Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication

This edition of *Campbell-Walsh Urology* is dedicated to the memory and contributions of Andrew Carl Novick. Andy was world class in every way—as a scholar, a surgeon, an innovator, and a friend. Andy assumed the chairmanship of Urology at the Cleveland Clinic in 1985 at the age of 37 and died at the too young age of 60 from complications of lymphoma. His lifetime dream of a urologic and kidney institute at the Cleveland Clinic was realized approximately 1 month before his death, with Andy as its first director. He joined the *Campbell*'s editorial staff as an associate for the 8th edition, was one of the five editors of the 9th edition, and was an equal contributor in organizing and selecting the authors for this 10th edition. Andy always strove for excellence and recognized and acknowledged quality. We hope he would have been proud of this edition.

Contributors

Robert Abouassaly, MD, MSc

Assistant Professor, Department of Urology
Case Western Reserve University School of Medicine;
Urologic Oncologist
Urologic Institute
University Hospitals Case Medical Center
Cleveland, Ohio

Paul Abrams, MD

Professor, Department of Urology
Bristol Urologic Institute
Southmead Hospital
Bristol, United Kingdom

Mark C. Adams, MD, FAAP

Professor, Department of Urology and Pediatrics
Vanderbilt University Medical Center;
Division of Pediatric Urology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Ashok Agarwal, PhD

Professor of Surgery
Department of Urology
Case Western Reserve University;
Director of Andrology
Director, Center for Reproductive Medicine
Department of Urology
Cleveland Clinic
Cleveland, Ohio

Mohamad E. Allaf, MD

Associate Professor, Departments of Urology, Oncology, and Biomedical Engineering
Johns Hopkins Medical Institutions;
Director of Minimally Invasive and Robotic Surgery
Johns Hopkins Hospital
Baltimore, Maryland

James Kyle Anderson, MD

Assistant Professor, Department of Urologic Surgery
University of Minnesota;
Staff Urologist, Department of Urologic Surgery
VA Medical Center
Minneapolis, Minnesota

Karl-Erik Andersson, MD, PhD

Professor, Department of Urology
Wake Forest University School of Medicine;
Professor, Institute for Regenerative Medicine
Wake Forest University Baptist Medical Center
Winston Salem, North Carolina

Kenneth W. Angermeier, MD

Associate Professor
Center for Genitourinary Reconstruction
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Emmanuel S. Antonarakis, MD

Assistant Professor of Oncology
Department of Medical Oncology
Johns Hopkins University;
Attending Physician, Department of Medical Oncology
Sidney Kimmel Comprehensive Cancer Center at John Hopkins
Baltimore, Maryland

Dean G. Assimos, MD

Professor of Surgical Sciences
Department of Urology
Wake Forest University School of Medicine;
Attending Physician, Department of Urology
Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

Anthony Atala, MD

W. Boyce Professor and Chair
Department of Urology
Wake Forest University School of Medicine;
Director, Wake Forest Institute for Regenerative Medicine
Winston Salem, North Carolina

Darius J. Bägli, MDCM, FRCSC, FAAP, FACS

Professor, Department of Surgery
Division of Urology and Institute of Medical Science
University of Toronto;
Senior Attending Urologist
Associate Surgeon-in-Chief
The Hospital for Sick Children;
Director of Urology Research
Senior Associate Scientist
Division of Developmental and Stem Cell Biology
The Hospital for Sick Children Research Institute
Toronto, Ontario, Canada

John Maynard Barry, MD

Professor Emeritus of Surgery
Divisions of Urology and Abdominal Organ Transplantation
The Oregon Health and Science University;
Staff Surgeon
University Hospital and Doenbecher Children's Hospital;
Consultant, Surgery
Veterans Affairs Medical Center
Portland, Oregon

Julia Spencer Barthold, MD

Professor of Urology and Pediatrics
Jefferson Medical College at Thomas Jefferson University
Philadelphia, Pennsylvania;
Associate Chief and Head of Urology Research Laboratory
Department of Surgery/Urology
Nemours/Alfred I. DuPont Hospital for Children;
Head, Urology Laboratory
Nemours Biomedical Research
Wilmington, Delaware

Stuart B. Bauer, MD

Professor of Surgery (Urology)
Harvard Medical School;
Senior Associate in Urology
Children's Hospital Boston
Boston, Massachusetts

Clair J. Beard, MD

Director, Testicular Cancer Center
Department of Radiation Oncology
Dana-Farber Cancer Institute and Brigham and Women's Hospital
Boston, Massachusetts

Arie S. Belldegrun, MD

Roy and Carol Doumani Chair in Urologic Oncology
Professor and Chief, Urologic Oncology
Director, Institute of Urologic Oncology
David Geffen School of Medicine at UCLA;
Department of Urology
Ronald Reagan UCLA Medical Center
Los Angeles, California

Mitchell C. Benson, MD

Herbert & Florence Irving and George F. Cahill Professor and Chair
Department of Urology
Columbia University College of Physicians and Surgeons;
Urologist-in-Chief, Department of Urology
New York-Presbyterian Hospital, Columbia University Medical Center
New York, New York

Brian M. Benway, MD

Assistant Professor, Department of Surgery
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, Missouri

Ryan Kent Berglund, MD

Assistant Professor of Surgery
Glickman Urologic and Kidney Institute
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University
Cleveland Clinic
Cleveland, Ohio

David M. Berman, MD, PhD

Associate Professor, Departments of Pathology, Oncology, and Urology
Johns Hopkins University School of Medicine;
Attending Pathologist
Johns Hopkins Hospital
Baltimore, Maryland

Sam B. Bhayani, MD

Associate Professor, Department of Surgery
Co-Director of Robotic Surgery
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, Missouri

Jay Todd Bishoff, MD, FACS

Clinical Professor of Surgery
Department of Urology
University of Utah School of Medicine;
Director, Intermountain Urological Institute
Intermountain Healthcare;
Director, Department of Urology
LDS Hospital
Salt Lake City, Utah;
Director, Department of Urology
Intermountain Medical Center
Murray, Utah

Michael L. Blute, Sr., MD

Professor, Department of Surgery
Mary C. DeFeudis Chair, Cancer Care and Research
University of Massachusetts Memorial Medical School;
Director, Cancer Center of Excellence
Interim Chief, Department of Urology
UMass Memorial Medical Center
Worcester, Massachusetts

Joseph G. Borer, MD

Assistant Professor, Department of Surgery
Harvard Medical School;
Assistant in Urology
Department of Urology
Children's Hospital Boston
Boston, Massachusetts

George J. Bosl, MD

Professor, Department of Medicine
Weill Cornell Medical College;
Chair, Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Charles B. Brendler, MD

Clinical Professor, Department of Surgery
Division of Urology
University of Chicago Medical Center
Chicago, Illinois;
Vice Chairman, Research and Development
Department of Surgery
North Shore University Health System
Evanston, Illinois

Gregory A. Broderick, MD

Professor, Department of Urology
Mayo Clinic College of Medicine;
Consultant, Department of Urology
Mayo Clinic
Jacksonville, Florida

James D. Brooks, MD

Associate Professor, Department of Urology
Stanford University School of Medicine
Stanford, California

Arthur L. Burnett, MD, MBA, FACS

Patrick C. Walsh Professor of Urology
Department of Urology
Johns Hopkins Medical Institutions
Baltimore, Maryland

Jeffrey A. Cadeddu, MD

Professor, Departments of Urology and Radiology
University of Texas Southwestern Medical Center
Dallas, Texas

Anthony A. Caldamone, MD, MMS, FAAP, FACS

Professor of Surgery (Urology) and Pediatrics
Division of Urology
Warren Alpert Medical School of Brown University
Rhode Island Hospital;
Head of Pediatric Urology
Hasbro Children's Hospital
Providence, Rhode Island

Steven C. Campbell, MD, PhD

Professor of Surgery
Department of Urology
Cleveland Clinic Lerner of College of Medicine at Case Western Reserve University;
Professor of Surgery
Director, Urology Residency Program
Vice Chairman, Urology
Center for Urologic Oncology
Cleveland Clinic
Cleveland, Ohio

Douglas A. Canning, MD

Professor, Department of Urology
University of Pennsylvania School of Medicine;
Director, Division of Pediatric Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Michael A. Carducci, MD

AEGON Professor in Prostate Cancer Research
Departments of Oncology and Urology
Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins
Baltimore, Maryland

Michael C. Carr, MD, PhD

Associate Professor, Department of Urology
University of Pennyslvania School of Medicine;
Attending Surgeon, Division of Pediatric Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Peter R. Carroll, MD, MPH

Professor and Chair, Department of Urology
University of California, San Francisco
UCSF Medical Center
San Francisco, California

Herbert Ballentine Carter, MD

Professor, Departments of Urology and Oncology
Johns Hopkins School of Medicine
Baltimore, Maryland

Anthony J. Casale, MD

Professor and Chairman, Department of Urology
University of Louisville;
Chief of Urology
Kosair Children's Hospital;
Chief of Urology and Surgery (Urology)
University of Louisville Hospital
Louisville, Kentucky

Pasquale Casale, MD

Assistant Professor, Department of Urology
University of Pennsylvania School of Medicine;
Attending Surgeon, Division of Pediatric Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

William J. Catalona, MD

Professor, Department of Urology
Northwestern University Feinberg School of Medicine;
Director, Clinical Prostate Cancer Program
Robert H. Lurie Comprehensive Cancer Center
Northwestern Memorial Hospital
Chicago, Illinois

R. Duane Cespedes, MD

Associate Professor, Department of Urology
Johns Hopkins School of Medicine;
Co-Director, Women's Center for Pelvic Health
James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Michael B. Chancellor, MD

Clinical Professor, Department of Urology
Oakland University William Beaumont School of Medicine;
Director, Neurourology Program
William Beaumont Hospital
Royal Oak, Michigan

Christopher R. Chapple, MD, FRCS (Urol), FEBU

Honorary Professor, Faculty of Health and Wellbeing
Sheffield Hallam University;
Honorary Senior Lecturer of Urology
University of Sheffield;
Consultant Urological Surgeon
Department of Urology
Sheffield Teaching Hospitals NHS Foundation Trust
Sheffield, United Kingdom;
Adjunct Secretary General for Education
European Association of Urology
Arnhem, The Netherlands

Christopher J. Chermansky, MD

Assistant Professor, Department of Urology
Louisiana State University Health Sciences Center
New Orleans School of Medicine
New Orleans, Louisiana

Robert L. Chevalier, MD

Harrison Professor of Pediatrics
Department of Pediatrics
University of Virginia;
Pediatric Nephrologist
University of Virginia Health System
Charlottesville, Virginia

George K. Chow, MD

Assistant Professor, Department of Urology
Consultant in Urology
Mayo Clinic
Rochester, Minnesota

Jeanne S. Chow, MD

Assistant Professor, Department of Radiology
Harvard Medical School;
Pediatric Radiologist
Children's Hospital Boston
Boston, Massachusetts

Benjamin I. Chung, MD

Assistant Professor, Department of Urology
Stanford University School of Medicine;
Director, Laparoscopic and Minimally Invasive Urologic Surgery
Department of Urology
Stanford Hospital and Clinics
Stanford, California

Ralph V. Clayman, MD

Dean, University of California, Irvine School of Medicine
Professor, Department of Urology
University of California, Irvine;
Professor, Department of Urology
UC Irvine Medical Center
Orange, California
Professor, Department of Urology
Long Beach Veterans Administration Hospital
Long Beach, California

Michael Joseph Conlin, MD, FACS

Associate Professor of Urology
Department of Surgery
Oregon Health & Science University
Portland, Oregon

Raymond A. Costabile, MD

Senior Associate Dean for Clinical Strategy
Professor, Department of Urology
University of Virginia
Charlottesville, Virginia

Paul L. Crispen, MD

Assistant Professor, Department of Surgery
Division of Urology
University of Kentucky
Lexington, Kentucky

Juanita M. Crook, MD, FRCPC

Professor, Department of Radiation Oncology
University of British Columbia;
Active Medical Staff
Department of Radiation Oncology
Kelowna General Hospital;
Radiation Oncologist
British Columbia Cancer Agency
Kelowna, British Columbia, Canada

Douglas M. Dahl, MD

Assistant Professor of Surgery (Urology)
Harvard Medical School;
Associate Urologist
Massachusetts General Hospital
Boston, Massachusetts

Anthony V. D'Amico, MD, PhD

Professor and Chief, Genitourinary Radiation Oncology
Brigham and Women's Hospital and Dana-Farber Cancer Institute
Boston, Massachusetts

John W. Davis, MD

Assistant Professor, Department of Urology
University of Texas MD Anderson Cancer Center
Houston, Texas

G. Joel DeCastro, MD, MPH

Assistant Professor, Department of Urology
Columbia University College of Physicians and Surgeons
New York, New York

John D. Denstedt, MD, FRCSC, FACS

Richard Ivey Professor and Chair, Department of Surgery
Schulich School of Medicine & Dentistry
The University of Western Ontario
Richard Ivey Professor and Chair, Division of Urology
Department of Surgery
London Health Sciences Centre and St. Joseph's Health Care London
London, Ontario, Canada

Theodore L. DeWeese, MD

Professor and Chair, Department of Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins University School of Medicine;
Radiation Oncologist-in-Chief
Johns Hopkins Hospital and Health System
Baltimore, Maryland

David Andrew Diamond, MD

Associate Professor of Surgery (Urology)
Harvard Medical School;
Senior Associate in Urology
Department of Urology
Children's Hospital Boston
Boston, Massachusetts

Roger R. Dmochowski, MD, FACS

Professor of Urologic Surgery
Vanderbilt University School of Medicine;
Director, Vanderbilt Continence Center
Director, Vanderbilt Female Reconstructive Fellowship
Executive Physician, Safety
Vanderbilt University Hospital
Nashville, Tennessee

Leo R. Doumanian, MD

Assistant Professor, Department of Urology
Temple University School of Medicine
Philadelphia, Pennsylvania

Marcus Drake, DM, MA, FRCS (Urol)

Senior Lecturer in Urology
School of Clinical Sciences
University of Bristol;
Consultant Surgeon
Urology Department
Southmead Hospital
Bristol, United Kingdom

Branden Duffey, DO

Endourology Fellow
Department of Urology
University of Minnesota and University of Minnesota Medical Center
Minneapolis, Minnesota

Daniel D. Dugi III, MD

Assistant Professor, Department of Urology
Oregon Health & Science University
Portland, Oregon

James A. Eastham, MD

Chief, Urology Service
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Louis Eichel, MD

Clinical Assistant Professor, Department of Urology
University of Rochester Medical Center;
Director, Minimally Invasive Surgery
Center For Urology
Rochester, New York

Mario A. Eisenberger, MD

R. Dale Hughes Professor of Oncology and Urology
Johns Hopkins University and The Johns Hopkins Hospital
Baltimore, Maryland

Jonathan I. Epstein, MD

Reinhard Professor of Urological Pathology
Departments of Pathology, Urology, and Oncology
Johns Hopkins Medical Institutions;
Director, Surgical Pathology
Department of Pathology
Johns Hopkins Hospital
Baltimore, Maryland

Carlos R. Estrada, Jr., MD

Assistant Professor, Department of Surgery
Harvard Medical School;
Assistant in Urology
Department of Urology
Children's Hospital Boston
Boston, Massachusetts

Robert L. Fairchild, PhD

Professor, Department of Molecular Medicine
Cleveland Clinic;
Professor, Department of Pathology
Case Western Reserve University School of Medicine
Cleveland, Ohio

Amr Fergany, MD, PhD

Staff Sections of Oncology, Minimally Invasive Surgery, and Robotics
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Michael N. Ferrandino, MD

Assistant Professor, Department of Surgery
Division of Urology
Duke University and Duke University Medical Center
Durham, North Carolina

Lynne R. Ferrari, MD

Associate Professor, Department of Anethesia
Harvard Medical School;
Medical Director, Preoperative Services and Operating Rooms
Chief, Division of Perioperative Anesthesia
Department of Anethesiology, Perioperative, and Pain Management
Children's Hospital Boston
Boston, Massachusetts

James H. Finke, PhD

Professor of Molecular Medicine
Department of Pathology
Case Western Reserve University School of Medicine;
Professor of Immunology
Joint-Appointment, Glickman Urological Institute and Taussig Cancer Institute
Cleveland Clinic
Cleveland, Ohio

John M. Fitzpatrick, MCh, FRCSI, FC Urol (SA), FRCSGlas, FRCS

Professor and Chairman, Department of Surgery
University College Dublin;
Professor of Surgery and Consultant Urologist
Department of Urology
Mater Misericordiae University Hospital
Dublin, Ireland

Robert C. Flanigan, MD

Albert J. Jr. and Claire R. Speh Professor and Chair
Department of Urology
Loyola University Medical Center and Stritch School of Medicine;
Professor, Department of Urology
Loyola University Health System
Maywood, Illinois

Stuart M. Flechner, MD, FACS

Professor, Department of Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Director of Clinical Research
Section of Renal Transplantation
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Tara Lee Frenkl, MD, MPH

Clinical Associate, Department of Surgery
Division of Urology
University of Pennyslvania Medical Center
Philadelphia, Pennsylvania

Dominic C. Frimberger, MD

Associate Professor, Department of Urology
University of Oklahoma Health Sciences Center;
Department of Urology
Children's Hospital and Presbyterian Hospital
Oklahoma City, Oklahoma

Pat F. Fulgham, MD, DABU, FACS

Clinical Professor, Department of Urology
University of Texas Southwestern Medical School;
Surgical Director, Oncology Services
Texas Health Presbyterian Dallas
Dallas, Texas

John P. Gearhart, MD

Professor and Director
Division of Pediatric Urology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Glenn S. Gerber, MD

Associate Professor of Surgery/Urology
University of Chicago Pritzker School of Medicine;
Director, Endourology
University of Chicago Medical Center
Chicago, Illinois

Jason L. Gerboc, DO

Staff Urologist
Department of Urology
Wilford Hall Medical Center
Lackland Air Force Base, Texas

Robert H. Getzenberg, PhD

The Donald S. Coffey Professor of Urology, Pharmacology, and Molecular Sciences
Department of Urology
Johns Hopkins University School of Medicine;
Director, James Buchanan Brady Urological Institute
Johns Hopkins Hospital
Baltimore, Maryland

Islam A. Ghoneim, MD, PhD

Staff, Urology Department
Cairo University
Cairo, Egypt;
Fellow, Department of Urology
Glickman Urologic and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Inderbir S. Gill, MD, MCh

Professor and Chairman, Department of Urology
Keck School of Medicine
University of Southern California
Director, USC Institute of Urology
Los Angeles, California

Timothy D. Gilligan, MD, MS

Director, Late Effects Clinic
Program Director, Hematology/Oncology Fellowship
Department of Solid Tumor Oncology
Taussig Cancer Institute;
Deputy Editor, Cleveland Clinic Journal of Medicine
Cleveland Clinic
Cleveland, Ohio

David A. Goldfarb, MD

Professor of Surgery
Department of Urology
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Surgical Director, Renal Transplantaton
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Marc Goldstein, MD, DSc (Hon)

Matthew P. Hardy Distinguished Professor, Urology and Reproductive Medicine
Weill Cornell Medical College;
Surgeon-in Chief, Male Reproductive Medicine and Surgery
Attending Urologist, Department of Urology
New York-Presbyterian Hospital, Weill Cornell Medical Center;
Senior Scientist, Center for Biomedical Reseach
The Population Council
New York, New York

Leonard G. Gomella, MD, FACS

Chairman, Department of Urology
The Bernard W. Godwin Jr. Professor of Prostate Cancer
Jefferson Medical College at Thomas Jefferson University;
Associate Director, Kimmel Cancer Center;
Director, Kimmel Cancer Center Network;
Chairman, Department of Urology
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Mark L. Gonzalgo, MD, PhD

Associate Professor, Department of Urology
Stanford University School of Medicine
Stanford, California

Ethan J. Halpern, MD, MSCE

Professor, Departments of Radiology and Urology
Jefferson Medical College at Thomas Jefferson University
Philadelphia, Pennsylvania

Misop Han, MD, MS

Associate Professor, Department of Urology
Johns Hopkins University School of Medicine;
Staff Surgeon, Department of Urology
Johns Hopkins Medical Institutions
Baltimore, Maryland

Philip M. Hanno, MD, MPH

Professor of Urology
Department of Surgery
University of Pennsylvania School of Medicine;
Attending Urologist, Department of Surgery
Hospital of the University of Pennsylvania and the Veterans Administration Medical Center
Philadelphia, Pennsylvania

Harry W. Herr, MD

Professor, Department of Urology
Weill Cornell Medical College;
Attending Surgeon, Department of Urology
Memorial Sloan-Kettering Cancer Center
New York, New York

Sender Herschorn, MDCM, FRCSC

Professor and Chairman, Division of Urology
Martin Barkin Chair, Urological Research
University of Toronto;
Attending Urologist, Division of Urology
Sunnybrook Health Sciences Centre
Toronto, Ontario, Canada

Thomas H.S. Hsu, MD

Director of Laparoscopic, Robotic, and Minimally Invasive Urologic Surgery
Northern California Kaiser Permanente Medical Center
Santa Clara, California

Mark Hurwitz, MD

Department of Radiation Oncology
Harvard Medical School;
Director, Regional Program Development
Department of Radiation Oncology
Dana-Farber/Brigham and Women's Cancer Center
Boston, Massachusetts

Douglas A. Husmann, MD

Professor and Chair, Department of Urology
Mayo Clinic
Rochester, Minnesota

Thomas W. Jarrett, MD

Professor and Chairman, Department of Urology
George Washington University School of Medicine
Washington, DC

J. Stephen Jones, MD, MBA

Professor of Surgery
Department of Urology
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Chairman, Department of Regional Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Gerald H. Jordan, MD, FACS, FAAP (Hon), FRCS (Hon)

Professor, Department of Urology
Eastern Virginia Medical School;
Urology of Virginia
Norfolk, Virginia

David B. Joseph, MD, FACS, FAAP

Professor, Department of Surgery
Chief, Pediatric Urology
University of Alabama at Birmingham;
Beverly P. Head Endowed Chair in Pediatric Urology
Children's Hospital
Birmingham, Alabama

Martin Kaefer, MD, FAAP, FACS

Professor, Department of Urology
Division of Pediatric Urology
Indiana University School of Medicine
Indianapolis, Indiana

Jihad H. Kaouk, MD

Professor, Department of Surgery
Cleveland Clinic Learner College of Medicine;
Director, Laparoscopic and Robotic Surgery
Department of Urology
Cleveland Clinic
Cleveland, Ohio

Irving D. Kaplan, MD

Assistant Professor, Department of Radiation Oncology
Harvard Medical School;
Staff Radiation Therapist
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Louis R. Kavoussi, MD, MBA

Chairman and Waldbaum-Gardner Distinguished Professor
Smith Institute for Urology
Hofstra North Shore–LIJ School of Medicine
New York, New York

Parviz K. Kavoussi, MD

Andrology Fellow
Department of Urology
University of Virginia
Charlottesville, Virginia;
Andrologist/Urologist
Austin Fertility & Reproductive Medicine
Austin, Texas

Patrick A. Kenney, MD

Clinical Associate, Department of Urology
Tufts University School of Medicine
Boston, Massachusetts;
Chief Resident, Institute of Urology
Lahey Clinic
Burlington, Massachusetts

Antoine E. Khoury, MD, FRCSC, FAAP

Professor, Department of Urology
Chief, Pediatric Urology
University of California, Irvine;
Medical Director, Pediatric Urology
Children's Hospital of Orange County;
Chief, Pediatric Urology
UCI Medical Center
Orange, California

Roger Sinclair Kirby, MD, MA, FRCS

Professor, Department of Urology
University of London;
The Prostate Centre
London, United Kingdom

Eric A. Klein, MD

Professor, Department of Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Chairman, Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Kathleen C. Kobashi, MD

Associate Clinical Professor, Department of Urology
University of Washington School of Medicine;
Head, Section of Urology and Renal Transplantation
Department of Surgery
Virginia Mason Medical Center
Seattle, Washington

Michael O. Koch, MD

Chairman and John P. Donohue Professor
Department of Urology
Indiana University School of Medicine
Indianapolis, Indiana

John N. Krieger, MD

Professor, Department of Urology
University of Washington School of Medicine;
Chief, Department of Urology
VA Puget Sound Health Care System;
Attending Surgeon, Department of Urology
University of Washington Medical Center and Harborview Medical Center
Seattle, Washington

Bradley P. Kropp, MD, FAAP

Professor and Vice Chairman, Department of Urology
Chief, Pediatric Urology
University of Oklahoma Health Science Center
Oklahoma City, Oklahoma

Alexander Kutikov, MD

Assistant Professor of Urologic Oncology
Department of Surgical Oncology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Sarah M. Lambert, MD

Assistant Professor, Department of Surgery
The University of Pennsylvania;
Staff Urologist, Department of Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Raymond S. Lance, MD

The Paul F. Schellhammer Professor of Cancer Research
Associate Professor, Departments of Urology and Microbiology and Cancer Biology
Eastern Virginia Medical School;
Sentara Norfolk General Hospital
Sentara Medical Group—Urology of Virginia
Norfolk, Virginia

Brian R. Lane, MD, PhD

Clinical Associate Professor, Department of Surgery
Michigan State University;
Attending Physician, Department of Urology
Spectrum Health Hospital System
Grand Rapids, Michigan

William A. Larchian, MD

Associate Professor, Department of Surgery
Case Western Reserve University School of Medicine;
Center for Urologic Oncology
Urological Institute
University Hospitals Case Medical Center
Cleveland, Ohio

Richard S. Lee, MD

Assistant Professor of Surgery (Urology)
Harvard Medical School;
Assistant in Urology
Children's Hospital Boston
Boston, Massachusetts

Herbert Lepor, MD

Professor and Martin Spatz Chairman, Department of Urology
Professor of Pharmacology
New York University School of Medicine;
Director, Urology
NYU Langone Medical Center
New York, New York

Seth P. Lerner, MD, FACS

Professor, Department of Urology
Baylor College of Medicine;
Medical Staff, Department of Urology
The Methodist, St. Luke's Episcopal Hospital and Ben Taub General Hospital
Houston, Texas

John A. Libertino, MD

Professor, Department of Urology
Tufts University School of Medicine
Boston, Massachusetts;
Chair, Institute of Urology
Director, Sophia Gordon Cancer Center
Lahey Clinic Medical Center
Burlington, Massachusetts

W. Marston Linehan, MD

Chief, Urologic Oncology Branch
National Cancer Institute;
Physician-in-Chief, Urologic Surgery
Clinical Research Center
National Institutes of Health
Bethesda, Maryland

James E. Lingeman, MD

Volunteer Clinical Professor, Department of Urology
Indiana University School of Medicine
Indianapolis, Indiana

Richard Edward Link, MD, PhD

Associate Professor, Department of Urology
Director, Division of Minimally Invasive Surgery
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Mark S. Litwin, MD, MPH

Professor of Urology and Health Services
UCLA School of Medicine and Public Health
University of California, Los Angeles
Los Angeles, California

Stacy Loeb, MD

Resident, Department of Urology
James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Yair Lotan, MD

Associate Professor, Department of Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Tom F. Lue, MD, ScD (Hon), FACS

Professor and Vice Chairman
Department of Urology
University of California, San Francisco
San Francisco, California

Dawn Lee MacLellan, MD, FRCSC

Assistant Professor, Departments of Urology, Surgery, and Pathology
Izaak Walton Killam Health Centre
Dalhousie University
Halifax, Nova Scotia, Canada

Stanley Bruce Malkowicz, MD

Co-Director, Urologic Oncology
Department of Urology
University of Pennsylvania
Philadelphia, Pennsylvania

Vitaly Margulis, MD

Assistant Professor, Department of Urology
The University of Texas Southwestern Medical Center
Dallas, Texas

Ranjiv I. Mathews, MD

Associate Professor, Pediatric Urology
James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Surena F. Matin, MD

Associate Professor, Department of Urology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Brian R. Matlaga, MD, MPH

Associate Professor, Department of Urology
Johns Hopkins University School of Medicine;
Director, Stone Disease
James Buchanan Brady Urological Institute
Baltimore, Maryland

Steven D. Mawhorter, MD, DTM&H

Associate Professor, Department of Medicine
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Staff Physician, Infectious Disease
Cleveland Clinic
Cleveland, Ohio

Kurt A. McCammon, MD, FACS

Assistant Professor and Chairman, Department of Urology
Eastern Virginia Medical School;
Chief, Department of Urology
Sentara Norfolk General Hospital;
Urology of Virginia
Norfolk, Virginia

W. Scott McDougal, MD, MA (Hon)

Professor of Urology
Harvard Medical School;
Chief, Urology
Massachusetts General Hospital
Boston, Massachusetts

James M. McKiernan, MD

John and Irene Given Associate Professor of Urology
Department of Urology
Columbia University College of Physicians and Surgeons;
Associate Attending Urologist
New York-Presbyterian Hospital, Columbia University Medical Center
New York, New York

Alan W. McMahon, MD

Associate Professor, Department of Medicine
University of Alberta
Edmonton, Alberta, Canada

Thomas Anthony McNicholas, MBBS, FRCS, FEBU

Visiting Professor, Faculty of Health and Human Services
University of Hertfordshire;
Consultant Urological Surgeon
Department of Urology
Lister Hospital
Hertfordshire, United Kingdom;
Honorary Senior Lecturer
Institute of Urology
University College London
London, United Kingdom

Alan Keith Meeker, PhD, MA

Assistant Professor, Departments of Pathology, Urology, and Oncology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Cathy Mendelsohn, PhD

Associate Professor, Departments of Urology, Pathology, and Genetics and Development
Columbia University College of Physicians and Surgeons
New York, New York

Carlos E. Méndez-Probst, MD

Fellow in Endourology
Department of Surgey
Schulisch School of Medicine and Dentistry
The University of Western Ontario and St. Joseph's Health Care London
London, Ontario, Canada

Maxwell V. Meng, MD

Associate Professor, Department of Urology
University of California, San Francisco
San Francisco, California

David C. Miller, MD, MPH

Assistant Professor, Department of Urology
University of Michigan Medical School
Ann Arbor, Michigan

Ian Milsom, MD, PhD

Professor, Department of Obstetrics and Gynecology
Institute of Clinical Sciences
Sahlgrenska Academy at Gothenburg University;
Consultant Gynecologist
Sahlgrenska University Hospital
Gothenburg, Sweden

Manoj Monga, MD, FACS

Professor, Department of Surgery
The Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Director, Steven Streem Center for Endourology & Stone Disease
Glickman Urological Institute
Cleveland Clinic
Cleveland, Ohio

Drogo K. Montague, MD

Professor, Department of Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Director, Center for Genitourinary Reconstruction
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Courtenay Kathryn Moore, MD

Assistant Professor, Department of Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Staff Physcian
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Alvaro Morales, MD, FACS, FRCS

Professor, Department of Urology
Director, Centre for Applied Urological Research
Queen's University;
Attending, Department of Urology
Kingston General Hospital and the Hotel Dieu Hospital
Kingston, Ontario, Canada

Allen F. Morey, MD, FACS

Professor and Paul C. Peters MD Chair of Urology
Department of Urology
University of Texas Southwestern Medical Center;
Chief, Urology Service
Parkland Health and Hospital System
Dallas, Texas

Michael J. Morris, MD

Assistant Professor, Department of Medicine
Weill Cornell Medical College;
Assistant Member, Genitourinary Oncology Service
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

John P. Mulhall, MD, MSc (Anat)

Professor, Department of Urology
Weill Cornell Medical College;
Director, Sexual and Reproductive Medicine
Department of Urology Service
Memorial Sloan-Kettering Cancer Center
New York, New York

Stephen Y. Nakada, MD

David T. Uehling Professor and Chairman
Department of Urology
University of Wisconsin, Madison;
Professor and Chairman, Department of Urology
University of Wisconsin Hospital and Clinics
Madison, Wisconsin

Joel B. Nelson, MD

Frederic N. Schwentker Professor and Chairman
Department of Urology
University of Pittsburgh School of Medicine;
Chairman, Department of Surgery
UPMC Shadyside Hospital
Pittsburgh, Pennsylvania

J. Curtis Nickel, MD, FRCSC

Professor, Department of Urology
Queen's University;
Staff Urologist
Kingston General Hospital;
Canada Institute of Health Research Tier One
Canada Research Chair in Urologic Pain and Inflammation
Kingston, Ontario, Canada

Victor W. Nitti, MD

Professor and Vice Chairman, Department of Urology
New York University School of Medicine;
Attending Physician, Department of Urology
NYU Langone Medical Center
New York, New York

[†]Andrew C. Novick, MD

Chairman, Glickman Urological Institute
Cleveland Clinic Foundation;
Professor of Surgery
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University
Cleveland, Ohio

Michael C. Ost, MD

Associate Professor, Department of Urology
University of Pittsburgh School of Medicine;
Associate Professor, Department of Urology
Children's Hospital of Pittsburgh
Magee-Women's Hospital
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

[†]Deceased.

Priya Padmanabhan, MD, MPH

Assistant Professor, Department of Urology
The University of Kansas Medical Center
Kansas City, Kansas

Jeffrey S. Palmer, MD, FACS, FAAP

Associate Professor of Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University
Cleveland, Ohio

Lane S. Palmer, MD, FAAP, FACS

Clinical Professor, Department of Urology
Albert Einstein College of Medicine
Bronx, New York;
Chief, Department of Pediatric Urology
Cohen Children's Medical Center of New York
North Shore–Long Island Jewish Health System
New Hyde Park, New York

John M. Park, MD

Cheng-Yang Chang Professor of Pediatric Urology
Department of Urology
University of Michigan Medical School;
The University of Michigan Health System
Ann Arbor, Michigan

Alan W. Partin, MD, PhD

Professor and Director of Urology
Johns Hopkins School of Medicine
Baltimore, Maryland

Christopher K. Payne, MD

Associate Professor, Department of Urology (and Gynecology, by courtesy)
Stanford University School of Medicine;
Director, Female Urology & Neurourology
Stanford University Medical Center
Stanford, California

Margaret S. Pearle, MD, PhD

Professor, Departments of Urology and Internal Medicine
University of Texas Southwestern Medical Center
Dallas, Texas

Craig A. Peters, MD, FACS, FAAP

Chief, Division of Surgical Innovation, Technology, and Translation
Principal Investigator, Sheikh Zayed Institute for Pediatric Surgical Innovation
Children's National Medical Center;
Professor of Urology and Pediatrics
The George Washington University
Washington, DC

Andrew C. Peterson, MD, FACS

Associate Professor of Urology
Department of Surgery
Duke University
Durham, North Carolina

Curtis A. Pettaway, MD

Professor, Departments of Urology and Cancer Biology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Paul K. Pietrow, MD

Director, Minimally Invasive Surgery
Hudson Valley Urology, PC
Poughkeepsie, New York

Louis Leon Pisters, MD

Professor, Department of Urology
Surgical Staff, Department of Urology
University of Texas MD Anderson Cancer Center
Houston, Texas

Elizabeth A. Platz, ScD, MPH

Professor, Department of Epidemiology
Johns Hopkins University Bloomberg School of Public Health
Baltimore, Maryland

Emilio D. Poggio, MD

Associate Professor of Medicine, Nephrology, and Hypertension
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University;
Director, Renal Function Laboratory
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

John C. Pope IV, MD

Associate Professor, Departments of Urology, Surgery, and Pediatrics
Vanderbilt University Medical Center;
Associate Professor, Pediatric Urology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Jeannette M. Potts, MD

Director, Pelvic Pain Center and Alternative Urological Therapies
Urological Institute
Case Western Reserve University;
University Hospitals of Cleveland
Cleveland, Ohio

University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Richard N. Yu, MD, PhD

Instructor in Surgery (Urology)
Harvard Medical School;
Department of Urology
Children's Hospital Boston
Boston, Massachusetts

Preface

The editors are proud and pleased to present the tenth edition of the acknowledged standard textbook of urology, now titled *Campbell-Walsh Urology*. The field of urology continues to evolve, constantly adding new material on basic physiology and pharmacology, epidemiology and pathophysiology, medical and surgical management, and ever-increasing sophistication in the methodology of the evaluation and conclusions drawn from retrospective and prospective outcome studies. This applies to virtually every area included under the urology umbrella, but with the proviso that little of the "classic" knowledge or techniques is ever totally discarded, as opposed to being modified or augmented. With this in mind, our goal was to put together, in a logical order, a series of comprehensive mini-texts on every major subject in the field while keeping within a four-volume framework. We have added 14 new chapters, 5 of which are the result of combining the subject matter of 2 separate existing chapters in the ninth edition, and added 70 new "best and brightest" authors, resulting in extensive revisions of many chapters, all as an attempt to provide the most contemporary information possible in an organized sequential format.

We have continued with the use of extensive boldface and Key Points boxes for special emphasis points. All tables and most figures and diagrams are in color. The text is fully accessible online for owners and contains an extensive video library. The book includes an Expert Consult website, which will provide semi-annual updates/reviews for each area of interest and allow you to access and perform rapid searches on the entire content of the book, with references linked to PubMed abstracts.

Volume 1 covers surgical anatomy; the essentials of clinical decision making, including a chapter on outcomes research; the basics of perioperative care, instrumentation, endoscopy, laparoscopy, and robotics; infection, inflammation, and pelvic pain; the fundamentals of molecular, cellular, and cancer biology and regenerative medicine; male reproductive function and dysfunction; sexual function and dysfunction in men and women; and benign and malignant diseases of the male genitalia, including cancers of the testis, penis, and urethra.

Volume 2 begins with renal physiology and pathophysiology, including renal hypertension and nephropathy secondary to various causes, including ischemia and obstruction. Upper urinary tract trauma constitutes a separate chapter, followed by a section on renal failure and transplantation. Urolithiasis—its pathophysiology, medical endourologic management, and surgical management—follows. The section on upper urinary tract neoplasms includes benign and malignant renal parenchymal tumors with management by observation, open and laparoscopic/robotic surgery, and ablative therapy, and urothelial tumors, including management by endoscopic, laparoscopic/robotic, and open surgery. A new chapter on retroperitoneal tumors is included. The volume ends with a consideration of adrenal physiology and pathophysiology, including benign and malignant disorders, and surgical considerations.

Volume 3 begins with a 21-chapter mini-text on lower urinary tract physiology, pharmacology, function, and dysfunction, including renal, pelvic, and ureteral transport. All aspects of evaluation, conservative and surgical therapy of urinary incontinence, pelvic floor prolapse, and other abnormalities of lower tract filling/storage and emptying are considered. There are separate stand-alone chapters on urodynamics and video-urodynamics, neuromuscular dysfunction, overactive bladder, nocturia (new chapter), electrical stimulation, drug therapy, prolapse repair, all types of sling tape and sphincter surgery for urinary incontinence, fistulae, diverticula, and special considerations in the elderly. Evaluation and management of bladder tumors, including laparoscopic and robotic applications, are the subject of 5 chapters, followed by 3 on the various types of urinary diversion procedures. Sections on genital and lower urinary tract trauma and lower urinary tract calculi follow, and the volume concludes with 21 chapters covering prostatic development and physiology, and benign and malignant diseases of the prostate. All management modalities for obstructive benign prostatic hyperplasia and for prostatic cancer are presented in detail in updated and totally new chapters.

Volume 4 remains a 28-chapter, 800-page updated textbook of pediatric urology with new chapters on renal functional development and its abnormalities, perioperative management, the extrophy–epispadias complex, pediatric stone disease, and renal transplantation.

The companion study guide for the tenth edition has been extensively redone and improved, including format, questions, answers, and explanations, under the leadership of W. Scott McDougal, MD, MA (Hon), a former head of the American Urological Association Examination Committee.

All of us remain proud and grateful to be a part of the continuing tradition of excellence of this textbook, and we wish to express our gratitude to the superb job done by all authors and to the outstanding staff at Elsevier who facilitated the organization and efforts necessary to bring this tenth edition to publication. In particular, Rebecca Gaertner, Senior Acquisitions Editor; Kristina Oberle, Senior Developmental Editor; Stefanie Jewell-Thomas, Acquisitions Editor; Kristine Feeherty, Senior Project Manager; and Jennifer Shreiner, Senior Developmental Editor.

Alan J. Wein, MD, PhD (Hon), FACS
On behalf of the editors

chapter 1

Surgical Anatomy of the Retroperitoneum, Adrenals, Kidneys, and Ureters

James Kyle Anderson, MD ● Jeffrey A. Cadeddu, MD

Retroperitoneum
Adrenal Glands
Kidneys
Ureters

There is no greater aid to surgical expertise than an intimate knowledge of anatomy. For the urologist, the areas of greatest importance are the retroperitoneum and pelvis. In this chapter, retroperitoneal structures important to the practice of urologic surgery are described in detail and clinical correlations are provided where helpful.

RETROPERITONEUM

The retroperitoneum is bounded posteriorly by the abdominal wall, which consists of the lumbodorsal fascia and the enclosed sacrospinalis and quadratus lumborum muscles (Fig. 1–1). Laterally, the retroperitoneum is contiguous with the preperitoneal fat and is bounded laterally by the transversus abdominis musculature of the lateral abdominal wall. The peritoneum is the anterior limit, whereas cranially the diaphragm (Fig. 1–2) limits the retroperitoneum. Caudally the retroperitoneum is contiguous with the extraperitoneal pelvic structures.

Posterior Abdominal Wall

Posterior Musculature and Lumbodorsal Fascia

See Figures 1–3 to 1–6 and Table 1–1. The lumbodorsal fascia surrounds the sacrospinalis and quadratus lumborum, which together comprise the posterior abdominal wall. The lumbodorsal fascia originates from the spinous processes of the lumbar vertebrae and extends anteriorly and cranially. As it progresses upward, it separates into three layers: posterior, middle, and anterior.

The posterior layer provides the posterior covering for the sacrospinalis muscle and is the origin of the latissimus dorsi muscle. The middle layer forms the fascial layer separating the anterior aspect of the sacrospinalis muscle from the posterior aspect of the quadratus lumborum. The anterior layer of the lumbodorsal fascia provides the anterior covering to the quadratus lumborum muscle and forms the posterior margin of the retroperitoneum. As one moves laterally away from the sacrospinalis and quadratus lumborum muscles, the lumbodorsal fascial layers fuse together and then connect with the transversus abdominis muscle.

The quadratus lumborum and sacrospinalis muscles (see Figs. 1–6 and 1–7) **form the muscular portion of the posterior abdominal wall, filling the space among the 12th rib, spine, and iliac crest.** The quadratus lumborum serves a number of functions. It supports the 12th rib, thus improving diaphragmatic contraction and inspiration, as well as aiding intercostal muscle function during forced expiration. Finally, it controls lateral bending of the trunk. The sacrospinalis also controls movement of the trunk by promoting extension of the spine. These muscular and fascial relationships become important clinically when performing a **dorsal lumbotomy incision.** As seen in Figure 1–7, this is a vertical incision lateral to the border of the sacrospinalis and quadratus lumborum. This approach

Key Points: Retroperitoneum

- The three layers of the lumbodorsal fascia cover the musculature of the posterior abdominal wall.
- The lower ribs are in intimate contact with the kidneys and adrenal glands. Injury to the lower ribs suggests injury to retroperitoneal structures.
- The renal artery lies posterior to the renal vein, but this relationship is reversed when the aorta and inferior vena cava divide into the common iliac vessels. Here, the common iliac arteries are anterior to the common iliac veins.
- As lymphatic drainage moves within the retroperitoneum from caudal to cranial there is also a predominantly right-to-left flow.
- The nervous system is divided into the autonomic and somatic systems.
- The autonomic system is further divided into sympathetic and parasympathetic innervation. The sympathetics originate from the thoracic and lumbar vertebrae. From the sympathetic chain ganglia preganglionic fibers proceed to autonomic plexuses. From these plexuses postganglionic sympathetic fibers proceed to their targets. The parasympathetics originate from the cranial and sacral vertebrae and again synapse in peripheral plexuses before proceeding to their targets.
- The somatic system provides innervation to the retroperitoneum and lower extremities via the lumbosacral plexus.

allows entrance to the retroperitoneum without violation of the musculature.

Lateral Flank Musculature

See Figure 1–8 and Table 1–1. Three muscular layers comprise the lateral flank musculature. From superficial to internal, these are the external oblique, internal oblique, and transversus abdominis muscles. The most superficial structure is the external oblique muscle. This muscle arises from the lower ribs and moves from lateral to medial as it progresses caudally. Final attachment is to the iliac crest caudally and the rectus sheath anteriorly. The posterior border remains free as it terminates before reaching the lumbodorsal fascia. Next is the internal oblique muscle. Again, this muscle arises from the lower rib cage, but the orientation of the fibers is from medial to lateral as they move caudally. Final attachment is to the iliac crest and lumbodorsal fascia. The final structures are the transversus abdominis muscle and transversalis fascia. The transversus abdominis muscle arises from the lumbodorsal fascia with fibers running directly transversely until it attaches anteriorly and medially onto the rectus sheath. Immediately deep to the transversus abdominis muscle is the transversalis fascia and then the retroperitoneal space. The function of the lateral flank musculature is to compress and stabilize the abdomen and trunk. This provides controlled movement and protection for the abdominal organs.

Psoas and Iliacus Muscles

The psoas major muscle originates on the 12th thoracic through the 5th lumbar vertebrae (see Fig. 1–6). A smaller psoas minor is identifiable in about one half of the population and resides medial to the psoas major. The psoas muscle(s) is covered by the psoas fascia. In close proximity to the psoas muscle is the iliacus muscle, which attaches to the inner aspect of the iliac pelvic wing. As the iliacus progresses caudally it joins with the psoas muscle to form the iliopsoas muscle. This combined muscle then joins to the lesser trochanter of the femur and controls flexion of the hip.

Lower Rib Cage

See Figure 1–9. In addition to the protection provided by the muscular layers of the posterior and lateral abdominal wall, **the 10th, 11th, and 12th ribs safeguard the upper retroperitoneal space and are intimately related to the adrenal glands and kidneys. Given the close proximity, injury to these ribs can be associated with significant retroperitoneal injury.** While providing protection, the lower ribs and the accompanying pleura and lung limit surgical exposure to the upper retroperitoneum. The limits of the pleura are the 8th rib anteriorly, the 10th rib in the midaxillary line, and the 12th rib posteriorly. Given this location of the pleura, flank incisions at or above the 11th or 12th ribs risk pleural violation.

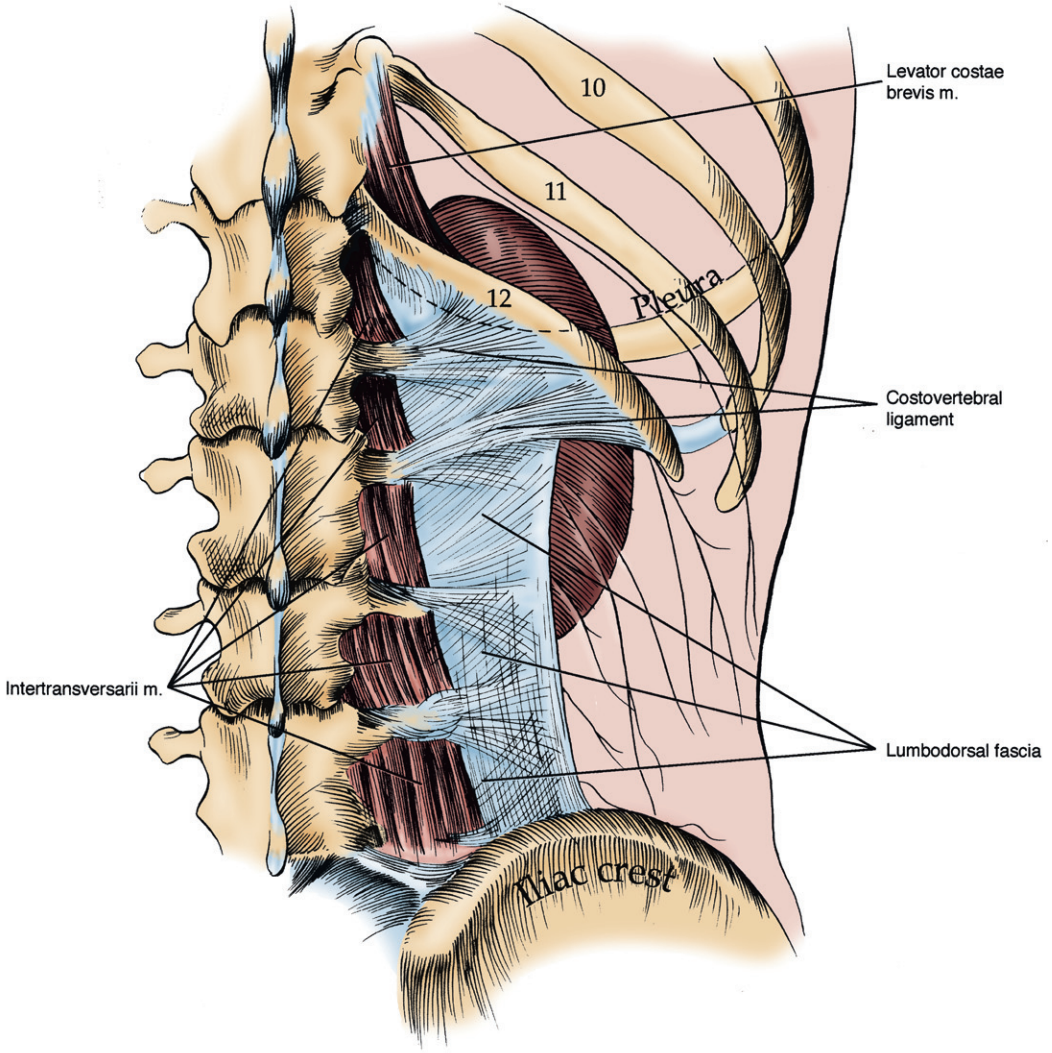

Figure 1–5. Posterior abdominal wall musculature, deep dissection. The lumbodorsal fascia and costovertebral ligament are visualized, arising from the transverse processes of the lumbar vertebrae. The relation of the kidney and pleura is also shown.

Great Vessels

The abdominal aorta and inferior vena cava are the great vessels of the abdomen, providing vascular supply to the abdominal organs and lower extremities (Figs. 1–10 and 1–11).

Abdominal Aorta

The aorta enters the abdomen via the aortic hiatus found between the diaphragmatic crura in the posterior diaphragm at the level of the 12th thoracic vertebrae (see Fig. 1–2). It continues caudally to the 4th lumbar vertebrae, where it bifurcates into the common iliac arteries. During its course through the abdomen the aorta gives off a number of large branches (Table 1–2). **The paired inferior phrenic arteries are first.** They supply the inferior diaphragm and the superior portion of the adrenal gland (see Fig. 1–2). **Next is the celiac trunk, which is the origin for the common hepatic, left gastric, and splenic arteries that supply the liver, stomach, and spleen, respectively. The paired adrenal arteries follow with an artery going to each adrenal gland. The superior mesenteric artery leaves the aorta on the anterior side and supplies the entire small intestine and majority of the large intestine.** Also of note, this artery communicates with the celiac trunk vasculature via the pancreaticoduodenal artery. Overlying the 2nd lumbar vertebrae, the paired renal arteries are the next branching point of the aorta. To the urologist, renal artery anatomy is obviously of great importance and is discussed in detail in the kidney section.

Moving distally on the aorta, the paired gonadal arteries are encountered. In the male this artery is also called the *testicular artery* and in the female it is the *ovarian artery.* The initial course in both the male and female is similar, with the artery moving caudally and laterally from the aorta, with **the right gonadal artery crossing anterior to the inferior vena cava. In men, the gonadal artery then crosses over the ureter and exits the retroperitoneum at the internal inguinal ring. In women the course is different: Instead of exiting the pelvis, the artery crosses medially back over the external iliac vessels and enters the pelvis.** It then proceeds via the suspensory ligament to the ovary. The destination of the gonadal artery (the testis in the male and the ovary in the female) has significant collateral sources of arterial blood, from the deferential and cremasteric arteries in the male and the uterine artery in the female. Thus the gonadal artery can generally be ligated during retroperitoneal surgery without detrimental effect.

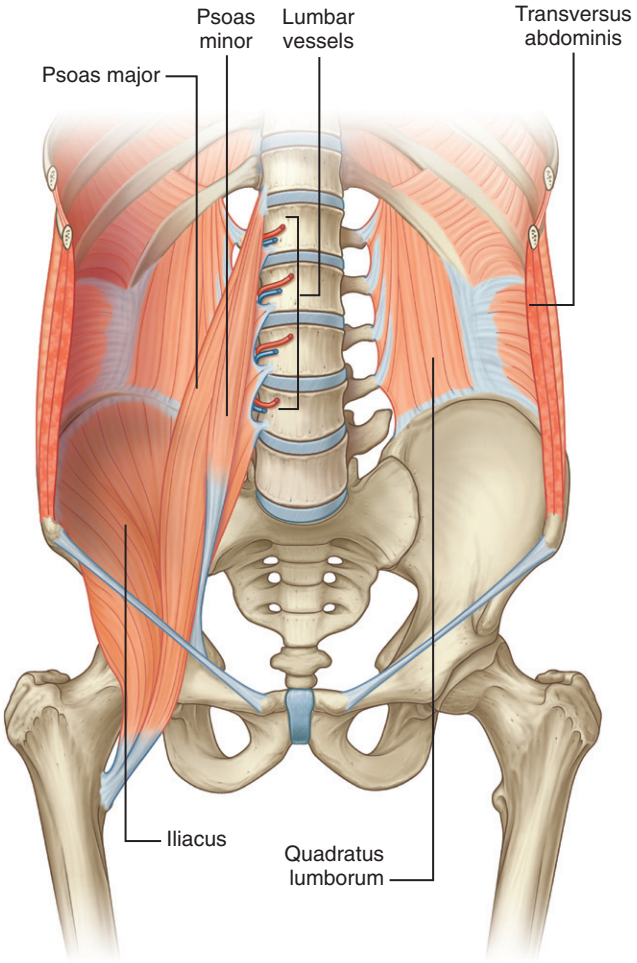

Figure 1–6. Muscles of the posterior abdominal wall. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 316.)

Table 1–1.

Musculature of the Posterior and Lateral Abdominal Wall

MUSCLE	ORIGIN	INSERTION	FUNCTION
Sacrospinalis	Sacrum and lumbar vertebrae	Lower ribs and thoracic vertebrae	Extension of the spine
Quadratus lumborum	5th lumbar vertebra	1st through 4th lumbar vertebrae, 12th rib	Depress and stabilize 12th rib, lateral bending of the trunk
External oblique	Lower eight ribs	Lateral lip of iliac crest, aponeurosis ending in midline raphe	Compress abdominal contents, flexion of the trunk
Internal oblique	Lumbodorsal fascia, iliac crest	Lower 4 ribs, aponeurosis ending in linea alba	Compress abdominal contents, flexion of the trunk
Transversus abdominis	Lumbodorsal fascia, medial lip of iliac crest	Aponeurosis ending in linea alba	Compress abdominal contents
Psoas	12th thoracic through 5th lumbar vertebrae	Lesser trochanter of femur	Flexion of the hip
Iliacus	Inner aspect of iliac pelvic wing	Lesser trochanter of femur	Flexion of the hip

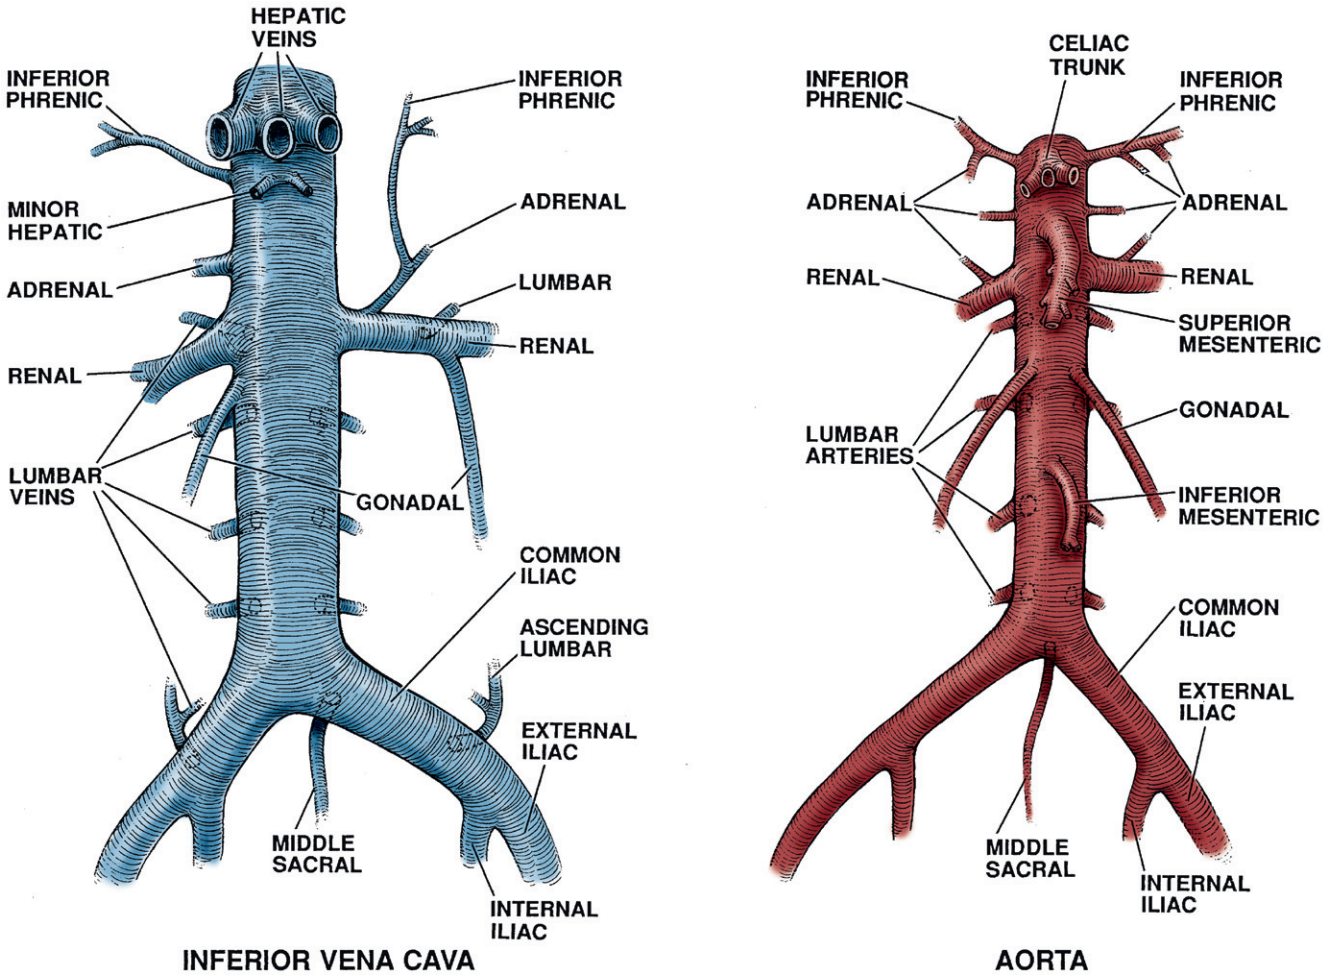

Figure 1–10. Inferior vena cava and abdominal aorta and their branches.

After the gonadal arteries, **the inferior mesenteric artery is found on the anterior side of the aorta before its bifurcation into the common iliac vessels.** This vessel provides vascular supply to the left third of the transverse colon, descending colon, sigmoid colon, and rectum. In patients without significant vascular disease, this artery can be sacrificed without ill effect because there is collateral circulation to these bowel segments from the superior mesenteric, middle hemorrhoidal, and inferior hemorrhoidal arteries.

In addition to the listed arteries that exit the aorta from its anterior or lateral aspect, there are a number of small branches from the posterior side of the aorta. **Lumbar arterial branches are found at regular intervals along the length of the aorta, with generally four pairs located within the retroperitoneum.** These branches supply the posterior body wall and spine. Again these arteries can generally be ligated without detrimental effects, although spinal ischemia and paralysis has occurred after ligation at multiple levels. **The final posterior branch from the aorta is the middle sacral artery,** which exits the aorta immediately before the branching of the common iliac arteries and then sends branches to the rectum and anterior sacrum. The common iliac arteries then proceed into the pelvis, thus completing the arterial course through the retroperitoneum.

Inferior Vena Cava

The inferior vena cava (IVC) arises from the confluence of the common iliac veins at the level of the fifth lumbar vertebra (see Fig. 1–10). **Because the common iliac veins lie medial and posterior to the iliac arteries, the confluence of the iliac veins is posterior and to the right of the aortic bifurcation.** As the IVC progresses cranially through the abdomen, tributaries include the gonadal, renal, adrenal, and hepatic veins. In addition, the middle sacral vein enters the inferior vena cava posteriorly and the lumbar veins enter throughout the length of the abdominal vena cava.

The first tributary encountered along the IVC is the **middle sacral vein,** which enters at the junction of the common iliac veins. Also entering along the posterior aspect of the IVC throughout its course are **lumbar veins.** These veins course anterior to the spinal transverse processes and generally parallel the lumber arteries. In addition to providing vascular drainage, the lumbar veins connect the IVC to the azygous venous system on the right side and hemiazygos venous system on the left side of the thorax. This provides alternate routes of venous drainage within the retroperitoneum (Fig. 1–12).

The next tributaries to the IVC are the gonadal veins, whose course is analogous to the gonadal arteries until approaching the

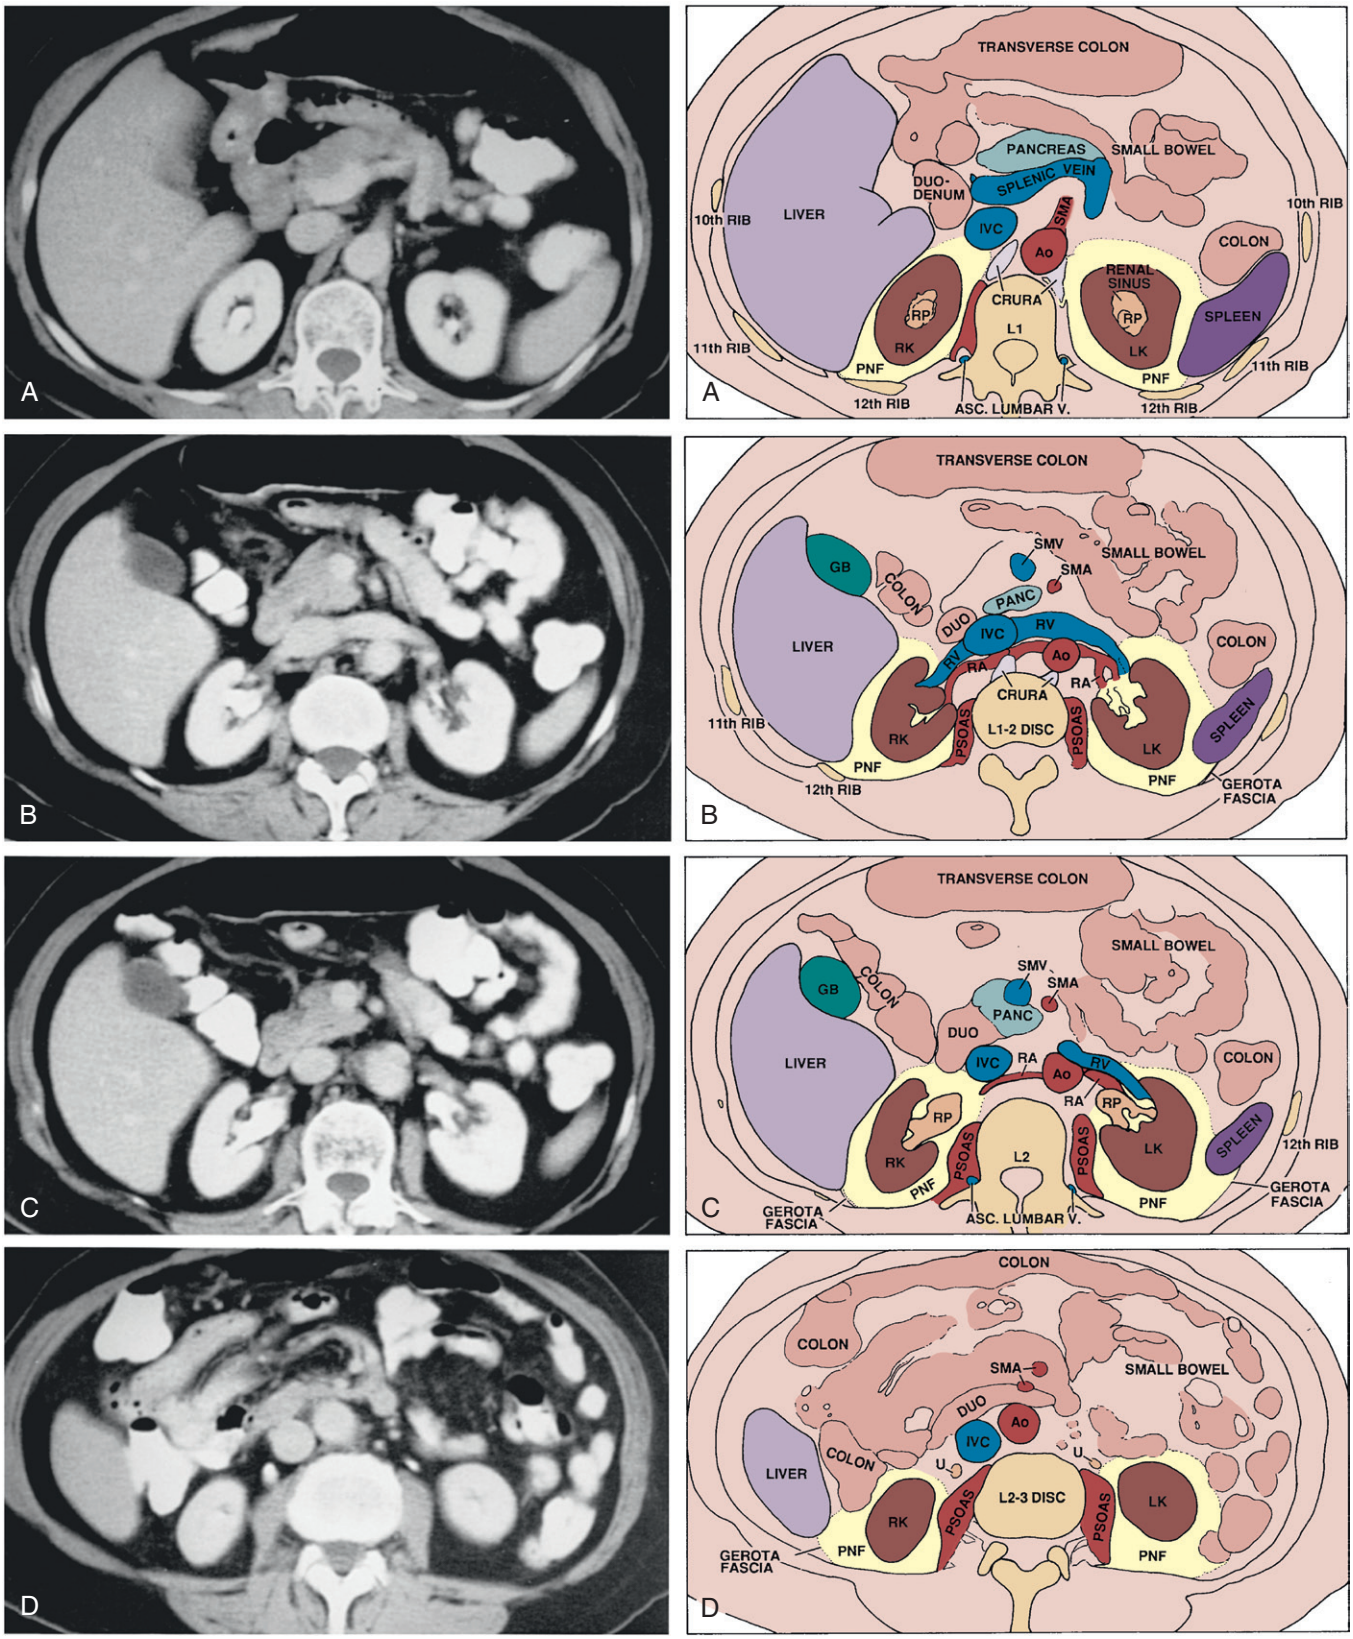

Figure 1–11. Cross-sectional anatomy of the upper abdomen at the level of the kidneys demonstrated with transverse sections obtained by computed tomography. Sections are arranged from most cephalic to caudal. **A,** Section through the upper poles of the kidneys, superior to the renal vascular pedicles. **B,** Section through the level of the renal arteries and veins. **C,** Slightly more inferior section showing the renal pelves and relation of the duodenum to the right renal hilum. **D,** Section through the lower poles of the kidneys showing the upper ureters. Ao, aorta; DUO, duodenum; GB, gallbladder; IVC, inferior vena cava; LK, left kidney; PANC, pancreas; PNF, perinephric fat; RA, renal artery; RK, right kidney; RP, renal pelvis; RV, renal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein; U, ureter.

Table 1–2.
Branches of the Abdominal Aorta

ARTERY	BRANCH	ORIGIN	PARTS SUPPLIED
Celiac trunk	Anterior	Immediately inferior to aortic hiatus of diaphragm	Abdominal foregut
Superior mesenteric artery	Anterior	Immediately inferior to celiac trunk	Abdominal midgut
Inferior mesenteric artery	Anterior	Inferior to renal arteries	Abdominal hindgut
Middle adrenal arteries	Lateral	Immediately superior to renal arteries	Adrenal glands
Renal arteries	Lateral	Immediately inferior to superior mesenteric artery	Kidneys
Testicular or ovarian arteries	Paired anterior	Inferior to renal arteries	Testes in male and ovaries in female
Inferior phrenic arteries	Paired	Immediately inferior to aortic hiatus	Diaphragm
Lumbar arteries	Posterior	Usually 4 pairs	Posterior abdominal wall and spinal cord
Median sacral arteries	Posterior	Just superior to aortic bifurcation, pass inferiorly across lumbar vertebrae, sacrum, and coccyx	
Common iliac arteries	Terminal	Bifurcation usually occurs at the level of L4 vertebra

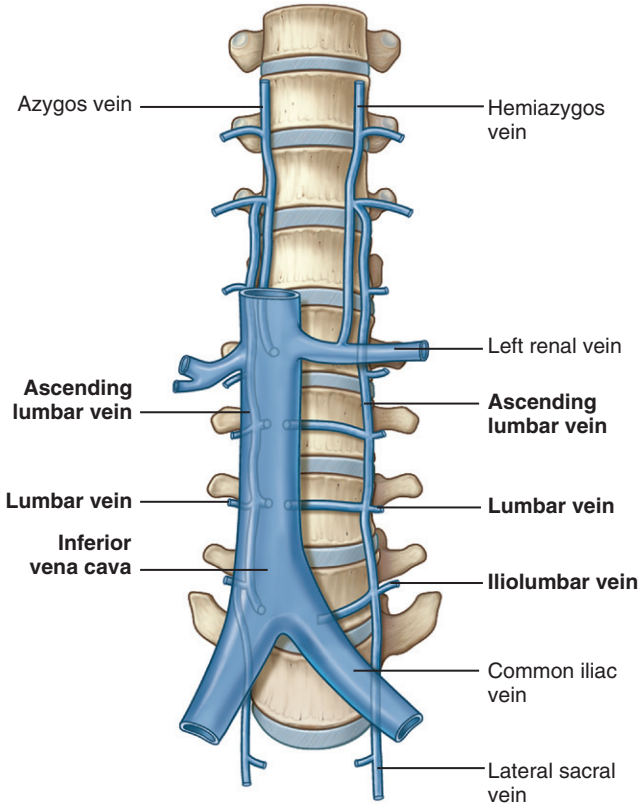

Figure 1–12. Lumbar, azygos, and hemiazygos veins. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 332.)

IVC. During the cranial portion of their course these veins are more lateral and closer to the ipsilateral ureter. Of surgical importance is their terminal drainage because **the right gonadal vein drains directly into the IVC and the left empties into the inferior aspect of the left renal vein** (see Fig. 1–10).

After the gonadal veins, the renal veins are encountered. **The renal veins are generally directly anterior to the accompanying renal artery, but it is not unusual for them to be separated by 1 to 2 cm in the craniocaudal direction.** The right renal vein typically is short and without branches, but in a small minority of patients the right gonadal vein can enter the right renal vein as opposed to the IVC. In a second anatomic variation, a lumbar vein will enter on the posterior aspect of the right renal vein as opposed to entering the IVC directly. The left renal vein is significantly longer than the right and receives additional branches before entering the IVC. Typically after exiting the renal hilum, the left renal vein receives a lumbar vein posteriorly, the left gonadal vein inferiorly, and the adrenal vein superiorly. Next, the left renal vein crosses anterior to the aorta and under the caudal edge of the superior mesenteric artery before draining into the IVC. Rarely the left renal vein crosses the aorta to the IVC in a retroaortic or circumaortic path.

Proceeding cranially, **the posterior aspect of the IVC receives the right adrenal vein.** This short vein is located posteriorly on the IVC, making it challenging to expose during right adrenal or renal surgery. As noted already, the left adrenal vein drains into the left renal vein as opposed to the IVC. **The inferior phrenic vein on the right side enters along the posterior or posterior lateral aspect of the IVC, with the left inferior phrenic vein typically entering the left renal vein.** The final tributaries to the IVC before it leaves the retroperitoneum are the short hepatic veins draining the liver. Inferiorly these veins are small, but superiorly three large hepatic trunks are encountered.

Lymphatics

Lymphatic drainage of the lower extremities, external genitalia, testes, kidneys, and intestines is located in the retroperitoneum (Fig. 1–13). Knowledge of these lymphatic channels is useful not only for urologic oncology (e.g., testis cancer) but also for prevention of complications such as lymphocele. Drainage of the lower extremities, perineum, and external genitalia progresses through the retroperitoneum via common iliac lymph vessels and then forms ascending vertical lumbar lymphatic chains. **There is flow not only cranially but also laterally, predominantly from the right to the left.** Gastrointestinal lymphatic drainage also follows the vascular supply, with the majority of the lymphatics paralleling the inferior mesenteric, superior mesenteric, and celiac arteries. Eventually these lymphatics join posterior to the aorta at the level of the first or second lumbar vertebrae to form the **thoracic duct.** This coalescence is classically marked by a

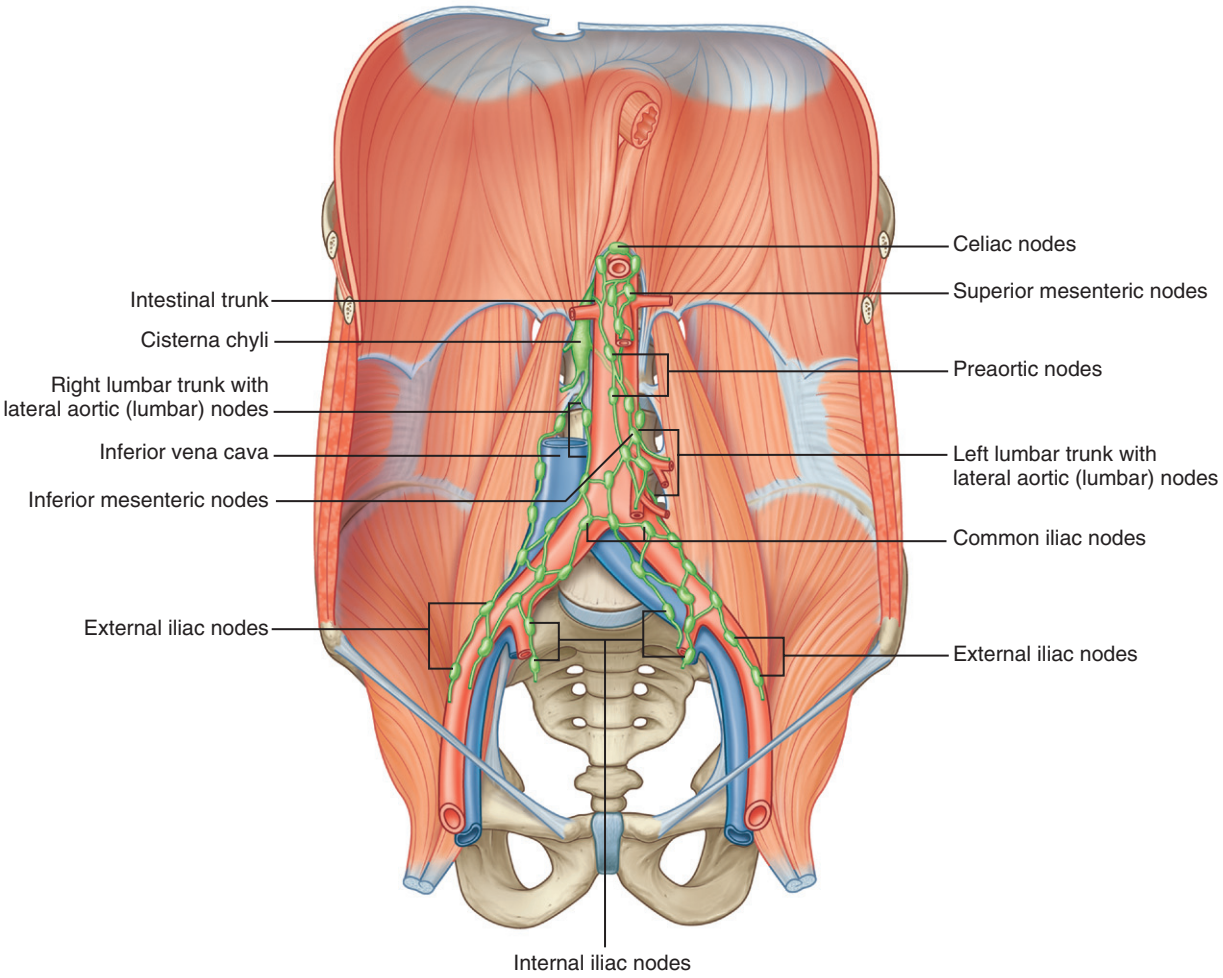

Figure 1–13. Retroperitoneal lymphatics. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 335.)

local dilation called **the cisterna chyli,** which tends to lie within the thorax just to the right of the aorta in a retrocrural position.

For the urologist, the lumbar lymphatics are important as the primary lymphatic drainage from two urologic organs: the kidneys and testes. Given the kidney's retroperitoneal location, the lumbar path of its lymphatic drainage is not surprising and is discussed in more depth later in this chapter. Embryologically, the testes develop within the retroperitoneum and maintain both blood flow (testicular arteries) and lymphatic drainage through this area even after they descend into the scrotum. To better describe the lymphatic drainage within the retroperitoneum, a practical system has been developed. This system defines three major nodal areas: right paracaval, interaortocaval, and left para-aortic. The right paracaval nodal region extends from the midline of the IVC to the right ureter. The interaortocaval region extends from the midline of the IVC to the midline of the aorta, and the left para-aortic region extends from the midline of the aorta to the left ureter.

Study of lymphatic metastases from testicular tumors have shown that testicular lymphatic drainage is consistent and follows the general scheme of vertical drainage with lateral flow from right to left. Lymphatic metastases from the right testis drain primarily into the interaortocaval nodes with significant drainage to the right paracaval nodes. In addition there is a small amount of drainage to the left para-aortic nodes. On the other hand, the left testis drains primarily to the left para-aortic nodes with significant drainage to the interaortocaval nodes. There is essentially no drainage to the right paracaval nodes from left-sided tumors.

Nervous System Structures

The nervous structures within the retroperitoneum are part of the peripheral nervous system and can be divided into two categories: autonomic and somatic nerves. **The autonomic nerves provide afferent and efferent innervation to organs, blood vessels, glands, and smooth muscles. They are further characterized by the presence of peripheral synapses. Thus there are at least two peripheral nerves between the central nervous system and the viscera. The somatic nerves supply afferent and efferent innervation to the skin, skeletal muscles, and joints.** Although these two nerve types leave the spinal column within shared spinal nerves, their course and functions quickly diverge.

Autonomic System

The autonomic system is further divided into sympathetic and parasympathetic fibers. The origin of these two nerve types is quite different, with **the sympathetic preganglionic fibers originating from the thoracic and lumbar portions of the spinal column and the parasympathetic preganglionic fibers beginning in the cranial and sacral spinal column**

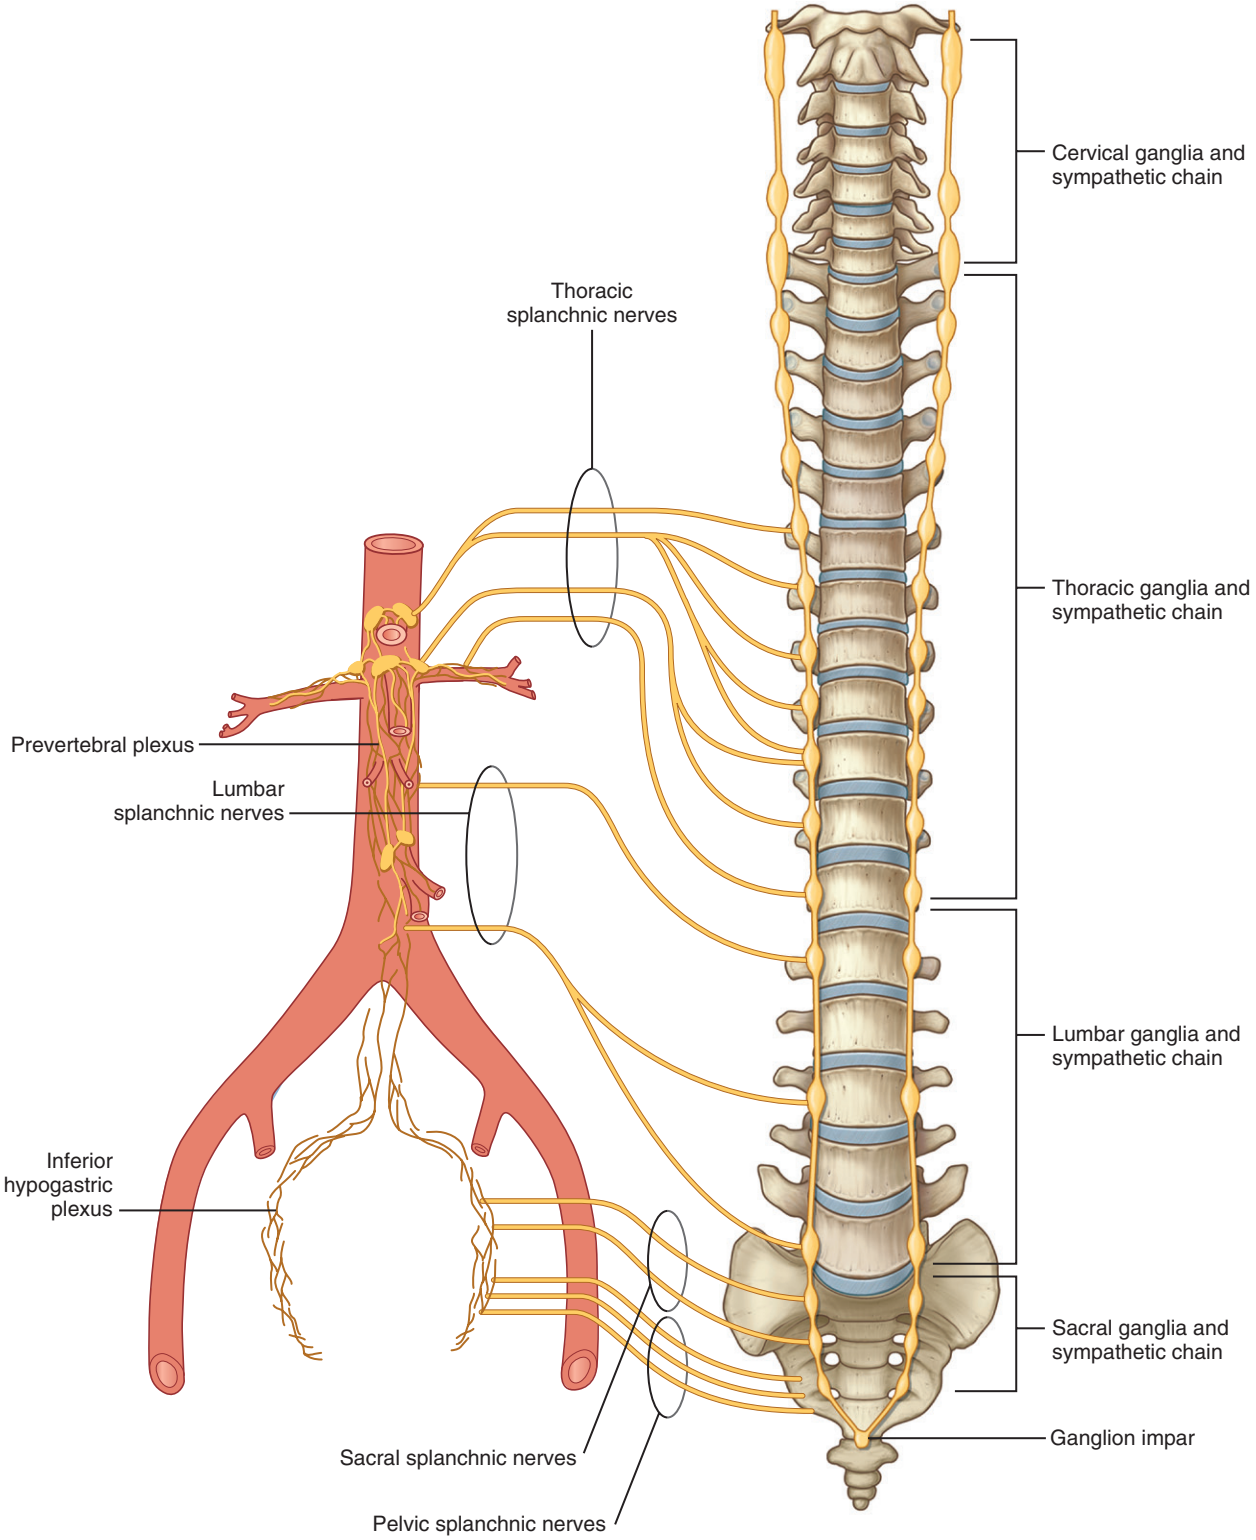

Figure 1–14. Sympathetic chain and splanchnic nerves. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 309.)

segments. Preganglionic sympathetic fibers enter the retroperitoneum through both the paired sympathetic chains and input from the lumbar spinal nerves (Fig. 1–14). **The lumbar portion of this sympathetic chain then sends preganglionic fibers to autonomic plexuses associated with the major branches of the abdominal aorta. Within these aortic plexuses the preganglionic fibers synapse and postganglionic fibers are then distributed to the various abdominal viscera and organs. Parasympathetic input from the vagus nerve also supplies these ganglia.**

In more detail, the thoracic and lumbar portions of the sympathetic chain originate from preganglionic sympathetic fibers arising from the first thoracic through the third lumbar spinal

nerves (see Fig. 1–14). **This chain then courses vertically along the anterolateral aspect of the spine just medial to the psoas muscle.** Within the retroperitoneum, lumbar arteries and veins are closely associated with the lumbar sympathetic chain, in some instances even splitting the fibers as they cross the chain perpendicularly. **From this sympathetic chain preganglionic fibers follow one of three courses. First, preganglionic fibers are sent to the various autonomic plexuses (splanchnic nerves). Once in the plexus, the preganglionic fibers synapse within a ganglion to postganglionic fibers, which in turn proceed to the abdominal viscera. Second, preganglionic fibers can synapse within the sympathetic chain ganglia and send postganglionic fibers to the body wall and lower extremities. Finally, preganglionic sympathetic fibers can proceed directly to the adrenal gland without synapsing. Within the adrenal medulla, these preganglionic fibers control release of catecholamines.**

The major autonomic nerve plexuses are associated with the primary branches of the aorta. These plexuses include the celiac, superior hypogastric, and inferior hypogastric plexuses (Fig. 1–15). These plexuses receive sympathetic input from the sympathetic chains via the greater, lesser, and least thoracic splanchnic nerves originating from the 5th through 12th thoracic spinal nerves. They also receive input from the lumbar portion of the sympathetic chain via the lumbar splanchnic nerves, as well as parasympathetic input via the vagus nerve.

The largest is the celiac plexus and is located on either side of the celiac arterial trunk as a paired structure. It is through this plexus that much or all of the autonomic input to the kidney, adrenal, renal pelvis, and ureter passes. In addition, some of the sympathetic innervation to the testes passes through this ganglion before continuing in parallel with the testicular artery to the testis. A separate aorticorenal ganglion usually exists as an inferior extension of the celiac ganglion, forming part of the renal autonomic plexus. The latter plexus surrounds the renal artery and its branches and is contiguous with the celiac plexus. At the lower extent of the abdominal aorta, **much of the autonomic input to the pelvic urinary organs and genital tract travels through the superior hypogastric plexus.** This plexus lies on the aorta anterior to its bifurcation and extends inferiorly on the anterior surface of the fifth lumbar vertebra. This plexus is contiguous bilaterally with inferior hypogastric plexuses, which extend into the pelvis. **Disruption of the sympathetic nerve fibers that travel through these plexuses during retroperitoneal dissection can cause loss of seminal vesicle emission and/or failure of bladder neck closure, resulting in retrograde ejaculation.**

Somatic

The somatic sensory and motor innervation to the abdomen and lower extremities arises in the retroperitoneum and is called the lumbosacral plexus. The lumbosacral plexus is formed from branches of all lumbar and sacral spinal nerves, with some contribution from the 12th thoracic spinal nerve as well (Fig. 1–16). Superiorly, nerves of this plexus form within the body of the psoas muscle and pierce this muscle, with more inferior branches passing medial to the psoas as the pelvis is entered (Fig. 1–17). The origins and functions of these lumbosacral somatic nerves are summarized in Table 1–3.

The subcostal nerve is the anterior extension of the 12th thoracic nerve and extends laterally beneath the 12th rib. As one proceeds inferiorly, the **iliohypogastric nerve** and the **ilioinguinal nerve** originate together as an extension from the first lumbar spinal nerve. These three nerves cross the anterior or inner surface of the quadratus lumborum muscle before piercing the transversus abdominis muscle and continuing their course between

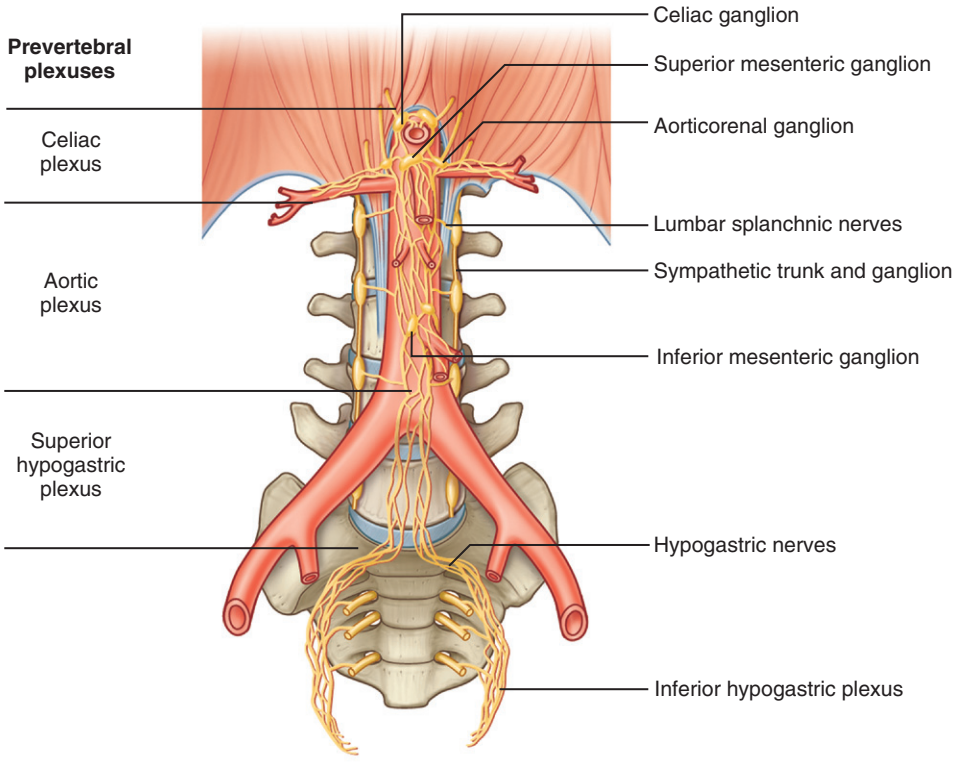

Figure 1–15. Autonomic plexuses associated with branches of the aorta. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 337.)

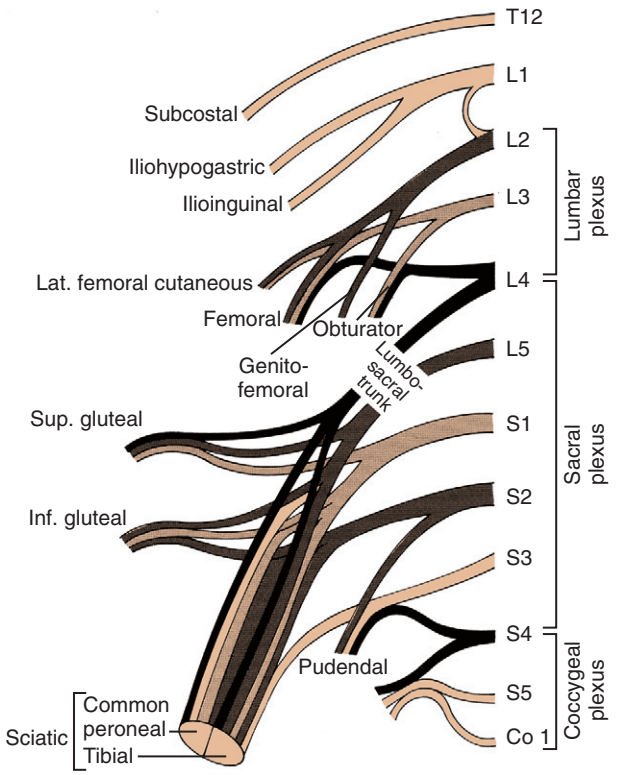

Figure 1–16. Diagrammatic representation of the lumbosacral nervous plexus.

this and the internal oblique muscle. Together they provide multiple motor branches to the muscles of the abdominal wall, as well as sensory innervation to the skin of the lower abdomen and genitalia. The **lateral femoral cutaneous nerve** and the **genitofemoral nerve** arise from the 1st through 3rd lumbar nerves and are primarily sensory nerves to the skin of the upper thigh and genitalia; however, the genital branch of the genitofemoral nerve also supplies the cremaster and dartos muscles in the scrotum. The genitofemoral nerve lies directly atop and parallels the psoas muscle throughout most of its retroperitoneal course and is easily identified in this position.

The **femoral nerve** is a larger structure arising from the second through fourth lumbar spinal nerves and is largely hidden by the body of the psoas muscle before exiting the abdomen just lateral to the femoral artery. This important nervous structure supplies the psoas and iliacus muscles, as well as the large muscle groups of the anterior thigh. It also provides sensory innervation of the anteromedial portions of the lower extremity. Intraoperatively, it may be compressed by retractor blades placed inferolaterally against the inguinal ligament in lower abdominal incisions, producing a significant motor palsy that prevents active extension of the knee.

The final lumbosacral plexus nerves include the **obturator and sciatic nerves.** The obturator nerve, an important pelvic landmark, arises behind the psoas muscle in the retroperitoneum from the third and fourth lumbar spinal nerves. It then courses inferiorly, where its major function is to supply the adductor muscles of the thigh. The **sciatic nerve** receives input from the

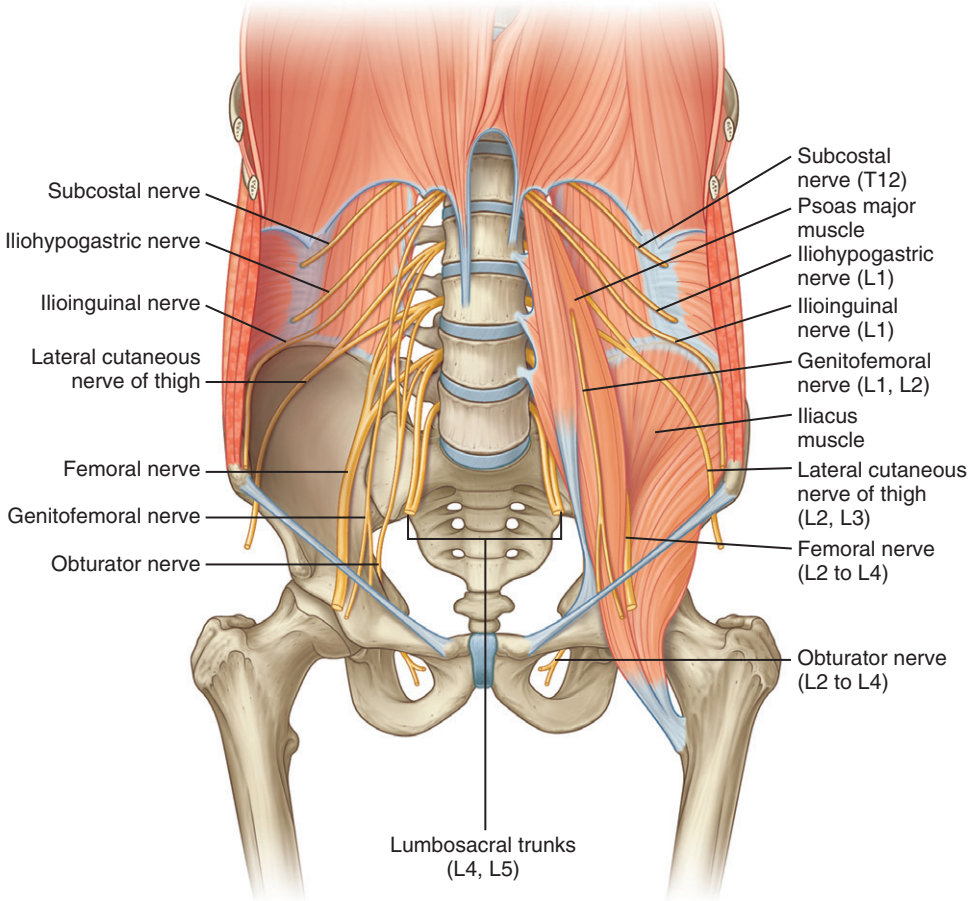

Figure 1–17. Lumbar plexus in the posterior abdominal region. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 341.)

Table 1–3.
Branches of the Lumbosacral Plexus

BRANCH	ORIGIN	SPINAL SEGMENTS	FUNCTION: MOTOR	FUNCTION: SENSORY
Iliohypogastric	Anterior ramus L1	L1	Internal oblique and transversus abdominis	Posterolateral gluteal skin and skin in pubic region
Ilioinguinal	Anterior ramus L1	L1	Internal oblique and transversus abdominis	Skin in the upper medial thigh, and either the skin over the root of the penis and anterior scrotum or the mons pubis and labium majus
Genitofemoral	Anterior rami L1 and L2	L1, L2	Genital branch—male cremasteric muscle	Genital branch—skin of anterior scrotum or skin of mons pubis and labium majus; femoral branch—skin of upper anterior thigh
Lateral cutaneous nerve of thigh	Anterior rami L2 and L3	L2, L3		Skin on anterior and lateral thigh to the knee
Obturator	Anterior rami L2 to L4	L2 to L4	Obturator externus, pectineus, and muscles in medial compartment of thigh	Skin on medial aspect of the thigh
Femoral	Anterior rami L2 to L4	L2 to L4	Iliacus, pectineus, and muscles in anterior compartment of thigh	Skin on anterior thigh and medial surface of leg

From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 340.

fourth lumbar through third sacral spinal nerves, taking final form in the deep posterior pelvis as the body's single largest nerve, supplying the bulk of both sensory and motor innervation to the lower extremity.

Duodenum, Pancreas, Colon

See Figure 1–18 on the Expert Consult website. The duodenum is divided into four anatomic components. The first (ascending) portion is short (5 cm) and intimately related to the gallbladder. **The second (descending portion) is of most importance to the urologist because it lies immediately anterior to the right renal hilum and pelvis.** This portion of the duodenum is frequently mobilized (referred to as a *Kocher maneuver*) to expose the right kidney, right renal pelvis, and additional upper abdominal structures. The second portion of the duodenum also receives the common bile duct and surrounds the head of the pancreas. The third (horizontal) and fourth (ascending) portions of the duodenum cross from right to left over the IVC and aorta before transitioning into the jejunum.

As noted earlier, the head of the pancreas is on the medial border of the descending duodenum. **The body and tail of the pancreas continue across the IVC and aorta to the left side of the abdomen, where the pancreas is closely related to the left adrenal gland and the upper pole of the left kidney.** The splenic artery and vein travel laterally along the posterior aspect of the pancreas, with the artery just superior to the vein. In this position these vascular structures are also closely related to the upper pole of the left kidney.

The final retroperitoneal gastrointestinal structure is the colon, with the ascending and descending portions being retroperitoneal. **Both the ascending colon at the hepatic flexure and descending colon at the splenic flexure overlie the ipsilateral kidney.** In addition, the hepatocolic ligament and splenocolic ligament tether the liver and spleen to the respective portions of the colon. Given the close anatomic relationship to the kidneys, mobilization of the colon and its mesentery is important for transperitoneal exposure of the kidneys and ureters.

ADRENAL GLANDS

See Figure 1–19 on the Expert Consult website.

Anatomic Relationships

The adult adrenal glands are 3 to 5 cm in greatest transverse dimension and weigh approximately 5 g. Grossly, they are yellow-orange and noticeably more orange than the surrounding adipose tissue. The position of this bilateral gland varies from right to left, but both glands are enclosed within the perirenal (Gerota) fascia and are separated from the upper pole of the kidneys by a layer of connective tissue.

The right gland is more superiorly located in the retroperitoneum and is pyramidal. It is almost directly cranial to the upper pole of the right kidney. Surrounding structures include the liver anterolaterally, the duodenum anteromedially, and the inferior vena cava medially. It is also important to note that there is often a retrocaval extension of one wing. The left gland is more

Key Points: Adrenal Glands

- Embryologically the adrenals are distinct from the kidney. Developmental abnormalities of one do not affect the other.
- The adrenal is divided into the medulla and the cortex.
- The adrenal medulla receives preganglionic sympathetic input that stimulates the release of catecholamines from medullary chromaffin cells.
- The adrenal cortex is composed of three distinct areas: the zona glomerulosa, zona fasciculata, and zona reticularis.
- Arterial supply to the adrenal comes from branches of the inferior phrenic artery, aorta, and renal artery.
- Venous drainage of the adrenal varies by side, with the right adrenal vein directly entering the IVC and the left adrenal vein draining into the left renal vein.

crescenteric and medial to the upper pole of the left kidney. The upper and anterior aspects are related to the stomach, tail of the pancreas, and splenic vessels.

Composition

Embryologically, the adrenal is distinct from the kidney. Thus in cases of renal ectopia, the adrenal gland is not affected. **Histologically, the adrenal is divided into two components: the centrally located medulla and the peripherally located cortex** (Fig. 1–20 on the Expert Consult website). **The medulla itself is composed of chromaffin cells derived from neural crest origin. These chromaffin cells are innervated directly by presynaptic sympathetic fibers traveling to the adrenal gland from the sympathetic chains. The secretion of neuroactive catecholamines by the adrenal medulla is thus under sympathetic control.**

The adrenal cortex is of mesodermal origin and makes up approximately 90% of the adrenal mass. It is composed of three layers, from external to internal: zona glomerulosa, zona fasciculata, and zona reticularis. Each layer has a different function, with the glomerulosa producing mineralocorticoids (e.g., aldosterone), the fasciculata producing glucocorticoids (e.g., cortisol), and the reticularis synthesizing sex steroids (androgens).

Adrenal Vessels

The arterial supply to the adrenal gland originates from three sources (Fig. 1–21). **Superiorly, branches from the inferior phrenic artery feed the adrenal, whereas middle branches originate directly from the aorta. Finally, branches from the ipsilateral renal artery supply the adrenal gland.** The venous drainage varies by side, although both adrenal glands are drained by a single large vein that exits anteromedially. On the left side this vein joins with the inferior phrenic vein and enters the cranial aspect of the left renal vein. On the right side, the adrenal vein enters the IVC directly on its posterolateral aspect. The lymphatic drainage of the adrenals follows the course of these veins and empties into para-aortic lymph nodes.

KIDNEYS

Gross and Microscopic Anatomy

The kidneys serve a number of important functions required to maintain normal human physiologic function. They are the primary organs for maintaining fluid and electrolyte balance, and they play a large role in maintaining acid-base balance. They produce renin, which plays a vital role in controlling blood pressure, and erythropoietin, which affects red blood cell production. They affect calcium metabolism, in particular calcium absorption, by converting a precursor of vitamin D to the most active form, 1,25-dihydroxyvitamin D.

Grossly, the kidneys are bilaterally paired reddish brown organs (see Figs. 1–1 and 1–22). Typically each kidney weighs 150 g in the male and 135 g in the female. The kidneys generally measure 10 to 12 cm vertically, 5 to 7 cm transversely, and 3 cm in the anteroposterior dimension. Because of compression by the liver, the right kidney tends to be somewhat shorter and wider. In children, the kidneys are relatively larger and possess more prominent fetal lobations. These lobations are present at birth and generally disappear by the first year of life, although occasionally they persist into adulthood. An additional common feature of the gross renal anatomy is a focal renal parenchymal bulge along the kidney's lateral contour, known as a *dromedary hump*. This is a normal variation without pathologic significance. It is more common on

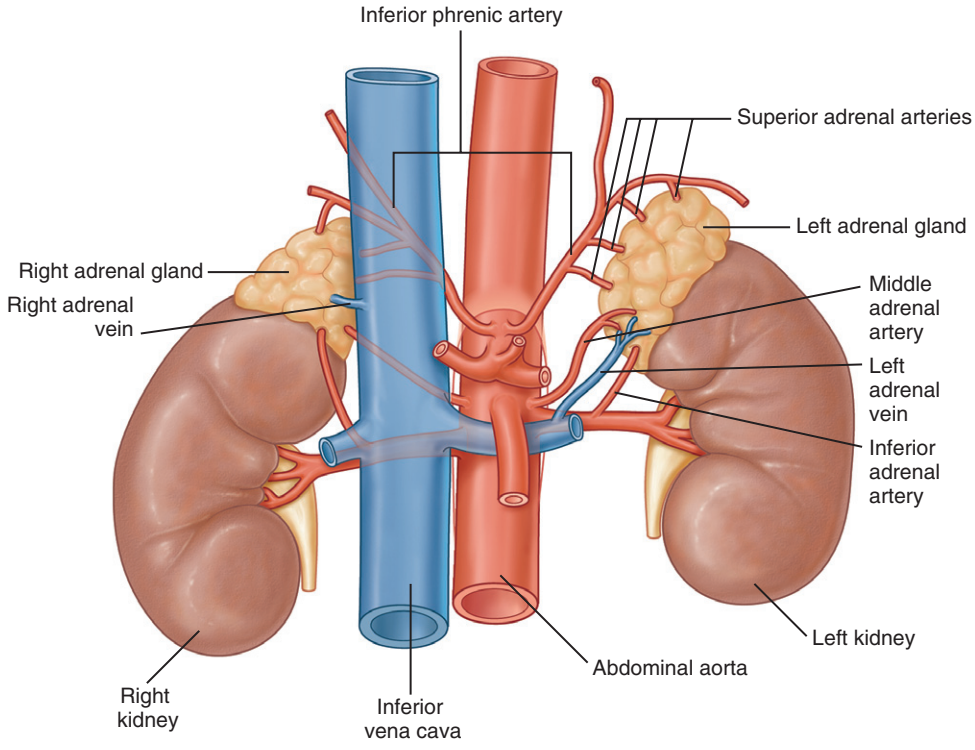

Figure 1–21. Arterial supply to the adrenal glands. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 329.)

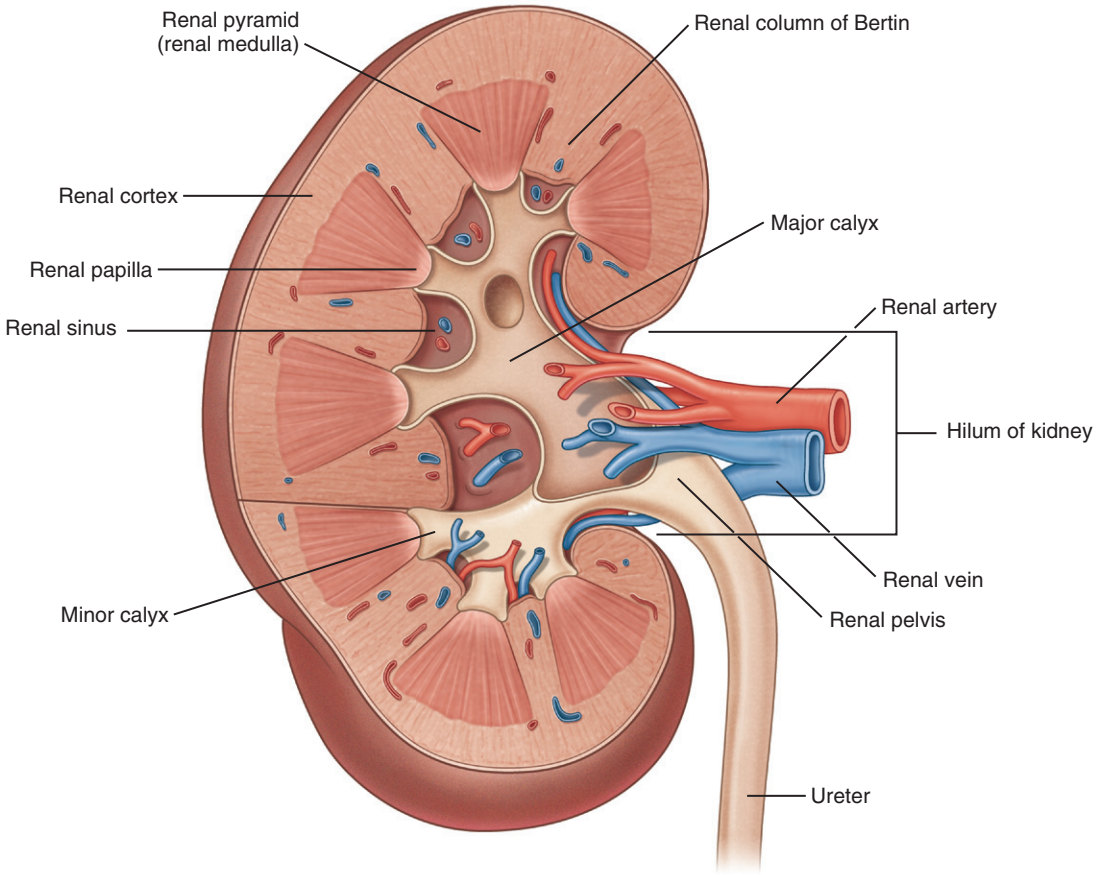

Figure 1–22. Internal structure of the kidney. (From Drake RL, Vogl W, Mitchell AWM. Gray's anatomy for students. Philadelphia: Elsevier; 2005. p. 323.)

the left than the right and is believed to be caused by downward pressure from the spleen or liver.

As one proceeds centrally from the peripherally located reddish brown parenchyma of the kidney, the renal sinus is encountered. Here the vascular structures and collecting system coalesce before exiting the kidney medially. These structures are surrounded by yellow sinus fat, which provides an easily recognized landmark during renal procedures such as partial nephrectomy. At its medial border, the renal sinus narrows to form the renal hilum. It is through the hilum that the renal artery, renal vein, and renal pelvis exit the kidney and proceed to their respective destinations.

Both grossly and microscopically there are two distinct components within the renal parenchyma: the medulla and the cortex. **Unlike the adrenal gland, the renal medulla is not a contiguous layer. Instead, the medulla is composed of multiple, distinct, conically shaped areas noticeably darker in color than the cortex** (see Fig. 1–22). **These same structures are also frequently called renal pyramids, making the terms *renal medulla* and *renal pyramid* synonymous. The apex of the pyramid is the renal papilla, and each papilla is cupped by an individual minor calyx.**

The renal cortex is lighter in color than the medulla and not only covers the renal pyramids peripherally but also extends between the pyramids themselves. The extensions of cortex between the renal pyramids are given a special name: the **columns of Bertin.** These columns are significant surgically because it is through these columns that renal vessels traverse from the renal sinus to the peripheral cortex, decreasing in diameter as the columns move peripherally. It is because of this anatomy that percutaneous access to the collecting system is made through a renal pyramid into a calyx, thus avoiding the columns of Bertin and the larger vessels present within them.

Many of these gross anatomic structures can be seen on modern imaging modalities such as computed tomography (see Fig. 1–11), as well as ultrasound and magnetic resonance imaging (Fig. 1–23).

Relations and Investing Fascia

Anatomic Relationships

The position of the kidney within the retroperitoneum varies greatly by side, degree of inspiration, body position, and presence of anatomic anomalies (Fig. 1–24 on the Expert Consult website). The right kidney sits 1 to 2 cm lower than the left in most individuals owing to displacement by the liver. Generally, the right kidney resides in the space between the top of the first lumbar vertebra to the bottom of the third lumbar vertebra. The left kidney occupies a more superior space from the body of the 12th thoracic vertebral body to the 3rd lumbar vertebra.

Of surgical importance are the structures surrounding the kidney (see Figs. 1–9 and 1–25). Both kidneys have similar muscular surroundings. Posteriorly, the diaphragm covers the upper third of each kidney, with the 12th rib crossing at the lower extent of the diaphragm. Also important to note for percutaneous renal procedures and flank incisions is that the pleura extends to the

Key Points: Kidneys

- The kidney is divided into cortex and medulla. The medullary areas are pyramidal, more centrally located, and separated by sections of cortex. These segments of cortex are called the *columns of Bertin*.
- Orientation of the kidney is greatly affected by the structures around it. Thus the upper poles are situated more medially and posteriorly than the lower poles. Also, the medial aspect of the kidney is more anterior than the lateral aspect.
- Gerota fascia envelops the kidney on all aspects except inferiorly, where it is not closed but instead remains an open potential space.
- From anterior to posterior, the renal hilar structures are the renal vein, renal artery, and collecting system.
- The renal artery splits into segmental branches. Typically, the first branch is the posterior segmental artery, which passes posterior to the collecting system. There are generally three to four anterior segmental branches that pass anteriorly to supply the anterior kidney.
- The progression of arterial supply to the kidney is as follows: renal artery → segmental artery → interlobar artery → arcuate artery → interlobular artery → afferent artery.
- The venous system anastomoses freely throughout the kidney. The arterial supply does not. Thus occlusion of a segmental artery leads to parenchymal infarction, but occlusion of a segmental vein is not problematic because there are many alternate drainage routes.
- Anatomic variations in the renal vasculature are common, occurring in 25% to 40% of kidneys.
- Each renal pyramid terminates centrally in a papilla. Each papilla is cupped by a minor calyx. A group of minor calyces join to form a major calyx. The major calyces combine to form the renal pelvis. There is great variation in the number of calyces, calyceal size, and renal pelvis size. The only way to determine pathologic from normal is by evidence of dysfunction.

level of the 12th rib posteriorly. Medially the lower two thirds of the kidney lie against the psoas muscle, and laterally the quadratus lumborum and aponeurosis of the transversus abdominis muscle are encountered. The effect of the muscular relations on the kidneys is severalfold (Fig. 1–26). First, the lower pole of the kidney lies laterally and anteriorly relative to the upper pole. Second, the medial aspect of each kidney is rotated anteriorly at an angle of approximately 30 degrees. An understanding of this renal orientation is again of particular interest for percutaneous renal procedures in which kidney orientation influences access site selection.

Anteriorly, the right kidney is bordered by a number of structures (see Fig. 1–25). Cranially, the upper pole lies against the liver and is separated from the liver by the peritoneum except for the liver's posterior bare spot. The hepatorenal ligament further attaches the right kidney to the liver because this extension of parietal peritoneum bridges the upper pole of the right kidney to the posterior liver. Also at the upper pole, the right adrenal gland is encountered. On the medial aspect, the descending duodenum is intimately related to the medial aspect of the kidney and hilar structures. Finally, on the anterior aspect of the lower pole lies the hepatic flexure of the colon.

The left kidney is bordered superiorly by the tail of the pancreas with the splenic vessels adjacent to the hilum and upper pole of the left kidney. Also cranial to the upper pole is the left adrenal gland and further superolaterally, the spleen. The splenorenal ligament attaches the left kidney to the spleen. This attachment can lead to splenic capsular tears if excessive downward pressure is applied to the left kidney. Superior to the pancreatic tail, the posterior gastric wall can overlie the kidney. Caudally, the kidney is covered by the splenic flexure of the colon.

Gerota Fascia

Interposed between the kidney and its surrounding structures is the perirenal or Gerota fascia (Figs. 1–27 through 1–29). This fascial layer encompasses the perirenal fat and kidney and encloses the kidney on three sides: superiorly, medially, and laterally. Superiorly and laterally Gerota fascia is closed, but medially it extends across the midline to fuse with the contralateral side. Inferiorly, Gerota fascia is not closed and remains an open potential space. Gerota fascia serves as an anatomic barrier to the spread of malignancy and a means of containing perinephric fluid collections. Thus perinephric fluid collections can track inferiorly into the pelvis without violating Gerota fascia.

Renal Vasculature

The renal pedicle classically consists of a single artery and a single vein that enter the kidney via the renal hilum (see Fig. 1–22). These structures branch from the aorta and inferior vena cava just below the superior mesenteric artery at the level of the second lumbar vertebra. **The vein is anterior to the artery. The renal pelvis and ureter are located farther posterior to these vascular structures.**

Renal Artery

Specifically, the right renal artery leaves the aorta and progresses with a caudal slope under the IVC toward the right kidney. The left renal artery courses almost directly laterally to the left kidney. Given the rotational axis of the kidney (see Fig. 1–26), both renal arteries move posteriorly as they enter the kidney. Also, both arteries have branches to the respective adrenal gland, renal pelvis, and ureter.

Upon approaching the kidney, the renal artery splits into four or more branches, with five being the most common. These are the renal segmental arteries (Fig. 1–30). Each segmental artery supplies a distinct portion of the kidney with no collateral circulation between them (Fig. 1–31). Thus occlusion or injury to a segmental branch will cause segmental renal infarction. Generally, the first and most constant branch is the posterior segmental branch, which separates from the renal artery before it enters the renal hilum. Typically there are four anterior branches, which from superior to inferior are apical, upper, middle, and lower. The relationship of these segmental arteries is important because the posterior segmental branch passes posterior to the renal pelvis while the others pass anterior to the renal pelvis. Ureteropelvic junction obstruction caused by a crossing vessel can occur when the posterior segmental branch passes anterior to the ureter causing occlusion. This division between the posterior and anterior segmental arteries has an additional surgical importance in that between these circulations is an avascular plane (see Figs. 1–26 and 1–31). This longitudinal plane lies just posterior to the lateral aspect of the kidney. Incision within this plane results in significantly less blood loss than outside this plane. However, there is significant variation in the location of this plane, requiring

delineation before incision. This can be done with either preoperative angiography or intraoperative segmental arterial injection of a dye such as methylene blue.

Once in the renal sinus, the segmental arteries branch into **lobar arteries,** which further subdivide in the renal parenchyma to form **interlobar** arteries (Fig. 1–32). These interlobar arteries progress peripherally within the cortical columns of Bertin, thus avoiding the renal pyramids but maintaining a close association with the minor calyceal infundibula. At the base (peripheral edge) of the renal pyramids, the interlobar arteries branch into **arcuate arteries.** Instead of moving peripherally, the arcuate arteries parallel the edge of the corticomedullary junction. **Interlobular arteries** branch off the arcuate arteries and move radially, where they eventually divide to form the **afferent arteries** to the glomeruli.

The 2 million glomeruli within each kidney represent the core of the renal filtration process. Each glomerulus is fed by an afferent arteriole. As blood flows through the glomerular capillaries, the urinary filtrate leaves the arterial system and is collected in the glomerular (Bowman) capsule. Blood flow leaves the glomerular capillary via the efferent arteriole and continues to one of two locations: secondary capillary networks around the urinary tubules in the cortex or descending into the renal medulla as the vasa recta.

Renal Veins

The renal venous drainage correlates closely with the arterial supply. **The interlobular veins drain the postglomerular capillaries. These veins also communicate freely via a subcapsular venous plexus of stellate veins with veins in the perinephric fat. After the interlobular veins, the venous drainage progresses through the arcuate, interlobar, lobar, and segmental branches, with the course of each of these branches paralleling the respective artery.** After the segmental branches, the venous drainage coalesces into three to five venous trunks that eventually combine to form the renal vein. **Unlike the arterial supply, the venous drainage communicates freely through venous collars around the infundibula, providing for extensive collateral circulation in the venous drainage of the kidney** (Fig. 1–33). **Surgically, this is important because unlike the arterial supply, occlusion of a segmental venous branch has little effect on venous outflow.**

The renal vein is located directly anterior to the renal artery, although this position can vary up to 1 to 2 cm cranially or caudally relative to the artery. The right renal vein is generally 2 to 4 cm in length and enters the right lateral to posterolateral edge of the IVC. The left renal vein is typically 6

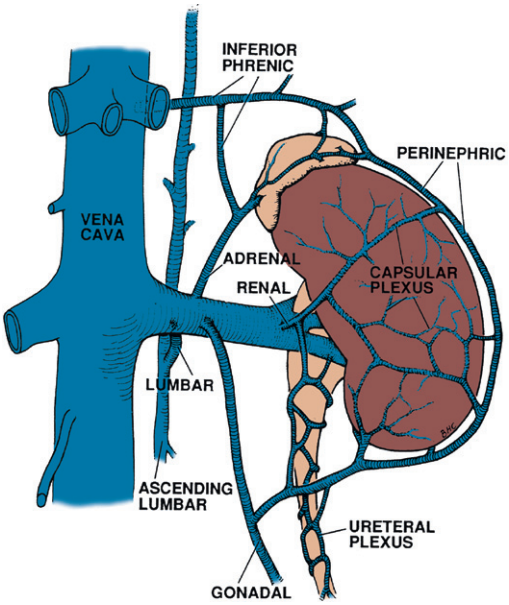

Figure 1–33. Venous drainage of the left kidney showing potentially extensive venous collateral circulation.

to 10 cm in length and enters the left lateral aspect of the IVC after passing posterior to the superior mesenteric artery and anterior to the aorta (Fig. 1–34 on the Expert Consult website). Compared with the right renal vein, the left renal vein enters the IVC at a slightly more cranial level and a more anterolateral location. **Additionally, the left renal vein receives the left adrenal vein superiorly, lumbar vein posteriorly, and left gonadal vein inferiorly** (see Fig. 1–33). The right renal vein typically does not receive any branches.

Common Anatomic Variants

Anatomic variations in the renal vasculature are common, occurring in 25% to 40% of kidneys. The most common variation is supernumerary renal arteries, with up to five arteries reported. This occurs more often on the left. These additional arteries can enter through the hilum or directly into the parenchyma. **Lower pole arteries on the right tend to cross anterior to the IVC, whereas lower pole arteries on either side can cross anterior to the collecting system, causing a ureteropelvic junction obstruction.** When the kidney is ectopic, supernumerary arteries are even more common and their origin even more varied, with the celiac trunk, superior mesenteric artery, or iliac arteries all possible sources of ectopic renal arteries. Supernumerary veins occur as well, but this is a less common entity. The most common example is duplicate renal veins draining the right kidney via the right renal hilum. Polar veins are quite rare. Finally, the left renal vein may course behind the aorta or divide and send one limb anterior and one limb posterior to the aorta, resulting in a collar-type circumaortic formation.

Renal Lymphatics

The renal lymphatics largely follow blood vessels through the columns of Bertin and then form several large lymphatic trunks within the renal sinus. As these lymphatics exit the hilum, branches from the renal capsule, perinephric tissues, renal pelvis, and upper ureter drain into these lymphatics. They then empty into lymph nodes associated with the renal vein near the renal hilum. From here, the lymphatic drainage between the two kidneys varies (Figs. 1–35 and 1–36). **On the left, primary lymphatic drainage is into the left lateral para-aortic lymph nodes including nodes anterior and posterior to the aorta between the inferior mesenteric artery and the diaphragm. Occasionally, there will be additional drainage from the left kidney into the retrocrural nodes or directly into the thoracic duct above the diaphragm. On the right, drainage is into the right interaortocaval and right paracaval lymph nodes** including nodes located anterior and posterior to the vena cava, from the common iliac vessels to the diaphragm. Occasionally, there will be additional drainage from the right kidney into the retrocrural nodes or the left lateral para-aortic lymph nodes.

Renal Collecting System

Microscopic Anatomy from Glomerulus to Collecting System

Microscopically, the renal collecting system originates in the renal cortex at the glomerulus as filtrate enters into Bowman capsule (Fig. 1–37 on the Expert Consult website). Together the glomerular capillary network and Bowman capsule form the renal corpuscle (malpighian corpuscle) (Fig. 1–38). The glomerular capillary network is covered by specialized epithelial cells called **podocytes** that, along with the capillary epithelium, form a selective barrier across which the urinary filtrate must pass. The filtrate is initially collected in Bowman capsule and then moves to the proximal convoluted tubule. The **proximal tubule** is composed of a thick cuboidal epithelium covered by dense

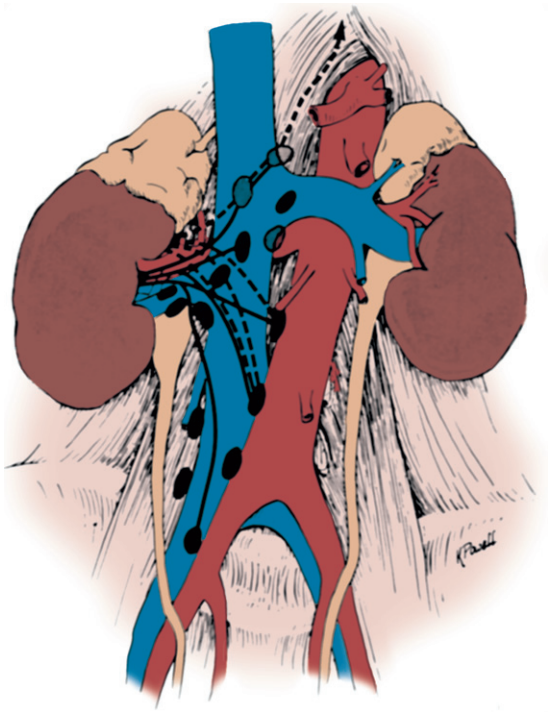

Figure 1–36. Regional lymphatic drainage of the right kidney. *Dark nodes,* anterior; *light nodes,* posterior. *Solid lines,* anterior lymphatic channels; *dashed lines,* posterior lymphatic channels. *Arrow* leads to the thoracic duct.

microvilli. These microvilli greatly increase the surface area of the proximal tubule, allowing a large portion of the urinary filtrate to be reabsorbed in this section of the nephron.

The proximal tubule continues deeper into the cortical tissue where it becomes the **loop of Henle.** The loop of Henle extends variable distances into the renal medulla. Within the renal medulla, the loop of Henle reverses course and moves back toward the periphery of the kidney. As it ascends out of the medulla the loop thickens and becomes the **distal convoluted tubule.** This tubule eventually returns to a position adjacent to the originating glomerulus and proximal convoluted tubule. Here the distal convoluted tubule turns once again for the interior of the kidney and becomes a collecting tubule. Collecting tubules from multiple nephrons combine into a collecting duct that extends inward through the renal medulla and eventually empties into the apex of the medullary pyramid, the renal papilla.

Renal Papillae, Calyces, and Pelvis

The renal papillae are the tip of a medullary pyramid and constitute the first gross structure of the renal collecting system. Typically, there are 7 to 9 papillae per kidney, but this number is variable, ranging from 4 to 18. The papillae are aligned in two longitudinal rows situated approximately 90 degrees from one another. There is an anterior row that owing to the orientation of the kidney faces in a lateral direction and a posterior row that extends directly posterior (see Figs. 1–26 and 1–39). **Each of these papillae is cupped by a minor calyx** (see Fig. 1–22). At the upper and lower poles, compound calyces are often encountered. These compound calyces are the result of renal pyramid fusion and because of their anatomy are more likely to allow reflux into the renal parenchyma (Fig. 1–40). Clinically, this can result in more severe scarring of the parenchyma overlying compound calyces.

After cupping an individual papilla, each minor calyx narrows to an infundibulum. Just as there is frequent variation in the number of calyces, the diameter and length of the infundibula vary greatly. **Infundibuli combine to form two or three major calyceal branches. These are frequently termed the *upper, middle,* and *lower pole calyces,* and these calyces in turn combine to form the renal pelvis. The renal pelvis itself can vary greatly in size, ranging from a small intrarenal pelvis to a large predominantly extrarenal pelvis.** Eventually the pelvis narrows to form the ureteropelvic junction, marking the beginning of the ureter.

On close examination, it is clear that there is significant variation in the anatomy of the renal collecting system (Figs. 1–41 through 1–43). Number of calyces, diameter of the infundibuli, and size of the renal pelvis all vary significantly among normal individuals. Even in the same individual, the renal collecting systems may be similar but are rarely identical. **Because of this variation, it can be difficult to distinguish pathologic from normal on the basis of anatomy alone. Instead, it is demonstrated dysfunction that is necessary to make the diagnosis of a pathologic anatomic formation within the renal collecting system.**

Renal Innervation

Sympathetic preganglionic nerves originate from the eighth thoracic through first lumbar spinal segments and then travel to the celiac and aorticorenal ganglia. From here, postganglionic fibers travel to the kidney via the autonomic plexus surrounding the renal artery. Parasympathetic fibers originate from the vagus nerve and travel with the sympathetic fibers to the autonomic plexus along the renal artery. The primary function of the renal autonomic innervation is vasomotor, with the sympathetics inducing vasoconstriction and the parasympathetics causing vasodilation. Despite this innervation, it is important to realize that the kidney functions well even without this neurologic control, as evidenced by the successful function of transplanted kidneys.

URETERS

The ureters are bilateral tubular structures responsible for transporting urine from the renal pelvis to the bladder (see Fig. 1–1). They are generally 22 to 30 cm in length with a wall composed of multiple layers (Fig. 1–44). The inner layer is transitional epithelium. Next is the lamina propria. This is a connective tissue layer that along with the epithelium makes up the mucosal lining. Overlying the lamina propria is a layer of smooth muscle that is contiguous with muscle covering the renal calyces and pelvis,

Key Point: Ureters

- The course of the ureter begins posterior to the renal artery and continues along the anterior edge of the psoas muscle. The gonadal vessels cross anterior to the ureter in this region. The ureter next passes over the iliac vessels, generally marking the bifurcation of common iliac into internal and external iliacs.

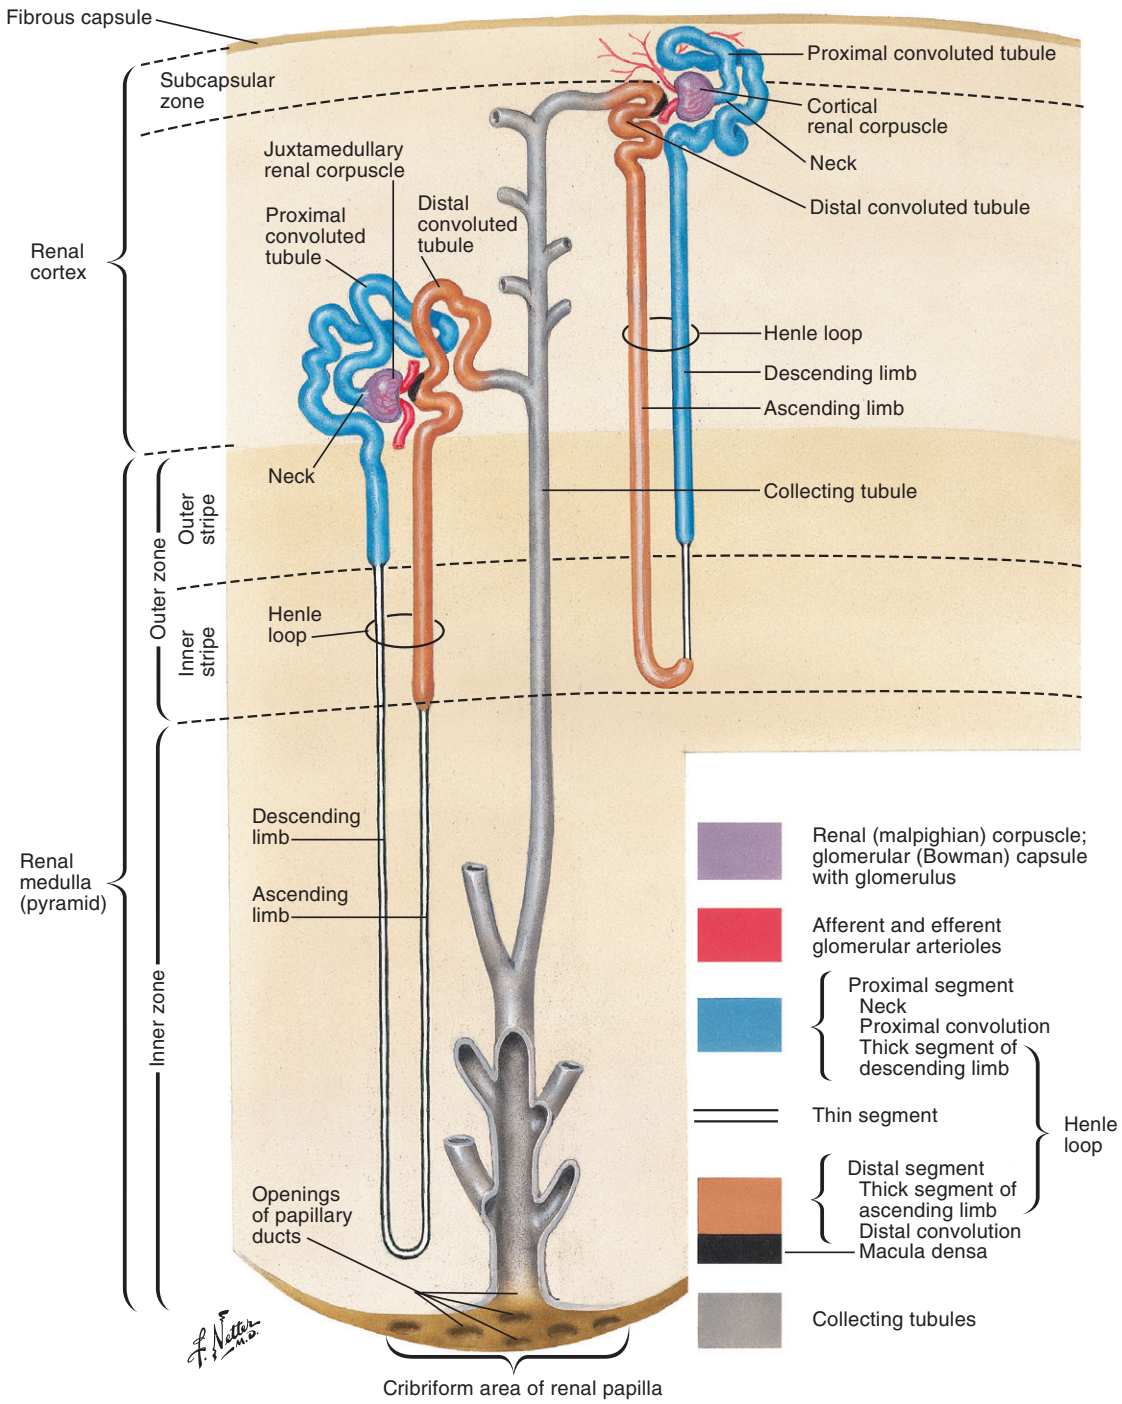

Figure 1–38. Renal nephron and collecting tubule. (From Netter FH. Atlas of human anatomy. 4th ed. Philadelphia: Elsevier; 2006. p. 336.)

although in the ureter this layer is divided into an inner longitudinal and an outer circular layer. Together, these muscular layers provide the peristaltic wave that actively transports urine from the renal collecting system through the ureter to the bladder. The outermost layer is the adventitia. This thin layer surrounds the ureter and encompasses the blood vessels and lymphatics that travel along the ureter.

Anatomic Relationships

Key to many urologic procedures is an understanding of ureteral anatomic relationships. The ureter begins at the ureteropelvic junction, which lies posterior to the renal artery and vein. It then progresses inferiorly along the anterior edge of the psoas muscle. Anteriorly, the right ureter is related to the ascending colon, cecum, colonic mesentery, and appendix. The left ureter is closely related to the descending and sigmoid colon and their accompanying mesenteries. Approximately a third of the way to the bladder the ureter is crossed anteriorly by the gonadal vessels. As it enters the pelvis the ureter crosses anterior to the iliac vessels. **This crossover point is usually at the bifurcation of the common iliac into the internal and external iliac arteries, thus making this a useful landmark for pelvic procedures.**

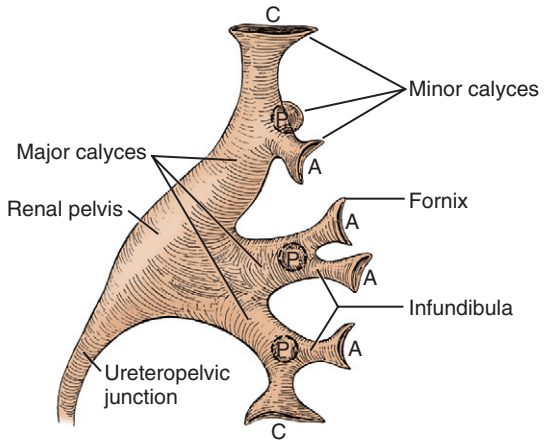

Figure 1–39. The renal collecting system (left kidney) showing major divisions into minor calyces, major calyces, and renal pelvis. A, anterior minor calyces; C, compound calyces at the renal poles; P, posterior minor calyces.

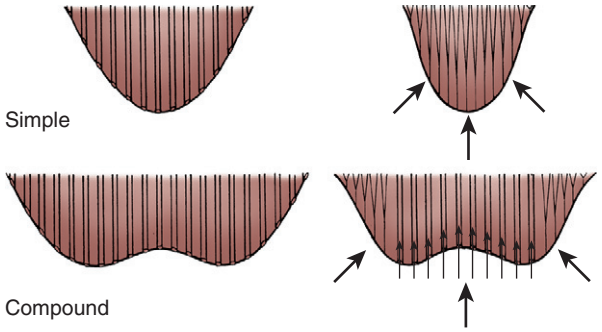

Figure 1–40. Diagram demonstrating structural and functional distinctions between simple and compound renal papillae. Back pressure causes closure of the collecting ducts in a simple papilla, effectively preventing reflux of urine into the renal parenchyma. The structure of the compound papilla allows intrarenal reflux of urine with sufficient back pressure.

Given the proximity of the ureters to several bowel segments, malignant and inflammatory processes of the terminal ileum, appendix, right or left colon, and sigmoid colon may involve the ureter. Effects can range from microhematuria to fistula or total obstruction. Within the female pelvis, the ureters are crossed anteriorly by the uterine arteries and are closely related to the uterine cervix. This location places the ureters at risk during hysterectomy. Pathologic processes of the fallopian tube and ovary may also encroach on the ureter at the pelvic brim.

Normal Variations in Ureteral Caliber

The normal ureter is not of uniform caliber, with three distinct narrowings classically described: the

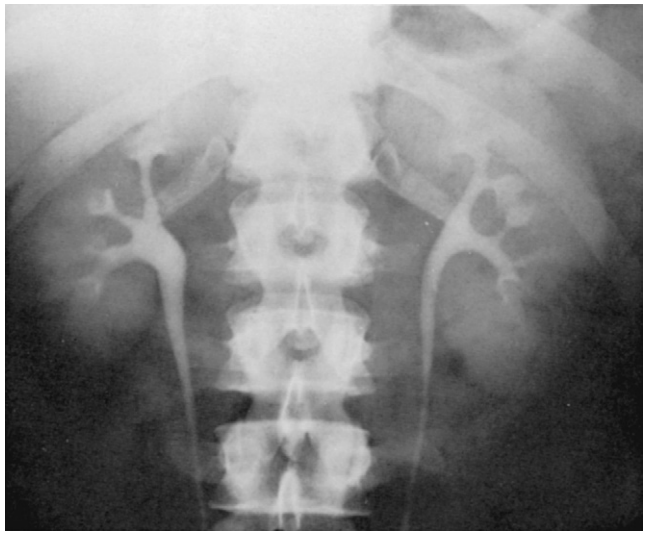

Figure 1–41. Normal bilateral renal collecting systems, demonstrated by excretory urography.

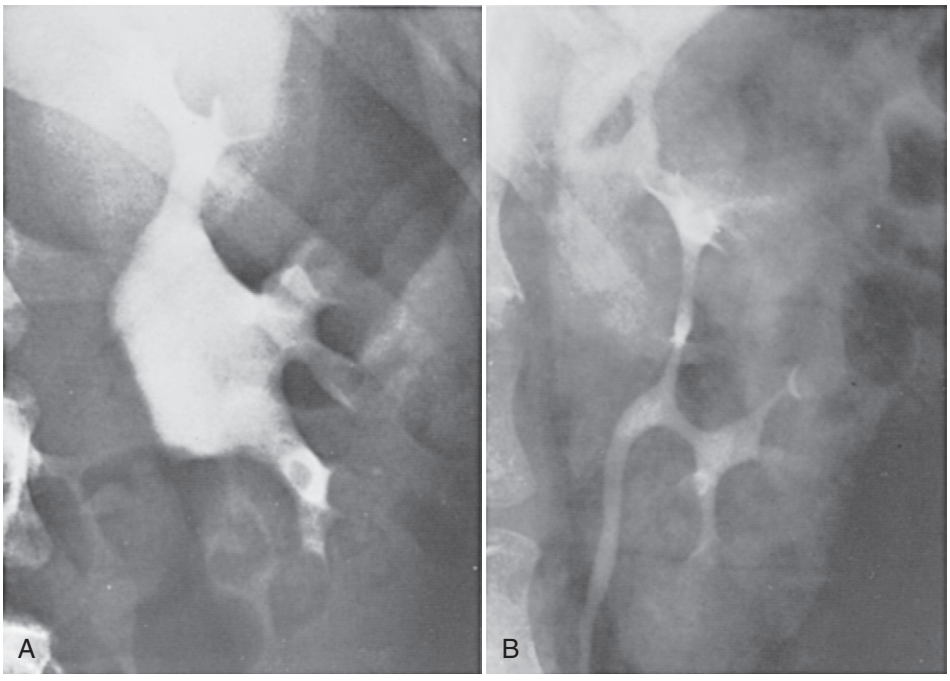

Figure 1–42. Significant variation between two normal renal pelves, demonstrated by excretory urography. **A,** Large, extrarenal pelvis. **B,** Narrow, completely intrarenal pelvis, barely larger in caliber than the ureter.

The rich vascular supply of the ureter is also demonstrated. LP, lamina propria; TC, transitional epithelium. (Courtesy of Dr. Hossein Saboorian.)

ureteropelvic junction, crossing of the iliac vessels, and the ureterovesical junction (Fig. 1–45). At the ureteropelvic junction, the renal pelvis tapers into the proximal ureter. In many cases, this perceived narrowing may be more apparent than real, with no evidence of obstruction evident on radiographic or endoscopic investigation. The second region of narrowing occurs as the ureter crosses the iliac vessels. This is due to a combination of extrinsic compression of the ureter by the iliac vessels and the necessary anterior angulation of the ureter as it crosses the iliac vessels to enter into the pelvis. There is also no intrinsic change in the ureteral caliber at this location. The third site of narrowing observed in the normal ureter is the ureterovesical junction. There is a true physical restriction of the ureter as it makes the intramural passage through the bladder wall to the ureteral orifice. These three sites of ureteral narrowing are clinically significant because they are common locations for urinary calculi to lodge during passage. In addition, the angulation of the ureter, first anteriorly as it passes over the iliac vessels, then posteromedially as it enters the pelvis and courses behind the bladder, may restrict successful passage of rigid endoscopes. Appreciation of this normal angulation and the three-dimensional course of the ureter is critical for safe and successful ureteral endoscopy.

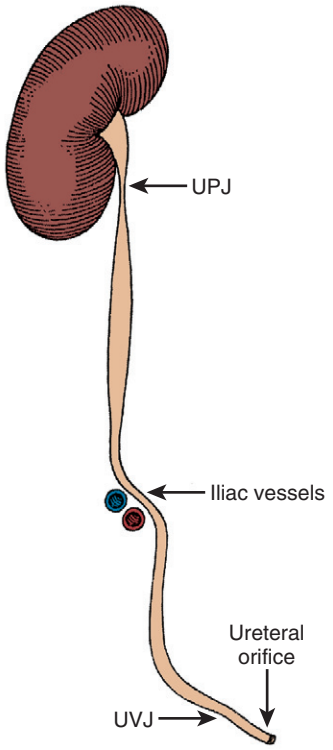

Figure 1–45. The ureter demonstrating sites of normal functional or anatomic narrowing at the ureteropelvic junction (UPJ), the iliac vessels, and the ureterovesical junction (UVJ). Note also the anterior displacement and angulation of the ureter, which occurs over the iliac vessels, as shown here diagrammatically.

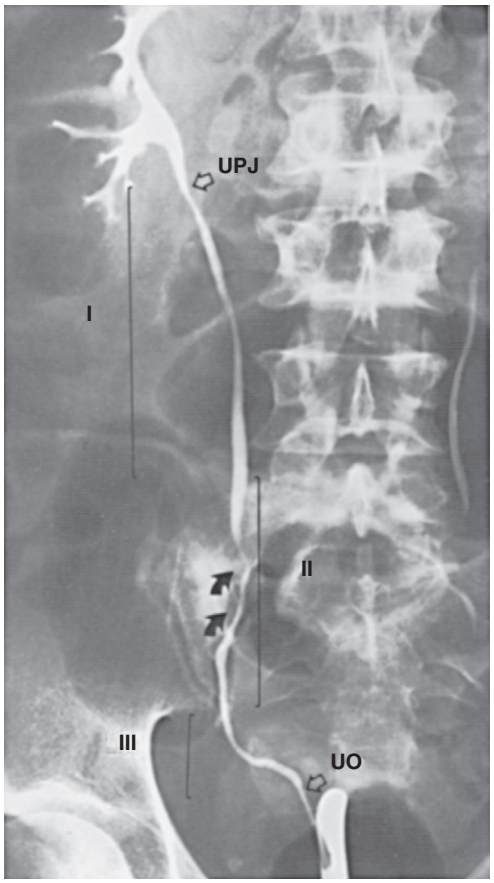

Figure 1–46. The right ureter, illustrated by retrograde injection of contrast material. UO, ureteral orifice in the bladder; UPJ, ureteropelvic junction; I, upper ureter, extending to the upper border of the sacrum; II, middle ureter, extending to the lower border of the sacrum; III, distal or lower ureter, traversing the pelvis to end in the bladder. *Arrows* indicate the course of the common iliac artery and vein.

Ureteral Segmentation and Nomenclature

The ureter is often arbitrarily divided into segments to assist ureteral description. The simplest system divides the ureter into the abdominal ureter extending from renal pelvis to the iliac vessels and the pelvic ureter extending from the iliac vessels to the bladder. **Alternatively, the ureter can be divided into upper, middle, and lower segments** (Fig. 1–46). **The upper ureter extends from the renal pelvis to the upper border of the sacrum. The middle ureter comprises the segment from the upper to the lower border of the sacrum. The lower (distal or pelvic) ureter extends from the lower border of the sacrum to the bladder.**

Ureteral Blood Supply and Lymphatic Drainage

The ureter receives its blood supply from multiple arterial branches along its course (Fig. 1–47). **Of greatest importance to the surgeon is that arterial branches to the abdominal ureter approach from a medial direction, whereas arterial branches to the pelvic ureter approach from a lateral direction.** For the upper ureter these branches originate from the renal artery, gonadal artery, abdominal aorta, and common iliac artery. After entering the pelvis, additional small arterial branches to the distal ureter may arise from the internal iliac artery or its branches, especially the vesical and uterine arteries, but also from the middle rectal and vaginal arteries. **After reaching the ureter, the arterial vessels course longitudinally within**

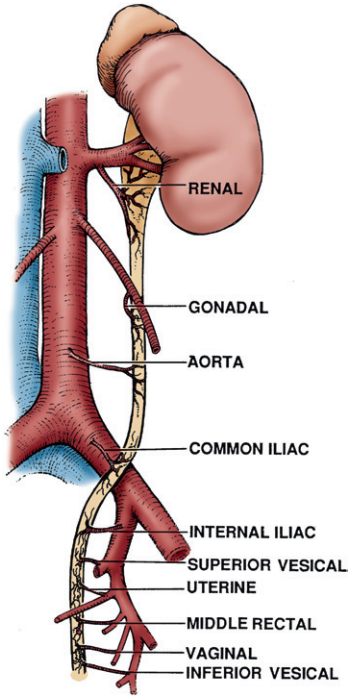

Figure 1–47. Sources of arterial blood supply to the ureter.

the periureteral adventitia in an extensive anastomosing plexus. It is this longitudinal vascularity that allows the ureter to be safely mobilized from the surrounding retroperitoneal tissues without compromising the vascular supply, provided that the periureteral adventitia is not stripped. The venous and lymphatic drainage of the ureter parallels the arterial supply. Thus ureteral lymphatic drainage varies by ureteral level. In the pelvis, ureteral lymphatics drain to internal, external, and common iliac nodes. In the abdomen the left para-aortic lymph nodes are the primary drainage site for the left ureter, whereas the abdominal portion of the right ureter is drained primarily to right paracaval and interaortocaval lymph nodes. The lymphatic drainage of the upper ureter and renal pelvis tends to join the renal lymphatics and is identical to that of the ipsilateral kidney.

Ureteral Innervation

The exact role of the ureteral autonomic input is unclear. Normal ureteral peristalsis does not require outside autonomic input but, rather, originates and is propagated from intrinsic smooth muscle pacemaker sites located in the minor calyces of the renal collecting system. The autonomic nervous system may exert some modulating effect on this process, but the exact role is unclear. The ureter receives preganglionic sympathetic input from the 10th thoracic through 2nd lumbar spinal segments. Postganglionic fibers arise from several ganglia in the aorticorenal, superior, and inferior hypogastric autonomic plexuses. Parasympathetic input is received from the 2nd through 4th sacral spinal segments.

Pain Perception and Somatic Referral

Renal pain fibers are stimulated by tension (distention) in the renal capsule, renal collecting system, or ureter. Direct mucosal irritation in the upper urinary tract may also stimulate nociceptors. Signals travel with the sympathetic nerves and result in a visceral-type pain referred to the sympathetic distribution of the kidney and ureter (eighth thoracic through second lumbar). Pain and reflex muscle spasm are typically produced over the distributions of the subcostal, iliohypogastric, ilioinguinal, and/or genitofemoral nerves, resulting in flank, groin, or scrotal (or labial) pain and hyperalgesia, depending on the location of the noxious visceral stimulus (Fig. 1–48).

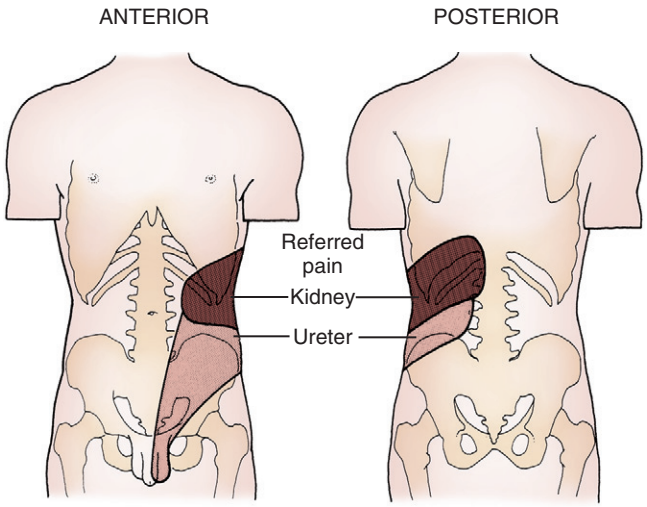

Figure 1–48. Patterns of referred somatic pain from the upper urinary tract.

chapter 2

Anatomy of the Lower Urinary Tract and Male Genitalia

Benjamin I. Chung, MD ● Graham Sommer, MD ● James D. Brooks, MD

Bony Pelvis
Anterior Abdominal Wall
Soft Tissues of the Pelvis
Pelvic Circulation
Pelvic Innervation
Pelvic Viscera
Perineum

This chapter provides a general anatomic framework to guide the pelvic surgeon. The bony, ligamentous, and muscular framework of the pelvis is presented first. Next, the pelvic vessels and nerves and the genital, urinary, and gastrointestinal viscera are discussed. Finally, the perineum and external genitalia are reviewed.

BONY PELVIS

The pelvic bones are the sacrum (the termination of the axial skeleton) and the two innominate bones. The latter are formed by the fusion of the iliac, ischial, and pubic ossification centers at the acetabulum (Fig. 2–1). The ischium and pubis also meet below, in the center of the inferior ramus, to form the obturator foramen. The weight of the upper body is transmitted from the axial skeleton to the innominate bones and lower extremities through the strong sacroiliac (SI) joints. As a whole, the pelvis is divided into a bowl-shaped false pelvis, formed by the iliac fossae and largely in contact with intraperitoneal contents, and the circular true pelvis wherein the urogenital organs lie. At the pelvic inlet, the true and false pelves are separated by the arcuate line, which extends from the sacral promontory to the pectineal line of the pubis. The lumbar lordosis that accompanies erect posture tilts the axis of the pelvic inlet so that it parallels the ground; the pelvic inlet faces anteriorly, and the inferior ischiopubic rami lie horizontal (Fig. 2–2). When approaching the pelvis through a low midline incision, the surgeon gazes directly into the true pelvis.

The anterior and posterior iliac spines, the iliac crests, the pubic tubercles, and the ischial tuberosities are palpable landmarks that orient the pelvic surgeon (see Fig. 2–1). Cooper (pectineal) ligament overlies the pectineal line and offers a sure hold for sutures in hernia repairs and urethral suspension procedures (Fig. 2–3). The ischial spine is palpable transvaginally and attaches to the pelvic diaphragm and the sacrospinous ligament. The sacrospinous ligament separates the greater and lesser sciatic foramina. Together with the sacrotuberous ligament, it stabilizes the SI joint by preventing downward rotation of the sacral promontory. The SI joint, synovial in type, gains additional strength from anterior and posterior ligaments. In pelvic trauma, fractures virtually never involve this joint but occur adjacent to it. The pubes, the thinnest of the pelvic bones, are nearly always fractured, and their fragments may injure the adjacent bladder, urethra, and vagina. Resection or congenital nonunion of the pubes (e.g., bladder exstrophy) does not affect ambulation because of the strength of the SI joint (Waterhouse et al, 1973; Golimbu et al, 1990).

ANTERIOR ABDOMINAL WALL

Skin and Subcutaneous Fasciae

To minimize scarring, incisions of the anterior abdominal wall and flank should follow Langer lines of cleavage. These lines parallel dermal collagen fibers and are oriented along lines of stress. They correspond to the segmental thoracic and lumbar nerves. The skin is backed by Camper fascia, a loose layer of fatty tissue that varies in thickness with the nutritional status of the patient. The superficial circumflex iliac, external pudendal, and superficial inferior epigastric vessels branch from the femoral vessels to run in this layer (Figs. 2–4 and 2–5). The superficial inferior epigastric vessels are encountered during inguinal incisions and can cause troublesome bleeding during placement of pelvic laparoscopic ports.

Scarpa fascia forms a distinct layer deep to Camper fascia, although it may be difficult to discern in older patients. Superiorly and laterally, it blends with Camper fascia. Inferiorly, it fuses with the deep fascia of the thigh 1 cm below the inguinal ligament along a line from the anterior superior iliac spine to the pubic tubercle. Medially, it is continuous with Colles fascia of the perineum (see Fig. 2–4). Colles fascia attaches to the posterior edge of the urogenital diaphragm and the inferior ischiopubic rami. It is continuous with the dartos fascia of the penis and scrotum. These fasciae can limit both the spread of infection in necrotizing fasciitis of the scrotum (Fournier gangrene) and the extent of urinary extravasation in an anterior urethral injury. For instance, blood and urine can accumulate in the scrotum and penis deep to the dartos fascia after an anterior urethral injury. In the perineum, their spread is limited by the fusions of Colles fascia

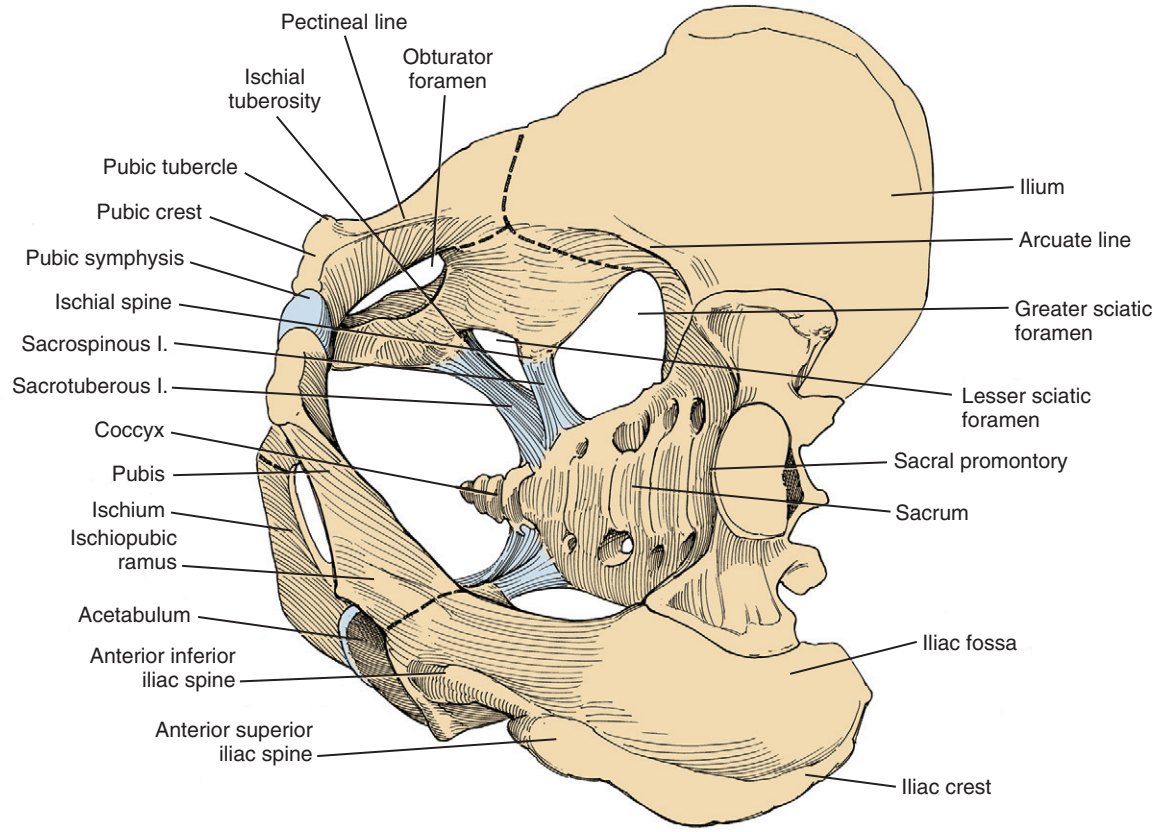

Figure 2–1. The bones and ligaments of the pelvis. (From Hinman F Jr. Atlas of urosurgical anatomy. Philadelphia: WB Saunders; 1993. p. 196.)

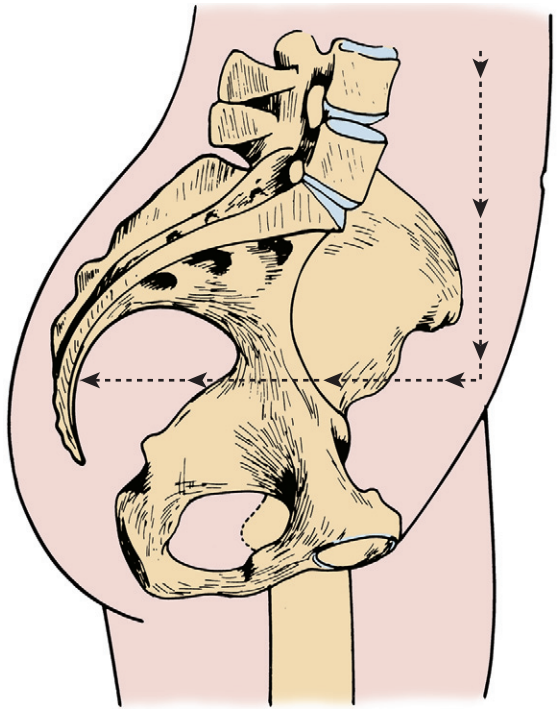

Figure 2–2. Pelvis in standing position. The axis of the pelvic cavity is horizontal because of lumbar lordosis. (From Zacharin RF. Pelvic floor anatomy and the surgery of pulsion enterocele. New York: Springer-Verlag; 1985. p. 15.)

to the ischiopubic rami laterally and to the posterior edge of the perineal membrane; the resulting hematoma is therefore butterfly shaped. Because of these fasciae, bleeding, infection, or urinary extravasation will not extend down the leg or into the buttock but can freely travel up the anterior abdominal wall deep to Scarpa fascia to the clavicles and around the flank to the back.

Abdominal Musculature

The abdominal musculature lies immediately below Scarpa fascia. The origins of the external oblique, internal oblique, and transversus abdominis muscles and the orientation of their fibers are presented in Chapter 1. **These muscles terminate on the anterior abdominal wall as broad, tough aponeurotic sheets that fuse in the midline (linea alba) and form the rectus sheath** (see Fig. 2–5). The linea alba is avascular and is a convenient point of access to the peritoneal and pelvic cavities. In its upper portion, the anterior rectus sheath is formed by the aponeurosis of the external oblique muscle and a portion of the internal oblique muscle (Fig. 2–6). The posterior sheath is derived from the remaining internal oblique aponeurosis and the transversus abdominis aponeurosis. Two thirds of the distance from the pubis to the umbilicus, the arcuate line is formed, as all aponeurotic layers abruptly pass anterior to the rectus abdominis, leaving this muscle clothed only by transversalis fascia and peritoneum posteriorly.

The rectus abdominis arises from the pubis medial to the pubic tubercle and inserts on the xyphoid process

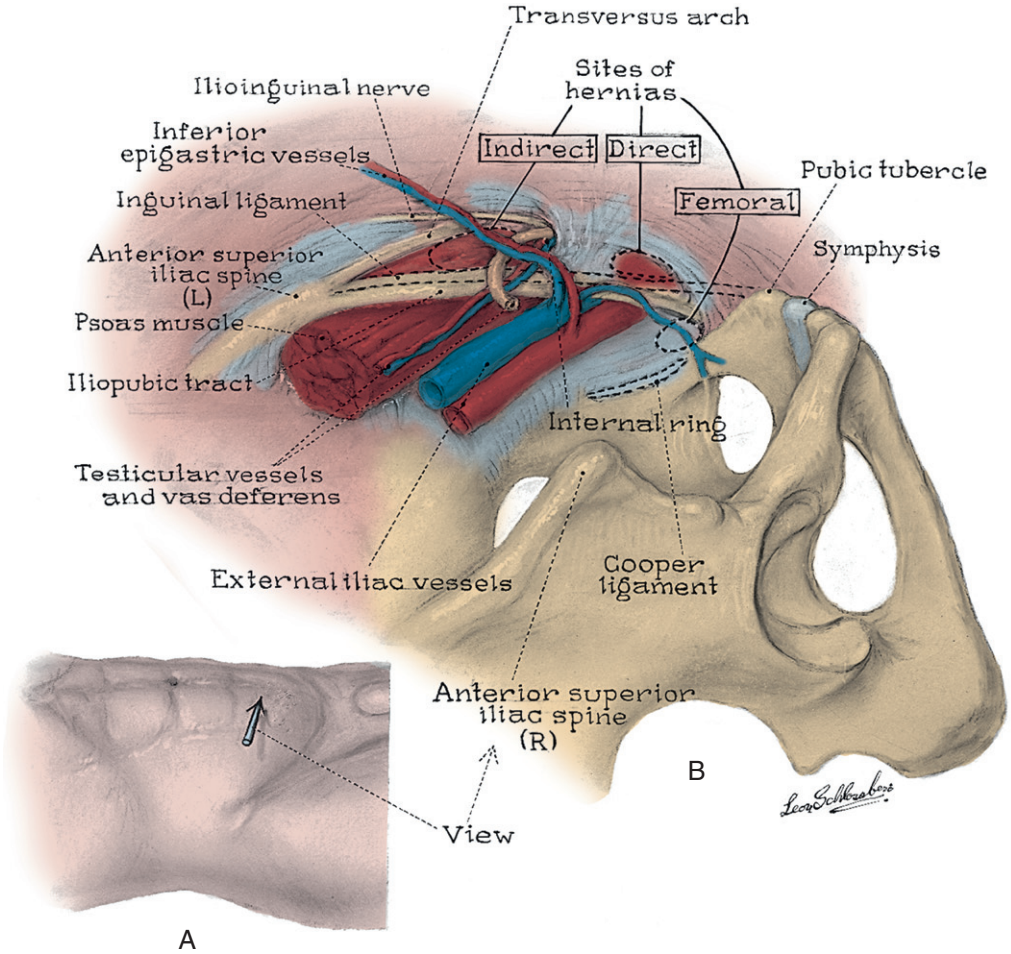

Figure 2–3. Topography (**A**) and posterior wall (**B**) of the left inguinal canal, viewed from the preperitoneal space. The location of three types of inguinal hernia is demonstrated. Figure 2–4. *Left,* Anterior view of the deep fasciae of the abdomen, perineum, and thigh. Note the superficial inferior epigastric artery passing superiorly in Camper fascia. *Right,* Midline sagittal view of the pelvic fasciae and their attachments.

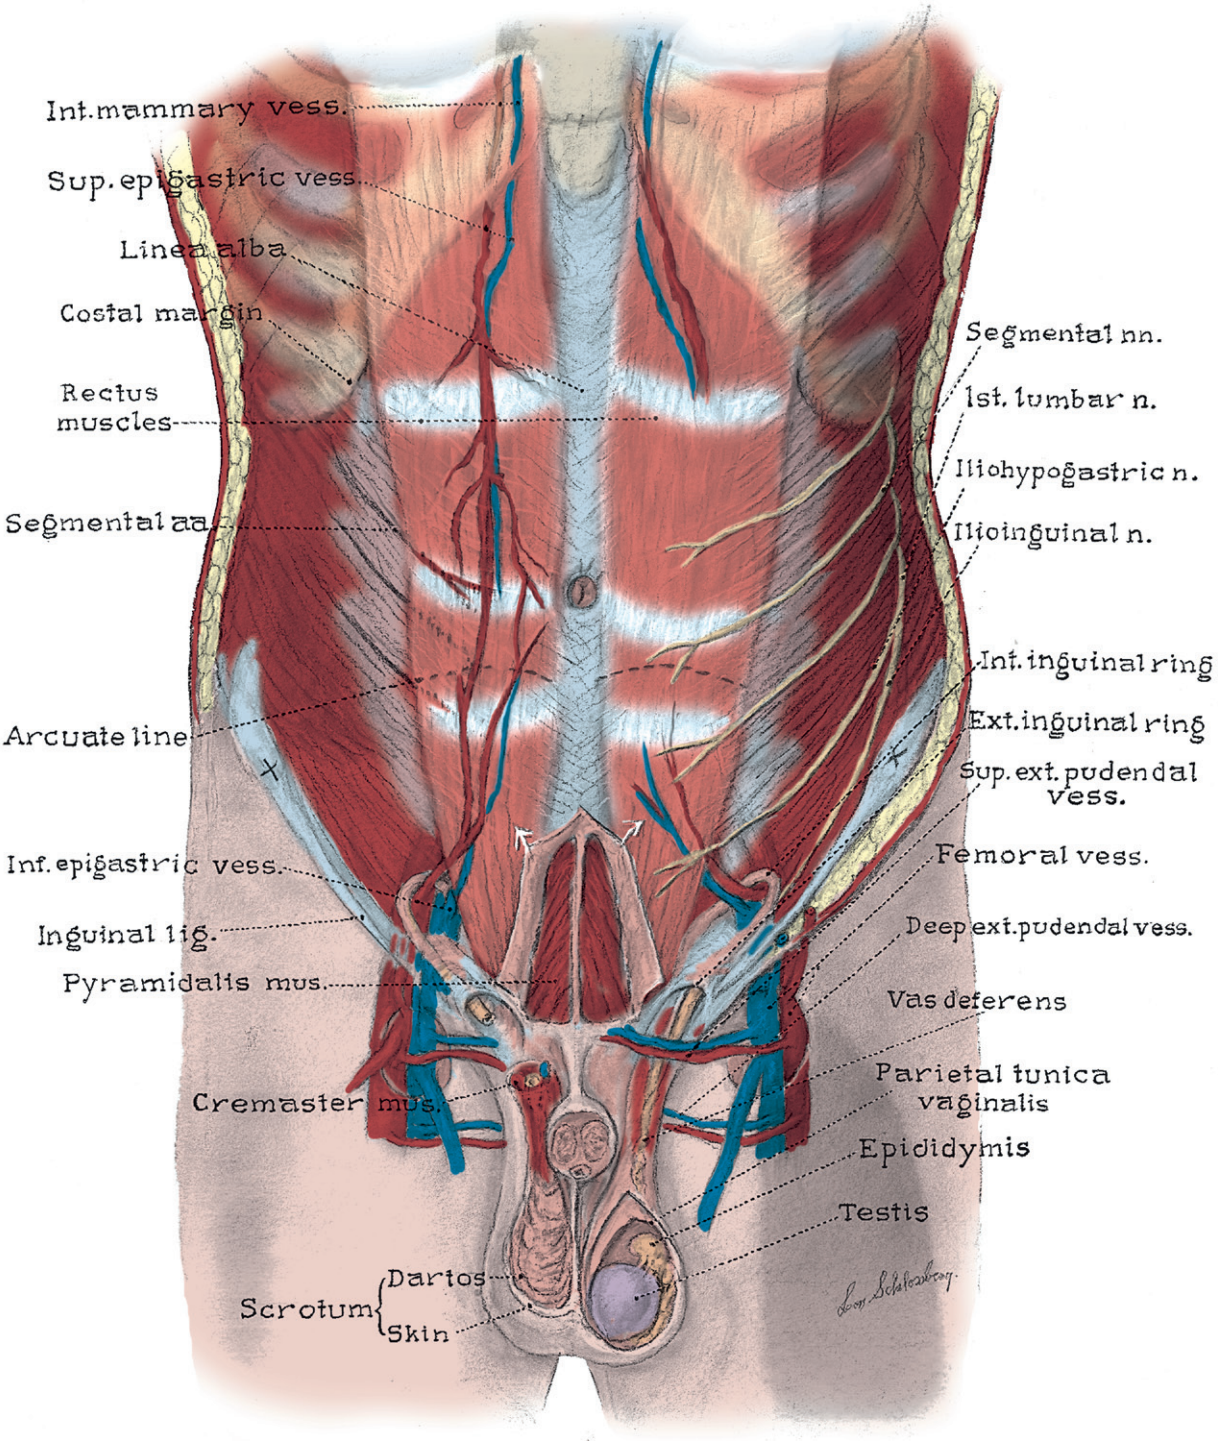

Figure 2–5. Muscles, vessels, and nerves of the anterior abdominal wall.

and adjacent costal cartilages. The muscle is crossed by three or four tendinous intersections that are firmly attached to the anterior rectus sheath; thus the muscle can be divided transversely without significant retraction. It is supplied by the last six thoracic segmental nerves that enter it laterally. Paramedian incisions lateral to the rectus divide these nerves, cause atrophy of the rectus, and predispose to ventral hernia. Anterior to the rectus and within its sheath, the triangle-shaped pyramidalis muscle arises from the pubic crest and inserts into the linea alba (see Fig. 2–5). It is supplied by the subcostal nerve (T12).

Inguinal Canal

The inguinal canal transmits the spermatic cord in the male, the round ligament in the female, and the ilioinguinal nerve in both sexes (Fig. 2–7; see also Fig. 2–5). Its anterior wall and floor are formed by the external oblique muscle, which folds over at its inferior edge as the inguinal ligament. Above the pubic tubercle, the fibers of the external oblique aponeurosis split to form the lateral edges (crura) of the external inguinal ring. Transverse (intercrural) fibers bridge the crura to

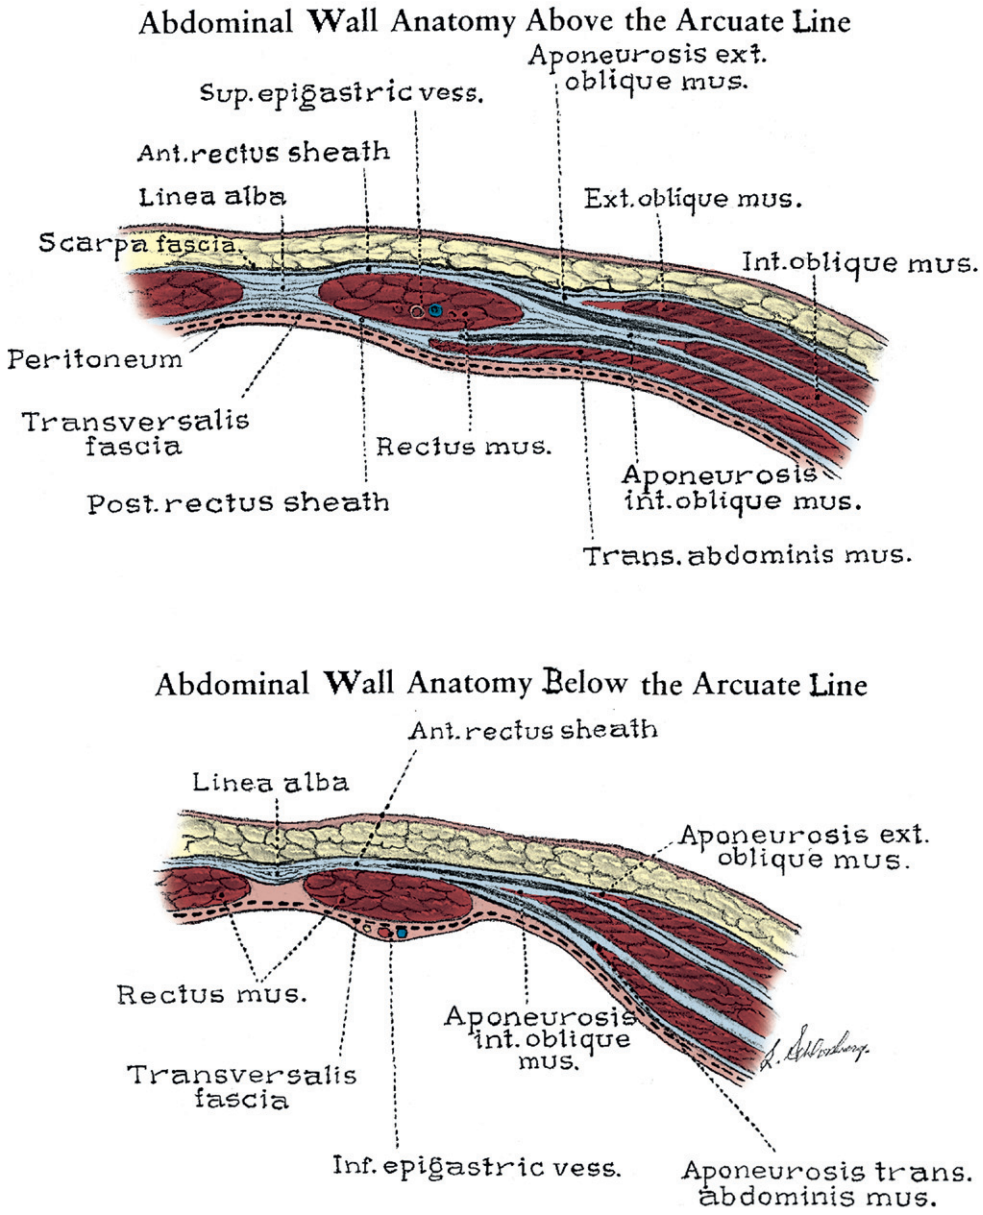

Figure 2–6. Cross section of the rectus sheath. *Top,* Above the arcuate line, the aponeurosis of the external oblique muscle forms the anterior sheath, and the transversus aponeurosis forms the posterior sheath. The internal oblique muscle splits to contribute to both the anterior and the posterior sheaths. *Bottom,* Below the arcuate line, all aponeuroses pass anterior to the rectus.

form the superior edge of the external ring. By dividing the intracrural fibers, the external oblique can be separated along its fibers to gain access to the cord. The posterior wall of the canal is formed by the transversalis fascia, which lines the inner surface of the abdominal wall. The cord structures pierce this fascia lateral to the inferior epigastric vessels at the internal inguinal ring (see Fig. 2–3). The internal inguinal ring lies midway between the anterior superior iliac spine and the pubic tubercle, above the inguinal ligament, and 4 cm lateral to the external ring. Fibers of the internal oblique and transversus abdominis arise from the iliopsoas fascia and inguinal ligament lateral to the internal ring and arch over the canal to form its roof. They fuse as the conjoint tendon, pass posterior to the cord, and insert into the rectus sheath and pubis. The conjoint tendon reinforces the posterior wall of the inguinal canal at the external ring. With contraction of the internal oblique and transversus muscles, the roof of the canal closes against the floor, preventing herniation of intra-abdominal contents into the canal. Hernias into the canal may occur medial (direct) or lateral (indirect) to the inferior epigastric vessels (see Figs. 2–3 and 2–7).

Internal Surface of the Anterior Abdominal Wall

Approached laparoscopically, **three elevations of the peritoneum, referred to as the *median, medial,* and *lateral umbilical folds,*** are visible on the anterior abdominal wall below the umbilicus (Fig. 2–8). The median fold overlies the median umbilical ligament (urachus), a fibrous remnant of the cloaca that attaches the bladder to the anterior abdominal wall. The obliterated umbilical artery in the medial umbilical fold serves as an

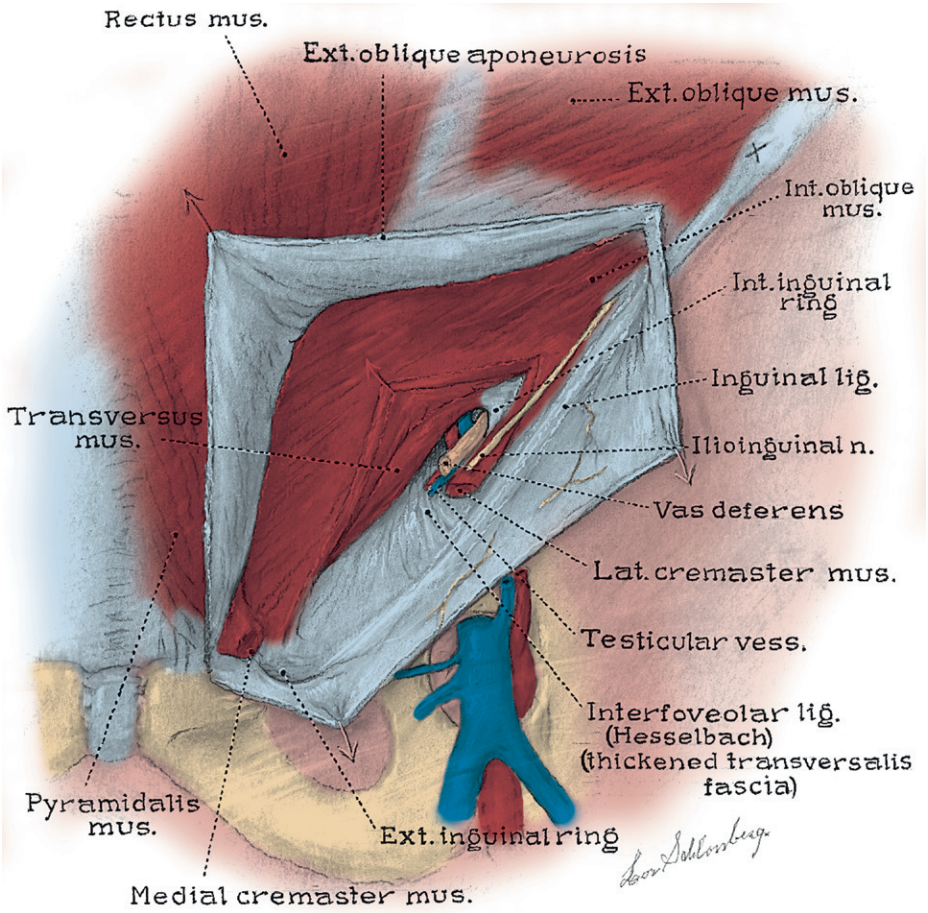

Figure 2–7. Deep structures of the left inguinal canal, viewed from the front.

important landmark for the surgeon. It may be traced to its origin from the internal iliac artery to locate the ureter, which lies on its medial side. During transperitoneal laparoscopic pelvic lymph node dissection, the obturator packet is accessed by incising the peritoneum lateral to the obliterated umbilical artery. In addition, during the performance of transperitoneal laparoscopic or robotic radical prostatectomy, the medial umbilical folds are used as landmarks to guide the dissection of the bladder to expose the space of Retzius. The lateral umbilical fold contains the inferior epigastric vessels as they ascend to supply the rectus abdominis.

SOFT TISSUES OF THE PELVIS

Pelvic Musculature

Muscles and fascia line the true pelvis and form its floor. The obturator internus arises from the inner surface of the obturator foramen and the obturator membrane and passes through the lesser sciatic foramen to insert on the femur (see Fig. 2–8). The fascia on the pelvic surface of this muscle is thickened into a tough line extending from the lower half of the pubis to the ischial spine. This tendinous arc of the levator ani serves as the origin of the muscles of the pelvic diaphragm: pubococcygeus and iliococcygeus (Fig. 2–9). These muscles are not truly separable, and they form a diaphragm that closes the pelvic outlet. Anteriorly, a narrow U-shaped hiatus remains, through which the urethra and rectum exit in the male, and the urethra, vagina, and rectum exit in the female (Fig. 2–10). The muscle bordering this hiatus has been referred to as *pubovisceral* because it provides a sling for (pubourethralis, puborectalis), inserts directly into (pubovaginalis, puboanalis, levator prostatae), or inserts into a structure intimately associated with the pelvic viscera (Lawson, 1974). The pubovisceral group provides strong fixation and support for the pelvic viscera. The coccygeus muscle extends from the sacrospinous ligament to the lateral border of the sacrum and coccyx to complete the pelvic diaphragm. Muscles of the pelvic diaphragm contain type I (slow-twitch) fibers, which provide tonic support to pelvic structures, and type II (fast-twitch) fibers, for sudden increases in intra-abdominal pressure (Gosling et al, 1981).The piriformis muscle arises from the lateral aspect of the sacrum and passes through and fills the greater sciatic foramen to form the posterolateral wall of the pelvis.

It is important to recognize that the pelvic diaphragm is not flat or bowl shaped, as it is frequently depicted. At the urogenital and anal hiatus, the muscles lie in a near-vertical configuration and are thickened inferiorly (see Fig. 2–10) (Brooks et al, 1998; Myers et al, 1998). Behind the anus, they flatten to form a nearly horizontal diaphragm, referred to as the *levator plate*. In the female, the levator plate provides critical support to the pelvic viscera, as discussed later.

Pelvic Fasciae

The pelvic fasciae are not merely collagenous; they are also rich in elastic tissue and smooth muscle. This suggests that they are active in the support, and possibly the function, of the pelvic viscera. The pelvic fasciae are continuous with the retroperitoneal fasciae and have been categorized somewhat

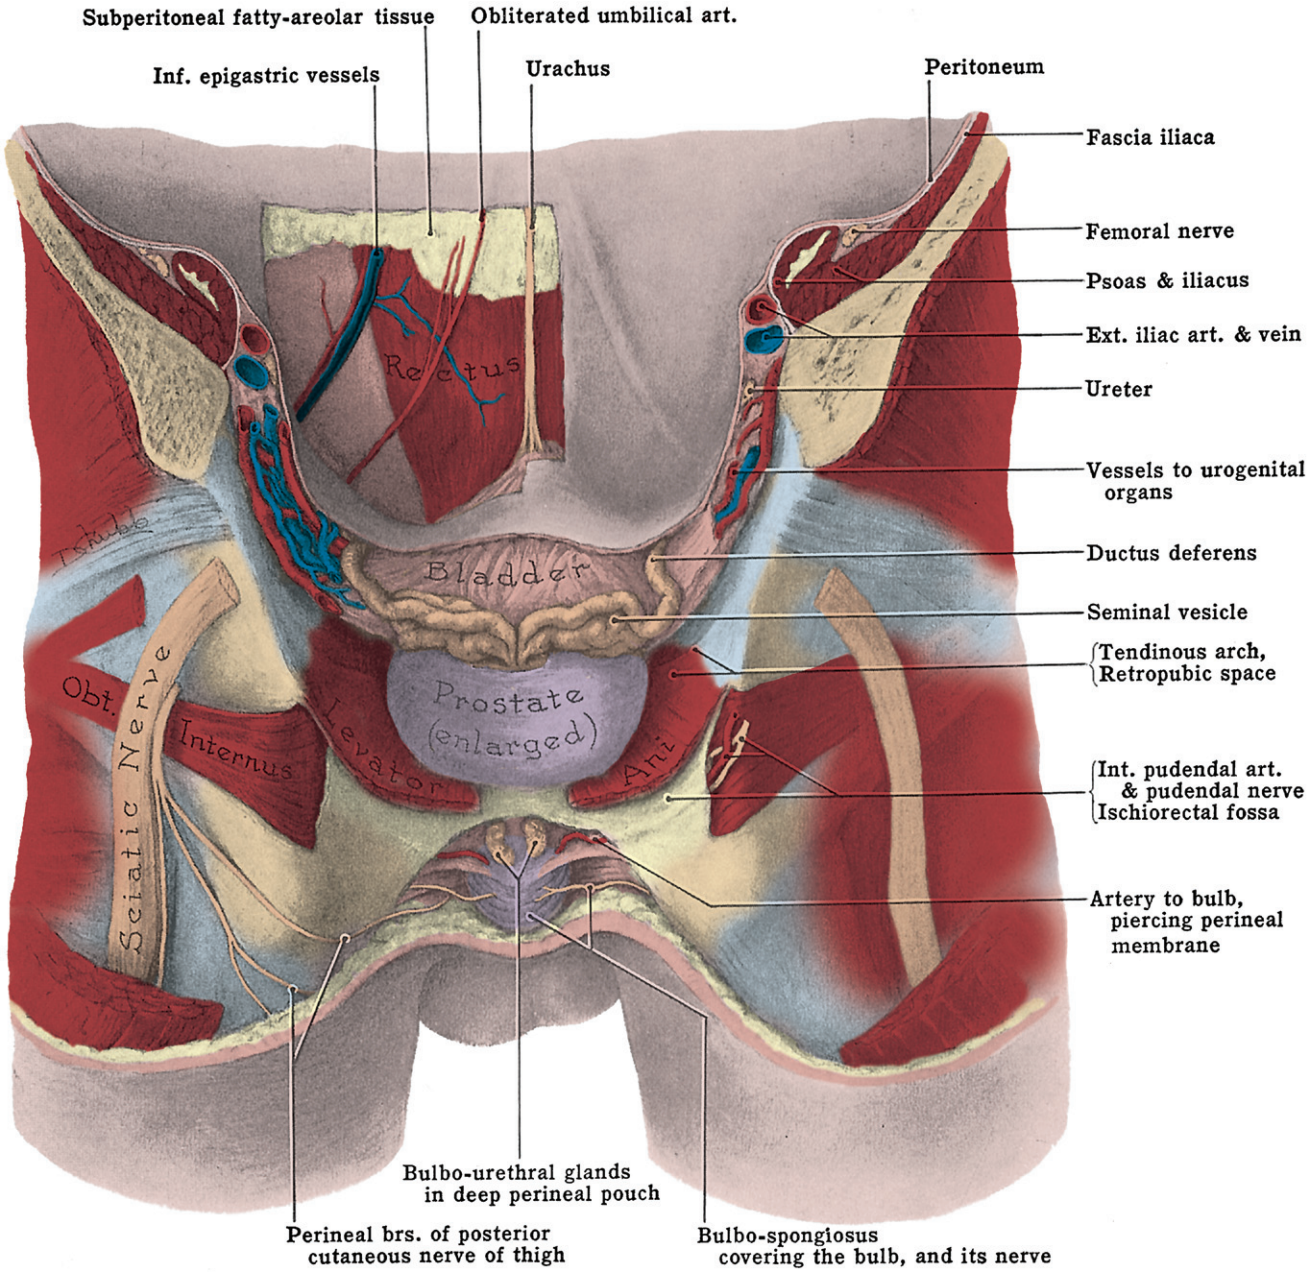

Figure 2–8. Male pelvis and anterior abdominal wall viewed from behind. The sacrum and ilia have been removed. (From Anderson JE. Grant's atlas of anatomy. 7th ed. Baltimore: Williams & Wilkins; 1978. Fig. 3–41.)

arbitrarily into outer, intermediate, and inner strata. The outer stratum, or endopelvic fascia, lines the inner surface of the pelvic muscles and is continuous with the transversalis layer of the abdomen. It is fixed to the arcuate line of the pelvis, Cooper ligament, the sacrospinous ligament, the ischial spine, and tendinous arc of the levator ani. The intermediate stratum embeds the pelvic viscera in a fatty, compressible layer that accommodates their filling and emptying. Its tissues are easily swept aside to reveal the retropubic, paravesical, rectogenital, and retrorectal potential spaces. All pelvic vessels and some pelvic nerves travel in this stratum and are subject to injury when these potential spaces are developed at surgery. The intermediate stratum coalesces around vessels and nerves supplying the pelvic organs to form named ligaments (e.g., cardinal, uterosacral, lateral, and posterior vesical) that suspend and tether these organs in the pelvis. This fascia also thickens around the pelvic urogenital organs to form their visceral fascia. These are not true ligaments but rather a meshwork of connective tissue and smooth muscle investing the visceral neurovascular pedicles (DeCaro et al, 1998). The inner stratum lies just beneath the peritoneum and is associated with the entire gastrointestinal tract. In the pelvis, it covers the rectum and dome of the bladder and forms the rectogenital septum (Denonvilliers fascia). This septum is the developmental remains of the rectogenital pouch of peritoneum that extended between the rectum and internal genitalia to the pelvic floor.

