excess solutes are eliminated.** Serum electrolytes, BUN, magnesium, and creatinine are checked daily until the diuresis resolves. If patients have signs of fluid overload, azotemia, or poor cognitive function, or if hypotension or other indicators of hypovolemia develop, more intense monitoring should be instituted. Vital signs and urine output are

checked more frequently. Electrolytes, BUN, magnesium, and creatinine are assessed every 12 hours, and more frequently if necessary. Urinary osmolarity should be checked in this setting. Hypo-osmolar urine is indicative of a primary water diuresis as opposed to a solute diuresis. Of note, an initial solute diuresis may convert to a pathologic water diuresis, underscoring the need for obtaining a baseline urine osmolarity and continued monitoring of this parameter.

The clinically stable patient with good cognitive function should be given free access to oral fluids. Intravenous fluids should probably not be administered, because this may prolong the period of diuresis. However, there may be a theoretical role for maintenance of volume expansion in this setting. Gulmi and associates (1995) demonstrated improved GFR in dogs undergoing volume expansion just prior to relief of BUO. This is linked to increased generation of ANP and the salutary effects of this peptide on RBF and GFR. A clinical trial is needed to determine whether this would facilitate recovery of GFR in humans.

Those with poor cognitive function should receive intravenous hydration, but below the normal maintenance amounts. The majority of these groups also have a self-limiting physiologic diuresis. On rare occasions, a pathologic diuresis develops and the patients can become hypovolemic because of excess water loss. They can develop electrolyte abnormalities as a result of this excess water loss, salt and potassium losses, or both. Massive polyuria with sodium, chloride, potassium, bicarbonate, phosphate, calcium, and magnesium wasting in this setting may promote electrolyte disturbances. These patients warrant the most intense monitoring and require careful electrolyte and fluid replacement, initially by an intravenous route. The urine is usually isosthenuric initially and intravenous fluid replacement with 0.45% saline administration at a rate lower than the urine output is recommended (Frøkiaer and Zeidel, 2007). Changes in the type and amount of intravenous fluid administration are based on the patient's clinical status, serum, and urinary electrolytes. Some patients have salt wasting associated with hyponatremia and hyperkalemia, mimicking adrenal insufficiency. This has been reported to occur mainly in children (Melzi et al, 1995). It is thought to be due to tubular resistance to aldosterone, and supporting evidence for this is the significantly increased serum aldosterone levels reported in these cases. The underlying cause may be a reduction in aldosterone receptors (Kuhnle et al, 1993).

Experimental Modulation of Postobstructive Diuresis

Animal and cell culture experiments demonstrate the potential of pharmacologically attenuating postobstructive diuresis. Ureteral obstruction induces expression of COX-2 in collecting duct cells (Guan et al, 1997). Evidence suggests that the downregulation of AQP2 receptors is mediated by COX-2. Administration of COX-2 inhibitors prevented the downregulation of AQP2 and significantly diminished postobstructive diuresis in rats with BUO (Cheng et al, 2004). In addition, with ureteral obstruction, there is blunted cAMP generation in response to vasopressin (Kim et al, 2001a). Vasopressin-induced, cAMP-mediated pathways induce phosphorylation and subsequent membrane insertion of AQP2 (Nishimoto et al, 1999; Van Balkom et al, 2002). A cAMP-independent, cyclic guanosine monophosphate (cGMP) pathway has been demonstrated in both in-vitro and in-vivo models to allow membrane insertion of AQP2 (Bouley et al, 2000). Acute exposure to the phosphodiesterase type 5 inhibitor sildenafil citrate elevated intracellular cGMP and has been shown to facilitate collecting duct accumulation of AQP2 (Bouley et al, 2005). **Although such data suggest that postobstructive diuresis can be manipulated pharmacologically, it is unclear whether such manipulation would be ultimately beneficial or harmful.**