The pelvic fasciae have been given a confusing array of appellations by anatomists and surgeons interested in female pelvic organ prolapse. To add to the confusion, the strength of pelvic fasciae can differ significantly between individuals and races and these differences may predispose some individuals to pelvic

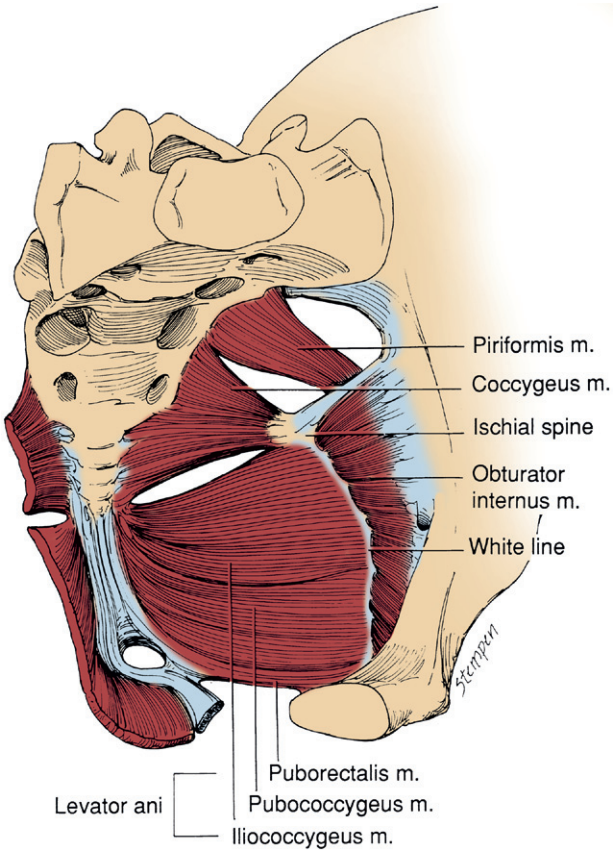

Figure 2–9. Muscles of the true pelvis (three-quarter view).

prolapse (Zacharin, 1985). **The pelvic fasciae have three important components: (1) Anteriorly, the puboprostatic ligaments** attach to the lower fifth of the pubis, lateral to the symphysis and to the junction of the prostate and external sphincter. They are called the pubourethral ligaments in the female and insert on the proximal third of the urethra (Fig. 2–11 on the Expert Consult website). (2) Laterally, the arcus tendineus fascia pelvis extends from the puboprostatic (pubourethral) ligament to the ischial spine (see Fig. 2–11). This fascia forms at the junction of the endopelvic and visceral fasciae. It should not be confused with the arcus tendineus levator ani, which lies above its anterior portion (Fig. 2–12). In the male, the arcus tendineus fascia pelvis is found at the base of a sulcus between the pelvic side wall and the prostate and bladder. In the female, it corresponds to the lateral attachment of the anterior bladder wall to the pelvic side wall. Paravaginal suspension procedures for stress urinary incontinence entail lateral reapproximation of the vaginal wall to this tendinous arc (Richardson et al, 1981). The lateral branches of the dorsal venous complex are directly beneath the arcus tendineus fascia pelvis; thus the endopelvic fascia should be opened lateral to this landmark. In the female, the fascia extending medially from this arch carries a variety of names (pubovesical, periurethral, urethropelvic ligament) and provides important support to the urethra and anterior vaginal wall. Damage to this fascia and its attachments has been implicated in urethrocele, cystocele, and stress urinary incontinence. (3) Posterior to the ischial spine, the fascia fans out to either side of the rectum and attaches to the pelvic side wall as the lateral and posterior vesical ligaments. In the female, these are the strong cardinal and uterosacral ligaments. They are not true ligaments; rather, they are condensations of intermediate stratum around visceral neurovascular pedicles. The peritoneum over these ligaments forms discrete folds (rectovesical in the male and rectouterine in the female) that can be appreciated at cystectomy (Fig. 2–13). Taken as a whole, the pelvic fasciae form a Y-shaped scaffolding for the pelvic viscera (see Fig. 2–12).

Fasciae of the Perineum and the Perineal Body

The weakest point in the pelvic floor, the urogenital hiatus, is bridged by the urogenital diaphragm, a structure unique to humans (see Fig. 2–10). The fibrous perineal membrane lies at the center of, and defines, the urogenital diaphragm (see Figs. 2–4, 2–10, and 2–14). It is triangular and spans the inferior ischiopubic rami from the pubis to the ischial tuberosities. Posteriorly, it ends abruptly; the superficial and deep transverse perinei run along its free edge (Fig. 2–15). The external genitalia attach to its inferior surface; superiorly, it supports the urethral sphincter (discussed later). The perineal body represents the point of fusion between the free posterior edge of the urogenital diaphragm and the posterior apex of the urogenital hiatus. This pyramid-shaped structure forms the hub of pelvic support. Virtually every pelvic muscle (superficial and deep transverse perinei, bulbocavernosus, levator ani, rectourethralis, external anal sphincter, striated urethral sphincter) and fascia (perineal membrane, Denonvilliers, Colles, and endopelvic) insert into the perineal body. At its core are abundant elastin and richly innervated smooth muscle, which suggests that it may have a dynamic role in support. Damage to the perineal body during perineal prostatectomy risks postoperative urinary incontinence.

PELVIC CIRCULATION

Arterial Supply

Major arteries of the pelvis are summarized in Table 2–1. At the bifurcation of the aorta, the **middle sacral artery** arises posteriorly and travels on the pelvic surface of the sacrum to supply branches to the sacral foramina and the rectum. The common iliac arteries arise at the level of the fourth lumbar vertebra, run anterior and lateral to their accompanying veins, and bifurcate into the external and internal iliac arteries at the SI joint (Fig. 2–16). The external iliac artery follows the medial border of the iliopsoas muscle along the arcuate line and leaves the pelvis beneath the inguinal ligament as the femoral artery (Fig. 2–17). Its inferior epigastric artery is given off proximal to the inguinal ligament and ascends medial to the internal inguinal ring to supply the rectus muscle and overlying skin. Because the rectus is richly collateralized from above and laterally, the inferior epigastric arteries may be ligated with impunity. A rectus myocutaneous flap based on this artery has been used to correct major pelvic and perineal tissue defects. Near its origin, the inferior epigastric artery sends a deep circumflex iliac branch laterally and a pubic branch medially. Both vessels travel on the iliopubic tract and may be injured during inguinal hernia repair. Its cremasteric branch joins the spermatic cord at the internal inguinal ring and forms a distal anastomosis with the testicular artery (Fig. 2–18). In 25% of people, an accessory obturator artery arises from the inferior epigastric artery and runs medial to the femoral vein to reach the obturator canal. This vessel must be avoided during obturator lymph node dissection.

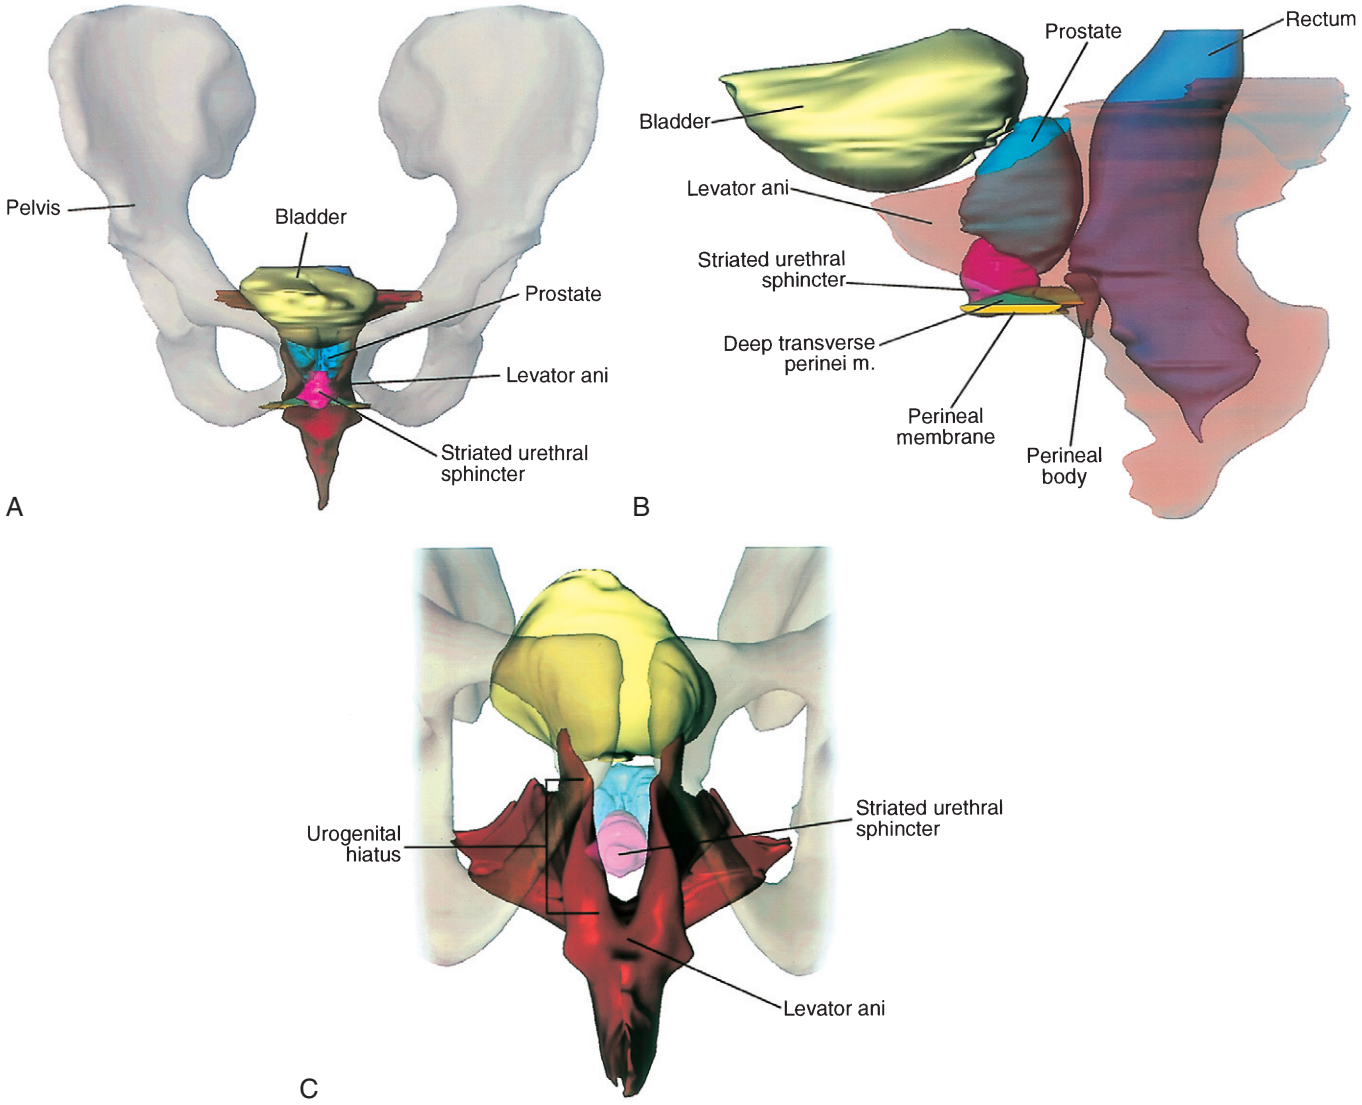

Figure 2–10. Location and contour of the levator ani and pelvic viscera. **A,** Anterior view demonstrating the near-vertical orientation of the lateral walls of the levator ani and the horizontal wings at its posterior superior aspect. **B,** Lateral view in which the levator ani has been made transparent. The perineal membrane bridges the urogenital hiatus, and the urethral sphincter fills much of the hiatus. **C,** View of the levator ani from below showing the urogenital hiatus and the thickened inferior border of the levator ani. The perineal body and related structures are not shown. (From Brooks JD, Chao W-M, Kerr J. Male pelvic anatomy reconstructed from the visible human data set. J Urol 1998;159:868–72.)

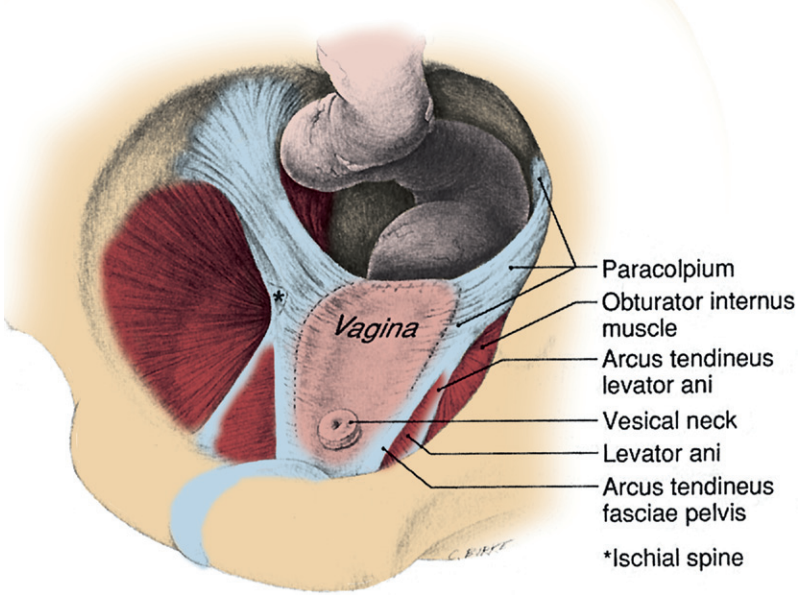

Figure 2–12. Vagina and supportive structures after removal of the bladder and uterus. The arcus tendineus fascia pelvis and the cardinal and uterosacral ligaments (paracolpium) form a continuous structure that supports the pelvic viscera. (From DeLancey JOL. Structural support of the urethra as it relates to stress urinary continence: the hammock hypothesis. Am J Obstet Gynecol 1994;170:1719.)

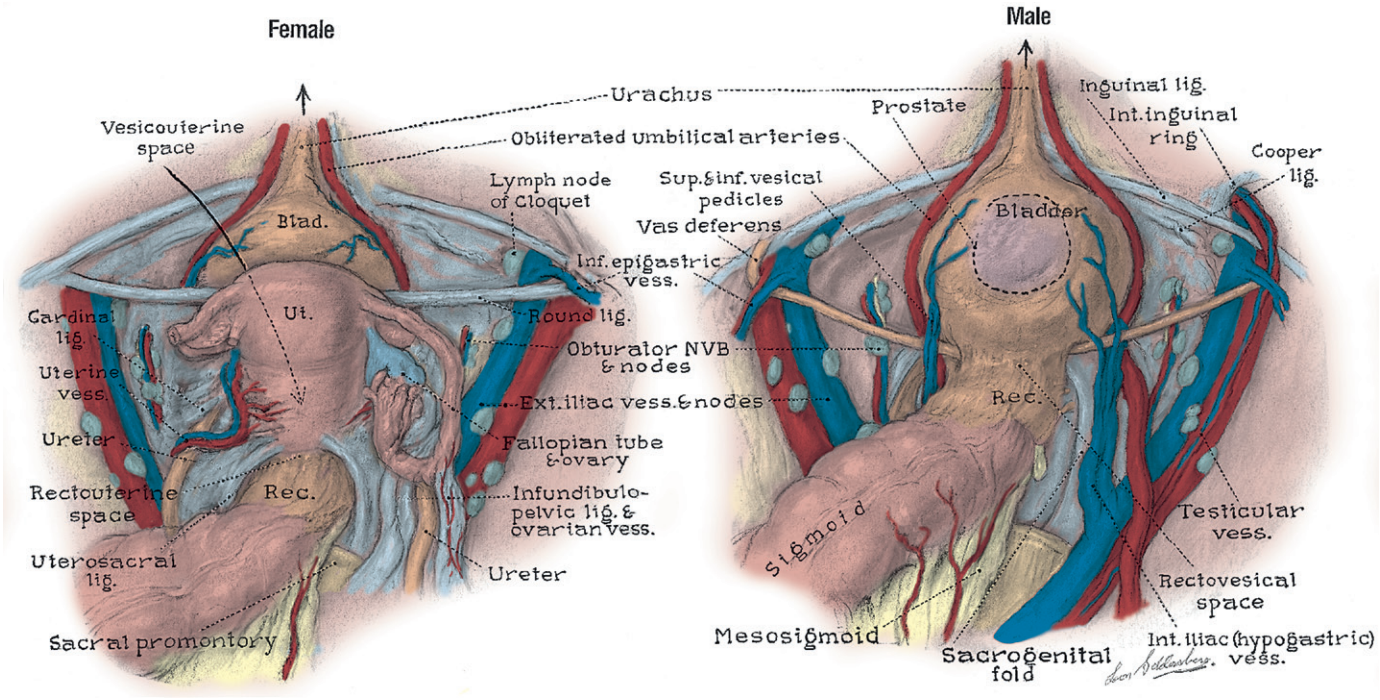

Figure 2–13. Peritoneal surfaces of the female and male pelves. In the female, the ureter passes medial to the ovarian vessels, then deep to the uterine artery within the substance of the cardinal ligament. The sacrogenital and sacrouterine folds represent the posterior portions of pelvic fascial support.

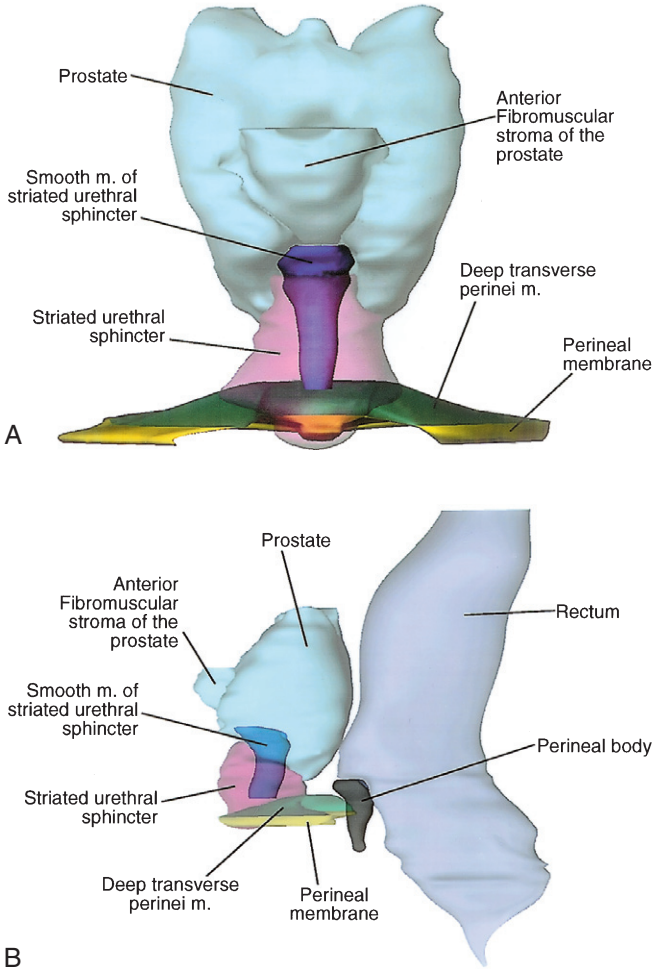

Figure 2–14. Structure of the male striated urethral sphincter. **A,** Anterior projection shows the cone shape of the sphincter and the smooth muscle of the sphincter. **B,** Viewed laterally, the anterior wall of the sphincter is nearly twice the length of the posterior wall, although both are of comparable thickness. (From Brooks JD, Chao W-M, Kerr J. Male pelvic anatomy reconstructed from the visible human data set. J Urol 1998;159:871.)

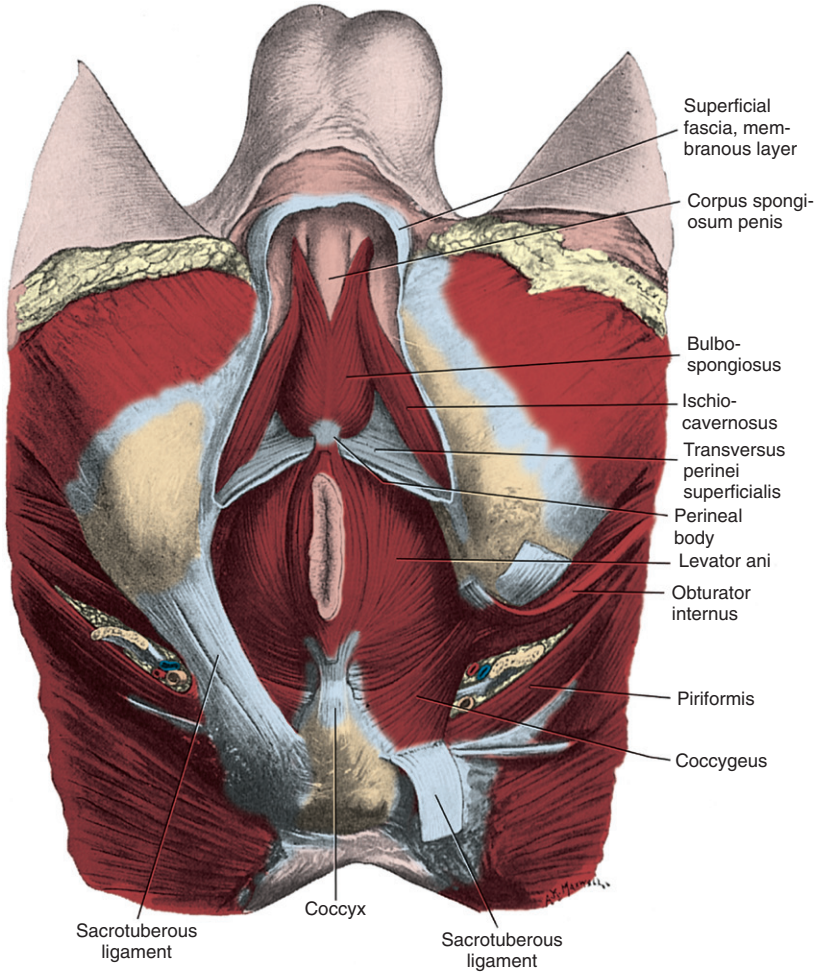

Figure 2–15. Muscles of the male perineum. The transversus perinei and ischiocavernosi frame the urogenital diaphragm. (From Williams PL, Warwick R. Gray's anatomy. 35th British ed. Philadelphia: WB Saunders; 1973. p. 530.)

Table 2–1.

Arteries of the Pelvis

ARTERY NAME	ORIGIN	SUPPLIES
Middle sacral	Aorta	Sacral nerves and sacrum
External Iliac Branches		
Inferior epigastric	External iliac	Rectus abdominis muscle and overlying skin and fascia
Deep circumflex iliac	Inferior epigastric	Inguinal ligament and surrounding structures laterally
Pubic	Inferior epigastric	Inguinal ligament and surrounding structures medially
Cremasteric	Inferior epigastric	Vas deferens and testis
Internal Iliac Branches		
Superior gluteal	Posterior trunk	Gluteus muscles and overlying skin
Ascending lumbar	Posterior trunk	Psoas and quadratus lumborum muscles and adjacent structures
Lateral sacral	Posterior trunk	Sacral nerves and sacrum
Superior vesical	Anterior trunk	Bladder, ureter, vas deferens, and seminal vesicle
Middle rectal	Anterior trunk	Rectum, ureter, and bladder
Inferior vesical	Anterior trunk	Bladder, seminal vesicle, prostate, ureter, and the neurovascular bundle
Uterine	Anterior trunk	Uterus, bladder, and ureter
Internal pudendal	Anterior trunk	Rectum, perineum, and external genitalia
Obturator	Anterior trunk	Adductor muscles of the leg and overlying skin
Inferior gluteal	Anterior trunk	Gluteus muscles and overlying skin

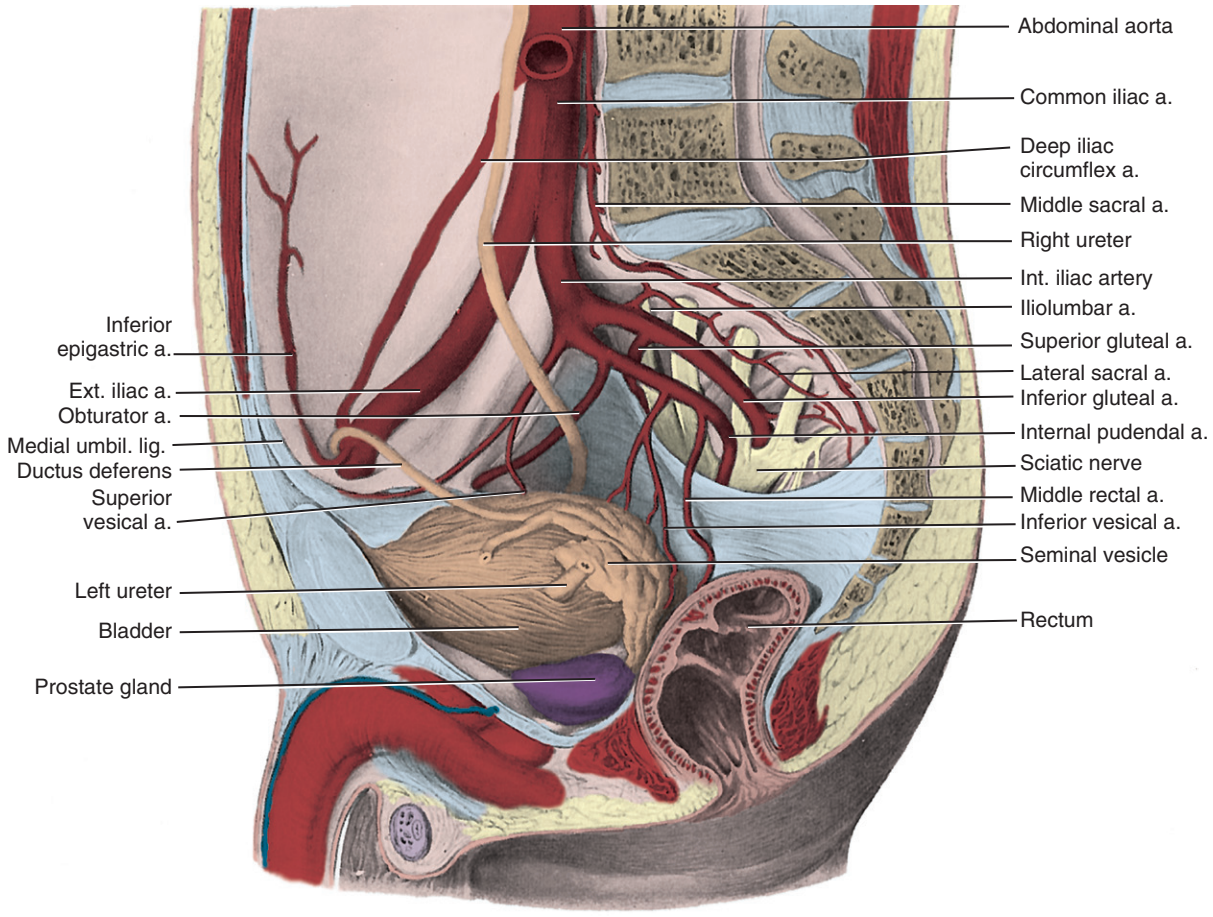

Figure 2–16. Right internal and external iliac arteries. The ureter and vas deferens pass medial to the vessels. (From Clemente CD. Gray's anatomy. 30th American ed. Philadelphia: Lea & Febiger; 1985. p. 750.)

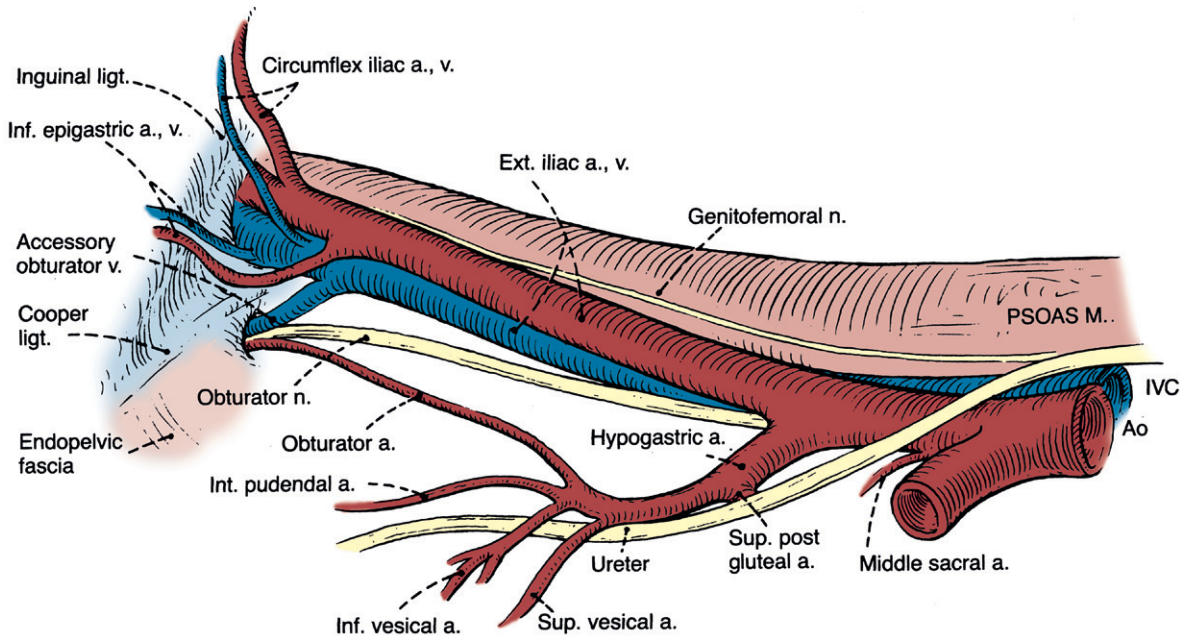

Figure 2–17. Right obturator fossa, showing the iliac vessels and obturator nerve. (From Skinner DG. Pelvic lymphadenectomy. In: Glenn JF, editor. Urological surgery. 2nd ed. New York: Harper & Row; 1975. p. 591.)

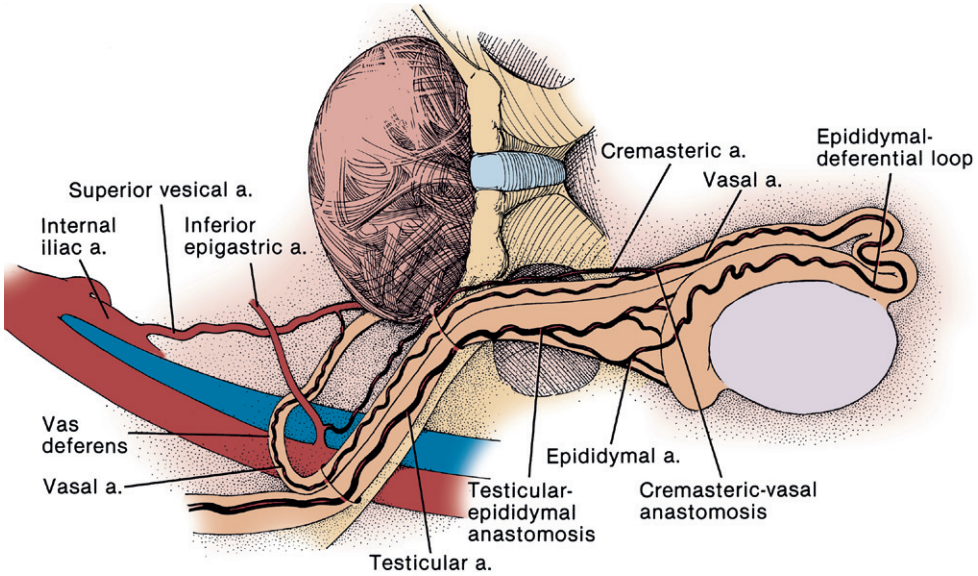

Figure 2–18. Collateral arterial circulation to the testis. (From Hinman F Jr. Atlas of urosurgical anatomy. Philadelphia: WB Saunders; 1993. p. 497.)

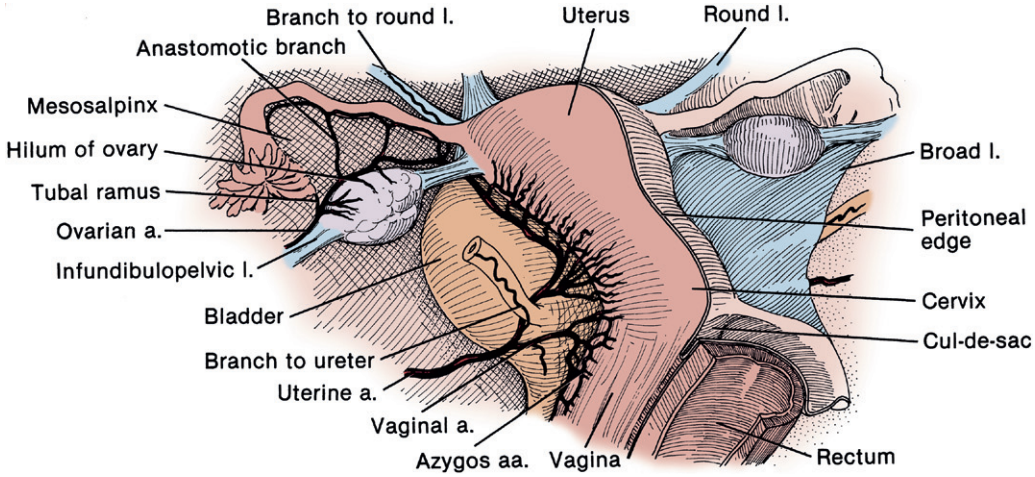

Figure 2–19. Female internal genitalia, from behind. The ureter passes beneath the uterine artery. (From Hinman F Jr. Atlas of urosurgical anatomy. Philadelphia: WB Saunders; 1993. p. 402.)

The internal iliac (hypogastric) artery descends in front of the SI joint and divides into an anterior and a posterior trunk (see Fig. 2–16). The posterior trunk gives rise to three parietal branches: (1) the superior gluteal, which exits the greater sciatic foramen; (2) the ascending lumbar, which supplies the posterior abdominal wall; and (3) the lateral sacral, which passes medially to join the middle sacral branches at the sciatic foramina.

The anterior trunk gives off seven parietal and visceral branches: (1) The superior vesical artery arises from the proximal portion of the obliterated umbilical artery and gives off a vesiculodeferential branch to the seminal vesicles and vas deferens. The artery of the vas deferens travels the length of the vas to meet the cremasteric and testicular arteries distally (see Fig. 2–18). Because of these anastomoses, the testicular artery may be sacrificed without compromising the viability of the testis. (2) The middle rectal artery gives small branches to the seminal vesicles and prostate and anastomoses with the inferior and superior rectal arteries in the rectal wall. (3) The inferior vesical branches supply the lower ureter, the bladder base, the prostate, and the seminal vesicles. In the female, they supply the ureter, the bladder base, and the vagina. (4) The uterine artery passes above and in front of the ureter ("water flows under the bridge") to ascend the lateral wall of the uterus and meet the ovarian artery in the lateral portion of the fallopian tube (see Figs. 2–13 and 2–19). The ureter is vulnerable during division of the uterine pedicles. (5) The internal pudendal artery leaves the pelvic cavity through the greater sciatic foramen, passes around the sacrospinous ligament, and enters the lesser sciatic foramen to gain access to the perineum. Its perineal course is discussed later. (6) The obturator artery, variable in origin, travels through the obturator fossa medial and inferior to the obturator nerve and passes through its canal to supply the adductors of the thigh (see Fig. 2–17). (7) The inferior gluteal artery travels through the greater sciatic foramen to supply the buttock and thigh.

The internal iliac artery can be ligated to control severe pelvic hemorrhage. Ligation decreases the pulse pressure, allowing hemostasis to occur more readily. Internal iliac blood flow does not stop but reverses its direction because of critical anastomoses (lumbar segmentals to iliolumbar; median sacral to lateral sacral; and superior rectal and middle rectal). Bilateral ligation almost invariably produces vasculogenic impotence.

Venous Supply

The dorsal vein of the penis passes between the inferior pubic arch and the striated urinary sphincter to reach the pelvis, where it trifurcates into a central superficial branch and two lateral plexuses (Reiner and Walsh, 1979) (Fig. 2–20). To minimize blood loss at radical retropubic prostatectomy, the dorsal vein complex is best divided distally, before its ramification. Part of this complex runs within the anterior and lateral wall of the striated sphincter; thus care must be taken not to injure the sphincter when securing hemostasis. The superficial branch pierces the visceral endopelvic fascia between the puboprostatic ligaments and drains the retropubic fat, anterior bladder, and anterior prostate (see Fig. 2–20).

The lateral plexuses sweep down the sides of the prostate, receiving drainage from it and the rectum, and communicate with the vesical plexuses on the lower part of the bladder. Three to five inferior vesical veins emerge from the vesical plexus laterally and drain into the internal iliac vein. In the female, the dorsal vein of the clitoris bifurcates to empty into the laterally placed vaginal plexuses. These connect with the vesical, uterine, ovarian, and rectal plexuses and drain into the internal iliac veins.

The internal iliac vein is joined by tributaries corresponding to the branches of the internal iliac artery and ascends medial and posterior to the artery. This vein is relatively thin walled and at risk for injury during dissection of the artery or the nearby pelvic ureter. The external iliac vein travels medial and inferior to its artery and joins the internal iliac vein behind the internal iliac artery. In half the patients, one or **more accessory obturator veins drain into the underside of the external iliac vein and can be easily torn during lymphadenectomy** (see Fig. 2–17).

Pelvic Lymphatics

The pelvic lymph nodes can be difficult to appreciate on gross examination because they are embedded in the fatty and fibrous tissue of the intermediate stratum. Three major lymph node groups are associated with the pelvic vessels (Fig. 2–21). A substantial portion of pelvic visceral lymphatic drainage passes through the **internal iliac nodes and their tributaries: the presacral, obturator, and internal pudendal nodes.** The external iliac nodes lie lateral, anterior, and medial to the vessels and drain the anterior abdominal wall, urachus, bladder, and, in part, internal genitalia. The external genitalia and perineum drain into the superficial and deep inguinal nodes (see later discussion). The inguinal nodes communicate directly with the internal and external iliac chains. The common iliac nodes receive efferent vessels from the external and internal iliac nodes and the pelvic ureter and drain into the lateral aortic nodes.

PELVIC INNERVATION

Lumbosacral Plexus

The lumbosacral plexus and its rami are well illustrated in Chapter 1; only the pelvic courses of its nerves are reviewed here (see Figs. 2–7 and 2–12 and Table 2–2). The **iliohypogastric nerve** (L1) travels between, and supplies, the internal oblique and the transversus muscles and pierces the internal and external oblique muscles 3 cm above the external inguinal ring to supply sensation over the lower anterior abdomen and pubis (see Fig. 2–5). The ilioinguinal nerve (L1) passes through the internal oblique muscle

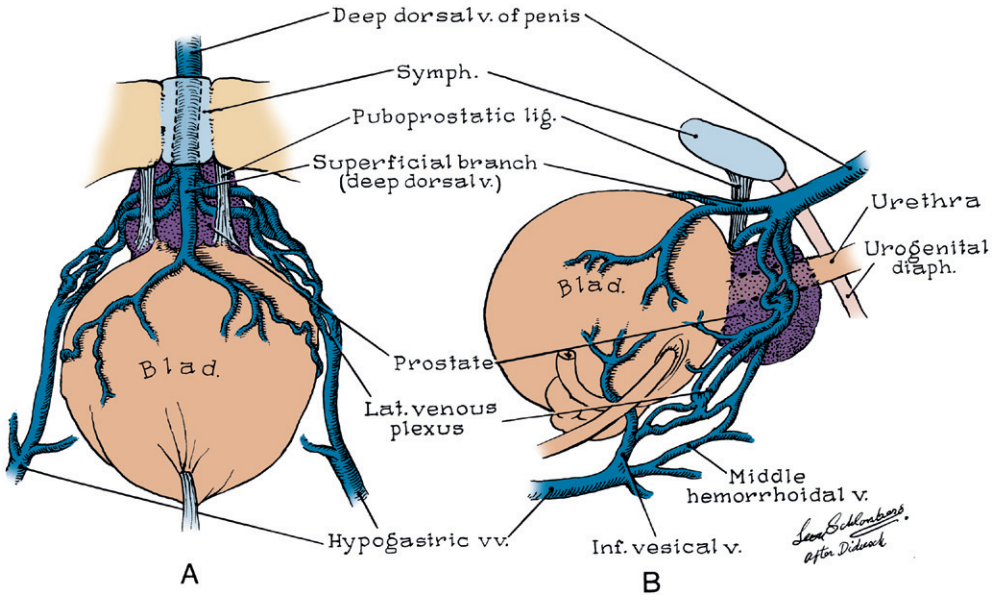

Figure 2–20. Pelvic venous plexus. **A,** Trifurcation of the dorsal vein of the penis, viewed from the retropubic space. The relationship of the venous branches to the puboprostatic ligaments is shown. **B,** Lateral view of the pelvic venous plexus after removal of the lateral pelvic fascia. Normally these structures are difficult to see because they are embedded in pelvic fascia. (From Reiner WG, Walsh PC. An anatomical approach to the surgical management of the dorsal vein and Santorini's plexus during radical retropubic surgery. J Urol 1979;121:200.)

to enter the inguinal canal laterally. It travels anterior to the cord and exits the external ring to provide sensation to the mons pubis and anterior scrotum or labia majora (see Figs. 2–5 and 2–7). The genitofemoral nerve (L1, L2) pierces the psoas muscle to reach its anterior surface in the retroperitoneum and then travels to the pelvis and splits into genital and femoral branches. The latter supplies sensation over the anterior thigh below the inguinal ligament. The genital branch follows the cord through the inguinal canal, supplies the cremaster muscle, and supplies sensation to the anterior scrotum.

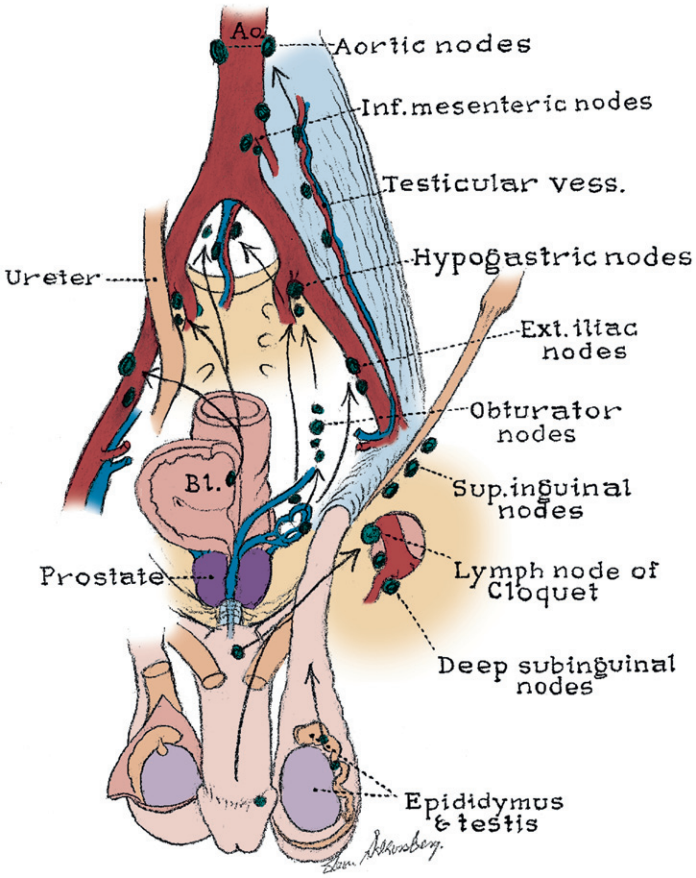

Figure 2–21. Lymphatic drainage of the male pelvis, perineum, and external genitalia.

For most of its pelvic course, the femoral nerve (L2, L3, L4) travels within the substance of the psoas muscle and then exits its lateral side to pass under the inguinal ligament (Fig. 2–22). It supplies sensation to the anterior thigh and motor innervation to the extensors of the knee. **During a psoas hitch, sutures should be placed in the direction of the nerve (and the psoas muscle fibers) to avoid nerve damage or entrapment. Retractor blades must not rest on the psoas muscle because they can produce a femoral nerve palsy,** a potentially dangerous setback after pelvic surgery. The lateral femoral cutaneous nerve (L2, L3) may be seen lateral to the psoas in the iliacus fascia.

The **obturator nerve** (L2, L3, L4) emerges in the true pelvis from beneath the psoas muscle, lateral to the internal iliac vessels, and passes through the obturator fossa to the obturator canal. In the fossa, it is lateral and superior to the obturator vessels and surrounded by the obturator and internal iliac lymph nodes. Damage to this nerve during pelvic lymphadenectomy weakens the adductors of the thigh.

The lumbosacral trunk (L4, L5) passes into the true pelvis behind the psoas and unites with the ventral rami

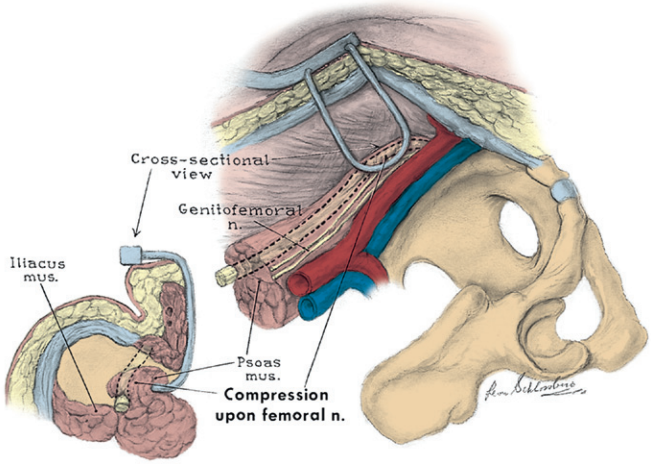

Figure 2–22. Femoral nerve as it relates to the psoas muscle. Retractor blades may compress this nerve to produce a femoral nerve palsy. (From Burnett AL, Brendler CB. Female neuropathy following major pelvic surgery: etiology and prevention. J Urol 1994;151:163.)

Table 2–2.

Somatic Nerves of the Lower Abdomen and Pelvis

NERVE NAME	ORIGIN	SUPPLIES
Iliohypogastric	L1	Motor supply to internal oblique, transversus muscles, sensation over lower anterior abdominal wall
Ilioinguinal	L1	Sensation over anterior pubis (mons) and anterior scrotum or labia
Genitofemoral	L1, L2	Genital branch: motor supply to cremaster muscle sensation to anterior scrotum Femoral branch: sensation to anterior thigh
Femoral	L2, L3, L4	Motor supply to extensors of the knee sensory to anterior thigh
Obturator	L2, L3, L4	Motor supply to adductors of the thigh, sensation to medial thigh
Lumbosacral trunk	L4, L5	Joins the sacral nerves to form the lumbosacral plexus that supplies motor and sensory innervation to the lower extremities
Posterior femoral cutaneous	S2, S3	Sensation to perineum, posterior scrotum, and posterior thigh
Pudendal	S2, S3, S4	Motor to levator ani, muscles of the urogenital diaphragm, anal and striated urethral sphincter, sensation to the perineum, scrotum, penis
Pelvic somatic efferents	S2, S3, S4	Motor supply to levator ani and striated urethral sphincter
Nervi erigentes	S2, S3, S4	Parasympathetic fibers from the sacral cord supply the pelvic viscera

of the sacral segmental nerves to form the sacral plexus. This plexus lies on the pelvic surface of the piriformis deep to the endopelvic fascia and posterior to the internal iliac vessels (see Fig. 2–16). It leaves the pelvis through the greater sciatic foramen immediately posterior to the sacrospinous ligament (where it may be injured during sacrospinous culposuspension) and supplies motor and sensory innervation to the posterior thigh and lower leg. An exaggerated lithotomy position may stretch this nerve or place pressure on its peroneal branch at the fibular head to produce foot drop. Pelvic and perineal branches of the sacral plexus include (1) the posterior femoral cutaneous nerve (S2, S3), which, after passing through the greater sciatic foramen, gives an anterior sensory branch to the perineum and posterior scrotum (see Fig. 2–8); (2) the pudendal nerve (S2, S3, S4), which follows the internal pudendal artery to the perineum (to be discussed); (3) the nervi erigentes (S2, S3, S4) to the autonomic plexus; and (4) pelvic somatic efferent nerves from the ventral rami of S2, S3, and S4 (Fig. 2–23). The latter nerves travel on the pelvic surface of the levator ani in close association with the rectum and prostate and are separated from the pelvic autonomic plexus by the endopelvic fascia. They supply the levator ani and extend anteriorly to the striated urethral sphincter (Lawson, 1974; Zvara et al, 1994).

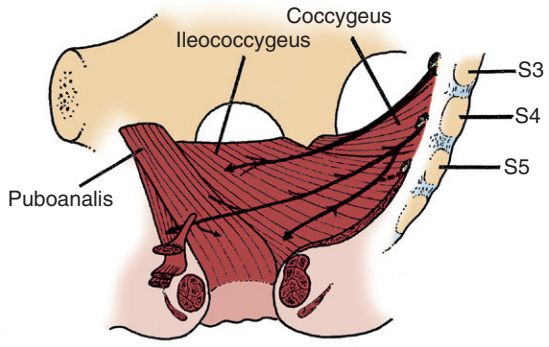

Figure 2–23. Pelvic floor somatic efferent nerves extending anteriorly on the pelvic surface of the levator ani to supply this muscle and the striated urethral sphincter. (From Lawson JO. Pelvic anatomy. I. Pelvic floor muscles. Ann R Coll Surg Engl 1974;54:250.)

Pelvic Autonomic Plexus

The presynaptic sympathetic cell bodies that project to the pelvic autonomic plexus reside in the lateral column of gray matter in the last three thoracic and first two lumbar segments of the spinal cord. They reach the pelvic plexus by two pathways: (1) The superior hypogastric plexus is formed by sympathetic fibers from the celiac plexus and the first four lumbar splanchnic nerves (Fig. 2–24). Anterior to the bifurcation of the aorta, it divides into two hypogastric nerves that enter the pelvis medial to the internal iliac vessels, anterior to the sacrum, and deep to the endopelvic fascia. (2) The pelvic continuations of the sympathetic trunks pass deep to the common iliac vessels and medial to the sacral foramina and fuse in front of the coccyx at the ganglion impar (see Fig. 2–24). Each chain comprises four to five ganglia that send branches anterolaterally to participate in the formation of the pelvic plexus.

Presynaptic parasympathetic innervation arises from the intermediolateral cell column of the sacral cord. Fibers emerge from the second, third, and fourth sacral spinal nerves as the pelvic splanchnic nerves (nervi erigentes) to join the hypogastric nerves and branches from the sacral sympathetic ganglia to form the inferior hypogastric (pelvic) plexus (see Fig. 2–24). Some pelvic parasympathetic efferent fibers travel up the hypogastric nerves to the inferior mesenteric plexus, where they provide parasympathetic innervation to the descending and sigmoid colon.

The pelvic plexus is rectangular, approximately 4 to 5 cm long, and its midpoint is at the tips of the seminal vesicles (Schlegel and Walsh, 1987). It is oriented in the sagittal plane on either side of the rectum and pierced by the numerous vessels going to and from the rectum, bladder, seminal vesicles, and prostate (Fig. 2–25). **Division of these vessels (the so-called lateral pedicles of the bladder and prostate) risks injury to the pelvic plexus with attendant postoperative impotence** (Walsh and Donker, 1982; Walsh et al, 1983). The right and left components of the pelvic plexus communicate behind the rectum and anterior and posterior to the vesical neck. Branches of the pelvic plexus follow pelvic blood vessels to reach the pelvic viscera, although nerves to the ureter may join it directly as it passes nearby. Visceral afferent and efferent nerves travel on the vas deferens to reach the testis and epididymis (see later discussion).

The most caudal portion of the pelvic plexus gives rise to the innervation of the prostate and the important cavernosal nerves (Walsh and Donker, 1982). After passing the tips of the seminal vesicles, these nerves lie within leaves of the lateral endopelvic fascia near its juncture with, but outside, Denonvilliers fascia (Lepor et al, 1985). They travel at the posterolateral border of the prostate on the surface of the rectum and are lateral to the prostatic capsular arteries and veins (see Fig. 2–25). Because the nerves are composed of multiple fibers not visible on gross inspection, these vessels serve as a surgical landmark for the course of these nerves (the neurovascular bundle of Walsh). During radical prostatectomy, the nerves are most vulnerable at the apex of the prostate, where they closely approach the prostatic capsule at the 5- and 7-o'clock positions. On reaching the membranous urethra, the nerves divide into superficial branches, which travel on the lateral surface of the striated urethral sphincter at 3- and 9-o'clock positions, and deep fibers, which penetrate the substance of this muscle and send twigs to the bulbourethral glands. As the nerves reach the hilum of the penis, they join to form one to three discrete bundles, related to the urethra at 1- and 11-o'clock positions, superficial to the cavernous veins and dorsomedial to the cavernous arteries (Fig. 2–26) (Lue et al, 1984; Breza et al, 1989). With the arteries, they pierce the corpora cavernosa to supply the erectile tissue (see later discussion). Small fibers also join the dorsal nerves of the penis as they course distally. In the female, the nerves to vestibular bodies and corpora cavernosa of the clitoris travel between the anterior vaginal wall and the bladder in association with the lateral venous plexuses.

PELVIC VISCERA

Rectum

The rectum begins with the disappearance of the sigmoid mesentery opposite the third sacral vertebra. **Peritoneum continues anteriorly over the upper two thirds of the rectum as the rectovesical pouch in males and as the rectouterine pouch (of Douglas) in females** (Fig. 2–27; see also Fig. 2–11). Incision of the anterior wall of this peritoneal pouch exposes the seminal vesicles behind the bladder. Inferior to this pouch, the

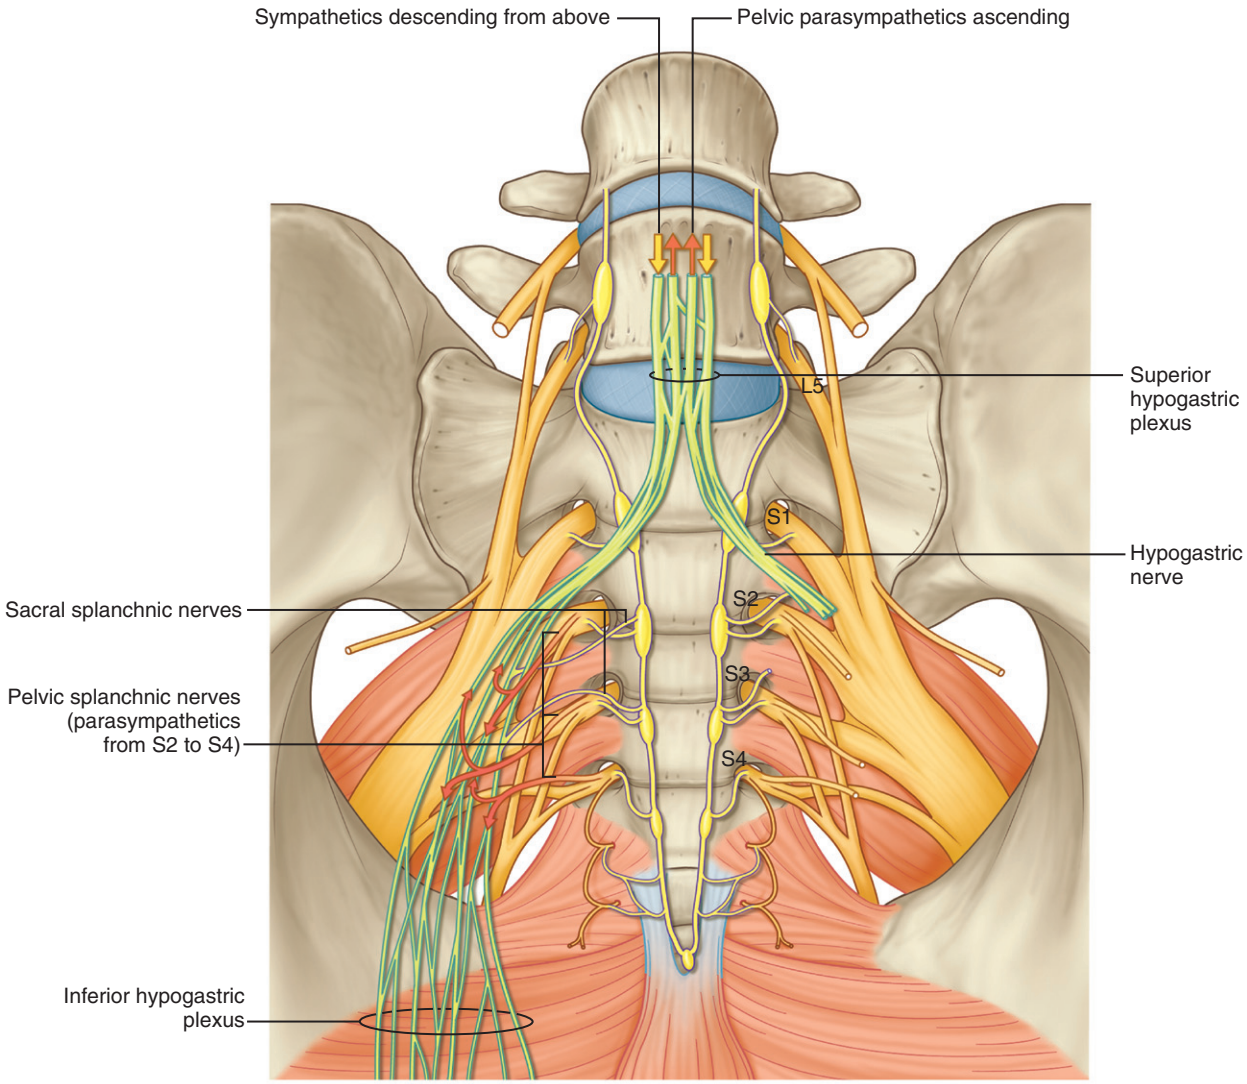

Figure 2–24. Sympathetic and parasympathetic contributions to the pelvic autonomic nervous plexus.

anterior rectum is related to its fascial continuation (the rectogenital or Denonvilliers fascia) down to the level of the striated urethral sphincter (see Figs. 2–4, 2–27, and 2–28). The rectum describes a gentle curve on the sacrum, coccyx, and levator plate (see Fig. 2–24) and receives innervation from the laterally placed pelvic autonomic plexus and blood supply from the superior (from inferior mesenteric), middle (from internal iliac), and inferior (from internal pudendal) rectal arteries.

The rectal wall is composed of an inner layer of circular smooth muscle and a virtually continuous sheet of outer longitudinal smooth muscle derived from the tenia of the colon. In its lowest part, the rectum dilates to form the rectal ampulla. At the most inferior portion of the ampulla, anterior fibers of the longitudinal muscle leave the rectum to join Denonvilliers fascia and the posterior striated urethral sphincter in the apex of the perineal body (Brooks et al, 2002). During perineal prostatectomy, these fibers, **the rectourethralis muscle, are 2 to 10 mm thick and must be divided to gain access to the prostate** (Fig. 2–29). The apices of the prostate and rectal ampulla are in close proximity, and rectal injuries during radical prostatectomy commonly occur at this location. As the rectourethralis is given off, the rectum makes a right-angle turn posteroinferiorly to exit the pelvis at the anal canal (see Fig. 2–10). The anatomy of the anal canal is considered with the perineum.

Pelvic Ureter

The ureter is divided into abdominal and pelvic portions by the common iliac artery. The structure of the ureter and its abdominal course are reviewed in Chapter 1. Intraoperatively, the ureter is identified by its peristaltic waves and is readily found anterior to the bifurcation of the common iliac artery. At ureteroscopy, pulsations of this artery can be seen in the posterior ureteral wall. **The ovarian vessels (infundibulopelvic ligament) cross the iliac vessels anterior and lateral to the ureter, and dissection of the ovarian vessels at the pelvic brim is a common cause of ureteral injury** (see Fig. 2–13) (Daly and Higgins, 1988). Pyeloureterography discloses a narrowing of the ureter at the iliac vessels, and ureteral calculi frequently become lodged at this location. Because the ureter and iliac vessels rest on

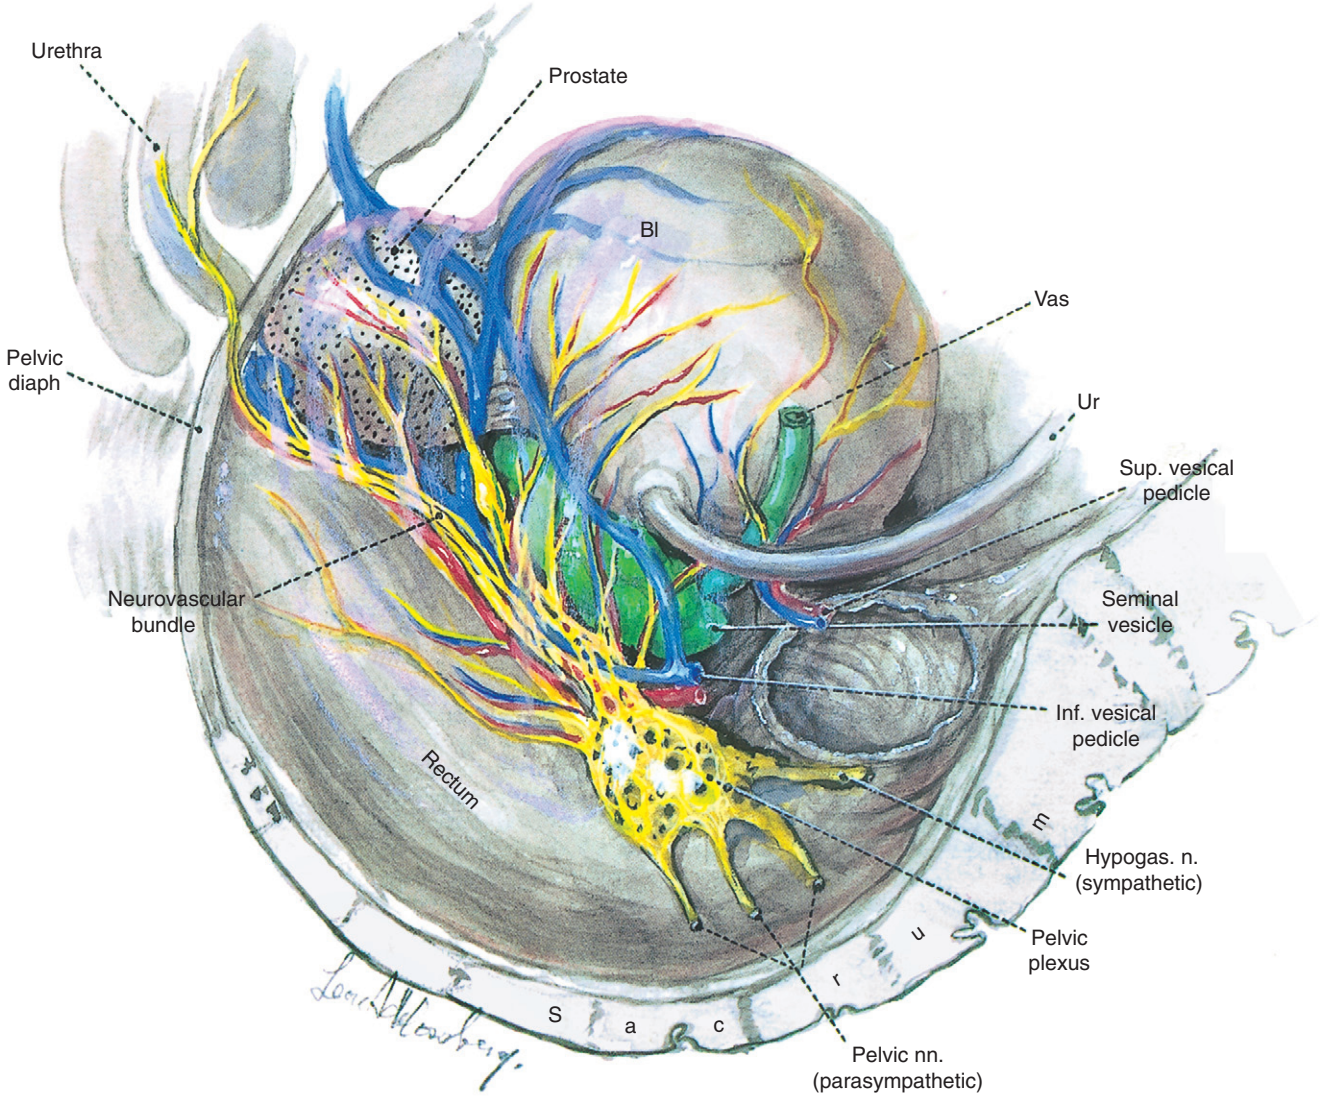

Figure 2–25. Lateral view showing the left pelvic autonomic nervous plexus and its relation to the pelvic viscera. (From Schlegel PN, Walsh PC. Neuroanatomical approach to radical cystoprostatectomy with preservation of sexual function. J Urol 1987;138:1403.)

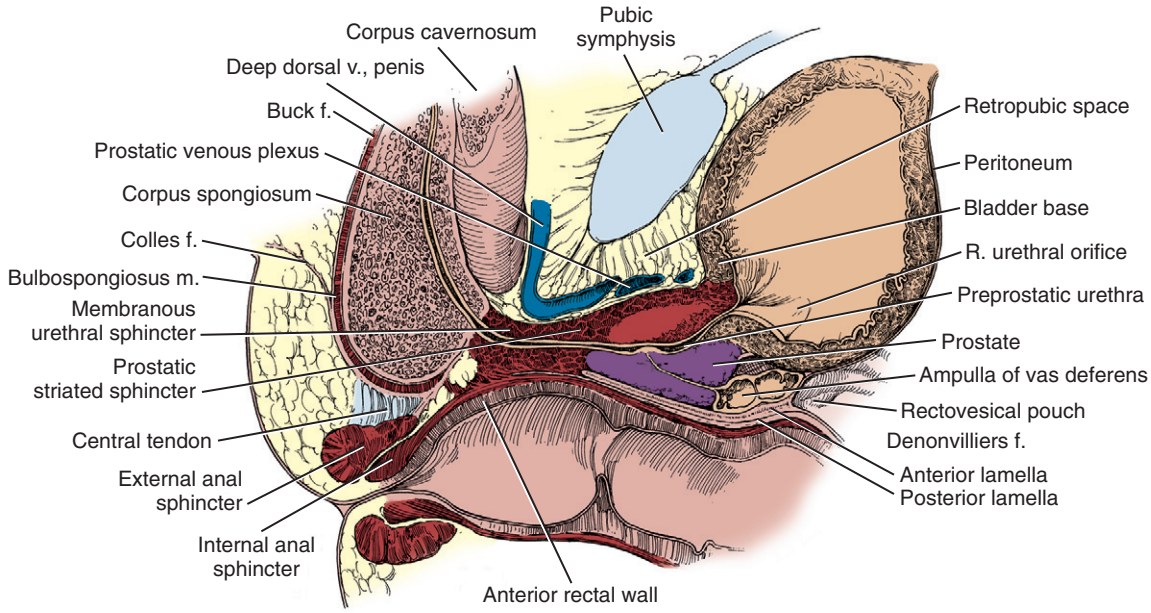

Figure 2–27. Sagittal section through the prostatic and membranous urethra, demonstrating the midline relations of the pelvic structures. (From Hinman F Jr. Atlas of urosurgical anatomy. Philadelphia: WB Saunders; 1993. p. 356.)

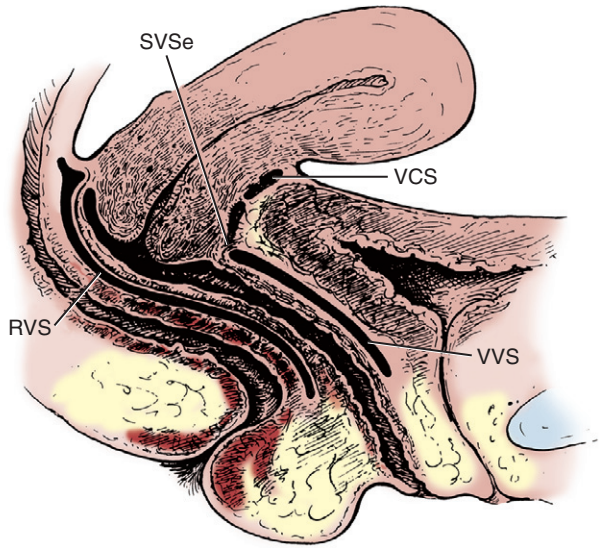

Figure 2–28. Median sagittal section of the female pelvis, showing the potential spaces between the pelvic organs. The posterior two thirds of the vagina lies nearly horizontal and rests with the uterine cervix on the rectum, which is in turn supported by the posterior portion of levator ani (the levator plate, not shown). RVS, rectovaginal space, the anterior wall is formed by the rectovaginal (Denonvilliers) fascia; SVSe, supravaginal septum, the fusion between the bladder and cervix; VCS, vesicocervical space; VVS, vesicovaginal space. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins; 1989. p. 34.)

the arcuate line, the ureter is subject to compression and obstruction by the gravid uterus and by masses within the true pelvis.

The ureters come within 5 cm of each other as they cross the iliac vessels. On entering the pelvis, they diverge widely along the pelvic side walls toward the ischial spines. The ureter travels on the anterior surface of the internal iliac vessels and is related laterally to the branches of the anterior trunk. Near the ischial spine, the ureter turns anteriorly and medially to reach the bladder. **In men,** the anteromedial surface of the ureter is covered by peritoneum, and the ureter is embedded in retroperitoneal connective tissue, which varies in thickness (see Fig. 2–13). As the ureter courses medially, it is crossed anteriorly by the vas deferens and runs with the inferior vesical arteries, veins, and nerves in the lateral vesical ligaments. Viewed from the peritoneal side, the ureter is just lateral and deep to the rectogenital fold. In women, the ureter first runs posterior to the ovary and then turns medially to run deep to the base of the broad ligament before entering a loose connective tissue tunnel through the substance of the cardinal ligament (see Fig. 2–13). As in the male, the ureter can be found slightly lateral and deep to the rectouterine folds of peritoneum. It is crossed anteriorly by the uterine artery and can be injured during hysterectomy. As it passes in front of the vagina, it crosses 1.5 cm anterior and lateral to the uterine cervix. The ureter can be injured at this level during hysterectomy, resulting in a ureterovaginal fistula. The ureter courses 1 to 4 cm on the anterior vaginal wall to reach the bladder. Occasionally, a stone lodged in the distal ureter can be palpated through the anterior vaginal wall. The intramural ureter is discussed with the bladder.

The pelvic ureter receives abundant blood supply from the common iliac artery and most branches of the internal iliac artery. The inferior vesical and uterine arteries usually supply the ureter with its largest pelvic branches. **Blood supply to the pelvic ureter enters laterally; thus the pelvic peritoneum should be incised only medial to the ureter.** Intramural vessels of the ureter run within the adventitia and generally follow one of two patterns. In approximately 75% of specimens, longitudinal vessels run the length of the ureter and are formed by anastomoses of segmental ureteral vessels. In the remaining ureters, the vessels form a fine interconnecting mesh (plexiform) with less collateral flow (Shafik, 1972). Therefore primary repair of injuries to the pelvic ureter fare poorly and are more prone to stricture formation (Hinman, 1993). Lymphatic drainage of the pelvic ureter is to the external, internal, and common iliac nodes. Pathologic enlargement of the common and internal iliac nodes can encroach on and obstruct the ureter.

The pelvic ureter has rich adrenergic and cholinergic autonomic innervation derived from the pelvic plexus. The functional

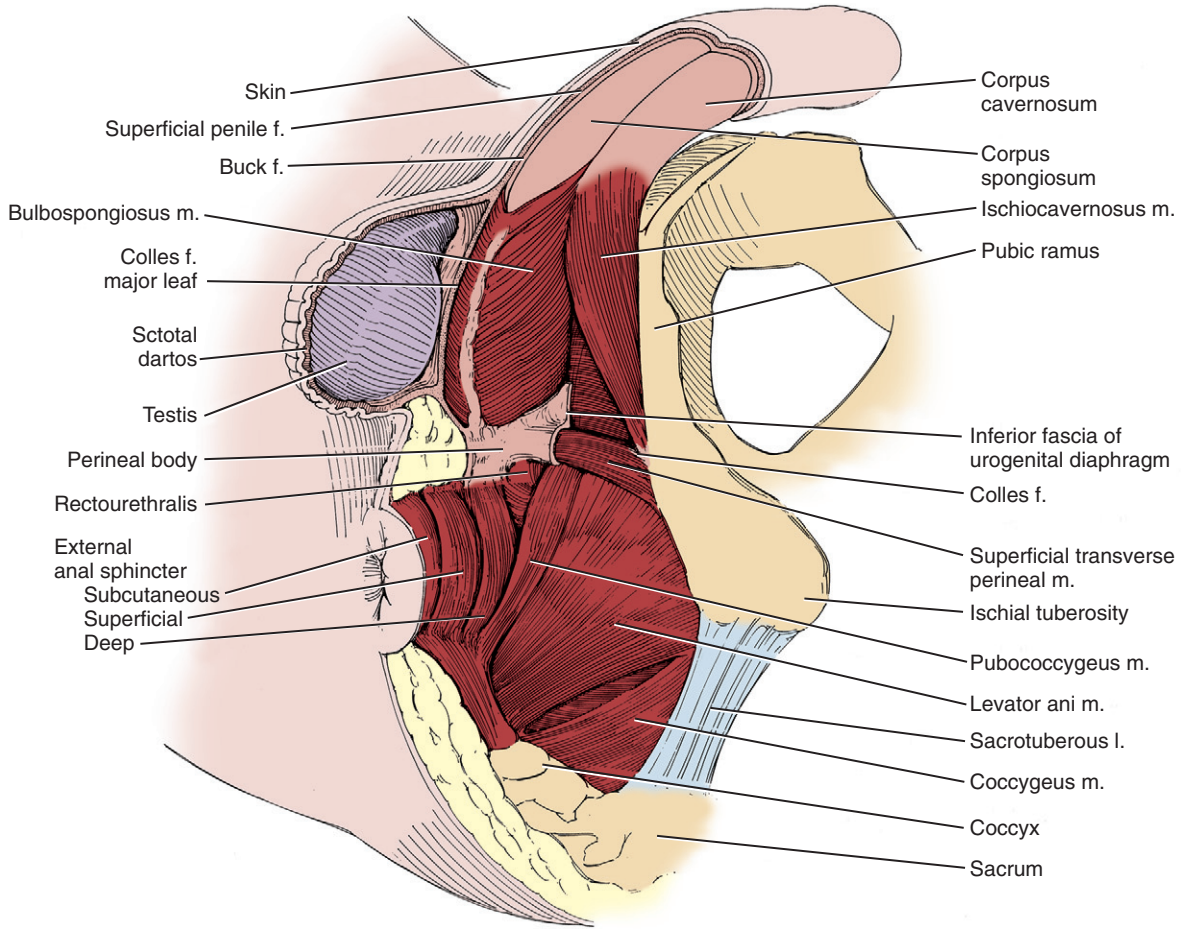

Figure 2–29. Muscles and superficial fasciae of the male perineum. (From Hinman F Jr. Atlas of urosurgical anatomy. Philadelphia: WB Saunders; 1993. p. 219.)

significance of this innervation is unclear, inasmuch as the ureter continues to contract peristaltically after denervation. Afferent neural fibers travel through the pelvic plexus and account for the visceral quality of referred pain from ureteral irritation or acute obstruction.

Bladder

Relationships

When filled, the bladder has a capacity of approximately 500 mL and assumes an ovoid shape. The empty bladder is tetrahedral and is described as having a superior surface with an apex at the urachus, two inferolateral surfaces, and a posteroinferior surface or base with the bladder neck at the lowest point (see Fig. 2–27).

The urachus anchors the bladder to the anterior abdominal wall (see Fig. 2–8). There is a relative paucity of bladder wall muscle at the point of attachment of the urachus, predisposing to diverticula formation. The urachus is composed of longitudinal smooth muscle bundles derived from the bladder wall. Near the umbilicus, it becomes more fibrous and usually fuses with one of the obliterated umbilical arteries. Urachal vessels run longitudinally, and the ends of the urachus must be ligated when it is divided. An epithelium-lined lumen usually persists throughout life and uncommonly gives rise to aggressive urachal adenocarcinomas (Begg, 1930). In rare instances, luminal continuity with the bladder serves as a bacterial reservoir or results in an umbilical urinary fistula.

The superior surface of the bladder is covered by peritoneum. Anteriorly, the peritoneum sweeps gently onto the anterior abdominal wall (see Fig. 2–13). With distention, the bladder rises out of the true pelvis and separates the peritoneum from the anterior abdominal wall. It is therefore possible to perform a suprapubic cystostomy without risking entry into the peritoneal cavity. Posteriorly, the peritoneum passes to the level of the seminal vesicles and meets the peritoneum on the anterior rectum to form the rectovesical space.

Anteroinferiorly and laterally, **the bladder is cushioned from the pelvic side wall by retropubic and perivesical fat and loose connective tissue. This potential space (of Retzius) may be entered anteriorly by dividing the transversalis fascia and provides access to the pelvic viscera as far posteriorly as the iliac vessels and ureters** (see Fig. 2–11). The bladder base is related to the seminal vesicles, ampullae of the vas deferentia, and terminal ureter. The bladder neck, located at the internal urethral meatus, rests 3 to 4 cm behind the midpoint of the symphysis pubis. It is firmly fixed by the pelvic fasciae (see earlier discussion) and by its continuity with the prostate; its position changes little with varying conditions of the bladder and rectum.

In the female, the peritoneum on the superior surface of the bladder is reflected over the uterus to form the vesicouterine pouch and then continues posteriorly over

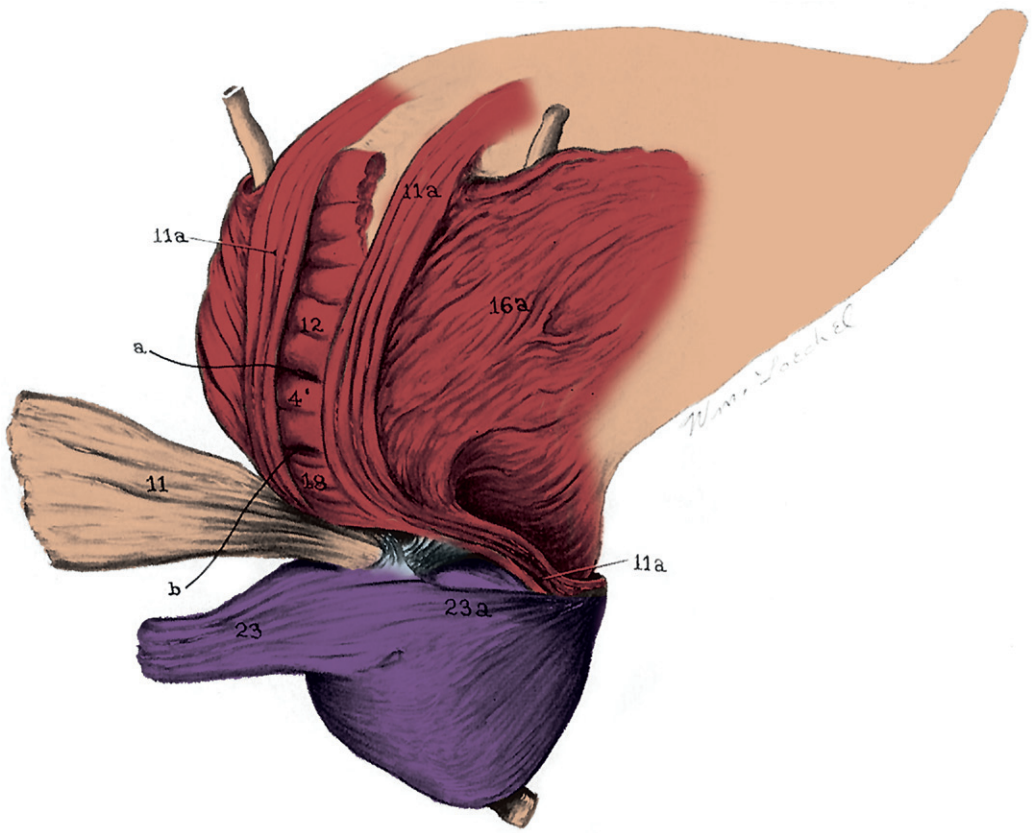

Figure 2–30. Dissection of the male bladder. 11, Posterior outer longitudinal detrusor, which forms the backing of the ureters (folded back); 11a, posterolateral portion of the outer longitudinal muscle forming a loop around the anterior bladder neck; 4′, 12, and 18, middle circular layer backing the trigone; 23 and 23a, lateral pedicle of the prostate. (From Uhlenhuth E. Problems in the anatomy of the pelvis. Philadelphia: JB Lippincott; 1953. p. 187.)

the uterus as the rectouterine pouch (see Fig. 2–13). The vagina and uterus intervene between the bladder and the rectum so that the base of the bladder and urethra rest on the anterior vaginal wall. Because the anterior vaginal wall is firmly attached laterally to the levator ani, contraction of the pelvic diaphragm (e.g., during increases in intra-abdominal pressure) elevates the bladder neck and draws it anteriorly. In many women with stress incontinence, the bladder neck drops below the pubic symphysis. In infants, the true pelvis is shallow and the bladder neck is level with the upper border of the symphysis. The bladder is a true intra-abdominal organ that can project above the umbilicus when full. By puberty, the bladder has migrated to the confines of the deepened true pelvis.

Structure

The internal surface of the bladder is lined with transitional epithelium, which appears smooth when the bladder is full but contracts into numerous folds when the bladder empties. This urothelium is usually six cells thick and rests on a thin basement membrane. Deep to this, the lamina propria forms a relatively thick layer of fibroelastic connective tissue that allows considerable distention. This layer is traversed by numerous blood vessels and contains smooth muscle fibers collected into a poorly defined muscularis mucosa. Beneath this layer lies the smooth muscle of the bladder wall. The relatively large muscle fibers form branching, interlacing bundles loosely arranged into inner longitudinal, middle circular, and outer longitudinal layers (Fig. 2–30). However, in the upper aspect of the bladder, these layers are clearly not separable, and any one fiber can travel between each of the layers, change orientation, and branch into longitudinal and circular fibers. This meshwork of detrusor muscle is ideally suited for emptying the spherical bladder.

Near the bladder neck, the detrusor muscle is clearly separable into the three layers described earlier. Here, the smooth muscle is morphologically and pharmacologically distinct from the remainder of the bladder because the large-diameter muscle fascicles are replaced by much finer fibers. The structure of the bladder neck appears to differ between men and women. In men, radially oriented inner longitudinal fibers pass through the internal meatus to become continuous with the inner longitudinal layer of smooth muscle in the urethra.

The middle layer forms a circular preprostatic sphincter that is responsible for continence at the level of the bladder neck (Fig. 2–31 on the Expert Consult website). The bladder wall posterior to the internal urethral meatus and the anterior fibromuscular stroma of the prostate form a continuous ringlike structure at the bladder neck (Brooks et al, 1998). The fact that perfect continence can be maintained in men in whom the striated urethral sphincter is destroyed attests to the efficacy of this sphincter (Waterhouse et al, 1973). This muscle is richly innervated by adrenergic fibers, which, when stimulated, produce closure of the bladder neck (Uhlenhuth, 1953). Damage to the sympathetic nerves to the bladder, as a result of diabetes mellitus or retroperitoneal lymph node dissection for testis cancer, can cause retrograde ejaculation.

The outer longitudinal fibers are thickest posteriorly at the bladder base. In the midline, they insert into the apex of the trigone and intermix with the smooth muscle of the prostate to provide a strong trigonal backing. Laterally, the fibers from this posterior sheet pass anteriorly and fuse to form a loop around the bladder neck (see Fig. 2–30). This loop is thought to participate in continence at the bladder neck. On the lateral and anterior surfaces of the bladder, the longitudinal fibers are not as well

developed. Some anterior fibers course forward to join the puboprostatic ligaments in men and the pubourethral ligaments in women. These fibers contribute smooth muscle to these supports and are speculated to contribute to bladder neck opening during micturition (DeLancey, 1989).

At the female bladder neck, the inner longitudinal fibers converge radially to pass downward as the inner longitudinal layer of the urethra, as described earlier. The middle circular layer does not appear to be as robust as that of the male, and several authors have denied its existence altogether (Gosling, 1979, 1985; Williams et al, 1989). Although several other investigators have noted an anterior loop of external longitudinal muscle (Fig. 2–32), the authors just cited deny the existence of this structure as well. They maintain instead that the external fibers pass obliquely and longitudinally down the urethra to participate in forming the inner longitudinal layer of smooth muscle. Regardless, the female bladder neck differs strikingly from the male in possessing little adrenergic innervation. In addition, its sphincteric function is limited; in 50% of continent women, urine enters the proximal urethra during a cough (Versi et al, 1986).

Ureterovesical Junction and the Trigone

As the ureter approaches the bladder, its spirally oriented mural smooth muscle fibers become longitudinal. Two to 3 cm from the bladder, a fibromuscular sheath (of Waldeyer) extends longitudinally over the ureter and follows it to the trigone (Tanagho, 1992). The ureter pierces the bladder wall obliquely, travels 1.5 to 2 cm, and terminates at the ureteral orifice (Fig. 2–33). As it passes through a hiatus in the detrusor (intramural ureter), it is compressed and narrows considerably. This is a common site in which ureteral stones become impacted. The intravesical portion of the ureter lies immediately beneath the bladder urothelium and therefore is quite pliant; it is backed by a strong plate of detrusor muscle. With bladder filling, this arrangement is thought to result in passive occlusion of the ureter, like a flap valve. Indeed, reflux does not occur in fresh cadavers when the bladder is filled (Thomson et al, 1994). Vesicoureteral reflux is thought to result from insufficient submucosal ureteral length and poor detrusor backing. Chronic increases in intravesical pressure resulting from bladder outlet obstruction can cause herniation of the bladder mucosa through the weakest point of the hiatus above the ureter and produce a "Hutch diverticulum" and reflux (Hutch et al, 1961).

The triangle of smooth urothelium between the two ureteral orifices and the internal urethral meatus is referred to as the *trigone of the bladder* (see Fig. 2–33). The fine longitudinal smooth muscle fibers from each ureter fan out over the base of the bladder to form a triangular sheet of muscle

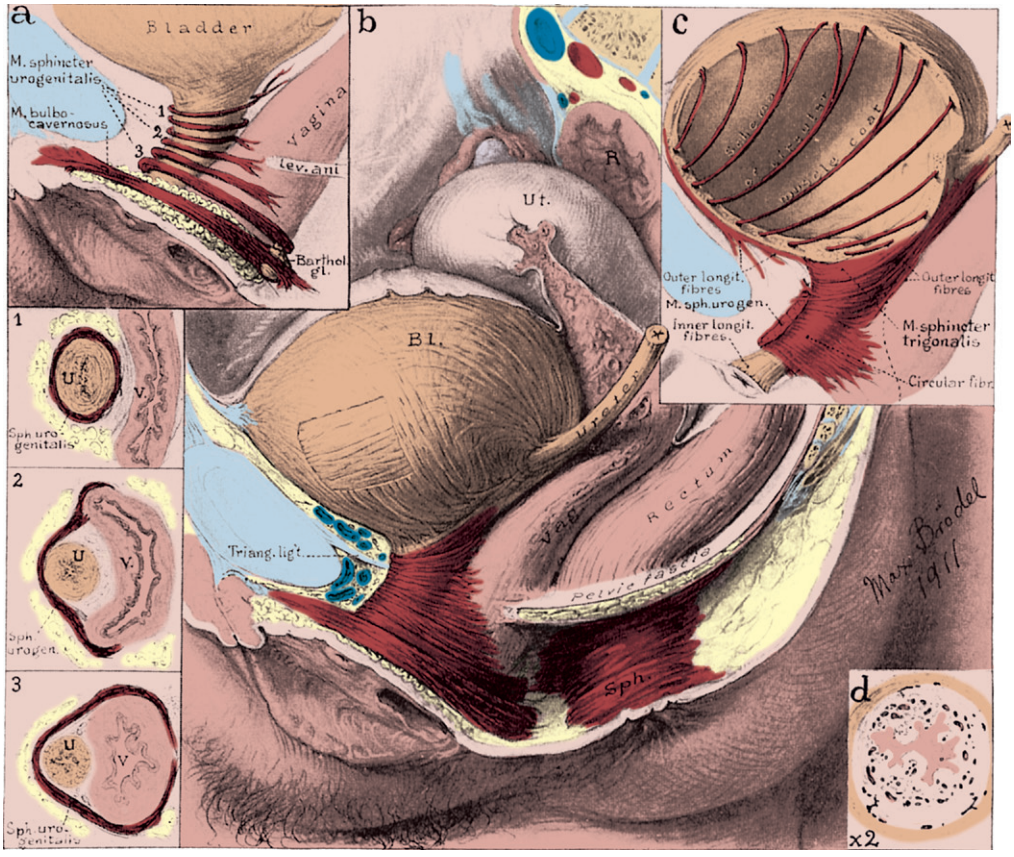

Figure 2–32. Female bladder and striated urethral sphincter. a, Diagram of striated urethral sphincter showing disposition of the muscle fibers. 1, The proximal third of the sphincter encircles the urethra entirely. 2, The middle bundles surround the urethra in front and pass off the lateral sides to blend with the vaginal wall (compressor urethrae). 3, The distal portion surrounds the urethra and vagina together and has been called the *urethrovaginal sphincter.* The bulbocavernosus also acts as a sphincter around the vaginal vestibule. b, Urethral sphincter in its entirety. The relationship of the pelvic viscera is shown. Interlacing detrusor fibers are also demonstrated. c, Posterolateral outer longitudinal detrusor muscle, looping anterior to the bladder neck. Inner longitudinal smooth muscle fibers run the length of the urethra, deep to the striated sphincter. d, Cross section of the urethra, showing thick, highly vascularized lamina propria and folded mucosa, which act as a urethral seal. Longitudinal smooth muscle surrounds the lamina propria. (Original art in the Max Brödel Archives, Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine.)

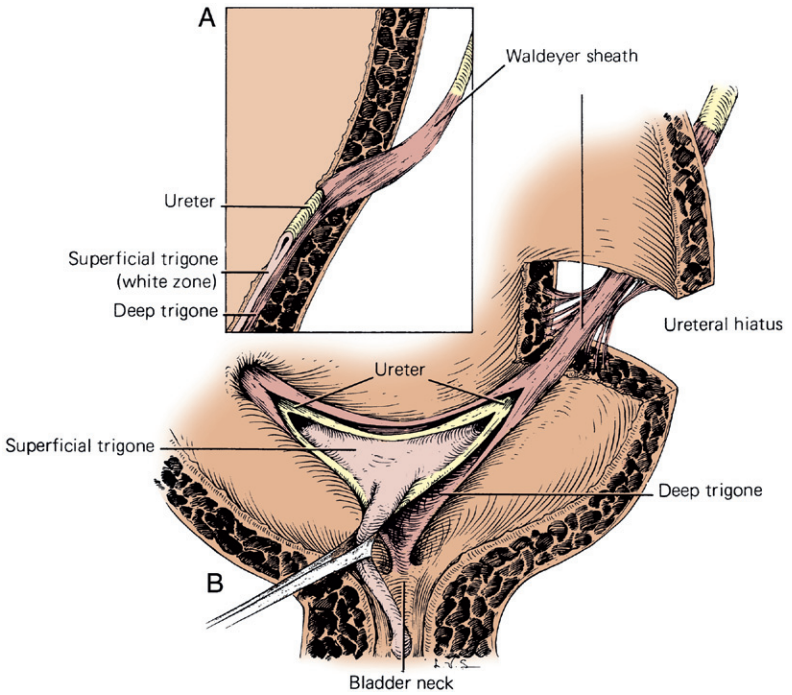

Figure 2–33. Normal ureterovesical junction and trigone. **A,** Section of the bladder wall perpendicular to the ureteral hiatus shows the oblique passage of the ureter through the detrusor and also shows the submucosal ureter with its detrusor backing. Waldeyer sheath surrounds the prevesical ureter and extends inward to become the deep trigone. **B,** Waldeyer sheath continues in the bladder as the deep trigone, which is fixed at the bladder neck. Smooth muscle of the ureter forms the superficial trigone and is anchored at the verumontanum. (From Tanagho EA, Pugh RCB. The anatomy and function of the ureterovesical junction. Br J Urol 1963;35:151.)

that extends from the two ureteral orifices to the internal urethral meatus. The edges of this muscular sheet can be thickened between the ureteral orifices (the interureteric crest or Mercier bar) and between the ureters and the internal urethral meatus (Bell muscle).

The muscle of trigone forms three distinct layers: (1) a superficial layer, derived from the longitudinal muscle of the ureter, which extends down the urethra to insert at the verumontanum; (2) a deep layer, which continues from Waldeyer sheath and inserts at the bladder neck; and (3) a detrusor layer, formed by the outer longitudinal and middle circular smooth muscle layers of the bladder wall. Through its continuity with the ureter, the superficial trigonal muscle anchors the ureter to the bladder. During ureteral reimplantation, this muscle is tented up and divided in order to gain access to the space between Waldeyer sheath and the ureter. In this space, only loose fibrous and muscular connections are found. This anatomic arrangement helps prevent reflux during bladder filling by fixing and applying tension to the ureteral orifice. As the bladder fills, its lateral wall telescopes outward on the ureter, thereby increasing intravesical ureteral length (Hutch et al, 1961).

The urothelium overlying the muscular trigone is usually only three cells thick and adheres strongly to the underlying muscle by a dense lamina propria. During filling and emptying of the bladder, this mucosal surface remains smooth.

Bladder Circulation

In addition to the vesical branches, the bladder may be supplied by any adjacent artery arising from the internal iliac artery. For convenience, surgeons refer to the vesical blood supply as the *lateral* and *posterior* pedicles, which, when the bladder is approached from the rectovesical space, are lateral and posteromedial to the ureters, respectively. These pedicles are the lateral and posterior vesical ligaments in the male and part of cardinal and uterosacral ligaments in the female (see Fig. 2–13). The veins of the bladder coalesce into the vesicle plexus and drain into the internal iliac vein. Lymphatics from the lamina propria and muscularis drain to channels on the bladder surface, which run with the superficial vessels within the thin visceral fascia. Small paravesical lymph nodes can be found along the superficial channels. The bulk of the lymphatic drainage passes to the external iliac lymph nodes (see Fig. 2–21). Some anterior and lateral drainage may go through the obturator and internal iliac nodes, whereas portions of the bladder base and trigone may drain into the internal and common iliac groups.

Bladder Innervation

Autonomic efferent fibers from the anterior portion of the pelvic plexus (the vesical plexus) pass up the lateral and posterior ligaments to innervate the bladder. The bladder wall is richly supplied with parasympathetic cholinergic nerve endings and has abundant postganglionic cell bodies. Sparse sympathetic innervation of the bladder has been proposed to mediate detrusor relaxation but probably lacks functional significance. A separate nonadrenergic, noncholinergic (NANC) component of the autonomic nervous system participates in activating the detrusor, although the neurotransmitter has not been identified (Burnett, 1995). As mentioned, the male bladder neck receives abundant sympathetic innervation and expresses α_1-adrenergic receptors. The female bladder neck has little adrenergic innervation. Nitric oxide synthase–containing neurons have been identified in the detrusor, particularly at the bladder neck, where they assist relaxation during micturition. The trigonal muscle is innervated by adrenergic and nitric oxide synthase–containing neurons. Like the bladder neck, it relaxes during micturition. Afferent innervation from the bladder travels with both sympathetic (via the hypogastric nerves) and parasympathetic nerves to reach cell bodies in the dorsal root ganglia located at thoracolumbar and sacral levels. As a consequence, presacral neurectomy (division of the hypogastric nerves) is ineffective in relieving bladder pain.

Prostate

Relationships

The normal prostate weighs 18 g; measures 3 cm in length, 4 cm in width, and 2 cm in depth; and is traversed by the prostatic urethra (see Fig. 2–27). Although ovoid, **the prostate is referred to as having anterior, posterior, and lateral surfaces, with a narrowed apex inferiorly and a broad base superiorly** that is contiguous with the base of the bladder. It is enclosed by a capsule composed of collagen, elastin, and abundant smooth muscle. Posteriorly and laterally, this capsule has an average thickness of 0.5 mm, although it may be partially transgressed by normal glands. Microscopic bands of smooth muscle extend from the posterior surface of the capsule to fuse with Denonvilliers fascia. Loose areolar tissue defines a thin plane between Denonvilliers fascia and the rectum. On the anterior and anterolateral surfaces of the prostate, the capsule blends with the visceral continuation of endopelvic fascia. Toward the apex, the puboprostatic ligaments extend anteriorly to fix the prostate to the pubic bone. The superficial branch of the dorsal vein lies outside this fascia in the retropubic fat and pierces it to drain into the dorsal vein complex.

Laterally, the prostate is cradled by the pubococcygeal portion of levator ani and is directly related to its overlying endopelvic fascia (see Figs. 2–8 and 2–10). Below the juncture of the parietal and visceral endopelvic fascia (arcus tendineus fascia pelvis), the pelvic fascia and prostate capsule separate and the space between them is filled by fatty areolar tissue and the lateral divisions of the dorsal vein complex. During a radical retropubic prostatectomy, the endopelvic fascia should be divided lateral to the arcus tendineus fascia pelvis to avoid injury to the venous complex. In the process, the endopelvic fascia overlying the levator ani is actually peeled off the muscle and displaced medially with the prostate. Although this is truly a parietal endopelvic fascia, it is commonly referred to as the "lateral prostatic fascia" (Myers, 1994). As mentioned earlier, the cavernosal nerves run posterolateral to the prostate in the substance of the parietal pelvic fascia (lateral prostatic fascia). Thus to preserve these nerves, this fascia must be incised lateral to the prostate and anterior to the neurovascular bundle (Walsh et al, 1983). Therefore an understanding of the fascial layers that overlie the prostate is crucial in the performance of an accurate nerve-sparing radical prostatectomy (Fig 2–34).

Recently, with the adoption of robotic and laparoscopic radical prostatectomy techniques, there has been a renewed interest in the description of these fascial layers with respect to the neurovascular bundle because these layers may be better visualized with the magnification afforded by these techniques (Tewari et al, 2006). Better definition of the "lateral prostatic fascia" at the level of the prostatic pedicles has become necessary in preserving the cavernosal nerves because the dissection is often performed antegrade in these techniques. Anatomic studies have revealed nerve bundles that course along the prostate laterally and anteriorly to the nerves, commonly referred to as the *neurovascular bundle* (Eichelberg et al, 2007; Raychaudhuri and Cahill, 2008). Whether these nerves contribute to erectile function remains controversial.

The apex of the prostate is continuous with the striated urethral sphincter (see Fig. 2–14). Histologically normal prostatic glands can be found to extend into the striated muscle with no intervening fibromuscular stroma or "capsule." At the base of the prostate, outer longitudinal fibers of the detrusor fuse and blend with the fibromuscular tissue of the capsule. As mentioned, the middle circular and inner longitudinal muscles extend down the prostatic urethra as a preprostatic sphincter. As with the apex, no true capsule separates the prostate from the bladder. In surgically resected prostate carcinomas, this peculiar anatomic arrangement can make interpretation of these margins difficult and has led some pathologists to propose that the prostate does not possess a true capsule (Epstein, 1989).

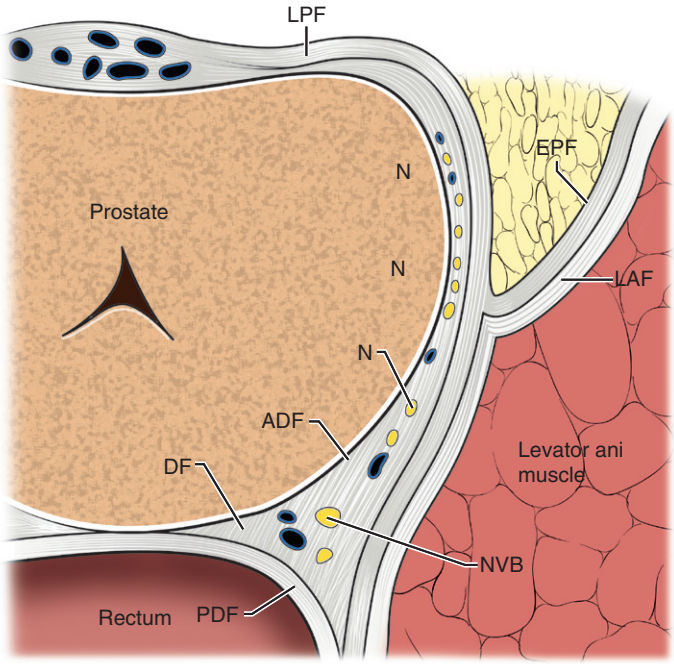

Figure 2–34. Cross section of prostate with prostatic fascial layers outlined including the lateral prostatic fascia (LPF), endopelvic fascia (EPF), levator ani fascia (LAF), Denonvilliers fascia (DF), anterior lamina of Denonvilliers fascia (ADF), posterior lamina of Denonvilliers fascia, neurovascular bundle (NVB), and lateral nerves (N). Structure

The prostate is composed of approximately 70% glandular elements and 30% fibromuscular stroma. The stroma is continuous with capsule and is composed of collagen and abundant smooth muscle. It encircles and invests the glands of the prostate and contracts during ejaculation to express prostatic secretions into the urethra.

The urethra runs the length of the prostate and is usually closest to its anterior surface. It is lined by transitional epithelium, which may extend into the prostatic ducts. The urothelium is surrounded by an inner longitudinal and an outer circular layer of smooth muscle. A urethral crest projects inward from the posterior midline, runs the length of the prostatic urethra, and disappears at the striated sphincter (Fig. 2–35). To either side of this crest, a groove is formed (prostatic sinuses) into which all glandular elements drain (McNeal, 1972). At its midpoint, the urethra turns approximately 35 degrees anteriorly, but this angulation can vary from 0 to 90 degrees (see Figs. 2–27, 2–31, 2–36, and 2–37). This angle divides the prostatic urethra into proximal (preprostatic) and distal (prostatic) segments that are

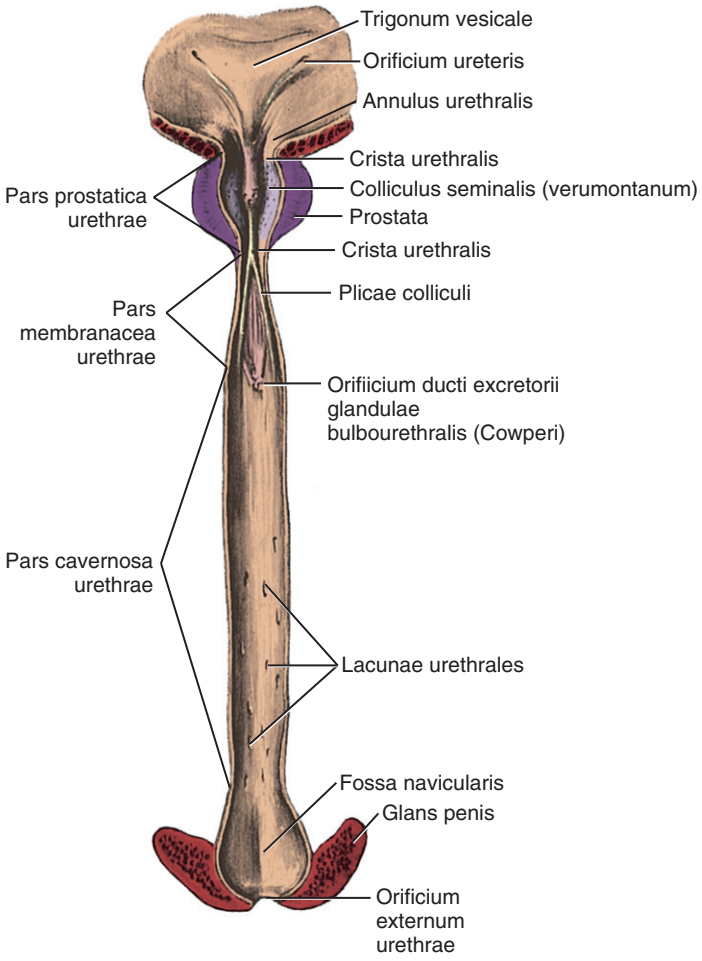

Figure 2–35. Posterior wall of the male urethra. (From Anson BJ, McVay CB. Surgical anatomy. 6th ed. Philadelphia: WB Saunders; 1984. p. 833.)

functionally and anatomically discrete (McNeal, 1972, 1988). In the proximal segment, the circular smooth muscle is thickened to form the involuntary internal urethral (preprostatic) sphincter described earlier. Small periurethral glands, lacking periglandular smooth muscle, extend between the fibers of the longitudinal smooth muscle to be enclosed by the preprostatic sphincter. Although these glands constitute less than 1% of the secretory elements of the prostate, they can contribute significantly to prostatic volume in older men as one of the sites of origin of benign prostatic hypertrophy.

Beyond to the urethral angle, all major glandular elements of the prostate open into the prostatic urethra. The urethral crest widens and protrudes from the posterior wall as the verumontanum (see Figs. 2–35, 2–37, and 2–38). The small slitlike orifice of the prostatic utricle is found at the apex of the verumontanum and may be visualized cystoscopically. The utricle is a 6-mm müllerian remnant in the form of a small sac that projects upward and backward into the substance of the prostate. In males with ambiguous genitalia, it may form a large diverticulum that protrudes from the posterior side of the prostate. To either side of the utricular orifice, the two small openings of the ejaculatory ducts may be found. The ejaculatory ducts form at the juncture of the vas deferens and seminal vesicles and enter the prostate base, where it fuses with the bladder. They course nearly 2 cm through the prostate in line with the distal prostatic urethra and are surrounded by circular smooth muscle (see Fig. 2–36; see also Figs. 2–27 and 2–31).

In general, **the glands of the prostate are tubuloalveolar with relatively simple branching and are lined with simple cuboidal or columnar epithelium. Scattered neuroendocrine cells, of unknown function, are found between the secretory cells. Beneath the epithelial cells, flattened basal cells line each acinus.** Each acinus is surrounded by a thin layer of stromal smooth muscle and connective tissue.

The glandular elements of the prostate have been divided into discrete zones, distinguished by the location of their ducts in the urethra, by their differing pathologic lesions, and, in some cases, by their embryologic origin (see Fig. 2–36). These zones can be demonstrated clearly with transrectal ultrasonography (Fig 2–39). **At the angle dividing the preprostatic and prostatic urethra, the ducts of the transition zone arise and pass beneath the preprostatic sphincter to travel on its lateral and posterior sides.** Normally, the transition zone accounts for 5% to 10% of the glandular tissue of the prostate. A discrete fibromuscular band of tissue separates the transition zone from the remaining glandular compartments and may be visualized at transrectal ultrasonography of the prostate. The transition zone commonly gives rise to benign prostatic hypertrophy, which expands to compress the fibromuscular band into a surgical capsule seen at enucleation of an adenoma. It is estimated that 20% of adenocarcinomas of the prostate originate in this zone.

The ducts of the central zone arise circumferentially around the openings of the ejaculatory ducts. This zone constitutes 25% of the glandular tissue of the prostate and expands in a cone shape around the ejaculatory ducts to the base of the bladder. The glands are structurally and immunohistochemically distinct from the remaining prostatic glands (which branch directly from the urogenital sinus), which has led to the suggestion that they are of wolffian origin (McNeal, 1988). In keeping with this suggestion, only 1% to 5% of adenocarcinomas arise in the central zone, although it may be infiltrated by cancers from adjacent zones.

The peripheral zone makes up the bulk of the prostatic glandular tissue (70%) and covers the posterior and lateral aspects of the gland. Its ducts drain into the prostatic sinus along the entire length of the (postsphincteric) prostatic urethra. Seventy percent of prostatic cancers arise in this zone, and it is the zone most commonly affected by chronic prostatitis.

Up to one third of the prostatic mass may be attributed to the nonglandular **anterior fibromuscular stroma.** This region normally extends from the bladder neck to the striated sphincter, although considerable portions of it may be replaced by glandular tissue in adenomatous enlargement of the prostate. It is directly continuous with the prostatic capsule, anterior visceral fascia, and anterior portion of the preprostatic sphincter and is composed of elastin, collagen, and smooth and striated muscle. It is rarely invaded by carcinoma.

Clinically, the prostate is often spoken of as having two lateral lobes, separated by a central sulcus that is palpable on rectal examination, and a middle lobe, which may project into the bladder in older men. These lobes do not correspond to histologically defined structures in the normal prostate but are usually related to pathologic enlargement of the transition zone laterally and the periurethral glands centrally.

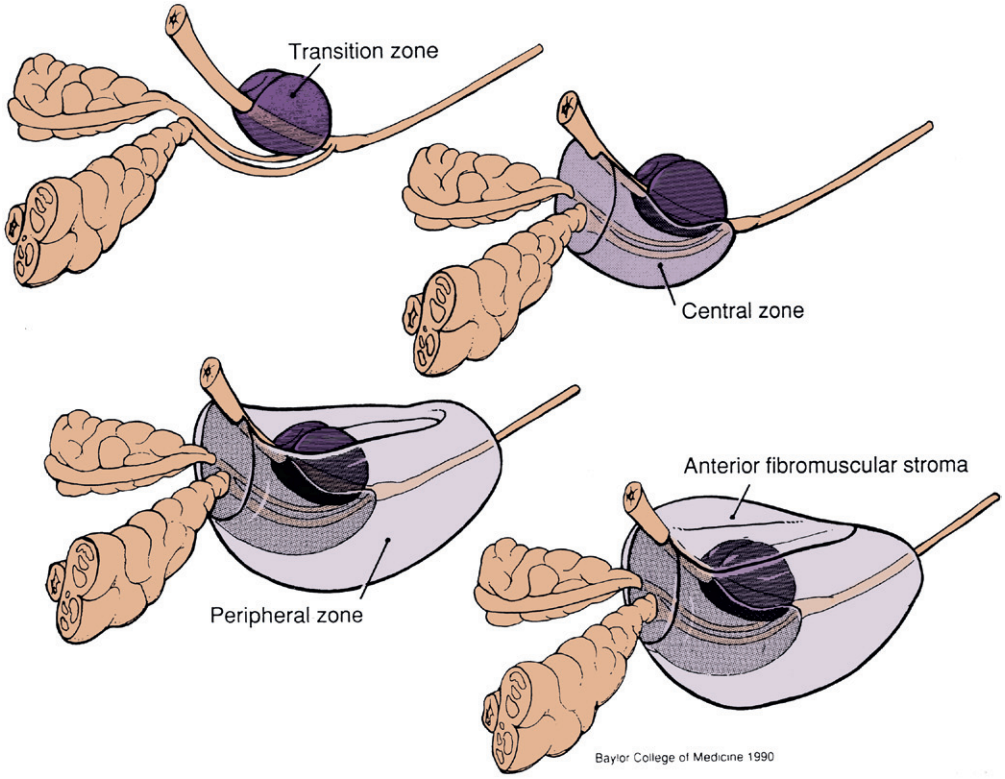

Figure 2–36. Zonal anatomy of the prostate as described by J.E. McNeal (Normal histology of the prostate. Am J Surg Pathol 1988;12:619–33). The transition zone surrounds the urethra proximal to the ejaculatory ducts. The central zone surrounds the ejaculatory ducts and projects under the bladder base. The peripheral zone constitutes the bulk of the apical, posterior, and lateral aspects of the prostate. The anterior fibromuscular stroma extends from the bladder neck to the striated urethral sphincter. (© 1990, Baylor College of Medicine.)

Vascular Supply

Most commonly, **the arterial supply to the prostate arises from the inferior vesical artery.** As it approaches the gland, the artery (often several) divides into two main branches (Fig. 2–40). The urethral arteries penetrate the prostatovesical junction posterolaterally and travel inward, perpendicular to the urethra. They approach the bladder neck in the 1- to 5-o'clock and 7- to 11-o'clock positions, with the largest branches located posteriorly. They then turn caudally, parallel to the urethra, to supply it, the periurethral glands, and the transition zone. Thus in benign prostatic hypertrophy, these arteries provide the principal blood supply of the adenoma (Flocks, 1937). When these glands are resected or

enucleated, the most significant bleeding is commonly encountered at the bladder neck, particularly at the 4- and 8-o'clock positions.

The capsular artery is the second main branch of the prostatic artery. This artery gives off a few small branches that pass anteriorly to ramify on the prostatic capsule. The bulk of this artery runs posterolateral to the prostate with the cavernous nerves (neurovascular bundles) and ends at the pelvic diaphragm. The capsular branches pierce the prostate at right angles and follow the reticular bands of stroma to supply the glandular tissues. Venous drainage of the prostate is abundant through the periprostatic plexus (see Fig. 2–20).

Lymphatic drainage is primarily to the obturator and internal iliac nodes (see Fig. 2–21). A small portion of drainage may initially pass through the presacral group or, less commonly, the external iliac nodes.

Nerve Supply

Sympathetic and parasympathetic innervation from the pelvic plexus travels to the prostate through the cavernous nerves. Nerves follow branches of the capsular artery to ramify in the glandular and stromal elements. Parasympathetic nerves end at the acini and promote secretion; sympathetic fibers cause contraction of the smooth muscle of the capsule and stroma.

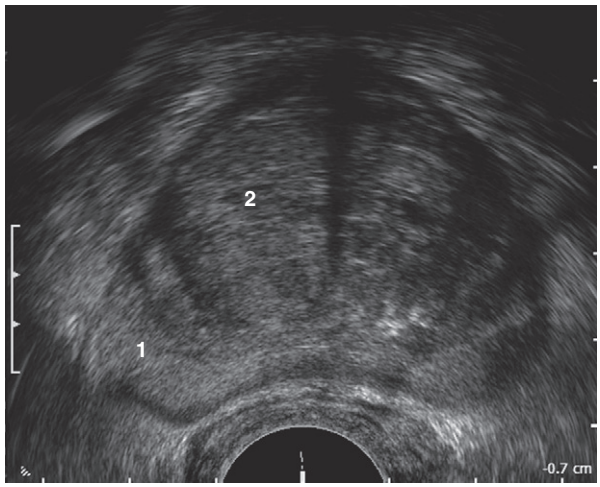

Figure 2–39. Transrectal ultrasound of the prostate demonstrating the 1, peripheral zone and 2, transition zone.

α_1-Adrenergic blockade diminishes prostate stromal and preprostatic sphincter tone and improves urinary flow rates in men affected with benign prostatic hypertrophy; this emphasizes that this disease affects both the stroma and the epithelium. Peptidergic and nitric oxide synthase–containing neurons also have been found in the prostate and may affect smooth muscle relaxation (Burnett, 1995). Afferent neurons from the prostate travel through the pelvic plexuses to pelvic and thoracolumbar spinal centers. A prostatic block may be achieved by instilling local anesthetic into the pelvic plexuses.

Membranous Urethra

In its course from the apex of the prostate to the perineal membrane, **the membranous urethra spans on average 2 to 2.5 cm** (range 1.2 to 5 cm) (Myers, 1991) (see Fig 2–37). It is surrounded by the striated (external) urethral sphincter, which is often incorrectly depicted as a flat sheet of muscle sandwiched between two layers of fascia. The striated sphincter is actually signet ring shaped, broad at its base, and narrowing as it passes through the urogenital hiatus of the levator ani to meet the apex of the prostate (see Fig. 2–14; see also Figs. 2–10, 2–27, and 2–38). In utero, this muscle forms a vertically oriented tube that extends from the perineal membrane to the bladder neck (Oelrich, 1980). As the prostate grows, posterior and lateral portions of this muscle atrophy, although transverse fibers persist on the entire anterior prostate through adulthood. At the apex of the prostate, circular fibers surround the urethra and thin posteriorly to insert into a fibrous raphe. Distally, the fibers do not meet posteriorly; rather, they acquire an Ω shape as they fan out laterally over the perineal membrane. Throughout its length, the posterior portion of the striated sphincter inserts into the perineal body. When the sphincter contracts, the walls of the urethra are pulled posteriorly toward the perineal body (Strasser et al, 1998). In contrast to the levator ani, the sphincter consists only of fine, type I (slow-twitch) fibers, rich in acid-stable myosin ATPase, which appear designed for tonic contraction. The myofibrils are surrounded by abundant connective tissue that blends with adjacent supporting structures.

The striated sphincter is related anteriorly to the dorsal vein complex (which may invade its anterior portion with age) and laterally to the levator ani. **Connective tissue from deep within the lateral and anterior walls inserts into the puboprostatic ligaments posteriorly and into the suspensory ligament of the penis anteriorly to form a sling of fibrous tissue that suspends the urethra from the pubis**

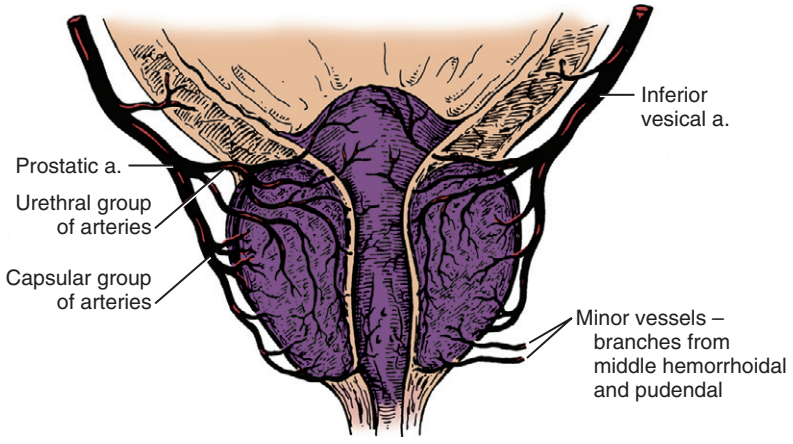

Figure 2–40. Arterial supply of the prostate. (Adapted from Flocks RH. The arterial distribution within the prostate gland: its role in transurethral prostatic resection. J Urol 1937;37:527.)

(Steiner, 1994). A similar suspensory mechanism is found in the female urethra (see later discussion and Fig. 2–41). Two bulbourethral glands lie superior to the perineal membrane and are invested in the broad base of sphincter muscle. During sexual excitement, these glands secrete clear mucus into the bulbous urethra.

The striated sphincter corresponds to the location of peak urethral closing pressure and is responsible for continence after prostatectomy. Components involved in generating this closing pressure are (1) the pseudostratified columnar epithelium, which contracts into radial folds as it meets to occlude the lumen; (2) the submucosa, which is rich with blood vessels and soft connective tissue and contributes to urethral sealing (Raz et al, 1972); (3) the longitudinal and circular urethral smooth muscle (intrinsic component of the external sphincter); (4) the striated sphincter; and (5) the pubourethral component of the levator ani.

Gross dissection and retrograde axonal tracing techniques have confirmed that the striated sphincter is supplied by the pudendal nerve (Tanagho et al, 1982). However, urologists have long been puzzled as to why pudendal nerve sectioning does not ablate sphincter activity. Lawson (1974) and Zvara and colleagues (1994) identified **a second source of somatic innervation to the sphincter: a branch of the sacral plexus that runs on the pelvic surface of the levator ani** (see Fig. 2–23). Injury to this nerve at radical prostatectomy may contribute to postoperative urinary incontinence (Hollabaugh et al, 1997). Autonomic innervation to the intrinsic smooth muscle of the membranous urethra is likely given by the cavernous nerves as they pass nearby, although dividing these nerves does not appear to affect urinary continence significantly (Steiner et al, 1991). Afferent fibers from the striated sphincter have not been defined but are sure to have interesting and important functional roles because this muscle lacks proprioceptive muscle spindles (Gosling et al, 1981).

Vas Deferens and Seminal Vesicle

As it arises from the tail of the epididymis, the vas (ductus) deferens is somewhat tortuous for 2 to 3 cm (Fig. 2–42). It runs posterior to the vessels of the cord and through the inguinal canal and emerges in the pelvis lateral to the inferior epigastric vessels (see Fig. 2–3). At the internal ring, it diverges from the testicular vessels and passes medial to all structures of the pelvic side wall to reach the base of the prostate posteriorly (see Figs. 2–3, 2–13, and 2–16). The terminal vas is dilated and tortuous (ampulla) and is capable of storing spermatozoa. The vas has a thick wall of outer longitudinal and inner circular smooth muscle and is lined by pseudostratified columnar epithelium with nonmotile stereocilia.

The seminal vesicle is a lateral outpouching of the vas, approximately 5 cm long, with a capacity of 3 to 4 mL (see Figs. 2–8, 2–36, and 2–43). Despite its name, it does not store sperm but contributes the largest portion of fluid to the ejaculate. The seminal vesicle comprises a single coiled tube with several outpouchings that is lined by columnar epithelium with goblet cells. The tube is encased in a thin layer of smooth muscle and is held in its coiled configuration by a loose adventitia.

The seminal vesicle and ampulla of the vas lie posterior to the bladder. The ureter enters the bladder medial to the tip of the seminal vesicle. As the seminal vesicle and vas join to form the ejaculatory duct, their smooth muscle coats fuse with the prostatic capsule at its base. **Denonvilliers fascia or, occasionally, the rectovesical pouch of peritoneum separates these structures from the rectum** (see Fig. 2–27). Unless involved by a pathologic process, these structures are not palpable on rectal examination.

The blood supply for the seminal vesicles and vasa comes from the vesiculodeferential artery, a branch of the superior vesical artery. This artery supplies the vas throughout its length and then passes onto the anterior surface of the seminal vesicle near its tip. During radical prostatectomy the artery is invariably found between the vas and seminal vesicle and must be isolated and controlled. Additional arterial supply may come from the inferior vesical artery. The pelvic vas and seminal vesicle drain into the pelvic venous plexus. Lymphatic drainage passes to the external and internal iliac nodes (see Fig. 2–21). Innervation

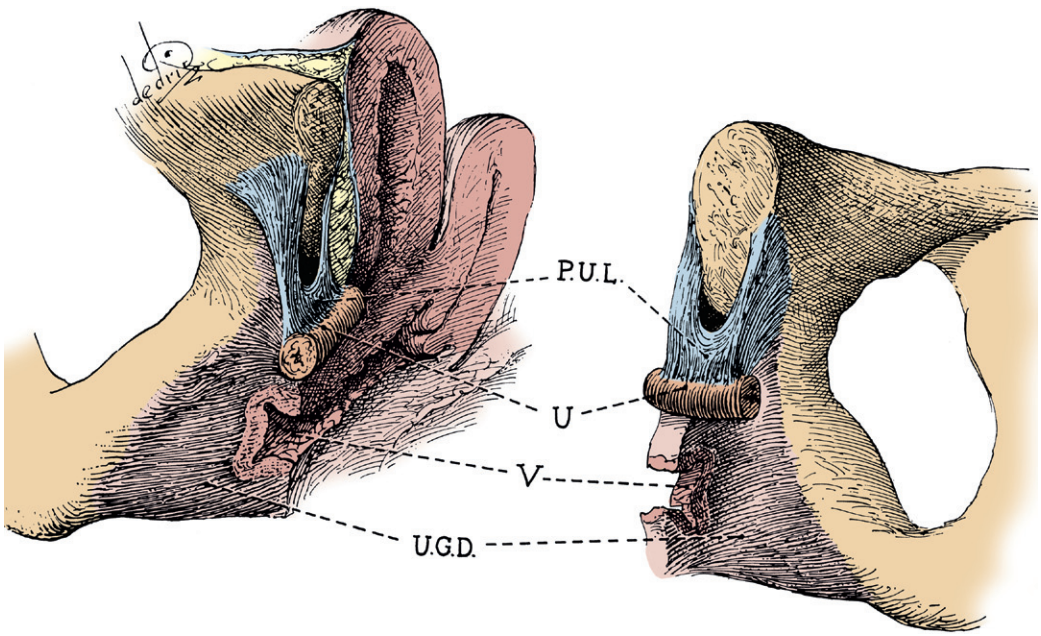

Figure 2–41. Urethral suspensory mechanism. The pubourethral ligament (P.U.L.) is composed of an anterior portion (suspensory ligament of the clitoris), a posterior portion (pubourethral ligament of endopelvic fascia), and an intermediate portion that bridges the other two. (From Milley PS, Nichols DH. The relationship between the pubo-urethral ligaments and the urogenital diaphragm in the human female. Anat Rec 1971;170:283.)

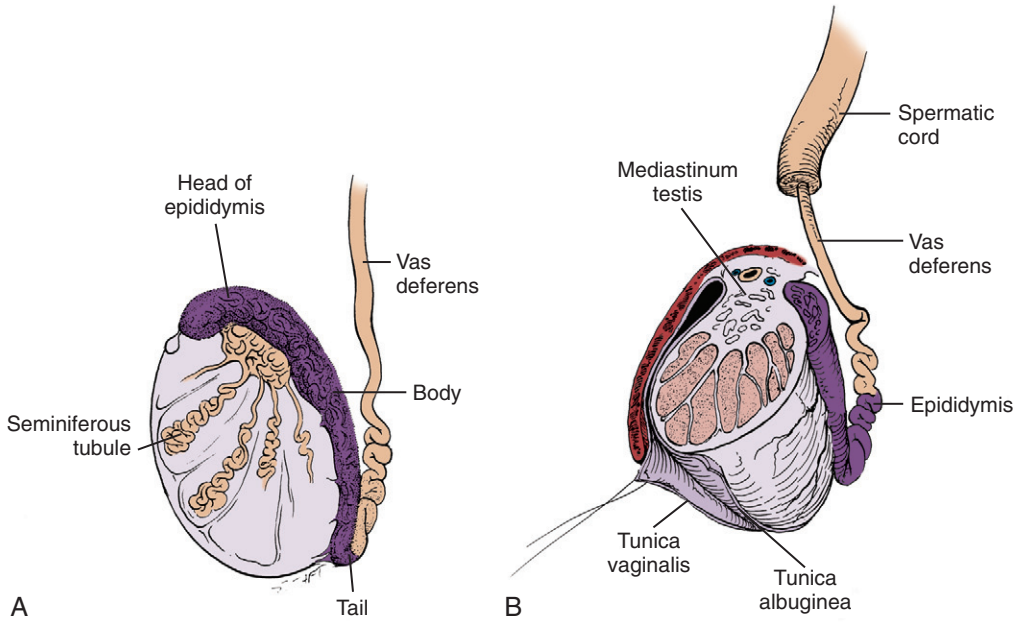

Figure 2–42. Testis and epididymis. **A,** One to three seminiferous tubules fill each compartment and drain into the rete testis in the mediastinum. Twelve to 20 efferent ductules become convoluted in the head of the epididymis and drain into a single coiled duct of the epididymis. The vas is convoluted in its first portion. **B,** Cross section of the testis, showing the mediastinum and septations continuous with the tunica albuginea. The parietal and visceral tunica vaginalis are confluent where the vessels and nerves enter the posterior aspect of the testis.

arises from the pelvic plexus, with major excitatory efferents contributed by the (sympathetic) hypogastric nerves (Kolbeck and Steers, 1993).

Female Pelvic Viscera

The uterus measures 8 × 6 × 4 cm in a normal woman and is composed largely of dense smooth muscle (see Figs. 2–19 and 2–44). It has a narrowed neck, the cervix, which opens through the anterior vaginal wall and a broad corpus that is capped by the rounded fundus. As discussed earlier, it lies in front of the rectum and over the dome of bladder; its impression can be observed cystoscopically (see Figs. 2–28 and 2–32). The fallopian tubes extend laterally from the junction of the corpus and fundus and are draped by leaves of peritoneum called the *broad ligaments* (see Figs. 2–13 and 2–19). As they extend to the pelvic side walls, the fallopian tubes angle up and backward to open posteromedially.

Figure 2–44. Key anatomic relationships in the female pelvis illustrated on sagittal midline T2-weighted magnetic resonance image. 1, urinary bladder; 2, pubic symphysis; 3, urethra; 4, vagina—note that the vagina is retroflexed posteriorly over the levator plate. The levator plate provides critical female pelvic support; 5, cervix; 6, uterus.

The tubes are divided into four segments—uterine, isthmus, ampulla, and infundibulum—and are crowned by the fimbriae. The ovary rests posterior to the elbow of the tube and is supported by its own peritoneal fold, the mesovarium. The ureter may be found directly posterior to the ovary, covered by pelvic peritoneum. The infundibulopelvic ligament, mentioned earlier,

suspends the ovary and lateral fallopian tube from the pelvic side wall and transmits the ovarian vessels to both structures. The round ligament of the ovary passes medially through the broad ligament to fix the ovary to the lateral wall of the uterus. Beneath its point of attachment, the round ligament of the uterus passes laterally, in the leaves of the broad ligament, to exit through to the inguinal canal and attach to the labial fat pad (see Figs. 2–13 and 2–19).

The uterine artery crosses in front of the ureter and runs in the broad and cardinal ligaments to supply the proximal vagina, uterus, and medial two thirds of the fallopian tube (see Fig. 2–19). It is joined by a rich plexus of uterine veins that freely connect with the ovarian veins. Nerves from the pelvic plexus travel to the female pelvic viscera through the cardinal and uterosacral ligaments in the company of the vessels; therefore hysterectomy can cause a flaccid neurogenic bladder.

The vagina extends inward from the vestibule at a 45-degree angle and then turns horizontal over the levator plate (see Figs. 2–28 and 2–44). It is lined by rugated nonkeratinized squamous epithelium backed by a thick, well-vascularized lamina propria. It is surrounded by a smooth muscle coat of inner circular and stronger external longitudinal layers. In cross section, the vagina is H shaped (see Fig. 2–41) as a result of firm attachments of its anterior wall to the levator ani at the arcus tendineus fascia pelvis, and of its posterior wall to the rectovaginal septum. The anterior vaginal wall is pierced by the cervix proximally. The shallow fossae around the cervix are referred to as the *anterior, lateral,* and posterior fornices. Because the apex of the vagina is covered with the peritoneum of the rectouterine pouch, the peritoneal cavity may be accessed through the posterior fornix (see Fig. 2–28).

Immediately in front of the cervix, the base of the bladder rests on the vaginal wall. Smooth muscle fibers tether the posterior bladder wall and base to the uterine cervix and vagina (see Figs. 2–28 and 2–44). Division of these fibers yields posterior access to the vesicovaginal space. This space extends distally to the proximal third of the urethra (where the urethra and vagina fuse) and is limited to each side by the lateral ligaments of the bladder. It may be accessed transvaginally through incision of the anterior vaginal wall in front of the cervix. Incision of the anterior vaginal wall to either side of the urethra leads into the retropubic space (see Fig. 2–12). The tough leaves of the visceral endopelvic fascia are felt medially and should be included in all transvaginal urethral suspension procedures (Mostwin, 1991).

The vagina is separated from the rectum by the rectovaginal septum (see Fig. 2–28), and rectoceles result from a loss of integrity of this septum. Deep to this septum lies a second potential space, the rectovaginal space. The bowel may herniate into this space to form an enterocele. On its lateral surfaces, the vagina is related to the levator ani. Near the vestibule, fibers of the levator ani blend and fuse with the vaginal muscularis. The vaginal vessels and nerves lie on the anterolateral surface of the vagina deep to the arcus tendineus fascia pelvis.

Female Urethra

On average, the female urethra traverses 4 cm from the bladder neck to the vaginal vestibule (see Fig. 2–44). **Its lining changes gradually from transitional to nonkeratinized stratified squamous epithelium. Many small mucous glands open into the urethra** and can give rise to urethral diverticula. Distally, these glands group together on either side of the urethra (Skene glands) and empty through two small ducts to either side of the external urethral meatus. A thick, richly vascular submucosa supports the urethral epithelium and glands (see Fig. 2–32). Together, the mucosa and submucosa form a cushion that contributes significantly to urethral closure pressure (Raz et al, 1972). These layers are estrogen dependent; at menopause they may atrophy, resulting in stress incontinence. A relatively thick layer of inner longitudinal smooth muscle continues from the bladder to the external meatus to insert into periurethral fatty and fibrous tissue. In contrast to the male proximal urethra, no circular smooth muscle sphincter can be identified. A rather thin layer of circular smooth muscle envelops the longitudinal fibers throughout the length of the urethra. It is thought that the longitudinal smooth muscle of the urethra contracts coordinately with the detrusor during micturition to shorten and widen the urethra (Gosling, 1979).

The striated urethral sphincter invests the distal two thirds of the female urethra (Oelrich, 1983). It is composed exclusively of delicate type I (slow-twitch) fibers surrounded by abundant collagen. Proximally, it forms a complete ring around the urethra that corresponds to the zone of highest urethral closure pressure (see Fig. 2–32). Farther down the urethra, the fibers do not meet posteriorly but continue off the lateral sides of the urethra onto the anterior and lateral wall of the vagina. Contraction of these fibers (the compressor urethrae) closes the urethra against the fixed anterior vaginal wall. Near the vestibule, the fibers completely surround the urethra and vagina to form a urethrovaginal sphincter. Contraction of this muscle group, along with bulbospongiosus, tightens the urogenital hiatus.

The suspensory ligament of the clitoris (anterior urethral ligament) and the pubourethral ligaments (posterior urethral ligaments) form a sling that suspends the urethra beneath the pubis (see Figs. 2–12 and 2–41) (Zacharin, 1963). The striated urethral sphincter receives dual somatic innervation, like that in the male, from the pudendal and pelvic somatic nerves (Borirakchanyavat et al, 1997). Little sympathetic innervation is found in the female urethra. Parasympathetic cholinergic fibers are found throughout the smooth muscle. Somatic and autonomic nerves to the urethra travel on the lateral walls of the vagina near the urethra. During transvaginal incontinence surgery, the anterior vaginal wall should be incised laterally to avoid these nerves and prevent type III urinary incontinence (Ball et al, 1997).

Female Pelvic Support

The pelvic muscles and fasciae cooperate to prevent prolapse of the urogenital organs through the hiatus. **Three functional supportive elements are recognized: (1) the pubovisceral and perineal muscles, which form a sphincter around the urogenital hiatus** (see Fig. 2–32); **(2) the levator plate,** which acts as a horizontal shelf beneath the bladder, uterine cervix, posterior vagina, and rectum (see Fig. 2–28); and **(3) the cardinal and uterosacral ligaments,** which anchor the pelvic viscera over the levator plate (Zacharin, 1985; Mostwin, 1991; DeLancey, 1993). The pelvic muscles contract tonically to counteract gravitational forces. In response to stress, the levator ani contracts, closing the urogenital hiatus and increasing the anteroposterior length of the levator plate. Increased intra-abdominal pressure forces the pelvic viscera downward against a fixed levator plate, closing the vagina like a flap valve.

Pelvic and perineal muscles play the greatest role in pelvic support. Damage to the perineal body during parturition destroys the urogenital sphincter, enlarges the urogenital hiatus,

and erodes the levator plate. Aging and birth trauma partially denervate and weaken the levator ani (Snooks et al, 1985). With loss of muscular support, intra-abdominal forces impinge directly on the pelvic fasciae; over time, these either tear or stretch. Procedures to correct pelvic prolapse or urinary incontinence that rely solely on these fasciae may be successful initially but do not fare well over time (Trockman et al, 1995). Repair of a single pelvic defect—a cystocele for instance—may unmask another (enterocele, rectocele); therefore successful repair of pelvic prolapse must address all components of anatomic support (Zacharin, 1985; DeLancey, 1993).

PERINEUM

The perineum lies among the pubis, thighs, and buttocks and is limited superiorly by the levator ani. Viewed from below, the symphysis pubis, ischial tuberosities, and coccyx outline the diamond shape of the perineum; the inferior ischiopubic rami and sacrotuberous ligaments form its bony and ligamentous walls (Fig. 2–45; see also Figs. 2–29 and 2–46). A line drawn through the ischial tuberosities divides the perineum into an anal and a urogenital triangle.

Anal Triangle

At the apex of the prostate, the rectum turns approximately 90 degrees posteriorly and inferiorly to become the anus (see Figs. 2–10 and 2–14). It traverses 4 cm to reach the skin near the center of the anal triangle. The subcutaneous fat that surrounds the anus is continuous with that of the urogenital triangle, buttocks, and medial thigh. Laterally, the fat fills the ischiorectal fossa, a space bounded by the levator ani medially, and obturator internus, and the sacrotuberous ligament laterally (see Fig. 2–15). Anteriorly, this space extends into a recess above the urogenital diaphragm; posteriorly, it is continuous with the intermediate stratum of the pelvis through the sciatic foramina. Through this continuity, infections may travel between the perineum and the pelvic cavity.

The anal sphincter is divided into internal and external components. **The internal sphincter represents a thickening of the inner circular smooth muscle layer of the rectum.** The outer longitudinal smooth muscle thins beyond the rectourethralis and blends with the external sphincter, although a few fibers insert in the skin around the anus (corrugator cutis ani) to give it a puckered appearance. **The external sphincter surrounds the internal sphincter and is divided into subcutaneous, superficial, and deep portions.** The subcutaneous part attaches to the perineal body by collagenous and muscular fibers that are thickest superficially and referred to as the *central tendon of the perineum*. The superficial sphincter attaches to the perineal body and coccyx. At the posterior inflection of the rectum, the deep sphincter blends with the puborectalis sling of levator ani. At this level, a firm band may be felt on rectal examination and corresponds to the internal and external sphincter. Division of this muscular band results in fecal incontinence. The prostate may be accessed anterior to the sphincter, by dividing the central tendon and sphincteric attachments to the perineum (Young procedure) or by following the anterior rectal wall beneath the external anal sphincter (Belt procedure).

Male Urogenital Triangle

The entire urogenital triangle is bridged by the urogenital diaphragm. The scrotum hangs from the anterior aspect of the urogenital triangle; in the posterior aspect, skin and subcutaneous fat overlie Colles fascia. The perineal membrane and the posterior and lateral attachments of Colles fascia limit a potential space known as the *superficial pouch* (see Figs. 2–4, 2–15, and 2–29). In this space, the three erectile bodies of the penis have their bony and fascial attachments (the root of the penis). The paired corpora cavernosa attach to the inferior ischiopubic rami and perineal membrane and are surrounded by the ischiocavernosus muscles. The corpus spongiosum dilates as the bulb of the penis and is fixed to the center of the perineal membrane. It is encompassed by the bulbospongiosus muscles (see Fig. 2–46) that arise from the perineal body and from a central tendinous raphe and pass around

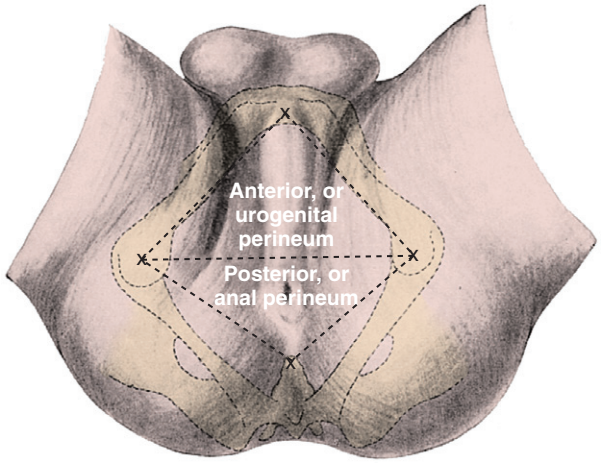

Figure 2–45. Male perineum. (From Anson BJ, McVay CB. Surgical anatomy. 6th ed. Philadelphia: WB Saunders; 1984. p. 893.)

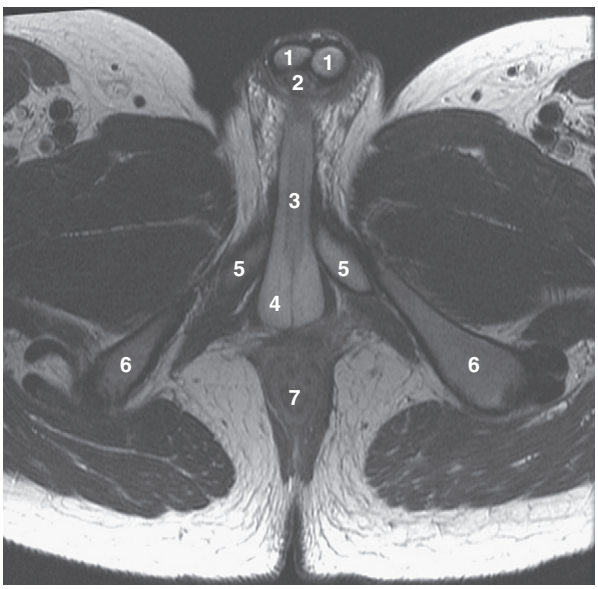

Figure 2–46. Axial T1-weighted magnetic resonance image of male pelvis. 1, corpora cavernosa in cross section; 2, corpus spongiosum in cross section; 3, corpus spongiosum in perineum; 4, bulbospongiosus muscle, which assists urine or seminal fluid expulsion from bulbar urethra; 5, crura of corpora cavernosa—note divergence of crura as they insert on pubic bone; 6, ischial tuberosities; 7, rectum.

the bulb to attach to the perineal membrane and dorsum of the penis. Contraction of the ischiocavernosus and bulbospongiosus muscles compresses the erectile bodies and potentiates penile erection. The transversus perinei muscles (superficial and deep) run along the posterior edge of the perineal membrane and are thought to stabilize the perineal body. Deep to the perineal membrane rests the striated urethral sphincter (discussed earlier).

Blood supply to the anal and urogenital triangles is derived largely from the internal pudendal vessels (Fig. 2–47). After entering the perineum through the lesser sciatic foramen, the artery runs in a fascial sheath on the medial aspect of obturator internus, the pudendal canal (of Alcock). Early in its course, it gives off three or four inferior rectal branches to the anus. Its perineal branch pierces Colles fascia to supply the muscles of the superficial pouch and continues anteriorly to supply the back of the scrotum. The internal pudendal terminates as the common penile artery (to be discussed).

The internal pudendal veins communicate freely with the dorsal vein complex by piercing the levator ani. These communicating vessels enter the pelvic venous plexus on the lateral surface of the prostate and are a common, often unexpected, source of bleeding during apical dissection of the prostate. The inferior rectal veins anastomose with the middle and superior rectal veins and produce an important connection between the portal and systemic circulation. Obstruction of the portal or systemic venous system may cause shunting of collateral venous drainage through the portal system, manifested by hemorrhoids.

The pudendal nerve follows the vessels in their course through the perineum (see Fig. 2–47). Its first branch, the dorsal nerve of the penis, travels ventral to the main pudendal trunk in Alcock canal. Several inferior rectal branches supply the external sphincter muscle and provide sensation to perianal skin. The perineal branches follow the perineal artery into the superficial pouch to supply the ischiocavernosus, bulbospongiosus, and transversus perinei muscles. A few of these branches continue anteriorly to supply sensation to the posterior scrotum. Additional perineal branches pass deep to the perineal membrane to supply the levator ani and striated urethral sphincter.

Penis

As discussed, the root of the penis is fixed to the perineum within the superficial pouch. **The corpora cavernosa join beneath the pubis (penile hilum) to form the major portion of the body of the penis.** They are separated by a septum that becomes pectiniform distally, so their vascular spaces freely communicate. They are enclosed by the tough tunica albuginea, which is predominantly collagenous (Fig. 2–48). Its outer longitudinal and inner circular fibers form an undulating meshwork when the penis is flaccid and appear tightly stretched with erection (Goldstein et al, 1982). Smooth muscle bundles traverse the erectile bodies to form the endothelium-lined cavernous sinuses. These sinuses give the erectile tissue a spongy appearance on gross examination.

Distal to the bulb, the corpus spongiosum tapers and runs on the underside (ventrum) of the corpora cavernosa (see Fig. 2–46) and then expands to cap them as the glans penis. The corona separates the base of the glans from the shaft of the penis. The

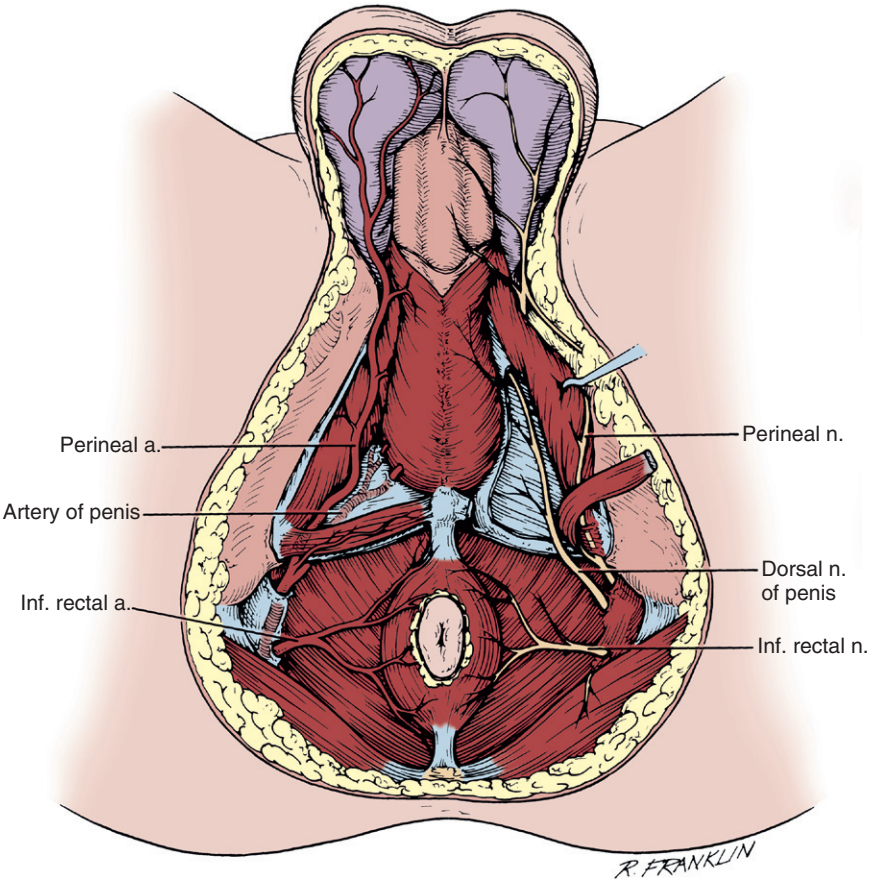

Figure 2–47. Male perineum, illustrating the internal pudendal artery and its branches on the left and the pudendal nerve and its branches on the right.

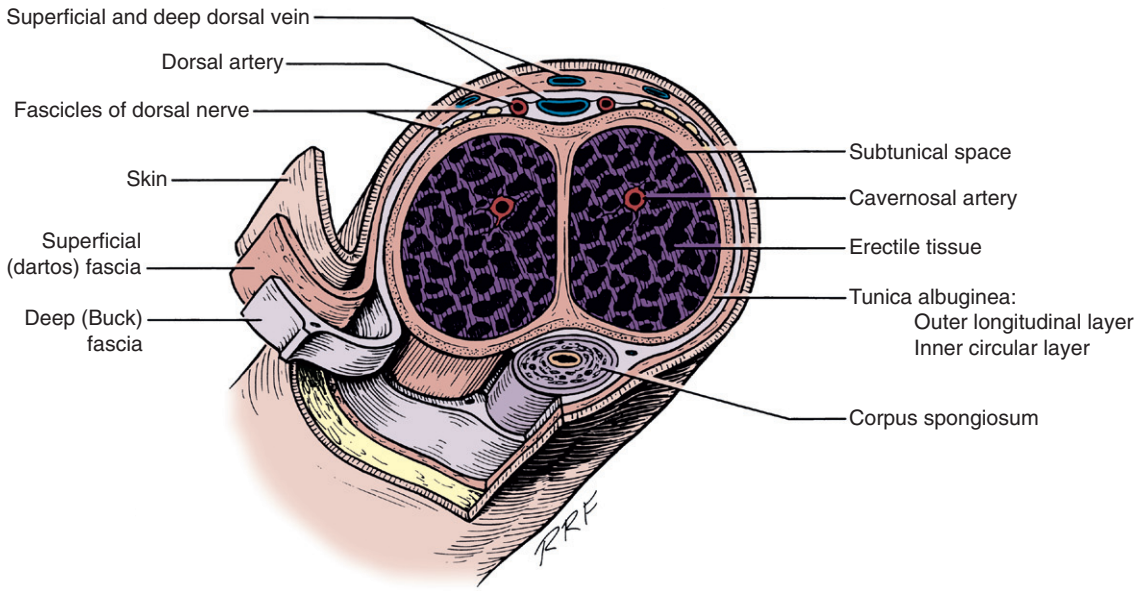

Figure 2–48. Cross section of the penis, demonstrating the relationship between the corporal bodies, penile fascia, vessels, and nerves. (From Devine Jr CJ, Angermeier KW. Anatomy of the penis and mate perineum. AUA Update Series 1994;13:10–23.)

spongiosum is traversed throughout its length by the anterior urethra, which begins at the perineal membrane (see Figs. 2–35 and 2–37). The anterior urethra is dilated in its bulbar and glanular segments (fossa navicularis) and narrowest at the external meatus. Proximally, it is lined by stratified and pseudostratified columnar epithelium, distally by stratified squamous epithelium. The mucus-secreting glands (of Littre) may be seen as small outpouchings of the mucosa.

Buck fascia surrounds both cavernosal bodies dorsally and splits to surround the spongiosum ventrally (see Fig. 2–48). Elastic and collagenous fibers from the rectus sheath blend with and surround Buck fascia as the fundiform ligament of the penis. Deeper fibers from the pubis form the suspensory ligament of the penis. In the perineum, Buck fascia fuses with the tunica albuginea deep to the muscles of the erectile bodies (Uhlenhuth et al, 1949). Distally, it fuses with the base of the glans at the corona. Bleeding from a tear in the corporal bodies (e.g., penile fracture) is usually contained within Buck fascia, and ecchymosis is limited to the penile shaft.

The skin of the penile shaft is highly elastic and without appendages (hair or glandular elements), except for the smegma-producing glands at the base of the corona. It is devoid of fat and quite mobile because of the loose attachment of its dartos backing to Buck fascia. Distally, it folds over the glans as the foreskin and attaches firmly below the corona. Its blood supply is independent of the erectile bodies and is derived from the external pudendal branches of the femoral vessels (see Fig. 2–5). These vessels enter the base of the penis to run longitudinally in the dartos fascia as a richly anastomotic network. Thus penile skin may be mobilized on a vascular pedicle as the ideal tissue for urethral reconstruction. The skin of the glans is immobile as a result of its direct attachment to the underlying, thin tunica albuginea.

The common penile artery continues in Alcock canal, above the perineal membrane, and terminates in three branches to supply the erectile bodies (Fig. 2–49). The bulbourethral artery penetrates the perineal membrane to enter the spongiosum from above at its posterolateral border. This large, short artery can be difficult to isolate and control during urethrectomy. It supplies the urethra, spongiosum, and glans. The cavernosal artery pierces the corporal body in the penile hilum to near the center of its erectile tissue. It gives off straight and helicine arteries that ramify to supply the cavernous sinuses. The dorsal artery of the penis passes between the crus penis and the pubis to reach the dorsal surface of the corporal bodies. It runs between the dorsal vein and the dorsal penile nerve and with them attaches to the underside of Buck fascia (see Fig. 2–26). As it courses to the glans, it gives off cavernous branches and circumferential branches to the spongiosum and urethra. The rich blood supply to the spongiosum allows safe division of the urethra during stricture repair (Devine and Angermeier, 1994).

The surgeon contemplating penile revascularization must be aware **that the penile arteries are highly variable in their branching, courses, and anastomoses** (Bare et al, 1994). It is not uncommon for a single cavernosal artery to supply both corporal bodies or to be absent altogether. Alternatively, an accessory pudendal artery may supplement or completely replace branches of the common penile artery. This artery usually arises from the obturator or inferior vesical arteries and runs anterolateral to or within the prostate to reach the penis in the company of the dorsal vein. This artery has been identified in 7 of 10 cadaveric specimens (Breza et al, 1989) and noted at 4% of radical prostatectomies (Polascik and Walsh, 1995); its resection at prostatectomy may adversely affect postoperative potency (Droupy et al, 1999).

At the base of the glans, several venous channels coalesce to form the dorsal vein of the penis, which runs in a groove between the corporal bodies and drains into the preprostatic plexus (see Fig. 2–26). The circumflex veins originate in the spongiosum and pass around the cavernosa to meet the deep dorsal vein perpendicularly. They are present only in the distal two thirds of the penile shaft and number 3 to 10. Intermediary venules form from the cavernous sinuses to drain into a subtunical capillary plexus. These plexuses give rise to emissary veins, which commonly follow an oblique path between the layers of the tunica and drain into the circumflex veins

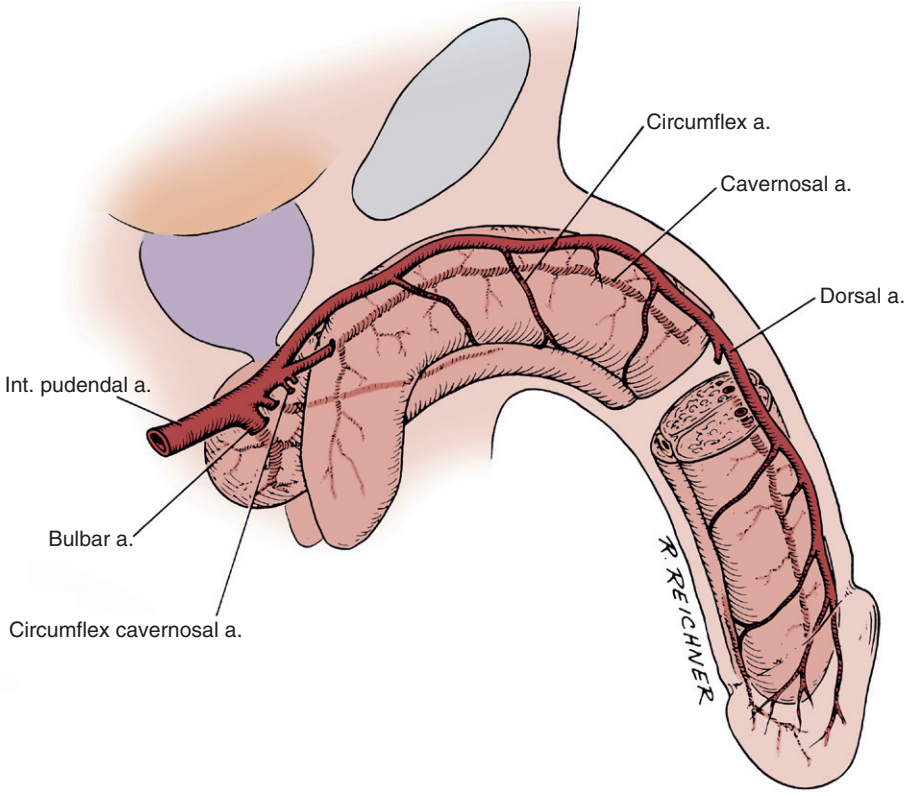

Figure 2–49. Arterial supply of the penis.

dorsolaterally. Emissary veins in the proximal third of the penis join on the dorsomedial surface of the cavernous bodies to form two to five cavernous veins. At the hilum of the penis, these vessels pass between the crura and the bulb, receiving branches from each, and join the internal pudendal veins. Valves are found in the emissary, cavernosal, and deep dorsal veins and may thwart attempts to revascularize the penis by arteriovenous anastomosis (Sohn, 1994).

The dorsal nerves provide sensory innervation to the penis. These nerves follow the course of the dorsal arteries and richly supply the glans (see Fig. 2–26). Small branches from the perineal nerve supply the ventrum of the penis near the urethra as far as the glans distally (Uchio et al, 1999). These nerves must be anesthetized when performing a penile block to numb the ventrum of the penis. The route of the cavernous nerves has been described. After piercing the corporal bodies, they ramify in the erectile tissue to supply sympathetic and parasympathetic innervation from the pelvic plexus. Tonic sympathetic tone inhibits erection. Parasympathetic nerves release acetylcholine, nitric oxide, and vasoactive intestinal polypeptide, which cause the cavernosal smooth muscle and arterial relaxation necessary for erection (Burnett, 1995). It is thought that during erection, the subtunical venules are occluded by being compressed against the nondistensible tunica albuginea. Insufficient venous occlusion, particularly in vessels draining into the deep dorsal and cavernosal veins, is thought to cause vasculogenic impotence.

Scrotum

The scrotal skin is pigmented, hair bearing, devoid of fat, and rich in sebaceous and sweat glands. It varies from loose and shiny to highly folded with transverse rugae, depending on the tone of the dartos smooth muscle. A midline raphe runs from the urethral meatus to the anus and represents the line of fusion of the genital tubercles. Deep to this raphe, the scrotum is separated into two compartments by a septum.

The dartos layer of smooth muscle is continuous with Colles, Scarpa, and the dartos fascia of the penis (see Figs. 2–4 and 2–29). The testes are suspended by their cords in the scrotal compartments. As the testes descend, they acquire coverings from the layers of the abdominal wall, known as the ***spermatic fascia,*** that form part of the scrotal wall (Fig. 2–50). The external spermatic fascia derives from the external oblique fascia and remains firmly attached to the borders of the external ring. The cremasteric muscle and fascia arise from the internal oblique muscle and attach laterally to the inguinal ligament and iliopsoas fascia and medially to the pubic tubercle. The internal spermatic fascia is a continuation of the transversalis fascia. The parietal and visceral tunica vaginalis surround the testis with a mesothelium-lined pouch and are derived from the peritoneum. They are continuous at the posterolateral border of the testis at its mesentery, where it is fixed to the scrotal wall. The testis is also fixed at its lower pole by the gubernaculum. Occasionally, the mesentery and gubernaculum may be deficient, leaving the testis unfixed (bell-clapper deformity) and predisposing to torsion of the cord.

The anterior wall of the scrotum is supplied by the external pudendal vessels and the ilioinguinal and genitofemoral nerves (see Fig. 2–5). The anterior vessels and nerves typically run parallel to the rugae and do not cross the raphe; thus transverse or midline raphe scrotal incisions are most hemostatic. The back of the scrotum is supplied by the posterior scrotal branches of the perineal vessels and nerves (see Fig. 2–47). In addition, the posterior femoral cutaneous nerve (S3) gives a perineal branch to supply the scrotum and perineum (see Fig. 2–8). In accordance with their origin, the spermatic fasciae have a blood

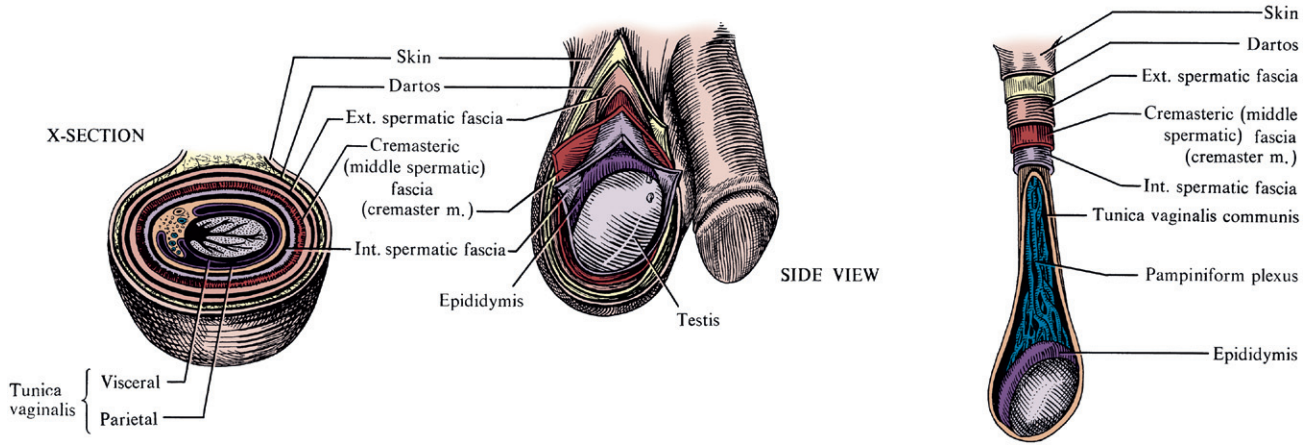

Figure 2–50. Scrotum and its layers. (From Pansky B. Review of gross anatomy. 6th ed. New York: McGraw-Hill; 1987. p. 483.)

supply (cremasteric, vasal, testicular) separate from that of the scrotal wall. Fournier gangrene usually does not involve these structures, and they may be spared during débridement.

Perineal Lymphatics

The penis, scrotum, and perineum drain into the inguinal lymph nodes. These nodes may be divided into superficial and deep groups, which are separated by the deep fascia of the thigh (fascia lata). In relation to the external pudendal, superficial inferior epigastric, and superficial circumflex iliac vessels, the superficial nodes lie at the saphenofemoral junction. At the saphenous opening (fossa ovalis) in the fascia lata, the greater saphenous vein joins the femoral vein and the superficial nodes communicate with the deep group. Most of the deep inguinal nodes lie medial to the femoral vein and send their efferents through the femoral ring (beneath the inguinal ligament) to the external iliac and obturator nodes. Just outside the femoral ring, a large node (Cloquet or Rosenmuller node) is consistently present.

The scrotal lymphatics do not cross the median raphe and drain into the ipsilateral superficial inguinal lymph nodes. Lymphatics from the shaft of the penis converge on the dorsum and then ramify to both sides of the groin. Those of the glans pass deep to Buck fascia dorsally and drain to superficial and deep groups in both sides of the groin. Direct lymphatic channels from the glans to the pelvic nodes, which bypass the inguinal nodes, have been proposed by anatomists; however, clinical studies have not confirmed their existence. Other studies have suggested that all penile lymphatic drainage passes through "sentinel nodes," which lie medial to the superficial inferior epigastric veins. Clinical studies have also called this speculation into question (Catalona, 1988). The perineal skin and fasciae drain into superficial inguinal nodes; the structures of the superficial pouch likely drain into the superficial and deep inguinal node groups.

Testes

The testes are 4 to 5 cm long, 3 cm wide, and 2.5 cm deep and have a volume of 30 mL. They are enclosed in a tough capsule comprising (1) the visceral tunica vaginalis; (2) tunica albuginea, with collagenous and smooth muscle elements; and (3) the tunica vasculosa. The epididymis attaches to the posterolateral aspect of the testis. Beneath it, the tunica albuginea projects inward to form

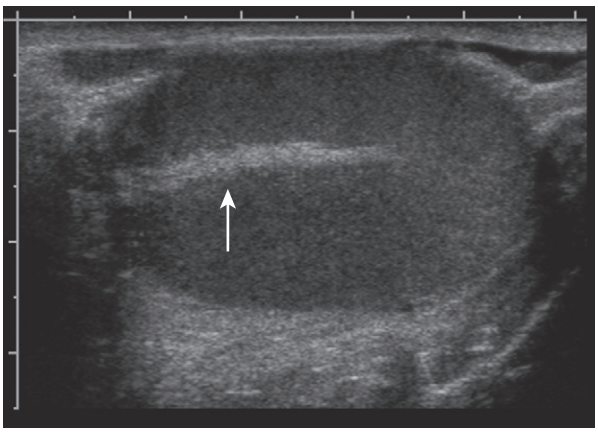

Figure 2–51. Testis ultrasound demonstrating rete testis *(arrow)*.

the mediastinum testis, the point at which vessels and ducts traverse the testicular capsule (see Fig. 2–42). Septa radiate from the mediastinum to attach to the inner surface of the tunica albuginea to form 200 to 300 cone-shaped lobules, each of which contains one or more convoluted seminiferous tubules. Each tubule is U shaped and has a stretched length of nearly 1 meter. Interstitial (Leydig) cells lie in the loose tissue surrounding the tubules and are responsible for testosterone production. Toward the apices of the lobules, the seminiferous tubules become straight (tubuli recti) and enter the mediastinum testis to form an anastomosing network of tubules lined by flattened epithelium. This network, known as the *rete testis* (Fig. 2–51), forms 12 to 20 efferent ductules and passes into the largest portion of the epididymis, the caput. Here, the efferent ductules enlarge, become more convoluted, and form conical lobules. The duct from each lobule drains into a single epididymal duct, which winds approximately 6 m within the fibrous sheath of the epididymis to form its body and tail. As the duct approaches the tail, it thickens and straightens to become the vas deferens.

The spermatic cord is composed of the vas deferens, testicular vessels, and spermatic fasciae. As discussed in Chapter 1, the testicular arteries arise from the aorta and travel in the intermediate stratum of the retroperitoneum to reach the internal inguinal ring. **Lateral to the internal inguinal ring, the attachments of**

the intermediate stratum form the lateral spermatic fascia. These attachments can be taken down at orchidopexy to gain cord length. At the internal ring, the vessels are joined by the genital branch of the genitofemoral nerve, ilioinguinal nerve, cremasteric artery, and vas deferens and its artery.

In its course to the testis, the testicular artery branches into an internal artery and an inferior testicular artery and into a capital artery to the head of the epididymis (see Fig. 2–18). The level of this branching varies and has been noted to occur within the inguinal canal in 31% to 88% of cases (Beck et al, 1992; Jarow et al, 1992). When performing an inguinal varicocelectomy, the surgeon must remember that there may be two or three arterial branches at this level (Hopps et al, 2003). A rich arterial anastomosis occurs at the head of the epididymis, between the testicular and the capital arteries, and at the tail between the testicular, epididymal, cremasteric, and vasal arteries (see Fig. 2–18). The testicular arteries enter the mediastinum and ramify in the tunica vasculosa, principally in the anterior, medial, and lateral portions of the lower pole and the anterior segment of the upper pole (Fig. 2–52 on the Expert Consult website and Fig. 2–53). Thus placement of a traction suture through the lower pole tunica albuginea risks damaging these important superficial vessels and devascularizing the testis (Jarow, 1991). Testicular biopsy should be carried out in the medial or lateral surface of the upper pole, where the risk of vascular injury is minimal.

The testicular veins form several highly anastomotic channels that surround the testicular artery as the pampiniform plexus. This arrangement allows countercurrent heat exchange, which cools the blood in the testicular artery. At the level of the inguinal canal, the veins join to form two or three channels and then a single vein that drains into the inferior vena cava on the right and the renal vein on the left. The testicular veins may anastomose with the external pudendal, cremasteric, and vasal veins (Fig. 2–54). These connections can allow varicoceles to recur after ablative procedures. Testicular lymphatic vessels drain to the para-aortic and interaortocaval nodes as detailed in Chapter 1.

Visceral innervation to the testis and epididymis travels by two routes. A portion arises in the renal and aortic plexuses and travels with the gonadal vessels. Additional gonadal afferent and efferent nerves course from the pelvic plexus in association with the vas deferens (Rauchenwald et al, 1995). Intractable orchialgia may respond to anesthesia of the pelvic plexus (Zorn et al, 1994). Intriguingly, some afferent and efferent nerves cross over to the contralateral pelvic plexus (Taguchi et al, 1999). This neural cross-communication might explain how pathologic processes in one testis (e.g., tumor or varicocele) may affect the function of the contralateral testis. The genital branch of the genitofemoral nerve supplies sensation to the parietal and visceral tunica vaginalis and the overlying scrotum.

Female Urogenital Triangle

The vestibule of the vagina runs vertically throughout the length of the urogenital triangle. The labia majora form its lateral sides and fuse anteriorly as the hood of the clitoris. The subcutaneous fat pad of the mons pubis continues posteriorly in the labia majora to frame the vestibule. The labial fat pads receive blood supply from the external pudendal vessels and may be raised on these vessels as a rotational flap for repair of vesicovaginal or urethrovaginal fistulas (Fig. 2–55). The urethra enters the vestibule between the clitoris and the vagina.

The structure of the superficial pouch is similar to that of the male (Fig. 2–56). The crura of the clitoris attach to the inferior ischiopubic rami, surrounded by the ischiocavernosus muscles, and converge to form the body of the clitoris. The vestibular bulbs lie to either side of the vaginal vestibule, covered by the bulbospongiosus muscles. As homologues of the penile bulb, they are composed of erectile tissue and meet anteriorly to form the glans of the clitoris. The vestibular glands are deep to the vestibular bulbs but, unlike the bulbourethral glands in the male, are superficial to the perineal membrane. Their ducts travel 2 cm to open in the vaginal vestibule on the posteromedial sides of the labia minora. The perineal membrane, pierced in its center by the vagina, is less well developed than that of the male. The innervation, blood supply, and lymphatic drainage of the external genitalia and superficial pouch are similar to those described in the male.

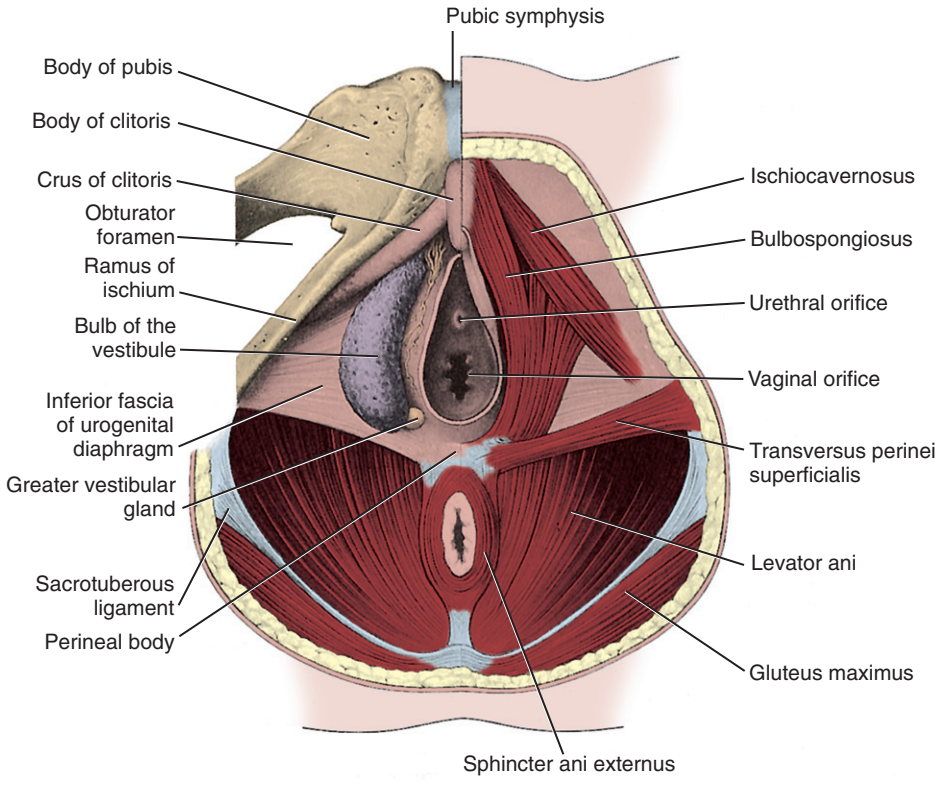

Figure 2–56. Female superficial perineal pouch. On the left side, the muscles have been removed to show the vestibular bulb and Bartholin gland. (From Williams PL, Warwick R. Gray's anatomy. 35th British ed. Philadelphia: WB Saunders; 1973. p. 1364.)

Key Points

- The pelvic cavity is divided into the false pelvis superiorly, and the true pelvis, inferiorly, wherein lie all of the pelvic organs.
- The bony prominences and ligaments of the pelvis and lower abdomen will orient the surgeon during physical examination and in the operating room.
- The pelvic floor is closed off by the levator ani and urogenital diaphragm and the muscles and fasciae of the pelvic floor provide critical support for the pelvic organs.
- The rectum, bladder, prostate, seminal vesicles, uterus, vagina, penis, and clitoris receive blood supply from the anterior trunk of the internal iliac artery and innervation from the pelvic autonomic plexus.
- The urethra, vagina, and anus exit through the perineum in association with the external genitalia.
- Detailed knowledge of the relationships of the pelvic organs to each other and the bones and muscles of the pelvis, as well as the locations of the blood supply and innervation of all pelvic and perineal structures, is critical for safely performing all pelvic operations.

Evaluation of the Urologic Patient: History, Physical Examination, and Urinalysis

Glenn S. Gerber, MD ● Charles B. Brendler, MD

History
Physical Examination
Urinalysis
Summary

Urologists have a unique position in medicine because their patients encompass all age groups including prenatal, pediatric, adolescent, adult, and geriatric. Because there is no medical subspecialist with similar interests, **the urologist has the ability to make the initial evaluation and diagnosis and to provide medical and surgical therapy for all diseases of the genitourinary (GU) system.** Historically, the diagnostic armamentarium included urinalysis, endoscopy, and intravenous pyelography. Recent advances in ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and endourology have expanded our diagnostic capabilities. Despite these advances, however, the basic approach to the patient is still dependent on taking a complete history, executing a thorough physical examination, and performing a urinalysis. These basics dictate and guide the subsequent diagnostic evaluation.

HISTORY

Overview

The medical history is the cornerstone of the evaluation of the urologic patient, and a well-taken history will frequently elucidate the probable diagnosis. However, many pitfalls can inhibit the urologist from obtaining an accurate history. The patient may be unable to describe or communicate symptoms because of anxiety, language barrier, or educational background. Therefore the urologist must be a detective and lead the patient through detailed and appropriate questioning to obtain accurate information. There are practical considerations in the art of history taking that can help to alleviate some of these difficulties. In the initial meeting, an attempt should be made to help the patient feel comfortable. During this time, the physician should project a calm, caring, and competent image that can help foster two-way communication. Impaired hearing, mental capacity, and facility with English can be assessed promptly. These difficulties are frequently overcome by having a family member present during the interview or, alternatively, by having an interpreter present.

Patients need to have sufficient time to express their problems and the reasons for seeking urologic care; the physician, however, should focus the discussion to make it as productive and informative as possible. Direct questioning can then proceed logically. The physician needs to listen carefully without distractions to obtain and interpret the clinical information provided by the patient. **A complete history can be divided into the chief complaint and history of the present illness, the patient's past medical history, and a family history.** Each segment can provide significant positive and negative findings that will contribute to the overall evaluation and treatment of the patient.

Chief Complaint and Present Illness

Most urologic patients identify their symptoms as arising from the urinary tract and frequently present to the urologist for the initial evaluation. For this reason, the urologist frequently has the opportunity to act as both the primary physician and the specialist. The chief complaint must be clearly defined because it provides the initial information and clues to begin formulating the differential diagnosis. Most importantly, **the chief complaint is a constant reminder to the urologist as to why the patient initially sought care.** This issue must be addressed even if subsequent evaluation reveals a more serious or significant condition that requires more urgent attention. In our personal experience, a young woman presented with a chief complaint of recurrent urinary tract infections (UTIs). In the course of her evaluation, she was found to have a right adrenal mass. We subsequently focused on this problem and performed a right adrenalectomy for a benign cortical adenoma. We forgot about the woman's original symptoms until she presented for her subsequent postoperative examination. She reminded us of her original symptoms at that time, and subsequent evaluation revealed that she had a nylon suture that had eroded into the anterior wall of her bladder from a previous abdominal vesicourethropexy performed 2 years earlier for stress urinary incontinence. Her UTIs resolved after surgical removal of the suture.

In obtaining the history of the present illness, **the duration, severity, chronicity, periodicity, and degree of disability are important considerations.** The patient's symptoms need to be clarified for details and quantified for severity. Listed next are a variety of typical initial complaints. Specific questions that focus the differential diagnosis are provided.

Pain

Pain arising from the GU tract may be quite severe and is usually associated with either urinary tract obstruction or inflammation. Urinary calculi cause severe pain when they obstruct the upper urinary tract. Conversely, large, nonobstructing stones may be totally asymptomatic. Thus a 2-mm-diameter stone lodged at the ureterovesical junction may cause excruciating pain, whereas a large staghorn calculus in the renal pelvis or a bladder stone may be totally asymptomatic. Urinary retention from prostatic obstruction is also quite painful, but the diagnosis is usually obvious to the patient.

Inflammation of the GU tract is most severe when it involves the parenchyma of a GU organ. This is due to edema and distention of the capsule surrounding the organ. Thus pyelonephritis, prostatitis, and epididymitis are typically quite painful. Inflammation of the mucosa of a hollow viscus such as the bladder or urethra usually produces discomfort, but the pain is not nearly as severe.

Tumors in the GU tract usually do not cause pain unless they produce obstruction or extend beyond the primary organ to involve adjacent nerves. Thus pain associated with GU malignancies is usually a late manifestation and a sign of advanced disease.

Renal Pain. Pain of renal origin is usually located in the ipsilateral costovertebral angle just lateral to the sacrospinalis muscle and beneath the 12th rib. **Pain is usually caused by acute distention of the renal capsule, generally from inflammation or obstruction.** The pain may radiate across the flank anteriorly toward the upper abdomen and umbilicus and may be referred to the testis or labium. A corollary to this observation is that renal or retroperitoneal disease should be considered in the differential diagnosis of any man who complains of testicular discomfort but has a normal scrotal examination. Pain due to inflammation is usually steady, whereas pain due to obstruction fluctuates in intensity. Thus the pain produced by ureteral obstruction is typically colicky in nature and intensifies with ureteral peristalsis, at which time the pressure in the renal pelvis rises as the ureter contracts in an attempt to force urine past the point of obstruction.

Pain of renal origin may be associated with gastrointestinal symptoms because of reflex stimulation of the celiac ganglion and because of the proximity of adjacent organs (liver, pancreas, duodenum, gallbladder, and colon). Thus renal pain may be confused with pain of intraperitoneal origin; it can usually be distinguished, however, by a careful history and physical examination. Pain that is due to a perforated duodenal ulcer or pancreatitis may radiate into the back, but the site of greatest pain and tenderness is in the epigastrium. Pain of intraperitoneal origin is seldom colicky, as with obstructive renal pain. Furthermore, pain of intraperitoneal origin frequently radiates into the shoulder because of irritation of the diaphragm and phrenic nerve; this does not occur with renal pain. Typically, patients with intraperitoneal pathology prefer to lie motionless to minimize pain, whereas patients with renal pain usually are more comfortable moving around and holding the flank.

Renal pain may also be confused with pain resulting from irritation of the costal nerves, most commonly T10-T12. Such pain has a similar distribution from the costovertebral angle across the flank toward the umbilicus. However, the pain is not colicky in nature. Furthermore, the intensity of radicular pain may be altered by changing position; this is not the case with renal pain.

Ureteral Pain. **Ureteral pain is usually acute and secondary to obstruction.** The pain results from acute distention of the ureter and by hyperperistalsis and spasm of the smooth muscle of the ureter as it attempts to relieve the obstruction, usually produced by a stone or blood clot. The site of ureteral obstruction can often be determined by the location of the referred pain. With obstruction of the midureter, pain on the right side is referred to the right lower quadrant of the abdomen (McBurney point) and thus may simulate appendicitis; pain on the left side is referred over the left lower quadrant and resembles diverticulitis. Also, the pain may be referred to the scrotum in the male or the labium in the female. Lower ureteral obstruction frequently produces symptoms of vesical irritability including frequency, urgency, and suprapubic discomfort that may radiate along the urethra in men to the tip of the penis. Often, by taking a careful history, the astute clinician can predict the location of the obstruction. Ureteral pathology that arises slowly or produces only mild obstruction rarely causes pain. Therefore ureteral tumors and stones that cause minimal obstruction are seldom painful.

Vesical Pain. Vesical pain is usually produced either by overdistention of the bladder as a result of acute urinary retention or by inflammation. **Constant suprapubic pain that is unrelated to urinary retention is seldom of urologic origin.** Furthermore, patients with slowly progressive urinary obstruction and bladder distention (e.g., diabetics with a flaccid neurogenic bladder) frequently have no pain at all despite residual urine volumes over 1L.

Inflammatory conditions of the bladder usually produce intermittent suprapubic discomfort. Thus the pain in conditions such as bacterial cystitis or interstitial cystitis is usually most severe when the bladder is full and is relieved at least partially by voiding. Patients with cystitis sometimes experience sharp, stabbing suprapubic pain at the end of micturition, and this is termed *strangury*. Furthermore, patients with cystitis frequently experience pain referred to the distal urethra that is associated with irritative voiding symptoms such as urinary frequency and dysuria.

Prostatic Pain. **Prostatic pain is usually secondary to inflammation with secondary edema and distention of the prostatic capsule.** Pain of prostatic origin is poorly localized, and the patient may complain of lower abdominal, inguinal, perineal, lumbosacral, penile, and/or rectal pain. Prostatic pain is frequently associated with irritative urinary symptoms such as frequency and dysuria, and, in severe cases, marked prostatic edema may produce acute urinary retention.

Penile Pain. **Pain in the flaccid penis is usually secondary to inflammation in the bladder or urethra, with referred pain that is experienced maximally at the urethral meatus.** Alternatively, penile pain may be produced by *paraphimosis,* a condition in which the uncircumcised penile foreskin is trapped behind the glans penis, resulting in venous obstruction and painful engorgement of the glans penis (see later). Pain in the erect penis is usually due to Peyronie disease or priapism (see later).

Testicular Pain. Scrotal pain may be either primary or referred. **Primary pain arises from within the scrotum and is usually secondary to acute epididymitis or torsion of the testis or testicular appendices.** Because of the edema and pain associated with both acute epididymitis and testicular torsion, it is frequently difficult to distinguish these two conditions. Alternatively, scrotal pain may result from inflammation of the scrotal wall itself. This may result from a simple infected hair follicle or sebaceous cyst, but it may also be secondary to Fournier gangrene,

a severe, necrotizing infection arising in the scrotum that can rapidly progress and be fatal unless promptly recognized and treated.

Chronic scrotal pain is usually related to noninflammatory conditions such as a hydrocele or a varicocele, and the pain is generally characterized as a dull, heavy sensation that does not radiate. Because the testes arise embryologically in close proximity to the kidneys, pain arising in the kidneys or retroperitoneum may be referred to the testes. Similarly, the dull pain associated with an inguinal hernia may be referred to the scrotum.

Hematuria

Hematuria is the presence of blood in the urine; **greater than three red blood cells per high-power microscopic field (HPF) is significant.** Patients with gross hematuria are usually frightened by the sudden onset of blood in the urine and frequently present to the emergency department for evaluation, fearing that they may be bleeding excessively. Hematuria of any degree should never be ignored and, in adults, should be regarded as a symptom of urologic malignancy until proved otherwise. In evaluating hematuria, several questions should always be asked, and the answers will enable the urologist to target the subsequent diagnostic evaluation efficiently:

Is the hematuria gross or microscopic?
At what time during urination does the hematuria occur (beginning or end of stream or during entire stream)?
Is the hematuria associated with pain?
Is the patient passing clots?
If the patient is passing clots, do the clots have a specific shape?

Gross versus Microscopic Hematuria. The significance of gross versus microscopic hematuria is simply that **the chances of identifying significant pathology increase with the degree of hematuria.** Thus patients with gross hematuria usually have identifiable underlying pathology, whereas it is quite common for patients with minimal degrees of microscopic hematuria to have a negative urologic evaluation.

Timing of Hematuria. The timing of hematuria during urination frequently indicates the site of origin. **Initial hematuria usually arises from the urethra;** it occurs least commonly and is usually secondary to inflammation. Total hematuria is most common and indicates that the bleeding is most likely coming from the bladder or upper urinary tracts. Terminal hematuria occurs at the end of micturition and is usually secondary to inflammation in the area of the bladder neck or prostatic urethra. It occurs at the end of micturition as the bladder neck contracts, squeezing out the last amount of urine.

Association with Pain. Hematuria, although frightening, is usually not painful unless it is associated with inflammation or obstruction. Thus patients with cystitis and secondary hematuria may experience painful urinary irritative symptoms, but the pain is usually not worsened with passage of clots. More commonly, **pain in association with hematuria usually results from upper urinary tract hematuria with obstruction of the ureters with clots.** Passage of these clots may be associated with severe, colicky flank pain similar to that produced by a ureteral calculus, and this helps identify the source of the hematuria.

Presence of Clots. The presence of clots usually indicates a more significant degree of hematuria, and, accordingly, the probability of identifying significant urologic pathology increases.

Shape of Clots. Usually, if the patient is passing clots, they are amorphous and of bladder or prostatic urethral origin. However, **the presence of vermiform (wormlike) clots, particularly if associated with flank pain, identifies the hematuria as coming from the upper urinary tract** with formation of vermiform clots within the ureter.

It cannot be emphasized strongly enough that **hematuria, particularly in the adult, should be regarded as a symptom of malignancy until proved otherwise and demands immediate urologic examination.** In a patient who presents with gross hematuria, cystoscopy should be performed as soon as possible, because frequently the source of bleeding can be readily identified. Cystoscopy will determine whether the hematuria is coming from the urethra, bladder, or upper urinary tract. In patients with gross hematuria secondary to an upper tract source, it is easy to see the jet of red urine pulsing from the involved ureteral orifice.

Although inflammatory conditions may result in hematuria, all patients with hematuria, except perhaps young women with acute bacterial hemorrhagic cystitis, should undergo urologic evaluation. Older women and men who present with hematuria and irritative voiding symptoms may have cystitis secondary to infection arising in a necrotic bladder tumor or, more commonly, flat carcinoma in situ of the bladder. **The most common cause of gross hematuria in a patient older than age 50 years is bladder cancer.**

Lower Urinary Tract Symptoms

Irritative Symptoms. *Frequency* is one of the most common urologic symptoms. The normal adult voids five or six times per day, with a volume of approximately 300 mL with each void. **Urinary frequency is due to either increased urinary output (polyuria) or decreased bladder capacity.** If voiding is noted to occur in large amounts frequently, the patient has polyuria and should be evaluated for diabetes mellitus, diabetes insipidus, or excessive fluid ingestion. Causes of decreased bladder capacity include bladder outlet obstruction with decreased compliance, increased residual urine, and/or decreased functional capacity due to irritation, neurogenic bladder with increased sensitivity and decreased compliance, pressure from extrinsic sources, or anxiety. By separating irritative from obstructive symptoms, the astute clinician should be able to arrive at a proper differential diagnosis.

Nocturia is nocturnal frequency. Normally, adults arise no more than twice at night to void. As with frequency, nocturia may be secondary to increased urine output or decreased bladder capacity. **Frequency during the day without nocturia is usually of psychogenic origin and related to anxiety. Nocturia without frequency may occur in the patient with congestive heart failure and peripheral edema in whom the intravascular volume and urine output increase when the patient is supine. Renal concentrating ability decreases with age; therefore urine production in the geriatric patient is increased at night, when renal blood flow is increased as a result of recumbency.** In general, nocturia may be attributed to nocturnal polyuria (nocturnal urine overproduction) and/or diminished nocturnal bladder capacity (Weiss and Blaivas, 2000). Nocturia may also occur in people who drink large amounts of liquid in the evening, particularly caffeinated and alcoholic beverages, which have strong diuretic effects. In the absence of these factors, nocturia signifies a problem with bladder function secondary to urinary outlet obstruction and/or decreased bladder compliance.

Dysuria is painful urination that is usually caused by inflammation. **This pain is usually not felt over the bladder but is commonly referred to the urethral meatus.** Pain occurring

at the start of urination may indicate urethral pathology, whereas pain occurring at the end of micturition (strangury) is usually of bladder origin. Dysuria is frequently accompanied by frequency and urgency.

Obstructive Symptoms. *Decreased force of urination* is usually secondary to bladder outlet obstruction and commonly results from benign prostatic hyperplasia (BPH) or a urethral stricture. In fact, except for severe degrees of obstruction, **most patients are unaware of a change in the force and caliber of their urinary stream.** These changes usually occur gradually and go generally unrecognized by most patients. The other obstructive symptoms noted later are more commonly recognized and are usually secondary to bladder outlet obstruction in men due to either BPH or a urethral stricture.

Urinary hesitancy refers to a delay in the start of micturition. Normally, urination begins within a second after relaxing the urinary sphincter, but it may be delayed in men with bladder outlet obstruction.

Intermittency refers to involuntary start-stopping of the urinary stream. It most commonly results from prostatic obstruction with intermittent occlusion of the urinary stream by the lateral prostatic lobes.

Postvoid dribbling refers to the terminal release of drops of urine at the end of micturition. **This is secondary to a small amount of residual urine in either the bulbar or the prostatic urethra that is normally "milked back" into the bladder at the end of micturition** (Stephenson and Farrar, 1977). In men with bladder outlet obstruction, this urine escapes into the bulbar urethra and leaks out at the end of micturition. Men will frequently attempt to avoid wetting their clothing by shaking the penis at the end of micturition. In fact, this is ineffective, and the problem is more readily solved by manual compression of the bulbar urethra in the perineum and blotting the urethral meatus with a tissue. Postvoid dribbling is often an early symptom of urethral obstruction related to BPH, but, in itself, seldom necessitates any further treatment.

Straining refers to the use of abdominal musculature to urinate. Normally, it is unnecessary for a man to perform a Valsalva maneuver except at the end of urination. Increased straining during micturition is a symptom of bladder outlet obstruction.

It is important for the urologist to distinguish irritative from obstructive lower urinary tract symptoms. This most frequently occurs in evaluating men with BPH. Although BPH is primarily obstructive, it produces changes in bladder compliance that result in increased irritative symptoms. In fact, men with BPH more commonly present with irritative than obstructive symptoms, and the most common presenting symptom is nocturia. **The urologist must be careful not to attribute irritative symptoms to BPH unless there is documented evidence of obstruction.** In general, lower urinary tract symptoms are nonspecific and may occur secondary to a wide variety of neurologic conditions, as well as to prostatic enlargement (Lepor and Machi, 1993). In this regard, two important examples are mentioned. Patients with high-grade flat carcinoma in situ of the bladder may present with urinary irritative symptoms. The urologist should be particularly aware of the diagnosis of carcinoma in situ in men who present with irritative symptoms, a history of cigarette smoking, and microscopic hematuria. In our personal experience, we cared for a 54-year-old man who presented with this history and was treated for BPH for 2 years before the diagnosis of bladder cancer was established. Once the correct diagnosis was made, the patient had developed muscle-invasive disease and required a cystectomy for cure.