SELECTED EXTRINSIC CAUSES OF URETERAL OBSTRUCTION

A plethora of intraperitoneal and extraperitoneal disease processes may ultimately result in ureteral obstruction. Hydronephrosis, either symptomatic or incidental, may thus be the initial presentation of these conditions. Herein, selected extrinsic causes of ureteral obstruction are reviewed.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is an uncommon condition in which a fibrotic and inflammatory mass envelops and potentially obstructs retroperitoneal structures, including either or both ureters. The initial report is now attributed to Albarran (1905), although idiopathic retroperitoneal fibrosis has had the eponym Ormond disease, after that author's description and definition of this clinical entity in 1948 (Albarran, 1905; Ormond, 1948). Of the two patients Ormond initially described, one had progressive renal deterioration and ultimately died of the disease, whereas the other underwent exploration and ureterolysis without subsequent signs or symptoms of recurrent ureteral obstruction during the ensuing 12 years, underscoring the need to recognize and address this process (Ormond, 1960).

Grossly, retroperitoneal fibrosis appears as a fibrous, whitish plaque that encases the aorta, inferior vena cava, and their major branches, and also the ureters, other retroperitoneal structures, and, at times, intraperitoneal structures including the gastrointestinal tract. Its longitudinal axis usually extends from the renal hilum to the pelvic brim, but it may extend into the pelvis, mediastinum, and even the optic orbit. Histologic features include a fibrous component and a chronic inflammatory infiltrate composed of lymphocytes, macrophages, plasma cells, and eosinophils. The infiltrate is both perivascular and diffuse. The fibrotic component consists of myofibroblasts and type-1 collagen (Corradi et al, 2007).

The etiology of retroperitoneal fibrosis is not well characterized. A number of mechanisms have been proposed. One is based on the development of vasculitis in the adventitial vessels of the aorta and perioaortic small vessels. This may lead to the release of antigens from atheromatous plaque such as ceroid, a complex lipoprotein, which induces an autoimmune antigenic response. The latter could induce local inflammation resulting in varying degrees of fibrosis (Baker, 2003). Antibodies for fibroblasts have been isolated in retroperitoneal fibrosis (Vaglio et al, 2006). In-vitro studies have demonstrated that such antibodies stimulate fibroblasts that could lead to the propagation of localized fibrosis (Chizzolini et al, 2002). Other immunologic events may play a role. Both CD3+ and CD20+ lymphocytes and IgG4-positive plasma cells have been identified (Corradi et al, 2007). The presence of clonal and oligoclonal B cells suggest that an errant B-cell disorder may play a role. Environmental toxins may play a role as suggested by the positive association between asbestos exposure and the development of retroperitoneal fibrosis (Uibu et al, 2004).

Limited information is available on its epidemiology. The incidence in Finland was reported to be 0.1 per 100,000 person-years

and the prevalence to be 1.38 per 100,000 inhabitants of this country (Uibu et al, 2004). The incidence has been estimated to be 1 in 200,000 in the Netherlands (Debruyne et al, 1982). It is more common in males, with a 2 to 3:1 male-to-female ratio. The mean age at onset is typically 50 to 60 years, but it may manifest in children as well as the elderly (Wu et al, 2002; Miller et al, 2003; Vaglio et al, 2006). Genetic influence is not thought to play a major role, because there have been no reports of familial clustering. Retroperitoneal fibrosis is associated with HLA-DRB1*03, an allele linked to a number of autoimmune diseases (Martorana et al, 2006).

Numerous medications have been associated with the development of retroperitoneal fibrosis and are listed in Table 40–2, along with other etiologies of this process. A definitive etiology of retroperitoneal fibrosis is found in only 30% of cases (Koep et al, 1977). The term "idiopathic retroperitoneal fibrosis" should be used only when an inciting etiology is not defined. **An underlying malignancy should always be considered, because one is reported to be present in 8% to 10% of such cases** (Amis, 1991). Unique infections can cause retroperitoneal fibrosis such as tuberculosis, histoplasmosis, and actinomycosis. It can occur after abdominal or pelvic surgery as well as abdominal trauma. Radiation and systemic chemotherapy have also been reported to induce it (Fassina et al, 2007; Vaglio et al, 2006).