The second important example is irritative symptoms resulting from neurologic disease such as cerebrovascular accidents, diabetes mellitus, and Parkinson disease. Most neurologic diseases encountered by the urologist are upper motor neuron in etiology and result in a loss of cortical inhibition of voiding with resultant decreased bladder compliance and irritative voiding symptoms. The urologist must be extremely careful to rule out underlying neurologic disease before performing surgery to relieve bladder outlet obstruction. Such surgery not only may fail to relieve the patient's irritative symptoms but also may result in permanent urinary incontinence.

Since its introduction in 1992, **the American Urological Association (AUA) symptom index has been widely used and validated as an important means of assessing men with lower urinary tract symptoms** (Barry et al, 1992). The original AUA symptom score is based on the answers to seven questions concerning frequency, nocturia, weak urinary stream, hesitancy, intermittency, incomplete bladder emptying, and urgency. The International Prostate Symptom Score (I-PSS) includes these seven questions, as well as a global quality-of-life question (Table 3–1). The total symptom score ranges from 0 to 35 with scores of 0 to 7, 8 to 19, and 20 to 35 indicating mild, moderate, and severe lower urinary tract symptoms, respectively. The I-PSS is a helpful tool both in the clinical management of men with lower urinary tract symptoms and in research studies regarding the medical and surgical treatment of men with voiding dysfunction.

The use of symptom indices has limitations, and it is important for the physician to discuss the patient's responses with him. It has been demonstrated that a grade 6 reading level is necessary to understand the I-PSS, and some patients with neurologic disorders and dementia may also have difficulty completing the symptom score (MacDiarmid et al, 1998). In addition, the symptom score and obstructive and irritative voiding symptoms are nonspecific, and the symptoms may be caused by a variety of conditions other than BPH. Similar symptom scores have been demonstrated to be present in age-matched men and women between 55 and 79 years of age (Lepor and Machi, 1993). **Despite these limitations, the I-PSS is a simple adjunct in assessing men with lower urinary tract symptoms and may be used in the initial evaluation of men with lower urinary tract symptoms, as well as in the assessment of treatment response.**

Incontinence. *Urinary incontinence* is the involuntary loss of urine. A careful history of the incontinent patient will often determine the etiology. Urinary incontinence can be subdivided into four categories.

Continuous Incontinence. **Continuous incontinence is most commonly due to a urinary tract fistula that bypasses the urethral sphincter.** The most common type of fistula that results in urinary incontinence is a vesicovaginal fistula usually secondary to gynecologic surgery, radiation, or obstetric trauma. Less commonly, ureterovaginal fistulas may occur from similar causes.

A second major cause of continuous incontinence is an ectopic ureter that enters either the urethra or the female genital tract. An ectopic ureter usually drains a small, dysplastic upper pole segment of kidney, and the amount of urinary leakage may be quite small. Such patients may void most of their urine normally but have a continuous amount of small urinary leakage that may be misdiagnosed for many years as a chronic vaginal discharge. In our experience, we cared for a 30-year-old woman—who had been misdiagnosed with enuresis in childhood and as having a chronic vaginal discharge in adult

Table 3–1.

International Prostate Symptom Score

SYMPTOM	NOT AT ALL	<1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS	YOUR SCORE
1. Incomplete emptying							
Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
2. Frequency							
Over the past month, how often have you had to urinate again <2 hours after you finished urinating?	0	1	2	3	4	5	
3. Intermittency							
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. Urgency							
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Weak stream							
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Straining							
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
	NONE	1 TIME	2 TIMES	3 TIMES	4 TIMES	≥5 TIMES	
7. Nocturia							
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5	
Total I-PSS Score							

QUALITY OF LIFE DUE TO URINARY SYMPTOMS	DELIGHTED	PLEASED	MOSTLY SATISFIED	MIXED—ABOUT EQUALLY SATISFIED AND DISSATISFIED	MOSTLY DISSATISFIED	UNHAPPY	TERRIBLE
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	0	1	2	3	4	5	6

From Cockett ATK, Aso Y, Denis L, et al. The Second International Consultation on Benign Prostatic Hyperplasia (BPH). In: Cockett ATK, Aso Y, Chatelain C, et al, editors. The Second International Consultation on Benign Prostatic Hyperplasia (BPH). Paris: Scientific Communication International; 1994. p. 553.

life—whose urinary leakage was totally corrected by surgical removal of the dysplastic, upper pole segment of her right kidney. Ectopic ureters never produce urinary incontinence in males because they always enter the bladder neck or prostatic urethra proximal to the external urethral sphincter.

Stress Incontinence. Stress incontinence refers to the sudden leakage of urine with coughing, sneezing, exercise, or other activities that increase intra-abdominal pressure. During these activities, intra-abdominal pressure rises transiently above urethral resistance, resulting in a sudden, usually small amount of urinary leakage. Stress incontinence is most common in women after childbearing or menopause and is related to a loss of anterior vaginal support and weakening of pelvic tissues. Stress incontinence is also observed in men after prostatic surgery, most commonly radical prostatectomy, in which there may be injury to the external urethral sphincter. **Stress urinary incontinence is difficult to manage pharmacologically, and patients with significant stress incontinence are usually best treated surgically.**

Urgency Incontinence. Urgency incontinence is the precipitous loss of urine preceded by a strong urge to void. This symptom is commonly observed in patients with cystitis, neurogenic bladder, and advanced bladder outlet obstruction with secondary loss of bladder compliance. It is important to distinguish urgency

incontinence from stress incontinence for two reasons. First, **urgency incontinence may result from a secondary underlying pathologic process, which should be identified;** treatment of this primary problem such as infection or bladder outlet obstruction may result in resolution of urgency incontinence. Second, patients with urgency incontinence are usually not amenable to surgical correction but, rather, are more appropriately treated with pharmacologic agents that increase bladder compliance and/or increase urethral resistance.

Overflow Urinary Incontinence. Overflow urinary incontinence, often called *paradoxical incontinence,* is secondary to advanced urinary retention and high residual urine volumes. In these patients, the bladder is chronically distended and never empties completely. Urine may dribble out in small amounts as the bladder overflows. This is particularly likely to occur at night when the patient is less likely to inhibit urinary leakage. **Overflow incontinence has been termed *paradoxical incontinence* because it can often be cured by relief of bladder outlet obstruction.** It is, however, often difficult to make the diagnosis of overflow incontinence by history and physical examination alone, particularly in the obese patient, in whom percussion of the distended bladder may be difficult. Overflow incontinence usually develops over a considerable length of time, and patients may be totally unaware of incomplete bladder emptying. Thus any patient with significant incontinence should undergo measurement of postvoid residual urine.

Enuresis. *Enuresis* refers to urinary incontinence that occurs during sleep. It occurs normally in children up to 3 years of age **but persists in about 15% of children at age 5 and about 1% of children at age 15** (Forsythe and Redmond, 1974). Enuresis must be distinguished from continuous incontinence, which occurs in the day and night and which, in a young girl, usually indicates the presence of an ectopic ureter. All children older than age 6 years with enuresis should undergo a urologic evaluation, although the vast majority will be found to have no significant urologic abnormality.

Sexual Dysfunction

Male sexual dysfunction is frequently used synonymously with *impotence* or erectile dysfunction, although impotence refers specifically to the inability to achieve and maintain an erection adequate for intercourse. Patients presenting with "impotence" should be questioned carefully to rule out other male sexual disorders including loss of libido, absence of emission, absence of orgasm, and, most commonly, premature ejaculation. Obviously, it is important to identify the precise problem before proceeding with further evaluation and treatment.

Loss of Libido. Because androgens have a major influence on sexual desire, a decrease in libido may indicate androgen deficiency arising from either pituitary or testicular dysfunction. This can be evaluated directly by **measurement of serum testosterone that, if abnormal, should be further evaluated by measurement of serum gonadotropins and prolactin.** Because the amount of testosterone required to maintain libido is usually less than that required for full stimulation of the prostate and seminal vesicles, patients with hypogonadism may also note decreased or absent ejaculation. Conversely, if semen volume is normal, it is unlikely that endocrine factors are responsible for loss of libido. A decrease in libido may also result from depression and a variety of medical illnesses that affect general health and well-being.

Impotence. *Impotence* refers specifically to the inability to achieve and maintain an erection sufficient for intercourse. **A careful history will often determine whether the problem is primarily psychogenic or organic.** In men with psychogenic impotence, the condition frequently develops rather quickly secondary to a precipitating event such as marital stress or change or loss of a sexual partner. In men with organic impotence, the condition usually develops more insidiously and frequently can be linked to advancing age or other underlying risk factors.

In evaluating men with impotence, it is important to determine whether the problem exists in all situations. Many men who report impotence may not be able to have intercourse with one partner but will with another. Similarly, it is important to determine whether men are able to achieve normal erections with alternative forms of sexual stimulation (e.g., masturbation, erotic videos). Finally, the patient should be asked whether he ever notes nocturnal or early morning erections. In general, **patients who are able to achieve adequate erections in some situations but not others have primarily psychogenic rather than organic impotence.**

Failure to Ejaculate. **An ejaculation may result from several causes: (1) androgen deficiency, (2) sympathetic denervation, (3) pharmacologic agents, and (4) bladder neck and prostatic surgery.** Androgen deficiency results in decreased secretions from the prostate and seminal vesicles causing a reduction or loss of seminal volume. Sympathectomy or extensive retroperitoneal surgery, most notably retroperitoneal lymphadenectomy for testicular cancer, may interfere with autonomic innervation of the prostate and seminal vesicles, resulting in absence of smooth muscle contraction and absence of seminal emission at time of orgasm. Pharmacologic agents, particularly α-adrenergic antagonists, may interfere with bladder neck closure at time of orgasm and result in retrograde ejaculation. Similarly, previous bladder neck or prostatic urethral surgery, most commonly transurethral resection of the prostate, may interfere with bladder neck closure, resulting in retrograde ejaculation. Finally, retrograde ejaculation may develop spontaneously in diabetic men.

Patients who complain of absence of ejaculation should be questioned regarding loss of libido or other symptoms of androgen deficiency, present medications, diabetes, and previous surgery. A careful history will usually determine the cause of this problem.

Absence of Orgasm. **Anorgasmia is usually psychogenic or caused by certain medications used to treat psychiatric diseases.** Sometimes, however, anorgasmia may be due to decreased penile sensation owing to impaired pudendal nerve function. Most commonly, this occurs in diabetics with peripheral neuropathy. Men who experience anorgasmia in association with decreased penile sensation should undergo vibratory testing of the penis and further neurologic evaluation as indicated.

Premature Ejaculation. Men who complain of premature ejaculation should be questioned carefully because this is obviously a subjective symptom. It is common for men to ejaculate within 2 minutes after initiation of intercourse, and many men who complain of premature ejaculation in actuality have normal sexual function with abnormal sexual expectations. However, there are men with true premature ejaculation who reach orgasm within less than 1 minute after initiation of intercourse. **This problem is almost always psychogenic** and best treated by a clinical psychologist or psychiatrist who specializes in treatment of this problem and other psychologic aspects of male sexual dysfunction. With counseling and appropriate modifications in sexual technique, this problem can usually be overcome. Alternatively, treatment with serotonin reuptake inhibitors such as sertraline

and fluoxetine has been demonstrated to be helpful in men with premature ejaculation (Murat Basar et al, 1999).

Hematospermia

Hematospermia refers to the presence of blood in the seminal fluid. **It almost always results from nonspecific inflammation of the prostate and/or seminal vesicles and resolves spontaneously, usually within several weeks.** It frequently occurs after a prolonged period of sexual abstinence, and we have observed it several times in men whose wives are in the final weeks of pregnancy. Patients with hematospermia that persists beyond several weeks should undergo further urologic evaluation, because, rarely, an underlying etiology will be identified. A genital and rectal examination should be done to exclude the presence of tuberculosis, a prostate-specific antigen (PSA) and a rectal examination done to exclude prostatic carcinoma, and a urinary cytology done to exclude the possibility of transitional cell carcinoma of the prostate. It should be emphasized, however, that hematospermia almost always resolves spontaneously and rarely is associated with any significant urologic pathology.

Pneumaturia

Pneumaturia is the passage of gas in the urine. In patients who have not recently had urinary tract instrumentation or a urethral catheter placed, this is almost always **due to a fistula between the intestine and the bladder. Common causes include diverticulitis, carcinoma of the sigmoid colon, and regional enteritis (Crohn disease).** In rare instances, patients with diabetes mellitus may have gas-forming infections, with carbon dioxide formation from the fermentation of high concentrations of sugar in the urine.

Urethral Discharge

Urethral discharge is the most common symptom of venereal infection. A purulent discharge that is thick, profuse, and yellow to gray is typical of gonococcal urethritis; the discharge in patients with nonspecific urethritis is usually scant and watery. A bloody discharge is suggestive of carcinoma of the urethra.

Fever and Chills

Fever and chills may occur with infection anywhere in the GU tract but are most commonly observed in patients with pyelonephritis, prostatitis, or epididymitis. **When associated with urinary obstruction, fever and chills may portend septicemia and necessitate emergency treatment to relieve obstruction.**

Medical History

The past medical history is extremely important because it frequently provides clues to the patient's current diagnosis. The past medical history should be obtained in an orderly and sequential manner.

Previous Medical Illnesses with Urologic Sequelae

There are obviously many diseases that may affect the GU system, and it is important to listen and record the patient's previous medical illnesses. **Patients with diabetes mellitus frequently develop autonomic dysfunction that may result in impaired urinary and sexual function.** A previous history of tuberculosis may be important in a patient presenting with impaired renal function, ureteral obstruction, or chronic, unexplained UTIs. Patients with hypertension have an increased risk of sexual dysfunction because they are more likely to have peripheral vascular disease and because many of the medications that are used to treat hypertension frequently cause impotence. Patients with neurologic diseases such as multiple sclerosis are also more likely to develop urinary and sexual dysfunction. In fact, 5% of patients with previously undiagnosed multiple sclerosis present with urinary symptoms as the first manifestation of the disease (Blaivas and Kaplan, 1988). As mentioned earlier, in men with bladder outlet obstruction, it is important to be aware of preexisting neurologic conditions. Surgical treatment of bladder outlet obstruction in the presence of detrusor hyperreflexia may result in increased urinary incontinence postoperatively. Finally, patients with sickle cell anemia are prone to a number of urologic conditions including papillary necrosis and erectile dysfunction secondary to recurrent priapism. There are obviously many other diseases with urologic sequelae, and it is important for the urologist to take a careful history in this regard.

Family History

It is similarly important to obtain a detailed family history because many diseases are genetic and/or familial. Examples of genetic diseases include adult polycystic kidney disease, tuberous sclerosis, von Hippel-Lindau disease, renal tubular acidosis, and cystinuria; these are but a few common and well-recognized examples.

In addition to these diseases of known genetic predisposition, there are other conditions in which the precise pattern of inheritance has not been elucidated but that clearly have a familial tendency. It is well known that individuals with a family history of urolithiasis are at increased risk for stone formation. More recently, it has been recognized that **8% to 10% of men with prostate cancer have a familial form of the disease that tends to develop about a decade earlier than the more common type of prostate cancer** (Bratt, 2000). Other familial conditions are mentioned elsewhere in the text, but suffice it to state again that obtaining a careful history of previous illnesses and a family history of urologic disease can be extremely valuable in establishing the correct diagnosis.

Medications

It is similarly important to obtain an accurate and complete list of present medications because many drugs interfere with urinary and sexual function. For example, **most of the antihypertensive medications interfere with erectile function, and changing antihypertensive medications can sometimes improve sexual function.** Similarly, many of the psychotropic agents interfere with emission and orgasm. In our own recent experience, we cared for a man who presented with anorgasmia. He had been to several physicians without improvement in this problem. When we obtained his past medical history, he mentioned that he had been taking a psychotropic agent for transient depression for several years, and his anorgasmia resolved when this no-longer-needed medication was discontinued. The list of medications affecting urinary and sexual function is exhaustive, but, once again, each medication should be recorded and its side effects investigated to be sure that the patient's problem is not drug related. A listing of common medications that may cause urologic side effects is presented in Table 3–2.

Previous Surgical Procedures

It is important to be aware of previous operations, particularly in a patient in whom surgery is intended. Obviously, previous operations may make subsequent ones more difficult. If the previous

Table 3–2.
Drugs Associated with Urologic Side Effects

UROLOGIC SIDE EFFECTS	CLASS OF DRUGS	SPECIFIC EXAMPLES
Decreased libido	Antihypertensives	Hydrochlorothiazide
		Propranolol
Erectile dysfunction	Psychotropic drugs	Benzodiazepines
Ejaculatory dysfunction	α-Adrenergic antagonists	Prazosin
		Tamsulosin
		α-Methyldopa
	Psychotropic drugs	Phenothiazines
		Antidepressants
Priapism	Antipsychotics	Phenothiazines
	Antidepressants	Trazodone
	Antihypertensives	Hydralazine
		Prazosin
Decreased spermatogenesis	Chemotherapeutic agents	Alkylating agents
	Drugs with abuse potential	Marijuana
		Alcohol
		Nicotine
	Drugs affecting endocrine function	Antiandrogens
		Prostaglandins
Incontinence or impaired voiding	Direct smooth muscle stimulants	Histamine
		Vasopressin
	Others	Furosemide
		Valproic acid
	Smooth muscle relaxants	Diazepam
	Striated muscle relaxants	Baclofen
Urinary retention or obstructive voiding symptoms	Anticholinergic agents or musculotropic relaxants	Oxybutynin
		Diazepam
		Flavoxate
	Calcium channel blockers	Nifedipine
	Antiparkinsonian drugs	Carbidopa
		Levodopa
	α-Adrenergic agonists	Pseudoephedrine
		Phenylephrine
	Antihistamines	Loratadine
		Diphenhydramine
Acute renal failure	Antimicrobials	Aminoglycosides
		Penicillins
		Cephalosporins
		Amphotericin
	Chemotherapeutic drugs	Cisplatin
	Others	Nonsteroidal anti-inflammatory drugs
		Phenytoin
Gynecomastia	Antihypertensives	Verapamil
	Cardiac drugs	Digoxin
	Gastrointestinal drugs	Cimetidine
		Metoclopramide
	Psychotropic drugs	Phenothiazines
	Tricyclic antidepressants	Amitriptyline
		Imipramine

surgery was in a similar anatomic region, it is worthwhile to try to obtain the previous operative report. In our own experience, this small additional effort has been rewarded on numerous occasions by providing a clear explanation of the patient's previous surgery that greatly simplified the subsequent operation. In general, **it is worthwhile obtaining as much information as possible *before* any intended surgery** because most surprises that occur in the operating room are unhappy ones.

Smoking and Alcohol Use

Cigarette smoking and consumption of alcohol are clearly linked to a number of urologic conditions. **Cigarette smoking is associated with an increased risk of urothelial carcinoma, most notably bladder cancer, and it is also associated with increased peripheral vascular disease and erectile dysfunction. Chronic alcoholism may result in autonomic and peripheral neuropathy with resultant impaired urinary and sexual function. Chronic alcoholism may also impair hepatic metabolism of estrogens, resulting in decreased serum testosterone, testicular atrophy, and decreased libido.**

In addition to the direct urologic effects of cigarette smoking and alcohol consumption, patients who are actively smoking or drinking at the time of surgery are at increased risk for perioperative complications. Smokers are at increased risk for both pulmonary and cardiac complications. If possible, they should **discontinue smoking at least 8 weeks before surgery to optimize their pulmonary function** (Warner et al, 1989). If they are unable to do this, they should at least quit smoking for 48 hours before surgery, because this will result in a significant improvement in cardiovascular function. Similarly, chronic alcoholics are at increased risk for hepatic toxicity and subsequent coagulation problems postoperatively. Furthermore, alcoholics who continue drinking up to the time of surgery may experience acute alcohol withdrawal during the postoperative period that can be life threatening. Prophylactic administration of lorazepam (Ativan) greatly reduces the potential risk of this significant complication.

Allergies

Finally, medicinal allergies should be questioned because, obviously, these medications should be avoided in future treatment of the patient. **All medicinal allergies should be marked boldly on the front of the patient's chart** to avoid potential complications from inadvertent exposure to the same medications.

In summary, a careful and thorough medical history including the chief complaint and history of present illness, past medical history, and family history should be obtained in every patient. Unfortunately, time constraints often make it difficult for the physician to spend the necessary time to obtain a full history. A reasonable substitute is to have a trained nurse or other health professional see the patient first. By using a standard history form, much of the information discussed previously can be obtained in a preliminary interview. It then remains for the urologist to only fill in the blanks, have the patient elaborate on potentially relevant aspects of the past medical history, and then perform a complete physical examination.

PHYSICAL EXAMINATION

A complete and thorough physical examination is an essential component of the evaluation of patients who present with urologic disease. Although it is tempting to become dependent on results of laboratory and radiologic tests, **the physical examination often simplifies the process and allows the urologist to select the most appropriate diagnostic studies.** Along with the history, the physical examination remains a key

Key Points

- The urologist can undertake the initial evaluation and establish a diagnosis for almost all patients with diseases of the GU system.
- A complete history and appropriate physical examination is critical in the assessment of urologic patients.
- A complete urinalysis including chemical and microscopic analyses should be performed because this may provide important information critical to the diagnosis and treatment of urologic patients.

component of the diagnostic evaluation and should be performed conscientiously.

General Observations

The visual inspection of the patient provides a general overview. The skin should be inspected for evidence of jaundice or pallor. The nutritional status of the patient should be noted. **Cachexia is a frequent sign of malignancy, and obesity may be a sign of underlying endocrinologic abnormalities.** In this instance, one should search for the presence of truncal obesity, a "buffalo hump," and abdominal skin striae, which are stigmata of hyperadrenocorticism. In contrast, debility and hyperpigmentation may be signs of hypoadrenocorticism. Gynecomastia may be a sign of endocrinologic disease and a possible indicator of alcoholism or previous hormonal therapy for prostate cancer. Edema of the genitalia and lower extremities may be associated with cardiac decompensation, renal failure, nephrotic syndrome, or pelvic and/or retroperitoneal lymphatic obstruction. Supraclavicular lymphadenopathy may be seen with any GU neoplasm, most commonly prostate and testis cancer; inguinal lymphadenopathy may occur secondary to carcinoma of the penis or urethra.

Kidneys

The kidneys are fist-sized organs located high in the retroperitoneum bilaterally. In the adult, the kidneys are normally difficult to palpate because of their position under the diaphragm and ribs with abundant musculature both anteriorly and posteriorly. Because of the position of the liver, the right kidney is somewhat lower than the left. **In children and thin women, it may be possible to palpate the lower pole of the right kidney with deep inspiration.** However, it is usually not possible to palpate either kidney in men, and the left kidney is almost always impalpable unless it is abnormally enlarged.

The best way to palpate the kidneys is with the patient in the supine position. **The kidney is lifted from behind with one hand in the costovertebral angle** (Fig. 3–1). On deep inspiration, the examiner's hand is advanced firmly into the anterior abdomen just below the costal margin. At the point of maximal inspiration, the kidney may be felt as it moves downward with the diaphragm. With each inspiration, the examiner's hand may be advanced deeper into the abdomen. Once again, it is more difficult to palpate kidneys in men because the kidneys tend to move downward less with inspiration and because they are surrounded with thicker muscular layers. In children, it is easier to palpate the kidneys because of decreased body thickness. In neonates, the kidneys can be felt quite easily by palpating the flank between the thumb anteriorly and the fingers over the costovertebral angle posteriorly.

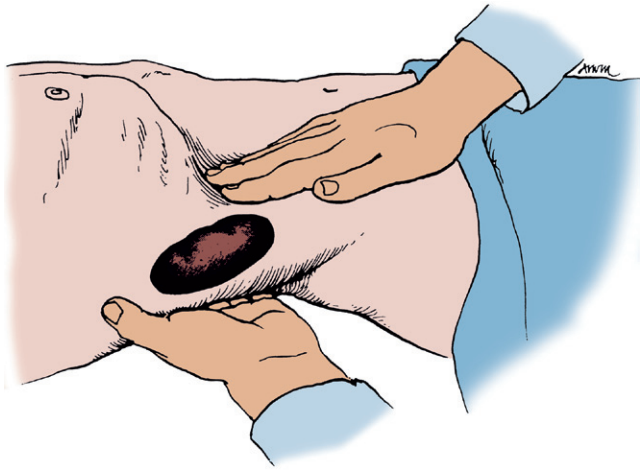

Figure 3–1. Bimanual examination of the kidney. (From Judge RD, Zuidema GD, Fitzgerald FT, editors. Clinical diagnosis. 5th ed. Boston: Little, Brown; 1989. p. 370.)

Transillumination of the kidneys may be helpful in children younger than 1 year of age with a palpable flank mass. Such masses are frequently of renal origin. A flashlight or fiberoptic light source is positioned posteriorly against the costovertebral angle. Fluid-filled masses such as cysts or hydronephrosis produce a dull reddish glow in the anterior abdomen. Solid masses such as tumors do not transilluminate. Other diagnostic maneuvers that may be helpful in examining the kidneys are percussion and auscultation. Although renal inflammation may cause pain that is poorly localized, percussion of the costovertebral angle posteriorly more often localizes the pain and tenderness more accurately. Percussion should be done gently because in a patient with significant renal inflammation, this may be quite painful. Auscultation of the upper abdomen during deep inspiration may occasionally reveal a systolic bruit associated with renal artery stenosis or an aneurysm. A bruit may also be detected in association with a large renal arteriovenous fistula.

Every patient with flank pain should also be examined for possible nerve root irritation. The ribs should be palpated carefully to rule out a bone spur or other skeletal abnormality and to determine the point of maximal tenderness. Unlike renal pain, radiculitis usually causes hyperesthesia of the overlying skin innervated by the irritated peripheral nerve. This hypersensitivity can be elicited with a pin or by pinching the skin and fat overlying the involved area. Finally, the pain experienced during the pre-eruptive phase of herpes zoster involving any of the segments between T11 and L2 may also simulate pain of renal origin.

Bladder

A normal bladder in the adult cannot be palpated or percussed until there is at least 150 mL of urine in it. At a volume of about 500 mL, the distended bladder becomes visible in thin patients as a lower midline abdominal mass.

Percussion is better than palpation for diagnosing a distended bladder. The examiner begins by percussing immediately above the symphysis pubis and continuing cephalad until there is a change in pitch from dull to resonant. Alternatively, it may be possible in thin patients and in children to palpate the

bladder by lifting the lumbar spine with one hand and pressing the other hand into the midline of the lower abdomen.

A careful bimanual examination, best done with the patient under anesthesia, is invaluable in assessing the regional extent of a bladder tumor or other pelvic mass. The bladder is palpated between the abdomen and the vagina in the female (Fig. 3–2) or the rectum in the male (Fig. 3–3). In addition to defining areas of induration, the bimanual examination allows the examiner to assess the mobility of the bladder; such information cannot be obtained by radiologic techniques such as CT and MRI, which convey static images.

Penis

If the patient has not been circumcised, the foreskin should be retracted to examine for tumor or balanoposthitis (inflammation of the prepuce and glans penis). **Most penile cancers occur in uncircumcised men and arise on the prepuce or glans penis.** Therefore in a patient with a bloody penile discharge in whom the foreskin cannot be withdrawn, a dorsal slit or circumcision must be performed to adequately evaluate the glans penis and urethra.

The position of the urethral meatus should be noted. It may be located proximal to the tip of the glans on the ventral surface (hypospadias) or, much less commonly, on the dorsal surface (epispadias). The penile skin should be examined for the presence of superficial vesicles compatible with herpes simplex and for ulcers that may indicate either venereal infection or tumor. The presence of venereal warts (condylomata acuminata), which appear as irregular, papillary, velvety lesions on the male genitalia, should also be noted.

The urethral meatus should be separated between the thumb and the forefinger to inspect for neoplastic or inflammatory lesions within the fossa navicularis. The dorsal shaft of the penis should be palpated for the presence of fibrotic plaques or ridges typical of Peyronie disease. Tenderness along the ventral aspect of the penis is suggestive of periurethritis, often secondary to a urethral stricture.

Scrotum and Contents

The scrotum is a loose sac containing the testes and spermatic cord structures. The scrotal wall is made up of skin and an underlying thin muscular layer. The testes are normally oval, firm, and smooth; in adults, they measure about 6 cm in length and 4 cm in width. They are suspended in the scrotum, with the right testis normally anterior to the left. The epididymis lies posterior to the testis and is palpable as a distinct ridge of tissue. The vas deferens can be palpated above each testis and feels like a piece of heavy twine.

The scrotum should be examined for dermatologic abnormalities. **Because the scrotum, unlike the penis, contains both hair and sweat glands, it is a frequent site of local infection and sebaceous cysts.** Hair follicles can become infected and may present as small pustules on the surface of the scrotum. These usually resolve spontaneously, but they can give rise to more significant infection, particularly in patients with reduced immunity and diabetes. Patients often become concerned about these lesions, mistaking them for testicular tumors.

The testes should be palpated gently between the fingertips of both hands. The testes normally have a firm, rubbery consistency with a smooth surface. Abnormally small testes suggest

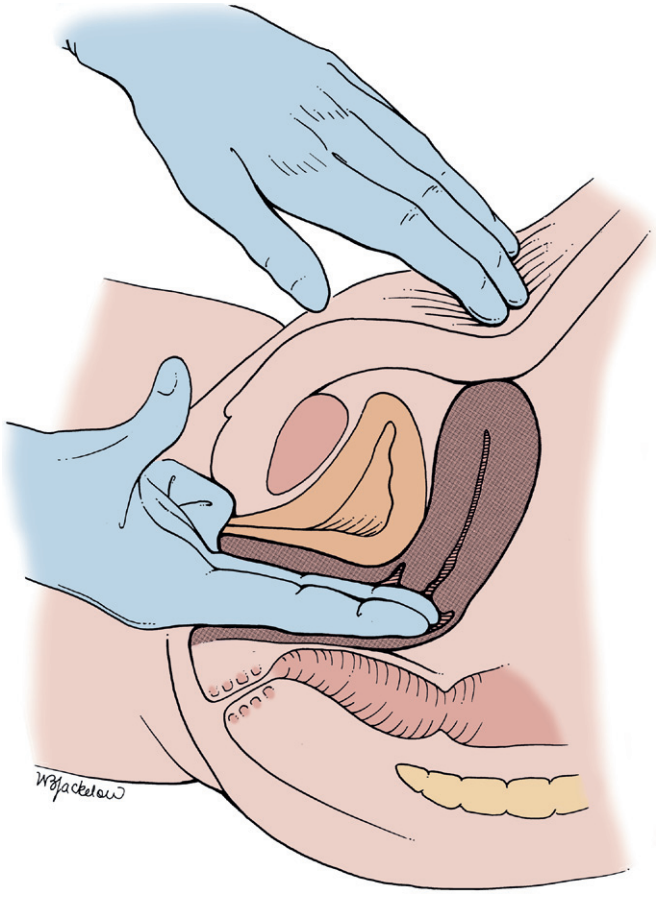

Figure 3–2. Bimanual examination of the bladder in the female. (From Swartz MH. Textbook of physical diagnosis. Philadelphia: WB Saunders; 1989. p. 405.)

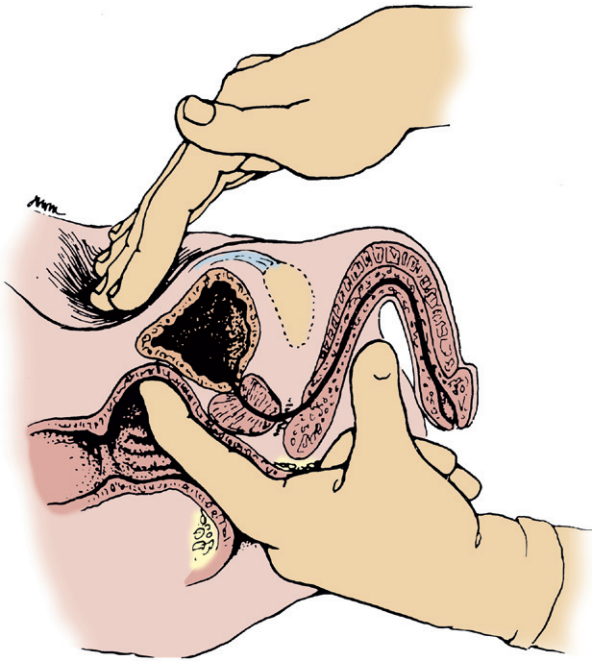

Figure 3–3. Bimanual examination of the bladder in the male. (From Judge RD, Zuidema GD, Fitzgerald FT, editors. Clinical diagnosis. 5th ed. Boston: Little, Brown; 1989. p. 376.)

hypogonadism or an endocrinopathy such as Klinefelter disease. **A firm or hard area within the testis should be considered a malignant tumor until proved otherwise.** The epididymis should be palpable as a ridge posterior to each testis. Masses in the epididymis (spermatocele, cyst, and epididymitis) are almost always benign.

To examine for a hernia, the physician's index finger should be inserted gently into the scrotum and invaginated into the external inguinal ring (Fig. 3–4). The scrotum should be invaginated in front of the testis, and care should be taken not to elevate the testis itself, which is quite painful. Once the external ring has been located, the physician should place the fingertips of his or her other hand over the internal inguinal ring and ask the patient to bear down (Valsalva maneuver). A hernia will be felt as a distinct bulge that descends against the tip of the index finger in the external inguinal ring as the patient bears down. Although it may be possible to distinguish a direct inguinal hernia arising through the floor of the inguinal canal from an indirect inguinal hernia prolapsing through the internal inguinal ring, this is seldom possible and of little clinical significance because the surgical approach is essentially identical for both conditions.

The spermatic cord is also examined with the patient in the standing position. A varicocele is a dilated, tortuous spermatic vein that becomes more obvious as the patient performs a Valsalva maneuver. The epididymis can again be palpated as a ridge of tissue running longitudinally, posterior to each testis. The testis should be palpated again between the fingers of both hands, once again taking care not to exert any pressure on the testis itself so as to avoid pain.

Transillumination is helpful in determining whether scrotal masses are solid (tumor) or cystic (hydrocele, spermatocele). A small flashlight or fiberoptic light cord is placed behind the mass. A cystic mass transilluminates easily, whereas light is not transmitted through a solid tumor.

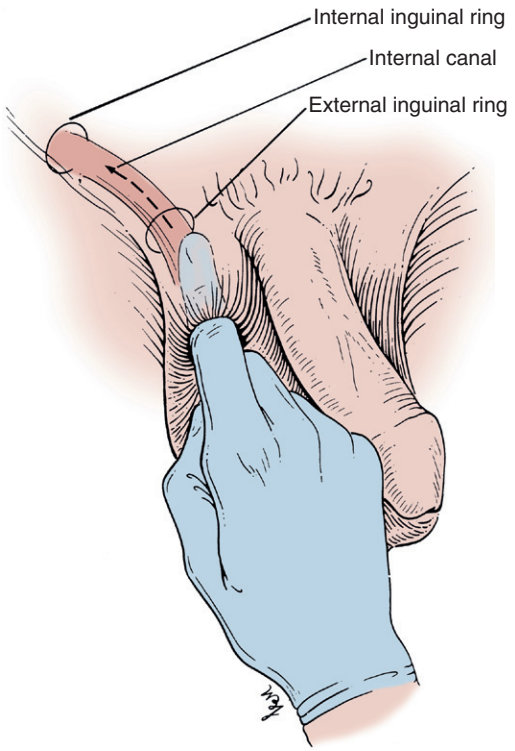

Figure 3–4. Examination of the inguinal canal. (From Swartz MH. Textbook of physical diagnosis. Philadelphia: WB Saunders; 1989. p. 376.)

Rectal and Prostate Examination in the Male

Digital rectal examination (DRE) should be performed in every male after age 40 years and in men of any age who present for urologic evaluation. Prostate cancer is the second most common cause of male cancer deaths after age 55 years and the most common cause of cancer deaths in men older than 70 years. Many prostate cancers can be detected in an early curable stage by DRE, and about 25% of colorectal cancers can be detected by DRE in combination with a stool guaiac test.

DRE should be performed at the end of the physical examination. It is done best with the patient standing and bent over the examining table or with the patient in the knee-chest position. In the standing position, the patient should stand with his thighs close to the examining table. The feet should be about 18 inches apart, with the knees flexed slightly. The patient should bend at the waist 90 degrees until his chest is resting on his forearms. The physician should give the patient adequate time to get in the proper position and relax as much as possible. A few reassuring words before the examination are helpful. The physician should place a glove on the examining hand and should lubricate the index finger thoroughly.

Before performing the DRE, the physician should place the palm of his other hand against the patient's lower abdomen. This provides subtle reassurance to the patient by allowing the physician to make gentle contact with the patient before touching the anus. It also allows the physician to steady the patient and provide gentle counterpressure if the patient tries to move away as the DRE is being performed. The DRE itself begins by separating the buttocks and inspecting the anus for pathology, usually hemorrhoids, but, occasionally, an anal carcinoma or melanoma may be detected. The gloved, lubricated index finger is then inserted gently into the anus. Only one phalanx should be inserted initially to give the anus time to relax and to easily accommodate the finger. Estimation of anal sphincter tone is of great importance; a flaccid or spastic anal sphincter suggests similar changes in the urinary sphincter and may be a clue to the diagnosis of neurogenic disease. If the physician waits only a few seconds, the anal sphincter will normally relax to the degree that the finger can be advanced to the knuckle without causing pain. The index finger then sweeps over the prostate; the entire posterior surface of the gland can usually be examined if the patient is in the proper position. **Normally, the prostate is about the size of a chestnut and has a consistency similar to that of the contracted thenar eminence of the thumb (with the thumb opposed to the little finger).**

The index finger is extended as far as possible into the rectum, and the entire circumference is examined to detect an early rectal carcinoma. The index finger is then withdrawn gently, and the stool on the glove is transferred to a guaiac-impregnated (Hemoccult) card for determination of occult blood. Although there may be a significant incidence of false-positive and false-negative results associated with fecal occult blood testing, particularly without dietary and drug restrictions, **the guaiac test is simple and inexpensive and may lead to the detection of significant gastrointestinal abnormalities** (Bond, 1999). Adequate tissues, soap, and towels should be available for the patient to cleanse himself after the examination. The physician should then

leave the room and allow the patient adequate time to wash and dress before concluding the consultation.

Pelvic Examination in the Female

Male urologists should always perform the female pelvic examination with a female nurse or other health care professional present. The patient should be allowed to undress in privacy and be fully draped for the procedure before the physician enters the room. The examination itself should be performed in standard lithotomy position with the patient's legs abducted. Initially, the external genitalia and introitus should be examined, with particular attention paid to atrophic changes, erosions, ulcers, discharge, or warts, all of which may cause dysuria and pelvic discomfort. The urethral meatus should be inspected for caruncles, mucosal hyperplasia, cysts, and mucosal prolapse. The patient is then asked to perform a Valsalva maneuver and is carefully examined for a cystocele (prolapse of the bladder) or rectocele (prolapse of the rectum). The patient is then asked to cough, which may precipitate stress urinary incontinence. Palpation of the urethra is done to detect induration, which may be a sign of chronic inflammation or malignancy. Palpation may also disclose a urethral diverticulum, and palpation of a diverticulum may cause a purulent discharge from the urethra. Bimanual examination of the bladder, uterus, and adnexa should then be performed with two fingers in the vagina and the other hand on the lower abdomen (see Fig. 3–3). Any abnormality of the pelvic organs should be evaluated further with a pelvic ultrasound or CT scan.

Neurologic Examination

There are various clinical situations in which the neurologic examination may be helpful in evaluating urologic patients. In some cases, the level of neurologic abnormalities can be localized by the pattern of sensory deficit noted during physical examination using a dermatome map (Fig. 3–5). Sensory deficits in the penis, labia, scrotum, vagina, and perianal area generally indicate damage or injury to sacral roots or nerves. In addition to sensory examination, testing of reflexes in the genital area may also be performed. The most important of these is the bulbocavernosus reflex (BCR), which is a reflex contraction of the striated muscle of the pelvic floor that occurs in response to various stimuli in the perineum or genitalia. This reflex is most commonly tested by placing a finger in the rectum and then squeezing the glans penis or clitoris. If a Foley catheter is in place, the BCR can also be elicited by gently pulling on the catheter. If the BCR is intact, tightening of the anal sphincter should be felt and/or observed. The BCR tests the integrity of the spinal cord mediated reflex arc involving S2-S4 and may be absent in the presence of sacral cord or peripheral nerve abnormalities.

The cremasteric reflex can be elicited by lightly stroking the superior and medial thigh in a downward direction. The normal response in males is contraction of the cremasteric muscle that results in immediate elevation of the ipsilateral scrotum and testis. There is limited clinical utility for testing superficial reflexes such as the cremasteric when investigating neurologic dysfunction. However, there may be a role for testing this reflex when assessing patients with suspected testicular torsion or epididymitis. Finally, an overly active cremasteric reflex in children can lead to the mistaken diagnosis of an undescended testis in some cases.

URINALYSIS

The urinalysis is a fundamental test that should be performed in all urologic patients. Although, in many instances a simple dipstick urinalysis will provide the necessary information, **a complete urinalysis includes both chemical and microscopic analyses.**

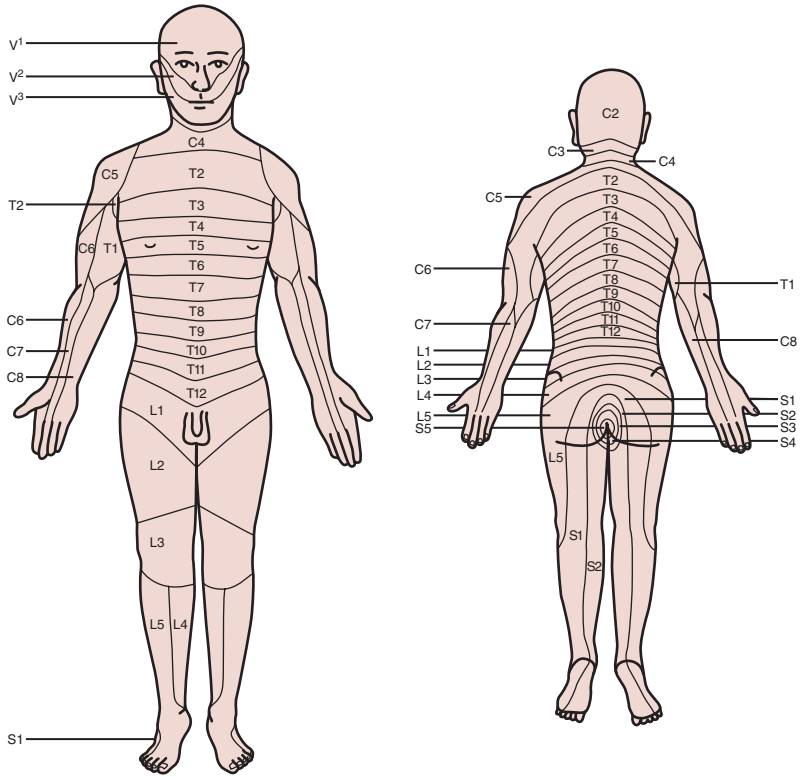

Figure 3–5. Sensory dermatome maps used to help localize the level of neurologic deficit.

Collection of Urinary Specimens

Males

In the male patient, a midstream urine sample is obtained. The uncircumcised male should retract the foreskin, cleanse the glans penis with antiseptic solution, and continue to retract the foreskin during voiding. The male patient begins urinating into the toilet and then places a wide-mouth sterile container under his penis to collect a midstream sample. This avoids contamination of the urine specimen with skin and urethral organisms.

In men with chronic UTIs, four aliquots of urine are obtained. **These aliquots have been designated Voided Bladder 1, Voided Bladder 2, Expressed Prostatic Secretions, and Voided Bladder 3 (VB1, VB2, EPS, and VB3).** The VB1 is the initial 5 to 10 mL of urine voided, whereas the VB2 is the midstream urine. The EPS is the secretions obtained after gentle prostatic massage, and the VB3 specimen is the initial 2 to 3 mL of urine obtained after prostatic massage. The value of these cultures for localization of UTIs is that the VB1 sample represents urethral flora; the VB2, bladder flora; and the EPS and VB3 samples, prostatic flora. The VB3 sample is particularly helpful when there is little or no prostatic fluid obtained by massage. To better obtain prostatic secretions, patients should be instructed to attempt to void during prostatic massage and to avoid tightening the anal sphincter and pelvic floor muscles. The four-part urine sample is particularly useful in evaluating men with suspected bacterial prostatitis (Meares and Stamey, 1968).

Females

In the female, it is more difficult to obtain a clean-catch midstream specimen. The female patient should cleanse the vulva, separate the labia, and collect a midstream specimen as described for the male patient. If infection is suspected, however, the midstream specimen is unreliable and should never be sent for culture and sensitivity. **To evaluate for a possible infection in a female, a catheterized urine sample should always be obtained.**

Neonates and Infants

The usual way to obtain a urine sample in a neonate or infant is to place a sterile plastic bag with an adhesive collar over the infant's genitalia. Obviously, however, these devices may not be able to distinguish contamination from true UTI. Whenever possible, **all urine samples should be examined within 1 hour of collection and plated for culture and sensitivity if indicated.** If urine is allowed to stand at room temperature for longer periods of time, bacterial overgrowth may occur, the pH may change, and red and white blood cell casts may disintegrate. If it is not possible to examine the urine promptly, it should be refrigerated at 5° C.

Physical Examination of Urine

The physical examination of the urine includes an evaluation of color, turbidity, specific gravity and osmolality, and pH.

Color

The normal pale yellow color of urine is due to the presence of the pigment urochrome. **Urine color varies most commonly because of concentration, but many foods, medications, metabolic products, and infection may produce abnormal urine color.** This is important because many patients will seek consultation primarily because of a change in their urine color. Thus it is important for the urologist to be aware of the common causes of abnormal urine color, and these are listed in Table 3–3.

Table 3–3.

Common Causes of Abnormal Urine Color

Colorless	Very dilute urine
	Overhydration
Cloudy/milky	Phosphaturia
	Pyuria
	Chyluria
Red	Hematuria
	Hemoglobinuria/myoglobinuria
	Anthocyanin in beets and blackberries
	Chronic lead and mercury poisoning
	Phenolphthalein (in bowel evacuants)
	Phenothiazines (e.g., Compazine)
	Rifampin
Orange	Dehydration
	Phenazopyridine (Pyridium)
	Sulfasalazine (Azulfidine)
Yellow	Normal
	Phenacetin
	Riboflavin
Green-blue	Biliverdin
	Indicanuria (tryptophan indole metabolites)
	Amitriptyline (Elavil)
	Indigo carmine
	Methylene blue
	Phenols (e.g., IV cimetidine [Tagamet], IV promethazine [Phenergan])
	Resorcinol
	Triamterene (Dyrenium)
Brown	Urobilinogen
	Porphyria
	Aloe, fava beans, and rhubarb
	Chloroquine and primaquine
	Furazolidone (Furoxone)
	Metronidazole (Flagyl)
	Nitrofurantoin (Furadantin)
Brown-black	Alcaptonuria (homogentisic acid)
	Hemorrhage
	Melanin
	Tyrosinosis (hydroxyphenylpyruvic acid)
	Cascara, senna (laxatives)
	Methocarbamol (Robaxin)
	Methyldopa (Aldomet)
	Sorbitol

From Hanno PM, Wein AJ. A clinical manual of urology. Norwalk (CT): Appleton-Century-Crofts; 1987. p. 67.

Turbidity

Freshly voided urine is clear. **Cloudy urine is most commonly due to phosphaturia,** a benign process in which excess phosphate crystals precipitate in an alkaline urine. Phosphaturia is intermittent and usually occurs after meals or ingestion of a large quantity of milk. Patients are otherwise asymptomatic. The diagnosis of phosphaturia can be accomplished either by acidifying the urine with acetic acid, which will result in immediate clearing, or by performing a microscopic analysis, which will reveal large amounts of amorphous phosphate crystals.

Pyuria, usually associated with a UTI, is another common cause of cloudy urine. The large numbers of white blood cells cause the urine to become turbid. **Pyuria is readily distinguished from**

phosphaturia either by smelling the urine (infected urine has a characteristic pungent odor) or by microscopic examination, which readily distinguishes amorphous phosphate crystals from leukocytes.

Rare causes of cloudy urine include chyluria (in which there is an abnormal communication between the lymphatic system and the urinary tract resulting in lymph fluid being mixed with urine), lipiduria, hyperoxaluria, and hyperuricosuria.

Specific Gravity and Osmolality

Specific gravity of urine is easily determined from a urinary dipstick and usually varies from 1.001 to 1.035. Specific gravity usually reflects the patient's state of hydration but may also be affected by abnormal renal function, the amount of material dissolved in the urine, and a variety of other causes mentioned later. A specific gravity less than 1.008 is regarded as dilute, and a specific gravity greater than 1.020 is considered concentrated. A fixed specific gravity of 1.010 is a sign of renal insufficiency, either acute or chronic.

In general, specific gravity reflects the state of hydration but also affords some idea of renal concentrating ability. Conditions that decrease specific gravity include (1) increased fluid intake, (2) diuretics, (3) decreased renal concentrating ability, and (4) diabetes insipidus. Conditions that increase specific gravity include (1) decreased fluid intake; (2) dehydration owing to fever, sweating, vomiting, and diarrhea; (3) diabetes mellitus (glucosuria); and (4) inappropriate secretion of antidiuretic hormone. Specific gravity will also be increased above 1.035 after intravenous injection of iodinated contrast and in patients taking dextran.

Osmolality is a measure of the amount of material dissolved in the urine and usually varies between 50 and 1200 mOsm/L. Urine osmolality most commonly varies with hydration, and the same factors that affect specific gravity will also affect osmolality. Urine osmolality is a better indicator of renal function, but it cannot be measured from a dipstick and must be determined using standard laboratory techniques.

pH

Urinary pH is measured with a dipstick test strip that incorporates two colorimetric indicators, methyl red and bromothymol blue, which yield clearly distinguishable colors over the pH range from 5 to 9. Urinary pH may vary from 4.5 to 8; the average pH varies between 5.5 and 6.5. A urinary pH between 4.5 and 5.5 is considered acidic, whereas a pH between 6.5 and 8 is considered alkaline.

In general, the urinary pH reflects the pH in the serum. In patients with metabolic or respiratory acidosis, the urine is usually acidic; conversely, in patients with metabolic or respiratory alkalosis, the urine is alkaline. Renal tubular acidosis (RTA) presents an exception to this rule. In patients with both type I and II RTA, the serum is acidemic, but the urine is alkalotic because of continued loss of bicarbonate in the urine. In severe metabolic acidosis in type II RTA, the urine may become acidic, but in type I RTA, the urine is always alkaline, even with severe metabolic acidosis (Morris and Ives, 1991). Urinary pH determination is used to establish the diagnosis of RTA; inability to acidify the urine below a pH of 5.5 after administration of an acid load is diagnostic of RTA.

Urine pH determinations are also useful in the diagnosis and treatment of UTIs and urinary calculus disease. **In patients with a presumed UTI, an alkaline urine with a pH greater than 7.5 suggests infection with a urea-splitting organism, most commonly *Proteus*.** Urease-producing bacteria convert ammonia to ammonium ions, markedly elevating the urinary pH and causing precipitation of calcium magnesium ammonium phosphate crystals. The massive amount of crystallization may result in staghorn calculi.

Urinary pH is usually acidic in patients with uric acid and cystine lithiasis. Alkalinization of the urine is an important feature of therapy in both of these conditions, and frequent monitoring of urinary pH is necessary to ascertain adequacy of therapy.

Chemical Examination of Urine

Urine Dipsticks

Urine dipsticks provide a quick and inexpensive method for detecting abnormal substances within the urine. Dipsticks are short, plastic strips with small marker pads that are impregnated with different chemical reagents that react with abnormal substances in the urine to produce a colorimetric change. **The abnormal substances commonly tested for with a dipstick include (1) blood, (2) protein, (3) glucose, (4) ketones, (5) urobilinogen and bilirubin, and (6) white blood cells.**

Substances listed in Table 3–3 that produce an abnormal urine color may interfere with appropriate color development on the dipstick. In our experience, this most commonly occurs in patients taking phenazopyridine (Pyridium) for a UTI. Phenazopyridine turns the urine bright orange and makes dipstick evaluation of the urine unreliable.

Appropriate technique must be used to obtain an accurate dipstick determination. The reagent areas on the dipstick must be completely immersed in a fresh uncentrifuged urine specimen and then must be withdrawn immediately to prevent dissolution of the reagents into the urine. As the dipstick is removed from the urine specimen container, the edge of the dipstick is drawn along the rim of the container to remove excess urine. The dipstick should be held horizontally until the appropriate time for reading and then compared with the color chart. **Excess urine on the dipstick or holding the dipstick in a vertical position will allow mixing of chemicals from adjacent reagent pads on the dipstick, resulting in a faulty diagnosis.** False-negative results for glucose and bilirubin may be seen in the presence of elevated ascorbic acid concentrations in the urine. However, increased levels of ascorbic acid in the urine do not interfere with dipstick testing for hematuria. Highly buffered alkaline urine may cause falsely low readings for specific gravity and may lead to false-negative results for urinary protein. Other common causes of false results with dipstick testing are outdated test strips and exposure of the sticks, leading to damage to the reagents. In general, when the sticks are damaged, there will be color changes on the pads before their immersion in urine. If such color changes are noted, results with the dipstick may be inaccurate.

Hematuria

Normal urine should contain fewer than three red blood cells per HPF. A positive dipstick for blood in the urine indicates either hematuria, hemoglobinuria, or myoglobinuria. **The chemical detection of blood in the urine is based on the peroxidase-like activity of hemoglobin.** When in contact with an organic peroxidase substrate, hemoglobin catalyzes the reaction and causes subsequent oxidation of a chromogen indicator, which

changes color according to the degree and amount of oxidation. The degree of color change is directly related to the amount of hemoglobin present in the urine specimen. Dipsticks frequently demonstrate both colored dots and field color change. If present, free hemoglobin and myoglobin in the urine are absorbed into the reagent pad and catalyze the reaction within the test paper, thereby producing a field change effect in color. Intact erythrocytes in the urine undergo hemolysis when they come in contact with the reagent test pad, and the localized free hemoglobin on the pad produces a corresponding dot of color change. Obviously, the greater the number of intact erythrocytes in the urine specimen, the greater the number of dots that will appear on the test paper, and a coalescence of the dots occurs when there are more than 250 erythrocytes/mL.

Hematuria can be distinguished from hemoglobinuria and myoglobinuria by microscopic examination of the centrifuged urine; the presence of a large number of erythrocytes establishes the diagnosis of hematuria. If erythrocytes are absent, examination of the serum will distinguish hemoglobinuria and myoglobinuria. A sample of blood is obtained and centrifuged. In hemoglobinuria, the supernatant will be pink. This is because free hemoglobin in the serum binds to haptoglobin, which is water insoluble and has a high molecular weight. This complex remains in the serum, causing a pink color. Free hemoglobin will appear in the urine only when all of the haptoglobin-binding sites have been saturated. In myoglobinuria, the myoglobin released from muscle is of low molecular weight and water soluble. It does not bind to haptoglobin and is therefore excreted immediately into the urine. Therefore in myoglobinuria the serum remains clear.

The sensitivity of urinary dipsticks in identifying hematuria, defined as greater than three erythrocytes/HPF of centrifuged sediment examined microscopically, is higher than 90%. Conversely, the specificity of the dipstick for hematuria compared with microscopy is somewhat lower, reflecting a higher false-positive rate with the dipstick (Shaw et al, 1985).

False-positive dipstick readings are most often due to contamination of the urine specimen with menstrual blood. Dehydration with resultant urine of high specific gravity can also yield false-positive results owing to the increased concentration of erythrocytes and hemoglobin. The normal individual excretes about 1000 erythrocytes/mL of urine, with the upper limits of normal varying from 5000 to 8000 erythrocytes/mL (Kincaid-Smith, 1982). Therefore examining urine of high specific gravity such as the first morning voided specimen increases the likelihood of a false-positive result. In addition to dehydration, another cause of false-positive results is exercise, which can increase the number of erythrocytes in the urine.

The efficacy of hematuria screening using the dipstick to identify patients with significant urologic disease is somewhat controversial. Studies in children and young adults have shown a low rate of significant disease (Woolhandler et al, 1989). In older adults, one study from the Mayo Clinic of 2000 patients with asymptomatic hematuria showed that only 0.5% had a urologic malignancy and only 1.8% developed other serious urologic diseases within 3 years after identification of the hematuria (Mohr et al, 1986). Conversely, investigators at the University of Wisconsin found that 26% of adults who had at least one positive dipstick reading for hematuria were subsequently found to have significant urologic pathology (Messing et al, 1987). Obviously, the age of the population, the completeness of the subsequent urologic evaluation, and the definition of significant disease all influence the disease rate in the group of patients with asymptomatic hematuria identified by dipstick screening. It is important to remember that, before proceeding to more complicated studies, the dipstick result should be confirmed with a microscopic examination of the centrifuged urinary sediment.

Differential Diagnosis and Evaluation of Hematuria. Hematuria may reflect either significant nephrologic or urologic disease. **Hematuria of nephrologic origin is frequently associated with casts in the urine and almost always associated with significant proteinuria. Even significant hematuria of urologic origin will not elevate the protein concentration in the urine into the 100 to 300 mg/dL or 2+ to 3+ range on dipstick,** and proteinuria of this magnitude almost always indicates glomerular or tubulointerstitial renal disease.

Morphologic evaluation of erythrocytes in the centrifuged urinary sediment also helps localize their site of origin. **Erythrocytes arising from glomerular disease are typically dysmorphic and show a wide range of morphologic alterations. Conversely, erythrocytes arising from tubulointerstitial renal disease and of urologic origin have a uniformly round shape;** these erythrocytes may or may not retain their hemoglobin ("ghost cells"), but the individual cell shape is consistently round. In individuals without significant pathology with minimal amounts of hematuria, the erythrocytes are characteristically dysmorphic but the number of cells observed is far fewer than that observed in patients with nephrologic disease. Erythrocyte morphology is more easily determined using phase contrast microscopy, but with practice this can be accomplished using a conventional light microscope (Schramek et al, 1989).

Glomerular Hematuria. Glomerular hematuria is suggested by the presence of dysmorphic erythrocytes, red blood cell casts, and proteinuria. Of those patients with glomerulonephritis proven by renal biopsy, however, about 20% will have hematuria alone without red blood cell casts or proteinuria (Fassett et al, 1982).

The glomerular disorders associated with hematuria are listed in Table 3–4. Further evaluation of patients with glomerular hematuria should begin with a thorough history. Hematuria in children and young adults, usually males, associated with low-grade fever and an erythematous rash suggests a diagnosis of immunoglobulin A (IgA) nephropathy (Berger disease). A family history of renal

disease and deafness suggests familial nephritis or Alport syndrome. Hemoptysis and abnormal bleeding associated with microcytic anemia are characteristic of Goodpasture syndrome, and the presence of a rash and arthritis suggest systemic lupus erythematosus. Finally, poststreptococcal glomerulonephritis should be suspected in a child with a recent streptococcal upper respiratory tract or skin infection.

Further laboratory evaluation should include measurement of serum creatinine, creatinine clearance, and, when proteinuria in the urine is 2+ or greater, a 24-hour urine protein determination. Although these tests will quantitate the specific degree of renal dysfunction, further tests are usually required to establish the specific diagnosis and particularly to determine whether the disease is due to an immune or a nonimmune etiology. **Frequently, a renal biopsy is necessary to establish the precise diagnosis, and biopsies are particularly important if the result will influence subsequent treatment of the patient.** Renal biopsies are extremely informative when examined by an experienced pathologist using light, immunofluorescent, and electron microscopy.

An algorithm for the evaluation of glomerular hematuria is provided in Figure 3–6.

IgA Nephropathy (Berger Disease). IgA nephropathy, or Berger disease, is the most common cause of glomerular hematuria, accounting for about 30% of cases (Fassett et al, 1982). Therefore it is described in greater detail in this section. IgA nephropathy occurs most commonly in children and young adults, with a male predominance (Berger and Hinglais, 1968). Patients typically present with hematuria after an upper respiratory tract infection or exercise. Hematuria may be associated with a low-grade fever or rash, but most patients have no associated systemic symptoms. Gross hematuria occurs intermittently, but microscopic hematuria is a constant finding in some patients. The disease is chronic, but the prognosis in most patients is excellent. Renal function remains normal in the majority, but about 25% will subsequently develop renal insufficiency. An older age at onset, initial abnormal renal function, consistent proteinuria, and hypertension are indicators of a poor prognosis (D'Amico, 1988).

The pathologic findings in Berger disease are limited to either focal glomeruli or lobular segments of a glomerulus. The changes are proliferative and usually confined to mesangial cells (Berger and Hinglais, 1968). Renal biopsy reveals deposits of IgA, IgG, and β_{1c}-globulin, although IgA and IgG mesangial deposits are found in other forms of glomerulonephritis as well. The role of IgA in the disease remains uncertain, although the deposits may trigger an inflammatory reaction within the glomerulus (van den Wall Bake et al, 1989). Because gross hematuria frequently follows an upper respiratory tract infection, a viral etiology has been suspected but not established. The frequent association between hematuria and exercise in this condition remains unexplained.

The clinical presentation of IgA glomerulonephritis is alarming and similar to certain systemic diseases including Schönlein-Henoch purpura, systemic lupus erythematosus, bacterial endocarditis, and Goodpasture syndrome. Therefore a careful clinical and laboratory evaluation is indicated to establish the correct diagnosis. The presence of red blood cell casts establishes the glomerular origin of the hematuria. In the absence of casts, a urologic evaluation is indicated to exclude the urinary tract as a source of bleeding and to confirm that the hematuria is arising from both kidneys. The diagnosis of IgA nephropathy is confirmed by renal biopsy demonstrating the classic deposits of immunoglobulins in mesangial cells, as described previously. Once the diagnosis has been established, repeat evaluations for hematuria are generally not indicated. Although there is no effective treatment for this condition, renal function remains stable in most patients and there are no other known long-term complications.

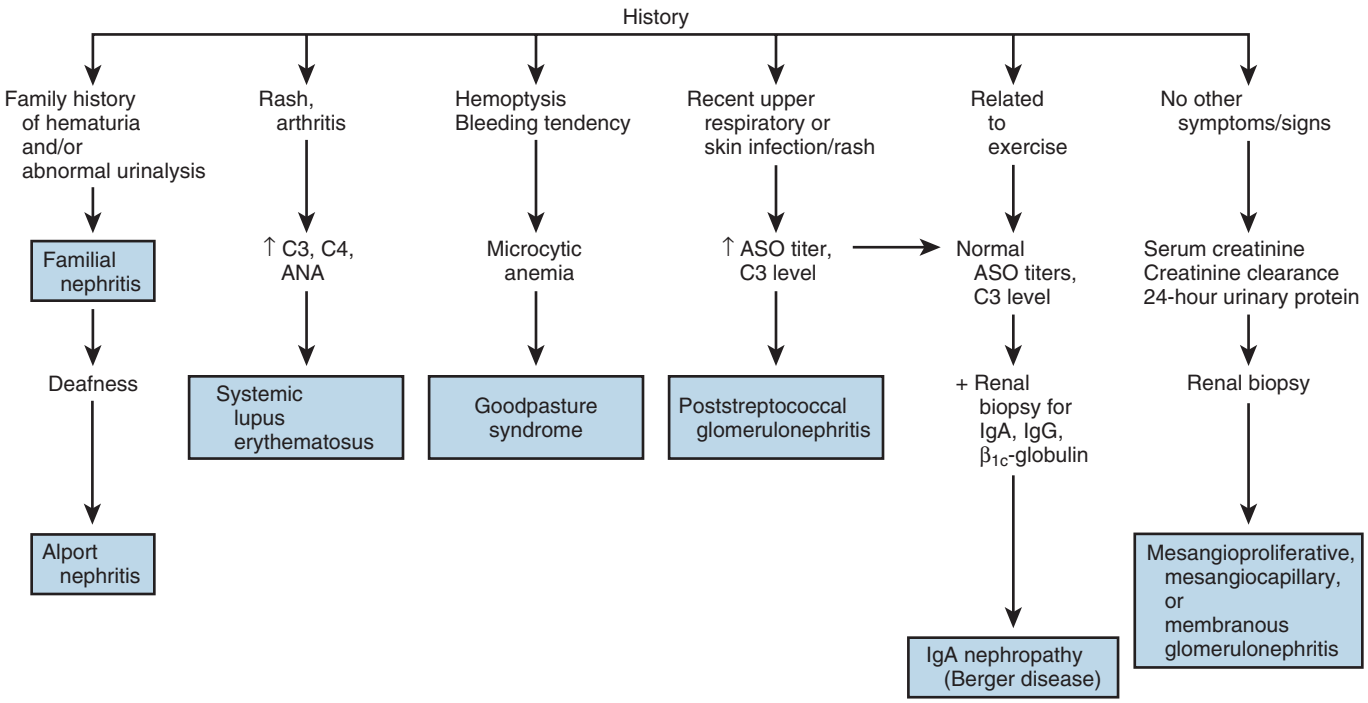

Figure 3–6. Evaluation of glomerular hematuria (dysmorphic erythrocytes, erythrocyte casts, and proteinuria). ANA, antinuclear antibody; ASO, antistreptolysin O; Ig, immunoglobulin.

Nonglomerular Hematuria

Medical. Except for renal tumors, nonglomerular hematuria of renal origin is secondary to either tubulointerstitial, renovascular, or systemic disorders. **The urinalysis in nonglomerular hematuria is distinguished from that of glomerular hematuria by the presence of circular erythrocytes and the absence of erythrocyte casts.** Like glomerular hematuria, nonglomerular hematuria of renal origin is frequently associated with significant proteinuria, which distinguishes these nephrologic diseases from urologic diseases in which the degree of proteinuria is usually minimal, even with heavy bleeding.

As with glomerular hematuria, a careful history frequently helps establish the diagnosis. A family history of hematuria or bleeding tendency suggests the diagnosis of a blood dyscrasia, which should be investigated further. A family history of urolithiasis associated with intermittent hematuria may indicate stone disease, which should be investigated with serum and urine measurements of calcium and uric acid. A family history of renal cystic disease should prompt further radiologic evaluation for medullary sponge kidney and adult polycystic kidney disease. **Papillary necrosis as a cause of hematuria should be considered in diabetics, African Americans (secondary to sickle cell disease or trait), and suspected analgesic abusers.**

Medications may induce hematuria, particularly anticoagulants. **Anticoagulation at normal therapeutic levels, however, does not predispose patients to hematuria.** In one study, the prevalence of hematuria was 3.2% in anticoagulated patients versus 4.8% in a control group. Urologic disease was identified in 81% of patients with more than one episode of microscopic hematuria, and the cause of hematuria did not vary between groups (Culclasure et al, 1994). Thus anticoagulant therapy per se does not appear to increase the risk of hematuria unless the patient is excessively anticoagulated.

Exercise-induced hematuria is being observed with increasing frequency. It typically occurs in long-distance runners (>10 km), is usually noted at the conclusion of the run, and rapidly disappears with rest. The hematuria may be of renal or bladder origin. An increased number of dysmorphic erythrocytes have been noted in some patients, suggesting a glomerular origin. Exercise-induced hematuria may be the first sign of underlying glomerular disease such as IgA nephropathy. Conversely, cystoscopy in patients with exercise-induced hematuria frequently reveals punctate hemorrhagic lesions in the bladder, suggesting that the hematuria is of bladder origin.

Vascular disease may also result in nonglomerular hematuria. Renal artery embolism and thrombosis, arteriovenous fistulas, and renal vein thrombosis may all result in hematuria. Physical examination may reveal severe hypertension, a flank or abdominal bruit, or atrial fibrillation. In such patients, further evaluation for renal vascular disease should be undertaken.

An algorithm for the evaluation of nonglomerular hematuria is provided in Figure 3–7.

Surgical. Nonglomerular hematuria or essential hematuria includes primarily urologic rather than nephrologic diseases. Common causes of essential hematuria include urologic tumors, stones, and UTIs.

The urinalysis in both nonglomerular medical and surgical hematuria is similar in that both are characterized by circular erythrocytes and the absence of erythrocyte casts. Essential hematuria is suggested, however, by the absence of significant proteinuria usually found in nonglomerular hematuria of renal parenchymal origin. It should be remembered, however, that proteinuria is not always present in glomerular or nonglomerular renal disease.

The American Urological Association (AUA) Best Practice Policy Panel on Microscopic Hematuria has formulated practice recommendations for the detection and evaluation of asymptomatic microscopic hematuria (Grossfeld et al, 2001a, 2001b). The panel concluded that, due to the lack of specificity of urinary dipstick examination, as well as the risk and expense of evaluation, patients with a positive dipstick test should only undergo complete evaluation for hematuria if this is confirmed by the finding of 3 or more RBC/HPF on subsequent microscopic evaluation. The mainstays of evaluation, according to the panel, are voided urinary cytology, cystoscopy, and urinary tract imaging using ultrasonography, CT, and/or intravenous urography (IVU). The use of these tests in an individual patient should be based in most cases on the relative risk of significant urinary tract pathology.

An algorithm for the evaluation of essential hematuria is provided in Figure 3–8.

Proteinuria

Although healthy adults excrete 80 to 150 mg of protein in the urine daily, the qualitative detection of proteinuria in the urinalysis should raise the suspicion of underlying renal disease. **Proteinuria may be the first indication of renovascular, glomerular, or tubulointerstitial renal disease, or it may represent the overflow of abnormal proteins into the urine in conditions such as multiple myeloma.** Proteinuria can also occur secondary to nonrenal disorders and in response to various physiologic conditions such as strenuous exercise.

The protein concentration in the urine obviously depends on the state of hydration, but it seldom exceeds 20 mg/dL. In patients with dilute urine, however, significant proteinuria may be present at concentrations less than 20 mg/dL. **Normally, urine protein is about 30% albumin, 30% serum globulins, and 40% tissue proteins, of which the major component is Tamm-Horsfall protein.** This profile may be altered by conditions that affect glomerular filtration, tubular reabsorption, or excretion of urine protein, and determination of the urine protein profile by such techniques as protein electrophoresis may help determine the etiology of proteinuria.

Pathophysiology. **Most causes of proteinuria can be categorized into one of three categories: glomerular, tubular, or overflow. Glomerular proteinuria is the most common type of proteinuria and results from increased glomerular capillary permeability to protein, especially albumin.** Glomerular proteinuria occurs in any of the primary glomerular diseases such as IgA nephropathy or in glomerulopathy associated with systemic illness such as diabetes mellitus. Glomerular disease should be suspected when the 24-hour urine protein excretion exceeds 1 g and is almost certain to exist when the total protein excretion exceeds 3 g.

Tubular proteinuria results from failure to reabsorb normally filtered proteins of low molecular weight such as immunoglobulins. In tubular proteinuria, the 24-hour urine protein loss seldom exceeds 2 to 3 g and the excreted proteins are of low molecular weight rather than albumin. Disorders that lead to tubular proteinuria are commonly associated with other defects of proximal tubular function such as glucosuria, aminoaciduria, phosphaturia, and uricosuria (Fanconi syndrome).

Overflow proteinuria occurs in the absence of any underlying renal disease and is due to an increased plasma concentration of abnormal immunoglobulins

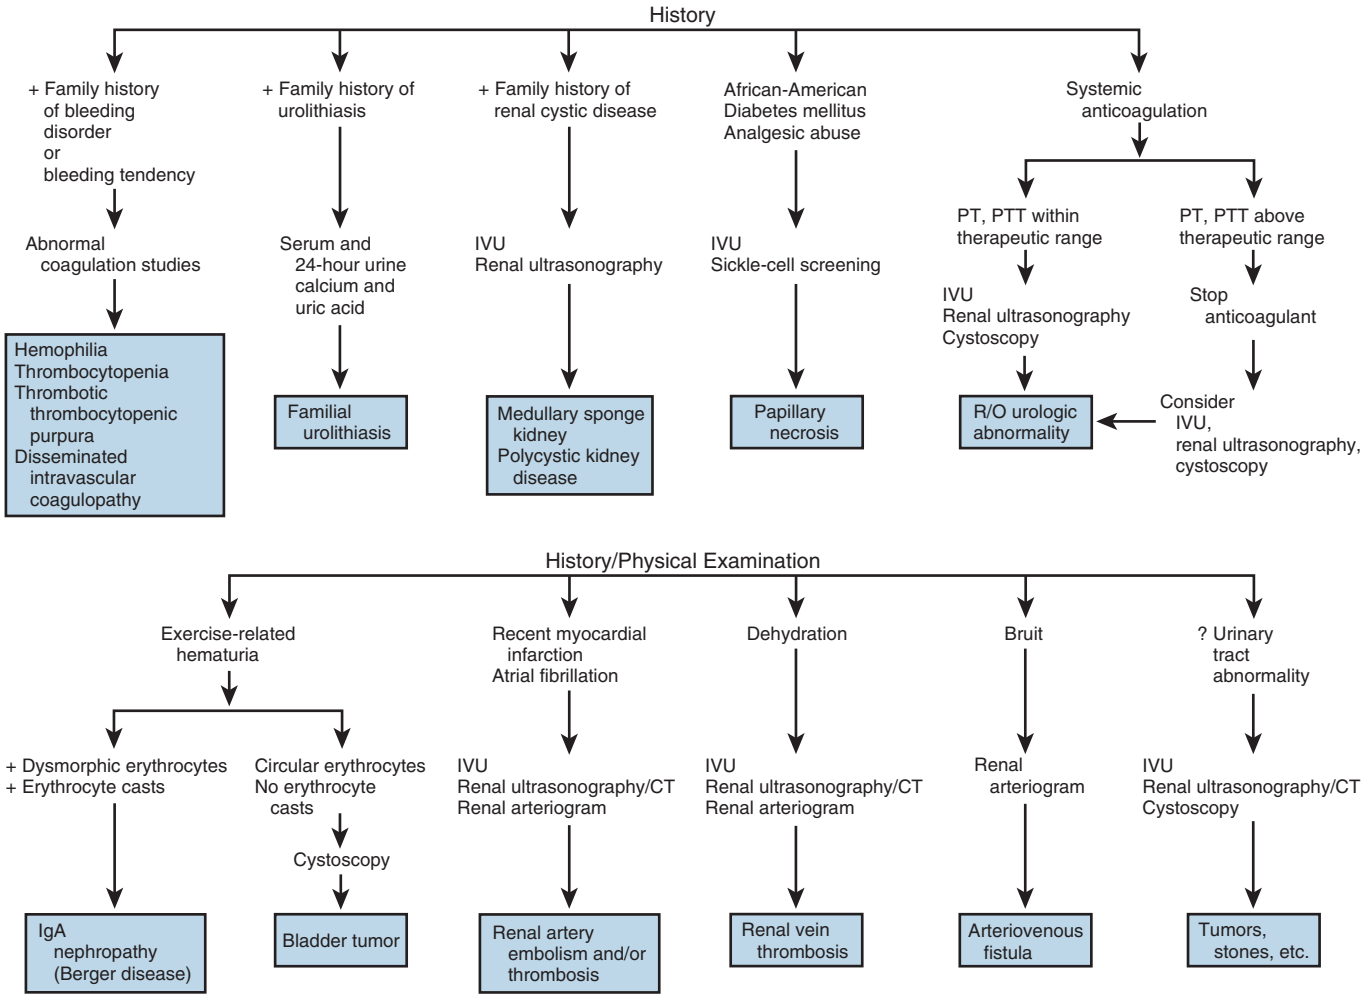

Figure 3–7. Evaluation of nonglomerular renal hematuria (circular erythrocytes, no erythrocyte casts, and proteinuria). CT, computed tomography; IgA, immunoglobulin A; IVU, intravenous urography; PT, prothrombin time; PTT, partial thromboplastin time; R/O, rule out.

and other low-molecular-weight proteins. The increased serum levels of abnormal proteins result in excess glomerular filtration that exceeds tubular reabsorptive capacity. The most common cause of overflow proteinuria is multiple myeloma, in which large amounts of immunoglobulin light chains are produced and appear in the urine (Bence Jones protein).

Detection. Qualitative detection of abnormal proteinuria is most easily accomplished with a dipstick impregnated with tetrabromophenol blue dye. The color of the dye changes in response to a pH shift related to the protein content of the urine, mainly albumin, leading to the development of a blue color. Because the background of the dipstick is yellow, various shades of green will develop, and the darker the green, the greater the concentration of protein in the urine. The minimal detectable protein concentration by this method is 20 to 30 mg/dL. **False-negative results can occur in alkaline urine, dilute urine, or when the primary protein present is not albumin.** Nephrotic range proteinuria in excess of 1 g/24 hr, however, is seldom missed on qualitative screening. Precipitation of urinary proteins with strong acids such as 3% sulfosalicylic acid will detect proteinuria at concentrations as low as 15 mg/dL and is more sensitive at detecting other proteins and albumin. Patients whose urine is negative on dipstick but strongly positive with sulfosalicylic acid should be suspected of having multiple myeloma, and the urine should be tested further for Bence Jones protein.

If qualitative testing reveals proteinuria, this should be quantitated with a 24-hour urinary collection. Further qualitative assessment of abnormal urinary proteins can be accomplished by either protein electrophoresis or immunoassay for specific proteins. **Protein electrophoresis is particularly helpful in distinguishing glomerular from tubular proteinuria. In glomerular proteinuria, albumin makes up about 70% of the total protein excreted, whereas in tubular proteinuria, the major proteins excreted are immunoglobulins with albumin making up only 10% to 20%. Immunoassay is the method of choice for detecting specific proteins such as Bence Jones protein in multiple myeloma.**

Evaluation. Proteinuria should first be classified by its timing into transient, intermittent, or persistent. Transient proteinuria occurs commonly, especially in the pediatric population, and usually resolves spontaneously within a few days (Wagner et al, 1968). It may result from fever, exercise, or emotional stress. In older patients, transient proteinuria may be due to congestive heart failure. If a nonrenal cause is identified and a subsequent urinalysis is negative, no further evaluation is necessary. Obviously, if proteinuria persists, it should be evaluated further.

Proteinuria may also occur intermittently, and this is frequently related to postural change (Robinson, 1985). Proteinuria that occurs only in the upright position is a frequent

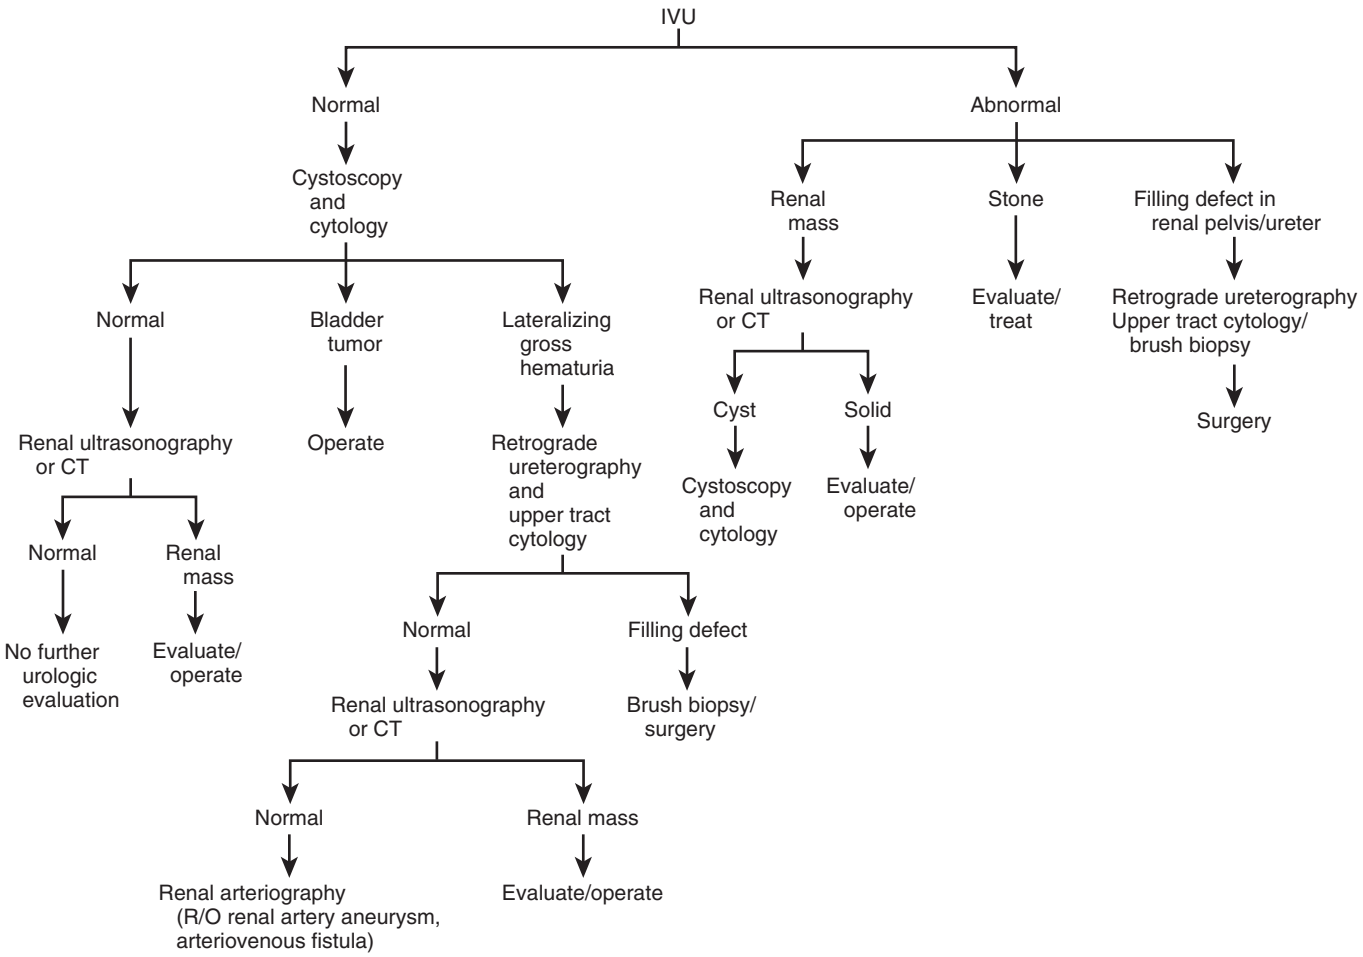

Figure 3–8. Evaluation of essential hematuria (circular erythrocytes, no erythrocyte casts, no significant proteinuria). CT, computed tomography; IVU, intravenous urography; R/O, rule out.

cause of mild, intermittent proteinuria in young males. Total daily protein excretion seldom exceeds 1 g, and urinary protein excretion returns to normal when the patient is recumbent. Orthostatic proteinuria is thought to be secondary to increased pressure on the renal vein while standing. It resolves spontaneously in about 50% of patients and is not associated with any morbidity. Therefore if renal function is normal in patients with orthostatic proteinuria, no further evaluation is indicated.

Persistent proteinuria requires further evaluation, and most cases have a glomerular etiology. A quantitative measurement of urinary protein should be obtained through a 24-hour urine collection, and a qualitative evaluation should be obtained to determine the major proteins excreted. The findings of greater than 2 g of protein excreted per 24 hours, of which the major components are high-molecular-weight proteins such as albumin, establish the diagnosis of glomerular proteinuria. Glomerular proteinuria is the most common cause of abnormal proteinuria, especially in patients presenting with persistent proteinuria. If glomerular proteinuria is associated with hematuria characterized by dysmorphic erythrocytes and erythrocyte casts, the patient should be evaluated as outlined previously for glomerular hematuria (see Fig. 3–6). Patients with glomerular proteinuria who have no or little associated hematuria should be evaluated for other conditions, of which the most common is diabetes mellitus. Other possibilities include amyloidosis and arteriolar nephrosclerosis.

In patients in whom total protein excretion is 300 to 2000 mg/day, of which the major components are low-molecular-weight globulins, further qualitative evaluation with immunoelectrophoresis is indicated. This will determine whether the excess proteins are normal or abnormal. Identification of normal proteins establishes a diagnosis of tubular proteinuria, and further evaluation for a specific cause of tubular dysfunction is indicated.

If qualitative evaluation reveals abnormal proteins in the urine, this establishes a diagnosis of overflow proteinuria. Further evaluation should be directed to identify the specific protein abnormality. The finding of large quantities of light-chain immunoglobulins or Bence Jones protein establishes a diagnosis of multiple myeloma. Similarly, the finding of large amounts of hemoglobin or myoglobin establishes the diagnosis of hemoglobinuria or myoglobinuria.

An algorithm for the evaluation of proteinuria is provided in Figure 3–9.

Glucose and Ketones

Urine testing for glucose and ketones is useful in screening patients for diabetes mellitus. Normally, almost all the glucose filtered by the glomeruli is reabsorbed in the proximal tubules. Although small amounts of glucose may normally be excreted in the urine, these amounts are not clinically significant and are below the level of detectability with the dipstick. If, however, the amount of

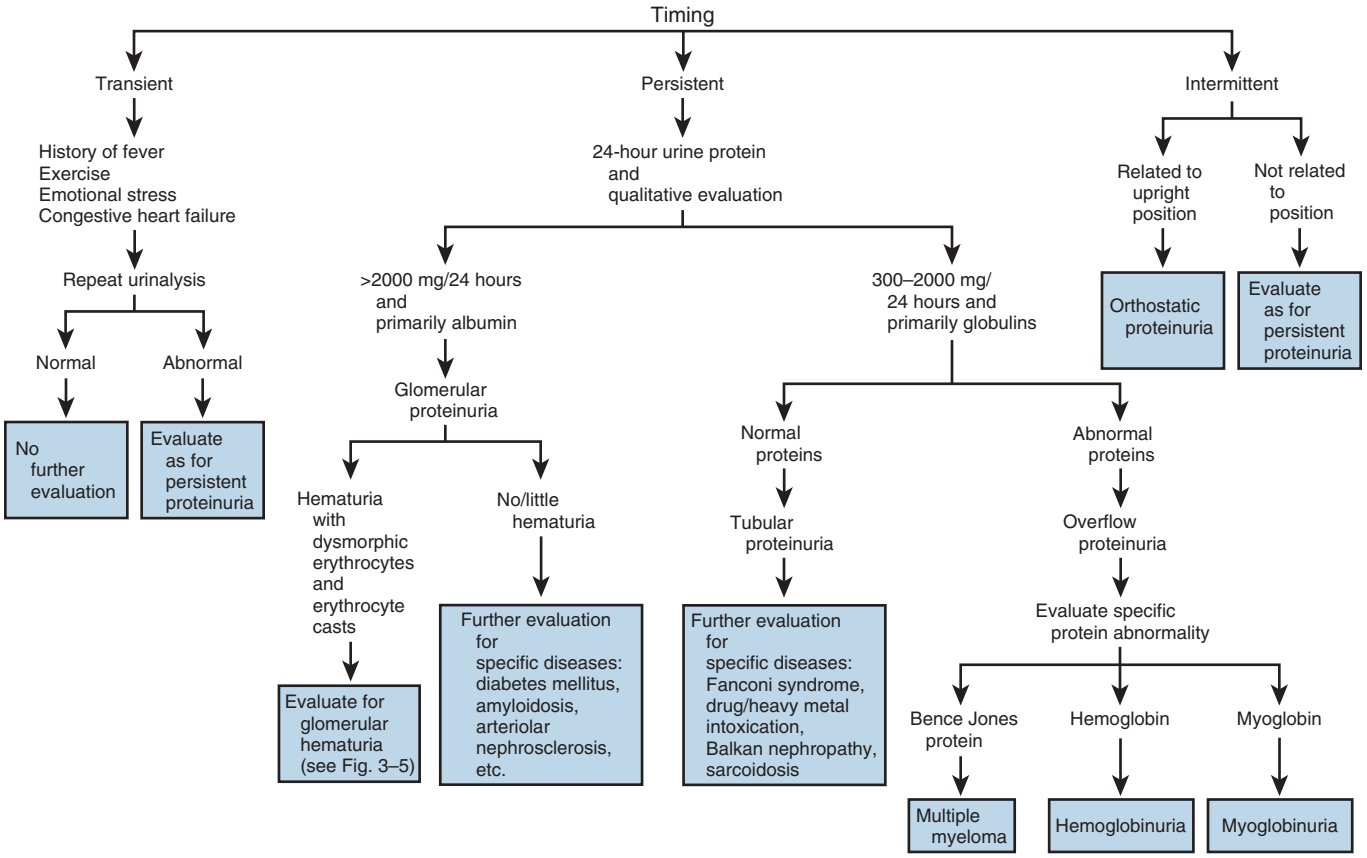

Figure 3–9. Evaluation of proteinuria.

glucose filtered exceeds the capacity of tubular reabsorption, glucose will be excreted in the urine and detected on the dipstick. **This so-called renal threshold corresponds to serum glucose of about 180 mg/dL; above this level, glucose will be detected in the urine.**

Glucose detection with the urinary dipstick is based on a double sequential enzymatic reaction yielding a colorimetric change. In the first reaction, glucose in the urine reacts with glucose oxidase on the dipstick to form gluconic acid and hydrogen peroxide. In the second reaction, hydrogen peroxide reacts with peroxidase, causing oxidation of the chromogen on the dipstick, producing a color change. **This double-oxidative reaction is specific for glucose, and there is no cross-reactivity with other sugars.** The dipstick test becomes less sensitive as the urine increases in specific gravity and temperature.

Ketones are not normally found in the urine but will appear when the carbohydrate supplies in the body are depleted and body fat breakdown occurs. This happens most commonly in diabetic ketoacidosis but may also occur during pregnancy and after periods of starvation or rapid weight reduction. **Ketones excreted include acetoacetic acid, acetone, and β-hydroxybutyric acid. With abnormal fat breakdown, ketones will appear in the urine before the serum.**

Dipstick testing for ketones involves a colorimetric reaction: sodium nitroprusside on the dipstick reacts with acetoacetic acid to produce a purple color. **Dipstick testing will identify acetoacetic acid at concentrations of 5 to 10 mg/dL but will not detect acetone or β-hydroxybutyric acid.** Obviously, a dipstick that tests positively for glucose should also be tested for ketones, and diabetes mellitus is suggested. False-positive results, however, can occur in acidic urine of high specific gravity, in abnormally colored urine, and in urine containing levodopa metabolites, 2-mercaptoethane sulfonate sodium, and other sulfhydryl-containing compounds (Csako, 1987).

Bilirubin and Urobilinogen

Normal urine contains no bilirubin and only small amounts of urobilinogen. There are two types of bilirubin, direct (conjugated) and indirect. Direct bilirubin is made in the hepatocyte, where bilirubin is conjugated with glucuronic acid. **Conjugated bilirubin has a low molecular weight, is water soluble, and normally passes from the liver into the small intestine through the bile ducts, where it is converted to urobilinogen. Therefore conjugated bilirubin does not appear in the urine except in pathologic conditions in which there is intrinsic hepatic disease or obstruction of the bile ducts.**

Indirect bilirubin is of high molecular weight and bound in the serum to albumin. It is water insoluble and therefore does not appear in the urine even in pathologic conditions.

Urobilinogen is the end product of conjugated bilirubin metabolism. Conjugated bilirubin passes through the bile ducts, where it is metabolized by normal intestinal bacteria to urobilinogen. Normally, about 50% of the urobilinogen is excreted in the stool and 50% reabsorbed into the enterohepatic circulation. A small amount of absorbed urobilinogen, about 1 to 4 mg/day, will escape hepatic uptake and be excreted in the urine. Hemolysis and hepatocellular diseases that lead to increased bile pigments can result in increased urinary urobilinogen. Conversely,

obstruction of the bile duct or antibiotic usage that alters intestinal flora, thereby interfering with the conversion of conjugated bilirubin to urobilinogen, will decrease urobilinogen levels in the urine. In these conditions, obviously, serum levels of conjugated bilirubin rise.

There are different dipstick reagents and methods to test for both bilirubin and urobilinogen, but the basic physiologic principle involves the binding of bilirubin or urobilinogen to a diazonium salt to produce a colorimetric reaction. False-negative results can occur in the presence of ascorbic acid, which decreases the sensitivity for detection of bilirubin. False-positive results can occur in the presence of phenazopyridine because it colors the urine orange and, similar to the colorimetric reaction for bilirubin, turns red in an acid medium.

Leukocyte Esterase and Nitrite Tests

Leukocyte esterase activity indicates the presence of white blood cells in the urine. The presence of nitrites in the urine is strongly suggestive of bacteriuria. Thus both of these tests have been used to screen patients for UTIs. Although these tests may have application in nonurologic medical practice, the most accurate method to diagnose infection is by microscopic examination of the urinary sediment to identify pyuria and subsequent urine culture. All urologists should be capable of performing and interpreting the microscopic examination of the urinary sediment. Therefore leukocyte esterase and nitrite testing are less important in a urologic practice. For purposes of completion, however, both techniques are described briefly herein.

Leukocyte esterase and nitrite testing are performed using the Chemstrip LN dipstick. Leukocyte esterase is produced by neutrophils and catalyzes the hydrolysis of an indoxyl carbonic acid ester to indoxyl (Gillenwater, 1981). The indoxyl formed oxidizes a diazonium salt chromogen on the dipstick to produce a color change. It is recommended that leukocyte esterase testing be done 5 minutes after the dipstick is immersed in the urine to allow adequate incubation (Shaw et al, 1985). The sensitivity of this test subsequently decreases with time because of lysis of the leukocytes. Leukocyte esterase testing may also be negative in the presence of infection because not all patients with bacteriuria will have significant pyuria. Therefore if one uses leukocyte esterase testing to screen patients for UTI, it should always be done in conjunction with nitrite testing for bacteriuria (Pels et al, 1989).

Other causes of false-negative results with leukocyte esterase testing include increased urinary specific gravity, glycosuria, presence of urobilinogen, medications that alter urine color, and ingestion of large amounts of ascorbic acid. **The major cause of false-positive leukocyte esterase tests is specimen contamination.**

Nitrites are not normally found in the urine, but many species of gram-negative bacteria can convert nitrates to nitrites. Nitrites can readily be detected in the urine because they react with the reagents on the dipstick and undergo diazotization to form a red azo dye. The specificity of the nitrite dipstick for detecting bacteriuria is higher than 90% (Pels et al, 1989). The sensitivity of the test, however, is considerably less, varying from 35% to 85%. The nitrite test is less accurate in urine specimens containing fewer than 10^5 organisms/mL (Kellog et al, 1987). As with leukocyte esterase testing, the major cause of false-positive nitrite testing is contamination.

It remains controversial whether dipstick testing for leukocyte esterase and nitrites can replace microscopy in screening for significant UTIs. This issue is less important to urologists, who usually have access to a microscope and who should be trained and encouraged to examine the urinary sediment. **A protocol combining the visual appearance of the urine with leukocyte esterase and nitrite testing has been proposed** (Fig. 3–10). It reportedly detects 95% of infected urine specimens and decreases the need for microscopy by as much as 30% (Flanagan et al, 1989). Other studies, however, have shown that dipstick testing is not an adequate replacement for microscopy (Propp et al, 1989). In summary, it has not been demonstrated conclusively that dipstick testing for UTI can replace microscopic examination of the urinary sediment. In our personal experience, we always examine the urinary sediment whenever we suspect a UTI and subsequently culture the urine when pyuria is identified.

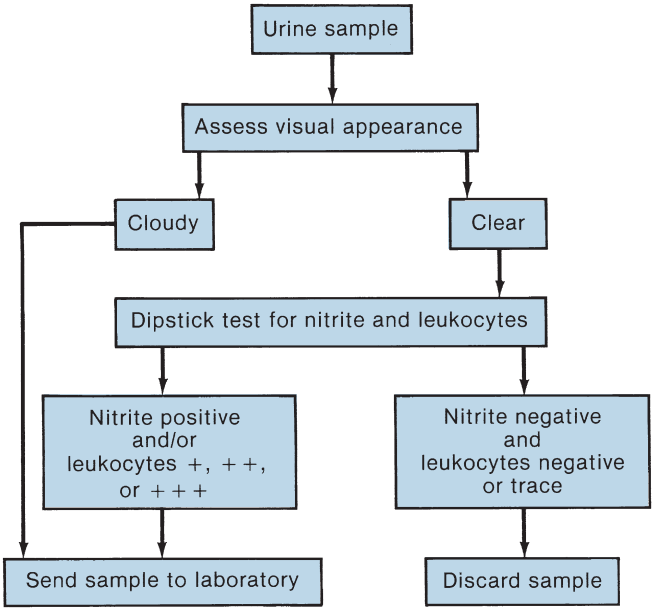

Figure 3–10. Protocol for determining the need for urine sediment microscopy in an asymptomatic population. (From Flanagan PG, Rooney PG, Davies EA, Stout RW. Evaluation of four screening tests for bacteriuria in elderly people. Lancet 1989;1:1117. © by The Lancet Ltd., 1989.)

Urinary Sediment

Obtaining and Preparing the Specimen

A clean-catch midstream urine specimen should be obtained. As described earlier, uncircumcised men should retract the prepuce and cleanse the glans penis before voiding. It is more difficult to obtain a reliable clean-catch specimen in females because of contamination with introital leukocytes and bacteria. If there is any suspicion of a UTI in a female, a catheterized urine sample should be obtained for culture and sensitivity.

If possible, **the first morning urine specimen is the specimen of choice and should be examined within 1 hour.** A standard procedure for preparation of the urine for microscopic examination has been described (Cushner and Copley, 1989). Ten to 15 milliliters of urine should be centrifuged for 5 minutes at 3000 rpm. The supernatant is then poured off, and the sediment is resuspended in the centrifuge tube by gently tapping the bottom of the tube. Although the remaining small amount of fluid can be poured onto a microscope slide, this usually results in excess fluid

on the slide. It is better to use a small pipette to withdraw the residual fluid from the centrifuge tube and to place it directly on the microscope slide. This usually results in an ideal volume of between 0.01 and 0.02 mL of fluid deposited on the slide. The slide is then covered with a coverslip. The edge of the coverslip should be placed on the slide first to allow the drop of fluid to ascend onto the coverslip by capillary action. The coverslip is then gently placed over the drop of fluid, and this technique allows for most of the air between the drop of fluid and the coverslip to be expelled. If one simply drops the coverslip over the urine, the urine will disperse over the slide and there will be a considerable number of air bubbles that may distort the subsequent microscopic examination.

Microscopy Technique

Microscopic analysis of the urinary sediment should be performed with both low-power (×100 magnification) and high-power (×400 magnification) lenses. The use of an oil immersion lens for higher magnification is seldom, if ever, necessary. Under low power, the entire area under the coverslip should be scanned. **Particular attention should be given to the edges of the coverslip, where casts and other elements tend to be concentrated.** Low-power magnification is sufficient to identify erythrocytes, leukocytes, casts, cystine crystals, oval fat macrophages, and parasites such as *Trichomonas vaginalis* and *Schistosoma hematobium*.

High-power magnification is necessary to distinguish circular from dysmorphic erythrocytes, to identify other types of crystals, and, particularly, to identify bacteria and yeast. In summary, **the urinary sediment should be examined microscopically for (1) cells, (2) casts, (3) crystals, (4) bacteria, (5) yeast, and (6) parasites.**

Cells

Erythrocyte morphology may be determined under high-power magnification. Although phase contrast microscopy has been used for this purpose, circular (nonglomerular) erythrocytes can generally be distinguished from dysmorphic (glomerular) erythrocytes under routine brightfield high-power magnification (Figs. 3–11 to 3–15). **This is assisted by adjusting the microscope condenser to its lowest aperture, thus reducing the intensity of background light. This allows one to see fine detail not evident otherwise and also creates the effect of phase microscopy because cell membranes and other sedimentary components stand out against the darkened background.**

Circular erythrocytes generally have an even distribution of hemoglobin with either a round or crenated contour, whereas dysmorphic erythrocytes are irregularly shaped with minimal hemoglobin and irregular distribution of cytoplasm. Automated techniques for performing microscopic analysis to distinguish the two types of erythrocytes have been investigated but have not yet been accepted into general urologic practice and are probably unnecessary. In one study using a standard Coulter counter, microscopic analysis was found to be 97% accurate in differentiating between the two types of erythrocytes (Sayer et al, 1990). **Erythrocytes may be confused with yeast or fat droplets** (Fig. 3–16). Erythrocytes can be distinguished, however, because yeast will show budding and oil droplets are highly refractile.

Leukocytes can generally be identified under low power and definitively diagnosed under high-power magnification (Figs. 3–17 and 3–18; see also Fig. 3–16). It is normal to find 1 or 2 leukocytes/

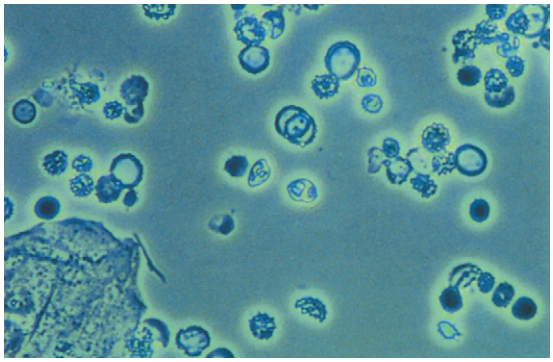

Figure 3–14. Red blood cells from a patient with Berger disease. Note variations in membranes characteristic of dysmorphic red blood cells.

HPF in men and up to 5/HPF in women in whom the urine sample may be contaminated with vaginal secretions. A greater number of leukocytes generally indicates infection or inflammation in the urinary tract. It may be possible to distinguish **old leukocytes, which have a characteristic small and wrinkled appearance** and which are commonly found in the vaginal secretions of normal women, from fresh leukocytes, which are generally indicative of urinary tract pathology. Fresh leukocytes are generally larger and rounder, and, when the specific gravity is less than 1.019, the granules in the cytoplasm demonstrate glitter-like movement, so-called glitter cells.

Epithelial cells are commonly observed in the urinary sediment. Squamous cells are frequently detected in female urine specimens and are derived from the lower portion of the urethra, the trigone of postpubertal females, and the vagina. **Squamous epithelial cells are large, have a central small nucleus about the size of an erythrocyte, and have an irregular cytoplasm with fine granularity.**

Transitional epithelial cells may arise from the remainder of the urinary tract (Fig. 3–19). Transitional cells are smaller than squamous cells, have a larger nucleus, and demonstrate prominent cytoplasmic granules near the nucleus. Malignant transitional cells have altered nuclear size and morphology and can be identified with either routine Papanicolaou staining or automated flow cytometry.

Renal tubular cells are the least commonly observed epithelial cells in the urine but are most significant because their presence in the urine is always indicative of renal pathology. Renal tubular cells may be difficult to distinguish from leukocytes, but they are slightly larger.

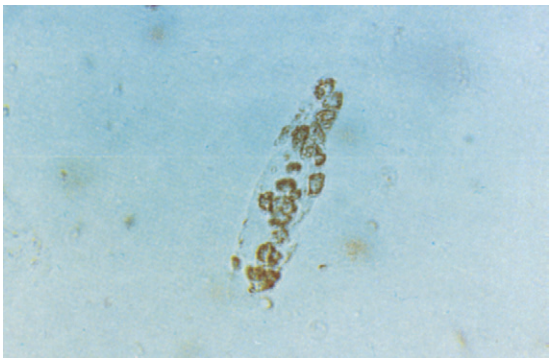

Figure 3–22. Cellular cast. Cells entrapped in a hyaline matrix.

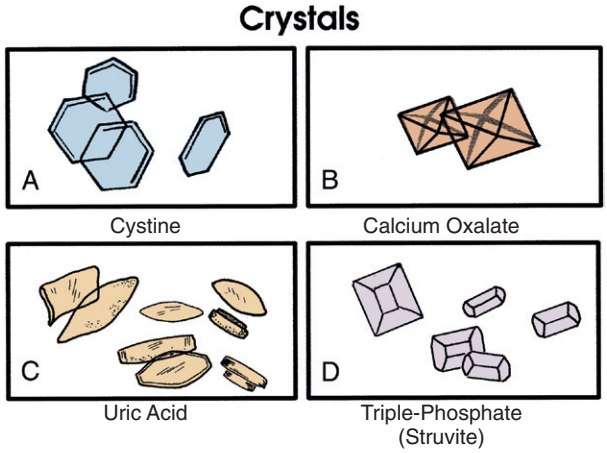

Figure 3–23. Urinary crystals. **A,** Cystine. **B,** Calcium oxalate. **C,** Uric acid. **D,** Triple phosphate (struvite).

Casts

A cast is a protein coagulum that is formed in the renal tubule and traps any tubular luminal contents within the matrix. **Tamm-Horsfall mucoprotein is the basic matrix of all renal casts; it originates from tubular epithelial cells and is always present in the urine.** When the casts contain only mucoproteins, they are called hyaline casts and may not have any pathologic significance. Hyaline casts may be seen in the urine after exercise or heat exposure but may also be observed in pyelonephritis or chronic renal disease.

Red blood cell casts contain entrapped erythrocytes and are diagnostic of glomerular bleeding, most likely secondary to glomerulonephritis (Figs. 3–20 and 3–21). White blood cell casts are observed in acute glomerulonephritis, acute pyelonephritis, and acute tubulointerstitial nephritis. Casts with other cellular elements, usually sloughed renal tubular epithelial cells, are indicative of nonspecific renal damage (Fig. 3–22). Granular and waxy casts result from further degeneration of cellular elements. Fatty casts are seen in nephrotic syndrome, lipiduria, and hypothyroidism.

Crystals

Identification of crystals in the urine is particularly important in patients with stone disease because it may help determine the etiology (Fig. 3–23). Although other types of crystals may be seen in normal patients, **the identification of cystine crystals establishes the diagnosis of cystinuria.** Crystals precipitated in acidic urine include calcium oxalate, uric acid, and cystine. Crystals precipitated in an alkaline urine include calcium phosphate and triple-phosphate (struvite) crystals. Cholesterol crystals are rarely seen in the urine and are not related to urinary pH. They occur in lipiduria and remain in droplet form.

Bacteria

Normal urine should not contain bacteria; and in a fresh uncontaminated specimen, the finding of bacteria is indicative of a UTI. Because each HPF views between 1/20,000 and 1/50,000 mL, each bacterium seen per HPF signifies a bacterial count of more than

30,000/mL. Therefore, **5 bacteria/HPF reflects colony counts of about 100,000/mL.** This is the standard concentration used to establish the diagnosis of a UTI in a clean-catch specimen. This level should apply only to women, however, in whom a clean-catch specimen is frequently contaminated. The finding of any bacteria in a properly collected midstream specimen from a male should be further evaluated with a urine culture.

Under high power, it is possible to distinguish various bacteria. Gram-negative rods have a characteristic bacillary shape (Fig. 3–24), whereas streptococci can be identified by their characteristic beaded chains (Figs. 3–25 and 3–26) and staphylococci can be identified when the organisms are found in clumps (Fig. 3–27).

Yeast

The most common yeast cells found in urine are *Candida albicans*. The biconcave oval shape of yeast can be confused with erythrocytes and calcium oxalate crystals, but **yeasts can be distinguished by their characteristic budding and hyphae** (see Fig. 3–16). Yeasts are most commonly seen in the urine of patients with diabetes mellitus or as contaminants in women with vaginal candidiasis.

Parasites

***Trichomonas vaginalis* is a frequent cause of vaginitis in women and occasionally of urethritis in men.** Trichomonads can be readily identified in a clean-catch specimen under low power (Fig. 3–28). Trichomonads are large cells with rapidly moving flagella that quickly propel the organism across the microscopic field.

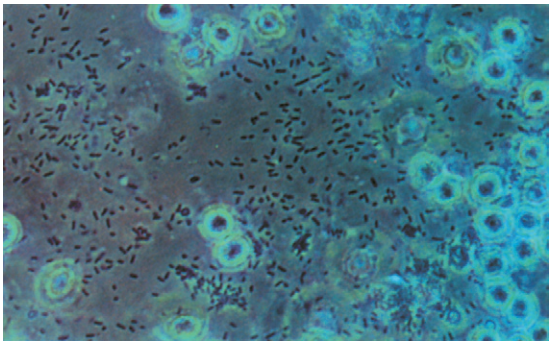

Figure 3–24. Gram-negative bacilli. Phase microscopy of *Escherichia coli.*

***Schistosoma hematobium* is a urinary tract pathogen that is not found in the United States but is extremely common in countries of the Middle East and North Africa. Examination of the urine shows the characteristic parasitic ova with a terminal spike.**

Expressed Prostatic Secretions

Although not strictly a component of the urinary sediment, the expressed prostatic secretions should be examined in any man suspected of having prostatitis. Normal prostatic fluid should contain few, if any, leukocytes, and the presence of a larger number or clumps of leukocytes is indicative of prostatitis. **Oval fat macrophages are found in postinfection prostatic fluid** (Figs. 3–29 and 3–30). Normal prostatic fluid contains numerous secretory granules that resemble but can be distinguished from leukocytes under high power because they do not have nuclei.

SUMMARY

This chapter has detailed the basic evaluation of the urologic patient, which should include a careful history, physical examination, and urinalysis. These three basic components form the cornerstone of the urologic evaluation and should precede any subsequent diagnostic procedures. After completion of the history, physical examination, and urinalysis, the urologist should be able to establish at least a differential, if not specific, diagnosis that will allow the subsequent diagnostic evaluation and treatment to be carried out in a direct and efficient manner.

Imaging plays an indispensable role in the diagnosis and management of urologic diseases. Because many urologic conditions are unable to be assessed by physical examination, conventional radiography has long been critical to the diagnosis of conditions of the kidneys, ureters, and bladder. Ultrasonography revolutionized the diagnosis of prostatic disease. The urologist's familiarity with ultrasonography led to its widespread use for many conditions in the office and the operating room. The development of axial imaging and the use of intravenous contrast agents have provided detailed anatomic, functional, and physiologic information about urologic conditions. In this chapter we discuss the indications for imaging in urology with an emphasis on the underlying physical principles of the imaging modalities. The strengths and limitations of each modality, as well as the techniques necessary to maximize image quality and minimize the risks and harms to urologic patients, are discussed.

CONVENTIONAL RADIOGRAPHY

Conventional radiography, though eclipsed by axial imaging for certain indications, remains useful in a variety of urologic conditions. Conventional radiography includes abdominal plain radiography, intravenous excretory urography, retrograde pyelography, loopography, retrograde urethrography, and cystography. Urologists increasingly perform and interpret conventional radiography examinations including fluoroscopic examinations in the office and operating room environments.

Physics

It is imperative that urologists understand the physics of conventional radiography and fluoroscopy, as well as the implications of radiation exposure to the patient and the operator. The underlying physical principles of conventional radiography involve emitting a stream of photons from an x-ray source. These photons travel through the air and strike tissue, imparting energy to that tissue. Some of the photons emerge from the patient with varying amounts of energy attenuation and strike an image recorder such as a film cassette or the input phosphor of an image-intensifier tube, thus producing an image (Fig. 4–1).

RADIATION MANAGEMENT IN URORADIOLOGY

When diagnostic radiation passes through tissue, it creates ion pairs. The resultant charge per unit mass of air is referred to as the **radiation exposure.** The current unit of radiation exposure is coulombs(C)/kg. **Absorbed dose** is the energy absorbed from the radiation exposure and is measured in units called gray (Gy). The older unit of absorbed dose was called the rad (1 rad = 100 Gy).

Because different types of radiation have different types of interaction with tissue, a conversion factor is applied to better express the amount of energy absorbed by a given tissue. The application of this conversion factor to the **absorbed dose** yields the **equivalent dose** measured in sieverts (Sv). For diagnostic radiographs the conversion factor is 1, so the absorbed dose is the same as the equivalent dose. When discussing the amount of radiation energy absorbed by patients during therapeutic radiation, the dose is given in gray. When discussing exposure to patients or medical personnel due to diagnostic ionizing radiation procedures, the dose is given in sieverts.

The distribution of energy absorption in the human body will be different on the basis of the body part being imaged and various other factors. The most important risk of radiation exposure from diagnostic imaging is the development of cancer. The **effective dose** is a quantity used to denote the radiation risk (expressed in **sieverts**) to a population of patients from an imaging study.

See Table 4–1 for a description of the relationship between these measures of radiation exposure.

The average person living in the United States is exposed to 1 to 3 mSv of radiation per year from ambient sources such as radon and cosmic rays. The recommended occupational exposure limit to medical personnel is 50 mSv per year (NCRP, 1993). Exposure to the eyes and gonads has a more significant biologic impact than exposure to the extremities, so recommended exposure limits vary according to the body part. However, there is no safe dose of radiation. An effective radiation dose of as little as 10 mSv may result in the development of a malignancy in 1 of 1000 individuals exposed (NRCNA, 2006).

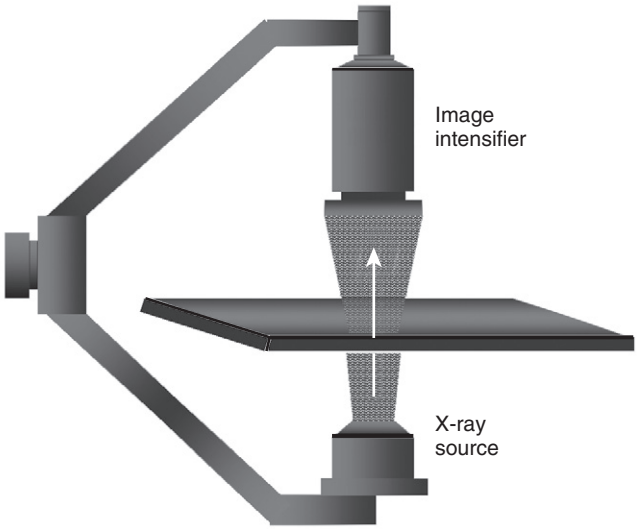

Figure 4–1. Equipment setup for fluoroscopy. The x-ray source located beneath the table reduces the radiation exposure to the proceduralist. Locating the image intensifier as close to the patient as feasible reduces scatter radiation. Equipment setup will vary on the basis of the application.

Relative Radiation Levels

The assessment of biologic risk from radiation exposure is complex. By estimating the range of effective doses for various imaging modalities, they can be assigned a **relative radiation level (RRL)** (Table 4–2).

The effective dose from a three-phase computed tomography (CT) scan of the abdomen and pelvis without and with contrast may be as high as 25 to 40 mSv. An often overlooked source of significant radiation exposure is fluoroscopy. Fluoroscopy for 1 minute results in a radiation dose to the skin equivalent to 10 times that of a single radiograph of the same anatomic area (Geise and Morin, 2000).

Radiation Protection

The cumulative dose of radiation to patients increases relatively rapidly with repeated axial imaging studies or procedures guided by fluoroscopy. Certain patient populations such as those with recurrent renal calculus disease or those with a urologic malignancy may be at risk because of repeated exposures to ionizing radiation. Attempts should be made to limit axial imaging studies to the anatomic area of interest and to substitute imaging studies not requiring ionizing radiation when feasible. The cumulative dose of radiation to medical personnel (including physicians) may increase relatively rapidly in circumstances where fluoroscopy is used.

Reduction in radiation exposure to medical personnel is achieved by three major mechanisms: (1) limiting the time of

Table 4–1.

Units of Radiation Exposure and Clinical Relevance of the Measures

RADIATION QUANTITY	TRADITIONAL UNIT	SI UNIT	CONVERSION	CLINICAL RELEVANCE
Exposure	Roentgen (R)	Coulomb (C)/kg	1 C/kg = 3876 R	Charge per unit mass
Absorbed dose	Rad	Gray (Gy)	1 Gy = 100 rad	Energy absorbed by tissue
Equivalent dose	Rem	Sievert (Sv)	1 Sv = 100 rem	Absorbed energy based on tissue type
Effective dose	Rem	Sievert (Sv)		Biologic risk associated with absorbed energy

Table 4–2.

Relative Radiation Level Designations along with Common Example Examinations for Each Classification

RELATIVE RADIATION LEVEL*	ADULT EFFECTIVE DOSE ESTIMATE RANGE	PEDIATRIC EFFECTIVE DOSE ESTIMATE RANGE	EXAMPLE EXAMINATIONS
O	0	0 mSv	Ultrasound, MRI
☢	<0.1 mSv	<0.03 mSv	Chest radiographs, hand radiographs
☢☢	0.1-1 mSv	0.03-0.3 mSv	Pelvis radiographs, mammography
☢☢☢	1-10 mSv	0.3-3 mSv	Abdomen CT, nuclear medicine bone scan
☢☢☢☢	10-30 mSv	3-10 mSv	Abdomen CT without and with contrast, whole body PET
☢☢☢☢☢	30-100 mSv	10-30 mSv	Transjugular intrahepatic portosystemic shunt placement, aortic aneurysm stent graft treatment

*The RRL assignments for some of the examinations cannot be made, because the actual patient doses in these procedures vary as a function of a number of factors (e.g., the region of the body exposed to ionizing radiation, the imaging guidance that is used). The RRLs for these examinations are designated as NS (not specified).
From American College of Radiology. ACR appropriateness criteria: radiation dose assessment introduction. ⟨http://www.acr.org/SecondaryMainMenuCategories/quality_safety/app_criteria/RRLInformation.aspx⟩; [accessed 19.01.11].

exposure; (2) maximizing distance from the radiation source; and (3) shielding. Radiation dose during fluoroscopy is directly proportional to the **time of exposure** and to the **number of exposures.** The exposure time during fluoroscopy should be minimized by using short bursts of fluoroscopy and using the "last image hold" feature of the fluoroscopy unit. Radiation beams diverge with distance and therefore radiation exposure diminishes as the square of the distance from the radiation source. Maintaining the maximum practical distance from an active radiation source significantly decreases exposure to medical personnel. Positioning the image intensifier as close to the patient as feasible substantially reduces scatter radiation. Standard aprons and thyroid shields provide significant shielding for medical personnel and should be worn by all personnel involved in the use of fluoroscopy.

Key Points: Conventional Radiography/Radiation Management in Uroradiology

- The effective radiation dose describes the potential for adverse health effects from ionizing radiation.
- The effective dose is a quantity used to denote the radiation risk (expressed in sieverts) to a population of patients from an imaging study. See Table 4–1 for a description of the relationship between these measures of radiation exposure.
- There is no safe dose of radiation.
- Filling of the bladder may stimulate bladder spasms at low volumes, and some patients are unable to hold adequate volumes for investigation. Bladder filling in patients with spinal cord injuries higher than T6 may precipitate autonomic dysreflexia.
- Relative radiation levels (RRL) categorize diagnostic imaging studies by their estimated effective dose of radiation.
- Radiation protection for medical personnel includes (1) limiting time of exposure, (2) maximizing distance from radiation source, and (3) shielding.

CONTRAST MEDIA

The urologist ordering a radiographic evaluation on a patient must consider the risks and benefits associated with a contrast-enhanced imaging study, as well as alternative imaging modalities that could provide the same information without the need for contrast exposure.

Many different types of contrast media have been used to enhance medical imaging and thus improve diagnostic and therapeutic decisions made by urologists. These agents are used on a daily basis throughout the world with great safety and efficacy. However, like all other pharmaceuticals, there are inherent risks associated with the use of contrast media. Adverse side effects and adverse drug reactions (ADRs) can be a direct result from the use of contrast media and vary from minor disturbances to severe, life-threatening situations. Imaging centers must be prepared with trained personnel, readily available medications, equipment, and an ongoing system to educate clinic personnel on the recognition and treatment of ADRs associated with contrast media.

Intravascular Iodinated Contrast Media

Iodine is the most common element in general use as an intravascular radiologic contrast medium (IRCM). With an atomic weight of 127, iodine has radiopacity, whereas other elements included in IRCM have no radiopacity and act only as carriers of the iodine elements, increasing solubility and reducing toxicity. Four basic types of iodinated IRCM are available for clinical use: ionic monomer, nonionic monomer, ionic dimer, and nonionic dimer. They can be further characterized as being iso-, hyper-, or low-osmolar compared with physiologic osmolality of 300 mOsm/kg H_2O (Table 4–3).

All are derived from a 2,4,6 tri-iodinated benzene ring compound with three atoms of iodine in the case of monomers and six atoms of iodine in the case of dimers. The chemical composition of these agents make them highly hydrophilic, low in lipid solubility, and of low binding affinity for protein receptors or membranes. Because they do not enter red blood cells or tissue cells and are rapidly excreted, they are designed for use in imaging and are not therapeutic. Approximately 90% will be eliminated by the kidneys within 12 hours of administration.

Table 4–3.

Properties of Commonly Used Radiocontrast Media

TYPE	GENERIC NAME	IODINE, mg/mL	OSMOLALITY, mOsm/KG	VISCOSITY, CPS AT 37° C
Iso osmolar				
Nonionic dimmer	Iotrolan	300	320	8.1
Nonionic dimmer	Iodixanol	320	290	11.4
Low osmolar				
Ionic dimmer	Meglumine ioxaglate	320	580	7.5
Ionic dimmer	Sodium oxalate	320	580	7.5
Nonionic monomer	Iopamidol	300	616	4.7
Nonionic monomer	Iohexol	300	640	6.3
Nonionic monomer	Ioversol	300	645	5.5
Nonionic monomer	Iopromide	300	610	4.6
High osmolar				
Ionic monomer	Sodium iothalamate	325	1843	2.75
Ionic monomer	Meglumine diatrizoate	306	1530	5.0

From Pannu N, Wiebe N, Tonelli M, et al. Prophylaxis strategies for contrast-induced nephropathy. JAMA 2006;295(23):2765–79.

Relative to the body's iron stores, large quantities of iodine are required for imaging enhancement. The total body iodine content, found mainly in the thyroid gland, is 0.01 g and the average daily turnover of iodine is only 0.0001 g. For renal CT imaging a common dose of IRCM will expose the patient to between 25 and 50 g of iodine, which is approximately 400,000 times the daily turnover rate in the human body, but this dose will rarely cause any toxicity or lasting effects (Morris, 1993).

Adverse Reactions to Intravascular Iodinated Contrast Media

Adverse drug reactions (ADR) associated with intravenous contrast media can be divided into two broad categories: idiosyncratic anaphylactoid (IA) and nonidiosyncratic (NI) reactions. IA reactions are most concerning because they are potentially fatal and can occur without any predictable or predisposing factors. Approximately 85% of IA reactions occur during or immediately after injection of IRCM and are more common in patients with a prior ADR to contrast media, asthmatics, diabetics, patients with impaired renal function or diminished cardiac function, and those who are taking β-adrenergic blockers.

The exact mechanism of IA reactions is not known but is thought to be a combination of systemic effects. IA reactions have not been shown to result from a true IgE antibody immunologic reaction to the contrast media (Dawson, 1999). At least four mechanisms may play a role in IA reactions: (1) release of vasoactive substances including histamine; (2) activation of physiologic cascades including complement, kinin, coagulation, and fibrinolytic systems; (3) inhibition of enzymes including cholinesterase, which may cause prolonged vagal stimulation; and (4) the patient's own anxiety and fear of the actual procedure. **IA reactions are not dose dependent. Severe reactions have been reported after only 1 mL injected at the beginning of the procedure and have also occurred after completion of a full dose despite no reaction to the initial test dose** (Nelson et al, 1988; Thomsen et al, 1999; ACR, 2008).

Nonidiosyncratic (NI) reactions are dose dependent and consequently related to the osmolality, concentration, volume, and injection rate of the IRCM. Because the concentration of absorbed or free iodine is low, only patients with an underlying iodine deficiency are at risk for increased intake of iodine during contrast imaging. Patients with endemic goiter may develop thyrotoxicosis after injection of IRCM agents.

The hyperosmolar contrast media (HOCM) have an osmolality that is five times greater than physiologic osmolality of body cells (300 mOsm/kg water). The hyperosmolar agents are associated with erythrocyte damage, endothelial damage, vasodilation, hypervolemia, interruption of the blood-brain barrier, and cardiac depression. Chemotoxic reactions to IRCM include cardiac, vascular, neurologic, and renal toxicity. The low osmotic contrast media (LOCM) have an osmolality the same as or slightly higher than physiologic osmolality and are associated with fewer ADRs and toxic events (Morcos, 1999).

Contrast Complications

All contrast ADRs are more common with HOCM (12%) compared with LOCM (3%) (Katayama et al, 1990; Heinrich et al, 2005). **Previous adverse reaction to IRCM and a history of asthma are two of the most concerning predisposing conditions predicating an ADR with use of contrast media. Additional factors that may predict an ADR include history of known allergy to iodine, severe cardiac disease, renal insufficiency, dehydration, sickle cell anemia, anxiety, apprehension, hyperthyroidism, and presence of adrenal pheochromocytoma.**

Minor Reactions

It is common to have nausea, flushing, pruritus, urticaria, headache, and even emesis after injection of IRCM. These reactions are usually mild and do not require additional treatment. Arm pain can also result from venous spasm or infiltration of the media outside the vein. An H_1 receptor blocker like diphenhydramine (Benadryl) PO/IM/IV 1 to 2 mg/kg, up to 50 mg may be helpful in this patient population.

Intermediate Reactions

Worsening or more severe minor reactions including hypotension or bronchospasm occur in 0.5% to 2% of patients. These are usually transient and do not need treatment. If necessary, 4 to 10 mg of chlorphenamine administered orally, IV, or IM; 5 mg of diazepam for anxiety; 100 to 500 mg of hydrocortisone IM or IV; or two to three puffs of beta-agonist inhalators for bronchospasm (bronchiolar dilators such as metaproterenol [Alupent], terbutaline [Brethaire], or albuterol [Proventil or Ventolin]) are administered; repeat as needed.

Severe Reactions

Life-threatening reactions occur in approximately 1/1000 uses for high-osmolar agents and are far less for low-osmolar contrast media, with both types of agents resulting in mortality rates of 1/170,000 uses (Spring et al, 1997). Severe reactions include seizure, laryngeal spasm, bronchospasm, pulmonary edema, cardiac arrhythmia, respiratory collapse, or cardiac arrest (Katayama et al, 1990). Ready access to a crash cart and trained personnel are necessary components of any imaging center. If needed, cardiopulmonary resuscitation is started immediately. Many different medications have been used for the treatment of an acute severe life-threatening reaction to IRCM. **However, rapid administration of epinephrine is the treatment of choice for severe contrast reactions. Current guidelines recommend immediate delivery of 0.01 mg/kg of body weight to a maximum of 0.5 mg of 1:1000 concentration of epinephrine, injected IM in the lateral thigh as first-line treatment.** Subcutaneous injection is much less effective. Intravenous injection can be given with more dilute concentration and must be given slowly (ACR, 2008; Lightfoot et al, 2009).

Large-volume extravasation can be seen with power injections not monitored with electrical skin impedance devices that detect extravasation and arrest the injection process. When large-volume extravasation of IRCM occurs, the result can be cellulitis, edema, and compartment syndrome leading to tissue necrosis. The most severe consequences may not be manifest immediately. Consequently, admission to the hospital for observation or frequent follow-up in the clinic may be necessary in some cases of large-volume extravasation.

Premedication Strategies

No known premedication strategy will eliminate the risk of a severe adverse reaction to IRCM. The regimens suggested in the literature include the use of

Table 4–4.

Premedication Strategies to Reduce Severity of Reactions to Contrast Media

Prednisone	50 mg by mouth at 13 hr, 7 hr, and 1 hr before contrast media injection **Plus** diphenhydramine (Benadryl)—50 mg IV, IM, or by mouth 1 hr before contrast medium injection
Methylprednisolone (Medrol)	32 mg by mouth 12 hr and 2 hr before contrast media injection **Plus** diphenhydramine (Benadryl)—50 mg IV, IM, or by mouth 1 hr before contrast medium injection

From American College of Radiology Manual on Contrast Media, version 6, pp. 9-10, <http://www.acr.org/SecondaryMainMenuCategories/quality_safety/contrast_manual.aspx> [accessed 01.10.10].

corticosteroids, antihistamines, H_1 and H_2 antagonists, and ephedrine. Patients at high risk should be premedicated with corticosteroids and possibly antihistamines 12 to 24 hours before and after use of IRCM. LOCM can be used in these patients. Several premedication regimens have been proposed to reduce the frequency and/or severity of reactions to contrast media. Two frequently used regimens are outlined in Table 4–4.

It has been demonstrated that the use of nonionic contrast media combined with a premedication strategy including corticosteroids results in a reduction in reaction rates compared with other protocols for patients who have experienced a prior contrast media–induced reaction. However, no controlled studies are available to determine whether pretreatment alters the incidence of serious reactions. Oral administration of steroids seems preferable to intravascular administration, and prednisone and methylprednisolone are equally effective. If the patient is unable to take oral medication, 200 mg of hydrocortisone IV may be substituted for oral prednisone. **One consistent finding is that the steroids should be given at least 6 hours before the injection of contrast media regardless of the route of steroid administration. It is clear that administration for 3 hours or less before contrast does not decrease adverse reactions** (Lasser, 1988).

Supplemental administration of an H_1 antihistamine (e.g., diphenhydramine), orally or IV, may reduce the frequency of urticaria, angioedema, and respiratory symptoms. In emergency situations, intravenous corticosteroid (e.g., 200 mg hydrocortisone) every 4 hours plus an H_1 antihistamine (e.g., 50 mg diphenhydramine) 1 hour before the procedure has been used. In patients who have a prior documented contrast reaction, the use of a different contrast agent has been advocated and may be protective. Switching to a different agent should be in combination with a premedication regimen.

Specific Clinical Considerations

Metformin. **Patients with type II diabetes mellitus on metformin oral biguanide hyperglycemic therapy may have an accumulation of the drug after administering IRCM, resulting in biguanide lactic acidosis presenting with vomiting, diarrhea, and somnolence. This condition is fatal in approximately 50% of cases** (Wiholm, 1993). **Biguanide lactic acidosis is rare in patients with normal renal function. Consequently, in patients with normal renal function and no known comorbidities there is no need to discontinue metformin before IRCM use, nor is there a need to check creatinine following the imaging study. However, in patients with renal insufficiency, metformin should be discontinued the day of the study and withheld for 48 hours. Postprocedure creatinine should be measured at 48 hours and metformin started once kidney function is normal** (Bailey and Turner, 1996). **It is not necessary to discontinue metformin before gadolinium-enhanced magnetic resonance studies when the amount of gadolinium administered is in the usual dose range of 0.1 to 0.3 mmol per kg of body weight.**

Contrast-Induced Nephropathy. Contrast-induced nephropathy (CIN) is defined as a rise in serum creatinine 25% above baseline, or more than 0.5 mg/dL within 3 days following exposure to contrast media, in the absence of an alternative cause. The precise cause of CIN continues to elude investigators but is believed to be a combination of tubular injury and renal ischemia (Katholi et al, 1998). High doses of IRCM can impair renal function in some patients for 3 to 5 days. CIN in patients with normal kidney function is rare (Pannu et al, 2006; Kelly et al, 2008). CIN is the third most common cause of acute kidney failure in the hospitalized patients (Nash et al, 2002). **The most common patient-related risk factors are chronic kidney disease (creatinine clearance <60 mL/min), diabetes mellitus, dehydration, congestive heart failure, age, hypertension, low hematocrit, and ventricular ejection fraction less than 40%. The patients at highest risk for developing CIN are those with both diabetes *and* preexisting renal insufficiency. The most common non–patient-related causes are high-osmolar contrast agents, ionic contrast, increased contrast viscosity, and large-contrast volume infusion** (Pannu et al, 2006).

Despite significant discussion on the part of radiologists and urologists, the literature does not support an absolute serum creatinine level that prohibits the use of contrast media. Prevention of CIN has been the subject of many research studies, and the results have been summarized by several different meta-analyses. In these meta-analyses the baseline serum creatinine of study participants ranged from 0.9 to 2.5 mg/dL. **In one survey the policies regarding the cutoff value for serum creatinine varied widely among radiology practices. Thirty-five percent of respondents used 1.5 mg/dL, 27% used 1.7 mg/dL, and 31% used 2.0 mg/dL (mean, 1.78 mg/dL) as a cutoff value in patients with no risk factors other than elevated creatinine; threshold values were slightly lower in diabetics (mean 1.68 mg/dL). Patients in end-stage renal disease who have no remaining natural renal function are no longer at risk for CIN and may receive LOCM or IOCM** (Elicker et al, 2006).

The summary of the meta-analysis for the prevention of CIN after contrast media use supports using hydration, bicarbonate, iso- or low-osmolar contrast media, and N-acetylcysteine. In one review article, N-acetylcysteine was determined to be more protective than hydration alone. Furosemide was found to increase the risk of developing CIN (Pannu et al, 2006; Kelly et al, 2008).

N-acetylcysteine is inexpensive, readily available, administered orally, and associated with few drug interactions or side effects. Its mechanism of protection against CIN is not understood but may serve as a scavenger of oxygen-free radicals and/or augment the vasodilatory effects of nitric oxide in the kidney (Safirstein et al, 2000). Doses used in the different studies ranged from 600 to

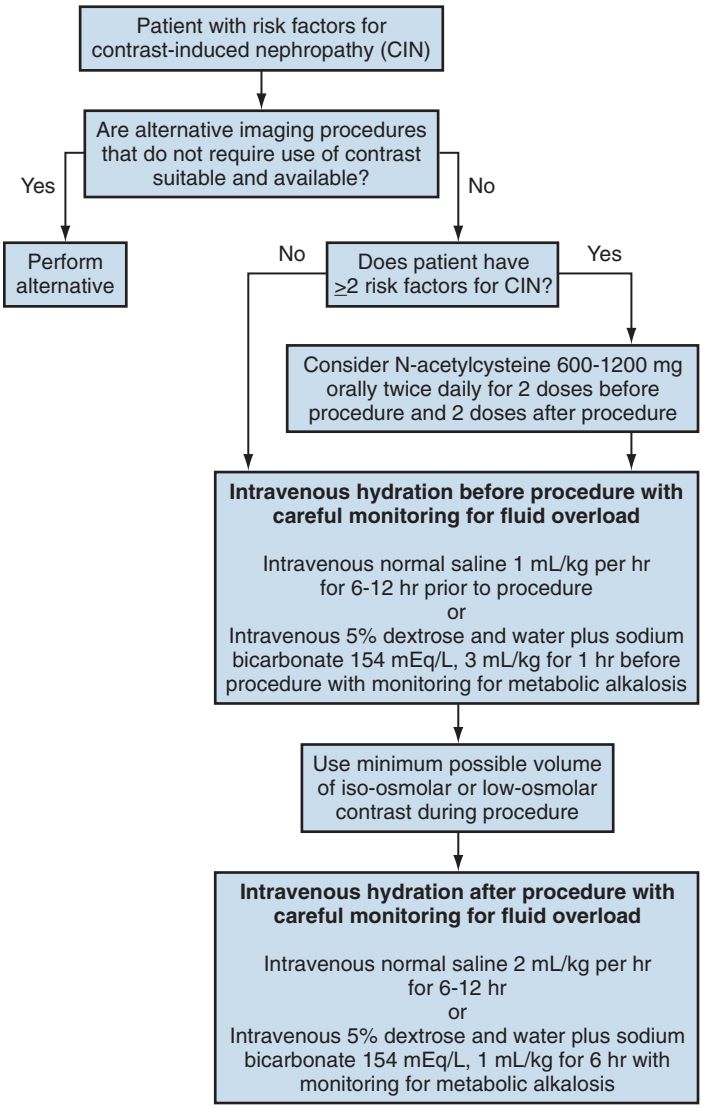

Figure 4–2. Preventive strategies for patient with risk factors for contrast-induced nephropathy (CIN).

1200 mg orally twice a day for 2 doses before the contrast-enhanced study and 2 doses after the procedure (Fig. 4–2).

Magnetic Resonance Imaging Contrast Agents

Because magnetic resonance imaging (MRI) offers previously unseen detailed soft tissue imaging compared with CT, it was initially believed that MRI would not require contrast enhancement. However, by 2005, almost 50% of MRI studies were being performed with contrast media. Extracellular MRI contrast agents contain paramagnetic metal ions. Copper, manganese, and gadolinium were the potential paramagnetic ions for use with MRI. Gadolinium, however, is the most powerful having seven unpaired electrons, but its toxicity required encapsulation by a chelate. Paramagnetic agents like gadolinium are positive enhancers reducing the T1 and T2 relaxation times and increasing tissue signal intensity on T1-weighted images, while having little effect on T2-weighted images.

Although gadolinium chelates can be differentiated on the basis of stability, viscosity, and osmolality, they cannot be differentiated on the basis of efficacy. Acute adverse reactions are encountered less frequently with gadolinium than after administration of iodinated contrast media. The frequency of all acute adverse events after an injection of 0.1 or 0.2 mmol/kg of gadolinium chelate ranges from 0.07% to 2.4%. The vast majority of these reactions are mild including coldness at the injection site, nausea, emesis, headache, warmth or pain at the injection site, paresthesias, dizziness, and itching. Reactions resembling an "allergic" response occur frequently, from 0.004% to 0.7%. Systemic reactions consisting of rash, hives, or urticaria are the most frequent of this group, and rarely bronchospasm. The severe, life-threatening anaphylactoid or nonallergic anaphylactic reactions are exceedingly rare (0.0001% to 0.001%). In a meta-analysis of 687,000 gadolinium doses for MRI, there were only five severe reactions. In another survey based on 20 million administered doses there were 55 cases (0.0003%) of severe reactions. Fatal reactions to gadolinium chelate agents have been reported, but they are extremely rare events (Murphy et al, 1999).

Extracellular MRI agents are known to interfere with some serum chemistry assays. For example, serum calcium tests will often be measured as a false reading of hypocalcemia for 24 hours after MRI with gadolinium enhancement, even though serum calcium is actually in the normal range. Other tests including iron, magnesium, iron binding capacity, and zinc may also have spurious results. Biochemical assessment is more reliable when performed 24 hours after exposure to gadolinium contrast media.

Nephrogenic Systemic Fibrosis

Gadolinium-based contrast media (GBCM) are considered to have no nephrotoxicity at approved dosages for MRI. Magnetic resonance with gadolinium has been used instead of contrast-enhanced CT in those at risk for developing worsening renal failure if exposed to iodinated contrast media. However, nephrogenic systemic fibrosis (NSF) has recently been reported in patients with advanced renal insufficiency (glomerular filtration rate [GFR] <30 mL/min). **Nephrogenic systemic fibrosis (NSF) is a fibrosing disease of the skin, subcutaneous tissues, lungs, esophagus, heart, and skeletal muscles. Initial symptoms typically include skin thickening and/or pruritus. Symptoms and signs may develop and progress rapidly, with some affected patients developing contractures and joint immobility within days of exposure. Death may result in some patients, presumably as a result of visceral organ involvement.**

In 1997 NSF was described in dialysis patients who had not been exposed to GBCM. The condition was previously known as nephrogenic fibrosing dermopathy. In 2006 and again in 2007 independent reports surfaced defining a strong association with gadolinium-based contrast media (Grobner, 2006; Marckmann et al, 2006). **Onset of NSF varies between 2 days and 3 months. Early manifestations include subacute swelling of distal extremities, followed by severe skin induration and later even organ involvement.** In a 2007 survey performed by the American College of Radiology, 156 cases of NSF were reported by 27 responding institutions; 140 of these 156 patients were known to have received GBCM. In 78 patients, the specific GBCM was known. Forty-five of them received gadodiamide, 17 gadopentetate dimeglumine, 13 gadoversetamide, and 3 gadobenate dimeglumine. NSF following gadoteridol administration has also been reported. Many of the cases in which agents other than

gadodiamide and gadopentetate dimeglumine were used are confounded by the fact that affected patients were injected with other agents as well (ACR, 2008). Patients with chronic kidney disease (CKD) have a 1% to 7% chance of developing NSF after MRI imaging with gadolinium agents (Todd et al, 2007).

Patients with GFR less than 30 mL/min/1.73m^2 (not on chronic dialysis) are the most difficult patient population in terms of choosing an imaging modality. They are at risk for CIN if exposed to iodinated contrast media for CT imaging and are also at significant risk of developing NSF if exposed to GBCM during MRI. Recent data suggest that the risk of NSF may be greatest in patients with a GFR of less than 15 mL/min/1.73m^2 and much less in patients with GFRs that are higher. Patients with severe chronic kidney disease have a 1% to 7% chance of developing NSF after GBCM MRI (Kanal et al, 2008). In the chronic kidney disease patient population, it is recommended that contrast media be avoided if possible. If MRI contrast media is absolutely essential, use of the lowest possible doses (needed to obtain a diagnostic study) of selected GBCM is recommended. In this setting, the patient should be informed of the risks of GBCM administration and must give their consent to proceed. There is no proof that any GBCM is completely safe in this patient group; however, some have suggested avoiding gadodiamide and considering use of macrocyclic agents (Kanal et al, 2008). Patients with CKD but GRF greater than 30 mL/min/1.73m^2 are considered to be at extremely low or no risk for developing NSF if a dose of GBCM of 0.1 mmol/kg or less is used. Patients with GFR greater than 60 mL/min/1.73 m^2 do not appear to be at increased risk of developing NSF, and the current consensus is that all GBCM can be administered safely to these patients. In their publications, the American College of Radiology stresses that the current information on NSF and its relationship to GBCM administration is preliminary and further research is necessary to better understand this potentially devastating complication.

Key Points: Contrast Media

- Type II diabetics with renal insufficiency on oral metformin biguanide hyperglycemic therapy are at risk for developing biguanide lactic acidosis after exposure to intravascular radiologic contrast media and should stop metformin the day before the procedure and restart 48 hours after if they have a normal or baseline serum creatinine.
- Patients at risk for adverse reaction to contrast include those with previous adverse reactions, a history of asthma, severe cardiac disease, renal insufficiency, dehydration, sickle cell anemia, anxiety, apprehension, hyperthyroidism, and presence of adrenal pheochromocytoma.
- The treatment of choice for a severe adverse drug reaction is 0.01 mg/kg of epinephrine (1:1000 concentration) IM in the lateral thigh.
- Patients at greatest risk for contrast-induced nephropathy are those with diabetes mellitus and dehydration.
- Steroids given to prevent adverse contrast agents should be given at least 6 hours before injection.

INTRAVENOUS UROGRAPHY

Once the mainstay of urologic imaging, the intravenous excretory urographic (IVU) study has essentially been replaced by CT and MRI. With the ability of new scanners to perform axial, sagittal, and coronal reconstruction of the upper tract urinary system, essentially all of the data and information obtained by traditional IVU can be realized with CT imaging. In addition, some parenchymal defects, cysts, and tumors can be better delineated with CT than IVU.

Technique

Bowel prep may help to visualize the entire ureters and upper collecting systems. Patients with chronic constipation may benefit most from complete bowel prep with clear liquids for 12 to 24 hours and an enema 2 hours before the procedure. Most patients will need only clear liquids for 12 hours and an enema 1 hour before the procedure.

Before injection of contrast, a scout radiograph or KUB (kidneys, ureters, bladder) film is taken demonstrating the top of the kidneys and the entire pelvis to the pubic symphysis. This allows determination of adequate bowel prep, confirms correct positioning, and exposes kidney stones or bladder stones.

Contrast is injected as a bolus of 50 to 100 mL of contrast. The nephrogenic phase is captured with a radiograph immediately after injection. In the past, tomograms were used to look for parenchymal defects but now CT or MRI is preferred. A film is taken at 5 minutes and then additional films at 5-minute intervals until the question that prompted the IVU is answered. Abdominal compression may be used to better visualize the ureters. Occasionally oblique films will be used to better define the course of the ureter in the bony pelvis and to precisely differentiate ureteral stones from pelvic calcifications.

Upright films may be helpful in certain situations. In the rare case of suspected symptomatic renal ptosis, IVU can be particularly helpful (Fig. 4–3). Supine films are compared with upright films to measure the degree of ptosis. Such a comparison cannot be made with MRI or CT. In the case of calyceal stones or milk of calcium stones, layering of the contrast can be helpful to evaluate the anatomy of the calyx harboring the stones.

Postvoid films are obtained to evaluate the presence of outlet obstruction, prostate enlargement, and bladder filling defects including stones and urothelial cancers.

Indications

1. Demonstrate the renal collecting systems and ureters
2. Investigate the level of ureteral obstruction in renal units displaying delayed function
3. Demonstrate intraoperative opacification of collecting system during extracorporeal shock wave lithotripsy or percutaneous access to the collecting system
4. Demonstrate renal function during emergent evaluation of unstable patients
5. Demonstrate renal and ureteral anatomy in special circumstances (e.g., ptosis, after transureteroureterostomy, after urinary diversion)

PLAIN ABDOMINAL RADIOGRAPHY

The plain abdominal radiograph is a conventional radiography study, which, in urology, is intended to display the kidneys, ureters and bladder. The plain abdominal radiograph may be employed (1) as a primary study or (2) as a scout film in anticipation of contrast media. Plain films are widely used in the management of renal calculus disease. Plain radiography is also useful in evaluation of the trauma patient because it can be performed as a

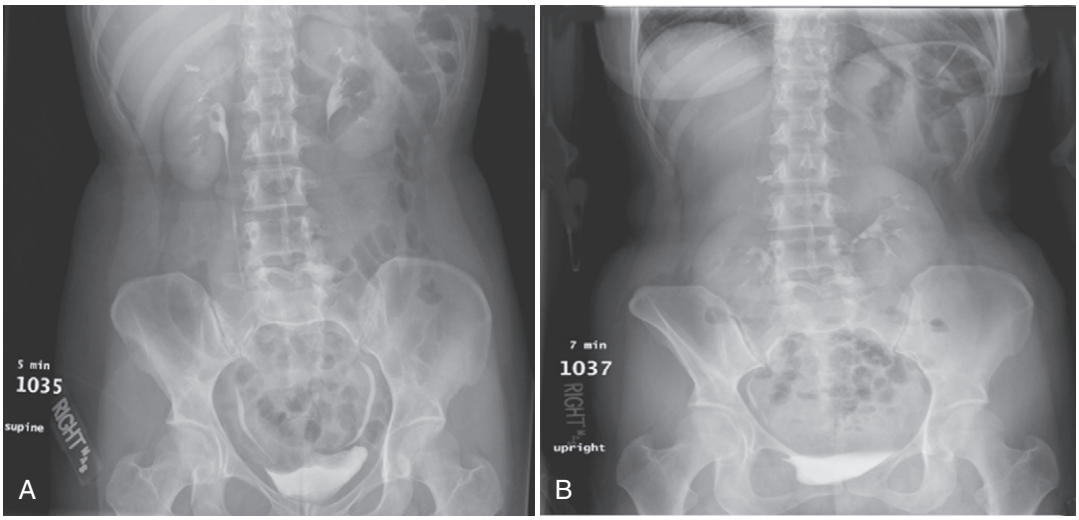

Figure 4–3. Intravenous excretory urogram (IVU) in a 40-year-old female with the complaint of a mobile mass in the right lower quadrant with standing associated with bilateral flank and back pain that resolved in the supine position. **A,** Supine IVU shows kidneys in the normal position, with normal ureters and proximal collecting systems. **B,** Standing film shows significant displacement of both kidneys with the right kidney moving onto the pelvis as described by the patient.

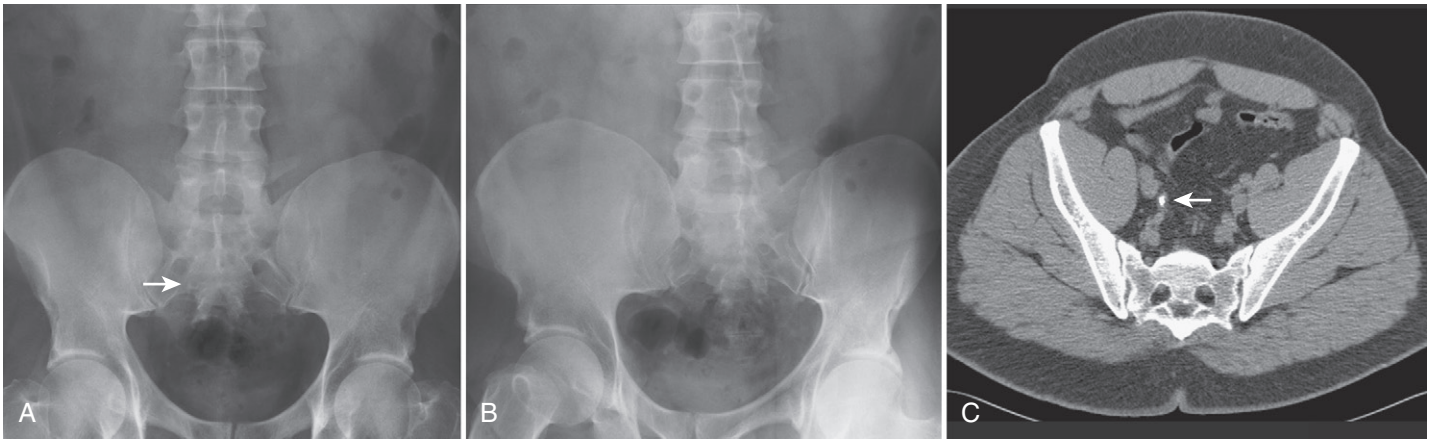

Figure 4–4. **A,** Right ureteral calculus *(arrow)* overlying the sacrum is difficult to visualize on the plain film. **B,** The right posterior oblique study fails to confirm the location of the ureteral calculus. **C,** Computed tomography confirms this 6-mm calculus in the right ureter at the level of the third sacral segment.

portable study in the trauma unit. Secondary findings on plain radiography such as rib fractures, fractures of the transverse processes of the vertebral bodies, and pelvic fractures may indicate serious associated urologic injuries.

Technique

An abdominal plain radiograph is obtained with the patient in the supine position, using an anterior to posterior exposure. The study typically includes that portion of the anatomy from the level of the diaphragm to the inferior pubic symphysis. It may occasionally be necessary to make two exposures to cover the desired anatomic field. Depending on the indication for the study, oblique films are obtained to clarify the position of structures in relation to the urinary tract. If small bowel obstruction or free peritoneal air is suspected, upright films will be obtained.

Indications

1. To be a preliminary film in anticipation of contrast administration
2. To assess the presence of residual contrast from a previous imaging procedure
3. To assess renal calculus disease before and after treatment
4. To assess the position of drains and stents
5. To be an adjunct to the investigation of blunt or penetrating trauma to the urinary tract

Limitations

Although plain film radiography is often used in the evaluation of renal colic, it is unreliable in the demonstration of calculus disease for various reasons: (1) overlying stool and bowel gas may obscure small calculi; (2) stones may be obscured by other structures such as bones or ribs (Fig. 4–4); (3) calcifications in pelvic veins or vascular structures may be confused with ureteral calculi; and (4) stones that are poorly calcified or composed of uric acid may be radiolucent. Nevertheless, plain film radiography is valuable in assessing the suitability of a patient for extracorporeal shock wave lithotripsy because the ability to identify the stone on fluoroscopy is critical to targeting. Furthermore, a KUB film is cost-effective for monitoring residual stone burden after treatment

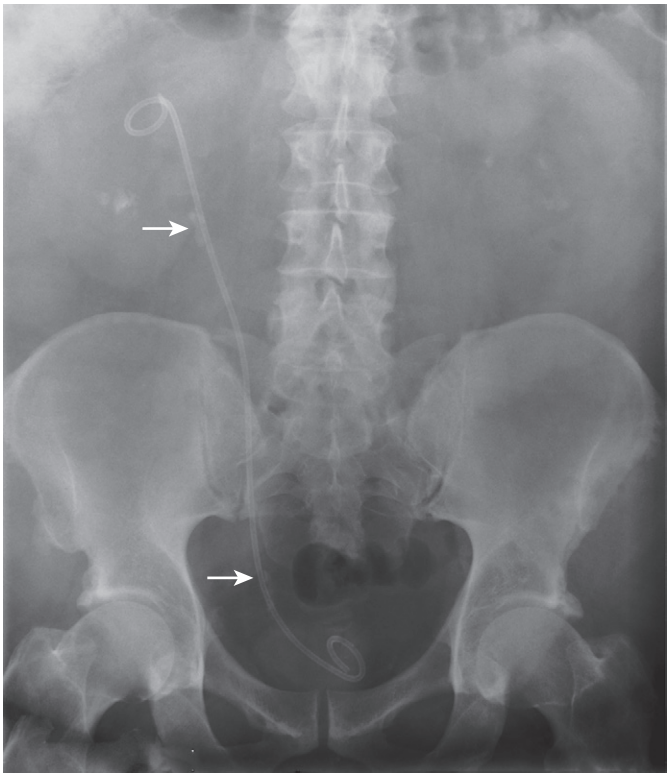

Figure 4–5. Kidney ureter bladder film demonstrating residual stone fragments *(arrows)* adjacent to a right ureteral stent 1 week following right extracorporeal shock wave lithotripsy.

(Fig. 4–5). For complex pathology of the urinary tract, plain abdominal radiography has been supplanted by axial imaging. Plain radiography has a limited role in evaluating soft tissue abnormalities of the urinary tract.

RETROGRADE PYELOGRAPHY

Retrograde pyelograms are performed to opacify the ureters and intrarenal collecting system by the retrograde injection of contrast media. Any contrast media that can be used for excretory urography is also acceptable for retrograde pyelography. Attempts should be made to sterilize the urine before retrograde pyelography because there is a risk of introducing bacteria into the upper urinary tracts or into the bloodstream. Although many studies are able to document the presence or absence of dilation of the ureter, retrograde pyelography has the unique ability to document the normalcy of the ureter distal to the level of obstruction and to better define the extent of the ureteral abnormality.

Technique

Retrograde pyelography is usually performed with the patient in the dorsal lithotomy position. An abdominal plain radiograph (scout film) is obtained to ensure that the patient is in the appropriate position to evaluate the entire ureter and intrarenal collecting system. Cystoscopy is performed and the ureteral orifice is identified.

Contrast may be injected through either a nonobstructing catheter or an obstructing catheter. Nonobstructing catheters include whistle tip, spiral tip, or open-ended catheters. Use of nonobstructing catheters allows passage of the catheter into the ureter and up to the collecting system, over a guidewire if necessary. Contrast can then be introduced directly into the upper collecting system, and the ureters can be visualized by injection of contrast as the catheter is withdrawn.

The other commonly employed method is the use of an obstructing ureteral catheter such as a bulb-tip, cone-tip, or wedge-tip catheter. These catheters are inserted into the ureteral orifice and then pulled back against the orifice to effectively obstruct the ureter. Contrast is then injected to opacify the ureter and intrarenal collecting system. Depending on the indication for the study, it is useful to dilute the contrast material to 50% or less with sterile fluid. This prevents subtle filling defects in the collecting system or ureter from being obscured. Contrast is injected slowly, usually requiring from 5 to 8 mL to completely opacify the ureter and intrarenal collecting system in adults (Fig. 4–6). More or less contrast may be required depending on the size of the patient and the capaciousness of the collecting system. Limited use of fluoroscopy while injecting will help prevent overdistension of the collecting system and reduce the risk of extravasation of contrast. Care should be taken to evacuate air bubbles from the syringe and catheter before injection. Such air bubble artifacts could be mistaken for stones or tumors.

Historically, when a retrograde pyelogram consisted of a series of radiographs taken at intervals, it was important to document various stages of filling and emptying of the ureter and collecting systems. Because of peristalsis the entire ureter will often not be seen on any given static exposure or view. With current equipment including tables that incorporate fluoroscopy, it is possible to evaluate the ureter during peristalsis in real time, thus reducing the need for static image documentation. Documentary still images or "spot films" may be saved for future comparison. Urologists interpret retrograde pyelograms in real time as they are performed.

Indications

1. Evaluation of congenital ureteral obstruction
2. Evaluation of acquired ureteral obstruction
3. Elucidation of filling defects and deformities of the ureters or intrarenal collecting systems
4. Opacification or distention of collecting system to assist percutaneous access
5. In conjunction with ureteroscopy or stent placement
6. Evaluation of hematuria
7. Surveillance of transitional cell carcinoma
8. In the evaluation of traumatic or iatrogenic injury to the ureter or collecting system

Limitations

Retrograde pyelography may be difficult in cases where the bladder is involved with diffuse inflammation or neoplastic changes, especially when bleeding is present. Identification of the ureteral orifices may be assisted by the intravenous injection of indigotindisulfonate sodium or methylene blue in such cases. Changes associated with bladder outlet obstruction may result in angulation of the intramural ureters. This may make cannulation with an obstructing catheter quite difficult. Attempts to cannulate the ureteral orifice may result in trauma to the ureteral orifice and extravasation of contrast material into the bladder wall. The potential for damage to the intramural ureter must be weighed against the potential information to be obtained by the retrograde pyelogram.

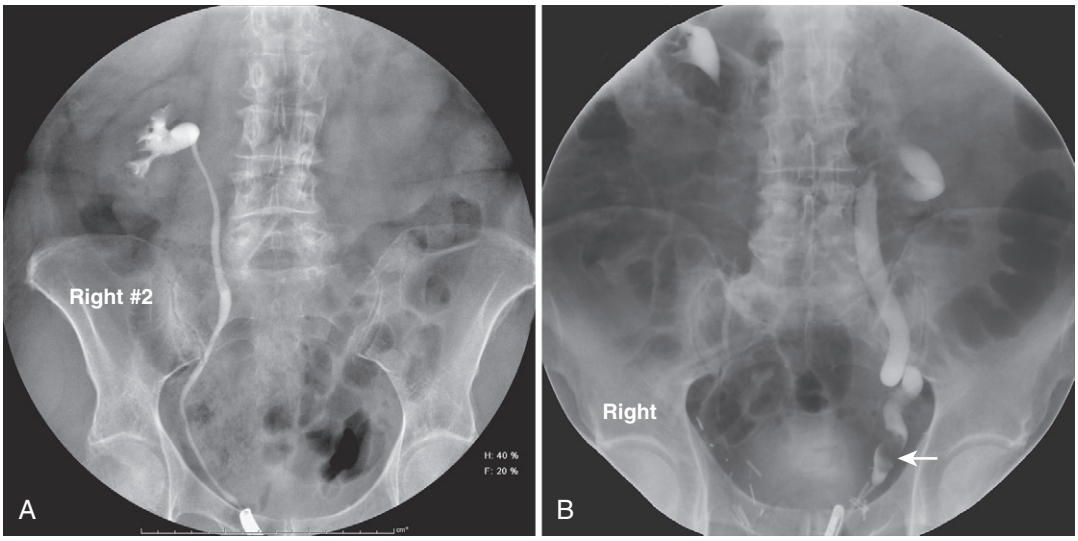

Figure 4–6. **A,** Right retrograde pyelogram performed using an 8-Fr cone-tipped ureteral catheter and dilute contrast material. The ureter and intrarenal collecting system are normal. **B,** Left retrograde pyelogram using an 8-Fr cone-tipped ureteral catheter. A filling defect in the left distal ureter *(arrow)* is a low-grade transitional cell carcinoma. The ureter demonstrates dilation, elongation, and tortuosity, the hallmarks of chronic obstruction.

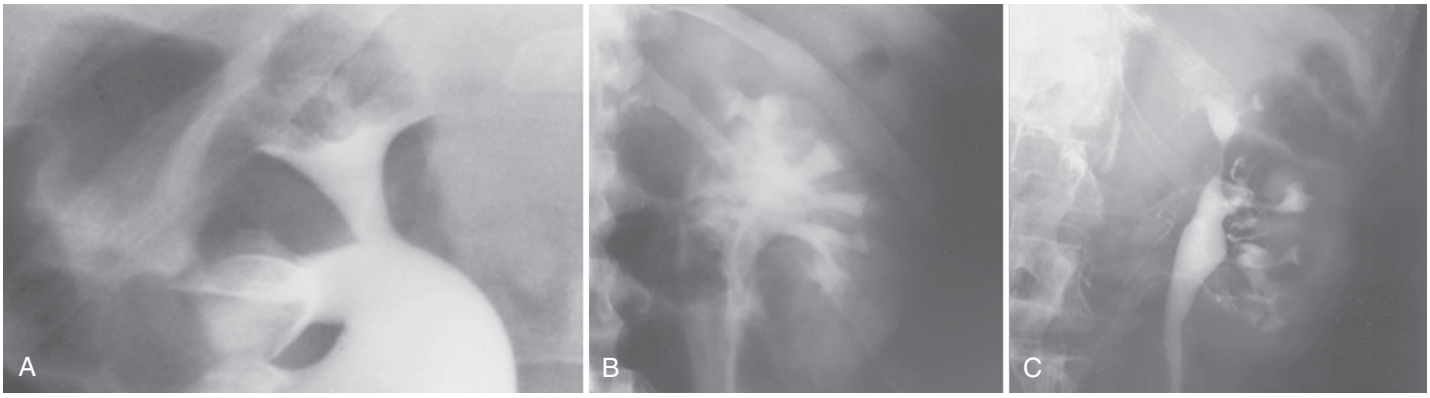

Figure 4–7. Patterns of backflow during retrograde pyelography. **A,** Pyelotubular backflow. **B,** Pyelosinus backflow. **C,** Pyelolymphatic backflow.

Complications

Backflow occurs during retrograde pyelography when contrast is injected under pressure and escapes the collecting system. Contrast may escape the collecting system by one of four routes: **Pyelotubular** backflow occurs when contrast fills the distal collecting ducts producing opacification of the medullary pyramids (Fig. 4–7A). **Pyelosinus** backflow occurs when a tear in the calyces at the fornix allows contrast to leak into the renal sinus (Fig. 4–7B). **Pyelolymphatic** backflow is characterized by opacification of the renal lymphatic channels (Fig. 4–7C). **Pyelovenous** backflow is seen when contrast enters the venous system, resulting in visualization of the renal vein.

Although backflow does not usually cause measurable clinical harm, the potential implications of backflow include (1) introduction of bacteria from infected urine into the vascular system and (2) the absorption of contrast media, which could result in adverse reactions in susceptible patients. It has been demonstrated that the risk of significant urinary tract infection is only about 10% and the risk of sepsis is low when antibiotic prophylaxis therapy is administered before endoscopic procedures (including retrograde pyelography) (Christiano et al, 2000). Although contrast reactions are rare with retrograde pyelography, they have been reported (Johenning, 1980; Weese et al, 1993). In patients with documented severe contrast allergy, prophylactic pretreatment may be appropriate. In those patients considered at risk, care should be taken to inject under low pressures to minimize the probability of backflow and absorption of the contrast into the vasculature system.

LOOPOGRAPHY

Loopography is a diagnostic procedure performed in patients who have undergone urinary diversion. Historically the term "loopogram" has been associated with ileal conduit diversion but may be used in reference to any bowel segment serving as a urinary conduit. When imaging patients with a continent diversion involving a reservoir or neobladder, "pouch-o-gram" would be more accurately descriptive. Because an ileal conduit urinary diversion usually has freely refluxing ureterointestinal anastomoses, the ureters and upper collecting systems may be visualized. In other forms of diversion, the ureterointestinal anastomoses may be purposely nonrefluxing. In such circumstances, when opacification of the upper urinary tract is desirable, antegrade ureteral imaging such as IVU, CT, or MRI urography or antegrade nephrostography may be required. When the patient has compromised

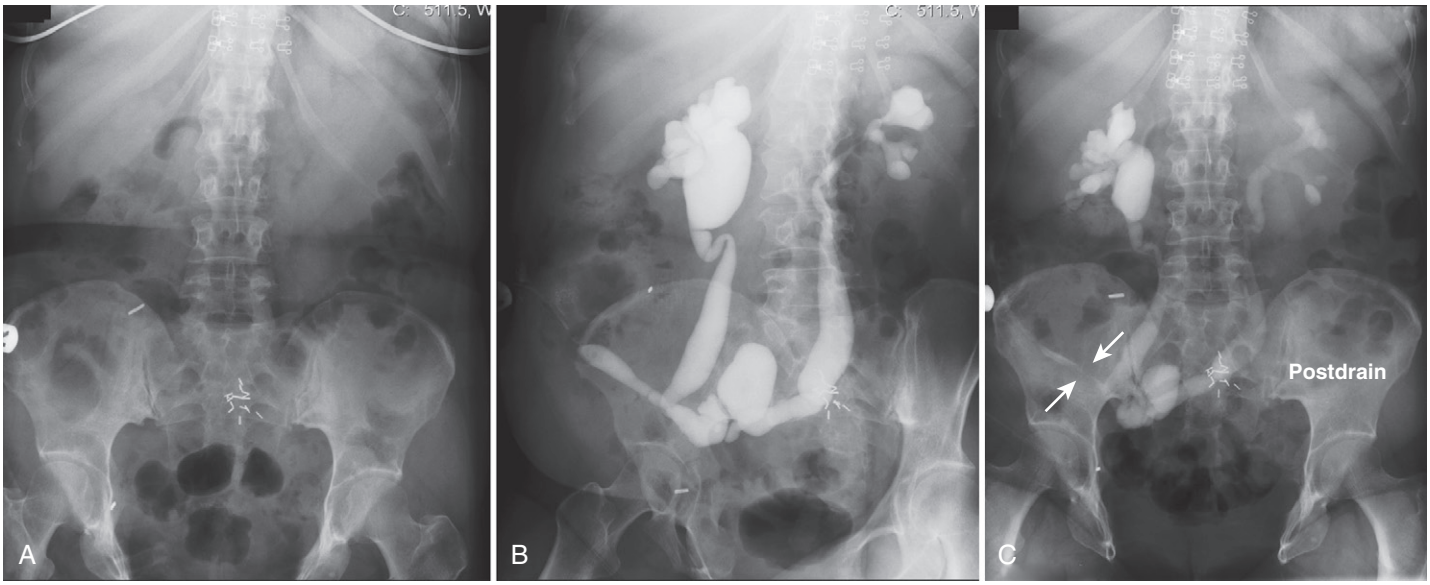

Figure 4–8. Loopography in a patient with epispadias/exstrophy and ileal conduit urinary diversion. The plain film (**A**) shows wide diastasis of the pubic symphysis. After contrast administration via a catheter placed in the ileal conduit, free reflux of both ureterointestinal anastomoses is demonstrated (**B**). A postdrain radiograph (**C**) demonstrates persistent dilation of the proximal loop indicating mechanical obstruction of the conduit *(arrows)*.

renal function or is allergic to iodinated contrast material, loopography can be performed with a low risk of systemic absorption (Hudsen et al, 1981).

Technique

The patient is positioned supine. An abdominal plain radiograph is obtained before the introduction of contrast material (Fig. 4–8A). A commonly employed technique is to insert a small-gauge catheter into the ostomy of the loop, advancing it just proximal to the abdominal wall fascia. The balloon on such a catheter can then be inflated to 5 to 10 mL with sterile water. By gently introducing contrast through the catheter, the loop can be distended, usually producing bilateral reflux into the upper tracts. Oblique films should be obtained in order to evaluate the entire length of the loop (Fig. 4–8B). Because of the angle at which many loops are constructed, a traditional anteroposterior (AP) view will often show a foreshortened loop and could miss a substantial pathology. A drain film should be obtained (Fig. 4–8C). This may demonstrate whether there is obstruction of the conduit.

Indications

1. Evaluation of infection, hematuria, renal insufficiency, or pain after urinary diversion
2. Surveillance of upper urinary tract for obstruction
3. Surveillance of upper urinary tract for urothelial neoplasia
4. Evaluation of the integrity of the intestinal segment or reservoir

RETROGRADE URETHROGRAPHY

A retrograde urethrogram is a study meant to evaluate the anterior and posterior urethra. Retrograde urethrography may be particularly beneficial in demonstrating the total length of a urethral stricture, which cannot be negotiated by cystoscopy. Retrograde urethrography also demonstrates the anatomy of the urethra distal to a stricture, which may not be assessable by voiding cystourethrography. Retrograde urethrography may be performed in the office or in the operating room before performing visual internal urethrotomy or formal urethroplasty.

Technique

A plain film radiograph is obtained before injection of contrast. The patient is usually positioned slightly obliquely to allow evaluation of the full length of urethra. The penis is placed on slight tension. A small catheter may be inserted into the fossa navicularis with the balloon inflated to 2 mL with sterile water. Contrast is then introduced via catheter-tipped syringe. Alternatively, a penile clamp (e.g., Brodney clamp) may be used to occlude the urethra around the catheter (Fig. 4–9).

Indications

1. Evaluation of ureteral stricture disease
2. Assessment for foreign bodies
3. Evaluation of penile or urethral penetrating trauma
4. Evaluation of traumatic gross hematuria

STATIC CYSTOGRAPHY

Static cystography is employed primarily to evaluate the structural integrity of the bladder. The shape and contour of the bladder may give information about neurogenic dysfunction or bladder outlet obstruction. Filling defects such as tumors and stones may be appreciated.

Technique

The patient is positioned supine. A plain radiograph is performed to evaluate for stones and residual contrast and to confirm position and technique. The bladder is filled with 200 to 400 mL of contrast depending on bladder size and patient comfort. Adequate filling is important to demonstrate intravesical pathology or bladder rupture. Oblique films should be obtained because

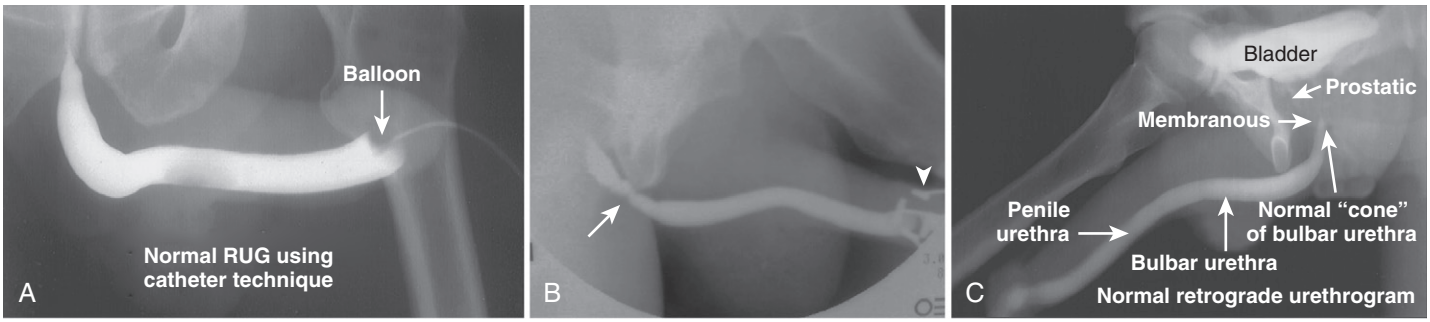

Figure 4–9. Normal retrograde urethrogram demonstrating (**A**) the balloon technique for retrograde urethrography; (**B**) Brodney clamp *(arrowhead)* technique; note the bulbar urethral stricture *(arrow)*. **C**, Normal structures of the male urethra as seen on retrograde urethrogram.

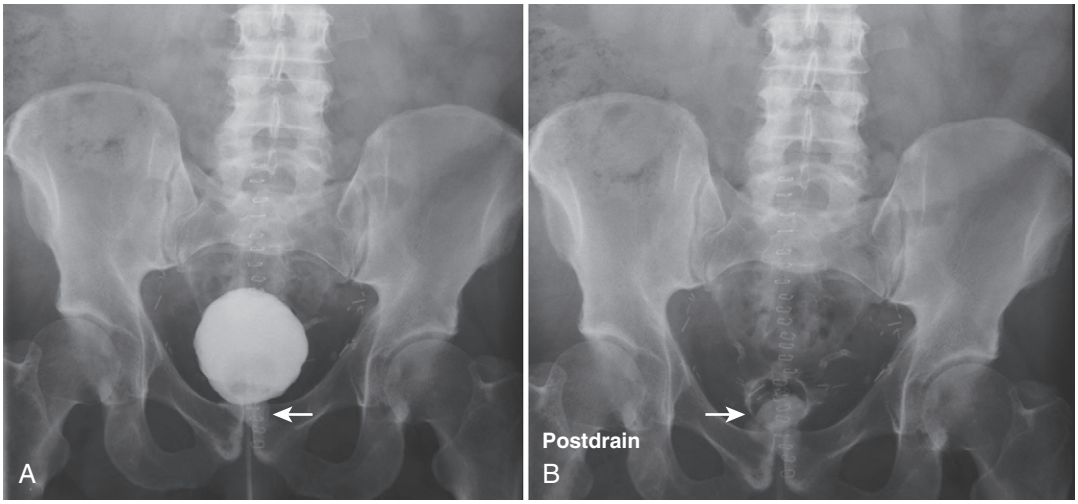

Figure 4–10. The patient has undergone radical retropubic prostatectomy. **A,** During bladder filling, contrast is seen adjacent to the vesicoureteral anastomoses *(arrow)*. **B,** The postdrain film clearly demonstrates a collection of extravasated contrast *(arrow)*.

posterior diverticula or fistulae may be obscured by the full bladder. A postdrainage film completes the study (Fig. 4–10).

Indications

1. Evaluation of intravesical pathology
2. Evaluation of bladder diverticula
3. Evaluation of inguinal hernia involving the bladder
4. Evaluation of colovesical or vesico-vaginal fistulae
5. Evaluation of bladder or anastomotic integrity after surgical procedure
6. Evaluation of blunt or penetrating trauma to the bladder

Limitations

Abdominal and pelvic CT is so commonly used in the evaluation of blunt or penetrating trauma to the abdomen that CT cystography is often performed in conjunction with the trauma evaluation. However, studies have shown that conventional static cystography is as sensitive as CT cystography in detecting bladder rupture (Quagliano et al, 2006; Broghammer and Wessells, 2008).

VOIDING CYSTOURETHROGRAM

A voiding cystourethrogram (VCUG) is performed to evaluate the anatomy and physiology of the bladder and urethra. The study provides valuable information regarding the posterior urethra in pediatric patients. VCUG has long been used to demonstrate vesicoureteral reflux.

Technique

The study may be performed with the patient supine or in a semiupright position using a table capable of bringing the patient into the full upright position. A preliminary pelvic plain radiograph is obtained. In children a 5- to 8-Fr feeding tube is used to fill the bladder to the appropriate volume. Patient comfort should be taken into account when determining the appropriate volume. In the adult population a standard catheter may be placed and the bladder filled to 200 to 400 mL. The catheter is removed and a film is obtained. During voiding, AP and oblique films are obtained. The bladder neck and urethra may be evaluated by fluoroscopy during voiding. Bilateral oblique views may demonstrate low-grade reflux, which cannot be appreciated on the AP film. In addition, oblique films will demonstrate bladder or urethral diverticula, which are not always visible in the straight AP projection. Postvoiding films should be performed (Fig. 4–11).

Indications

1. Evaluation of structural and functional bladder outlet obstruction
2. Evaluation of reflux
3. Evaluation of the urethra in males and females

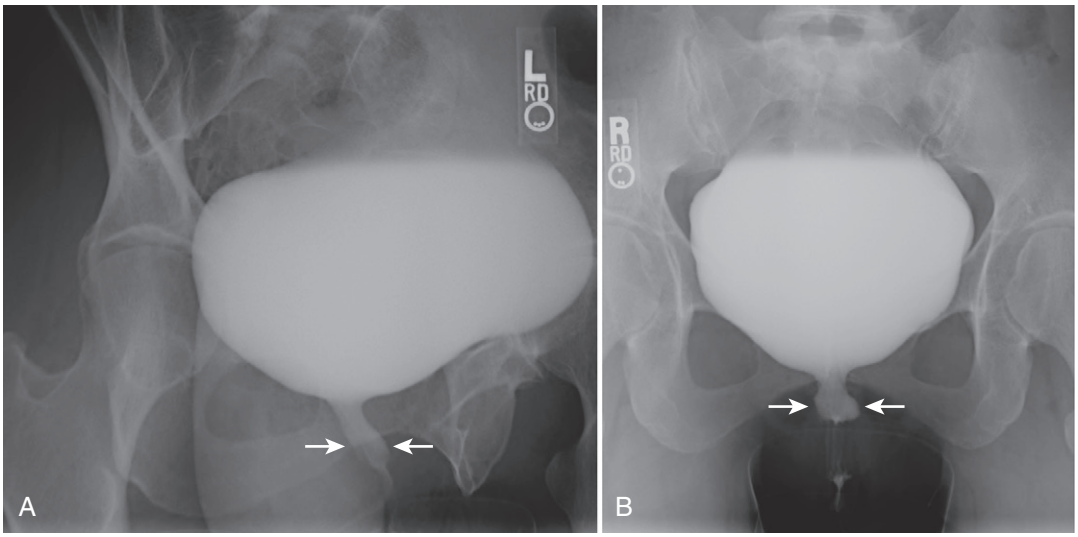

Figure 4–11. A voiding cystourethrography performed for the evaluation of recurrent urinary tract infection in this female patient. **A,** An oblique film during voiding demonstrates thickening of the midureteral profile *(arrows)*. **B,** After interruption of voiding, a ureteral diverticulum is clearly visible extending posteriorly and to the left of the midline *(arrows)*.

Limitations

This study requires bladder filling using a catheter. This may be traumatic in children and difficult in some patients with anatomic abnormalities of the urethra or bladder neck. Filling of the bladder may stimulate bladder spasms at low volumes, and some patients are unable to hold adequate volumes for investigation. **Bladder filling in patients with spinal cord injuries higher than T6 may precipitate autonomic dysreflexia** (Barbaric, 1976; Fleischman and Shah, 1977; Linsenmeyer et al, 1996).

ULTRASONOGRAPHY

The use of ultrasonography is fundamental to the practice of urology. Ultrasonography is a versatile and relatively inexpensive imaging modality that has the unique feature of being the only imaging modality to provide real-time evaluation of urologic organs and structures without the need for ionizing radiation. In order for urologists to best use this technology on behalf of their patients, they must have a mature understanding of the underlying physical principles of ultrasound. They must also understand how the manipulation of ultrasound equipment can affect the quality of ultrasound images. The technical skills required to perform and interpret urologic ultrasonography represent a combination of practical scanning ability and knowledge of the underlying disease process in organs being imaged. In order to communicate the findings appropriately, urologists should understand the nomenclature of ultrasonography and have a specific plan for documentation of each type of study. Understanding how ultrasonography interacts with human tissues will allow urologists to use this modality effectively, appropriately, and safely.

Principles

All ultrasound imaging is the result of the interaction of sound waves with tissues and structures within the human body. Ultrasound waves are produced by applying short bursts of alternating electrical current to a series of crystals housed in the transducer. Alternating expansion and contraction of the crystals via the piezoelectric effect creates a mechanical wave that is transmitted

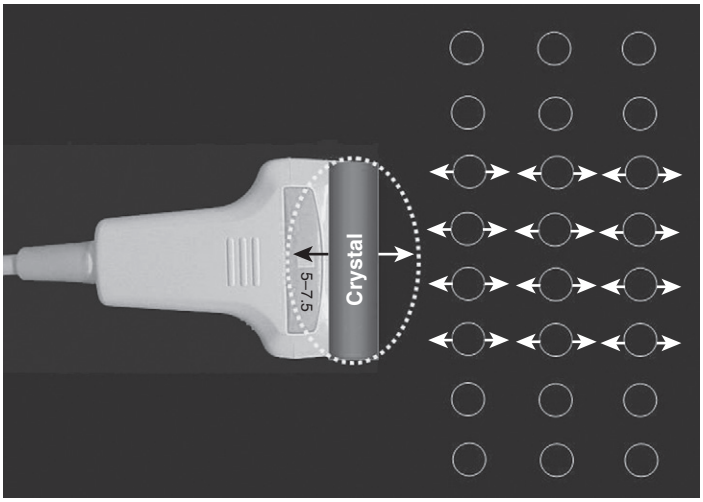

Figure 4–12. The alternating expansion and contraction of the crystal produces longitudinal mechanical waves. In this simplified schematic drawing, the individual molecules (depicted as *circles*) are displaced in the direction of the propagated wave.

through a coupling medium to the skin and then into the body. The waves that are produced are longitudinal waves. In a longitudinal wave the particle motion is in the same direction as the propagation of the wave (Fig. 4–12). This motion produces areas of rarefaction and compression of tissue in the direction of travel of the ultrasound wave (Fig. 4–13). A portion of the wave is reflected toward the transducer. The transducer then serves as a receiver and "listens" for the returning sound wave reconverting the mechanical to electrical energy. The transducer must be in direct, secure contact with the subject to transmit and receive the reflected sound waves.

The appearance of the image produced by ultrasonography is the result of the interaction of mechanical ultrasound waves with biologic tissues and materials. Because ultrasound waves are transmitted and received at frequent intervals, the images can be rapidly reconstructed and refreshed, providing a real-time image. The frequency of the sound waves used for urologic ultrasound imaging is in the range of 3.5 MHz to 12 MHz.

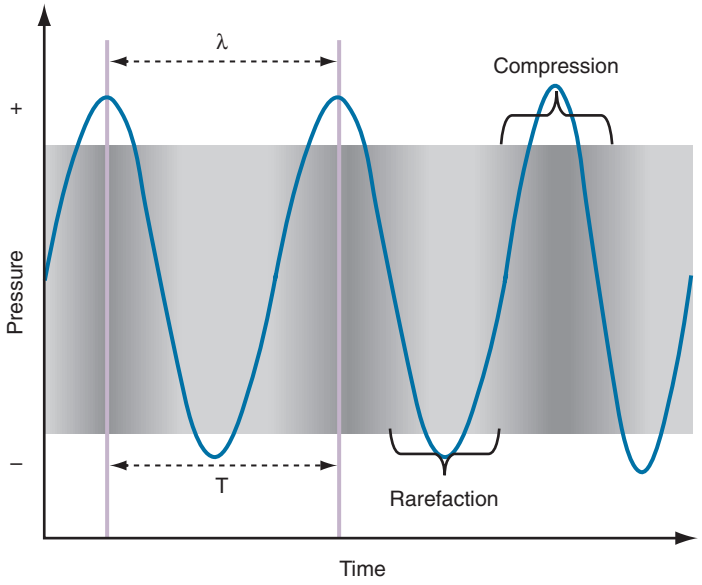

Figure 4–13. Areas of compression alternating with areas of rarefaction are depicted as a sine wave. The wavelength (λ) is the length from peak compression to peak compression in this drawing. This graphic depiction is critical to the understanding of the behavior of sound waves in the human body and of how ultrasound images are generated. (Adapted from Merritt CRB. Physics of ultrasound. In: Rumack CM, Wilson SR, Charboneau JW, editors: Diagnostic ultrasound. 3rd ed. St Louis: Elsevier; 2005. p. 4.)

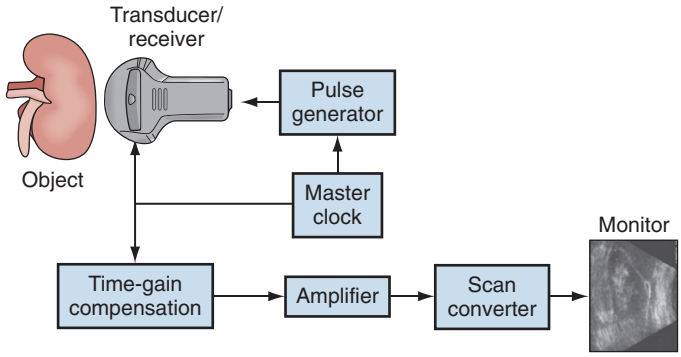

Figure 4–14. In this simplified schematic diagram of ultrasound imaging, the ultrasound wave is produced by virtue of a pulse generator controlled by a master clock. The reflected waves received by the transducer are analyzed for amplitude and transit time within the body. The scan converter produces the familiar picture seen on the monitor. The actual image is a series of vertical lines that are continuously refreshed to produce the familiar real-time, gray-scale image.

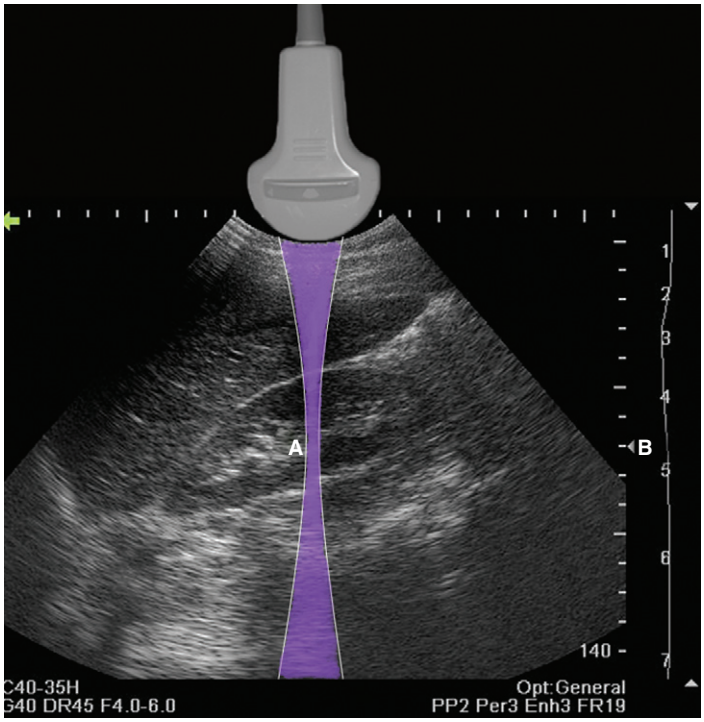

Figure 4–15. The shape of the ultrasound beam is simulated in this drawing (purple). The focal zone (**A**) is located to produce the best lateral resolution of the medial renal cortex. The location of the focal zone is designated by the caret (**B**). The location of the focal zone can be adjusted by the operator.

Mechanical waves are represented graphically as a sine wave alternating between a positive and negative direction from the baseline. Ultrasound waves are described using the standard nomenclature for sine waves. A wavelength (λ) is described as the distance between one peak of the wave and the next peak. The complete path traveled by the wave from one peak to the next is called a *cycle*. One cycle per second is known as *1 hertz* (Hz). The "period" is the time it takes for one complete cycle of the wave.

The "amplitude" of a wave is the maximal excursion in the positive or negative direction from the baseline. Amplitude corresponds to the mechanical energy associated with the sound wave and is a key property in assigning pixel brightness to a gray-scale ultrasound image. The greater the amplitude is, the brighter the corresponding pixel.

Ultrasound Image Generation

The image produced by an ultrasound machine begins with the transducer. In ultrasound imaging, the transducer has a dual function as a sender and receiver. Sound waves are created in short pulses and transmitted into the body and are then at least partially reflected. Reflected mechanical sound waves are received by the transducer and converted back into electrical energy. The transducer acts as a receiver more than 99% of the time. The electrical energy is converted by the ultrasound instrument to an image displayed on a monitor (Fig. 4–14).

Resolution

The resolution of an ultrasound image refers to the ability to discriminate two objects in close proximity to one another. **Axial resolution** refers to the ability to identify as separate two objects in the direction of the traveling sound wave. Axial resolution is directly dependent on the frequency of sound waves. The higher the sound wave's frequency is, the better the axial resolution. **Lateral resolution** refers to the ability to identify separately objects that are equidistant from the transducer. Lateral resolution is a function of the focused width of the ultrasound beam and is a characteristic of the transducer. The location of the narrowest beam width can be adjusted by the user. The more focused the beam is, the better the lateral resolution at that location. Thus image quality can be enhanced by locating the narrowest beam width (focus or focal zone) at the depth of the object or tissue of interest (Fig. 4–15).

The velocity with which a sound wave travels through tissue is a product of its frequency and wavelength (Fig. 4–16). The **average velocity of sound in human tissues is 1540 meters per**

second. Because the average velocity of sound in tissue is a constant, changes in frequency will result in changes in wavelength.

The optimal ultrasound image requires tradeoffs between resolution and depth of penetration. High-frequency transducers of 6 to 10 MHz may be used to image structures near the surface of the body (e.g., testis, pediatric kidney) with excellent resolution. However, deeper structures (e.g., right kidney, bladder) require lower frequencies of 3.5 to 5 MHz to penetrate. Such images will have poorer axial resolution.

Mechanisms of Attenuation

As sound waves transit tissues, energy is lost or attenuated. Mechanisms of attenuation include **reflection, scattering, interference, and absorption**. Reflection is the key physical phenomenon that allows for information to return to the transducer as mechanical energy. Reflection occurs when ultrasound waves strike an object, a surface, or a boundary (called an **interface**) between unlike tissues. The shape and size of the object and the angle at which the advancing wave strikes the object are critical determinants of the amount of energy reflected. The amount of energy reflected from an interface is also influenced by the **impedance** of the two tissues at the interface. Impedance is a property that is influenced by tissue stiffness and density. It is the difference in impedance that allows an appreciation of interfaces between different types of tissue (Table 4–5).

The impedance difference between perinephric fat and the kidney allows a sharp visual distinction at the interface. If the impedance difference between tissues is small (such as that between liver and kidney), the interface between the tissues will be more difficult to see (Fig. 4–17A). If impedance differences are large, there will be significant reflection of the sound wave producing an acoustical shadow distal to the interface (Fig. 4–17B).

Scattering occurs when sound waves strike a small or irregular object. The resulting spherical wave overlaps those of surrounding scattering objects (Fig. 4–18).

When interacting sound waves are in phase or out of phase, their amplitude will be enhanced or diminished. This **pattern of interference** is partially responsible for the echo architecture or texture of organs. One pattern of interference, commonly called **"speckling"** (Fig. 4–19), is seen in organs with fine, internal histology such as the testis.

Absorption occurs when the mechanical energy of the ultrasound waves is converted to heat. Absorption is directly proportional to frequency. Therefore the higher the frequency of the incident wave, the greater will be the absorption of energy and the more tissue heating that will result. It follows that higher-frequency waves are more rapidly attenuated and therefore have a limited depth of penetration (Fig. 4–20).

$$v = f \times \lambda$$
$$\textit{velocity} = \textit{frequency} \times \textit{wavelength}$$

Figure 4–16. The relationship between velocity, frequency, and wavelength of sound waves in tissue. Wavelength and frequency vary in an inverse relationship.

Artifacts

The interaction of ultrasound waves with tissues may produce images that do not reflect the true underlying anatomy. These misrepresentations are called "artifacts." Artifacts may be

Table 4–5.