Table 40–2.

Suspected Causes of Retroperitoneal Fibrosis

Drugs
Methysergide
Hydralazine
Reserpine
Haloperidol
LSD
Methyldopa
β Blockers
Ergotamine alkaloids
Phenacetin
Amphetamines
Pergolide
Bromocriptine
Chemicals
Avitene
Methyl methacrylate
Talcum powder
Retroperitoneal tumors
Inflammatory processes
Ascending lymphangitis
Chronic inflammatory bowel disease
Asbestosis
Amyloidosis
Erdheim-Chester disease
Sarcoidosis
Hemorrhage
Abdominal and pelvic surgery
Ruptured viscera
Henoch-Schönlein purpura with hemorrhage
Periarteritis
Aortic or iliac artery aneurysm
Inflammatory response to advanced atherosclerosis
Collagen vascular disease
Infection
Gonorrhea
Tuberculosis
Chronic urinary tract infection
Syphilis
Radiation injury
Other
Biliary tract disease
Endometriosis

A number of associations between retroperitoneal fibrosis and systemic diseases have been reported including autoimmune and inflammatory processes. These include autoimmune pancreatitis, autoimmune thyroid disease, small- and medium-sized vessel vasculitis, ankylosing spondylitis, rheumatoid arthritis, glomerulonephritis, sclerosing cholangitis, primary biliary cirrhosis, uveitis, psoriasis, and amyloidosis and Erdheim-Chester disease (Vaglio et al 2006; Loddenkemper et al, 2008).

Patients usually have nonspecific symptoms, which may include back, abdominal, or flank pain, weight loss, anorexia, and malaise. Signs can be similarly nonspecific and include hypertension (in 50%), fever, and lower extremity edema. Because of its insidious nature, many patients do not present until late in the disease course, manifesting with signs or symptoms attributable to ureteral or vascular obstruction (Amis, 1991). Reported laboratory abnormalities are nonspecific and include elevations in acute phase reactants, such as erythrocyte sedimentation rate and C-reactive protein (in 80% to 100%), elevated serum creatinine, hypergammaglobulinemia, and normochromic, normocytic anemia (Monev, 2002; Vaglio et al, 2006). Tests for autoimmune diseases may also be positive, such as those for antinuclear antibodies, rheumatoid factor, and antibodies against smooth muscle, double-stranded DNA, extractable nuclear antigen and neutrophil cytoplasm (Vaglio et al, 2006).

Before the advent of cross-sectional imaging, radiologic diagnosis relied upon imaging not the disease process itself but its secondary effects on the ureters. The classic radiologic findings included medial deviation of extrinsically compressed ureters with hydronephrosis. Medial deviation is a nonspecific finding, because it has been demonstrated in up to 18% of normal subjects (Saldino and Palubinskas, 1972). Hydronephrosis is typically demonstrated on ultrasonography, and there may also be a smooth, well-demarcated, hypoechoic or isoechoic mass anterior to the lumbar or sacral spine (Amis, 1991). Retrograde pyelography typically demonstrates hydronephrosis, with medially deviated and segmentally narrowed ureters without filling defects (Fig. 40–10). Currently, cross-sectional imaging with CT or MRI is the modality of choice for evaluating patients with suspected retroperitoneal fibrosis. Both modalities have been demonstrated to delineate accurately the extent of the disease when correlated with surgical exploration (Mulligan et al, 1989). **CT typically reveals a well-demarcated retroperitoneal mass, isodense with muscle on unenhanced studies** (Fig. 40–11) (Vivas et al, 2000). It typically surrounds the lower abdominal aorta, inferior vena cava, and iliac vessels—frequently enveloping the ureters. In contrast, masses secondary to malignancy usually displace the aorta anteriorly and the ureters laterally. Variable degrees of contrast enhancement may be seen, typically more pronounced earlier in the course of the disease when the presumably more-immature plaque has increased vascularity (Amis, 1991). Some have advocated noncontrast multidetector CT imaging combined with antegrade CT pyelography for evaluation, because it can define the fibrotic process and the level and degree of ureteral obstruction without administration of intravenous contrast material (Ghersin et al, 2004). However, the invasive nature of this diagnostic approach limits its applicability.