Density and Impedance of Tissues Encountered During Urologic Ultrasound

	DENSITY	IMPEDANCE
Air and other gases	1.2	0.0004
Fat tissue	952	1.38
Water and other clear liquids	1000	1.48
Kidney (average of soft tissue)	1060	1.63
Liver	1060	1.64
Muscle	1080	1.70
Bone and other calcified objects	1912	7.8

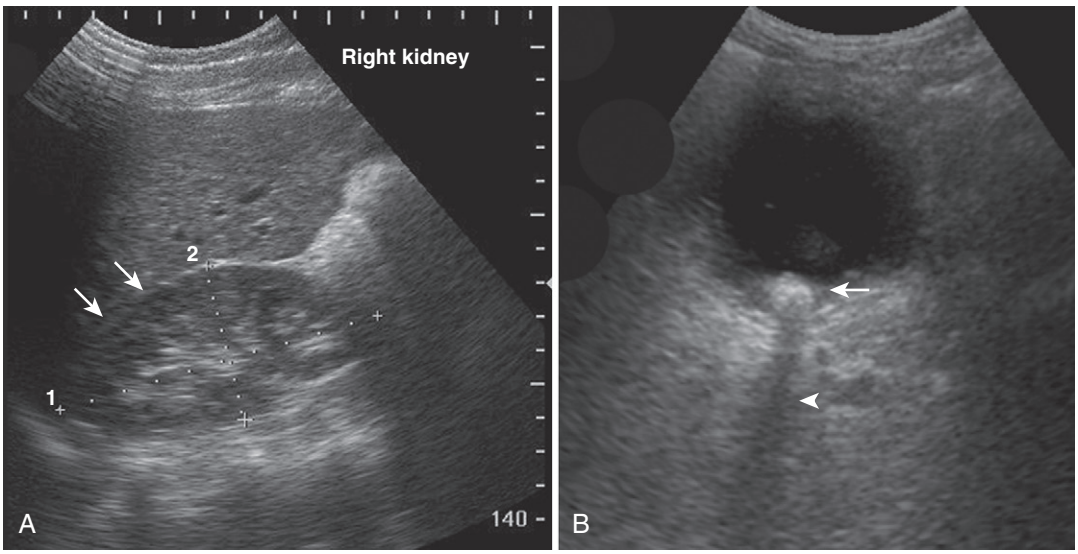

Figure 4–17. **A,** In this sagittal view of the right kidney, the paucity of perinephric fat and the small impedance difference make it difficult to distinguish the interface between the kidney and the liver *(arrows)*. **B,** The large impedance difference at the interface between urine and this bladder stone *(arrow)* results in significant reflection and attenuation of the sound wave. An acoustic shadow is seen distal to the stone *(arrowhead)*.

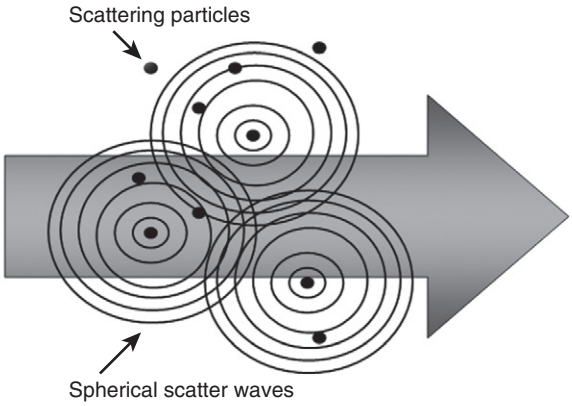

Figure 4–18. Scattering is a phenomenon that occurs when sound waves strike small objects. The resulting pattern of energy dispersal often results in interference.

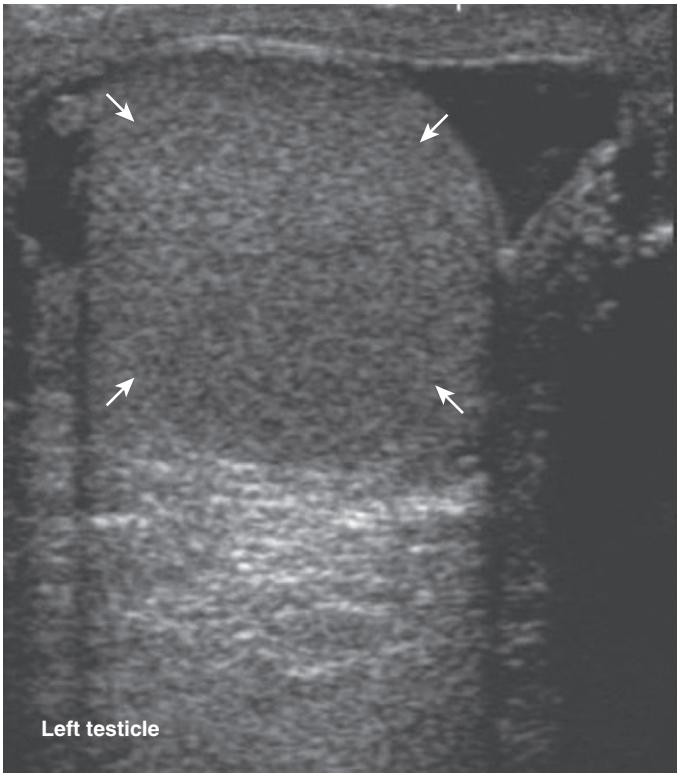

Figure 4–19. Fine internal echogenicity called "speckle" is caused by scattering of sound waves and the resultant pattern of interference. Note the resulting finely granular, homogenous echogenicity *(arrows)* of the testicular parenchyma.

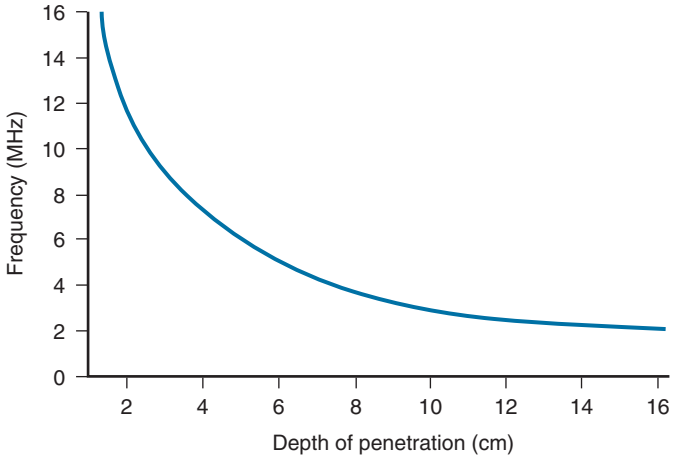

Figure 4–20. The relationship between frequency and tissue penetration. High-frequency sound waves are rapidly attenuated and are unable to penetrate deeply. Conversely, low-frequency waves are less attenuated and able to penetrate deeply to internal structures.

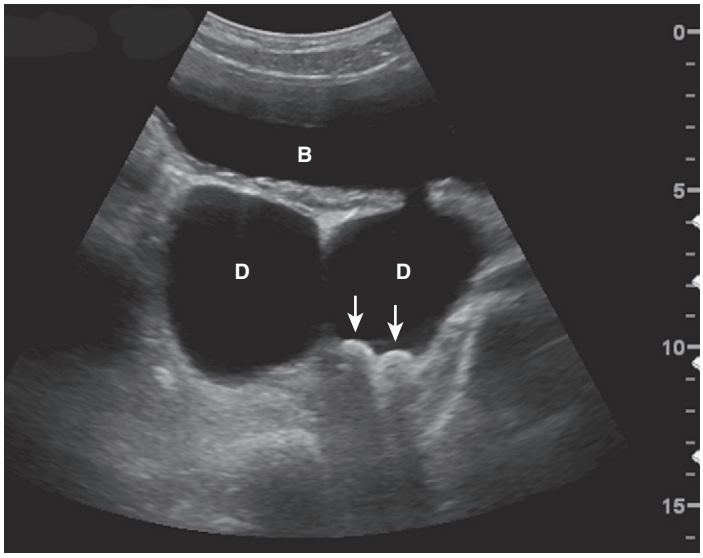

Figure 4–21. In this transverse view of the urinary bladder (B), there are two large bladder diverticula (D). Two stones *(arrows)* strongly reflect and attenuate the incident sound wave, producing an acoustical shadow. Note that the stones appear crescentic even though they are ovoid in shape.

misleading but, if recognized, may also assist diagnosis. **Acoustical shadowing** occurs when there is significant attenuation of sound waves at a tissue interface. Echo information posterior to the interface may be obscured or lost. An anechoic or hypoechoic "shadow" is produced. Under these conditions, three-dimensional objects such as stones may appear as crescentic objects, making it difficult to obtain accurate measurements (Fig. 4–21). Important pathology posterior to such an interface may be missed. This problem may often be overcome by changing the angle of insonation, changing the frequency of the transducer, or changing the focal zone of the transducer.

Increased through transmission is observed when sound waves are less attenuated while passing through a given structure or tissue than by the surrounding tissues. For example, when imaging a simple cyst of the kidney, sound waves passing through the cyst are less attenuated than those passing through the surrounding renal cortex and renal sinus. When the waves transiting the cyst strike the back wall of the cyst and posterior renal tissue, the waves are more energetic on arrival to these tissues. The reflected sound waves are also more energetic and less attenuated as they return to the transducer. The result is that tissue posterior to the cyst appears hyperechoic compared with the surrounding renal tissue, even though the tissues are histologically identical (Fig. 4–22). The effect of this artifact can be mitigated by changing the angle of insonation or adjusting the time-gain compensation (TGC) settings.

An **edging artifact** occurs when sound waves strike a curved surface or interface at an incident angle, resulting in refraction of the wave along the plane of the interface (Fig. 4–23).

An incident wave at this angle (the critical angle) will not be directly reflected to the transducer, resulting in a hypoechoic "shadow." This artifact is commonly seen in testicular ultrasonography and transrectal ultrasonography (Fig. 4–24). It can be overcome by changing the angle of insonation.

A **reverberation artifact** results when there are large differences in impedance between two adjacent tissues or surfaces with a strong reflection of the incident wave. The ultrasound wave bounces back and forth (reverberates) between the transducer interface and the reflective interface. With the second transit of the sound wave, the ultrasound equipment interprets a second object that is twice as far away as the first. There is ongoing attenuation of the sound wave with each successive reverberation, resulting in a slightly less intense image displayed on the screen. Therefore echoes are produced, spaced at equal intervals from the transducer but progressively less intense (Fig. 4–25).

The reverberation artifact can also be seen in cases where the incident sound wave strikes a series of smaller reflective objects (such as the gas-fluid mixture in the small bowel), which results in multiple reflected sound waves of various angles and intensity (Fig. 4–26). The resultant echo pattern is a collection of hyperechoic artifactual reflections distal to the structure with progressive attenuation of the sound wave.

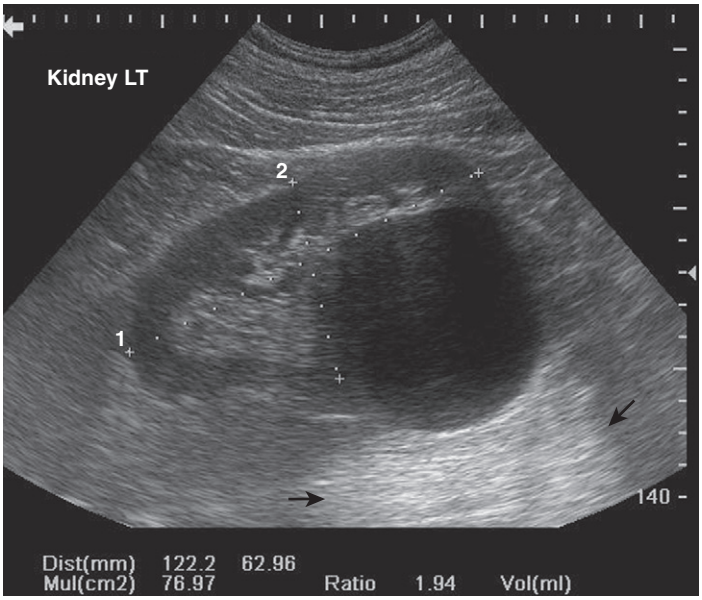

Figure 4–22. Increased thru-transmission (also called *distal enhancement*) is demonstrated in this longitudinal view of the left kidney. The tissue distal to the cyst appears hyperechoic (indicated by *arrows*) compared with adjacent tissue.

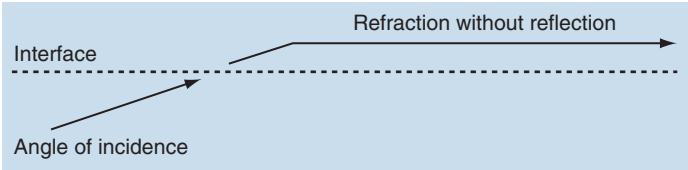

Figure 4–23. When sound waves strike a surface or interface at a "critical angle," the wave is refracted without significant reflection.

Modes of Ultrasound

Gray-Scale Ultrasound

Gray-scale B-mode ultrasonography is the most commonly employed mode of ultrasound. This pulsed-wave technique produces real-time two-dimensional images consisting of shades of gray. The generation of this image involves assigning a pixel brightness to the amplitude of the returning sound waves received by the transducer. The position of the pixel is determined by the duration of the round trip of the sound wave. Individual lines of data are displayed sequentially on the monitor to produce a continuous or real-time image. Evaluation of gray-scale imaging requires the ability to recognize normal patterns of echogenicity from anatomic structures. Variations from these expected patterns of echogenicity indicate disorders of anatomy or physiology.

Doppler Ultrasound

The Doppler ultrasound mode depends on the physical principle of frequency shift when sound waves strike a moving object. The basic principle of Doppler ultrasound is that sound waves of a certain frequency will be shifted or changed on the basis of the direction and velocity of the moving object, as well as the angle of insonation. This phenomenon allows for the characterization of motion, most commonly the motion of blood through vessels, but it may also be useful for detecting the flow of urine.

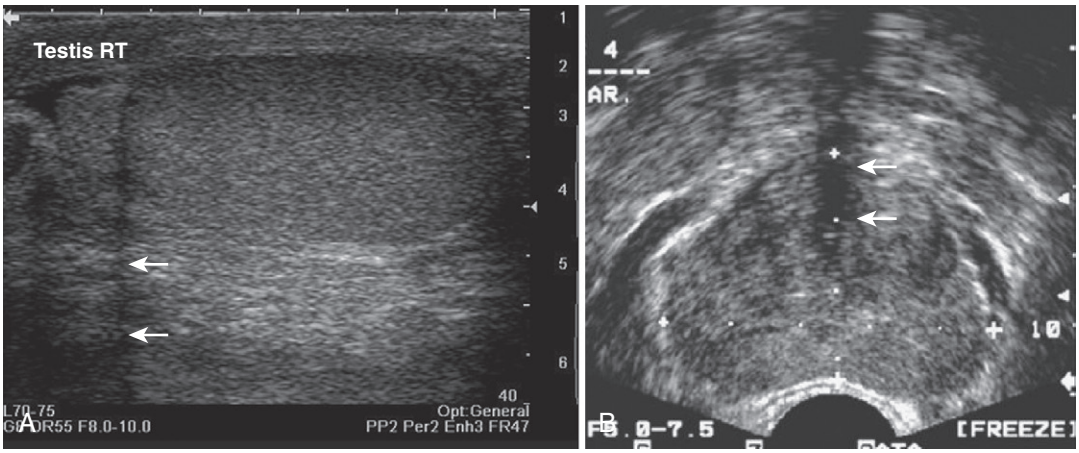

Figure 4–24. **A,** The curved surface of the tunica albuginea of the upper pole of testis creates a critical angle edging artifact *(arrows)*. **B,** The rounded surfaces of the lateral lobes of the prostate as they meet in the prostatic urethra create an edging artifact *(arrows)* in this transverse image of the prostate.

Color Doppler ultrasonography allows for evaluation of the velocity and direction of motion. A color map may be applied to direction with the most common assignation of the color blue to motion away from the transducer and red for motion toward the transducer. The velocity of motion is designated by the intensity of the color; thus the brighter the color is, the more rapid the motion. Color Doppler may be used to evaluate the presence of absence of blood flow in the kidney, testes, penis, and prostate. It also may be useful in the detection of ureteral "jets" of urine emerging from the ureteral orifices.

Color Flow with Spectral Display is a mode that allows the interrogation of particular areas within an ultrasound image for flow and displays the flow as a continuous wave form. This mode is commonly used to evaluate the pattern and velocity of blood flow in the intrarenal or penile vasculature. The waveform provides information about peripheral vascular resistance in the tissues. The most commonly used index of these velocities is the resistive index. The **resistive index** is a ratio of peak systolic velocity minus the end-diastolic velocity over the peak systolic velocity. This index is helpful in characterizing a number of clinical conditions including renal artery stenosis, ureteral obstruction, and penile arterial insufficiency.

Power Doppler ultrasonography is a mode that assigns the amplitude of frequency change to a color map. This does not permit evaluation of velocity or direction of flow but is less affected by back-scattered waves and therefore a more sensitive mode for detecting blood flow. Power Doppler is less angle dependent than color Doppler and is three to five times as sensitive as color Doppler ultrasound for detecting flow.

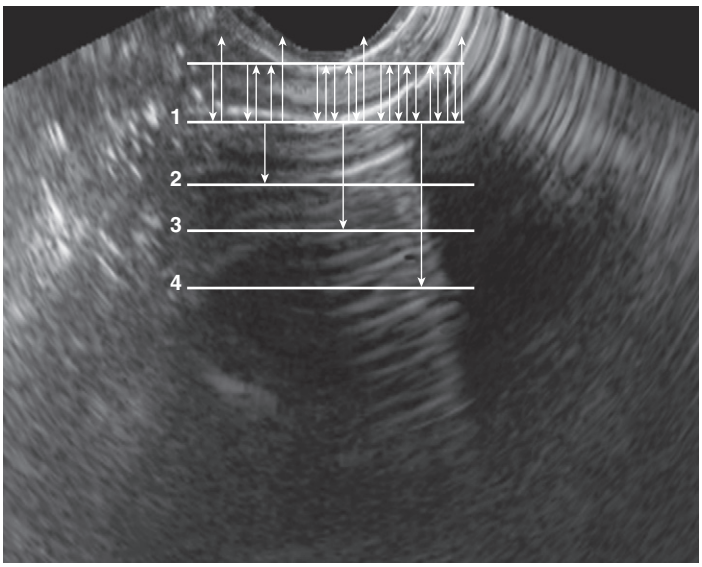

Figure 4–25. Reverberation artifact: The strongly reflective interface is projected with decreasing amplitude as the incident sound wave makes multiple round trips.

Harmonic Scanning

Harmonic scanning makes use of aberrations related to the nonlinear propagation of sound waves within tissue. These asymmetrically propagated waves generate fewer harmonics, but those that are generated have greater amplitudes. Because these harmonics are not subject to scattering associated with the incident wave, there is less noise associated with the signal. By concentrating on the harmonic frequencies produced within the body and reflected to the transducer, it is possible to produce an image with less artifact and greater resolution (Fig. 4–27).

Spatial Compounding

Spatial compounding is a scanning mode whereby the direction of insonation is electronically altered and a composite image is generated. This technique reduces the amount of artifact and noise, producing a scan of better clarity.

Three-Dimensional Scanning

Three-dimensional (3-D) scanning has been used extensively in obstetrics and gynecology but so far has limited application in urology. 3-D scanning produces a composite of images (data set), which can then be manipulated to generate additional views of the anatomy in question (Fig. 4–28). 3-D rendering may be important in procedural planning and precise volumetric assessments

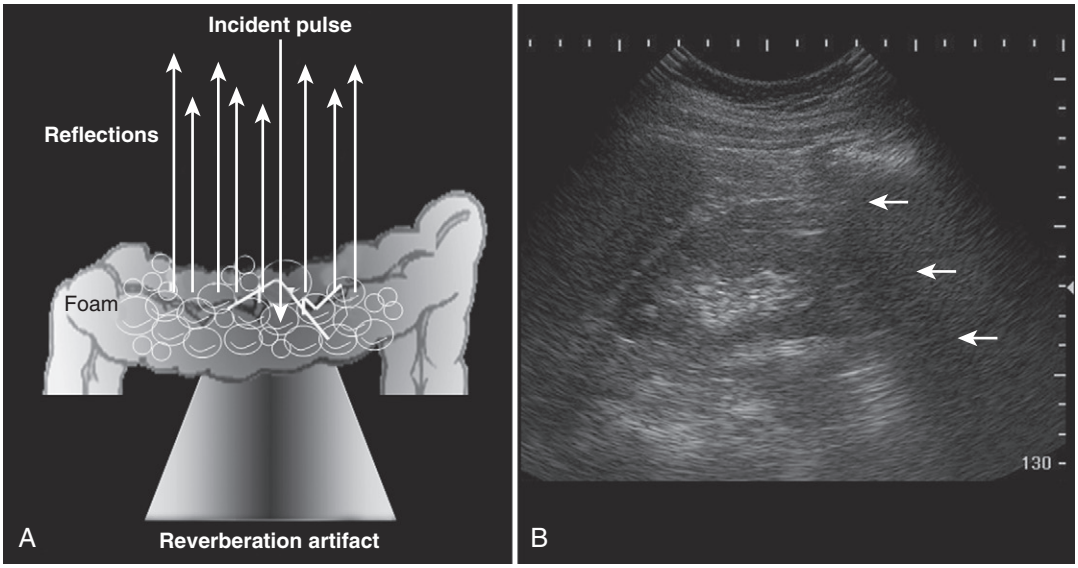

Figure 4–26. When ultrasound strikes a structure such as bowel, which contains gas bubbles (**A**), the resultant reverberation artifact has a characteristic appearance sometimes called a "comet tail." **B,** A comet tail artifact produced by bowel gas *(arrows)* obscures the lower pole of the kidney.

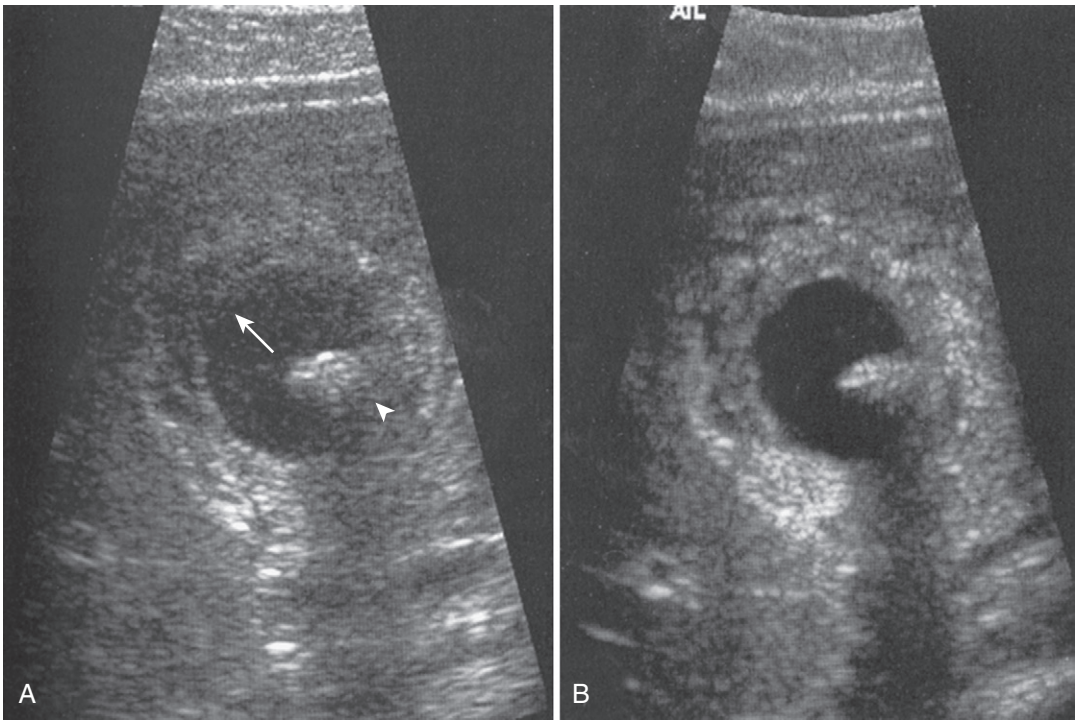

Figure 4–27. **A,** Standard gray-scale image of a cyst containing a mural nodule *(arrowhead)*. Note the artifactual echogenicity within the cyst *(arrow)*. **B,** The same structure on harmonic scanning is more clearly seen. There is less artifact within and distal to the cyst. (From Rumack CM, Wilson, SR, Charboneau JW, Johnson J, editors. Diagnostic ultrasound. 3rd ed. St Louis: Elsevier; 2005. Fig. 1–17, p. 17.)

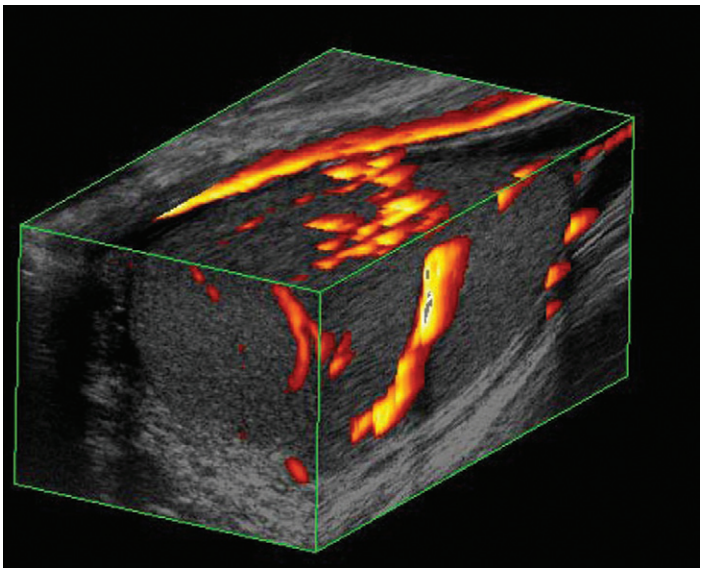

Figure 4–28. A three-dimensional image of the testis demonstrating intratesticular blood flow on power Doppler. The image can be virtually rotated and manipulated to produce unique anatomic perspectives. (Used with permission by BK Medical.)

(Ghani et al, 2008a, 2008b). 3-D scanning may allow the recognition of some tissue patterns that would otherwise be inapparent on two-dimensional scanning (Mitterberger et al, 2007b; Onik and Barzell, 2008).

Contrast Agents in Ultrasound

Intravenous compounds that contain microbubbles have been used for enhancing the echogenicity of blood and tissue.

Description of ultrasound images

The liver is used as a benchmark for echogenicity:

- Hypoechoic = darker and black
- Hyperechoic = brighter and white
- Isoechoic = similar to reference point of liver
- Anechoic = black, without echoes

Figure 4–29. The nomenclature for describing the appearance of ultrasound images.

Microbubbles are distributed in the vascular system and create strong echoes with harmonics when struck by sound waves. The bubbles themselves are rapidly degraded by their interaction with the sound waves. Contrast agents may be useful in prostatic ultrasonography by enhancing the ability to recognize areas of increased vasculature. The use of intravenous ultrasound contrast agents is considered investigational but has shown promise in a number of urologic scanning situations (Mitterberger et al, 2007a; Wink et al, 2008).

Documentation

When urologists perform and interpret ultrasound studies, it is important that appropriate nomenclature be used to describe the objects imaged (Fig. 4–29). By convention, the liver is used as a benchmark for echogenicity. If a structure is hypoechoic, it means it is darker than the surrounding tissues. If it is hyperechoic, it means it is brighter than the surrounding tissues. Isoechoic means it is similar to the surrounding tissues. Structures that do not generate echoes are called *anechoic*. A simple cyst is an example of a structure with an anechoic interior. In general, a high water content causes tissue to appear hypoechoic. In general, a high fat content causes tissue to appear hyperechoic.

By convention, structures imaged by ultrasonography should be oriented so that the superior aspect of the structure is to the left as the image is viewed and the inferior aspect of the structure to the right. With paired structures it is critically important to document right or left. It is useful to use equipment-generated icons to illustrate patient position and the orientation of insonation (Fig. 4–30).

The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.

Patient Safety

Diagnostic ultrasonography transmits energy into the patient that has the potential to produce biologic effects. The two main categories of biologic effects are **mechanical effects** and **thermal effects.**

The mechanical effects of ultrasonography are torque and streaming. The mechanical effects of an acoustic field may produce a phenomenon called *cavitation.* **Cavitation** occurs when small gas-filled bubbles form and then collapse. These collapsing bubbles liberate a large amount of energy, which may cause damage to tissue in certain circumstances. Mechanical effects are most likely to be observed around gas-containing structures such as lung and bowel. The thermal effects of ultrasonography are primarily the result of tissue heating resulting from the absorption of energy. The amount of tissue heating is influenced by several factors including beam focusing, transducer frequency, exposure time, scanning mode, and tissue density.

To assist the sonographer in monitoring the bioeffects of ultrasound, the ultrasonography community has adopted the **output display standard (ODS).** Two values are typically displayed: the **mechanical index (MI)** and the **thermal index (TI).** These indices are calculated **estimates** of the potential for bioeffects of ultrasonography based on the mode of ultrasonography being used, frequency, power output, and time of insonation. The MI indicates the probability that cavitation will occur. For tissues not containing stabilized gas bodies (lung and intestine), the risk of cavitation is low as long as the MI is less than or equal to 0.7. For structures adjacent to lung or intestine, scanning time should be limited if the MI exceeds 0.4. The TI indicates the probability that tissue temperature within the sonographic field will be increased by 1° C. The precise consequences of tissue heating are not completely understood, but even tissue temperature elevations of up to 6° C are not likely to be dangerous unless exposure time exceeds 60 seconds. The MI and TI are typically displayed on the monitor during ultrasound examinations, and all practitioners should be familiar with the location. **It is important to note that these indices are not safety limits.**

In general, ultrasonography performed by urologists has a low risk for patient harm as long as standard protocols are followed (Fowlkes, 2008). Although tissue heating may occur, there are no confirmed biologic effects of tissue heating in nonfetal scanning except when they are sustained for extended periods. Users should be aware that for soft tissues not known to contain gas bodies, there is no basis in present knowledge to suggest an adverse nonthermal bioeffect from current diagnostic instruments not exceeding the U.S. Food and Drug Administration output limits (Fowlkes, 2008). Nevertheless, all urologists should endeavor to follow the principles of **ALARA,** which stands for **"As Low As Reasonably Achievable."** The ALARA principle is intended to limit the total energy imparted to the patient during an examination. This can be accomplished by (1) keeping power outputs low, (2) using appropriate scanning modes, (3) limiting examination times, (4) adjusting focus and frequency, and (5) using the cine function during documentation.

In summary, ultrasound scanning offers an excellent, cost-effective modality for diagnosing and treating urologic conditions. **The most important factor in ultrasound safety is the informed operator.** Urologists should endeavor to perform limited examinations using consistent technique for specific indications. Patient safety and equipment maintenance should be emphasized in all the environments where ultrasound technology is used.

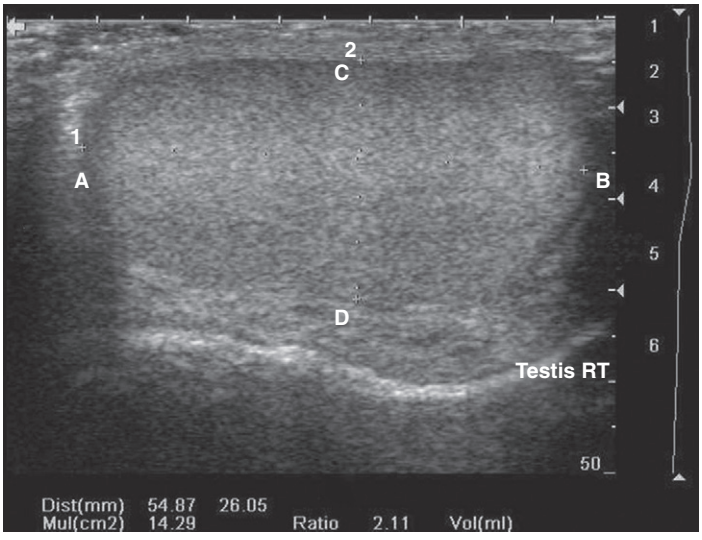

Figure 4–30. In this sagittal image of the right testis, the superior pole of the testis (A) is to the left, the inferior pole of the testis (B) is to the right. The anterior aspect of the testis (C) is at the top of the image and the posterior aspect (D) at the bottom. Without the label, there would be no way to distinguish the right from the left testis.

Clinical Urologic Ultrasound

The use of ultrasonography in urology has expanded dramatically because of its profound utility in the clinic and operating room. Long the mainstay of the diagnosis of prostatic disease, ultrasonography is increasingly being used by urologists in the clinical environment for initial diagnosis, interventional management, and longitudinal follow-up of urologic diseases.

Renal Ultrasound

Introduction. Urologists, by virtue of their intimate knowledge of surgical anatomy of the kidneys and retroperitoneum, are uniquely qualified to perform and interpret selected ultrasound examinations of the abdomen. These skills are relevant in both the office and the operating room environment. Urologists generally perform abdominal ultrasonography for a specific clinical indication and less often for general screening of the abdominal contents. Therefore in most clinical situations, a limited retroperitoneal examination is used in urologic practice.

Technique. The transducer normally used for renal ultrasonography is a curved array transducer of 3.5 to 5.0 MHz. Transducers of a higher frequency may be used for pediatric patients. For intraoperative and laparoscopic renal ultrasonography, a linear array transducer of 6 to 10 MHz is typically employed.

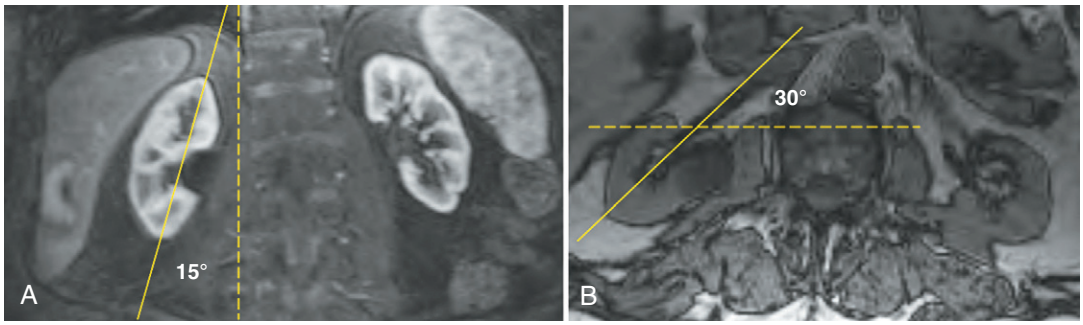

Figure 4–31. The lower pole of the kidney is displaced 15 degrees laterally compared with the upper pole (**A**). The kidney is rotated 30 degrees posterior to the true coronal plane (**B**). The lower pole of the kidney is slightly anterior compared with the upper pole.

Scanning of the right kidney is performed with the patient supine. The kidney is located by beginning in the midclavicular line in the right upper quadrant. In the sagittal plane the transducer is moved laterally until the midsagittal plane of the kidney is imaged. Once the kidney has been imaged anteriorly and posteriorly in the sagittal plane, the probe is rotated 90 degrees counterclockwise. The midtransverse plane will demonstrate the renal hilum containing the renal vein. The kidney is scanned from upper pole to lower pole.

The technique and documentation for left renal ultrasonography is identical to that of the right side. However, the left kidney is slightly more cephalad than the right kidney. Bowel gas is more problematic on the left because of the position of the splenic flexure of the colon. Visualization of the left kidney often requires the patient to be turned into a lateral position. Ultrasound imaging of the left kidney lacks the liver as an acoustic window, and it is sometimes more difficult to image the left kidney in a true sagittal plane.

Indications

1. Assessment of renal and perirenal masses
2. Assessment of the dilated upper urinary tract
3. Assessment of flank pain during pregnancy
4. Evaluation of hematuria in patients who are not candidates for intravenous pyelography (IVP), CT, or MRI because of renal insufficiency, contrast allergy, or physical impediment
5. Assessment of the effects of voiding on the upper urinary tract
6. Evaluation for and monitoring of urolithiasis
7. Intraoperative renal parenchyma and vascular imaging for ablation of renal masses
8. Percutaneous access to the renal collecting system
9. Guidance for transcutaneous renal biopsies, cyst aspiration, or ablation of renal masses
10. Postoperative evaluation of patients after renal and ureteral surgery
11. Postoperative evaluation of renal transplant patients

Normal Findings. It is helpful during scanning of the kidney to understand its anatomic position within the retroperitoneum. This assists identifying the midsagittal plane, which serves as a reference point for a complete examination (Fig. 4–31).

The adult right kidney in the sagittal view demonstrates a cortex that is usually hypoechoic with respect to the liver. The central band of echoes in the kidney is a hyperechoic area that contains the renal hilar adipose tissue, blood vessels, and collecting system. Acoustic shadowing from ribs overlying the inferior pole can be eliminated by moving the probe to a more lateral position or into the intercostal space. By having the patient take a deep breath, the kidney can be moved inferiorly to assist complete imaging (Fig. 4–32).

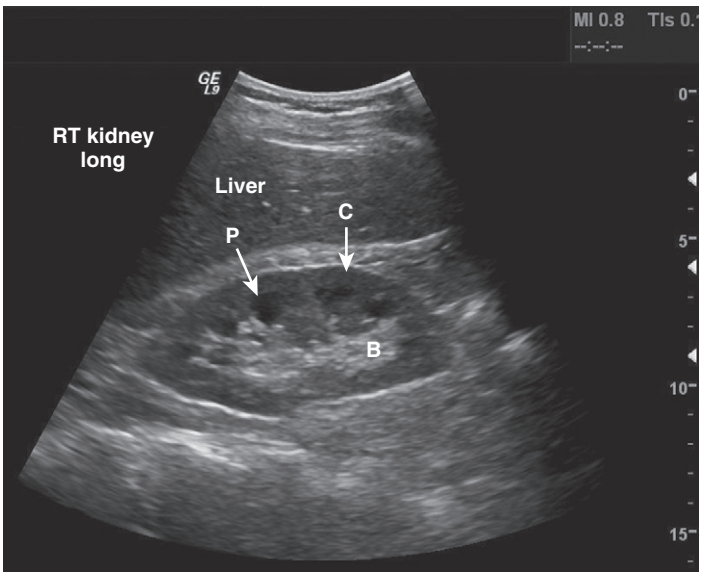

Figure 4–32. Midsagittal plane of the kidney. Note the relative hypoechogenicity of the renal pyramids (P) compared with the cortex (C). The central band of echoes (B) is hyperechoic compared with the cortex. The midsagittal plane will have the greatest length measurement pole to pole. A perfectly sagittal plane will result in a horizontal long axis of the kidney.

The echogenicity of the kidney varies with age. The renal cortex of an infant is relatively hyperechoic compared with that of an adult. In addition, there is a smaller and less apparent central band of echoes in the infant. In the adult, the echogenicity of the renal cortex is usually hypoechoic with respect to the liver (Emamian et al, 1993a). In patients with chronic medical renal diseases the renal cortex is often thinned and isoechoic or hyperechoic with respect to the liver (O'Neill, 2001).

Renal size changes over the lifetime of an individual. Nomograms for pediatric renal size should be consulted. These are based on age, height, and weight of the patient. The average adult kidney measures 10 to 12 cm in length and 4 to 5 cm in width. Measurements of renal volume may be appropriate in cases of severe renal impairment. Renal measurements should be obtained in the midsagittal plane and midtransverse plane. Measurements taken in other than the midsagittal plane and midtransverse may be spuriously low. The thickness of the parenchyma is the average distance between the renal capsule and the central band of echoes. The precise location for making this measurement is somewhat

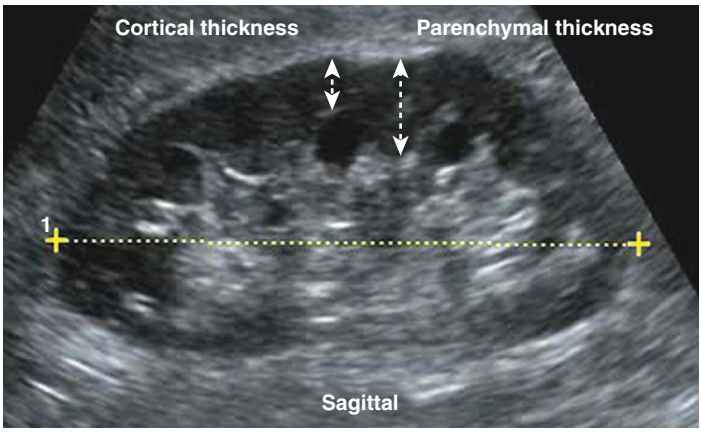

Figure 4–33. The distinction between renal cortical thickness and renal parenchymal thickness is that the renal parenchyma is measured from the central band of echoes to the renal capsule. The renal cortex is measured from the outer margin of the medullary pyramid to the renal capsule.

subjective. The midlateral renal parenchyma in the sagittal view is a common choice for obtaining this measurement (Fig. 4–33). Although there is no universal standard, the renal cortical thickness should be greater than 7 mm (Roger et al, 1994), and the renal parenchymal thickness should be greater than 15 mm in adults (Emamian et al, 1993b).

Doppler ultrasound may be helpful in evaluating the renal artery and renal vein and assessing the vascular resistance in the kidney. Doppler modes may also be useful in evaluating neovascularity associated with renal tumors and in correctly characterizing hypoechoic structures in the renal pelvis such as a parapelvic cyst, the renal vein, or the dilated collecting system.

Limitations. Some patients are not favorable candidates for renal ultrasonography. Obesity, intestinal gas, and physical deformity may be impediments to complete renal evaluation. Renal ultrasonography has poor sensitivity for renal masses less than 2 cm (Warshauer et al, 1988). There is a lack of specificity for renal tumor type except for angiomyolipoma. Angiomyolipoma has characteristics that are distinctive on ultrasonography (highly echoic), but some small renal cell carcinomas have been shown to be indistinguishable from angiomyolipoma by ultrasound criteria (Yamashita et al, 1992; Forman et al, 1993).

Transabdominal Pelvic Ultrasound

Introduction. Transabdominal pelvic ultrasonography is a tremendously versatile tool for the urologist. It is a noninvasive method for evaluating the lower urinary tract and prostate in men and the bladder in women. A curved array transducer of 3.5 to 5 MHz is most commonly employed to perform transabdominal ultrasonography. In pediatric patients a higher-frequency transducer may be used. In cases where only a residual urine or bladder volume is to be determined, an automated bladder scanner is often employed.

Technique. Bladder ultrasonography is most commonly performed with the patient supine and the sonographer on the patient's right side. The scan should be performed in a warm room, and the patient draped to provide for comfort and privacy. If necessary, a roll may be placed beneath the patient's hips. Scanning technique depends on the circumstances and the reason for the examination but in general should be performed with a moderately filled bladder. The bladder should be scanned in a sagittal and transverse manner angling the probe into the pelvis so that the bladder can be visualized beneath the pubic bone. Although the prostate cannot be imaged with the same resolution achieved during transrectal scanning, the size and morphology of the prostate can be demonstrated. Although transabdominal scanning is the most common means of evaluating the bladder, the bladder may also be assessed via a transvaginal and transrectal approach. These approaches are useful in patients who are obese or who are not suitable candidates for transabdominal scanning.

Indications

1. Measurement of bladder volume or postvoid residual urine
2. Assessment of prostate size and morphology
3. Demonstration of secondary signs of bladder outlet obstruction
4. Evaluate bladder wall configuration and thickness
5. Evaluation of hematuria of lower urinary tract origin
6. The detection of ureteroceles
7. Assessment for ureteral obstruction
8. Detection of perivesical fluid collections
9. Evaluation of clot retention
10. Confirmation of catheter position
11. Removal of retained catheter
12. Guidance of suprapubic tube placement
13. To establish bladder volume before flow rate determination

Normal Findings. Transabdominal pelvic ultrasonography should include evaluation of the lumen of the bladder, as well as bladder wall configuration and thickness. The presence of specific lesions such as stones or tumors should be documented. The structures immediately surrounding the bladder may also be evaluated including the distal ureters, the prostate in men, and the uterus and ovaries in women (Fig. 4–34). The emergence of urine from the ureteral orifices (ureteral jets) can be demonstrated. The clinical value of demonstrating ureteral jets has been questioned. Up to 10 minutes of continuous observation may be required to verify the absence of a ureteral jet (Fig. 4–35) (Delair and Kurzrock, 2006).

Bladder volume can be calculated manually by obtaining measurements in the midtransverse and midsagittal planes (Fig. 4–36). Numerous studies have shown that for bladder volumes between 100 and 500 mL, such calculated volumes are within 10% to 20% of the actual bladder volume (Roehrborn et al, 1986).

Measuring bladder wall thickness may assist the clinician in understanding the degree of bladder outlet obstruction (Fig. 4–37). Bladder wall thickness varies depending on the volume of urine in the bladder and on which part of the bladder wall is measured. It has been shown that measuring bladder wall thickness may predict bladder outlet obstruction with greater accuracy than free uroflowmetry, postvoid residual urine, and prostate volume (Oelke et al, 2007).

Transabdominal prostatic ultrasonography requires angling the probe beneath the pubic bone. In the transverse plane the transducer is fanned inferiorly until the largest transverse diameter of the prostate is identified. Measurements of the transverse width and height are obtained (Fig. 4–38A). The transducer is then rotated 90 degrees clockwise to produce a true sagittal image of the prostate. The transducer is fanned until the midline is identified. This is recognized by a v-shaped indention at the bladder neck (Fig. 4–38B). Depending on the degree of prostatic hypertrophy and the presence or absence of a middle lobe, this "v" may be more or less apparent and more or less anterior or posterior in its position. A sagittal measurement is made from the bladder neck to the apex of the prostate. The apex of the prostate may be identified by using the hypoechoic urethra as a guide.

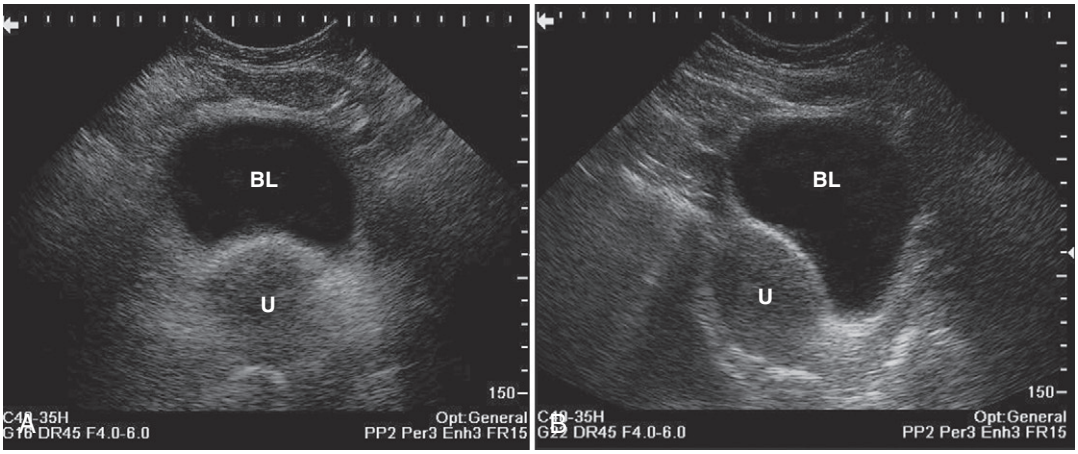

Figure 4–34. **A,** Transverse view of the bladder in this female patient demonstrates the uterus (U). **B,** Sagittal view of the bladder shows the uterus posterior to the bladder.

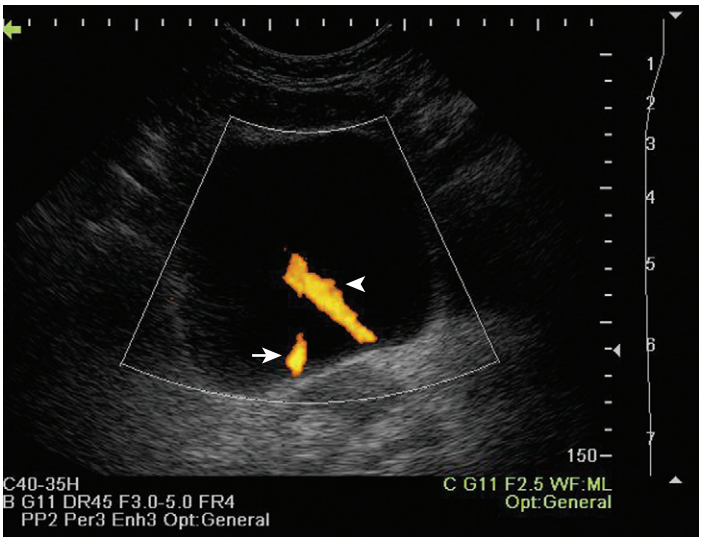

Figure 4–35. In this transverse view of the bladder, urine "jets" emerging from the left *(arrow)* and right *(arrowhead)* ureteral orifices are demonstrated by power Doppler.

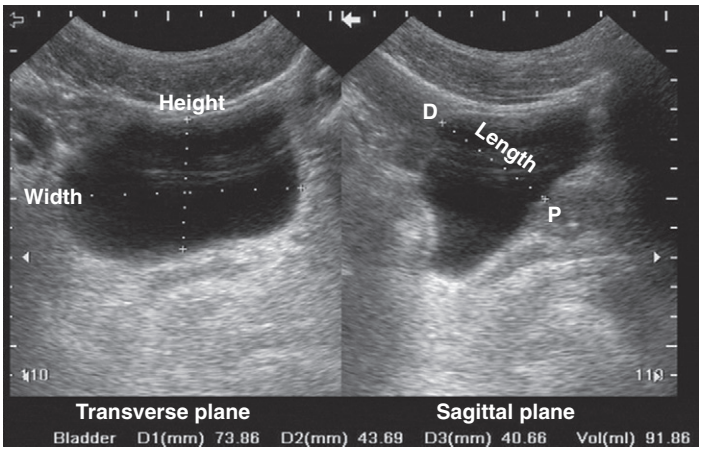

Figure 4–36. Measurement of bladder volume using this formula: bladder volume = width (transverse plane) × height (transverse plane) × length (midsagittal plane) × 0.625. In the sagittal plane, the dome (D) of the bladder is to the left and the prostate (P) to the right.

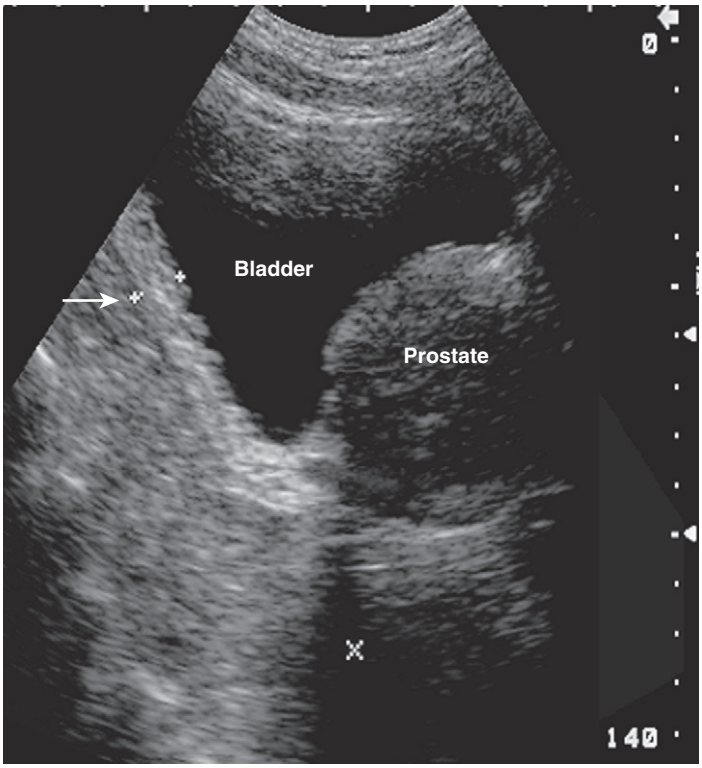

Figure 4–37. Bladder wall thickness may provide information about bladder outlet obstruction. In this sagittal view, bladder wall thickness is measured posteriorly *(arrow)* near the midline. Note the trabeculation of the relatively hyperechoic bladder wall.

The degree of protrusion of the prostate into the bladder may have some predictive value for bladder outlet obstruction. It has been shown that intravesical prostatic protrusion correlates relatively well with formal urodynamic evaluation of bladder outlet obstruction (Chia et al, 2003; Keqin et al, 2007). The measurement is obtained by drawing a line corresponding to the bladder base on sagittal scan and measuring the perpendicular distance from bladder base to greatest protrusion of the prostate into the bladder (Fig. 4–39).

Transabdominal ultrasonography of the prostate is useful in characterizing prostatic urethral length, the size and configuration

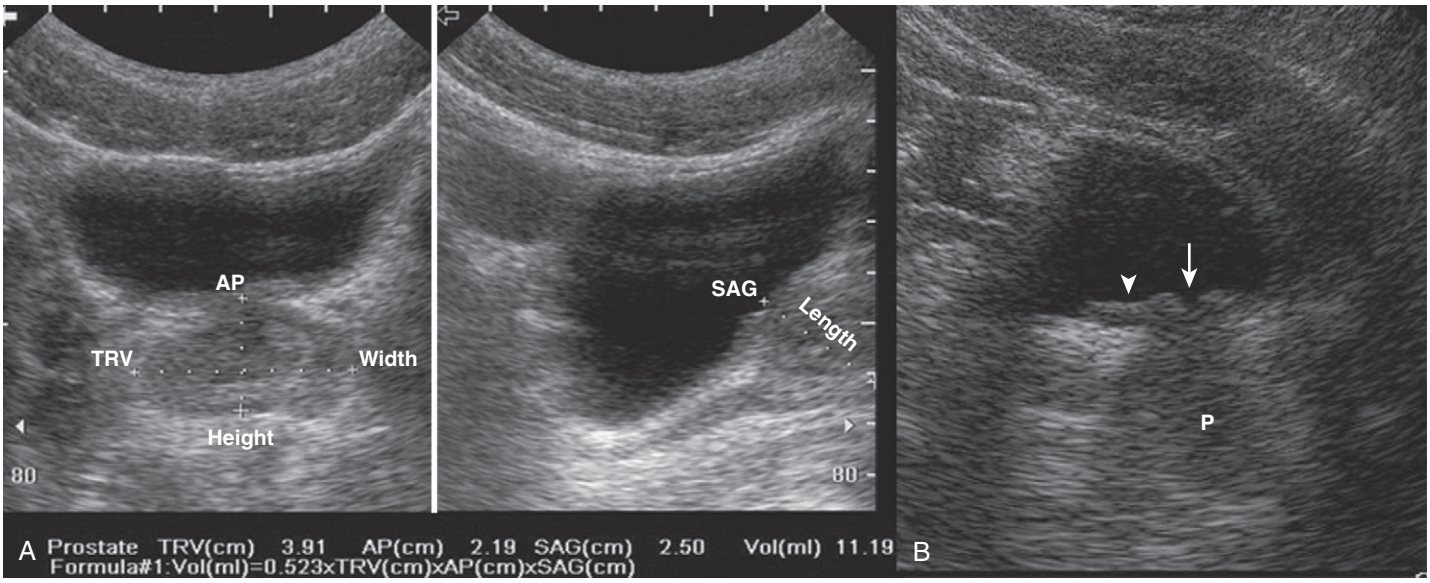

Figure 4–38. **A,** Transabdominal ultrasound is extremely useful for measuring prostatic volume and evaluating prostatic morphology. The volume of the prostate can be calculated using this formula: prostate volume (mL) = width (cm) × height (cm) × length (cm) × 0.523. **B,** In this midsagittal view of the prostate, the bladder neck is identified as a V-shaped indentation *(arrow)*. Note the characteristically hyperechoic trigone *(arrowhead)*.

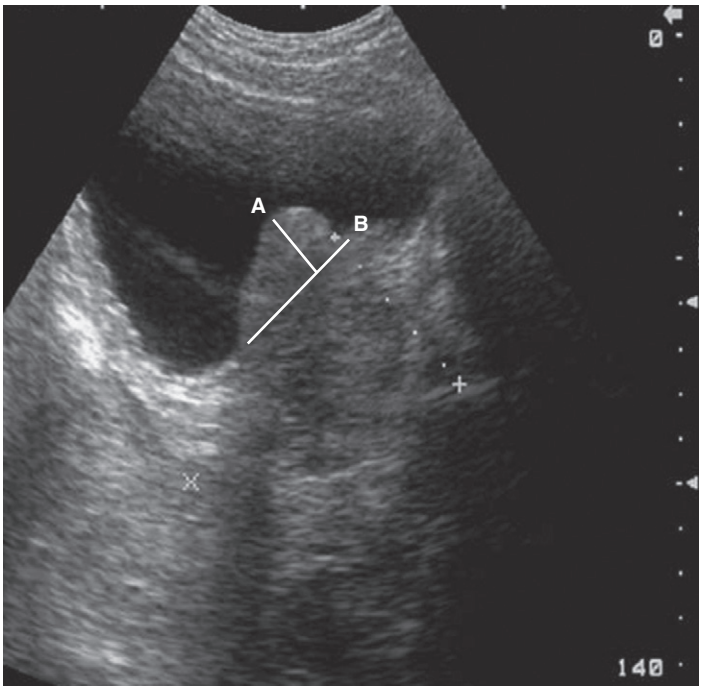

Figure 4–39. In this sagittal view of the prostate, the middle lobe extends into the bladder (A). The bladder base is defined by the line (B). The length of line (A) is the intravesical prostatic protrusion (IPP).

of the middle lobe of the prostate, and some secondary information about the physiology of bladder outlet obstruction. This information is valuable in treatment planning for bladder outlet obstruction.

Limitations. Transabdominal pelvic ultrasonography yields limited information in patients with an empty bladder. The ability to identify distal ureteral obstruction, bladder stones, and bladder tumors requires a full bladder. Although prostatic morphology and volume can be assessed with an empty bladder, it is much easier when the bladder is full. Pelvic structures may be difficult to evaluate in patients with a protuberant abdomen or panniculus. **Automated measurement of bladder volume or residual urine, though using ultrasonography, is not an imaging study.** Lack of imaging confirmation can lead to inaccurate residual urine determinations in patients with obesity, clot retention, ascites, bladder diverticulum, or perivesical fluid collection (e.g., urinoma, lymphocele).

Ultrasonography of the Scrotum

Introduction. No aspect of urologic care is better suited to the use of ultrasonography than evaluation of the scrotum. Urologists have a surgical understanding of the anatomy and extensive experience with the diagnosis and treatment of disorders that affect the scrotum. Because the scrotum and its contents are superficial, high-frequency transducers may be employed to yield excellent and detailed anatomic and physiologic information. Imaging information can be correlated with findings on direct physical examination.

Technique. Sound technique is critical to performing adequate ultrasonography of the scrotum. In general, the examination should be carried out in a quiet room that is adequately warm for patient comfort. The patient should be supine with the scrotum supported on a towel or on the anterior thighs. The patient should be draped in such a way as to hold the penis out of the way and to ensure patient privacy. Copious amounts of conducting gel should be used to provide a good interface between the transducer and the scrotal skin because air trapping by scrotal hair will result in unwanted artifacts. Complete but gentle contact between skin and transducer is essential because excessive pressure results in movement of testis or compression of the testis. Compression may change echogenicity and obscure fine anatomic detail. In addition, compression may significantly alter volume measurements.

Scrotal ultrasonography is performed with a high-frequency linear array transducer, generally in the range of 6 to 12 MHz. Transducers may be 4 to 7.5 cm in width. Some sonographers prefer the maneuverability of a 4-cm transducer, whereas others

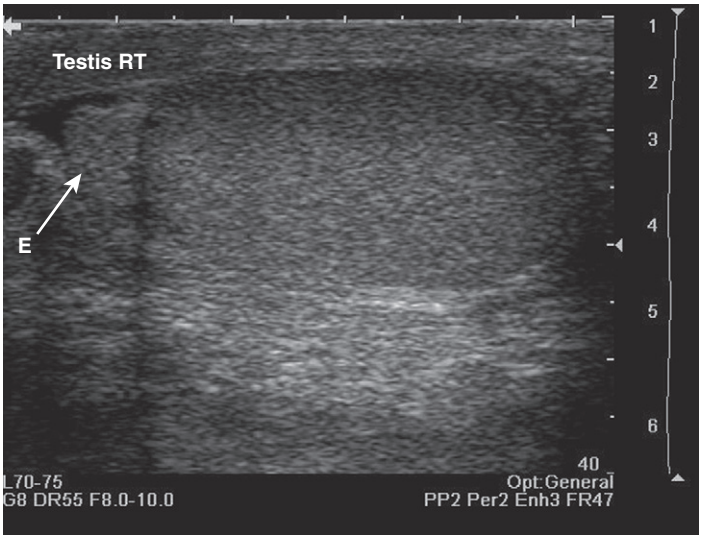

Figure 4–40. In this longitudinal view the head of the epididymis (E) is seen to the left, and the lower pole of the testis is to the right. Normal testicular sonographic anatomy is characterized by a homogeneous finely granular appearance of the testis.

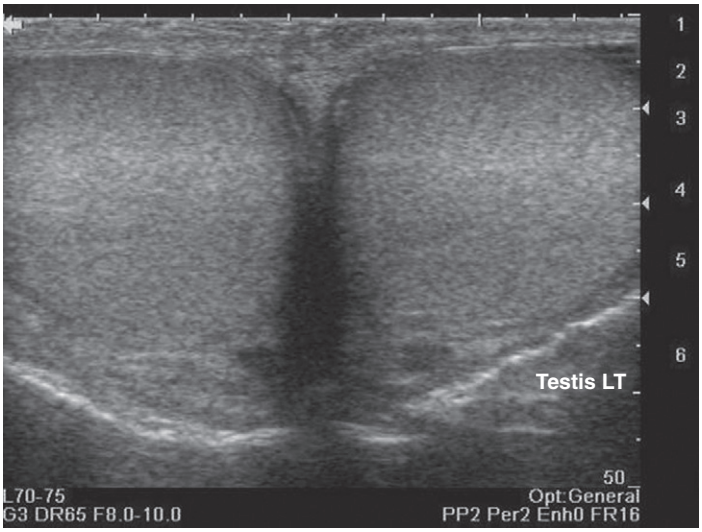

Figure 4–41. Simultaneous bilateral views are important to rule out a diffuse infiltrative process such as lymphoma. A diffuse and homogenous change in echogenicity in one testis could otherwise be unappreciated. In this example, the testes are symmetric and normal.

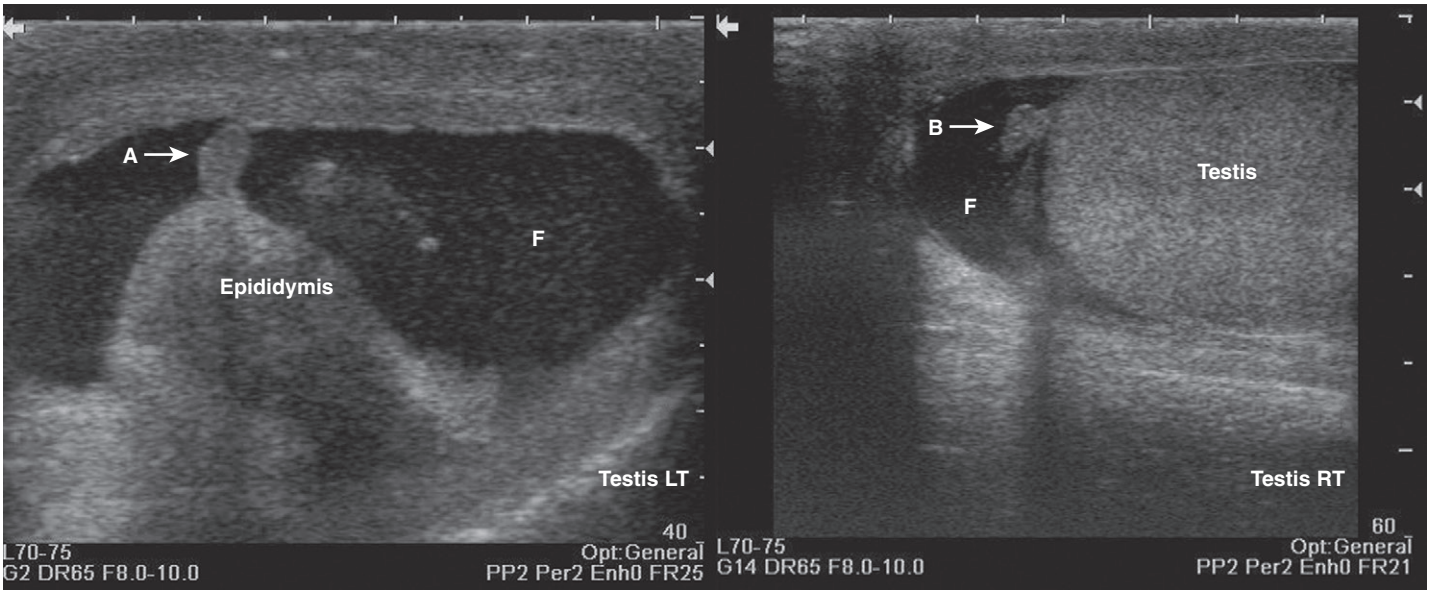

Figure 4–42. The presence of paratesticular fluid (F) permits the identification of the appendix epididymis (A) and the appendix testis (B).

prefer the longer 7.5-cm transducer for its ability to simultaneously image the entire testis in the sagittal plane. Imaging should be done in a systematic fashion and should include sagittal and transverse views of the testis. The sagittal view should proceed from the midline medially and then laterally and from the midtransverse section of the testis to the upper pole and the lower pole of the testis. In addition to the testis, the epididymis and entire scrotal contents should be imaged.

Indications

1. Assessment of scrotal and testicular mass
2. Assessment of scrotal and testicular pain
3. Evaluation of scrotal trauma
4. Evaluation of infertility
5. Follow-up of scrotal surgery
6. Evaluation of the empty or abnormal scrotum

Normal Findings. It is important to document the size and, if appropriate, the volume of the testes. The echo architecture of the testis should be described (Fig. 4–40). It is important to compare the testes for echogenicity because some infiltrative processes may result in diffuse changes in a testis that would only be noticed when that testis is compared with its contralateral mate (Fig. 4–41). For example, lymphomatous or leukemic involvement of the testis may result in a diffusely hypoechoic and homogeneous appearance, which may be unilateral (Mazzu et al, 1995).

If paratesticular fluid is present, the epididymis and the testicular and epididymal appendages are more easily identified (Fig. 4–42).

Normal testicular blood flow may be demonstrated with color or power Doppler (Barth and Shortliffe, 1997) (Fig. 4–43). Intratesticular blood flow is low velocity with the average peak systolic

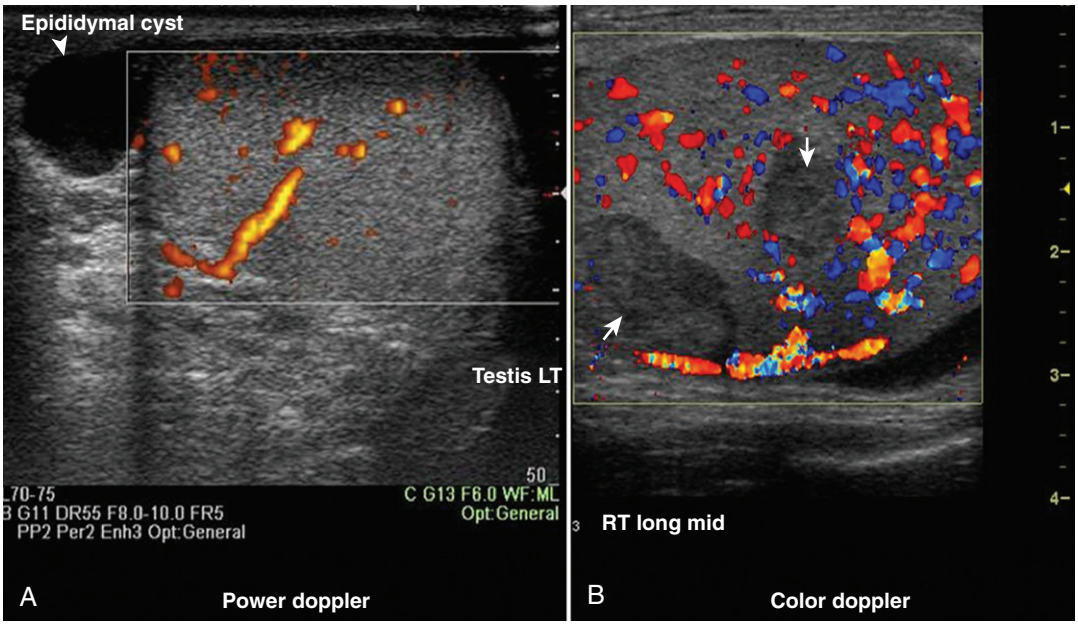

Figure 4–43. **A,** Normal intratesticular blood flow by power Doppler; note the epididymal cyst *(arrowhead)*. **B,** Increased blood flow in an irregular pattern demonstrated by color Doppler was associated with necrotizing vasculitis; note the relatively hypoechoic areas of decreased vascularity *(arrows)*.

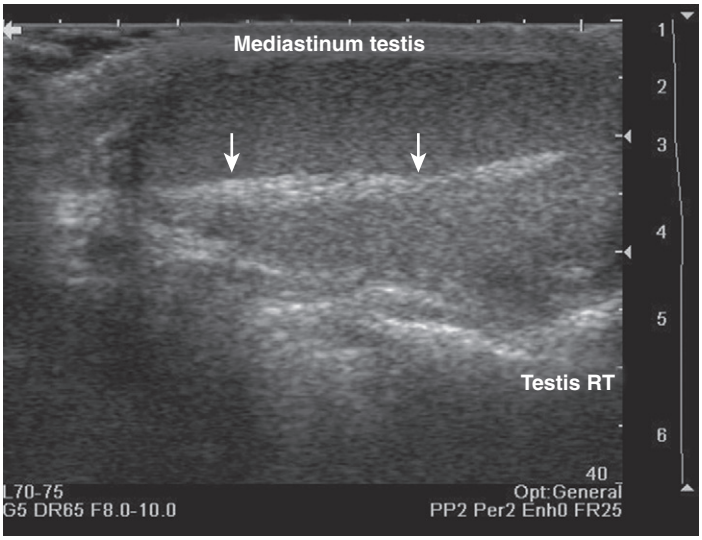

Figure 4–44. The sagittal image of this testis demonstrates a common anatomic finding, the hyperechoic mediastinum testis *(arrows)*. The mediastinum testis is a normal structure resulting from the coalescence of the fibrous septa of the testis.

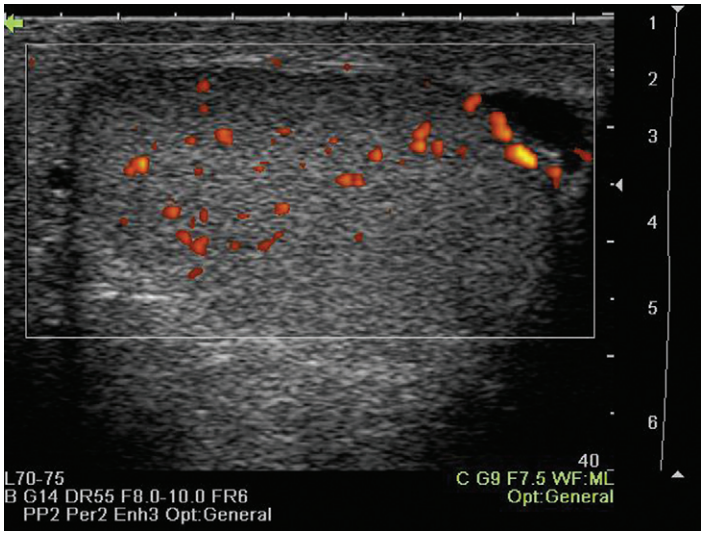

Figure 4–45. Demonstration of intratesticular blood flow by power Doppler in this normal testis.

velocity (PSV) of less than 10 cm/sec (Middleton et al, 1989). Intratesticular blood flow is primarily supplied by the testicular artery, which ultimately divides to supply the individual testicular septa. The fibrous septa coalesce to form the mediastinum testis, which is a hyperechoic linear structure seen in the sagittal plane (Fig. 4–44).

Limitations. Caution should be used when interpreting Doppler flow studies in the evaluation of suspected testicular torsion. The hallmark of testicular torsion is the absence of **intratesticular** blood flow (Fig. 4–45). Paratesticular flow in epididymal collaterals may appear within hours of torsion. Comparison with the contralateral testis should be performed to ensure that the technical attributes of the study are adequate to demonstrate intratesticular blood flow.

Ultrasonography of the Penis and Male Urethra

Introduction. Ultrasonography of the penis and male urethra provides exquisite anatomic detail and may be used in many cases in lieu of studies requiring ionizing radiation.

Technique. Penile and urethral ultrasonography is performed with a 6- to 12-MHz linear array transducer. The technique for penile and urethral ultrasonography includes imaging the phallus in the longitudinal and transverse plane. The examination should be performed in a systematic fashion beginning at the base of the

penis and proceeding distally to the glans. It is possible to get an image of the proximal urethra and corporal bodies by scanning through the scrotum or the perineum.

It may be helpful when evaluating the penile urethra, especially for stricture disease, to inject gel into the urethra in a retrograde fashion. This distends the urethra and allows better identification of urethral anatomy and the anatomy of the corpus spongiosum.

Indications

1. Evaluation of erectile dysfunction
2. Documentation of fibrosis of the corpora cavernosa
3. Localization of foreign body
4. Evaluation of urethral stricture
5. Evaluation of urethral diverticulum
6. Assessment of penile trauma or pain

Normal Findings. Transverse scanning of the phallus reveals the two corpora cavernosa dorsally and the urethra ventrally. The sagittal view of the phallus demonstrates the corpora cavernosa with a hyperechoic, double linear structure representing the cavernosal artery (Fig 4–46). The corpus spongiosum is isoechoic to slightly hypoechoic and contains the coapted urethra. The urethra is collapsed except during voiding.

Limitations. The evaluation of erectile dysfunction requires qualitative and quantitative measurements of blood flow in the penile arteries. Such evaluation requires blood flow measurements before and after the intracavernosal injection of vasoactive substances.

Transrectal Ultrasonography of the Prostate

Transrectal ultrasonography of the prostate (TRUS) is the sonographic imaging procedure most commonly performed by urologists. The technique, indications, normal findings, and complications are discussed in Chapter 97.

NUCLEAR SCINTIGRAPHY

Radionuclide imaging is the procedure of choice to evaluate renal obstruction and function. It is sensitive to changes that induce focal or global changes in kidney function. Because neither gadolinium nor iodinated intravenous contrast agents are used, scintigraphy does not damage the kidney, has no lingering toxicity, results in minimal absorbed radiation, and is free from allergic reactions. Compared with other diagnostic imaging studies such as retrograde pyelogram, renal scintigraphy is noninvasive, has minimal risk, minimal discomfort, and allows determination of the function of the kidney.

Key Points: Ultrasonography

- An ultrasound wave is a mechanical wave creating alternating areas of compression and rarefaction in tissue.
- Axial resolution improves with increasing frequency of the ultrasound wave.
- Depth of ultrasound penetration decreases with increasing frequency.
- Optimal ultrasound imaging requires trade-offs between resolution and depth of penetration.
- Artifacts may be helpful in the diagnosis of certain conditions.
- The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.
- The mechanical index and the thermal index are not safety limits.
- The ALARA principle is intended to limit the total energy imparted to the patient during an examination.
- The most important factor in ultrasound safety is the informed operator.
- Angiomyolipoma has a characteristic hyperechoic appearance, but some renal cell carcinomas are also hyperechoic.
- Automated measurement of bladder volume or residual urine, though using ultrasonography, is not an imaging study.
- The hallmark of testicular torsion is the absence of intratesticular blood flow.

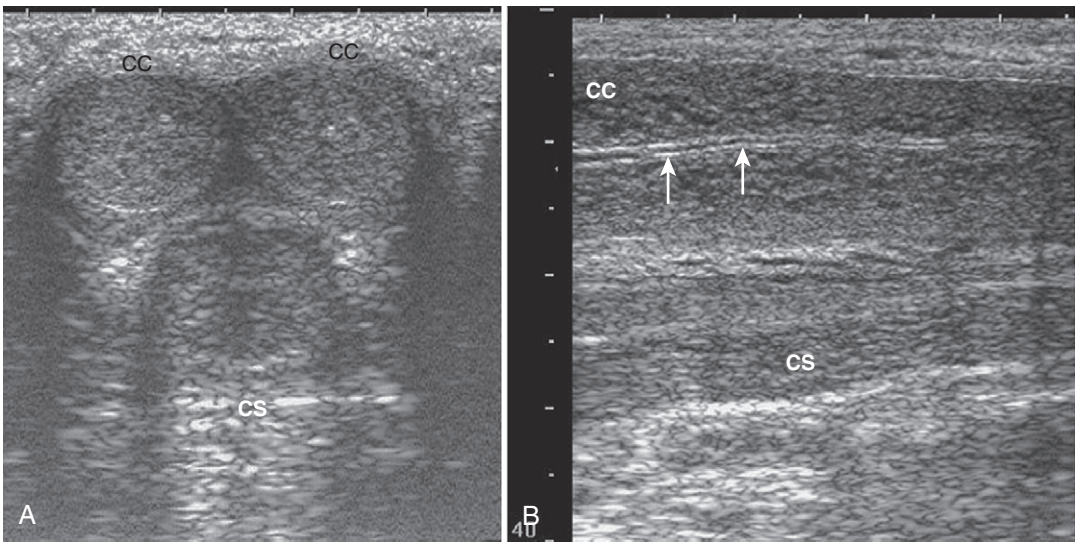

Figure 4–46. **A,** In the transverse plane scanning from the dorsal surface of the midshaft of the penis the corpora cavernosa (CC) are paired structures seen dorsally while the corpus spongiosum (CS) is seen ventrally in the midline. **B,** In the parasagittal plane the corporus cavernosum (CC) is dorsal with the relatively hypoechoic corpus spongiosum (CS) seen ventrally. Within the corporus cavernosum the cavernosal artery is identified as a bright hyperechoic structure *(arrows)*.

Once the agent is injected IV, gamma scintillation cameras measure radiation emitted from the radioisotope and digital workstations gather, process, and display the information. There is an extensive list of radiopharmaceuticals used for renal scintigraphy. This section is limited to those agents most commonly used in urologic practice.

Technetium 99m-diethylene triamine pentaacetic acid (^{99m}Tc-DTPA) is primarily a glomerular filtration agent (Peters, 1998; Gates, 2004). It is most useful for evaluation of obstruction and renal function. Because it is excreted through the kidney and dependent on glomerular filtration rate (GFR), it is less useful in patients with renal failure because impaired GRF may limit adequate evaluation of the collecting system and ureters. It is readily available and relatively inexpensive (Klopper et al, 1972).

Technetium 99m-dimercaptosuccinic acid (^{99m}Tc-DMSA) is cleared by both filtration and secretion.

^{99m}Tc-DMSA localizes to the renal cortex with little accumulation in the renal papilla and medulla (Lin et al, 1974). Therefore it is most useful for identifying cortical defects and ectopic or abhorrent kidneys. With these properties, ^{99m}Tc-DMSA can distinguish a benign functioning abnormality in the kidney from a space-occupying malignant lesion, which would not have normal renal function. No valuable information on the ureter or collecting system can be obtained with ^{99m}Tc-DMSA, but it remains a standard for renal cortical imaging.

Technetium 99m-mercaptoacetyl triglycine (^{99m}Tc-MAG3) is an excellent agent for imaging due to its photon emission, 6-hour half-life, and ease of preparation. It is cleared mainly by tubular secretion (Fritzberg et al, 1986). **A small amount, approximately 10%, of MAG3 is excreted by extrarenal means and most of this is hepatobiliary excretion** (Eshima et al, 1990; Itoh, 2001). Because it is extensively bound to protein in plasma, it is limited in its ability to measure GFR but is an excellent choice for patients with renal insufficiency and urinary obstruction. The tracer is well suited for evaluation of renal function and diuretic scintigraphy. Also, it is an excellent tracer to evaluate renal plasma flow.

Diuretic Scintigraphy

Nuclear medicine imaging plays a crucial role unmet by CT, MRI, or ultrasonography in the diagnosis of upper tract obstruction and its unique characteristics provide noninvasive information regarding dynamic renal function. The diuretic renal scan using ^{99m}Tc-MAG3 is able to provide differential renal function and clearance time comparing right and left kidneys, which is pivotal in patient management. The initial phase is the flow phase in which 2-second images are gathered for 2 minutes and then 1-second images for 60 seconds. The flow phase shows renal uptake, background clearance, and abnormal vascular lesions, which may indicate arteriovenous malformations, tumors, or active bleeding. In the second phase the renal phase, time-to-peak uptake is typically between 2 and 4 minutes. The renal phase is the most sensitive indicator of renal dysfunction. One-minute images are taken for 30 minutes. In the final phase, the excretory phase, 1-minute images are taken for 30 minutes. **A diuretic (usually furosemide 0.5 mg/kg) is administered when maximum collecting system activity is visualized. The $T_{1/2}$ is the time it takes for collecting system activity to decrease by 50% from that at the time of diuretic administration. This is highly technician dependent because the diuretic must be given when the collecting system is displaying maximum activity. Transit time through the collecting system in less than 10 minutes is consistent with a normal, nonobstructed collecting system. $T_{1/2}$ of 10 to 20 minutes shows mild to moderate delay and may be a mechanical obstruction. The patient's perception of pain after diuretic administration can be helpful for the treating urologist to consider when planning surgery in the patient with middle to moderate obstruction. A $T_{1/2}$ of greater than 20 minutes is consistent with a high-grade obstruction. Level of obstruction can usually be determined, as can abnormalities such as ureteral duplication** (Ell and Gambhir, 2004). A normal renal scan is shown in Figure 4–47.

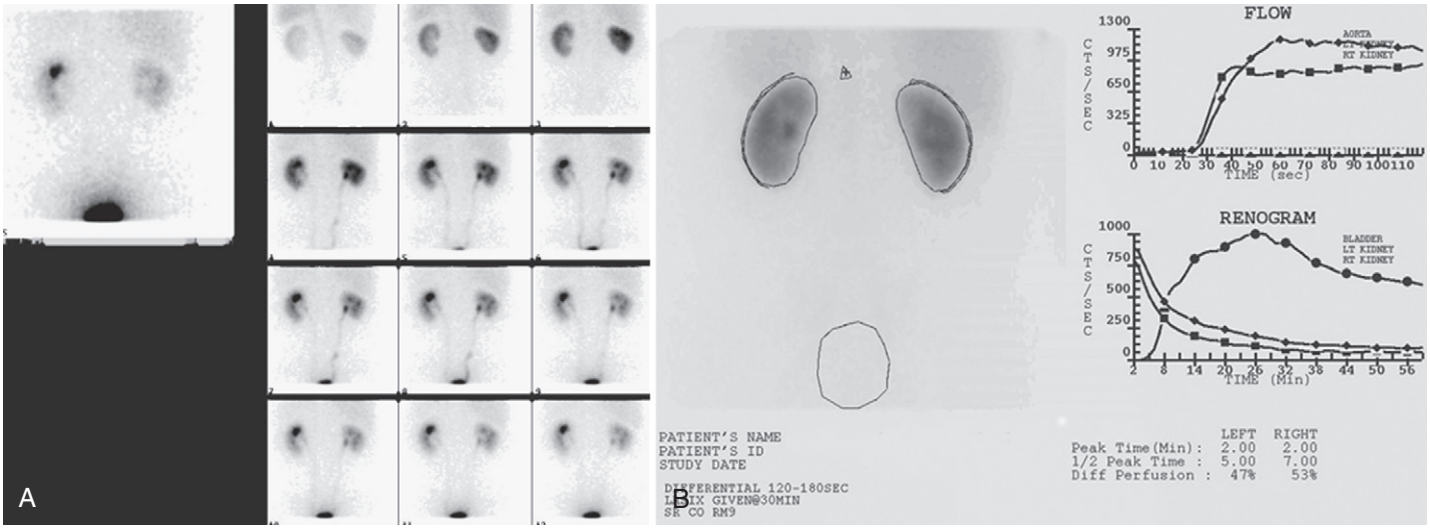

Figure 4–47. **A,** Technetium 99m mercaptoacetyl triglycine (^{99m}Tc-MAG3) perfusion images demonstrate normal, prompt, symmetric blood flow to both kidneys. **B,** Perfusion time-activity curves demonstrating essentially symmetric flow to both kidneys. Note the rising curve typical of ^{99m}Tc-MAG3 flow studies. Dynamic function images demonstrate good uptake of tracer by both kidneys and prompt visualization of the collecting systems. This renogram demonstrates prompt peaking of activity in both kidneys. The downslope represents prompt drainage of activity from the kidneys. Printout of quantitative data shows the differential renal function to be 47% on the left, 53% on the right. The normal half-life for drainage is less than 20 minutes when ^{99m}Tc-MAG3 is used. The $T_{1/2}$ is 5 minutes on the left and 7 minutes on the right, consistent with both kidneys being unobstructed.

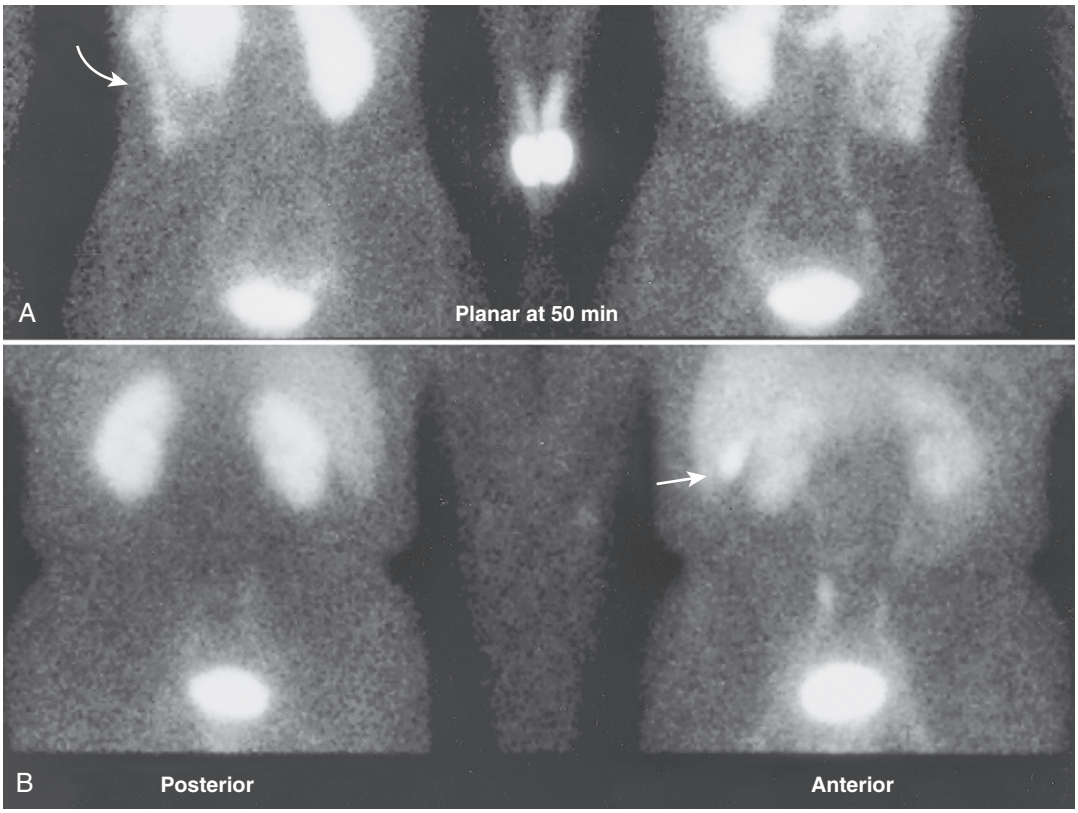

Figure 4–48. Delayed static images in the posterior and anterior projections demonstrate intestinal activity (*arrow* in **A**) and gallbladder activity (*arrow* in **B**), reflecting a normal mode of excretion of technetium 99m mercaptoacetyl triglycine (^{99m}Tc-MAG3). Gallbladder activity, in particular, can cause false-positive interpretation when it overlies activity in the renal collecting system or is inappropriately included in the area of interrogation. Liver activity is variable and tends to be more pronounced in children and patients with renal insufficiency.

Hepatobiliary excretion can cause false-positive readings if the area of intestinal activity or gallbladder activity is included in the area of interrogations during the study (Fig. 4–48).

The diuretic renal scan is another imaging study where communication with the interpreting physician is vital for correct performance of the test, as well as appropriate interpretation. For example, there are times when patients with unilateral or bilateral ureteral stents are sent for diuretic scintigraphy to determine differential renal function. If a bladder catheter is not placed and open to drainage during the diuretic renal scan, the radiopharmaceutical excreted from the healthy kidney may wash up into or back flow via the ureteral stent into the stented kidney, giving the false-positive appearance to have more function that is physiologically present. This false-positive test may lead to inappropriately reconstructing a kidney that in reality has little or insufficient function.

Nuclear Medicine in Urologic Oncology

Whole Body Bone Scan

Conventional radionuclide imaging in urologic malignancy has long been the standard for detecting bone metastasis. The whole body bone scan or skeletal scintigraphy is the most sensitive method for detecting bone metastasis (Narayan et al, 1988). A "positive" bone scan is not specific for cancer and may require plain film radiography, CT, or MRI to confirm, as well as correlation with prior history of bone fractures, trauma, surgery, or arthritis. In patients with diffuse metastatic bone involvement, the bone scan can be mistaken for normal because there is uniformly increased uptake in the boney structures (Kim et al, 1991).

Positron Emission Tomography

The most recent advance in nuclear scintigraphy is in the detection of primary and metastatic cancer using positron emission tomography (PET). Molecular imaging with PET may help individualize the surgical and medical care of urologic oncology patients. PET is certainly having an impact in general oncology and is being actively investigated for use in urologic malignancies. The exact role in the practice of urology has yet to be determined but will certainly have a great role in the future as more tracers specific to urologic cancers are discovered. Using the combination of nuclear imaging and ever-increasing knowledge about cancer cell biology, radiotracers have been developed to be incorporated into dividing cells or cellular mechanisms involved in the increased metabolic activity of malignancies, which can then be detected using PET imaging. Combining PET with high-resolution CT (PET/CT) has the ability to increase our detection of recurrent or metastatic urologic cancers. Many different isotopes are being investigated for the detection of metastatic disease. One example is 18F fluorodeoxyglucose (FDG), which was first introduced in 1976. This isotope takes advantage of increased glycolysis and decreased dephosphorylation in some malignant cells. The 18F fluorodeoxyglucose is transported into cancer cells, where it is preferentially retained relative to normal tissue. This allows detection of some primary and metastatic cancers using PET/CT imaging.

There are some data on the use of PET/CT in testis cancer, where PET/CT was found to have a higher

diagnostic accuracy than CT for staging and restaging in the assessment of a CT-visualized residual mass following chemotherapy for seminoma and nonseminomatous germ cell tumors (Albers et al, 1999; Hain et al, 2000). There may be a role for detection of recurrent nonteratoma disease and the assessment of residual masses after chemotherapy. In a series of seminoma patients who were evaluated postchemotherapy for residual retroperitoneal masses, PET was accurate in 14/14 patients with tumors greater than 3 cm and in 22/23 patients with lesions less than 3 cm. Overall the sensitivity and specificity was 89% and 100%, respectively (De Santis et al, 2004). The accuracy of PET seems to be compromised if performed within 2 weeks of completion of chemotherapy, likely due to decreased metabolism and increased macrophage activity (Eary, 1999). It is recommended that PET/CT be delayed for 4 to 12 weeks following completion of chemotherapy (Shvarts et al, 2002).

PET/ CT may have a promising role in clear cell renal cell carcinoma. An antibody (cG250) recognizing carbonic anhydrase IX has been developed. Carbonic anhydrase IX is a protein related to the unrestrained growth of clear cell renal cancers. A positron-emitting radionuclide (iodine 124) has been attached to the cG250 antibody and injected into renal cell cancer patients. The radionuclide antibody complex attaches to the carbonic anhydrase IX protein from clear cell renal cancer cells and can be detected on PET/CT imaging. Using this scheme in 26 patients with renal tumors, before surgery, there was 94% sensitivity and 100% specificity in renal cell carcinoma (Larson and Schröder, 2008).

At least seven tracers are being investigated for detection of metastatic prostate cancer. Each tracer is directed at a different part of cell function such as glycolysis, amino acid transport, choline kinase activity, fatty acid synthesis, androgen receptor, and bone mineralization. FDG as a PET tracer was investigated in 91 patients with PSA recurrence after radical prostatectomy. FDG-PET was able to detect local or systemic recurrence in only 34% of patients (Schröder et al, 2005).

Few studies have addressed the use of PET in bladder cancer. FDG is renal excreted and not useful in bladder cancer. Only 78% of bladder cancer could be visualized using 11C-methioninie tracer, and PET did not improve local staging of the disease. 11 C-choline was also found to be a poor predictor of primary or metastatic urothelial carcinoma (Ahlstrom et al, 1996; de Jong et al, 2002).

PET/CT in urologic oncology is in its infancy. With a seemingly countless number of potential targets for tracers, it will be many years into the future before it defines its role and use in urology. PET has the capability of demonstrating in vivo gene expression. As a result, the ultimate utility may transcend diagnostic imaging and allow determination of the efficacy of targeted gene therapy.

PET is still in the early stages of investigation for urologic tumors. It is more sensitive for detection of seminoma and nonseminoma after chemotherapy compared with CT imaging.

COMPUTED TOMOGRAPHY

The 1979 Nobel Prize in Medicine and Physiology was awarded to Allan M. Cormack and Sir Godfrey N. Hounsfield for the development of computer-assisted tomography. Although basic principals remain the same, significant advances over the past 30 years have resulted in the development of multidetector CT devices, improving soft tissue detail and allowing the possibility of rapid 3-D reconstruction of the entire genitourinary system.

Key Points: Nuclear Scintigraphy

- During diuretic renal scan, the diuretic must be given when maximum activity is seen in the kidney.
- An elimination $T_{1/2}$ less than 10 minutes is an unobstructed system and a $T_{1/2}$ greater than 20 minutes is consistent with high-grade obstruction.
- If ureteral stents are in place, patients undergoing diuretic renal scan should have an unclamped bladder catheter in place during the study.
- Technetium 99m-mercaptoacetyl triglyceride (MAG3) is the agent of choice for diuretic renal scan to determine differential renal function and obstruction.

CT has become one of the most integral parts of urologic practice, and the CT urogram (CTU) has replaced IVU as the imaging modality of choice in modern urology for the workup of hematuria, urologic malignancies, detection of kidney stones, and preoperative planning. As in the case of conventional radiographic imaging, the basis for CT imaging is the attenuation of x-ray photons as they pass through the patient. Tomography is an imaging method that produces 3-D images of internal structures by recording the passage of x-rays as they pass through different body tissues. In the case of CT, a computer reconstructs cross-sectional images of the body on the basis of measurements of x-ray transmission through thin slices of the body tissue (Brant, 1999). A collimated x-ray beam is generated on one side of the patient, and the amount of transmitted radiation is measured by a detector placed on the opposite side of the x-ray beam. These measurements are then repeated systematically, while a series of exposures from different projections is made as the x-ray beam rotates around the patient. The result is production of a 3-D image of internal structures in the human body by recording the passage of different energy waves through various internal structures. Data collected by the detectors is as reconstructed by computerized algorithms to result in a viewable tomographic display.

Several different imaging variables are adjusted to allow adequate, detailed image resolution, while minimizing the time on the scanner and limiting exposure to radiation. The variable application of pitch, beam collimation, detector size, and tube voltage are used by the radiologist and imaging technologist for ideal image requisition. A detailed description of each of these variables is beyond the scope of this chapter. (See "Suggested Readings" later.)

Perhaps the greatest recent advancement in CT is the use of helical image acquisition techniques with multichannel detectors or multidetectors (MDCT). In a helical CT the patient moves through a continuously rotating gantry. The helical raw images are processed using interpolation algorithms in order to visualize the internal structures as sagittal, coronal, or axial reconstructed images. The "single-slice spiral CT," introduced in 1988, had a single row of detectors and required multiple passes to visualize a small area of interrogation. The scanners in use today have more than 64 rows of detectors, which allow the patient's entire body to be imaged during a single breath hold, with few or no motion artifacts (Wang and Vannier, 1994; Mahesh, 2002) (Fig. 4–49).

MDCT offers the advantages of faster scanning, fewer motion artifacts, thinner imaging sections, more precise diagnostic accuracy, increased concentration of contrast material, shorter scanning time, and significant increase in anatomic coverage with a

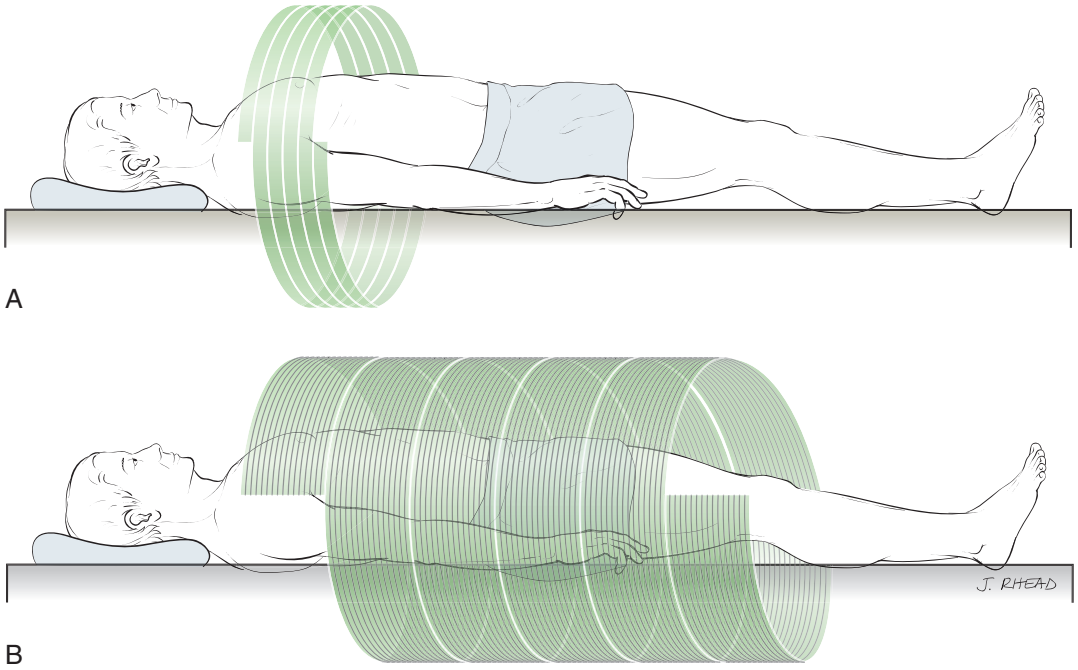

Figure 4–49. **A,** A computed tomography scanner with a single-row detector requires five circular passes around the patient to image a small area of the patient's body. **B,** With a 16-slice, multirow detector the chest, abdomen, and pelvis can be imaged with five circular passes, easily obtained during a single breath hold. The thin slices offered by the 16-slice detector offer much greater detail of internal structures.

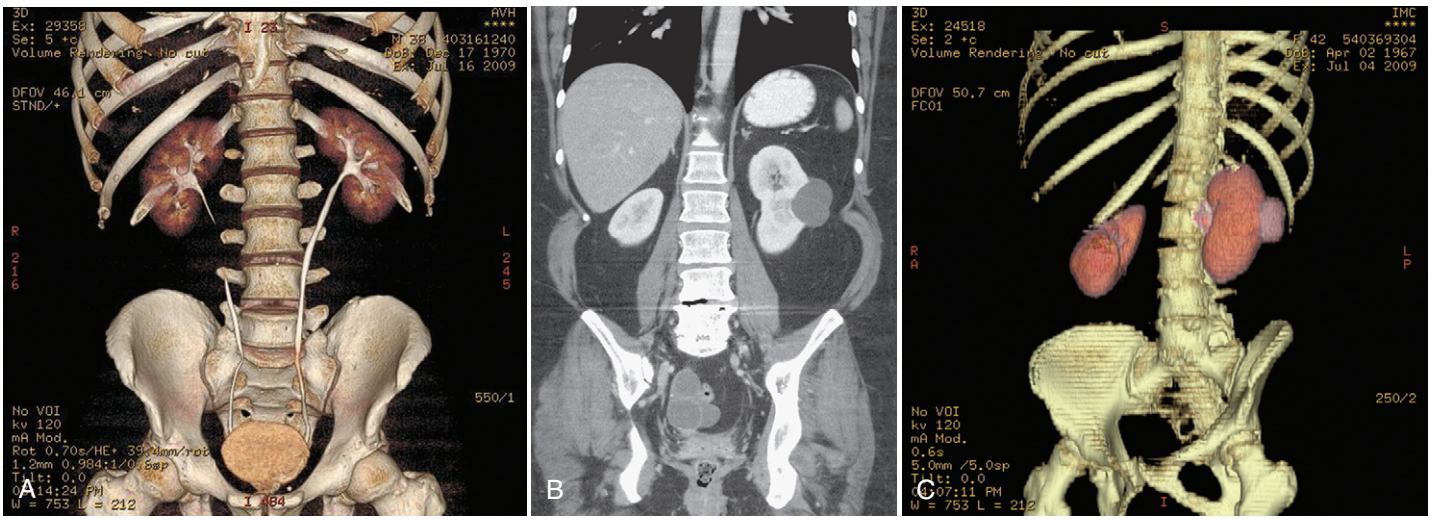

Figure 4–50. **A,** Three-dimensional (3-D) colored reconstruction of the kidneys ureter and bladder from computed tomography urogram. **B,** Coronal reconstruction in a patient with a clear cell renal cell carcinoma in a complex renal cystic mass and enhancing mural nodule. **C,** 3-D Reconstruction of the same patient with slight posterior rotation.

single scan. For example, a 16-slice MDCT can scan the chest, abdomen, and pelvis in 20 seconds.

Readily available software is capable of 3-D processing of CT images to recreate the urinary system. These 3-D images offer improved preoperative planning, appreciation of proximity to adjacent organs, the ability to define vasculature, and improved communication with patients, who can now easily see their particular pathology and better appreciate the challenges faced by their surgeon (Fig. 4–50).

Real-time CT fluoroscopy is now available as an option on new CT imaging equipment. CT fluoroscopy gives a 3-D CT image that is much more detailed and offers greater soft tissue contrast and resolution than conventional CT. The most common use in urology is for biopsy of the kidney. CT fluoroscopy helps to overcome movement of the kidney during respiratory variation. It has also been used for fluid aspiration, drain placement, catheter placement, percutaneous cryoablation, and radiofrequency ablation of renal tumors. **One significant disadvantage of CT fluoroscopy is increased radiation exposure to the patient and radiologist or surgeon performing the procedure** (Daly et al, 1999; Keat, 2001; Gupta et al, 2006).

The CTU is an excretory urography in which MDCT is used for imaging of the urinary tract. It is indicated in the workup of hematuria, kidney stones, renal masses, renal colic, and urothelial tumors. The CT scan examination starts with the physician's request for imaging.

Radiologists around the world appreciate, from the urologist, a brief description of the question to be answered by the CT scan. Equipped with a better understanding of why the CT was ordered, the radiologist and the CT technician can adjust different CT variables and choose the appropriate contrast media needed to deliver a valuable report back to the ordering urologist.

Urologists often request a CT evaluation of the abdomen and pelvis. An abdominal CT starts at the diaphragm and ends at the iliac crest. If the pelvis is to be imaged, a separate request is usually required. The pelvic CT begins at the iliac crest and terminates at the pubis symphysis. Intravenous contrast may be required for better delineation of soft tissue. Oral contrast is not commonly used in urology but may be helpful in certain cases to differentiate bowel from lymph nodes, scar, or tumor (Fig. 4–51)

Hounsfield Units

A single CT image generated by the scanner is divided into many tiny blocks of different shades of black and white called pixels. The actual grayscale of each pixel on a CT depends on the amount of radiation absorbed at that point, which is termed an *attenuation value*. **Attenuation values are expressed in Hounsfield units (HU). The HU scale or attenuation value is based on a reference scale where air is assigned a value of –1000 HU and dense bone is assigned the value of +1000 HU. Water is assigned 0 HU.**

Urolithiasis

Patients presenting to the emergency department with abdominal pain or renal colic are frequently evaluated with CT imaging. The use of nonenhanced CT imaging to identify urolithiasis was first reported in 1995 (Smith et al, 1995) and has now become the standard diagnostic tool to evaluate renal colic. It offers the advantages over IVU of avoiding contrast and has the ability to diagnose other abdominal abnormalities that can also cause abdominal pain. MDCT can readily diagnose radiolucent stones that may not have been seen on IVU, as well as small stones even in the distal ureter (Federle et al, 1981). **With the exception of some indinavir stones, all renal and ureteral stones can be detected on helical CT scan** (Schwartz et al, 1999). In the workup of urolithiasis, the unenhanced CT has a sensitivity ranging between 96% and 100% and specificity ranging between 92% and 100% (Memarsadeghi et al, 2005). **Stones in the distal ureter can be difficult to differentiate between pelvic calcifications. In these cases the urologist needs to look for other signs of obstruction that indicate the presence of a stone including ureteral dilation, inflammatory changes in the perinephric fat, hydronephrosis, and a soft tissue rim surrounding the calcification within the ureter. The soft tissue rim around a stone represents irritation and edema in the ureteral wall** (Heneghan et al, 1997; Dalrymple et al, 2000) (Fig. 4–52).

Stone patients are frequently subjected to radiation exposure as part of diagnosis, treatment, and follow-up. Increasing awareness of the potential long-term adverse effects of radiation exposure has encouraged urologists and radiologists to discover means to decrease the amount of radiation exposure. The low-dose unenhanced helical CT scan is gaining increasing popularity for initial diagnosis of renal colic suspected to be due to urolithiasis and for follow-up in stone patients. Using low-dose CT protocols, the specificity and sensitivity of unenhanced low-dose helical CT scan are approximately 96% and 97%, respectively. Low-dose techniques offer a 99% positive at 90%-negative predictive value for urolithiasis. The end result is a 50% to 75% decrease in the patient's total radiation exposure for each CT obtained (Liu et al, 2000; Hamm et al, 2002; Kalra et al, 2005).

Cystic and Solid Renal Masses

The frequent CT imaging in emergency department patients has resulted in an increase in the detection of incidental renal masses. Using CT imaging the mass can be characterized as a simple or complex cyst or a solid mass. On the basis of the HU attenuation scale we would expect simple cysts to have HU near zero (Fig. 4–53).

When the unenhanced CT images of a renal mass are compared with the enhanced images obtained in the cortical medullary or nephrogenic phase, an increase in HU (measured in the area of the renal mass) by 15 to 20 HU confirms the presence of a solid enhancing mass, which is usually renal cancer. The presence of fat, which should enhance less than 10 HU, is diagnostic for angiomyolipoma. A hyperdense cyst shows no change in density between the postcontrast and delayed-phase images (Fig. 4–54).

Complex cystic masses are usually characterized on the basis of the Bosniak classification system. The most important criteria used to differentiate a lesion that should be considered for surgery versus a nonsurgical lesion is the presence or absence of tissue vascularity or enhancement. Bosniak category I, II, and IIF lesions do not enhance to any measurable degree. Category I lesions are simple cysts and considered to be benign. Category II lesions are more complicated and may have calcifications, high attenuation fluid, and several thin septae. Category III lesions are more complex, have small areas of calcification, and may also have irregular walls or septate where there is measurable enhancement. Cystic lesions discovered on CT scan that are difficult to categorize as either II or III are now currently categorized as IIF. **Category IV lesions are cystic masses that meet all the criteria of category III but also have enhancing soft tissue components adjacent or independent of the wall or septum of the cyst. Bosniak III and IV lesions have an increased likelihood of being malignant and require close follow-up or surgical extirpation** (Bosniak, 1997; Isreal and Bosniak, 2005).

Hematuria

The CTU is one of the most common studies ordered for the workup of gross or microscopic hematuria. With MDCT it is possible to perform a comprehensive evaluation of the patient with one single examination (Chai et al, 2001). The study images the abdomen and pelvis and typically includes four different phases. The first scan is an unenhanced CT to distinguish between different masses that can be present in the kidney and uncover kidney stones that would later be obscured by the excretion of contrast into the renal collecting system. At 30 to 70 seconds after contrast injection, the corticomedullary phase is captured with another pass through the MDCT, helping to define vasculature and perfusion. The nephrogenic phase occurs between 90 to 180 seconds after injection of contrast and, when compared with the nonenhanced images, allows sensitive detection and characterization of renal masses. The final phase is the excretory phase, imaged approximately 3 to 5 minutes after injection of contrast. The excretory phase allows complete filling of the collecting system

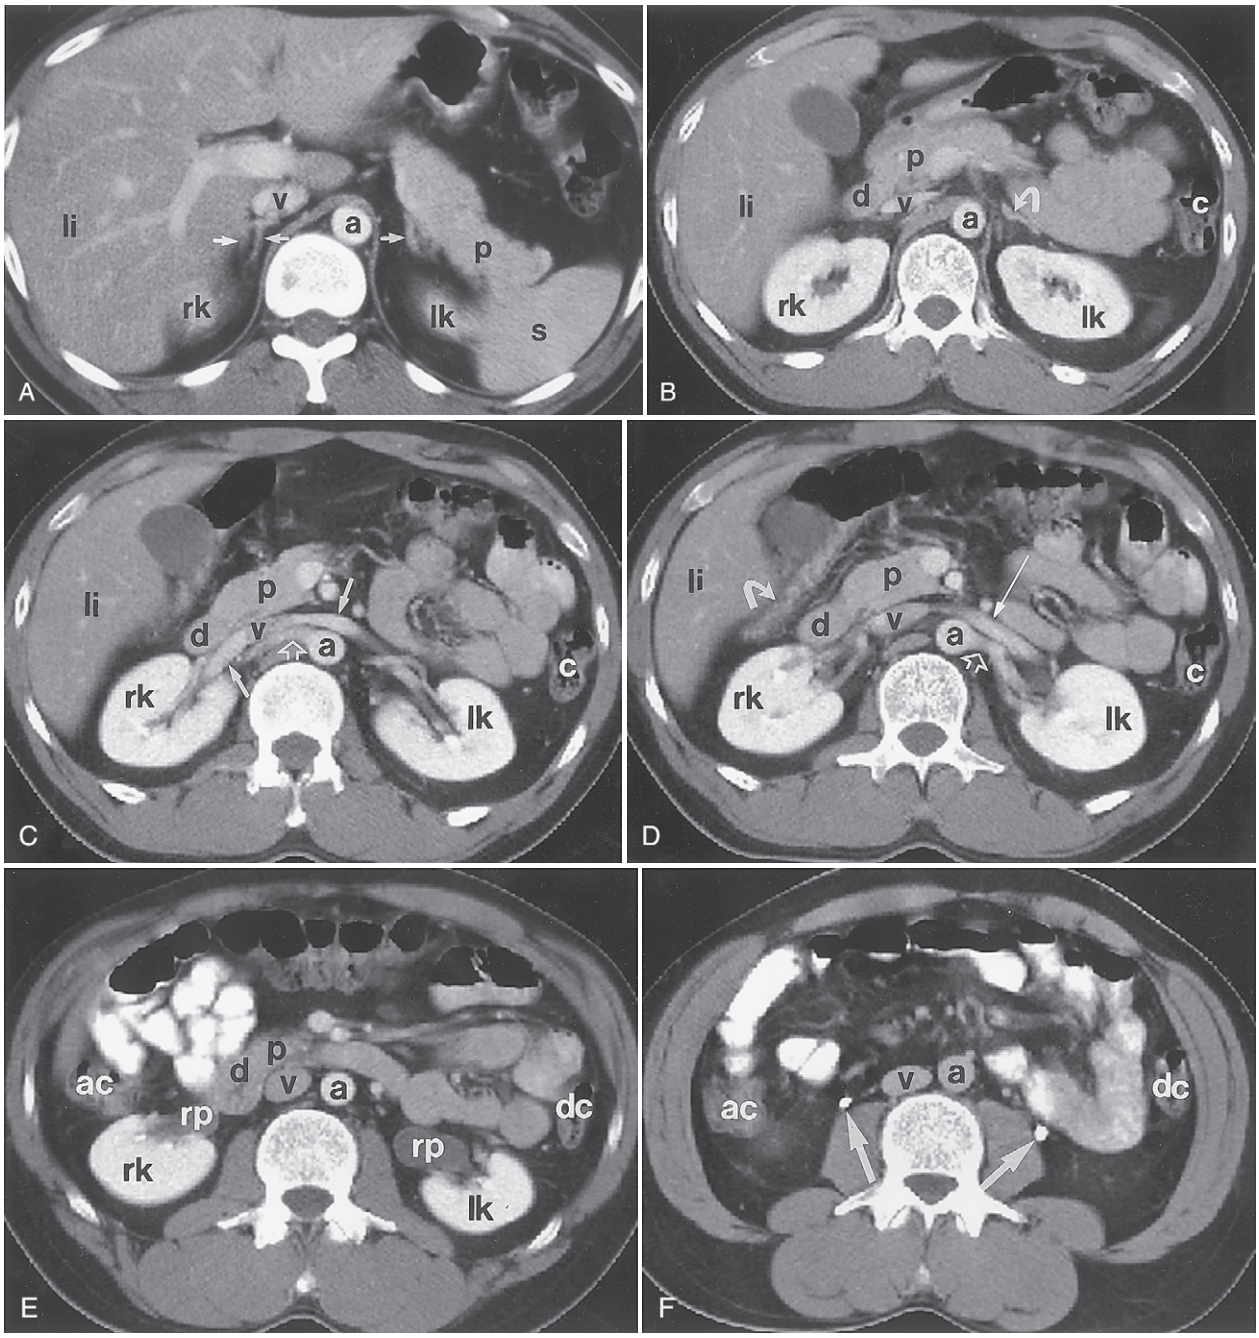

Figure 4–51. Computed tomography (CT) of the abdomen and pelvis demonstrating normal genitourinary anatomy. **A,** The adrenal glands are indicated with *arrows*. and usually allows visualization of the ureter (Joudi et al, 2006) (see Fig. 4–54).

CTU has been shown to be sensitive in detecting upper tract urothelial cancers. In one series of 57 patients with hematuria, 38 were found to have urothelial carcinoma. CT urography detected 37/38 urothelial cancers for a sensitivity of 97%, compared with retrograde pyelogram, which detected 31/38 lesions and had a sensitivity of 82%. Approximately 90% of malignant upper tract lesions can be detected with CT urography (McCarthy and Cowan, 2002; Lang et al, 2003; Caoili et al, 2005). CT urography is not as sensitive as cystoscopy for the detection of urothelial tumors in the bladder. Only large bladder tumors are visualized with CT imaging studies as filling defect in the lumen of the bladder. Carcinoma in situ cannot be visualized on CT scanning and therefore cystoscopy is still an important part of a comprehensive hematuria workup.

Key Points: CT Imaging

- The CT urogram is an excellent imaging choice to evaluate the kidney, upper tract collecting system, and ureter.
- The CT urogram is highly sensitive and specific for upper tract urothelial carcinoma.
- A renal mass in the kidney seen on CT urogram that enhances more than 15 to 20 HU is most likely a renal cancer.
- With the exception of indinavir stones, all types of urolithiasis are visible on unenhanced CT of the abdomen and pelvis.

MAGNETIC RESONANCE IMAGING

CT imaging remains the mainstay of urologic cross-sectional body imaging; however, MRI is increasingly being applied to the genitourinary system. With constant improvements in technology, MRI is gradually narrowing the overall resolution quality gap between it and CT. A significant advantage of MRI is the excellent contrast resolution of soft tissue, without the need for contrast in many situations. Currently MRI is used when patients cannot be given iodinated contrast and when tissue findings in the urinary system cannot be resolved using CT or ultrasonography.

To obtain magnetic resonance images, the patient is placed on a gantry that passes through the bore of the magnet. When exposed to a magnet field of sufficient strength, the free water protons in the patient orient themselves along the magnetic field's z-axis. This is the head-to-toe axis, straight through the bore of the magnet. A radiofrequency (RF) antenna or "coil" is placed over the body part to be imaged. It is the coil that transmits the RF pulses through the patient. When the RF pulse stops, protons

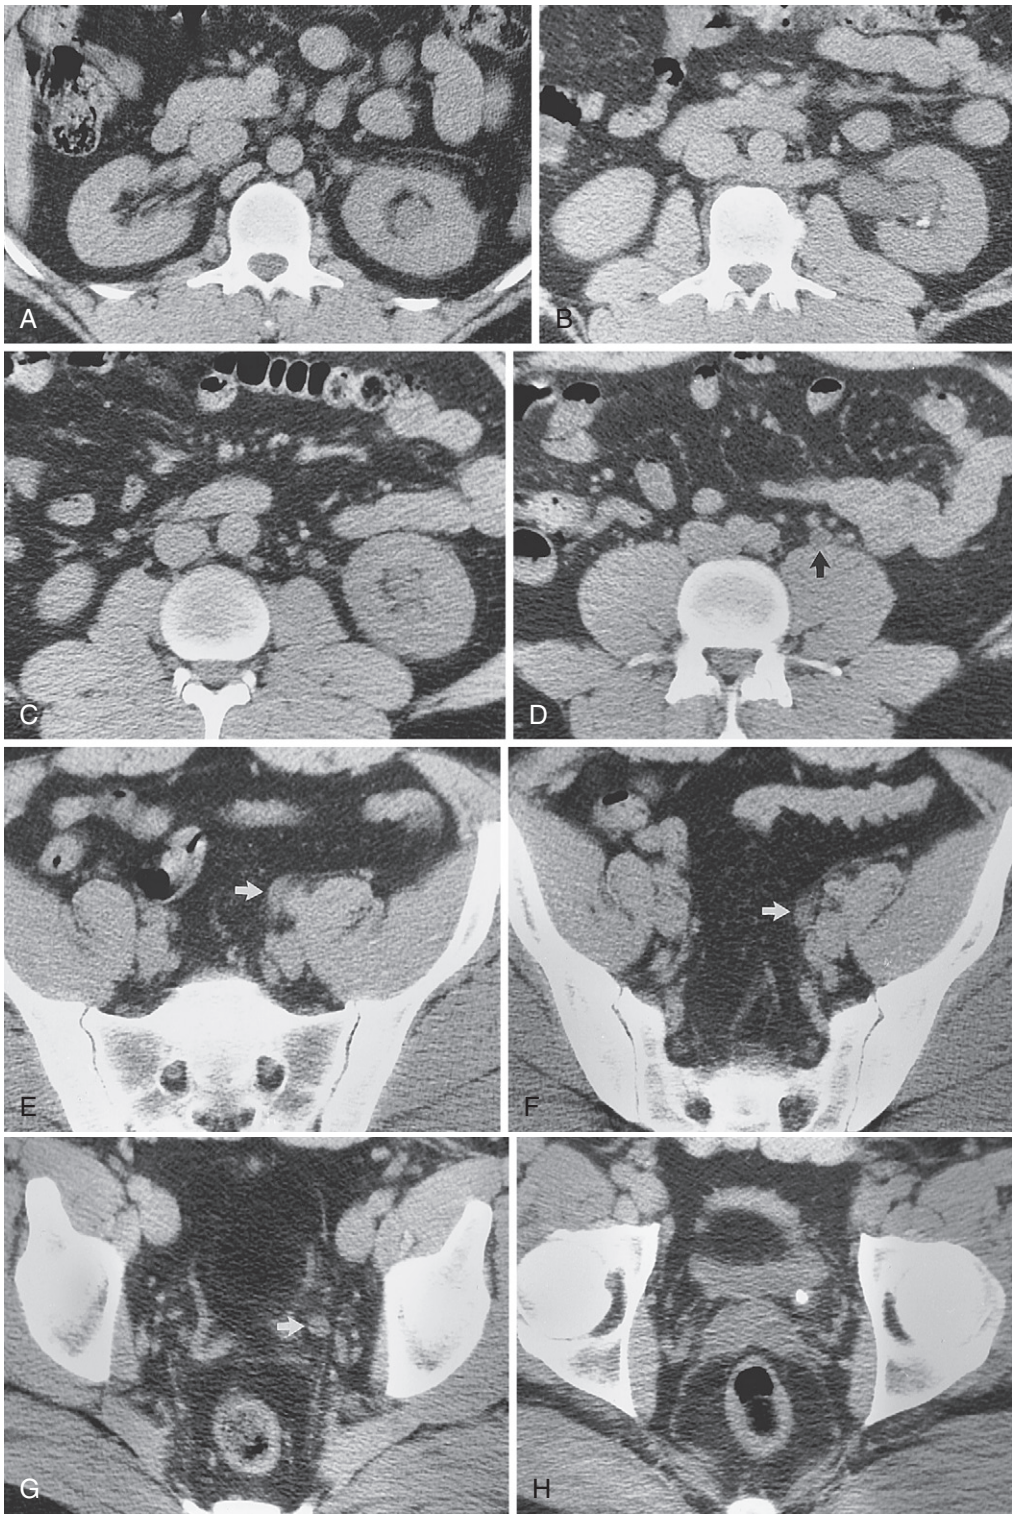

Figure 4–52. Computed tomography of the abdomen and pelvis in a patient with an obstructing ureteral stone at the level of the ureterovesical junction (UVJ). **A,** Level of the left upper pole. Mild renal enlargement, caliectasis, and perinephric stranding are apparent. **B,** Level of the left renal hilum. Left pyelectasis with a dependent stone, mild peripelvic and perinephric stranding, and a retroaortic left renal vein are shown. **C,** Level of the left lower pole. Left caliectasis, proximal ureterectasis, and mild periureteral stranding are present. **D,** Level of the aortic bifurcation. The dilated left ureter *(arrow)* has lower attenuation than do nearby vessels. **E,** Level of the upper portion of the sacrum. A dilated left ureter *(arrow)* crosses anteromedial to the common iliac artery. **F,** Level of the midsacrum. A dilated left ureter *(arrow)* is accompanied by periureteral stranding. **G,** Level of the top of the acetabulum showing a dilated pelvic portion of the left ureter *(arrow)*. **H,** Level of the UVJ. Figure 4–53. Renal computed tomography (CT) demonstrating normal nephrogenic progression. **A,** Unenhanced CT scan obtained at the level of the renal hilum shows right (R) and left (L) kidneys of CT attenuation values slightly less than those of the liver (H) and pancreas (P). A, abdominal aorta; M, psoas muscle; S, spleen; V, inferior vena cava. **B,** Enhanced CT scan obtained during a cortical nephrographic phase, generally 25 to 80 seconds after contrast medium injection, reveals increased enhancement of the renal cortex (C) relative to the medulla (M). The main renal artery is indicated with *solid arrows* bilaterally. Main renal veins *(open arrows)* are less opacified with respect to the aorta (A) and arteries. D, duodenum; P, pancreas; V, inferior vena cava. **C,** CT scan obtained during the homogeneous nephrographic phase, generally between 85 and 120 seconds after contrast medium administration, reveals a homogeneous, uniform, increased attenuation of the renal parenchyma. The wall of the normal renal pelvis (RP) is paper thin or not visible on the CT scan. A, abdominal aorta; V, inferior vena cava. **D,** CT scan obtained during the excretory phase shows contrast medium in the renal pelvis (RP) bilaterally; this starts to appear approximately 3 minutes after contrast medium administration.

Figure 4–54. Small renal cell carcinoma in the infrahilar lip of the right kidney is not easily seen on unenhanced image (**A**). On corticomedullary phase image (**B**), the lesion is subtly visible as a hyperenhancing focus within the renal medulla. On nephrographic (**C**) and pyelographic phase (**D**) images, the full extent of the lesion *(arrow)* within the medulla and cortex is depicted. (Reprinted from Brink JA, Siegel CL. Computed tomography of the upper urinary tract. In: Pollack HM, McClennan BL, Dyer R, Kenney PJ, editors. Clinical urography. 2nd ed. Philadelphia: WB Saunders; 2000.)

release their energy, which is detected and processed to obtain the magnetic resonance image. A magnetic resonance sequence exploits the body's different tissue characteristics and the particular manner that each type of tissue absorbs and then releases this energy.

Weighting of the image depends on how the energy is imparted through the physics of the pulse sequence and whether the energy is released quickly or slowly. Images are described as being T1 or T2 weighted. The T1-weighted images are generated by the time to return to equilibrium in the z-axis. The T2-weighted images are generated by the time required to return to equilibrium in the xy-axis. **On T1-weighted magnetic resonance images, fluid has a low signal and appears dark. T2-weighted magnetic resonance images have a high signal and appear bright. In the kidney this translates into the cortex having a higher signal or being brighter than the medulla, which gives off a lower signal and is darker** (Fig. 4–55).

Intravenous gadolinium contrast enhancement can be used in renal imaging to augment the relaxation of protons on T1-weighted images, making the kidney brighter and increasing the chance of detecting and characterizing a renal mass. Urine in the bladder has low-signal intensity or appears dark on T1-weighted images and demonstrates high-signal intensity or is bright on T2-weighted images (Bassignani, 2006) (Fig. 4–56) (Table 4–6).

Indications

MRI is indicated in the evaluation of solid renal masses, cystic renal masses, staging of renal malignancy, evaluation of venous structures, determination of vena cava involvement by renal cell carcinoma, and characterization of adrenal pathology. MRI is an imaging modality preferred over CT scanning in patients with a history of contrast allergy, compromised renal function, or suspected renal vein or vena cava involvement of renal cell carcinoma.

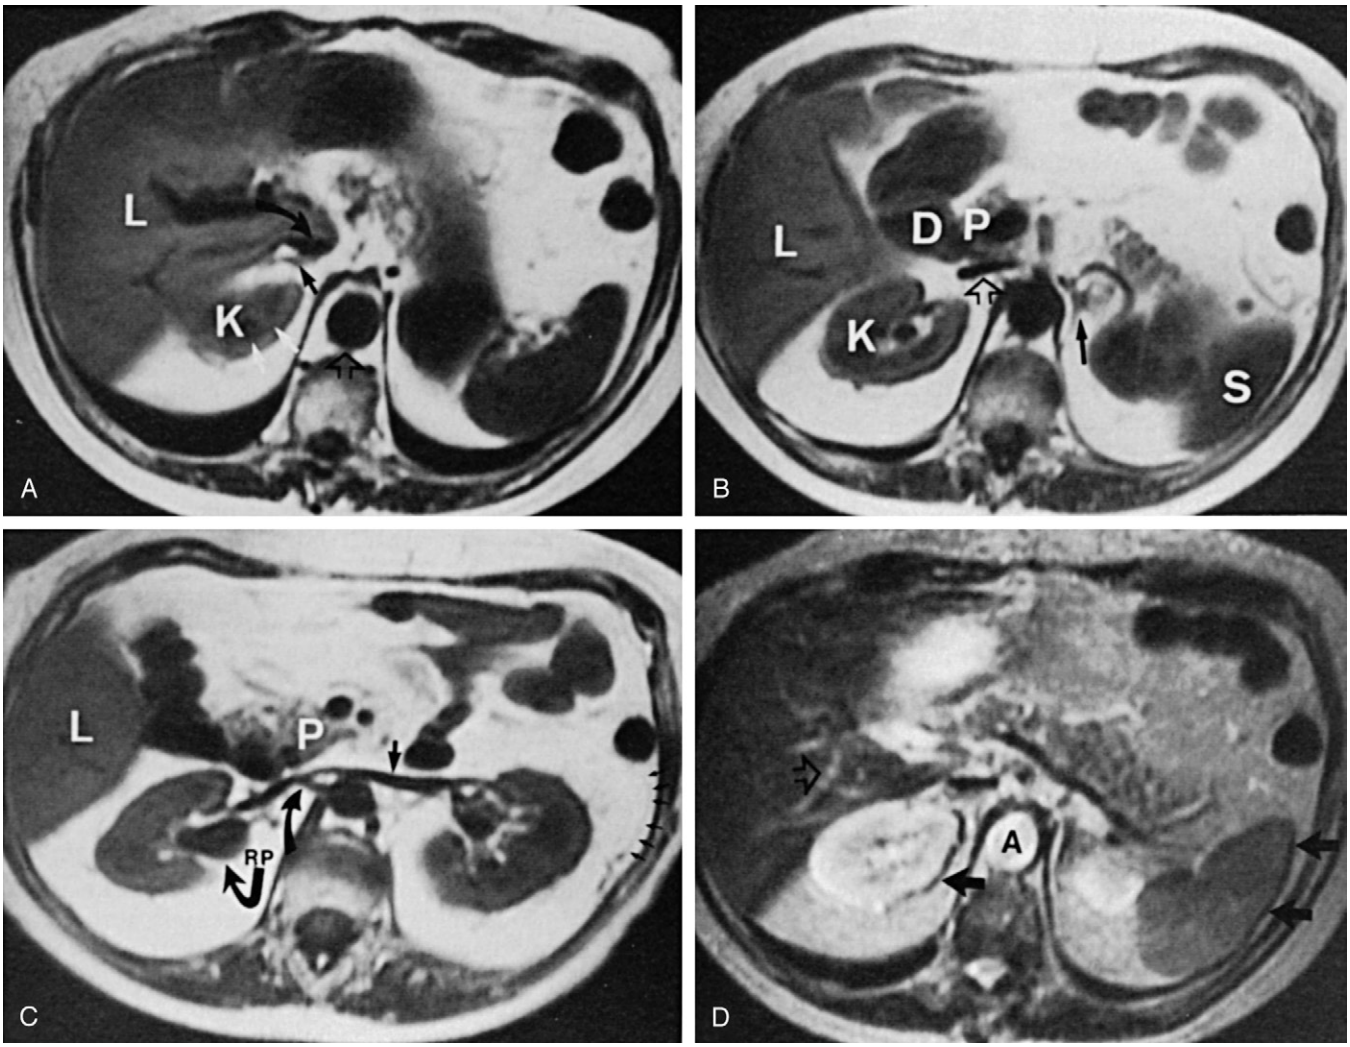

Figure 4–55. Magnetic resonance imaging (MRI) of the upper abdomen and kidneys. Axial MRI (T1-weighted) was taken through the level of the upper pole of the left kidney (K). The renal medulla is of lower signal intensity *(white arrows)* than the cortex, and it appears darker. The right adrenal gland *(arrow)* is identified with an inverted-V configuration, immediately posterior to the inferior vena cava *(curved arrow)*. The inferior vena cava and the aorta *(open short arrow)* demonstrate the flow void phenomenon and appear low in signal intensity. **B,** T1-weighted, short TR/TE (TR = 400 msec, TE = 20 msec) scan performed 1.5 cm below that shown in **A**. The left adrenal gland is now identified *(black arrow)*. The liver (L), kidney (K), spleen (S), duodenum (D), pancreas (P), and inferior vena cava *(open arrow)* are also noted. **C,** T1-weighted, short TR/TE (TR = 400 msec, TE = 20 msec) scan through the renal hilum is shown. The left renal vein is identified *(short arrow)* as it traverses anterior to the aorta and enters the inferior vena cava. The right renal artery *(upper curved arrow)* is identified posterior to the inferior vena cava. The somewhat diluted extrarenal pelvis (RP) is identified as a structure of low-signal intensity arising in the hilum. A minimal amount of renal sinus fat is identified as a high-signal region surrounding the renal pelvis. Gerota fascia is visualized faintly *(short arrows)* on the left. Also identified are the liver (L) and the pancreas (P). **D,** T2-weighted image in the midabdomen. The kidney is of higher signal intensity than the liver or spleen. Chemical shift artifact is demonstrated *(arrows)*. The aorta (A) and intrahepatic vessels *(open arrow)* are of high signal intensity owing to the gradient moment nulling techniques that have been employed to minimize motion artifacts in this patient. (Reprinted from Kressel HY, Chen Q, Prasad P, Hatabu H. Magnetic resonance imaging. In: Pollack HM, McClennan BL, Dyer R, Kenney PJ, editors. Clinical urography. 2nd ed. Philadelphia: WB Saunders; 2000.)

Some patients are not suited for imaging using MRI or have implants that make MRI dangerous. Patients who should not undergo MRI are those who have difficulty with breath holding, severe claustrophobia, pacemakers, sterile magnetic implants, retained magnetic foreign bodies, cochlear implants, neurovascular aneurysm clips, or cardiac defibrillators. MRI is also a poor choice to evaluate the presence of urolithiasis because stones do not have signal characteristics that allow them to be detected.

MRI for urologic abnormalities usually requires 30 minutes inside the bore of the magnet. Patients are required to hold their breath for 20 to 30 seconds during the imaging sequence. Patients who are not cooperative or have difficulty holding their breath will compromise the quality and value of the magnetic resonance study.

Renal Magnetic Resonance Imaging

MRI is superior to CT imaging in the workup for renal cell carcinoma when surgical planning related to invasion into the renal vein or inferior vena cava is required. MRI can detect venous invasion with the sensitivity of 100% compared with 79% for CT imaging (Kallman et al, 1992). MRI is equivalent to CT scanning detecting renal tumors of 1 cm or greater and also in detecting

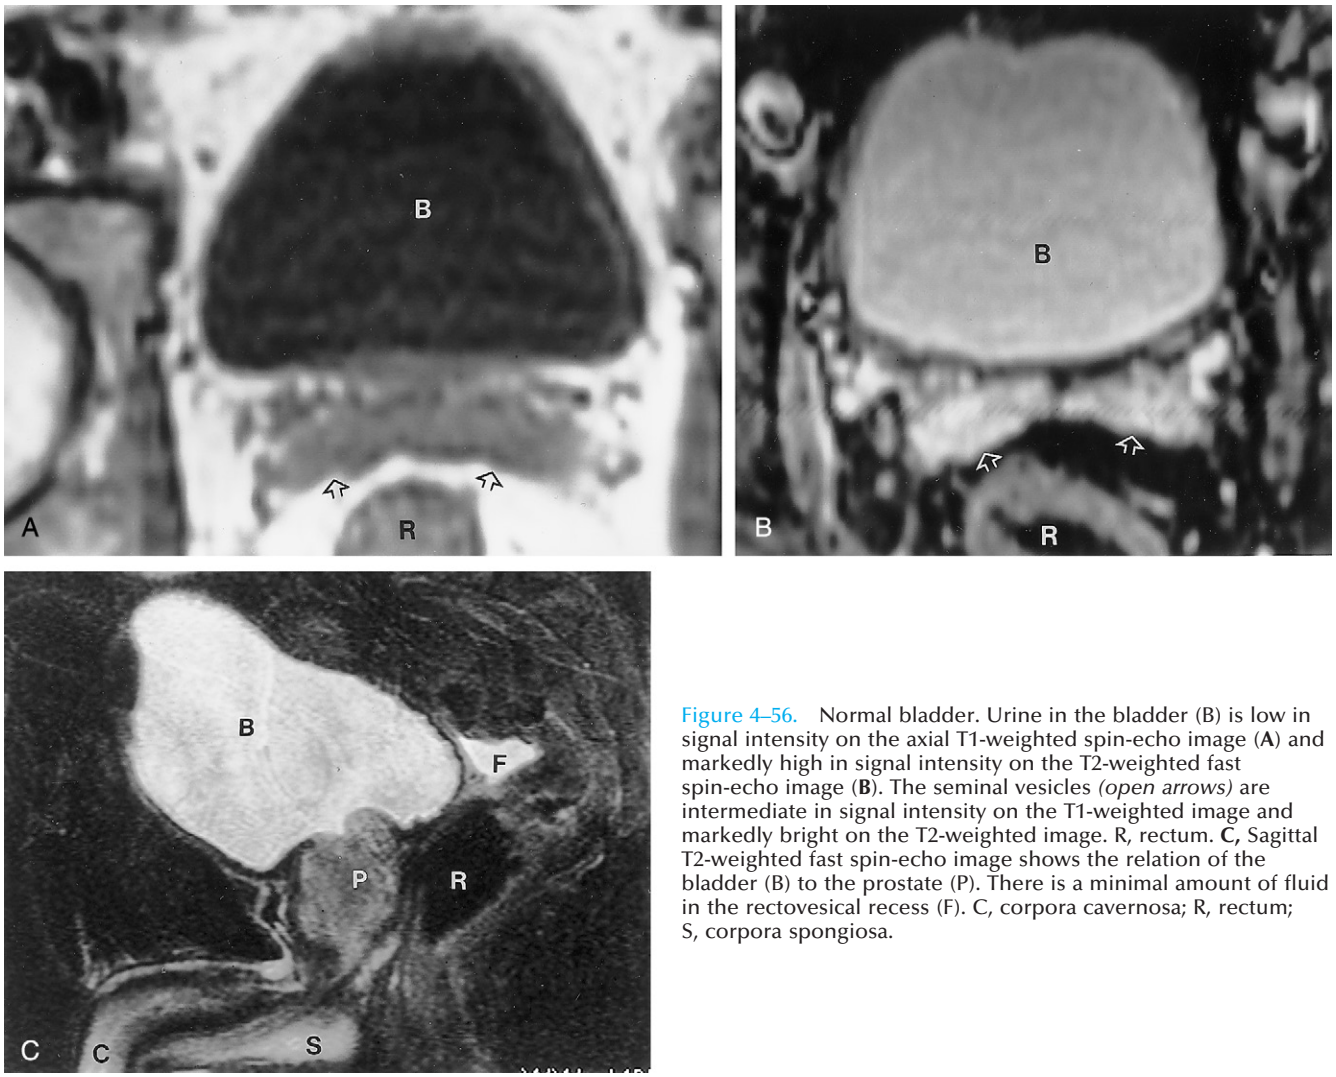

Figure 4–56. Normal bladder. Urine in the bladder (B) is low in signal intensity on the axial T1-weighted spin-echo image (**A**) and markedly high in signal intensity on the T2-weighted fast spin-echo image (**B**). The seminal vesicles *(open arrows)* are intermediate in signal intensity on the T1-weighted image and markedly bright on the T2-weighted image. R, rectum. **C,** Sagittal T2-weighted fast spin-echo image shows the relation of the bladder (B) to the prostate (P). There is a minimal amount of fluid in the rectovesical recess (F). C, corpora cavernosa; R, rectum; S, corpora spongiosa.

Table 4–6.

Characteristics of Magnetic Resonance T1- and T2-Weighted Images

	T1-WEIGHTED	T2-WEIGHTED
Body fluid: bladder, gallbladder, cerebrospinal fluid	Low signal or dark	High signal or bright
Fat	High signal or bright	High signal or bright
Kidney	Cortex high signal or bright Medulla low signal or dark	High signal or bright

lymphadenopathy associated with renal cell cancer (Pretorius et al, 2000).

The most important characteristic of a solid neoplasm is the presence of enhancement. Magnetic resonance enhancement is evaluated by comparing nonenhanced T1-weighted images to gadolinium-enhanced T1-weighted images. Any detectable lesion is assessed for measurable increase in signal intensity after gadolinium contrast administration. If the lesion is brighter on the postcontrast image and increases in signal intensity by more than 15%, it is declared enhancing and is consistent with renal cancer. Benign lesions including angiomyolipomas will also enhance with gadolinium contrast. However, on T1-weighted images high-signal fat content will be detected. Neither MRI nor CT imaging can differentiate an oncocytoma from renal cell carcinoma (Pretorius et al, 2000).

Simple cysts have similar characteristics on ultrasound, CT, and MRI. Complex cysts can also be differentiated or characterized on MRI. Hemorrhage within the cyst results in a high signal on T1-weighted images because of the paramagnetic effects of blood breakdown products (Roubidoux, 1994). Proteinaceous contents within a cyst can also yield high signal on T1-weighted images, and on T2-weighted images old hemorrhage results in a black ring along the cyst wall. **For benign, complex cysts there should be no enhancement of any component of the cyst** (Israel et al, 2004). **Because MRI is insensitive to calcifications, any calcifications present on the lining of a complex cyst are not seen on MRI. When evaluating independent risk factors for renal cell carcinoma, enhancement of the cyst wall was more sensitive and specific for the presence of**

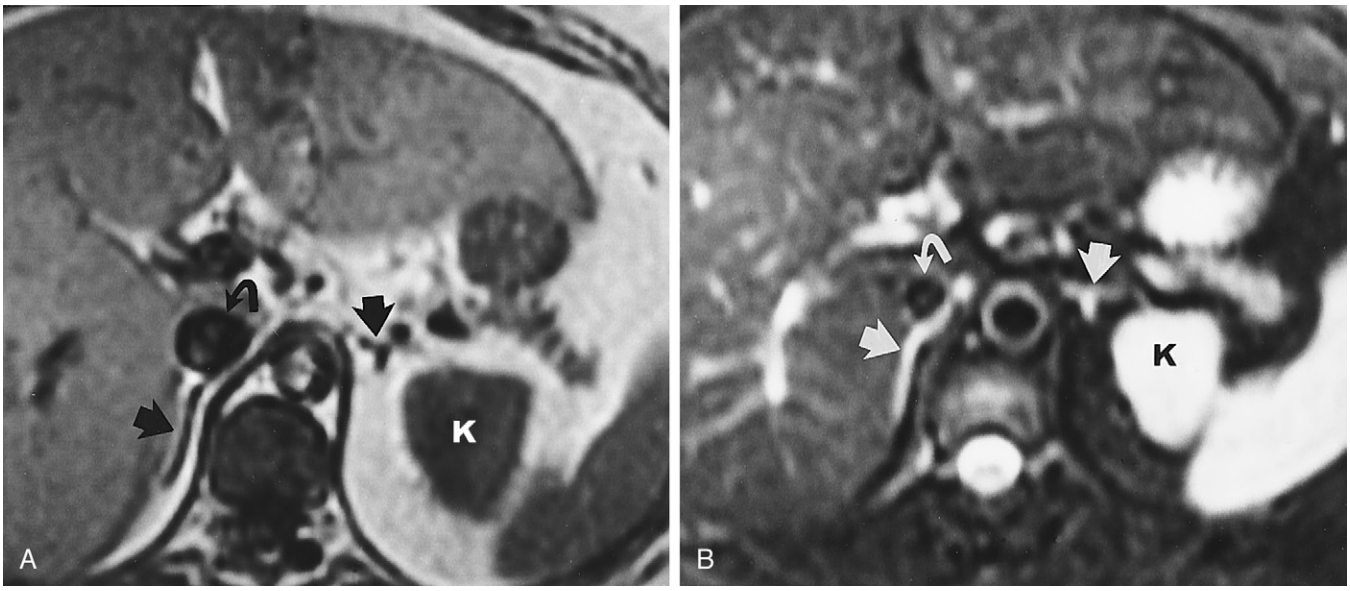

Figure 4–57. Magnetic resonance imaging of normal adrenals. **A,** Axial T1-weighted image (two-dimensional flash, TR = 130 msec, TE = 4 msec) shows the normal adrenals *(straight arrows)*. Note the vena cava *(curved arrow)* and the left kidney (K). **B,** Axial T2-weighted image (TR = 2000 msec/TE = 100 msec) with fat suppression of the same patient. The adrenals appear relatively hyperintense. (Reprinted from Mitty H, Parsons RB. Adrenal embryology, anatomy, and imaging techniques. In: Pollack HM, McClennan BL, Dyer R, Kenney PJ, editors. Clinical urography. 2nd ed. Philadelphia: WB Saunders; 2000.)

renal cell carcinoma than were calcifications on the cyst wall. On CT scan, calcifications can cause artifact that can inhibit the ability to detect enhancement of small nodules within the wall of a complex cyst. MRI has the advantage of not being influenced by calcifications embedded within the wall of a complex cyst. Therefore MRI is more likely to detect enhancement of a renal cell carcinoma in the wall of the complex cyst compared with CT imaging when mural calcifications are present (Israel and Bosniak, 2003).

Key Points: MRI

- When a renal mass is seen on MRI, the most important characteristic indicating the presence of a malignancy is enhancement of the mass.
- Nephrogenic systemic fibrosis is seen in patients with severe renal insufficiency who are exposed to gadolinium contrast media.
- Pheochromocytoma, metastatic lesion to the adrenal gland, and primary adrenal cortical carcinoma are all bright on T2-weighted images.

Adrenal Magnetic Resonance Imaging

MRI has proven to be of great value in the evaluation of the adrenal gland. MRI can easily separate adrenal adenomas from adrenal metastasis without using intravenous contrast. The high lipid content in adenomas makes them more readily differentiated from malignant processes that do not have high lipid content (Dunnick and Korobkin, 2002). The pheochromocytoma is also characterized by MRI without the need for contrast enhancement, avoiding a potential hypertensive crisis that has been associated with iodine contrast media in these patients. **Pheochromocytoma, adrenal cortical carcinoma, and metastatic lesions to the adrenal gland are usually of high signal intensity or bright on T2-weighted images** (Korobkin et al, 1996). **The benign adrenal myolipoma is easily demonstrated on T1-weighted images because fat within these lesions has a high signal or is bright compared with surrounding tissue** (Fig. 4–57).

Using MRI artifact referred to as *chemical shift,* MRI can define benign lipid-containing adenomas. The term chemical shift describes an artifact that occurs when approximately the same amount of lipid and water are in the same volume being imaged. The two different signals of these components cancel one another out when the chemical shift is maximized. The lipid-sensitive sequence is performed in two separate sequences of one scan. In one sequence known as "in phase," chemical shift artifact is at a minimum and the signals of lipid and water are additive. In the second sequence or "opposed phase," chemical shift artifact is at a maximum and the signals of lipid and water cancel one another, resulting in the adrenal mass being darker on the opposed phase images compared with the in-phase images. Loss of signal on chemical shift MRI is 95% sensitive and 100% specific for adrenal adenoma (Hood et al, 1999; Israel et al, 2004; Elsayes et al, 2005).

Outcomes Research

Mark S. Litwin, MD, MPH

Access to Care

Costs of Care

Quality of Care

Health-Related Quality of Life

Future Implications

The discipline of health services research, often loosely referred to as *outcomes research,* focuses on the study of access to care, costs of care, and quality of care.

ACCESS TO CARE

Access to care includes the "actual use of personal health services and everything that facilitates or impedes their use. **It is the link between health services systems and the populations they serve"** (Andersen and Davidson, 2001). Andersen presented a behavioral model for considering health care access in which three categories of factors determine how and whether individuals use medical services. These include predisposing factors (e.g., health beliefs, attitudes); enabling factors (e.g., health insurance, geographic proximity); and need factors (e.g., the presence of symptoms or diseases) (Aday and Andersen, 1981; Andersen, 1995). Barriers to health care access often result from financial determinants such as the lack of health insurance or adequate income, logistic challenges in coordinating child care, public transportation, and work schedules; clinic waiting times; and difficulties with the geographic proximity of clinics and hospitals (Griffiths et al, 2004).

Adequate access requires more than a guarantee of payment for services; even with generous benefits, individuals must navigate nonfinancial barriers. Among these are minority status (Mandelblatt et al, 1999; Eisenberg and Power, 2000; Institute of Medicine, 2003; Lurie and Dubowitz, 2007); gender (Saigal et al, 2008); environmental factors (Davidson et al, 2004); health behaviors (Call et al, 2006); acculturation, language, and citizenship (De Alba et al, 2005; Echeverria and Carrasquillo, 2006; Flores, 2006); provider proximity (Schroen et al, 2005); available safety-net services (Call et al, 2006); and the absence of a usual source of care (Sox et al, 1998; Petterson et al, 2009).

Barriers to access may also result from more subtle factors such as fear of the health care system, ethnic disparities, cultural norms, embarrassment, perceived health status (Fitzpatrick et al, 1998), lack of self-efficacy, knowledge (Deibert et al, 2007), or special social circumstances. Even in health care systems that are considered to provide "equal access," such as the U.S. Veterans Affairs hospitals, different patient groups use outpatient and inpatient care at markedly different rates, leading to variations in outcomes. Differences in access to care have been cited as a fundamental reason for disparities in health status among various populations (Kelley et al, 2005a, 2005b).

In this context, differential access to care has been proposed as an important determinant of racial/ethnic disparities in prostate cancer screening, treatment, morbidity, and mortality (Mandelblatt et al, 1999; Hoffman et al, 2001; Underwood et al, 2004; Talcott et al, 2007). This is supported by empiric data demonstrating that African-American men with prostate cancer are more likely than whites to be uninsured; to receive their usual medical care in a public clinic or emergency department; and to see different clinicians on subsequent prostate cancer–related visits (Talcott et al, 2007). Likewise, discrepancies in accessibility and continuity of medical care may explain the lower use and awareness of prostate specific antigen (PSA) testing among Hispanic men in the United States (Spencer et al, 2006; McFall, 2007); it remains unknown whether access or continuity issues mediate the greater dissatisfaction with prostate cancer treatment decisions among Hispanic men (Hoffman et al, 2003).

Access to health care reflects not only the potential for entry into the health care system, but also the actual consumption of services. In one public-assistance program for low-income, uninsured men with prostate cancer, special attention to overcoming the financial and nonfinancial barriers has eliminated racial/ethnic disparities in health services utilization (Miller et al, 2008a). Nonetheless, because men from historically disadvantaged groups often do not access adequate and timely care, they continue to suffer a disproportionate burden (Miller et al, 2009b).

COSTS OF CARE

The cost of medical care may be measured in many ways. Although it is difficult to put a price tag on the toll of human suffering, physicians today are asked to reduce costs, improve quality, and provide services for greater numbers of patients in an increasingly austere environment. This often requires rationing of resources, though it is seldom explicitly labeled as such. In the present era of sweeping change in health care financing and health services delivery, increasing emphasis has been placed on efficiency in the allocation of scarce medical resources. The field of medical economics is well beyond its nascence, and broad public interest has emerged in studying the costs of medical and surgical therapies. As we spend more administrative dollars on cost containment, scrutiny is reaching all potential areas for conservation including oncology, a province once considered sacred and off limits to cost-cutting efforts.

Urologists have long been attentive to issues of cost in managing health care. In his autobiography, Hugh Hampton Young, the father of American urology, described a patient on whom he agreed to perform a prostatectomy in the 1920s for a fixed fee of $500 with a promise of only 3 weeks in the hospital. Because the patient suffered complications and remained hospitalized for much longer than planned, Young had to spend his entire professional fee plus an additional $350 to pay off the hospital bill (Young, 1940).

Health policy decisions today are based not only on biomedical research but also on sound evaluations of health care costs. The introduction of oral erectogenics, beginning in the late 1990s, provides a perfect illustration of the tension between therapeutic advances and economic forces. The scientific discoveries that led to the advent of sildenafil and similar agents (Rajfer et al, 1992) were rewarded with a Nobel Prize, yet insurers initially fervently resisted paying for them (Lee, 1999). This led to potent controversy, generated numerous studies, and even raised constitutional law questions (Keith, 2000; Smith and Roberts, 2000; Connolly, 2001). As a surgical subspecialty with large numbers of Medicare patients, many of whom suffer waning turgor, urology is a discipline in which cost-saving maneuvers may have tremendous financial impact.

Terms and Methods of Analysis

In its purest form, **research on health care costs involves counting the amount of money that is expended on facilities, equipment, supplies, and personnel during the provision of medical care.** But many costs are hidden. A more extensive approach would also include the opportunity cost of the time patients spend receiving care. For example, when estimating the cost of an interval cystoscopy after resection of a bladder tumor, a thorough assessment would include not only the cost of overhead, supplies, lidocaine jelly, urine cytology, and professional fees but also the cost to the patient in lost wages—or to his or her employer in lost productivity—during the time away from work for the procedure, travel, or any complications. This component is not insignificant. Employee absence from work has been estimated to cost U.S. businesses tens of millions of dollars annually (Walsh et al, 1989; Luz and Green, 1997; Stewart et al, 2003).

Because true costs are difficult to quantify at the individual, institutional, or population level, researchers instead often report data on charges. ***Charges* represent the amount that is billed for a service, whereas *costs* reflect what the provider expended to supply that service.** Most of the available administrative databases in health care are based on either financial discharge abstracts from hospitals or claims data from large payers, insurance companies, or government agencies such as the Center for Medicare and Medicaid Services. These data sets primarily include information on charges and payments, but not costs. The major advantage of using charge data is that they are much easier to obtain. The primary disadvantage is that they may not accurately reflect the true underlying costs of individual medical services. For example, a hospital that is losing money on intravenous pyelograms may make up the deficit by increasing its charges for urine cytologies. This practice may help balance the annual budget, but it corrupts the quality of the charge data. An economic analysis using charges for bladder cancer follow-up in this hospital will err by incorporating the inflated amounts charged for interval urine cytologies. Some analysts attempt to circumvent this problem by calculating a ratio of costs to charges for entire facilities, individual medical services, or diagnosis-based categories of care. Although imperfect, charges are frequently used to estimate the amount of money spent on health care.

To avoid the inherent problems in calculating costs and charges, some researchers instead measure *resource utilization* in terms of duration, frequency, and intensity of services (Munoz et al, 1988b). One of the most commonly reported units of comparative analysis is length of stay (LOS). After 1983, when the prospective payment system was instituted to reimburse hospitals a predetermined amount of money on the basis of the diagnosis-related group (DRG) into which each Medicare inpatient is classified (Munoz et al, 1988a; Kahn et al, 1990; Munoz et al, 1990a, 1990b, 1990c), attention to LOS as an outcome variable in cost analyses greatly increased. In the United States, inpatient LOSs are now believed to have reached their floor, and effort has shifted from this measure.

Costs of care may be measured as intensity or numbers of services provided. For example, rather than calculating the costs or charges for a 3-day hospitalization for radical nephrectomy, analysis may be based on the total number of complete blood counts, chest radiographs, bags of intravenous fluid, doses of antibiotic, and doses of narcotic and antibiotic ordered on any given day of the hospital stay or during the entire stay. By examining duration or frequency of medical services when studying costs, researchers can avoid the biases involved in using financial data.

Cost-effectiveness analysis is another popular technique used to evaluate new or established medical therapies. A cost-effectiveness analysis is performed by developing a probability model of the possible medical outcomes of different interventions (or a nonintervention such as watchful waiting for benign prostatic hyperplasia) (Saigal et al, 2007), identifying the expenses associated with each outcome, and comparing the results, typically reported as cost per year of life saved (Shepard and Thompson, 1979; Henriksson and Edhag, 1987; Chandhoke and DeAntoni, 1998; Manca et al, 2003). **Years of life saved, or *life-years (LYs),* are calculated for a population, not for individuals.** Ten LYs might represent 2 patients, each of whom survives for 5 additional years, or 120 patients, each of whom survives for 1 additional month (Smith et al, 1993). LYs are usually adjusted to account for different health states that may result from various treatments. These are called *quality-adjusted life-years (QALYs)*. For example, when comparing two treatments for localized prostate cancer, if both options are determined to cost $10,000 per year of life saved, then the two may seem equivalent. However, if one treatment yields years that are compromised by bothersome sexual dysfunction, while the other yields years that are free of such problems, then the difference in quality of the years saved must be factored into the equation. Analyses that rely on QALYs are facilitated by the estimation of patient utilities, or preferences, for various health states (Nease and Owens, 1994; Albertsen et al, 1998; Saigal et al, 2001; Saigal et al, 2002). If patients appraise an impotent year as being worth less than a potent year, then quality adjustments may make the first treatment more expensive per QALY saved. *Cost-benefit analysis* differs by including not only the costs but also the equivalent monetary value of any benefits garnered during the extra years of life. Often, this refers to wages earned or income accrued during that time. In more sophisticated analyses, future income and expenses related to a particular health state are discounted to present value by incorporating projected interest and inflation rates over time.

Cost studies may be undertaken as descriptive analyses that chronicle the economic burden of one disease in a group of patients, such as the cost of care for interstitial cystitis in a managed care plan (Clemens et al, 2008). They may examine the

financial impact on the general population such as national annual expenditures for urolithiasis (Lotan, 2009). They may also track cumulative costs over time, such as for different prostate cancer treatments (Wilson et al, 2007). Alternatively, they may present economic models comparing different approaches to managing an illness such as whether it is more costly to correct cryptorchidism in infants or older boys (Hsieh et al, 2009), or to manage small renal tumors with laparoscopic or percutaneous cryoablation (Badwan et al, 2008).

Patterns of Care

Much of the current research into the cost of treating patients is predicated on the observation that patterns of care differ substantially for certain conditions. Physician demographics and patient age have been found to affect practice patterns (Bennett et al, 1991; O'Leary et al, 2000; Bird et al, 2003; Joudi et al, 2003; Fallon et al, 2005). The availability of evidence does not always predict the diffusion of new technologies (Michel, 2006), especially in urology. For example, robotic prostatectomy has seen nearly ubiquitous adoption, largely driven by overwhelming commercial and market forces, despite the absence of evidence showing superiority (Hu et al, 2006, 2009). Conversely, some advances with strong evidence-based advantages such as partial or laparoscopic nephrectomy for small renal masses or neobladder reconstruction following cystectomy, have diffused much more slowly (Gore et al, 2006; Miller et al, 2008b).

Despite the relative scarcity of cost analyses in urology, significant variations in length of stay and charges have been reported for many nonurologic medical and surgical hospitalizations (Fisher et al, 2003a, 2003b; Weinstein et al, 2004; Wennberg, 2004). Cost savings can be achieved by identifying variations in urologists' practice habits and targeting them for reduction in intensity and duration (Sage et al, 1988; Kramolowsky et al, 1995a, 1995b). These changes in urologic practice have been shown to result in equivalent medical outcomes (Cleary et al, 1991), despite the finding that patients historically have tended to dislike shorter postoperative hospital stays (Litwin et al, 1997; Durieux et al, 2004). Overall, studies have been mixed. Some have described the successful use of cost-control mechanisms in urology (Cuckow, 1992a, 1992b), whereas others have failed to show sustained results (Forrest et al, 1981).

Analysis of both medical and surgical DRGs indicates that consistent patterns of resource utilization are identifiable during the course of hospitalizations, suggesting that elements of utilization may be managed more effectively to yield cost savings (Carter and Melnick, 1990). This is particularly true in treatments for genitourinary conditions such as hematuria, incontinence, or prostatitis (Taylor et al, 2008), many of which may be standardized. Urology is a fertile area for economic analysis because so little is known about the cost-effectiveness of screening and treatment interventions for even the most common genitourinary conditions (Perlman et al, 1996; Grossfeld and Carroll, 1998; Benoit et al, 2001; Mor et al, 2001; Shaw, 2004).

The advent of managed care has greatly assisted the study of practice patterns and medical outcomes. **Most researchers agree that health maintenance organizations (HMOs) improve access to medical services and cost efficiency of care without compromising quality** (Holtgrewe, 1998a, 1998b; Haffer and Bowen, 2004; Roetzheim et al, 2008). However, contrary evidence suggests that cancer patients may wait longer for treatment in HMOs than in fee-for-service plans (Greenwald, 1987). Among men newly diagnosed with prostate cancer, those cared for in HMOs are almost 1.5 times more likely to receive radiation than surgery for clinically localized tumors. This appears consistent with the general HMO emphasis on outpatient care. In this study, HMO patients had a lower overall mortality rate than did non-HMO patients. Interestingly, low-income men treated in HMOs enjoyed survival times that were significantly greater than for middle- or high-income men in HMOs or fee-for-service plans (Greenwald and Henke, 1992).

The National Institute of Diabetes and Digestive and Kidney Diseases funds the Urologic Diseases in America project (www.udaonline.net), which seeks to define the burden of urologic disease on the American public by quantifying trends in resource utilization, practice patterns, costs, outcomes, and epidemiology across the spectrum of urologic conditions (Litwin et al, 2005; Miller et al, 2009a). Documenting these trends has broad implications for quality of health care, access to care, and the equitable allocation of scarce resources, both in terms of medical services and research budgets. Among the most financially burdensome urologic conditions are urolithiasis (Lotan, 2009), urinary tract infection (Griebling, 2005a, 2005b), urinary incontinence (Anger et al, 2006), and benign prostatic hyperplasia (Nickel, 2006a, 2006b). Urologic diseases exert a substantial impact on resource utilization within the U.S. Veterans Affairs health system (Anger et al, 2008).

Case Mix

When studying patterns of care or medical costs, it is critical to adjust for case mix. ***Case mix* refers to the severity of illness and degree of comorbidity in a group of patients** (Iezzoni, 1996, 1997). These patient characteristics may influence treatment outcomes. For example, because they typically have a greater burden of comorbidity, older patients are more likely to experience complications after surgery. This comorbidity must be accounted for in evaluations of clinical outcomes (Glance et al, 2008). If this fact is not considered when comparing surgical complication rates across hospitals, evaluators may erroneously conclude that a hospital with an older patient population is providing poorer-quality care. To use outcomes to measure quality of care, we need to adjust for these other factors including baseline patient characteristics and intervening treatments. This adjustment (referred to as case-mix adjustment or risk adjustment) can be extremely complex, and the selection of factors must be carried out carefully so that outcomes can be interpreted accurately. For a variety of reasons, sicker patients cost more, and it is important to control for this difference in comparative analyses. When examining the factors that lead to higher hospital charges for more ill patients, two forces must be considered: duration and intensity of care. **Duration is usually quantified as inpatient LOS, whereas intensity of care may be assessed as numbers of services or charges per day.** Patients with greater comorbidity may remain hospitalized longer even if they do not receive more intense care during their stays. Duration and not intensity appears to be the primary force driving up hospital charges for sicker urology patients (Litwin et al, 1993).

Typically, comorbidity is quantified by extracting diagnoses from claims data (Klabunde et al, 2002); however, some comorbidity measures rely on patient self-report. Various comorbidity measures (Kaplan and Feinstein, 1974; Charlson et al, 1987; Greenfield et al, 1993, 1995; Crabtree et al, 2000; Di Gangi et al, 2003) have been used by researchers to adjust for case mix and predict mortality from competing causes in clinical studies. Although all perform

reasonably well in the research setting, most are based on diagnoses from retrospective chart review and difficult to apply clinically (Albertsen et al, 1996).

The impact of case mix on urologic disease outcomes has been studied most broadly in men treated for prostate cancer. The presence and severity of cardiovascular disease negatively affect outcomes in men treated with radiation or surgery (van de Poll-Franse et al, 2008a, 2008b). Higher body mass index is associated with poorer outcomes after robotic prostatectomy. In obese men, surgical times are more than an hour longer, blood loss is higher, and positive margin rates are higher (Herman et al, 2007). Obese men undergoing open radical prostatectomy have more aggressive tumors, more positive margins, and higher rates of biochemical progression than nonobese men (Freedland et al, 2008), although their long-term survival is unaffected (Siddiqui et al, 2006). Comorbidity is more important than age in predicting perioperative mortality rates after radical prostatectomy (Alibhai et al, 2005, 2006; Daskivich et al, 2010a).

The available general comorbidity indices do not appear to be equally effective at adjusting for case mix in men with prostate cancer (Alibhai et al, 2008). The optimal comorbidity index for prostate cancer should be disease specific and use empirically derived weights for component conditions (Klabunde et al, 2007). The Total Illness Burden Index for Prostate Cancer (TIBI-CaP) is a patient-reported measure of comorbidity, which identifies patients at high risk for non–prostate cancer mortality. It is a robust predictor of both mortality and future quality of life. Men in the highest risk category are 13 times more likely to die of causes other than prostate cancer over a 3.5-year period than the men who had the lowest scores (Litwin et al, 2007; Daskivich et al, 2010b).

Comorbidities such as obesity also affect the incidence and severity of benign urologic conditions (e.g., urinary incontinence, chronic prostatitis/chronic pelvic pain syndrome, benign prostatic hyperplasia/lower urinary tract symptoms, erectile dysfunction) (Pontari et al, 2005; Bhojani et al, 2008a, 2008b; Subak et al, 2009). The interrelationships between erectile dysfunction, obesity, cardiovascular disease, and metabolic syndrome are complex (Bener et al, 2008; Yassin et al, 2008).

Cost Savings in Urology

Physicians have been largely successful at attenuating the increases in hospital costs by eliminating unnecessary hospital days, but maximal savings may have been reaped from this strategy (Bodenheimer, 2005). Nevertheless, continued tailoring of the intensity and duration of service to patient burden of illness may still be shown to reduce costs. Urology has played a central role in the ongoing struggle to balance the competing priorities of minimizing costs and maximizing quality in health care (Loughlin, 2003). One recent government strategy adopted in pursuit of this goal is Medicare's pay-for-performance initiative, in which providers are differentially reimbursed on the basis of their adherence to various condition-specific quality indicators (Corrigan and Ryan, 2004), many of which also result in cost savings.

QUALITY OF CARE

Quality of care research evaluates "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" (Lohr 1990; Lohr et al, 1992; Institute of Medicine, 2001). Several initiatives are under way to collect and disseminate performance information about medical care. For example, the National Committee on Quality Assurance (www.ncqa.org) provides information to health care purchasers about the comparative performance of health plans in the United States. The Joint Commission (www.jointcommission.org) applies outcomes-based quality measures to accredit hospitals. Hundreds of performance indicators have been collected in its National Library of Healthcare Indicators. The Foundation for Accountability (www.facct.org), a consumer organization, "creates tools that help people understand and use quality information, develops consumer-focused quality measures, supports efforts to gather and provide quality information, and encourages health policy to empower and inform consumers."

The conceptual framework for the measurement of quality of care in medicine was established 45 years ago by Donabedian (Donabedian, 1966). In this model, quality of care measures are categorized into three domains—structure, process, and outcome. Structure of care includes the equipment, resources, and provider experience necessary to provide care. Examples include volume of cases and board certification of providers. Process of care refers to technical and interpersonal elements of care that transpire between doctor and patient such as the extent of the history and physical examination, documentation of the workup, and ordering of diagnostic and laboratory tests. Process measures are often considered to be the best measure of quality (Brook et al, 1996; Brook et al, 2000). Outcomes of care include survival rates, complications, and patient-reported outcomes (PROs) such as health-related quality of life. As underscored in his exposition on quality of care, Blumenthal argues that the most important new development in our current understanding of medical outcomes was the recognition that it is patients who define which outcomes are most important and whether or not they have been achieved (Blumenthal, 1996a, 1996b; Blumenthal and Epstein, 1996). Hence we have seen the advent of patient-reported outcomes as primary end points in clinical trials and the primary focus of much attention in evidence-based medicine. In 2006 the U.S. Food and Drug Administration formally issued guidance for the development of PROs to be used in its assessment of new drugs and devices (www.fda.gov) (Sloan et al, 2007).

Leading the national effort in the United States to establish an infrastructure for improving quality of care, the federal Agency for Healthcare Quality and Research (AHRQ) has published a series of quality indicators (www.qualityindicators.ahrq.gov). On the basis of extensive reviews of available evidence, AHRQ developed four categories of quality indicators (prevention, patient safety, inpatient, and pediatric), which are now being used to modulate hospital and physician reimbursement. In this model, quality of care is assumed to be directly related to adherence to these published quality indicators.

One substrate for the study of quality of care in urology is prostate cancer; it is prevalent, costly, and associated with great clinical uncertainty (Miller et al, 2005). RAND Corporation researchers proposed a detailed infrastructure for measuring structure, process, and outcomes of care in men with prostate cancer (Litwin et al, 2000; Spencer et al, 2003). This underpinned a national assessment of quality of care by applying specific quality indicators developed from the RAND work. Wide geographic variations exist in compliance with the RAND quality indicators; teaching/research hospitals and Comprehensive Cancer Centers have the highest compliance; racial differences are not observed for any indicator (Spencer et al, 2008). Early data suggest that radiation oncologists provide care that appears more compliant than that of urologists with the RAND quality indicators (Miller et al, 2007).

Structure of Care

Structure encompasses the human, technical, and financial resources needed to provide medical care. Organizations such as the Joint Commission and the American College of Surgeons measures have generally relied on structural measures in their accreditation procedures. Important structural attributes for quality of care may include clinician characteristics (e.g., percentage of physicians who have board certification, average years of experience, distribution of specialties); organizational characteristics (e.g., staffing patterns, reimbursement method); patient characteristics (e.g., insurance type, illness profile); and community characteristics (e.g., *per capita* hospital beds, transportation system, environmental risks). Structural measures specific to prostate cancer quality could include the presence of a multidisciplinary cancer center or psychologic support services.

Although certain structural characteristics may be necessary to provide good care, they are usually insufficient to ensure quality of care. Therefore the best structural measures are those that can be shown to have a positive influence on the process of care and on patient outcomes, although this relationship has not been confirmed (Brook et al, 1990). One structural measure that is positively associated with outcomes is the volume or number of cases treated by a particular physician or institution (Joshi and Miller, 2004; Joudi and Konety, 2004; Katz et al, 2004; Lee et al, 2004; Nuttall et al, 2004; Dibra et al, 2005; Killeen et al, 2005; Lyman et al, 2005; Vitale et al, 2005; Anger et al, 2007; Jeldres et al, 2008).

Evidence links surgical volume with outcomes across multiple disease conditions; however, the explanation and significance of this finding remains unclear. First noted in 1979 (Luft et al, 1979), the volume-outcomes relationship has been extensively explored for various surgical and medical conditions. An Institute of Medicine analysis of 27 diagnoses and procedures revealed that in general volume is associated with morbidity and mortality outcomes, but the magnitude of the relationship varies widely (Halm et al, 2002). Surgical volume has gained traction in health policy decisions as a marker of surgical quality (Cooperberg et al, 2009).

Patients who undergo urologic cancer surgery for prostate, bladder, kidney, or testis tumor are less likely to experience complications and mortality if their surgery is performed by a high-volume surgeon in a high-volume hospital (Joudi and Konety, 2004; Taub et al, 2004; Hollenbeck et al, 2007; Hollenbeck et al, 2007; Gilbert et al, 2008; Siu et al, 2008; Mayer et al, 2009). This observation also holds in men undergoing transurethral prostatectomy (Riley and Lubitz, 1986).

Patients treated at facilities or by surgeons who performed fewer radical prostatectomies experience more surgical complications than those treated by higher-volume providers (Lu-Yao et al, 1996; Ellison et al, 2000; Begg et al, 2002; Hu et al, 2003). Patients undergoing external beam radiation fare better when the radiation oncologist has a caseload of at least 10 per year or 200 cumulatively (Jeldres et al, 2008). It is not clear which characteristics of providers (surgeons or hospitals) performing many surgeries contribute to better outcomes; however, high volume appears to be an important predictor of good-quality care. As predicted with great prescience 3 decades ago by Harvard's then-surgeon-in-chief, Dr. Francis D. Moore (Moore, 1980), regionalization of care for complex surgical procedures addresses disparities in quality. This has occurred for malignant and benign conditions in urology (Hollenbeck et al, 2005; Hollenbeck et al, 2006; Morris et al, 2006).

Process of Care

Process of care is the set of activities that goes on between patients and practitioners and is often divided into interpersonal process and technical process. *Interpersonal process* refers to how the clinician relates to the patient and includes issues such as whether the clinician supplies sufficient information in a clear enough manner for the patient to make an informed treatment choice. Patient survey data are generally used to assess quality of interpersonal process.

***Technical process* refers to whether medically appropriate decisions are made when diagnosing and treating the patient and whether care is provided in an effective and skillful manner.** One way to evaluate the appropriateness of medical treatment is to determine if the care provided is consistent with current medical knowledge and adheres to the professional standard. This assessment can be done by developing *quality indicators* that describe a process of care that should occur for a particular type of patient in a specific clinical circumstance. In order to be valid, these quality indicators should be based on the evidence in the medical literature and on current professional standards of care. Determining the latter often requires an expert panel in order to achieve consensus. The performance of physicians and health plans is then assessed by calculating rates of adherence to the indicators for a sample of patients.

Using quality indicators to evaluate appropriateness of care is relatively straightforward. However, assessing the effectiveness or skill of technical process of care is much more difficult. Indeed, direct observation may be necessary to assess quality of technical process of care. Alternatively, we may have to rely on measuring outcomes to evaluate whether care was provided in a skillful manner. For example, measurement of surgical blood loss or number of specimens with positive margins, both surgical outcomes, may be indicators of the quality of surgical technical process. Conversely, operative time may represent the surgeon's manual dexterity or the technical complexity of a case. Hence celerity is not generally considered an accurate indicator of operative quality.

Process measures form the basis for most extant quality assurance efforts including the National Center for Quality Assurance's Health Plan Employer Data and Information Set (HEDIS) and underlie most of the new "pay-for-performance (P4P)" incentives being pursued for reimbursement incentive systems (Epstein et al, 2004). However, quality assessment efforts should also incorporate structure and outcome measures. Birkmeyer and colleagues have suggested a framework in which quality metrics are driven by the risk a procedure poses to a patient and the average hospital caseload for the procedure (Birkmeyer et al, 2004). For high-risk, low-volume procedures such as nephrectomy with caval thrombectomy, structural measures are most appropriate because samples are too small to assess processes and outcomes. For high-risk, high-volume procedures such as radical prostatectomy, efforts may be more focused on processes and outcomes. The National Surgical Quality Improvement Program (NSQIP) developed by the U.S. Department of Veterans Affairs (VA) (Khuri et al, 1998) and under evaluation for non-VA hospitals (Fink et al, 2002) provides a framework for high-risk, high-volume procedures.

Outcomes of Care

Outcomes include changes in patients' current and future health status including health-related quality of life and satisfaction. Cancer researchers generally use survival

or progression-free survival as the main outcome measure in clinical studies. Sometimes proxy measures (also called *surrogate end points* or *intermediate outcomes*) that do not measure the outcome directly but are thought to be correlated with it are used. When a proxy measure is used as a quality indicator, there must be evidence that the proxy measure is truly a substitute for the outcome of interest. For example, rapid PSA velocity after treatment for localized prostate cancer appears to be associated with cause-specific mortality (Patel et al, 1997; D'Amico et al, 2005), so PSA doubling time may be a reasonable proxy outcome. Although the ultimate outcome may be mortality, many conditions in urology such as prostate cancer take an indolent course, making mortality impractical (and often irrelevant). In such conditions, more proximal outcomes such as length of stay, complications, and the need for salvage therapy provide a useful proxy (Hu et al, 2008). For proxy measures to be useful as quality measures, intervention should affect both the measure and the underlying disease (Schatzkin et al, 1996).

The most important patient-reported outcome is health-related quality of life, a multidimensional construct that includes somatic symptoms, functional ability, emotional well-being, social functioning, body image, as well as overall well-being (Guyatt et al, 1986; Cella and Bonomi, 1995; Guyatt et al, 1997). Quality of life assessment, typically by patient survey, provides a comprehensive evaluation of how the illness and its treatment affect patients.

Another patient-reported outcome commonly measured is patient satisfaction (Strasser et al, 1993), which refers to patients' perceptions of the quality of care they received. Patient satisfaction is also usually assessed by patient survey. One limitation of satisfaction ratings is that patients are not generally able to evaluate the technical quality of their care. In fact, studies have found no consistent relationship between patient satisfaction and technical quality of care (Cleary and McNeil, 1988; Hayward et al, 1993). That is, a physician who interacts with patients in a warm and open way may provide care that is technically poor (Aharony and Strasser, 1993). In addition, patients' satisfaction ratings may vary with their expectations. Nonetheless, when used in conjunction with other measures, data about patient satisfaction can provide useful information about overall quality of care.

Challenges to Using Outcomes to Evaluate Quality of Care

Adverse outcomes may be uncommon events, so large samples of patients may be necessary when using outcome measures to detect differences in quality among health systems or hospitals. For example, to detect a 2% point difference in the rate of postoperative wound infections between two hospitals (e.g., 5% for 1 and 7% for the other), each hospital would need to have at least 1900 patients who had the surgery.

In addition, a single outcome may be affected by many different factors, making it difficult to establish accountability. When comparing differences in surgical outcomes across hospitals, one does not know if the differences in outcomes are related to the skill of the surgeon, the competence of the surgical team, the postoperative care, the case mix, or some unmeasured factor. And the more time that elapses between the intervention and the outcome, the more difficult this problem becomes. For example, comparing 10-year outcomes in women treated for incontinence at different facilities, what is more important, the quality of the initial treatment or the quality of care for recurrent symptoms?

Outcomes can also be measured for more than one purpose. Although we are interested in developing outcome measures for evaluating the quality of care received by patients with urologic diseases, outcomes are also used clinically to track a patient's progress and, in clinical trials, to measure the efficacy or effectiveness of a new drug or intervention (Williams et al, 2004). The same measures can sometimes be used for both purposes, but certain measures are better suited for one purpose or the other. For example, 5-year survival rates are a standard measure used in many studies of new cancer treatments. However, when measuring quality of care for purposes of accountability or quality improvement, we generally need a shorter time horizon than 5 years. If we compared the 5-year survival of patients with bladder cancer at two institutions, we might indeed find that one institution had higher survival rates, suggesting that it had better quality of care. However, during those 5 years, changes in staff, revamped procedures, or new technology may have improved or weakened the quality of care at the hospitals, thereby making the comparison of only historical relevance.

Other Quality Measurement Approaches

In addition to the Donabedian model, other approaches to measuring quality of care rely on implicit review or assessment without explicit criteria. This typically involves having an acknowledged expert carry out a formal evaluation of the episode of care by reviewing the medical chart without the establishment of specific criteria for quality. The evaluator makes an implicit judgment of whether or not the care rendered was of high quality. This approach is *de facto* qualitative and may not yield results that are as valid and reproducible.

HEALTH-RELATED QUALITY OF LIFE

Health-related quality of life (HRQOL) is one of several variables commonly studied in the field of medical outcomes research. HRQOL encompasses a wide range of human experience including the daily necessities of life such as food and shelter, intrapersonal and interpersonal responses to illness, and activities associated with professional fulfillment and personal happiness (Patrick and Erickson, 1993). Contemporary interpretations of HRQOL are based on the World Health Organization's longstanding definition of health as a "state of complete physical, mental, and social well-being and not merely the absence of disease" (WHO, 1948). Because illness may affect both quantity and quality of life, all constituents of well-being must be addressed when treating patients with urologic diseases. Perhaps most importantly, HRQOL involves patients' own perceptions of their health and ability to function in life. Indeed, patient perceptions of physical function have prognostic value in predicting survival (Fossa, 1994). In light of evidence that survival and clinical outcomes may be similar across treatments for many conditions, quality of life considerations may be the critical factor in medical decision making for some instances.

Key Point: World Health Organization Definition of Health

- Health is not merely the absence of disease but a state of complete physical, mental, and social well-being.

Although quantity of life is relatively easy to assess in terms of survival, the measurement of quality of life presents more challenges, primarily because it is less familiar to most clinicians (Litwin, 1994; Meyer and Clayton, 2009). To quantify these qualitative phenomena, the principles of psychometric test theory are applied. This discipline provides the theoretic underpinnings for the science of survey research (Tulsky, 1990; Aaronson, 1991; Deyo et al, 1991; McSweeny and Creer, 1995; Testa and Simonson, 1996; Guyatt et al, 1997). Data are collected with HRQOL surveys, called instruments. Instruments typically contain questions, or items, that are organized into scales. Each scale measures a different aspect, or domain, of HRQOL. For example, items on a particular instrument may address a patient's ability to have an erection and his satisfaction with ejaculation, both of which might be included in a sexual domain.

Some scales comprise dozens of items, whereas others may include only one or two items. Each item contains a stem (which may be a question or a statement) and a response set. Most response sets are one of the following types: (1) Likert scale, in which the respondent selects from a list of degrees of agreement or disagreement with the stem; (2) Likert-type scale, in which the respondent chooses from a list of text responses; (3) visual analog scale, in which the respondent marks a point on a line that is anchored on both ends by descriptors; and (4) numeric rating scale, in which the respondent chooses a number, usually between 0 and 10. Other response sets and approaches have been developed for children, people of low literacy, and various other populations (Nelson et al, 1990; Adler et al, 2000; Finlay and Lyons, 2001).

It is axiomatic that HRQOL assessments capture patients' own perceptions of their health and ability to function in life. Instruments are best when they are self-administered by the patient, but if interviewer assistance is required, it must be from a neutral third party in a standardized fashion. Some studies have demonstrated that physicians typically underestimate the symptom burden experienced by prostate cancer patients, perhaps because their queries are not sensitive enough or because patients tend to understate their problems when speaking directly with the primary caregiver (Slevin et al, 1988; Fossa et al, 1990; Litwin et al, 1998b; Sonn et al, 2009). Other studies, however, suggest that physicians tend to overestimate the impact of the disease and its treatment on patients' psychosocial functioning and sense of well-being (Fossa et al, 1996; Lampic et al, 1996; Sneeuw et al, 1997) Conversely, spouses may overstate some domains and understate others when compared with patient assessments (Sprangers and Aaronson, 1992). Kornblith et al (1994) presented results from a large sample of patients and spouses, both of whom were administered several validated HRQOL measures. Spouses reported greater psychologic distress but fewer sexual problems than did patients themselves. In a study of perspectives on HRQOL during antihypertensive therapy, Testa (1993) demonstrated that physicians were less sensitive to the impact of side effects, reporting less than 15% of the symptoms reported by patients. Spousal reports were more sensitive than patient self-assessments, particularly in the area of sexual functioning.

HRQOL Instruments

HRQOL instruments may be general or disease specific. General HRQOL domains address the components of overall well-being, whereas disease-specific domains focus on the impact of particular organic dysfunctions that may affect HRQOL. General HRQOL instruments typically address general health perceptions, sense of overall well-being, and function in the physical, emotional, and social domains. Disease-specific HRQOL instruments focus on special and/or more directly relevant domains such as anxiety about cancer recurrence, dizziness from antihypertensive medications, or suicidal thoughts during depression therapy (Patrick and Deyo, 1989). **Disease-specific and general HRQOL domains often impact each other, leading to important interactions that must be considered in the interpretation of HRQOL data** (Fossa et al, 1997). Further research is necessary in urology to explore how much of the variation in overall HRQOL is explained by variation in the disease-specific domains.

In some conditions such as chronic renal failure, cirrhosis with ascites, and stroke, general HRQOL may be so profoundly impacted that disease-specific HRQOL assessment is unnecessary. In many indolent conditions, however, the treatments may alter bodily functions that are not fully appreciated by assessing only the broader domains of general HRQOL. Conversely, in patients with advanced cancer, HRQOL may be affected predominantly by pain, fatigue, and other constitutional symptoms that are well captured by general HRQOL instruments.

Numerous HRQOL instruments have been validated for use in urologic and other conditions. Many psychologists, sociologists, and statisticians devote their entire professional careers to the activity of developing and validating these instruments. Most medical research collaboratives devote substantial efforts to the development and standardization of HRQOL instruments (Moinpour et al, 1990; Sprangers et al, 1998). One medical journal, *Quality of Life Research,* is dedicated exclusively to presenting this research. Hence an abundance of literature exists on general HRQOL, and a significant body of work has been published on HRQOL in patients with various conditions (McDowell and Ewell, 1987; Patrick and Erickson, 1993). In urology, HRQOL research has been broad, but much has focused on individuals with prostate cancer, urinary incontinence, benign prostatic hyperplasia, end-stage renal disease, and bladder cancer (Edgell et al, 1996; Blaivas, 1998; Eton and Lepore, 2002; Botteman et al, 2003; Penson et al, 2003; Matza et al, 2004). A comprehensive resource for validated HRQOL instruments is available at www.proqolid.org. The National Cancer Institute has been particularly active in establishing interest in outcomes measurement for patients with malignant disease (www.outcomes.cancer.gov). Table 5–1 presents many of the validated health-related quality of life instruments available for the assessment of patients with urologic conditions. For each instrument, the table includes the number of items, recall time, and Flesh-Kinkaid reading grade level (Flesch, 1948; Kincaid et al, 1975).

General HRQOL Instruments

General quality of life instruments have been extensively studied and validated in many types of patients, sick and well. Examples include the RAND Medical Outcomes Study 36-Item Health Survey, also known as the SF-36 (Ware and Sherbourne, 1992; Ware et al, 1994; Gandek et al, 1998b), the Quality of Well-Being scale (Kaplan et al, 1976; Kaplan and Bush, 1982; Kaplan and Anderson, 1988; Anderson et al, 1989; Kaplan et al, 1997; Kaplan et al, 1998), the Sickness Impact Profile (Bergner et al, 1976; Bergner et al, 1981), and the Nottingham Health Profile (Martini and McDowell, 1976; McDowell et al, 1978; Hunt et al, 1985). Each assesses various components of HRQOL including physical and emotional functioning, social functioning, and symptoms. Each has been thoroughly validated and tested for reliability, validity, and responsiveness.

Table 5–1.

Characteristics of Health-Related Quality of Life (HRQOL) Instruments in Urologic Diseases

INSTRUMENT NAME	ITEMS	TIME RECALL, WEEKS	READING GRADE LEVEL OF ITEMS, MEDIAN (RANGE)	REFERENCE
General HRQOL				
MOS 36-Item Health Survey (SF-36)	36	4	5.9 (2.2-12.0)	(Ware and Sherbourne, 1992)
MOS 12-Item Health Survey (SF-12)	12	4	5.2 (2.2-12.0)	(Ware et al, 1996)
Quality of Well-Being Scale (QWB)	24	1	6.3 (0.9-12.0)	(Kaplan et al, 1976)
Sickness Impact Profile (SIP)	136	1 and 7	7.4 (0.5-12.0)	(Bergner et al, 1981)
Nottingham Health Profile (NHP)	38	At present	4.5 (2.1-12.0)	(Hunt et al, 1985)
Profile of Mood States (POMS)	65	1	7.2 (0.6-12.0)	(Norcross et al, 1984)
Mental Health Inventory (MHI)	38	4	5.8 (0.6-12.0)	(Berwick et al, 1991)
McGill-Melzack Pain Questionnaire	20	At present	N/A	(Melzack, 1975)
General HRQOL in Cancer				
Functional Assessment of Cancer Therapy–General (FACT-G)	28	1	3.4 (1.1-12.0)	(Cella et al, 1993)
Cancer Rehabilitation Evaluation System Short Form (CARES-SF)	59	4	8.2 (1.0-12.0)	(Schag et al, 1991)
European Organization for Research and Treatment of Cancer Quality of Life Questionnaire C30 (EORTC-QLQ-C30)	30	1	2.6 (1.8-12.0)	(Aaronson et al, 1993)
Rotterdam Symptom Checklist	27	1	4.6 (0.7-12.0)	(de Haes et al, 1990)
Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q)	41	1	6.2 (2.1-12.0)	(Shrader-Bogen et al, 1997)
Prostate Cancer				
University of California, Los Angeles Prostate Cancer Index (UCLA-PCI)	20	4	5.2 (1.2-12.0)	(Litwin et al, 1998a)
UCLA-PCI Short Form (UCLA-PCI-SF)	15	4	4.9 (1.2-12.0)	(Litwin and McGuigan, 1999)
Expanded Prostate Cancer Index-50 (EPIC-50)	50	4	5.8 (2.5-11.9)	(Wei et al, 2000)
Functional Assessment of Cancer Therapy–Prostate (FACT-P)	47	1	2.8 (0.5-12.0)	(Esper et al, 1997)
Prostate Cancer Specific Quality of Life Instrument (PROS-QOLI)	10	1 and 7	6.4 (2.8-10.4)	(Stockler et al, 1998)
European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Prostate Module (EORTC-QLQ-PR25)	25	1	6.7 (0.5-12.0)	(Borghede and Sullivan, 1996)

Male Sexual Quotient Questionnaire (MSQ)	10	6	7.0 (14-12.0)	(Abdo, 2007)

The RAND Medical Outcomes Study 36-Item Health Survey (a.k.a., SF-36) is one of the most commonly used instruments and is regarded by some as a "gold standard" measure of general HRQOL. It is a 36-item, self-administered instrument that takes less than 10 minutes to complete and quantifies HRQOL in multi-item scales that address eight different health concepts—physical function, role limitation due to physical problems, bodily pain, general health perceptions, social function, emotional well-being, role limitation due to emotional problems, and energy/fatigue. The SF-36 may also be scored in two summary domains—physical and mental. Recently, a shorter 12-item version, the SF-12, has been developed for use in studies requiring greater efficiency. It provides a somewhat narrower view of overall health status and is usually scored only in the two summary domains (Ware et al, 1995; Ware et al, 1996; Gandek et al, 1998a). A useful resource for clinicians and researchers interested in the SF-36, SF-12, and related measures may be found at www.sf-36.org.

The Quality of Well-Being scale (QWB) summarizes three aspects of health status—mobility, physical activity, and social activity—in terms of QALY, quantifying HRQOL as a single number that may range from death to complete well-being. The original QWB contains only 18 items, but it requires a trained interviewer. A newer self-administered version of the QWB is now available and has been shown to produce scores that are equivalent to the interviewer-administered version and stable over time (Kaplan et al, 1997). The Sickness Impact Profile (SIP) measures health status by assessing the impact of sickness on changing daily activities and behavior. It is self-administered but contains 136 items and can take 30 minutes or longer to complete. The Nottingham Health Profile (NHP) covers six types of experience that may be affected by illness: pain, physical mobility, sleep, emotional reactions, energy, and social isolation by using a series of weighted yes or no items. It contains 38 self-administered items and can be completed fairly quickly.

Mental health is often measured with the Profile of Mood States (POMS) (Jacobson et al, 1978; Norcross et al, 1984; Cella et al, 1987; Albrecht and Ewing, 1989), a 65-item self-administered instrument that measures dimensions of affect or mood in six domains including anxiety, depression, anger, vigor, fatigue, and confusion. A validated short form is also available (Baker et al, 2002). Another commonly used measure of depression is the Center for Epidemiologic Studies Depression index (CES-D) (Weissman et al, 1977). Comprising items from previously developed scales, the CES-D includes 20 statements of depressive symptoms, which the respondent rates with a frequency ranging from rarely/none of the time to most/all of the time. A score of 16 or higher indicates a high likelihood of depression.

Another approach to quantifying general HRQOL is to blend a self-assessment of physical, emotional, and social functioning and well-being with a self-report of preferences, or utilities, for those health states. Developed by the Euroqol Group, a measurement collaborative, the EQ-5D is such an instrument (EuroqolGroup, 1990; Brooks, 1996; Johnson and Coons, 1998; Johnson et al, 1998; Sullivan et al, 2005). It is a short, generic measure of

well-being in five dimensions (mobility, self-care, usual activities, pain/discomfort, and anxiety/depression), each of which is colored with a self-rating of no problems, mild/moderate problems, or severe problems. Responses are then weighted to yield a summary index, which ranges from worst to best possible health. Used extensively throughout the world, it was developed to incorporate patient preferences with the health states assessed by several existing generic instruments.

Benign Disease-Targeted HRQOL Instruments

The best-known outcomes instrument in urology is no doubt the American Urological Association Symptom Index (AUASI) (Barry et al, 1992a, 1992b; Barry et al, 1995a). Its simplicity belies its elegance and utility. Developed and published in the early 1990s, the AUASI revolutionized the longitudinal assessment of men with prostatic obstruction. For generations, urologists assessed men with prostatic enlargement by recording an inventory of obstructive and irritative voiding symptoms in qualitative categories such as 3+ hesitancy and nocturia ×2. Previous symptom indices (Barry et al, 1992a) never quite reached a tipping point, but with the imprimatur of the American Urological Association, the AUASI was rapidly and widely adopted as a quantitative measure of voiding symptoms (Gee et al, 1995). It includes seven items, each self-rated on a scale of 0 to 5, yielding a summary score that ranges from 0 to 35. Symptom scores are considered mild (0-7), moderate (8-19), or severe (20-35). A 3-point difference is considered clinically meaningful (Barry et al, 1995a). With the addition of a separate quality of life item that is not included in the summary score, the worldwide urology community embraced the AUASI as the International Prostate Symptom Score (IPSS).

The other areas in benign urology that have garnered the most interest in outcomes assessment are renal transplantation (Butt et al, 2008) and female urinary incontinence. The majority of HRQOL assessments in renal transplant patients rely on general measures such as the SF-36, the SIP, or the RAND Kidney Disease Quality of Life Index (Hays et al, 1994). Studies of quality of life have shown that women with stress or urge incontinence are more likely to experience social isolation, emotional disturbances, and sleep disturbances (Ekelund et al, 1993; Grimby et al, 1993). Younger women and those with primarily urge incontinence are most profoundly affected (Wyman et al, 1987; Hunskaar and Vinsnes, 1991).

Numerous validated instruments are available for the academic and clinical study of women with urinary incontinence. Table 5-2 lists several questionnaires that were highly recommended by the Third International Consultation on Incontinence (Donovan et al, 2005). The Urinary Incontinence–Specific Quality of Life Instrument (I-QOL) (Patrick et al, 1999b) contains 22 statements, such as "I worry about not being able to get to the toilet on time." The respondent endorses each on a 5-point scale that ranges from not at all to extremely. Item responses are converted to a 100-point scale with higher scores representing better outcomes.

The 30-item Incontinence Impact Questionnaire (IIQ) and 19-item Urogenital Distress Inventory (UDI) (Shumaker et al, 1994) are often used together in their validated short forms that contain seven and six items, respectively (Uebersax et al, 1995). They address both the dysfunction and the distress associated with urinary incontinence with items such as "Has urine leakage/prolapse affected household chores?" and "How much are you bothered by frequent urination?" The response set for each statement is a 4-point scale that ranges from not at all to greatly.

In the 15-item quality of life index from the Stress-Related Leak, Emptying Ability, Anatomy, Protection, Inhibition, Quality of Life, Mobility and Mental Status (SEAPI-QMM) instrument, each symptom is graded 0 to 3 to yield a score range of 0 to 45 with higher scores indicating worse outcomes (Stothers, 2004). Results are stratified into several domains including social interactions, personal strain, interference with sexual activity, and global impact.

Table 5–2.

Selected Validated Instruments for Urinary Incontinence Recommended by the Third International Consultation on Incontinence

Symptoms	
Women	Urogenital Distress Inventory (UDI)
	Urogenital Distress Inventory Short Form (UDI-6)
	Incontinence Severity Index
	Bristol Female Lower Urinary Tract Symptoms (BFLUTS)
Men	International Continence Society male (ISCmale)
	Danish Prostate Symptom Score (DAN-PSS)
Quality of Life Impact	
Men and women	Incontinence–Quality of Life (I-QOL)
	SEAPI-QMM
Women	King's Health Questionnaire
	Incontinence Impact Questionnaire (IIQ)
	Incontinence Impact Questionnaire Short Form (IIQ-7)
	Urinary Incontinence Severity Score (UISS)
	CONTILIFE
Symptoms and Quality of Life Impact	
Men and women	International Consultation on Incontinence Questionnaire (ICIQ)
Women	Bristol Female LUTS–Short Form (BFLUTS-SF)
	Stress and Urge Incontinence and Quality of Life Questionnaire (SUIQQ)
Men	ICS male Short Form (ICSmaleSF)

Adapted from Donovan J, Bosch R, et al. Symptom and quality of life assessment. Third International Consultation on Incontinence. In: Abrams P, Cardozo L, Wein A, editors. United Kingdom: Health Publications; 2005. p. 519–84. Table 5–3.

The term *overactive bladder* is commonly used to denote urinary frequency with or without urge incontinence. It was coined by the pharmaceutic industry during the development and promotion of new oral medications to treat these symptoms. A variety of instruments is available to assess patients with symptoms of overactive bladder. As in many urologic conditions, this condition is driven by patient experience and hence measures of outcome must be standardized within or across studies (Coyne et al, 2002; Brubaker et al, 2006; Coyne et al, 2006).

Several reviews of available instruments summarize their psychometric properties and performance in various populations and stress the importance of standardization in measurement (Lose et al, 2001; Symonds, 2003; Haywood et al, 2008).

Cancer-Specific HRQOL Instruments

Because of the well-documented impact of malignancies and their treatment on HRQOL, cancer-specific domains have also been investigated extensively. Numerous instruments have been developed and tested that measure the special impact of cancer (regardless of primary site) on patients' routine activities. Examples include the European Organization for the Research and

Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-C30) (Aaronson et al, 1993), the Functional Assessment of Cancer Therapy (FACT) (Cella et al, 1993), and the Cancer Rehabilitation Evaluation System (CARES) and its short form (CARES-SF) (Schag and Heinrich, 1990; Schag et al, 1991; Schag et al, 1994). Each has been validated and tested in patients with various types of cancer. Readers are directed to the Quality of Life Instruments Database (www.qolid.org) for guidance when selecting an instrument for quality of life measurement in studies of prostate or other cancers.

The EORTC QLQ-C30 was designed to measure cancer-specific HRQOL in patients with a variety of malignancies. Its 30 items address domains that are common to all cancer patients. The questionnaire includes five functional scales (physical, role, emotional, cognitive, and social functioning); a global health scale; three symptom scales (fatigue, nausea/vomiting, and pain); and six single items concerning dyspnea, insomnia, appetite loss, constipation, diarrhea, and financial difficulties due to disease. The EORTC QLQ-C30 has performed well in populations with urologic malignancies (Curran et al, 1997). Disease-specific modules for cancers of the prostate (Aaronson and van Andel, 2001), breast (Sprangers et al, 1996), lung (Bergman et al, 1994), head and neck (Bjordal et al, 1994), and other sites have been developed according to methodologically rigorous techniques. Additional disease-specific modules are available.

The FACT is usually applied as a two-part instrument that includes a general item set pertaining to all cancer patients (FACT-G) and one of several item sets containing special questions for patients with specific tumors. Each item is a statement that a patient may agree or disagree with across a 5-point range. The FACT-G domains include well-being in five main areas: physical, social/family, relationship with doctor, emotional, and functional. The FACT-G includes 28 items and is easily self-administered. Disease-specific modules are available for numerous patient tumor groups including prostate (Esper et al, 1997), bladder (Mansson et al, 2002), colorectal (Ward et al, 1999), breast (Brady et al, 1997), ovary (Basen-Engquist et al, 2001), and other cancers. Modules are also available for issues specific to bone marrow transplantation (McQuellon et al, 1997), anemia, and fatigue (Cella, 1997; Yellen et al, 1997).

The CARES Short Form (CARES-SF) is a 59-item, self-administered instrument that measures cancer-related quality of life with five multi-item scales: physical, psychosocial, medical interaction, marital interaction, and sexual function. A large and valuable database of patients with many different tumors including urologic tumors has been collected by the instrument's authors (Schag et al, 1994). These data are helpful when comparing the experience of prostate cancer patients with that of patients with other types of cancer.

Selecting a Quality of Life Instrument

Investigators or clinicians considering measuring HRQOL in a clinical study or in clinical practice should choose an instrument (or instruments) depending on the particular population being studied and the clinical questions being asked. Using previously validated instruments, to the extent they are applicable and appropriate, obviates the need for an arduous process of instrument development and validation. A general and a disease-specific module in combination are suitable for most studies. However, if a particular domain (e.g., pain) is the focus of the study, specific, expanded questionnaires should be sought focusing on the area of interest. Respondent burden needs to be considered, particularly for longitudinal studies where subjects will complete the same instruments multiple times. Pretesting instruments that will be used in clinical studies is advisable.

Psychometric Validation of New HRQOL Instruments

The development and validation of new instruments and scales is a long and arduous process. It is not undertaken lightly. Simply drawing up a list of questions that seem appropriate is fraught with potential traps and pitfalls. For this reason, it is always preferable to use established, validated HRQOL instruments (Guyatt et al, 1992).

When scales and instruments are developed, they are first pilot tested to ensure that the target population can understand and complete them with ease. Pilot testing is usually preceded by focus groups to refine the wording of items and to ensure comprehensive coverage of concepts and domains deemed important by respondents. Pilot testing of an instrument should also include formal cognitive testing. This process is typically led by behavioral scientists who specialize in developing and assessing the wording and ordering of questionnaire items to ensure that they can be easily understood by respondents, and that the answers that respondents provide are what investigators hope to learn from their study. Cognitive testing is usually performed on a small number of respondents, usually 5-10 volunteers, who are asked to "think aloud" during the process of questionnaire completion. Following cognitive testing, a larger pilot test is then performed on a somewhat larger sample, using the exact same planned enrollment procedures and materials that are intended for the full study. Pilot testing can reveal problems that might otherwise go unrecognized by researchers. For example, many terms that are commonly used by medical professionals are poorly understood by patients. This may result in missing data if patients leave questions blank. In fact, because the average adult reads at the fifth- to eighth-grade level, items should be drafted at no higher than an eighth-grade reading level (Paasche-Orlow et al, 2003). Furthermore, because many patients with urologic malignancy are older and may have poor eyesight, pilot testing often identifies easily corrected visual barriers such as type size and page layout. In addition, self-administered instruments with complicated skip patterns (e.g., "If you answered yes to item 16b, continue with item 16c; if you answered no to item 16b, skip to item 19a") may be too confusing for even the most competent patients to follow. This, too, can result in missing data and introduce difficulties in the analysis. Pilot testing is a necessary and valuable part of instrument development. It serves as a reality check on those developing the scales.

Scales and instruments are also evaluated for three fundamental statistical properties—reliability, validity, and responsiveness (Stewart et al, 1992; Lohr et al, 1996; Litwin, 2002).

Reliability

Reliability (Table 5–3) **refers to how free the scale is of measurement error;** that is, what proportion of a patient's test score is true and what proportion is due to chance variation. Two of the most commonly used metrics are test-retest and internal consistency reliability.

Test-retest reliability is the most commonly used indicator of survey instrument reliability. It is measured by having the same respondents complete a survey at two different points in time to

Table 5–3.
Reliability Assessments for Health-Related Quality of Life Instruments

TYPE OF RELIABILITY	CHARACTERISTICS	COMMENTS
Test-retest	Measures the stability of responses over time, typically in the same group of respondents	Requires administration of survey to a sample at 2 different and appropriate points in time. Time points that are too far apart may produce diminished reliability estimates that reflect actual change over time in the variable of interest.
Intraobserver	Measures the stability of responses over time, in the same individual respondent	Requires completion of a survey by an individual at 2 different and appropriate points in time. Time points that are too far apart may produce diminished reliability estimates that reflect actual change over time in the variable of interest.
Alternate-form	Uses differently worded stems or response sets to obtain the same information about a specific topic	Requires 2 items in which the wording is different but aimed at the same specific variable and at the same vocabulary level
Internal consistency	Measures how well several items in a scale vary together in a sample	Usually requires a computer and statistician to carry out calculations
Interobserver	Measures how well 2 or more different respondents rate the same phenomenon	May be used to demonstrate reliability of a survey or may itself be the variable of interest in a study

see how stable their responses are. It is a measure of how reproducible a set of results is. Correlation coefficients are then calculated to compare the two sets of responses. These correlation coefficients are collectively referred to as the survey instrument's test-retest reliability. In general, the correlation coefficients are considered good if they are at least 0.70. This implies that the survey responses are reasonably consistent from one point in time to another. When measuring test-retest reliability, one must be careful not to select items or scales that measure variables likely to change over short periods of time. Variables that are likely to change over a given period of time will produce low test-retest reliability in measurement instruments. This does not mean that the survey instrument is performing poorly but simply that the attribute itself has changed. One can certainly measure characteristics that tend to change over time. In fact, this is often the purpose of HRQOL research. But test-retest reliability must be documented over shorter periods to decrease the degree of measurement error attributable to the survey itself.

When measuring test-retest reliability, one must also consider that individuals may become familiar with the items and answer partly on the basis of their memory of what they answered the last time. Called the *practice effect,* this presents a challenging problem to address in measures of test-retest reliability over short periods of time. As a result of the practice effect, test-retest reliability figures can be falsely inflated.

Alternate-form reliability provides one way to escape the problem of the practice effect. It involves using differently worded items to measure the same attribute. Questions and responses are reworded or their order is changed to produce two items that are similar but not identical. One must be careful to create items that address the same exact aspect of behavior with the same vocabulary level and the same level of difficulty. Items must differ only in their wording. Items or scales are administered to the same population at different time points, and correlation coefficients are again calculated. If these are high, the survey instrument or item is said to have good alternate-form reliability. One common way to test alternate-form reliability is to change the order of the response set. Changing the order of the response set is most effective when the two time points are close together. This approach forces the respondent to read the items and response sets carefully, thereby decreasing the practice effect. Another way to test alternate-form reliability is to change the wording of the response sets without changing the meaning (Fig. 5–1). Another common method to test alternate-form reliability is to change the actual wording of the items themselves. Again, one must be careful to design items that are truly equivalent to each other. Items that are worded with different degrees of reading difficulty do not measure the same attribute.

Item 1: Circle one number in each response set

During the last week, how often did you usually empty your bladder?	
1 to 2 times per day	1
3 to 4 times per day	2
5 to 8 times per day	3
12 times per day	4
More than 12 times per day	5
During the last week, how often did you usually empty your bladder?	
Every 12 to 24 hours	1
Every 6 to 8 hours	2
Every 3 to 5 hours	3
Every 2 hours	4
More than every 2 hours	5

Item 2: Circle one number in each response set

During the last 4 weeks, how much did you leak urine?	
Never	1
A little bit	2
A moderate amount	3
A lot	4
Constantly	5
During the last 4 weeks, how much did you leak urine?	
I used no pads in my underwear	1
I used 1 pad per day	2
I used 2 to 3 pads per day	3
I used 4 to 6 pads per day	4
I used 7 or more pads per day	5

Figure 5–1. Alternate-form reliability. Equivalent but differently worded response sets to two items on urinary function are presented. The response sets for each item are differently worded but functionally equivalent. This makes them good candidates for use in a test of alternate-form reliability.

They are more likely to measure the reading comprehension or cognitive function of the respondent.

Sometimes data are not collected from a group of subjects but are recorded by a single observer. In this case, test-retest reliability is assessed by having that individual make two separate measurements. Both data sets from the same observer are then compared with each other. The correlation between two data sets from the same individual is commonly known as *intraobserver reliability.* It measures the stability of responses from the same respondent and is a form of test-retest reliability.

Interobserver (inter-rater) reliability provides a measure of how well two or more evaluators agree in their assessment of a variable. It is usually reported as a correlation coefficient between different data collectors. When survey instruments are self-administered respondent and designed to measure the respondent's own behaviors or attitudes, interobserver reliability is not used. However, whenever there is a subjective component in the measurement of an external variable, it is important to calculate this statistic. Sometimes interobserver reliability is used as a psychometric property of a survey instrument, whereas other times it is itself the variable of interest. Interobserver reliability is often used when the measurement process is less quantitative than the variable being measured.

***Internal consistency reliability* is a measure of the similarity of an individual's responses across several items, indicating the homogeneity of a scale** (Tulsky, 1990). It is applied not to single items but to groups of items that are thought to measure different aspects of the same concept. Internal consistency is an indicator of how well the different items measure the same issue. This is important because a group of items that purports to measure one variable should indeed be clearly focused on that variable. Although single items may be quicker and less expensive to administer, the data set is richer and more reliable if several different items are used to gain information about a particular behavior or topic. The statistic most often used to quantify this unidimensionality or internal consistency of a scale is called Cronbach coefficient alpha (Cronbach, 1951). Internal consistency can be reported for any scale with more than one item, whereas test-retest reliability requires the scale to be administered to some patients twice within a short interval, preferably less than 1 month.

Validity

Validity (Table 5–4) **refers to how well the item, scale, or instrument measures the attribute it is intended to measure.** An item designed to measure pain should measure pain and not some related variable like anxiety. A scale meant to measure emotional quality of life should not measure depression, which is a related but different variable. When an instrument has validity, it is said to measure the truth. Validity provides evidence to support drawing inferences about quality of life from the scale scores. Validity has three general forms: content, criterion, and construct.

Content validity, sometimes casually referred to as face validity, involves a subjective assessment of the scope and completeness of a scale and is usually measured in the early stages of an instrument's development from experts and patient focus groups. The assessment of content validity typically involves an organized review of an instrument's contents to ensure that it includes everything it should and does not include anything it should not. Patients should be involved in this assessment. Clinicians may be unaware of the subtle nuances experienced by patients who live day to day with a given condition. Families also may provide helpful insights into dimensions that might otherwise be overlooked by experts. This said, it remains important for clinicians to review the items for relevance to and focus on the variables of interest. Content validity is not quantified with statistics. Rather, it is presented as an overall opinion of a group of trained judges. Nevertheless, it provides a good foundation on which to build a methodologically rigorous assessment of a survey instrument's validity.

Criterion validity is a more quantitative approach to assessing the performance of scales and instruments. It requires the correlation of scales scores with results from other established tests (concurrent validity) or with future measurable outcomes (predictive validity). For example, concurrent validity of a new sexual function scale might be correlated with objective performance on infusion cavernosometry. Likewise, the predictive validity of a new quality of life scale for physical function might be correlated with the number of subsequent physician visits or hospitalizations.

Concurrent validity requires that the survey instrument in question be judged against some other method that is acknowledged as a gold standard for assessing the same variable. It may be a published psychometric index, a scientific measurement of some factor, or another generally accepted test. The fundamental requirement is that it be regarded as a good way to measure the same concept. The statistic is calculated as a correlation coefficient with that test. A high correlation suggests good concurrent validity. Alternatively, a test may be selected for comparison that is expected to measure an attribute or behavior that is opposite to the dimension of interest. In this case, a low correlation indicates good concurrent validity. The reason one would not simply use the established gold standard as a measure of choice is that it may be too cumbersome, expensive, or invasive to apply.

Table 5–4.

Validity Assessments for Health-Related Quality of Life Instruments

TYPE OF VALIDITY	CHARACTERISTICS	COMMENTS
Content	Formal expert review of how good an item or series of items appear	Usually assessed by individuals with expertise in some aspect of the subject under study
Criterion: Concurrent	Measures how well the item or scale correlates with gold-standard measures of the same variable	Requires the identification of an established generally accepted gold standard
Criterion: Predictive	Measures how well the item or scale predicts expected future observations	Used to predict outcomes or events of significance that the item or scale might subsequently be used to predict
Construct	A theoretic measure of how meaningful a survey instrument is, usually after years of experience by numerous investigators	Not easily quantifiable

Predictive validity is the ability of a survey instrument to forecast future events, behaviors, attitudes, or outcomes. It may be used during the course of a study to predict response to a stimulus, success of an intervention, or time to a medical end point. Over a brief interval, predictive validity is similar to concurrent validity in that it involves correlating the results of one test with the results of another test administered around the same time. If the time frame is longer and the second test occurs much later, then the assessment is of predictive validity. Like concurrent validity, predictive validity is calculated as a correlation coefficient between the initial test and the secondary outcome.

Construct validity is the most valuable yet most difficult way of assessing a survey instrument. Often determined only after years of experience with an instrument, it is a measure of how meaningful the scale or survey instrument is when in practical use. It is typically not calculated as a statistic, but as a gestalt of how well a survey instrument performs in a multitude of settings and populations over a number of years. Construct validity implies that the instrument of interest yields results that are similar to (convergent validity) or different from (divergent validity) several other methods for obtaining the same information about a given trait or concept.

Responsiveness

Responsiveness of an HRQOL instrument refers to how sensitive the scales are to change over time (Deyo et al, 1991; Stockler et al, 1998). That is, a survey may be reliable and valid when used at a single point in time, but in some circumstances it must also be able to detect meaningful improvements or decrements in quality of life during longitudinal studies. The instrument must "react" in a time frame that is relevant for patients over time. Because HRQOL may change over time, longitudinal measurement of these outcomes is important (Olschewski and Schumacher, 1990; Zwinderman, 1990). Different domains may become more or less prominent over time as the course of disease and recovery evolves. Although their perception of cure waxes and wanes with time since treatment or the latest PSA level, patients may feel more or less impacted by their HRQOL impairments.

In order to make useful inferences regarding absolute scores or change scores over time, it is important to determine what meaning different numeric values have (Samsa et al, 1999). For example, the minimally important difference of the AUASI (Barry et al, 1992b) has been measured at 3 points (Barry et al, 1995b). When no such thresholds have been established, one can roughly approximate the smallest difference that is important to the patient as one third to one half of a standard deviation (Norman et al, 2003; Sloan and Dueck, 2004). A more quantitative approach involves calculating an effect size, or Guyatt statistic, typically expressed as the ratio of the raw change in score among those who change to the standard deviation of the change among those who did not change (Guyatt et al, 1987; Guyatt et al, 2002).

Over time, patients' perceptions of quality of life impairments may change. This phenomenon, known as *response shift,* must be considered when evaluating longitudinal patterns in HRQOL outcomes (Breetvelt and Van Dam, 1991; Sprangers, 1996).

Responsiveness and minimally important difference may be ascertained by correlation with a self-administered global response assessment (GRA) item that measures improvement or worsening over time on a Likert-type scale such as markedly, moderately, or minimally worse; unchanged; or minimally, moderately, or markedly better.

Comparison Groups

Prospective, longitudinal data collection beginning at baseline before treatment is always best because this approach may reveal time-dependent evolution of HRQOL domains (Talcott et al, 1998). Patients may then serve as their own controls. Assessing HRQOL at baseline before treatment allows for the inclusion of baseline age- or comorbidity-related changes that should not be attributed to treatment. This approach facilitates the stratification of discriminants from determinants of HRQOL.

However, investigators often use methodologies in which HRQOL is assessed cross-sectionally, rather than longitudinally. In cross-sectional surveys, patients cannot serve as their own temporal controls because recall of pretreatment HRQOL is notoriously inaccurate (Aseltine et al, 1995; Herrmann, 1995). Hence studies must rely on appropriate comparison groups. Selecting the best comparison group is an important step in conducting a meaningful analysis of HRQOL outcomes. If normal is defined as the absence of any dysfunction, then treatment groups may be held to too high a standard. For example, in order to interpret the HRQOL effects of prostate cancer treatment meaningfully, a valid context is provided by assessing HRQOL in older men without prostate cancer (Litwin, 1999) or in prostate cancer patients on watchful waiting. Hence in comparisons of the effect of treatment efficacy on HRQOL, longitudinal studies starting pretreatment provide the most compelling results. In cross-sectional studies, a suitable comparison group is critical.

Cultural Issues and Translations

When designing new HRQOL instruments or applying established ones in populations of different ethnicity or nationality, one must make sure that the items translate well into both the language and culture of the target audience. Although the items may have been linguistically translated into a new language, they may not measure the same dimension in that culture (Herdman et al, 1997). This is particularly relevant when studying social attitudes and health behaviors (e.g., as related to pain, sexual function, or urinary incontinence). Different cultures have different concepts of health, well-being, illness, and disease. A well-developed concept in one culture may not even exist in another. Failing to be attentive to multicultural issues may result in significant bias when collecting data. For example, when classifying ethnicities, survey researchers often categorize all Asians together. For some projects this may be acceptable; however, many attitudes and behaviors vary markedly among Chinese, Japanese, Filipino, Korean, Indian, and other cultures within Asia. By collapsing them all into one group, researchers may overlook differences that are important to the conclusions.

When translating an HRQOL instrument into a new language, one must also consider issues of linguistics. Specific methodologies have been developed for cross-validating HRQOL instruments in other languages (Vela Navarrete et al, 1994; Boyle, 1997). One begins by having two to three bilingual individuals perform independent "forward translations" into the new language. Next, these translators reconcile any differences in word choice in the new language. Next, two to three different bilingual individuals perform independent "back translations," in which the reconciled translation is converted back into the primary language. Then, translators independently review the forward, reconciled, and back translated versions in order to iron out any language

differences in the translation and agree on a final wording in the new language. Finally, after pilot testing the instrument with bilingual subjects, a larger-scale validation must be conducted in order to establish reliability and validity in the new language. This process has been accomplished for a variety of instruments used in the assessment of patients with urologic diseases (Sagnier et al, 1994; Arocho et al, 1995; Sagnier et al, 1996; Boyle, 1997; Krongrad et al, 1997; Badia et al, 1998; Gandek et al, 1998a, 1998b; Patrick et al, 1999a; Collins et al, 2001; Hochreiter et al, 2001; Kakehi et al, 2002; Duarte et al, 2005).

During a recent linguistic translation of an instrument to measure symptoms in men with chronic prostatitis, researchers collected data from many Spanish-speaking patients including subjects from Argentina, Mexico, Spain, and the United States. The translation had high overall reliability; however, respondents expressed difficulty in distinguishing the response categories "a menudo" ("often") from "normalmente" ("usually") in one of the items. Hence the researchers revised "a menudo" to "muchas veces" ("much of the time") and "normalmente" to "casi siempre" ("almost always") to improve the distinctiveness of response categories.

In addition to varying cultural perspectives on disease and health, international differences in health systems may also have a substantial impact on the way patients view their quality of life. For example, in countries where patients are required to pay all or most of the treatment costs, spending a lot of money for marginally better survival rates may have a larger effect on quality of life than the disease or treatments. Furthermore, in cultures where the patient's relatives are compelled to absorb the costs of care, the quality of life of the entire family unit should also be considered.

Caveats on the Collection of HRQOL Data

Although there are some single instruments that are multidimensional, many quality of life researchers have endorsed a "battery approach," in which the various components of HRQOL are measured with different scales to assure that each domain receives adequate attention. Longer instruments can provide greater precision, but they also increase the chance that patients will tire of the exercise and not provide reliable or valid answers. This is particularly true in the multicenter clinical trial setting. Hence shorter instruments are generally preferable when obtaining HRQOL measurements under such circumstances. In general, it is easier and more efficient to use established instruments that have already undergone psychometric validation. HRQOL data collected using published instruments allow the researcher to compare the study results to data from other samples or diverse populations with various chronic diseases. Nevertheless, sometimes it is necessary to develop new questionnaire items to ensure that a particular concept is adequately evaluated. Under such circumstances new scales can be tested for reliability and validity during the course of data collection.

Once an instrument is thoroughly pilot tested and found to be reliable and valid, it must be administered in a manner that minimizes bias. Quality of life data cannot and should not be collected from patients directly by the treating health care provider. Patients often provide socially desirable responses under such circumstances (Tannock, 1990). This introduces measurement error. No matter how objective the treating clinician may claim to be, it is impossible for him or her to collect objective and unbiased outcomes data through direct questioning. Variations in phrasing, inflection, eye contact, rapport, mood, and other factors are difficult or impossible to eliminate. Data must be gathered by disinterested third parties using established psychometric scales and instruments.

FUTURE IMPLICATIONS

HRQOL research questions begin with the need for basic descriptive analysis of quality of life in patients treated for urologic diseases. Depiction of the fundamental elements in quality of life for these individuals requires study of their health perceptions and how their daily activities are affected by both their general health and their cancer. Physical and emotional well-being form the cornerstone of this approach, but research must also extend to other issues that can affect a patient's quality of life and satisfaction such as eating and sleeping habits, anxiety and fatigue, depression, rapport with the physician, presence of a spouse or partner, and social interactions. Characterization of all domains must address not only the actual functions but also the relative importance of these issues to patients.

Beyond simple descriptive analysis, HRQOL outcomes must be compared between patients undergoing different modes of therapy. General and disease-specific HRQOL must be measured to facilitate comparison with patients treated for diabetes, heart disease, arthritis, and other common chronic conditions. Quality of life outcomes may be correlated with medical variables such as comorbidity or sociodemographic variables such as age, race, education, income, insurance status, geographic region, and access to health care. In this context, HRQOL may be linked with many factors other than the traditional medical ones.

All clinical trials and observational cohort studies in patients with benign or malignant urologic disease should include an HRQOL component. Two cohort studies have been particularly fruitful in prostate cancer. First, the Cancer of the Prostate Strategic Urologic Research Endeavor (CAPSURE) is a longitudinal disease registry of more than 10,000 men with prostate cancer (Lubeck et al, 1996; Lubeck et al, 1997; Cooperberg et al, 2004), which has provided valuable insights into evolving practice patterns, technology diffusion, outcomes, and severity of disease from data collected in community settings across the United States. Second, the Prostate Cancer Outcomes and Satisfaction with Treatment: Quality Assessment (PROST-QA) is a consortium of nine academic centers that has tracked more than 1800 patients and spouses for several years with a specific focus on quality of life outcomes after surgery or radiation (Sanda et al, 2008).

Resources are scarce in any clinical trial, but clinical trials provide the best setting for prospective outcomes measurement and contribute to the thoughtful interpretation of more clinical endpoints (Steineck et al, 2002). Nonetheless, HRQOL data collections are labor-intensive; hence, when planning clinical trial budgets investigators must be aware that they are expensive to include. The more instruments that are selected, the richer the potential database, however it is important to remain parsimonious in instrument selection, choosing only the relevant domains of HRQOL.

The ultimate goal of quality of life research is to improve medical care and assist in medical decision-making (Table 5–5). Individual patients who incorporate quality of life considerations into their decision equations tend to feel better about their treatment choices, are more satisfied overall with their care, and

Table 5–5.

Quality of Life Objectives in Research and Practice

To assess overall treatment efficacy including subjective morbidity
To help determine whether the goals of treatment have been met
To educate patients and clinicians about the full spectrum of treatment outcomes
To facilitate medical decision making
To provide the defining issue if treatments are otherwise equivalent

experience less regret (Cassileth et al, 1989). Hence patient education provides a potent impetus for studying and reporting quality of life. With accurate measurement of quality of life outcomes, we can better assess whether the specific and overall goals of therapy have been met. This allows individuals and societies to balance the competing health care priorities of optimizing survival, quality of life, and resource utilization. Furthermore, the evaluation of patient-perceived HRQOL permits assessment of low-grade subjective morbidity that, although not typically life-threatening, may present considerable distress for the patient. These outcomes are often overlooked during the busy daily routine of patient care.

PREOPERATIVE EVALUATION

The perioperative management of patients undergoing urologic surgery continues to evolve. Over the past 2 decades, the economics of health care has added increasing pressure for more outpatient surgery and decreased hospital stays. Furthermore, the acuity of surgical patients is increasing in that patients are older with more significant comorbidities. It has become standard for patients undergoing even the most sophisticated and complex urologic procedures in the hospital to be admitted on the same day of the surgery. **Therefore the urologic surgeon is responsible for assuring that the patient has been thoroughly evaluated by the other physicians in the health care team and presents to the operating room in the most optimized medical condition.** The preoperative use of appropriate medical specialist consults will result in improved patient safety and obviate the need for unnecessary cancelled surgeries due to the inadequacy of medical optimization.

PRESURGICAL TESTING

The goal of presurgical testing is to identify undiagnosed comorbidity or significant exacerbation of existing comorbid illnesses that may affect the operative outcome (Townsend et al, 2008). Although the preoperative evaluation should be individualized on the basis of age, history, and physical examination, each hospital or surgery center generally has specific guidelines for the necessary presurgical tests. Interestingly, routine testing has never been shown to be cost effective. In fact, it is less predictive of perioperative morbidity than the American Society of Anesthesiologists (ASA) status or the American Heart Association (AHA)/American College of Cardiology (ACC) guidelines for surgical risk. Generally, presurgical testing includes complete blood count (CBC), basic metabolic panel (BMP), prothrombin time/partial prothrombin time/international normalized ratio (PT/PTT/INR; controversial), electrocardiogram (ECG), and chest radiograph. The routine use of a PT/PTT in a patient not using warfarin or in a patient who gives no prior history of increased bleeding with other surgical procedures is controversial. **Often overlooked but extremely important is the requirement for a urine pregnancy test on the morning of surgery in any woman of childbearing age unless the ovaries or uterus have been previously surgically removed** (Halaszynski et al, 2004). The value of a preoperative ECG in identification of underlying acute cardiac disease and predicting perioperative cardiac morbidity is also controversial. Some studies show that ECG abnormalities have no significant predictive value (Goldman et al, 1978), whereas others have shown that an abnormal ECG was the best diagnostic predictor of an adverse cardiac event (Carliner et al, 1985). Nonetheless, current recommendations generally suggest that a preoperative ECG be done in patients older than 40 years of age or those with a history of any cardiac disease. Similarly, the routine preoperative use of a chest radiograph, in the absence of preexisting cardiopulmonary disease, is not indicated. Overall, even an ASA Task Force on preanesthesia evaluation could not make firm recommendations other than "preoperative tests may be ordered, required, or performed on a selective basis for purposes of guiding or optimizing perioperative management" (Practice advisory, 2002).

SURGICAL RISK EVALUATION

American Society of Anesthesiologists Classification and Risk Stratification

Approximately 27 million patients undergo surgery each year in the United States and 8 million or 30% have significant coronary artery disease or other cardiac comorbidities. Appropriately, the cardiovascular system is targeted during the preoperative assessment of patients. The ASA classification was first developed in 1961 and has been revised to categorize risk into six stratifications.

- ASA Class I—Normal healthy patient
- ASA Class II—Patient with mild systemic disease

Table 6–1.

Goldman's Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Third heart sound or jugular venous distention	11
Recent myocardial infarction	10
Nonsinus rhythm or premature atrial contraction on electrocardiogram	7
>5 premature ventricular contractions	7
Age >70 yr	5
Emergency operations	4
Poor general medical condition	3
Intrathoracic, intraperitoneal, or aortic surgery	3
Important valvular aortic stenosis	3
For noncardiac surgery, the risk of cardiac complications are:	
• *0-5 points = 1% risk*	
• *6-12 points = 7% risk*	
• *13-35 points = 14% risk*	
• *>26 points = 78% risk*	

Adapted from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. Crit Care Med 2004;32:S126–36.

Table 6–2.

Modified Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Ischemic heart disease	1
Congestive heart failure	1
Cerebral vascular disease	1
High-risk surgery	1
Preoperative insulin treatment for diabetes	1
Preoperative creatinine of ≥2 mg/dL	1
Each increment in point increases risk of perioperative cardiovascular morbidity	

Adapted from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. Crit Care Med 2004;32:S126–36.

- ASA Class III—Patient with severe systemic disease that limits activity but is not incapacitating
- ASA Class IV—Patients who have incapacitating disease that is a constant threat to life
- ASA Class V—Moribund patient not expected to survive 24 hours with or without an operation
- ASA Class VI—A declared brain-dead patient whose organs are being removed for donor purposes
- ASA Class E—Emergent nature of surgery (added through I through V classes)

The goal of the classification system is to assess the overall physical status of the patient before surgery (not to assess surgical risk), and although quite subjective, it remains as a significant independent predictor of mortality (Davenport et al, 2006). Other tools to assess the preoperative risks were developed by multivariate statistical analysis of patient-related factors correlated with surgical outcomes. One such scoring system, Goldman's criteria (Table 6–1), assigns points to easily reproducible characteristics. The points are then added to compute the perioperative risk of cardiac-related complication. Another system, the Cardiac Risk Index, simplified this concept employing only six predictors to estimate cardiac complication risk in noncardiac surgical patients (Table 6–2) (Akhtar and Silverman, 2004).

Cardiac Evaluation

The preoperative cardiac evaluation, which consists of an initial history and physical examination and ECG, attempts to identify potential serious cardiac disorders such as coronary artery disease, heart failure, symptomatic arrhythmias, the presence of a pacemaker or implantable defibrillator, or a history of orthostatic hypotension (Eagle et al, 1996). Furthermore, it is essential to define the severity and stability of existing cardiac disease before surgery. Cardiac-specific risk is also altered by the patient's functional capacity, age, and other comorbid conditions such as diabetes, peripheral vascular disease, renal dysfunction, and chronic obstructive pulmonary disease. The American College of Cardiology and American Heart Association recently collaborated to develop guidelines regarding perioperative cardiac evaluation before surgery (Fleisher et al, 2007a). The guidelines generally use three categories of clinical risk predictors: clinical markers, functional capacity, and type of surgical procedure (Eagle et al, 2002).

Clinical Markers

The major clinical predictors of increased perioperative cardiovascular risk are a documented acute myocardial infarction less than 7 days previously, a recent myocardial infarction (defined as >7 days but <1 month before surgery), unstable angina, evidence of any ischemic burden by clinical symptoms or noninvasive testing, decompensated heart failure, significant arrhythmias, and severe valvular disease. Intermediate predictors include mild angina, previous myocardial infarction by history or pathologic Q waves, compensated heart failure, diabetes, or renal insufficiency (creatinine >2 mg/dL). Minor predictors of risk are advanced age, abnormal electrocardiogram, rhythms other than sinus (i.e., atrial fibrillation), history of stroke, or uncontrolled systemic hypertension. The historical dictum of the timing of elective surgery after a myocardial infarction into a 3-month and 6-month interval is now currently avoided (Tarhan et al, 1972). **The ACC cardiovascular database committee stratifies risk on the basis of the severity of the myocardial infarction and the likelihood of reinfarction based on a recent exercise stress test.** However, in the absence of adequate clinical trials on which to base firm recommendations, it is reasonable to wait 4 to 6 weeks after myocardial infarction to perform elective surgery.

Functional Capacity

Functional capacity, or one's ability to meet aerobic demands for a specific activity, is quantified as metabolic equivalents or METs. For example, a 4-MET demand is comparable with a patient's ability to climb two flights of stairs. This simple measurement continues to be an easy and inexpensive method to determine a patient's cardiopulmonary functional capacity (Biccard, 2005). **The Duke Activity Status Index** (Table 6–3) **allows the physician to easily determine a patient's functional capacity** (Hlatky et al, 1989). **Generally, a capacity of 4 METs indicates no further need for invasive cardiac evaluation.**

Surgery-Specific Cardiac Risk

Two important factors determine the surgery-specific cardiac risk: the type of surgery and the degree of hemodynamic stress. Surgery-specific risk is stratified into high-, intermediate-, and low-risk procedures. High-risk procedures include both major emergent surgery, particularly in the elderly, and surgery associated with

Table 6–3.

Duke Activity Status Index*

ACTIVITY	YES	NO
Can you take care of yourself (eating, dressing, bathing, or using the toilet)?	2.75	0
Can you walk indoors such as around your house?	1.75	0
Can you walk a block or two on level ground?	2.75	0
Can you climb a flight of stairs or walk up a hill?	5.50	0
Can you run a short distance?	8.00	0
Can you do light work around the house like dusting or washing dishes?	2.70	0
Can you do moderate work around the house like vacuuming, sweeping floors, or carrying in groceries?	3.50	0
Can you do heavy work around the house like scrubbing floors or lifting and moving heavy furniture?	8.00	0
Can you do yardwork like raking leaves weeding or pushing a power mower?	4.50	0
Can you have sexual relations?	5.25	0
Can you participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?	6.00	0
Can you participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?	7.50	0

Duke activity status index (DASI) = SUM (values for all 12 questions).
Estimated Peak Oxygen Uptake (VO_{2peak}) in mL/min = (0.43 × [DASI]) + 9.6.
VO_{2peak} mL/kg/min × 0.286 (mL/kg/min)$^{-1}$ = METS.
*The most widely recognized measure of cardiorespiratory fitness is maximal oxygen consumption (VO_{2peak}) measured in mL/kg/min. The Index score correlates directly with VO_{2peak} and therefore is an indirect measure of maximal METS.
Adapted from Hlatky MA, Boineau RE, Higginbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). Am J Cardiol 1989;64:651–4.

increased operative time resulting in large fluid shifts or blood loss. Intermediate risk procedures include intraperitoneal surgery, laparoscopic procedures, and robotic-assisted laparoscopic surgeries. Low-risk procedures include endoscopic procedures or superficial surgeries (i.e., not involving entrance into a body cavity) (Eagle et al, 2002).

Pulmonary

Preoperative pulmonary evaluation is important in all urologic procedures but critical in those surgeries involving the thoracic or abdominal cavities. These later procedures, which include intra-abdominal, laparoscopic, or robotic surgeries, can decrease pulmonary function and predispose to pulmonary complications. Accordingly, it is wise to consider pulmonary functional assessment in patients who have significant underlying medical disease, significant smoking history, or overt pulmonary symptoms. Pulmonary function tests that include a forced expiratory volume in 1 second (FEV_1), forced vital capacity, and the diffusing capacity of carbon monoxide are quite easily obtainable and provide a preoperative baseline. **Patients with an FEV_1 of less than 0.8 L/sec or 30% of predicted are at high risk for complications** (Arozullah et al, 2003). Specific pulmonary risk factors include chronic obstructive pulmonary disease, smoking, preoperative sputum production, pneumonia, dyspnea, and obstructive sleep apnea**. It has been shown that smokers have a four-fold increased risk for postoperative pulmonary morbidity and as high as a 10-fold higher mortality rate** (Fowkes et al, 1982). In general, it is interesting to note that patients with restrictive pulmonary disease fare better than those with obstructive pulmonary disease because the former group maintains an adequate maximal expiratory flow rate, which allows for a more effective cough with less sputum production (Pearce and Jones, 1984). In addition to the specific pulmonary risk factors, general factors contribute to increased pulmonary complications such as increased age, lower serum albumin levels, obesity, impaired sensorium, previous stroke, immobility, acute renal failure, and chronic steroid use.

Specific preoperative interventions can decrease pulmonary complications. Smoking must be discontinued at least 8 weeks before surgery to achieve a risk reduction. Patients who discontinue smoking less than 8 weeks before surgery may actually have a higher risk of complication because the acute absence of the noxious effect of cigarette smoke decreases postoperative coughing and pulmonary toilet. **However, patients who have stopped smoking at least 8 weeks preoperatively will significantly lower their complication rate, and patients who have ceased smoking for more than 6 months have a pulmonary morbidity comparable with nonsmokers** (Warner et al, 1989). The use of preoperative bronchodilators in COPD patients can dramatically reduce postoperative pulmonary complications. Aggressive treatment of preexisting pulmonary infections with antibiotics, as well as the pretreatment of asthmatic patients with steroids, is essential in optimizing pulmonary performance. Likewise, the use of epidural and regional anesthetics, vigorous pulmonary toilet, rehabilitation, and continued bronchodilation therapy are all beneficial (Arozullah et al, 2003).

Hepatobiliary

Because the survival of patients with advanced liver disease has improved over the past decade, surgery is being performed more frequently in these patients. Furthermore, patients with mild to moderate hepatic disease are often asymptomatic. These patients need to be identified and evaluated before surgery. Patients are usually aware of a prior diagnosis of hepatitis, and they should be questioned regarding the timing of diagnosis and the precipitating factors. This history is particularly important in a situation when a member of the health care team is inadvertently stuck with a needle or scalpel during the surgical procedure. A review of systems should include questions regarding pruritus, excessive bleeding, abnormal abdominal distention, and weight gain. On physical examination, jaundice and scleral icterus may be evident with serum bilirubin levels higher than 3 mg/dL. Skin changes such as caput medusae, palmar erythema, spider angiomas, and clubbing all indicate hepatic dysfunction. Severe manifestations include abdominal distention, encephalopathy, asterixis, or cachexia. Again, identification of underlying hepatic illness is important in the preoperative risk assessment of the patient. Although the estimation of perioperative mortality is limited by the lack of high-quality clinical studies, the use of the Child classification and Model for End-Stage Liver Disease (MELD) score offers a reasonable estimation.

The Child classification assesses perioperative morbidity and mortality in patients with cirrhosis and is based on the patient's serum markers (bilirubin, albumin, prothrombin time) and severity of clinical manifestations (i.e., encephalopathy and ascites). **Mortality risk for patients undergoing surgery stratified by Child class is as follows: Child Class A—10%, Child Class B—30%, and Child Class C—76% to 82%.** The Child classification also correlates with the frequency of complications such as liver failure, encephalopathy, bleeding, infection, renal failure, hypoxia, and intractable ascites. Independent risk factors

other than the Child class that can increase the mortality rate in patients with liver disease include emergency surgery and chronic obstructive pulmonary disease (O'Leary et al, 2009; Pearce and Jones, 1984).

The MELD score is perhaps a more accurate assessment of perioperative mortality in patients with hepatic dysfunction. The score is derived from a linear regression model based on serum bilirubin, creatinine levels, and the international normalized ratio (INR). It is more accurate than the Child classification in that it is objective, gives weights to each variable, and does not rely on arbitrary cut-off values (Teh et al, 2007). **Clinicians can use a website (http://mayoclinic.org/meld/mayomodel9.html) to calculate the 7-day, 30-day, 90-day, 1-year, and 5-year surgical mortality risk on the basis of the patient's age, ASA class, INR, serum bilirubin, and creatinine levels.** Taken together, the Child classification and the MELD score complement each other and provide an accurate assessment of the risk of surgery in cirrhotic patients (O'Leary and Friedman, 2007; O'Leary et al, 2009).

OPTIMIZATION OF COMORBID ILLNESS

Just as adequate preoperative evaluation is important, optimization of comorbid illness is critical in reducing perioperative morbidity and mortality. With regards to cardiac disease, many studies have evaluated the prophylactic use of nitrates, calcium-channel blockers, and β-blockers for patients who are at risk for perioperative myocardial ischemia. Only β-blockade has shown to improve outcomes (Pearse et al, 2004). In a landmark study, Mangano and colleagues reported in the *New England Journal of Medicine* that there was an improvement in outcomes with the prophylactic use of atenolol in patients undergoing vascular surgery (Mangano et al, 1996). Similarly, a retrospective, cooperative group study of more than half a million patients showed that perioperative beta blockade is associated with a reduced risk of death among high-risk patients undergoing major noncardiac surgery (Lindenauer et al, 2005). In addition to β-blockade, the concept of goal-directed therapy, employing the judicious use of fluids, inotropes, and oxygen therapy to achieve therapeutic goals, may further reduce perioperative risk (Pearse et al, 2004). This concept was validated by Shoemaker, who reported an impressive reduction in mortality from 28% to 4% ($P < .02$) when goal-directed therapy was used (Shoemaker et al, 1988).

As with cardiac comorbidity, the preoperative management of the diabetic patients is quite important. Perioperative hyperglycemia can lead to impaired wound healing and a higher incidence of infection (Golden et al, 1999). Hypoglycemia in an anesthetized or sedated diabetic patient may be unrecognized and carries its own significant risks. **Noninsulin diabetics may need to discontinue long-acting hypoglycemics because of this risk of intraoperative hypoglycemia. Shorter-acting agents or sliding scale insulin regimens are generally preferable.** It is recommended that blood glucose levels be controlled between 80 and 250 mg/dL. Frequent fingerstick glucose checks and the use of a sliding scale short-acting insulin regimen are used in the postoperative period. Once the patient is eating, the usual insulin regimen can be resumed. Patients who monitor their diabetes with the use of insulin pumps should continue their basal insulin infusions on the day of surgery. The pump is then used to correct the glucose level as it is measured. It is important to know the sensitivity factor that corrects the glucose so that the patient's sugars can be managed in the operating room (Townsend et al, 2008).

Patients with either hyperthyroidism or hypothyroidism should be evaluated by an endocrinologist and surgery should be deferred until a euthyroid state is achieved. **The greatest risk in the hypothyroid patient is thyrotoxicosis or thyroid storm, which can present with fevers, tachycardia, confusion, and cardiovascular collapse.** Atrial fibrillation may also be present in 20% of hyperthyroid patients (Klein and Ojamaa, 2001). With regards to hyperthyroidism, careful attention should be given to the airway because the trachea can be compressed or deviated by a large goiter. Generally, antithyroid medications such as propylthiouracil or methimazole, as well as β-blockers, are continued on the day of surgery. In the event of thyroid storm, iodine and steroids may be necessary (Schiff and Welsh, 2003). Hypothyroidism is generally associated with an increased sensitivity to medications such as anesthetic agents and narcotics. Severe hypothyroidism can be associated with myocardial dysfunction, coagulopathy, electrolyte imbalance, and a decreased gastrointestinal motility. Symptoms include lethargy, cold intolerance, hoarseness, constipation, dry skin, and apathy. The decrease in metabolic rate produces periorbital edema, thinning of the eyebrows, brittle hair, dry skin, hyperthermia, bradycardia, and a prolonged relaxation of the deep tendon reflexes (Murkin, 1982). Once the diagnosis is confirmed by a low thyroxine level and an elevated thyroid stimulating hormone level, thyroid replacement with levothyroxine can be initiated (Schiff and Welsh, 2003).

The evaluation of the patient either taking corticosteroids or suspected of having an abnormal response of the hypothalamic-pituitary-adrenal axis (HPA) is also important. There is a wide variability in the HPA suppression in patients on exogenous steroids. Nonetheless, it seems clear that oral steroids equivalent to less than 5 mg of prednisone for any duration of time does not cause clinically significant suppression of the HPA axis. **By contrast, any patient taking more than 20 mg of prednisone or its equivalent per day for more than 3 weeks or who is clinically Cushingoid has probable HPA axis suppression** (LaRochelle et al, 1993). HPA suppression can even occur in patients using potent topical steroids at doses of 2 g per day, as well as in patients using inhaled corticosteroids at doses of 0.8 mg per day. Although the duration of a functional HPA axis suppression after glucocorticoids have been stopped is debatable, perioperative supplemental steroids are recommended for patients who had HPA axis suppressive doses within 1 year of surgery. A low-dose ACTH stimulation test can be used to assess the HPA axis and the need for stress steroids. For patients who take 5 mg of prednisone or the equivalent each day, no supplemental steroids are necessary and the usual daily glucocorticoid dose may be given in the perioperative period. **For those in whom the HPA axis is presumed to be suppressed or is documented to be suppressed, then 50 to 100 mg of intravenous hydrocortisone is given before the induction of anesthesia and 25 to 50 mg of hydrocortisone is given every 8 hours thereafter for 24 to 48 hours until the usual steroid dose can be resumed.** Minor procedures under local anesthesia do not require stress-dose steroids (Schiff and Welsh, 2003).

SPECIAL POPULATIONS

Elderly

In the next 20 years, the percentage of patients older than 85 years of age may reach 5% or 15 million people. This represents a rapidly

growing segment of our aging population (Monson et al, 2003). Accordingly, octogenarians and nonagenarians are undergoing an increasing number of surgeries annually. Because of the elderly patients' special physiologic, pharmacologic, and psychologic needs, a unique set of health care challenges are encountered. It is still unclear whether advanced age independently predicts surgical risk or whether it is coexisting medical conditions that adversely affect surgical outcomes. However, in a large study published by Turrentine, it was shown that increased age independently predicted morbidity and mortality (Turrentine et al, 2006). This confirmed the study by Vemuri, who also found increased age as an independent risk factor for morbidity and mortality in patients undergoing aneurysm surgery (Vemuri et al, 2004). The studies suggest that perhaps the elderly patient cannot meet the increased functional demand required during perioperative and postoperative period. Hypertension and dyspnea were the most frequently seen comorbid risk factors in patients older than 80 years, and preoperative transfusion history, emergency operation, and weight loss best predicted postoperative morbidity. Each 30-minute increment of operative time increased the odds of mortality by 17% in octogenarians (Turrentine et al, 2006). A unique and important factor in the perioperative care of the elderly is in the identification and prevention of delirium. Often overlooked as "sundowning," delirium can be the first clinical sign of metabolic and infectious complications (Townsend et al, 2008).

Morbid Obesity

With the rising incidence of obesity, as well as the vast experience gathered from bariatric surgery, the care of the morbidly obese patient has been extensively studied. One must carefully weigh the risk of any surgical procedure with the natural history of the disease when deciding the optimal time of the surgery in the morbidly obese. **It is estimated that patients with a body mass index (BMI) of greater than or equal to 45 kg/m^2 may lose anywhere from 8 to 13 years of life** (Fontaine et al, 2003). The careful selection of the morbidly obese patient for elective surgery is of paramount importance. Cardiac symptoms such as exertional dyspnea and lower extremity edema are nonspecific in the morbidly obese patients, and many of these patients have poor functional capacity. The physical examination often underestimates cardiac dysfunction in the severely obese patient. Severely obese patients with greater than three coronary heart disease risk factors may require noninvasive cardiac evaluation (Poirier et al, 2009). Obesity is associated with a vast array of comorbidities. Morbidly obese patients often have atherosclerotic cardiovascular disease, heart failure, systemic hypertension, pulmonary hypertension related to sleep apnea and obesity, hypoventilation, cardiac arrhythmias, deep vein thrombosis, history of pulmonary embolism, and poor exercise capacity. There are also numerous pulmonary abnormalities that result in a ventilation perfusion mismatch and alveolar hypoventilation. Obesity is a risk factor for postoperative wound infections, and, when appropriate, laparoscopic surgery should be considered.

Pregnancy

Urologic surgery in the pregnant woman is generally related to the management of renal colic and urinary tract stones. In the asymptomatic woman, the stones can be discovered during the sonographic evaluation of the fetus or during the evaluation of the pregnant woman who is experiencing renal colic. **The fetus is at the highest risk from radiation exposure from the preimplantation period to approximately 15 weeks' gestation.** Because the radiation dose that is associated with congenital malformations is 10 cGy, the evaluation of renal colic in a pregnant patient is performed usually with sonography (radiation dose with abdominal CT: 1 cGy, intravenous pyelogram: 0.3 cGy). The indications for operative intervention in the pregnant patient are discussed elsewhere in this book. Anesthetic risks during pregnancy concern both the mother and the fetus. During the first trimester, the fetus may be directly exposed to the teratogenic effects of certain anesthetic agents. Later in pregnancy, anesthesia places the mother at risk for preterm labor and the fetus at risk for hypoxemia secondary to changes in uterine blood flow and maternal acid base balance. These risks seem to be greatest during the first and third trimesters. **For semielective procedures, an attempt should be made to delay surgery until after the first trimester.** However, one must consider the continued exposure of the underlying condition in relation to the operative risks to both the mother and the fetus. **The second trimester is the safest time to perform surgery because organ system differentiation has occurred and there is almost no risk for anesthetic-induced malformation or spontaneous abortion.** When contemplating surgery on the pregnant female, consultation with the obstetrician, perinatologist, and anesthesiologist is essential. These specialists will help determine the optimum technique to monitor the status of the fetus in the pregnant mother. Fetal heart rate monitors and tocometer monitoring for uterine activity are used before and after the procedure. Postoperative pain is best managed with narcotic analgesics because they have not been shown to cause birth defects in humans when used in normal dosages. Nonsteroidal antiinflammatory medication should be avoided because of the risk for premature closure of the ductus arteriosus. Chronic use of narcotics during pregnancy may cause fetal dependency, and it is recommended that the pregnant postsurgical patient be weaned off narcotic use as soon as possible (Mikami et al, 2008).

Nutritional Status

Malnutrition compromises host defenses and increases the risk of perioperative morbidity and mortality. Adequate nutritional status is essential for proper wound healing, management of infections, return of gastrointestinal activity, and maintenance of vital organ function (McDougal, 1983). The preoperative evaluation of the patient's nutritional status consists of the assessment of any recent weight loss and the measurement of the lymphocyte count and serum albumin. A 20-pound weight loss in the preceding 3 months before surgery is considered to be a reflection of severe malnutrition. The lymphocyte count and serum albumin level reflect visceral protein status with lower levels indicating malnutrition (Reinhardt et al, 1980). There are two methods for nutritional support. Total parenteral nutrition (TPN) is used for patients who are severely malnourished and who have a nonfunctioning gastrointestinal tract. Several studies have shown that 7 to 10 days of preoperative parenteral nutrition improves postoperative outcome in undernourished patients (Von Meyenfeldt et al, 1992). On the contrary, its use in well-nourished or mildly undernourished patients is either of no benefit or even with increased risk of sepsis (Perioperative total parenteral nutrition in surgical patients, 1991). On the other hand, enteral nutrition has a fewer complications than TPN and can provide a more balanced physiologic diet. Elemental nutrition is accomplished via a feeding tube, a gastrostomy, or feeding jejunostomy. Enteral nutrition maintains the gut-associated lymphoid tissue, enhances mucosal blood flow, and

maintains the mucosal barrier. There are hundreds of enteral products on the market, and most have a caloric density of 1 to 2 kcal/mL. These formulas are also lactose free and provide the recommended daily allowances of vitamins and minerals in less than 2 L per day. The patients on enteral feeds must be monitored for improvement in nutritional status, gastrointestinal intolerance, and fluid and electrolyte imbalance. **Preoperative enteral feedings can decrease postoperative complication rates by 10% to 15% when used for 5 to 20 days before surgery** (Guidelines, 2002). **The guidelines recommend postoperative parenteral nutrition in patients who are unable to meet their caloric requirements within 7 to 10 days.** Just as in the perioperative state, enteral feedings are preferred over parenteral nutrition when feasible. Moreover, the routine use of postoperative TPN has not proven useful in well-nourished patients or in those with adequate oral intake within 1 week after surgery (Byers and Hameed, 2008). Complications can occur with either enteral nutrition or parenteral nutrition. Dislodgement of nasoenteral tubes and percutaneous enteral catheters can result in pulmonary and peritoneal complications. Adynamic ileus may also occur because of decreased splanchnic perfusion, sympathetic tone, or opiate use. With regards to TPN, establishing central access is associated with a significant risk of complications. These include pneumothorax/hemothorax secondary to poor line placement and chylothorax secondary to thoracic duct injury. Line sepsis is the most common complication of indwelling central catheters and necessitates catheter removal. Venous thrombosis with associated thrombophlebitis and extremity edema has been reported. Catheter thrombosis has also been reported and can be treated with thrombolytic agents (Guidelines, 2002).

PREPARATION FOR SURGERY

Antibiotic Prophylaxis

In 1999 the Centers for Disease Control (CDC) issued its third report on the prevention of surgical site infections (SSIs) highlighting the importance of standardization of prophylaxis treatment to prevent this universal surgical complication (Mangram et al, 1999). **The report indicated that SSIs account for approximately 40% of nosocomial infections in surgical patients and potentially prolong hospital stay by 7 to 10 days.** A study of national SSIs from the 2005 Healthcare Cost and Utilization Project National Inpatient Sample (HCUP NIS) calculated an increase in hospital stay of 9.7 days and in per-patient cost of $20,892 (de Lissovoy et al, 2009). This translated nationally into an additional 1 million inpatient hospital days and additional health care cost of $1.6 billion. Bowater and colleagues recently published a systematic review of meta-analyses (level 1 evidence) and concluded that there was substantial evidence that antibiotic prophylaxis was an effective prevention for SSI over a wide variety of surgical procedures (Bowater et al, 2009). **Given both the ethical responsibility of the surgeon to decrease surgical morbidity and the recent policy shift by the Centers of Medicare and Medicaid Services to withhold reimbursement for hospital admissions secondary to specific SSI, it is mandatory for urologists to understand the principles behind and practice SSI prevention.**

Along with antibiotic prophylaxis, proper hand washing/scrubbing and sterile preparation of the operative field have always been central to the prevention of SSI. For procedures involving the gastrointestinal tract, mechanical and oral antibiotic bowel preparation had been standard practice until more recent literature calling into question its usefulness (discussed later). Preoperative hair removal has not been associated with a decrease in SSI, but if performed, use of mechanical clippers or depilatory creams as opposed to razors are associated with a decrease risk of SSI (Wolf et al, 2008).

The risk of SSI and therefore the recommendation for antibiotic prophylaxis is composed of three risk factors: the patient's susceptibility to and the ability to respond to localized and systemic infection, procedural risk of infection, and the potential morbidity of infection. Patient-related factors, listed in Table 6–4, increase risk by decreasing natural defenses, increasing the local bacterial concentration, and/or altering the spectrum of bacterial flora. Secondly, surgical procedure–specific factors can affect the route of entry, site of infection, and pathogen involved. This idea was first described in the landmark study from the National Research Council and later formalized by the CDC; specifically, surgical wounds are now classified by degree of contamination (i.e., the inoculum of potential pathogen) (Table 6–5; Hart et al, 1968). To predict the risk of SSI, several scoring systems have been developed incorporating patient-related factors with wound classification. Finally, the risk to the patient from SSI is an important

Table 6–4.

Patient Factors That Increase the Risk of Infection

Advanced age
Anatomic anomalies
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Chronic indwelling hardware
Infected endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Data from Cruse PJ. Surgical wound infection. In: Wonsiewicz MJ, editor. Infectious disease. Philadelphia: WB Saunders; 1992. p. 758–764; and Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250–78; quiz 279–80.

Table 6–5.

Surgical Wound Classification

Clean	• Uninfected wound without inflammation or entry into the genital, urinary, or alimentary tract • Primary wound closure closed drainage
Clean contaminated	• Uninfected wound with controlled entry into the genital, urinary, or alimentary tract • Primary wound closure closed drainage
Contaminated	• Uninfected wound with major break in sterile technique (gross spillage from gastrointestinal tract or nonpurulent inflammation) • Open fresh accidental wounds
Dirty infected	• Wound with preexisting clinical infection or perforated viscera • Old traumatic wounds with devitalized tissue

Data from Garner JS. CDC guideline for prevention of surgical wound infections, 1985. Supersedes guideline for prevention of surgical wound infections published in 1982. (Originally published in 1995.) Revised. Infect Control 1986;7(3):193–200; and Simmons BP. Guideline for prevention of surgical wound infections. Infect Control 1982;2:185–96.

consideration in determining the need for prophylaxis. For example, routine cystoscopy in the evaluation of microhematuria in an otherwise young, healthy patient may not warrant prophylaxis; however, the same procedure in an elderly, insulin-dependent diabetic (immunocompromised) does warrant prophylaxis given the high likelihood that a postprocedural urinary tract infection would result in a significant deterioration in the patient's overall health. Understanding the three factors together then allows the urologist to make a rational decision as to the risk/benefit of antibiotic prophylaxis.

Once the decision for antibiotic prophylaxis is made, the keys to successful prevention are proper timing and administration of the antibiotic and the proper choice of antibiotic for the particular procedure. Since the pivotal study by Classen and colleagues, particular emphasis has been placed on the timing of prophylaxis to be given within 2 hours of incision (Classen et al, 1992). This emphasis is exemplified by the Joint Commission's Surgical Care Improvement Project (SCIP) guideline for administration of antibiotic prophylaxis 60 minutes before incision in a broader effort to decrease surgical complications by 25% by 2010. A recent multi-institutional trial involving more than 4400 patients at 29 institutions reported results of their analysis on the optimal timing of antibiotic prophylaxis (Steinberg et al, 2009). **Their results suggested an improvement in prevention of SSI when antibiotics were administered within 30 minutes of incision as compared with 31 to 60 minutes (adjusted odds ratio [OR] 1.48, *P* = .06).** More importantly, this larger study confirmed the significantly increased risk of SSI when antibiotics were administered at the time of or following incision with adjusted OR of 2.20, $P = .02$. The duration of antibiotic prophylaxis is more controversial; however, most recommendations advocate no more than 24 hours in a patient without an established infection. Routine antibiotic use beyond 24 hours increases the risk of *Clostridium difficile* colitis, increases the development of antibiotic resistance, and increases costs. Along with timing and duration, proper administration of antibiotics implies proper dosing. Antibiotic dose is dependent on the patient's body weight, renal function/hepatic function, and duration of procedure (requiring re-dosing if >4 hours). The second key to successful prevention is the proper choice of antibiotic for the procedure in question. As mentioned earlier, surgery-specific factors affect the type of pathogen, route of entry, and likelihood of systemic infection. For example, the choice of antibiotic is different before a transurethral resection of the prostate (need coverage for common urinary tract pathogens) as compared with a cystectomy with planned sigmoid colon urinary diversion (need coverage for anaerobic bacteria). Another important consideration is the rate of antibiotic resistance in the community. **Although there is level 1 evidence for the use of fluoroquinolones as prophylaxis for urologic endoscopic procedures, the emerging *Escherichia coli* resistance in the community is changing practice patterns in many practices and high-resistance hospitals.** One resource that is particularly useful is the hospital antibiogram. These reports are published monthly at most major hospitals and quantify the susceptibility/resistance of common organisms to a wide variety of antibiotics. A summary of the recent American Urological Association (AUA) best practice statement on antibiotic prophylaxis is shown in Table 6–6.

Bowel Preparation

Since antibiotics were first shown to reduce infectious complications in gastrointestinal surgery, mechanical and antibiotic bowel preparation has been a mainstay of urologic surgery employing intestinal segments. The rationale for bowel preparation before intestinal surgery is to decrease intraluminal feces and decrease bacterial colony counts in order to decrease the rate of anastomotic leak, intra-abdominal abscesses, and wound infections. The bacterial flora in the bowel consists of aerobic organisms, the most common of which are *Escherichia coli* and *Enterococcus faecalis,* and anaerobic organisms, the most common of which are *Bacteroides* species and *Clostridium* species. **The bacterial concentration ranges from 10 to 10^5 organisms per gram of fecal content in the jejunum, 10^5 to 10^7 in the distal ileum, 10^6 to 10^8 in the ascending colon, and 10^{10} to 10^{12} in the descending colon.** The preparation itself consists of two components: antibiotic preparation and mechanical preparation. Because there are only a few small series in the urologic literature, the rationale for each must be inferred from the general surgery literature, specifically, from colorectal surgery literature.

Although preoperative parenteral antibiotic prophylaxis before intestinal surgery is well established and widely used, oral antibiotic preparation is still somewhat controversial. Several oral antibiotic regimens are used today. The most commonly used regimen, oral neomycin and erythromycin, first became established with the landmark study by Drs. Nichols and Condon in 1977 (Clarke et al, 1977). In a double-blind, placebo-controlled study, 167 patients undergoing elective colonic surgery were randomized to receive mechanical bowel preparation with or without oral neomycin and erythromycin. The overall septic complications were 43% in the mechanical-only prep and 9% in the antibiotic plus mechanical prep group, $P = .001$. With the widespread use of preoperative parenteral antibiotics, the benefit of oral preparation has been debated. Several older studies reported decreased infectious complications; however, these studies were small and there have been no randomized controlled trials to document the benefit. **The disadvantage of oral antibiotic preparation is primarily related to increased incidence of pseudomembranous colitis secondary to *C. difficile* infection.** In a retrospective analysis of 304 patients, Wren and colleagues reported a significantly decreased incidence of *C. difficile* colitis in patients who did not receive oral antibiotics before elective colorectal surgery (2.6% vs. 7.2%, $P = .03$) (Wren et al, 2005). Despite the lack of evidence in the literature, a recent survey of colorectal surgeons revealed that up to 87% of surgeons continue to administer oral antibiotic bowel preparation before elective surgery (Zmora et al, 2003).

Mechanical bowel preparation predates the use of antibiotics in intestinal surgery and was thought to decrease the rate of anastomotic complications. Before the development of nonabsorbable liquids, patients underwent several days of oral laxatives, bowel irrigations via nasogastric tubes, and repeat enemas. These regimens were associated with significant patient discomfort and clinical morbidity due to electrolyte imbalances. The development of polyethylene glycol solution (GoLytely) and sodium phosphate solution (Fleet's Phospho-soda) reduced much of the electrolyte disturbances and allowed for mechanical bowel preparation to be done in the outpatient setting. **Both regimens are suitable for most patients; however, polyethylene glycol is preferred in the elderly and in patients with renal insufficiency, congestive heart failure, existing electrolyte disturbances, and cirrhosis because it is completely nonabsorbable.**

The benefit of mechanical bowel preparation has been assumed for decades as evidenced by 99% positive response by colorectal surgeons when asked if mechanical preparation is routinely used

Table 6–6.

AUA Best Practice Statement on Recommended Antimicrobial Prophylaxis for Urologic Procedures

PROCEDURE	ORGANISMS*	PROPHYLAXIS INDICTATED?	ANTIMICROBIALS OF CHOICE	ALTERNATIVE ANTIMICROBIALS	DURATION
Lower Tract Instrumentation					
Removal of external urinary catheter	GU tract	If risk factors	• Fluoroquinolone • TMP-SMX	• Aminoglycoside ± ampicillin • 1st/2nd gen. cephalosporin • Amoxicillin/clavulanate	≤24 hr
Cystography, urodynamic study, or simple cystoscopy	GU tract	If risk factors	• Fluoroquinolone • TMP-SMX	• Aminoglycoside ± ampicillin • 1st/2nd gen. cephalosporin • Amoxicillin/clavulanate	≤24 hr
Cystoscopy with manipulation	GU tract	All	• Fluoroquinolone • TMP-SMX	• Aminoglycoside ± ampicillin • 1st/2nd gen. cephalosporin • Amoxicillin/clavulanate	≤24 hr
Prostate brachytherapy or cryotherapy	Skin	Uncertain	• 1st gen. cephalosporin	• Clindamycin	≤24 hr
Transrectal prostate needle biopsy	Intestine	All	• Fluoroquinolone • 2nd/3rd gen. cephalosporin	• Aminoglycoside + metronidazole or clindamycin	≤24 hr
Upper Tract Instrumentation					
Shock-wave lithotripsy	GU tract	All	• Fluoroquinolone • TMP-SMX	• Aminoglycoside ± ampicillin • 1st/2nd gen. cephalosporin • Amoxicillin/clavulanate	≤24 hr
Percutaneous renal surgery	GU tract Skin	All	• 1st/2nd gen. cephalosporin • Aminoglycoside + metronidazole or clindamycin	• Ampicillin/sulbactam • Fluoroquinolone	≤24 hr
Ureteroscopy	GU tract	All	• Fluoroquinolone • TMP-SMX	• Aminoglycoside ± ampicillin • 1st/2nd gen. cephalosporin • Amoxicillin/clavulanate	≤24 hr
Open or Laparoscopic Surgery					
Vaginal surgery (including urethral sling procedures)	GU tract Skin Group B *Streptococcus*	All	• 1st/2nd gen. cephalosporin • Aminoglycoside + metronidazole or clindamycin	• Ampicillin/sulbactam • Fluoroquinolone	≤24 hr
Open/lap without entering GU tract	Skin	If risk factors	• 1st gen. cephalosporin	• Clindamycin	Single dose
Surgery involving entry into GU tract	GU tract Skin	All	• 1st/2nd gen. cephalosporin • Aminoglycoside + metronidazole or clindamycin	• Ampicillin/sulbactam • Fluoroquinolone	≤24 hr
Intestinal surgery	GU tract Skin Intestinal flora	All	• 2nd/3rd gen. cephalosporin • Aminoglycoside + metronidazole or clindamycin	• Ampicillin/sulbactam • Ticarcillin/clavulanate • Piperacillin/tazobactam • Fluoroquinolone	≤24 hr
Implanted prosthesis	GU tract Skin	All	• Aminoglycoside + 1st/2nd gen. cephalosporin or vancomycin	• Ampicillin/sulbactam • Ticarcillin/clavulanate • Piperacillin/tazobactam	≤24 hr

Table 6–7.

Mechanical and Pharmacologic Venous Thromboembolism Prophylaxis

PROPHYLAXIS	DOSE	ADVANTAGES	DISADVANTAGES
Pneumatic compression stockings	N/A	• Can be used in patients with high bleeding risk • Easily standardized for all patients • Studied in multiple patient groups	• No standards for size, pressure • Individual models not specifically studied • Less effective than pharmacologic prophylaxis in high-risk groups
Low-molecular-weight heparin	40 mg SQ once daily	• Once-daily dosing • Less risk of heparin-induced thrombocytopenia • No blood monitoring necessary	• Not reversible • Cost • Relative contraindication in patients with renal insufficiency
Low-dose unfractionated heparin	5000 U SQ every 8 hr	• Reversible • Can be used safely in patients with renal insufficiency • Relatively inexpensive	• Needs redosing every 8-12 hr • Heparin-induced thrombocytopenia

(Zmora et al, 2003). However, recent randomized controlled trials (RCT) have called into doubt the true benefit. Slim and colleagues recently published a meta-analysis of RCTs including a total of 4859 patients (Slim et al, 2009). The analysis included 14 trials including 2 recently completed large trials from the Netherlands and Sweden (Contant et al, 2007; Jung et al, 2007). **Overall, the analysis revealed that mechanical bowel preparation provided no benefit for anastomotic leak (OR 1.12, 95%; CI 0.82 to 1.53; *P* = .46), abdominal/pelvic abscess (OR 0.90, CI 0.47 to 1.72; *P* = .75), or mortality (OR 0.91, CI 0.57 to 1.45; *P* = .70).** In fact, when considering overall SSI, mechanical bowel preparation was associated with a significantly increased risk (OR 1.40, CI 1.05 to 1.87; *P* = .02). These results were reiterated in a recent Cochrane review, which found no significant differences in anastomotic leak rate, wound infection, need for reoperation, and mortality rates (Guenaga et al, 2009). The authors concluded that there was no evidence that mechanical bowel preparation improves patient outcome following elective colorectal surgery. Although similar studies have not been done in patients undergoing elective urologic surgery, urologists can infer from the colorectal literature and should re-evaluate the common practice of mechanical bowel preparation before urologic intestinal surgery. Two specific exceptions are transrectal ultrasound-guided prostate needle biopsy (PNBx) and laparoscopic urologic surgery. Given the portal of entry and subsequent risk of bacteremia, most urologists advocated for mechanical rectal cleansing with an enema before transrectal PNBx. With regards to laparoscopy, minimally invasive surgeons have long believed that preoperative bowel preparation improves operative exposure due to bowel decompression and decreases the incidence of postoperative ileus. However, to date there have been no trials to support this assertion.

Venous Thromboembolic Prophylaxis

Venous thromboembolic (VTE) complications are a major cause of potentially preventable morbidity and mortality among surgical patients in the United States. A recent study from the Center for Quality Improvement and Patient Safety and the Agency for Healthcare Research and Quality found postoperative VTE as the second most common cause of excess length of stay, charges, and mortality among surgical patients discharged from acute care hospitals (Zhan and Miller, 2003). Urology patients in particular have an increased incidence estimated to be 10% to 40% in patients without any prophylaxis (Geerts et al, 2008). Although these estimates are based on historical studies before the routine use of mechanical prophylaxis and the recognition of the benefits of early ambulation, the increased risk continues in more recent studies with reported incidence of 1% to 5%. Urologic patients followed prospectively in the European RISTOS study developed VTE in 1.9% undergoing open surgery despite a high rate of prophylaxis (Scarpa et al, 2007). Overall, VTE represents the most important cause of nonsurgical mortality among urology patients (Forrest et al, 2009).

Although the use of perioperative mechanical prophylaxis (pneumatic compression stockings) is fairly universal, pharmacologic prophylaxis is only administered after weighing the risk of VTE versus risk of perioperative bleeding complications (Table 6–7). Leonardi and colleagues reviewed and analyzed 33 randomized controlled trials to assess the incidence of bleeding complications in general surgery patients receiving pharmacologic prophylaxis (Leonardi et al, 2006). **Although there was a significantly higher rate of minor complications (injection site bruising and wound hematoma), there was no significant difference in major complications (i.e., GI tract [0.2%] or retroperitoneal bleeding [<0.1%]).** Although these results are generally applicable to urology patients, certain urologic procedures have a specifically higher rate of bleeding complications such as transurethral resection of the prostate and partial nephrectomy. Regarding an individual's risk of VTE, both surgery-related risk factors and patient-related risk factors must be considered. Surgical factors specific to urologic surgery to be weighed include general versus neuraxial anesthesia, supine versus dorsal lithotomy position, abdominal versus pelvic surgery with/without lymphadenectomy, and open versus laparoscopic approach. Patient-related risk factors are listed in Table 6–8 with increasing age, malignancy, history of cancer therapy, and others being fairly common among urology patients. In fact, both the RISTOS study and a recent report on minimally invasive radical prostatectomy confirmed several of these factors as increased risk of VTE in urologic patients (Scarpa et al, 2007; Secin et al, 2008). In 2008 the American College of Chest Physicians (ACCP) issued guidelines on the prevention of VTE with a strong recommendation that hospitals develop a formal, active strategy to address VTE prevention. **Although prior recommendations from the ACCP advocated individualized risk assessment models to guide therapy, the current recommendations advocate implementation of group-specific thromboprophylaxis routinely for all patients who belong to each of the major surgical groups (i.e., urologic surgery)** (Geerts et al, 2008). The AUA recently published a best practice statement on

Table 6–8.

Patient-Related Factors Increasing Risk for Venous Thromboembolism (VTE)

Surgery
Trauma (major trauma or lower-extremity injury)
Immobility, lower-extremity paresis
Cancer (active or occult)
Cancer therapy (hormonal, chemotherapy, angiogenesis inhibitors, radiotherapy)
Venous compression (tumor, hematoma, arterial abnormality)
Previous VTE
Increasing age
Pregnancy and the postpartum period
Estrogen-containing oral contraceptives or hormone replacement therapy
Selective estrogen receptor modulators
Erythropoiesis-stimulating agents
Acute medical illness
Inflammatory bowel disease
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Obesity
Central venous catheterization
Inherited or acquired thrombophilia

Table 6–9.

Patient Risk Assessment Model (A) and American Urological Association Best Practice Recommendations (B)

A

Patient Risk Stratification	
Low risk	• Minor surgery in patients <40 yr with no additional risk factors
Moderate risk	• Minor surgery in patients with additional risk factors • Surgery in patients aged 40-60 yr with no additional risk factors
High risk	• Surgery in patients >60 yr • Surgery in patients aged 40-60 yr with additional risk factors (see Table 6–8)
Highest risk	• Surgery in patients with multiple risk factors (e.g., age >40 yr, cancer, prior venous thromboembolism)

B

Level of Risk	**Recommendations**
Low risk	• No prophylaxis other than early ambulation
Moderate risk	• Heparin 5000 units every 12 hr subcutaneous starting after surgery or • Enoxaparin 40 mg (for Cr Cl < 30 mL/min, use 30 mg) subcutaneous daily or • Pneumatic compression device if risk of bleeding is high
High risk	• Heparin 5000 units every 12 hr subcutaneous starting after surgery or • Enoxaparin 40 mg (for Cr Cl < 30 mL/min, use 30 mg) subcutaneous daily or • Pneumatic compression device if risk of bleeding is high
Highest risk	• Enoxaparin 40 mg (for Cr Cl < 30 mL/min, use 30 mg) subcutaneous daily and adjuvant pneumatic compression device, or • Heparin 5000 units every 8 hr subcutaneous starting after surgery and adjuvant pneumatic compression device

the use of VTE prophylaxis in urologic patients (Forrest et al, 2009). Their recommendations combine an individualized risk assessment model with each type of urologic surgery. For example, a high-risk patient (multiple patient risk factors) and low-risk surgery may require pharmacologic prophylaxis just as a low-risk patient undergoing high-risk surgery. The recommendations are summarized in Table 6–9.

Antithrombotic Therapy

With most urologic patients suffering from medical comorbidities, urologists frequently encounter patients on chronic vitamin K antagonists (e.g., warfarin) or anti-platelet therapy for the management of atrial fibrillation, mechanical heart valves, or coronary artery disease. The perioperative management of interruption of this antithrombotic therapy can be a challenging problem. Unlike VTE pharmacologic prophylaxis, warfarin and antiplatelet therapy have been shown to be associated with significant bleeding complications after surgery. Therefore urologists must carefully consider the risk of interruption of chronic anticoagulation to determine the best course of perioperative management of these medications.

Chronic anticoagulation with warfarin is most frequently encountered in patients with atrial fibrillation, mechanical heart valves, or prior VTE. **The pharmacologic half-life of warfarin is 36 to 42 hours, and therefore most guidelines recommend cessation of therapy 5 days before surgery to ensure an INR less than 1.5.** The larger issue is whether patients require bridge with short-term anticoagulation between the time of subtherapeutic INR and surgery. The decision is based on risk of thrombotic event. Regarding atrial fibrillation, clinical scoring systems such as congestive heart failure-hypertension-age-diabetes-stroke ($CHADS_2$) stratify patients into risk groups that predict risk of stroke off anticoagulation. Patients with mechanical heart valves can also be stratified into risk groups according to the location (mitral versus aortic) and type of valve used. Similarly, patients with a prior history of VTE are stratified according to duration since last VTE and the patient's risk of recurrent VTE (Table 6–10). **In general, the ACCP, which released its guidelines in 2008, recommends that patients in the moderate- and high-risk groups undergo bridging anticoagulation with therapeutic dose subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin** (Douketis et al, 2008).

An increasing number of patients are receiving chronic antiplatelet therapy in the prevention of cardiovascular events and, more importantly, in the prevention of coronary stent thrombosis. Although the former indication poses little controversy for the urologist, the latter indication presents a significant and complex clinical question in which the urologist must weigh the risk of bleeding with the potentially devastating risk of perioperative stent thrombosis. Aspirin and clopidogrel are the two most commonly used antiplatelet drugs and are frequently used together.

Table 6–10.

Risk Stratification for Arterial/Venous Thromboembolism Events during Perioperative Period in Patients on Chronic Anticoagulant Therapy

	Indications for Anticoagulant Therapy		
	MECHANICAL HEART VALVE	ATRIAL FIBRILLATION	RECENT VENOUS THROMBOEMBOLISM (VTE)
Low	• Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	• $CHADS_2$ score of 0-2 (and no prior stroke or transient ischemic attack)	• Single VTE occurred >12 mo ago and no other risk factors
Moderate*	• Bileaflet aortic valve prosthesis and 1 of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age >75 yr	• $CHADS_2$ score of 3-4	• VTE within the past 3-12 mo • Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation) • Recurrent VTE • Active cancer (treated within 6 mo or palliative)
High*	• Any mitral valve prosthesis • Recent (within 6 mo) stroke or transient ischemic attack	• $CHADS_2$ score of 5 or 6 • Recent (within 3 mo) stroke or transient ischemic attack • Rheumatic valvular heart disease	• Recent (within 3 mo) VTE • Severe thrombophilia (e.g., deficiency of protein C, protein S or antithrombin, antiphospholipid antibodies, multiple abnormalities)

*Patients at moderate or high risk are recommended to undergo bridging anticoagulation with therapeutic-dose subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin.

Adapted from Douketis JD, Berger PB, Dunn AS, et al. The perioperative management of antithrombotic therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133:299S–339S.

Both are irreversible inhibitors of platelet function and therefore need to be stopped 7 to 10 days before surgery in order to minimize bleeding risk. **Current recommendations require dual antiplatelet therapy for 6 weeks after bare metal coronary stents and 12 months for drug-eluting stents. Premature interruption of antiplatelet therapy has been associated with a 25% to 50% risk of significant myocardial infarction with resultant increased perioperative mortality** (O'Riordan et al, 2009). In most cases, urologists should defer elective surgery until after antiplatelet therapy can be safely interrupted. Even then, because acute stent thrombosis has been described with drug-eluting stents after 12 months, urologists should strongly consider at least single-agent antiplatelet therapy in these patients. Given the current lack of clinically useful alternatives to antiplatelet therapy, in cases in which surgery cannot be delayed (i.e., malignancy), the ACCP strongly recommends continuing aspirin and clopidogrel during the perioperative period (Douketis et al, 2008). Obviously, communication between the urologist and the cardiologist throughout the perioperative period is essential to minimize complications.

ANESTHETIC CONSIDERATIONS

The basic tenet of anesthesia is to deliver hypnosis, amnesia, and analgesia while maintaining satisfactory operating conditions. An understanding of the basic pharmacologic principles, anesthetic equipment and monitoring, and patient analgesia is important to any surgeon including the urologist for successful operative outcomes and avoidance of surgical complications. Although urologists are performing increasingly more procedures in the office, the bulk of urologic surgery occurs in the operating room under monitored anesthesia care (MAC), regional anesthesia, or general anesthesia. Current practice in operative anesthesia employs a combination of inhalational agents and intravenous medications along with analgesics (for pain control) and benzodiazepines (for anxiolysis and amnesia). Of course, improved presurgical evaluation, pharmacologic drugs, and perioperative monitoring have dramatically decreased the risks of anesthesia. A recent study of New York hospital-based and free-standing ambulatory surgical centers reported the risk of all-cause mortality of 1 in 49,012 and immediate rate of admission to an inpatient facility of 0.6% (Fleisher et al, 2007b).

Selection of Mode of Anesthesia

An important role of the urologist in the anesthetic evaluation is to determine what mode of anesthesia is best for the particular patient and surgical procedure. The choice depends on patient-related factors including comorbidities, airway, and patient preference and procedural factors including complexity, duration, anatomic location, and expected fluid/blood loss. A basic understanding of each method of anesthesia and the pharmacologic principles will aid the urologist in making recommendations to the anesthesiologist.

Monitored Anesthesia Care

Although monitored anesthesia care (MAC) is defined as conscious sedation under the care of an anesthesiologist in a monitored situation, MAC encompasses a wide range of levels of anesthesia from minimal sedation to brief intervals of unconscious general anesthesia. Most commonly, anesthesiologists combine intravenous opioid analgesics and benzodiazepines to maintain a sufficient level of patient comfort and anxiolysis. MAC is widely used in urology in the ambulatory setting and is suitable for short-duration endoscopic procedures, transrectal ultrasound-based procedures, and, when combined with a local anesthetic, superficial procedures of the external genitalia. Conscious sedation can be administered in the office setting but only with proper monitoring of the patient during and after the procedure. **The Joint Commission has strict guidelines to ensure that the patients receive the same level of monitoring as if under the care of an anesthesiologist including a requirement for a trained monitoring assistant, immediate access to airway and resuscitation equipment, and specific preprocedure/postprocedure evaluations.**

Regional Anesthesia

Regional anesthesia incorporates different levels of anesthesia directed to the surgical site including local anesthesia, spinal anesthesia, and epidural anesthesia. The use of local anesthetics is typically combined with MAC for superficial procedures in an isolated anatomic location. The keys to proper local anesthetic administration are avoidance of intravascular injection and knowledge of pharmacology. The two most commonly used drugs are lidocaine and bupivacaine with the primary difference being the onset and duration of action.

Spinal and epidural anesthesia involves injection of anesthetic (most commonly lidocaine or bupivacaine) into the subarachnoid space or epidural space with direct effect on the spinal cord resulting in sensory, motor, and sympathetic blockade. In urologic procedures, epidural anesthesia is most useful for postoperative pain management for major abdominal procedures, thereby avoiding the adverse effects of high doses of intravenous opioids (i.e., respiratory depression, gastrointestinal dysfunction). Spinal anesthesia is suitable for most urologic endoscopic procedures and lower abdominal surgical procedures and is limited only by the duration of anesthesia required. Spinal anesthesia avoids the cardiopulmonary effects and complications of general anesthesia. Several factors affect the spinal level and efficacy of administration. Generally, larger volume and increased doses result in longer duration and increased cephalad migration. The addition of low-dose opioids and/or vasoconstrictors prolongs the duration of analgesia while reducing the dose of anesthetic. The anesthetic-related adverse effect is hypotension as a result of sympathetic blockade and occurs in 10% to 40% of patients (Di Cianni et al, 2008). **The primary technique-related complication is postdural puncture headache (results from cerebrospinal fluid leak) with an incidence of less than 2% with currently used 29-gauge pencil-tipped needles** (Turnbull and Shepherd, 2003). **Overall, spinal anesthesia has become safe with the incidence of serious neurologic deficits being 0.05%.**

General Anesthesia

Inhalational General Anesthesia

Inhalational drug development has emphasized inhalational agents that facilitate rapid induction and emergence and are nontoxic. **Two of the most important characteristics of inhalational anesthetics are the blood/gas (B/G) solubility coefficient and the minimum alveolar concentration (MAC). The B/G refers to the serum uptake of the inhaled agent, and the MAC is a measure of the potency of a volatile anesthetic (i.e., the serum level required to prevent movement in response to a skin incision in 50% of patients).** The various inhalational agents differ not only in the B/G and MAC but also in the cardiopulmonary effects. Obviously, a basic understanding of these properties is important for the urologic surgeon, especially during instances of surgical complication.

Nitrous oxide (NO) is one of the most commonly used agents due to its propensity of rapid induction and emergence; however, due to its low potency, it is often combined with other agents. Because of NO's high B/G and tendency to increase the volume and pressure of closed spaces, its use is contraindicated in certain clinical situations such as small bowel obstruction and pneumothorax. During laparoscopic abdominal procedures, surgeons often prefer to avoid the use of NO due to resultant bowel distention and subsequent interference in the operative field. Although this effect is debated in the surgical literature, El-Galley and colleagues reported significantly increased bowel distention and surgical interference with NO use in patients undergoing laparoscopic donor nephrectomy (El-Galley et al, 2007).

Once introduced in the 1950s, halothane rapidly became one of the most commonly used anesthetic agents due to its high potency. **However, halothane has several important risks that have since limited its use. It has significant cardiac effects and can precipitate failure in patients with left ventricular dysfunction. Furthermore, it sensitizes the myocardium to the effects of catecholamines (relevant for local anesthetics injected into the surgical site).** Finally, there is a 1 in 35,000 incidence of fulminant hepatitis, which can be lethal due to overaccumulation of toxic metabolites. More recent advancements in inhalational agents have focused on reduction in toxicity while maintaining the potency and rapidity of halothane. Three of the most commonly used current agents are isoflurane, sevoflurane, and desflurane. Isoflurane, less expensive than the other agents due to availability of generic equivalents, is widely used due to its low cardiac depression, less myocardial sensitization to catecholamines, and minimal metabolism. The primary unique toxicity is variable response tachycardia, which can lead to significantly increased myocardial oxygen consumption. Unlike isoflurane which has a putrid odor, sevoflurane is often used for inhalation induction (odorless) due to its rapid induction and emergence, decreased incidence of postoperative nausea (important in outpatient surgery), and minimal cardiac toxicity. It is the generally preferred agent for difficult airways requiring mask induction and in patients with severe bronchospastic disease. Desflurane, like isoflurane, has a pungent odor and is not used for inhalational induction. Its primary advantage over isoflurane is a more rapid recovery in patients requiring anesthesia over 3 hours.

Intravenous General Anesthesia

Intravenous anesthesia consists of a combination of induction agent, opioid, and neuromuscular relaxant. Anesthesiologists often prefer intravenous induction with a combination of inhalational and intravenous agents for maintenance of anesthesia. Intravenous induction offers several advantages in that it is rapid, minimizes patient discomfort, and is preferred by children and most adults. Thiopental, the oldest and least expensive agent, is a suitable choice for uncomplicated patients but is limited in more complex cases due to its significant vasodilation, cardiac depression, and risk of bronchospasm, especially in patients with reactive airway disease. Ketamine is a preferred choice for procedures that are brief and superficial because of its profound amnesia and somatic analgesia. It is associated with increased arteriolar and bronchomotor tone and is advantageous during induction for hypovolemic and asthmatic patients. **Propofol is among the most commonly used anesthetic agents, especially in outpatient surgery. It has a rapid onset, produces excellent bronchodilation in patients with reactive airway disease, and perhaps most importantly, is associated with smooth, nausea-free emergence from anesthesia.** Its primary adverse effect is significant blood pressure reduction. Midazolam, never used as a single agent, produces profound amnesia and anxiolysis while having rapid onset/short duration and producing minimal cardiac side effects.

Although these agents induce unconsciousness and amnesia, opioids have become an integral component to all forms of anesthesia. Opioids result in significant analgesia without an increase in cardiac side effects. Several studies have documented the decreased requirements of other agents when used in combination with opioids, thus reducing the overall cardiopulmonary side effects of anesthesia (Fukuda, 2009). Opioids themselves are differentiated in their potency, onset of action, duration of action, and metabolism/excretion. **Fentanyl (synthetic opioid) is probably the most widely used because of its potency (100 to 150 times that of morphine), rapid onset, and short duration of action.** Newer synthetics are geared to shorter duration and more rapid metabolism.

For major operative cases, complete neuromuscular relaxation is required for sufficient exposure and successful outcome. Although full relaxation can be achieved with intravenous and inhalational agents, the dose required is extremely high. The use of intravenous neuromuscular blockers allows for neuromuscular relaxation and minimization of inhalational/intravenous drugs. **There are two types of neuromuscular blockers: depolarizing drugs, which depolarize the plasma membrane of skeletal muscle fibers making the fibers resistant to further stimulation by acetylcholine, and nondepolarizing drugs, which block the binding of acetylcholine to cholinergic receptors on the presynaptic and postsynaptic membrane.** Succinylcholine, the only depolarizing drug on the market, is chosen for its rapid onset (used in rapid induction sequences), relatively short duration (around 5 minutes), and rapid metabolism. Its use is limited due to the risk of malignant hyperthermia (when used in combination with volatile inhalational agent), hyperkalemia, and bradycardia in children. In cases where succinylcholine is contraindicated, nondepolarizing agents are used. Several nondepolarizing drugs are available and differ in routes of metabolism and adverse effects. Furthermore, multiple medications including desflurane can alter the metabolism of these drugs and potentiate their actions. The most important consideration in the use of neuromuscular blockers is the assessment of adequate return of neuromuscular function following withdrawal of the drug. The most common complication of neuromuscular-blocking drugs is inadequate reversal resulting in respiratory failure and reintubation. Numerous reports in the literature correlate residual neuromuscular blockade with increased postoperative pulmonary complications in the postanesthetic care unit (PACU) and in the postoperative period. **The concept of train of four fade ratio (TOF) was developed to devise an objective measure of adequate neuromuscular function. This concept refers to the magnitude of the fourth of four twitches in response to maximal stimuli to the ulnar nerve delivered at 0.5-sec intervals. Historically, a TOF of 0.7 (meaning that the fourth twitch was 70% the magnitude of the first twitch) correlated with adequate return of neuromuscular function; however, more recent standards have raised the threshold to 0.9 as an indicator of complete return of neuromuscular function** (Kopman et al, 1997). Currently, anesthesiologists use several clinical assessments including head lift, tongue depressor test, and hand grip to estimate a TOF of 0.9. A recent study revealed that using clinical assessments alone, 16% and 45% of patients 2 hours after single intubating dose of neuromuscular blocker had TOF of less than 0.7 and less than 0.9, respectively, in the PACU (Debaene et al, 2003). As such, current recommendations are that quantitative TOF measurement (acceleromyography) be combined with clinical assessments before extubation in the operating room (Viby-Mogensen, 2009).

BLOOD PRODUCTS

Given the vascular nature of urologic organs, the urologist often confronts the issue of indication and necessity of transfusion in the perioperative period. Therefore it is important that the urologist understand the indications, implications, and risks associated with blood product transfusion. Before the AIDS epidemic, blood transfusion was liberally administered often for any patient with hematocrit less than 30%. However, fear and concern about the infectious risk led to the convening of a National Institutes of Health (NIH) panel to develop consensus recommendations for the indication of blood product transfusion (NIH Consensus Statement, 1988). The principles in these guidelines largely hold true today as reflected by the ASA practice guidelines issued in 2006 (Practice guidelines, 2006). **To summarize, the guidelines indicate that transfusion is rarely indicated with hematocrit greater than 30% and often indicated for hematocrit less than 21%. For levels between 21% and 30%, clinical factors such as risk of complications from inadequate oxygenation should guide the need for transfusion balancing the risks and benefits.** In general, patients with relatively minor comorbidities can tolerate hematocrit of greater than 21% before transfusion is indicated. Patients with moderate to severe comorbidity (i.e., significant pulmonary compromise, coronary artery disease, or vascular insufficiency, or with signs/symptoms of hypovolemic, hemorrhagic shock) warrant transfusion to achieve hematocrit greater than 30%. Ultimately, until technology is derived to directly measure inadequate oxygen-carrying capacity, the urologist should individualize the decision to transfuse for each patient and clinical situation.

A major advance in blood banking and product transfusion has been the development of component therapy allowing for administration for specific fractions of whole blood. Packed red blood cells (PRBCs) are equivalent to whole blood minus the plasma component. Whereas the hematocrit in whole blood is 40%, it is 70% in PRBC units. These units are reconstituted and administered with crystalloid. Given the lack of the remaining components, in instances of massive PRBC transfusions and associated bleeding, platelets and occasionally fresh frozen plasma should be given to avoid dilutional coagulopathy. Platelet transfusion is rarely indicated empirically except in patients with significant thrombocytopenia (<50,000/mm^3) and planned surgical procedure or with moderate thrombocytopenia (50,000-100,000/mm^3) and either high-risk procedure or evidence of platelet dysfunction. Similarly, empiric transfusion with fresh frozen plasma (FFP) for massive transfusion is not indicated. With the development of component therapy, the use of FFP increased dramatically, leading to consensus statements from the NIH and the ASA to guide practitioners (Consensus conference, 1985; Practice guidelines, 2006). **The current indications for FFP transfusion are immediate reverse of warfarin-induced coagulopathy, replacement in patients with specific clotting factor deficiencies, and evidence of bleeding and INR greater than 1.5. According the ASA guidelines, in patients with massive transfusion and no INR readily available, FFP should be given after replacement of 1 blood volume.**

There are well-documented risks of transfusion, and these risks should always be discussed with the patient before administration. Hemolytic transfusion reactions occur due to incompatibility between donor and recipient (either ABO or non-ABO incompatibility). According to the U.S. Food and Drug Administration (FDA) Annual Summary, from 2005-2007 transfusion reactions accounted for 22% of transfusion-related fatality in the United States (FDA Annual Summary for Fiscal Year 2007, 2007). Transfusion reactions occur relatively frequently and, if identified early, can be treated with rare catastrophic events. The early signs/symptoms include fever, chills, chest pain, hypotension, and bleeding diathesis occurring during or immediately after transfusion. Reactions may also occur in a delayed fashion, which is characterized by significant intravascular hemolysis secondary to recipient antibodies. The treatment of transfusion reaction is centered on fluid resuscitation, cessation of the transfusion, and alkalinization of the urine to prevent renal failure. **The most common cause of transfusion-related fatality is transfusion-related acute lung injury (TRALI). This entity accounted for 55% of transfusion mortality from 2005-2007. The injury is characterized by noncardiogenic pulmonary edema injury and manifests itself 1 to 2 hours after transfusion.** Although no specific treatment other than supportive measures are indicated, most patients recover without significant sequelae. Finally, one of the most feared complications (at least in the public eye) is the transmission of bacterial/viral infection. Although the risk of hepatitis virus and human immunodeficiency virus (HIV) transmission were unacceptably high in the 1970s and 1980s, the initiation of more stringent screening procedures for high-risk populations and the development of nucleic acid amplification technology (PCR and transcription-mediated amplification) have resulted in dramatically reduced risk and incidence of viral transmission. **Currently, the risk of HIV and hepatitis C transmission is approximately 1 in 2 million cases, whereas the risk of hepatitis B is 1 in 200,000.** The highest risk of infectivity occurs with platelet transfusion in which bacterial contamination develops at a rate of 1 in 5000 units (Eder et al, 2007).

PATIENT ENVIRONMENT

Patient Temperature

Although hypothermia can be therapeutic in certain situations of trauma and brain injury, for elective surgical procedures, hypothermia is associated with significantly increased morbidity to the patient. **There are two primary reasons for hypothermia to develop in the operating room. Anesthetic agents induce peripheral vasodilation redistributing heat from the core (trunk, head) with resultant drop in immediate core temperature after induction. Throughout the rest of the procedure, radiation and conductive heat loss account for most of the heat loss during a surgical procedure.** Normothermia is defined as core temperature between 36° C and 38° C, and even hypothermia of 1° C to 2° C results in adverse effect. **Rajagopalan and colleagues performed a meta-analysis of randomized controlled trials and reported that mild hypothermia (decrease of 1°C) resulted in a 16% increase in estimated blood loss and 22% increase in transfusion requirements** (Rajagopalan et al, 2008). The increased bleeding risk is thought to result from a hypothermia-associated decrease in clotting cascade enzymatic function and platelet aggregation. Even more significant is the increase in the risk of surgical site infections (SSI) associated with mild hypothermia (34° C to 36° C). Hypothermia increases the risk of SSI by impairing immune mechanisms and vasoconstriction, resulting in regional tissue hypoxia. In a landmark study, Kurz and colleagues with The Study of Wound Infection and Temperature Group tested the hypothesis that hypothermia increases the rate of wound infection and hospital stay in 200 patients undergoing elective colorectal surgery (Kurz et al, 1996). **Hypothermia was associated with a three times increased risk of wound infection and a 2.6-day increase in hospitalization.** More recent studies have generally confirmed these findings in other series of surgical patients (Mauermann and Nemergut, 2006). In its overall goal of reducing SSI, the SCIP has also included perioperative normothermia as one of its guidelines. Strategies to improvement maintenance of normothermia including regular use of warming blankets, warmed intravenous fluids, warmed irrigation fluids (especially during TURP and other prolonged endoscopic procedures), warmed/humidified CO_2 gas during laparoscopy, and increase in ambient operating room temperature. Although there have been few studies in the urologic literature, the findings can be generalized to all surgical patients.

Skin Preparation

Sterile skin preparation is fundamental in the prevention of SSI for any procedure. Currently, the most commonly used skin antiseptics are alcohol, povidone-iodine, or chlorhexidine based. Whichever antiseptic is chosen, the solution should be applied in concentric circles from the center of the surgical site and be allowed to dry before incision. **A recent review from the Cochrane database did not find sufficient evidence to recommend one skin preparation over another** (Edwards et al, 2004). Furthermore, although the CDC clearly recommends preoperative showering/bathing to reduce SSI, there is no evidence that bathing with an antiseptic solution reduces the rate of infection (Webster and Osborne, 2007). Regarding hair removal, the CDC recommends that if hair removal is performed, it should be performed immediately before the surgical procedure and performed with clippers (rather than shaving) (Mangram et al, 1999).

Patient Safety

In 1991 Brennan and colleagues published their seminal work describing adverse events, defined as injuries caused by medical management in hospitalized patients, revealing that 48% of the events accompanied a surgical operation (Brennan et al, 1991; Leape et al, 1991). This important study inspired the publication of "To Err Is Human, Building a Safer Health System," a comprehensive study by the Institute of Medicine on medical errors. Regarding surgical patients, the most frequent venue of preventable injuries is the operating room. **Although the surgeon is the "captain of the ship" and ultimately responsible, it takes cognizance and attention to detail from each member of the operating room team to prevent iatrogenic injuries to the patient.** Three causes of immediately preventable injuries are retractor-associated injuries, thermal injuries, and patient position–related injuries. There are several reports in the literature documenting increased rate of neuropathy (especially femoral nerve) following laparotomy with self-retaining retractors versus without self-retaining retractors (Irvin et al, 2004). Careful attention to be certain that the lateral blades do not directly compress the psoas muscle and only cradle the rectus abdominal muscles will ensure avoidance of femoral neuropathy.

Furthermore, periodic reinspection of the retractor blades is also warranted. Many devices used in urologic surgery employ thermal energy for desired effect and therefore can result in thermal injury to the patient. These include Bovie cautery, argon beam coagulator, bipolar devices, and laser. In both endoscopic and laparoscopic surgery, high-wattage light sources are used to illuminate the operative field. While illuminated, the ends of the light cords can result in burns when in direct contact with the patient (even through draping). These light sources should be turned off at all times when not in use. Special mention is deserved for the morbidly obese patient. The operating room should be equipped with a hydraulic table, extra-long instruments, additional padding, wide venous compression devices, and side extensions to ensure a safe operating room environment for the patient.

Patient Positioning

Although often given only a cursory evaluation, proper patient positioning in the operating room can prevent potentially devastating complications. Ultimately, proper positioning is the shared responsibility of each member of the operating room team. Much of the knowledge and guidelines for avoidance of position-related injury are drawn from the anesthesia literature. In fact, in response to a 1999 study of the ASA Closed Claims Database, which found neuropathy as second-leading cause of liability, the ASA published a practice advisory for the prevention of perioperative peripheral neuropathies (Practice advisory, 2000). The recommendations are listed in Table 6–11. **Although the exact mechanisms of peripheral neuropathy are not always known, the etiology of position-related neuropathy is generally secondary to excessive stretch, prolonged compression, or ischemia.** Given the variety of different patient positions used in urologic surgery, it is critical for the urologist to be an active participant in the positioning of the patient and to understand the potential patient compromise that accompanies each position.

The supine position, used in abdominal, pelvic, and penile procedures, is generally considered the safest patient position. However, several specific issues should be considered. **Excessive upper extremity abduction (>90 degrees) can lead to tension on the brachial plexus, leading to upper extremity neuropathy.** The arm board should be padded to avoid excessive pressure on the ulnar groove and spiral groove of the humerus (radial nerve injury). In cases in which the arms are tucked at the patient's side, care must be taken to avoid excessive pressure on hand and forearm. Moreover, peripheral intravenous catheter infiltration must be identified quickly because forearm compartment syndrome may develop.

One of the most frequent positions used in urology is the lithotomy position. Improper positioning can lead to transient and occasionally prolonged lower extremity neuropathy. In a retrospective evaluation of more than 190,000 cases from 1957 to 1991 involving the lithotomy position, persistent neuropathy was found in 0.03%; however, the same group in a prospective study of 991 patients reported an incidence of 1.5% (15 patients) with resolution of symptoms by 6 months in all but one patient (Warner et al, 1994, 2000). **The basic principle of position involves manipulation of both lower extremities simultaneously with flexion of the hips at 80 to 100 degrees with 30- to 45-degree abduction.** The legs should be padded to avoid excessive compression against the stirrup. Particular caution should be given to the patient's hands to avoid entrapment within the moving parts of the stirrups.

For most open and laparoscopic upper urothelial tract and renal procedures, the patient is placed in some degree of lateral decubitus position. Proper padding of the patient is important with appropriate anterior and posterior support to maintain the decubitus position. The most frequent focus of compromise involves

Table 6–11.

American Society of Anesthesiologists Task Force Recommendations on the Prevention of Perioperative Peripheral Neuropathies

Preoperative assessment	When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position
Upper extremity positioning	Arm abduction should be limited to 90 degrees in supine patients; patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees
	Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable
	Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided
	Extension of the elbow beyond a comfortable range may stretch the median nerve
Lower extremity positioning	Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve
	Prolonged pressure on the peroneal nerve at the fibular head should be avoided
	Neither extension nor flexion of the hip increases the risk of femoral neuropathy
Protective padding	Padded armboards may decrease the risk of upper extremity neuropathy
	The use of chest rolls in laterally positioned patients may decrease the risk of upper extremity neuropathies
	Padding at the elbow and at the fibular head may decrease the risk of upper and lower extremity neuropathies, respectively
Equipment	Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper-extremity neuropathies
	Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies
Postoperative assessment	A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies
Documentation	
	Charting specific positioning actions during the care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning and (2) providing information that continuous improvement processes can use to effect refinements in patient care

Adapted from Practice advisory for the prevention of perioperative peripheral neuropathies: a report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies. Anesthesiology 2000;92:1168–82.

positioning of the arms and potential for brachial plexus injury. The ipsilateral arm should be placed on an elevated arm rest or gel pad avoiding abduction more than 90 degrees and excessive stretch on the shoulder. The contralateral arm should be placed on an arm board with ulnar padding. Furthermore, in patients in full flank position, an axillary roll should be placed just caudal to the axilla (not in the axilla) to avoid compression of the contralateral brachial plexus. Finally, after the patient is positioned and before sterile draping, the operating table should be fully rotated to ensure that the patient is adequately secured in all positions.

Two patient positions used in specific urologic cases deserve attention: the prone position for percutaneous nephroscopy and the full Trendelenburg position for robotic-assisted laparoscopic procedures in the pelvis. In the prone position, special care should be taken to pad the torso, elbows, hips, and legs. The anesthesiologist should ensure that the endotracheal tube and all vascular access are properly secured. Coordination of the entire team is required during transfer from the supine position on the stretcher to the prone position on the operating room table. A stretcher should always be available immediately in case of airway compromise and the need for rapid transfer to the supine position. Regarding the full Trendelenburg position for minimally invasive pelvic procedures, the primary issues involve the physiologic changes in respiratory function, cardiovascular function, and increases in central venous and intracranial pressures. **Patient positioning should focus on properly securing and padding the patient to the operating table to prevent cephalad sliding. Although fixed shoulder braces will undoubtedly prevent patient movement, these braces should be avoided due to the risk of brachial plexus compression and resultant neuropathy.**

ABDOMINAL INCISIONS AND WOUND CLOSURE

Abdominal Incisions

Urologic surgery can encompass a large area of the trunk, and therefore the urologist should be familiar with all type of incisions of the abdomen. The most commonly used incision in surgery including urology is the midline abdominal incision. This incision can provide access to the entire peritoneum and retroperitoneum. For procedures focused on particular areas of the abdomen, alternative incisions provide more focused exposure with certain benefits. A Pfannenstiel incision (transverse lower abdominal incision) can be used for virtually all pelvic procedures and results in improved cosmesis and possibly decreased pain. For access to the lower third of the ureter, a Gibson incision (i.e., an oblique incision in the lower quadrant) can be used. Using a Gibson incision, entry into the retroperitoneum is gained by splitting the external and internal oblique muscles in the direction of its fibers. Access to the upper abdomen and retroperitoneum for renal and adrenal surgery can be gained using various kinds of incisions. An extraperitoneal approach is best performed via a flank incision over the 11th or 12th rib, with or without partial rib removal. An extraperitoneal approach avoids the complications of transperitoneal surgery such as bowel injury, postoperative ileus, and adhesion formation. Transperitoneal access can be obtained via an anterior subcostal incision (two finger breadths below the costal margin). This incision provides better access to the midline vascular structures by allowing for complete medial mobilization of the posterior peritoneum. For large or locally advanced (vena cava thrombus) tumors, a thoracoabdominal or chevron incision generally provides the best exposure. A thoracoabdominal approach is preferred for large upper retroperitoneal tumors or tumors with extension into the thoracic cavity (supradiaphragmatic vena cava tumor thrombus). On the other hand, a chevron incision is preferred for access to both the right and left abdomen (e.g., bilateral renal tumors). In summary, proper choice of incision is often critical to successful surgical outcome, especially for complex operative cases.

Wound Healing

Knowledge of the basic principles of wound healing is important in order to properly assess incision closure and its associated complications. All cutaneous wounds progress stepwise through a series of events toward complete wound repair, understanding that in a particular wound, different phases of events may occur simultaneously. **The series of steps can be divided broadly into three stages: reactive phase, proliferative phase, and maturational phase.** The reactive phase occurs immediately with the two primary responses of hemostasis and inflammation. Disruption of vascular membranes results in platelet activation and aggregation, which in turn initiate the inflammatory response. During this stage of wound healing, inflammatory cells including polymorphonuclear cells, macrophages, and lymphocytes migrate into the wound and become activated, leading to cytokine activation and secretion of various growth factors. The second stage, proliferative, results in the formation of granulation tissue. The stage is characterized by proliferation of endothelial cells and fibroblasts leading angiogenesis and epithelialization, which eventually results in growth of immature blood vessels and deposition of extracellular matrix and early collagen scaffolding. Finally, the maturation stage occurs with further deposition of collagen and wound contraction. **The maturational phase begins approximately 1 week after injury and progresses rapidly over 6 weeks with increasing wound strength over the next 12 months. The scar regains approximately 3% strength after 1 week, 20% after 3 weeks, and 80% after 3 months** (Witte and Barbul, 1997).

Wound Closure

Along with choice of incision, proper closure is necessary to avoid certain surgical complications including wound infection and fascial dehiscence. In general there are three types of wound closure: primary, secondary, and tertiary (or delayed primary closure). In the vast majority of elective cases, the urologist should attempt a permanent closure following the operation (primary closure). Secondary closure is reserved for heavily contaminated wounds for which the fascia is closed primarily, but the skin/subcutaneous tissues are allowed to heal re-epithelialization and contraction. Tertiary closures are reserved for patients with abdominal compartment syndrome or in patients requiring re-explorations in which temporary closure is initially performed with intention of future permanent closure. Unless the case is heavily contaminated, incision closure involves reapproximation of the fascia (in one or multiple layers) and the skin. Choice of suture type by the surgeon depends on preferences of braided versus nonbraided, monofilament versus multifilament, and absorbable versus nonabsorbable. A full description of different suture types and their properties is listed in Table 6–12 (Hochberg et al, 2009). Although the method of fascial closure has been studied extensively, a definitive, superior method is not

Table 6–12.

Properties of Suture Materials

SUTURE	ORIGIN	TISSUE ABSORPTION	PHYSICAL CONFIGURATION	TENSILE STRENGTH	COMMENTS
Vicryl	Synthetic	Absorbable	Braided	65% 2 wk 40% 4 wk	Slower loss of function and higher knot-breaking strength compared with polyglycolic acid (Dexon)
Dexon	Synthetic	Absorbable	Braided	63% 2 wk 17% 3 wk	Lubricant coating decreases coefficient of friction
Monocryl	Synthetic	Absorbable	Monofilament	30%-40% 2 wk (dyed) 25% 2 wk (undyed)	Excellent tensile strength allows use of smaller sutures for skin closure
PDS	Synthetic	Delayed absorbable	Monofilament	74% 2 wk 50% 4 wk 25% 6 wk	No absorption until after 90 days; low reactivity, tends to maintain strength in presence of infection; newer barbed version is knotless
Maxon	Synthetic	Delayed absorbable	Monofilament	81% 2 wk 59% 4 wk 30% 6 wk	
Chromic gut	Natural	Absorbable	Monofilament	0% 3 wk	Can also be found as plain gut (untreated) for faster absorption
Nylon	Synthetic	Nonabsorbable	Monofilament	50% 1-2 yr	Very low tissue reactivity
Prolene	Synthetic	Nonabsorbable	Monofilament	No significant loss over time	High plasticity, extremely smooth surface (requires extra knot throws)
Silk	Natural	Nonabsorbable	Braided	Degraded over time	Braided for easier handling; can be prone to infection
Mersilene	Synthetic	Nonabsorbable	Braided or monofilament	No significant loss over time	Braided should not be used in infection

universally agreed on. van't Reit and colleagues performed the most recent meta-analysis of available randomized controlled trials (van 't Riet et al, 2002). **In all, 6566 patients from 15 studies were included with the primary outcome measure being incidence of incisional hernia. Their analysis indicated that between slowly absorbable or nonabsorbable sutures, there was no difference in risk of incisional hernia in continuous versus interrupted fascial closures although nonabsorbable closure was associated with increased wound pain and sinus formation. For rapidly absorbable suture types, continuous fascial closure was significantly associated with increased rate of incisional hernias.** Due to the limited number of patients, a definitive conclusion could not be made for interrupted rapidly absorbable suture closure versus continuous slowly nonabsorbable suture closure. The authors, however, concluded that mass closure with slowly absorbable suture in a continuous fashion is the optimal method. To address the limitation found in the recent meta-analysis, Seiler and colleagues completed a randomized control trial of 625 patients (Seiler et al, 2009). Patients were randomized to one of three arms: interrupted closure with rapidly absorbable suture or continuous closure with one of two different slowly absorbable sutures. They found no significant difference in incisional hernia (15.9% vs. 8.4% vs. 12.2%, $P = .09$), fascial dehiscence, wound infection, or serious adverse events. In conclusion, although incisions may be closed either with interrupted, rapidly absorbable suture closure or with continuous slowly absorbable suture closure, careful attention should be given to the technique given the relatively high incidence of incisional hernia.

Perhaps the most frequently encountered complication of abdominal wounds is the surgical site infection. Because of different reporting methods and descriptions in the literature, the National Health Care Safety Network of the CDC published definitions of surgical site infections with clearly defined, objective criteria (Kirby and Mazuski, 2009). The infections are classified as follows:

- Superficial incisional infection: involves only skin and subcutaneous tissue occurring within 30 days of surgery
- Deep incisional infection: involves deep soft tissues (muscle or fascial planes) within 30 days of surgery (or within 1 year if implant is in place)
- Organ/space infection: involves any part of the body that is opened or manipulated by the operative procedure and has purulent drainage from a drain placed in the wound or evidence of infection by radiographic imaging

Specific risk factors predisposing for surgical site infections were previously listed in Table 6–4. The mainstay of treatment centers on adequate drainage of the infected area. **Superficial infections and some deep incisional infections can generally be managed with opening of the skin incision and packing of the wound. Care should be taken to open the incision widely to ensure complete drainage of underlying purulent fluid. The use of oral/intravenous antibiotics is not necessary unless it is associated with significant skin cellulitis (erythema extending >2 cm from incision edge or systemic signs of toxicity, e.g., fever, sepsis)** (Barie and Eachempati, 2005). Once opened, the wound should be allowed to heal by secondary intention. Many deeper incisional infections are too extensive for bedside incision and require operative debridement under anesthesia. It is critical for careful examination of any infected wound for signs of necrotizing infection most commonly secondary to *Clostridia perfringens*. Signs include drainage of grayish, dishwater-colored fluid, frank necrosis of the fascial layer, and wound crepitus. A necrotizing infection requires immediate return to the operating room for wide debridement and washout. In contrast to incisional infections, deeper organ/space infections may present without superficial signs at the level of the incision. Rather, patients often show systemic signs of infection, pain, and or sepsis leading to cross-sectional imaging revealing the putative source. Again, the principle of adequate drainage applies, and management involves

percutaneous or operative drainage of the abscess fluid. A controversial issue in the prevention of organ/space infections is the routine placement of drainage systems at the time of the initial operative procedure. A wide variety of surgical drains is available. Drains are broadly categorized as open/nonsuction, closed/nonsuction, and closed/suction drains. Open/nonsuction drains are employed when accurate quantification of drainage amount is not necessary. These drains are associated with less patient discomfort and are the easiest to remove. Closed drains are chosen if quantification of drainage amounts or characterization of drainage fluid is necessary. The use of suction in closed drain systems is generally preferred if immediate recognition of small amounts of drainage is important (e.g., a drain around an ureterointestinal anastomosis). Although drains continue to be widely used in various urologic procedures, several prospective studies in the general surgical literature have failed to show significant benefit; therefore most experts caution against their routine use (unless strong indication exists) (Barie, 2002).

Perhaps the most dreaded complication of surgical incisions is acute wound failure (or fascial dehiscence). Overall, the incidence of fascial dehiscence is 1% to 2% and usually occurs 1 week after surgery, although it may occur up to 30 days postoperatively. Risk factors for dehiscence include patient-related factors (advanced age, malnutrition, corticosteroid use, obesity, and prior history of radiotherapy); surgical site infection; and technical errors at the time of wound closure. The most common technical errors associated with wound failure are placing the suture too close to the fascial edge, knot slippage, and excessive suture tension. **Multiple studies have investigated the type of closure and there is no difference in dehiscence risk between interrupted and continuous closures as long as rapidly absorbable sutures are not used with the latter.** Historically, in high-risk patients retention sutures were strongly advocated and widely used as a preventive measure for wound dehiscence. Literature evidence, however, was primarily retrospective and subsequent prospective trials have failed to show evidence of benefit (Carlson, 1997). One recent trial by Rink and colleagues randomized 95 high-risk patients to retention sutures versus standard closure reporting that although no difference in wound failure rates was seen, retention sutures were associated with significantly increased rate of patient morbidity, primarily pain (Rink et al, 2000). As such, recent surgical trends suggest a movement away from the use of retention sutures and, alternatively, toward the increased use of grafts and synthetic mesh in wounds thought to be at increased risk of fascial dehiscence. **When acute wound failure does occur, it is usually immediately preceded by a sudden gush of serosanguineous fluid from the wound. Some small fascial disruptions can be managed conservatively with wound packing and close observation, but the majority of disruptions, particularly in the setting of bowel evisceration, mandate urgent return to the operating room. At the bedside, sterile, saline-moistened towel should be placed over the eviscerated components while the patient is being prepared for the operating room.** At the time of reoperation, the fascial edges are inspected for the etiology of the disruption. In cases of technical errors or fascial tearing in which the fascial edges are healthy and can be brought together without tension, a primary closure is appropriate. In all other cases, the fascial edges are debrided and the wound is closed with absorbable mesh or biologic prosthetic grafts. A full discussion of the different materials is beyond the scope of this chapter, but needless to say, strong consideration should be given for an intraoperative general surgical consult.

Key Points

- Proper preoperative evaluation of the patient will prevent unanticipated cancellations and decrease the risk of postoperative complications.
- The indications for preoperative cardiac testing depend on three factors including the functional capacity of the patient, cardiac risk factors, and surgical specific risk factors.
- Surgical site infections are one of the leading causes of perioperative complications and increased hospital stay. Antibiotic prophylaxis is indicated in virtually all surgical procedures.
- Venous thromboembolism is a common complication of urologic procedures, and the AUA recommends either mechanical or pharmacologic prophylaxis (or both for highest risk) for all urologic procedures.
- Proper understanding of the pharmacologic principles of anesthesia will allow the urologist to actively participate in the decision process of choosing which mode of anesthesia will be appropriate for a particular patient and procedure.
- Current guidelines advocate blood product transfusion for hematocrit less than 21% in most patients unless there are specific cardiopulmonary risk factors.
- Perioperative hypothermia of even 1° C to 2° C is associated with increased estimated blood loss and increased risk of surgical site infection.
- Proper choice of surgical incision results in optimal surgical exposure and therefore improved outcomes.
- Current literature suggests that closure with continuous, slowly absorbing suture results in the lowest risk of incisional-related complication.

Fundamentals of Instrumentation and Urinary Tract Drainage

Carlos E. Méndez-Probst, MD ● Hassan Razvi, MD, FRCSC ● John D. Denstedt, MD, FRCSC, FACS

Lower Urinary Tract

Upper Urinary Tract Ureteral Stents

Endoscopy of the lower urinary tract and the establishment of urinary tract drainage are basic skills required by all urologists and uniquely define the specialty of urology. A basic understanding of the indications, instrumentation used, and the techniques involved in urethral catheterization, ureteral stent placement, and nephrostomy insertion are essential and are covered in this chapter.

LOWER URINARY TRACT

For Urethral Catheterization

Historical Background

Instruments to drain the urinary bladder are among the most ancient medical devices in the historical record. One of the earliest descriptions of a urinary catheter can be found in the Hippocratic text *On Diseases* (400 BC), in which bladder drainage was considered a basic skill in the armamentarium of Greek physicians (Moog et al, 2005a). The practice of bladder catheterization to permit urine drainage seems to have been widespread throughout the ancient world, with records of its application also found in India, Egypt, and the Byzantine and Roman empires. In Avicenna's *Canon of Medicine,* mention is also made of urethral catheterization as a means to deliver intravesical therapy (Madineh, 2009). Surviving examples of early catheters include hollow tubes made of bronze, paper, animal hide, cloth soaked in wax, and lead (Moog et al, 2005b). In the 16th century, Ambroise Pare used catheters made of silver, brass, and copper. In the early 18th century, natural rubber was first used and the coudé tip was introduced by Mercier not long after. The self-retaining balloon catheter was introduced in the 20th century by Foley (Ellis, 2006), leading the way to permit development of catheters of synthetic materials with specialized coatings and drug-eluting properties.

Indications

The most common indications for the use of a bladder catheter can be broadly divided into two main categories: to obtain drainage or to allow the instillation of diagnostic or therapeutic agents.

The relief of acute or chronic urinary retention due to either bladder outlet obstruction or neurogenic bladder dysfunction is probably the most common indication for urethral catheterization (UC). Following in frequency is its use to monitor urinary output.

Urinary diversion by a catheter is used to allow healing after lower urinary tract surgery/trauma and to evacuate the bladder when the urine contains particulate matter, especially in combination with simultaneous irrigation (post transurethral resection, clot/purulent material evacuation). Other indications include the collection of microbiologic clean urine (uncooperative patients because of age or mental status or comorbidities that prevent voluntary voiding) and to measure postvoid residual urine volume samples for diagnostic purposes.

Urethral catheterization is also used to provide access to the bladder for urinary tract imaging studies such as cystography, which requires the instillation of radiographic contrast material.

UC with a pressure monitoring catheter is used during urodynamic testing for physiologic assessment of voiding function. It is also used to allow instillation of pharmacologic agents for local therapy of some bladder pathologies such as chemo/immunotherapy for transitional cell carcinoma (mitomycin, bacillus of Calmette Guerin), interstitial cystitis (dimethyl sulfoxide), and intractable hematuria (e.g., alum, formalin instillation).

Catheter Selection

The size and type of urinary catheter used depends on the indication for catheter insertion, age of the patient, and type of fluid expected to be drained. Currently there is a wide variety of catheter types. Catheters can be classified on the basis of material, coating, number of channels (Fig. 7–1), and tip form (Fig. 7–2). Each of these characteristics is reviewed.

Catheter size is measured in the Charrière or French scale, whereby one Fr or Ch is equal to 0.33 mm. This measurement indicates the total circumference of the catheter and not the lumen size. As a general rule, catheter size should be the smallest size that can accomplish the desired drainage (i.e., 12 to 14 Fr for clear urine and 20 to 24 for thick pus or blood-filled urine). In children, choosing a catheter of appropriate size is essential to avoid unnecessary urethral trauma (Table 7–1). The use of feeding tubes as urethral catheters should be discouraged because their stiffness and length can be a source of complications (ischemic ulcers, urethral strictures, and knotting in the bladder) (Smith, 2003; Robson et al, 2006).

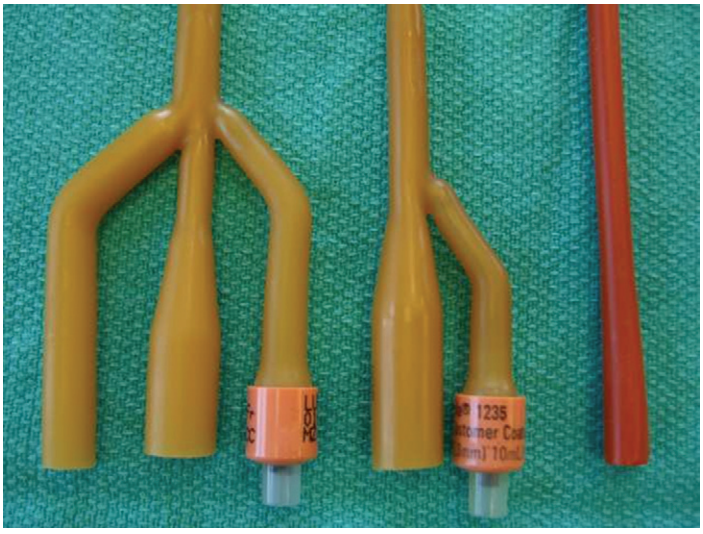

Figure 7–1. Three-way, two-way, and single-lumen catheters.

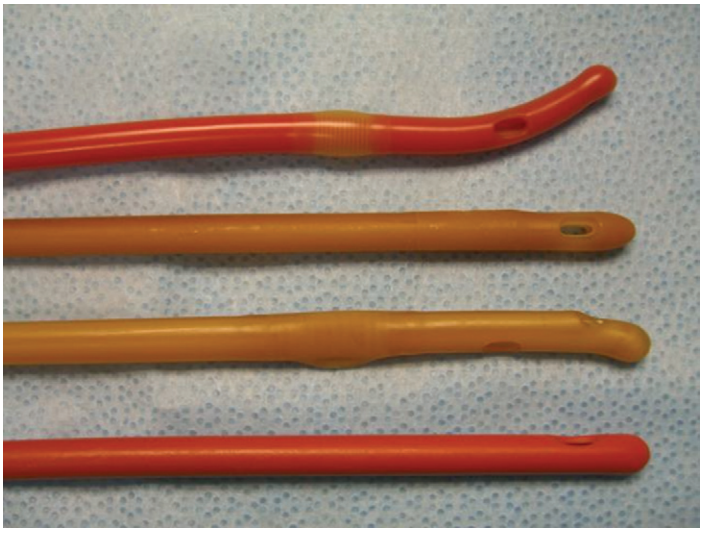

Figure 7–2. From top to bottom: coudé tip, two-way Foley, three-way Foley, and Nelaton.

Material

Modern urinary catheters are most frequently made of latex, rubber, silicone, and polyvinylchloride (PVC). Rubber and latex catheters are often chosen for short-term drainage. Silicone catheters are indicated when there is rubber/latex sensitivity or allergy and are particularly suited for patients requiring a longer period of indwelling time. Silicone is relatively inert, causing less tissue reaction, and is associated with less bacterial adherence than other catheter materials (Roberts et al, 1990). Evidence suggests that the use of silicone catheters is associated with a lower incidence of urinary tract infections compared with those made of latex (Crnich et al, 2007).

Coating

Various coatings on urethral catheters have been applied in an attempt to reduce urethral trauma and infection risks. The use of hydrophilic coatings has been evaluated among patients on chronic self-intermittent catheterization, with some studies suggesting less discomfort, a decrease in symptomatic urinary tract infection (UTI) rates, and urethral strictures (Wyndaele J, 2002; Vapnek et al, 2003; De Ridder et al, 2005; Bjerklund et al, 2007). Thus far, the evidence is contradictory for the use of antiseptic-coated catheters to prevent the incidence of UTIs, with most of the studies to date having been restricted to small pilot studies (Johnson et al, 2006).

The application of a viable bacterial coating onto catheter surfaces as a method of reducing catheter-associated urinary tract infection (CAUTI) by bacterial interference is a novel approach that has shown promise in a small pilot study involving the use of *Escherichia coli*–coated catheters. The rationale is based on natural competition by nonpathogenic bacteria overpowering any pathogenic bacteria that may enter the urinary tract (Trautner et al, 2007). Further study is necessary to confirm if this will be an effective strategy.

Table 7–1.

Catheter Size Based on Age

AGE IN YR	CATHETER SIZE (FR)
<5	5-8
5-10	8-10
10-14	10
>14	10-14

Number of Channels

The most basic catheters are constructed with a single lumen to permit urinary drainage or irrigation/instillation. Additional lumens are added to permit addition of a retention balloon (two-way catheter) and for simultaneous drainage and irrigation (three-way catheter). The ability to allow bidirectional flow with a three-way catheter is particularly useful when there is need to drain thick fluid such as pus or blood from the bladder because it allows thinning of the solute, preventing reaccumulation by rapid exchange of clean fluid in a washing effect. The insertion of a three-way catheter for continuous bladder irrigation is most often performed after transurethral resection procedures of the bladder or prostate, which additionally can be combined with a large-volume retention balloon (30 to 50 mL), which under slight traction can often achieve complete hemostasis of the resected prostatic fossa. It should be borne in mind, however, that the addition of a multichannel catheter is accomplished by decreasing the overall internal diameter or lumen of the main drainage channel; a 24-Fr three-way catheter has a smaller internal drainage diameter than a 24-Fr two-way, which has a narrower lumen than a 24-Fr one-way catheter.

Tip Shape

Most catheters are designed with a blunt straight tip that is blind ending. Catheters with curved tips or with an end hole have specific utility in certain clinical scenarios (e.g., a coudé tip for patients with a high bladder neck or prominent median prostate lobe, a Councill catheter when catheterization over a guidewire is required). The various catheters and their typical applications are presented in (Table 7–2).

Technique of Catheter Insertion

Once the need for urethral catheterization has been established, the procedure should be described to the patient and potential complications discussed. A focused clinical history including allergies, urologic pathology, previous urologic surgeries, and catheterization attempts may increase suspicion of the potential for difficulties with catheterization.

Table 7–2.

Features of Ureteral Catheters

FORM OF TIP	SIDE HOLE	RETAINING MECHANISM	NAME	USES (ADVANTAGES)
Straight	Single or multiple	None	Robinson Nelaton Jaques	One-time drainage, instillation or irrigation in children, females, and most males
		Balloon	Foley	Continuous drainage or irrigation in children, females, and most males
		Balloon/retention plug	Madduri	Used for urethrography, allows proximal and distal occlusion and contrast instillation in the intermediate section
		2 or 4 wings	Malecot	Continuous drainage or irrigation in children, females, and most males (less prone to retaining mechanism failure and increased lumen diameter because no channel is necessary for device activation)
		Umbrella	Pezzer	Continuous drainage or irrigation in children, females, and most males (less prone to retaining mechanism failure and increased lumen diameter because no channel is necessary for device activation)
Curved		Balloon	Coudé	Continuous drainage or irrigation (ease of insertion males with enlarged prostate midlobe or high bladder neck)
End hole			Councill	Continuous drainage or irrigation in children, females, and most males (end hole permits insertion or exchange over a previously placed guidewire)
			Whistle tip	Has a large diameter end hole occupying half of its beveled tip, for increased drainage/instillation capacity

The patient should be in the supine position at a comfortable height for the physician performing catheterization. In female patients a "frog-leg" position is most suitable, and the use of stirrups can be considered, especially in the obese.

Catheterization should be carried out in a sterile fashion with antiseptic preparation and draping of the patient's meatal and genital area.

When catheterization for more than just immediate urinary drainage is required, the catheter's retention balloon should be tested and every catheter should be generously coated with sterile lubricant before insertion.

Anesthetic

The use of topical anesthetic gels before urethral catheterization is widely practiced; however; the evidence to support their use is conflicting. The agent used, temperature of the drug on administration, and indwell times before instrumentation are variable across the studies (McFarlane et al, 2001; Ho et al, 2003; Chung et al, 2007; Garbutt et al, 2008). There is some evidence that cooling to 4° C diminished the discomfort of lignocaine gel instillation, probably due to a cryo-analgesic effect (Thompson et al, 1999; Goel and Aron, 2003). Studies employing 2% lidocaine gel left indwelling at least 15 minutes have been reported to be associated with less pain (Siderias et al, 2004). If topical anesthesia is to be used, evidence suggests it requires a minimum of 10 minutes of exposure (depending on the agent), sufficient volume of the agent (20 to 30 mL), and slow instillation time (>3 to 10 seconds) (Schede and Thüroff, 2006; Tzortzis et al, 2009) to have the most effect.

The systemic absorption of topical urethral lidocaine through intact mucosa is minimal, resulting in low measurable concentrations at doses of up to 550 mg (Ouellette et al, 1985). Rare toxicity has been reported, however, after traumatic procedures that disrupt the mucosal barrier, leading to high and rapid peak concentrations. Seizures, confusion, and disorientation, which usually precede cardiovascular toxicity (Sundaram, 1987; Priya et al, 2005), have been described.

The main benefit of intraurethral anesthetic gel during bladder catheterization may be the additional lubrication providing less traumatic catheter passage and reduced patient discomfort on that basis.

The steps involved in urethral catheter placement obviously vary between males and females. Therefore the techniques for each are described separately. The techniques described pertain to the use of the standard Foley catheter, which is the most commonly used catheter for straightforward bladder drainage.

Male Patients

Anatomic Considerations

The male urethra follows a sigmoid curse, with a proximal curve at the junction of the membranous and bulbar urethra and another at the junction of the bulbar and penile urethra. The adult male urethra is approximately 18 to 20 cm in length, and its diameter is variable, from a mere slit to 6 mm during the passage of urine (Urinary system, 1995).

After sterile skin preparation and draping, grasp the shaft of the penis with the nondominant hand (which is now regarded as contaminated) and hold the penis at a 90-degree angle or perpendicular to the patient. This maneuver eliminates the distal or pendulous urethral curvature. Insert the lubricated tip of the catheter into the urethral meatus and gently but firmly continue to advance the catheter for 7 to 10 cm, while simultaneously bringing the shaft of the penis to the horizontal plane or parallel to the patient. Continue to advance the catheter, while expecting to feel a slight increase in resistance as the membranous urethra (external striated sphincter) is traversed.

Once the entire length of the catheter has been introduced (up to the juncture of the connector or to the two-way bifurcation), wait for spontaneous urine passage, confirming proper placement of the catheter. If spontaneous drainage of urine is not seen, gently press on the patient's suprapubic area. If despite this maneuver no drainage occurs, slowly instill 20 mL of saline using a

catheter-tipped syringe into the drainage port of the catheter and then slowly aspirate the fluid instilled. This maneuver should clear any obstruction of the catheter side hole by lubricant or other material. If the catheter is in the bladder, fluid should be aspirated without resistance. If the catheter is still within the urethra, the negative pressure produced during aspiration will cause collapse of the urethral wall and will not permit the return of the instilled fluid.

Only when the position of the catheter has been verified should the retaining balloon be inflated, with the amount of fluid indicated on the catheter. Most catheters do safely permit twice the indicated amount of fluid without risk of balloon rupture. Sterile water is the preferred solution for balloon inflation. Air is compressible and might leak, and electrolyte or glucose-based solutions can precipitate and occlude the tubing and valve mechanism.

The catheter should be attached to a sterile closed bag system as soon as urine is draining. The drainage bag should be placed below the level of the bladder to encourage one-way gravity flow with the tubing as straight as possible and avoiding kinks that might impair drainage. It has been shown that even the retention of 50 mL of urine in catheterized patients has been associated with an increase in UTIs in up to one third of the patients (Garcia et al, 2007).

The temporal exception to this is in patients with acute urinary retention with significant bladder distension in which rapid bladder drainage might precipitate decompression-induced hematuria or "ex vacuo hematuria." In these patients the catheter should be intermittently clamped and released to permit gradual bladder decompression over 30 to 60 minutes.

If the patient is uncircumcised, at this point return the foreskin to its normal reduced position to avoid paraphimosis.

Secure the catheter to the patient, allowing for a normal range of motion and without tension, using adhesive tape or a commercial securing device.

Female Patients

Anatomic Considerations

The female urethra is approximately 3.5 to 4 cm long. The meatus is usually in an anterior location and the bladder neck in a posterior location in the horizontal plane, giving the urethra a slight posterior inclination.

After antiseptic preparation and sterile draping, use the nondominant hand to spread the patient's labia (now considered contaminated) to reveal the urethral meatus. After lubrication, insert the tip of the catheter and gently advance using a slightly downward direction, until about half the length of the catheter has been inserted. Check for urine return and activate the anchoring mechanism if used.

Difficulties during female catheterization may be encountered for several reasons including the inability to locate the urethral meatus due to obesity and age-related changes and less frequently to strictures (postsurgery, radiotherapy, neoplastic causes).

In the obese patient, the use of one or more assistants to provide labial retraction or the use of stirrups can be helpful. In the case of postmenopausal vaginal atrophy or other conditions resulting in the urethral meatus receding into the introitus, we suggest the following alternatives. Holding the index and middle fingers of the nondominant hand together, slowly slide posterior along the introitus until the urethral meatus is palpated and then proceed to slide the fingers just distal to the inferior margin of the meatus. Using the dominant hand, pass the catheter along the groove made by the fingers (this serves a dual purpose—it creates a posterior border with the fingertips and provides a guide for the catheter). As the catheter tip crosses the meatus, it can be felt with the fingertips, thus ensuring proper placement. A second maneuver is to use a vaginal speculum to aid in the retraction and fixation of the introitus. Finally use a coudé tip catheter angled upward and gently slide the tip along the anterior vaginal wall in the midline, until it enters the meatus, and then advance into the bladder.

Special Considerations in Children

Whenever possible the procedure should be explained in clear and age-appropriate language to the child.

Catheterization in children is most commonly performed for drainage, performance of voiding cystourethrogram, or obtaining urine for culture. When attempting to obtain a urine sample for cultures, the use of a portable bladder ultrasound is recommended to ensure that an adequate amount of urine is present in the bladder, thus minimizing the risk of unproductive catheterization (Robson et al, 2006).

In female children the correct identification of the urethral meatus is essential to avoid unnecessary catheter contact with the sensitive introitus, leading to discomfort and possibly loss of cooperation by the child. The meatus is just above the superior margin of the introitus and frequently hidden by the superior portion of the hymen. Gentle downward pressure on the upper aspect of the hymen with a cotton ball may allow visualization of the meatus. Failing this maneuver, the catheter tip should be inserted just above the hymen in the midline.

In uncircumcised boys, retract the foreskin only until the meatus is visible. In infants and children younger than 3 years of age, when the normal foreskin adhesions have not yet involuted, simply align the preputial opening with the meatus to assist catheter insertion.

Difficult Catheterization

Difficulty inserting a catheter into the bladder is most commonly due to prostatic growth, urethral stricture(s), bladder neck contracture, or false passage from previous urethral instrumentation. Rarely it is the result of phimosis or urethral calculi. Although these difficulties occur mostly in men, the techniques described herein may be applied to place a catheter regardless of gender (Fig. 7–3).

If there is no clinical history of previous sexually transmitted infections (STIs), catheterization, trauma, urethral surgery, or radiotherapy in an adult male over 40 years of age, the most likely cause is prostatic enlargement. Using adequate urethral lubrication and a 16- or 18-Fr coudé tip silicone catheter is often successful in this scenario. If multiple previously unsuccessful attempts have been made and urethral trauma is suspected due to the appearance of a bloody urethral discharge, a false passage or a stricture is likely. A single atraumatic attempt can be made using a 12-Fr silicon/straight or coudé tip catheter. If this maneuver is unsuccessful, then depending on the availability of equipment and the level of experience of the clinician, several other options can be considered. The authors' preference is to use a flexible cystoscope, allowing a direct visual approach that can be both diagnostic and therapeutic and minimizes the risk of further urethral injury. Under direct vision, the area where the false passage was created or the site of stricture formation is identified and an

attempt is made to identify the true urethral lumen. Once identified, a 0.035 in Teflon-coated guidewire (e.g., Bentson type) is passed along the urethral lumen and into the bladder. Depending on the circumstances, urethral dilation may be required as in the situation of a tight urethral stricture or bladder neck contracture. Dilation can be accomplished over the guidewire using Amplatz dilators or purpose-built commercially available urethral dilators (Fig. 7–4A-C). Once the urethral lumen is deemed of adequate diameter to permit placement of the catheter size required, a Councill catheter, which can be advanced over the guidewire into the bladder, is selected.

If flexible instruments are unavailable and a urethral stricture is suspected, then a blind technique. although less desirable, can be used. This technique involves using filiforms and followers (Fig. 7–5).

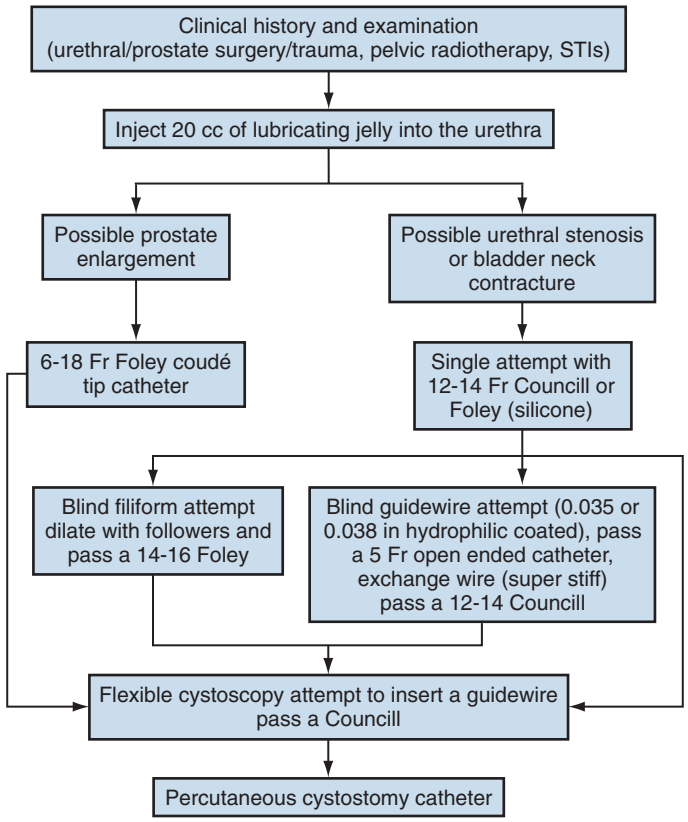

Figure 7–3. Management of the difficult-to-catheterize patient.

The first step is to pass a small female filiform catheter. In many cases the initial filiform will frequently end up entrapped in the stricture membrane or in the false passage, rather than following the true lumen. Insertion of additional filiforms will then fill the false passage or stricture membrane until one is successfully directed into the true lumen. Once a filiform is successfully passed, male sections (followers) of increasing size are attached to the filiform to permit sequential dilation of the urethra. Once dilation to at least 14 to 16 Fr has been achieved, a 12- to 14-Fr catheter is then passed.

Alternatively, one can blindly pass a Councill catheter to the point of resistance and then attempt to advance a hydrophilic-coated guidewire. If guidewire advancement seems to go easily, a 5-Fr open-ended or angled ureteral catheter can be advanced over the wire to permit urine drainage and confirm bladder positioning. Once bladder positioning of the guidewire is assured, urethral dilation can be performed over the guidewire followed by Councill catheter placement.

Both blind techniques require a level of experience, especially a tactile sense of what is acceptable resistance during guidewire and filiform insertion. It is worth restating our belief that whenever possible the use of flexible cystoscopy and a direct visual approach are preferable. The use of fluoroscopy is another alternative, but the lack of immediate availability in most settings may logistically limit utility.

If none of these techniques are successful, a suprapubic catheter should then be inserted.

Complications of Urethral Catheterization

UTIs account for 40% of all nosocomial infections. The major risk factor is the use of urethral catheters, which are responsible for up to (80%) of UTIs in the hospital setting (Ha and Cho, 2006). Risk factors for CAUTIs include patients requiring more than 6 days of catheterization, female gender, active nonurinary infection sites, preexisting medical conditions, malnutrition, renal insufficiency, catheter insertion other than in the operating room, and having drainage tubing or a bag elevated above the level of the bladder (Maki and Tambyah, 2001).

Avoidance of unnecessary catheterization, atraumatic technique at insertion, and the use of a closed collection circuit have been shown to decrease the incidence of CAUTI. The use of aseptic technique, although universally practiced and recommended by expert opinion, is not evidence based (Pratt et al, 2007).

The use of antiseptic gels or irrigations of the bladder or collection bag, catheter clamping, or antireflux valves have not been shown to prevent CAUTIs (Phipps et al, 2006; Jahn et al, 2007; Tenke et al, 2008). Multiple trials to date have failed to show that

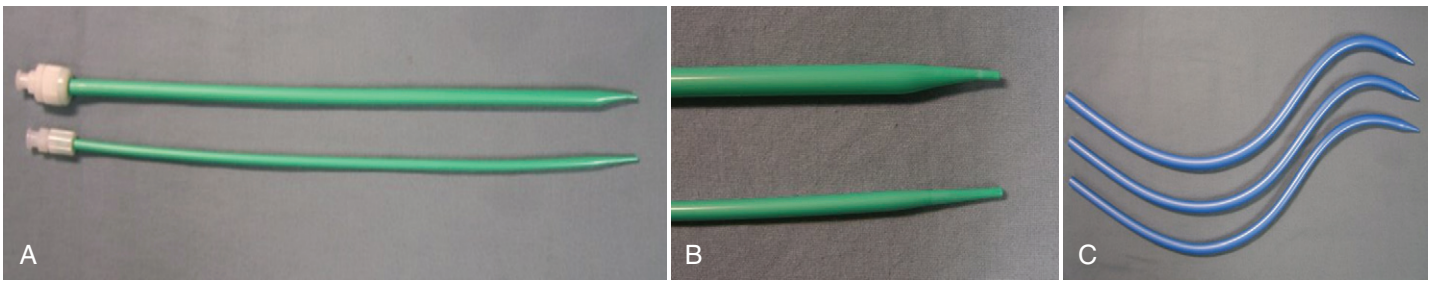

Figure 7–4. **A,** Urethral dilators (12 and 18 Fr); **B,** dilator tip, showing gradual increase of diameter; **C,** Male urethral dilators.

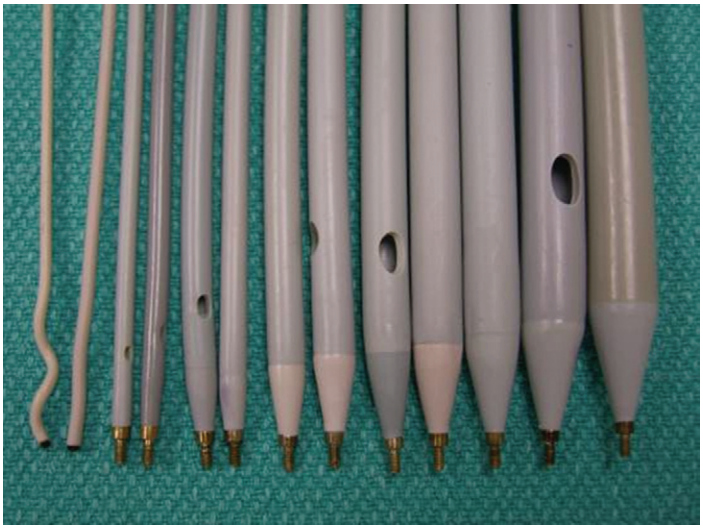

Figure 7–5. Filiform dilators (left pair) and followers, from 2 Fr to 30 Fr.

hydrogel-coated catheters have a role in reducing the incidence of infections. The application of antibiotic coatings onto catheter surfaces and the concept of drug elution have shown some promise in preclinical investigations such as the application of nitrofurazone and minocycline/rifampin coatings, which have shown effectiveness in limited trials by reducing the incidence of asymptomatic bacteriuria (Lee et al, 2004; Stensballe et al, 2007). Evidence of the benefit of employing silver alloy coating to catheter surfaces has been conflicting (Davenport and Keeley, 2005; Srinivasan et al, 2006; Schumm et al, 2008). A recent Cochrane review reported a decrease in the rates of asymptomatic bacteriuria; however, whether this equates to a decrease in symptomatic infections is not clear (Jahn et al, 2007). The routine use of catheter coatings is currently not supported by the available literature.

A unique complication of urethral catheterization is the inability to remove the catheter from the bladder. This problem has been reported in the pediatric population when using feeding tubes that can become knotted or entangled. A more frequent occurrence, however, is the inability to remove a straight Foley catheter, either due to encrustation, entrapment by sutures, or inability to disengage/deflate the retaining balloon. The latter problem may be due to a faulty valve, inflation channel blockage, or rarely crystallization within the balloon.

If the catheter has been indwelling for a long period of time, encrustation should be considered and imaging studies (plain film or ultrasound) will be confirmatory. In many instances the encrustation is easily dislodged with gentle traction on the catheter. For more significant encrustations, one can consider using a semirigid ureteroscope and the holmium:YAG laser to remove the stone fragments. If the catheter is quite rigidly fixed and in the setting of recent bladder or prostate surgery, semirigid ureteroscopy along the catheter and using the holmium:YAG to release the suture have also been described (Bagley et al, 1998; Nagarajan et al, 2005). Because the suture materials used in bladder and prostate surgery are often absorbable, waiting for suture dissolution is another option.

An inability to deflate a Foley balloon can be managed using a stepwise approach. One should first attempt to place another 1 to 2 mL of fluid in the balloon to ensure normal balloon contour, which may be important with the large-volume balloons. Failing this maneuver, the next step is to cut the inflation port. If the valve is the source of the problem, balloon deflation should then occur.

If the balloon remains inflated, the problem is along the catheter's inflation lumen or in the balloon itself. Although overinflation of the balloon has been described in an attempt to rupture the balloon, we do not recommend it because this maneuver may be painful to the patient and may cause bladder injury and fragmentation and retention of the balloon fragments (Gülmez et al, 1996). Similarly, the use of chemical instillations such as ether or toluene to induce balloon rupture should be discouraged because these agents can cause chemical cystitis (Patterson et al, 2006).

Our preferred approach is to insert a surgical steel wire (24 or 28 gauge; often included as an obturator for small-caliber ureteral catheters) or the stiff end of a 0.035-inch hydrophilic-coated guidewire through the valve inflation lumen. This usually bypasses the site of obstruction or creates a small perforation of the balloon.

Should none of these maneuvers be successful, the use of ultrasound-guided needle puncture can be conducted with a long spinal needle (22 gauge) using either a transrectal, transvaginal, or suprapubic surface probe (Daneshmand et al, 2002). In most instances, retained catheters can be removed without the need for open surgery.

Other complications of urethral catheterization include hematuria, urethral and meatal strictures, urethral perforation, and allergic reactions including anaphylaxis (Thomas et al, 2009; Wyndaele, 2002). Especially at risk are patients with long-term indwelling catheters, in whom other complications may also include malignant neoplasms (2.3% to 10%), stone formation (46% to 53%), bladder neck and urethral erosions (Igawa et al, 2008).

Suprapubic Catheterization

Indications

Suprapubic catheter (SC) insertion is most often selected for those patients in whom urethral access is not possible such as complete urethral stenosis, bladder neck contracture, and traumatic urethral disruption. Also, some patients who do not meet these criteria may be candidates for selective SC (Abrams et al, 2008), especially in the context of the need for a chronic indwelling catheter (i.e., neurogenic bladder, poor patient or cooperation/support for clean intermittent catheterization) because some evidence suggests that an SC may be associated with less discomfort than a urethral catheter (McPhail et al, 2006). The evidence that SC reduces the risk for symptomatic bacteriuria is relatively weak (Niël-Weise and van den Broek, 2005). Relative indications for SC placement also include patients who decline urethral catheterization for sexual or self-image purposes.

Indications for short-term SC as a method of postoperative urinary diversion to allow bladder or urethral healing include following surgical procedures (e.g., open prostatic adenectomy, intestinal bladder substitution) or in the pediatric patients following reflux surgery, and during trans urethral prostate resection to theoretically prevent fluid absorption in high risk surgical patients (Sanchez Zalabardo et al, 2003).

Technique (Percutaneous)

The distended bladder should be palpated or percussed to delineate its borders. Failure to palpate the bladder is a relative contraindication to blind percutaneous access techniques and should prompt the clinician to either wait until the bladder is more distended and palpable or use ultrasound imaging guidance for catheter placement (Aguilera et al, 2004). Because of the wide

availability of portable ultrasound, ease of use, and added safety over the blind technique, we strongly advocate for its preferential use in percutaneous cystostomy placement to reduce possible complications.

The patient's infraumbilical abdomen should be prepped and draped in a sterile field. Local anesthesia should be infiltrated into the skin and subcutaneous tissues. A 5- to 10-mm incision is then made 3 to 4 cm above the symphysis pubis in the midline of the abdomen.

Access can then be obtained using a trocar technique, in which a sharp stylet or trocar is used to penetrate the layers of the abdominal wall and bladder. Once entry into the bladder is confirmed by urine flashback or aspiration, the stylet is withdrawn while the catheter is advanced (coaxial system) or the catheter can be fed through the lumen (peel away sheath system). The anchoring mechanism is then activated, the catheter is sutured to the patient's skin, and a sterile dressing is applied to the site.

An alternative approach employs the Seldinger technique. An 18-gauge hollow needle is advanced under continuous aspiration with a syringe until urine flashback appears, confirming the bladder has been entered. The needle is then advanced 1 cm more, the syringe is detached from the needle, and a floppy-tip guidewire (0.035 or 0.038 in Bentson) is advanced and coiled in the bladder. The needle is withdrawn, a small incision is made on the anterior abdominal fascia, and the tract is coaxially dilated either in one step with a balloon-dilating catheter or with sequential graduated dilators (Fig. 7–6). A 16- to 18-Fr Councill catheter can then be advanced over the guidewire and into the bladder.

Contraindications to the use of a blind percutaneous approach are uncorrected coagulopathy, previous lower abdominal surgery, or pelvic radiation (Lawrentschuk et al, 2003). In these situations, an open technique with exposure of the anterior surface of the bladder should be used. The use of a retrograde simultaneous cystoscopy to manually displace the bladder dome and serve as a visual and palpatory reference in both the closed and open technique has been described in an effort to diminish the chance of bowel injury (Alagiri and Seidmon, 1998; Lawrentschuk et al, 2003; Sawant et al, 2009).

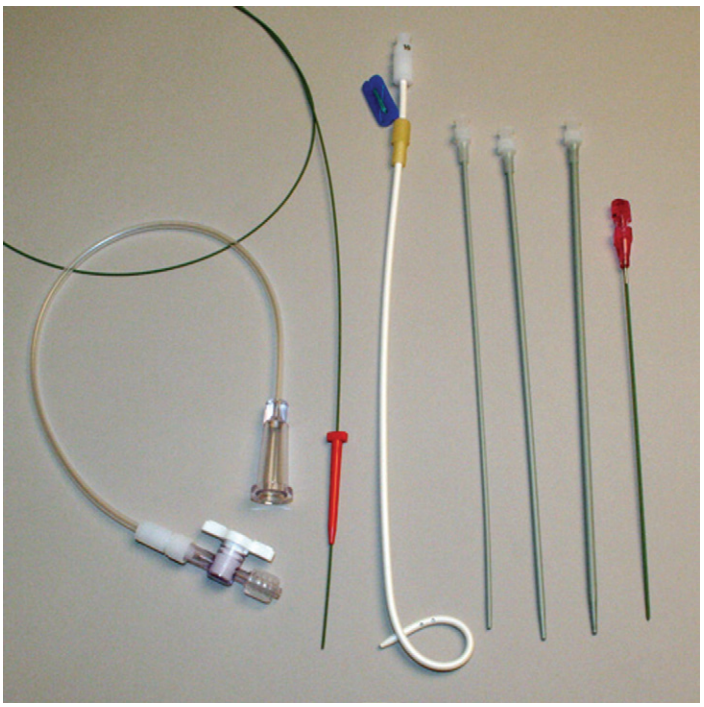

Figure 7–6. Percutaneous suprapubic catheter kit (left to right, guidewire, drainage bag connection tubing, Cope loop catheter, Amplaz dilators, and cystostomy needle). (Courtesy of Cook Urological, Spencer, IN.)

Technique (Open)

The open technique entails prepping and draping the anterior abdomen of the patient. An incision is made approximately 2 to 3 cm above superior margin of the symphysis pubis in the midline. Both blunt and sharp dissections are then used to expose the anterior layer of rectus fascia, which is then incised. The Retzius space is developed with blunt dissection, taking care not to enter the peritoneal cavity until the anterior wall of the bladder is identified. Two 1-0 silk stay sutures are used to stabilize the bladder wall, and electrocautery is used to make a 1-cm incision in all layers of the bladder in between the sutures. Urine is drained, and a suprapubic catheter is placed through the abdominal wall by a stab incision, inserted into the bladder, and secured with a purse string or uninterrupted running suture (2-0 absorbable suture). The anchoring device is deployed at this point to avoid entrapment or puncture by the suture, and the anterior rectus fascia, sub-cutaneous tissue, and skin are closed per personal preferences.

Complications

Potential complications associated with suprapubic catheters include those related to initial insertion (hematuria, perivesical fluid collections, surrounding organ injury). With long-term use other adverse events can include catheter blockage/encrustation, dislodgement, skin site infections, symptomatic UTI, urothelial neoplasms, and stone formation (Shiøtz et al, 1989; Sheriff et al, 1998; Berman et al, 2003; Lawrentschuk et al, 2003; Kumar and Pati, 2005; Ahluwalia et al, 2006; Feifer and Corcos, 2008; Sugimura et al, 2008).

UPPER URINARY TRACT URETERAL STENTS

Rudimentary versions of a ureteral stent were first conceived and used in the late 19th and early 20th centuries on the basis of Albarran's pioneering work to aid in open surgery of the ureter. Zimskind in 1967 was the first to describe endoscopic stent placement to relieve ureteral obstruction. This early era was plagued with frequent stent migration and device expulsion. A novel design developed by Gibbons in the 1970s initially addressed this issue, but it was not until the revolutionary development of the Double J and pigtail stents independently by Finney and Hepperlen and colleagues (1978) that the use of ureteral stents became widespread (Watterson et al, 2002, Chew and Denstedt, 2004).

Ureteral stents have become a fundamental tool in today's urologic armamentarium and are employed for a number of indications including obstruction relief as a prophylaxis against obstruction or ureteral injury and as use as a ureteral splint.

Indications for Ureteral Stents Placement

Stents are often inserted to relieve either extrinsic (tumor, retroperitoneal fibrosis) or intrinsic ureteral obstruction (stones, tumors, strictures) as a temporary measure while definitive treatment is

instituted or as permanent measure when no corrective treatment is possible. In the context of bilateral obstruction, solitary kidney (anatomic or functional), refractory renal colic or obstruction associated with infection (fever, leukocytosis, pyuria) stent placement to secure drainage is often an emergent absolute indication.

Current percutaneous lithotripsy techniques do not require routine stenting. Exceptions to this practice include extensive perforation of the collecting system, significant stone burden remains with the need for subsequent shock wave lithotripsy (SWL), ureteral obstruction due to edema, concurrent ureteropelvic obstruction, stone fragment migration into the ureter, supracostal access, and persistent urinary fistula after nephrostomy tube removal.

The use of routine stenting before SWL is not associated with either a decrease of steinstrasse formation or increase in stone-free rates. However, stenting is clearly associated with increased morbidity. Kirkali and colleagues (1993) reported on 351 patients with renal stones less than 30 mm. The stone-free rate was not significantly different between groups (stented 31% vs. unstented 30%). Half of the patients in the stented group reported bladder discomfort and symptoms that were relieved on removal of the stent. In another report, stented subjects experienced significantly higher incidence and duration of urinary symptoms (urgency, hematuria, bladder discomfort, and frequency) compared with nonstented subjects (Preminger et al, 1989). Indications for pre-SWL stenting are stone burden greater than 2 cm (Libby et al, 1988; Sulaiman et al, 1999; Preminger et al, 2005), when bilateral SWL is to be undertaken (at least one renal unit), and when treating a solitary kidney.

In 2007 a cosponsored American Urological Association/European Association of Urology guideline panel recommended that routine ureteral stent insertion is not necessary after SWL for ureteral calculi because available evidence shows it does not improve patient outcomes (Preminger et al, 2007). Current evidence has also shown that routine stenting after uncomplicated ureteroscopy is unnecessary because unstented patients do not experience an increased risk of complications and have fewer postoperative symptoms (Hosking et al 1999; Rane et al, 2000; Denstedt et al, 2001). Stenting in association with ureteroscopy is recommended in patients with an impacted ureteral calculi, incomplete fragmentation, after formal ureteral dilation, and if there are procedural complications such as ureteral perforation.

Urinary calculi during pregnancy, although uncommon, presents a unique therapeutic challenge. Drainage, if indicated, can be achieved with an internal stent or a percutaneous nephrostomy tube; however, the indwelling time should be limited and exchange is recommended at a 6-week interval due to the increased risk of rapid encrustation triggered by gestational hyperuricosuria and hypercalciuria (Riddell and Denstedt, 2000).

Another indication for stenting (Double J or 5 open-ended ureteral catheter exteriorized and taped to the urethral catheter) is to serve as a surgical landmark for ureteral identification in order to avoid iatrogenic ureteral injury in abdominal or pelvic surgery. Light-emitting ureteral stents have been developed to serve as an additional optical aid, which may be especially helpful in the context of video-assisted surgery (i.e., laparoscopy), in which the tactile sense is diminished.

The use of a stent for ureteral splinting brings us back to the earliest uses of stents. In this setting the stent accomplishes two tasks—one is as a splint or scaffold to promote organized tissue healing and the other equally important role is to allow unhindered urinary flow across the healing segment of the ureter. The main areas where stents are used are following ureteral trauma such as perforation or transection and following ureteral repair (i.e., primary reanastomosis, urinary-intestinal anastomosis, ureterotomy, ureteral reimplantation). One particular indication is kidney transplants because stenting reduces the risk of major urologic complications (obstruction, urinary fistulas) (Wilson et al, 2005) without increasing the risk of infections (Eschwege et al, 1996).

Stents can be used to prevent the occurrence of urinary fistulas (i.e., after percutaneous nephrostolithotomy [PCNL], ureteral anastomosis) or treat them by creating a path of preferential flow away from the defect. Their use is indicated in cases of upper urinary tract fistulas (renal or ureteral) or retroperitoneal urinomas after blunt or open trauma (Haas et al, 1998).

Technique of Ureteral Stent Insertion

The insertion of a ureteral stent can be accomplished via one of several approaches (either open or endoscopic and by antegrade or retrograde techniques). The retrograde approach is most commonly used, often as an adjunct to ureteroscopy or SWL. Although retrograde insertion can be performed with either the aid of flexible or rigid cystoscopy, the need for fluoroscopy and a guidewire are common to both techniques. The safest way to place an internal ureteral stent is by advancing the stent over a guidewire. This can be accomplished by passing a stent that is open at both ends through the working channel of a rigid cystoscope through which a guidewire has been passed and advanced up the ureter to the renal pelvis. The stent is advanced with a pusher while visually observing the ureteral orifice through the cystoscope. Advancement of the stent up the ureter should be monitored fluoroscopically. When the pusher becomes visible at the level of the bladder neck, the wire is extracted, allowing the stent to curl in the bladder.

An alternative technique that relies more on fluoroscopic visualization for stent placement and less on cystoscopic visualization is often advantageous when dealing with more challenging stent placements such as impacted ureteral stones or malignant obstruction (Figs. 7–7 through 7–16).

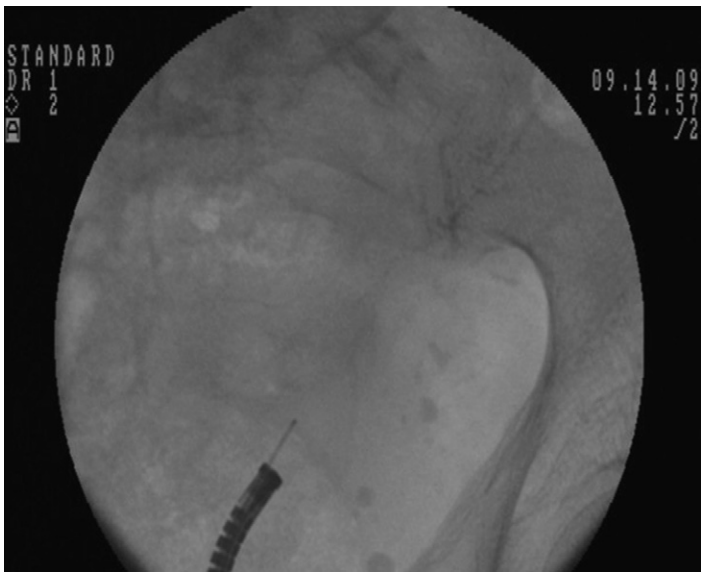

Figure 7–7. Flexible cystoscopy is used to locate and, under fluoroscopic guidance, pass a floppy tip guidewire through the ureteral meatus.

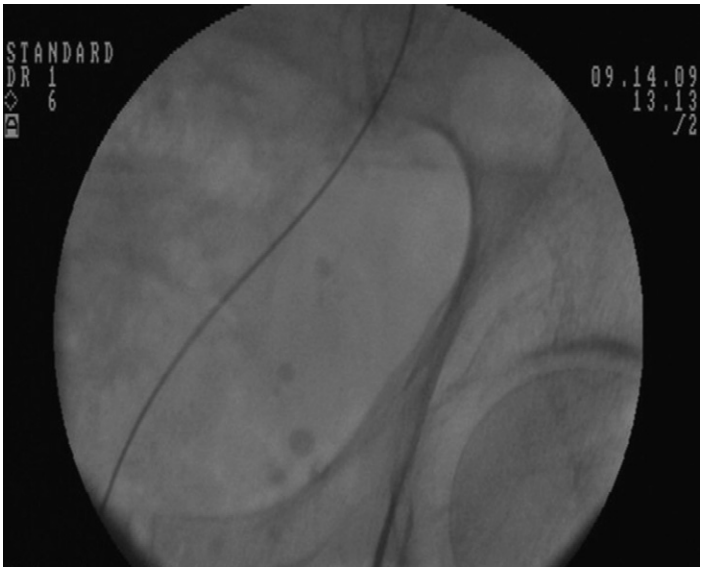

Figure 7–8. Guidewire is advanced in a retrograde fashion.

Figure 7–10. 8/10 coaxial dilator is passed into the ureter.

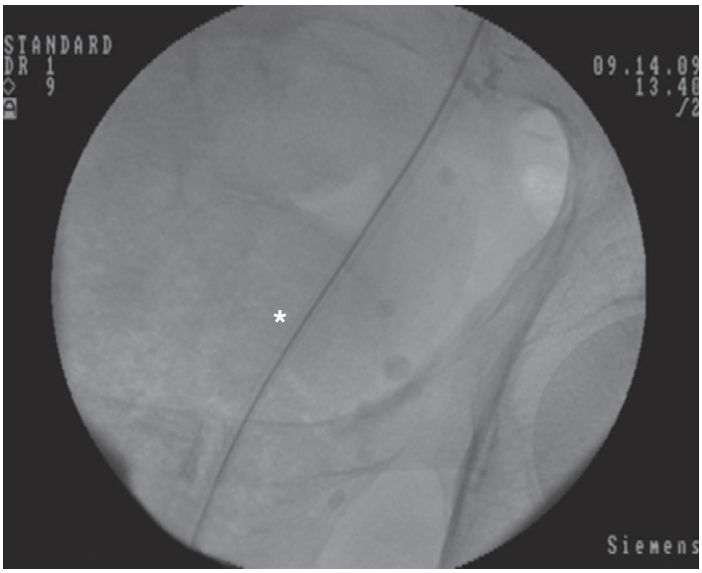

Figure 7–9. The 8 portion has been removed. *Asterisk* shows the faint outline of the 10 portion along the guidewire.

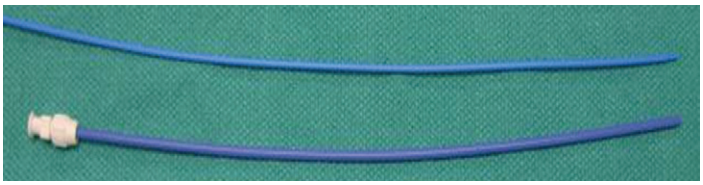

Figure 7–11. A disassembled 8/10 coaxial dilator (bottom is 10 Fr, top is 8 Fr).

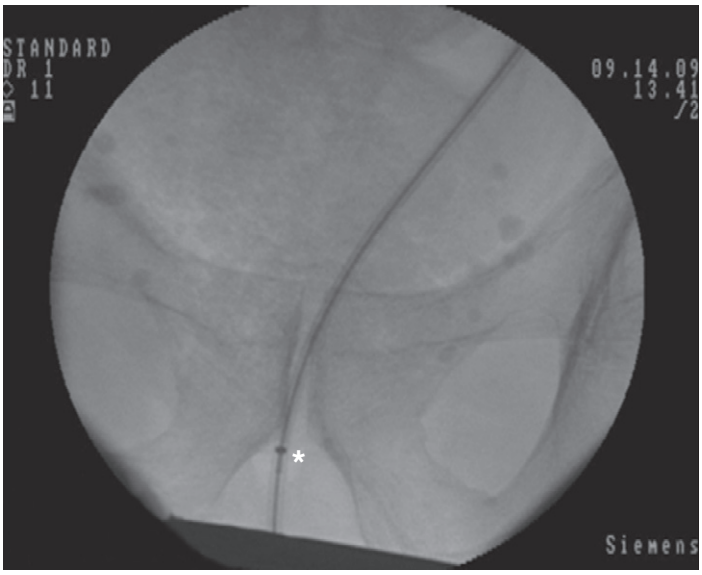

Figure 7–12. The stent is inserted into the ureter. *Asterisk* shows the tip of the stent.

After obtaining bladder access with either a flexible or rigid cystoscope, a floppy-tip guidewire is advanced into the ureteral meatus and coiled in the renal pelvis using fluoroscopy, the cystoscope is then removed and an 8- to 10-Fr coaxial dilator is advanced under fluoroscopy until the 10-Fr sheath is at the urethral meatus. The 8-Fr internal dilator is removed, leaving a conduit (10-Fr outer sheath) through which to advance the stent.

The ureteral stent is then advanced over the guidewire through the 10-Fr sheath by using a pusher with a small fluoroscopically visible metal band at its tip. The metal tip pusher is advanced under fluoroscopic control to the upper border of the pubic symphysis in male patients and lower border in female patients, while stabilizing the position of the lower end of the stent. The 10-Fr sheath and subsequently the guidewire are removed, allowing the stent to curl in the bladder.

Stent Technology

In the more than 30 years that have elapsed since the introduction of the first self-retaining ureteral stents, there have been ongoing efforts to design a stent with better patient tolerability and biocompatibility. In the following sections we address some of the

Figure 7–13. A metal tip pusher is used to advance the stent to the desired position. *Asterisk* shows the pushers radiopaque marker.

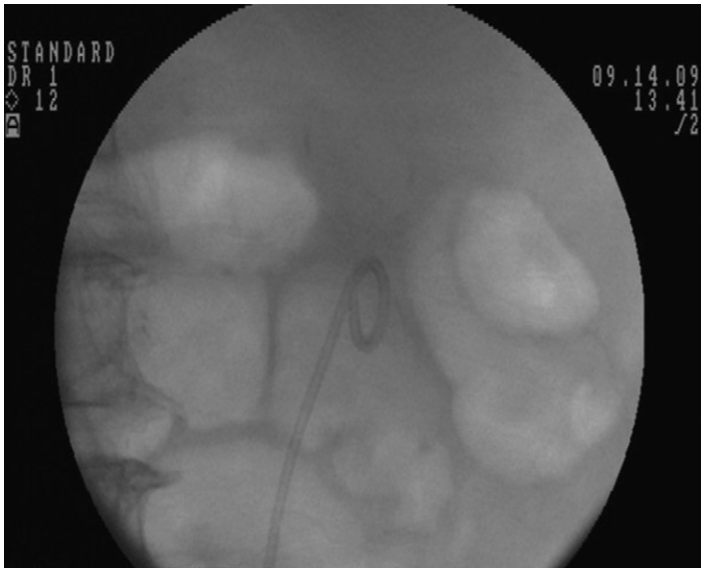

Figure 7–14. The distal third of the guidewire is removed to form the kidney coil.

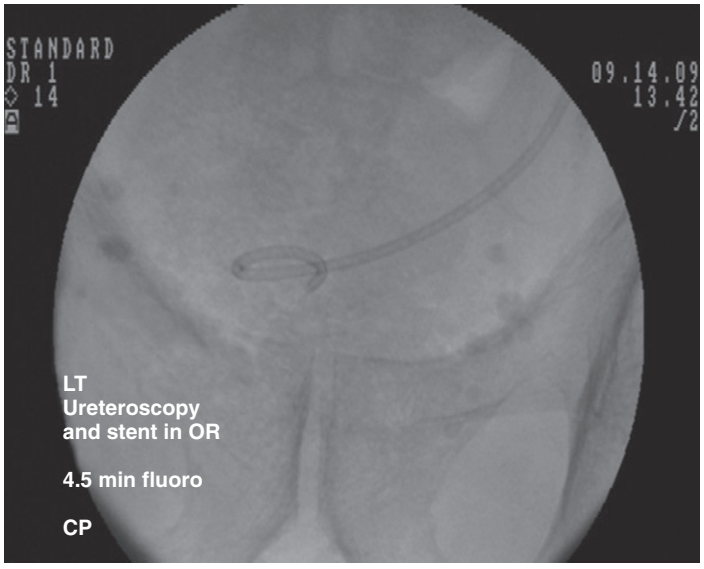

Figure 7–16. While maintaining the pusher's position, the guidewire is removed to form the bladder coil. Then the pusher is removed.

characteristics of current stents, as well as future trends in stent technology.

The physical characteristics of a stent are dictated by the material employed and design used in its construction. Early stents were manufactured out of glass, tantalum, or vitalum tubes (Wignall and Denstedt, 2008). Polyethylene (PE) was the first plastic polymer used in stents; however, it proved to be fracture prone and has since fallen out of favor. Silicon is the most biocompatible material tested to date; however, due to its less than optimal handling characteristics (high friction coefficient and extreme flexibility) and low radial force, which makes it prone to occlusion (Chew and Denstedt, 2004), it is not widely used. Polyurethane shares characteristics common to both silicon and PE, making a good overall stent material. Various proprietary polymers are now available including C-flex, Silitek, Tecoflex, and Percuflex. These materials have been developed in an effort to increase biocompatibility and handling.

A further evolution in stent materials has been the design of biodegradable stents, which in theory could eliminate the need for cystoscopic stent removal. The main challenge of this technology has been the inability to reliably control the degradation rate. The first attempts used pH-triggered degradation of stent polymers (Shlick and Planz, 1997, 1998). In vitro studies demonstrated an ability to cause stent dissolution, but in vivo studies are lacking. Dissolution of a poly-L-lactic-co-glycolide (PLGA) stent has also been demonstrated in a porcine model for short-term drainage after endopyelotomy (Olweny et al, 2002). Although dissolution was achieved, tissue inflammation was a prominent finding.

A poly-L-D-lactide copolymer stent tested in a canine model demonstrated 50% stent dissolution at 12 weeks, 100% dissolution, and no difference in histologic changes when compared with a nondegradable stent at 24 weeks (Lumiaho et al, 2000). Uriprene, a copolyester compound, has been tested in the porcine model showing complete degradation by 10 weeks without a difference in the inflammatory response when compared with conventional stents and without any retained fragments in the subepithelial tissues (Hadaschik et al, 2008). Only one trial to date involving human subjects has been reported using a proprietary polymer material stent (Lingeman et al, 2003). In 88 patients stented post-ureteroscopy, the stent was effective in providing ureteral drainage in 78.2% of patients with a 7.9% stent-related complication rate, mostly due to proximal/distal migration or fragment retention. Eighty-four percent of the patients were stent free at 30 days and 96.6% at 90 days. Although early in development, tissue-engineering techniques have been used to create stents made from chondrocytes over an absorbable scaffold (Amiel et al, 2001) and may overcome the limitations identified with prior dissolving stents.

The development of metallic mesh stents to combat stent occlusion by radial compression in the setting of chronic extrinsic ureteral obstruction is a relatively recent innovation. These devices can be self-expandable, balloon expandable, mesh, or continuous wire stents with or without thermo-expandable shape memory. Indications to date have primarily been for patients with malignant ureteral obstruction, in whom a conventional stent would not reliably relieve obstruction. The literature to date describing the experience with metallic stents is limited to small series, given the narrow indications for their use (Kulkarni and Bellamy, 2001). Complications reported include failure to relieve obstruction, erosion, encrustation, and migration (Pauer and Lugmayr, 1996; Diaz-Lucas et al, 1997; Arya et al, 2001; Agrawal et al, 2009; Liatsikos et al, 2010). The most recently released metallic stent is the titanium Resonance stent (Cook). Borin and colleagues (2006) reported follow-up of 14 months, with an overall 30% failure rate mostly due to epithelial ingrowth and 24% macroscopic encrustation rate. Garg and colleagues (2009) reported their experience with the use of the Resonance stent in benign conditions (ureteral and ureteroenteric strictures), finding an 89% rate of distal migration in their population. Nagele and colleagues (2008) reported that after a mean 8.6-month follow-up, 57% of the stents had to be removed (urinary symptoms, drainage failure, hematuria, infection, or encrustation).

Stent Design Modifications

Most ureteral stents on the market today are based on a common design consisting of a central lumen, multiple side holes, and a mechanism to limit stent movement (Fig. 7–17). The most commonly used stent is the double pigtail configuration in some variation such as the Double J stent, the dual durometer (softer distal curl and rigid proximal curl), or those with tail shape changes (e.g., Percuflex Tail Plus has a 3-Fr lumen-less soft tail, Polaris Loop has two thinner tail loops) (Dunn et al, 2000; Liatsikos et al, 2002).

Various design changes to the original standard double-coiled internal ureteral stent have appeared.

One such design modification aimed at improving stone clearance after lithotripsy is in the form of a self-expanding stent (OPEN Pass J) with multiple baskets in the stent body to increase ureteral lumen diameter (up to 6.5 mm) and trap stone fragments until stent removal (L'Esperance et al, 2007).

In an effort to improve urinary drainage in the setting of extrinsic ureteral compression, a double-lumen stent (SP-1 and SP-2 ACMI) demonstrated a lower flow versus two side-by-side 7-Fr stents but greater flow when compared with a single 7-Fr stent when tested in an ex-vivo model (Hafron et al, 2006). The Open-8 and Open-I are stents designed to provide drainage using a similar principle, on an I beam or open-sided omega configuration.

Other designs intended to improve drainage are the grooved stents (Towers Peripheral Ureteral Stent by Cook and Lithostent by ACMI), polyurethane metal-reinforced spiral stents (by Braun) designed to resist extrinsic compression and severe angulation (Tschada et al, 1994), and an externally ridged stent (Spirastent by Urosurge) theoretically aimed at increasing extra luminal flow and stone passage (Stoller et al, 2000).

Task-specific stents such as a stent incorporating a magnetic tip for noncystoscopic retrieval (Magnetip by ACMI) and variable-diameter tapered stents for splinting after endopyelotomy have also been developed.

Another exciting area in stent development involves application of coatings onto stents in an effort to reduce friction,

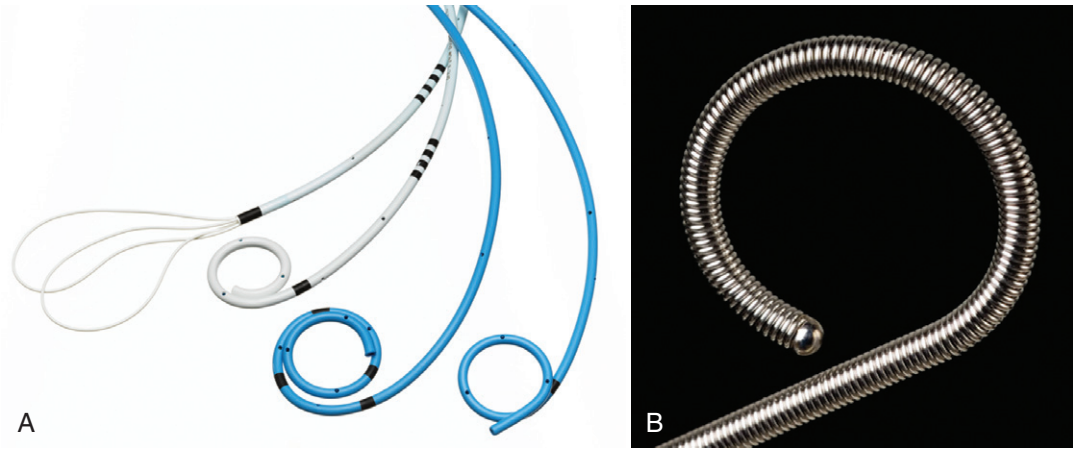

Figure 7–17. **A,** Types of ureteral stents. **B,** Metallic ureteral stent. (**A,** Courtesy of Boston Scientific Corporation, Natick, MA. **B,** Courtesy of Cook Urological, Spencer, IN.)

encrustation, bacterial biofilm formation, or patient discomfort. Various coatings have been successfully applied, albeit with varying degrees of clinical effectiveness.

A hydrogel coating made of a hydrophilic polymer film attached to the stent surface allows water absorption, increasing the elasticity and decreasing friction in an attempt to ease insertion and enhance patient comfort.

Bacterial oxalate decarboxylase, monomethoxy poly(ethyleneglycol)-3,4-dihydroxyphenylalanine (mPEG-$DOPA_3$), and diamond-like carbon coatings have all shown promising results in small trials to reduce encrustation or bacterial adherence both in vitro and in vivo (Watterson et al, 2003; Laube et al, 2007; Ko et al, 2008). Data on the use of heparin-coated stents have been conflicting. A recent in-vitro trial showed no difference in either bacterial adherence or biofilm formation (Lange et al, 2009), but small, uncontrolled clinical series (in total >20 patients) demonstrated a significant reduction in both encrustation and biofilm (Riedl et al, 2002; Tenke et al, 2004; Cauda et al, 2008). Additional clinical trials are necessary to fully validate these results. Stickler and colleagues (2002) have developed a phosphoryl-choline (PC)-coated stent in an attempt to mimic cell membrane lipids and to increase biocompatibility. In a 12-week trial involving 44 patients, the PC coating decreased encrustation by 14%, biofilm formation by 40%, and bacterial colonization by 17%.

Although the initial foray into stent coating development has failed to entirely eliminate the problems of stent discomfort and infections, the results have been encouraging enough to stimulate ongoing research in this area. Within the next decade it is likely we will see a number of products for clinical use using drug elution technology.

Stent Complications

Although ureteral stents play an essential role in various endourologic and open surgical procedures, the potential complications related to their use should not be underestimated. In one series, 32% of patients had their ureteral stents removed sooner than planned due to complications attributable to the stent (Ringel et al, 2000).

Stent Symptoms

From a patient perspective, stent morbidity can be significant. Lower urinary tract symptoms such as frequency, urgency, dysuria, and pain (flank or suprapubic) occur almost universally (Haleblian et al, 2008). More than 80% of patients experience stent-related pain affecting daily activities, 32% report sexual dysfunction, and 58% report reduced work capacity (Joshi et al, 2003).

The pathophysiology of these symptoms has not been completely elucidated, but it is most commonly believed that adverse stent symptoms are induced by bladder mucosal irritation due to contact by the distal curl of the stent, smooth muscle spasm, and reflux of urine resulting in flank pain.

The anatomic position of the stent curl has been shown to increase symptoms if it is located in a calyx or if it crosses the midline of the bladder (El Nahas et al, 2006). Rane and colleagues (2001) showed that an incomplete distal curl also increased discomfort. Stent composition does not seem to impact the incidence of symptoms with the currently available stent materials (Pryor et al, 1991).

Multiple pharmacologic approaches have been applied to stent symptoms such as oral anticholinergics, phenazopyridine, and standard analgesic medications (Norris et al, 2008). Intravesical instillation of ketorolac or oxybutynin decreased pain after stent insertion for up to 60 minutes when compared with placebo or to lidocaine (Beiko et al, 2004). The use of α_1-adrenoreceptor blockers (tamsulosin and alfuzosin) has demonstrated beneficial effects reducing stent symptoms and pain (Deliveliotis et al, 2006; Damiano et al, 2008).

Urinary Tract Infection

As with any implanted foreign body, stents are a potential target for bacterial colonization and a source of urinary infection. The duration of stent insertion is a significant risk factor with 6.8% of patients becoming infected and 20.5% developing stent colonization at 30 days versus 28.6% developing a UTI and 64.9% stent colonization after 90 days. Predisposing factors include chronic renal failure, diabetes, and female gender (Kehinde et al, 2002).

Migration

Stent migration is reported in 2% to 8% of patients and is usually related to a stent that was incorrectly sized for the patient's height (Breau and Norman, 2001). Jeon and colleagues (2007) have advocated for the determination of ureteral length measurement using a guidewire rather than patient height to more accurately allow stent length selection. Treatment for distal migration is reinsertion, and in the case of proximal migration the use of a ureteral dilation balloon (Chin and Denstedt, 1992) or ureteroscopy can be used to retrieve the stent.

Forgotten Stent

This is a source of considerable impact on patient well-being and a threat to renal function. Every effort should be made to counsel patients on the importance of returning for follow-up and stent removal. The establishment of a stent registry has also been described as a method of tracking patients in order to avoid the forgotten or neglected stent (Lynch et al, 2007).

Encrustation

Minor degrees of encrustation, particularly on the bladder curl, are not uncommon in many stented patients. More extensive encrustation often related to the forgotten/retained stent can be one of the most challenging tasks for the urologist requiring various endourologic interventions and on occasion open surgery. If left untreated, extreme degrees of encrustation may lead to compromise of the renal unit and even patient mortality (Walther et al, 1985; Singh et al, 2005).

The duration of indwelling time seems to affect the rate of stent encrustation with polyurethane stents (9.2% before 6 weeks, 47.5% in 6 to 12 weeks, and 76.3% after 12 weeks) (El-Faqih et al, 1991). An interesting observation, however, is that not all stents become encrusted, even after long indwell times. In a series of patients who had an indwelling stent for more than 1 year (mean 36 months), Park and colleagues (2004) found this occurred in only 33% of the stents. Reported risk factors are urinary tract infections (especially when involving urease-producing microorganisms) and pregnancy (Vanderbrink et al, 2008). Most manufacturers recommend that indwelling times should be limited to 4 months. Those at heightened risk of accelerated encrustation such as the pregnant patient should have their stents removed within 6 to 8 weeks (Aravantinos et al, 2006).

The discovery of the encrusted stent is often unsuspected until the withdrawal attempt is made and may be faced by the urologist in an office setting where fluoroscopy is not available. In this situation attempts to remove the stent are associated with resistance or even inability to pull the stent without causing severe pain to the patient. At this point no further traction should be attempted to avoid stent fragmentation, ureteral trauma, or even avulsion. Radiologic imaging, ideally with computed tomography (CT), must be arranged to assess the stone burden and proximal coil orientation. It has been our experience that often a kidney, ureter, bladder radiograph underestimates the degree of encrustation.

If no obvious encrustation is seen on CT, stent retrieval can be reattempted under fluoroscopic guidance. The distal end of the stent should be grasped and if possible exteriorized in an attempt to pass a guidewire through the stent lumen. This maneuver may allow straightening of the proximal coil, permitting stent removal.

If gross encrustation is present, additional treatment will be required. Depending on the sites of encrustation and the degree, single or multimodal approaches may be necessary. SWL has been successful for small-volume renal coil calcifications. PCNL for the larger proximal stone burdens is sometimes required. Cystolithotapaxy and ureteroscopy are used for mostly distally located encrustations. The holmium:YAG laser has been particularly useful in these settings. Renal function studies should be ordered in cases of severe gross encrustation. When renal function has been severely compromised, nephrectomy may be most appropriate.

Endourologic treatment either singly or in multiple stages ultimately succeeds in removing up to 85% to 97% of the stents (Bultitude et al, 2003; Gonzalez Ramirez et al, 2009).

Although chemolysis (Suby solution or hemiacidrin) has been reported as an alternative to invasive treatment of encrusted stents, Vanderbrink and colleagues (2008) suggest it should be reserved as a last resort measure due to its irritating effects on the urinary tract and potential electrolytic imbalances if systemic absorption occurs.

Nephrostomy Tube Drainage

The use of a percutaneously inserted nephrostomy tube for the direct drainage of a kidney was first described in 1955 by Goodwin and colleagues. The procedure remained relatively uncommon until 1976, when Fernström and Johansson purposely established a percutaneous tract for the removal of kidney calculi. With the popularity of PCNL, percutaneous nephrostomy access became a common technique in the endourologist's armamentarium.

Clinical situations occur when a ureteral stent may not provide adequate urinary drainage of the upper urinary tract. Nephrostomy tube (NT) insertion may be a more effective option. As a method of urinary tract drainage, it has been shown in several studies that NTs provide better urine flow in comparison with internal stents. Stented subjects experience both low- and high-pressure vesico-ureteral reflux (Ramsay et al, 1985; Fine et al, 1989; Hübner et al, 1992, 1993) and may not drain at all, especially in the setting of extrinsic ureteral compression (Docimo and Dewolf, 1989). Stents can induce deleterious physiologic and histologic effects on the ureter not observed with NTs. Ryan and colleagues (1994) showed elevated intrapelvic pressures and reduced or absent and ureteral peristalsis, increasing the time it took an artificial stone to traverse the length of the ureter from 3.4 days to 16 days in stented versus unstented ureters, respectively. Microscopic analysis showed collagen deposition and muscular hypertrophy in ureters that were stented.