MRI offers cross-sectional and multiplanar evaluation of the retroperitoneal fibrosis plaque (Fig. 40–12). **Theoretically, MRI**

allows superior soft tissue discrimination and can more accurately distinguish the plaque from the great vessels than unenhanced CT. In addition, the disease can be followed without the radiation exposure of repeated CT (Burn et al, 2002). Fat saturation images are recommended to permit optimal discrimination from surrounding tissues (Elsayes et al, 2007; Cronin et al, 2008). Typically, T1-weighted images of the lesion reveal low to medium signal intensity (hypointense compared with muscle); T2-weighted imaging is variable. Low T2 signal intensity has been correlated with mature plaque (Mulligan et al, 1989). High signal intensity on T2-weighted images suggests increased water content and hypercellularity and may be due to inflammation associated with retroperitoneal fibrosis. However, the latter may be due to an underlying malignant process (Amis, 1991; Burn et al, 2002). A low intensity signal is present if the majority of the plaque is composed of fibrosis. With gadolinium administration, variable enhancement of the plaque may be seen, with a greater degree of enhancement in the more acute phases of the disease process. Enhancement ratios can be calculated with dynamic gadolinium enhancement, and investigators have used these ratios to assess disease activity and monitor treatment responses (Burn et al, 2002). ^{18}F-fluorodeoxyglucose positron emission tomography (F-18 FDG PET) is an imaging modality that detects hypermetabolic activity. It may depict the degree of inflammation in the plaque, which may predict response to immunosuppressive therapy as well as its therapeutic response (Vaglio et al, 2006; Young et al, 2008). The utility of F-18 FDG PET for management of retroperitoneal fibrosis is not yet defined; thus, further studies are warranted. Gallium-67 single photon emission–computed tomography (SPECT) scintigraphy has been used for evaluating responses to medical therapy of retroperitoneal fibrosis and for detection of recurrent disease. It demonstrates both the mass lesion and its inflammatory component (van Bommel et al, 2007).

If there is evidence of obstructive uropathy at presentation, therapy should be first directed at its correction. This may be accomplished with internalized ureteral stents, but percutaneous nephrostomy may be necessary if stenting is not possible or ineffective. **Biopsy to exclude malignancy should be performed next. This can be attempted percutaneously with CT, MRI, or ultrasound guidance.** Core tissue biopsy (histologic confirmation) is preferred over fine needle aspiration cytologic assessment. Although some have reported the latter to be an effective technique, others have noted pitfalls (Stein et al, 1997; Dash et al, 1999; Jogai, 2005). If this is not technically possible, or the tissue obtained is inadequate, an open surgical or laparoscopic biopsy is recommended with concomitant ureterolysis if malignancy is not suspected on frozen-section analysis. If the percutaneous biopsy demonstrates findings compatible with retroperitoneal fibrosis, possible inciting medications should be discontinued.

The potential morbidity of ureterolysis, accurate image-guided biopsy techniques, and more sensitive cross-sectional imaging studies for diagnosis and follow-up have made medical therapy the preferred approach in this setting. However, notably, there have

been no randomized prospective studies addressing the merits of initial medical therapy versus a surgical approach. Patients should be informed about the side effects of the proposed medical therapy and the risk of disease progression or undiagnosed malignancy. Medical therapy has been directed to address the presumed autoimmune and inflammatory components of retroperitoneal fibrosis.