Nephrostomy Tube Design

Nephrostomy tubes must accomplish the same tasks as standard urethral catheters, mainly to provide unimpaired kidney drainage while being able to remain within the renal cavities resisting accidental dislodging; however, there is also the need to place the catheter blindly through a surgically created tract, so guidance capability is necessary. Councill catheters are commonly used as NTs because they have the previously mentioned qualities. Other catheters used for NT drainage are modified Foley (by cutting an end hole) and Pezzer and Malecot catheters. The latter two have the advantage of having a larger lumen due to their lack of retention balloon tubing.

Re-entry catheters are designed to permit nephrostomy drainage while ensuring access to the ureter should this be necessary (Paul et al, 2003) (Fig. 7–18).

Both the Smith and Hulbert percutaneous endopyelotomy stents (Cook Medical) have a variable diameter starting at 10 to 22 Fr and gradually tapering to 8.2 to 4.7 Fr, distally ending with a pigtail curl. This configuration allows for splinting of the upper urinary tract after endopyelotomy or ureterotomy, while allowing percutaneous drainage/access.

Circle or U-loop NT designs are available to provide continuous irrigation or drug instillation into the kidney while ensuring drainage.

Indications

Short Term

One of the most common indications for acute nephrostomy tube insertion is to establish urinary tract drainage following a failed attempt at retrograde stent insertion. An inability to insert a retrograde stent may be due to several reasons including an impacted ureteral stone or malignant obstruction. In patients with high-grade bilateral ureteric obstruction or obstruction of a solitary renal unit leading to obstructive nephropathy and metabolic derangements, the ability to place the nephrostomy tube in a

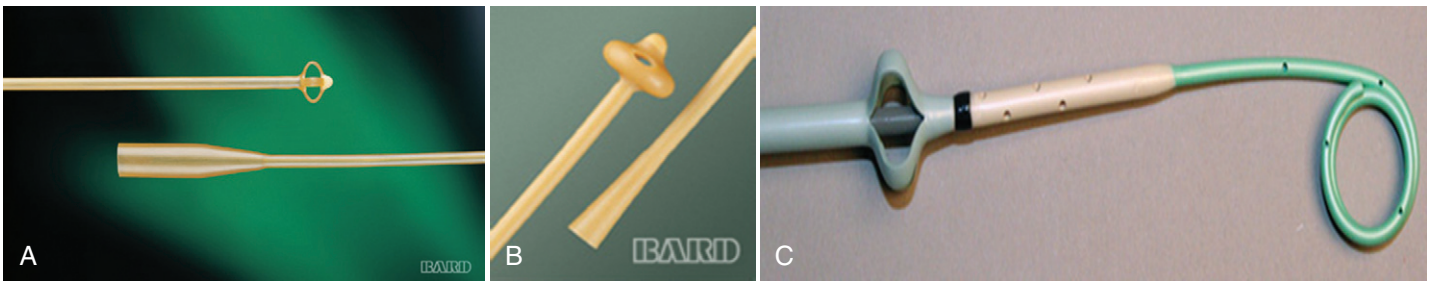

Figure 7–18. Types of nephrostomy catheters. **A** to **C**, Malecot, Pezzer, and Hulbert re-entry catheter.

radiology procedure room under local anesthesia may be the safest and most expeditious way to achieve upper tract drainage. Similarly, the patient presenting with urinary tract sepsis and hemodynamic instability may be a more appropriate candidate for urgent NT insertion rather than an attempt at ureteral stent placement in some circumstances and depending on the local logistics.

An NT is often placed as an adjunct to another procedure such as PCNL to aid hemostasis, drain purulent material or blood clots, and provide future renal access if necessary. Administration of therapeutic drugs (chemolysis, chemotherapy, or immunotherapy) in the context of renal calculi or upper urinary tract malignancy, respectively, is another well described use for an NT.

An NT can also serve a diagnostic role in the performance of the Whittaker test or contrast instillation to clarify complex anatomy (nephrostography).

The insertion of a nephrostomy tube at the completion of PCNL was long considered an essential step of the procedure until recently. Various authors have demonstrated NTs can be safely avoided in select patients (Karami et al, 2007; Shah et al, 2009).

Long Term

It is in the setting of palliative care and extrinsic obstruction where chronic NT tubes might have a significant role. Ku and colleagues (2004) compared NT versus ureteral stent in the setting of advanced extrinsic ureteral obstruction and found stents were exchanged more often than NTs and diversion failure was also more frequent with stents (11% vs. 1.3%). There was no difference in the rate of acute pyelonephritis; however, patient's self-perception and quality of life were better with the use of chronic NTs.

Complications

NT-related complications can occur at the time of obtaining initial renal access, and additionally those that occur as a result of the nephrostomy tube itself. It is estimated that the overall complication rate associated with NTs is approximately 8.8% to 10%.

Complications related to the access procedure include hematuria; clot colic; and pulmonary injuries (pneumothorax, empyema, hydrothorax or hemothorax), which may be as high as 8% to 12% with upper calyceal approaches and sepsis (1.3% to 2.2%). Rarer complications include injuries to nearby organs (liver, spleen, and bowel) and arteriovenous fistulas. The need for blood transfusion related to the NT insertion alone is reported to be as high as 3.2% in some series (Lewis and Patel, 2004; Wah et al, 2004; Hausegger and Portugaller, 2006).

Biofilm Formation on Urinary Tract Biomaterials

Despite a wide array of novel materials available for the manufacture of urinary catheters, no biomaterial used to date is able to withstand the effects of the urinary environment (Wollin et al, 1998). Biofilms and their related complications are a significant cause of morbidity in the urologic patient requiring a urinary drainage device and remain the most common cause of stent failure (Chew et al, 2006).

A biofilm is the microorganism's attempt to control its immediate environment by limiting exposure to harmful factors (waste products, antimicrobial agent, the host's immune response) while enhancing the exposure to trophic factors. The organisms residing in the biofilm can also undergo other adaptative changes such as metabolic dormancy, which may lead to increased antibiotic resistance (Fujiwara et al, 1998; Donlan, 2003). The structure of a biofilm is complex, usually consisting of three layers: the innermost or linking film that is attached to the surface of the tissue or biomaterial, a base film that contains the attached microorganisms, and the outermost layer called the surface film that can be used as a point of access/egress for planktonic organisms (Beiko et al, 2004).

Biofilm structure and the bacterium residing within it behave more like a tissue of a higher organism (Costerton et al, 1995). It has been shown that bacteria within the biofilm can "communicate" with one another and initiate cell dispersal and detachment (Davies et al, 1998). The size of the biofilm can range from a few isolated monolayers to 400 cells deep, effectively covering the complete luminal area of a catheter and reaching a population of up to 5×10^9 colony-forming units (Ganderton et al, 1992).

The initial step in biofilm genesis is the deposition of a layer of urine constituents (proteins, electrolytes, and organic molecules) called a conditioning film. This step usually occurs within minutes after the device has been implanted (Tieszer et al, 1998; Wollin et al, 1998) and modifies the surface of the biomaterial by providing or blocking possible receptor sites for uropathogens. The next step in biofilm formation is microbial adhesion to the surface of the biomaterial, a process influenced by multiple physical properties such as electrostatic and hydrophobic interactions, ionic forces, osmolality and urinary pH (Gristina, 1987; Pratt-Terpstra et al, 1989; Uyen et al, 1989; Printzen, 1996; Reid et al, 1996, 1999). Following this event, the organism undergoes cell division, forming microcolonies that develop inside a matrix of bacterial exopolysaccharide and glycocalix. Once this point is reached, biofilm eradication is usually not possible with anything less than the removal of the involved biomaterial.

Biofilm formation in some cases is a preliminary step to biomaterial encrustation. Urease-producing bacteria cause an increase in urinary pH and, once attached to the biofilm, lead to the precipitation of magnesium and calcium, forming struvite encrustations across the surface (Sofer and Denstedt, 2000).

Thus the development of a biofilm-resistant stent has to achieve success over several factors: a large number of bacterial species able to cause stent-related infections, deposition of host urinary conditioning films that coat and negate the effects of a desirable surface or coating or both, and the microorganism's ability to destroy and exclude host protection factors and antibiotics and to remain metabolically dormant (Denstedt and Cadieux, 2009).

Without question, the future of urinary catheter development requires a better understanding of biofilm formation and ways to avoid their occurrence. This knowledge along with improvements in biomaterials and in drug elution technology will pave the way for the next evolution in urologic device development.

Principles of Endoscopy

Branden Duffey, DO ● Manoj Monga, MD, FACS

Equipment
Cystourethroscopy
Upper Urinary Tract Endoscopy
Patient Preparation

The purpose of this chapter is to introduce the basic principles of endoscopy as they relate to retrograde instrumentation and visualization of both the lower and the upper urinary tract. In addition to discussing strategies for both routine and difficult retrograde access, emphasis is placed on patient positioning and preparation, basic equipment, and ancillary instrumentation required for both cystourethroscopy and ureteropyeloscopy. In-depth discussion of treatment strategies for specific pathologic processes is beyond the scope of this chapter and the reader is directed to specific chapters throughout this text.

EQUIPMENT

Retrograde visualization of the urinary tract is a routine part of the urologist's practice and may be performed in a variety of settings. Straightforward procedures (i.e., cystoscopy with minimal intervention) may be performed in the office setting and requires only an endoscope, light source, and irrigating fluid. The urologist views the procedure through the optical eyepiece at the proximal end of the instrument. Either xenon or halogen external light sources deliver cool light to the endoscope through a fiberoptic cable. Typical irrigation fluids include sterile water, glycine, or normal saline. If electrocautery use is anticipated, a solution free of electrolytes should be used. Video-endoscopic units, comprising a light source, camera for the endoscope, image processor and recorder, and monitor, are usually arranged on a mobile tower and commonly found in both the office and operating room settings (Fig. 8–1). Images are transmitted to the image processor by a camera attached to the eyepiece and displayed on a viewing monitor. In the case of digital endoscopes there is no eyepiece and the image is sent directly to the image processor. In both cases, still images and live sequences can be transferred to a recording device for incorporation into the medical record, postprocedure review, and patient education. Video-endoscopic units are advantageous in that they (1) avoid surgeon contact with bodily fluids; (2) may facilitate more ergonomic surgeon positioning during the procedure; (3) enhance the teaching of endourologic skills; and (4) may decrease discomfort in male patients during cystoscopy performed using local anesthesia (Patel et al, 2007). Light source modifications, specifically narrow band imaging and porphyrin-based fluorescence, have been developed in efforts to improve the detection of urothelial carcinoma during endoscopy. Narrow band imaging technology filters white light into two separate bands (415 nm and 540 nm) that are absorbed by hemoglobin, which aids in the detection of hypervascular urothelial neoplasia (Herr and Donat, 2008). In fluorescence-based endoscopy, a solution of 5-aminolevulinic acid or hexaminolevulinate is instilled in the bladder and then inspected with blue light (wavelength 380 to 450 nm). These substances aid in tumor detection because they are converted to porphyrins that preferentially accumulate in neoplastic cells and fluoresce red when illuminated with blue light (Kriegmair et al, 1996). Urology-specific endoscopy suites are found in the operating room and generally have full video capabilities in addition to fluoroscopy provided by either a mobile C-arm or endoscopy table. Fluoroscopy is used to perform retrograde pyelography and ureteral stenting and to localize endoscopes and instruments during the procedure. It is imperative that operating room personnel minimize radiation exposure by wearing leaded aprons, thyroid shields, and eyewear.

CYSTOURETHROSCOPY

Indications

Cystourethroscopy is used to directly visualize the anterior urethra, posterior urethra, and the bladder. One of the most common indications for cystourethroscopy is the evaluation of microscopic and gross hematuria. Other indications for cystourethroscopy include evaluation of voiding symptoms, surveillance of urothelial carcinoma, foreign body removal, and assisting in difficult placement of a catheter. Although its primary use is in the diagnosis and treatment of lower urinary tract disorders, it is also used to access the upper urinary tract for both diagnostic and therapeutic interventions.

Specific to the lower urinary tract, cystourethroscopy is an adjunctive procedure that permits macroscopic visualization that may be correlated with signs and symptoms of lower urinary tract pathologic processes. Additionally, fluid and tissue specimens may be obtained for cytologic and histologic evaluation.

The upper urinary tract may be accessed using cystoscopic techniques. Diagnostic evaluation of the upper urinary tract is accomplished by selective intubation of the ureteral orifices and retrograde instillation of contrast material. Ureteral catheters and brushes can be passed into the upper urinary tract to obtain specimens for cytologic and histologic evaluation. In cases of upper tract obstruction, ureteral stents are often placed with cystoscopic assistance. Fluoroscopy is utilized in many, if not all, of these retrograde interventions.

Figure 8–1. Video-endoscopic unit consisting of a portable cart, monitor, light source, image processor, video-recording device, and printer.

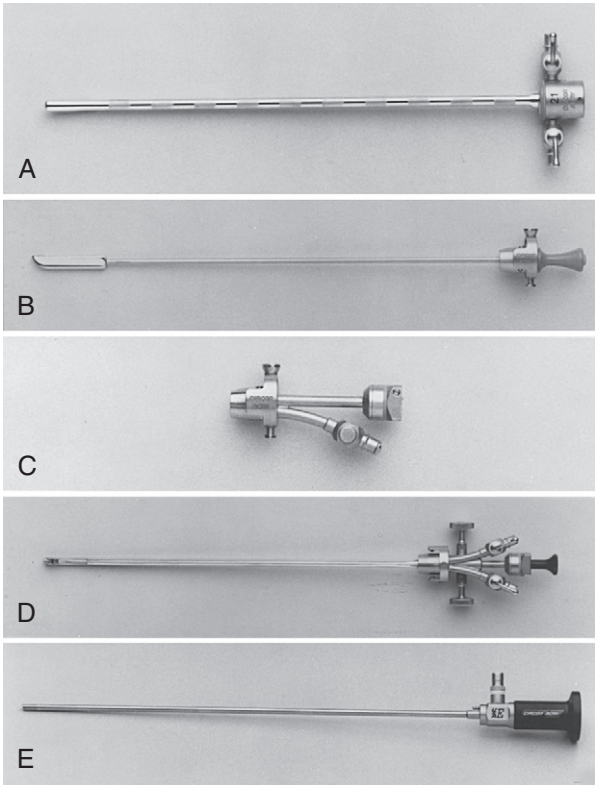

Figure 8–2. Rigid cystoscope consists of metal sheath to which a water source is attached (**A**); obturator (**B**); bridge (**C**); deflector system (Alberran lever) (**D**); and lens to which a light source is attached (**E**). (**A** to **E,** Courtesy of Circon Corp., Santa Barbara, CA.)

Equipment

Cystourethroscopy may be accomplished using either a rigid or flexible endoscope. Both of these instruments allow for thorough endoscopy and access to the upper urinary tract but have specific advantages that may direct their use depending on the clinical situation. Rigid endoscopes are of benefit in that (1) the rod-lens optical system allows for improved image quality compared with the fiberoptic system utilized in flexible endoscopes; (2) a larger working channel allows passage of a wider variety of instruments; (3) the larger lumen allows for improved irrigant flow and thus visualization; (4) they are easier to manipulate and orient during endoscopy; and (5) they are easier to stabilize with one hand, which allows the surgeon's second hand to manipulate accessory instruments through the working channel. Advantages of the flexible cystourethroscope include (1) improved patient comfort; (2) increased options for patient positioning; (3) ease in passage over an elevated bladder neck or median lobe; and (4) the ability to deflect the endoscope tip in any direction, permitting full inspection of the bladder.

Endoscope sizes are expressed using the French (Fr) scale and refer to the outer circumference in millimeters. Pediatric endoscopes are generally 8 to 12 Fr whereas adult scopes range from 16 to 25 Fr. The size of the endoscope selected will depend on the specific procedure performed, the need for additional working instruments, and the degree of irrigant flow that will be required, but in general the smallest diameter endoscope that will accomplish the goals of the procedure is selected to minimize genitourinary tract trauma.

Rigid cystourethroscopes require assembly before use and are composed of a sheath, obturator, bridge, and optical telescopic lens (Fig. 8–2). Markings on the sheath indicate the endoscope size as well as the maximum size of a single instrument or two instruments (as in the case of a bridge with two working channels) the endoscope will accept (Fig. 8–3). Irrigant is instilled through tubing that is attached to the sheath. Obturators are inserted into the working sheath to provide a smooth blunt surface during endoscope passage. Typically, an obturator will be employed for insertion of the rigid cystoscope in females whereas direct visualization will be utilized for cystoscope insertion in males. The

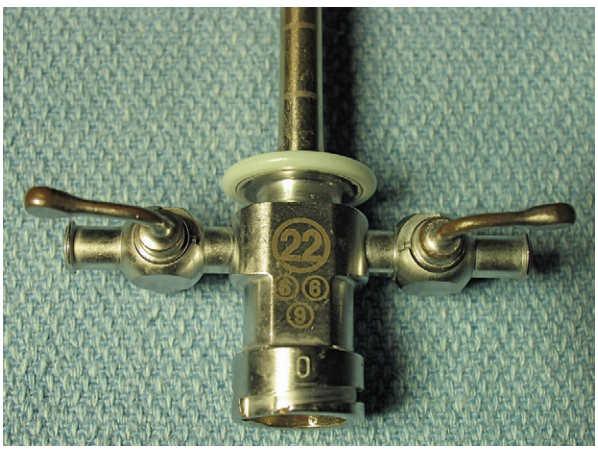

Figure 8–3. Markings on a rigid cystoscope sheath. The largest number indicates the outer diameter (22 Fr). The smaller numbers below indicate the size of the two largest simultaneous instruments (6 Fr) or single largest instrument (9 Fr) that may be passed through the sheath.

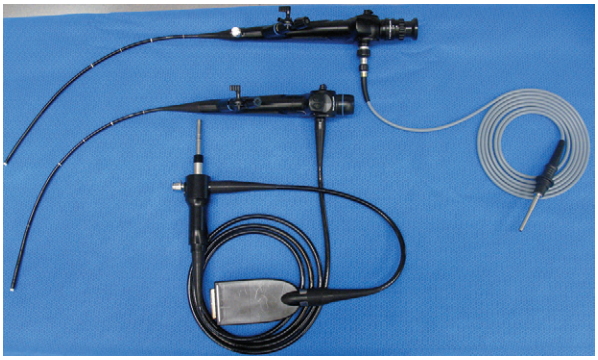

Figure 8–4. Flexible cystoscopes with an attached light source and flexible tips. Imaging systems in flexible cystoscopes are either fiberoptic *(top)* or digital *(bottom)*.

bridge is attached to the sheath and may have one or two working channels, facilitating the passage of instruments into the endoscope. The Albarran bridge enables the urologist to deflect catheters and wires placed through the working channel by manipulating a lever attached to the bridge. The telescopic lens is attached to the sheath by means of the bridge. The light source cable is connected to the telescope.

Telescopes used in rigid cystoscopy utilize a rod-lens system. The telescope's metal shaft contains a series of cylindrical lenses with air interfaces that transmit both light to the object to be viewed and the image to the eyepiece. Telescopes are available with different angled tips to enhance viewing of specific structures. Urethroscopy is best accomplished with a 0-degree or 12-degree lens providing a straight-ahead view. In the bladder, a 30-degree lens is commonly used and provides excellent visualization of the trigone, dome, and posterior and lateral walls. Telescopes with a 70-degree lens provide better visualization of the anterior wall, dome, and inferior lateral walls. Telescopes with a 120-degree lens are utilized for inspection of the bladder neck.

Flexible cystourethroscopes are available in fiberoptic and digital models (Fig. 8–4). Traditional flexible endoscopes contain fiberoptic bundles within a flexible shaft that illuminate the viewing area and transmit images to the eyepiece. The tip of the endoscope may be deflected up to 210 degrees by a lever near the eye piece. The endoscope shaft has a channel that is shared for irrigation and the passage of working instruments. Recent advances in solid-state camera chips have facilitated the development of digital cystourethroscopes. In these models an imaging chip is placed at the distal end of the endoscope that converts light into an electrical charge that is eventually displayed on a viewing screen. Digital systems are advantageous because they have higher optical resolution, contrast, and color differentiation; in many centers digital systems have replaced fragile fiberoptic systems, which are prone to breakage (Quayle et al, 2005; Borin et al, 2006). However, the durability of digital scopes has yet to be established.

Patient Preparation

Before performing cystourethroscopy it is important to ensure the patient does not have a urinary tract infection, because mechanical manipulation and bladder distention can exacerbate the infection. Informed consent should be obtained after explaining the procedure, its purpose, and the associated risks and benefits. **Antimicrobial prophylaxis is not recommended before simple cystourethroscopy unless patient risk factors are present** (Table 8–1) (Wolf et al, 2008). **When risk factors are present or additional manipulation (e.g., bladder biopsy, ureteral catheterization) is anticipated, prophylactic antibiotics should be administered before the procedure with an expected treatment duration of 24 hours or less.** Antimicrobial agents of choice in these situations are the fluoroquinolones and trimethoprim-sulfamethoxazole. The patient is placed in the dorsal lithotomy position for rigid cystourethroscopy or the supine position for flexible cystourethroscopy (with a slight frog-leg position for females) and prepped and draped sterilely.

Table 8–1.

Patient Risk Factors Precluding Simple Cystoscopy Without Antimicrobial Prophylaxis

Advanced age
Anatomic anomalies of the urinary tract
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Externalized catheters
Colonized endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Preoperative intraurethral injection of a water-soluble lubricant-anesthetic is often used in an attempt to provide greater patient comfort and enable the surgeon to access the upper urinary tract and perform bladder and urethral biopsies as well as bladder fulguration. In male patients a urethral clamp may be used to retain the urethral anesthetic, allowing for prolonged direct contact with the urethral mucosal surfaces before instrumentation. Goldfischer and colleagues (1997) found that 30 mL of intraurethral lidocaine gel left to dwell for 20 minutes before rigid cystoscopy significantly reduced procedure-related pain in men but not women. Most randomized prospective placebo-controlled studies of flexible cystoscopy conclude that lubricant-anesthetic instillation does not decrease patient discomfort (Patel et al, 2008b).

Several strategies have been evaluated to improve patient comfort and tolerance during cystourethroscopy. Positioning the video monitor so the patient and surgeon can simultaneously view the procedure may be beneficial in male patients but not females (Patel et al, 2007, 2008a). A real-time explanation of the procedure may decrease patient anxiety and discomfort. Specifically, male patients are reassured and counseled that discomfort will be encountered in the membranous and prostatic urethra; they are informed that the length of this segment is 2 to 5 cm, and they are encouraged to relax their pelvic muscles during this portion of the examination to facilitate scope passage (Taghizadeh et al, 2006).

Technique

Before cystourethroscopy the urethral meatus should be inspected. If it is not large enough to permit passage of the endoscope, sequential dilation may be performed using well-lubricated metal sounds. Once the urethral meatus is large enough to permit passage of the endoscope, the sheath should be generously lubricated and a survey of lower urinary tract anatomy is performed.

In males the glans is grasped and the penis held on stretch at 90-degree angle to the abdominal wall during visualization of the

Figure 8–5. When performing flexible cystoscopy the distal penis is grasped between the surgeons third and fourth fingers. This allows the penis to be placed on continuous gentle stretch while the thumb and index finger guide the cystoscope into the urethral meatus.

fossa navicularis, penile urethra, and bulbar urethra. For flexible cystoscopy, the glans is held on stretch between the third and fourth digits, allowing the thumb and forefinger to remain free to guide the endoscope through the urethra (Fig. 8–5). The cystourethroscope tip is inserted and the irrigant turned on, distending the urethra to allow for clear visualization. Periurethral glands of Littre are noted as they enter the urethra dorsally. Strictures may be encountered that require dilation (see Chapter 7) or visual internal urethrotomy (see Chapter 36). The membranous urethra is identified by its striated mucosa and may visibly contract. As the membranous urethra is traversed, the cystourethroscope must be directed anteriorly to navigate the transition from the proximal bulbar urethra to the membranous urethra and into the prostatic urethra. As the distal prostatic urethra is entered, the verumontanum is identified posteriorly. Prostate length, the lateral lobes, and the median lobe are evaluated as the cystourethroscope continues its passage to the bladder. Additional anterior angulation may be necessary to elevate the endoscope over the bladder neck and pass into the bladder.

In females the urethral meatus is visually inspected and then cystoscopy is performed by inserting the cystourethroscope and directing it cephalad and anterior. For rigid cystoscopy, it is our preference in most cases to bluntly cannulate the female urethra with an obturator in the sheath and perform urethroscopy while withdrawing the cystourethroscope.

Once the bladder is entered it should be systematically surveyed and the observations recorded. A 30-degree telescope is generally used for initial inspection. The trigone and interureteric ridge are identified just inside the bladder neck. The ureteral orifices, located at the lateral most aspects of the interureteric ridge, should be evaluated for location, number, and the efflux of urine. The floor and posterior wall of the bladder are evaluated next. Systematic inspection of the dome, anterior wall, and lateral walls is performed by rotation of the cystoscope to redirect the 30-degree lens, or with the assistance of a 70-degree telescope, using the air bubble at the dome as a landmark. The anterior wall just beyond the bladder neck is best evaluated using the 70-degree telescope in the partially filled bladder and applying manual suprapubic pressure to bring it into view. After thorough inspection of the bladder and urethra, the bladder is drained and the instrument removed.

Special Considerations

Suprapubic Tubes

Patients with urinary drainage from a suprapubic catheter deserve special mention based on the additional clinical scenarios and technical aspects associated with evaluation of the lower urinary tract. Indications for cystourethroscopy are the same as described earlier but also include regular inspection for bladder stones and surveillance for bladder tumors in patients with suprapubic catheters longer than 5 to 10 years (Kaufman et al, 1977; DeVivo et al, 1985; Hess et al, 2003; Subramonian et al, 2004). Endoscopy may be performed per urethra (when patent) or through the suprapubic tract. Navigation and visualization of the suprapubic tract is usually straightforward in patients with normal body habitus and a mature urinary tract. Conversely, immature urinary tracts or those traversing a large mobile pannus may be difficult to follow. When these situations occur, it is helpful to place a wire through the suprapubic tract into the urinary bladder to guide the endoscope during inspection. The wire can be backloaded into the working channel to further guide the endoscope. Rigid cystoscopes may fit into large mature urinary tracts and are advantageous when ancillary procedures are indicated, but they may be difficult to maneuver in long urinary tracts and orientation in the bladder can be challenging. Flexible cystoscopes offer improved maneuverability and may fit into smaller urinary tracts. For prolonged endoscopic procedures, continuous irrigation can be facilitated by endoscopy through the urinary tract with simultaneous drainage of irrigation through the urethra or vice versa. Identification of the ureteral orifices may be challenging owing to edema related to the indwelling catheter or to the angle of vision through the tract. This may be overcome by the use of a flexible cystoscope to visualize the efflux of urine after administration of intravenous indigo carmine or methylene blue.

Continent Urinary Diversions

Continent urinary diversion is a common urinary reconstructive technique used after cystectomy. Diversions can be broadly categorized as cutaneous continent diversions or orthotopic diversions. In cutaneous continent urinary diversions, detubularized bowel is arranged to create a urinary reservoir with a catheterizable limb anastomosed to the umbilicus or another site on the abdominal wall that provides access for drainage. In orthotopic diversions the urinary reservoir is anastomosed to the urethra, allowing for volitional voiding. Detailed understanding of the diversion construction is crucial before any endoscopic intervention. Key elements include the type and location of the ureteroenteric anastomosis, the presence or absence of an afferent limb, and the continence mechanism employed. Many neobladders have an afferent limb extending from the reservoir to which the ureters are anastomosed. In orthotopic neobladders the continence mechanism is the external urinary sphincter. Typical continence mechanisms in cutaneous catheterizable diversions include the tunneled appendix (Mitrofanoff), the tapered/imbricated terminal ileum and ileocecal valve, and the intussuscepted nipple valve (see Chapter 86). The Mitrofanoff and tapered/imbricated ileal continence mechanisms are fragile, and aggressive manipulation can lead to stomal stenosis and/or loss of urinary continence.

In these cases, simple visualization and reservoir filling through the catheterizable channel may be performed with small caliber flexible endoscopes (e.g., a flexible ureteroscope), but if ancillary procedures are indicated, percutaneous access should be used (Patel and Bellman, 1995). Similarly, percutaneous access

Key Points: Cystourethroscopy

- Endoscope sizes are expressed using the French (Fr) scale and refer to the outer circumference in millimeters.
- In general the smallest diameter endoscope that will accomplish the goals of the procedure is selected to minimize genitourinary tract trauma.
- Antimicrobial prophylaxis is not recommended before simple cystourethroscopy unless patient risk factors are present.
- A prophylactic antimicrobial agent should be administered before cystoscopy with anticipated additional manipulation (e.g., biopsy, fulguration, ureteral catheterization) and simple cystoscopy in patients with risk factors.

for interventions other than simple diagnostic procedures in orthotopic neobladders may avoid the risk of bladder neck contracture or sphincteric damage. In both types of diversions, orientation and visualization can be impaired by mucus and debris, bowel peristalsis, mucosal folding, and tortuous afferent limbs. Steps to overcome these difficulties include thorough irrigation and use of fluoroscopy with intravesical administration of a contrast agent to identify the os of the afferent limb and guide endoscope advancement. When present, afferent limbs are best visualized with flexible endoscopes because they are best suited to navigate limb folding, kinking, and tortuosity.

UPPER URINARY TRACT ENDOSCOPY

Indications

Ureteroscopy is a standard urologic technique that provides direct visualization of the upper urinary tract, facilitating both diagnostic and therapeutic interventions. Ureteroscopy is most commonly used for the treatment of nephrolithiasis (see Chapter 48). Other common indications include evaluation of lateralizing hematuria, abnormal urinary cytology, and abnormal upper tract imaging studies. Surveillance and treatment of upper tract urothelial carcinoma may be performed using ureteroscopic techniques (see Chapter 53). Ureteroscopy may also be utilized in cases of ureteral stricture and ureteropelvic junction obstruction (see Chapter 41).

Equipment

Ureteroscopes

Ureteroscopes are available as flexible or semirigid instruments. Semirigid ureteroscopes have a shaft that is able to accommodate a small amount of bend and typically have a tapered distal tip (6.0 to 7.5 Fr) that gradually widens toward the eyepiece (8.0 to 9.5 Fr). The metal shaft contains fiberoptic bundles for light and image transmission as well as an irrigation channel and one or more working channels (2.4 to 4.0 Fr) for the passage of instruments. A digital semirigid ureteroscope based on a charge-coupled device (CCD) video-chip technology has been released by Olympus (Center Valley, PA). The clinical benefit of digital semirigid ureteroscopy has yet to be determined because the potential improvement in visualization is accompanied by an increase in the distal tip diameter that may impair ureteral intubation. Compared with their flexible counterparts, semirigid ureteroscopes offer larger irrigation channels, improved irrigant flow and visualization, and generally a larger field of view. **Semirigid ureteroscopy is typically used for diagnosis and treatment of pathologic processes below the iliac vessels.** In female patients the semirigid endoscope can frequently be passed safely into the proximal ureter, but this is less common in males. In males, a longer urethral length, a relatively immobile prostatic urethra, and more developed psoas muscles make semirigid ureteroscope navigation past the iliac vessels difficult. Caution should be exercised when performing semirigid ureteroscopy in the proximal ureter because the shaft can accommodate some flexion but may bend or even fracture as the shaft fatigues.

Flexible ureteroscopes contain imaging systems and working channels within a flexible shaft that allows for complete visualization of the entire upper urinary tract including the lower pole of the kidney. Flexible ureteroscopy is typically used for the diagnosis and treatment of pathologic processes above the level of the iliac vessels. Flexible ureteroscopy in the more distal portions of the ureter may be challenging owing to the inherent flexible nature of the instrument (lack of rigidity) and difficulty stabilizing the distal portion of the instrument.

Table 8–2 lists some of the currently available flexible ureteroscopes. The distal tip of these endoscopes ranges from 5.3 to 8.7 Fr and gradually tapers toward the proximal shaft. Active deflection of the distal tip typically ranges from 130 to 250 degrees in one direction and 160 to 275 degrees in the other, with newer flexible ureteroscopes having exaggerated primary deflection that allows

Table 8–2.

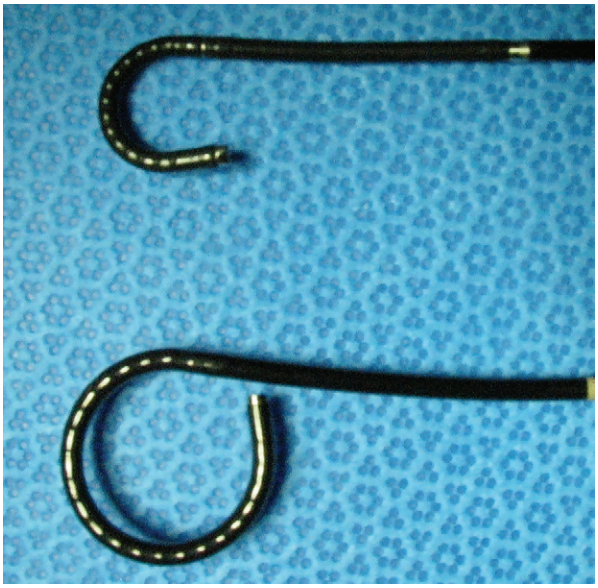

Figure 8–6. Flexible ureteroscopes with standard primary deflection *(above)* and exaggerated primary deflection *(below)*.

for improved visualization of the lower pole and increased ease of manipulation (Fig. 8–6) (Monga et al, 2007). Secondary active deflection, available in the DUR-8 Elite (Gyrus-ACMI, Southborough, MA) and the Stryker Flexvision (Stryker Endoscopy, San Jose, CA), refers to a segment of active deflection several centimeters proximal to the area of primary deflection that, when activated by a second hand-piece lever, provides an additional 130 degrees of visualization and facilitates entry into the lower pole calyx. Passage of working instruments (e.g., lasers, baskets) tends to increase the stiffness of the ureteroscope shaft, reduce maximal deflection, and decrease irrigation flow through the shared 3.6-Fr channel (Abdelshehid et al, 2005; Bach et al, 2008; Paffen et al, 2008). Imaging systems in flexible ureteroscopes are either traditional fiberoptic systems or digital, based on CCD or complementary metal–oxide–semiconductor (CMOS) technology. Preliminary clinical experience suggests that digital ureteroscopes offer improved optical resolution compared with their fiberoptic counterparts (Traxer et al, 2007). Technologic advancements in flexible ureteroscopes have enabled reductions in shaft diameter, improved visualization, and provided a greater range of deflection, but they remain fragile instruments with significant purchase and repair costs (Chiu et al, 2004; Sung et al, 2005; Monga et al, 2006).

Ancillary Equipment

Wires. Guidewires used during retrograde instrumentation serve to provide access to a particular area of the urinary tract and serve as a guide to pass catheters, stents, and sheaths (Clayman et al, 2004; Liguori et al, 2008). Guidewire properties vary with respect to length, diameter, composition, tip design, surface coating, and shaft rigidity. Guidewire diameters and lengths range from 0.018 to 0.038 inch and 145 to 280 cm, respectively. The ideal guidewire should have a flexible lubricous tip allowing for easy atraumatic passage through a tortuous, obstructed ureter while providing sufficient rigidity of the shaft for the passage of catheters and instruments. The physical properties and design of the various wires lend to their use in different situations.

Basic guidewire composition consists of an inner core that determines shaft rigidity and an outer covering responsible for low resistance passage through the ureter. The outer surface, designed to reduce friction during passage, is typically coated with either a polytetrafluoroethylene (PTFE)-jacketed tightly coiled stainless steel spring or a hydrophilic polymer. The distal tip is a 3- to 15-cm section designed to be flexible and soft, minimizing tissue trauma during passage. Distal tips may be straight or angled and may be coated with a hydrophilic polymer. The PTFE-coated floppy tipped Bentson-type wire is a typical general purpose guidewire. Hydrophilic polymer coated wires are excellent for maneuvering in a tortuous ureter and around impacted ureteral calculi but often lack sufficient rigidity for the passage of catheters or stents and may migrate out of the ureter during manipulation. Extra-stiff wires with a stainless steel core add increased shaft rigidity (resistance to kinking) and are commonly utilized for passage of ureteral access sheaths, catheters, and coaxial or balloon ureteral dilators. Hybrid wires, such as the Sensor (Boston Scientific, Natick, MA), combine a hydrophilic tip for ease of passage with a PTFE-coated nickel-titanium (nitinol) shaft for increased stiffness to facilitate coaxial placement of stents or sheaths.

Flexible ureteroscope passage may be facilitated by backloading it over a wire and passing it into the ureter under visual or fluoroscopic guidance. Passage over an extra-stiff wire can lead to working channel damage and costly repairs (Vanlangendonck and Landman, 2004). Dual floppy-tip wires have a softer proximal tip and may reduce working channel damage.

Ureteral Dilators. Ureteral dilation is utilized in the treatment of strictures and to facilitate ureteroscopy. **Ureteral dilation is most commonly required at the ureterovesical junction, the narrowest portion of the ureter, to permit ureteroscope passage.** Dilation may be needed more proximally in cases of benign, malignant, or iatrogenic strictures. Coaxial dilation may be accomplished by passing successively larger tapered polyethylene catheters; however, this may be associated with significant shearing forces and ureteral injury (Ford et al, 1984; Gaylis et al, 2000). **Balloon dilators** exert radial force on a specific ureteral segment through 4- to 7-Fr catheters passed over a wire with inflatable balloons ranging from 4 to 10 cm in length, have a 4- to 10-mm outer diameter, and can exert pressures up to 20 atm (Hendlin et al, 2005). In-vitro testing can predict which balloons will function the best if presented with tight radial constriction (Hendlin et al, 2005). Typically, a retrograde pyelogram is first performed to delineate the area of narrowing. With the use of fluoroscopy the radiopaque markers at the proximal and distal ends of the balloon are placed across the area needing treatment. Then, an assistant fills the balloon with a contrast agent using a pressurizing system while the surgeon stabilizes it to prevent inadvertent migration.

Older, larger-diameter ureteroscopes routinely required ureteral dilation for successful passage into the upper tract. **Technologic advancements in the field of endoscopy have facilitated the miniaturization of endoscopes and eliminated the need for ureteral dilation in routine cases** (Rodrigues et al, 1990; Stoller et al, 1992; Harmon et al, 1997). **Ureteral dilation is not necessary in every ureteroscopic intervention and should be performed only when ureteroscope passage is impaired.**

Irrigation Systems. Irrigation during ureteroscopy is essential to maintain a clear visual field by displacing stone fragments, blood, and cellular debris and by distending the luminal structure under inspection. Irrigation systems either are gravity dependent (passive) or are driven by a hand or foot pump (active). Passive system irrigation systems provide the least amount of impulse, which may prevent stone migration, but are limited in the ability to provide enough force necessary for specific intraoperative conditions

(Hendlin et al, 2008). Gravity irrigation alone may not provide sufficient flow to clear the visual field while instruments are in the working channel (Abdel Razzak and Bagley, 1994; Chiu et al, 2003). Active hand irrigation can generate renal pressures of 100 mm Hg or more (Auge et al, 2004a). Although active irrigation systems allow for finer control of the amount and force of irrigation used, they generate higher pressures, which can lead to stone migration, bleeding from hydrodistention, and pyelolymphatic or pyelovenous fluid absorption. **Care should be taken to use only as much irrigation needed to provide a clear visual field.** Ureteral access sheaths may be used to decrease renal pressures during ureteroscopy (Auge et al, 2004a). Irrigants used are typically physiologic solutions (i.e., normal saline). However, with a ureteral access sheath in place, fluid absorption is low (estimated to be 1 mL/min of ureteroscopy) and may permit the use of alternative irrigants (i.e., water) that improve light transmission and visibility (Cybulski et al, 2004a). Studies utilizing water for ureteroscopy have focused on short (<1 hour), uncomplicated procedures. Pharmacologic adjuvants have recently been evaluated as a way to further decrease intraluminal pressure through ureteropelvic relaxation during ureteroscopy. In-vitro and in-vivo studies have shown that catecholamines, calcium channel blockers, and a potassium channel opener (PKF 217–744b) relax ureteral smooth musculature (Selmy et al, 1994; Weiss et al, 2002; Holst et al, 2005; Jung et al, 2008). Future research is required to determine if the addition of a muscle relaxant drug to the irrigation fluid is a practical idea to facilitate a safer endoscopic procedure.

Ureteral Access Sheaths. The ureteral access sheath was initially developed in the 1970s to facilitate insertion of flexible ureteroscopes (Takayasu and Aso, 1974). These sheaths are placed over a wire, consist of an outer sheath and a tapered dilating obturator, are frequently coated with hydrophilic polymers for easier insertion, and range in outer diameter and length from 9 to 18 Fr and 20 to 55 cm, respectively (Fig. 8–7).

Ureteral access sheaths have been shown to significantly reduce renal pressures during ureteroscopy, functioning as an open conduit into to the kidney, allowing fluid to enter through the endoscope and exit through the sheath around the scope (Landman et al, 2002; Rehman et al, 2003; Auge et al, 2004a). **Shorter operative times and reduced costs have been demonstrated when ureteral access sheaths are utilized during ureteroscopy.** Use of these sheaths during ureteroscopy provides direct visualization of ureteroscope insertion and simple reentry and facilitates ureteroscopic basketing and retrieval of calculi that would otherwise require lithotripsy into smaller fragments able to pass spontaneously (Kourambas et al, 2001; Monga et al, 2001). Ureteral access sheaths decrease endoscope damage and prolong the period between servicing by reducing both axial forces on the ureteroscope and working channel trauma from repetitive backloading over a wire (Pietrow et al, 2002). Kourambas and associates (2001) noted decreased postoperative symptoms when a ureteral access sheath was used for ureteral dilation when compared with balloon dilation.

Figure 8–7. The distal *(top)* and proximal *(bottom)* portions of a typical ureteral access sheath. The distal portion of the internal obturator *(blue)* is tapered, gradually widening to meet the hydrophilic sheath. The access sheath is placed over a super-stiff guidewire and the internal obturator is removed before ureteroscope insertion. The proximal end of the obturator accepts a Luer-Lok syringe, facilitating retrograde pyelography.

Although these sheaths are associated with cost savings and shorter operative times there is only a single series addressing stone-free rates after ureteroscopy with adjunctive ureteral access sheath placement: in their retrospective review in 2005 of 256 ureteroscopic procedures for the removal of renal calculi, L'Esperance and colleagues reported the overall stone-free rate in the ureteral access sheath group was significantly higher than in the non–ureteral access sheath group (79% and 67%, respectively). All studies evaluating the impact of a ureteral access sheath on outcomes and cost are retrospective—no level 1 evidence exists to support or refute their use.

Concerns regarding ureteral stricture formation from ureteral access sheath–induced ischemia and necrosis have largely been disregarded, because the incidence of stricture after ureteroscopy with a ureteral access sheath has been demonstrated to be the same as that with ureteroscopy alone (1.4%) (Delvecchio et al, 2003; Vanlangendonck and Landman, 2004). Rapoport and colleagues (2007) evaluated return trips to the emergency department after ureteroscopy and observed that use of a ureteral access sheath increased the likelihood of return to the emergency department if no stent was placed. They advocate ureteral stent placement in cases in which a ureteral access sheath has been used.

Indications for use of these sheaths has been extended as an adjunct to percutaneous nephrolithotomy. The ureteral access sheath simplifies ureteroscope passage into the upper tract with the patient in the prone position. The ureteroscope is advanced into the calyx of interest and facilitates percutaneous access by providing a landmark for needle puncture and may be used to snare wires to establish through-and-through access. Landman and associates (2002) found that placement of a ureteral access sheath during percutaneous nephrolithotomy significantly reduces intrarenal pressures and increases irrigant flow. Initial clinical experience treating large upper tract calculi using a combined percutaneous and retrograde approach with a ureteral access sheath in place has been favorable. A large renal stone burden may be successfully managed through a single percutaneous access with limited blood loss and no effect on stone-free rates (Landman et al, 2003; Marguet et al, 2005).

The 12/14-Fr ureteral access sheath is our most commonly utilized sheath and can be placed in most unstented patients. At this size, flow and intrarenal pressures are improved compared with the 10/12-Fr sheath and are equivalent to the larger 14/16 Fr sheath (Rehman et al, 2003). If the 12/14-Fr sheath cannot be passed, the 10/12-Fr sheath is used. It is the preference at our institution to use a 35-cm sheath in female patients and a 45-cm sheath in male patients.

Two problems associated with the use of ureteral access sheaths include buckling in the bladder during insertion and kinking after removal of the inner dilator. In-vitro studies can be used to predict which ureteral access sheath will function best with regard to buckling or kinking (Monga et al, 2004b; Pedro et al, 2007a). The Flexor sheath (Cook Medical, Bloomington, IN) is least likely to buckle at forces commonly used for sheath placement, an observation validated in a randomized prospective clinical trial (Monga et al, 2004a; Pedro et al, 2007b).

Intracorporeal Lithotriptors. Several intracorporeal lithotriptors are reviewed in detail in Chapter 48. In this section

the intracorporeal lithotriptors most commonly utilized during ureteroscopy area reviewed. **Ballistic lithotripsy utilizes pneumatic or electrokinetic energy sources to forcefully drive a projectile or ballistic body against a probe tip, creating a "jackhammer" effect** (Leidi et al, 1997; Keeley et al, 1999; Aghamir et al, 2003). Advantages of ballistic lithotripsy include reusable components and thus lower costs, ability to fragment all types of calculi including calcium monohydrate and cystine, and a high safety margin because little heat is generated at the probe tip. Disadvantages include the inability to simultaneously remove fragments while breaking up stones, lack of effective probes for use during flexible ureteroscopy, and stone retropulsion (Michel et al, 2002; Auge et al, 2004b). The lack of effective flexible probes prohibits flexible ureteroscopy, limiting its use to semirigid ureteroscopes. Proximal migration may place stone fragments in inaccessible locations requiring either flexible ureteroscopy or extracorporeal shockwave lithotripsy. Delvecchio and associates (2000) described a ballistic lithotripter combined with a suction device that facilitated fragment removal while preventing proximal migration and yielded a 3-month stone-free rate of 95%.

Electrohydraulic lithotripsy (EHL) probes utilize electrical energy to overcome the resistance between two insulated electrodes to produce a spark (Vorreuther and Engelmann, 1995). **The spark leads to formation of cavitation bubbles that may collapse symmetrically or asymmetrically resulting in a secondary shockwave or high-speed microjets, respectively. Both secondary shockwaves and microjets are involved in stone fragmentation** (Willscher et al, 1988; Denstedt and Clayman, 1990). Advantages of EHL include low cost and probe flexibility. A recent evaluation of flexible ureteroscopes showed that the 1.9-Fr EHL probe caused a similar decrement in maximal tip deflection compared with the 200-µm laser fiber, allowing for lithotripsy throughout the entire upper urinary tract (Abdelshehid et al, 2005). The main disadvantage of EHL is its propensity to damage the ureteral mucosa and associated ureteral perforation. The diameter of the cavitation bubble varies with the energy applied but can be 1.5 cm or greater and deliver substantial energy to surrounding tissues. Reported ureteral perforation rates may be as high as 40%, with the risk of perforation higher in the treatment of stones that are harder (higher energy requirements) or impacted (mucosal edema and impaired visualization) (Raney, 1978). Retropulsion of stones with EHL is more pronounced than with the holmium:yttrium-aluminum-garnet (YAG) laser and may decrease stone-free rates (Yang and Hong, 1996; Teichman et al, 1997).

The holmium:YAG laser is recognized to be the gold standard for ureteroscopic intracorporeal lithotripsy. The holmium laser crystalline matrix is a YAG crystal doped with chromium, thulium, and holmium (Teichmann et al, 2007). The pulsed solid-state laser operates in the near-infrared portion of the electromagnetic spectrum at 2100 nm. **At this wavelength the laser energy is strongly absorbed by water molecules and propagates no farther than 0.5 to 1.0 mm, providing a substantial safety margin during intracorporeal lithotripsy.** At 2100 nm the laser energy is effectively delivered through flexible silica quartz fibers ranging from 200 to 1000 µm. Generally, 200- to 400-µm fibers are used during ureteroscopy. **Holmium laser lithotripsy occurs primarily through a photothermal mechanism resulting in calculus vaporization** (Dushinski and Lingeman, 1998; Wollin and Denstedt, 1998).

Advantages of the holmium:YAG laser are many and include:

- All stone types can be fragmented (Wollin and Denstedt, 1998).
- Lithotripsy produces smaller stone fragments compared with other lithotriptor systems, reducing the need to basket fragments (Teichman et al, 1998).
- The production of weak shock waves causes less calculus retropulsion compared with other lithotriptors (Teichman et al, 1998; Vassar et al, 1999).
- Stone-free rates or 90% or more have been reported in several case series (Grasso, 1996; Yip et al, 1998; Sofer et al, 2002).
- There is a wide margin of safety with less adjacent tissue trauma (Grasso and Chalik, 1998; Wollin and Denstedt, 1998).

The primary disadvantage of the holmium:YAG laser is the high initial purchase price of the generator and laser fibers. However, this disadvantage may be offset by the wide variety of other upper tract conditions that may be addressed using this laser, including ureteral strictures, ureteropelvic junction obstruction, urothelial carcinoma, and symptomatic calyceal diverticula. **Limiting pulse energy to 1.0 J or less and varying the pulse frequency as needed can facilitate efficient lithotripsy by yielding smaller stone fragments, reducing stone retropulsion, and minimizing laser fiber damage** (Spore et al, 1999; Lee et al, 2003).

Stone Migration Devices. The risk of proximal migration is influenced by the type of intracorporeal lithotriptor used, irrigant fluid pressure, stone volume, site and degree of calculus obstruction, and degree of proximal ureteral dilation (Delvecchio et al, 2000; Lee et al, 2003; Ahmed et al, 2009). Proximal migration may result in lower stone-free rates and increased need for additional procedures (Teichman et al, 1997). Several devices have been developed to minimize calculus retropulsion and proximal migration during lithotripsy (Fig. 8–8). The **Stone Cone** (Boston Scientific, Natick, MA) is composed of a nitinol-wrapped stainless steel wire arranged in concentric coils and placed proximal to calculi before lithotripsy (Dretler, 2001). The Stone Cone has been shown to reduce the incidence of residual stone fragments larger than 3 mm and the need for auxiliary procedures (Desai et al, 2002). The **NTrap** (Cook Medical, Bloomington, IN) consists of a mesh netting composed of tightly woven nitinol fibers that is deployed through a 3-Fr catheter and placed proximal to calculi functioning as a backstop (Holley et al, 2005). In-vitro studies have shown that the Stone Cone and NTrap eliminated retropulsion and equally improved fragmentation efficiency during holmium laser lithotripsy (Lee et al, 2008). The **Accordion** (PercSys, Palo Alto, CA)

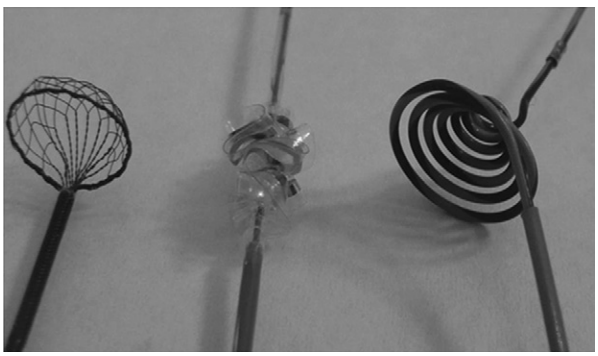

Figure 8–8. Stone migration devices designed to prevent calculus retropulsion during lithotripsy. *From left to right:* NTrap (Cook Medical, Bloomington, IN), Accordion (PercSys, Palo Alto, CA), and Stone Cone (Boston Scientific, Natick, MA).

consists of a two-part nylon and stainless steel guidewire with a short length of polyurethane film attached to the wire sections that forms a bottle-brush–like obstruction within the ureteral lumen preventing stone retropulsion (Chew, 2007). An in-vitro study showed that the anti-retropulsion section of the Accordion was significantly more resistant to laser damage compared with other stone migration devices (Vejdani et al, 2009). Viscous lubricant and lidocaine jelly have been injected proximal to calculi to improve lithotripsy, proximal migration rates, and stone-free rates (Ali et al, 2004; Mohseni et al, 2006; Zehri et al, 2008). **UroJel** (Fossa Medical, Boston, MA) is a thermosensitive polymer that is solid at body temperature and liquid at cooler temperatures (Mirabile et al, 2008). It is deployed proximal to a stone through a ureteral catheter and temporarily occludes the ureter preventing proximal migration. After lithotripsy, polymer dissolution occurs by irrigating it with cool saline. A recent in-vitro study showed that UroJel effectively occludes the ureter during ureteroscopic lithotripsy without damaging the urothelium (Mirabile et al, 2008).

Baskets. Ureteroscopic baskets are most commonly utilized to retrieve ureteral and renal calculi but are also of use in ureteral tumor biopsy. Baskets are composed of flat, round, or triangular wires of either nitinol or stainless steel and are configured into tipped (helical or spherical) or tipless designs. Basket size ranges from 1.3 to 3.2 Fr. They are deployed under direct vision through the ureteroscope and are activated with a handheld device that controls basket opening and, in some cases, rotation and deflection. Basket size, configuration, material, opening characteristics, and safety profiles may direct the surgeon to use a specific basket depending on the clinical situation.

Nitinol-based wires are advantageous in that they are flexible, are kink resistant, and permit a tipless basket design (Fig. 8–9). The tipless design is less traumatic during use in the ureter and kidney compared with tipped baskets, especially when retrieving or repositioning calyceal stones (Honey, 1998; el-Gabry and Bagley, 1999; Kourambas et al, 2000). The flexibility of nitinol baskets is superior to that of their stainless steel counterparts, allowing for consistent retrieval from lower pole calyces (Honey, 1998). Smaller baskets (≤1.5 Fr) improve irrigant flow and may permit passage of a laser alongside it in the ureteroscope working channel, which is a distinct advantage when multiple exchanges between the basket and the intracorporeal lithotripter are anticipated or when calculi are entrapped in the basket (Canales et al, 2006). Some basket models have rotation or deflection capabilities that may improve stone capture and retrieval and assist in the lithotripsy of entrapped calculi (Canales et al, 2006; Zeltser and Bagley, 2007). Flat wire design baskets are useful in the biopsy and retrieval of papillary ureteral lesions. Stainless steel baskets offer improved radial dilation forces, which may be beneficial when significant ureteral edema or stone impaction is present (Hendlin et al, 2004). Drawbacks of stainless steel baskets include an increased tendency for ureteral perforation and decreased flexibility, which limits their use in flexible ureteroscopes. **Complications of ureteroscopic basketing range widely in severity and include ureteral avulsion, intussusception, abrasion, perforation, postoperative stricture formation, and basket breakage or entrapment** (de la Rosette et al, 2006). **The following principles are key in preventing basketing-related complications: (1) avoidance of forceful basket manipulation, (2) limiting retrieval to calculi or fragments that are small enough to be easily extracted with minimal trauma, (3) direct visualization of the basket and its contents at all times, and (4) avoiding contact of the laser with the basket unless the laser is employed intentionally to release an entrapped stone.**

PATIENT PREPARATION

A variety of techniques and approaches may be used to access, visualize, and treat pathologic processes of the upper urinary tract. The methods presented here reflect our techniques and preferences, but the basic endoscopic principles apply to all surgeons performing ureteroscopy.

Before performing ureteroscopy, informed consent must be obtained, specifically addressing the purpose of the procedure, the associated risks and benefits, the potential complications, and the possibility of inserting an indwelling ureteral stent. Anesthetic choices include local anesthesia with or without intravenous sedation, regional anesthesia (either spinal or epidural), and general anesthesia (Cybulski et al, 2004b; Park et al, 2004; Reisiger et al, 2007). General anesthesia is most commonly used at our institution, especially during lithotripsy when inadvertent patient movement could result in ureteral trauma. Most ureteroscopic procedures can be

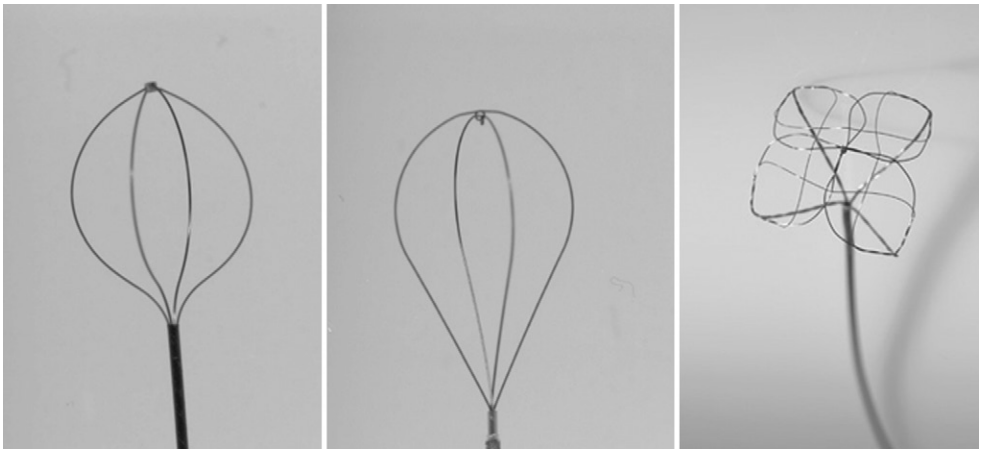

Figure 8–9. Nitinol baskets utilized in ureteroscopy. *From left to right:* 1.5-Fr Halo (Sacred Heart Medical, Minnetonka, MN) used for routine ureteral and pelvicalyceal stone retrieval; 2.2-Fr N-Circle (Cook Medical, Bloomington, IN) basket frequently utilized for retrieving adherent intrarenal calculi; and 2.4-Fr N-Compass (Cook Medical, Bloomington, IN) with a multiwire parachute-like basket well suited for capturing small stone fragments.

Key Points: Upper Urinary Tract Endoscopy

- Semirigid ureteroscopy is typically utilized for diagnosis and treatment of pathologic processes below the iliac vessels. Flexible ureteroscopy is typically used above the iliac vessels.
- Ureteral dilation is not necessary in every ureteroscopic intervention and should be performed only when ureteroscope passage is impaired.
- Utilizing the minimum amount of irrigation necessary to provide a clear view during ureteroscopy minimizes stone migration, bleeding from hydrodistention, and pyelolymphatic or pyelovenous backflow.
- Ureteral access sheaths reduce operative time and costs, simplify ureteroscope reentry, facilitate calculus retrieval, and reduce ureteroscope damage.
- The holmium:YAG laser is the gold standard for ureteroscopic intracorporeal lithotripsy.
- Holmium laser lithotripsy occurs primarily through a photothermal mechanism resulting in calculus vaporization.
- Limiting pulse energy to 1.0 J or less and varying pulse frequency as needed can facilitate efficient lithotripsy by yielding smaller stone fragments, reducing stone retropulsion, and minimizing laser fiber damage.

performed as an outpatient procedure. All patients undergoing elective ureteroscopy should have a negative urine culture or have completed a course of culture-directed antimicrobial therapy before instrumentation.

Antimicrobial Prophylaxis

Urinary tract infection occurs in 4% to 25% of patients undergoing ureteroscopy (Rao et al, 1991; Puppo et al, 1999; Grabe, 2001, 2004). Knopf and associates (2003) noted a significant reduction in postoperative bacteriuria in patients who received a single dose of levofloxacin before ureteroscopy versus those who received no preoperative antibiotics (13% vs. 2%). Christiano and colleagues (2000) demonstrated that a single preoperative dose of ciprofloxacin is as effective and costs less than a single dose of intravenous cefazolin. **In 2007 the American Urological Association released a best practice statement on urologic surgery antimicrobial prophylaxis, recommending that all patients undergoing ureteroscopy receive antimicrobial prophylaxis** (Wolf et al, 2008). The antimicrobial agents of choice are the fluoroquinolones and trimethoprim-sulfamethoxazole, and the duration of therapy should be less than 24 hours.

Patient Positioning

Ureteroscopy may be performed with the patient in the supine, prone, and flank positions. When performed in the prone position, ureteroscopy is commonly utilized as an adjunct for establishment of percutaneous access and percutaneous nephrolithotomy (Kidd and Conlin, 2003; Marguet et al, 2005). In most cases it is our preference to position the patient in the dorsal lithotomy position. Many surgeons prefer to have the ipsilateral leg somewhat straighter and lower than the contralateral leg because this may increase the surgeon's working space to operate rigid instruments in line with the ureter and may facilitate ureteral access and navigation over the psoas muscle. **When operating in the kidney or proximal ureter, slight Trendelenburg positioning may aid calculi displacement into an upper pole calyx, a location that is typically easier to access than the lower pole. When operating in the middle and distal ureter, reverse Trendelenburg positioning may reduce lithotripsy- and irrigation-induced calculus retropulsion.**

Cystoscopy

Cystoscopy is performed before ureteroscopy to insert a 0.035 to 0.038-inch hybrid wire with a hydrophilic tip and stiff shaft (i.e., Sensor, Boston Scientific, Natick, MA) into the ureter and up to the renal pelvis until it is coiled. Either rigid or flexible cystoscopy may be used for initial wire placement. **If the ureteral orifice is difficult to identify, the following steps may be taken:** (1) identify the contralateral ureteral orifice and follow the ureteric ridge across the trigone to the expected location on the side of interest; (2) empty the bladder if it is full, which may compress the orifice and displace it laterally; (3) fill the bladder if it is empty, because mucosal folds in the bladder can preclude identification of the orifice; (4) exchange the telescopic lens for a 30 or 70-degree lens (if using a rigid cystoscope); (5) switch from rigid to flexible cystoscope or vice versa; and (6) intravenously administer colored dye (i.e., indigo carmine) and identify the ureteral orifice of interest when a blue jet of urine is observed.

Safety Guidewire

Before upper tract manipulation, a guidewire should be placed under cystoscopic and fluoroscopic guidance. **This wire functions as a safety wire that preserves access to the kidney and allows for placement of an indwelling ureteral stent in cases that are complicated by ureteral perforation or excessive bleeding that impairs adequate visualization and requires termination of the procedure. Standard practice is to have a safety wire in place throughout the procedure. Some authors have recently reported ureteroscopy without a guidewire** (Johnson et al, 2006; Eandi et al, 2008). **However, typically a guidewire does not interfere with successful completion of an endoscopic procedure and often not only serves as a safety precaution but also straightens a tortuous ureter and facilitates advancement of the ureteroscope.**

Typically one will be able to cannulate the ureteral orifice with the floppy end of the wire. Occasionally it may be necessary to utilize a 5-Fr open-ended ureteral catheter over the guidewire to help stabilize it at the ureteral orifice. Patients who have undergone reconstructive procedures such as ureteroneocystostomy, urinary diversion, and renal transplant may require a combination of angled wires and catheters to achieve an appropriate wire tip angle to cannulate the ureteral orifice (Del Pizzo et al, 1998; Nelson et al, 2003; Wallis et al, 2003). Resistance to the passage of the guidewire may be appreciated by tactile or visual feedback as noted on fluoroscopy or by detecting buckling of the wire in the bladder under direct vision through the cystoscope. If this occurs, a 5-Fr open-ended catheter is gently advanced over the guidewire under fluoroscopic guidance to the point of obstruction; then the guidewire is removed and a retrograde pyelogram is performed to delineate the anatomy.

Ureteral calculi or neoplasia, ureteral tortuosity, and ureteropelvic junction obstruction may impede guidewire placement. **If the wire cannot pass any of these obstructions, the wire is**

left just distal to the obstruction and the following steps may be attempted: (1) insert a 5-Fr ureteral catheter over the wire to increase the stiffness of the wire and provide backing to pass the wire beyond the obstruction; (2) exchange the wire for one with a hydrophilic tip and reattempt passage; and (3) exchange the 5-Fr ureteral catheter for an angled ureteral catheter or vascular catheter in combination with the straight or angled hydrophilic tipped guidewire and reattempt passage. If these maneuvers are unsuccessful, percutaneous access and an antegrade approach may be necessary. Alternatively, ureteroscopy can be performed to the level of obstruction in an attempt to identify the ureteral lumen at the site of obstruction and a guidewire can then be advanced under direct vision through the ureteroscope.

An appropriately placed guidewire should traverse the entire ureter and coil in the intrarenal collection system. If there is any question regarding where the guidewire has been passed, a retrograde pyelogram should be performed by exchanging the wire for a 5-Fr ureteral catheter and instilling radiopaque contrast to outline the collection system. Ureteral perforation may occur during wire manipulation and is evidenced by extravasation of contrast material on the retrograde pyelogram. In cases of severe hydroureteronephrosis with ureteral tortuosity, the proximal ureter may be quite capacious and permit guidewire coiling within the proximal ureter, making it difficult to determine the proximal location of the wire. In these cases, retrograde pyelography should be used to confirm appropriate wire positioning within the renal pelvis.

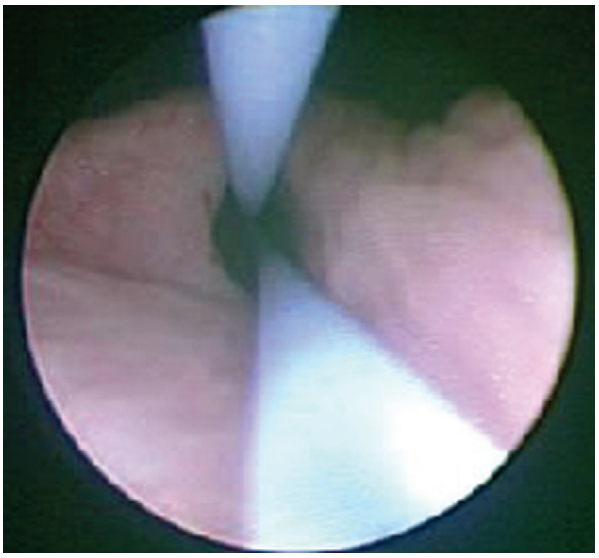

Figure 8–10. Passing a semirigid ureteroscope between two "railroad" wires during difficult ureteral access. The ureteroscope is maneuvered underneath the safety wire *(top),* tenting up the orifice. A second wire *(bottom)* is passed through the working channel and up the ureter with fluoroscopic guidance. The ureteroscope is then gently advanced between the wires until ureteral access is achieved.

Ureteroscope Insertion

Once the safety wire is in place the bladder is completely drained and the cystoscope is removed. The next step depends on whether semirigid or flexible ureteroscopy is planned. Semirigid ureteroscopy is performed when the pathologic process of interest is known or expected to reside in the distal or middle ureter. In addition to clearing the distal ureter of a pathologic process, semirigid ureteroscopy also dilates the ureteral orifice and permits the passage of a second "working" wire under direct vision, expediting subsequent flexible ureteroscopy or placement of a ureteral access sheath. When semirigid ureteroscopy is elected, the ureteroscope is gently advanced under direct vision with care to avoid creating false passages in the urethra. The ureteroscope is passed into the bladder and guided into the ureter alongside the safety wire. Typically, attempts to lift the guidewire with the tip of the ureteroscope positioned under the guidewire may facilitate entry into the orifice. **If the ureteroscope does not pass easily, the following steps may be performed:** (1) rotate the beak of the ureteroscope while engaging the ureteral orifice and providing adequate irrigation; (2) pass a super-stiff wire into the ureter through the working channel, rotate the ureteroscope so that the tip lies between the two wires, and guide the ureteroscope into the ureter between the two "railroading" wires (Fig. 8–10); (3) dilate the ureteral orifice with a 6/10-Fr coaxial dilator over a guidewire; (4) dilate the ureteral orifice with a 4-mm radially expanding balloon dilator; or (5) if the preceding measures fail, place an indwelling ureteral stent and allow for passive dilation for 2 weeks. Once the semirigid ureteroscope has been passed to the point where further inspection is limited by ureteral course, diameter, or length, a second wire is placed under direct vision and the ureteroscope is removed. Alternatively, if semirigid ureteroscopy is not utilized to inspect the distal ureter, a second wire may be placed through either an 8/10-Fr coaxial dilator or a 6/10-Fr dual lumen catheter over the safety wire.

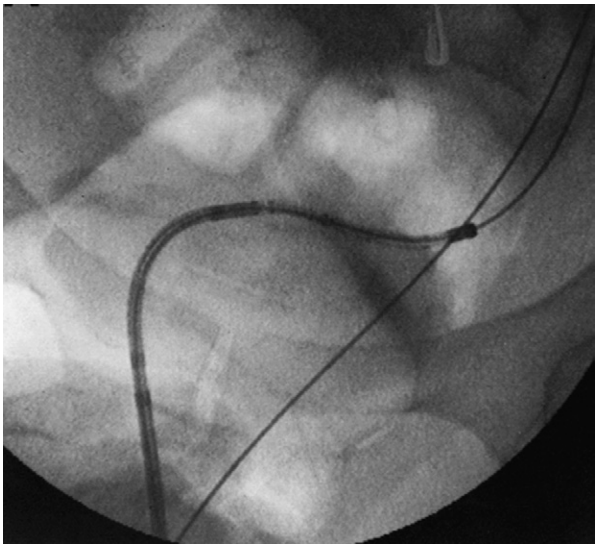

Figure 8–11. Difficulty passing a flexible ureteroscope frequently manifests as buckling in the bladder.

The flexible ureteroscope may be advanced into the ureter by backloading it over a double floppy tip super-stiff working wire and guiding it into the ureter under fluoroscopic guidance. This technique is used when less than three passes of the ureteroscope are planned (i.e., diagnostic ureteroscopy, ureteral biopsy, and small urinary stone burden). The ureteroscope should be kept as straight as possible during insertion by adequate tensioning of the working wire by the assistant while the surgeon advances the endoscope. Difficulty traversing the ureteral orifice with the flexible ureteroscope frequently manifests as buckling within the bladder (Fig. 8–11). Passage is facilitated by similar maneuvers as previously described for semirigid ureteroscopes, in particular rotating the ureteroscope to realign the working channel with the

Key Points: Patient Preparation

- The American Urological Association best practice statement on urologic surgery antimicrobial prophylaxis recommends that all patients undergoing ureteroscopy receive antimicrobial prophylaxis.
- Safety wires should be placed at the onset of ureteroscopy, facilitate indwelling ureteral stent placement should the procedure be terminated for ureteral perforation or bleeding, straighten a tortuous ureter, and ease ureteroscope advancement.
- When ureteral obstruction preventing passage of a wire is encountered the following tactics can be employed: increasing wire rigidity with a 5-Fr ureteral catheter, exchanging wires for one with a straight or angled hydrophilic tip, and exchanging the 5-Fr ureteral catheter for an angled ureteral or vascular catheter.
- When difficulty is encountered during ureteroscope passage the following maneuvers may be performed: (1) ureteroscope rotation; (2) passing the ureteroscope between two "railroad" wires; (3) ureteral dilation with either balloon or coaxial dilators; and (4) placement of stent to allow passive dilation for 2 weeks.

ureteral orifice. Alternatively, placement of a ureteral access sheath over a super-stiff working wire facilitates ureteroscope passage through the ureteral orifice and obviates the need for backloading.

Training and Practicing Laparoscopic and Robotic Surgery
Conclusion

More than 100 years ago the "father of modern medicine," Sir William Osler, challenged surgeons to perpetually refine their craft, stating, "Diseases that harm require treatments that harm less." In pursuit of this noble goal the urologists of the 20th century brought us great achievements in our field, but it has been over the past 25 years, in particular, that the specialty of minimally invasive urology has become predominant. The earliest techniques that laid the foundation for modern laparoscopic and robotic urologic procedures were developed at academic institutions throughout the world and have continuously been validated and improved. Subsequently, an increasing number of multi-institutional studies have emerged comparing laparoscopic and robotic procedures to their open surgical counterparts and showing equivalent efficacy, acceptable efficiency, as well as the distinct advantages of decreased postoperative pain, better cosmesis, faster recovery, a shorter hospital stay, and, in many cases, less cost. Indeed, it has become increasingly clear that the objectives of many open urologic surgeries, be it of the adrenal gland, kidney, ureter, bladder, prostate, or lymph nodes, can now be achieved with minimally invasive surgery with less patient injury and suffering. Therefore, whereas open surgery has had a steadily diminishing role in the treatment of urologic diseases, laparoscopic and robotic surgery have moved into the mainstream of urologic surgery and knowledge of the required principles and techniques is essential for the practicing urologist. This chapter is intended to provide a basic fund of knowledge on which the aspiring minimally invasive urologist can build.

PREOPERATIVE PATIENT MANAGEMENT

Patient Selection and Contraindications

Careful patient selection and identification of possible relative and absolute contraindications are vital to a successful outcome of laparoscopic and robotic procedures. To this end, a meticulous past history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation for possible minimally invasive surgery.

Age- and health-based laboratory studies, an electrocardiogram, and a chest radiograph should be obtained according to the same criteria established for any other significant surgical procedure that is undertaken with general anesthesia.

In patients presenting with severe chronic obstructive pulmonary disease (COPD), further studies (i.e., arterial blood gases and pulmonary function tests) are required. In patients with severe COPD, helium as an alternative insufflant should be considered and available at the time of the procedure. Cardiac arrhythmias should be evaluated and treated preoperatively because hypercarbia and the resulting acidosis may have adverse effects on the myocardium, thereby exacerbating any preexisting myocardial instability.

Contraindications to laparoscopic surgery include uncorrectable coagulopathy, intestinal obstruction unless intention to treat, significant abdominal wall infection, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, and suspected malignant ascites. Select circumstances in which laparoscopy is being contemplated necessitate careful risk-benefit analysis and detailed and specific informed consent with the patient. The following conditions may portend potential difficulties with a laparoscopic approach.

Morbid Obesity. Laparoscopic procedures in morbidly obese patients are technically challenging. Difficulties may include inadequate length of instruments, decreased range of motion of trocars and instruments, need for higher pneumoperitoneum pressures to elevate the abdominal wall, and poor anatomic orientation owing to excessive amounts of adipose tissue. Traditionally, these difficulties translated into a higher rate of associated complications; in a multi-institutional review of laparoscopy in

125 morbidly obese individuals, one or more intraoperative or postoperative complications occurred in 30% (Mendoza et al, 1996). In comparison to open surgery, however, it has been found that the laparoscopic approach to renal and adrenal procedures actually has a lower complication rate than the open approach. In a comparison of major laparoscopic renal and adrenal procedures (N = 21) versus similar open procedures (N = 21) in obese patients (body mass index [BMI] ≥ 30), although operative time was longer in the former group (210 minutes vs. 185 minutes; $P = .16$), the laparoscopic group had significantly superior outcomes regarding blood loss (100 mL vs. 350 mL; $P = .001$), resumption of oral intake and ambulation (<1 day vs. 5 days; $P = .001$), narcotic analgesic requirements (12 mg vs. 279 mg; $P = .001$), median hospital stay (<1 day vs. 5 days; $P = .001$), and convalescence (3 weeks vs. 9 weeks; $P = .001$). The overall complication rate in the laparoscopic group was 29% (19% major, 10% minor) versus 67% in the open group (33% major, 33% minor) ($P = .16$) (Fazeli-Matin et al, 1999). These findings have been further confirmed at several other centers (Fugita et al, 2004; Kapoor et al, 2004) even for complicated procedures such as partial nephrectomy (Colombo et al, 2007; Romero et al, 2008) and nephroureterectomy (Brown et al, 2008).

With regard to laparoscopic and robotic radical prostatectomy in obese men, it has been found that although the operation can be performed without compromising pathologic outcomes, obese patients have a greater risk of perioperative complications (26% vs. 5%) (Ahlering et al, 2005). Obese patients had a higher rate of deep vein thrombosis and pulmonary embolism (10%). Additionally, obese patients were less likely to achieve continence and more likely to have higher urinary bother scores at 3-, 6-, and 9-month follow-up.

Extensive Prior Abdominal or Pelvic Surgery. When extensive intra-abdominal or pelvic adhesions are suspected, careful consideration must be given to the possible site of Veress needle insertion as well as to obtaining open access with a Hasson-style cannula. The surgeon needs to understand the five potential points of Veress needle access to the abdomen (umbilicus and at the Palmer point—midclavicular line subcostal on either side, and just off the iliac crest—two fingerbreadths up and two fingerbreadths medial) as well as have knowledge regarding open (e.g., Hasson type) access. Alternatively, in these patients a retroperitoneal approach may be preferable to a transperitoneal approach or the procedure can be initiated retroperitoneally and the peritoneum then entered (Cadeddu et al, 1999).

A patient history of prior retroperitoneal surgery increases the difficulty of reentering the retroperitoneal space and therefore should be approached with caution. Subsequent attempts at extraperitoneoscopy or retroperitoneoscopy should only be ventured by individuals with considerable experience and comfort with this approach. In the authors' experience, prior percutaneous renal procedures do not necessarily constitute a contraindication to subsequent retroperitoneoscopy, provided that entry is away from the area of the prior nephrostomy tube placement.

Pelvic Fibrosis. Pelvic fibrosis owing to previous peritonitis, pelvic surgery, or extensive endometriosis may constitute a severe technical challenge to the laparoscopic surgeon when surgery of the lower urinary tract is indicated. Similar problems may be encountered when trying to perform pelvic lymph node dissection in patients who have a hip prosthesis; leakage of the polymethylmethacrylate cement can create a dense inflammatory reaction and fibrosis in the adjacent pelvis (Cooper et al, 1997).

Organomegaly. Known or preoperatively diagnosed organomegaly necessitates a cautious approach when obtaining the pneumoperitoneum. The site of Veress needle insertion must be chosen at a safe distance from any enlarged organs. Alternatively, open access with the Hasson cannula may be considered. Open access should be considered in cases of marked hepatomegaly or splenomegaly.

Ascites: Benign Etiology. Patients with severe ascites are under increased risk of injury to the bowel owing to closer proximity of bowel loops to the anterior peritoneum. In addition, a watertight wound closure is required and a firm wound dressing should be applied to prevent prolonged postoperative leakage.

Pregnancy. Initial access to the abdomen must be obtained at a safe distance from the fundus of the gravid uterus. As such, trocar placement is usually performed more cephalad on the abdominal wall, depending on the fundus of the uterus. The left or right upper quadrant in the subcostal midclavicular line (i.e., at Palmer point) is often the preferred site of access. Prolonged intra-abdominal pressures of 15 mm Hg or greater may result in hypotension, owing to significantly reduced venous return because the vena cava is already mechanically compromised by the enlarged uterus. Prolonged CO_2 pneumoperitoneum, which may result in maternal hypercarbia and acidosis with subsequent adverse effects on the fetus, should be avoided. Accordingly, a working pneumoperitoneum of 10 mm Hg is recommended in the pregnant patient. The second trimester is a preferred time for necessary surgery given the completion of fetal organogenesis and less chance of inducing labor.

As pregnancy progresses beyond the 20th week the technical possibility of performing laparoscopic procedures decreases significantly, correlating with the increasing size of the gravid uterus. Both laparoscopic nephrectomy and adrenalectomy have been successfully accomplished in the pregnant female (Nezhat et al, 1997; O'Connor, et al, 2004; Sainsbury et al, 2004).

Hernia. A diaphragmatic hernia may result in leakage of a significant amount of CO_2 into the mediastinum, which, although rarely noted, may eventually result in clinical problems such as respiratory compromise or cardiac tamponade (e.g., pneumopericardium) (Knos et al, 1991).

Any evidence of uncorrected or surgically corrected umbilical hernia or abdominal wall hernia should rule out these sites for obtaining a pneumoperitoneum.

Iliac or Aortic Aneurysm. Significant aneurysms warrant evaluation by the vascular surgeon. If the aneurysm does not require immediate surgical correction, insertion of the Veress needle should be performed in the left upper quadrant to stay well away from the area of the aneurysm. Of course, open access with the Hasson technique can be employed. Insertion of accessory trocars must be done under strict endoscopic control to avoid the area of the aneurysm.

Informed Consent

Although laparoscopic/robotic surgery is generally associated with decreased pain and morbidity, it should be remembered that there is considerable potential for serious complications, similar to that associated with standard open incisional surgery. It is essential for the patient to understand the inherent risk with all minimally invasive procedures such that the procedure may need to be converted to open surgery owing to hemorrhage, bowel injury, failure to progress, or other complications at any point during the intraoperative or postoperative course. Alternatively, in select cases, with less emergent complications, conversion to a completely open approach may be avoided by first switching to a hand-assisted approach and only going to an open approach if the

hand-assisted approach fails to provide the necessary control of the situation.

All alternative forms of surgical or nonsurgical treatment (if applicable), with their known advantages and disadvantages, must be discussed. The patient needs to be aware of both complications unique to laparoscopy and robotic surgery (e.g., fatal gas embolism, problems owing to hypercarbia, postoperative crepitus, pneumothorax, electrosurgical bowel injury, or robotic mechanical failure), and procedure-specific complications (e.g., damage of obturator nerve in pelvic lymphadenectomy).

Time spent obtaining informed consent is well invested. It is both the patient's right and the physician's responsibility. A good beginning augurs a good end.

Bowel Preparation

For extraperitoneoscopy and retroperitoneoscopy, no bowel preparation is necessary, but it may help with postoperative constipation. For transperitoneal laparoscopic/robotic procedures *not* involving the use of bowel segments for urinary tract reconstruction, a light mechanical bowel preparation can be given in an effort to decompress the bowel. A traditional example of such a prep would consist of a clear liquid diet and a Dulcolax suppository or half a bottle of magnesium citrate the day before the procedure. More recently, emphasis has been placed on "fast tracking" patients in an effort to streamline care and decrease length of hospital stay. Breda and associates (2007) found that a modified bowel prep and avoidance of narcotic analgesics postoperatively (with routine administration of ketorolac) was instrumental in achieving a hospital stay of 1.1 days for patients undergoing laparoscopic donor nephrectomy. The bowel prep consists of clear liquids for 2 days before surgery, two bottles of magnesium citrate the day before surgery, an enema the night before surgery, and nothing to eat after midnight (Breda et al, 2007).

The need for a full mechanical (e.g., GoLYTELY, 2 to 4 L, or 3 ounces of Fleet Phospho-Soda followed by a clear liquid diet and Fleet enema) and antibiotic (e.g., neomycin, 1 g by mouth, and metronidazole, 500 mg by mouth; three doses of each the day before surgery, plus 1 g of intravenous cefotetan on call to the operating room) bowel preparation is subject to question and becomes an issue only if one anticipates encountering dense intraabdominal adhesions or if the surgery involves entering the bowel (e.g., enteric augmentation of the bladder or enteric conduit formation).

Preparation of Blood Products

Serum type and screen are sufficient for diagnostic laparoscopy or procedures associated with a low chance of major hemorrhage. More extensive laparoscopic/robotic procedures (e.g., nephrectomy, partial nephrectomy, adrenalectomy), especially early in one's experience, should be managed like any other major open surgical procedure, with packed red blood cells available before surgery. This is most important during one's initial major laparoscopic/robotic cases; with experience, a "type and hold" suffices because the need for transfusion among patients undergoing major procedures, such as radical nephrectomy or radical nephroureterectomy, is quite low (3% to 12%), with an estimated average blood loss in the range of 106 to 255 mL (Ono 1999; Dunn et al, 2000; Jeschke et al, 2000; Shalhav et al, 2000). Similarly, the transfusion rate with laparoscopic/robotic radical prostatectomy is low (2.5% at experienced centers) such that a "type and hold" is sufficient (Guillonneau and Vallancien 2000; Ahlering et al, 2004).

Optional Preoperative Endourologic and Radiologic Procedures

Preoperative computed tomography (CT), spiral angiographic CT with 3D reconstruction, and magnetic resonance imaging (MRI) are helpful in depicting the anatomic relationship of the operative site to adjacent organs and/or blood vessels. Of course, the necessary studies required as part of a routine metastatic workup for cancer are mandatory. For partial nephrectomy or in the patient with ureteropelvic junction obstruction, preoperative spiral CT angiography with 3D reconstruction can be helpful. These studies may help to clearly define the renal vasculature and in the case of a renal mass can clearly delineate the optimal plane and depth of dissection. For the latter situation, coronal and sagittal views may be requested. When nephrectomy is performed for large malignant renal tumors (i.e., >10 cm), preoperative embolization of the renal artery may be considered immediately before the laparoscopic surgery; this procedure allows the surgeon to secure and divide the renal vein earlier in the transperitoneal procedure (i.e., before taking the renal artery) and may help to decompress collateral veins. In other disease states, preoperative placement of a ureteral catheter or a percutaneous drainage catheter can be quite helpful because intraoperative filling (e.g., with indigo carmine–stained saline) and drainage of the surgical site can aid in its identification and subsequent treatment (e.g., pyeloplasty, lymphocele or intrarenal cyst, calyceal diverticulum). Conversely, removal of an indwelling stent before a ureteral reconstructive procedure is recommended by some to enable the surgeon to work with a noninflamed ureter, thus facilitating the creation of a noninflamed anastomosis and subsequent healing.

A variety of catheters, both opaque and light bearing, can be placed in the ureter to facilitate ureteral identification and dissection in nephrectomy, pyeloplasty, nephroureterectomy, ureterolysis, ureterolithotomy, and retroperitoneal lymph node dissection. The need for preplacement of a ureteral stent is dependent on the pathologic process and the surgeon's prior laparoscopic/robotic experience.

IN THE OPERATING ROOM

Setup of the Operating Room

The operating room has to provide enough space to accommodate all necessary personnel and the equipment required by both the surgeon and the anesthesiologist. Positioning of equipment, surgeon, assistants, nurses, anesthesiologist, and other support staff should be clearly defined and established for each laparoscopic or robotic case. All equipment must be fully functional and in operating condition before any laparoscopic procedure is started (Table 9–1). A separate tray with open laparotomy instruments must be ready for immediate use in the event of complications or problems necessitating emergent open incisional surgery.

Patient Positioning and Draping

Positioning of the patient depends primarily on the procedure to be performed. In the supine position the arms can be tucked snugly at the sides or rest on specially designed sleds. In the

Table 9–1.

Instrumentation Checklist for Making a Skin Incision for Obtaining the Pneumoperitoneum

1. Irrigation-aspiration unit is working.
2. Electrosurgical unit is working.
3. CO_2 tank is full, with extra CO_2 tank in the room.
4. Camera is white balanced, and light source is working.
5. Insufflation is checked for flow and response to kinking of the tubing.
6. Veress needle is checked for flow and proper tip retraction.

Trendelenburg or lateral position, tape and security belts applied across the chest and thighs provide safe and stable positioning of the patient; shoulder braces should not be used because of a risk of brachial plexus injury. In the lateral position, all bony prominences in contact with the table must be carefully padded; likewise, the point of contact between any of the positioning straps and the hip or shoulder should be padded. In the lateral position, the bottom leg is flexed approximately 45 degrees while the upper leg is kept straight; pillows are placed between the legs as a cushion and also to elevate the upper leg so that it lies level with the flank, thereby obviating any undue stretch on the sciatic nerve. Pads should be placed between the table and the knee and ankle of the lower leg because these are high pressure areas. In the lateral decubitus position an axillary roll should be used. Application of an active warming system may prevent hypothermia, should a lengthy laparoscopic procedure be anticipated.

A host of new advances in padding and table mounted accessories are now available but none has been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position. Researchers at the University of California, Irvine, showed that women have significantly lower interface pressures than men (Deane et al, 2008). A BMI greater than or equal to 25, use of a kidney rest, and full table flexion as opposed to half-table flexion were all associated with increases in interface pressures; of these, use of the kidney rest was believed to be the most detrimental and its use beyond 20 to 30 minutes was disparaged. Therefore, male patients with a BMI of 25 or higher undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis from flank pressure. In this study the unaugmented operating table mattress was superior to egg crate or gel padding as an augmenting surface material; of note, egg crate padding was equal or superior to the more expensive gel padding.

Table-mounted accessories for all major commercial operating room tables now exist that aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. Specifically, for lateral decubitus positioning the buttock and upper back can be supported by padded reinforced stabilizer bars that mount on the side rails of the table. The entire bed and especially the kidney rest can also be padded and the upper arm can be supported on a table-mounted adjustable armboard. Special head supports for the lateral decubitus position are also available. For laparoscopic or robotic procedures on the pelvis, the patient can be placed in Trendelenburg position with the legs on split-leg positioners. Shoulder supports or braces should never be used in this position owing to the risk of brachial nerve injury. Allen stirrups have fallen out of favor because of the risk of calf neuropraxia. Split-leg positioners are available as built-in table features (Fig. 9–1A on the Expert Consult website) or as optional add-on features that can be used with any table (see Fig. 9–1B on the Expert Consult website).

The full extent of the abdominal wall should be prepared and draped from nipples to pubis. In some procedures, it is advantageous to extend the preparation to the knees and to drape the external genitalia into the surgical field. For example, gently pulling on the testis may help identify the intrapelvic location of the vas deferens and spermatic vessels, transvaginal palpation facilitates identification of the cervical cuff and posterior bladder junction, and free access to the urethral meatus enables the performance of auxiliary procedures such as flexible cystoscopy or manipulation of ureteral catheters during nephroureterectomy or for stent placement during pyeloplasty.

Before laparoscopic or retroperitoneoscopic procedures, placement of a nasogastric/orogastric tube and a Foley catheter should be performed to decompress the stomach and bladder, respectively, thereby decreasing the chance of injury of abdominal contents during surgery. Pneumatic compression stockings are applied for antiembolic prophylaxis. The administration of 5000 units of subcutaneous heparin preoperatively is also an option in higher-risk patients, such as the morbidly obese.

STRATEGIC PLACEMENT OF OPERATIVE TEAM AND EQUIPMENT

Standard Laparoscopic Carts. Traditionally, the mandatory hardware for laparoscopic procedures (monitor, light source, insufflator) is located on carts or "towers" that can be rolled around the operating room and be adapted to various types of surgical procedures and approaches (Fig. 9–2A on the Expert Consult website). If only one monitor is used (as in intrapelvic procedures), it is typically placed at the foot of the table or between the legs if the patient is in stirrups or on split-leg positioners. If two monitors are used, they are positioned on both sides of the table to allow an unobstructed view for all key operative team staff.

The main laparoscopic cart should contain the insufflator, placed at the surgeon's eye level to allow continuous monitoring of the CO_2 pressure. The light source, camera controls, and any recording device are usually also on the cart. Placement of a *sterile* plastic sheet over the front of this cart enables the surgical team to directly control the intensity of the light as well as the pneumoperitoneum pressure with these controls on the equipment.

Integrated Endoscopy Systems. More recently, most major manufacturers of endoscopy equipment offer "integrated" systems that consist of flat panel displays and equipment towers that are mounted on adjustable ceiling booms (see Fig. 9–2B on the Expert Consult website). Thus, the display monitors can be suspended over the patient and placed directly in front of the surgeon at any height or angle. This feature may reduce eye and body strain. Furthermore, the tower containing the light source, camera system, and insufflator can be placed in any area around the patient depending on the operation at hand. The more sophisticated systems are frequently controlled by a touch screen display used by the surgeon or a nurse, or by voice command, or by using the controls on the camera head instead of manually adjusting instruments at the tower level. In addition to the laparoscopic equipment, other aspects of the operating room environment can be controlled from the touch screen or by voice, such as the room lighting, input from digital radiology systems, and recording devices. Although they are not a necessity, these types of systems offer unique advantages with regard to operating room efficiency

and may further improve the ergonomics for the operating surgeon and staff.

Robotic Systems. Currently, the only robotic surgical system in widespread use for laparoscopic surgery is the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA). In its current state this system can be used in almost any modern operating room. The three major components of the system are the robotic tower to which the instruments attach and are mechanically manipulated within the patient, a surgeon's console that is the workstation at which the surgeon sits to manipulate the robotic instruments, and finally the ancillary vision cart that supports a flat screen monitor, an insufflator, light source, and components of the camera system (Fig. 9–3 on the Expert Consult website). Additional monitors (either standard or boom-mounted flat screen) can be linked with the robotic system and used for the assistant and support staff image viewing.

Placement of the Operative Team for Laparoscopic Procedures

Transperitoneal Procedures in the Upper Abdomen. For laparoscopic procedures such as nephrectomy the patient is positioned in a modified lateral decubitus position for transperitoneal laparoscopic renal surgery procedures. This is at approximately a 30-degree angle to the table and allows for more effective lateral retraction of the kidney and exposure of the renal vessels during the hilar dissection. The kidney rest may be elevated at the outset and the table slightly flexed if necessary to provide adequate exposure for port placement; **after port placement, the kidney rest should be completely lowered.** The surgeon and assistant usually stand opposite the area of surgical interest (i.e., for a left nephrectomy the surgeon and assistant stand on the patient's right side). The instrument table and the scrub nurse are best located on the opposite side of the patient such that instruments can be handed to the surgeon over the table (Fig. 9–4). Incoming lines from insufflators, suction/irrigation, and electrosurgical devices enter from the contralateral side of the table. Optional technology (e.g., harmonic scalpel, argon beam coagulator) must be arranged in an orderly fashion using either preexisting or improvised pockets of the surgical drape. Again, these lines ideally should enter the field from the contralateral side of the table or from the ipsilateral head of the table. Additional technology (e.g., laparoscopic ultrasound probe) may be moved to the operating table depending on the surgeon's needs as well as on the availability of space.

To provide more comfortable positioning of the surgeon's arms, a 6 × 4-foot, 6-inch lift can be used, because most operating tables designed before widespread use of laparoscopy cannot be lowered sufficiently to allow the surgeon to hold the laparoscopic instruments with his or her elbows held comfortably at the side rather than extended laterally. This is most important during suturing. Several newer tables recently on the market, however, can be set at very low elevations (e.g., 60 cm) for the Maquet Alphamaxx (Getinge USA, Rochester, NY) so that platforms are not necessary.

Retroperitoneal Upper Abdominal Procedures. For retroperitoneal procedures the patient is placed in the true, 90-degree lateral decubitus position with the body at a right angle to the table. All of the proper steps for padding in this position should be followed (see earlier). **The table is angled at the hip to accentuate and increase the distance between the 12th rib and the iliac crest. Maximizing this distance is paramount with regard to port placement.** If necessary, the kidney rest can be raised; however, the surgeon must keep in mind that this causes increased pressure on the tableside hip and may increase the risk of pressure necrosis if left elevated for prolonged periods of time.

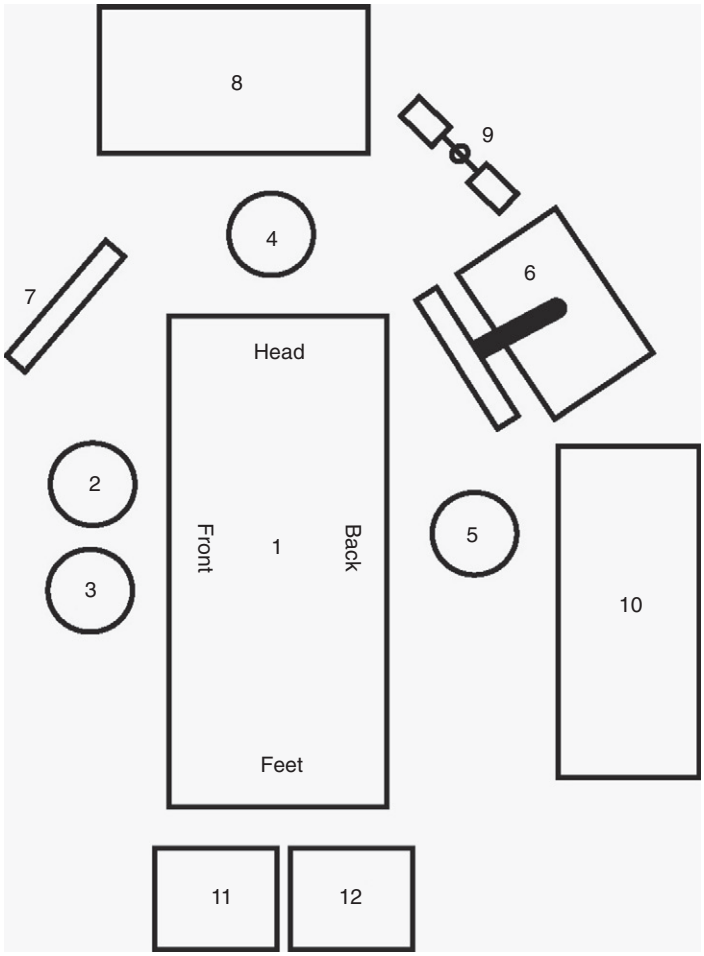

Figure 9–4. Placement of the operative team for transperitoneal procedures in the upper abdomen: 1, operating table; 2, surgeon; 3, assistant; 4, anesthesiologist; 5, scrub assistant; 6, laparoscopic cart/tower; 7, auxiliary video monitor; 8, anesthesia equipment; 9, suction/irrigation unit; 10, scrub assistant's instrument table; 11, electrocautery unit #1; and 12, electrocautery unit #2.

Most experts recommend lowering the kidney rest except when it is needed for key portions of a case. The operative field should include the space between the costal margin and the iliac crest and from the umbilicus to the spine. Both the primary surgeon and the camera assistant stand facing the patient's back (Fig. 9–5). The scrub nurse/technician stands facing the patient's front, and instruments are handed across the patient accordingly.

Transperitoneal and Extraperitoneal Pelvic Procedures

The patient is positioned in the supine position with the legs on split-leg positioners or elevated in stirrups that have knee and leg supports to avoid perineal nerve injury. The table is angled (flexed) slightly at the hip to accentuate the pelvis. The patient's arms are tucked at the sides; plastic sleds can be used to support the arms. Adequate padding should be applied to the arms and legs. A slightly snug chest strap should be placed directly across the patient's chest. The table is placed in the 30-degree Trendelenburg position. Genitalia are draped into the operative field, which extends from the mid chest to thighs and from midaxillary line to midaxillary line. The surgeon stands on the side of the table where he or she is comfortable, and the assistant stands on the side of the table opposite the surgeon (Fig. 9–6).

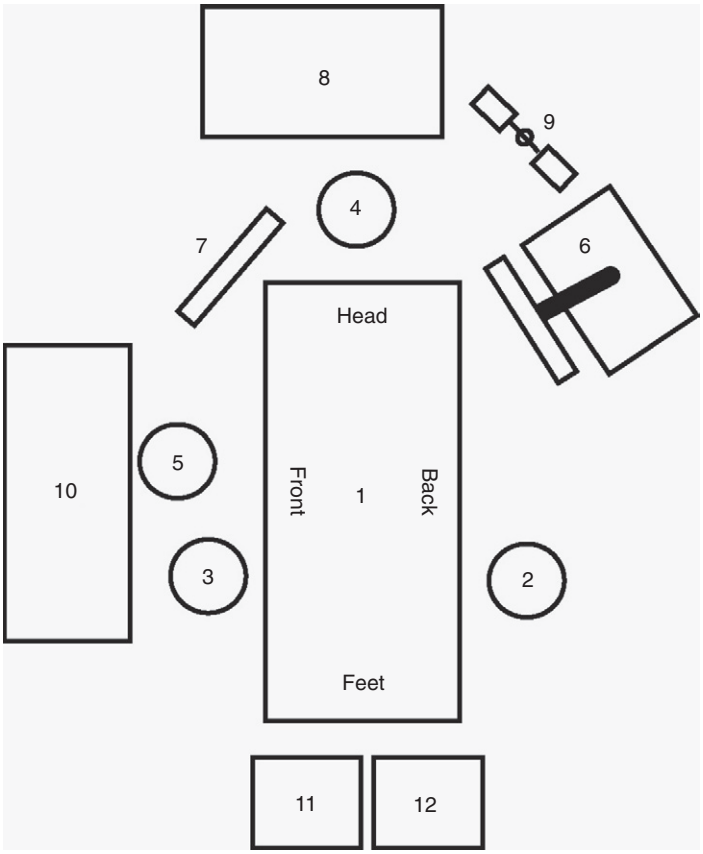

Figure 9–5. Placement of the operative team for retroperitoneal procedures in the upper abdomen: 1, operating table; 2, surgeon; 3, assistant; 4, anesthesiologist; 5, scrub assistant; 6, laparoscopic cart/tower; 7, auxiliary video monitor; 8, anesthesia equipment; 9, suction/irrigation unit; 10, scrub assistant's instrument table; 11, electrocautery unit #1; and 12, electrocautery unit #2.

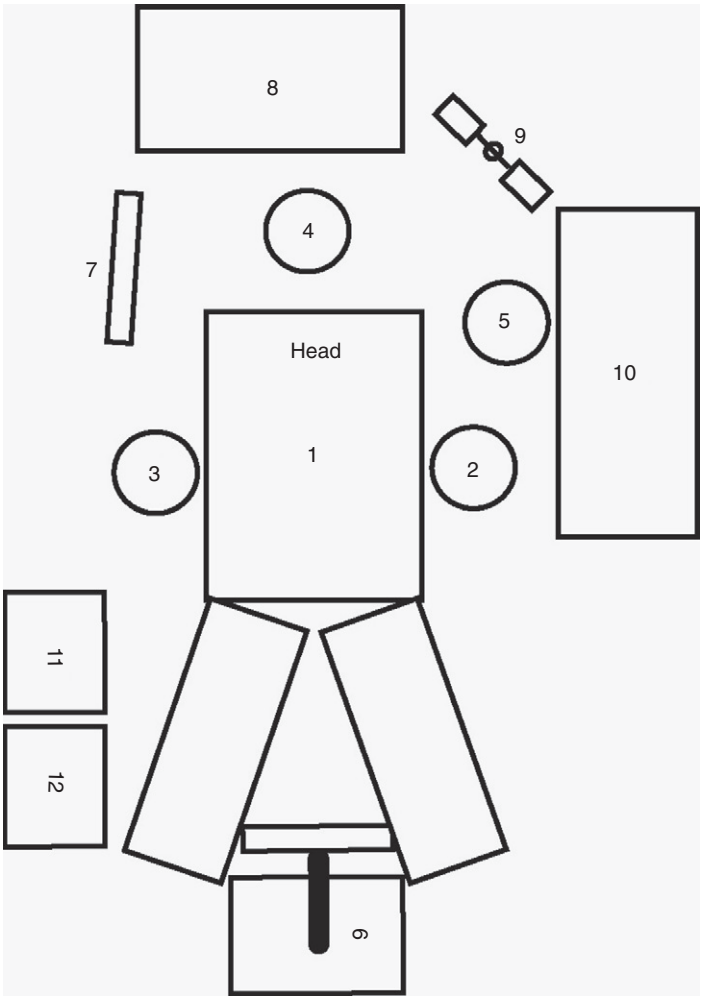

Figure 9–6. Placement of the operative team for pelvic surgery: 1, operating table; 2, surgeon; 3, assistant; 4, anesthesiologist; 5, scrub assistant; 6, laparoscopic cart/tower; 7, auxiliary video monitor; 8, anesthesia equipment; 9, suction/irrigation unit; 10, scrub assistant's instrument table; 11, electrocautery unit #1; and 12, electrocautery unit #2.

Robotic Surgery. For robotic procedures involving the kidney and adrenal gland the patient is positioned exactly as described for transperitoneal upper abdominal surgery as described earlier. The surgeon and assistant stand on the side opposite the pathologic process. The robotic tower is positioned on the ipsilateral side of the pathology such that the robotic arms stretch over the patient and can then be docked to the preplaced ports. In general it is best to angle the robot slightly such that the lens is pointing directly toward the site of interest (Fig. 9–7 on the Expert Consult website). Following this the surgeon ungowns and takes his or her place at the surgeon's console while the assistant remains on the side of the table opposite the robotic tower.

For robotic procedures on the pelvis the patient is positioned exactly as described earlier for laparoscopic pelvic procedures. After port placement the robotic tower is placed between the patient's legs and the assistant can remain on either side of the table depending on surgeon preference. The scrub nurse/technician can be positioned on the same side as the assistant to facilitate passing instruments because passing instruments across the robotic arms can be cumbersome.

PERFORMING THE PROCEDURE

Before the Initial Incision

A checklist ensuring that all essential equipment is present and operational should be completed just before initiating the pneumoperitoneum (see Table 9–1). For laparoscopic surgery this list should include (1) light cable on the table, connected to the light source and operational; (2) laparoscope connected to the light cable and to the camera, with an image that has been white balanced and focused using a white gauze sponge; (3) operational irrigator/aspirator; (4) insufflator tubing connected to the insufflator, which is turned on to allow the surgeon to see that there is proper flow of CO_2 through the tubing; kinking of the tubing should result in an immediate increase in the pressure recorded by the insufflator, with concomitant cessation of CO_2 flow; (5) an extra tank of CO_2 in the room; and (6) a Veress needle, checked to ensure that its tip retracts properly and that, when it is connected to the insufflator tubing, the pressure recorded with 2 L/min CO_2 flow through the needle is less than 2 mm Hg.

Additional items to check when utilizing the da Vinci Robotic System would include ensuring that all plugs for the console, vision cart, and surgical cart are plugged into different circuits and that all cables connecting these carts are connected properly. The system should be turned on and the self test and homing routine should be complete. The 3D camera and endoscopes should be calibrated, the image black/white balanced, and target alignment should be performed according to the manufacturer's instructions. The surgical cart should be draped and ready.

Achieving Transperitoneal Access

Pneumoperitoneum

The insufflant system (i.e., insufflator, tubing, and chosen gas) is essential for establishing a pneumoperitoneum. This is brought into use after either closed (i.e., Veress needle) or open (i.e., Hasson cannula or hand-assist device) access to the peritoneal cavity is established. If hand-assisted or single-port access laparoscopy is to be performed, the pneumoperitoneum can be established directly after placement of the port.

Most commonly, CO_2 is used as the insufflant because it does not support combustion and is very soluble in blood (LD_{50} for CO_2 is 1750 mL) (air = 357 mL) (Bordelon and Hunter, 1994). However, in patients with chronic respiratory disease, CO_2 may accumulate in the bloodstream to dangerous levels. Accordingly, in these patients, helium may be used for insufflation once the initial pneumoperitoneum has been established with CO_2 (Leighton et al, 1993). The drawback of helium is that it is much less soluble in blood than CO_2; however, its use precludes problems of hypercarbia. For this reason, even in patients with chronic respiratory disease, the procedure is initiated with CO_2 and then the change is made during the case to helium if necessary. Other gases that were once used as insufflants (room air, oxygen, nitrous oxide) are no longer routinely used because of their potential side effects (e.g., air embolus, intra-abdominal explosion, potential to support combustion). "Noble gases" such as xenon or argon are inert and nonflammable but are not routinely used for insufflation because of their high cost and poor solubility in blood.

Closed Technique: Veress Needle

Sites for Needle Passage. Disposable (70- or 120-mm, 14-gauge, and 2-mm outer diameter) as well as nondisposable (metal) Veress needles can be used. Proper needle function is ensured before the procedure. The blunt tip of the needle is tested to make sure it retracts easily; also, the needle is connected to the CO_2 line to ensure that there is no resistance to gas inflow (i.e., at 2-L/min flow, pressure remains at ≤2 mm). Lastly, saline is flushed through the needle with the tip manually occluded to make sure there is no leakage at the juncture between the shaft and the hub of the needle.

With the patient in the supine position, the head of the bed is lowered 10 to 20 degrees; insertion of the Veress needle is commonly accomplished at the superior border of the umbilicus (Fig. 9–8). There are certain advantages to choosing the umbilical area as the site for initial trocar placement: the abdominal wall is thinnest, and postoperative cosmesis is excellent. However, this point of entry is fraught with the potential for injury to a major vessel, in particular the left common iliac vessels, aorta, or vena cava.

Another important factor with regard to passing the Veress needle is body habitus; in obese patients, the umbilicus tends to migrate inferiorly. In nonobese patients the umbilicus lies in its commonly described position, directly above the bifurcation of the aorta and vena cava. Thus, for umbilical access in nonobese patients the Veress needle should be passed through the abdominal wall angled toward the pelvis to avoid injury to the bowel and great vessels that lie directly beneath. In more obese patients, because the umbilicus lies more caudad, less angulation is needed and the Veress needle should be passed perpendicular to the umbilical incision (Loffer and Pent, 1976). In addition, it has also been found that pneumoperitoneum pressure and volume as well as the ease of trocar or needle insertion is not significantly affected by body habitus. In a combined human and porcine study, McDougall and associates (1994) prospectively performed pressure-volume analysis on 41 individuals undergoing transperitoneal laparoscopic procedures and found that 94% of the maximal intraperitoneal volume is achieved with an insufflation pressure of 15 mm Hg. Additional pressure (up to 30 mm Hg) did not significantly increase volume. Furthermore, in the porcine component of the study, elevation of the pneumoperitoneum pressure above 15 mm Hg did not significantly ease bladed trocar insertion. **Therefore the pneumoperitoneum pressure need never be raised above 15 mm Hg unless it is done so in the setting of a vascular venous injury to control bleeding** (a discussion of this technique is outlined later).

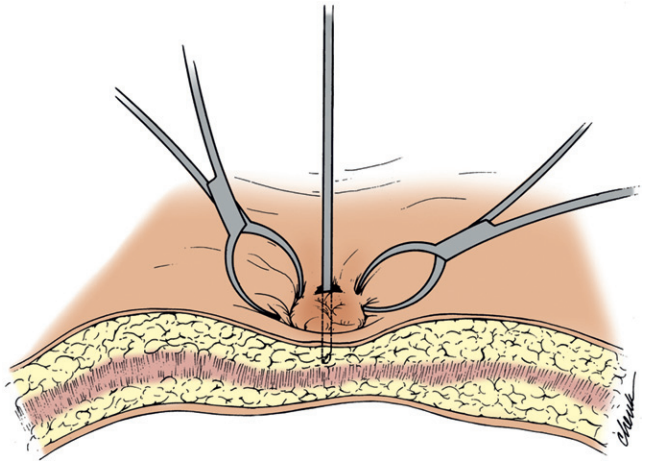

Figure 9–8. Insertion of Veress needle at umbilicus. The towel clips stabilize the abdominal wall as the needle is advanced. (From Clayman RV, McDougall EM, editors. Laparoscopic urology. St. Louis: Quality Medical Publishing; 1993.)

If the patient is in a lateral decubitus position, then the Veress needle is passed 2 fingerbreadths medial and 2 fingerbreadths superior to the anterior superior iliac spine. Just before insertion of the Veress needle a 12-mm incision is made in the previously described area, in anticipation of placing a 10- to 12-mm trocar. The subcutaneous tissues are spread with a Kelly clamp, and the anterior fascia is secured with an Allis clamp. The abdominal wall is stabilized, but not lifted, with the Allis clamp. The Veress needle is grasped at midshaft and is passed perpendicularly through the 12-mm incision using a gentle, steady pressure; two points of resistance are traversed: the abdominal wall fascia and the peritoneum. With this approach, the only organ at risk is the bowel; neither a vascular organ nor a major vessel can be injured using this insertion site.

Other potential insertion sites when the patient is either supine or in a lateral decubitus position are at the Palmer point (i.e., subcostal in the midclavicular line on the right side) and at the corresponding site on the left side. In this instance, stabilization or even a slight upward tension on the Allis clamps is essential; the needle if inserted too deeply will potentially hit the liver on either side or, rarely, the spleen, so care must be exercised. Chung and coworkers (2003) applied this method of laparoscopic access and trocar placement in 622 consecutive cases. Prior abdominal surgery had been performed in 192 patients (31%), and the BMI was 30 or greater in 98 patients. Blind Veress needle placement was successful in 579 (93%), and outcome was not associated with laterality, type of surgery, or prior surgery. In 34 cases (5%), a minor laceration to the liver was managed conservatively without sequelae; and in 21 cases (3%) the omentum or falciform ligament

was traversed without significant injury. No major complications, such as vascular or hollow-organ perforation, were caused by either the Veress needle or trocar. Neither the spleen nor bowel was ever injured. No patient developed an incisional hernia at the upper quadrant trocar site (Chung et al, 2003).

Aspiration/Irrigation/Aspiration. With the use of a 10-mL syringe containing 5 mL of saline, the Veress needle is aspirated to check for blood or bowel contents. If this test result is negative, then the saline is injected into the abdominal cavity; this should occur without any resistance. Next, the plunger of the syringe is again withdrawn; no fluid should return into the barrel of the syringe. An additional injection of 2 to 3 mL of saline will help to expel any omentum that may have been sucked into the needle tip with the original aspiration technique. Lastly, the syringe is detached from the Veress needle and any fluid left in the hub of the needle should fall swiftly into the peritoneal cavity (i.e., the "drop" test).

Advancement Test. If the needle has truly just entered the peritoneal cavity, then the surgeon ought to be able to advance the needle 1 cm deeper without the tip meeting any resistance. Resistance at this stage usually means the needle is still in the preperitoneal space and needs to be advanced through the remaining peritoneum.

Once proper needle placement is verified, insufflation is started at 2 L/min with the abdominal pressure set at 10 mm Hg. If free flow of CO_2 is noted (i.e., intra-abdominal pressure remains <10 mm Hg), then after 0.5 L has entered the abdomen the flow can be increased to maximal capacity of 9 L/min (however, no more than 2 L/min flow can be achieved through a 14-gauge needle) and the abdominal pressure set at 15 mm Hg. As soon as the preset limit of 15 mm Hg of intra-abdominal pressure is reached, free flow stops.

In a previously operated abdomen, Veress needle insertion should be performed in an unscarred quadrant of the abdomen. Alternatively, if there is no scar-free area, then an open technique (see later) should be used.

Open Access Techniques. The pneumoperitoneum can be more easily, and in one's early experience, more safely established using an open technique; however, its use involves making a larger incision and increases the chances of port-site gas leakage during the procedure. **The open technique is recommended specifically when extensive adhesions are anticipated. Studies in general surgery have shown the open technique to be as efficient as the closed approach and slightly more or equally as safe** (Bonjer et al, 1997).

In the unscarred abdomen, a 2-cm semicircular incision is made at the lower edge or slightly below the umbilicus. The fascia and peritoneum are opened individually with a transverse incision, sufficient to accommodate the surgeon's index finger. After visual and digital confirmation of entry into the peritoneal cavity, two 0 silk traction sutures are placed on either edge of the fascia. Next, the Hasson cannula is advanced through the incision with the blunt tip protruding (Fig. 9–9A). The funnel-shaped adapter of the Hasson cannula is advanced until it rests firmly in the incision, and it is then tightened onto the cannula with the attached screw; fixation to the abdominal wall is provided with the fascial sutures that are wrapped around the struts on the funnel-shaped adapter of the Hasson cannula, thereby anchoring it in place. After removal of the obturator, free flow of CO_2 into the peritoneal cavity is achieved by attaching the CO_2 tubing to the cannula. The insufflator can be set at maximum inflow, thereby creating the pneumoperitoneum quickly.

A far simpler type of open cannula is a balloon retention device (e.g., Blunt Tip Trocar With Balloon Tip, US Surgical, Norwalk, CT)

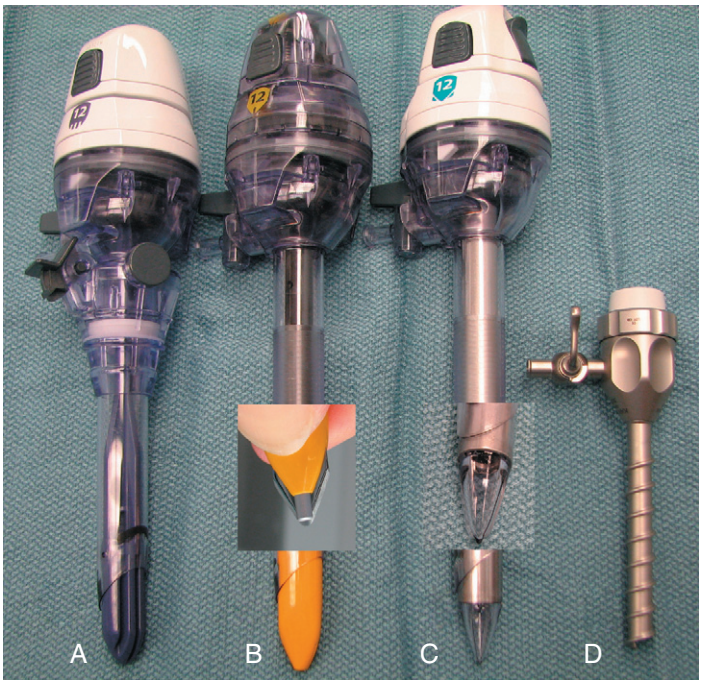

Figure 9–9. Various trocar designs showing (**A**) Hasson type, (**B**) bladed, (**C**) fascial dilating, and (**D**) screw-like designs. Enlarged images of the bladed and dilating tips are provided.

(Fig. 9–10 on the Expert Consult website). Once the cannula is positioned in the abdominal cavity, the balloon is inflated; the cannula is pulled upward until the balloon is snug on the underside of the abdominal wall. Next, the soft foam collar on the outside surface of the cannula is slid downward until it is snug on the skin and locked in place. This process creates an excellent seal, precluding gas leakage as well as subcutaneous emphysema.

Closed Technique

Blind Trocar Insertion. Generally this technique is not considered basic and should be used by the experienced laparoscopist in patients who are very unlikely to have intra-abdominal adhesions. Indeed, although reports of its use have been very favorable in the gynecologic literature, the authors are unaware of any reports in the urologic literature; similarly, none of the authors has employed this method.

This method is performed by means of a subumbilical 12-mm transverse incision; the rectus sheath on either side of the incision is grasped with a towel clip, and a surgeon on either side lifts the abdominal wall upward. It is claimed that this creates a distance of 6 to 8 cm between the underside of the abdominal wall and the underlying viscera. A 5-mm incision is made in the elevated rectus sheath, and a 10- to 12-mm disposable shielded or optical view trocar is passed vertically. In a prospective randomized study, comprising 578 patients, the direct insertion technique was found to be associated with fewer complications (4.2%) than a standard Veress insertion (complications of 14.6%); also of note, entry failure occurred in only 0.7% of the direct trocar insertion patients versus 4.6% of the Veress needle group (Gunenc et al, 2005). However, this complication rate for the Veress needle is distinctly higher than cited in other major series or meta-analyses in which Veress needle–associated vascular or bowel injuries were noted in 0.8% and 0.8% of patients (Bonjer et al, 1997).

EndoTip Entry. For this technique the abdominal wall is not tented using towel clips. It is left flat. A 5-mm incision is made in the skin at an appropriate site for a 5-mm port. The EndoTip trocar

(Storz, Germany) is a 5-mm trocar with a "corkscrew"-type self advancing and self-retaining entry system and a blunt tip (see Fig. 9–9D). The trocar can be advanced through the abdominal wall while a 5-mm, 0-degree lens is positioned inside the trocar 1 cm from the advancing tip. Once the abdominal wall muscle is engaged, the EndoTip can be lifted up slightly while continuing to rotate it through the tissues; this maneuver lifts the peritoneum, and one can watch as the blunt tip works its way through the peritoneum and into the abdominal cavity. Again, this technique should be used only in patients in whom intra-abdominal adhesions are unlikely.

Hand Port Access. If the hand port is going to be placed in the midline, then the midline should be marked before placing the patient in the 45-degree (modified) flank position. The pneumoperitoneum can be obtained before or after making the hand port incision, but if one wishes to ensure the minimum size of the skin incision then the incision should be made after obtaining the pneumoperitoneum because this places the skin more on stretch. However, if the surgeon has little experience with achieving a pneumoperitoneum, the safest maneuver is to place the hand port into a 7-cm open incision and then create the pneumoperitoneum through the hand port.

If one elects to obtain a pneumoperitoneum first, then the surgeon should carefully plan out the hand port entry site as well as the additional instrument and camera port sites. Every hand port device has a "footprint" that can be drawn on the abdominal wall; that footprint varies depending on the diameter of the external appliance. **Care should be taken to plan out the additional trocar sites carefully to avoid interference between the hand port and the instrument ports;** this is most easily done once the pneumoperitoneum has been established. After the footprint is traced, the hand port incision site is marked; the length of the incision should correspond to the surgeon's glove size (i.e., 7 glove size = 7-cm incision). The skin is incised, and the fascia is divided. The peritoneum is entered, and the insufflation is temporarily stopped. The hand port device is then placed according to the manufacturer's instructions. Additional 5-mm or 10- to 12-mm ports can be placed rapidly under manual control with the surgeon's intra-abdominal hand being used to guide the additional trocars through the abdominal wall. Alternatively, a trocar can be placed through the hand port and the abdomen can be re-insufflated. A laparoscope can then be placed through the port and the rest of the trocars can be placed under direct vision.

Laparoendoscopic Single-Site Surgery (LESS) and Natural Orifice Transluminal Endoscopic Surgery (NOTES). Recent advances in abdominal access technology combined with the development of curved and articulating laparoscopic instrumentation have made it possible to perform selected procedures through a single incision (typically 2.5 cm transumbilical); using three access ports through this incision, the laparoscope and two working instruments can be introduced.

Much the same as for hand port access the incision can be made before or after obtaining a pneumoperitoneum depending on surgeon preference. Typically, the incision is made periumbilically for cosmetic purposes. If large/intact specimen extraction is required for the procedure at hand (as in donor nephrectomy), the incision should be made just large enough to remove the specimen. If specimen removal is not necessary or the specimen is small, then the incision can be minimized to as little as 2.5 cm. Once the incision is made, several ports side by side or a single tri-port access device can be placed and a pneumoperitoneum is re-established at high flow. Thus far, LESS has been used for a variety of upper abdominal procedures including adrenalectomy (Hirano et al, 2005; Castellucci et al, 2008); renal biopsy (Kaouk et al, 2008b); renal cyst decortication; renal tumor cryoablation (Goel and Kaouk, 2008); pyeloplasty (Kaouk et al, 2008a); ileal ureter interposition; psoas hitch ureteroneocystostomy; simple, radical, and donor nephrectomy (Gill et al, 2008; Ponsky et al, 2008b; Raman et al, 2008); and partial nephrectomy (Kaouk et al, 2008b). Additionally, pelvic procedures have been performed including varicocelectomy (Kaouk and Palmer 2008), sacroculpopexy (Kaouk et al, 2008b), radical prostatectomy, and radical cystectomy with extended lymphadenectomy (Kaouk et al, 2008b).

The theoretical advantages of LESS over standard multi-incision laparoscopy are improved cosmesis, decreased pain, and faster recovery time. At the present time, however, there are insufficient data regarding LESS available to either support or refute these potential benefits (Raman et al, 2008). Research in this area is ongoing, and until well established methods and results are available surgeons are urged to approach LESS in a responsible and graduated fashion. Proper training through a combination of educational courses, hands-on laboratory training, case observation, and proctoring should be undertaken by surgeons who wish to start a successful program in LESS. One method of transitioning from standard laparoscopy to LESS for selected procedures is to gradually decrease the number of ports one uses until the procedure can be performed through a single incision. **Conversely, when one is having difficulty performing a procedure using LESS, the surgeon should not hesitate to place one or more extra trocars at separate incision sites to improve triangulation and thereby ensure safety and a quality result.**

Although the transgastric removal of an appendix in 2004 and the transvaginal removal of the gallbladder in 2007 have stimulated much interest in the realm of general surgery, natural orifice transluminal endoscopic surgery (NOTES) has remained an investigational laboratory procedure in urology. Using a transgastric and transvaginal approach, Ponsky and colleagues (2008b) have removed a porcine kidney whereas Lima and colleagues (2007) have used a transgastric and transvesical approach to excise, but not remove, the porcine kidney. These latest developments are built on the original work by Gettman and associates in 2002 in which transvaginal nephrectomies were accomplished in the pig. However, to date, there have been no NOTES procedures in clinical urology (Lima et al, 2006; Isariyawongse et al, 2008).

Instrumentation for Developing the Retroperitoneal Space

Balloon Dilation

Gradual distention of a balloon dilator in the retroperitoneal space atraumatically displaces the mobile fat and moves the peritoneum forward relative to the immobile body musculature. This device thus creates a working space equivalent to the size of the balloon.

Commercially Available Balloons. A commercially available trocar-mounted preperitoneal balloon dissector (PDB) (Covidien Ltd., Mansfield, MA) is commonly employed. The transparent, high-tensile strength silicone balloon is inflated with a sphygmomanometer bulb insufflator using room air (Fig. 9–11). The balloon has a maximum capacity of 800 mL (40 pumps of the inflating bulb). A primary advantage is that the balloon is affixed to the end of a stiff, hollow, transparent plastic shaft. The shaft allows precisely directed placement of the balloon dilator (see later).

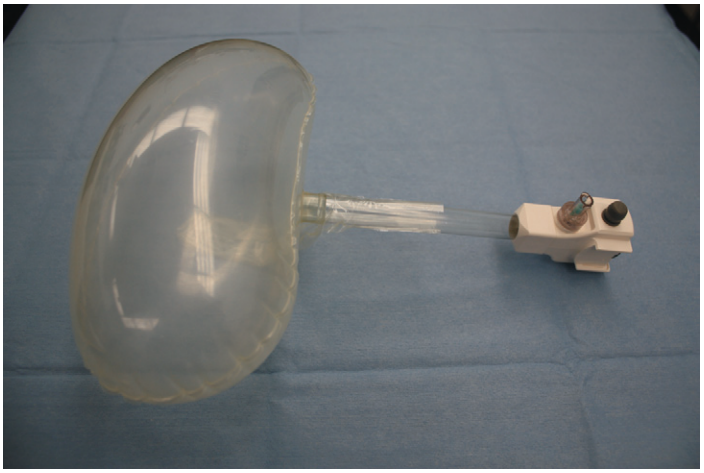

Figure 9–11. Example of a commercially available balloon dilator for creating space in the retroperitoneum: preperitoneal balloon dissector. (Courtesy of Covidien Ltd., Mansfield, MA.)

Furthermore, because the laparoscope can actually be inserted into the shaft of the balloon dilator during the inflation process it provides the capability for endoscopic confirmation of the proper positioning of the transparent balloon and of the adequacy of the controlled radial dilation of the extraperitoneal area. Balloon dilators are commercially available in two different shapes: a round balloon for dilation of the pelvic extraperitoneal space and a horizontally oriented, oblong-shaped balloon for dilation of the retroperitoneal space.

Self-Styled Dilators. Gaur's original (1992) version of the balloon dilator was a size 7 surgeon's glove mounted on a No. 8 red rubber catheter. The external end of the catheter was connected to a sphygmomanometer bulb insufflator, and the balloon was insufflated to 110 mm Hg. After this initial description, several other self-styled dilators were described: the middle finger of a size 7 to 8 glove, two fingers of a size 7 to 8 glove tied over each other for additional strength, a sterile condom, and the cot of an O'Connor-style drape mounted on a 16- or 18-Fr red rubber or whistle-tip catheter (Webb et al, 1993; Chiu et al, 1995). For the balloons made from the middle finger of a surgeon's glove, the finger is affixed to the rubber catheter with two 0 silk sutures. These self-styled dilators were filled with saline rather than air. The device may be backloaded into a well-lubricated (i.e., K-Y jelly) 30-Fr Amplatz sheath to facilitate introduction through a laparoscopic port. Although it is economically advantageous, drawbacks of the self-styled balloon include the lack of a stiff shaft to manually direct the balloon into a specific location for precise dilation as well as the inability to endoscopically monitor the dilation process from within the balloon.

An ex-vivo laboratory study demonstrated that increasing volumes of saline induced gradual pressure increments within the middle finger of a surgeon's glove. At a volume of 1000 mL, the average pressure was 15 mm Hg. Pressures remained 15 mm Hg at 1500 mL and increased to 17 mm Hg at 2000 mL (McDougall et al, 1994). In practice there is no need to exceed the 1000-mL limit. Also, latex balloons have less tensile strength than silicone balloons, making them more likely to rupture. Regardless, with either balloon setup, on the few occasions that either type of balloon has ruptured there has been no obvious complication. However, the latex balloon has a tendency to rupture into multiple pieces whereas the Silastic balloon usually leaves only one large fragment, making retrieval an easier task.

Complications associated with balloon dilation stem from improper balloon placement or balloon rupture. Intramuscular dilation may result in hernia formation, or inadvertent peritoneal disruptions may occur (Gaur, 1992; Adams et al, 1996).

Manual Dilation. Creation of a working space within the retroperitoneum may be achieved exclusively with a combination of digital and laparoscopic instrument dissection (Kerbl et al, 1993). After access to the extraperitoneal area is gained, to-and-fro movements of the laparoscope are performed to create a working space (McKernan, 1995). This technique has been employed to perform various simple and advanced procedures in the retroperitoneum (Rassweiler et al, 1998a; Abbou et al, 1999). Although it is effective, potential disadvantages of this technique include frequent cleaning of the laparoscope and the lack of clear landmarks initially due to the smaller, undeveloped working space.

Technique for Balloon Placement: Open (Hasson) Technique. This is the most commonly employed technique because it affords the greatest precision during development of the retroperitoneal space (Gill, 1998). Initial access is obtained through a 2.0- to 2.5-cm transverse incision in the midaxillary line, just below the tip of 12th rib. The wound is opened with a pair of S-retractors. Under direct vision, the posterior layer of the lumbodorsal fascia is incised and muscle fibers are split or divided. The retroperitoneal space is entered, **under direct vision,** by making a small incision in the anterior thoracolumbar fascia with an electrocautery blade or, less commonly, by bluntly piercing the fascia digitally or with a hemostat. Care should be taken that this fascial opening is snug around the index finger and no larger, so that intraoperative air leak is minimized. Index finger palpation of the belly of the psoas muscle posteriorly and the Gerota fascia–covered inferior pole of the kidney anteriorly confirms proper entry into the retroperitoneal space (Fig. 9–12A). The index finger is employed to digitally create a space in this precise location for placement of the balloon dilator; two inflations of the balloon are then done—one directed cephalad and the second directed caudad to fully dilate the retroperitoneal space (see Fig. 9–12B). Thus, balloon dilation is performed anterior to the psoas muscle and fascia and outside and posterior to the Gerota fascia. In cases involving definitive ureteric mobilization (e.g., retroperitoneoscopic donor nephrectomy, nephroureterectomy, ureterolithotomy, pyeloplasty), an additional balloon dilation may be performed more caudad to the primary site of dilation (Gill et al, 1995). Similarly, during a retroperitoneoscopic adrenalectomy, it is helpful after the initial balloon dilation to move the balloon up higher in the retroperitoneum and perform a second even more cephalic balloon dilation along the undersurface of the diaphragm (Sung and Gill, 2000).

Instrumentation for Developing the Extraperitoneal Space

Open (Hasson) Technique

A 1.5- to 2-cm curvilinear incision is made along the inferior umbilical crease. The anterior rectus sheath is incised vertically for 1.5 cm, and the rectus muscle is separated in the midline to expose the posterior rectus sheath. With the surgeon's index finger positioned posterior to the rectus muscle and anterior to the posterior rectus sheath, gentle tunneling motions are made in a caudal direction until the area of the symphysis pubis is reached. At this

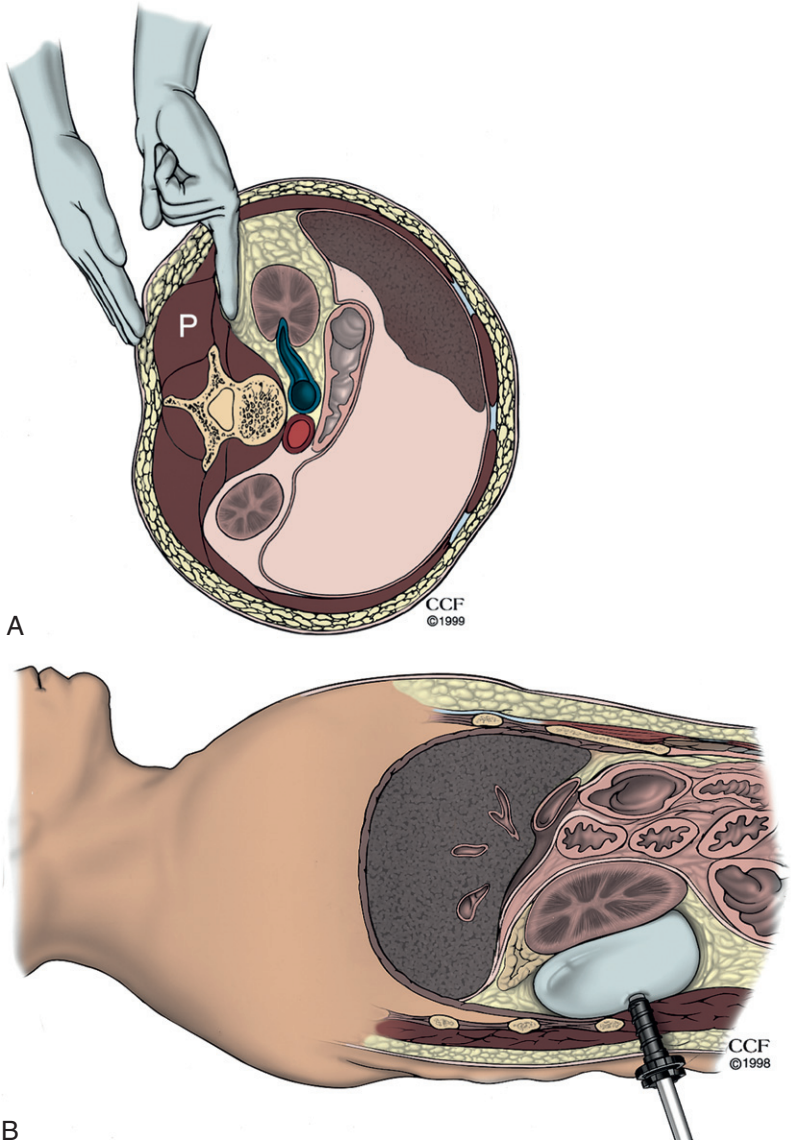

Figure 9–12. **A**, Access into the right retroperitoneum. Through the primary port incision at the tip of the lowest (12th) rib, open access is gained into the retroperitoneum after piercing the thoracolumbar fascia. Finger dissection is performed anterior to the psoas muscle and fascia to create a space for insertion of the balloon dilator. Confirmation that the finger dissection is indeed being performed in the proper plane is obtained by palpating the psoas and erector spinae muscles between the retroperitoneally located index finger and the fingertips of the opposite hand positioned on the patient's back. The fat-covered lower pole of the kidney can be palpated in a cephalad direction by turning the finger clockwise in the retroperitoneum on the right side. **B**, Balloon dilation in the posterior pararenal space facilitates the creation of a working space for retroperitoneal laparoscopic nephrectomy *(coronal view)*. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1998-2011. All Rights Reserved.)

distal location, the fascia transversalis is punctured with the fingertip and gentle side-to-side digital dissection is performed in the prevesical space, posterior to the pubic bone. Into this predeveloped space, a balloon dilator (see earlier) is inserted and distended to create an adequate working space. Balloon dilation effectively displaces the prevesical fat and reflects the peritoneum cephalad. The balloon is initially inflated in the midline and then re-inflated on either side to further expand the working area (Meraney and Gill, 2001).

Caveat: The classic Hasson cannula requires the placement of two 0 silk sutures into the fascia that are then affixed to the cone-shaped portion of the cannula to effect a seal between the cannula and the fascia. This arrangement invariably results in a significant leakage of gas because the seal is rarely airtight. Indeed, in earlier studies of retroperitoneoscopy, excessive subcutaneous emphysema and higher carbon dioxide levels were the norm owing to use of the standard Hasson cannula (Wolf et al, 1995; Ng et al, 1999); this situation was rectified with the introduction of the open access blunt port, which has a balloon to secure it against the underside of the abdominal wall and a soft foam cuff to secure it to the outer abdominal wall, thereby effecting an airtight seal (Ng et al, 1999).

Access Technology: Trocars, Hand-Ports, and Single-Port Access

Trocars. Trocars enable the laparoscopist to introduce working instruments into the gas-filled abdomen or retroperitoneum. They also maintain or reestablish a pneumoperitoneum by conveying the insufflant and may serve as pathways for delivering small amounts of dissected tissue from the surgical area. Typically a trocar consists of an outer hollow sheath (also called a cannula or port) and an inner bladed obturator, which is removed as soon as the outer sheath has entered the peritoneal cavity.

A variety of nondisposable and disposable trocars are available. Standard models range from 3 to 20 mm in diameter and 5 to 20 cm in length. One-way valves within the trocar allow the surgeon to exchange instruments through the port without the escape of significant amounts of gas. Some older trocar models have trapdoor or flap valves. In such trocars it is necessary to depress the valve lever to open the valve widely during retrieval of tissue or needles. More recently, multi-seal type valves have become available for 10- and 12-mm trocars that accommodate the passage of 5 mm and larger instruments without any air leak occurring; if large amounts of tissue are to be withdrawn, removal

of the outer seal or of the entire valve is necessary for this procedure. The outer seal/valve can then be replaced before reinserting instruments.

Initially, only sharp tipped/bladed trocars were available. On these trocars the sharp obturator incised the various layers of tissue as it entered the peritoneal cavity. To protect the underlying viscera from the sharp tip of these trocars, a plastic safety shield was later incorporated into the disposable trocars that would spring forward to shield the blade once the trocar entered the gas-filled abdomen (see Fig. 9–9B). **However, bladed trocars should be only of historical interest because they have been superseded by safer noncutting dilating trocars, which no longer require a safety shield.** These trocars enter the abdomen by spreading the abdominal wall musculature, rather than cutting it (see Fig. 9–9C). As such there is less chance of injuring an abdominal wall vessel and the resulting entry site is less prone to subsequent herniation; indeed, the risk of either of these complications is fivefold less than with blunt versus sharp trocars (Hashizume and Sugimachi, 1997; Thomas et al, 2003).

As with the older sharp trocars there are both disposable and nondisposable blunt trocar units. The Step Needle/Sleeve (Covidien Ltd., Mansfield, MA) is a disposable system that uses a needle port with an outer diameter of 2.1 mm (6.5 Fr) that incorporates a Veress needle introducer. After correct and successful puncture of the abdomen and establishment of the pneumoperitoneum, the Veress needle introducer is removed and the needlescopic port serves either as a camera-bearing sheath of a 1.9-mm needlescope or as a working port for needlescopic scissors or graspers used to perform needlescopic surgery. Alternatively, the needle can carry the initial port into the abdomen; this is an expandable port that in its collapsed state is 2.1 mm at the distal tip and 3.8 mm along the body of the trocar. This trocar can then be expanded by passage of a blunt-tipped obturator to expand the collapsed sheath to 5 mm, 10 mm, or 12 mm, depending on the surgeon's needs. The port has an adjustable seal that allows introduction of laparoscopic instruments within a range of 4.4 to 12 mm in diameter. Thus, the tissues of the abdominal wall are stretched rather than incised, thereby precluding the need for placement of fascial sutures at the end of the procedure.

Other blunt-tipped trocars are produced by all of the major trocar manufacturers. These devices have a variety of tips that enable their placement by spreading the tissues; some also have a clear plastic tip such that the surgeon can pass an endoscope into the trocar to endoscopically monitor its passage through the abdominal wall and its entry into the gas-filled abdomen. One of the blunt-tipped disposable trocars incorporates a curved cutting blade that is trigger activated by the surgeon as the clear port is passed under endoscopic control (i.e., Visiport Plus RPF Single Use Optical Trocar with Versiport Plus RPF Converterless Trocar Sleeve, US Surgical, Norwalk, CT). This hybrid of a blunt and sharp trocar is used sparingly owing to the cutting blade, which can still injure vessels or viscera; also the port site created by passage of this trocar requires a sutured closure of the fascia.

The only reusable blunt-tip port, the EndoTip system (Karl Storz, Culver City, CA), is a screwlike device that has no sharp points or cutting edges (see Fig. 9–9D). It comes in 5-, 10-, and 12-mm designs; however, the 10- and 12-mm trocars require use of a cumbersome reducer system because they are not of a multiseal design (see earlier). It is introduced through the skin incision, by rotating the cannula in a clockwise manner until the gas-filled abdomen is entered; alternatively, an appropriately sized 0-degree lens laparoscope can be used to monitor the penetration of the various tissue layers. Indeed, this combination can be used in the situation when use of the Veress needle to obtain a pneumoperitoneum has failed; in this case, once the EndoTip engages the abdominal wall musculature the device is held upward while continuing to rotate it—in this manner the peritoneum is lifted upward and safely entered. Unlike the action of trocars with a sharp tip, the tissue is not cut but is only displaced and bluntly dilated, thereby preserving the closing mechanism of the overlying muscle and fascia. Because of its innovative design, this device reduces injury to the intra-abdominal organs, stays securely in place, and seals the point of entry against any inadvertent loss of gas.

On removal of any of the blunt-tip ports, the fascia does not need to be sutured, except when it is placed in a non-midline area. However, some surgeons do not place a suture even with midline placement provided that postoperative palpation of the entry site reveals a small defect (Siqueira et al, 2004).

All primary and some secondary trocars have sidearm insufflation line input valves and a small distal hole near the tip to prevent formation of a vacuum, which may suck viscera into the cannula when the cannula is removed. Some less expensive, smaller trocars do not have sidearm stopcocks and can be used only as secondary trocars.

Reducers allow downsizing of working channels in 10-mm or larger trocars to accommodate smaller, 5-mm working instruments without any leakage of CO_2; however, the development of multiseal technology has resulted in valves that can accommodate 5- to 12-mm instruments without the need for a reducer. This development saves significant time during a long procedure.

Retention of the cannula at the port site is essential to decrease air leak and subcutaneous emphysema and facilitate the timely completion of a procedure. In the past it was necessary to affix a suture to the insufflation sideport and the skin to secure the trocar. At present, myriad retention mechanisms prevent dislocation of cannulas: threaded sleeves, adjustable threaded sleeves, expandable arms, and inflatable balloons. In this regard the older plastic devices used to affix a metal trocar to the abdominal wall should never be used; this combination can result in inadvertent capacitive coupling electrosurgical injury to the bowel or other viscera owing to the insulating effect of the plastic device.

Hand-Assist Devices. The first generation of hand port devices consisted of the Handport, Intromit, and Pneumosleeve. As with most first-generation laparoscopic devices, they were adequate with regard to functionality but each had its drawbacks (Stifelman and Nieder, 2002). These products have now been replaced by a second generation of improved devices: The Gelport (Applied Medical, Rancho Santa Margarita, CA), the Omniport (Advanced Surgical Concepts, Wicklow, Ireland), and the LapDisc (Ethicon Endosurgery, Cincinnati, OH).

The Gelport (Fig. 9–13A on the Expert Consult website) consists of a gel-like disc that easily admits the surgeon's hand and then molds around the wrist and arm. The latest Gelport design has a 12-cm footprint. To set up the two-piece Gelport system the surgeon inserts the lubricated wound protector through a 7- to 8-cm incision and adjusts it to create a tight seal across the abdominal wall. A gel disc is then snapped on top of the wound protector and held in place with a small lever. The Gelport offers the advantages of never losing a pneumoperitoneum on hand exchange because it immediately seals after hand removal and it does not require adjustment to maintain a seal. Additional instruments can be passed alongside the surgeon's hand, through the gel material, also without loss of the pneumoperitoneum.

The Lapdisc (see Fig. 9–13B on the Expert Consult website) is a one-piece unit that has an inner diaphragm that is used to anchor it across the abdominal wall and an outer appliance that dials down a thin plastic sheet, like a camera iris, around the surgeon's wrist. Although this device has a low profile and small footprint (12 cm) it does result in loss of the pneumoperitoneum every time the hand is removed and reinserted and instruments cannot be passed parallel to the surgeon's hand.

The Omniport (see Fig. 9–13C on the Expert Consult website) is a balloon-like device that anchors itself as one piece across the abdominal wall. The inflated device also creates a seal between itself and the surgeon's wrist. The device has a smaller footprint (12 cm); however, it must be uninflated and reinflated each time a hand is exchanged, which results in loss of the pneumoperitoneum. Furthermore, no additional devices can be passed parallel to the surgeon's hand through the device.

In a recent study, 130 urologists participating in a series of hand-assist courses evaluated the different devices for a variety of features. The overall scores in this study were 8.6, 7.4, and 7.3 on a scale of 10 (10 being best) for the Gelport, LapDisc, and OmniPort, respectively (Patel and Stifelman, 2004). Advantages of the Gelport included sturdiness, ease of hand exchange, maintenance of the pneumoperitoneum, as well as the ability to pass both a hand and a laparoscopic instrument simultaneously. Of note, the price to the surgeon of using a hand-assist device is not inconsequential. For the surgeon, pain and numbness of the hand/wrist/forearm and, to a lesser extent, overall fatigue are much greater when using a hand-assist device versus standard laparoscopy (Monga et al, 2004; Gofrit et al, 2008).

Access Devices and Techniques for LESS. There are two basic methods used to achieve intra-abdominal access for LESS. One technique is to make a 2.5-cm incision, typically periumbilical or transumbilical (although an alternate site may be necessary), through which a skin flap can be raised off of the abdominal wall fascia. Then, through this single incision several (two to four) standard 5-mm laparoscopic ports can be placed in close proximity to one another. A laparoscope and working instruments can then be placed through these ports. **The size of the skin incision should correspond to the surgical task at hand. If the procedure does not require removal of a large intact specimen, then the incision should be minimized to as little as 2.5 cm. If the procedure requires large intact specimen removal (as in donor nephrectomy), then the incision should be large enough to extract the specimen.**

Another technique is to use a commercially available single site surgery device. These devices currently require a single incision that is typically placed periumbilically or transumbilically unless the procedure dictates an alternate site. Currently there are three devices that are available for commercial use. The TriPort (Advanced Surgical Concepts, Bray, Ireland) is a two-piece system consisting of an inner diaphragm that works like a wound protector and an outer piece containing the ports (Fig. 9–14A). The wound protector component is adjustable and cinches down the outer attachment, creating a tight seal on the abdominal wall. The TriPort, which requires a 12- to 25-mm incision, has room for a 5-mm laparoscope and two 5-mm working instruments plus a separate insufflation valve. The same manufacturer also makes a four-port model called the QuadPort that contains two 12-mm and two 5-mm instrument insertion sites; it requires a 2.5- to 6.5-cm incision. The Uni-X (Pnavel Systems, Cleveland, OH) is a similar device that is anchored to the abdominal wall by preplaced facial sutures. It has three 5-mm insertion sites and can be placed through a 1.5-cm incision (Kaouk et al, 2008b).

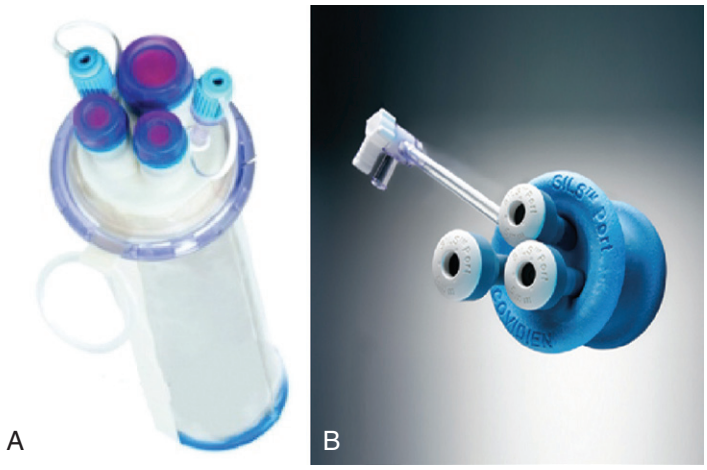

Figure 9–14. Commercially available ports for LESS surgery. **A,** Triport. **B,** SILS port.

The SILS port (Covidien Ltd., Mansfield, MA) can be placed into a 2-cm incision and can house three 5-mm ports or two 5-mm ports and a 5- to 10-mm port (see Fig. 9–14B).

These devices have been used successfully to perform single-site nephrectomy, adrenalectomy, pyeloplasty, renal cyst decortications, and renal cryoablation (Castellucci et al, 2008; Gill et al, 2008; Goel and Kaouk, 2008; Kaouk et al, 2008b; Ponsky et al, 2008b; Rane and Rao, 2008).

Placement of Initial Trocar. For pelvic procedures, the patient is usually positioned with the head slightly down and the intra-abdominal CO_2 pressure is kept at 15 mm Hg. After establishment of a Veress needle pneumoperitoneum (i.e., closed technique), the edges of the wound and subcutaneous tissue are spread with a blunt forceps. Next, the trocar is held in the dominant hand with the middle finger extending along the shaft and the trocar is inserted using a twisting downward motion. If the surgical site is in the mid to upper abdomen, then the trocar is passed perpendicular to the umbilical incision; however, for pelvic procedures, the trocar is directed 70 degrees caudad. Proof of entering the gas-filled intraperitoneal cavity is the sound of CO_2 escaping from the open sidearm. After the sidearm is closed, the obturator is removed and the CO_2 insufflation line is connected to the side port of the trocar. If using a clear blunt port, a 0-degree laparoscopic lens is placed so the entire entry of the trocar is endoscopically monitored.

For procedures such as nephrectomy or nephroureterectomy the patient is placed in the modified flank (i.e., lateral decubitus) position and the pneumoperitoneum pressure is increased to 20 mm Hg. The initial incision is usually either 2 fingerbreadths medial and 2 fingerbreadths superior to the anterior-superior iliac spine or subcostal in the midclavicular line (e.g., at the Palmer point on the right). The trocar is passed perpendicular to the skin incision in the manner described for the transumbilical approach.

When an **open technique** is performed to obtain the pneumoperitoneum, the Hasson-style cannula used to obtain access to the abdomen also serves as the initial trocar.

Transperitoneal Approach: Abdominal Inspection. The sterile laparoscope is white balanced. If the laparoscope is a standard optical lens then it can be pre-warmed using a thermos with warm water. Although it is a minor extra expense, a dedicated fluid warmer to

warm the shaft of the standard endoscope is a very useful adjunct. However, **newer endoscopes that have electronics embedded in the tip of the shaft should not be submerged in water.** A standard defogging agent may also be applied to the tip of the endoscope.

The **entire abdomen** is inspected systematically. Initially, abdominal inspection is performed to rule out any injury to the underlying viscera that may have occurred during access or placement of the initial trocar. The laparoscope is then introduced through a second port to "look back" at the initial port placement site. Then, if the patient is supine, the following pelvic anatomic landmarks are visualized: bladder, urachus, medial umbilical ligaments, and internal inguinal rings, followed by the appendix and the lower parts of the colon; in the male the vasa deferentia can sometimes be seen, whereas in the female the round ligaments, uterus, and ovaries are viewed. Next, turning toward the upper abdomen, the liver, gallbladder, spleen, stomach, omentum, and small bowel are visualized. However, abdominal inspection is usually limited to the superior ipsilateral half of the abdomen if the patient has undergone insufflation and port placement in the lateral decubitus position.

Hand-Assist Placement. The hand-assist device can be placed either as an initial "port" or as a secondary port depending on the surgeon's preference. The former approach is easier because the procedure then begins with making a standard midline (for right or left renal surgery) or right lower quadrant (i.e., for right renal surgery) 6.5- to 7.5-cm incision at the planned hand-assist site. The peritoneal cavity is entered in the standard open surgical fashion, following which the hand-assist device is placed. Next, a blunt cannula is passed through the hand-assist device and a pneumoperitoneum is established. Alternatively, a Veress or Hasson pneumoperitoneum may be initially established and the hand-assist device can then be placed under endoscopic monitoring. Before initiating a hand-assist procedure, the surgeon is advised to wrap the arm/glove seam on the hand that is to be used through the handport either with a 1010 drape or an Ioban (3M, St. Paul, MN) "sticky drape" to waterproof his or her arm; if a 1010 drape is used, the surgeon will need to place a second glove on the hand-port hand to prevent its dislodgment during the procedure.

Additional blunt ports can be rapidly and safely placed using the surgeon's one hand to place the port while the intra-abdominal hand is used to palpate the tip of the trocar and hence guide its entry into the abdomen. **Lastly, the use of a brown glove on the intra-abdominal hand is recommended because they do not reflect the light from the laparoscope and thus reduce glare** (Wolf, 2005).

Secondary Trocar Placement

Transperitoneal Standard. Number, size, and exact location of secondary trocars depend largely on the intended laparoscopic procedure. Their configuration should be planned so that neither the tips nor handles of the cannulas cross or come into close contact with one another (a problem termed *crossing swords* and *rollover*, respectively) such that adequate working space is provided for all instruments to be used during a particular procedure and allowing for effective triangulation at the surgical site by the endoscope and two working ports. In general, it is reasonable to place the ports in a four-point diamond pattern such that the site of the operation is encircled within the diamond. **This is particularly important when considering reconstructive renal procedures, because the angle between the horizontal plane and the needle drivers should be less than 55 degrees whereas the angle between the surgeon's suturing instruments should be in the 25- to 45-degree range** (Rassweiler and Frede, 2002).

Secondary trocars are placed under direct optical control. The 30-degree lens is ideal for this portion of the procedure because turning the lens 180 degrees away from the surgical site provides the surgeon with a panoramic view of the anterior abdominal wall. The operative lights are dimmed, and the tip of the laparoscope is moved upward toward the intended site of port placement, thereby, in the thin patient, transilluminating any superficial blood vessels that need to be avoided while passing the trocar. Using a No. 12 hook or No. 15 small blade, a skin incision is made just wide enough to accept the selected cannula. When placing secondary ports, it is of great importance to direct them toward the intended surgical field to provide tension-free maneuverability of the laparoscopic instruments. This is especially important in obese patients because the errant port will provide resistance to the surgeon throughout the rest of the procedure. Similar to placement of the initial port, all secondary ports are advanced through the abdominal wall using a slow, twisting motion and constant pressure. If necessary, the abdominal wall can be elevated by towel clips placed at the edges of the skin incision made for port entry, to facilitate safe advancement of trocars into the peritoneal cavity. Each secondary port is passed into the peritoneal cavity under meticulous endoscopic monitoring. After placement of the second port, a 5- or 10-mm laparoscope is advanced through this port to inspect the entry site of the first trocar into the peritoneal cavity to rule out any inadvertent injury to the bowel, underlying viscera, or an abdominal wall vessel. To prevent dislocation, ports that do not possess self-retaining mechanisms may be anchored to the skin using No. 2 nonabsorbable sutures. In this regard it is very important for the surgeon to never use a plastic retention sleeve with a metal cannula; this combination creates a situation in which stray electrosurgical current may injure the bowel or other structures adjacent to the cannula since the plastic sleeve insulates the abdominal wall, resulting in increased current density along the metal intra-abdominal portion of the cannula.

Transperitoneal: Hand-Assist. When the hand-assist device is in place, then secondary trocars can be placed with digital guidance. After inspection of the abdomen rules out any potentially interfering adhesions, the surgeon's index finger is placed on the underside of the abdominal wall at the planned site of trocar placement. A skin incision is made over the surgeon's index finger and the nonbladed trocar is passed with the other hand and guided by the surgeon's finger into the abdominal cavity. This is a very rapid and safe way to place all of the secondary nonbladed trocars.

Retroperitoneoscopy Approach. After controlled balloon dilation of the retroperitoneum, the balloon dilator is replaced with a 10-mm Bluntport (US Surgical, Norwalk, CT). A feature unique to this port is the presence of an internal doughnut-shaped retention balloon and an external adjustable foam cuff, a combination that effectively creates an airtight seal at the location of the primary port site (see Fig. 9–10 on the Expert Consult website). **Use of this device minimizes CO_2 leakage around the 1.5-cm primary port incision, thus reducing the incidence of subcutaneous emphysema and hypercarbia.** In our experience this is far superior to the reusable Hasson cannula; with this device efforts directed at minimizing gas leak, such as placing a deep mattress stay suture or placing petroleum jelly gauze around the cannula, were rarely effective.

For retroperitoneoscopy, several port arrangements are possible: a three-port (I distribution) approach can be employed (Gill, 1998;

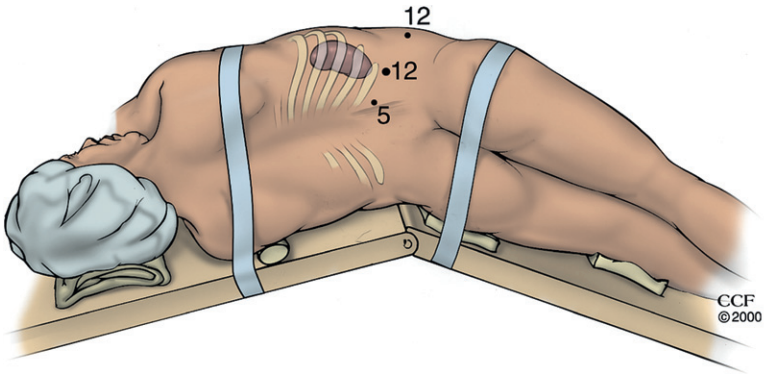

Figure 9–15. For retroperitoneal laparoscopy the patient is positioned in the standard full-flank position. The kidney rest is elevated, and the operating table is flexed to maximize the space between the iliac crest and the lowest rib. A three-port approach is employed. The primary 12-mm port is placed inferior to the tip of the 12th rib. An anterior 12-mm port is placed near the anterior axillary line 3 cm cephalad to the iliac crest. A posterior 5-mm port is placed at the junction of the lateral border of the paraspinal muscles and the 12th rib. (*Note:* After port placement, the kidney rest is lowered.) (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1998-2011. All Rights Reserved.)

Hsu et al, 1999), the authors prefer a four-port approach (T distribution), whereas Abbou and colleagues (1999) described a five-port approach (W distribution). A 30-degree or flexible laparoscope is used, and all secondary nonbladed ports are introduced under laparoscopic or digital control. The posterior secondary port is placed at the lateral border of the paraspinal muscles along the inferior border of the lowermost (12th) rib, and an anterior port is placed at the anterior axillary line, subcostal; thus the three ports are all in a line, hence an I-shaped configuration (Fig. 9–15). A fourth port may be placed, in the middle axillary line, 2 to 3 fingerbreadths above the anterior-superior iliac spine near the Petit triangle thereby creating a T configuration. Placement of this anterior port any closer to the iliac crest limits the amount of cranial angulation of the cannula. A fifth port can be placed just lateral to the anterior axillary line and on the same level as the fourth port, creating a W configuration. Depending on the anticipated technical difficulty of the procedure, patient obesity, and tumor size, for the I configuration, two 12-mm secondary ports or one 5-mm port and one 12-mm secondary port are used. In either situation, a 12-mm port is routinely placed for the surgeon's dominant hand to allow interchangeable use of various large-caliber instruments, including a 10-mm Endo Clip applier, a 12-mm Endo GIA stapler, a 10-mm right-angle dissector, and a 10-mm reusable expandable retractor. The two secondary ports should be inserted as far apart as possible to minimize the possibility of instrument tips clashing within the retroperitoneum. The additional two ports can be 5, 10, or 12 mm depending on the surgeon's preference. Contrary to common conception, the occurrence of an inadvertent peritoneotomy during retroperitoneoscopy does not usually interfere with the subsequent steps of the procedure and conversion to a transperitoneal laparoscopic technique is not mandatory (Gill et al, 2000).

Extraperitoneal Access to the Pelvis. After balloon dilation the Bluntport is inserted at the infraumbilical incision. The retention balloon is inflated, and the foam cuff is cinched down onto the abdomen. **For robotic procedures a standard 12-mm trocar is placed in the extraperitoneal space and hence care should be taken not to create an incision larger than 12 mm** (Esposito et al, 2008). The extraperitoneal space is insufflated with CO_2 at a pressure of 12 to 15 mm Hg, and secondary ports are introduced under visual control. Depending on the procedure to be performed, three to four secondary ports are inserted in a triangle-, diamond-, fan-, or W-shaped configuration. Pneumoextraperitoneum is reduced to 10 to 12 mm Hg for the remainder of the procedure. Unlike with retroperitoneoscopy, the occurrence of a peritoneotomy during extraperitoneoscopy may interfere with the performance of subsequent extraperitoneal dissection and conversion to a transperitoneal technique may be required (Meraney and Gill, 2001).

Robotic Considerations. If a robotic procedure is planned, then the camera port is a 12-mm trocar site and the two (or three if the fourth arm is employed) auxiliary ports are 8 mm. All the ports need to be placed 8 to 10 cm apart to reduce the possibility of the robotic arms clashing with each other. In addition, if the patient is in a flank position, then the lowest port placement should not be inferior to the umbilicus or else the arm may be blocked from a full range of motion by the patient's upside leg. An assistant's port is placed on a line either caudal or inferior to the robotic arms; placement of the assistant's port in between the arms of the robot makes it quite awkward for the assistant to work and limits the range of motion of the assistant's instrument owing to clashing with the arms of the robot.

Laparoscopic Instrumentation

Instruments for Visualization

To create a laparoscopic image, four components are required: the laparoscope, light source, camera, and monitor. To record the image, video recorders, digital video disc, and video printers are available. Laparoscopes that are most commonly used have 0- or 30-degree lenses (range, 0 to 45 degrees) and are available in sizes from 2.7 to 10 mm (most commonly, 5 or 10 mm); however, newer deflectable laparoscopes now exist in which the tip of the endoscope can deflect in four directions up to 90 degrees (Olympus, Melville, NY). Another novel endoscope design is the EndoCAMeleon (Karl Storz, Tuttlingen, Germany). This scope maintains the familiar feel of a standard rigid laparoscope but has a variable-view swing prism that enables the surgeon to change viewing angles from 0 to 30, 45, 90, or 120 degrees. An advantage of the EndoCAMeleon is that it has a standard eyepiece, allowing it to be used with most camera systems.

With standard laparoscopes, image transmission employs an objective lens, a rod-lens system with or without an eyepiece, and a fiberoptic cable. From the eyepiece, the optical image is magnified and transferred to the camera and onto the monitor. Light is transmitted from the light source through the fiberoptic cable onto the light post of the laparoscope (Fig. 9–16A on the Expert Consult website). Some newer laparoscopes have a mini charge-coupled device (CCD) camera mounted at the tip (EndoEYE, Olympus, Melville, NY), which improves image quality and avoids the need for an external light chord that can sometimes impede the movement of other instruments (see Fig. 9–16B on the Expert Consult website). Historically the advantage of the larger

laparoscopes is that they could provide a wider view, better optical resolution, and a brighter image. However, today, many of the 5-mm laparoscopes provide an image that rivals traditional 10-mm scopes. These 5-mm laparoscopes, especially those designed with a low profile handle and a deflectable tip, are particularly of use for LESS procedures.

A special variant is the offset "working laparoscope," which includes a working channel for passage of basic laparoscopic instrumentation; use of this type of laparoscope enables the surgeon to work in a direct line with the image and may allow a reduction in the number of trocars needed to accomplish a particular procedure. However, the working channel occupies space that would otherwise be used for the optical system; thus the resulting image is usually of lesser quality compared with that of laparoscopes without this feature.

The **camera system** consists of a camera and a video monitor. All currently made cameras can be gas or liquid sterilized, thereby facilitating their use and limiting possible intraoperative contamination. For standard laparoscopes the camera is attached directly to the end of the laparoscope and transfers the view of the surgical field through a cable to the camera box unit. After reconstruction of the optical information the image is displayed on one or two video monitors.

A wide variety of cameras are currently available: single-chip, single-chip/digitized, three-chip, three-chip/digitized, interchangeable fixed-focus lenses, zoom lenses, beam splitter, and direct coupler. Three-chip cameras are superior to single-chip cameras in that they provide a higher-quality image with superior color resolution. Again, some endoscopes have the added advantage of having the chip directly at the tip of the laparoscope such that the images are directly processed without interruption thus greatly improving image quality (EndoEYE, Olympus, Melville, NY). This allows the entire system to be built into the handle such that the endoscope connects directly to the camera box; as such, a better image is obtained and the handle has a very low profile (see Fig. 9–16B on the Expert Consult website). **To obtain a "true" upright image of the surgical field on the monitor, the camera's orientation mark must be placed at the 12-o'clock position. With 0-degree laparoscopes the camera is locked to the eyepiece in the "true" position. In contrast, with the 30-degree laparoscope the camera is loosely attached to the eyepiece of the laparoscope so the laparoscope can be rotated. Accordingly, the assistant must hold the camera in the "true" upright position with one hand while rotating the laparoscope through a 360-degree arc to peer over and around vascular and other intra-abdominal structures; the 30-degree lens thus provides the surgeon with a more complete view of the surgical field than does a 0-degree lens. A more recent advancement in laparoscope technology is the four-way deflectable endoscope (EndoEYE Deflectable Tip Video Laparoscope, Olympus, Melville, NY), which offers many potential angles from which to view a structure but requires an adept assistant.**

Three-Dimensional (3D) Laparoscopic Systems. 3D laparoscopic systems offer the surgeon the distinct advantage of depth perception. Optimal 3D laparoscopy is performed with a two-lens system that duplicates the two-eye perception of 3D. In this way binocular vision is maintained. The most commonly used 3D vision system currently in use is the InSite Vision System (Intuitive Surgical, Sunnyvale, CA), which provides vision for the da Vinci Robotic System. The laparoscope and high definition camera are heavy (4 lb for the standard scope and camera head and 5.5 lb for the high-definition scope and camera head) but are controlled by a robotic arm that is under direct control of the surgeon from the ergonomic console. The surgeon maintains a steady, magnified 3D view of the surgical field. Zero- and 30-degree lenses are currently available.

Handheld 3D laparoscopic systems are also available but currently require the surgeon to wear headgear with miniature video screens to display the 3D image (EndoSite 3Di Digital Vision System, Viking Systems Inc., La Jolla, CA). With these systems it is often useful to employ the use of a mechanical or robotic camera manipulator because the slight movements associated with handheld camera manipulation can be distracting when displayed in 3D.

The most vexing problem with any laparoscope is fogging of the lens. To prevent fogging of the laparoscope after insertion into the warm intraperitoneal cavity it is advisable to initially warm the laparoscope in a container holding warm saline before it is passed into the abdomen. The most efficient way to warm the laparoscope is to use a dedicated solution warming basin that is long enough to accommodate the laparoscope; alternatively a warming thermos can be used (Applied Medical, Rancho Santa Margarita, CA). In addition, wiping the tip with a commercial defogging fluid or with povidone-iodine solution is also recommended. Should moisture buildup occur between the eyepiece and the camera both components must be disconnected and carefully cleansed with a dry gauze pad; this is not a problem with the digital endoscopes because the only connection is from the endoscope directly into the display box. **Again, digital endoscopes that house electronic components at the tip of the instrument should NOT be submerged in water.**

Video monitors are available in various sizes ranging from 15 to 26 inches and come in the form of standard cathode ray tube (CRT) monitors or newer flat panel displays. With standard CRT monitors, a larger monitor does not produce a better picture; indeed, given the same number of lines on both monitors, a higher-resolution image is obtained with a smaller screen. To obtain a better image, more lines of resolution are needed. High-resolution monitors have 1125 lines of resolution but must be matched with a camera system of similar capability. Flat panel video monitors are becoming more popular; one advantage is that these screens are usually mounted on a ceiling boom that allows the surgeon to obtain a clear view of both the monitor and the surgical field with the patient in any position. In addition, the flat screen can be lowered and angled close to the surgical site, thereby placing the surgeon's line of sight and the actual operating field in a truer alignment. Flat panel displays are available in standard and high-definition resolution.

Light sources use high-intensity halogen, mercury, or xenon vapor bulbs with an output of 250 to 300 watts. In addition to manual control of brightness, some units have automatic adjustment capabilities to prevent too much illumination, which may result in a "washed-out" image. Any breakage of fibers in the fiberoptic cable, which may occur during sterilization and/or improper handling, results in decreased light transfer from the light source to the laparoscope. Newer light cables are transparent, allowing the surgeon to actually see when light-bearing cables have been damaged. In the event of bulb failure, an extra bulb (or light source) should always be available.

Videocassette recorders, digital video recorders, and video printers serve for documentation of laparoscopic procedures. Videocassette recorders are very reliable for taping procedures but are very cumbersome when it comes to storing, viewing, and editing for replay. Newer systems that use digital tapes,

compact discs, or digital video discs are much more compact and easier to use when it comes to replaying and editing for video production. With regard to still images, the newer digital recorders have the advantage of storing thousands of images and maintain the ability to print paper copies of the desired images.

Instrumentation for Grasping and Blunt Dissection

Most graspers and dissectors are used in their 5-mm size but are available in a range from 3 to 12 mm, in predominantly reusable forms. Grasping instruments have either single-action (only one jaw moves during opening) or double-action (both jaws move) tip design.

Wide variations exist with regard to configuration of tip, surface characteristics of jaws, handle design, and possible electrosurgical properties. Tip designs include blunt-coarse, pointed (dolphin), straight (duck bill), curved (Maryland), and angled. The surface of the jaws may be atraumatic or traumatic. Serrated or smooth surfaces allow gentle tissue manipulation in atraumatic graspers (e.g., bowel forceps with a 3-cm long grasping jaw). Traumatic graspers have toothed or clawed surfaces on their jaws to allow them to grasp and hold tissues firmly. In addition, each of these instruments may be equipped with tip-rotation and/or articulating features. Both reusable and disposable instruments are available.

Depending on the design of the handle, grasping instruments may be locking or nonlocking. Most nonlocking forceps have a scissor-type handle. Different designs allow for locking capabilities; in particular, bar-type and spring-loaded locking handles are convenient when prolonged grasping of tissue is required. Some newer dissectors in addition to grip and rotation actually offer additional degrees of freedom by means of an articulating joint activated through wrist movements of the surgeon (RealHand, Novare Surgical, Cupertino, CA; Autonomy Lapro-Angle, Cambridge Endoscopic Devices Inc., Framingham, MA) (Fig. 9–17). **These instruments are most helpful if one is to perform a LESS procedure because the angulation of the shaft then provides the triangulation necessary for approaching the surgical field.** In addition, the shafts of these instruments may be of variable length (i.e., 34, 45, or 75 cm), again allowing for less clashing of handles during a LESS procedure.

In addition to standard dissecting instruments, both the laparoscopic suction apparatus as well as the "heel" of the hook electrode can be used for effective and rapid blunt dissection. Along these same lines, the development of laparoscopic "peanuts" or Kittners (i.e., 5- and 10-mm gauze-tipped disposable dissectors) has been most helpful. These disposable blunt dissectors typically come with the usual absorbent material on the tip, in which case the device needs to be continually switched out for a fresh Kittner owing to absorption of fluid or blood during the procedure. A newer nonporous material has now been affixed to the 10-mm Kittners, allowing one device to suffice through an entire case (Vascular Technologies Inc., Nashua, NH). These dissectors can be twirled or moved side to side or up and down in an area of adipose tissue to rapidly tease away the fat surrounding vital structures such as the renal hilum or the adrenal gland. In addition, the device can be used to raise an entire "line" of tissue (e.g., pararenal fat), allowing for its rapid and safe division because neither the shaft nor tip of the Kittner will conduct electrosurgical current.

Water Jet Dissection. Water jet dissectors such as the Helix Hydro-Jet (ERBE, Tubingen, Germany) use an extremely thin, high-pressure laminar liquid jet to develop a cleavage plane in tissues. Pressures of 250 to 350 psi are sufficient for dissecting soft tissue while leaving vascular structures and nerves intact (Shekarriz et al, 2004). The device is activated using a foot pedal and the water jet is administered from a 5-mm wand. This device may have particular application in parenchymal transection as in partial nephrectomy or in nerve-sparing procedures such as during retroperitoneal lymph node dissection (Basting et al, 2000; Shekarriz et al, 2004). However, owing to fluid accumulation in the abdomen, changes in tissue turgor (i.e., fluid laden) and, in particular, splash back from the fluid stream that can foul the laparoscope lens, these devices have not come into widespread usage.

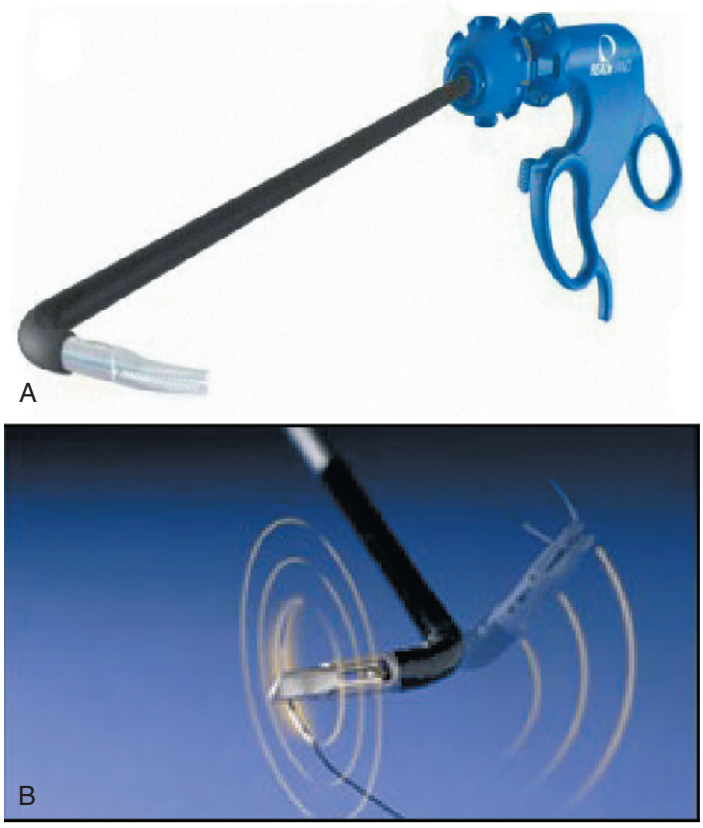

Figure 9–17. Examples of deflecting graspers. **A**, RealHand (Novare Surgical, Cupertino, CA). **B**, Autonomy Lapro-Angle (Cambridge Endoscopic Devices Inc., Framingham, MA).

Instrumentation for Incising and Hemostasis

Laparoscopic scissors, scalpels, electrocautery, and lasers (CO_2, neodymium:yttrium-aluminum-garnet [Nd:YAG], or potassium titanyl phosphate [KTP]) are used to incise or cut tissue during laparoscopic surgery.

Laparoscopic scissors are available in disposable and nondisposable forms. The blades of laparoscopic scissors are shorter than their open surgical counterparts. The configuration of the tip may be useful for selected situations: serrated tips for cutting fascia, hooked tips for cutting sutures, microscissors for spatulating the ureter during a pyeloplasty, and curved tips for dissection. Incision of the tissue is achieved using either an electrosurgical ("hot") or a mechanical ("cold") approach. The scissors may come with either permanent blades or with replaceable tips; the latter ensures "sharp" scissors for each procedure. In addition, the shaft of the scissors may rotate and, in some disposable scissors, even articulate up to 90 degrees. The latter feature is particularly helpful when spatulating the ureter during a pyeloplasty.

A **laparoscopic scalpel** is also available. It is of particular use for incision of the ureter during laparoscopic ureterolithotomy.

For **electrosurgical incision** of tissue, a selection of different electrodes is available: needle electrodes (Corson type) produce fine cuts that are useful in making peritoneal incisions, spatula electrodes are used in blunt dissection and cutting, and hook electrodes (J and L configurations) are of particular value during dissection of vessels because tissue can be pulled away from delicate structures before the cutting current is activated. **The thinner the metal tip of the probe, the higher the density of the electrical current, and the greater the cutting power.**

As with all insulated instruments, certain precautions must be followed during monopolar electrosurgery to avoid local or distant transmitted thermal injury. Consequently, the electrosurgical probe should not be activated unless the metal part is in complete view. The insulation of the electrosurgical instrument should be carefully checked for any damage. The probe should not be activated unless it is in direct contact with the tissue to be incised. Also, use of the monopolar electrosurgical instrument through a metal rather than a plastic cannula decreases the chances of inadvertent electrosurgical injury owing to capacitive coupling. In this regard, one should never use a metal trocar in conjunction with an outer plastic retaining ring because stray current can no longer be harmlessly dissipated through the metal cannula directly to the surrounding peritrocar abdominal wall and hence, any juxtaposed visceral structure may be damaged in an area remote to the laparoscopist's vision. The same precautions apply with monopolar equipped grasping forceps, which might be used during a procedure to obtain hemostasis.

To avoid the potential dangers of stray current from use of monopolar electrosurgical equipment, the surgeon can use monopolar current in conjunction with active electrode monitoring (Encision Inc., Boulder, CO). This instrumentation is constructed such that there is ongoing feedback during activation of the electrosurgical current; as such, any break in the insulation of the shaft results in immediate deactivation of the instrument.

Floating Ball Electrode (Monopolar Device). The Endo FB3.0 floating ball electrode (Salient Surgical Technologies, Dover, NH) is a saline cooled radiofrequency surface coagulator/sealer. Skimming a FB3.0 floating ball over a tissue surface in small circles seals the tissue, stopping the flow of blood and other fluids by effectively shrinking the natural collagen in the tissue. The wet energy from the FB3.0 cools tissue and keeps temperatures less than 100° C, preventing tissue charring and eschar formation. This device has been proven to be quite useful for coagulating the parenchymal bed after partial nephrectomy before application of a hemostatic agent and/or bolster (Stern et al, 2004; Urena et al, 2004).

Bipolar Electrosurgical Devices. The laparoscopic surgeon can also use bipolar electrosurgical devices that require less energy for performance than their monopolar counterparts. There is also a decreased likelihood of injury to surrounding tissue because the electrical current is passing only from one jaw to the other, thereby precluding the potential problems of capacitive coupling commonplace with monopolar electrosurgical current. With bipolar current, the extent of coagulative damage is less than with monopolar electrosurgery: 1 to 6 mm versus 5 to 7 mm with monopolar current (Landman et al, 2003).

The LigaSure vessel-sealing system (Valleylab, Boulder, CO) consists of a 5- or 10-mm grasper/dissector connected to a bipolar radiofrequency generator. When the vascular structure is grasped by the instrument the tissue is evaluated by a feedback-response system that subsequently delivers the optimal energy required to seal the vessel effectively. Because of the high-current and low-voltage output, the vascular structure enclosed by the jaws of the instrument degrades quickly and a protein-based seal is presumably created; this mechanism of electrical current delivery to the tissues results in less charring and less collateral thermal damage (1 to 3 mm) (Landman et al, 2003). Indeed, use of this instrument during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al, 2008).

An audible signal alerts the surgeon that the sealing of the vessel is complete; the instrument has a trigger activated blade that the surgeon can then use to cut the sealed tissue. Vessels up to and including 7 mm appear to be effectively occluded with this device (Carbonell et al, 2003; Landman et al, 2003). Recent porcine studies have confirmed that the LigaSure effectively seals veins, arteries up to 9 mm in diameter, and ureters of a similar size to above normal physiologic pressures, but only with one LigaSure application to the structure as opposed to multiple applications. Indeed, multiple applications may weaken the seal (Truong et al, 2008).

Another simultaneous vessel sealing and cutting device is the EnSeal PTC. This is a 5-mm instrument that can also act as a grasper/dissector. The electrode design employs a temperature sensitive polymer that helps to limit current spread to surrounding tissues. The device has an I-beam–shaped blade that draws the jaws of the instrument together with increasing force as the blade is advanced through the tissue. Hence, the surgeon can control the rate of cutting by how quickly the instrument handle is squeezed. The device can be used to seal vessels up to 7 mm but is reported to require a longer vessel sealing time than the LigaSure V (Ethicon Endosurgery, Cincinnati, OH) (Lamberton et al, 2008).

Laser Instrumentation. **Lasers** (CO_2, KTP, Nd:YAG, holmium) are most frequently used through the working channel of an operating laparoscope. The CO_2 laser provides excellent cutting and vaporization of surface lesions; it requires a rigid hand piece and probe. In contrast, the 400- and 600-μm KTP fibers are flexible and allow for noncontact cutting and fulguration. Nd:YAG laser fibers are also flexible and allow noncontact fulguration and contact cutting. Holmium laser fibers are also flexible and are used in a contact mode for cutting. Fibers with sculpted tips provide more precise cutting. Laser-specific goggles must be worn during all laser-related procedures by every individual in the operating room, including the patient. Lasers are not used in urologic laparoscopy; likewise, in general surgery they have largely been supplanted by electrosurgical instruments. Only in gynecology is the CO_2 laser used extensively, generally in the treatment of endometriosis.

Ultrasound Instrumentation. Ultrasonic technology is another option for cutting and hemostasis in endoscopic surgery. It provides an especially attractive alternative to monopolar electrosurgery when one is working around particularly delicate tissues or operating on patients with an implanted pacemaker/cardioverter defibrillator (Gossot et al, 1999; Strate et al, 1999). In ultrasonic surgery, electrical energy is transformed into mechanical energy by the use of a piezoelectric crystal system. Mechanical vibrations produced by this system in the tip of the instrument are capable of causing the following effects on tissue: cavitation, coaptation/coagulation, and cutting (Strate et al, 1999).

In the ultrasonically activated harmonic scalpel/shears, electrical energy is produced by a power-supply generator and transformed into mechanical vibration at the tip of the instrument through a piezoelectric crystal interface (Suzuki et al, 1995; Takeda et al, 1997; Gossot et al, 1999). Mechanical vibration with a tip excursion of 80 to 200 μm (at a frequency of 55.5 kHz) is subsequently transferred to the tip of the instrument. Multifunctionality (grasping, cutting, dissecting, and coagulation) is provided with the shears. In addition to the absent risk of local thermal

damage and tissue charring because of a working temperature of less than 80° C, the depth of penetration is limited to the targeted tissue within a diameter of 1 mm (Landman et al, 2003). Reduced tissue charring may result in a reduced rate of postoperative adhesions (Amaral and Chrotstek, 1997). As with bipolar energy, use of ultrasonic energy during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al, 2008). In addition, the harmonic scalpel eliminates other problems associated with monopolar electrosurgery, specifically, problems of remote site tissue damage owing to capacitive coupling, insulation defects in the instrumentation, and direct coupling. Potential disadvantages of the harmonic technology include slower vessel sealing (Lamberton et al, 2008) and the fact that the metal portion of the shears becomes quite hot during activation (often over 200° C compared with the bipolar energy–based devices which stay below 100° C) and must not come into direct contact with any bowel surrounding the area of dissection. In fact, the harmonic shears take roughly twice as long to cool to a "safe" temperature after firing (often up to 45 seconds) (Kim et al, 2008).

Other Instrumentation. The **argon beam coagulator** provides a noncontact form of electrocoagulation. Electrical current originating from a monopolar electrosurgical generator is conducted to the tissue through an ionized argon gas stream. The gas stream blows away blood from the tissue, resulting in better exposure of the bleeding site and, hence, more effective delivery of the electrosurgical current. Argon is a colorless, odorless, inert gas that clears the body within one respiratory cycle (Quinlan et al, 1992). Holding the handpiece at an oblique 60-degree angle within 1 cm of the surface of the target tissue provides optimal coagulation effects. During argon beam coagulation, the sidearm on one of the laparoscopic ports must be opened to prevent buildup of excessive intra-abdominal pressures. Because argon beam coagulation has its major advantage when hemostasis must be achieved over a diffusely bleeding surface, its most practical indication in laparoscopic urologic surgery is during partial nephrectomy, during wedge excision of a small renal tumor, or for control of small liver or spleen lacerations.

Surgical Pharmaceuticals. Recently, a vast array of topical hemostatic agents, sealants, and glues have entered the surgical realm. These agents, depending on their individual properties, can be used for a variety of surgical tasks and have become a valuable addition to the surgeon's tray.

Fibrin-Based Glue. Fibrin glue has been used to promote hemostasis in parenchymal beds, in particular after partial nephrectomy or to seal a liver laceration. The two components of the fibrin glue, fibrinogen and thrombin, are delivered through separate channels and then combine at the tip of the delivery system during application to the tissue. Fibrin glue has an adhesive quality once dry where it essentially hardens into a rubbery coagulum. Tisseel VH Fibrin Sealant (Baxter, Glendale, CA) has the maximum concentration of human fibrinogen available (75 to 115 mg/mL). It can be delivered by means of a laparoscopic applicator in liquid form or in an aerosolized form. One disadvantage of Tisseel is that it requires a preparation time of 20 minutes before it can be applied by the surgeon. If the application at hand requires immediate application (bleeding) then fibrin glue is not a viable option unless it has been prepared in anticipation of possible hemorrhage. Once prepared, Tisseel VH has a shelf life of 36 hours.

Another fibrin-based sealant that can be delivered in a similar manner is Evicel (Johnson & Johnson, New Brunswick, NJ). This agent, which contains 40 to 60 mg/mL human fibrinogen, comes frozen and thus requires no reconstitution. It can be thawed in the hand in 5 minutes and available in another minute. Once thawed, Evicel has a shelf life of 1 month under refrigeration (Tredree et al, 2006). Another advantage is that it contains no bovine serum components (e.g., aprotinin) and hence can be used in individuals with allergies to bovine-derived products. This product can also be applied laparoscopically with an available applicator.

Although all types of fibrin glue use pooled human fibrinogen, the preparations are treated to inactivate viruses. As of 2006 there were no reported cases of viral transmission to a recipient (Tredree et al, 2006).

Non–Fibrin-Based Surgical Hemostats. In contrast to the fibrin-based glues, other hemostatic agents such as thrombin-soaked oxidized cellulose particles (FloSeal, Baxter, Glendale, CA; Surgifoam, Johnson & Johnson, Princeton, NJ) have no adhesive capability at all but are excellent hemostatic agents in the presence of active bleeding from parenchymal surfaces such as a partial nephrectomy bed, a liver/spleen laceration, or an oozing adrenal bed. This agent is also prepared by the scrub assistant and takes 2 minutes to prepare. It is applied through a tube applicator with a syringe. It is most effective when pressure is applied after its delivery; this can be done either with an instrument (e.g., 10-mm gauze-tipped dissector) or with a bolster.

Avitene Microfibrillar Collagen Hemostat (Davol, Cranston, RI) is an active collagen hemostat that accelerates clot formation by enhancing platelet aggregation and the release of fibrin. Similar to FloSeal, it has no tissue sealing capability but is useful for counteracting parenchymal bleeding. EndoAvitene is available in a preloaded endoscopic delivery system designed for use in endoscopic procedures. Developed to easily pass through standard trocars and cannulas, it is available in both 5- and 10-mm diameters.

Chemical-Based Sealants. BioGlue (CryoLife, Inc., Kennesaw, GA) is a two-component adhesive composed of purified bovine serum albumin and glutaraldehyde. The solutions are mixed during application from a controlled delivery system. The glutaraldehyde then crosslinks the BSA molecules to each other and then to the tissue protein at the site of use. Once applied, the agent polymerizes within 20 to 30 seconds and reaches its full bonding strength within 2 minutes. The delivery system comes ready for immediate use. BioGlue is a sealant and must be applied to a dry field and allowed to dry. Thus it cannot be used to counteract active bleeding but can be used to seal a raw, nonbleeding surface.

CoSeal (Baxter, Glendale, CA) is a completely synthetic product composed of two distinct polyethylene glycol polymers that chemically bond together to seal tissue surfaces, suture lines, and synthetic grafts. It does not require thawing, heating, or light activation and hence can be ready in 1 minute. It must be applied to a dry (non-bloody) surface because it does not interact with the clotting cascade and hence is not useful in the setting of active hemorrhage.

Now that the benefits of such substances have come into the spotlight in surgery it is important for the surgeon to be familiar with the properties of these various agents and thereby able to choose one that is most appropriate for the job at hand. A comparison of popular hemostatic agents is presented in Table 9–2.

Instrumentation for Suturing and Tissue Anastomosis

Suturing and knot tying are among the most difficult tasks in laparoscopic surgery. A significant amount of practice is needed to achieve a sufficient level of proficiency. **Laparoscopic needle**

Table 9–2.

Some Commonly Used Topical Tissue Sealants and Hemostatic Agents

AGENT	MANUFACTURER (TIME TO SET UP)	ACTIVE INGREDIENTS	KEY USES/ PROPERTIES
Tisseel	Baxter, Glendale, CA (20 min)	Fibrinogen CaCl Aprotinin Thrombin	Topical hemostasis Tissue glue
CrossSeal	Johnson & Johnson, New Brunswick, NJ (Immediate)	Fibrinogen CaCl Aprotinin Thrombin	Topical hemostasis Tissue glue
FloSeal	Baxter, Glendale, CA (2 min)	Crosslinked gelatin granules Thrombin	Topical hemostasis
EndoAvetine	Davol, Cranston, RI (Immediate)	Avetine Microfibrillar collagen powder	Topical hemostasis
BioGlue	CryoLife Inc., Kennesaw, GA (Immediate)	Bovine serum albumin and glutaraldehyde	Tissue sealant
CoSeal	Baxter, Glendale, CA (Immediate)	Two polyethylene glycol polymers	Tissue sealant

Figure 9–18. Different handle designs for commonly used laparoscopic needle drivers.

holders have one fixed jaw and one jaw that opens by squeezing the spring-loaded handle of the instrument (Fig. 9–18). They all have a locking mechanism to secure the needle in their jaws; this is done with a ratchet, spring-loaded, or Castroviejo-type mechanism. Some needle holders also possess a feature that allows the jaws to rotate around the main axis relative to the handle. The handles may be straight or provide a pistol-type grip. In addition to standard rigid needle drivers some companies have recently developed articulating needle drivers that aid in obtaining more optimal suturing angles with the needle. The actuation of the articulation mechanism is controlled by the surgeon's wrist motion (see Fig. 9–17) (Laparo-Angle, CambridgeEndo, Hopkinton, MA; RealHand, Novare Surgical, Cupertino, CA).

The Endo Stitch (Covidien Ltd., Mansfield, MA) device is an innovative, disposable, 10-mm instrument that facilitates laparoscopic suture placement and knot tying (Adams et al, 1995). The suture is secured to the center of a straight needle with two pointed ends, thereby allowing tissue penetration in either direction. The needle is shuttled back and forth between the jaws of the instrument after each passage through the tissue, applying a long-known principle used in sewing machines. In this way, passing the needle through the tissue and regrasping the needle after it has traversed the tissue become simple tasks because they are done by a one-handed squeeze of the handle and a flip of the needle-securing lever, respectively. Use of this sewing apparatus has had a major impact on decreasing operative times, especially in laparoscopic pyeloplasty (Chen et al, 1998). However, one drawback of suturing in this manner is that the site of needle passage is invariably larger than the needle itself (i.e., because the suture is passed alongside the needle each time); hence if used to close a cavotomy there is oozing along the needle tract that requires placement of either fibrin glue or thrombin-soaked oxidized cellulose. With experience with standard laparoscopic needle holders and especially with the advent of robotic-assisted procedures, use of the Endo Stitch has become less common.

Lapra-Ty clips (Ethicon Endo-Surgery, Somerville, NJ) are a very useful adjunct to suturing and knot tying. These 3.5-mm clips are made of absorbable polydioxanone and are designed to provide secure anchoring of sutures for up to 14 days in low-tension to mid-tension environments (Ames et al, 2005). According to the manufacturer, these suture anchors can be secured to the end of a single strand of polyglactin 910 (Vicryl) suture as fine as 4-0. Experimental models from two different laboratories have shown that these clips are least likely to fall off of polyglactin 910 sutures from size 1-0 to 3-0 (Ames et al, 2005; Weld et al, 2008). In the laboratory environment Lapra-Ty clips have been shown to be slip resistant with 2-0 Monocryl and PDS suture as well. In multiple test trials for each suture type, a percentage of monofilament sutures size 3-0 and smaller as well as 4-0 suture of any type did have slippage of the clip. Hence, it seems logical to avoid Lapra-Ty use with 4-0 suture and to avoid excessive tension when using these clips with 3-0 monofilament suture. **The clip acts as a knot, thereby precluding time-consuming intracorporeal laparoscopic knot tying** (Fig. 9–19). When they are used to secure a single suture, it is helpful if the suture has a pre-tied loop on its end; the needle is passed through the tissues to be secured and is then passed through the pre-tied loop. Next, the suture is pulled taut, thereby tightening its hold on the encircled tissue; the Lapra-Ty clip is then affixed to the suture material just as it exits the loop. For a running suture, the Lapra-Ty clip can be used both to anchor the end of the suture and to secure the suture on completion of the run. It has also been found to be useful for anchoring bolsters during renorrhaphy for laparoscopic partial nephrectomy (Orvieto et al, 2004).

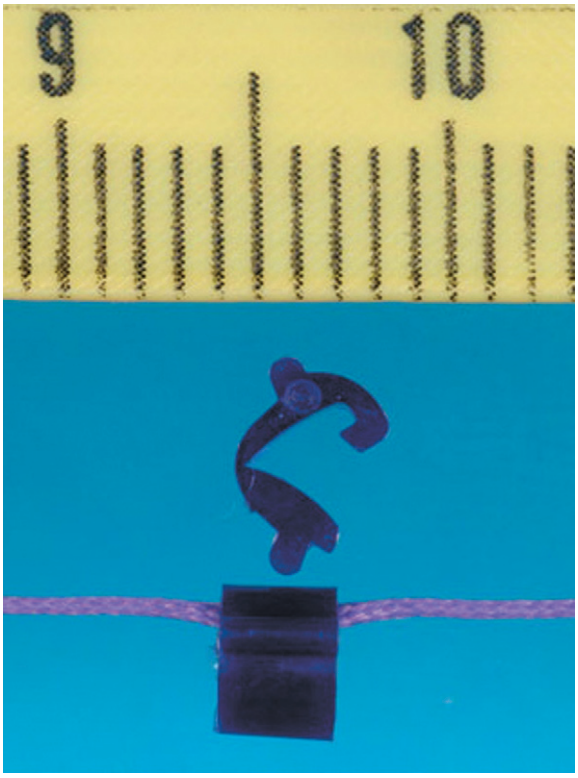

Figure 9–19. Example of a Lapra-Ty Clip (Ethicon Endo-Surgery, Somerville, NJ) affixed to a suture.

Figure 9–20. Example of a laparoscopic stapling device.

Instrumentation for Stapling and Clipping

Stapling Devices. Various stapling devices are available for tissue occlusion and division (Fig. 9–20). The Endo GIA Universal 12-mm stapler/linear cutting device (Covidien Ltd., Mansfield, MA) requires a 12-mm port and delivers two triple-staggered rows of staples and simultaneously cuts in between the rows. The universal stapler can be loaded with a variety of 30-, 45-, or 60-mm loads and fired any number of times. Similarly, the ETS-Flex 45 stapler (Ethicon, Somerville, NJ) also requires a 12-mm port and delivers two triple rows of staples while cutting between rows 3 and 4. This stapler has a maximum fire limit of 8 staple loads. Articulating/roticulating staplers are available from both companies, which enable the surgeon to properly align the instrument with the tissue to be occluded and divided. **Each staple load cartridge is color coded depending on the size of the staples: 2.0-mm staples (gray) or 2.5-mm staples (white) are preferred for vascular (renal vein or renal artery) stapling, whereas 3.8-mm (blue) and 4.8-mm (green) staples are used in thicker tissues (ureter, bowel, bladder).** In addition, for laparoscopic live donor nephrectomy, a single Endo-TA (linear noncutting) stapler can be used to secure the patient's side of the renal vein, thereby providing a longer donor renal vein, because there is no need to trim staples from the vessels before anastomosis in the recipient (Meng et al, 2003). Linear noncutting staplers deliver either three or four staple rows, 30 or 60 mm long. These staplers can also be used to close an enterotomy after a side-to-side bowel anastomosis. **When using laparoscopic staplers, special attention must be paid to the markers on the cartridge to ensure that all the targeted tissue is properly situated proximal to the markers before the cartridge is fired. The stapler should not be fired across any previously placed clips because this is thought to possibly cause stapler malfunction.** Indeed, in a 9-year review of stapler use (1992–2001), Brown and Woo (2004) noted U.S. Food and Drug Administration–recorded reports of 112 mortalities and 2180 injuries attributed to use of the stapler; overall, malfunctions were reported 22,804 times.

Clipping Devices. Disposable and nondisposable clip appliers are available from different manufacturers. Generally they contain occlusive clips ranging in size from 6 to 11 mm; they require either 5-, 10-, or 12-mm laparoscopic ports. Disposable clip appliers possess a rotating shaft and multifire, self-reloading features, whereas nondisposable instruments have to be reloaded for each clip to be deployed at the site of surgery and often do not have a rotating shaft. A right-angle clip applier that fits through a 10-mm trocar and deploys an 8-mm titanium clip is also available (US Surgical, Norwalk, CT).

Electrocoagulation must be avoided in the vicinity of clips placed for occlusion of vessels to prevent conductive tissue necrosis and subsequent clip dislocation. To ensure reliable function, the closed ends of the occlusive clips must be seen extending slightly beyond the targeted vessel and should be placed perpendicular to the longitudinal axis of the vessel.

In addition to the metal "crush" type clips, polymer clips that completely encircle and lock down around a vessel are available (Hem-o-Lok polymer ligation clip system Weck Closure Systems, Research Triangle Park, NC). They are available in four sizes (M, ML, L, and XL). Up to 10 mm of tissue can be ligated through a 5-mm trocar, and up to 16 mm of tissue can be ligated through a 10-mm trocar. Of note, because of results from a survey put forth by the American Society of Transplant Surgeons, in which use of these clips was associated with hemorrhage from the renal artery stump, the company producing the clips put fourth a statement contraindicating their use for securing the renal artery during laparoscopic live donor nephrectomies (Friedman et al, 2006). Subsequently, a multi-institutional study of 1695 patients from nine different institutions undergoing laparoscopic donor nephrectomy with ligation of the renal artery with Hem-o-Lok clips concluded that the clips were safe to use because in their review there were no adverse bleeding events (Ponsky et al, 2008a). **The authors did acknowledge, however, that proper technique of application must be strictly adhered to, including application of at least two clips on the stump of the artery and that a 2-mm cuff of artery should be left distal to the clips** (Table 9–3). Removal of a Hem-o-Lok clip is possible using the removal instrument provided by the company should a structure be clipped in error.

Instrumentation for Specimen Entrapment

Various organ entrapment and retrieval systems are available. Depending on the size of the tissue and on whether in-situ morcellation or intact organ retrieval is planned, the laparoscopic surgeon is able to choose among different-sized sacks, materials, and

Table 9–3.

Basic Principles of Hem-o-Lok Clip Placement

Complete circumferential dissection of the vessel
Visualization of the curved tip of the clip around and beyond the vessel, often with curved end of the clip placed between artery and vein
Confirmation of the tactile snap when the clip engages
No cross clipping
Not squeezing clip handles too hard (compared with the application of metal clips)
Careful removal of the applier after application given; the tips are sharp and can cause a laceration of nearby vessels (e.g., renal vein)
During transaction of vessels only a partial division is performed initially to confirm hemostasis before complete transaction.
Minimum of two clips placed on the patient side of the renal hilar vessel

From Ponsky L, Cherullo E, Moinzadeh A, et al. The Hem-o-Lok clip is safe for laparoscopic nephrectomy: a multi-institutional review. Urology 2008;71(4): 593–6.

designs. Studies have been conducted to test organ retrieval bags for permeability to tumor cells and bacteria before and after morcellation, as well as for stability during morcellation and resistance to tearing forces (Urban et al, 1993; Rassweiler et al, 1998b). The originally designed (1990) LapSac (Cook Urological, Spencer, IN), which is made of nylon with a polyurethane inner coating and a polypropylene drawstring, is the least susceptible entrapment sack to tearing (Eichel et al, 2004) or leakage of cells. However, deployment of the LapSac and subsequent organ entrapment remain challenging endeavors. To aid in the opening of the LapSac, the neck of the sack can be modified at the time of surgery by the surgeon; using a nitinol guidewire a double wrap (every other hole) of the guidewire is placed around the neck of the sack, such that both ends of the guidewire exit the sack similar to the drawstring (Sundaram et al, 2002). The outward expansion of the nitinol guidewire serves to "open" the neck of the sack. The drawstring is then cut and removed. The sack is loaded onto a nondisposable two tine LapSac introducer (i.e., Cook Urological, Spencer, IN). For a right kidney, the sack is rolled from top to bottom in a clockwise manner, whereas for a left kidney it is rolled from top to bottom in a counterclockwise manner; the handles of the two tine introducer and the ends of the nitinol guidewire should all be on the same side. This ensures that as the sack is unwound in the abdomen, the bottom of the sack remains caudal to the neck of the sack thereby facilitating its complete expansion in the abdomen. If this is not done, then the bottom of the sack lies cephalad to the body of the sack and the surgeon needs to expend additional energy and time to move the bottom of the sack caudal. As a rule, it is easiest to deploy the LapSac through the umbilical or supraumbilical 12-mm port site with the laparoscope placed in the subcostal midclavicular 12-mm port; if an 8 × 10-inch sack is being used (i.e., the largest available sack) the cannula is removed and the LapSac is passed under endoscopic guidance through the 12-mm incision site. Once the sack is completely in the abdomen it is then unwound and the introducer is removed; the 12-mm port is replaced. Atraumatic grasping forceps are then used to unfurl the sack. The sack is further expanded by passing the laparoscope into it and moving the endoscope in an ever-widening circle as it is being withdrawn; the nitinol guidewire at the neck of the sack further aids the opening of the sack. The specimen is moved cephalad until it lies on the surface of the liver or spleen before the entrapment sack is inserted. The three tabs of the mouth of the sack can be secured with locking grasping forceps, thereby opening the sack as though it were a tent. The base of the sack is then moved to a position beneath the edge of the liver or spleen; the specimen can then be moved into the sack. Up to a 2-kg specimen can be secured within the LapSac.

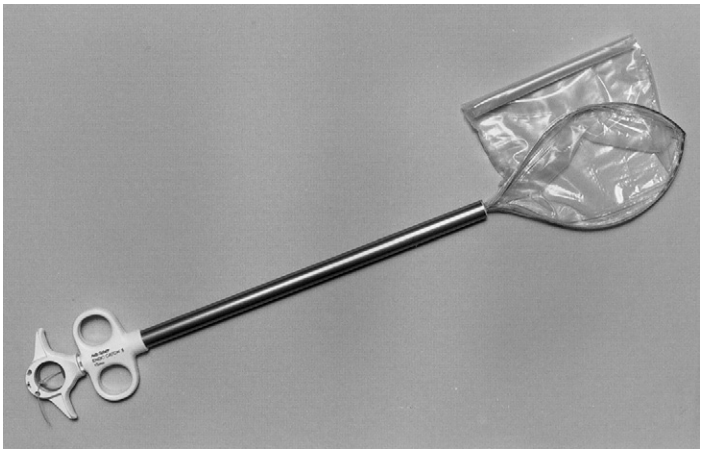

Figure 9–21. Organ retrieval bag.

Other entrapment sacks offer marked advantages when the only goal is organ entrapment and intact removal, rather than morcellation. These sacks have spring wires that, when activated by the surgeon, deploy the bag after its introduction into the abdomen; this facilitates tissue entrapment because the broad wire supports stabilize the opened sack, thereby allowing the surgeon to literally scoop the specimen into the sack (Fig. 9–21). The entrapped specimen can easily be withdrawn through a hand-assist site or by enlarging a laparoscopic port site, usually to 5 to 7 cm for most specimens.

Instrumentation for Morcellation

Various techniques of tissue morcellation have been used in laparoscopic surgery. The simplest method for fragmentation of tissue within the entrapment sack is use of the index finger or ring forceps. The first mechanical morcellation devices worked by punching out pieces of tissue (i.e., serrated-edge macromorcellators) (Semm, 1991). They were designed for removing relatively small amounts of tissue. The advent of laparoscopic nephrectomy resulted in the development of a foot-activated, aspirating, electrical morcellator for tissue fragmentation and evacuation (Cook Urological, Spencer, IN) (Clayman et al, 1992). However, this instrument is no longer available, having been removed from the market in 2001. Traditionally, ring forceps or a large Kelly clamp have been used. Recently, however, it has been shown that ring forceps are the preferred instrument for manual morcellation because they are less likely to puncture the entrapment sack (Eichel et al, 2004). A larger type of ring forceps that has proved helpful in this regard is the Sopher forceps that are commonly used in obstetrics and gynecology; the sturdy jaws of the Sopher forceps are 14 × 45 mm versus only 12 × 22 for the usual ring forceps. If morcellation is performed intracorporeally, the entrapment sack should be a LapSac; however, a variation recently reported by Landman and colleagues for morcellation uses one of the plastic entrapment sacks. In this method, the morcellation is performed above the abdominal wall, by extending the extraction site incision to 3 cm in length. **All tissue is fragmented and removed under direct vision above the abdominal surface; at no time is the morcellating**

instrument out of the direct vision of the surgeon. With this approach, specimens could be morcellated rapidly, with the entire entrapment and morcellation process taking only 13 minutes for clinical specimens as large as 700 g; also fragment size increased from 1.5 to 4.5 g, which might afford better tissue assessment with regard to capsular, vascular, or renal sinus fat invasion (Landman et al, 2003).

When morcellating a renal malignancy, the neck of the sack is triply draped to preclude any contamination: a towel drape, sticky drape (Ioban, 3M, St. Paul, MN) **and nephrostomy drape are commonly used. At the end of the morcellation procedure, the morcellating surgeon and assistants re-gown and re-glove. The extraction site can be bathed in povidone-iodine in an effort to further reduce the chance of any wound seeding.** Indeed, there has been only one noted wound seeding with morcellation in a LapSac (Fentie et al, 2000); however, with intact specimen extraction without entrapment there has also been a wound seed reported (Iwamura et al, 2004). Indeed, in a multi-institutional study, comprising 2064 radical nephrectomies among which 826 were removed by entrapment and morcellation, there was no instance of a wound seeding with tumor (Micali et al, 2004).

Instrumentation for Aspiration and Irrigation

Available as disposable and nondisposable devices, a combination of aspiration and irrigation abilities in one instrument is most practical. The aspirator, which is connected to a suction system, consists of a 5- or 10-mm metal tube, with suction controlled by either a one-way stopcock or a spring-controlled trumpet valve. The irrigation channel is also operated by either a one-way stopcock or a trumpet valve. The irrigation fluid is pressurized to allow for effective delivery of the irrigant and flushing of any bleeding site for accurate hemostasis. Usually, saline or lactated Ringer solution is used as the irrigation fluid. Heparin (5000 units/L) may be added to prevent blood clots from forming, should there be any intraoperative bleeding.

Instrumentation for Retraction

Retractors greatly facilitate laparoscopic surgery. They help expose the area of surgical interest by holding away tissue and organs (e.g., fat, liver, bowel). Sometimes they also facilitate vascular dissection by putting tissue and/or organs closely associated with the vascular structures on stretch. Many varieties of retractors with different features are available. The simplest retractor is a metal bar with an atraumatic tip or a curved saddle shape; the latter is helpful for retracting a vessel during lymph node dissection. Similarly, the disposable laparoscopic "peanut," in either its 5- or 10-mm rendition, is very helpful because it can both dissect and atraumatically retract tissue.

However, the most useful retractors are the expanding types: fan retractors with three or four atraumatic finger-like extensions, fan retractors with V-hinge joints, balloon retractors, and kite-style instruments (e.g., PEER retractors) (Jarit, Hawthorne, NY) (Brooks, 1993). The 5-mm kite style retractor provides a 2 × 3-cm retracting area, whereas the 10-mm instrument doubles the area of direct retraction to 4 × 3 cm (Fig. 9–22 on the Expert Consult website); this type of retractor is very helpful for firm retraction, such as on the kidney to put the renal hilum on stretch.

Another type of retractor is malleable and thus can be shaped to the needs of the surgeon. The Diamond-Flex angled 80-mm triangular retractor (Snowden Pencer, Tucker, GA) can be adapted to many different angles, curves, and shapes, and the surgeon can lock in its particular configuration. This feature is of particular value when retraction of a delicate organ such as the liver is required. This instrument forms a broad retracting surface 8 cm in length.

Retraction of tube-like structures (e.g., vessels, ureter) can also be achieved by placing a suture, a vessel loop, or an umbilical tape around the tissue and applying traction either with a grasper inside the abdomen or by pulling the ends of the retraction loop out of the abdomen through a small stab incision using a Carter-Thomason device (Carter, 1994) or by encircling the structure with a suture affixed to a Keith needle, which can be passed across the abdominal wall, around the structure to be retracted and then back out the abdominal wall (see later under Exiting the Abdomen). The retraction loop can then be secured under slight tension on the surface of the abdomen with a small hemostat. Care should be taken during the use of this technique because excessive tension may injure the structure being retracted.

Also, for blunt retraction, the surgeon's hand, placed into a hand-assist device, is most helpful. In this regard, two key aspects for retraction are of note. First is the concept that the hand should be deployed such that the palm faces the laparoscope as much as possible. In this manner, tissue is brought by the hand toward the laparoscope. It is helpful to use a brown glove that will not reflect the light as much as the standard glove. A second helpful maneuver is the C configuration, as described by Strup, to dissect the renal hilum (Strup et al, 2005). In this maneuver the forearm is passed through the hand-assist device parallel to the aorta/cava while the palm faces laterally. The wrist is flexed to 45 to 90 degrees to allow the fingers to lift the kidney while the thumb pushes inferomedial to retract the tissues overlying the renal hilum. Accordingly, excellent traction and countertraction are achieved, which may speed a safe hilar dissection (Wolf, 2005).

Mechanical Assistants. External mechanical devices such as the EndoHolder (Codman, Raynham, MA) or the LaproStat (Civco, Kalona, IA) can be used to keep grasping forceps or locking retractors in position, thereby taking the place of a tableside assistant. This device is usually mounted on the side of the table opposite the surgeon; the malleable free arm of it is then affixed to the shaft of a grasping forceps or laparoscopic retractor. When the surgeon has employed the retractor to its given purpose, the malleable arm of the external mechanical device is locked in place, thereby providing reliable, continued traction. The advantage of the EndoHolder is that it has no disposables associated with it; however, it is constructed with a gooseneck configuration that requires the scrub nurse to unscrew it and reaffix it each time the retractor needs to be moved. In contrast, the LaproStat, once locked, can still be moved without having to unlock it; however, this device requires use of a new sterile plastic disposable drape for each case (cost: $10.00 US).

Robotic Instrumentation. For the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA) the camera lens fits through a variety of standard 12-mm disposable trocars. The 8- and 5-mm instruments fit through proprietary reusable 8- and 5-mm trocars that couple directly with the robotic arms. These reusable metal trocars have disposable valves that must be changed with each new case. Similarly, a wide variety of articulating instruments are available. The proprietary Endowrist technology offers articulation at the tip of the instruments with 7 degrees of freedom, mimicking the wrist movements of the surgeon at the robotic console (Fig. 9–23). A full line of 8-mm scissors, dissectors, bipolar dissectors, electrocautery cutting devices, needle drivers, clip appliers, retractors, as well as an ultrasonic scalpel are available. The 5-mm line of instruments is slightly more limited but still offers a relatively complete line of instruments. It should be noted, however, that the 5-mm

Figure 9–23. Examples of 8-mm interchangeable instruments for the da Vinci Robotic System.

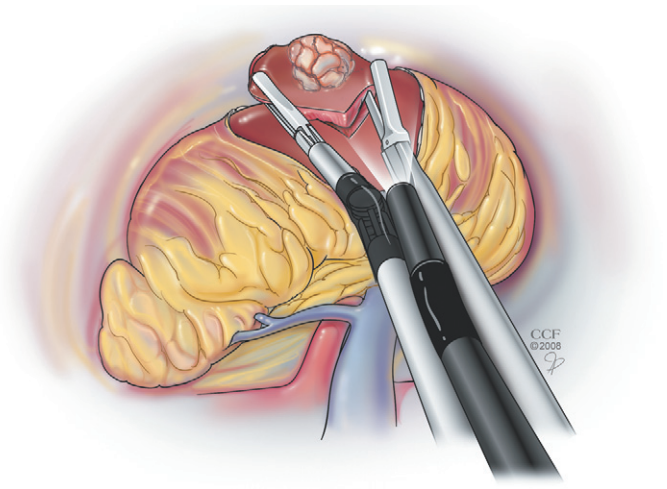

Figure 9–24. Deflecting laparoscopic instrumentation can be used to maintain triangulation during LESS. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1998-2011. All Rights Reserved.)

robotic laparoscope offers a two-dimensional (2D) not 3D image. All robotic instruments for the da Vinci Surgical System (except the laparoscopes) have a 10-case limit before they must be replaced. The number of "lives" left on each instrument should be recorded with each case. **An additional safety feature on all robotic grasping devices is a small Allen bolt that can manually open the jaws of the instrument in the case of a robotic arm malfunction or loss of power in which the grasper is locked on to tissue or a needle at the time of failure.** Of note, robot failure is quite rare; in the series from the University of Chicago, a robot failure was recorded in less than 1% of cases; half of these problems (e.g., failure to power up, optical malfunction) were discovered before the patient entered the operating room. In addition, in the few instances in which there was a system malfunction (e.g., loss of 3D vision, robotic arm failure) during the case (0.4%) the procedure could still be completed without converting to an open option (Zorn et al, 2007).

Instrumentation for LESS

A detailed description of abdominal access and access devices for LESS such as the TriPort and Uni-X has previously been presented in this chapter. By definition, in LESS, all of the instrumentation for the case including a camera/lens for visualization as well as working instruments to perform the procedure must be placed though a single incision. This creates ergonomic challenges with regard to instrument collisions inside and outside the abdominal cavity. Furthermore, the typical trocar arrangement for laparoscopy that affords one the ability to "triangulate" is largely lost with LESS. Much of the emphasis on instrumentation for LESS therefore centers on minimizing instrument collisions outside the abdominal cavity and re-creating the "triangulation" necessary to approach the surgical site safely (Fig. 9–24).

With regard to endoscope choice, one issue encountered is that the light cord often attaches to the telescope at a 90-degree angle and can thus hinder the movement of the lens or other instruments (see Fig. 9–16A on the Expert Consult website). To avoid this problem one can use an endoscope that has the light cord attached end-on from the back directly into the endoscope (Karl Storz, Tuttlingen, Germany) or a one-piece endoscope that already has an end-on integrated light cord (Olympus, Orangeburg, NY) (see Fig. 9–16B on the Expert Consult website). Alternatively an extra-long laparoscopic lens can be used to keep the light cord away from the shorter standard working laparoscopic instruments. Similarly, using laparoscopic instruments of different lengths can help keep the handles from clashing with one another.

With regard to overcoming the parallel nature of the instrument paths and reestablishing a triangular arrangement of instrumentation, several technologic advances have been developed so far. At the very least an angled lens (30- or 45-degree fixed angle) should be used. Preferably, a laparoscope with a deflecting tip (Olympus EndoEYE) or adjustable angle tip (Karl Storz Endo-CAMeleon) should be used because these telescope designs offer the greatest adjustability for optimal viewing.

Additionally, the use of articulating instrumentation is essential to avoid instrument collision outside the abdomen and to achieve proper triangulation for tissue retraction, exposure, and dissection. Disposable articulating instruments are available from Real Hand (Novare Surgical Systems, Cupertino, CA) and from Autonomy Laparo-angle (Cambridge Endo, Framingham, MA) (see Fig. 9–17). In the near future, curved laparoscopic instrumentation (not yet commercially available) will likely be quite helpful and may provide a nondisposable alternative to the current articulating instruments, which are all one-time-use items.

Finally, the use of the robot for LESS procedures has been introduced in the laboratory, originally by Box and colleagues (2008) to perform a transumbilical and transvaginal nephrectomy. Subsequently using the robot arms on both the transumbilical navel port system and on a transvaginal port, Haber and associates (2008) successfully performed a series of pyeloplasties, partial nephrectomies, and total nephrectomies. To be sure, the ability of the robotic arms to articulate is a major plus and one can envision that LESS will follow the path of standard laparoscopy into the robotic age.

Instrumentation for Natural Orifice Transluminal Endoscopic Surgery (NOTES)

The concept of NOTES is not truly new; indeed, the first NOTES procedure would have been Philipp Bozzini's cystoscopy in 1804. What is new is the use of flexible endoscopic technology to perform procedures heretofore unthinkable with a transgastric (e.g., appendectomy in 2004 by Rao and Reddy) or transvaginal approach (e.g., appendectomy in 2004 and cholecystectomy in 2007 independently by Bressler and then Marescaux). Over time these increasingly complex endoscopes have developed from purely diagnostic instruments for visualization of intraluminal surfaces to highly functional endoscopes capable of carrying therapeutic tools that can be used to treat visualized problems. Recently,

Figure 9–25. **B,** Special suture anchors for enterotomy closure (g-Cath, USGI Medical, San Juan Capistrano, CA).

further advances in this type of technology have led to the development of endoscopes specifically for transluminal surgery. The potential advantages of transluminal endoscopic surgery are better cosmesis, less pain, elimination of the risk for wound infection, hernias, and a reduction in adhesions (Swanstrom et al, 2008a, 2008b).

There are several prototype endoscopes currently under evaluation for NOTES. Generally these endoscopes offer larger working channels than standard endoscopes and allow larger instrumentation. Some endoscopes such as the Transport (USGI Medical, San Juan Capistrano, CA) are designed with a guideable locking overtube through which other instruments can be placed; within the 20-mm overtube there are four ports (7 mm, 6 mm, 4 mm, and 4 mm) to accommodate the endoscope and up to three additional instruments. One of the working channels houses a standard 6-mm endoscope for vision, and the other working channels are for instrumentation (Fig. 9–25A on the Expert Consult website). Some endoscopes offer triangulating instrumentation. Major hurdles still exist in terms of developing better and more effective instrumentation and especially devices for suturing and enterotomy closure. The Transport, for instance, can be used to perform enterotomy closure using special suture anchors (g-Cath, USGI Medical, San Juan Capistrano, CA) (see Fig. 9–25B).

Thus far, in urologic practice, NOTES is still in an experimental phase, albeit the seminal paper on this topic being Gettman and associates' porcine transvaginal nephrectomies in 2002. Case reports of NOTES transgastric and transvaginal nephrectomy (Isariyawongse et al, 2008), transgastric and transvesical (Lima et al, 2007) and transvaginal and transumbilical (actually NOTES assisted) nephrectomy with the Transport system (Box et al, 2008) in swine have been reported; however, NOTES has not been applied clinically as of the end of 2008.

Exiting the Abdomen

Port Removal

Port removal and fascial closure are key elements of the procedure that, if not performed in a step-by-step, organized fashion, can result in major, possibly fatal, complications. Herniation, possible bowel incarceration, and postoperative hemorrhage are the results of a poorly performed or haphazard, overly rapid exiting of the abdomen.

Before port removal is initiated, the operative site and the intra-abdominal entry sites of each cannula must be carefully inspected with the intra-abdominal pressure lowered to 5 mm Hg. After achieving perfect hemostasis, the surgical site is irrigated with the option of leaving behind 500 to 1000 mL of irrigation fluid, which contains cefazolin, 1 g/L, and heparin, 5000 U/L. Whether this maneuver truly results in a lower incidence of postoperative adhesions or in less infection is undetermined. To avoid any possible acute herniation of intra-abdominal contents into the previous port sites, removal of all laparoscopic ports must be undertaken strictly under laparoscopic visual control.

In the rare case in which bladed trocars are used, after inspection at 5 mm Hg, the first 10- or 12-mm port is removed and the fascia at the entry site is secured with 0-0 Vicryl. This is most efficiently accomplished using a commercially available dual-channeled cone and a suture-passing device such as a Carter-Thomason suture passer (see later) (Inlet Medical, Eden Prairie, MN). This suture is not tied at the time of placement, but instead a 10-mm plastic introducer rod is passed back into the abdominal cavity through the port site incision. The 10-mm cannula is then slid over the 10-mm plastic introducer and the plastic introducer is removed. In this manner, the ports can continue to be used for the passage of the 10-mm laparoscope and the passage of a grasping forceps to facilitate the closure of each 10-mm port site. Accordingly, all fascial sutures are placed under direct endoscopic control as the 10-mm laparoscope is moved from port to port to visualize the placement of each suture. After all fascial sutures have been placed, each 5-mm port is removed under endoscopic control at 5 mm Hg pressure; 5-mm ports are not closed in the adult but are closed in the pediatric patient (there is also a 5-mm cone to aid closure of the 5-mm port with a needle-nosed suture passer). Then each of the non–endoscope-bearing 10-mm ports can be removed under endoscopic control and the fascial suture can be tied and the closure inspected endoscopically. The final 10-mm port is removed with the endoscope in place to assess for any bleeding along the tract; however, the hemostasis of this port site should have been ensured at the time of placement of the fascial closure suture. In this manner, each port is visually assessed for any bleeding at 5 mm Hg, thereby precluding the possibility of removing a port and missing an injured vessel. After removal of all ports, the CO_2 is allowed to pass out passively through the 5-mm port sites.

Presently, with the shift away from bladed to nonbladed trocars, the need for port closure for even 12 mm ports has come into question. Reports by Shalhav have shown that 12-mm ports regardless of site (i.e., midline vs. transmuscular) do not require fascial closure (Siqueira et al, 2004). **In the literature, the switch from bladed to blunt trocars has resulted in a marked decrease in abdominal wall bleeding (from 0.83% to only 0.16%) and in port site hernia formation (1.83% to 0.19%)** (Hashizume and Sugimachi, 1997; Thomas et al, 2003).

With regard to the hand-assist device, it should be removed before removal of the other port sites. The hand-assist device wound is closed as one would close a typical abdominal wound; however, **recent data support an interrupted closure with nonabsorbable suture** (Troxel and Das, 2005) **because complications from the hand-port site (11%, see later) exceed what would be expected with a standard laparoscopic approach by almost fourfold overall.** Indeed, wound infection, hernia or dehiscence at the hand-port site has been noted in 6.8%, 3.5%, and 0.5% of patients, respectively, in the series from the University of Michigan (Montgomery et al, 2005). After closure, the pneumoperitoneum is reestablished and the other port sites are closed as previously described. Proceeding in this

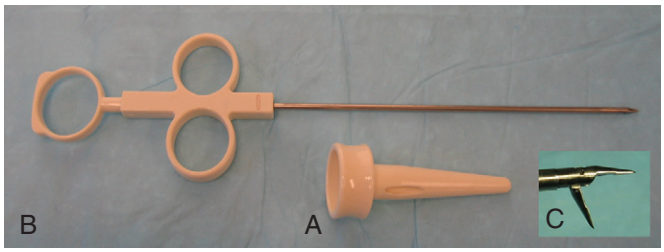

Figure 9–26. Carter-Thomason device. Cone (**A**); needle-point, single-action grasper (**B**); and tip of grasper in open condition (**C**).

fashion precludes the chance of injuring the bowel or omentum beneath the hand-port site and ensures an airtight closure.

Instrumentation for Port Site Closure

Several possibilities for closure of port sites exist. The **simplest method** is retracting the skin with Senn retractors, grasping the fascia with Kocher clamps, and suturing it with absorbable 0-0 suture. However, in any patient with a BMI greater than 30, securely accessing the fascia is very difficult to accomplish.

Fortunately, several devices for complete en bloc closure of fascia, muscle, and peritoneum under direct vision have been developed (Carter 1994; Monk et al, 1994; Garzotto et al, 1995; Elashry et al, 1996). These work well in patients of all sizes.

The **Carter-Thomason needlepoint suture passer** (Inlet Medical, Eden Prairie, MN) consists of a 5-, 10-, or 12-mm cone that has two integrated, hollow, angled, cylindrical passages located 180 degrees opposite each other (Fig. 9–26). With the sharp-needlepoint, single-action grasper, the 0-0 Vicryl suture is inserted through one of the cylinders in the metal or plastic cone, thereby traversing muscle, fascia, and peritoneal layers in an ever-widening angle; the end of the suture is grasped with a 5-mm grasper through one of the other ports. The needlepoint grasper is reintroduced through the other cylinder of the cone, and the intra-peritoneal end of the suture is grasped by the needlepoint grasper and pulled out of the abdomen. The cone is slid off both ends of the suture. Subsequently, closure of the fascia, muscle layer, and peritoneum is accomplished by tying the suture. **The Carter-Thomason needlepoint device not only is helpful for wound closure but also can be used as a fifth port during nephrectomy to help hold the sack open or to encircle the ureter with a vessel loop through a small stab incision.**

The **disposable Endo Close** suture carrier (Covidien Ltd., Mansfield, MA) is a device with a spring-loaded suture carrier at its tip. Loaded with a suture, the device traverses fascia, muscle, and peritoneum alongside the port. After reinsertion on the opposite side of port entry, it is reloaded with the suture, aided by a 5-mm grasper, and is pulled out again under optical control so that the suture can then be tied.

A far simpler, less expensive, homemade solution is available to all surgeons for closing ports in a large patient. This **angiocatheter technique** applies the previously described principles. A 14-gauge, sheathed needle is passed alongside the port through the abdominal layers. After removal of the needle, a 0-0 Vicryl suture is inserted through the angiocatheter sheath until it is deep inside the peritoneal cavity. After the sheath is removed, the same maneuver is repeated on the opposite side, but this time a 30-inch 0-0 Prolene suture folded in half is passed into the peritoneal cavity through the sheath to act as a retrieving loop. A 5-mm grasper passed through another port is then passed through the loop of 0-0 Prolene suture and used to grasp the end of the 0-0 Vicryl suture. The 0-0 Vicryl suture is pulled through the Prolene loop and released. By pulling the Prolene loop upward through the angiocatheter sheath, the entrapped 0-0 Vicryl suture is then retrieved from the abdomen. After the angiocatheter sheath is removed, the two ends of the suture can be tied or the cannula replaced until all of the designated port sites have been properly sutured (see later).

Removal of 5-mm Ports. All 5-mm sheaths are removed under optical control at 5 mm Hg. In adults, the fascia of the 5-mm port entry sites is not sewn closed; however, in children, these port sites require closure with a single absorbable suture.

Closure of the Skin

The skin of all 10-mm port sites is closed with subcuticular 4-0 absorbable suture. Adhesive strips are applied to all port sites to close (for incisions <10 mm) or to further approximate (for incisions ≥10 mm) the skin. As an alternative, the skin can be closed using octylcyanoacrylate glue. This has been found to speed closure time and provide an equivalent cosmetic result compared with suturing (Sebesta and Bishoff, 2004).

POSTOPERATIVE PATIENT MANAGEMENT

Limited laparoscopic procedures (e.g., laparoscopic varicocelectomy, diagnostic laparoscopy) may allow discharge of patients the same day on an outpatient basis. More extensive procedures may require several days of hospitalization.

After a routine major laparoscopic or robotic procedure emphasis can be placed on "fast tracking" the patient. Fast tracking actually starts preoperatively (as mentioned earlier in this chapter) during which time the patient is premedicated with an antiemetic agent, a non-narcotic pain reliever such as ketorolac (if not a renal failure patient), and an antacid. All incision cites are infiltrated with 1% lidocaine before making the incision to minimize postoperative pain. To avoid postoperative ileus and constipation, patients without renal insufficiency can be administered ketorolac every 6 hours for a total of four doses to avoid narcotic analgesic use. Routine use of a nonsedating antiemetic agent for the first 24 hours is also advisable.

The patient is usually given clear liquids on returning to the outpatient area or the hospital floor. A regular diet is provided either the evening of surgery or the morning thereafter.

Ambulation depends on the type of procedure performed as well as the overall health status and morbidity of the patient before surgery. The healthy patient after a laparoscopic/robotic procedure is encouraged to ambulate as soon as possible after the procedure. Pneumatic compression stockings for prophylaxis against deep venous thrombosis are left on until the patient is fully ambulatory. The use of subcutaneous heparin injection for deep venous thrombosis prophylaxis should be used at the discretion of the surgeon (a full discussion of this topic is provided later in this chapter).

For procedures not involving the bladder, the Foley catheter is removed either while the patient is still in the operating room (pneumoperitoneum <2 hours) or the following morning (pneumoperitoneum >2 hours). Indwelling Foley time will vary after procedures involving the bladder. A good rule of thumb is to leave the catheter for 7 days after a procedure in which the bladder was opened. For procedures involving the bladder in a previously

irradiated field it may be necessary to allow additional time for healing. Nasogastric tubes are removed in the operating room immediately on completion of the procedure for most procedures but may be left in longer if bowel is used for urinary diversion or augmentation depending on surgeon preference.

Antibiotics are usually discontinued after 24 hours unless the risk of infection is high as in the case of nephrectomy for xanthogranulomatous pyelonephritis. Laboratory values are obtained in a standardized manner (hemoglobin, hematocrit, sodium, bicarbonate, chloride, potassium, creatinine) postoperatively and the next morning as needed. In general, for a healthy patient undergoing an uneventful laparoscopic procedure, no laboratory studies are needed. However, after a major procedure or for high-risk patients, postoperative and 24-hour laboratory studies are warranted. This is especially important in the patient with pulmonary disease because the greatest risk of hypercarbia may occur 2 to 3 hours after the procedure. After an uncomplicated laparoscopic procedure, a postoperative chest radiograph is no longer recommended (Simon et al, 2005).

Parenteral analgesia (e.g., morphine, ketorolac) is given on the day of surgery and is usually replaced by oral pain medication on the first postoperative day. By using the previously stated or similar methods to "fast track" patients after laparoscopic nephrectomy there has been a significant reduction in nausea, improved pain control, and shortened hospital stay (Recart et al, 2005).

PHYSIOLOGIC CONSIDERATIONS IN THE ADULT

The rapidly expanding number of newly developed laparoscopic and robotic procedures in operative urology has resulted in an increasing need for urologists, as well as anesthesiologists, to familiarize themselves with both the physiology and the potential complications related to the pneumoperitoneum and patient positioning.

Choice of Insufflant

Carbon Dioxide

CO_2 is the insufflant most commonly used for laparoscopic surgery. Owing to its properties (colorless, noncombustible, and inexpensive), it is favored by most laparoscopists. Prolonged postoperative distention of the abdomen does not occur because CO_2 is quickly absorbed (Wolf and Stoller, 1994). It is highly soluble in water and easily diffuses in body tissues. Because of its high diffusion coefficient relative to oxygen and other respiratory gases, it readily moves out of the peritoneal cavity, owing to a high diffusion gradient caused by the difference in concentration of CO_2 between the intraperitoneal space and the surrounding components (e.g., blood). However, the characteristic of rapid absorption, which lessens the chance of a CO_2 gas embolus, may also lead to potential problems (e.g., hypercapnia, hypercarbia, associated cardiac arrhythmias). In particular, patients with COPD may not be able to compensate for the absorbed CO_2 by increased ventilation; this may result in dangerously elevated levels of CO_2 in these patients, thereby necessitating the direct testing of arterial blood gases during laparoscopy in the pulmonary compromised patient population. Carbon dioxide also stimulates the sympathetic nervous system, which results in an increase in heart rate, cardiac contractility, and vascular resistance. Lastly, CO_2 is also stored in various body compartments (e.g., viscera, bones, muscles). After prolonged laparoscopic procedures it may take hours before the patient has eliminated the extra CO_2 that has accumulated in these storage areas; again, this is more often the case and a problem in patients with pulmonary compromise (Lewis et al, 1972; Puri and Singh, 1992; Tolksdorf et al, 1992; Wolf and Stoller, 1994). Therefore, as previously noted, all patients, and in particular those with pulmonary disease, must be closely monitored after a lengthy laparoscopic procedure for possible signs or symptoms of hypercarbia; indeed, their greatest chance of compromise due to hypercarbia may occur after extubation in the postanesthesia recovery room.

Alternative Gases

Nitrous oxide is less irritating to the peritoneum and causes fewer acid-base changes and cardiovascular adverse effects (e.g., arrhythmias) compared with CO_2 (Scott and Julian, 1972; El-Minawi et al, 1981; Minoli et al, 1982; Sharp et al, 1982). However, some studies have shown that nitrous oxide insufflation reduces cardiac output and increases mean arterial pressure, heart rate, and central venous pressure (Marshall et al, 1972; Shulman and Aronson, 1984). Because nitrous oxide supports combustion it can be used only during laparoscopic procedures that do not involve the use of electrosurgical instruments.

Helium is an inert and noncombustible insufflant. Initial studies performed in various animal models showed favorable effects on arterial partial pressure of CO_2 and pH with no evidence of hypercarbia (Fitzgerald et al, 1992; Leighton et al, 1993; Rademaker et al, 1995). These results were corroborated by clinical studies (Bongard et al, 1991; Fitzgerald et al, 1992; Leighton et al, 1993; Neuberger et al, 1994; Rademaker et al, 1995; Jacobi et al, 1997). **As such, helium is particularly useful for the patient with pulmonary disease in whom hypercarbia would be poorly tolerated.** In a recent study from Johns Hopkins University, 10 patients at high risk for hypercarbia underwent laparoscopic renal surgery with helium insufflation. These patients were successfully managed, with only one patient developing an end-tidal CO_2 over 45 mm Hg (Makarov et al, 2007). **Likewise, if hypercarbia develops during a laparoscopic procedure with CO_2, rather than aborting the procedure or converting to an open approach the surgeon can change the insufflant to helium and usually salvage the case** (Brackman et al, 2003). There is also evidence that the use of helium may cause a decrease in tumor cell growth and inflammatory reactions within the peritoneal cavity (Jacobi et al, 1997, 1999; Dahn et al, 2005). It has also been demonstrated that helium insufflation can be used for laparoscopic procedures (e.g., cholecystectomy, appendectomy, hernia repair) performed under local and regional anesthesia in high-risk patients, not only because of its favorable metabolic features but also because of its lack of peritoneal irritation and its association with decreased postoperative pain (Crabtree and Fishman, 1999). However, laparoscopists have to bear in mind that helium may be associated with a higher risk of gas embolism because of its lower blood solubility. When helium is going to be used, it is advised to initially obtain the pneumoperitoneum with CO_2 and then change to helium, thereby lowering the chances of a helium gas embolus. Also, helium is significantly more expensive than CO_2 ($45 vs. $11 per tank). Lastly, when using helium a separate "yoke" (i.e., line from the gas tank to the insufflator) is needed; accordingly, one needs to make sure that a "helium yoke" is available in the operating room or make arrangements to have one provided when performing

laparoscopy on patients with severe pulmonary compromise. In practice, the use of helium may be quite difficult; however, argon may also be used in circumstances when hypercarbia occurs. Indeed, the gas from the argon beam coagulator can be used to maintain the pneumoperitoneum. With argon being an inert gas, like helium, the same precautions, however, apply (Badger et al, 2008).

Other insufflants **(e.g., room air, oxygen)** have been used to establish a pneumoperitoneum in the past. However, possible serious side effects (e.g., air embolus, intra-abdominal explosion, combustion with oxygen and room air) have terminated their clinical use. Other options for insufflants include some of the other noble gases (e.g., xenon and krypton), which are inert and nonflammable; however, their widespread clinical use has not been adopted.

Choice of Pneumoperitoneum Pressure

Overall, the most commonly selected pressure for performing laparoscopy is 15 mm Hg. However, McDougall and colleagues (1994) showed a marked reduction in oliguria when working at 10 mm Hg. In contrast, Kavoussi preferred a pressure of 20 mm Hg, noting increased insufflant filling volume of 22% and possibly less venous bleeding during the procedure (Adams, et al, 1999). In contrast, McDougall and colleagues (1994) noted that, despite the increased volume, there was only a very small increase in abdominal girth at higher pressures. Indeed, recent studies support a pressure of 12 mm Hg, as this results in no perturbations in cardiac parameters (i.e., no change in stroke volume) versus a pressure of 15 mm Hg (Mertens zur Borg et al, 2004). Working at lower pneumoperitoneum pressures has also been found to reduce postoperative pain (Sarli et al, 2000).

Various cardiovascular, renal, and respiratory effects seen during different intra-abdominal pressures in the supine state are summarized in Table 9–4. It is of note that these physiologic parameters may be further altered (i.e., overridden or reversed) owing to the health of the individual patient and to changes in the patient's position.

Table 9–4.

Pressure Effects: 5, 10, 20, and 40 mm Hg

EFFECTS	5 mm Hg	10 mm Hg	20 mm Hg	40 mm Hg
Cardiovascular				
Heart rate	↑	↑	↑	↓
Mean arterial pressure	↑	↑	↑	↑
Systemic vascular resistance	↑	↑	↑	↑
Venous return	→/↓	↓↑	↓↑	↓
Cardiac output	→/↓	→/↑	→/↓	↓
Renal				
Glomerular filtration rate	→	↓	↓↓	↓↓
Urine output	→	↓	↓↓	↓↓
Respiratory				
End-tidal CO_2	→	→/↑	→/↑	↑
Pco_2	→	↑	↑	↑
Arterial pH	→	→/↓	↓	↓

CO_2, carbon dioxide; PCO_2, partial pressure of carbon dioxide.

Cardiovascular Effects of the Pneumoperitoneum

Venous Flow

Animal studies have shown that the effects of the pneumoperitoneum on venous return depend on atrial pressures, which, in turn, are a reflection of the hydration state of the subject (Ivankovich et al, 1975; Diamant et al, 1978; Kashtan et al, 1981). If atrial pressures are low (normal or hypovolemic state), then, during a pneumoperitoneum of up to 20 mm Hg, venous return is reduced owing to increased compression of the vena cava from the pneumoperitoneum. If atrial pressures are high (hypervolemic state), the vena cava resists elevated intra-abdominal pressure and venous return is actually enhanced. However, these principles apply only to an intra-abdominal pressure of up to 20 mm Hg. By further increasing pneumoperitoneum pressures, especially to 40 mm Hg and above, capacitance vessels are collapsed, vascular resistance increases, blood flow decreases markedly, and venous return is significantly reduced. Lower extremity venous return is also reduced by elevated intra-abdominal pressures. Reduced venous blood flow in the lower extremities could facilitate deep vein thrombosis; however, this remains a rare clinical complication of laparoscopy (Jorgensen et al, 1993).

These pathophysiologic insights, gained through animal experiments, have been corroborated by clinical studies (Kelman et al, 1972; Motew et al, 1973; Lee, 1975; Jorgensen et al, 1993).

As a result of these trials, intra-abdominal pressures during laparoscopy should not be allowed to exceed 20 mm Hg over extended periods (Arthur, 1970; Seed et al, 1970; Lee, 1975), and a working pressure of 10 to 12 mm Hg is recommended.

Cardiac Arrhythmias

Tachycardia and ventricular extrasystoles may be seen as results of hypercapnia (Scott and Julian, 1972). Peritoneal irritation may lead to vagal stimulation and subsequently to bradyarrhythmias (Doyle and Mark, 1989). Also, dysrhythmias can serve as clinical warning signs for the occurrence of pneumothorax, hypoxia, and gas embolism (Wolf and Stoller, 1994).

Unreliability of Central Venous Pressure Readings

As previously noted, intravenous pressures may actually rise with low intra-abdominal pressures. In addition, increasing intra-abdominal pressures may artificially elevate central venous pressure readings owing to an increase in intrathoracic pressure. Therefore, it is important for the anesthetist *not* to rely on central venous pressure readings for any clinical decision making. If information regarding vascular volume and central venous pressure is needed, a Swan-Ganz catheter should be placed.

Respiratory Effects of the Pneumoperitoneum

Pressure-Mediated Effects

Owing to increased intra-abdominal pressure, diaphragmatic motion is limited. Pulmonary dead space remains unchanged, but functional reserve capacity decreases (Wolf and Stoller, 1994). The average peak airway pressure needed to keep up a constant tidal volume increases parallel to the increasing intra-abdominal pressure (Alexander et al, 1969; Motew et al, 1973; Wolf and Stoller, 1994).

Although usually not of great clinical importance in a healthy patient population, it is advisable to use positive end-expiratory pressure techniques when patients with lung disease undergo general anesthesia for a laparoscopic procedure (Ekman et al, 1988; Wolf and Stoller, 1994; Hazebroek et al, 2002).

Non–Pressure-Related Respiratory Effects

The head-down position has an adverse effect on respiration. It elevates the diaphragm and decreases vital capacity. It can also lead to a dislocation of the endotracheal tube that, in turn, may cause right main bronchus intubation. Although of little clinical significance in healthy patients, the head-down position may cause pulmonary edema in patients with increased left-sided heart pressures (Prentice and Martin, 1987). Also, during lengthy procedures performed in the head-down position it is useful to limit fluid administration if possible because it will minimize facial swelling postoperatively.

Renal and Other Visceral Effects of the Pneumoperitoneum

Oliguria

Increased intra-abdominal pressure was found to be associated with a significant decrease in urinary output. A number of investigators, with the oldest study dating back to 1923, have observed oliguria and anuria associated with an ongoing increase in intra-abdominal pressure (Thorington and Schmidt, 1923; Harmann et al, 1982; Richards et al, 1983). Decreased renal vein blood flow and direct renal parenchymal compression, rather than marked hormonal changes or ureteral compression, have been shown to be the likely reasons for the oliguric state (Chiu et al, 1994; McDougall et al, 1996). Of interest, renal cortical blood flow decreased with increasing intra-abdominal pressures, whereas renal medullary blood flow increased up to pressures of 20 mm Hg; above this level, medullary blood flow also decreased (Chiu et al, 1994). In a porcine study, neither application of dopamine nor insertion of ureteral catheters was able to improve oliguria owing to elevated intra-abdominal pressure (McDougall et al, 1996). These changes occurred regardless of intraperitoneal or extraperitoneal insufflation. Of note, oliguria was not a problem if a gasless, abdominal wall lift method was used to establish the working space in the abdomen. The decreased renal blood flow seen during pneumoperitoneum may be associated with changes in endothelin-1 (ET) and/or nitric oxide (NO). One recent study in a rat model showed that the effects of pneumoperitoneum can be accentuated using ET or NO blockers or avoided by using ET or NO potentiators (Abassi et al, 2008). There is also experimental evidence showing increased apoptosis in the renal cortex and medulla of rats that have undergone pneumoperitoneum compared with controls. The level of apoptosis appears to be pressure dependent, again supporting the use of lower insufflation pressures, as recommended (i.e., ≤12 mm Hg) (Khoury et al, 2008).

These experimental findings in animals have been corroborated in the clinical setting (Iwase et al, 1992; Chang et al, 1994; McDougall et al, 1996); however, at least one recent clinical study did show that low-dose dopamine (2 μg/kg/min) can prevent the dip in urine output associated with pneumoperitoneum (Perez et al, 2002). Whether antidiuretic hormone and plasma arginine vasopressin, both of which have been measured at increased levels by some investigators, play a major role in oliguria during clinical laparoscopic procedures remains unclear (Melville et al, 1985; Solis Herruzo et al, 1989). **In general, if one desires to avoid an oliguric state during a laparoscopic procedure, a pressure of 10 mm Hg or less is recommended. In addition, clinically the use of furosemide (Lasix) (mg dose = 20 times the patient's creatinine), mannitol (12.5 to 25 g), and dopamine at 2 μg/kg/min can help to overcome oliguria. With this regimen and judicious fluid administration, the patient can usually be maintained with a urine output in excess of 100 mL/hr. The key is to use these pharmaceutical modalities in lieu of excessive hydration and fluid boluses** (Perez et al, 2002), **which may lead to significant fluid overload and edema.**

Effects on Mesenteric Blood Flow and Intestinal Motility

Decreased blood flow during laparoscopic procedures was found not only in the kidney but also in mesenteric vessels and other organs (e.g., liver, pancreas, stomach, spleen, small and large intestines) (Caldwell and Ricotta, 1987; Ishizaki et al, 1993; Hashikura et al, 1994). This may rarely lead to mesenteric thrombosis with catastrophic results. This complication may take days to develop (Schorr, 1998).

Open, incisional abdominal surgery usually results in some postoperative impairment of gastric and intestinal emptying owing to intestinal paralysis (physiologic ileus) (Kemen et al, 1991). Interestingly, clinical observation and studies undertaken during laparoscopic and open surgical cholecystectomy have shown that laparoscopic surgery causes less significant disturbances of the gastrointestinal motility pattern, therefore resulting in no or less postoperative physiologic ileus than occurs with open surgery (Sezeur et al, 1993; Halevy et al, 1994). The exact mechanisms responsible for this difference have yet to be defined; however, it is postulated that perhaps it is related to the hypercarbia (Aneman et al, 2000). Additionally, intestinal perfusion does not change significantly during prolonged pneumoperitoneum at a pressure of 15 mm Hg with CO_2 or helium (Goitein et al. 2005); however, at least in the rat model, there does seem to be an increase in bacterial translocation that is proportional to the pneumoperitoneum pressure (Sukhotnik et al, 2006).

Also, despite the increased intra-abdominal pressures associated with laparoscopy, there has been no increased incidence of gastroesophageal reflux and regurgitation in patients undergoing laparoscopic procedures (Schippers et al, 1992).

Acid-Base Metabolic Effects of Pneumoperitoneum

Animal and human studies have demonstrated that prolonged laparoscopic procedures may result in hypercarbia and respiratory acidosis (Motew et al, 1973). Because there is no increase in ventilatory dead space during laparoscopy, the resulting respiratory acidosis has been attributed to transperitoneal absorption of CO_2 during establishment and maintenance of the pneumoperitoneum (Motew et al, 1973; Leighton et al, 1993). Although the resulting mild respiratory acidosis does not adversely affect otherwise normal patients and can be corrected by increasing the minute ventilation, increased absorption of CO_2 can become dangerous in patients with COPD owing to their impaired ability to release pulmonary CO_2. **To ensure proper monitoring of acid-base status, intermittent arterial blood gas sampling should be performed in patients with COPD and**

during any laparoscopic procedure that requires more than 1 hour of CO_2 insufflation; also in the patients with COPD, arterial blood gas sampling should continue in the postanesthesia recovery area because after extubation these patients may be at risk of significant hypercarbia owing to subsequent mobilization of procedurally absorbed CO_2.

Pneumoinsufflation with CO_2 results in variable amounts of gas absorption, thereby raising the partial pressure of CO_2 in the blood. Carbon dioxide is absorbed from the peritoneal membrane during transperitoneal laparoscopy and from preperitoneal adipose and connective tissue during retroperitoneoscopy and extraperitoneoscopy (Collins, 1981). Others have also implicated the disrupted microvascular and lymphatic channels for CO_2 absorption during preperitoneal laparoscopy (Glascock et al, 1996). The potential for developing hypercarbia exists during both transperitoneal and preperitoneal laparoscopy. Conceivably, this assumes greater importance in patients with preexisting airway and cardiovascular compromise. Although transperitoneal and retroperitoneoscopic approaches are routinely employed safely at numerous centers worldwide, vigilant perioperative anesthetic management is essential to prevent the development of potential complications related to CO_2 buildup.

End-tidal CO_2 and O_2 saturation are monitored intraoperatively using a capnometer. Furthermore, arterial blood gases are obtained during prolonged laparoscopic procedures and in patients with increased risk of developing hypercarbia (owing to airway disease, renal failure, congestive heart failure, or advanced age). A rise in end-tidal CO_2 should prompt the anesthesiologist to adjust the respiratory rate and tidal volume to enhance CO_2 elimination. Simultaneously, the surgeon should decrease the insufflation pressure of CO_2 or, if necessary, desufflate the abdomen completely until the hypercarbia has been resolved. Several studies have demonstrated that CO_2 absorption during either laparoscopic approach (transperitoneal or retroperitoneal) increases significantly during the initial 30 to 60 minutes of the procedure and reaches a steady-state plateau thereafter (Wolf et al, 1995; Ng et al, 1999). Which one of the two approaches is associated with greater CO_2 absorption remains a debated issue. Although some studies have demonstrated greater absorption during transperitoneal laparoscopy (Giebler et al, 1997), others have demonstrated greater absorption during retroperitoneal laparoscopy using a standard Hasson cannula (Wolf et al, 1995). However, in another study, no significant clinical difference was seen (Ng et al, 1999), provided a blunt port type Hasson cannula was used that tightly sealed the site of entry in between the balloon and soft cuff carried on the shaft of the cannula.

Hemodynamic Effects Related to Patient Position and Type of Approach

Several animal and human studies have examined hemodynamic changes owing to different surgical positions (Kelman et al, 1972; Joris et al, 1993; Williams and Murr, 1993). In the supine position, cardiac output remains unchanged or decreases when intra-abdominal pressures are less than 15 mm Hg, whereas mean arterial pressure (MAP) and systemic vascular resistance increase (Pearle, 1996). If pneumoperitoneum pressures are increased beyond 20 mm Hg, cardiac output is reduced because of decreasing venous return and hence MAP decreases.

Changes in patient position have a marked impact on hemodynamic parameters. Specifically, in the head-up position, heart rate increases, MAP decreases, systemic vascular resistance increases, and cardiac output decreases; in contrast, in the head-down position, heart rate drops, MAP rises, systemic vascular resistance falls, and cardiac output increases (Pearle, 1996). These results have also been shown to hold true in steep Trendelenburg position used for laparoscopic and robotic radical prostatectomy (Falabella et al, 2007). The head-down position seems to be favorable for the laparoscopy patient owing to higher cardiac output caused by increased venous return. However, this beneficial effect is completely negated if pneumoperitoneum pressure is increased to 30 to 40 mm Hg; at pressures this high, the concomitant decrease in venous return results in a decrease in cardiac output.

There is some evidence that the extraperitoneal approach may be beneficial in this regard compared with transperitoneal laparoscopy. Giebler and coworkers (1997) demonstrated that transperitoneal laparoscopy was associated with more pronounced changes in cardiac output ($P = .001$), pulmonary artery pressure ($P = .007$), central venous pressure ($P = .001$), iliac venous pressure ($P = .001$), and inferior vena caval pressure gradient ($P = .00001$) as compared with retroperitoneal laparoscopy. With regard to pelvic laparoscopy, Meininger and associates (2004) compared the effects of prolonged intraperitoneal and extraperitoneal CO_2 insufflation on hemodynamics and gas exchange. With both insufflation methods, arterial CO_2 pressure increased rapidly, reaching higher levels with extraperitoneal insufflation. Therefore patients managed with extraperitoneal insufflation required a significantly higher minute ventilation. Heart rate and central venous pressure increased in both groups, whereas mean arterial blood pressure and pH decreased.

Hormonal and Metabolic Effects during Laparoscopic Surgery

As in other surgical procedures, several hormones (e.g., β-endorphin, cortisol, prolactin, epinephrine, norepinephrine, dopamine) have been noted to increase during laparoscopic surgery as a response to tissue manipulation, intraoperative trauma, and postoperative pain (Cooper et al, 1982; Lehtinen et al, 1987; Lefebvre et al, 1992). The clinical significance of increased serum arginine vasopressin levels seen in open surgery and in response to intraperitoneal insufflation during laparoscopy remains unexplained (Cochrane et al, 1981; Melville et al, 1985; Solis Herruzo et al, 1989).

Several adverse metabolic changes observed during open cholecystectomy are less pronounced with laparoscopic cholecystectomy: (1) reduced postoperative plasma glucose elevation, (2) less decrease in insulin sensitivity, and (3) reduced hepatic stress response (Thorell et al, 1993; Jakeways et al, 1994; Glerup et al, 1995).

One important feature of the catabolic response is a complex intra-organ shift of nitrogen; this reaction has been best characterized in the liver (Glerup et al, 1995). The conversion of amino acids to urea by the liver is much higher after open incisional cholecystectomy than it is after laparoscopic cholecystectomy; hence, the catabolic reaction of the body is decreased with a laparoscopic versus an open, incisional approach (Fischer, 1995). Indeed, in the laparoscopic patient, the reduced postoperative hepatic catabolic stress associated with reduced tissue loss of amino-nitrogen may, in some way, be responsible for the more rapid convalescence that is the hallmark of laparoscopy in general. Lastly, catabolic responses, in the form of released cytokines and opioids, owing to augmented neurohumoral stimuli resulting

from incisional tissue trauma may also be lessened with a laparoscopic approach (Fischer, 1995).

Immunologic Effects of Laparoscopic Surgery

A number of animal and clinical studies measuring a wide spectrum of inflammatory response mediators (e.g., C-reactive protein, interleukin-6) and other markers of cellular immune functions (pan–T cells [CD3], helper T cells [CD4], suppressor cells [CD8], and natural killer cells [CD16]; delayed-type hypersensitivity skin tests; serial phytohemagglutinin-induced T cell proliferation) have suggested that laparoscopic procedures generally result in less immunosuppression than do their open surgical counterparts (Kloosterman et al, 1994; Trokel et al, 1994; Cristaldi et al, 1997; Karayiannakis et al, 1997; Nguyen et al, 1999; Bolla and Tuzzato, 2003). This may also play a role in hastening convalescence after laparoscopic procedures. Some data have also suggested that the CO_2 pneumoperitoneum in and of itself, as opposed to exposure of tissues to room air, results in a more favorable immunologic state (Watson et al, 1995). Also, experimental evidence shows that less tumor cell growth occurs after laparoscopic procedures than after open procedures (Bouvy et al, 1997). Although these data are intriguing, further well-designed, prospectively randomized clinical studies are needed to compare immunologic responses after laparoscopic versus open surgical procedures for urologic cancer. Whether decrease in inflammatory response mediators and improved postlaparoscopic immune status will translate into a better long-term prognosis for patients with urologic cancers remains to be determined. Indeed, in a recent study by Landman and colleagues (2004) in patients undergoing open or transperitoneal laparoscopic radical/total nephrectomy for renal cancer there was no discernible difference in immunologic parameters; part of the explanation for this observation could well be secondary to the immunosuppressive effects of the tumor itself.

TROUBLESHOOTING IN LAPAROSCOPIC SURGERY

Historically, in large series, the overall incidence of laparoscopic complications in urology has been in the range of 4%. Mortality has been distinctly unusual, with a rate of 0.03% to 0.08% (Mintz 1977; Winfield et al, 1991; Chapron et al, 1998; Fahlenkamp et al, 1999; Harkki-Siren et al, 1999). However, because of the increasing complexity of laparoscopic urologic procedures (e.g., nephrectomy, prostatectomy) and the continued decrease in simpler laparoscopic procedures (e.g., varicocelectomy, bladder neck suspension, pelvic lymph node dissection), laparoscopic complications in urology appear to be on the rise. In one update from Johns Hopkins University regarding transperitoneal laparoscopic retroperitoneal procedures (e.g., renal surgery, retroperitoneal lymph node dissection), Parsons and colleagues (2004) report a 0.2% mortality rate and a 12% overall complication rate. Of concern, the most often cited injury was vascular, occurring in 2.8% of patients followed by bowel injury in 1.1% of patients (Table 9–5). The authors attribute this increased incidence to the larger number of surgeons now doing laparoscopy and moving through the learning curve, the addition of several new procedures that are substantially more challenging than past procedures (e.g., partial nephrectomy, retroperitoneal lymph node dissection), and the aging and higher risk of our population in general (Parsons et al, 2004). Of interest, the complications for pelvic laparoscopy although higher than for retroperitoneal laparoscopy are of a more minor nature. Indeed, Vallancien and colleagues (2002) noted a 22.6% overall complication rate among 1311 procedures, of which 84% were pelvic; however, there were no deaths and the most often injured organ was bowel at 1.2%; vascular injuries were cited in only 0.5% of their procedures (see Table 9–5). Another recent meta-analysis of radical prostatectomy techniques compared open, laparoscopic, and robotic complications. The overall complication rates for the different approaches were 10.3%, 15.6%, and 6.6%, respectively (Berryhill et al, 2008). Another recent series of 1500 robotic radical prostatectomy cases reported a postoperative complication rate of 4.3%. Intraoperatively, the complication rate was only 0.13% (two rectal injuries) (Patel et al, 2008). Possible reasons for the difference in the complication rates between laparoscopic and robotic prostatectomy might be that the robotic platform expedites the learning curve for the procedure, provides a more comfortable working environment for the surgeon, and allows the surgeon to work in an intuitive 3D environment with 6 degrees of freedom instrumentation.

Table 9–5.

Major Complications of Transperitoneal Abdominal Surgery

TOTAL PROCEDURES	894* (100% ABDOMINAL)	1311† (84% PELVIC)
Overall complications	13.2%	22.6%
Intraoperative/ postoperative	5.7%/7.5%	3.6%/19%
Deaths	0.2%	0%
Vascular injury	2.8%	0.5%
Bowel injury	1.1%	1.2%
Adjacent organ injury	1.1%	0.8%
Conversion rate	1.7%	1.7%

Minimizing the Incidence of Complications during the Laparoscopic Learning Curve

Early in one's experience with laparoscopic and robotic surgery it is wise to apply this minimally invasive approach to low-risk surgical candidates of normal body habitus. In addition, it is advisable and recommended by many laparoscopic organizations, as well as by hospital credentialing boards, that the neophyte minimally invasive surgeon seek training in three arenas: (1) in-depth instructional courses, including didactic, "live-case" transmissions and "hands-on" laboratory sessions; (2) preceptor training in which the surgeon-in-training views more than five or more procedures being done by an already skillful laparoscopic surgeon; and (3) a mentoring experience, during which a trained laparoscopic surgeon oversees the initial procedures performed by the surgeon-in-training (Society of American Gastrointestinal and Endoscopic Surgeons, 2003). Further training can be obtained through self-teaching using videotapes and a pelvic trainer. The latter is extremely helpful for developing one's sense of laparoscopic

proprioception and for becoming facile with laparoscopic suturing and knot tying. Data have clearly shown benefits for individuals who have taken the time to practice their laparoscopic skills using a pelvic trainer in all areas of laparoscopy (cutting, clipping, and suturing) compared with individuals who had no such training (Derossis et al, 1998). Similarly, participation in a 1-week mini-residency has been found to increase the likelihood that participants would perform more complex laparoscopic procedures (81% of participants) (Corica et al, 2006). The use of virtual reality simulators is under evaluation but further validation testing is required before these complex and often expensive trainers can be recommended strongly. A detailed discussion of laparoscopic and robotic practice and training is presented later in this chapter.

General Procedural Complications

Aside from training in the basic psychomotor skills, neophyte minimally invasive surgeons must be educated with regard to prevention, recognition, and appropriate treatment of complications. Accordingly the following section covers the myriad complications that can occur with any laparoscopic/robotic procedure. Recognition, resolution, and prevention of these various problems are discussed.

Malfunction of Equipment

A successful outcome of any laparoscopic procedure depends not only on the psychomotor technical skills of the surgeon but also on a proper working knowledge of all the equipment involved in performing these procedures. To ensure undisturbed functioning of all technology, the surgeon must be supported by well-trained staff who are capable not only of quickly recognizing any equipment malfunction but also of providing an immediate, adequate response to correct problems. In this regard, the Society of American Gastrointestinal Endoscopic Surgeons has issued a troubleshooting guide for video and electronic failure. Newer laparoscopy systems have become more simplified in some ways offering automatic settings, touch screen control, and voice command; however, these new systems can be more taxing as well because they offer a host of optional settings and capabilities. For integrated operating room systems offered by most major equipment manufacturers the surgeon and operating room staff need to receive in-depth training on the system's operation, capabilities, and limitations. In this way, equipment failure will be minimized. Additionally, the contact information for the equipment vendor's trouble shooting experts should be readily available.

With regard to the da Vinci Robotic System, equipment malfunction is rare. In a review of 11 institutions with a total of 8240 cases reviewed, the overall incidence of malfunction was 0.4%. Of the 34 cases with malfunction, 24 cases were canceled before the procedure, 2 cases were converted to laparoscopic, and 8 were converted to open surgery (Lavery et al, 2008).

Complications Related to Obtaining the Pneumoperitoneum

Complications Associated with Closed Access (Veress Needle Placement)

Preperitoneal Placement. Preperitoneal placement of the Veress needle may preclude successful trocar placement. If not recognized early, 1 to 2 L of CO_2 may be instilled; indeed, once this much CO_2 has been insufflated into the preperitoneal space, many signs indicative of correct intraperitoneal insufflation may be present (e.g., distention, tympanic sound on percussion) thereby misleading the surgeon until the first trocar is placed. **The first sign of preperitoneal insufflation is that there may be a steep rise in pressure with only 500 mL of CO_2; plus, if more CO_2 is instilled, unequal distention of the abdomen occurs.** If this early sign is missed, then the laparoscope reveals only fat after trocar placement; the intraperitoneal viscera are not seen.

The next step is to evacuate the CO_2 through the sidearm of the trocar and proceed with an open insertion technique. The initial incision can be widened, and the peritoneal surface can be grasped with a pair of Allis clamps and incised. A Hasson cannula is then secured in place, as previously described, and the peritoneal cavity is insufflated.

Several steps can be taken to avoid this complication. First, if the Veress needle is preperitoneal on initial insufflation, pressures are usually higher than the maximal initial allowable pressure of 10 mm. Second, if the Veress needle is preperitoneal, it cannot be easily advanced 1 cm deeper without resistance. If one has truly entered the peritoneal cavity properly, the Veress needle should be able to be moved 0.5 to 1 cm deeper without meeting any resistance (the "advancement test").

Vascular Injuries. During initial placement of the Veress needle at the umbilicus, minor or major intra-abdominal blood vessels may be punctured by the 14-gauge needle. The first sign of intravascular entry is blood appearing in the hub of the needle. Aspiration results in additional blood filling the syringe. As long as the needle has not been manipulated, it can usually be withdrawn without excessive bleeding. An alternative site for Veress needle placement or open cannula insertion should be used at this point.

To prevent this problem it is important when using an umbilical approach to direct the Veress needle toward the hollow of the pelvis. Passing the Veress needle through a 12-mm incision, bluntly spreading the subcutaneous fat, and grasping and stabilizing the anterior fascia with a pair of Allis clamps may help prevent this problem when using an umbilical access. These maneuvers become especially important in children, who have less space between intra-abdominal structures and the abdominal wall. **Lastly, for a case in which this problem occurs, it is important that the path of the initial Veress needle passage be traced on proper entry into the abdomen. The prior site of the Veress needle passage is carefully inspected at a pressure of 5 mm Hg; any site of bleeding can be expeditiously treated by the application of a surgical hemostatic agent such as thrombin-impregnated gelatin matrix or fibrin glue. Gentle pressure can be applied to the bleeding vessel.** Likewise, any hemodynamic instability associated with loss of "working space" within the abdomen during the procedure should alert the surgeon to the possibility of an expanding "unseen" retroperitoneal hematoma, a distinctly unusual occurrence.

Prevention of vascular complications can be further achieved in one of two manners. First, using a nonumbilical site for Veress needle passage (i.e., just superior and medial to the iliac crest or subcostal in the midclavicular line) places no major vessels in danger. Second, the use of only blunt trocars decreases the chance of injury of the epigastric vessels by fivefold (reduced incidence from 0.83% to 0.16%) (Hashizume and Sugimachi, 1997; Thomas et al, 2003).

Visceral Injuries. During Veress needle placement, intra-abdominal organs may be punctured. The initial signs of this complication consist of aspiration of blood, urine, or bowel contents through the Veress needle or, in the case of a solid organ, high pressures on initial insufflation.

Management consists of simply removing the Veress needle. The Veress needle may then be reintroduced at a different site, or an open cannula placement can be used through a separate incision site. On entry into the abdomen, any bleeding site on the liver or spleen can be treated with an argon beam coagulator or the application of a surgical hemostatic agent (e.g., thrombin containing gelatin matrix or fibrin glue) (see earlier).

Bowel or bladder entry of the Veress needle needs no further treatment other than needle withdrawal. These problems can be prevented by placing a nasogastric tube and a transurethral indwelling bladder catheter to decompress the stomach and bladder, respectively, before Veress needle passage. Stabilization of the abdominal wall fascia with towel clips or Allis clamps at the time of Veress needle puncture may help in stabilizing the fascia. One should not lift up on the fascia because this will only increase the space between the fascia and the peritoneum while not changing the intra-abdominal space. Likewise, insufflation should never be initiated unless *all* of the signs for proper peritoneal entry (negative aspiration, easy irrigation of saline, negative aspiration of saline, positive drop test, and normal advancement test) have been confirmed.

Complications Related to Insufflation and Pneumoperitoneum

Bowel Insufflation. If entry into the bowel is not recognized at the time of irrigation and aspiration through the Veress needle, then the surgeon may well insufflate the small or large bowel. The first sign of this problem is asymmetrical abdominal distention. Associated signs may be passage of flatus and insufflation of only a small amount of CO_2 (<2 L) before high pressures are reached.

If this complication is suspected, then the insufflation line should be disconnected; the outflow of gas will immediately confirm bowel entry. The needle can be withdrawn, and open access cannula placement should be done at a different abdominal site. Prevention of this problem is ensured if one properly performs the aspiration/irrigation/aspiration tests recommended for safe Veress needle placement and if one avoids sites of prior surgery. Similarly, initial open cannula insertion may decrease the chances of this complication.

Gas Embolism. Carbon dioxide gas has favorable solubility in blood, as opposed to air, helium, or nitrous oxide ($LD_{50} = 1750$ mL); however, use of CO_2 may still result in a gas embolus. The most common cause of CO_2 embolism is puncture of a blood vessel or organ with the Veress needle, followed by insufflation; this can occur only when the surgeon has ignored the previously described tests for proper entry into the peritoneal cavity. The first sign of intravascular insufflation is acute cardiovascular collapse. Other signs include dysrhythmias, tachycardia, cyanosis, and pulmonary edema. The diagnosis is usually made by the anesthesiologist based on an abrupt increase of end-tidal CO_2 accompanied by a sudden decline in oxygen saturation and then a marked decrease in end-tidal CO_2 (Loris, 1994). Sometimes, a "millwheel" precordial murmur can be auscultated (Keith et al, 1974). In addition, the anesthesiologist may notice foaming of a drawn blood sample owing to the presence of insufflated CO_2.

The treatment is immediate cessation of insufflation and prompt desufflation of the peritoneal cavity. The patient, if at all possible, is turned into a left lateral decubitus, head-down position (i.e., right side up) in hopes of minimizing right ventricular outflow problems and forcing the air embolus to rise into the apex of the right ventricle. The patient is hyperventilated with 100% oxygen. Advancement of a central venous line into the right side of the heart with subsequent attempts to aspirate gas may rarely be helpful. The use of hyperbaric oxygen and cardiopulmonary bypass have also been reported (McGrath et al, 1989; Diakun, 1991; Abdel-Meguid and Gomella, 1996).

This devastating complication can be precluded by meticulous attention to Veress needle and initial trocar placement and performance of each of the recommended tests for intraperitoneal entry. Insufflation should never be initiated if the surgeon has even the slightest doubt about correct positioning of the Veress needle; instead, the surgeon should withdraw the Veress needle and pass it at an alternate site or immediately proceed with open cannula access.

Barotrauma. Prolonged elevated pressures (>15 mm Hg) may result in barotrauma (McGrath et al, 1989; Diakun, 1991; Abdel-Meguid and Gomella, 1996). Prolonged high pressures may be caused by insufficient and infrequent monitoring of CO_2 pressure, malfunction of the insufflator, or additional pressures produced by auxiliary devices (e.g., argon beam coagulator, CO_2-cooled laser). Furthermore, barotrauma may be caused by ventilation techniques using positive end-expiratory pressure resulting in rupture of a pulmonary bleb or bulla.

The initial sign of barotrauma may be hypotension owing to decreased cardiac output secondary to an acute drop in venous return caused by compression of the vena cava. Also, a pneumothorax or pneumomediastinum may develop because of high ventilation pressures. Increased intra-abdominal pressures may exacerbate a hiatal hernia as well.

The anesthesiologist usually alerts the surgeon to the problem of excessive intra-abdominal pressure; it usually presents as an increase in ventilation pressures. The surgeon should desufflate the abdomen and, once the hemodynamic changes have been reversed, reinitiate the pneumoperitoneum at 10 mm Hg. Any malfunctioning insufflator should be replaced. Also, if one is using an argon beam coagulator or a CO_2-cooled laser device, the sidearm on one port should be left open to allow high-pressure excess gas to readily escape while the device is being activated.

These problems are avoided by the alert, meticulous surgeon. The insufflator should always be checked before initiating the procedure; at maximum inflow settings, gas should flow freely at less than 2 mm Hg pressure down the opened, unconnected insufflation line, and when the line is purposely kinked by the surgeon, the insufflator-recorded pressure should rise rapidly to its preset limit (usually 15 mm Hg), the inflow of CO_2 should cease, and the high pressure alarm should sound. Again, troubleshooting the insufflator should be part of the routine prelaparoscopy check in every case.

Subcutaneous Emphysema. This problem develops owing to improper placement of the Veress needle or, more commonly, to leakage of CO_2 around ports. The latter situation occurs when port site incisions are too large, when the procedure is particularly lengthy, or when high intra-abdominal pressures are used. The pathognomonic sign is crepitus over the abdomen and thorax; in male patients, a pneumoscrotum may also develop.

If the problem is due to improper placement of the Veress needle, then withdrawal of the Veress needle and open insertion are recommended. If the problem develops intraoperatively, the surgeon should check for gas leakage around a port site. If this is found, the surgeon can either place a purse-string suture around the port or, preferably, change the trocar to a larger size or switch to the balloon-based Hasson type cannula, which creates a tight seal between the intra-abdominal balloon and its outer soft foam cuff. Also, the surgeon should consider reducing the insufflation pressure.

This complication is eminently avoidable if the surgeon adheres to all the diagnostic tests for proper Veress needle placement and if the port site incisions are carefully tapered to the size of the port to be placed. In this regard, it is important to place each port so that it is pointing toward the surgical field, to avoid the continued forceful redirection of the port during the procedure that results in widening of the tissue tract around the port and subsequent escape of CO_2 into the surrounding subcutaneous tissues. In addition, the cannulas must be secured so they do not pull back into the abdominal wall tissues; to this end, the surgeon can use a screw-type cannula or may elect to simply use a suture to fix the sidearm of the port to the skin, thereby precluding its retraction beyond a certain point. If the former solution is chosen, the surgeon must be careful to never use a plastic retaining collar with a metal trocar; this situation greatly increases the chance of inadvertent monopolar electrosurgical injury owing to stray current along the exposed shaft of the now partially insulated metal trocar. Also, the insufflator must be tested before each procedure, as part of a preincisional routine checklist, to make sure it is functioning properly, so that when high pneumoperitoneum pressures develop, the inflow of CO_2 automatically ceases.

Several studies have demonstrated that the incidence of subcutaneous emphysema is somewhat higher during retroperitoneal laparoscopy than during transperitoneal laparoscopy, albeit without any clinically significant sequelae (Wolf et al, 1995; Zhao et al, 2008). However, the risk of surgical emphysema and other CO_2-related sequelae during retroperitoneoscopic and extraperitoneoscopic surgery can be effectively minimized by adopting a variety of practical measures (Gill, 1998; Ng et al, 1999). Specifically working at a lower pressure is helpful (i.e., 12 mm Hg). In one study, in the initial 20 cases with an insufflation pressure of 15 mm Hg, subcutaneous emphysema was noted in three patients (15%); however, in the subsequent 180 cases the insufflation pressure was maintained below 12 mm Hg and subcutaneous emphysema was noted in only two patients (1.1%) (Rassweiler et al, 1998a). Also, use of the balloon-based Hasson cannula to seal the initial entry site is important. Invariably, the problem resolves itself during the initial 2 to 3 postoperative days.

Pneumomediastinum, Pneumothorax, and Pneumopericardium. Gas leaking along major blood vessels through congenital defects or secondary enlargement of openings in the diaphragm may lead to pneumomediastinum, pneumopericardium, or pneumothorax (Kalhan et al, 1990; Pascual et al, 1990; See et al, 1993; Abreu et al, 2004; Zhao et al, 2008). Although a pneumomediastinum is usually not associated with specific clinical symptoms, a pneumopericardium may result in impaired cardiac function. The incidence of the latter complication is estimated to be 0.8% (Abreu et al, 2004). The diagnosis is rarely made during the procedure unless cardiac impairment occurs. Usually, the diagnosis is made on a chest radiograph taken in the recovery room. However, if there is sudden cardiac decompensation during a procedure, the same maneuvers are undertaken as described for treatment of a suspected gas embolism—interruption of the procedure and desufflation of the abdomen. If there is a strong suspicion of pericardial tamponade, pericardiocentesis is indicated.

A pneumothorax may be associated with pneumomediastinum, barotrauma, or with direct puncture of the pleural space with a trocar (Doctor and Hussain, 1973; Kalhan et al, 1990; Pascual et al, 1990). The incidence of this complication in a recent series was 1.6% to 4.0% (Abreu et al, 2004; Zhao et al, 2008). Like subcutaneous emphysema, the incidence of pneumothorax is more common in retroperitoneal procedures (Zhao et al, 2008). The earliest signs of this problem may be the development of subcutaneous emphysema, especially in the neck and chest area. More ominous signs, such as hypotension and decreased breath sounds with an increase in ventilatory pressure, are indicative of a *tension* pneumothorax. Although a chest radiograph will confirm the diagnosis, the development of pulmonary collapse with loss of breath sounds on one side mandates immediate decompression of the chest by passage of a 16-gauge needle into the second or third intercostal space in the midclavicular line followed by tube thoracostomy if a tension pneumothorax is suspected (See et al, 1993).

Of note, the occurrence of pulmonary complications appears to be greater with a retroperitoneal approach. Indeed, in one large series, 90% of these complications were associated with retroperitoneoscopy, whereas only 10% of these problems occurred in patients undergoing transperitoneal laparoscopy (Abreu et al, 2004).

Prevention of these problems is similar to the means to avoid subcutaneous emphysema: keep the intra-abdominal pressure at 15 mm Hg or less, make sure all port site incisions are tight around the laparoscopic cannulas, and make sure all cannulas are well seated in the peritoneal cavity. In addition, all trocars must remain below the 12th rib. While dissecting in the upper quadrants of the abdomen, especially during laparoscopic ablative renal surgery, the surgeon should be aware of the anatomic relationships of the kidneys, adrenal glands, and great vessels to the diaphragm to avoid direct injury.

Complications during Open Access (Hasson Technique). Potential problems associated with open access are similar to, albeit less frequent than, problems associated with a closed Veress needle pneumoperitoneum. The biggest major risk in this regard is injury to underlying viscera while traversing the peritoneum. In a densely scarred abdomen, the bowel may be adherent to the underside of the abdominal wall and hence may still be injured. If a bowel injury is recognized early, it can often be repaired through the same incision that was made for insertion of the Hasson cannula. Although vascular injury with this approach is distinctly rare, the surgeon must realize that even with open access this devastating complication can occur (Hanney et al, 1999).

The only minor risk in using the open access technique is failure of the surgeon to obtain secure transfascial retaining sutures on either side of the cannula. If this is not done, the bulb of the Hasson cannula will not be seated tightly into the incision, thereby resulting in significant leakage of gas and subsequent subcutaneous emphysema. One way to prevent this problem is to also place a purse-string suture in the fascia to better secure it to the hub struts of the Hasson cannula. In addition, some Hasson type cannulas have built-in retention systems. The Bluntport (US Surgical, Norwalk, CT) has a retention balloon that can be inflated in the peritoneal cavity and then drawn up tightly against the peritoneal side of the abdominal wall; an outer foam sealing ring can then be advanced down the extra-abdominal shaft of the cannula, thereby sandwiching the abdominal wall between the inflated balloon and the foam seal, effectively precluding any leakage of gas during the case. This is especially effective when doing retroperitoneoscopic procedures. Another self-sealing trocar, the Anchorport (SurgiQuest, Orange, CT) has an elastic self-sealing trocar shaft that automatically forms to the patient's body wall when the inner cannula is removed, creating a tight seal.

Complications Related to Initial "Blind" Placement of the First Trocar after Obtaining a Veress Needle Pneumoperitoneum. With the advent of nonbladed trocars (several of which also have clear tips for direct visualization of individual abdominal wall layers during port placement), the likelihood of catastrophic injuries to vital

structures has been markedly reduced (Thomas et al, 2003). Accordingly, the authors no longer consider the use of bladed trocars to be clinically appropriate and these trocars have been removed from our operating rooms.

Injury to Gastrointestinal Organs. Perforation of the small or large intestine during passage of the primary port is the most common cause of trocar-induced injury of gastrointestinal organs. Other organs (e.g., stomach) are affected much less frequently. Given the lateral positioning of the spleen and liver, injury of these organs with the passage of the primary trocar is distinctly unusual. The first sign that one has entered the bowel depends on whether the injury is through one wall or both walls ("through-and-through" injury) of the bowel. In the former instance, as soon as the laparoscope is introduced the surgeon sees the mucosal folds of the interior of the bowel. However, with a through-and-through injury the diagnosis is not made until the first secondary trocar is passed; **at that time the surgeon should routinely pass the laparoscope through the secondary port to inspect the puncture site of the initial port.** The trocar will be seen passing completely through both walls of the bowel. If the surgeon fails to perform this maneuver routinely this injury will not be noted until the end of the case when the trocars are being removed, thereby resulting in a broader injury and a prolonged time of intraperitoneal contamination. A missed bowel injury of this nature leads to peritonitis, when diagnosed intraoperatively, and possible death, when discovered only in the postoperative period.

In the case of a one-wall injury of the bowel, the surgeon can elect to leave the trocar in place and pass a second trocar in another location using an open access technique. On inspection of the abdomen the site of injury to the bowel will be immediately apparent because the initial trocar will still be residing in the bowel. At this time, the surgeon may elect to open and repair the bowel or, if skilled in laparoscopy, may place two more ports and proceed to close the bowel using laparoscopic suturing or stapling techniques. An intraoperative consultation with a general surgeon should be obtained regardless of whether the urologist performs the repair; from a medicolegal and quality of care standpoint, involvement of the general surgeon at the time of the acute event facilitates subsequent care should further complications arise while ensuring the best possible repair of the injury at the time of the acute event.

When the injury to the bowel is a through-and-through injury, the safest path is to open and proceed with repair; alternatively, if particularly skilled, one may consider laparoscopic repair. In either case, the abdomen should be irrigated with 4 to 5 L of saline containing an antibiotic solution and the patient must be placed on broad-spectrum, triple-drug antibiotic coverage.

In an effort to preclude bowel injury, a mechanical and antibiotic bowel preparation is recommended in patients with a history of extensive prior abdominal surgery. For those patients with a low risk of bowel injury, a simple mechanical preparation to "empty" the bowels should suffice. Commonly this is accomplished with magnesium citrate the day before the procedure; in addition, the patient can be placed on a clear liquid diet for 1 to 2 days preoperatively.

Perforation of the stomach is distinctly rare; however, to best preclude this problem patients should refrain from oral intake for 12 hours before surgery. To decompress the stomach, a nasogastric or orogastric tube should be placed before puncture of the abdomen with the Veress needle. The management of this complication is the same as for injury to the bowel with primary closure and general surgery consultation. In all of these cases a nasogastric tube is left indwelling until the output to gravity is minimal.

Injury to Intra-Abdominal Vessels. Major vascular injury is a rare but serious complication, occurring in 0.11% to 2% of cases (Hanney et al, 1995; Geers and Holden, 1996; Usal et al, 1998; Lin and Grow, 1999; Vallancien et al. 2002; Parsons et al, 2004) (Fig. 9–27). It is far more common in procedures related to the retroperitoneum, as opposed to pelvic laparoscopy. The aorta and common iliac arteries are most frequently involved. The inferior vena cava is less affected because of its lateral location in relation to the aorta; likewise, the common iliac vein is rarely involved given its posterior position in relation to the common iliac artery. Rarely, in a patient with adhesions or prior surgery, intestinal mesenteric vessels servicing a "fixed" loop of bowel may be injured. In addition, the epigastric vessels are at risk for injury during trocar placement.

The first sign of a major vascular complication is the onset of sudden hypotension and associated tachycardia. If the trocar has not been moved, then, as the obturator is withdrawn, the diagnosis is made immediately based on whether there is a pulsatile (arterial) or nonpulsatile (venous) profuse return of blood from the trocar sheath. If the trocar has been displaced from the injured vessel, then, depending on the vessel injured, the surgeon will see blood rapidly accumulating in the abdominal cavity, a mesenteric hematoma, blood dripping from the trocar entry site, or, rarely, blood that preferentially accumulates retroperitoneally, in which case, the space within the peritoneal cavity will appear to be markedly reduced and actively decreasing because of the expanding retroperitoneal hematoma.

The response to injury to a major arterial structure must be rapid. A vascular or trauma surgeon should be called to the room. If blood is coming through the trocar, then the trocar should be closed and left in place. An emergency laparotomy is performed, and the trocar is followed to its point of entry into the vessel. Controlling sutures can be placed on either side of the trocar or a Satinsky clamp can be placed to isolate the area of injury, so that, as the trocar is withdrawn, the wound can be rapidly controlled. Alternatively, the procedure can be converted to a hand-assisted approach and the surgeon can then use the intra-abdominal hand to control the bleeding vessel.

If the injury is discovered at the time of passage of the laparoscope (i.e., the trocar is no longer residing in the vessel), then the sheath and laparoscope can be swung up to the underside of the abdominal wall and an immediate cutdown can be done on top of the laparoscope and sheath, thereby providing for a rapid and safe laparotomy. The site of injury must be rapidly located and controlled. Again, the aid of a vascular or trauma surgeon in this case is quite helpful.

The best way to handle this complication is to avoid it completely. In this regard, knowledge of the exact location and possible anatomic variations of major intra-abdominal blood vessels is mandatory. The CT scan should be reviewed before passage of any trocars to look for vena caval or other abnormalities of the great vessels. Because of limited intraperitoneal space, special care must be given to trocar placement in children and very thin adults. Strict adherence to laparoscopic guidelines, such as ensuring that all the safety signs of passage of a Veress needle are present before proceeding with trocar passage, obtaining an adequate pneumoperitoneum before trocar passage (intra-abdominal pressure may be raised to 25 mm Hg temporarily for placement of the primary trocar), passing the initial trocar under direct endoscopic control (i.e.,

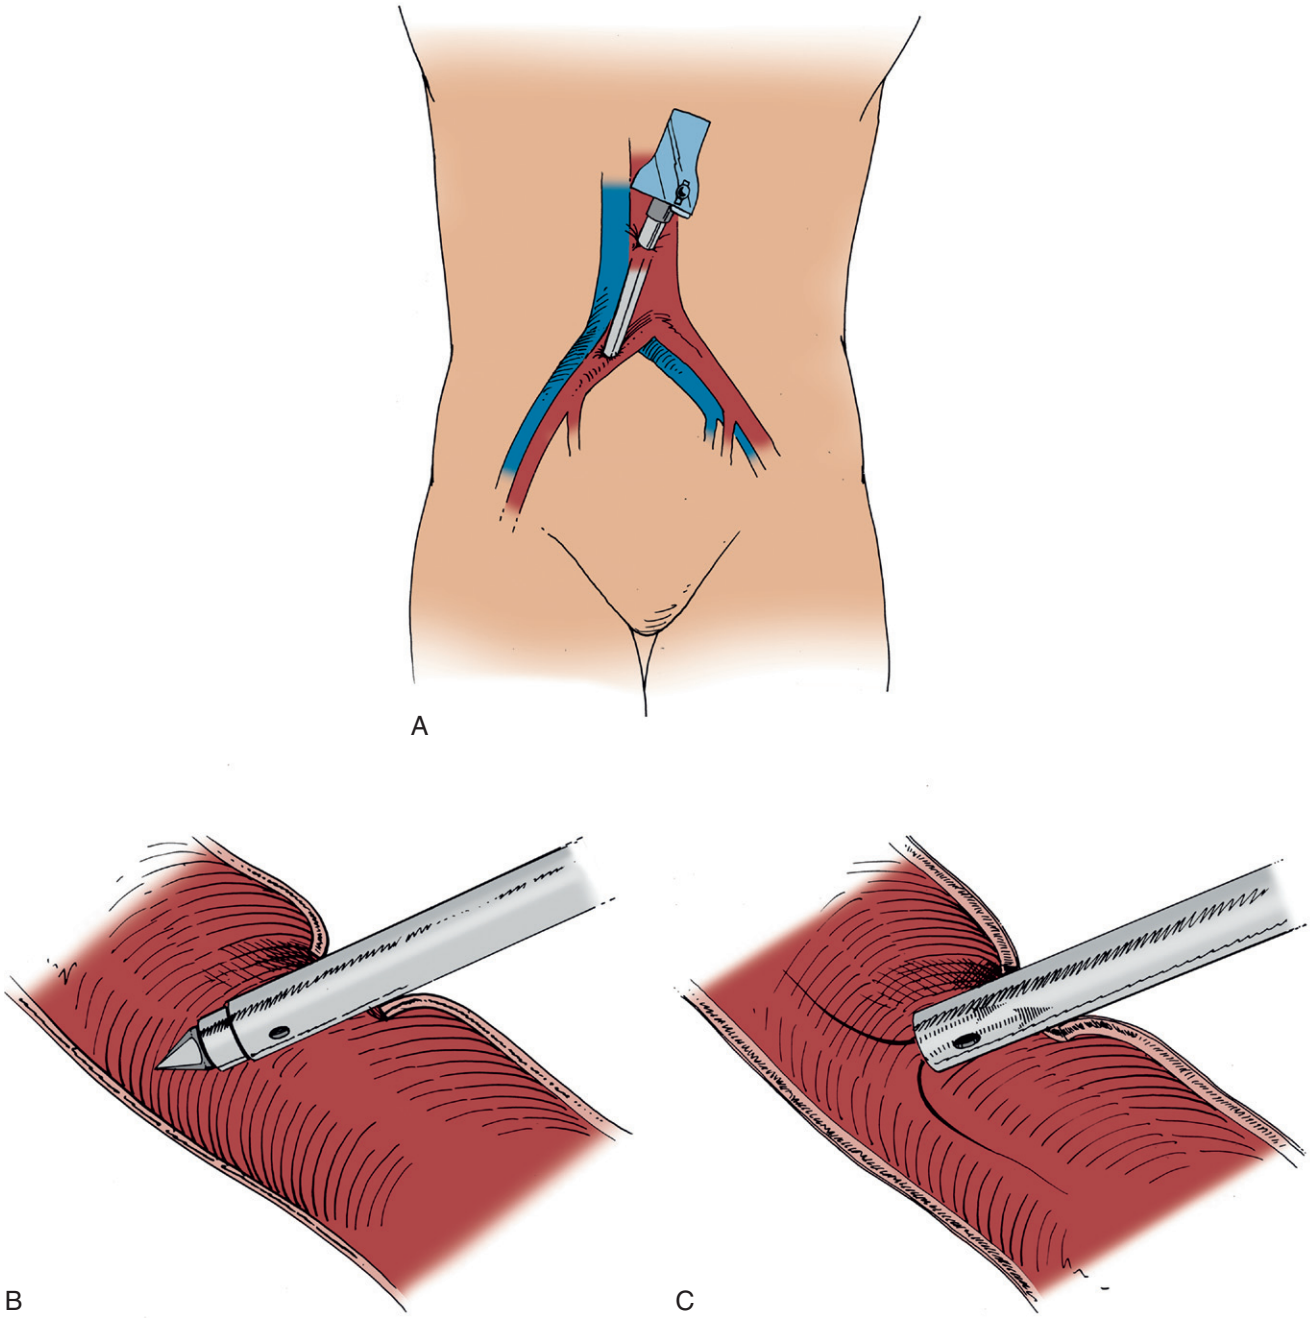

Figure 9–27. **A** and **B,** The right common iliac artery has been punctured by a trocar. **C,** As soon as the obturator is removed, blood fills the cannula. (From Clayman RV, McDougall EM, editors. Laparoscopic urology. St. Louis: Quality Medical Publishing; 1993.)

clear plastic port), and avoiding initial trocar passage through an abdominal scar, are important in helping to prevent this problem. Similarly, avoidance of the epigastric vessels is ensured if trocars are either placed in the midline or at least 6 cm lateral to the midline.

With regard to hemorrhage, when the situation is recognized but controlled, which occurs more commonly with venal caval than arterial injuries, the surgeon has the ability to "prepare" for subsequent conversion. In that regard, a second suction unit should be obtained, the vascular or trauma surgeon should be in attendance, and the anesthesiologist has time to make sure the patient is well hydrated and that blood is in the room for transfusion. In addition, before conversion, the use of a 4 × 8-inch laparoscopic pad, which can be introduced through a 12-mm port may be helpful (personal communication: I. Gill); however, if the bleeding is profuse then the surgeon should have available ample amounts of large gauze rolls (e.g., Kerlix) for packing the area as soon as the abdomen is opened.

Furthermore, it is helpful to consider having a "hemorrhage" tray available in the operating room at all times (Table 9–6). **This laparoscopic tray should contain a Satinsky clamp, a 10-mm suction tip for large clot evacuation, an Endo Stitch device with 4-0 Vicryl suture, a Lapra-Ty clip applier and a rack of Lapra-Ty clips (6 clips**

Table 9–6.

Contents of Hemorrhage Tray for Laparoscopic Surgery

Laparoscopic Satinsky clamp
Ten-millimeter suction/irrigation tip
Endo Stitch device with 4-0 absorbable suture
Lapra-Ty clip applier and a packet of Lapra-Ty clips
Six-inch length of 4-0 vascular suture on an SH needle with a Lapra-Ty clip preplaced on the end
Two laparoscopic needle drivers
Topical hemostatic agent of choice

per rack), two laparoscopic needle holders, and 4-0 vascular suture. With this tray available, some injuries to major venous structures (e.g., inferior vena cava) can be successfully resolved laparoscopically.

Injury to the Urinary Tract. Urinary tract injuries during laparoscopy are most commonly associated with trocar passage. The incidence of this problem varies widely as reported in the gynecologic literature: 0.02% to 8.3% range (Ostrzenski and Ostrzenska, 1998; Lin and Grow, 1999; Soong et al, 2007). Usually, these injuries occur to the bladder at the time of initial trocar placement. Chances of this problem occurring have been greatly reduced by the introduction of blunt trocars.

Trocar injuries of the urinary tract have reportedly affected only the bladder. The initial sign of this problem is pneumaturia or macroscopic hematuria. The diagnosis is confirmed by retrograde intravesical instillation of indigo carmine diluted with saline; this allows the surgeon to rapidly identify the cystotomy site. The injury can be repaired laparoscopically, either with laparoscopic suturing techniques or by use of the laparoscopic tissue stapler; extensive defects may require open surgical repair (Ostrzenski and Ostrzenska, 1998). These injuries should always be closed and not left to heal "on their own" with prolonged Foley catheter drainage.

Prevention of this problem is simple. Preoperative placement of a urethral catheter to drain the bladder is recommended for all major laparoscopic urologic cases. Not only does it largely preclude bladder injury, but it also provides the necessary means for monitoring urine output during major laparoscopic urologic procedures.

Complications Related to Placement of Secondary Trocars

Bleeding at the Cannula Site. Blood dripping from the port entry site and onto the underlying abdominal viscera is the first sign of an injured abdominal wall vessel. The exact site of hemorrhage is determined by cantilevering the trocar into each of the four quadrants and noting which positioning of the trocar tamponades the bleeding.

Definitive therapy for this problem can be undertaken in one of three ways. The simplest method, albeit the most costly, is the insertion of curved electrosurgical scissors or forceps through another port; this instrument can be articulated up into the port site to electrocoagulate the bleeding site.

The least expensive method is to suture the area of hemorrhage. This can be accomplished by inserting a straight Keith needle with a 0-0 absorbable suture from the outside of the abdomen at one side of the affected quadrant and then grasping the needle with laparoscopic forceps and pushing it back out of the abdomen at the opposite side of the affected quadrant until it can be recovered on the surface of the abdomen (Fig. 9–28 on the Expert Consult website). This broad suture is then tied over a gauze 4 × 4-inch bolster on the abdominal surface; the port can be used throughout the procedure. Alternatively, various port closure devices, in particular the Carter-Thomason device, may be used to similarly pass a suture to control the bleeding (Ortega, 1996); at the end of the procedure, a device of this nature should be used to definitively close the port site and occlude the injured vessel.

This problem can often be avoided by routinely transilluminating the abdominal wall, especially in the thin patient, before trocar placement so large surface vessels can be avoided. In addition, the routine spreading of the subcutaneous tissues of the proposed port site with a blunt clamp (e.g., Kelly clamp) may be helpful. Also, the use of only blunt trocars reduces the chance of vascular wall injury nearly 10-fold. Finally, careful laparoscopic inspection of the peritoneal surface before each secondary port site placement is helpful to identify the area of the inferior epigastric vessels as well as any overlying peritoneal vessels, which can then be avoided; in this regard, port sites should be placed either in the midline or at least 6 cm lateral to the midline (Hashizume and Sugimachi, 1997).

Trocar Position-Related Problems. Three potential problems may occur when the secondary trocars are not properly positioned: "crossing swords," "striking handles," and "rollover." The problem of "crossing swords" is due to the trocars being placed too close to one another; as a result, the intra-abdominal portions of two trocars cross each other so that the two cannot easily be used to deliver instruments to the same surgical site (Fig. 9–29). Similarly, the problem of "striking handles" is also due to trocars being placed too close to one another; as a result, the upper portions of the trocars strike one another on the abdominal surface, again precluding delivery of instruments to a specific surgical site. "Rollover" is a variant of the crossing swords problem, but it occurs between the laparoscope and an instrument. Instead of running parallel to the surgical site, the primary cannula holding the laparoscope and one of the instrument-holding secondary ports are pointed toward each other; as the instrument is advanced toward the surgical site, it strikes and is deflected by the larger laparoscope, thereby rolling over the laparoscope and hence suddenly moving out of the field of view. Because of the large size of most laparoscopes and the much smaller size of the working instruments, it is commonly the surgeon who is most sensitive to this problem.

By definition, these problems are more likely to occur during laparoendoscopic single-site surgery. Because the ports are purposely placed in close proximity to one another the surgeon must use advanced techniques or special equipment such as articulating instrumentation or using instruments with different shaft lengths or a low-profile 5-mm laparoscope to overcome these pitfalls. Similarly, when using the da Vinci Robotic System the ports should be placed at least 8 to 10 cm away from one another to avoid robotic arm collision. This can sometimes be challenging on thin patients with limited abdominal wall space.

Usually these problems are a minor annoyance, and the surgeon and assistant need to experience the problem only once to adjust for it. Specifically, to avoid the problem of "striking handles," the sheaths can be withdrawn a bit from the abdomen, thereby increasing the space between the handles of the instruments. The problems of "crossing swords" and "rollover" can be remedied by moving the handles of the crossing trocars closer to one another, thereby moving the tips of the trocars farther apart. When this is done to correct a "rollover" the surgical site may be displaced into one corner of the monitor; however, the desired delivery of the instrument to the surgical site can then be accomplished. A

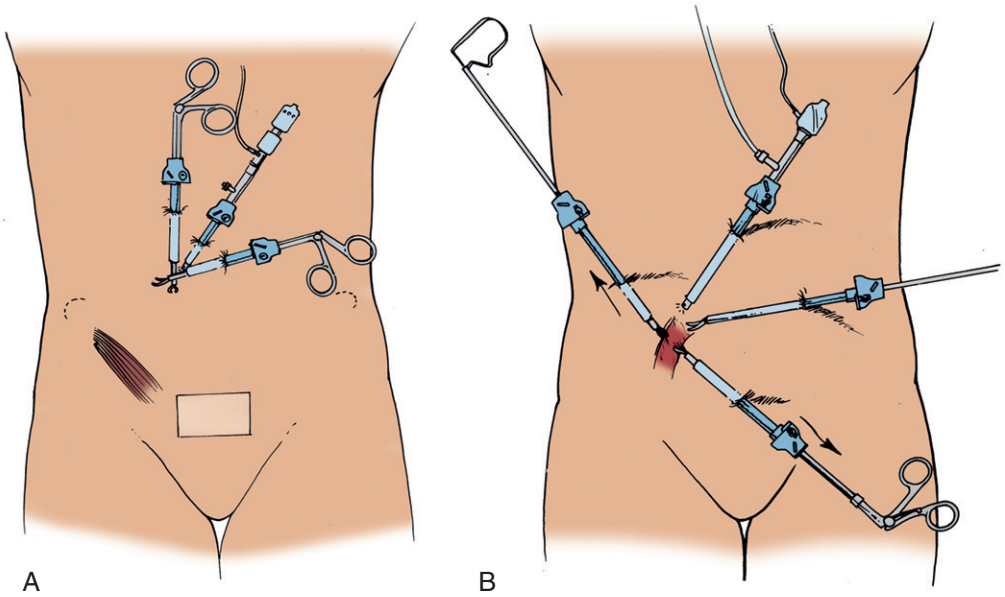

Figure 9–29. **A,** The cannulas have been placed too close to each other; hence, the intra-abdominal portions of the cannulas are also too close to each other, thereby impairing use of instruments passed through the ports. **B,** Correct spacing of the trocars eliminates this problem. (From Clayman RV, McDougall EM, editors. Laparoscopic urology. St. Louis: Quality Medical Publishing; 1993.)

30-degree laparoscopic lens can usually allow the laparoscope to be placed parallel to the instrument it is rolling over and then rotated to maintain the operative site image and eliminate the rollover. Alternatively, the handle of the instrument causing the rollover can be moved toward the extra-abdominal end of the laparoscope, thereby "separating" them intra-abdominally.

The best way to handle these situations is to properly place and direct each trocar at the beginning of the case. For some procedures, such as pyeloplasty, this may be accomplished by placing all the trocars on the same line (i.e., midline) so they are all working parallel to each other, whereas for procedures such as nephrectomy the goal is to place the trocars so that they surround the surgical site, forming a diamond pattern within which the kidney lies. Regardless, each trocar needs to be inserted such that it "points" to the pathology; this precludes the problem of having to redirect the trocar throughout the case, adding to surgeon fatigue and unnecessary trauma to the peritoneum and abdominal wall musculature. Also, the surgeon should avoid advancing sheaths too far into the abdomen. This can be accomplished by selecting the proper length of trocar for each patient. **Lastly, if trocar interactions become particularly vexing during a procedure, the surgeon should not hesitate to place an additional 5-mm secondary trocar in a more conducive site to eliminate the problem.**

Complications Related to General Anesthesia Unique to Laparoscopy

Cardiac Arrhythmias and Cardiac Arrest. Cardiac arrhythmias are frequently seen during anesthesia in laparoscopic procedures. The most common arrhythmia is sinus tachycardia; bradyarrhythmias (e.g., atrioventricular dissociation, nodal rhythm, sinus bradycardia) may develop independently or in combination with tachycardia during the same procedure (Myles, 1991). Conditions leading to development of arrhythmias are CO_2 insufflation, hypercapnia, increased vagal tone owing to traction on pelvic or peritoneal structures, Trendelenburg position, anesthetic drugs (especially halothane in combination with spontaneous ventilation), preoperative patient anxiety, endobronchial intubation, and gas embolism (Harris et al, 1984; Myles, 1991). In rare cases, asystolic cardiac arrest and cardiovascular collapse may develop (Shifren et al, 1992).

The role of the anesthesiologist throughout the laparoscopic procedure is of paramount importance. Continuous monitoring of cardiovascular (electrocardiogram, arterial blood pressure), and pulmonary (capnometry, in-line oxygen, airway pressures and tidal volume, frequent arterial blood gas analyses) parameters is essential. Invasive cardiac monitoring should be instituted in patients with heart disease (using a Swan-Ganz catheter) or in high-risk (i.e., American Society of Anesthesiologists type 3 or 4) patients when prolonged and complicated laparoscopic procedures are expected, especially because a central venous pressure line cannot be relied on for accurate readings during laparoscopy.

Because hypercarbia is one of the most common underlying causes of cardiac arrhythmias it is essential to monitor and control this problem. Overall, hypercapnia can be corrected rapidly by adjustment of ventilatory rate and tidal volume, use of positive end-expiratory pressure as needed, and reduction of intra-abdominal pressure to 10 mm Hg. The surgeon can also desufflate the abdomen for 5 to 10 minutes to allow the anesthesiologist to "catch up" and correct the hypercarbia; pneumoperitoneum can then be reinitiated at a lower pressure (5 to 10 mm Hg).

In rare cases, if the hypercarbia cannot be controlled by these maneuvers, helium should be substituted for CO_2 as the insufflant; however, this is a rare event and one that can usually be predicted before the procedure. For patients with preoperatively known severe pulmonary compromise, it is prudent to have a tank of helium and the proper helium yoke available in the operating room so the insufflant can be easily switched. Alternatively, argon gas can be used in the acute situation because it is readily available in many operating rooms owing to the argon beam coagulator (Badger et al, 2008).

In the event of cardiac arrest, the surgeon should immediately desufflate the abdomen and provide cardiac massage (compressions) while the anesthesiologist administers 100% oxygen and appropriate drug therapy. If a CO_2 embolus is suspected, additional

maneuvers, such as immediately turning the patient to a left lateral decubitus, head-down position and possibly attempting to aspirate the embolus, may be performed.

Preventive measures include avoidance of excessive intra-abdominal pressures (>25 mm Hg) over a prolonged period of time and avoidance of certain anesthetic agents or situations (e.g., halothane and spontaneous ventilation). Premedication with atropine may prevent excessive vagal stimulation (Wolf and Monk, 1996).

Changes in Blood Pressure. Hypertension may be caused by inadequate general anesthesia, elevated intra-abdominal pressures, or hypercarbia. Hypotension may be the result of hypoxia, pneumothorax, pneumomediastinum, gas embolus, or hemorrhage (Abdel-Meguid and Gomella, 1996).

Intermittent or continuous noninvasive blood pressure measurements or invasive monitoring of intra-arterial (e.g., radial artery) pressure is part of all laparoscopic procedures. In the event of a marked change in blood pressure, one of the aforementioned conditions must be ruled out. **The initial response of the surgeon, provided that there is neither active bleeding nor evidence of retroperitoneal hemorrhage, should be to desufflate the abdomen.** In addition to desufflation, therapy specific to an underlying laparoscopic cause may include CO_2 elimination by increased ventilation, attempts to increase oxygen saturation, treatment of an underlying pneumothorax, pneumomediastinum, or gas embolus, and pharmacologic (vasodilators or vasoconstrictors) therapy.

Aspiration of Gastric Contents. Aspiration of gastric contents may occur more frequently in patients with a hiatal hernia, significant obesity, diabetes with a history of gastroparesis, or any form of gastric outlet obstruction (Hanley, 1992). The combination of elevated intra-abdominal pressures from the pneumoperitoneum, morbid obesity, and use of the Trendelenburg position increases the likelihood of this complication (Abdel-Meguid and Gomella, 1996).

The diagnosis is easily made because the problem usually occurs during intubation, with associated coughing. The response to suspected aspiration depends on the intubation status of the patient. If the patient is not intubated, the head should be turned sideways and all gastric secretions should be vigorously suctioned (Hagberg and Boin, 1999). If the endotracheal tube is already in place, it should be left in situ and aggressive suctioning should be initiated. If aspiration of gastric contents occurs postoperatively, reintubation with mechanical ventilation and positive end-expiratory pressure may be indicated (Hagberg and Boin, 1999). Neither corticosteroid nor broad-coverage antibiotic administration is indicated (Tasch, 1999).

To prevent this problem in high-risk patients, oral or intravenous administration of 10 mg of metoclopramide is recommended. This medication may decrease the incidence of aspiration by increasing the tone of the lower esophageal sphincter. In addition, in patients with known gastroesophageal reflux, H_2 blockers reduce gastric acidity and attendant morbidity if aspiration of gastric contents should occur (Hanley, 1992; Abdel-Meguid and Gomella, 1996). Also, in patients with known gastroesophageal reflux or other predisposing factors for gastric aspiration, a cuffed endotracheal tube should always be placed. Lastly, among these high-risk patients, administration of atropine should be avoided because it decreases the tone of the lower esophageal sphincter (Duffey, 1979).

Hypothermia. The patient's body core temperature may drop during prolonged laparoscopic procedures, especially if there is leakage of insufflant around the port sites. The CO_2 that is used is typically neither warm nor humidified. The resulting decrease in temperature may be 0.3° C for each 50 L of CO_2 insufflated (Ott, 1991a). The ambient operating room temperature may exacerbate this effect.

The clinical effects of hypothermia are well described. Core body temperatures around the 35° C level may result in (1) increased bleeding tendency owing to impaired platelet function, reduced activity of coagulation factors in the coagulation cascade, and enhanced fibrinolysis; (2) increased adrenergic response with vasoconstriction and increased arterial blood pressure; (3) prolonged recovery time due to increased blood gas solubility; (4) twofold to threefold increase in the incidence of early postoperative myocardial ischemia in high-risk patients; and (5) impaired wound healing and increased susceptibility to wound infections (Rosenberg and Frank, 1999).

In general there are no specific anesthetic symptoms that can be appreciated intraoperatively except for cardiac arrhythmias. In particular, atrial fibrillation may occur in extreme cases of hypothermia (body core temperature around 30° C). In such a case, if the patient arrests, cardiac resuscitative efforts should be **prolonged** because the patient must be warmed for resuscitative efforts to have their proper impact. The problem is combated by use of warm intravenous fluid and application of active warming systems.

In almost all cases, hypothermia can be avoided. Adjuncts to support the patient's body temperature include intravenous fluid warming, active warming by forced-air systems, circulating warm-water mattresses, and radiant heaters (Rosenberg and Frank, 1999). In addition, warming and humidifying CO_2 to physiologic levels, especially when a prolonged laparoscopic procedure is anticipated, is helpful (Ott, 1991b). However, warming the insufflant alone, should be avoided, because this causes a drying of the intraperitoneal tissues and has been associated with increased postoperative patient discomfort (Slim et al, 1999).

Complications Related to the Surgical Procedure

Bowel Injury: Electrosurgical Etiology. Electrosurgically induced thermal injury may occur because of one of four mechanisms: inappropriate direct activation, coupling to another instrument, capacitive coupling, and insulation failure. Active electrode trauma by unintended activation causes direct bowel or other organ injury; it may occur when the instrument is left unobserved within the peritoneal cavity or when electrode activation is carried out by someone other than the primary surgeon. Furthermore, active electrode trauma may be seen when coagulation extends beyond the intended site and reaches other adjacent structures (e.g., bowel, blood vessels, nerves, ureter); this is more commonly seen when high electrocoagulation settings (i.e., >30 watts) are used instead of blended or pure cutting current. Direct coupling may occur when the active electrosurgical instrument touches another instrument that is in direct contact with other tissue (e.g., bowel). If this happens outside the field of view provided by the laparoscope, it may remain unnoticed by the surgical team. Injury owing to capacitive coupling occurs when the surrounding charge, which is intrinsic to all activated monopolar electrodes, is not allowed to conduct back to and disperse through the abdominal wall (Zucker et al, 1995; Munro, 1997). This condition may develop when a metal cannula is anchored to the skin with a nonconductive plastic grip, which, as previously noted, should never be done (Fig. 9–30). As a result, the electrical field, which builds up around the activated electrosurgical instrument and is conducted to the metal trocar through which it has been placed, cannot then be conducted to the abdominal wall because the plastic retainer acts

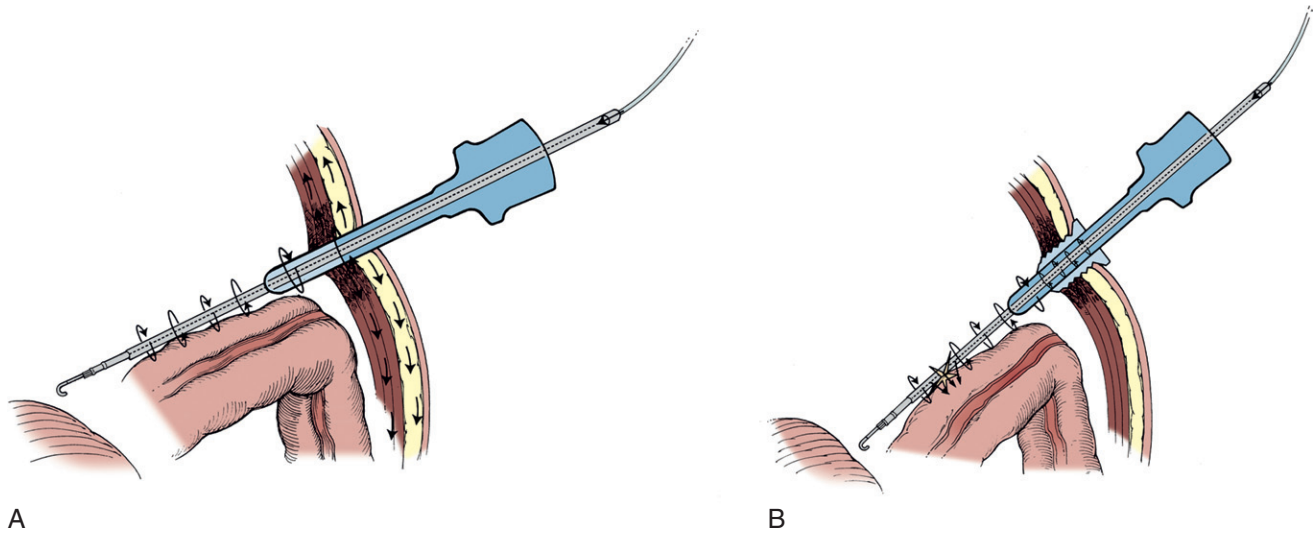

Figure 9–30. Capacitive coupling. **A,** Charge surrounding the activated monopolar electrode is conducted back to the all-metal cannula and dispersed by the abdominal wall. **B,** The electrosurgical instrument is being used through a metal cannula that has been anchored to the skin with a nonconductive plastic grip; accordingly, the electrical field cannot be conducted to the abdominal wall because the plastic retainer acts as an insulator; a stronger electrical charge is thus conducted to any other tissue in contact with the cannula.

as an insulator. This may lead to a high power density along the portion of the metal cannula that is inside the abdomen; the electrical charge built up on the cannula can then travel to other tissues in contact with the cannula. Similarly, capacitive coupling may constitute a risk when electrosurgical probes are used through operating laparoscopes, which are, in turn, inserted through plastic sheaths. The metal shaft of the laparoscope then becomes a repository for electrical current and may discharge this energy to any tissue in contact with the laparoscope. In general, the side-arm operating laparoscope is rarely used during urologic procedures. The risk of this complication is also increased when older generators with high-voltage output and/or electrodes with thicker diameters are used, especially in coagulation rather than cutting mode (Munro, 1997). Lastly, insulation breakdown may allow current to escape along the shaft of the instrument, thereby harming tissues that are otherwise outside the field of view of the laparoscope. Insulation breakdown along the shaft of the instrument may be a result of repeated use, resterilization, or mechanical damage to the instrument during repeated insertion through a trocar. In this situation, the small break in insulation results in an area of very high power density that then discharges to the nearest soft tissue.

Intraoperatively, thermal injuries of the bowel may present as whitish spots on the serosal lining. In severe cases, the muscularis mucosae or the intestinal lumen may be seen. However, in many patients, the event of thermal injury of the bowel is not realized at the time of the procedure. **Postoperatively, the patient with unrecognized bowel trauma may not develop fever, nausea, or signs of peritonitis for many days; indeed, the full extent of the bowel necrosis may take up to 18 days to fully develop** (Abdel-Meguid and Gomella, 1996). **Therefore, the problem often does not become manifest until the patient has actually been discharged from the hospital.**

Accordingly, bowel injury must be ruled out for any patient who develops a fever beyond postoperative day 1 or who complains of increasing abdominal discomfort. Abdominal radiographs are notoriously inaccurate because the CO_2 from the laparoscopy may remain as "free air" for upwards of 9 days after the procedure; however, an ileus pattern is usually present. The more sensitive test is an abdominal CT scan with oral contrast accompanied by delayed films, usually 6 or more hours after the initial oral contrast load. Laboratory values may be remarkable for leukocytosis with an associated left shift (i.e., increased percentage of neutrophils); in some patients, the latter occurs in the face of a normal or even low leukocyte count, making the "left shift" a more reliable sign than the absolute white cell count.

Minor postoperative thermal injuries of the bowel, discovered late in the postoperative period (i.e., >5 to 7 days postoperatively) may be managed conservatively, aided by administration of antibiotics and an elemental diet. Indeed, a closed fistula may develop that will heal with this approach. However, if the patient does not respond rapidly or develops worsening peritonitis, open surgical exploration is mandatory. Thermal injury caused by monopolar cautery often results in tissue damage that extends beyond the visible area of necrosis. With this in mind, the surgeon should perform a bowel resection with a safety margin of 6 cm on either side before completing an end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

Thermal injury caused by bipolar electrosurgery is more confined to the visible area of damage. These injuries only occur due to direct firing of the instrument on the bowel. If the injury is small, it can be managed by simple excision of the defect and closure of the bowel wall. Bipolar injuries that involve more than half of the circumference of the bowel should be treated by excision of the affected segment of the bowel followed by end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

The goal of every laparoscopic surgeon is to never experience a thermal complication. To this end there are several actions the surgeon can take to lessen the risks. First, electrosurgical instruments must be carefully inspected before use for any "breaks" in the insulation; if these are found, the instrument must be sent out to be recoated. Next, electrosurgical instruments should never be left untended within the abdomen; when not in use they must be removed from the abdomen. Also, control of electrode activation should be performed *only* by the primary surgeon. The foot pedal

should be placed so that only the surgeon can depress it. To facilitate surgeon-only activation of the instrument, some newer laparoscopic instruments such as the 5-mm LigaSure (ValleyLab, Boulder, CO) are designed with ergonomic thumb-operated mechanisms that only the operative surgeon can activate. Also, isolation of the area to be cauterized from the surrounding tissues (vessels, nerves, ureter), as well as use of bipolar electrocautery, reduces the risk of thermal injury to other tissues. In addition, the electrosurgical device should never be activated unless the entire extent of the metal portion of the instrument is in view; this includes not only the active tip of the instrument but also any exposed, uncoated metal joints that may lie just behind the tip of the instrument. In this manner both inadvertent direct injury to adjacent tissue and direct coupling to another instrument can be avoided. Problems of capacitive coupling can be precluded by not creating a situation in which a mixture of conducting and nonconducting elements are used by the surgeon (e.g., metal trocars combined with plastic retainers, electrosurgical devices through uncoated operating laparoscopes passed through plastic trocars). In addition, use of modern generators and small-diameter electrodes significantly decreases the risk of capacitive coupling (Munro, 1997), as does greater use of blended or pure cutting current. The high voltages needed for pure coagulation current pose the greatest threat for electrosurgical injury, especially through the mechanism of capacitive coupling and insulation failure. Lastly, an active electrode monitoring system (Encision, Boulder, CO) is extremely helpful; with this system, any sudden break in the insulation of the electrosurgical instrument (e.g., with scissors or hook electrode) results in immediate shutdown of the electrosurgical current, thereby precluding an electrosurgical injury.

Bowel Injury: Mechanical. Inadvertent mechanical damage can be caused by a wide variety of sharp and blunt instruments (e.g., laparoscopic graspers, scissors, retractors). This type of injury is more visible to the surgeon and is usually discovered intraoperatively or at the end of the procedure when the surgical site is irrigated. Direct visual identification during the procedure allows the surgeon to repair the injury laparoscopically, even though the patient has not had a formal bowel preparation. Given its localized nature, bowel resection is rarely necessary. The abdomen should be irrigated copiously at the end of the procedure with 4 to 5 L of an antibiotic-containing solution.

If the situation is missed during the procedure, then postoperatively symptoms develop much earlier than with an electrosurgical injury. Fever, nausea, ileus, and peritonitis develop in the very early postoperative period. Diagnosis is confirmed by an abdominal CT scan with oral contrast material. This type of injury should be managed with immediate return to the operating room to correct the problem by local excision or resection of bowel with subsequent end-to-end anastomosis and copious irrigation of the abdomen (see later).

Delicate handling of tissue with laparoscopic instruments by the main surgeon and the assistants is essential to avoiding this complication. Likewise, it is important that introduction of laparoscopic instruments into the peritoneal cavity be done under strict visual control. Instruments should never be left untended; if they are not in use, they should be withdrawn from the abdominal cavity. Attentiveness, economy of motion, and deftness of touch are essential characteristics of both the successful open and laparoscopic surgeon.

Vascular Injury. Fortunately, direct vascular injury during laparoscopic dissection is a rare event. The use of only blunt trocars, the small nature of the instrumentation, the limitations on surgical speed, and the magnification of the surgical field by the laparoscope all combine to decrease this potential problem.

During right renal dissection, in particular, the chance of a vena cava or renal vein injury is heightened. When this occurs the surgeon can undertake several steps to resolve the bleeding. **First, the pneumoperitoneum pressure can be raised to 25 mm Hg, thereby slowing or stopping any venous bleeding.** With the use of the irrigator/aspirator, the blood can be cleared and the bleeding site identified; if necessary a second insufflator can be brought into the room and connected to maintain pneumoperitoneum pressure even during use of suction at the site of injury. Next, through one of the 12-mm ports, a gauze sponge or a 4 × 18-inch laparotomy pad can be introduced into the abdomen and handled with a grasping forceps, thereby allowing the surgeon to identify and tamponade the area of bleeding. If the injury is small, then it may respond to simple tamponade; alternatively, a hemostatic patch and/or fibrin glue or thrombin-impregnated granules (e.g., Floseal) may be applied. If the injury is larger, then the surgeon must decide whether to obtain a vascular consult and proceed to convert to an open procedure or to attempt securing the injury with a laparoscopic Satinsky clamp and proceed with intracorporeal suturing, either freehand or with an Endo Stitch and 4 inches of a 4-0 Vicryl suture with a Lapra-Ty clip secured at its end. Care should be taken to use a laparoscopic grasper to introduce the Lapra-Ty clip into the abdomen first, followed by the Endo Stitch device; the shaft of the Endo Stitch cannot be passed alongside the Lapra-Ty clip because the two together are too broad to pass side by side through a 12-mm cannula. With the Endo Stitch device a running suture is done, with the initial Lapra-Ty clip serving as the distal "knot"; after the defect is closed, the suture is again secured with a Lapra-Ty clip. *One caveat is important:* specifically, owing to the larger holes in the tissue caused by the Endo Stitch needle and suture passing side by side the sewn tissue may ooze slightly after the repair; this can be nicely controlled by the application of thrombin-impregnated granules (e.g., Floseal). Throughout this period, it is essential for the anesthesiologist to administer sufficient fluids or blood replacement to preclude a hypovolemic state because the hypovolemic patient has a higher risk of possible air embolism at these higher intra-abdominal pressures (O'Sullivan et al, 1997).

If the surgeon is able to gain temporary control of the vessel with a grasper then it is often helpful to place an extra 5-mm port that can be used by the assistant for suction/irrigation or to optimize the plane of approach to the injury, thereby facilitating laparoscopic suturing. Either way the additional port allows the surgeon to repair the bleeding site using two hands and with excellent visualization of the surgical field.

Alternatively, the surgeon can convert from standard laparoscopy to a hand-assisted approach. The hand in this case is valuable because it can rapidly tamponade the bleeding site. In this regard it is recommended, if at all possible, to pinch the sidewalls of the vein (e.g., inferior vena cava) closed rather than just putting direct pressure on the top of the injury; the latter approach has a tendency to result in a gradual enlargement of the hole in the vein. Also, by pinching the hole closed, a Satinsky clamp can be more easily passed beneath the surgeon's fingers to provide reliable control of the injury in preparation for a sutured repair.

Minor arterial injuries usually respond to tamponade. Larger aortic or renal artery injuries are much more difficult to resolve laparoscopically. Although the latter, if it occurs during a planned nephrectomy, can be handled by expeditiously taking the renal artery with a vascular stapler, the former almost invariably leads to immediate conversion and open repair. In this case, the area of

injury should be tamponaded with a laparoscopic forceps. A vascular surgeon can be called into the room and the surgeon can proceed to rapidly make a midline incision by swinging one of the midline ports up to the underside of the abdominal wall and cutting down on the shaft of the port. The tamponading laparoscopic forceps directs the surgeon immediately to the site of injury, which can then be properly repaired.

As mentioned previously in this chapter, because most bleeding episodes are unexpected, it is wise to have in the room a hemorrhage tray equipped with all instruments necessary to control bleeding. In most cases, a successful outcome is heavily dependent on a rapid and effective response on the part of the surgeon, which is only possible if the equipment is immediately available and the operating room team is knowledgeable and efficient. A hemorrhage tray that can quickly be opened in case of a vascular injury containing all needed instruments is highly recommended (see Table 9–6). The authors recommend that this tray be wrapped in a red cloth or other highly visible unique wrapping so it is always readily identifiable in the operating room.

Injury to the Urinary Tract

Bladder Injury. Electrocautery dissection, blunt and sharp dissection (with laparoscopic scissors), and laser dissection have been identified as intraoperative causes of bladder injury (Ostrzenski and Ostrzenska, 1998). Concomitant bladder or pelvic anomalies or pathologic conditions (acute or chronic inflammation, prior pelvic or bladder surgery, endometriosis, malignant infiltration, bladder diverticula, amyloidosis, or previous radiation) are predisposing factors that increase the chances of this complication (Ostrzenski and Ostrzenska, 1998).

When a bladder injury has occurred, the intraoperative signs may be subtle. One of the first signs is the presence of blood or gas in the Foley catheter bag. Also, the surgeon may notice clear fluid welling up in the pelvis, although this sign is often obscured if irrigation has been used during the procedure.

Postoperatively, if the bladder injury was missed, the patient may develop oliguria and urinary ascites; this may be accompanied by hyponatremia and, rarely, hyperkalemia with mild elevation of the serum creatinine concentration owing to the peritoneal absorption of urine. Patients who have been discharged from the hospital because of the minor nature of their laparoscopic procedure may contact their physician complaining of lower abdominal discomfort, abdominal swelling, fever, and, in the case of a gynecologic procedure, vaginal discharge.

The intraoperative suspicion of a bladder injury may first arise due to the recognition of an air-expanded urine collection bag; this presumptive diagnosis can be confirmed by the injection of saline mixed with indigo carmine through the Foley catheter. Postoperatively, the diagnosis can be made by radiologic examinations (pelvic ultrasonography, pelvic CT, and/or voiding cystourethrography). Similarly, an endoscopic examination with the injection of 5 mL of indigo carmine intravenously is helpful if a vesical fistula is suspected; the surgeon can then look for blue-tinged vaginal or rectal discharge (Chapron et al, 1995; Ostrzenski and Ostrzenska 1998).

The intraoperative diagnosis of a bladder injury can be followed by laparoscopic repair: suturing with absorbable suture, closing the defect with a laparoscopic stapler, or, if the injury is quite small, using preformed suture loops to encircle and secure the cystotomy (Poffenberger, 1996; Ostrzenski and Ostrzenska, 1998). More extensive defects may require open incisional repair.

When bladder injury is diagnosed postoperatively, the key factor is whether the drainage is extraperitoneal or intraperitoneal, which is largely dependent on the preceding laparoscopic access. Extraperitoneal extravasation without any complicating additional problems may be treated by simple placement of a transurethral indwelling Foley catheter. Intraperitoneal drainage is an indication for subsequent laparoscopic or open repair.

Prevention of bladder injury requires preoperative placement of a Foley catheter. Strict adherence to basic laparoscopic principles remains the hallmark of an uncomplicated laparoscopic procedure; in this regard, avoidance of excessive coagulation near the bladder and dissection with exact knowledge of bladder anatomy (urachus, medial umbilical, and vesicocervical ligaments) are key.

Ureteral Injury. Ureteral injury is usually a result of thermal damage caused by dissection using monopolar electrocautery in the immediate vicinity of the ureter. Its incidence in laparoscopic hysterectomy is 1%; it may also occur during laparoscopic endometriosis ablation and tubal ligation and has been reported during pelvic lymphadenectomy and laparoscopic radical prostatectomy (Baumann et al, 1988; Grainger et al, 1990; Poffenberger, 1996; Liu et al, 1997; Ostrzenski and Ostrzenska, 1998; Guillonneau et al, 2002).

The intraoperative diagnosis is made by the astute laparoscopist when urine is seen to be welling up in the wound. However, if irrigation has been used during the procedure this sign is invariably obscured. As opposed to a bladder injury, macroscopic hematuria or pneumaturia is distinctly unusual with this injury.

Typically, ureteral injuries remain unnoticed throughout the laparoscopic procedure. Within 2 to 3 days after surgery, patients may present with abdominal and/or flank pain, fever, signs of peritonitis, and leukocytosis (Grainger et al, 1990; Liu and McFadden, 2000).

Most of these diagnoses are made during the postoperative period when an intravenous pyelogram or abdominal/pelvic CT is ordered owing to the patient's complaint of flank pain, abdominal swelling, and/or the physical signs of urinary ascites. Depending on the function of the contralateral kidney and the amount of urine leakage, serum chemistries may reveal hyponatremia and, rarely, hyperkalemia with a mild elevation in the serum creatinine concentration.

If identified intraoperatively, the injury can be repaired laparoscopically. If the injury is due to mechanical trauma, simple closure of the defect can be accomplished with laparoscopic suturing techniques followed by stent placement. If the injury is due to monopolar electrosurgical current, then a formal resection of the affected area and an end-to-end spatulated ureteroureterostomy and stent placement are indicated; ureteral reimplantation is indicated if the level of injury is at the ureterovesical junction. This can be done laparoscopically but may require conversion to an open procedure. An indwelling ureteral stent is placed.

If the problem is detected in the postoperative period, the first step is to place an indwelling ureteral stent and a bladder drainage catheter. If a stent cannot be placed, then a laparoscopic or open surgical intervention is indicated to repair the area of injury; alternatively one can consider a percutaneous nephrostomy and an antegrade attempt at stent placement before seeking a laparoscopic/open solution. Once a cystogram reveals reflux without extravasation, the bladder drainage catheter can be removed. The stent is left in place for 6 to 8 weeks. Careful follow-up is necessary to rule out the development of a ureteral stricture that may require endourologic or formal surgical repair.

Prevention of this injury again harkens back to the importance of the surgeon's knowledge of laparoscopic anatomy and the course of the ureter with regard to its topographic relation to other

anatomic structures (medial umbilical ligament, round ligament or vas deferens, and common iliac artery). During dissection, the use of monopolar electrosurgical coagulation current should be used with great discretion around the ureter. In particular, a "cutting" rather than "coagulation" mode should be used whenever possible; when employing "coagulation" current the wattage should not exceed 30 watts. In addition, fine-tipped electrosurgical instruments should be employed and the duration of discharge should be brief (i.e., multiple short bursts of current rather than a continuous multisecond discharge).

Pancreatic Injury. Injury to the pancreas during left-sided laparoscopic adrenalectomy or radical nephrectomy is most commonly associated with mechanical retraction. The tail of the pancreas overlies the adrenal and may be injured during dissection of the medial aspect of the adrenal and the securing of the splenorenal ligament. The incidence of this complication is 2.1% for radical left nephrectomy and 8.6% for left adrenalectomy (Varkarakis et al, 2004). Of note, the diagnosis is rarely made intraoperatively; indeed, 75% of pancreatic injuries are diagnosed during the postoperative period.

Among the few in whom this diagnosis is made intraoperatively, general surgery consultation can be obtained and the injury possibly repaired by freeing up the tail of the pancreas and excising the injured portion with an Endo GIA stapler. However, more commonly the patient presents postoperatively with abdominal discomfort. Evaluation reveals elevated serum lipase and amylase levels, as well as leukocytosis. CT reveals a fluid collection that can often be drained percutaneously. A nasogastric tube is placed and oral intake is stopped. When drainage drops below 50 mL/24 hr, the drain can be removed, followed by removal of the nasogastric tube and initiation of a low fat diet. Of note, the average hospital stay among patients with this complication was 18 days.

Prevention of this complication requires the surgeon to widely dissect the line of Toldt and the splenophrenic attachments. The latter are freed to the level of the diaphragm. The colon is broadly reflected from the Gerota fascia, and the splenocolic and splenorenal ligaments are divided. With these maneuvers the spleen and colon rotate medially carrying with them the tail of the pancreas, well away from the medial surface of the adrenal gland.

Splenic Injury. The advent of laparoscopic surgery has been associated with a significant decrease in incidental splenectomy, with a fall from 4.3% to only 1.5%. These injuries are invariably discovered intraoperatively and can effectively be treated with argon beam coagulation or with one of the newer hemostatic agents such as fibrin glue or thrombin-impregnated granules. **Avoidance of this complication is best achieved by wide mobilization of the spleen during left radical/total nephrectomy.** To this end the splenophrenic attachments as well as the splenocolic and splenorenal ligaments need to be divided. Retraction in the area of the spleen should never be on the spleen itself but beneath the area of the splenocolic ligament such that the retractor is placed on these thicker tissues (Cooper et al, 1996; Simon et al, 2004).

Also, the laparoscopic surgeon must ever be vigilant of the splenic vein. This often tortuous vein may run parallel and within millimeters of the superomedial surface of the adrenal gland and the upper pole of the left kidney.

Nerve Injury. There is no problem more vexing to physician and patient alike than a postoperative nerve injury; a technically and surgically successful procedure is marred by an acute complication in a totally unrelated area. This problem is invariably due to patient positioning in combination with the duration of the procedure. The exact incidence of this problem is not known, but in a recent survey of neuromuscular injuries associated with laparoscopic urologic surgery completed by 18 urologists from 15 institutions in the United States it was found that of a total of 1651 procedures there were 46 neuromuscular injuries in 45 patients (2.7%). This included abdominal wall neuralgia (14), extremity sensory deficit (12), extremity motor deficit (8), clinical rhabdomyolysis (6), shoulder contusion (4), and back spasm (2) (Wolf et al, 2000). If the patient is inadequately positioned and/or padded, nerve damage may result owing to abnormal nerve stretching or compression. Among position-related nerve injuries, the brachial plexus appears to be most at risk. Injury may be inflicted in several ways: (1) abduction of the arm beyond 90 degrees, (2) extreme outward rotation of the head of the humerus, and (3) compression damage when shoulder braces are used in the Trendelenburg position, which pushes the clavicle into the retroclavicular space. Other nerves that can be affected by positioning include the femoral nerve, owing to extreme lateral rotation and abduction of the hip joint, and the sciatic nerve, owing to stretching along the superior leg when the patient is in the lateral decubitus position (Hershlag et al, 1990; Abdel-Meguid and Gomella, 1996). In addition, nerves may be injured during the surgery itself because of either direct mechanical injury or monopolar electrosurgical current. In this regard, the nerves most susceptible to damage in urologic laparoscopy are the obturator nerve during pelvic lymphadenectomy and the genitofemoral nerve during radical nephrectomy/nephroureterectomy. The diagnosis is invariably made postoperatively. On awakening from anesthesia, the patient complains of weakness or inability to contract the affected musculature, paresthesias, and/or anesthesia of the innervated skin areas.

Mechanical or electrosurgical injury to a nerve during laparoscopy may be recognized intraoperatively. A common example is transection of the obturator nerve during pelvic lymphadenectomy. A neurosurgical consultation can be obtained, and the nerve can be repaired with 6-0 suture using an open or laparoscopic approach.

In contrast, nerve palsy owing to positioning is recognized only postoperatively, often in the postanesthesia recovery room or on the first postoperative day when the patient tries to ambulate. From both a medical and a legal standpoint, a neurology consultation should be obtained as soon as the patient calls the surgeon's attention to a possible nerve injury. Neurologic examination with possible nerve conduction studies to document acute damage is important. Physical therapy may facilitate recovery. However, recovery in these cases, if it does not occur within the first few postoperative days, is often slow, requiring months.

Prevention is paramount. Table-mounted accessories for all major commercial operating room tables now exist that aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. The kidney rest, if used, should be lowered after the pneumoperitoneum or retroperitoneum is obtained and trocars placed. Special head supports are also available. If the arms are to be at the patient's side, they should be pronated to protect the brachial plexus. If the patient is to be in a lateral decubitus position, all bony prominences should be padded with additional gel pads (i.e., hip, knee, and ankle on the downside leg); a pillow is always placed between the legs. Padding should also be placed beneath Velcro straps and tape which may be used on the upside hip and shoulder. Shoulder braces should not be used owing to risk of brachial plexus injury. Instead, a well-padded wide strap directly across the upper chest is an excellent way to secure the patient when in the extreme Trendelenburg position, which is often required during laparoscopic radical

prostatectomy. Extreme abduction of the hip is also to be avoided. Padding must be checked each time the table position is changed. Lastly, as with all areas of laparoscopy, judicious use of monopolar coagulation current and knowledge of anatomy are key to avoiding direct nerve injury during the procedure.

Complications Related to Exiting the Abdomen

Bowel Entrapment. During removal of laparoscopic ports and release of the pneumoperitoneum, omentum, or bowel may be entrapped at one of the port sites. If missed during the process of cannula removal, then in the early postoperative period, usually on the second or third postoperative day, the patient develops an ileus and point tenderness at the port site incision.

The treatment is laparoscopic. The pneumoperitoneum is reestablished through one of the unaffected port sites, and three ports are replaced: one for the camera and two for grasping forceps. The entrapped bowel is visualized, and an atraumatic bowel clamp is placed on the bowel on either side of the area of herniation. Once this is done, the skin sutures of the affected port site are carefully cut and the wound is opened; the surgeon uses a fingertip to manually reduce the bowel into the abdominal cavity. The bowel can then be carefully inspected; if it appears viable, which is usually the case, it can be left in place and the port site closed. Rarely is formal bowel resection and anastomosis required.

This particular problem is the result of a technical error. Indeed, most laparoscopic ports have a hole drilled into the side of the port within a few millimeters of the end of the port's shaft. This hole equalizes the pressure in the port and the abdomen as the port is pulled out of the abdomen, thereby precluding any bowel being withdrawn with the port. Furthermore, if each port site is endoscopically inspected at the time of cannula removal, bowel or omentum that may have entered the port site can be readily identified and positioned back into the abdominal cavity. When the last endoscope-bearing port is removed, the assistant should pull up on the closure sutures or on a fascial clamp, and the surgeon should back the cannula out of the wound and up onto the shaft of the endoscope so that the endoscope is the last thing to leave the abdomen. This maneuver, again, visually assures the surgeon that no bowel or omentum has entered the track of the final trocar.

Bleeding at the Sheath Site. This problem has been previously discussed under the heading of trocar placement. However, there are times when this problem does not become apparent until the end of the procedure owing to tamponade from the trocar itself. Again, it is essential to inspect each trocar site at 5 mm Hg to rule out this problem. Its resolution and avoidance are as previously described.

Early Postoperative Complications

Acute Hydrocele. When significant amounts of irrigation fluid are used during a laparoscopic case in a male, it is not unusual for this fluid to accumulate in the scrotum if the patient has a patent processus vaginalis or a small hernia. The problem is usually not recognized until late in the first postoperative day when the patient is ambulating. The scrotum enlarges noticeably, and there may be dull, aching scrotal discomfort.

Direct visual inspection and transillumination suffice to make the diagnosis. If a possible underlying testicular pathologic process is a concern, scrotal ultrasonography can be done.

Treatment of acute hydrocele is simply observation and scrotal support. Reabsorption of fluid occurs within a week. Preventative effort with regard to this problem involves aspiration of irrigation fluid at the end of the procedure.

Scrotal and Abdominal Ecchymosis. This is another problem that may not become apparent until the second postoperative day. It is usually a result of delayed subcutaneous bleeding from one of the port sites. There are no specific symptoms, but the purplish discoloration of a large area of skin surrounding a port site is very disconcerting to the patient and family. Indeed, with pelvic ports, the discoloration in the male patient may involve the scrotum, too. There is no specific treatment other than observation and reassurance. The purplish discoloration of the skin eventually turns yellow and then disappears. The patient should be informed of these expected changes in color to preclude further alarm. The best method of prevention is to observe each port entry site after port removal to check for evidence of bleeding.

Pain. Pain may be localized or diffuse. If postoperative pain is limited to a port site, it may be secondary to herniation (immediate or late) or to infection (late). Localized pain combined with a subcutaneous bulge may indicate a rectus sheath hematoma, bleeding and hematoma formation at a port site, or a port site hernia. Pain at a port site without swelling may be due to a particularly broad fascial suture or palpation of the knot of a port site fascial suture in a thin patient. Early in the postoperative course, port site discomfort is to be expected; however, if it appears to be increasing on subsequent postoperative days, then herniation should be suspected.

Immediate, severe, diffuse abdominal pain may be related to the release of noxious material during the procedure (e.g., cyst fluid in patients with autosomal-dominant polycystic kidney disease) or to a bowel injury. Immediate postoperative scapular discomfort may be a result of the CO_2 pneumoperitoneum itself causing some irritation of the diaphragm; rarely, this discomfort may be sufficiently severe to mimic the symptoms of a pulmonary embolus. Of note is that this pain is invariably along the area of the right posterior shoulder region. Delayed diffuse abdominal discomfort and development of peritoneal signs or simply ongoing abdominal discomfort accompanied by low-grade fever may be due to an unsuspected bowel injury; usually, this is the result of a monopolar electrosurgical injury and may present as late as 18 days after the procedure. Of note, these patients may not have a leukocytosis; however, the differential usually shows a left shift.

The cause of localized pain can usually be discerned by the astute surgeon. A fascial knot or hematoma causing localized port site pain can be readily palpated; similarly, a port site hematoma is discernible by the firm mass it produces. When none of these signs is present in a patient complaining of localized pain over a port site, a hernia should be suspected; CT readily reveals the diagnosis.

For diffuse pain, an associated low-grade fever and mild leukocytosis/leukopenia with a left shift are hallmarks of bowel injury. This is best diagnosed by CT with oral contrast material and repeat CT 6 to 8 hours later. If chest pain is present, an electrocardiogram plus cardiac enzymes as well as spiral CT of the chest with intravenous administration of a contrast agent or ventilation-perfusion scan of the lungs plus arterial blood gas tests should be performed to rule out myocardial infarction and pulmonary embolism, respectively.

The treatment of localized pain is directed by the diagnosis. Thus, for localized pain owing to a hematoma or a fascial suture, time, reassurance, and a heating pad are all that is necessary. For a port site hernia, laparoscopic reduction, as previously described, is the next step. The treatment of diffuse pain is guided by the CT results. For suspected bowel injury, if it is early in the postoperative course (i.e., if the patient is still in the hospital), reexploration

and surgical correction are indicated. If the bowel injury is detected late and CT shows that it is already confined, then it can be managed as a closed fistula with observation and an elemental or parenteral diet; it often takes months for the problem to completely resolve when managed nonsurgically.

Prevention of most of these causes of postoperative pain requires a meticulous, careful inspection of the entire abdomen before ending the procedure. Various methods have been tried, with variable success, to decrease discomfort owing to the pneumoperitoneum; these have included placement of a drain to help expel all the CO_2, flushing of the abdomen with nitrous oxide at the end of the procedure to expel the CO_2 and replace it with a less irritating gas, maintaining the pneumoperitoneum pressure as low as possible (i.e., 10 to 12 mm Hg), and selective bathing of the surgical site with a solution of local anesthetic (e.g., 30 mL of ¼% bupivacaine).

Incisional Hernia. In adults, the occurrence of an incisional hernia is usually confined to port sites larger than 10 mm. However, in the pediatric population, this complication can occur even with 5-mm ports. The patient usually complains of localized discomfort accompanied by nausea and signs of ileus. Rarely, diffuse abdominal pain and/or signs of a complete bowel obstruction may be present. On examination there is tenderness and, at times, swelling overlying the affected port site. A plain film of the abdomen may show an ileus pattern; however, the definitive study is abdominal CT, which can actually reveal the bowel protruding above the fascial level.

Laparoscopic repair with dissection of the hernia and subsequent intra-abdominal closure can be accomplished. The method for performing this procedure has already been described. In complicated cases in which a strangulated hernia is suspected or confirmed laparoscopically, open surgical repair is indicated.

This problem is most easily avoided by performing a meticulous fascial suture closure of all "bladed" trocar entry sites equal to or larger than 10 mm in all adults. This should always be done under direct endoscopic monitoring. In children, it is advisable to perform fascial closure of any "bladed" port site 5 mm or larger. The fascial layer is usually closed with an absorbable 0-0 suture as previously described. For patients in whom only nonbladed trocars have been used, fascial closure is indicated only of the midline ports or any port site that has been unduly stretched (e.g., passage of a LapSac entrapment sack). Indeed, some authors recommend no closure even of midline nonbladed trocar sites. Although there has been one report of a hernia developing after use of a nonbladed trocar, this is distinctly rare (Lowry et al, 2003). Indeed, the incidence of postoperative hernia formation has been noted to fall from 1.8% with bladed trocars to only 0.19% for nonbladed larger trocars (Boike et al, 1995; Hashizume and Sugimachi, 1997; Thomas et al, 2003). Of note, with midline hand-assist approaches, a higher incidence of hernia formation has been identified than would otherwise be expected: 4.0% to 7.3%. As such, some authors have recommended closure of this midline incision with interrupted nonabsorbable suture rather than a running, absorbable closure (Troxel and Das, 2005).

Deep Venous Thrombosis and Pulmonary Embolism. Although it seems reasonable to expect decreased venous return and, hence, increased stasis with concomitant higher risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) in patients undergoing laparoscopy, this is remarkably **not** the case. Indeed, there is no evidence that this complication occurs more often during laparoscopic procedures versus open incisional surgery (Abdel-Meguid and Gomella, 1996; Secin et al, 2008).

Signs of DVT include localized calf tenderness with associated swelling. However, most patients with postoperative DVT have a subclinical course. Indeed, unfortunately, the most common clinical scenario is detection of a DVT only after a patient has developed a PE. Signs of PE include acute shortness of breath, decreased oxygen saturation, and pleuritic chest pain. Additionally, an electrocardiogram might show a right-sided heart strain pattern. The diagnosis of a DVT is made clinically and confirmed using Doppler ultrasonography of the lower extremities. PE is diagnosed most expeditiously by contrast-enhanced chest CT.

Treatment is immediate anticoagulation, initially with heparin and then with warfarin. In patients with a pulmonary embolus who are not candidates for anticoagulation, a vena caval filter can be placed under radiographic control.

Thus far there have been no randomized controlled trials addressing the issue of DVT prophylaxis in patients undergoing laparoscopic and robotic surgery. **The American Urological Association has released a "Best Practice Policy Statement" for the prevention of DVT in patients undergoing urologic surgery. Noting the lack of data available directly pertaining to laparoscopic and robotic surgery, the panel recommended the use of pneumatic compression stockings placed before the procedure for all patients. Additionally, they acknowledged that certain high-risk groups may require the use of low-dose unfractionated heparin or low molecular weight heparin before, during, or after surgery.**

Pneumatic compression stockings should be placed preoperatively and continued for 48 to 72 hours postoperatively. Additionally, in morbidly obese patients or in individuals at high risk for thrombosis, the addition of unfractionated perioperative heparin (5000 units 2 hours preoperatively and then every 12 hours postoperatively) has also been recommended (Clagett et al, 1995; Capan and Miller, 1999). However, **with specific respect to upper retroperitoneal (renal/adrenal/ureter) laparoscopic procedures, at least one recent study by** Montgomery and Wolf (2005) **indicated that sequential pneumatic compressive stockings provide equivalent DVT prophylaxis compared with subcutaneous fractionated heparin and that the use of subcutaneous heparin may increase the incidence of hemorrhagic complications.** Three-hundred and forty-four patients (172 in each group) nonrandomly received heparin or sequential pneumatic compressive stockings as DVT prophylaxis beginning on the day of surgery. In both groups the rate of thrombotic complication was 1.2%. The rate of hemorrhagic complication was 9.3% in the heparinized group, of which 7.0% were considered major. The hemorrhagic complication rate was only 3.5% in the sequential pneumatic compressive stockings group, with 2.9% considered major (P = .045). **Thus, after urologic laparoscopy of the upper retroperitoneum, subcutaneous heparin may be associated with increased hemorrhagic complications, without a reduction in thrombotic complications, compared with sequential pneumatic compressive stockings;** however, it must be stressed that this was a nonrandomized study obtained from a prospective database augmented by retrospective chart review. Another retrospective multi-institutional review of DVT and PE comprised 5951 patients undergoing laparoscopic or robotic radical prostatectomy; 31 (0.5%) developed symptomatic thrombotic complications (22 DVT, 4 PE, and 5 with both). Two patients died of PE (Secin et al, 2008). These results are similar to the rates of thromboembolic complication

with open radical retropubic prostatectomy (Lepor and Kaci, 2003).

Wound Infections. Superficial wound infections may occur at any of the port entry sites. This problem usually presents as local tenderness, redness, and swelling; rarely, it is accompanied by a low-grade fever. Incision and drainage of the port site are both diagnostic and therapeutic; antibiotic therapy is routinely administered.

Prevention of this complication is similar to that done in open surgery and includes attention to antiseptic preparation and sterile draping of the abdominal wall, irrigation of each port site at the end of the procedure, and meticulous closure of the wound. Overall, this is a rare complication with standard laparoscopy. However, with the hand-assist approach a higher incidence of wound infections has been noted. In one report the postoperative wound infection rate at the hand-assist site was 9% (Nelson and Wolf, 2002).

Rhabdomyolysis. Rhabdomyolysis is a devastating complication after laparoscopic surgery. The exact incidence of this problem is not known, but in one survey of neuromuscular injuries associated with laparoscopic urologic surgery completed by 18 urologists from 15 institutions in the United States it was found that of a total of 1651 procedures there were 6 cases (0.4%) of clinical rhabdomyolysis (Wolf et al, 2000). In a more recent study, it was estimated that the occurrence of this problem among patients undergoing retroperitoneal laparoscopic procedures (e.g., renal, ureteral, adrenal) was higher, 1% (Reisiger et al, 2005). Rhabdomyolysis is invariably associated with male patients undergoing longer laparoscopic renal procedures, especially if the kidney rest has been employed for the entire case. Although extra padding applied to pressure areas can be useful in avoiding nerve compression and rhabdomyolysis, gel pads and foam "egg crate" padding have not been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position (Deane et al, 2008). Women have significantly lower interface pressures than men. A BMI of 25 or greater, use of a kidney rest, and full-table flexion as opposed to half-table flexion were all associated with increases in interface pressures; of these, use of the kidney rest was believed to be the most detrimental and its use beyond 20 to 30 minutes was disparaged. Therefore, male patients with a BMI of 25 or greater undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis due to flank pressure. In this study the unaugmented operating table mattress was superior to egg crate or gel padding as an augmenting surface material; of note, egg crate padding was equal or superior to the more expensive gel padding.

Rhabdomyolysis presents immediately in the postanesthesia recovery room with the patient complaining of severe pain in the downside hip area. Brown urine may also be noted. The serum creatine kinase value invariably exceeds 5000 units/dL. The treatment is hydration and alkalinization; these maneuvers are undertaken to try to prevent subsequent renal failure. Acute renal failure and the need for transient dialysis occurs in a minority of patients. The more difficult and ominous problem is that of long-term disability caused by muscle necrosis. Extended physical therapy is often required.

Prevention of this problem is essential. This can, to some extent, be done by avoiding use of the kidney rest or employing it for only the earliest part of the case (i.e., less than an hour) and avoiding prolonged periods of hypotension during the procedure (Cadeddu et al, 2001; Kuang et al, 2002; Parsons et al, 2004; Reisiger et al, 2005). Lastly, with increasing skill and experience, few procedures should proceed beyond 5 hours.

Late Postoperative Complications

Complications beyond the 3-week postoperative period are rare. These include primarily lymphatic complications and incisional hernia. The latter has been addressed in the prior discussion because it can also appear as an early postoperative complication.

Lymphocele Formation. Lymphocele formation is most commonly associated with pelvic procedures, such as pelvic lymph node dissection (1.3% incidence) (Kavoussi et al, 1993) or with renal transplantation. The lymphocele may take weeks to develop and may occur despite a transperitoneal approach. Presentation may be by a mass effect, but the astute clinician should realize that it may also present due to local compression causing lower extremity edema, and in rare cases, venous thrombosis and pulmonary embolism. The lymphocele is diagnosed readily by CT. **Treatment is immediate percutaneous drainage. Sclerosant therapy can be used to treat the lymphocele; however, if unsuccessful or if the lymphocele is not amenable to percutaneous drainage, then a transperitoneal laparoscopic marsupialization procedure is usually successful.** At the time of the procedure, a tag of omentum can be placed into the opening made in the lymphocele to try to prevent closure of the opening and recurrence.

Prevention of lymphocele formation requires marked attention to clipping suspected lymphatic structures. Monopolar electrocoagulation does not work well to seal lymphatics. Bipolar or harmonic devices have been shown to effectively seal lymphatic channels; the bipolar devices created seals that were 5- to 10-fold stronger than the harmonic device (Box et al, 2009).

Chylous Ascites. After left-sided retroperitoneal surgery (i.e., left radical nephrectomy, donor nephrectomy, left-sided retroperitoneal lymph node dissection), the patient may return complaining of a distended abdomen. Although this complaint is common in the initial few days after a laparoscopic procedure, owing to the pneumoperitoneum, irrigation fluid, and/or ileus, it is distinctly rare late in the patient's course. There is no associated fever, pain, or bowel dysfunction, and routine laboratory studies are within normal limits. If the suspicion is high for chylous ascites, one may simply prescribe a low fat, medium-chain triglyceride diet and choose to observe the patient. Usually the condition is self-limited and resolves without any intervention.

If the presentation is not straightforward, then abdominal CT will reveal the underlying problem and diagnose the presence of ascites. If tapped, the fluid, which is commonly turbid, should be sent for culture, complete blood cell count, and determination of triglyceride, cholesterol, and electrolyte levels. The chylous ascitic fluid may well have elevations in the level of lymphocytes, cholesterol, and triglycerides, the latter two being particularly more likely if following a fatty meal.

Treatment is usually dietary, as previously noted. One may also consider giving somatostatin (Leibovitch et al, 2002). In the rare situation in which the fluid does not resolve with these conservative measures or if the patient is symptomatic, the fluid can be tapped once or twice. If it continues to accumulate, then an open or laparoscopic exploration is undertaken; before the procedure, the patient should be given a "fatty" meal or an intravenous load of hyperalimental lipids, which should create a whitish discoloration of the lymphatic fluid and make the point of lymphatic

leakage more visible. Once identified, the leaking lymphatic channel is dissected and secured with either suture or clips (Molina et al, 2003).

Prevention of this type of problem is extremely difficult because the lymphatics are not readily visible during the procedure. In addition, with the recent advent of avoiding clips around the renal hilum, the problem may become more prevalent. To date, instances of post-laparoscopic chylous ascites have been cited only sparingly in the literature (Leibovitch et al, 2002; Molina et al, 2003). However, the authors believe that because the condition is usually self-limited and responds well to dietary measures, it is likely underreported.

LIMITATIONS AND ADVANTAGES OF TRANSPERITONEAL VERSUS EXTRAPERITONEAL APPROACH TO THE FLANK AND PELVIS

Laparoscopy versus Retroperitoneoscopy

Limitations. Retroperitoneoscopy is associated with unique anatomic orientation and a relatively restricted initial working area compared with transperitoneal laparoscopy. This results in a steeper learning curve with the former technique. Moreover, the fact that a comparatively limited space is available necessitates precise accuracy regarding the strategic placement of ports. The degree of technical difficulty increases in the presence of large-sized specimens. Additionally, retroperitoneoscopic entrapment of these larger specimens may be difficult. The latter problem can be overcome by laparoscopically creating an intentional peritoneotomy at the end of the procedure to allow entrapment of the specimen within the larger peritoneal cavity. Laparoscopic reconstruction and intracorporeal suturing are technically demanding procedures; in the retroperitoneal space, reconstruction can be more challenging compared with transperitoneal laparoscopy due to suboptimal instrument angulation and a smaller working space. One potential way to overcome some of these limitations is to use a robotic approach to the retroperitoneum. Kaouk and coworkers (2008c) reported the Cleveland Clinic experience using a robotic retroperitoneal approach to perform dismembered pyeloplasty in 10 patients. They noted that the enhanced dexterity of the robotic platform did facilitate reconstructive suturing in a smaller working space. Although a retroperitoneal approach might not be advantageous for every surgery there are certain instances in which this approach might be more appropriate (as in the case of multiple prior transabdominal surgeries).

If a patient has a history of prior open retroperitoneal surgery, subsequent attempts at retroperitoneoscopy should be approached with extreme caution. However, as mentioned earlier in this chapter, prior percutaneous renal procedures do not necessarily constitute a contraindication to subsequent retroperitoneoscopy. Lastly, of interest is an increase in pulmonary complications after retroperitoneoscopy versus transperitoneal laparoscopy (see later).

Advantages. With retroperitoneoscopy, morbidity that is usually associated with the transperitoneal approach is commonly avoided (Kavoussi et al, 1993). The risks of inadvertent bowel injury and postoperative ileus are minimized, although not eliminated. This results in a slightly more rapid postoperative recovery. During retroperitoneoscopy and extraperitoneoscopy the bowel can be effectively and safely retracted within its peritoneal cover. Although out of sight, the bowel should never be out of mind, because bowel injuries can still occur. Transperitoneal laparoscopy may be associated with an increased incidence of postoperative shoulder-tip pain, a feature rarely associated with retroperitoneoscopy. In addition, extraperitoneoscopy and retroperitoneoscopy are associated with a significantly lower incidence of postoperative trocar site hernias.

A significant benefit of this technique is rapid and direct access to the renal hilum, with the renal artery being the first hilar structure encountered and controlled. Furthermore, if a partial nephrectomy is planned, it may be more effective to approach a posterior tumor from the retroperitoneal approach whereas anterior tumors are often more easily approached from the transperitoneal approach.

Transperitoneal versus Extraperitoneal Pelvic Surgery

The transperitoneal approach to the pelvis offers easy access to all areas of the pelvic cavity after which the space of Retzius, iliac/obturator fossa, or the rectovesical space is entered directly through the peritoneum. The working space is maximized because the peritoneum does not limit camera or instrument motion once it is incised. The potential limitations associated with this approach, however, are that it is possible to cause mechanical or thermal injury to the bowel and it may be necessary to utilize more extreme Trendelenburg positioning or additional retraction of the bowel to prevent it from impinging on the operative field. The possibility of prolonged ileus has also been suggested; however, in a large prospective study comparing 165 transperitoneal versus 165 extraperitoneal laparoscopic radical prostatectomy patients, Ruiz and colleagues (2004) did not find significant differences between the two groups in terms of hospital stay or medical and surgical complications. Operative time was half an hour shorter in the extraperitoneal group (220.0 vs. 248.5 minutes, $P < .0001$); however, there was also a trend toward higher positive margins in patients with pT2 (organ confined) cancers in the extraperitoneal group (17.0% vs. 13.0%; $P = .42$). In two other studies comparing the two approaches, patients undergoing radical prostatectomy were matched with regard to important preoperative attributes and the authors found no significant differences between the extraperitoneal and transperitoneal approaches regarding all important parameters except that the operative time for the extraperitoneal approach is generally a little shorter (30 minutes) (Erdogru et al, 2004; Madi et al, 2007). Interestingly, in one study comparing the two approaches with 50 patients in each arm, in addition to there being no difference between the groups with regard to intraoperative and postoperative parameters, free intraperitoneal air was found on all extraperitoneal patients on the kidney-ureter-bladder radiograph taken on postoperative day 1 (Bivalacqua et al, 2008). Thus this finding should not necessarily be interpreted as an ominous sign of bowel injury unless the patient has other signs and symptoms present (i.e., fever, pain, nausea, elevated white blood cell count). One undeniable advantage in favor of the extraperitoneal approach is that it avoids the necessity of lysis of adhesions in patients who have had prior abdominal surgery. In contrast, for patients who have had prior laparoscopic inguinal hernia repair, a transperitoneal approach is more advantageous.

In summary, for most cases there does not seem to be a clear advantage to using a transperitoneal versus extraperitoneal

approach for laparoscopic pelvic surgery. In selected cases described earlier there may be advantages of one approach over the other. The usual determinant for the laparoscopic approach is that of surgeon preference.

TRAINING AND PRACTICING LAPAROSCOPIC AND ROBOTIC SURGERY

Surgeons learning how to perform laparoscopic procedures face several hurdles, including an altered 2D view of a 3D space, counterintuitive control of instruments, different ergonomic constraints, and an altered perspective of surgical anatomy (Piechaud and Pansadoro, 2006). Robotic surgical systems such as the da Vinci Robotic System overcome several of these issues by providing 3D vision and intuitive instrument motion but they, too, have hurdles, such as complete lack of tactile feedback and a learning curve regarding the syncopation of the surgeon's console. Additionally, much like life in general, the only thing constant about laparoscopic and robotic surgery is change. It is therefore necessary for minimally invasive surgeons, no matter how experienced, to master new skills and familiarize themselves with new technologies as they develop. With an ever-increasing emphasis on patient safety and operating room efficiency it is widely accepted that new surgical skills and techniques should be developed and honed outside the operating room and then transferred into the operating room once proficiency has been developed.

Equipment for Practicing Laparoscopic and Robotic Surgery

A wide variety of practice models exist for both laparoscopic and robotic surgery ranging from inanimate laparoscopic training boxes to live animal and human cadaveric models. There has also been heightened interest in the development of computer-driven virtual reality trainers that can be used to practice standard techniques and whole procedures. As a general premise, nonliving models should be used unless it is absolutely essential to have a live model.

Standard Laparoscopic Training Boxes. The items necessary for a basic laparoscopic training box are a box with an opaque top that is suitable for placement of laparoscopic ports and a vision system consisting of a video monitor, a source of light, and a camera or camera/lens combination. Several commercially available training boxes are available that contain all of the necessary components (Fig. 9–31 on the Expert Consult website). Alternatively, one can construct a training box from relatively inexpensive materials such as a cardboard box and a web camera with a computer screen or video camera. Although it adds a hint of reality, trocars are not mandatory. In general the instruments and camera should be configured in a triangular fashion such that the camera lies between the right- and left-hand instruments. For optimal ergonomic positioning the angle formed between the right- and left-hand instruments should be between 25 and 45 degrees. Additionally, the angle between the instruments and the horizontal plane should be less than 55 degrees (Frede et al, 1999). Some more formal training boxes will have built-in camera holders such that one person can practice alone without the assistance of a "camera driver." When possible, however, a camera driver can adjust the lens/camera in, out, up, and down to match the motions of the surgeon. This is most helpful during more delicate maneuvers such as suturing in which panning the view from wide to closeup is essential. This gives the assistant the opportunity to practice "driving camera," which is also an essential skill for laparoscopy.

Instruments. Necessary instruments might include laparoscopic graspers, scissors, and dissectors, essentially any instrument necessary to meet the requirements of the training drill. Practice for basic suturing requires a pair of laparoscopic needle drivers and some suture. A 3-0 suture on an SH needle is best for general practice. Other suture and needle types can be used for practicing more specialized procedures.

Inanimate Training Models. Training models for basic tasks such as touching areas of the box at different depths and heights within space, passing objects between instruments and through and around obstacles, and other helpful maneuvers such as cutting and tissue manipulation can be constructed from common materials such as paper, sponges, rubber gloves, rubber tubing, and other commonly found, abundant materials (Fig. 9–32 on the Expert Consult website). Alternatively, a wide variety of commercially available models exist that are more realistic looking and may mimic actual operative scenarios more closely (Fig. 9–33 on the Expert Consult website). Whether simple or complex, training models can be placed within standard training boxes and act as the basis for general skills acquisition and progression.

Nonliving Animal Tissue Models. The advantage of using real but nonliving animal tissue to create training models is that it creates a more realistic environment providing true to life tissue handling. Generally the tissues used are inexpensive and can be purchased at a butcher shop or market. The disadvantage is that it requires more intense cleanup after practice. Generally the field inside the training box is set up to mimic a specific surgical scenario and develop specific skills. For instance, the stomach and esophagus of a chicken can be divided and then sewn back together laparoscopically to practice the fashioning of a vesicourethral anastomosis or pyeloplasty (Laguna et al, 2006; Ramachandran et al, 2008).

Live Animal Models. The obvious advantage of live animal models is the opportunity to train under more realistic conditions, including more accurate anatomic relationships of tissue and the necessity for hemostasis that does not exist with inanimate models. The disadvantages of using live animal models is that it requires extensive resources such as a veterinary facility, personnel for care of and providing anesthesia for the animals, and, eventually, euthanasia of the animals. For these reasons, practicing surgical skills on live animals is not appropriate for daily practice. Instead, these opportunities are usually reserved for formal training courses or when the need for a realistic environment warrants the necessary resources. In general the species of animal used for practice must have a sufficient peritoneal compartment to provide an adequate working space. For fine procedures, animals as small as rabbits can be used. Swine are the most common animals used for laparoscopic and robotic training because they are readily available, they have the appropriate size peritoneal compartment, and their anatomy mimics relatively well that of humans. It must be noted, however, that the amount of bleeding that comes from a pig kidney (in partial nephrectomy, for example) is not realistic compared with that of a human. Additionally, the porcine bladder is almost completely intraperitoneal.

Cadaveric Models. One of the first experiences most medical students have in training is anatomy, and this entails cadaveric dissection. The reason is simple. Short of operating on real patients there is no better or more realistic way to learn human anatomy. This holds true for surgical practice as well: however, owing to the

major resources necessary to have an anatomic gift program and the significantly high cost for a cadaver compared with alternative models, it is often not practical to use cadavers. If, however, facilities and funding are available and there is a need for practicing a procedure in the most realistic environment, there is no substitute for cadaveric models.

Virtual Reality Trainers. Virtual reality (VR) trainers are computer-based simulators that offer the opportunity to practice laparoscopic and robotic skills through specific tasks as well as whole procedures. Typically, trainees view the computer-generated operative field or training drill on a computer monitor and perform tasks using laparoscopic manipulators. The instruments are depicted on the viewer and correspond with the trainee's movements. A major advantage of VR trainers is that they can collect information regarding trainee performance and track progress over time in terms of precision, economy of motion, and other parameters of interest. Because the trainers are computer based it is possible to develop training programs and curricula including didactics, videos, and live practice sessions. The trainee can progress through the curriculum based on performance. VR trainers have been shown to improve the skills of trainees helping to prepare them for better performance during live surgery (Seymour et al, 2002; Lucas et al, 2008). Several commercially produced VR trainers for laparoscopy are available but are quite costly owing to the advanced technology and software development necessary. An experimental VR trainer for robotic surgery is also under development (Albani and Lee, 2007).

Formal Training Programs. Surgical competence is defined by technical and nontechnical skills (Hoznek et al, 2006). Traditionally these skills have been passed down from teacher to apprentice in the process of caring for and operating on real patients during residency training. The technical skills were taught during real operative procedures and the nontechnical skills such as surgical judgment, problem anticipation and avoidance, economy of motion, and so on were gained by experience of the trainee with supervision from a more senior instructor. In this way, traditional residency programs have been more "learning" programs than "teaching" programs. With ever-increasing emphasis being placed on patient safety, operating room efficiency, and cost containment there has been a great interest in evaluating the efficacy of formal training programs in laparoscopic and robotic surgery. Such programs offer the opportunity to receive formal instruction in a safe, stress-free environment with the intention of honing both technical and nontechnical skills.

With this concept in mind one method of concentrated instruction and skills acquisition is the "mini-residency" or "mini-fellowship." In this training model surgeons spend a period of several days (typically 5 days) receiving concentrated instruction on a given set of surgical skills or procedures including didactic sessions, clinical case observation, and laboratory training using both inanimate and animate models. Typically, the attendees also gain access to expert proctors during their initial learning curve for the new procedure. Mini-residency training has been shown to be effective in helping postgraduate urologists incorporate new laparoscopic and robotic procedures into their clinical practices. In one study of laparoscopic renal surgery mini-fellowship trainees at the University of California, Irvine, 73% of attendees were performing laparoscopic renal surgery 3 years later (Kolla et al, 2010). This was also found with robotic surgical training: of 47 urologists who took a 5-day training course for robotic radical prostatectomy, 90% were performing the procedure in their own practice at 3-year follow-up (Gamboa et al, 2009).

Key Points

- Careful patient selection and identification of possible relative and absolute contraindications are vital to a successful outcome of laparoscopic and robotic procedures. To this end, a meticulous past history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation for possible minimally invasive surgery.
- Now that the benefits of surgical pharmaceuticals have come into the spotlight, it is important for the surgeon to be familiar with the properties of these various agents and thereby able to choose one that is most appropriate for the job at hand.
- After a routine major laparoscopic or robotic procedure emphasis can be placed on "fast tracking" the patient. Fast tracking actually starts preoperatively during which time the patient is pre-medicated with an antiemetic agent, a nonnarcotic pain reliever such as ketorolac (if not a renal failure patient), and an antacid. All incision sites are infiltrated with 1% lidocaine before making the incision to minimize postoperative pain. To avoid postoperative ileus and constipation, patients without renal insufficiency can be administered ketorolac every 6 hours for a total of four doses to avoid narcotic analgesic use. Routine use of a nonsedating antiemetic agent for the first 24 hours is also advisable.
- Intra-abdominal pressures during laparoscopy should not be allowed to exceed 20 mm Hg over extended periods, and a working pressure of 10 to 12 mm Hg is recommended.
- Early in one's experience with laparoscopic and robotic surgery it is wise to apply the minimally invasive approach to low-risk surgical candidates of normal body habitus. In addition, it is advisable and recommended by many laparoscopic organizations, as well as by hospital credentialing boards, that the neophyte minimally invasive surgeon seek training in three arenas: (1) in-depth instructional courses, including didactic, "live-case" transmissions and "hands-on" laboratory sessions; (2) preceptor training in which the surgeon-in-training views more than five or more procedures being done by an already skillful laparoscopic surgeon; and (3) a mentoring experience, during which a trained laparoscopic surgeon oversees the initial procedures performed by the surgeon-in-training.

CONCLUSION

Yesterday's humor is today's reality. Cartoons in the 1990s often depicted several surgeons standing around an operating table with a patient in whom numerous laparoscopic ports had been placed. The caption was "Can anyone open?" While this concern has been a rallying cry for the maximally invasive surgeon, the less invasive surgeon sees this as a manifestation of the progress that has occurred in the past 15 years. Laparoscopic procedures unthinkable in early 1990 are now routine. The indications for performing these procedures through a single site are expanding. The use of a robotic surgical platform to perform complex reconstructive procedures is improving the precision and often the outcomes of these operations and makes it possible for a greater number of urologists to perform high-quality laparoscopic procedures. As

robotics and flexible endoscopically guided technologies advance in the future we may see adoption of NOTES and our patients may undergo operations that leave no visible scar. The benefit will be more proficient laparoscopic and robotic surgeons who can handle any procedure and any complication without the massive incisions of yore. It is hoped that in the near future a similar cartoon may show a group of urologists in an image-guidance suite or in an office gathered around a patient with the caption: "Can anyone do laparoscopy?" Such should be the next step of our surgical and pharmacologic paths of discovery. At that point Osler's 20th century admonition, "Diseases that harm require treatments that harm less," will be truly fulfilled. We are as yet still on the bridge to the future.

Other Infections

Urinary tract infections (UTIs) are common, affect men and women of all ages, and vary dramatically in their presentation and sequelae. They are a common cause of morbidity and can lead to significant mortality. Although the urinary tract is normally free of bacterial growth, bacteria that generally ascend from the rectal reservoir may cause UTIs. When bacterial virulence increases or host defense mechanisms decrease, bacterial inoculation, colonization, and infection of the urinary tract occur. Careful diagnosis and treatment result in successful resolution of infections in most instances. A better understanding of the pathogenesis of UTIs and the role of host and bacterial factors has improved the ability to identify patients at risk and prevent or minimize sequelae. Clinical manifestations can vary from asymptomatic bacterial colonization of the bladder to irritative symptoms such as frequency and urgency associated with bacterial infection; upper tract infections associated with fever, chills, and flank pain; and bacteremia associated with severe morbidity, including sepsis and death. New antimicrobial agents that achieve high urinary and tissue levels, that can be administered orally, and that are not nephrotoxic have significantly reduced the need for hospitalization for severe infection. Shorter-course therapy and prophylactic antimicrobial agents have reduced the morbidity and cost associated with recurrent cystitis in women. Although the vast majority of patients respond promptly and are cured by therapy, early identification and treatment of patients with complicated infections that place them at significant risk remains a clinical challenge to urologists.

DEFINITIONS

UTI is an inflammatory response of the urothelium to bacterial invasion that is usually associated with bacteriuria and pyuria.

***Bacteriuria* is the presence of bacteria in the urine, which is normally free of bacteria.** It has been assumed to be a valid indicator of either bacterial colonization or infection of the urinary tract. Although this is usually true, studies in animals (Hultgren et al, 1985; Mulvey et al, 1998) and humans (Elliott et al, 1985) have indicated that bacteria may be in the urothelium in the absence of bacteriuria. Alternatively, bacteriuria may represent bacterial contamination of an abacteriuric specimen during collection.

The possibility of contamination increases as the reliability of the collection technique decreases from suprapubic aspiration to catheterization to voided specimens. The term *significant bacteriuria* has a clinical connotation and is used to describe the number of bacteria in a suprapubically aspirated, catheterized, or voided specimen that exceeds the number usually caused by bacterial contamination of the skin, the urethra, or the prepuce or introitus, respectively. Hence it represents a UTI.

Bacteriuria can be *symptomatic* or *asymptomatic*. When it is detected by population studies (screening surveys), *screening bacteriuria* is a more precise and descriptive term than *asymptomatic bacteriuria,* especially because the latter term is clinically useful for describing the presence or absence of symptoms in an individual patient.

***Pyuria,* the presence of white blood cells (WBCs) in the urine, is generally indicative of infection and an inflammatory response of the urothelium to the bacterium.** Bacteriuria without pyuria is generally indicative of bacterial colonization without infection of the urinary tract. Pyuria without bacteriuria warrants evaluation for tuberculosis, stones, or cancer.

Infections are often defined clinically by their presumed site of origin.

Cystitis describes a clinical syndrome of dysuria, frequency, urgency, and occasionally suprapubic pain. These symptoms, although generally indicative of bacterial cystitis, may also be associated with infection of the urethra or vagina or noninfectious conditions such as interstitial cystitis, bladder carcinoma, or

Figure 10–1. Excretory urogram demonstrates focal, coarse scarring in the right kidney of an 18-year-old girl with a history of many recurrent fevers between 2 months and 2 years of age. A cystogram when the patient was 2 years old established an atrophic left kidney with marked reflux up to the left kidney and slight reflux up to the right kidney. Excretory urography at the age of 6 years established severe atrophy of the left kidney. She had no infections between the ages of 6 and 15 years. Several reinfections occurred at the age of 15 years, and they ceased with prophylactic therapy. Her blood pressure has remained normal, and her serum creatinine level was 0.9 mg/dL at the age of 18 years. At 21 years of age she stopped antimicrobial prophylaxis for 18 months without infections or introital colonization with Enterobacteriaceae. Note that all calyces are blunted and that one extends to the capsule *(arrowhead)* because of atrophy of the overlying cortex.

calculi. Conversely, patients may be asymptomatic and have infection of the bladder and possibly the upper urinary tract.

***Acute pyelonephritis* is a clinical syndrome of chills, fever, and flank pain that is accompanied by bacteriuria and pyuria, a combination that is reasonably specific for an acute bacterial infection of the kidney.** The term should not be used if flank pain is absent. It may have no morphologic or functional components detectable by routine clinical modalities. There may be serious difficulties in diagnosing spinal cord–injured and elderly patients who may be unable to localize the site of their discomfort.

Chronic pyelonephritis describes a shrunken, scarred kidney, diagnosed by morphologic, radiologic, or functional evidence of renal disease that may be postinfectious but is frequently not associated with UTI. Bacterial infection of the kidney may cause a *focal, coarse scar* in the renal cortex overlying a calyx, almost always accompanied by some calyceal distortion (Fig. 10–1), which can be detected radiographically or by gross examination of the kidney. Less commonly, renal scarring from infection can result in atrophic pyelonephritis or generalized thinning of the renal cortex, with a small kidney appearing radiographically similar to one with postobstructive atrophy (Fig. 10–2).

Table 10–1.

Factors That Suggest Complicated UTI

Functional or anatomic abnormality of urinary tract
Male gender
Pregnancy
Elderly patient
Diabetes
Immunosuppression
Childhood UTI
Recent antimicrobial agent use
Indwelling urinary catheter
Urinary tract instrumentation
Hospital-acquired infection
Symptoms for more than 7 days at presentation

Reprinted from Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 212.

UTIs may also be described in terms of the anatomic or functional status of the urinary tract and the health of the host.

***Uncomplicated* describes an infection in a healthy patient with a structurally and functionally normal urinary tract.** The majority of these patients are women with isolated or recurrent bacterial cystitis or acute pyelonephritis, and the infecting pathogens are usually susceptible to and eradicated by a short course of inexpensive oral antimicrobial therapy.

***A complicated* infection is associated with factors that increase the chance of acquiring bacteria and decrease the efficacy of therapy** (Table 10–1). **The urinary tract is structurally or functionally abnormal, the host is compromised, and/or the bacteria have increased virulence or antimicrobial resistance. The majority of these patients are men.**

Renal diseases that reduce the concentrating ability of the kidney or neurologic conditions that alter bladder-emptying capabilities are commonly encountered functional abnormalities.

Examples of anatomic abnormalities include obstruction associated with calculi or enlargement of the prostate or congenital or acquired sites of residual urine, such as calyceal or bladder diverticula. A complicated infection is frequently caused by bacteria that have exposure to many antimicrobial agents.

Chronic is a poor term that should be avoided in the context of UTIs, except for chronic pyelonephritis or bacterial prostatitis, because the duration of the infection is not defined.

UTIs may also be defined by their relationship to other UTIs:

A ***first*** or ***isolated*** infection is one that occurs in an individual who has never had a UTI or has one remote from a previous UTI.

An ***unresolved*** infection is one that has not responded to antimicrobial therapy.

A ***recurrent*** infection is one that occurs after documented, successful resolution of an antecedent infection.

The term *reinfection* describes a new event associated with reintroduction of bacteria into the urinary tract from outside.

***Bacterial persistence* refers to a recurrent UTI caused by the same bacteria reemerging from a focus within the urinary tract, such as an infectious stone or the prostate.** *Relapse* is frequently used interchangeably. These definitions require careful clinical and bacteriologic assessment and are important because they influence the type and extent of the patient's evaluation and treatment.

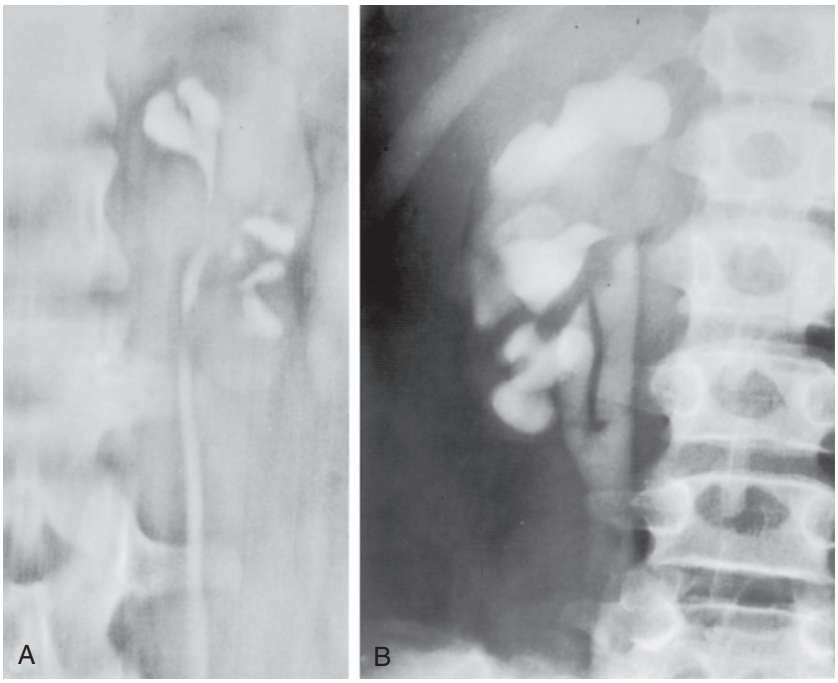

Figure 10–2. **A,** Excretory urogram of the contralateral left kidney from the same patient as in Figure 10–1. The severe pyelonephritic atrophy, undoubtedly caused by febrile urinary infections during early infancy with reflux into different segments of the kidney, produced irregular cortical scarring. Note how all the calyces extend to the capsule with irregular, intervening areas of cortex. **B,** Pyelonephritic atrophy, suggestive of postobstructive atrophy, in a 20-year-old woman with spina bifida, neurogenic bladder, and many episodes of fever and bacteriuria in early childhood. Observe the uniform, regular atrophy of the renal cortex that suggests reflux of bacteria simultaneously into virtually all nephrons. This type of pyelonephritic atrophy is uncommon compared with that shown in **A** and is characteristic of obstruction with superimposed infection.

***Antimicrobial prophylaxis* is the prevention of reinfections of the urinary tract by the administration of antimicrobial drugs.** If the term is used correctly in reference to the urinary tract it can be assumed that bacteria have been eliminated before prophylaxis is begun. **Surgical antimicrobial prophylaxis entails administration of an antimicrobial agent before and for a *limited* time after a procedure to prevent local or systemic postprocedural infections.**

***Antimicrobial suppression* is the prevention of growth of a focus of bacterial persistence that cannot be eradicated.** A low, nightly dosage of an antimicrobial agent usually results in the urine showing no growth, as in the case of a small infectious stone or in bacterial prostatitis caused by *Escherichia coli*. *Suppressive* is also a useful term when recurrent acute symptoms are prevented in a poor-risk patient, such as one with a large staghorn calculus in whom the antimicrobial agent reduces but does not eliminate the bacteria in the urine.

Domiciliary* or *outpatient UTIs occur in patients who are not hospitalized or institutionalized at the time they become infected. **The infections are generally caused by common bowel bacteria** (e.g., Enterobacteriaceae or *Enterococcus faecalis*), which are susceptible to most antimicrobial agents.

***Nosocomial* or *health care–associated UTIs* occur in patients who are hospitalized or institutionalized,** and these are typically caused by *Pseudomonas* and other more antimicrobial-resistant strains.

Key Points: Definitions

- Infection of the urinary tract occurs when bacterial virulence increases and/or host defense mechanisms decrease.
- The majority of patients respond promptly to short courses of antimicrobial therapy.
- Early identification and treatment of complicated UTIs is essential to prevent major sequelae or death.

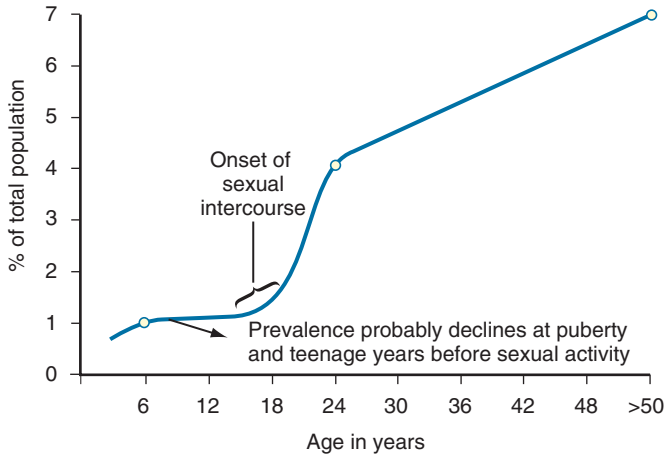

Figure 10–3. Prevalence of bacteriuria in females as a function of age. (From Stamey TA. The prevention of recurrent urinary infections. New York: Science and Medicine; 1973.)

INCIDENCE AND EPIDEMIOLOGY

UTIs are considered to be the most common bacterial infection. They account for more than 7 million visits to physicians' offices and necessitate or complicate over 1 million office visits and 1 million emergency department visits, resulting in 100,000 hospitalizations annually (Patton et al, 1991, Hooton and Stamm, 1997; Foxman et al, 2000). **They account for 1.2% of all office visits by women and 0.6% of all office visits by men** (Schappert, 1997).

The overall prevalence of bacteriuria in women has been estimated at 3.5%, with prevalence generally increasing with age in a linear trend (Evans et al, 1978). Surveys screening for bacteriuria have shown that about 1% of schoolgirls (aged 5 to 14 years) (Kunin et al, 1962) have bacteriuria and that this figure increases to about 4% by young adulthood and then by an additional 1% to 2% per decade of age (Fig. 10–3). **Nearly 30% of women will**

have had a symptomatic UTI requiring antimicrobial therapy by age 24, and almost half of all women will experience a UTI during their lifetime. The prevalence of bacteriuria in young women is 30 times more than in men. However, **with increasing age, the ratio of women to men with bacteriuria progressively decreases. At least 20% of women and 10% of men older than 65 years have bacteriuria** (Boscia and Kaye, 1987; Juthani-Mehta, 2007).

The incidence of bacteriuria also increases with institutionalization or hospitalization and concurrent disease (Sourander, 1966). In a study of women and men older than 68 years, Boscia and Kaye (1987) found that 24% of functionally impaired nursing home residents had bacteriuria compared with 12% of healthy domiciliary subjects (Boscia et al, 1986). UTIs account for approximately 38% of the 2 million nosocomial infections each year (Sedor and Mulholland, 1999; Lo et al, 2008). More than 80% of nosocomial UTIs are secondary to an indwelling urethral catheter (Sedor and Mulholland, 1999). The incidence of UTIs is also increased during pregnancy and in patients with spinal cord injuries, diabetes, multiple sclerosis, and human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS).

The financial impact of community-acquired UTIs is nearly $1.6 billion in the United States alone (Foxman, 2002); the annual cost of nosocomial UTIs has been estimated to range from between $515 million and $548 million (Jarvis, 1996).

Little is known about the natural history of untreated bacteriuria in women because most women are treated when they are diagnosed, but a few studies in which treatment with antimicrobial agents is compared with placebo have been done. These show that 57% to 80% of bacteriuric women who are untreated or treated with placebo clear their infections spontaneously (Mabeck, 1972; Guttmann, 1973). Mabeck (1972) found that 8 of 53 bacteriuric women placed on placebo needed treatment with an antimicrobial agent because of symptoms, but 32 of the remaining 45 women cleared without treatment within a month, and 43 of the 45 had spontaneously cleared of bacteriuria within 5 months; only 2 women remained persistently bacteriuric.