The administration of corticosteroids has been used for primary therapy. Although many steroid regimens have been described, appropriate dosing schedules and duration of therapy have not been clearly established. The sequence suggested by Kardar and colleagues (2002) has been demonstrated to be effective after long-term follow-up. Their algorithm for adults consists of prednisolone administered at an oral dose of 60 mg on alternate days for 2 months, tapered to 5 mg daily over the next 2 months. The latter dose is continued for a total of 2 years. Of the 11 patients who completed this regimen, at a median follow-up of 63 months, 9 maintained a good response, 1 required ureterolysis, and 1 recurred but responded to reinitiation of therapy. van Bommel and associates (2007) treated 24 patients with prednisone for 1 year. They were initially treated with 60 mg per day for 6 weeks and tapered to 10 mg over the next 2 to 3 months, a dosage which was maintained for the remainder of the year. Six subjects (25%) had no response to the therapy, while 12 of 16 responders (67%) had relapses, with the majority responding to reinitiation of prednisone or alternative medical therapy at a median follow-up of 55 months. Fry and colleagues (2008) treated 27 patients with 30 to 40 mg of prednisolone per day for a mean of 34 months. Ureteral stents were typically removed at 12 months. Twenty-four (89%) initially responded, and 6 recurred at a mean of 15 months after steroid withdrawal.

Tamoxifen, a nonsteroidal antiestrogen, has also been used for primary treatment. It is thought to alter TGF-β, potentially limiting fibrosis. van Bommel and associates (2007) treated 19 patients with 20 mg of tamoxifen per day. The median duration of treatment was 8.5 months (range 5.5 to 15 months). Fourteen responded to therapy (74%) and 5 failed (26%). Successful combination therapy using a tapered steroid regimen and daily tamoxifen has also been described (Tziomalos et al, 2004).

Other treatments have been used as primary or salvage therapy for those afflicted with retroperitoneal fibrosis. Marcolongo and colleagues (2004) reported 26 patients who were treated with a 6-month course of prednisone, combined with either 6 months of cyclophosphamide or 1 year of azathioprine. Severe adverse effects in the cyclophosphamide group included death in one, sepsis in one, and severe leukopenia in two patients. In the azathioprine group, activation of hepatitis, pancreatitis, and oral candidiasis developed. All surviving patients had disease resolution, although seven required a second course of treatment. Swartz and associates (2008) treated 16 patients with idiopathic retroperitoneal fibrosis with a 3- to 6-month course of prednisone in conjunction with mycophenolate mofetil for approximately 2 years. One half of these patients were subjected to ureterolysis or ureteral reconstruction, while the others just underwent ureteral stenting. All had resolution or improvement of symptoms and were rendered stent free. Other groups have reported success with this regimen. Adler and colleagues (2008) treated 9 patients having histologically confirmed retroperitoneal fibrosis with these same two drugs for 6 months. All had radiographic regression of the retroperitoneal fibrosis, and 7 were rendered stent free. Scheel and associates reported on 7 patients receiving a similar regimen (Scheel et al, 2007). Six of 7 had radiographic regression, and 10 of 11 with obstructed renal units became stent free. Vega and colleagues (2008) administered colchicine and prednisone or deflazacort (steroid preparation) to 7 patients and reported that the majority experienced a regression in their disease. The coadministration of steroids in all of these series does not permit the determination of the efficacy of these various respective agents.

Ureterolysis is undertaken if medical therapy fails or if the patient is not a candidate for medical therapy. Traditionally, this has been done by an open surgical approach, but successful laparoscopic and robotic ureterolysis have been reported and may be feasible options (Duchene et al 2007; Stifelman et al, 2008). Bilateral ureterolysis is recommended, even in the setting of unilateral disease, as the disease typically progresses to involve the contralateral side. The ureteral dissection should begin in a region free of disease, and care must be taken to avoid devascularization of the ureter. A biopsy of the fibrotic area should be repeated to limit the risk of sampling error associated with percutaneous biopsy. Several strategies have been employed to prevent recurrent ureteral involvement in the fibrotic process. **The ureter may be displaced to a lateral position, brought to an intraperitoneal location by closing the peritoneum behind it, or wrapped within a sleeve of omentum. No single method has been definitively demonstrated to generate superior results** (Barbalias and Liatsikos, 1999). If it

is determined intraoperatively that ureterolysis is not technically possible, alternatives include ileal ureter replacement, autotransplantation, chronic ureteral stenting, or nephrostomy tube drainage.

Ureteral stents can generally be removed 6 to 8 weeks after ureterolysis (Varkarakis and Jarrett, 2005). Some have advocated postoperative medical therapy to expedite disease resolution or prevent recurrence (Varkarakis and Jarrett, 2005). Others have not found differences in outcomes for those who receive versus those who are not administered adjuvant therapy (Duchene et al, 2007).

Reported success rates for small series involving ureterolysis are 66% to 100%. The best success rate was reported by Elashry and colleagues (1996): 100% for seven laparoscopic and 100% in six open surgical procedures. Duchene and associates (2007) subjected 31 patients to laparoscopic or robotic ureterolysis and reported that this was successful in 38 of 46 obstructed renal units (83%). Alexopoulos and associates (1987), however, noted only 66% long-term success with ureterolysis combined with postoperative steroid administration in six patients. Of note, one of their patients failed 16 years after surgery and became dialysis dependent. **Long-term follow-up in those subjected to medical or surgical therapy is warranted.** Serial cross-sectional imaging should be obtained to assess for disease recurrence, progression, or findings suggestive of malignancy. Renal function should also be monitored.

Pelvic Lipomatosis

Pelvic lipomatosis is a rare, benign condition marked by exuberant pelvic overgrowth of nonmalignant but infiltrative adipose tissue, usually in the abdominal and pelvic cavities. The fat deposition generally occurs in the perivesical and perirectal spaces. Engels first described the condition in 1959, and it has been the subject of several reviews and many case reports in the interim. The largest review to date comprised 130 patients, whose mean age at presentation was 48 years. Racial and gender differences were noted, with 67% of the patients black and 33% white; there was an 18:1 male-to-female ratio (Heyns, 1991).

The etiology and incidence of this disorder are unknown. Obesity has been proposed to play a role, because radiographic improvement and worsening have been noted in response to weight loss and gain, respectively (Sacks et al, 1975). In addition, obesity has been noted in more than one half of the patients afflicted by pelvic lipomatosis (Heyns, 1991). However, if pelvic lipomatosis were simply a manifestation of obesity, its observed frequency should be far greater (Morretin and Wilson, 1971). The reported occurrence of pelvic lipomatosis in two brothers raises the possibility of an underlying genetic etiology (Tong et al, 2002). An abnormality in the chromatin-regulating high-mobility group A (HMGA) proteins has been implicated as a possible causative factor in pelvic lipomatosis, because transgenic mice with truncated HMGA developed pelvic lipomatosis (Fedele et al, 2001). Possible etiological genetic mutations have been traced to the HMGA2 gene located on the hypermobile cluster on chromosome 12 (Fedele et al, 2001). It is believed that pelvic lipomatosis may be a chronic inflammatory response triggered by urinary tract infection.

Approximately one half of patients present with lower urinary tract symptoms and one quarter with bowel symptoms, typically constipation. Suprapubic, back, flank, or perineal discomfort can also be an initial clinical manifestation. The nonspecific nature of these symptoms may result in a significant delay in diagnosis (Heyns, 1991). **Physical findings may include a suprapubic mass, a high-riding prostate, and an indistinct pelvic mass.** Hypertension has been reported in as many as one third of patients (Klein et al 1988; Heyns, 1991).