Once a patient has an infection, he or she is likely to develop subsequent infections. Many adults had UTIs as children, underscoring the importance of genotypic factors in UTIs (Gillenwater et al, 1979). Of 45 women with untreated UTIs whose infection cleared, 20 (46%) had recurrences within a year (Mabeck, 1972).

When women with recurrent bacteriuria were observed after treatment, about one sixth (37 of 219) had a very high recurrence rate (2.6 infections per year) whereas the remaining women had a recurrence rate of only 0.32 per year (Mabeck, 1972). Similar separation was seen in a prospective study in which only 28.6% of 60 women who experienced their first symptomatic UTI had recurrent infections over the first 18 months of observation, as opposed to recurrences in 82.5% of 106 women who had had previous UTIs (Harrison et al, 1974). **Other investigators also have found that the probability of recurrent UTIs increases with the number of previous infections and decreases in inverse proportion to the elapsed time between the first and the second infections** (Mabeck, 1972). Of these recurrent infections, 71% to 73% are caused by reinfection with different organisms, rather than recurrence with the same organism (Mabeck, 1972; Guttmann, 1973).

Women with frequent reinfections have a rate of 0.13 to 0.25 UTIs per month (1.6 to 3.1 infections per year) when the infections are treated with antimicrobial agents (Mabeck, 1972; Guttmann, 1973; Kraft and Stamey, 1977; Vosti, 2002).

In a prospective long-term study of 235 women with more than 1000 confirmed infections studied over a period ranging from 1 to nearly 20 years, about half of the patients had clusters of infections, which ranged in frequency from 2 to 12 infections per cluster. Infections were followed by remission-free intervals that averaged approximately 1 year. **Most reinfections occurred after 2 weeks** (Harrison et al, 1974) and within 5 months (Mabeck, 1972), and most occurred early in this interval (Kraft and Stamey, 1977; Vosti, 2002) (Fig. 10–4). Rates of reinfection were independent of bladder dysfunction, radiologic changes of chronic pyelonephritis, and vesicoureteral reflux (Guttmann, 1973). The reinfections did not occur evenly over time. In the Stanford series (Kraft and Stamey, 1977), 23 women with frequent recurrent infections were studied with monthly urine cultures when asymptomatic and with immediate cultures when symptomatic for cystitis, for a mean of 3 years. Thirty-four percent of infections were followed by infection-free intervals of at least 6 months (average, 12.8 months), and 22 of the 23 women had such intervals. However, even these long intervals were followed by further infections (Kraft and Stamey, 1977), thus underscoring the importance of genotypic factors in the pathogenesis of UTIs in women (Schaeffer et al, 1981).

When the Stanford data (Kraft and Stamey, 1977) on recurrent UTIs in highly susceptible females are analyzed by examining sets of infections separated by remissions of at least 6 months, 69% of the sets contain only one infection. After this first set, the remaining sets show a 33% remission rate in infections, which means a patient who has two or more infections within 6 months has only a 33% probability of remaining free of infection for the next 6 months. Therefore, **if antimicrobial prophylaxis is started after the second or any succeeding infection within a set, about two thirds of the women will benefit.**

Whether a patient receives no treatment at all or short-term, long-term, or prophylactic antimicrobial treatment the risk of recurrent bacteriuria remains the same; prophylactic antimicrobial therapy reduces reinfections but does not alter the underlying predisposition to recurring infection. Asscher and associates (1973) found that reinfections occurred in 17 patients (34%) treated with a 7-day course of nitrofurantoin and in 13 patients (29%) receiving

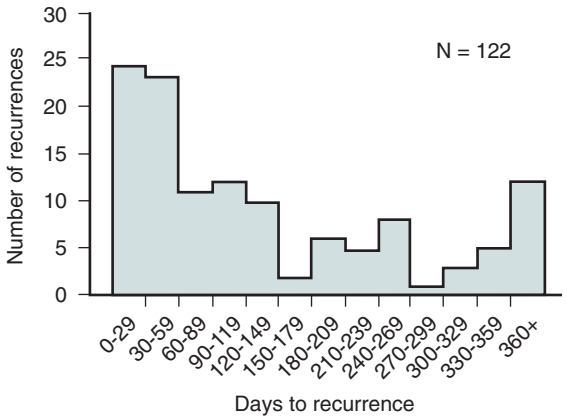

Figure 10–4. Days between recurrent UTIs grouped by 30-day intervals. (From Kraft JK, Stamey TA. The natural history of symptomatic recurrent bacteriuria in women. Medicine 1977;56:55.)

placebo during a 3- to 5-year follow-up. Mabeck (1972) found that 46% (20 of 43) of untreated patients had recurrent infections by 12 months compared with about 40% of treated patients who had recurrences. Both studies suggest that it makes little difference whether a UTI is cured with an antimicrobial agent or is allowed to clear spontaneously—the susceptibility to recurrent UTI remains the same. Moreover, patients with frequent UTI who take prophylactic antimicrobial agents for extended periods (≥6 months) may decrease their infections during the time of prophylaxis but the rate of infection returns to the pretreatment rate after prophylaxis is stopped (Vosti, 1975; Stamm et al, 1980a). Even long interruptions in the pattern of recurrence, therefore, do not appear to alter the patient's basic susceptibility to infections.

The sequelae of complicated UTIs are substantial. It is well established in the presence of obstruction, infection stones, diabetes mellitus, and other risk factors that UTIs in adults can lead to progressive renal damage (Freedman, 1975). **The long-term effects of uncomplicated recurrent UTIs are not completely known, but, so far, no association between recurrent infections and renal scarring, hypertension, or progressive renal azotemia has been established** (Asscher et al, 1973; Freedman, 1975). Indeed, one investigator was unable to find a single case of unequivocal nonobstructive chronic pyelonephritis in 22 patients in whom chronic pyelonephritis was the cause of end-stage renal failure (Schechter et al, 1971). Similar data were reported by Huland and Busch (1982).

In pregnant women the prevalence and rate of recurrent infection are the same but their bacteriuria progresses to acute clinical pyelonephritis more frequently than in nonpregnant women. This variation in the natural history of recurrent infections in females is discussed in a later section on UTIs in pregnancy.

Key Points: Incidence and Epidemiology

- UTIs are the most common bacterial infection.
- They cause significant morbidity but do not cause renal damage unless comorbidities are present.
- Antimicrobial therapy reduces morbidity and the time to recurrent bacteriuria, but the risk of recurrence remains the same.

PATHOGENESIS

UTIs are a result of interactions between the uropathogen and the host. Successful infection of the urinary tract is determined in part by the virulence factors of the bacteria, the inoculum size, and the inadequacy of host defense mechanisms. These factors also play a role in determining the ultimate level of colonization and damage to the urinary tract. Whereas increased bacterial virulence appears to be necessary to overcome strong host resistance, bacteria with minimal virulence factors are able to infect patients who are significantly compromised.

Routes of Infection

Ascending Route

Most bacteria enter the urinary tract from the bowel reservoir via ascent through the urethra into the bladder. Adherence of pathogens to the introital and urothelial mucosa plays a significant role in ascending infections. This route is further enhanced in individuals with significant soilage of the perineum with feces, women who use spermicidal agents (Hooton et al, 1996; Foxman, 2002; Handley et al, 2002), and patients with intermittent or indwelling catheters.

Although cystitis is often restricted to the bladder, approximately 50% of infections can extend into the upper urinary tract (Busch and Huland, 1984). The weight of clinical and experimental evidence strongly suggests that **most episodes of pyelonephritis are caused by retrograde ascent of bacteria from the bladder through the ureter to the renal pelvis and parenchyma. Although reflux of urine is probably not required for ascending infections, edema associated with cystitis may cause sufficient changes in the ureterovesical junction to permit reflux.** Once the bacteria are introduced into the ureter, they may ascend to the kidney unaided. However, this ascent would be greatly increased by any process that interferes with the normal ureteral peristaltic function. Gram-negative bacteria and their endotoxins, as well as pregnancy and ureteral obstruction, have a significant antiperistaltic effect.

Bacteria that reach the renal pelvis can enter the renal parenchyma by means of the collecting ducts at the papillary tips and then ascend upward within the collecting tubules. This process is hastened and exacerbated by increased intrapelvic pressure from ureteral obstruction or vesicoureteral reflux, particularly when it is associated with intrarenal reflux.

Hematogenous Route

Infection of the kidney by the hematogenous route is uncommon in normal individuals. However, the kidney is occasionally secondarily infected in patients with *Staphylococcus aureus* bacteremia originating from oral sites or with *Candida fungemia*. Experimental data indicate that infection is enhanced when the kidney is obstructed (Smellie et al, 1975).

Lymphatic Route

Direct extension of bacteria from the adjacent organs via lymphatics may occur in unusual circumstances, such as a severe bowel infection or retroperitoneal abscesses. There is little evidence that lymphatic routes play a significant role in the vast majority of UTIs.

Urinary Pathogens

Most UTIs are caused by facultative anaerobes usually originating from the bowel flora. Uropathogens such as *Staphylococcus epidermidis* and *Candida albicans* originate from the flora of the vagina or perineal skin.

***E. coli* is by far the most common cause of UTIs, accounting for 85% of community-acquired and 50% of hospital-acquired infections.** Other gram-negative Enterobacteriaceae, including *Proteus* and *Klebsiella,* and gram-positive *E. faecalis* and *Staphylococcus saprophyticus* are responsible for the remainder of most community-acquired infections. Nosocomial infections are caused by *E. coli, Klebsiella, Enterobacter, Citrobacter, Serratia, Pseudomonas aeruginosa, Providencia, E. faecalis,* and *S. epidermidis* (Kennedy et al, 1965). Less common organisms such as *Gardnerella vaginalis, Mycoplasma* species, and *Ureaplasma urealyticum* may infect patients with intermittent or indwelling catheters (Josephson et al, 1988; Fairley and Birch, 1989).

The prevalence of infecting organisms is influenced by the patient's age. For example, *S. saprophyticus* is now recognized as causing approximately 10% of symptomatic lower UTIs in young, sexually active females (Latham et al, 1983) whereas it rarely causes infection in males and elderly individuals. A seasonal variation with a late summer to fall peak has been reported (Hovelius and Mardh, 1984).

Fastidious Organisms

Anaerobes in the Urinary Tract

Although symptomatic anaerobic infections of the urinary tract are documented, they are uncommon. However, the distal urethra, perineum, and vagina are normally colonized by anaerobes. Whereas 1% to 10% of voided urine specimens are positive for anaerobic organisms (Finegold, 1977), anaerobic organisms found in suprapubic aspirates are much more unusual (Gorbach and Bartlett, 1974). Clinically symptomatic UTIs in which only anaerobic organisms are cultured are rare, but these organisms must be suspected when a patient with bladder irritative symptoms has cocci or gram-negative rods seen on microscopic examination of the centrifuged urine (catheterized, suprapubic aspirated, or voided midstream urine) and routine quantitative aerobic cultures fail to grow organisms (Ribot et al, 1981).

Anaerobic organisms are frequently found in suppurative infections of the genitourinary tract. In one study of suppurative genitourinary infections in males, 88% of scrotal, prostatic, and perinephric abscesses included anaerobes among the infecting organisms (Bartlett and Gorbach, 1981). The organisms found are usually *Bacteroides* species, including *B. fragilis*, *Fusobacterium* species, anaerobic cocci, and *Clostridium perfringens* (Finegold, 1977). The growth of clostridia may be associated with cystitis emphysematosa (Bromberg et al, 1982).

Mycobacterium tuberculosis and Other Nontuberculous Mycobacteria

Mycobacterium tuberculosis and other nontuberculous mycobacteria may be found when cultures for acid-fast bacteria are requested; they do not grow under routine aerobic conditions and may be found during evaluation for sterile pyuria. It has been emphasized that the mere presence of mycobacteria may not indicate tissue invasion. Therefore factors such as symptoms, endoscopic or radiologic evidence of infection, abnormal urine sediment, the absence of other pathogens, repeated demonstration of the organism, and the presence of granulomas should be considered before therapy is instituted (Brooker and Aufderheide, 1980; Thomas et al, 1980). (*M. tuberculosis* is discussed in Chapter 16.)

Chlamydia

Chlamydiae are not routinely grown in aerobic culture but have been implicated in genitourinary infections. (Their role in the urinary tract is discussed in Chapter 13.)

Bacterial Virulence Factors

Virulence characteristics play a role in determining both if an organism will invade the urinary tract and the subsequent level of infection within the urinary tract. It is generally believed that uropathogenic strains resident in the bowel flora, such as uropathogenic *E. coli* (UPEC), can infect the urinary tract not only by chance but also by the expression of virulence factors that enable them to adhere to and colonize the perineum and urethra and migrate to the urinary tract where they establish an inflammatory response in the urothelium (Schaeffer et al, 1981; Yamamoto et al, 1997; Schlager et al, 2002; Moreno et al, 2008). The same virulence factors can be found on bacterial strains that cause recurrent UTI in patients (Foxman et al, 1995). Some of these virulence determinants are located on one of approximately 20 UPEC-specific pathogenicity-associated islands ranging from 30 to 170 kb (Hacker, 1999; Oelschlaeger et al, 2002). These pathogenicity islands collectively increase the size of the pathogen genome by about 20% over a commensal strain. A recent genomic analysis of a UPEC strain revealed the presence of genes for putative chaperone-usher systems as well as autotransporter proteins that may function as adhesins, toxins, proteases, invasins, serum resistance factors, or motility mediators (Henderson and Nataro, 2001). One UPEC-specific autotransporter, Sat, seems toxic to urinary tract cells in vitro (Guyer et al, 2000) and can cause cytoplasmic vacuolation and severe histologic damage in mouse kidneys (Guyer et al, 2002). Another toxin, hemolysin HlyA, forms pores in a variety of host cell membranes (Uhlen et al, 2000). In addition to proteases and toxins, UPEC produces several iron acquisition systems, including aerobactin (Johnson et al, 1988; Johnson, 2003) and the more recently described IroN system (Russo et al, 1999; Sorsa et al, 2003). Lastly, most UPEC strains produce an acid polysaccharide capsule that protects the bacteria from phagocytosis by human polymorphonuclear leukocytes and inhibits activation of complement (Johnson, 2003).

Early Events in UPEC Pathogenesis

Bacterial Adherence

Bacterial adherence to vaginal and urothelial epithelial cells is an essential step in the initiation of UTIs. This interaction is influenced by the adhesive characteristics of the bacteria, the receptive characteristics of the epithelial surface, and the fluid bathing both surfaces. Bacterial adherence is a specific interaction that plays a role in determining the organism, the host, and the site of infection. Portions of this section on bacterial adherence have been published (Schaeffer et al, 1981).

Bacterial Adhesins. UPEC expresses a number of adhesins that allow it to attach to urinary tract tissues (Mulvey, 2002). These adhesins are classified as either fimbrial or afimbrial, depending on whether the adhesin is displayed as part of a rigid fimbria or pilus (Fig. 10–5). Bacteria may produce a number of

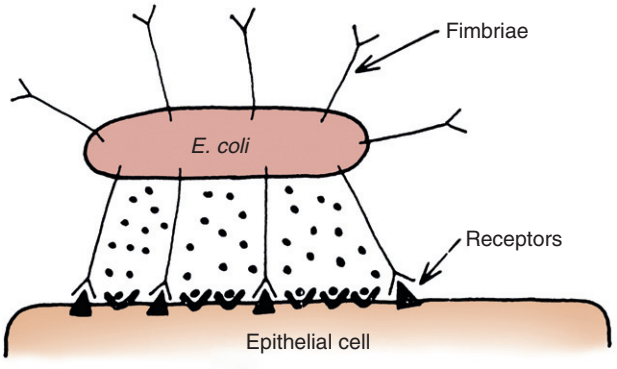

Figure 10–5. Bacterial adherence. Adhesins on pili (fimbriae) mediate attachment to specific epithelial cell receptors.

antigenically and functionally different pili on the same cell; others produce a single type; in some, no pili are seen (Klemm, 1985). A typical piliated cell may contain 100 to 400 pili. The pilus is usually 5 to 10 nm in diameter, is up to 2 μm long, and appears to be composed primarily of subunits known as pilin (Klemm, 1985). Pili are defined functionally by their ability to mediate hemagglutination of specific types of erythrocytes. The most well-described pili are types 1, P, and S.

Type 1 (Mannose Sensitive) Pili. Type 1 pili are commonly expressed on both nonpathogenic and pathogenic *E. coli*. Type 1 pili consist of a helical rod composed of repeating FimA subunits joined to a 3-nm wide distal tip structure containing the adhesin FimH (Jones et al, 1995). These pili mediate hemagglutination of guinea pig erythrocytes (Duguid et al, 1979). The reaction is inhibited by the addition of mannose; thus type 1 pili are termed *mannose-sensitive hemagglutination* (MSHA) (Svenson et al, 1984; Reid and Sobel, 1987).

The role of type 1 pili as a virulence factor in UTIs has been established. This evidence has been obtained (1) from the analysis of bacteria isolated from the urine of patients with UTIs, which were found to express mannose-sensitive (MS) adhesins (Ljungh and Wadstrom, 1983); (2) from studies with animal models (Fader and Davis, 1982; Hagberg et al, 1983a, 1983b; Iwahi et al, 1983; Hultgren et al, 1985) in which inoculation of type 1 piliated organisms into the bladder resulted in significantly more colonization of the urinary tract than inoculation of nonpiliated organisms; and (3) from the observation that anti-type 1 pili antibodies and competitive inhibitors such as methyl-α-D-mannopyranoside protected mice from contracting UTIs (Aronson et al, 1979; Hultgren et al, 1985). **Recent studies have demonstrated that interactions between FimH and receptors expressed on the luminal surface of the bladder epithelium are critical for the ability of many UPEC strains to colonize the bladder and cause disease** (Connell et al, 1996; Langermann et al, 1997; Thankavel et al, 1997; Mulvey et al, 1998).

P (Mannose Resistant) Pili. **P pili confer tropism to the kidney, the designation "P" standing for pyelonephritis** (Mulvey, 2002). P pili, which are found in most pyelonephritogenic strains of UPEC, mediate hemagglutination of human erythrocytes that is not altered by mannose and is thus termed *mannose-resistant hemagglutination* (MRHA) (Kallenius et al, 1979). The adhesin PapG, at the tip of the pilus, recognizes the α-D-galactopyranosyl-(1-4)-β-D-galactopyranoside moiety present in the globoseries of glycolipids (Kallenius et al, 1980; Leffler and Svanborg-Eden, 1980), which are found on P-blood group antigens and on uroepithelium (Svenson et al, 1983).

The MRHA adhesins of UPEC that do not show the digalactoside-binding specificity have been provisionally named X adhesins (Vaisanen et al, 1981). In some strains of UPEC, hemagglutination is mediated by nonpiliated adhesins or hemagglutinins (Duguid et al, 1979).

Svanborg-Eden and coworkers (1978) were the first to report a correlation between bacterial adherence and severity of UTIs. They showed that UPEC strains from girls with acute pyelonephritis had high adhesive ability whereas strains causing asymptomatic bacteriuria or from the feces of healthy girls had low bacterial adherence. Between 70% and 80% of the pyelonephritic strains, but only 10% of the bowel isolates, had adhesive capacity. Furthermore, P pili were present in 91% of urinary strains causing pyelonephritis, 19% of strains causing cystitis, and 14% of strains causing asymptomatic bacteriuria but only 7% of bowel isolates from healthy children, highlighting the correlation between bacterial adherence and UTIs (Kallenius et al, 1981).

Whereas MRHA and P pili are strongly associated with pyelonephritis, these virulence factors are not associated with renal scarring and reflux due to bacterial infection (Vaisanen et al, 1981). Studies suggest minimal correlation between P-piliated *E. coli* strains and recurrent pyelonephritis with gross reflux in girls (Lomberg et al, 1983). Thus it would appear that P pili in acute pyelonephritis are important mainly in nonrefluxing or minimally refluxing children.

Other Adhesins. S pili, which bind to sialic acid residues via the SfaS adhesin, have been associated with both bladder and kidney infection (Mulvey, 2002). F1C pili bind to glycosphingolipids in renal epithelial cells and induce an interleukin-8 inflammatory response (Backhed et al, 2002).

UPEC also expresses a group of afimbrial adhesins (AFA), which have been clustered with the Dr adhesin family for their recognition of decay-accelerating factor and for their similar genetic structure. Decay-accelerating factor is found on numerous different epithelial sites, and Dr adhesins are known to bind to many locations throughout the urinary tract (Anderson et al, 2004b).

Phase Variation of Bacterial Pili in Vivo

Early evidence for the role of type 1 and P pili in adherence in UTIs in humans was contradictory. Pili were visible by electron microscopy on *E. coli* in the urine of 31 of 37 patients (Ljungh and Wadstrom, 1983). Conversely, no MS adhesins were found in 22 of 24 urine isolates from patients with indwelling catheters (Ofek et al, 1981), and 19 of 20 samples from patients with acute UTIs were devoid of pili and nonadherent until subcultured in broth (Harber et al, 1982). Assessment of pili production by clinical *E. coli* isolates demonstrates that environmental growth conditions can produce rapid changes in pilus expression (Duguid et al, 1966; Goransson and Uhlin, 1984; Hultgren et al, 1986), wherein cells switch back and forth between piliated and nonpiliated phases (Eisenstein, 1981). For example, some bacteria grown in a broth medium express pili whereas the same strain grown on the same medium in a solid state will cease production of pili. **This process, called phase variation, can also occur in vivo and has obvious biologic and clinical implications.** For example, the presence of type 1 pili may be advantageous to the bacteria for adhering to and colonizing the bladder mucosa but disadvantageous because the pili enhance phagocytosis and killing by neutrophils (Silverblatt et al, 1979).

An animal model of ascending UTIs and studies of bacterial isolates from different sites in patients with UTI provide evidence that phase variation can occur during *E. coli* UTI in vivo. Type 1 piliated *E. coli* organisms that were capable of phase variation were introduced into the mouse bladder in the piliated phase, and the bacteria recovered from the bladder and urine 24 or more hours after inoculation were tested for piliation. All of the animals had bladder colonization, and 78% of the bacteria recovered showed type 1 piliation. The bacteriologic state of the urine often differed from that of the bladder. The urine was sterile in 59% of the animals with bladder colonization, and the organisms recovered from the urine were often nonpiliated.

When bladder and kidney cultures were examined 1, 3, and 5 days after intravesical inoculation of piliated bacteria, organisms recovered from the bladder remained piliated, whereas organisms recovered from the kidney showed significantly less piliation (Schaeffer et al, 1987) (Fig. 10–6).

Studies in humans using indirect immunofluorescence of fresh urine bacteria have confirmed in-vivo expression and phase

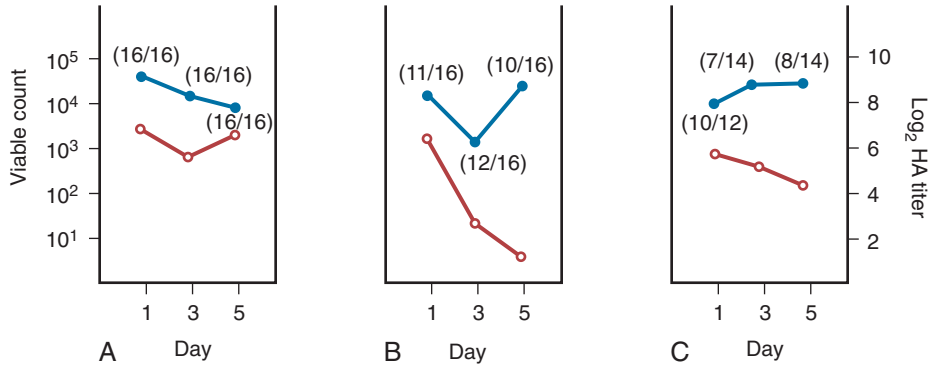

Figure 10–6. Time study after intravesical inoculation with *E. coli* strain I-I49 that compared the mean viable bacteria count *(solid circles)* and hemagglutination (HA) titer *(open circles)* for bladders (**A**), kidneys (**B**), and urine specimens (**C**) from the same animals. Each point is the mean of all the animals tested. The numbers in parentheses show the proportion of animals inoculated that gave positive cultures. The HA titers were tested after 18 hours of growth on agar. The HA titer of bacteria recovered from the kidney decreased significantly by day 5 ($P < .001$). (**A** to **C,** From Schaeffer AJ, Schwan WR, Hultgren SJ, Duncan JL. Relationship of type 1 pilus expression in *Escherichia coli* to ascending urinary tract infections in mice. Infect Immun 1987;55:373–80.)

variation of pili. Analysis of the urine of adults with lower UTI detected type 1 pili in 31 of 41 specimens and P pili in 6 of 18 specimens (Kisielius et al, 1989). The piliation status of the bacterial population in the urine was heterogeneous, varying from predominantly piliated to a mixture of piliated and nonpiliated cells (Fig. 10–7). Strains isolated from different sites in the urogenital tract showed variation in the state of piliation. These results demonstrate that type 1 and P pili are expressed and subject to phase variation in vivo during acute UTIs.

This process of phase variation has obvious biologic and clinical implications. For example, the presence of type 1 pili may be advantageous to the bacteria for initially adhering to and colonizing the bladder mucosa. Subsequently, type 1 pili may be unnecessary for strains in suspension in urine and in fact detrimental because they enhance apoptosis, phagocytosis, and killing by neutrophils (Silverblatt et al, 1979; Mulvey et al, 1998). In the kidney, P pili may then take over as the primary mediator of bacterial attachment by means of their binding to the glycolipid receptors (Stapleton et al, 1995).

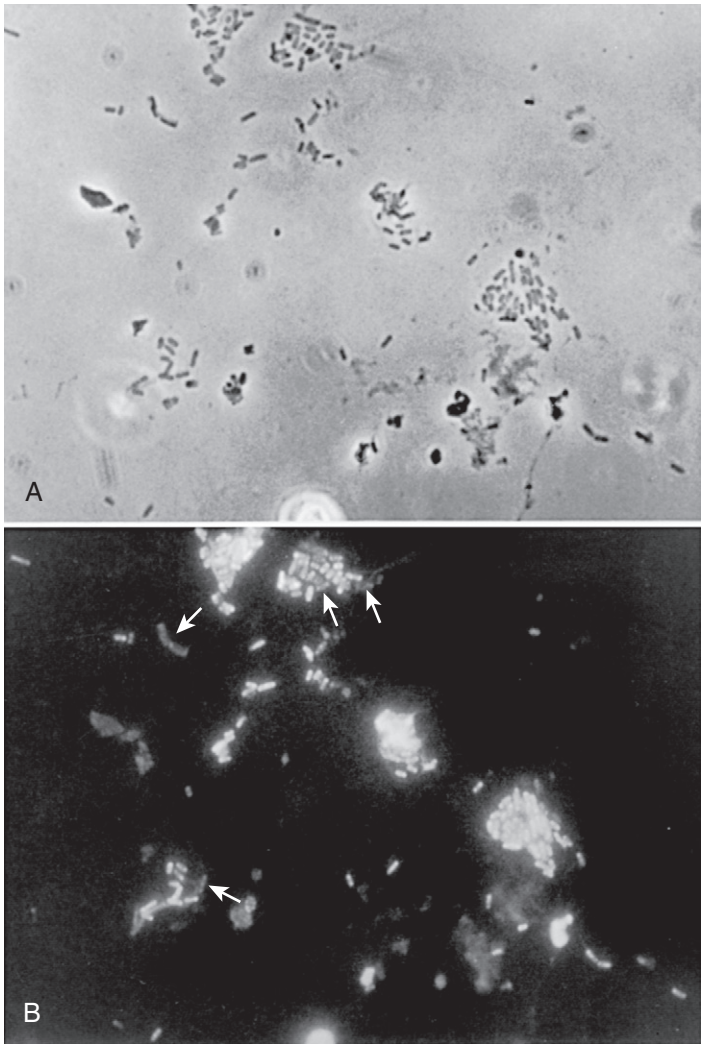

Figure 10–7. Phase-contrast micrograph (**A**) and immunofluorescence micrograph (**B**) of a sample stained with antiserum to type 1 pili of strain I-49 and with FITC-conjugated second antibody against nonadherent *E. coli* in the urine of a patient with acute UTI show a mixture of piliated and nonpiliated (*arrows* in **B**) cells. (**A** and **B,** From Kisielius PV, Schwan WR, Amundsen SK, et al. In vivo expression and variation of *Escherichia coli* type 1 and P pili in the urine of adults with acute urinary tract infections. Infect Immun 1989;57:1656.)

Epithelial Cell Receptivity

Vaginal Cells

The significance of epithelial cell receptivity in the pathogenesis of ascending UTI has been studied initially by examining adherence of *E. coli* to vaginal epithelial cells and uroepithelial cells collected from voided urine specimens. Fowler and Stamey (1977) established that certain indigenous microorganisms (e.g., lactobacilli, *S. epidermidis*) avidly attached themselves to washed epithelial cells in large numbers. When vaginal epithelial cells were collected from patients susceptible to reinfection and compared with such cells obtained from controls resistant to UTI, the *E. coli* strains that cause cystitis adhered much more avidly to the epithelial cells from the susceptible women. **These studies established increased adherence of pathogenic bacteria to vaginal epithelial cells as the first demonstrable biologic difference that could be shown in women susceptible to UTI.**

Subsequently, Schaeffer and colleagues (1981) **confirmed these vaginal differences in women, but in addition they observed that the increased bacterial adherence was also characteristic of buccal epithelial cells.** As can be seen in

Figure 10–8, there is a striking similarity in the ability of both cell types to bind to the same *E. coli* strain. In addition, there was a significant relationship between vaginal cell and buccal cell receptivity. Seventy-seven different *E. coli* strains were tested for their ability to bind to vaginal and buccal epithelial cells. A direct nonlinear relationship between buccal and vaginal adherence in controls and patients was confirmed for urinary, vaginal, and anal isolates. Thus high vaginal cell receptivity was associated with high buccal cell receptivity.

These observations emphasize that the increase in receptor sites for UPEC on epithelial cells from women with recurrent UTIs is not limited to the vagina and thus suggest that a genotypic trait for epithelial cell receptivity may be a major susceptibility factor in UTIs. This concept was extended by examining the human leukocyte antigens (HLAs), which are the major histocompatibility complex in humans and have been associated statistically with many diseases (Schaeffer et al, 1983). The A3 antigen was identified in 12 (34%) of the patients, which is significantly higher than the 8% frequency observed in healthy controls. Thus HLA-A3 may be associated with increased risk of recurrent UTIs.

Variation in Receptivity. A small variation in both vaginal cell and buccal cell receptivity may be observed from day to day in healthy controls. Adherence ranges from 1 to 17 bacteria per cell and appears to be both cyclic and repetitive. When adherence was correlated with the days of a woman's menstrual cycle, higher values were noted in the early phase, diminishing shortly after the time of expected ovulation (day 14). The number of bacteria per epithelial cell often correlated with the value obtained on the same day of the menstrual cycle 1 or 2 months previously. Premenopausal women are particularly susceptible to attachment of uropathogenic *E. coli* and nonpathogenic lactobacilli at certain times during the menstrual cycle and to *E. coli* during the early stages of pregnancy. **The importance of such hormones as estrogens in the pathogenesis of UTI is therefore a matter of great interest, especially because the clinical urologist may see women who have recurrent cystitis at regular intervals, possibly in response to these hormonal changes.**

Reid and Sobel (1987) found that uropathogens attached in larger numbers to uroepithelial cells from women older than 65 years of age than to cells from premenopausal women 18 to 40 years of age. Raz and Stamm (1993) noted that susceptibility to recurrent UTI was increased by the lowered estrogen levels found in the postmenopausal women and that estrogen replacement decreased uropathogenic bacterial colonization and the incidence of UTI.

Blood group antigens and carbohydrate structures bound to membrane lipids or proteins also constitute an important part of the uroepithelial cell membrane. The presence or absence of blood group determinants on the surface of uroepithelial cells may influence an individual's susceptibility to a UTI. Sheinfeld and associates (1989) determined the blood group phenotypes in women with recurrent UTI and compared them with those of age-matched women controls. Women with Lewis Le(a–b–) and Le(a+b–) phenotypes had a significantly higher incidence of recurrent UTIs than women with Le(a–b+) phenotypes. There was no significant difference in the distribution of ABO or P blood group phenotypes. The Lewis antigen controls fucosylation. The protective effect in women with the Le(a–b+) phenotype may be due to fucosylated structures at the vaginal cell surface or in the overlying mucus, which decreases availability of putative receptors for *E. coli* (Navas et al, 1993). The nonsecretor status has also been associated with female acute uncomplicated pyelonephritis, especially in premenopausal women (Ishitoya et al, 2002). Stapleton and coworkers (1995) have shown that unique *E. coli*-binding glycerides are found in vaginal epithelial cells from nonsecretors but not from

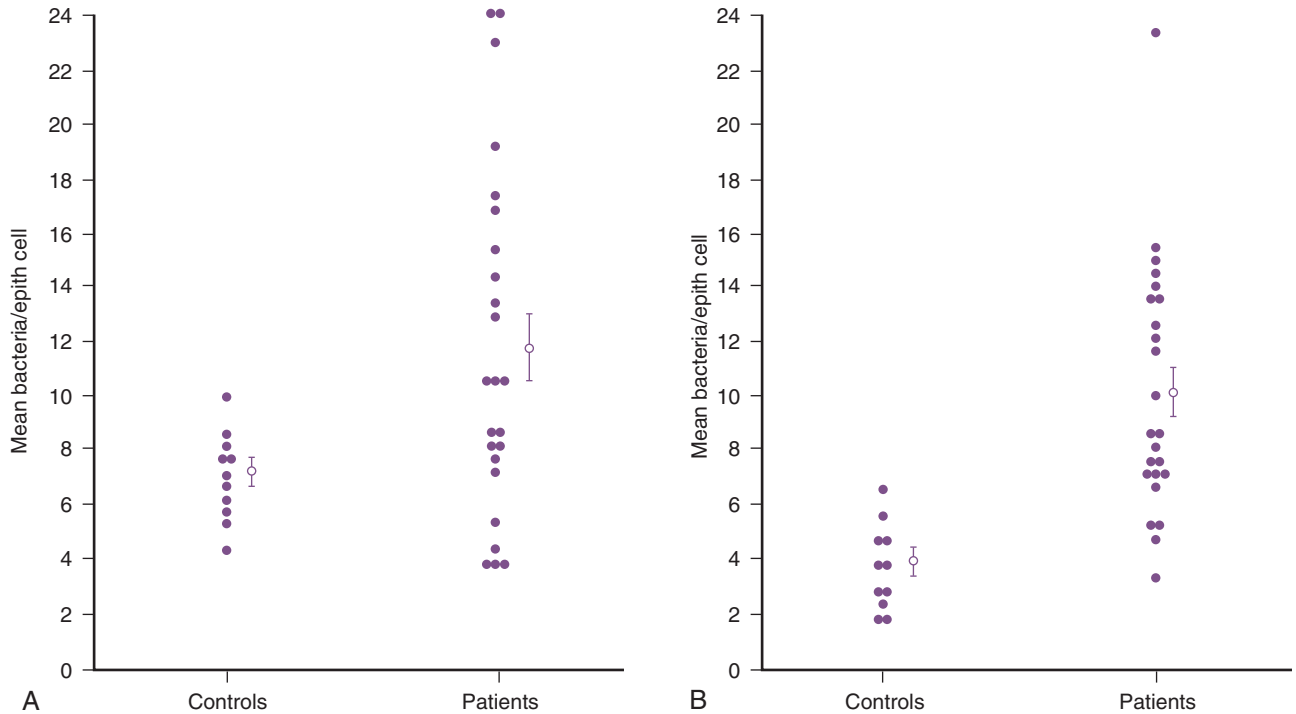

Figure 10–8. In-vitro adherence of *E. coli* to vaginal (**A**) and buccal (**B**) cells from healthy controls and patients with recurrent UTIs. Values represent an average of 14 (**A**) and 11 (**B**) determinations in each individual. The *open circles* and *bars* represent the means + standard error of the mean. (**A** and **B,** From Schaeffer AJ, Jones JM, Dunn JK. Association of in vitro *Escherichia coli* adherence to vaginal and buccal epithelial cells with susceptibility of women to recurrent urinary tract infections. N Engl J Med 1981;304:1062–6.)

secretors. **These studies individually and collectively support the concept that there is an increased epithelial receptivity for *E. coli* on the introital, urethral, and buccal mucosa that is characteristic of women susceptible to recurrent UTIs and may be a genotypic trait.**

The possibility that vaginal mucus might influence bacterial receptivity was investigated by Schaeffer and colleagues (1994). Type 1 piliated *E. coli* bound to all of the vaginal fluid specimens (Venegas et al, 1995). The binding capacity of vaginal fluid from women colonized with *E. coli* in vivo was greater than that from noncolonized women (Schaeffer, 1999). The importance of vaginal fluid in bacteria/epithelial cell interactions was investigated in an in-vitro model that measured the effect of vaginal fluid on the binding of bacteria to an epithelial cell line (Gaffney et al, 1995). Vaginal fluid from colonized women enhanced binding of bacteria to epithelial cells. Conversely, vaginal fluid from noncolonized women inhibited adherence. Thus the vaginal fluid appears to influence adherence to cells and, presumably, vaginal mucosal colonization. Subsequent studies demonstrated that secretory IgA is the primary glycoprotein responsible for vaginal fluid receptivity (Rajan et al, 1999).

Bladder Cells

FimH binds mannosylated residues on the uroplakin molecules covering bladder superficial epithelial cells. The luminal surface of the bladder is lined by umbrella cells. The apical surfaces of umbrella cells appear as a quasi-crystalline array of hexagonal complexes composed of four integral membrane proteins known as uroplakins (Sun, 1996). In-vitro binding assays have shown that two of the uroplakins, UPIa and UPIb, can specifically bind UPEC expressing type 1 pili (Wu et al, 1996). High-resolution freeze-fracture electron microscopy has shown that the tips of these pili, including the adhesins, are buried in the central cavity of the uroplakin hexameric rings (Mulvey et al, 2000) (Fig. 10–9A). **Thus fimH-mediated binding to the bladder epithelium is the initial step in the intricate cascade of events leading to UTIs.**

UPEC Persistence in the Bladder. Soon after attachment to the epithelium, UPEC is quickly internalized into the bladder superficial cells (Martinez and Hultgren, 2002; Anderson et al, 2004b) (Fig. 10–9B). FimH is essential for UPEC invasion; isogenic fimH-mutants do not invade, and invasion of wild-type bacteria can be inhibited by the addition of mannose. In addition, polystyrene latex beads coated with fimH are quickly internalized in a process identical to bacteria expressing type 1 pili. This process is the result of localized actin rearrangement and engulfment of the bound bacterium by zippering of the membrane around the microorganism (Martinez and Hultgren, 2002). Invasion into the superficial epithelium of the bladder allows UPEC to establish a new niche in an effort to protect itself from the host innate immune response (Anderson et al, 2004b).

Once intracellular, the UPEC organisms rapidly grow and divide within the cell cytosol, forming small clusters of bacteria termed *early intracellular bacterial communities* (IBCs) (Anderson et al, 2004b; Justice et al, 2004). As they grow, the bacteria maintain their typical rod shape of approximately 3 μm and form a loosely organized cluster, with microorganisms randomly oriented in the cell cytoplasm. Between 6 to 8 hours after inoculation, early IBCs

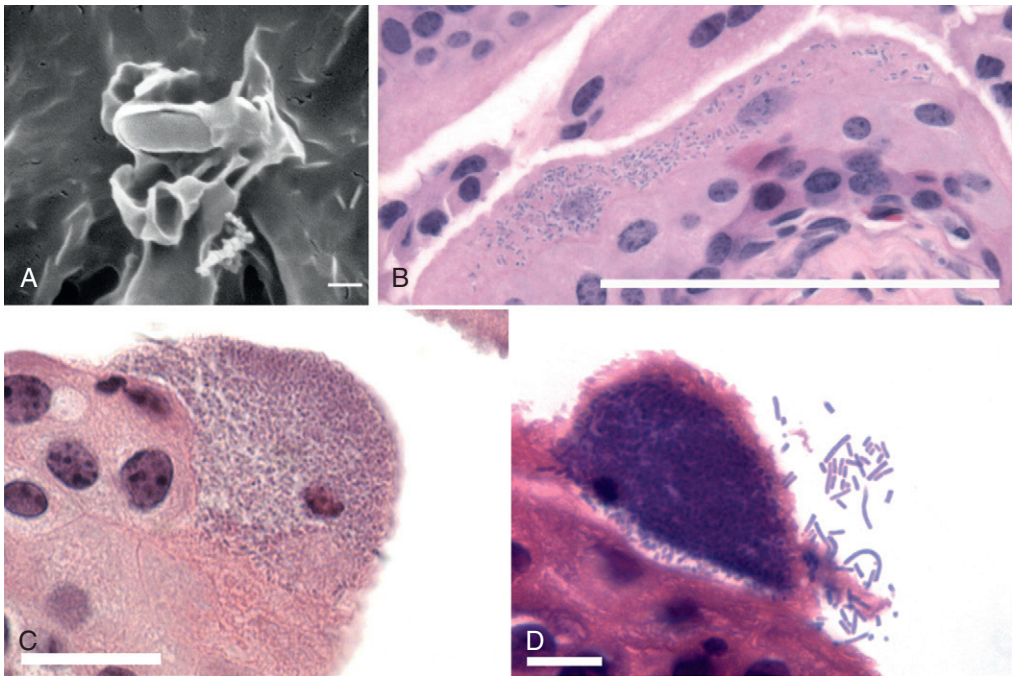

Figure 10–9. UPEC binds, invades, and multiplies inside the superficial cells of the bladder epithelium. **A,** Scanning electron microscopy shows a single UPEC bound to the surface of a bladder cell. Type 1 pilus-mediated contact between bacterium and host cell initiates signaling cascades in the bladder cell, leading to localized actin rearrangements and membrane protrusions around the bacterium. Scale bar, 0.5 μm. **B,** Once inside the bladder superficial cells, UPEC rapidly multiplies to form disordered bacterial clusters in the host cell cytoplasm, called an early intracellular bacterial community (IBC). Bacteria are visible as dark-staining rods inside the cell in this hematoxylin and eosin (H&E)-stained thin bladder section. Scale bar, 100 μm. **C,** H&E-stained thin bladder section reveals a middle IBC, wherein the constituent bacteria have organized themselves into a biofilm-like state within the bladder cell. Scale bar, 20 μm. **D,** A late IBC, visible by H&E staining, is typified by detachment of peripheral bacteria and fluxing of these organisms into the bladder lumen. Scale bar, 10 μm. (From Anderson GG, Martin SM, Hultgren SJ. Host subversion by formation of intracellular bacterial communities in the urinary tract. Microbes Infect 2004;6:1094–1101.)

show a drop in bacterial growth rate resulting in doubling times greater than 60 minutes, a significant shortening of the bacterial morphology to an average of 0.7 µm, and a phenotypic switch into a biofilm-like community (Justice et al, 2004) (see Fig 10–9C).

Biofilms shield bacteria from environmental challenges such as antimicrobial agents and the host immune response (Donlan and Costerton, 2002). **Characteristics of the biofilm that increase protection include the slower growth rate of the bacteria with associated physiologic changes, expression of factors that inhibit antimicrobial activity, and the inability of the antimicrobial agent to penetrate the biofilm matrix** (Anderson et al, 2004b). The biofilm also protects the bacteria from neutrophils because they are unable to effectively penetrate the IBC and engulf the bacteria. In animal models, bacteria on the edge of IBCs eventually detach, differentiate to typical rod morphology, become motile, and then escape the host cell into the bladder lumen in a process called fluxing (Mulvey et al, 2001) (see Fig. 10–9D). These bacteria may become highly filamentous, reaching up to 70 µm or greater in length. This process occurs by approximately 24 hours after inoculation (Justice et al, 2004). It is possible that the filaments may help the bacteria evade the immunologic response.

The escaped bacteria readhere and reinvade superficial cells to lead to second IBC formation. In subsequent rounds, further IBC formation occurs. After a few days, the invasive bacteria become more quiescent. In animal models, the bacteria can persist in this dormant reservoir state for some time before reemerging to cause recurrent UTIs (Anderson et al, 2004a).

Natural Defenses of the Urinary Tract

Periurethral and Urethral Region

The normal flora of the vaginal introitus, the periurethral area, and the urethra usually contain microorganisms such as lactobacilli, coagulase-negative staphylococci, corynebacteria, and streptococci that form a barrier against uropathogenic colonization (Fair et al, 1970; Pfau and Sacks, 1977; Marrie et al, 1978). Changes in the vaginal environment related to estrogen, cervical IgA (Stamey et al, 1978), and low vaginal pH (Stamey and Timothy, 1975) may alter the ability of these bacteria to colonize. More commonly, however, acute changes in colonization have been associated with use of antimicrobial agents and spermicidal agents that alter the normal flora and increase the receptivity of the epithelium for uropathogens.

Little is known about the factors that predispose patients to urethral colonization with uropathogens. The proximity of the urethral meatus to the vulvar and perianal areas suggests that contamination occurs frequently. The nature of urethral defense mechanisms other than flow of urine is largely unknown. Bacterial multiplication in the normal urethra may be inhibited by the indigenous flora (Chan et al, 1984). Although colonization of the periurethral and urethral regions is prerequisite to most infections, the ability of the organisms to overcome the normal defense mechanisms of the urine and the bladder is clearly pivotal.

Urine

In general, fastidious organisms that normally colonize the urethra will not multiply in urine and rarely cause UTIs (Cattell et al, 1974). In contrast, urine will usually support the growth of nonfastidious bacteria (Asscher et al, 1968). Urine from normal individuals may be inhibitory, especially when the inoculum is small (Kaye, 1968). The most inhibitory factors are the osmolality, urea concentration, organic acid concentration, and pH. Bacterial growth is inhibited by either very dilute urine or a high osmolality when associated with a low pH. Much of the antimicrobial activity of urine is related to a high urea and organic acid content (Solomon et al, 1983). From a clinical perspective, however, these conditions do not appear to significantly distinguish between patients who are susceptible or resistant to infection.

Uromodulin (Tamm-Horsfall protein), a kidney-derived mannosylated protein that is present in an extraordinarily high concentration in the urine (greater than 100 mg/mL), may play a defensive role by saturating all the mannose-binding sites of the type 1 pili, thus potentially blocking bacterial binding to the uroplakin receptors of the urothelium (Duncan, 1988; Kumar and Muchmore, 1990).

Bladder

Bacteria presumably make their way into the bladder fairly often. Whether small inocula of bacteria persist, multiply, and infect the host depends in part on the ability of the bladder to empty (Cox and Hinman, 1961). Additional factors responsible for defense involve both innate and adaptive immunity and exfoliation of epithelial cells.

Immune Response

Pathogen Recognition. The host recognition of the pathogen is mediated by a series of pathogen-associated molecular pattern receptors (PAMPs), such as Toll-like receptors (TLRs) (Anderson et al, 2004b), which provide the link between recognition of invading organisms and development of the innate immune response. TLRs recognize molecular patterns that are conserved among many species of pathogens, such as lipopolysaccharide (LPS) and peptidoglycan (PG), and activate signaling pathways that initiate immune and inflammatory responses to kill pathogens. Superficial bladder epithelial cells express TLR4 on their membranes, which along with CD14 recognize LPS from the bacteria and activate the innate immune response (Anderson et al, 2004a). The newly identified TLR11, which recognizes UPEC and protects the kidneys from ascending infection, is also expressed on uroepithelial cells as well as renal cells (Zhang et al, 2004).

The innate system response to an infection in the bladder or kidneys is primarily local inflammation.

The innate immune response occurs more rapidly than the adaptive response and involves a variety of cell types, including polymorphonuclear leukocytes, neutrophils, macrophages, eosinophils, natural killer cells, mast cells, and dendritic cells. In addition, increased transcription of inducible nitric oxide synthase by polymorphonuclear leukocytes results in high levels of nitric oxide and related breakdown products that also have toxic effects on the bacteria (Poljakovic et al, 2001; Poljakovic and Persson, 2003). The innate response aids in establishing adaptive immunity due to interactions of macrophages, dendritic cells, and natural killer cells with T and B lymphocytes. Adaptive immunity involves the specific recognition of pathogens by T and B lymphocytes and production of high-affinity antibodies, a process that occurs 7 to 10 days after infection.

The urinary tract is part of the secretory immune system. In pyelonephritis, IgG and SIgA appear in the urine and may become evident before antibodies are detected in the serum. These antibodies are synthesized locally within the kidney and may enhance bacterial opsonization and ingestion by local phagocytic cells. These antibodies may have further protective function. Svanborg-Eden and Svennerholm (1978) showed that IgG and SIgA derived

from the urine of patients with acute pyelonephritis reduced in-vitro adherence of the same strain of *E. coli* to uroepithelial cells. Similarly, immunization with *E. coli* P pili resulted in immunoglobulin production in experimental animals that prevented ascending pyelonephritis by reducing the adhesive capacity of the invading autologous uropathogenic *E. coli* (Roberts and Phillips, 1979; O'Hanley, 1983).

The possibility that immunologic factors may be modified to reduce susceptibility to infection has been explored primarily through immunization in animal and human systems. For example, in a monkey model, vaccination with P fimbria has been shown to reduce adherence of P-fimbriated *E. coli* to uroepithelial cells and prevent acute pyelonephritis (Roberts and Phillips, 1979). Similarly, vaccination of mice with FimH adhesin prevents cystitis in mice (Langermann et al, 1997). Vaccination of women may reduce colonization of the vaginal introitus and subsequent ascending bacteria (Uehling et al, 1994).

Induced Exfoliation. Mulvey and colleagues (1998) **demonstrated that exfoliation and excretion of infected and damaged superficial cells is mediated by type 1 piliated bacteria that induce programmed cell death.** By utilizing an in-vivo mouse model, it has been demonstrated that mice exhibiting a strong exfoliation response to UPEC infiltration are unlikely to form IBCs (Anderson et al, 2004b). However, mice with a much milder exfoliation response tend to form biofilms, which become sequestered in the bladder and presumably could lead to recurrent UTIs. **It has also been shown that many uropathogenic bacteria can suppress NFκB, increase apoptosis, and decrease the inflammatory responses** (Klumpp et al, 2001), **a process that could lead to subsequent bacterial invasion into deeper tissues. Thus in some instances apoptosis may be a bacterial offense maneuver rather than a host defense.**

Alterations in Host Defense Mechanisms

Obstruction

Obstruction to urine flow at all anatomic levels is a key factor in increasing host susceptibility to UTI. Obstruction inhibits the normal flow of urine, and the resulting stasis compromises bladder and renal defense mechanisms. **Stasis also contributes to the growth of bacteria in the urine and their ability to adhere to the urothelial cells.** In the animal model of experimental hematogenous pyelonephritis the kidney is relatively resistant to infection unless a ureter is ligated. Under these circumstances only the obstructed kidney becomes infected (Beeson and Guze, 1956). Clinical observations support the role of obstruction in pathogenesis of UTI and in increasing severity of infection. **Mild episodes of cystitis or pyelonephritis can become life threatening when obstruction to urine flow becomes present.** Although obstruction clearly increases the severity of infection, it need not be a predisposing factor. For example, men with large residual urine may remain uninfected for years. However, if they are catheterized, even small inocula may lead to severe infections that are difficult to eradicate.

Vesicoureteral Reflux

Hodson and Edwards (1960) first described the association of vesicoureteral reflux, UTI, and renal clubbing and scarring. **Children with gross reflux and UTIs usually develop progressive renal damage manifested by renal scarring, proteinuria, and renal failure. Those with a lesser degree of reflux usually improve or completely recover spontaneously or after treatment of the UTI. In adults, the presence of reflux does not appear to decrease renal function unless there is stasis and concurrent UTIs.**

Underlying Disease

There is a high incidence of renal scarring in patients with underlying conditions that cause chronic interstitial nephritis, virtually all of which produce primary renal papillary damage. These conditions include diabetes mellitus, sickle cell disorders, adult nephrocalcinosis, hyperphosphatemia, hypokalemia, analgesic abuse, sulfonamide nephropathy, gout, heavy-metal poisoning, and aging (Freedman, 1979).

Diabetes Mellitus

An increased incidence of clinical asymptomatic and symptomatic UTIs appears to occur in women with diabetes mellitus, but there is no substantial increase among diabetic men (Vejlsgaard, 1973; Ooi et al, 1974; Forland et al, 1977; Meiland et al, 2002). Diabetes also results in three times more hospitalizations for acute pyelonephritis among women (10.86/10,000) than for men (3.32/10,000) (Nicolle et al, 1996). Autopsy studies have shown the incidence of pyelonephritis to be fourfold to fivefold higher in diabetic than in nondiabetic individuals (Robbins and Tucker, 1944). However, such studies may be misleading because it is difficult to distinguish renal parenchymal changes resulting from pyelonephritis from the interstitial inflammatory changes of diabetic nephropathy.

Although most UTIs in diabetic patients are asymptomatic, diabetes appears to predispose the patient to more severe infections. There is no evidence that increased frequency of infection is due to glycosuria (Geerlings et al, 2000). One study using antibody-coated bacteria techniques to localize the site of infection showed the upper urinary tract to be involved in nearly 80% of diabetic patients with UTIs (Forland et al, 1977). This evidence of increasing immunologic response in diabetic patients who acquire bacteriuria suggests renal parenchymal involvement and a potential increase in morbidity.

Infections are frequently caused by atypical organisms such as yeast and result in upper tract infections and significant sequelae such as emphysematous pyelonephritis, papillary necrosis, perinephric abscess, or metastatic infection (Wheat, 1980; Stapleton, 2002).

Renal Papillary Necrosis

The role of infection in the development and progression of renal papillary necrosis (RPN) is controversial. **Multiple predisposing conditions have been associated with the development of RPN, particularly diabetes, analgesic abuse, sickle cell hemoglobinopathy, and obstruction** (Table 10–2).

Clinically, RPN is a spectrum of disease. Patients may have an acute fulminating illness with rapid progression or may have a chronic disease that is incidentally discovered. Some patients may chronically pass necrotic tissue in their urine (Hernandez et al, 1975), and some may never pass papillae (Lindvall, 1978). Retained necrotic papillae may calcify, especially in association with infection. Furthermore, this necrotic tissue may form the nidus for chronic infection. Opportunistic fungal infections have been reported (Madge and Lombardias, 1973; Juhasz et al, 1980; Vordermark et al, 1980; Tomashefski and Abramowsky, 1981). Renal ultrasonography may be useful to diagnose RPN (Buonocore et al, 1980; Hoffman et al, 1982).

Table 10–2.

Conditions Associated with Renal Papillary Necrosis

Diabetes mellitus
Pyelonephritis
Urinary tract obstruction
Analgesic abuse
Sickle cell hemoglobinopathies
Renal transplant rejection
Cirrhosis of the liver
Dehydration, hypoxia, and jaundice of infants
Miscellaneous: renal vein thrombosis, cryoglobulinemia, renal candidiasis, contrast media injection, amyloidosis, calyceal arteritis, necrotizing angiitis, rapidly progressive glomerulonephritis, hypotensive shock, acute pancreatitis

From Eknoyan G, Qunibi WY, Grissom RT, et al. Renal papillary necrosis: an update. Medicine 1982;61:55.

The early diagnosis of RPN is important to improve prognosis and reduce morbidity. In addition to chronic infection, patients with analgesic abuse–associated papillary necrosis may have an increased incidence of urothelial tumors; routine urinary cytologic examinations may be helpful to diagnose these tumors early (Jackson et al, 1978). In patients who have analgesic abuse–induced RPN, the disease stabilizes if the analgesic intake is stopped (Gower, 1976). Furthermore, adequate antimicrobial therapy to control infection and early recognition and treatment of ureteral obstruction caused by sloughed necrotic tissue can minimize a decline in renal function. A patient who suffers from an acute ureteral obstruction due to a sloughed papilla and who has a concomitant UTI has a urologic emergency. In this case, immediate removal of the obstructing papilla by stone basket (Jameson and Heal, 1973) or acute drainage of the kidney by ureteral catheter or percutaneous nephrostomy is necessary.

Other conditions that may increase the susceptibility of the kidney to infection include hypertension and vascular obstruction (Freedman, 1979). Association of renal infection with several other renal diseases, including glomerulonephritis, atherosclerosis, and tubular necrosis, which are not associated with papillary necrosis, does not lead to pyelonephritis and scarring.

Human Immunodeficiency Virus

UTIs are fivefold more prevalent in HIV-positive individuals than in control subjects (Schonwald et al, 1999). Furthermore, the pathologic flora are more reminiscent of complicated UTIs. It also appears that HIV-positive patients with UTIs have a tendency for recurrence and require longer treatment.

Pregnancy

The prevalence of bacteriuria in pregnant women varies from 4% to 7%, and the incidence of acute clinical pyelonephritis ranges from 25% to 35% in untreated bacteriuric women (Stamey, 1980). This is probably the result of dilation of the ureters and pelvis of the kidney secondary to pregnancy-related hormonal alterations. In addition, urine obtained from pregnant women exhibits a more suitable pH for growth of *E. coli* in all stages of gestation (Asscher et al, 1973). **It is not surprising that untreated bacteriuria in the first trimester is accompanied by a substantial increase in the incidence of acute pyelonephritis, because half of these women have upper tract bacteriuria** (Fairley et al, 1966). Untreated bacteriuria involving these dilated upper tracts would be expected to produce a significant number of abnormalities that should be radiologically apparent. Kincaid-Smith and Bullen (1965) performed a culture on 4000 women at their first antenatal visit. Of 240 bacteriuric women, 148 returned for excretory urography 6 weeks after delivery. Approximately 40% of these patients had radiologic abnormalities consistent with pyelonephritis or analgesic nephritis. Brumfitt and colleagues (1967) showed that the incidence of radiologic abnormalities in bacteriuria of pregnancy was proportional to the difficulty in clearing the infection. Patients who responded promptly to a single course of therapy had a 23% incidence of radiologic abnormalities, but those who remained bacteriuric despite repeated therapeutic efforts had a 65% incidence of radiologic changes. Thus prolonged bacteriuria and pyelonephritis of pregnancy appear to be associated with significant radiologic abnormalities. However, there is little evidence to suggest that bacteriuria of pregnancy or acute pyelonephritis of pregnancy causes these renal radiologic abnormalities.

Spinal Cord Injury with High-Pressure Bladders

Of all patients with bacteriuria, no group compares in severity and morbidity with those who have spinal cord injury. Nearly all these patients require catheterization early after their injuries because of bladder overactivity or flaccidity, and significant numbers develop ureterectasis, hydronephrosis, reflux, and renal calculi. Bacteriologic and urodynamic advances in the management of these patients have vastly reduced their morbidity and mortality. Special problems associated with spinal cord injury are presented in a later section.

Key Points: Pathogenesis

- Most UTIs are caused by bacteria, usually originating from the bowel flora.
- Bacterial virulence factors, including adhesin, play a role in determining which bacteria invade and the extent of infection.
- Increased epithelial cell receptivity predisposes patients to recurrent UTIs and is a genotypic trait.
- Obstruction to urine flow is a key factor in increasing host susceptibility to UTIs.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Cystitis is usually associated with dysuria, frequency, and/or urgency. Suprapubic pain and hematuria are less common. Lower tract symptoms are commonly present and usually predate the appearance of upper tract symptoms by several days. Pyelonephritis is classically associated with fever, chills, and flank pain. Nausea and vomiting may be present. Renal or perirenal abscess may cause indolent fever and flank mass and tenderness. In the elderly the symptoms may be much more subtle (e.g., epigastric or abdominal discomfort) or the patient may be asymptomatic (Romano and Kaye, 1981). Patients with indwelling catheters often have asymptomatic bacteriuria, but fever associated with bacteremia may occur rapidly and become life threatening.

Diagnosis

Presumptive diagnosis of UTI is made by direct or indirect analysis of the urine and is confirmed by urine culture. The urine and the urinary tract are normally free of bacteria and inflammation. False-negative urinalysis and culture can occur in the presence of UTI, particularly early in an infection when the numbers of bacteria and WBCs are low or diluted by increased fluid intake and subsequent diuresis. Occasionally, the urine may be free of bacteria and WBCs despite bacterial colonization and inflammation of the uroepithelium (Elliott et al, 1985; Hultgren et al, 1985). False-positive urinalysis and culture are caused by contamination of the urine specimen with bacteria and WBCs during collection. This is most likely to occur in voided specimens but can also occur during urethral catheterization. Suprapubic aspiration of bladder urine is least likely to cause contamination of the specimen; therefore it provides the most accurate assessment of the status of bladder urine.

Urine Collection

Voided and Catheterized Specimens. **Diagnostic accuracy can be improved by reducing bacterial contamination when the urine is collected.** In circumcised men, voided specimens require no preparation. For men who are not circumcised, the foreskin should be retracted and the glans penis washed with soap and then rinsed with water before specimen collection. The first 10 mL of urine (representative of the urethra) and a midstream specimen (representative of the bladder) should be obtained. Prostatic fluid is obtained by performing digital prostatic massage and collecting the expressed prostatic fluid on a glass slide. In addition, collection of the first 10 mL of voided urine after massage will reflect the prostatic fluid added to the urethral specimen. **Catheterization of a male patient for urine culture is not indicated unless the patient cannot urinate.**

In women, contamination of a midstream urine specimen with introital bacteria and WBCs is common, particularly when the woman has difficulty spreading and maintaining separation of the labia. Therefore the female should be instructed to spread the labia, wash and cleanse the periurethral area with a moist gauze, and then collect a midstream urine specimen. Cleansing with antiseptics is not recommended because they may contaminate the voided specimen and provide a false-negative urine culture. **The voided specimen is contaminated if it shows evidence of vaginal epithelial cells and lactobacilli on urinalysis, and a catheterized specimen should be collected.**

Catheterization and collection of a midcathterized specimen is more accurate than a voided specimen but carries a risk of iatrogenic infection. **Although a single dose of an oral antimicrobial agent, such as trimethoprim-sulfamethoxazole (TMP-SMX) may be effective for prophylaxis, because antimicrobial usage encourages development of bacterial resistance, prophylaxis should be limited to high-risk patients. Men should be catheterized for a urine culture if they cannot urinate.**

Suprapubic Aspiration. Suprapubic aspiration is highly accurate, but because it carries some morbidity there is limited clinical usefulness except for a patient who cannot urinate on command, such as patients with spinal cord injuries. It is highly useful in newborns (Newman et al, 1967) and in patients with paraplegia. A single aspirated specimen reveals the bacteriologic status of the bladder urine without introducing urethral bacteria, which can start a new infection.

Before a suprapubic aspiration is performed, the patient should force fluids until the bladder is full. The site of the needle puncture is in the midline, between the symphysis pubis and the umbilicus and directly over the palpable bladder. The full bladder in the male is usually palpable because of its greater muscle tone; unfortunately, the full bladder in the female is frequently not palpable. In such patients, the physician performing the aspiration must rely on the observation that suprapubic pressure directly over the bladder produces an unmistakable desire to urinate. After determining the approximate site for needle puncture, the local area is shaved and the skin is cleansed with an alcohol sponge; a cutaneous wheal is raised with a 25-gauge needle and any local anesthetic. A 3.5-inch spinal, 22-gauge needle is introduced through the anesthetized skin. The progress of the needle is arrested just below the skin within the anesthetized area, and with a quick plunging action, similar to that of any intramuscular injection, the needle is advanced into the bladder. Most patients experience more discomfort from the initial anesthetization of the skin than they feel during the second stage when the needle is advanced into the bladder. After the needle has been introduced, a 20-mL syringe is used to aspirate 5 mL of urine for culture and 15 mL of urine for centrifugation and urinalysis. The obturator is reintroduced into the needle, and both needle and obturator are withdrawn. A small dressing is placed over the needle site in the skin. If urine is not obtained with complete introduction of the needle, the patient's bladder is not full and is usually deep within the retropubic area. When no urine is obtained on the first attempt, it is probably wise to wait until the bladder is full.

Urinalysis

For patients with urinary symptoms, microscopic urinalysis for bacteriuria, pyuria, and hematuria should be performed. Urinalysis provides rapid identification of bacteria and WBCs and presumptive diagnosis of UTI. Usually, the sediment from a 5- to 10-mL specimen obtained by centrifugation for 5 minutes at 2000 rpm is analyzed. Microscopic bacteriuria is found in more than 90% of infections with counts of 10^5 colony-forming units (cfu) per milliliter of urine or greater and is a highly specific finding (Stamm, 1982; Jenkins et al, 1986). However, bacteria are usually not detectable microscopically with lower colony count infections (10^2 to 10^4/mL). **This important error (i.e., a false-negative result) occurs because of the limitation imposed by the microscope on the volume of urine that can be observed.** If the volume of urine that can easily rest beneath a standard 22-mm cover glass is carefully measured (0.01 mL) and the number of high dry fields (×570 magnification) present beneath the cover glass is estimated, it is disturbing to find that one high dry field represents a volume of approximately 1/30,000 mL. There are excellent studies showing that the bacterial count must be approximately 30,000/mL before bacteria can be found in the sediment, stained or unstained, spun or unspun (Sanford et al, 1956; Kunin, 1961). For these reasons, a negative urinalysis for bacteria never excludes the presence of bacteria in numbers of 30,000/mL and less.

The second error of urinalysis (i.e., a false-positive result) is the reverse of the first error: bacteria are seen in the microscopic sediment but the urine culture shows no growth. The voided urine from a female patient can contain many thousands of lactobacilli and corynebacteria. These bacteria are readily seen under the microscope; and although they are gram-positive, they often appear gram-negative (gram-variable) if stained. Strict anaerobes, usually gram-negative bacilli, also make

up a significant mass of the normal vaginal flora (Marrie et al, 1978).

In practice, these problems can be minimized by using other information provided by urinalysis that can help the clinician to decide whether a patient has a UTI (Stamm et al, 1982b). **The validation of the midstream urine specimen can be questioned if numerous squamous epithelial cells (indicative of preputial, vaginal, or urethral contaminants) are present.**

Pyuria and hematuria are good indicators of an inflammatory response. Although the number of WBCs per high-power field in a centrifuged urine sample is useful, it is important to remember that other factors can influence the number of cells seen. These include the state of hydration; the intensity of tissue reaction; the method of urine collection; the volume, speed, and time of centrifugation; and the volume in which the sediment is resuspended.

The presence of bacteruria has a sensitivity of 40% to 70% and a specificity of 85% to 95%, depending on the number of bacteria observed (Fihn, 2003).

Significant pyuria can be determined simply and reliably with a microscope by accurately examining the centrifuged sediment or by using a hemocytometer to count the number of WBCs in the unspun urine. One to 2 WBCs per high-power field (HPF) in sediment from a centrifuged specimen represents about 10 WBCs/mm^3 in an unspun specimen. More than 2 WBCs per HPF in a centrifuged specimen or 10 WBCs/mm^3 of urine correlates well with the presence of bacteriuria and is rarely seen in nonbacteriuric patients (Stamm et al, 1981). **In clinical studies, determination of pyuria in voided urine specimens has a reported sensitivity of 80% to 95% and a specificity of 50% to 76% for UTI (depending on the definition of infection, the patient population, and the method used to evaluate for pyuria)** (Stamm, 1982; Schultz et al, 1984; Wong et al, 1984; Wigton et al, 1985).

The absence of pyuria should cause the diagnosis of UTI to be questioned until urine culture data are available. Conversely, many diseases of the urinary tract produce significant pyuria in the absence of bacteriuria. Whereas tuberculosis is the well-recognized example of abacterial pyuria, staghorn calculi and stones of smaller size can produce intense pyuria with clumps of WBCs in the absence of UTI. Almost any injury to the urinary tract, from chlamydial urethritis to glomerulonephritis and interstitial cystitis, can elicit large numbers of fresh polymorphonuclear leukocytes (glitter cells). Depending on the stage of hydration, the intensity of the tissue reaction producing the cells, and the method of urine collection, any number of WBCs can be seen in the microscopic sediment in the presence of an uninfected urinary tract.

Microscopic hematuria is found in 40% to 60% of cases of cystitis and is uncommon in other dysuric syndromes (Stamm et al, 1980b; Wigton et al, 1985).

Rapid Screen Methods. Biochemical and enzymatic tests have been devised to detect bacteriuria and pyuria (Pezzlo, 1988). The Griess test detects the presence of nitrite in urine that is formed when bacteria reduce the nitrate normally present in urine. Tests for detecting pyuria by determining leukocyte esterase activity have also been developed (Chernow et al, 1984). In a study comparing traditional urine culture with these indirect tests, the combination of nitrite and leukocyte esterase tests (either test positive) had a sensitivity of 71% and a specificity of 83% when compared with 10^3 cfu/mL or greater of urine cultures (Pfaller and Koontz, 1985). However, several investigators (Pels et al, 1989; Hurlbut and Littenberg, 1991) noted substantial variability in the sensitivity and specificity results, which could be markedly influenced by the types of patients and infections chosen to evaluate the tests. This concept of spectrum bias was illustrated by a study that reported differences in the sensitivity of reagent strip testing, ranging from 56% to 92%, by changing only the groups of patients included in the analysis. Although false-positive results are relatively uncommon, the borderline sensitivity of these tests, especially among patients with less characteristic symptoms of UTIs, does not allow these inexpensive tests to replace careful microscopic urinalysis in symptomatic patients (Semeniuk and Church, 1999). **Their main role is in screening asymptomatic patients** (Pezzlo, 1988).

Urine Culture

Two techniques for urine culture are available. Direct surface plating of a known amount of urine on split-agar disposable plates is the traditional quantitative culture technique used by most microbiology laboratories. One half of the plate is blood agar, which grows both gram-positive and gram-negative bacteria, and the other is desoxycholate or eosin-methylene blue (EMB), which grows gram-negative bacteria (some of them, such as *E. coli*, in a very characteristic manner). Simple curved-tip eye droppers are sufficient to deliver about 0.1 mL of urine onto each half of the plate. After overnight incubation, the number of colonies is estimated, often identified (after some experience), and multiplied by 10 to report the number of cfu per milliliter of urine. The technique has been presented elsewhere in detail (Stamey, 1980).

A simpler but somewhat less accurate technique is the use of dip slides (Fig. 10–10). These inexpensive plastic slides are attached to screw-top caps; they have soy agar (a general nutrient agar to grow all bacteria) on one side and EMB or MacConkey agar for gram-negative bacteria on the opposite side. A slide is dipped into urine, the excess is allowed to drain off, and the slide is replaced in its plastic bottle and incubated. The volume of urine that attaches to the slide is between 1/100 mL and 1/200 mL. Hence, the colony count is 100 to 200 times the number of colonies that become visible with incubation. In actual practice, the growth is compared with a visual standard and reported as such. The species

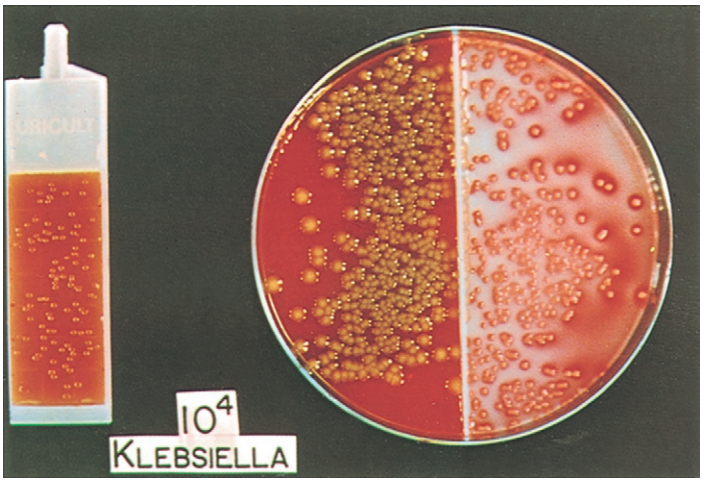

Figure 10–10. The dip slide on the left is compared with a split-agar surface plate on the right. The urine contained 10,000 colonies of *Klebsiella* per milliliter (about 200 times the number of colonies on the dip slide and 10 times the number on either side of the split-agar plate).

of bacteria is more difficult to recognize when this technique is used, but the technique is completely adequate.

The urine must be refrigerated immediately on collection and should be cultured within 24 hours of refrigeration. One advantage to the dip slide is the ease with which the urine can be immediately cultured without the necessity of refrigeration. Patients can culture their own urine at home, keep the slide at room temperature, and bring it to the office within 48 hours.

Although most bacteria allowed to incubate for several hours in bladder urine reach cfu counts of 10^5/mL, this statistical number is fraught with two limitations. The first is that 20% to 40% of women with symptomatic UTIs present with bacteria counts of 10^2 to 10^4 cfu/mL of urine (Stamey et al, 1965; Mabeck, 1969; Kunz et al, 1975; Kraft and Stamey, 1977), probably because of the slow doubling time of bacteria in urine (every 30 to 45 minutes) combined with frequent bladder emptying (every 15 to 30 minutes) from irritation. **Thus, in dysuric patients, an appropriate threshold value for defining significant bacteriuria is 10^2 cfu/mL of a known pathogen** (Stamm and Hooton, 1993). Fortunately, most of these patients have symptoms of UTI and pyuria on urinalysis.

The second limitation of the 10^5 cutoff is overdiagnosis. Women susceptible to infection often carry large numbers of pathogenic bacteria on the perineum that contaminate otherwise sterile bladder urine. Uncircumcised men may harbor uropathogenic bacteria on their foreskins. In the original studies by Kass (1960), a single culture of 10^5 cfu/mL or more had a 20% chance of representing contamination. There is no statistical way to avoid these two major limitations on the interpretation of the midstream voided culture in women and in uncircumcised men without careful preparation.

Localization

Kidney

Fever and Flank Pain. Fever and flank pain are thought to indicate pyelonephritis, but few studies have tested the hypothesis. Aggressive localization studies in children and adults (Huland and Busch, 1982; Busch and Huland, 1984), as well as in patients with end-stage renal disease (Huland et al, 1983), have shown substantial incidences of fever and even flank pain in bacteriuric patients in whom infection was localized to the bladder (see later section on Acute Pyelonephritis).

Ureteral Catheterization. **Ureteral catheterization allows not only separation of bacterial persistence into upper and lower urinary tracts but also separation of the infection between one kidney and the other, and even localization of infection to ectopic ureters or to nonrefluxing ureteral stumps (by using saline solution irrigation)** (Stamey, 1980).

Stamey began in 1959 to localize the site of bacteriuria by ureteral catheterization studies; the technique was published in 1963 (Stamey and Pfau, 1963) and the results in 1965 (Stamey et al, 1965). The technique is simple but exacting; the urologist should consult a more detailed description (Stamey, 1980) before actually performing this localization technique. The validity depends on controlling the number of bacteria from the bladder that contaminate the ureteral catheters as they pass through the bladder into the ureteral orifices. The bladder must be thoroughly irrigated before both ureteral catheters are passed into a small volume of residual irrigating fluid. A sample is obtained through both ureteral catheters simultaneously, and then each catheter is passed into the ureter or renal pelvis. Four serial cultures are obtained from each kidney. It is mandatory that the patient be started on the appropriate antimicrobial agent before leaving the cystoscopy room. In addition to quantitative bacterial counts on each specimen, determination of either specific gravity or urine creatinine levels on the renal samples can be very helpful in interpreting a change in diuresis in relation to bacterial counts. Examples of infections localized to the bladder, to one kidney, and to both kidneys have been published (Stamey, 1980). Clinical examples of results from each site are shown in Table 10–3.

When this technique was applied to large numbers of bacteriuric patients, 45% were found to have bladder infection only; 27%, unilateral renal bacteriuria; and 28%, bilateral renal bacteriuria (Table 10–4) (Stamey et al, 1965). These figures have been confirmed by at least five investigators in three countries (the United States, England, and Australia) and can be taken as a good approximation for any general bacteriuric adult population. **Although renal stones and other kidney abnormalities in the presence of bacteriuria can increase the proportion of renal infections, the urologist should never assume the kidney is involved if an important decision is to be made.**

Tissue and Stone Cultures. It is clinically useful to culture stones removed from the urinary tract to document that bacteria reside within their interstices. Tissue cultures are primarily useful for research information.

Table 10–3.

Clinical Examples of Ureteral Catheterization Studies in Localizing the Site of Bacteriuria

SOURCE OF RENAL INFECTION	BLADDER INFECTION (BACTERIA/mL)	LEFT RENAL INFECTION (BACTERIA/mL)	RIGHT RENAL INFECTION (BACTERIA/mL)	BILATERAL (BACTERIA/mL)
CB	$>10^5$	5000	$>10^5$	4000
WB	900	300	1000	20
LK_1	20	2000	20	400
LK_2	0	2200	0	350
LK_3	0	2500	0	500
LK_4	0	2200	0	400
RK_1	10	0	10,000	260
RK_2	0	0	10,000	220
RK_3	0	0	8000	300
RK_4	0	0	12,000	250

CB, catheterized patient, cystoscopic specimen; LK_1, LK_2, etc., serial cultures of urine from the left kidney; RK_1, RK_2, etc., serial cultures of urine from the right kidney; WB, controlled, "wash bladder" specimen collected after copious irrigation of the bladder.

Table 10–4.

Localization of UTIs in 95 Females and 26 Males with Bacteriuria

NO. PATIENTS	BLADDER ONLY	UNILATERAL RENAL BACTERIURIA	BILATERAL RENAL BACTERIURIA
95 females	38 (40%)	27 (28%)	30 (32%)
26 males	16 (62%)	6 (26%)	4 (15%)
121 combined	54 (45%)	33 (27%)	34 (28%)

From Stamey TA, Govan DE, Palmer JM. The localization and treatment of urinary tract infections: the role of bactericidal urine levels as opposed to serum level. Medicine 1965;44:1.

Using sterile technique at the operating table, the surgeon places the stone or fragment of tissue into a sterile culture tube containing 5 mL of saline solution; the culture is packed in ice and sent to the bacteriologic laboratory, where, after agitation of the stone or tissue in the 5 mL of saline solution, 0.1 mL is surface-streaked on both blood agar and EMB agar. The saline solution is then poured off the specimen; and, with sterile forceps, the stone or tissue is transferred to a second 5 mL of sterile saline solution. After agitation to ensure a reasonable washing action, the saline solution is again decanted and the specimen is transferred to a third 5 mL of saline solution and finally to a fourth 5 mL of saline solution. This last saline solution wash is cultured quantitatively in the same manner as the first. The remainder of this fourth 5 mL of saline solution is poured with the stone into a sterile mortar and pestle dish.

After the stone is crushed (or the tissue is ground in a tissue blender) in the fourth saline solution wash, 0.1 mL is again cultured on both blood agar and EMB agar. The difference in colony counts between the first and the fourth saline solution washes represents the washing effect of the saline solution transfers on the surface bacteria of the stone or tissue. The difference between the fourth saline wash before and after crushing (or grinding, for tissue) represents the difference between surface bacteria and bacteria within the specimen.

Prostate and Urethral Localization Studies. The technique for localizing infections to the urethra or prostate is covered in detail in Chapter 11.

Key Points: Clinical Manifestations

- The urine and the urinary tract are normally sterile.
- Bacteriuria and WBCs provide a presumptive diagnosis of UTI.
- In diagnosing patients, 10^2 cfu/mL confirms a symptomatic UTI.

IMAGING TECHNIQUES

Imaging studies are not required in most cases of UTI because clinical and laboratory findings alone are sufficient for correct diagnosis and adequate management of most patients. However, infection in most men or a compromised host, febrile infections, signs or symptoms of urinary tract obstruction, failure to respond to appropriate therapy, and a pattern of recurrent infections suggesting bacterial persistence within the urinary tract warrant imaging for identification of underlying abnormalities that require modification of medical management or percutaneous or surgical intervention.

Table 10–5.

Indications for Radiologic Investigation in Acute Clinical Pyelonephritis

Potential ureteral obstruction (e.g., due to stone, ureteral stricture, tumor)
History of calculi, especially infection (struvite) stones
Papillary necrosis (e.g., patients with sickle cell anemia, severe diabetes mellitus, analgesic abuse)
History of genitourinary surgery that predisposes to obstruction, such as ureteral reimplantation or ureteral diversion
Poor response to appropriate antimicrobial agents after 5 to 6 days of treatment
Diabetes mellitus
Polycystic kidneys in patients in dialysis or with severe renal insufficiency
Neuropathic bladder
Unusual infecting organisms, such as tuberculosis, fungus, or urea-splitting organisms (e.g., *Proteus*)

Indications

Radiologic studies are unnecessary for evaluation of most women with genitourinary infections. Several reports of women patients with recurrent UTIs show that excretory urograms are unnecessary for routine evaluation if women who have special risk factors are excluded (Fair et al, 1979; Engel et al, 1980; Fowler and Pulaski, 1981; Fairchild et al, 1982). In none of these studies was information that was useful in the management of these patients obtained from excretory urograms. Furthermore, excluding excretory urograms in the routine evaluation of such patients represents a substantial financial saving.

However, in high-risk patients, including women with febrile infections and most men, radiologic studies may determine acute infectious processes that require further intervention or may find the cause of complicated infections.

First, radiologic procedures are needed in patients with risk factors that may require intervention in addition to antimicrobial treatment (Table 10–5).

A UTI associated with possible urinary tract obstruction must be evaluated. These are patients with calculi, especially infection (struvite) stones; ureteral tumors; ureteral strictures; congenital obstructions; or previous genitourinary surgery, such as ureteral reimplantation or urinary diversion procedures that may have caused obstruction. Patients with diabetes mellitus can develop special complications from UTIs; they may acquire emphysematous pyelonephritis or papillary necrosis. Impacted necrotic papillae may cause acute ureteral obstruction. Patients with polycystic kidney disease who are on dialysis are particularly prone to developing perinephric abscesses.

Urologic imaging is indicated in patients whose symptoms of acute clinical pyelonephritis persist after 5 to 6 days of appropriate antimicrobial therapy; they often have perinephric or renal abscesses. In addition, patients with unusual organisms, including urea-splitting organisms (e.g., *Proteus* species), should be examined for abnormalities within the urinary tract, such as obstructing stones, strictures, or fungus balls.

Table 10–6.

Correctable Urologic Abnormalities That Cause Bacterial Persistence

Infection stones
Chronic bacterial prostatitis
Unilateral infected atrophic kidneys
Ureteral duplication and ectopic ureters
Foreign bodies
Urethral diverticula and infected periurethral glands
Unilateral medullary sponge kidneys
Nonrefluxing, normal-appearing, infected ureteral stumps after nephrectomy
Infected urachal cysts
Infected communicating cysts of the renal calyces
Papillary necrosis
Perivesical abscess with fistula to bladder

The second reason for radiologic evaluation is to diagnose a focus of bacterial persistence. **In patients whose bacteriuria fails to resolve after appropriate antimicrobial therapy or who have rapid recurrence of infection, abnormalities that cause bacterial persistence should be sought.** Although these patients are uncommon, it is important to identify them because they may have correctable urologic abnormalities that represent the only surgically curable causes of recurrent UTIs. Acquired or congenital urologic abnormalities that can cause unresolved or recurrent UTIs are listed in Table 10–6.

Ultrasonography

The renal ultrasound study is an important renal imaging technique because it is noninvasive, easy to perform, and rapid and offers no radiation or contrast agent risk to the patient. It is particularly useful in identifying calculi and hydronephrosis, pyonephrosis, and perirenal abscesses. A single radiograph for calculi should accompany ultrasonography. Ultrasonography is also useful for diagnosing postvoid residual urine. A disadvantage is that the study is dependent on the interpretative and performance skills of the examiner. Furthermore, the study may be technically poor in patients who are obese or who have dressings, drainage tubes, or open wounds overlying the area of interest.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

The radiologic modalities that offer the best anatomic detail are CT and MRI. They are more sensitive than excretory urography or ultrasonography in the diagnosis of acute focal bacterial nephritis, renal and perirenal abscesses, and radiolucent calculi (Kuhn and Berger, 1981; Mauro et al, 1982; Wadsworth et al, 1982; Soulen et al, 1989; Soler et al, 1997). When used to localize renal and perirenal abscesses, CT improves the approach to surgical drainage and permits percutaneous approaches. MRI has not superseded CT in the evaluation of renal inflammation, but it has provided some advantages in delineating extrarenal extension of inflammation.

Voiding Cystourethrography

The voiding cystourethrogram is an important examination in assessing vesicoureteral reflux. It may be used to evaluate patients with neuropathic bladders and the rare female patient who has a urethral diverticulum causing her persistent infections.

Radionuclide Studies

Hippuran I-131 and technetium-99m (^{99m}Tc) glucoheptonate scans are used to detect focal parenchymal damage, renal function impairment, and decreased renal perfusion in acute renal infections (McAfee, 1979). Although gallium-67 scanning has been reported to be useful in the diagnosis of pyelonephritis and renal abscess, it is uncommonly required and may be positive in noninfectious entities. Indium-111–labeled WBC studies have limited efficacy in establishing the presence of an inflammatory focus, particularly when the patient's clinical presentation does not suggest an infectious process.

Key Points: Imaging Techniques

- Imaging studies are not required in most women with UTIs.
- Men and compromised patients or those who do not respond to therapy require imaging to identify abnormalities.
- CT and MRI provide the best anatomic data on the site, cause, and extent of infection.

PRINCIPLES OF ANTIMICROBIAL THERAPY

Therapy for UTIs must ultimately eliminate bacterial growth in the urinary tract. This can occur within hours if the proper antimicrobial agent is used (Stamey, 1980). **Efficacy of the antimicrobial therapy is critically dependent on the antimicrobial levels in the urine and the duration that this level remains above the minimal inhibitory concentration of the infecting organism** (Hooton and Stamm, 1991). **Hence, resolution of infection is closely associated with the susceptibility of the bacteria to the concentration of the antimicrobial agent achieved in the urine** (McCabe and Jackson, 1965; Stamey et al, 1965, 1974). The concentration of useful antimicrobial agents in the serum and urine of healthy adults is shown in Table 10–7, which demonstrates that the urinary levels are often several hundred times greater than the serum levels. Inhibitory concentrations in urine are achieved after oral administration of all commonly used antimicrobial agents, except for the macrolides (erythromycin). The question of serum levels versus urinary levels is a practical one because the policy of testing antimicrobial susceptibility agents at concentrations obtainable only in the serum discourages the physician from using drugs that are effective at the urinary level; for example, oral penicillin G for *E. coli* and *Proteus mirabilis* and tetracycline for *P. aeruginosa*.

The concentration of the antimicrobial agent achieved in blood is not important in treatment of uncomplicated UTIs. However, blood levels are critical in patients with bacteremia and febrile urinary infections consistent with parenchymal involvement of the kidney and prostate.

In patients with renal insufficiency, dosage modifications are necessary for agents that are cleared primarily by the kidneys and cannot be cleared by another mechanism. In renal failure, the kidneys may not be able to concentrate

Table 10–7.

Serum and Urinary Antimicrobial Levels in Adults*

ANTIMICROBIAL AGENT	DOSE (mg)	PEAK SERUM LEVEL (mg/L)	PERCENTAGE BOUND TO PROTEIN	HALF-LIFE SERUM PEAK (hr)	MEAN (ACTIVE) URINE LEVELS* (g/mL)	DOSE EXCRETED IN URINE (%)	DOSE ACTIVE IN URINE (IF DIFFERENT) (%)
Ampicillin	250 PO qid	3 at 2 hr	15	1	350	42	–
Carbenicillin	764 PO qid	11-17 at 1.5 hr	60	1.2	1000	40	–
Cephalexin	250 PO qid	9 at 2 hr	12	0.9	800	98	–
Ciprofloxacin	500 PO bid	2.3 at 1.2 hr	35	3.9	200	30	–
Colistin	75 IM bid	1.8 at 4 hr	10	2	34	75	50
Gentamicin	1 mg/kg IM tid (200 mg/day)	4 at 1 hr	Negligible	2	125	80	–
Kanamycin	500 IM bid	18 at 1 hr	Negligible	2	750	94	–
Levofloxacin	500 mg PO qd	6.0 mg/L	30-50	6	N/A	95	95
Nalidixic acid	1000 PO qid	34 at 2-23 hr	85	1.5	75	79	5
Nitrofurantoin	100 PO qid	<2		0.3	150	42	–
Norfloxacin	400 PO bid	1.5 at 1.5 hr	15	3.3	170	27	–
Penicillin G	500 PO qid	1 at 1 hr	60	0.5	300	20	–
Sulfamethizole	250 PO qid		98	10	700	95	85
Tetracycline hydrochloride	250 PO qid	2-3 at 4 hr	31	6	500	60	–
TMP-SMX	160/800 PO bid	1.7/32 at 2 hr	45/66	10/9	150/400	55/50	–/37
Trimethoprim	100 PO bid	1.0 at 2-4 hr	45	10	92	55	–

TMP-SMX, trimethoprim-sulfamethoxazole.
*These average urinary concentrations are based on the amount of biologically active drug excreted by normal kidneys at a urine flow rate of 1200 mL/24 hr.
Modified from Stamey TA. The pathogenesis and treatment of urinary infections. Baltimore: Williams & Wilkins; 1980. p. 59.

an antimicrobial agent in the urine; hence, difficulty in eradicating bacteria may occur. Urinary tract obstruction may also reduce concentration of antimicrobial agents within the urine.

A decision regarding the antimicrobial selection and the duration of therapy must consider the spectrum of activity of the drug against the known pathogen or the most probable pathogens based on the presumed source of acquisition of infection, whether the infection is judged to be uncomplicated or complicated, potential adverse effects, and cost. An often underemphasized but important characteristic is the drug's impact on the bowel and vaginal flora and the hospital bacterial environment. Bacterial susceptibility will vary dramatically in patients exposed to antimicrobial agents and in individuals in inpatient and outpatient settings. It is imperative that each clinician keep abreast of changes that affect antimicrobial use and susceptibility patterns.

Bacterial Resistance

In the past several years, the frequency and spectrum of antimicrobial-resistant UTIs have increased in both the hospital and community. The increasing frequency of drug resistance has been attributed to combinations of microbial characteristics, bacterial selection pressure due to antimicrobial use, and societal and technologic changes that enhance the transmission of drug resistance (Cohen, 1992).

Bacterial resistance may occur because of inherited chromosomal-mediated resistance or by acquired chromosomal- or extrachromosomal (plasmid)-mediated resistance due to exposure of an organism to antimicrobial agents.

Inherited chromosomal resistance exists in a bacterial species because of the absence of the proper mechanism on which the antimicrobial agent can act. For example, *Proteus* and *Pseudomonas* species are always resistant to nitrofurantoin.

Acquired chromosomal resistance occurs during therapy for UTIs. Before antimicrobial therapy, relatively resistant bacteria called mutators may be present in the urine at very low concentrations. Frequencies in mutations for high-level antimicrobial resistance are 1000-fold higher in mutators than in normal strains, indicating the increased adaptability of these strains (Miller et al, 2004). The remainder of the bacteria, which are susceptible to the administered antimicrobial agent, will be eradicated by therapy, but within 24 to 48 hours a repeat urine culture will show high bacterial counts of the resistant mutant. In essence, the antimicrobial therapy has selected out the resistant mutant. This phenomenon is most likely to occur when the antimicrobial level in the urine is close to or below the minimal inhibitory concentration of the drug. **Selection of resistant clones in the course of therapy for a previously sensitive bacteriuric population occurs between 5% and 10% of the time, clearly not an insignificant factor and one that must be considered in resolving bacteriuria.** Underdosing and noncompliance, as well as diuresis induced by increased fluid intake, can contribute to this process. Therefore the clinician should select an antimicrobial agent with a urinary concentration that exceeds the minimal inhibitory concentration by the widest margin possible, avoid underdosing, and emphasize patient compliance.

Extrachromosomal-mediated resistance may be acquired and transferable via plasmids, which contain the genetic material for the resistance. **This so-called R-factor resistance occurs in the bowel flora and is much more common than selection of preexisting mutants in the urinary tract. All antimicrobial classes are capable of causing plasmid-mediated resistance. However, for the fluoroquinolones resistance is rarely transmitted by plasmids and nitrofurantoin plasmid-mediated resistance has not been reported.** Therefore patients previously exposed to β-lactams, aminoglycosides, sulfonamides, TMP, and tetracycline will often have R-factor resistance to both the antimicrobial agent to which

the bacteria were exposed and also to other antimicrobial agents. In addition, the plasmids carrying the resistant genetic material are transferable both within species and across genera. Thus, for example, a patient receiving tetracycline may harbor several bowel strains that are resistant to tetracycline, ampicillin, sulfonamides, and TMP. **Because the bowel flora is the major reservoir for bacteria that ultimately colonize the urinary tract, infections that occur after antimicrobial therapy and that can cause plasmid-mediated resistance are commonly caused by organisms with multidrug resistance. However, resistant *E. coli* in the bowel flora that infect the urinary tract almost always show susceptibility to nitrofurantoin or to the quinolones.**

Antimicrobial resistance is also influenced by the duration and amount of antimicrobial agent used. For example, documented increased use of fluoroquinolones in the hospital setting has been directly associated with increased resistance of bacteria (particularly *Pseudomonas*) to the fluoroquinolones. Resistance tends to increase the longer the agent is used. Conversely, reduction in duration of therapy and in the amount of the drug used may lead to reemergence of more susceptible strains.

Most studies reporting antimicrobial resistance have been based on surveys of laboratory isolates, generally without correlation with clinical or epidemiologic factors (e.g., the presence and nature of symptoms, age, sex, and whether the infection was complicated). Gupta and colleagues (1999) determined the prevalence of and trends in antimicrobial resistance among uropathogens isolated from a large, well-defined population of women with acute uncomplicated cystitis. Over a 5-year period, the prevalence of resistance to TMP/SMX, ampicillin, and cephalothin increased significantly, whereas resistance to nitrofurantoin and ciprofloxacin remained uncommon. **However, fluoroquinolone resistance of *E. coli* has increased from less than 1% to 10% in hospitalized patients** (Karlowsky et al, 2003). In a transplant unit, where fluoroquinolones are commonly administered prophylactically, *E.* coli resistance can be 80%. **Previous use of fluoroquinolones and the presence of underlying urologic diseases were the strongest determinants for UTIs caused by resistant strains** (Ena et al, 1995). Fluoroquinolone resistance is an increasing problem in some European countries. A multiple-resistant phenotype involving fluoroquinolone resistance is now present in most countries in Europe, and this phenotype is selected for not only by the use of quinolones but also by the use of ampicillin, sulfamethoxazole, and TMP/SMX (Kahlmeter and Menday, 2003). This is a concern because fluoroquinolones, which are associated with chromosomal-mediated but not plasmid-mediated resistance, are the current drug of choice for patients who have been exposed to agents causing plasmid-mediated resistance.

The clinical significance of these in-vitro trends in resistance has been addressed in studies that correlated in-vitro resistance to TMP/SMX with clinical outcome in uncomplicated cystitis and pyelonephritis (Gupta and Stamm, 2002). Clinical failures occurred in 40% to 50% of women if the bacteria were resistant and the bacteriologic failure approached 60%. (For further information on the role of TMP-SMX in prophylaxis, see Bladder Infections, later in this chapter.)

Antimicrobial Formulary

The mechanism of action, reliable coverage, and common adverse reactions, precautions, and contraindications for antimicrobial agents used in the treatment of UTIs are indicated in Tables 10–8, 10–9, and 10–10, respectively.

Table 10–8.

Mechanism of Action of Common Antimicrobials Used in the Treatment of UTIs

DRUG OR DRUG CLASS	MECHANISM OF ACTION	MECHANISMS OF DRUG RESISTANCE
β-Lactams (penicillins, cephalosporins, aztreonam)	Inhibition of bacterial cell wall synthesis	Production of β-lactamase Alteration in binding site of penicillin-binding protein Changes in cell wall porin size (decreased penetration)
Aminoglycosides	Inhibition of ribosomal protein synthesis	Downregulation of drug uptake into bacteria Bacterial production of aminoglycoside-modifying enzymes
Quinolones	Inhibition of bacterial DNA gyrase	Mutation in DNA gyrase-binding site Changes in cell wall porin size (decreased penetration) Active efflux
Nitrofurantoin	Inhibition of several bacterial enzyme systems	Not fully elucidated—develops slowly With prolonged exposure
Trimethoprim-sulfamethoxazole	Antagonism of bacterial folate metabolism	Draws folate from environment (enterococci)
Vancomycin	Inhibition of bacterial cell wall synthesis (at β-lactams)	Enzymatic alteration of peptidoglycan different point than target

Trimethoprim/Sulfamethoxazole

The combination of TMP-SMX has been the most widely used antimicrobial agent for the treatment of acute UTIs. TMP alone is as effective as the combination for most uncomplicated infections and may be associated with fewer side effects (Johnson and Stamm, 1989); however, the addition of SMX contributes to efficacy in the treatment of upper tract infection via a synergistic bactericidal effect and may diminish the emergence of resistance (Burman, 1986) and does attain therapeutic levels in most tissues. **TMP alone or in combination with SMX is effective against most common uropathogens, with the notable exception of *Enterococcus* and *Pseudomonas* species. TMP and TMP-SMX are inexpensive and have minimal adverse effects on the bowel flora. Disadvantages are relatively common adverse effects, consisting primarily of rashes and gastrointestinal complaints** (Cockerill and Edson, 1991). TMP-SMX should be avoided during pregnancy.

Nitrofurantoin

Nitrofurantoin is effective against common uropathogens, but it is not effective against *Pseudomonas* and

Table 10–9.

Reliable Coverage of Antimicrobials Used in the Treatment of UTIs of Commonly Encountered Pathogens*

ANTIMICROBIAL AGENT OR CLASS	GRAM-POSITIVE PATHOGENS	GRAM-NEGATIVE PATHOGENS
Amoxicillin or ampicillin	*Streptococcus* Enterococci	*Escherichia coli* *Proteus mirabilis*
Amoxicillin with clavulanate	*Streptococcus* Enterococci	*E. coli* *P. mirabilis* *Klebsiella* species
Ampicillin with sulbactam	*Staphylococcus* (not MRSA) Enterococci	*P. mirabilis* *Haemophilus influenzae, Klebsiella* species
Antistaphylococcal penicillins	*Streptococcus* *Staphylococcus* (not MRSA)	None
Antipseudomonal penicillins	*Streptococcus* Enterococci	Most, including *Pseudomonas aeruginosa*
First-generation cephalosporins	*Streptococcus* *Staphylococcus* (not MRSA)	*E. coli* *P. mirabilis* *Klebsiella* species
Second-generation cephalosporins (cefamandole, cefuroxime, cefaclor)	*Streptococcus* *Staphylococcus* (not MRSA)	*E. coli, P. mirabilis* *H. influenzae, Klebsiella* species
Second-generation cephalosporins (cefoxitin, cefotetan)	*Streptococcus*	*E. coli, Proteus* species (including indole-positive) *H. influenzae, Klebsiella* species
Third-generation cephalosporins (ceftriaxone)	*Streptococcus* *Staphylococcus* (not MRSA)	Most, excluding *P. aeruginosa*
Third-generation cephalosporins (ceftazidime)	*Streptococcus*	Most, including *P. aeruginosa*
Aztreonam	None	Most, including *P. aeruginosa*
Aminoglycosides	*Staphylococcus* (urine)	Most, including *P. aeruginosa*
Fluoroquinolones	*Streptococcus**	Most, including *P. aeruginosa*
Nitrofurantoin	*Staphylococcus* (not MRSA) Enterococci	Many Enterobacteriaceae (not *Providencia, Serratia, Acinetobacter*) *Klebsiella* species
Trimethoprim-sulfamethoxazole	*Streptococcus* *Staphylococcus*	Most Enterobacteriaceae (not *P. aeruginosa*)
Vancomycin	All, including MRSA	None

*Depends on the antimicrobial agent.
MRSA, methicillin-resistant *Staphylococcus aureus*.

***Proteus* species** (Iravani, 1991). **It is rapidly excreted from the urine but does not attain therapeutic levels in most body tissues, including the gastrointestinal tract. Therefore it is not useful for upper tract and complicated infections** (Wilhelm and Edson, 1987). **It has minimal effects on the resident bowel and vaginal flora and has been used effectively in prophylactic regimens for more than 40 years.** Acquired bacterial resistance to this drug is exceedingly low. Nitrofurantoin should be used only during the first two trimesters of pregnancy.

Cephalosporins

All three generations of cephalosporins have been used for the treatment of acute UTIs (Wilhelm and Edson, 1987). In general, as a group, activity is high against Enterobacteriaceae and poor against enterococci. First-generation cephalosporins have greater activity against gram-positive organisms as well as common uropathogens such as *E. coli* and *Klebsiella pneumoniae,* whereas second-generation cephalosporins have activity against anaerobes. Third-generation cephalosporins are more reliably active against community-acquired and nosocomial gram-negative organisms than other β-lactam antimicrobials. **Selective pressure engendered by these broad-spectrum agents should limit their use to complicated infections and situations in which parenteral therapy is required and resistance to standard antimicrobial agents is likely. They are also safe for use during pregnancy.**

Aminopenicillins

Ampicillin and amoxicillin have been used often in the past for the treatment of UTIs, but the emergence of resistance in 40% to 60% of common urinary isolates has lessened the usefulness of these drugs (Hooton and Stamm, 1991). The effects of these agents on the normal bowel and vaginal flora can predispose patients to reinfection with resistant strains and often lead to candidal vaginitis (Iravani, 1991). The addition of the β-lactamase inhibitor clavulanate to amoxicillin greatly improves activity against β-lactamase–producing bacteria resistant to amoxicillin alone. However, its high cost and frequent gastrointestinal side effects limit its usefulness. The extended-spectrum penicillin derivatives (e.g., piperacillin, mezlocillin, azlocillin) retain ampicillin's activity against enterococci and offer activity against many ampicillin-resistant gram-negative bacilli. **This makes them attractive agents for use in patients with nosocomially acquired UTIs and as the initial parenteral treatment of acute uncomplicated pyelonephritis acquired outside of the hospital, although less expensive agents are equally effective.**

Aminoglycosides

When combined with TMP-SMX or ampicillin, aminoglycosides are the first drugs of choice for febrile UTIs. Their nephrotoxicity and ototoxicity are well recognized; hence, careful monitoring of patients for renal

Table 10–10.

Common Adverse Reactions, Precautions, and Contraindications for Antimicrobial Agents Used in Treatment of UTI

DRUG OR DRUG CLASS	COMMON ADVERSE REACTIONS	PRECAUTIONS AND CONTRAINDICATIONS
Amoxicillin or ampicillin	Hypersensitivity (immediate or delayed) Diarrhea (esp. with ampicillin), GI upset AAPMC Maculopapular rash (not hypersensitivity) Decreased platelet aggregation	Increased risk of rash with concomitant viral disease, allopurinol therapy
Amoxicillin with clavulanic acid	Increased diarrhea, GI upset with amoxicillin/clavulanic acid	
Ampicillin with sulbactam	Same as amoxicillin with ampicillin	
Antistaphylococcal penicillins	Same as with amoxicillin/ampicillin GI upset (with oral agents) Acute interstitial nephritis (esp. with methicillin)	
Antipseudomonal penicillins	Same as with amoxicillin/ampicillin Hypernatremia (these drugs are given as sodium salt; esp. carbenicillin, ticarcillin) Local injection site reactions	Use with caution in patients very sensitive to sodium loading.
Cephalosporins	Hypersensitivity (less than with penicillins) GI upset (with oral agents) Local injection site reactions AAPMC Positive Coombs test Decreased platelet aggregation (esp. with cefotetan, cefamandole, cefoperazone)	Should not be used in patients with immediate hypersensitivity to penicillins; may use with caution in patients with delayed hypersensitivity reactions.
Aztreonam	Hypersensitivity (less than with penicillins)	Less than 1% incidence of cross reactivity in penicillin-or-cephalosporin-allergic patients; may be used with caution in these patients
Aminoglycosides	Ototoxicity: vestibular and auditory components Nephrotoxicity: nonoliguric azotemia Neuromuscular blockade with high levels	Avoid in pregnant patients. Avoid if possible in patients with severely impaired renal function, diabetes, or hepatic failure. Use with caution in myasthenia gravis patients (owing to potential for neuromuscular blockade). Use with caution with other potentially ototoxic and nephrotoxic drugs.
Fluoroquinolones	Mild GI effects; dizziness, lightheadedness; photosensitivity CNS effects, including dizziness, tremors, confusion, mood disorder, hallucinations Tendon rupture	Avoid in children or pregnant patients due to arthropathic effects. Concomitant antacid or iron or zinc or sucralfate use dramatically decreases oral absorption; use another antimicrobial agent or discontinue sucralfate use while on quinolones. Space administration of quinolones from antacids or iron or zinc products by at least 2 hr to ensure adequate absorption. Ensure adequate patient hydration. These agents can significantly increase theophylline plasma levels (ciprofloxacin and enoxacin seem to have a greater effect than norfloxacin or ofloxacin); avoid quinolones or monitor theophylline levels closely. These agents can lower seizure threshold; avoid in patients with epilepsy and in patients with other risk factors (medications or illness) that may lower the seizure threshold. Monitor glucose levels in patients on antidiabetic agents because hypoglycemia and hyperglycemia have been reported in patients treated concurrently with fluoroquinolones and antidiabetic agents. These agents can enhance warfarin effects; closely monitor coagulation tests.
Nitrofurantoin	GI upset Peripheral polyneuropathy (esp. in patients with impaired renal function, anemia, diabetes, electrolyte imbalance, vitamin B deficiency, and debilitated) Hemolysis in patients with G6PD deficiency Pulmonary hypersensitivity reactions can range from acute to chronic and include cough, dyspnea, fever, and interstitial changes	Do not use in patients with low creatinine clearance (<50 mL/min) because adequate urine concentrations will not be achieved. Monitor long-term patients closely. Avoid concomitant probenecid use, which blocks renal excretion of nitrofurantoin. Avoid concomitant magnesium or quinolones, which are antagonistic to nitrofurantoin.

Table 10–10.

Common Adverse Reactions, Precautions, and Contraindications for Antimicrobial Agents Used in Treatment of UTI—cont'd

DRUG OR DRUG CLASS	COMMON ADVERSE REACTIONS	PRECAUTIONS AND CONTRAINDICATIONS
Trimethoprim-sulfamethoxazole	Hypersensitivity, rash GI upset Photosensitivity Hematologic toxicity (AIDS patients)	Higher incidence of all adverse reactions occurs in AIDS patients and the elderly. Avoid in pregnant patients. Avoid in patients receiving warfarin; concomitant use can significantly elevate prothrombin time.
Vancomycin	"Red-man's syndrome": flushing, fever, chills, rash, hypotension (histaminic effect) Nephrotoxicity and/or ototoxicity when combined with other nephrotoxic and/or ototoxic drugs Local injection site reactions	Use with caution with other potentially ototoxic and nephrotoxic drugs.

AAPMC, antimicrobial-associated pseudomembranous colitis; CNS, central nervous system; GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase.

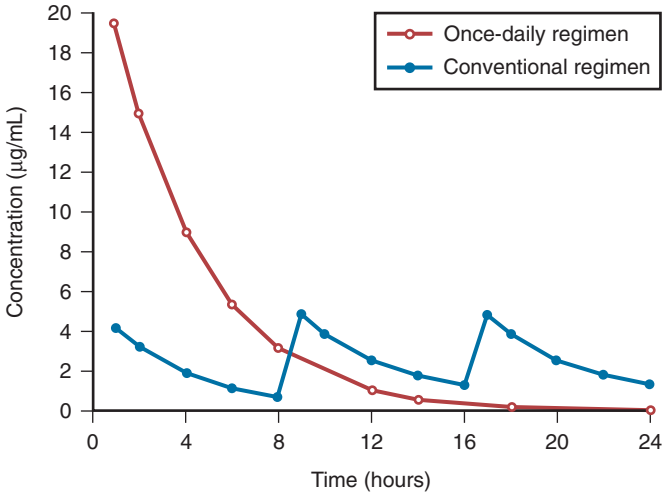

Figure 10–11. Simulated concentration-versus-time profile of once-daily (7 mg/kg/24 hr) and conventional (1.5 mg/kg/8 hr) regimens for patients with normal renal function. (From Nicolau DP, Freeman CD, Belliveau PP, et al. Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. Antimicrob Agents Chemother 1995;39:650–5.)

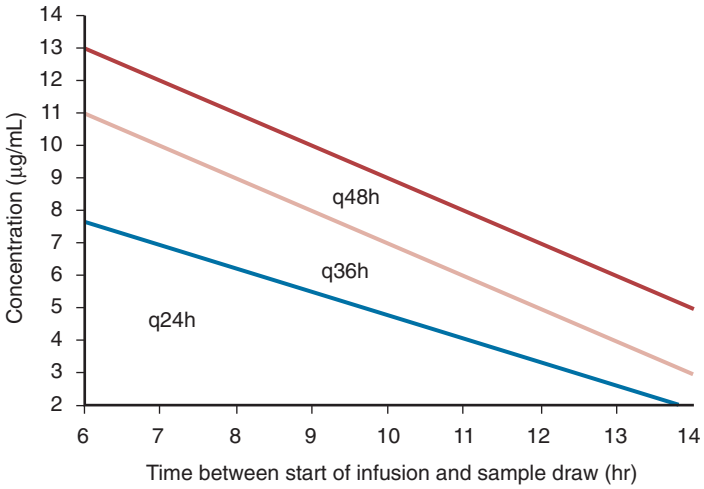

Figure 10–12. Once-daily aminoglycoside nomogram for gentamicin and tobramycin at 7 mg/kg. (From Nicolau DP, Freeman CD, Belliveau PP, et al. Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. Antimicrob Agents Chemother 1995;39:650–5.)

and auditory impairment associated with infection is indicated. Once-daily aminoglycoside regimens have been instituted to maximize bacterial killing by optimizing the peak concentration-to-minimal inhibitory concentration ratio and reduce potential for toxicity (Fig. 10–11) (Nicolau et al, 1995). Administering an aminoglycoside as a single daily dose can take advantage not only of its concentration-dependent killing ability but also of two other important characteristics: time-dependent toxicity and a more prolonged post-antimicrobial effect (Gilbert, 1991; Zhanel et al, 1991). The regimen consists of a fixed 7-mg/kg dose of gentamicin or 5 to 7 mg/kg of tobramycin. Subsequent interval adjustments are made by using a single concentration in serum and a nomogram designed for monitoring of once-daily therapy (Fig. 10–12). Antimicrobial doses are given at the interval determined by the drug concentration of a sample obtained after the start of the initial infusion. For example, if the serum concentration was 7 mg/mL 10 hours after the start of the infusion, subsequent 7 mg/kg doses would be given every 36 hours. This regimen is clinically effective, reduces the incidence of nephrotoxicity, and provides a cost-effective method for administering aminoglycosides by reducing ancillary service times and serum aminoglycoside determinations.

Aztreonam

Aztreonam has a similar spectrum of activity as the aminoglycosides, and as with all β-lactams, it is not nephrotoxic. However, its spectrum of activity is less broad than the third-generation cephalosporins. **It should be used primarily in patients who have penicillin allergies.**

Fluoroquinolones

Fluoroquinolones share a common predecessor in nalidixic acid and inhibit DNA gyrase, a bacterial enzyme integral to replication. The fluoroquinolones have a broad spectrum of activity that makes them ideal for the empirical treatment of UTIs. **They are highly effective against Enterobacteriaceae as well as *P. aeruginosa*. Activity is also high against *S. aureus* and *S. saprophyticus*, but, in general, antistreptococcal coverage is marginal.** Most anaerobic bacteria are resistant to these

drugs; therefore the normal vaginal and bowel flora are not altered (Wright et al, 1993). **Bacterial resistance initially appeared to be uncommon, but it is being reported at an increasing rate because of indiscriminate use of these agents** (Wright et al, 1993; Vromen et al, 1999).

These drugs are not nephrotoxic, but renal insufficiency prolongs the serum half-life, requiring adjusted dosing in patients with creatinine clearances of less than 30 mL/min. Adverse reactions are uncommon; gastrointestinal disturbances are more common. Hypersensitivity, skin reactions, mild central and peripheral nervous system reactions, and even acute renal failure have been reported (Hootkins et al, 1989). Achilles tendon disorders, including rupture, have been estimated to occur in 20 cases per 100,000 and therefore fluoroquinolone use should be discontinued at the first sign of tendon pain (Greene, 2002). The mechanism of tendon rupture is unclear, but ciprofloxacin stimulates matrix-degrading protease activity from fibroblasts and exerts an inhibitory effect on fibroblast metabolism and synthesis of matrix ground substance, factors that may contribute to tendinopathy (Williams et al, 2000). Administration of the fluoroquinolones to immature animals has caused damage to the developing cartilage; therefore they are currently contraindicated in children, adolescents, and pregnant or nursing women (Christ et al, 1988). There are important drug interactions associated with the fluoroquinolones. Antacids containing magnesium or aluminum interfere with absorption of fluoroquinolones (Davies and Maesen, 1989). Certain fluoroquinolones (enoxacin and ciprofloxacin) elevate plasma levels of theophylline and prolong its half-life (Wright et al, 1993). For most uncomplicated UTIs, the fluoroquinolones have been only slightly more effective than TMP-SMX. However, as resistance to TMP-SMX increases, the fluoroquinolones have distinct advantages in empirical treatment of patients recently exposed to antimicrobial agents and in the outpatient treatment of complicated UTIs (Dalkin and Schaeffer, 1988; Gupta et al, 1999). They may be considered as first-line agents in areas where a significant level of resistance (greater than 20%) exists (in common bacteria) to agents such as ampicillin and TMP-SMX.

Choice of Antimicrobial Agents

Many antimicrobial agents have been shown to be effective in the treatment of UTIs. **Factors important in aiding selection of empirical therapy include whether the infection is complicated or uncomplicated; the spectrum of activity of the drug against the probable pathogen; a history of hypersensitivity; potential side effects, including renal and hepatic toxicity; and cost.** In addition, favorable or unfavorable effects of the antimicrobial agent on the vaginal and bowel flora are important in women with recurrent UTIs. The bacterial susceptibility and cost of the drug vary dramatically among inpatient and outpatient settings throughout the country. It is imperative, therefore, that each clinician keep abreast of changes in bacterial susceptibility and cost and use current information when choosing antimicrobial agents.

Duration of Therapy

The duration of therapy needed to cure a UTI appears to be related to a number of variables, including the extent and duration of tissue invasion, the bacterial concentration in urine, the achievable urine concentration of the antimicrobial agent, and risk factors (see later) that impair the host and natural defense mechanisms.

Key Points: Principles of Antimicrobial Therapy

- Effective antimicrobial therapy must eliminate bacterial growth in the urinary tract.
- Antimicrobial resistance is increasing because of excessive utilization.
- Antimicrobial selection should be influenced by efficacy, safety, cost, and compliance.

ANTIMICROBIAL PROPHYLAXIS FOR COMMON UROLOGIC PROCEDURES

Principles

Surgical antimicrobial prophylaxis entails treatment with an antimicrobial agent before and for a *limited* time after a procedure to prevent local or systemic postprocedural infections. For most procedures, prophylaxis should be initiated between 30 minutes and 120 minutes before the procedure (Bratzler and Houck, 2004). **Efficacious levels should be maintained for the duration of the procedure and, in special circumstances, a limited time (24 hours, at most) after the procedure** (Bratzler and Houck, 2004). Although prospective studies addressing prophylaxis for urologic procedures exist, most focus on only a narrow spectrum of procedures. However, application of the principles of these studies with additional consideration of both the patient and the type of procedure provides a framework for determining when and what type of antimicrobial prophylaxis may be indicated. An additional, nontraditional type of prophylaxis in urology entails periprocedural treatment of the urinary tract with an antimicrobial agent to prevent local or systemic sequelae from the manipulation of colonized hardware such as a stent or urethral catheter.

A wide array of patients undergo invasive procedures in urology. The ability of a host to respond to bacteriuria or bacteremia and the sequelae of a possible infection are two important considerations when assessing the need for antimicrobial prophylaxis. Factors that affect the host's ability to respond to infection include advanced age, anatomic anomalies, poor nutritional status, smoking, chronic corticosteroid use, other concurrent medication use, and immunodeficiencies such as untreated HIV infection (Table 10–11). Additionally, chronic indwelling hardware, infected endogenous material such as stones, distant infectious sites, and prolonged hospitalizations also increase the risk of infectious complications by increasing the local bacterial concentration and/or altering the spectrum of bacterial flora. The potential seeding of artificial heart valves or prosthetic joints increases the sequelae of a systemic infection in hosts who otherwise may not be at an increased risk of infection. Thus a thorough history and examination of the patient is crucial in directing antimicrobial prophylaxis before a urologic procedure.

The type of procedure will also help direct the timing, duration, and spectrum of antimicrobial prophylaxis needed (see Table 10–12 for a summary of antimicrobial prophylaxis

Table 10–11.

Host Factors That Increase the Risk of Infection

Advanced age
Anatomic anomalies
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Chronic indwelling hardware
Infected endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Data from Cruse PJ. Surgical wound infection. In: Wonsiewicz MJ, editor. Infectious disease. Philadelphia: WB Saunders; 1992. p. 758–64; and Mangram AJ et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250–78; quiz 279–80.

recommendations). Consideration should be given to the extent of the local tissue injury incurred and the anticipated type of flora at the site.

Antimicrobial prophylaxis is not without morbidity because allergic complications, although rare, may result in minor reactions such as rash or gastric disturbances or significant sequelae such as early withdrawal of therapy, allergic nephritis, or anaphylaxis.

Urethral Catheterization and Removal

The indications for the routine use of prophylactic antimicrobial agents before urethral catheterization vary and depend on the health, sex, and specific living circumstances of the individual patient as well as on the indication for catheterization (Schaeffer, 2006). **The risk of infection after one-time urethral catheterization is 1% to 2% in healthy domiciliary women; however, this risk rises significantly in hospitalized patients** (Turck et al, 1962; Thiel and Spuhler, 1965). Thus for patients with risk factors for infection (see Table 10–11), antimicrobial prophylaxis with an oral agent such as TMP-SMX or a fluoroquinolone should decrease the risk of postprocedural infection (see Table 10–12).

Prolonged use of an indwelling urethral catheter is common in hospitalized patients and is associated with an increased risk of bacterial colonization, with a 3% to 10% incidence of bacteriuria per catheter day in one study and 100% incidence of bacteriuria with long-term catheterization (>30 days) (Kass, 1956; Nickel et al, 1985; Liedl, 2001). Prophylactic administration of antimicrobial agents during catheterization is not generally recommended because bacterial resistance can develop rapidly and complicate subsequent antimicrobial treatment (Clarke et al, 2005). This is supported by the Cochrane Database of Systematic Reviews that concluded that antimicrobials given postprocedurally until removal or for the first three postoperative days did not reduce rates of bacteriuria or infection (Niël-weise and Van der Broek, 2005).

The natural history of bacteriuria after catheter removal has not been comprehensively studied. Harding and associates (1991) reported that in asymptomatic bacteriuric women who had been catheterized for 4 to 6 days, 25% developed a UTI within 14 days of catheter removal. In this study, 1-day treatment with TMP-SMX was as effective as a 10-day course at resolving infections. Similar studies on the natural history of postcatheterization bacteriuria have not been performed in male patients. Note that antimicrobial treatment before removal of an indwelling catheter in a patient suspected of having bacteriuria is not considered prophylaxis but rather is treatment for a presumptive UTI and duration of treatment generally should follow previously outlined guidelines for uncomplicated or complicated UTIs.

Data from Polastri and colleagues (1990) suggest that antimicrobial prophylaxis for chronic indwelling catheter changes is not indicated. In their study of 46 catheter changes, bacteremia occurred 4% of the time and when noted was associated with very low concentrations of bacteria in the cultures. Systemic sequelae were not noted.

Urodynamics

Urodynamics, like cystoscopy, is a minimally traumatic procedure with limited urothelial injury that poses a small risk of local infection in hosts with normal anatomy and immune response. Several recent studies support this notion. In a series of women with urinary incontinence randomized to receive 1 day of nitrofurantoin or placebo, Cundiff and coworkers (1999) noted no difference in postprocedural UTI (5% vs. 7%) 1 week after evaluation. Similarly, Peschers and associates (2001) reported infections 1 week after multichannel urodynamics in 5% and 6% in nondiabetic women treated with placebo or cotrimoxazole. Conversely, Kartal and colleagues (2006) demonstrated a reduction in UTIs from 14% to 1% with administration of a single dose of ciprofloxacin in a blinded 192 patient trial. Most series examining the use of antimicrobial prophylaxis exclude patients with altered anatomy such as large prostates or comorbidities, including neurogenic bladder, spinal cord injury, or diabetes, all factors that increase the risk of infection. This is illustrated in work performed by Payne and colleagues in which frequencies of bacteriuria after urodynamics were much higher in men (36%) compared with the women studied (15%) (Payne et al, 1988). **In sum, antimicrobial prophylaxis should be considered for patients with a more complex clinical history or anatomy such as men with large postvoid residual amounts or spinal cord–injured patients.**

Transrectal Ultrasound-Guided Prostate Biopsy

The use of prophylactic antimicrobials for transrectal ultrasound-guided prostate biopsy reduces postprocedural fever and UTI in most studies. The class and duration of antimicrobial treatment are more varied and controversial. One major population-based screening program reported fever (>38.5° C [101.3° F]) in 3.5% of cases utilizing 1 day of TMP-SMX for most cases and ciprofloxacin for patients with comorbid conditions. This series did not report the frequency of UTIs. Alternatively, Sieber and associates (1997) reported a 0.1% rate of UTI in a large community-based practice in men given 4 days of ciprofloxacin. More recent studies suggest a single-dose/day of fluoroquinolones is as effective as 3 days of treatment (Sabbagh et al, 2004). Together these data suggest that a minimum of 1 day of an antimicrobial agent is indicated for transrectal ultrasound-guided prostate biopsies and that in otherwise healthy men confounding factors including cost of drugs can help direct the class and duration of therapy (Griffith et al, 2002).

Table 10–12.

Guide for Antimicrobial Prophylaxis for Uncomplicated Urologic Procedures

PROCEDURE	ORGANISMS	PROPHYLAXIS INDICATED	ANTIMICROBIAL(S) OF CHOICE	ALTERNATIVE ANTIMICROBIAL(S)	DURATION OF THERAPY*
Lower Tract Instrumentation					
Removal of external urinary catheter	GU tract†	If risk factors§	Fluoroquinolone TMP-SMX¶	Aminoglycoside ± ampicillin 1st/2nd gen. cephalosporin¶	≤24 hr¶
Cystography, urodynamic study, or simple cystourethroscopy	GU tract	If risk factors§	Fluoroquinolone TMP-SMX	Amoxicillin/clavulanate Aminoglycoside ± ampicillin 1st/2nd gen. cephalosporin	≤24 hr
Cystourethroscopy with manipulation‖	GU tract	All	Fluoroquinolone TMP-SMX	Amoxicillin/clavulanate	≤24 hr
Prostate brachytherapy or cryotherapy	Skin	Uncertain	1st gen. cephalosporin	Aminoglycoside ± ampicillin 1st/2nd gen. cephalosporin Amoxicillin/clavulanate Clindamycin**	≤24 hr
Transrectal prostate biopsy	Intestine††	All	Fluoroquinolone	Aminoglycoside ± metronidazole or clindamycin**	≤24 hr
Upper Tract Instrumentation					
Shock-wave lithotripsy	GU tract	All	Fluoroquinolone TMP-SMX	Aminoglycoside ± ampicillin 1st/2nd gen. cephalosporin	≤24 hr
Percutaneous renal surgery	GU tract and skin‡‡	All	1st/2nd gen. cephalosporin Aminoglycoside + metronidazole or clindamycin	Amoxicillin/clavulanate Ampicillin/sulbactam Fluoroquinolone	≤24 hr
Ureteroscopy	GU tract	All	Fluoroquinolone TMP-SMX	Aminoglycoside ± ampicillin 1st/2nd gen. cephalosporin Amoxicillin/clavulanate	≤24 hr
Open or Laparoscopic Surgery					
Vaginal surgery	GU tract, skin, and group B *Streptococcus*	All	1st/2nd gen. cephalosporin Aminoglycoside + metronidazole or clindamycin	Ampicillin/sulbactam	≤24 hr
Without entering urinary tract	Skin	If risk factors	1st gen. cephalosporin	Fluoroquinolone	Single dose
Involving entry into urinary tract	GU tract and skin	All	1st/2nd gen. cephalosporin Aminoglycoside + metronidazole or clindamycin	Clindamycin	≤24 hr
Involving intestine§§	GU tract, skin, and intestine	All	2nd/3rd gen. cephalosporin Aminoglycoside + metronidazole or clindamycin	Ampicillin/sulbactam Fluoroquinolone	≤24 hr
Involving implanted prosthesis	GU tract and skin	All	Aminoglycoside + 1st/2nd gen. cephalosporin or vancomycin	Ampicillin/sulbactam Ticarcillin/clavulanate Piperacillin/tazobactam Fluoroquinolone Ampicillin/sulbactam Ticarcillin/clavulanate Piperacillin/tazobactam	≤24 hr

Order of agents in each column is not indicative of preference. The absence of an agent does not preclude its appropriate use depending on specific situations.
*Additional antimicrobial therapy may be recommended at the time of removal of an externalized urinary catheter.
†GU tract: Common urinary tract organisms are *E. coli, Proteus* species, *Klebsiella* species, *Enterococcus.*
§If urine culture shows no growth before the procedure, antimicrobial prophylaxis is not necessary.
¶Or full course of culture-directed antimicrobial agents for documented infection (which is treatment, not prophylaxis).
‖Includes transurethral resection of bladder tumor and prostate, and any biopsy, resection, fulguration, foreign body removal, urethral dilation or urethrotomy, or ureteral instrumentation including catheterization or stent placement/removal.
**Clindamycin or an aminoglycoside + metronidazole or clindamycin is an alternative to penicillins and cephalosporins in patients with penicillin allergy, even when not specifically listed.
††Intestine: common intestinal organisms are *E. coli, Klebsiella* species, *Enterobacter, Serratia* species, *Proteus* species, *Enterococcus,* and anaerobes.
‡‡Skin: common skin organisms are *S. aureus,* coagulase negative *Staphylococcus* species, group A *Streptococcus* species.
§§For surgery involving the colon, bowel preparation with oral neomycin plus either erythromycin base or metronidazole can be added to or substituted for systemic agents.
gen, generation; GU, genitourinary; TMP-SMX, trimethoprim-sulfamethoxazole.
Drug doses: ampicillin, 25 mg/kg/dose; gentamicin, 1.5 mg/kg/dose; cefazolin, 25 mg/kg/dose.
Adapted from Wolf JS, Bennett CJ, Dmochowski RR, et al. Best practice statement on urologic surgery antimicrobial prophylaxis. J Urol 2008;179:1379–90.

Shockwave Lithotripsy

The incidence of UTIs after shockwave lithotripsy is reported to range from 0% to 28% without antimicrobial prophylaxis. A recent meta-analysis of contemporary randomized controlled trials examined the utility and cost-effectiveness of antimicrobial prophylaxis for shockwave lithotripsy and demonstrated, in individuals with sterile preprocedure urine cultures, a reduction in the rate of UTIs after shockwave lithotripsy from 5.7% to 2.1% (Pearle and Roehrborn, 1997). This analysis also demonstrated cost-effectiveness of prophylaxis when consideration was given for the treatment of the rare but more morbid complications of urosepsis and pyelonephritis. A history of a recent UTI or of infectious stones should warrant a full treatment course of antimicrobial agents before shockwave lithotripsy.

Endoscopic Procedures: Lower Urinary Tract

Cystoscopy

Cystoscopy is a minimally traumatic procedure with limited urothelial injury performed on a diverse spectrum of patients including young healthy women and older men. Several prospective trials (Manson, 1988; Clark and Higgs, 1990; Burke et al, 2002) of patients with preprocedure sterile urine report culture-proven rates of UTI between 2.2% and 7.8% after cystoscopy without antimicrobial prophylaxis. In Clark's report the risk of infection was higher in patients with a previous history of UTI. In a similarly designed study, Rane and colleagues (2001) report a significantly higher postprocedure culture-proven infection rate of 21% without antimicrobial prophylaxis. More recently, Johnson and colleagues (2007) reported a randomized controlled trial of over 2000 patients that demonstrated reductions in bacteriuria with administration of single-dose trimethoprim or ciprofloxacin. In all the studies, single doses of antimicrobial agents reduced infections to between 1% and 5%. In none of these studies were significant systemic infections reported after the cystoscopic procedures.

Together these studies illustrate two key concepts: (1) despite appropriate periprocedural preparation, a small inoculum of bacteria is likely introduced into the bladder during cystoscopy and (2) the significance of the bacteriuria is dependent on host factors, including the ability to mount an appropriate immune response to bacterial inoculation and the ability to clear the bacterial inoculation. For example, in a man with urinary retention, a small inoculum of bacteria could persist and divide in the retained fraction of urine and result in a symptomatic infection. In a host with a reduced ability to respond to infection this bacteriuria could become significant. In contrast, a middle-aged woman undergoing cystoscopy for microscopic hematuria is more likely to efficiently empty her bladder and clear the inoculum but may be exposed to an increased inoculum of bacteria if inappropriately prepared for the examination. **Thus we recommend prophylaxis when aberrant host factors could increase the probability or significance of an infection** (see Table 10–12). A single dose of a fluoroquinolone is commonly used but other agents such as trimethoprim have also been utilized.

Transurethral Resection of the Prostate and Bladder

Therapeutic transurethral lower urinary tract procedures increase the risk of localized infections compared with simple diagnostic cystoscopy. Although not delineated in any prospective studies, several risk factors likely increase infectious complications, including trauma to the mucosa, increased duration and/or degree of difficulty of the procedure, pressurized irrigants, and manipulation or resection of infected material. The most well-studied lower urinary tract procedure is transurethral resection of the prostate. In a meta-analysis of 32 studies (Berry and Barratt, 2002), a risk reduction was noted in bacteriuria from 26% to 9% on postoperative urine cultures obtained 2 to 5 days after the procedure for patients treated with prophylactic antimicrobial agents. Similarly, septicemia (defined as rigors, persistently elevated temperature [>38.5° C], and an elevated C-reactive protein level) decreased from 4.4% to 0.9% with antimicrobial prophylaxis. The most effective antimicrobial classes included fluoroquinolones, aminoglycosides, cephalosporins, and TMP/SMX (Bactrim, cotrimoxazole). Single doses of antimicrobial agents did lower the relative risk of bacteriuria but not as significantly as antimicrobial agents administered for short courses (2 to 5 days) while the urethral catheter remained in place. Although continuation of antimicrobial therapy while the catheter is in place is not truly prophylaxis, continuation of the initial prophylactic antimicrobial agent for an anticipated short period of time (with catheter in place) does not increase the risk of developing antimicrobial-resistant organisms. No recent trials have investigated prophylaxis for transurethral resection of bladder tumors; however, evidence from transurethral resection of the prostate procedures would suggest that prophylaxis would reduce bacteriuria in these procedures.

Patients who are known preoperatively to have UTIs should have the infections eradicated before the procedure is started; hence, in these patients, preoperative antimicrobial agents are therapeutic and not prophylactic. Failure to eradicate bacteriuria results in bacteremia in 50% of patients (Morris et al, 1976).

Diagnostic and therapeutic upper tract studies are performed with pressurized irrigants and may induce urothelial injury. Prophylaxis with antimicrobial agents that cover uropathogens is indicated.

Endoscopic Procedures: Upper Urinary Tract

Ureteroscopy

Diagnostic and therapeutic upper tract endoscopic procedures have an increased risk of localized infections compared with simple diagnostic cystoscopy due to several factors, including increased trauma to the mucosa, increased duration and/or degree of difficulty of most ureteroscopic procedures, increased pressure of irrigants, and (when applicable) manipulation or resection of infected material. The use of antimicrobial prophylaxis is supported by a randomized trial by Knopf and colleagues (2003) in which prophylactic fluoroquinolone administration significantly reduced postprocedure UTIs in a healthy population of individuals with ureteral stones and uninfected preoperative urine. If an infection or infectious material is suspected, culture and a full treatment course of an appropriate antimicrobial is recommended before the procedure.

Percutaneous Procedures

Percutaneous renal surgery is commonly performed for large renal stones, ureteropelvic junction obstruction, and transitional cell carcinoma surveillance. Pyrexia and bacteremia occur frequently and likely stem from a combination of renal parenchymal injury, pressurized irrigation, and, in some cases, manipulation of

infectious stones. Several studies demonstrated a relationship between the risk of postoperative infectious complications (including bacteriuria and sepsis) and the duration of the procedure and amount of irrigant used (Dogan et al, 2002). If preoperative urine cultures are positive, treatment of the infection should occur before surgery. Conversely, if preoperative cultures are negative, antimicrobial prophylaxis covering common urinary pathogens should be instituted (Wolf et al, 2008) (see Table 10–12).

Open and Laparoscopic Surgery

Open surgical procedures can be classified as clean, clean contaminated, contaminated, and dirty (Table 10–13). **Antimicrobial prophylaxis is indicated for clean contaminated and contaminated wounds, whereas antimicrobial treatment with an appropriate agent should be instituted for dirty-infected wounds.** To date, no large studies have evaluated the risk of surgical site infections for different laparoscopic urologic procedures. However, data in the general surgery literature suggest that the laparoscopic approach lowers the risk of surgical site infections (Kluytmans, 1997). Clean surgeries in urology include radical nephrectomy if the urinary tract is not entered. All urologic procedures in which the urinary tract is opened electively are considered clean contaminated procedures, whereas entry into an infected urinary tract is considered a contaminated procedure and carries a higher rate of surgical site infection (Cruse, 1992). Antimicrobial agents should be active against the most likely infecting organism and should be administered within 1 hour of the procedure and discontinued 24 hours after because several studies have failed to demonstrate beneficial effects of long courses of prophylaxis (Conte et al, 1972; Goldmann et al, 1977). In the United States, first-generation cephalosporins are commonly used for prophylaxis of clean contaminated procedures because they have low incidences of allergic reactions, long half-lives, and low cost. For patients with a β-lactam allergy, the 2004 National Surgical Infection Prevention Project (NSIPP) guidelines recommend either vancomycin or clindamycin. Prophylaxis for urinary reconstruction with intestine requires increased anaerobic coverage, and thus use of second-generation cephalosporins is recommended (Bratzler and Houck, 2004). When use of the colon or appendix is anticipated for urologic reconstruction, the 2004 NSIPP recommendations include orally administered antimicrobial bowel preparation (neomycin plus erythromycin or neomycin plus metronidazole) 18 to 24 hours before surgery and parenteral cefotetan or cefoxitin 30 to 60 minutes before incision (Bratzler and Houck, 2004). Recommendations for patients with a β-lactam allergy include clindamycin plus gentamicin, aztreonam, or ciprofloxacin. Dirty wounds in urology include all abscesses and traumatic perforation of the genitourinary tract. Treatment of a dirty wound should begin with broad coverage of anticipated organisms and intraoperative wound cultures. Subsequent therapy and treatment duration depends on the sensitivities of the cultured organism.

Table 10–13.

Surgical Wound Classification

Clean	Uninfected wound without inflammation or entry into the genital, urinary, or alimentary tract Primary wound closure ± closed drainage
Clean contaminated	Uninfected wound with controlled entry into the genital, urinary, or alimentary tract Primary wound closure ± closed drainage
Contaminated	Uninfected wound with major break in sterile technique (gross spillage from gastrointestinal tract or nonpurulent inflammation) Open fresh accidental wounds
Dirty infected	Wound with preexisting clinical infection or perforated viscera Old traumatic wounds with devitalized tissue

Adapted from Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250–78; quiz 279–80.

Special Considerations

Patients with Risk of Endocarditis

The risk of endocarditis after urologic procedures is low; however, the urinary tract is the second most common site of entry of organisms that cause endocarditis (Dajani et al, 1997). **Nonetheless, the 2007 American Heart Association's updated guidelines no longer recommend antimicrobial prophylaxis solely to prevent infectious endocarditis.** This recommendation is based on an overall assessment that antimicrobial prophylaxis during genitourinary procedures is not an effective strategy for the prevention of infectious endocarditis and is outweighed by the risk of antimicrobial-related adverse events.

Patients with Indwelling Orthopedic Hardware

Bacterial seeding of implanted orthopedic hardware is a rare but morbid event. A joint commission of the American Urological Association, the American Academy of Orthopaedic Surgeons, and infectious disease specialists convened in 2003 and released an advisory statement on antimicrobial prophylaxis for urologic patients with total joint replacement (American Urological Association and American Academy of Orthopaedic Surgeons, 2003) (Table 10–14). **In general, antimicrobial prophylaxis for urologic patients with total joint replacements, pins, plates, or screws is not indicated. Prophylaxis is advised for individuals at higher risk of seeding a prosthetic joint, including those with recently inserted implants**

Table 10–14.

Antimicrobial Regimens for Patients with Indwelling Orthopedic Hardware

PATIENT TYPE	ANTIMICROBIAL RECOMMENDATION
Total joint inserted >2 years ago, pins, plates, screws + no host risk factors	Not recommended empirically
Total joint inserted <2 years ago or aberrant host factor(s)	Oral quinolone or ampicillin, 2 g IV + gentamicin, 1.5 mg/kg IV, 30-60 min before procedure Substitute vancomycin, 1 g IV, over 1-2 hr before procedure if ampicillin allergy

From American Urological Association, American Academy of Orthopaedic Surgeons. Antibiotic prophylaxis for urological patients with total joint replacements. J Urol 2003;169:1796–7.

(within 2 years) and/or host risk factors as delineated earlier. Prophylaxis on the basis of potential seeding of a prosthetic joint should be instituted for procedures including stone manipulation, transmural incision of the urinary tract, upper tract endoscopic procedures, procedures involving bowel segments, and transrectal prostate biopsy. Additionally, patients with recent prosthetic joints or compromised host factors and urinary diversions, indwelling stents or catheters, a recent history of urinary retention, or UTIs should receive antimicrobial prophylaxis before urinary tract procedures. The AUA Advisory Statement recommends for these patients either an oral quinolone or ampicillin, 2 g IV (vancomycin, 1 g IV over 1 to 2 hours for ampicillin-allergic patients), and gentamicin, 1.5 mg/kg IV, 30 to 60 minutes before the procedure.

Key Points: Antimicrobial Prophylaxis for Common Urologic Procedures

- Antimicrobial prophylaxis entails treatment with an antimicrobial agent before and for a limited time after a procedure to prevent local or systemic postprocedural infections.
- The type of procedure and competency of the host defenses determine the need for antimicrobial prophylaxis.
- Special considerations for antimicrobial prophylaxis include patients with indwelling orthopedic hardware.

Table 10–15.

Risk Factors for UTIs

Reduced Urine Flow
Outflow obstruction, prostatic hyperplasia, prostatic carcinoma, urethral stricture, foreign body (calculus)
Neurogenic bladder
Inadequate fluid uptake (dehydration)
Promote Colonization
Sexual activity—increased inoculation
Spermicide—increased binding
Estrogen depletion—increased binding
Antimicrobial agents—decreased indigenous flora
Facilitate Ascent
Catheterization
Urinary incontinence
Fecal incontinence
Residual urine with ischemia of bladder wall

BLADDER INFECTIONS

Uncomplicated Cystitis

Most cases of uncomplicated cystitis occur in women. Each year, approximately 10% of women report having had a UTI and more than 50% of all women have at least one such infection in their lifetime (Foxman et al, 2000). Uncomplicated cystitis occasionally occurs in prepubertal girls, but it increases greatly in incidence in late adolescence and during the second and fourth decades of life. Twenty-five to 30 percent of women 20 to 40 years of age have a history of UTIs (Kunin, 1987). **Although it is much less common, young men may also experience acute cystitis without underlying structural or functional abnormalities of the urinary tract** (Krieger et al, 1993). Risk factors (Table 10–15) include sexual intercourse and use of spermicides (Hooton et al, 1996; Foxman, 2002; Handley et al, 2002). Sexual transmission of uropathogens has been suggested by demonstrating identical *E. coli* in the bowel and urinary flora of sex partners (Johnson and Stamm, 1989).

Clinical Presentation

The presenting symptoms of cystitis are variable but usually include dysuria, frequency, and/or urgency (Fig. 10–13). **Suprapubic pain, hematuria, or foul-smelling urine may develop. The probability of cystitis in a woman with these symptoms alone or in combination is 50% to 90%, respectively** (Bent et al, 2002). When a woman who previously has had cystitis has symptoms suggesting a recurrence, the probability that an infection is present is about 90% (Gupta et al, 2001). Because acute cystitis, by definition, is a superficial infection of bladder mucosa, fever, chills, and other signs of dissemination are not present. Some patients may experience suprapubic tenderness, but most have no diagnostic physical findings. In women, physical examination should include the possibility of vaginitis, herpes, and urethral pathology, such as a diverticulum.

A remarkably narrow spectrum of etiologic agents with highly predictable profiles of antimicrobial susceptibility cause infections in young women with acute uncomplicated cystitis. ***E. coli* is the causative organism in 75% to 90% of cases of acute cystitis in young women** (Latham et al, 1983; Ronald, 2002). ***S. saprophyticus*, a commensal organism of the skin, is the second most common cause of acute cystitis in young women, accounting for 10% to 20% of these infections** (Jordan et al, 1980). **Other organisms less commonly involved include *Klebsiella* and *Proteus* species and *Enterococcus*. In men, *E. coli* and other Enterobacteriaceae are the most commonly identified organisms.**

Laboratory Diagnosis

The presumptive laboratory diagnosis of acute cystitis is based on microscopic urinalysis, which indicates microscopic pyuria, bacteriuria, and hematuria. Indirect dipstick tests for bacteria (nitrite) or pyuria (leukocyte esterase) may also be informative and more convenient but are less sensitive than microscopic examination of the urine. Dipsticks are most accurate when the presence of either nitrite or leukocyte esterase is considered a positive result. **Urine culture remains the definitive test; and in symptomatic patients the presence of 10^2 cfu/mL or more of urine usually indicates infection** (Stamm et al, 1982b).

However, routine urine cultures are often not necessary. It is generally more cost-effective to manage many patients who have symptoms and urinalysis findings characteristic of uncomplicated cystitis without an initial urine culture because treatment decisions are usually made and therapy is often completed before culture results are known (Komaroff, 1986). This position was supported by a cost-effectiveness study (Carlson and Mulley, 1985) in which it was estimated that the routine use of pretherapeutic urine cultures for lower UTI increases costs by 40% but decreases the overall duration of symptoms by only 10%.

Thus in women with recent onset of symptoms and signs suggesting acute cystitis and in whom factors associated with upper tract or complicated infection are absent, a urinalysis that is positive for pyuria, bacteriuria, or hematuria, or a combination, should provide

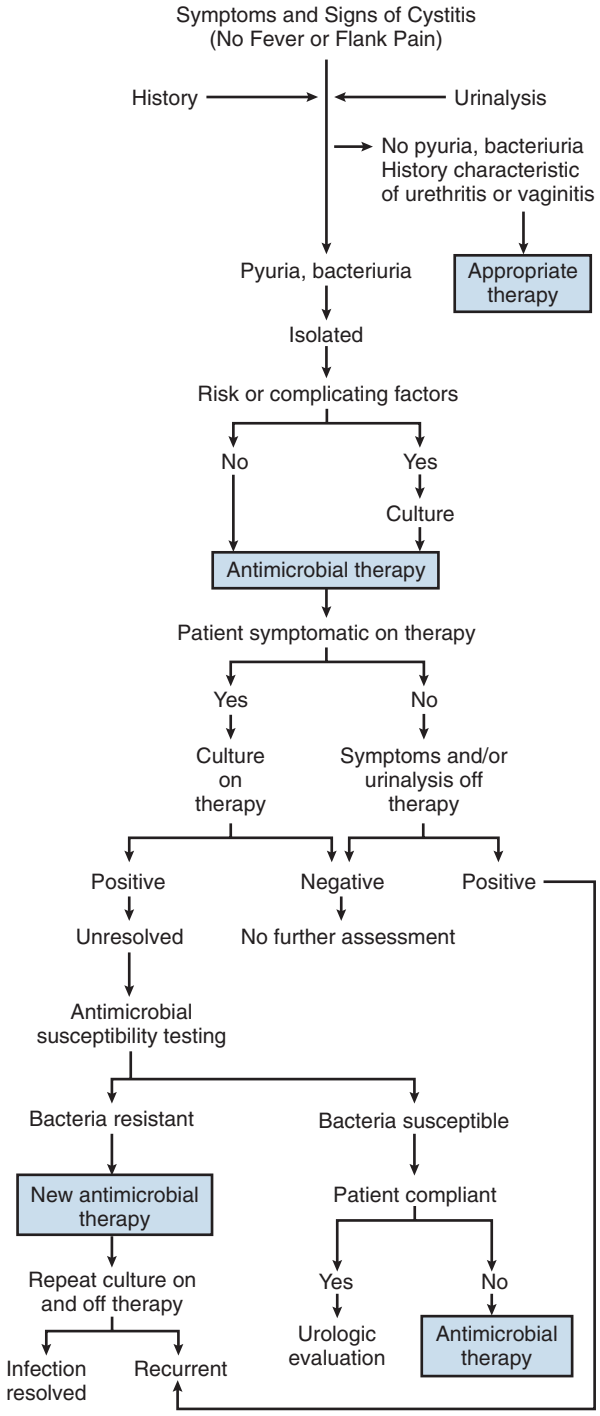

Figure 10–13. Management of acute cystitis.

sufficient documentation of UTI and a urine culture may be omitted (McIsaac et al, 2002). **A urine culture should be obtained for patients in whom symptoms and urine examination findings leave the diagnosis of cystitis in doubt. Pretherapeutic cultures and susceptibility tests are also essential in the management of patients with recent antimicrobial therapy or UTI.** In these situations, various pathogens may be present and antimicrobial therapy is less predictable and must be tailored to the individual organism (Stamm, 1986).

Differential Diagnosis

Cystitis must be differentiated from other inflammatory infectious conditions in which dysuria may be the most prominent symptom, including vaginitis, urethral infections caused by sexually transmitted pathogens, and miscellaneous noninflammatory causes of urethral discomfort (Komaroff, 1984). Characteristic features of the history, physical examination, and voided urine or other specimens allow patients with dysuria to be assigned to one of these diagnostic categories. Vaginitis is characterized by irritative voiding associated with vaginal irritation and is subacute in onset. A history of vaginal discharge or odor and multiple or new sexual partners is common. Frequency, urgency, hematuria, and suprapubic pain are not present. Physical examination reveals a vaginal discharge, and examination of vaginal fluid demonstrates inflammatory cells. Differential diagnosis includes herpes simplex virus infection, gonorrhea, infection with *Chlamydia,* trichomoniasis, yeast infection, and bacterial vaginosis. Urethritis causes dysuria that is usually subacute in onset and is associated with a history of discharge and new or multiple sexual partners. Frequency and urgency of urination may be present but are less pronounced than in patients with cystitis, and fever and chills are absent. Urethral discharge with inflammatory cells or initial pyuria in the male is characteristic. The common causes of urethritis include Neisseria gonorrhoeae, *Chlamydia,* herpes simplex virus, and trichomoniasis. Appropriate cultures and immunologic tests are indicated. Urethral injury associated with sexual intercourse, chemical irritants, or allergy may also cause dysuria. A history of trauma or exposure to irritants and a lack of discharge or pyuria are characteristic.

Management

Antimicrobial Selection. Oral antimicrobial agents for treatment of acute uncomplicated cystitis are listed in Table 10–16. **TMP and TMP-SMX are effective and inexpensive agents for empirical therapy,** resulting in bacteriologic cure (i.e., eradication of the pathogen from the urine) within 7 days after the start of treatment in approximately 94% of women (Warren et al, 1999). **They are recommended in areas where the prevalence of resistance to these drugs among *E. coli* strains causing cystitis is less than 20%** (Warren et al, 1999). The probability of resistant strains can be predicted in part from the history of recent antimicrobial usage. Women who have taken TMP-SMX recently are approximately 16 times as likely to be infected with an isolate resistant to this agent compared with women who have not taken the antimicrobial agent recently. In addition, those who have taken any other antimicrobial agent are more than twice as likely to be infected with a resistant isolate (Brown et al, 2002). With a 30% rate of resistance to TMP-SMX, the bacteriologic eradication rate is predicted to be 80% and the clinical cure rate is predicted to be 85% (Gupta et al, 2001). When used alone, TMP is as efficacious as TMP-SMX and is associated with fewer side effects, presumably because of the absence of the sulfa component (Harbord and Gruneberg, 1981). It can be prescribed to patients who are allergic to sulfa. However, TMP can cause hypersensitivity and rashes that may be erroneously attributed to sulfa (Alonso et al, 1992).

Nitrofurantoin has maintained an excellent level of activity over 4 decades and is well tolerated, but it is more expensive than TMP-SMX and it is considerably less active against aerobic gram-negative rods other than *E. coli*. Furthermore, it is usually prescribed for 7 days and may cause

Table 10–16.

Treatment Regimens for Acute Cystitis

CIRCUMSTANCES	ROUTE	DRUG	DOSAGE (mg)	FREQUENCY PER DOSE	DURATION (DAYS)	COST PER DAY*
Women						
Healthy	Oral	Ciprofloxacin	500 mg	bid	3	$0.50
		Levofloxacin	500 mg	qd		$5.07
		TMP-SMX	1 double-strength tablet (160-800 mg)	bid		$0.26
		Trimethoprim	100 mg	bid		$1.32
		Nitrofurantoin macrocrystals	100 mg	bid		$3.24
		Norfloxacin	400 mg	bid		
Symptoms for >7 days, recent UTI, age >65 yr, diabetes, diaphragm use		TMP-SMX or Fluoroquinolone	As above	As above	7	As above
Pregnancy	Oral	Amoxicillin	250 mg	tid	7	$0.68
		Cephalexin	500 mg	qid		$1.76
		Nitrofurantoin macrocrystals	As above	As above		As above
		TMP-SMX*	As above	As above		As above
Men						
Healthy and age <50 yr	Oral	TMP-SMX	As above	As above	7	As above
		Fluoroquinolone	As above	As above		As above

*Use of TMP-SMX during the first trimester of pregnancy is cautioned because there is early potential for teratogenicity and late potential for kernicterus after delivery.
From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.

gastrointestinal upset. It is not associated with plasmid-mediated resistance, however, so it is an excellent choice for patients with recent exposure to most other antimicrobial agents. The high in-vitro resistance to ampicillin and sulfonamide and the high cost of amoxicillin/clavulanate and the cephalosporins limit their usefulness.

The fluoroquinolones offer excellent activity and are well tolerated. Resistance to the fluoroquinolones remains below 5% in most places (Fihn et al, 1988); however, it is increasing in certain areas. Twice-daily and once-daily extended-release fluoroquinolones are equally effective (Henry et al, 2002). Their use for uncomplicated cystitis should be limited to patients with allergy to TMP-SMX, to patients with previous exposure to antimicrobial agents causing bacterial resistance, and to areas where the prevalence of resistance to TMP or TMP-SMX is 20% or greater (Warren et al, 1999; Hooton et al, 2004).

The effects of an antimicrobial agent on the vaginal flora are also important in recurrence of bacteriuria (Fihn et al, 1988). The concentrations of TMP and the fluoroquinolones that have been studied in vaginal secretions are high, eradicating *E. coli* but minimally altering normal anaerobic and microaerophilic vaginal flora (Hooton and Stamm, 1991). Single-dose regimens using these drugs are less effective than multiple-day regimens in this regard (Fihn et al, 1988), which probably explains why there are more early recurrent infections after single-dose therapy with these drugs. Nitrofurantoin and β-lactam drugs are generally not effective in eliminating *E. coli* from the vagina.

Duration of Therapy. **Three-day therapy is the preferred regimen for uncomplicated cystitis in women** (Norrby, 1990; Warren et al, 1999). In an excellent review of more than 300 separate clinical trials of single-dose, 3-day, or 7-day treatment with TMP, TMP-SMX, fluoroquinolones, and β-lactam antimicrobial therapies, it was concluded that, irrespective of the antimicrobial used, 3-day therapy is more effective than single-dose therapy. Three-day therapy with TMP-SMX, TMP, amoxicillin, or cloxacillin has been associated with cure rates similar to longer courses of therapy and an incidence of adverse effects about as low as that seen with single-dose therapy and lower than seen with longer courses of therapy (Charlton et al, 1976; Kunin, 1985; McCue, 1986; Warren et al, 1999). Because 7-day therapy often causes more adverse effects, it is recommended only for women with symptoms of 1 week or more, men, and individuals with possible complicating factors. Other options include nitrofurantoin, perhaps as 7-day therapy, and fosfomycin single-dose therapy; each of these requires further study. β-Lactams as a group are less effective in treatment of cystitis than TMP, TMP-SMX, and the fluoroquinolones.

Seven-day therapy is the preferred regimen in uncomplicated cystitis in men.

Cost of Therapy. **The cost of treating a UTI involves not only the initial evaluation and cost of the drug but also what occurs subsequently. The most important prediction of high cost-effectiveness is high efficacy against the most common urinary pathogen, *E. coli*.** The lower the effectiveness against this bacterium, the greater the number of revisits, cases of progression to pyelonephritis, and follow-up costs. Antimicrobial cost is a poor prediction of cost-effectiveness, as illustrated by the finding that the most expensive and least expensive drugs, the fluoroquinolones and TMP-SMX, are approximately equally cost-effective (Rosenberg, 1999). Both of these drugs are more cost-effective than nitrofurantoin and amoxicillin.

Follow-Up

Approximately 90% of women are asymptomatic within 72 hours after initiating antimicrobial therapy (Fihn et al, 1988). **Follow-up visit or culture is not required in young women who are asymptomatic after therapy. A follow-up visit, urinalysis, and urine culture are recommended in older women or those with potential risk factors and in men. Urologic evaluation is unnecessary in women and is usually unnecessary in young men who respond to therapy** (Lipsky, 1989; Abarbanel et al, 2003). **However, UTIs in most men should be considered**

complicated until proven otherwise. Andrews and associates (2002) showed that approximately 50% of men with UTIs have a significant abnormality. Furthermore, if a patient does not respond to therapy, appropriate microbiologic urologic evaluations should be undertaken for the causes of unresolved and complicated UTIs.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is a microbiologic diagnosis based on the isolation of a specified quantitative count of bacteria in a properly collected specimen of urine from a patient who is without symptoms or signs referable to UTI. In healthy individuals, the absence of symptoms is clear cut, but in, for example, catheterized or neurologically comprised patients it may be difficult to discern whether the UTI is truly asymptomatic. Kass (1962) originally proposed that for asymptomatic women two consecutive voided urine specimens with isolation of the same bacterial strain in quantitative counts of 10^5 cfu/mL is consistent with asymptomatic bacteriuria. In men, a single clean-catch voided specimen with similar counts is adequate. A single catheterized urine specimen with a solitary isolate with a quantitative count of 10^2 cfu/mL identifies bacteriuria in women or men (Nicolle et al, 2005). The prevalence of pyuria with asymptomatic bacteriuria ranges from approximately 30% in young women (Hooton et al, 2000) to 100% in catheterized patients. In addition, many coexisting factors, such as stones, can incite inflammation in these patients and therefore the presence or absence of pyuria is not sufficient to diagnose bacteriuria nor does it differentiate symptomatic from asymptomatic patients or provide indication for antimicrobial treatment (Nicolle et al, 2005).

The prevalence of asymptomatic bacteriuria varies widely and depends on the age, sex, and the presence of other genitourinary abnormalities (Table 10–17). *E. coli* is the most common isolate among patients with bacteriuria, and it contains fewer virulence characteristics than isolates from patients with symptomatic infections (Svanborg and Godaly, 1997). Other Enterobacteriaceae (e.g., *P. mirabilis*) and gram-positive uropathogens, including group B streptococci and coagulase-negative staphylococci, become more prevalent in concert with increased underlying abnormalities. For patients who are institutionalized and/or with indwelling urologic devices, *P. aeruginosa*, *Proteus,* and other highly resistant organisms are more prevalent.

Management of asymptomatic bacteriuria is determined by the population and their risk for adverse outcome, which can be prevented with antimicrobial treatment of asymptomatic bacteriuria (Nicolle et al, 2005) (Table 10–18). **These recommendations are based on the observation that in adult populations asymptomatic bacteriuria has not been shown to be harmful.** Furthermore, although persons with bacteriuria are at increased risk of symptomatic urinary tractions, treatment of asymptomatic bacteriuria does not decrease the frequency of symptomatic infections or improve other outcomes. **Thus, in populations other than those for whom treatment has been documented to be beneficial (e.g., pregnant women and patients undergoing urologic interventions), screening for or treatment of asymptomatic bacteriuria is not appropriate and should be discouraged** (Nicolle et al, 2005).

Table 10–17.

Prevalence of Asymptomatic Bacteriuria in Selected Populations

POPULATION	PREVALENCE (%)	REFERENCE
Healthy, premenopausal women	1.0-5.0	Nicolle, 2003
Pregnant women	1.9-9.5	Nicolle, 2003
Postmenopausal women aged 50-70 years	2.8-8.6	Nicolle, 2003
Diabetic patients		
Women	9.0-27	Zhanel, 1991
Men	0.7-11	Zhanel, 1991
Elderly persons in the community		
Women	10.8-16	Nicolle, 2003
Men	3.6-19	Nicolle, 2003
Elderly persons in a long-term care facility		
Women	25-50	Nicolle, 1997

Complicated Cystitis

Complicated UTIs are those that occur in a patient with a compromised urinary tract or that are caused by a very resistant pathogen (Table 10–19). **These complicating factors may be readily apparent from the severity of the presenting illness or the past medical history. However, they may not be obvious at first and may only become evident from subsequent failure of the patient to respond to appropriate therapy** (see discussion on unresolved or recurrent UTIs, later).

Table 10–19.

Complicating Host Factors

Functional/structural abnormalities of urinary tract
Recent urinary tract instrumentation
Recent antimicrobial agent use
Diabetes mellitus
Immunosuppression
Pregnancy
Hospital-acquired infection

Table 10–20.

Treatment of Complicated UTIs

COMMON PATHOGENS	MITIGATING CIRCUMSTANCES	RECOMMENDED EMPIRICAL TREATMENT
E. coli, Proteus species, *Klebsiella* species, *Pseudomonas* species,	Mild-to-moderate illness, no nausea or vomiting—outpatient therapy	Oral* norfloxacin, ciprofloxacin, or ofloxacin for 10-14 days
Serratia species, enterococci, staphylococci	Severe illness or possible urosepsis—hospitalization required	Parenteral† ampicillin and gentamicin, ciprofloxacin, levofloxacin, ceftriaxone, aztreonam, ticarcillin-clavulanate or imipenem-cilastin until fever gone; then oral* trimethoprim-sulfamethoxazole, norfloxacin, ciprofloxacin, or levofloxacin for 14-21 days

*Oral regimens for pyelonephritis and complicated UTI: trimethoprim-sulfamethoxazole, 160 to 800 mg q12h; norfloxacin, 400 mg q12h; ciprofloxacin, 500 mg q12h; levofloxacin, 500 mg/day.

†Parenteral regimens: ciprofloxacin, 400 mg q12h; levofloxacin, 500 mg/day; gentamicin, 1 mg/kg q8h; ceftriaxone, 1 to 2 g/day; ampicillin, 1 g q6h; imipenem-cilastin, 250 to 500 mg q6-8h; ticarcillin-clavulanate, 3.1 g q6h; and aztreonam, 1 g q8-12h.

Modified from Stamm WE, Hooton TM. Management of urinary tract infections in adults. N Engl J Med 1993;329:1328–34. Copyright 1993, Massachusetts Medical Society. All rights reserved.

The clinical spectrum ranges from mild cystitis to life-threatening kidney infections and urosepsis (kidney infections and urosepsis are discussed subsequently). These infections can be caused by a broad range of bacteria with resistance to multiple antimicrobial agents. Therefore urine cultures are mandatory to identify the bacteria and its antimicrobial susceptibility.

Because of the wide range of host conditions and pathogens and a lack of adequate controlled trials, guidelines for empirical therapy are limited. For patients with mild to moderate illness who can be treated as an outpatient with oral therapy, the fluoroquinolones provide a broad spectrum of activity with excellent urine and tissue levels and safety. If the susceptibility pattern of the pathogen is known, TMP-SMX may be effective (Table 10–20).

For patients requiring hospitalization, intravenous antimicrobial agents should be administered based on the susceptibility patterns of the known uropathogens at that institution.

Because therapy will be compromised without addressing the complicating factor(s), every effort should be made to correct any underlying urinary tract abnormalities and treat host factors that exacerbate the infection.

Therapy is usually continued for 10 to 14 days and switched from parenteral to oral therapy when the patient is afebrile and clinically stable. Repeat urine cultures should be performed if the patient fails to respond to therapy.

Table 10–21.

Causes of Unresolved Bacteriuria, in Descending Order of Importance

Bacterial resistance to the drug selected for treatment
Development of resistance from initially susceptible bacteria
Bacteriuria caused by two different bacterial species with mutually exclusive susceptibilities
Rapid reinfection with a new, resistant species during initial therapy for the original susceptible organism
Azotemia
Papillary necrosis from analgesic abuse
Giant staghorn calculi in which the "critical mass" of susceptible bacteria is too great for antimicrobial inhibition
Self-inflicted infections or deception in taking antimicrobial drugs (a variant of Munchausen syndrome)

Unresolved UTIs

Clinical Presentation

Unresolved infection indicates that initial therapy has been inadequate in eliminating symptoms and/or bacterial growth in the urinary tract. If the symptoms of UTI do not resolve by the end of treatment or if symptoms recur shortly after therapy, urinalysis and urine culture with susceptibility testing should be obtained. If the patient's symptoms are significant, empirical therapy with a fluoroquinolone is appropriate pending results of the culture and susceptibility testing.

The causes of unresolved bacteriuria during antimicrobial therapy are shown in Table 10–21. **Most commonly, the bacteria are resistant to the antimicrobial agent selected to treat the infection.** Typically, the patient has received the antimicrobial therapy in the recent past and developed bowel colonization with resistant bacteria. β-Lactams, tetracycline, and sulfonamides are notorious for causing plasmid-mediated R factors that simultaneously carry resistance to multiple antimicrobial agents. **The second most common cause is development of resistance in a previously susceptible population of bacteria during the course of treatment of UTIs. This problem occurs in approximately 5% of the patients receiving antimicrobial therapy. It is easy to recognize clinically because the culture on therapy shows that the previous susceptible population has been replaced by resistant bacteria of the same species.** It can be shown that resistant organisms were actually present before contact with the initial antimicrobial agent, but they were present in such low numbers that it was impossible to detect by in-vitro susceptibility studies before therapy. When the antimicrobial concentration in the urine is insufficient to kill all the bacteria present, the more resistant forms will emerge. This characteristically is seen in patients who are underdosed or who are poorly compliant and hence have inadequate dose regimens. **The third cause is the**

presence of an unsuspected, second pathogen that was present initially and is resistant to the antimicrobial therapy chosen. Treatment of the dominant organism unmasks the presence of the second strain. **The fourth cause is rapid reintroduction of a new resistant species while the patient is undergoing initial therapy.** Rapid reinfection that mimics unresolved bacteriuria should alert the clinician to the possibility of an enterovesical fistula.

If the culture obtained on therapy shows that the initial species is still present and susceptible to the antimicrobial chosen to treat the infection, the unresolved infection must be caused by either inability to deliver an adequate concentration of antimicrobial agents into the urinary tract or an excessive number of bacteria that "override" the antimicrobial activity. In patients with azotemia, a determination of urinary antimicrobial concentrations usually shows that the level of the drug is below the minimal inhibitory concentration of the infecting organism.

In patients with papillary necrosis, severe defects in the medullary concentrating ability dilute the antimicrobial agent. A large mass of bacteria within the urinary tract is most commonly associated with a giant staghorn calculus. Even though adequate urinary levels of bactericidal drugs are present, the concentration is inadequate to sterilize the urine. This occurs because even susceptible bacteria cannot be inhibited once they reach a certain critical density, particularly if attached to a foreign body.

The last cause of unresolved bacteriuria occurs in those patients who have variants of Munchausen syndrome. These patients secretly inoculate their bladders with uropathogens or omit their oral antimicrobial agents while steadfastly asserting that they never miss a dose. The patient with Munchausen syndrome presents with an inconsistent clinical history and invariably a normal urinary tract on urologic imaging. Careful bacteriologic observations usually indicate the implausibility of the clinical picture.

Laboratory Diagnosis

Urinalysis and urine culture are mandatory to determine the cause of unresolved bacteriuria. The first four causes that are associated with resistant bacteria require no further evaluation. However, if reculture shows that the bacteria is sensitive to the antimicrobial agent the patient is taking, renal function and radiologic evaluation should be performed to identify renal or urinary tract abnormalities.

Management

Initial empirical antimicrobial selection should be based on the assumption that the bacteria are resistant. Therefore an antimicrobial agent different from the original agent should be selected. Fluoroquinolones offer excellent coverage in most cases and should be given for 7 days. When the bacterial susceptibilities are available, adjustments can be made if necessary. Urine cultures should be performed during and 7 days after therapy to ensure microbiologic efficacy.

Recurrent UTIs

Recurrent UTIs are caused by either reemergence of bacteria from a site within the urinary tract (bacterial persistence) or new infections from bacteria outside the urinary tract (reinfection). Clinical identification of these two types of recurrence is based on the pattern of recurrent infections (Fig. 10–14). **Bacterial persistence must be caused by the same organism in each instance, and infections that occur at close intervals are characteristic. Conversely, reinfections usually occur at varying and sometimes long intervals and often are caused by different species. The distinction between bacterial persistence and reinfection is important in management because patients with bacterial persistence can usually be cured of the recurrent infections by identification and surgical removal or correction of the focus of infection. Conversely, women with reinfection usually do not have an alterable urologic abnormality and require long-term medical management. Reinfections in men are uncommon and may be associated with an underlying abnormality, such as urethral stricture; therefore, at a minimum, endoscopic evaluation is indicated.**

Bacterial Persistence

Once the bacteriuria has resolved (i.e., the urine shows no growth for several days after the antimicrobial agent has been stopped), recurrence with the same organism can arise from a site *within* the urinary tract that was excluded from the high urine concentrations of the

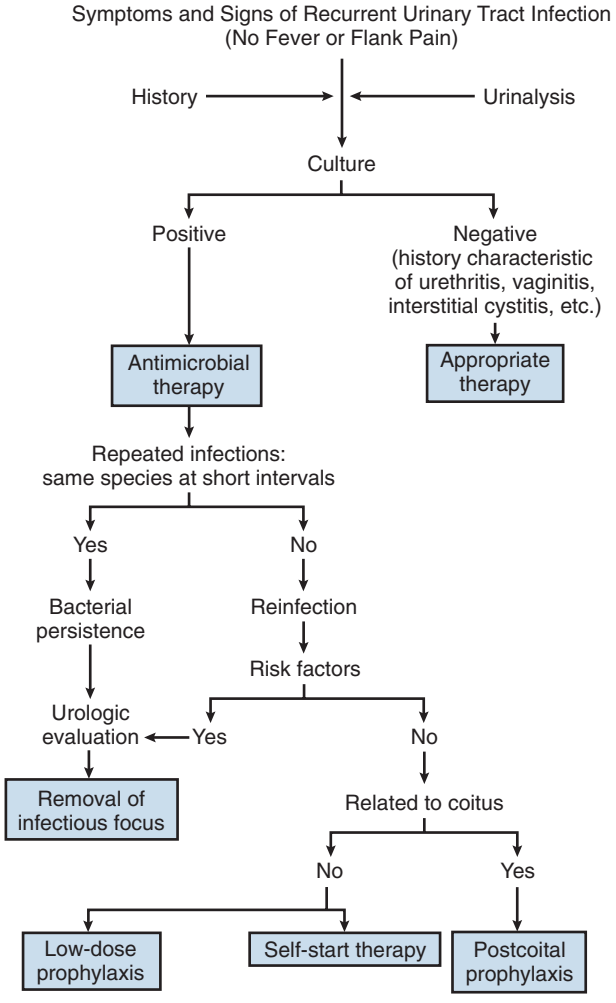

Figure 10–14. Management of recurrent UTI.

antimicrobial agent. The 12 correctable urologic abnormalities that cause bacteria to persist within the urinary tract between episodes of recurrent bacteriuria are listed in Table 10–6. The relationship of these abnormalities to bacterial persistence, as well as the documentation that surgical excision removes the infection as a source of recurrent bacteriuria, is presented elsewhere in detail (Stamey, 1980). Once the urologist recognizes that the cause of the patient's recurrent bacteriuria is bacterial persistence, Table 10–6 should serve as a checklist for known, correctable causes. Some of the causes are subtle, and many require cystoscopic localization of the infection with ureteral catheters to accurately define the focus of bacterial persistence.

Although patients with bacterial persistence are relatively uncommon, their identification is important because they represent the only surgically curable cause of recurrent UTIs. A systematic radiologic and endoscopic evaluation of the urinary tract is mandatory. CT and cystoscopy provide the initial screening. Retrograde urography may be required in selected patients to delineate abnormalities, such as diverticulum or nonrefluxing ureteral stump.

Urea-Splitting Bacteria That Cause Struvite Renal Stones. The infection that ultimately leads to an infection stone commonly begins inconspicuously as inadequately treated cystitis. Most patients with *P. mirabilis* cystitis do not form struvite stones. But struvite stones form in those patients who have a protracted infection with *P. mirabilis*, an infection that is often asymptomatic or minimally symptomatic. *P. mirabilis* causes intense alkalinization of the urine with precipitation of calcium, magnesium, ammonium, and phosphate salts and the subsequent formation of branched struvite renal stones. Bacteriuria in most of these patients with struvite stones recurs almost immediately on stopping antimicrobial therapy, usually within 5 to 7 days. The bacteriologic consequences are substantial because the bacteria persist inside these struvite stones even when the urine shows no growth. Indeed, struvite infection stones, together with the occasional oxalate or apatite stone that becomes secondarily colonized, constitute the major cause of bacterial persistence in women in the absence of azotemia.

Underlying urinary tract abnormalities are not a prerequisite for this type of infection. However, patients with indwelling catheters, urinary diversions, or other urinary tract abnormalities are particularly susceptible to these infections. Urea-splitting organisms, such as *P. mirabilis,* cause infection stones that are relatively radiolucent. If such a stone is suspected, plain film tomograms or CT scans without contrast medium enhancement should be obtained (Greenberg et al, 1982). Medical management with continued suppressive antimicrobial therapy and acidification temporarily relieves symptoms and retards deterioration of renal function in some patients. Complete removal of the calculus is generally required for bacteriologic cure and to prevent renal damage due to obstruction (Silverman and Stamey, 1983). Percutaneous nephrolithotomy and extracorporeal shockwave lithotripsy are now the preferred treatment for most renal and upper ureteral calculi.

When extracorporeal shockwave lithotripsy is used to fragment infection stones, the patient should be maintained on appropriate antimicrobial therapy until the fragments pass. Occasionally, long-term antimicrobial therapy can result in eradication of bacteriuria even if some fragments persist after lithotripsy, presumably because the shockwaves have rendered the entrapped bacteria more susceptible to antimicrobial therapy (Michaels et al, 1988). **If percutaneous or open surgery is used, all the residual particles of struvite stones must be removed at surgery to prevent recurrent bacteriuria from bacterial persistence in the calculus.** Rocha and Santos (1969) have shown that soaking these stones in iodine and alcohol for 6 hours will not kill the bacteria within the interior of the stone. **The importance of recognizing this fact is twofold: (1) The bacteria cannot be killed by antimicrobial therapy, even though the urine may show no growth for months or even years** (Shortliffe et al, 1984), **and (2) any fragments left behind at the time of surgical removal leave residual bacteria within the interstices of the stone; these bacteria ensure recurrence of the staghorn calculus with its attendant morbidity.**

If fragments remain after surgery, a small, multiholed polyethylene catheter should be left for postoperative irrigation with Renacidin or Suby G solution (Silverman and Stamey, 1983). Follow-up radiographs are essential to ensure that all the stone fragments are removed, and cultures must demonstrate that the urease-splitting bacteria are eradicated.

Most of the other congenital or acquired abnormalities listed in Table 10–6 require surgical removal for eradication of the source of bacterial persistence. Chronic bacterial prostatitis is treated initially with long-term antimicrobial therapy and, in select cases, by radical transurethral resection (Mears, 1978).

In patients in whom the focus of infection cannot be eradicated, long-term, low-dose antimicrobial suppression is necessary to prevent symptoms of infection. The antimicrobial drugs used for low-dose prophylaxis will also be effective for bacterial suppression if the persistent strain is susceptible. These include nitrofurantoin, TMP-SMX, cephalexin, and the fluoroquinolones.

Reinfections

Patients with recurrent infections caused by different species or occurring at long intervals almost invariably have reinfections. These reinfections most often occur in women and girls and are associated with ascending colonization from the bowel flora. Reinfections in men are often associated with a urinary tract abnormality. The possibility of a vesicoenteric or vesicovaginal fistula should be considered when the patient has any history of pneumaturia, fecaluria, diverticulitis, obstipation, previous pelvic surgery, or radiation therapy. **Evaluation of the patient with presumed reinfections must be individualized.**

Failure to recognize and correct abnormalities that reduce formation, transmission, and elimination of urine by the urinary tract increases the incidence of reinfection in susceptible patients and reduces the effectiveness of antimicrobial therapy. Abnormalities should be corrected and urinary tract function restored by medical, pharmacologic, or surgical management. A thorough urologic evaluation is essential in all men and in women with evidence of upper tract infections (fevers, chills, flank pain, hemorrhagic cystitis, or other risk factors, such as history of unexplained hematuria, obstructive symptoms, neurogenic bladder dysfunction, renal calculi, fistula, analgesic abuse, or severe disease such as diabetes mellitus). In women, diaphragm-spermicide use has been associated with an increased risk of UTI and vaginal colonization with *E. coli* (Hooton et al, 1991b). Spermicides containing the active ingredient nonoxynol-9 may provide a selective advantage in colonizing the vagina, perhaps by a reduction in vaginal lactobacilli and through enhancement of adherence of *E. coli* to epithelial cells (Gupta et al, 2000; Hooton et al, 1991a). Thus spermicides should be discontinued in women with recurrent UTI and other forms of contraception should be used.

Postmenopausal women have frequent reinfections (Hooton and Stamm, 1991; Raz and Stamm, 1993). These infections are sometimes attributable to residual urine after voiding, which is often associated with bladder or uterine prolapse. In addition, the lack of estrogen causes marked changes in the vaginal microflora, including a loss of lactobacilli and increased colonization by *E. coli* (Raz and Stamm, 1993). Estrogen replacement frequently restores the normal vaginal environment, allows recolonization with lactobacilli, and thus eliminates bacterial uropathogenic colonization. A reduced incidence of UTIs has been documented with this approach (Raz and Stamm, 1993).

Urinary tract imaging will demonstrate the anatomy of the urinary tract and provide reasonable assessment of its functional status. In healthy women, upper tract abnormalities associated with reinfections are very rare; therefore routine urologic imaging is not indicated. Cystoscopy should be performed in men or women who have frequent reinfections and symptoms suggestive of obstruction, bladder dysfunction, and fistula. If the patient has residual urine that is judged to be significant (e.g., 100 mL) and due to a narrowing of the urethra, a single dilation of the urethra to improve bladder emptying would appear appropriate. There is little evidence, however, that repeated urethral dilation is indicated in the routine management of most women.

Antimicrobial management in women who have had two or more symptomatic UTIs over a 6-month period or three or more episodes within a 12-month period involves one of three regimens: low-dose continuous prophylaxis, self-start intermittent therapy, or postintercourse prophylaxis.

Low-Dose Continuous Prophylaxis

Biologic Basis of Successful Prophylaxis: Antimicrobial Effect on Bowel and Vaginal Bacterial Flora. The success of prophylaxis depends, in large part, on the effect an antimicrobial agent has on the introital and bowel reservoirs of pathogenic bacteria. Antimicrobial agents that eliminate pathogenic bacteria from these sites and/or do not cause bacterial resistance at the sites can be effective for antimicrobial prophylaxis of UTIs (Table 10–22).

Winberg and his colleagues were among the first to emphasize that oral antimicrobial therapy causes resistant strains in the bowel flora and subsequent resistant UTIs (Lincoln et al, 1970; Winberg et al, 1973). The increase in resistant strains of *E. coli*, as well as the proliferation of other Enterobacteriaceae species, *Candida albicans*, enterococci, and other pathogenic bacteria in the bowel and vaginal flora that accompanies even short-term, full-dose oral administration of tetracyclines, ampicillin, sulfonamides, amoxicillin, and cephalexin is well documented (Sharp, 1954; Daikos et al, 1968; Hinton, 1970; Lincoln et al, 1970; Datta et al, 1971; Gruneberg et al, 1973; Winberg et al, 1973; Toivanen et al, 1976; Ronald et al, 1977; Preiksaitis et al, 1981). These ecologic changes may interfere with antimicrobial prophylaxis in the urinary tract and must be considered in the choice of prophylactic agents.

Effective Drugs. The oral antimicrobial agents with minimal adverse effects on the bowel and vaginal flora are TMP-SMX or TMP alone, nitrofurantoin, cephalexin (in minimal dosage), and the fluoroquinolones.

TMP-SMX eradicates gram-negative aerobic flora from the bowel and vaginal fluid. Vaginal fluid measurements of TMP and SMX in patients showed that TMP infused across the noninflamed vaginal wall and produced concentrations that exceeded serum levels (Stamey and Condy, 1975); SMX was undetectable in vaginal fluid. These observations on diffusion and concentration of TMP and vaginal fluid and on the effects of TMP-SMX in clearing Enterobacteriaceae from the rectal and vaginal flora clearly indicate why TMP-SMX is such a powerful prophylactic agent for the prevention of reinfections in the female. These important biologic effects occur in addition to the bactericidal levels of TMP-SMX that are present in the urine during nightly prophylaxis.

Kasanen and his colleagues (1978) in Finland studied the bowel flora in volunteers and patients who took 100 mg of TMP per day for periods of 3 weeks to 36 months; 4 of 20 patients treated for long periods developed coliforms resistant to TMP (>8 μg/mL). Svensson and his associates (1982) gave 100 mg of TMP once daily for 6 months to 26 patients with recurrent UTIs. The infection recurrence rate before prophylaxis was 26 per 100 months compared with 3.3 recurrences per 100 months during prophylaxis (P = .001). The postprophylactic infection rate returned to 23 recurrences per 100 months. It is important to note that all *E. coli* UTIs after prophylaxis were sensitive to TMP, the number of rectal Enterobacteriaceae was markedly reduced during prophylaxis, and, although a 10% incidence of TMP-resistant organisms from rectal swabs was observed less than 1 month into prophylaxis there was no significant further accumulation of resistant bacteria.

These studies on TMP alone suggest that it should be as effective as TMP-SMX for prophylactic prevention of recurrent UTIs. Stamm and coworkers (1980a) noted only one resistant strain of *E. coli* in 316 rectal, urethral, and vaginal isolates from 15 patients receiving 100 mg of TMP and 15 others receiving 40 mg of TMP with 200 mg of SMX nightly for 6 months; their unbelievably low recovery of TMP-resistant *E. coli* was due to their method of sampling, which did not include streaking cultures from these colonization sites directly onto media containing TMP.

These studies on TMP-SMX and TMP prophylactic therapy usually have been limited to 6 months to test continuing susceptibility in patients with reinfections. Two studies (Pearson et al, 1979; Harding et al, 1982), however, continued TMP-SMX prophylaxis from 2 to 5 years without showing any increase in "breakthrough" infections or any increase in TMP-resistant recurrent infections. Indeed, in the 15 patients treated for 2 years with one-half tablet of TMP-SMX thrice weekly (Harding et al, 1982), 100 of 116 cultures from the periurethral area (91%) and 60 of 97 cultures from the anal canal (68%) showed no aerobic gram-negative bacilli at these colonization sites.

Nitrofurantoin, which does not alter the bowel flora, is present for brief periods at high concentrations in the urine and leads to repeated elimination of bacteria from the urine, presumably interfering with bacterial initiation of infection. Because of either its complete absorption in the upper intestinal tract or its degradation and inactivation in the intestinal tract, it produces minimal effects on bowel flora (Stamey et al, 1977). Unlike the situation in prophylaxis with TMP-SMX that eliminates colonization, in prophylaxis with nitrofurantoin colonization of the vaginal introitus with Enterobacteriaceae continues throughout therapy. The bacteria colonizing the vagina nearly always remain susceptible because of the lack of bacterial resistance in the bowel flora. Patients on long-term therapy should be monitored for adverse reactions (e.g., pulmonary fibrosis). **The risk of an adverse reaction increases with age, with the greatest number occurring in patients older than 50 years. If a patient develops a chronic cough, the drug should be discontinued and a chest radiograph obtained.**

Fairley and his associates (1974) first reported on the prophylactic efficacy of 500 mg of cephalexin per day in preventing recurrent infections during a 6-month period of observation. Of

Table 10–22.

Low-Dose Prophylaxis for Recurrent UTIs in Women

INVESTIGATORS	REGIMEN	INFECTIONS PER PATIENT-YEAR
Bailey et al (1971)	Nitrofurantoin, 50 or 100 mg daily	0.09
	Nitrofurantoin, 50 mg daily	0.19
	Placebo	2.1
Harding and Ronald (1974)	Sulfamethoxazole, 500 mg daily	2.5
	TMP-SMX, 40 and 200 mg daily	0.1
	Methenamine mandelate, 2 g daily, plus ascorbic acid, 2 g	1.6
Kasanen et al (1974)	Nitrofurantoin, 50 mg daily	0.32
	Methenamine hippurate, 1 g daily	0.39
	Trimethoprim, 100 mg daily	0.13
	TMP-SMX, 80 and 400mg daily	0.19
Gower (1975)	Cephalexin, 125 mg daily	0.10
Stamey et al (1977)	TMP-SMX, 40 and 200 mg daily	0.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.74
Harding et al (1979)	TMP-SMX, 40 and 200 mg daily three times weekly	0.1
Stamm et al (1980)	TMP-SMX, 40 and 200 mg daily	0.15
	Trimethoprim, 100 mg daily	0.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.14
	Placebo	2.8
Brumfitt et al (1981)	Nitrofurantoin, 50 mg twice daily	0.19
	Methenamine hippurate, 1 g twice daily	0.57
Harding et al (1982)	TMP-SMX, 40 and 200 mg three times weekly	0.14
Brumfitt et al (1983)	Trimethoprim, 100 mg daily	1.53
	Methenamine hippurate, 1 g daily	1.38
	Povidone-iodine wash, twice daily	1.79
Wong et al (1985)	TMP-SMX, 40 and 200 mg daily	0.2
	Self-administered cotrimoxazole, 4 × 80 and 400 mg	2.2
Martinez et al (1985)	Cephalexin, 250 mg daily	0.18
Brumfitt et al (1985)	Trimethoprim, 100 mg daily	1.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.16
Nicolle et al (1989)	Nitrofurantoin, 200 mg daily	0.00
	Norfloxacin, 200 mg daily	0.00
Raz and Boger (1991)	Norfloxacin, 200 mg daily	0.04

TMP-SMX, trimethoprim-sulfamethoxazole.
From Nicolle LE, Ronald AR. Recurrent urinary tract infection in adult women: diagnosis and treatment. Infect Dis Clin North Am 1987;1:793–806.

the 22 patients, 17 remained free of infection, an impressive record because several patients had papillary necrosis, chronic pyelonephritis, and even renal calculi. Gower (1975) treated 25 women with 125 mg of cephalexin nightly for 6 to 12 months and found only 1 infection, whereas 13 of 25 women receiving a placebo had infection.

Martinez and coworkers (1985) studied the effect on the vaginal and rectal flora of 250 mg of cephalexin nightly for 6 months in 23 patients with reinfections of the urinary tract. Throughout prophylaxis, 22 of the 23 patients maintained a sterile urine; a single patient developed two enterococcal UTIs, both of which responded to nitrofurantoin. No change was detected in the rectal or vaginal carriage of Enterobacteriaceae. More importantly, not a single resistant strain of *E. coli* was detected in 154 cultures obtained at monthly intervals during cephalexin therapy. These results are in contrast to those of Preiksaitis and colleagues (1981), who found rectal Enterobacteriaceae resistance in 38% of patients when cephalexin was administered at a dose of 500 mg four times daily for 14 days. **Cephalexin at 250 mg or less nightly is an excellent prophylactic agent because bowel flora resistance does not develop at this low dosage.**

With short-course fluoroquinolone therapy (Hooton et al, 1989), eradication of Enterobacteriaceae from the bowel and vaginal (Nord, 1988; Tartaglione et al, 1988) flora has been documented, observations that have been exploited in the use of these agents for prophylaxis. More recently, Nicolle and coworkers (1989) documented the prophylactic efficacy of norfloxacin for the prevention of recurrent UTIs in women. Of 11 women who completed 1 year of prophylaxis (with 200 mg orally), all remained free of infection. By comparison, the majority of individuals receiving placebos developed UTIs. The drug was well tolerated. In addition to preventing symptomatic UTIs, norfloxacin virtually eradicated periurethral and bowel colonization with aerobic gram-negative organisms. A larger study by Raz and Boger (1991) confirmed these results.

Because the fluoroquinolones are expensive and can be used only in nonpregnant women, we favor their use only when antimicrobial resistance or patient intolerance to TMP-SMX, TMP, nitrofurantoin, or cephalexin occurs. Further studies are required to determine the minimal effective regimen and efficacy of the fluoroquinolones for prophylaxis of recurrent UTIs in women.

Efficacy of Prophylaxis. Low-dose continuous prophylaxis is indicated when the urine culture shows no growth (usually when a patient has completed antimicrobial therapy). Nightly therapy is then begun with one of the following drugs: (1) nitrofurantoin, 50 to 100 mg half-strength (HS) (Stamey et al, 1977); (2) TMP-SMX, 40 to 200 mg (Stamm et al, 1982a); (3) TMP, 50 mg (Stamm et al, 1982a); or (4) cephalexin (Keflex), 250 mg (Martinez et al, 1985). **Prophylactic therapy has been repeatedly**

documented as being effective in the management of women with recurrent UTIs, with recurrences decreased by 95% when compared with placebo or with the patients' prior experiences as controls. These reported results of prophylaxis, together with agents and doses, have been summarized by Nicolle and Ronald (1987) (see Table 10–22). These studies consistently show a remarkable reduction in the reinfection rate from 2.0 to 3.0 per patient-year to 0.1 to 0.4 per patient-year with the use of prophylaxis. Urinary antiseptics, such as methenamine mandelate or hippurate, have resulted in some decrease in recurrences, but they are not as effective as antimicrobial agents.

Every-other-night therapy is also effective and is probably practiced by most patients. **When breakthrough infections occur, they are not necessarily accompanied by symptoms; therefore we advocate monitoring for infections every 1 to 3 months, even in asymptomatic patients. Breakthrough infections usually respond to full-dose therapy with the drug used for prophylaxis. However, cultures and susceptibility tests may indicate that another drug is indicated. After the infection is cured, prophylaxis may be reinstituted. Low-dose prophylaxis is usually discontinued after about 6 months, and the patient is monitored for reinfection.** Approximately 30% of women will have spontaneous remissions that last up to 6 months (Kraft and Stamey, 1977). Unfortunately, many of the remissions are followed by reinfections, and low-dose prophylaxis must be reinstituted. At this point, many patients prefer an alternative form of management.

Self-Start Intermittent Therapy. **With self-start intermittent therapy, the patient is given a dip slide device to culture the urine and is instructed to perform a urine culture when symptoms of UTI occur** (Schaeffer and Stuppy, 1999; Blom et al, 2002). The patient is also provided a 3-day course of empirical, full-dose antimicrobial therapy to be started immediately after performing the culture. It is important that the antimicrobial agent selected for self-start therapy have a broad spectrum of activity and achieve high urinary levels to minimize development of resistant mutants. In addition, there should be minimal or no side effects on the bowel flora. Fluoroquinolones are ideal for self-start therapy because they have a spectrum of activity broader than any of the other oral agents and are superior to many parenteral antimicrobials, including aminoglycosides. Nitrofurantoin and TMP-SMX are acceptable alternatives, although they are somewhat less effective. Antimicrobial agents such as tetracycline, ampicillin, SMX, and cephalexin in full doses should be avoided because they can give rise to resistant bacteria (Wong et al, 1985).

The culture is brought to the office as soon as possible. If the culture is positive and the patient is asymptomatic, a culture is performed 7 to 10 days after therapy to determine efficacy. In most cases, the therapy is limited to two inexpensive dip slide cultures and a short course of antimicrobial therapy. If the patient has symptoms that do not respond to initial antimicrobial therapy, a repeat culture and susceptibility testing of the initial culture specimen are performed and therapy adjusted accordingly. If symptoms of infection are not associated with positive cultures, urologic evaluation should be performed to rule out other causes of irritative bladder symptoms, including carcinoma in situ, interstitial cystitis, and neurogenic bladder dysfunction. The authors' experience with this technique has been very favorable, and is particularly attractive to patients who have less frequent infections and are willing to play an active role in their diagnosis and management.

Postintercourse Prophylaxis. Antimicrobial management through postintercourse prophylaxis is based on research establishing that sexual intercourse can be an important risk factor for acute cystitis in women (Nicolle et al, 1982). Diaphragm users have a significantly greater risk of UTI than do women who use other contraceptive methods (Fihn et al, 1985). Postintercourse therapy with antimicrobial agents, such as nitrofurantoin, cephalexin, TMP-SMX, or a fluoroquinolone taken as a single dose, will effectively reduce the incidence of reinfection (Pfau et al, 1983; Melekos et al, 1997).

Other Strategies. Cranberry juice contains proanthocyanidins that block adherence of pathogens to uroepithelial cells in vitro (Foo et al, 2000). Randomized trials in low-risk patients show that 200 to 750 mL daily of cranberry or lingonberry juice or cranberry-concentrate tablets reduce the risk of symptomatic, recurrent infection by 12% to 20% (Avorn et al, 1994; Kontiokari et al, 2001; Stothers, 2002; McMurdo et al, 2009). However, the actual cranberry content of juices and tablets varies substantially; therefore their efficacy is not predictable (Consumer Reports, 2001; Klein, 2002). Furthermore, other trials of cranberry products show no benefit and there is no evidence that they are effective for treatment of UTIs (Jepson et al, 2001; Raz et al, 2004).

Other factors, such as hygiene, frequency and timing of voiding, wiping patterns, use of hot tubs, and type of undergarments, have not been shown to predispose women to recurrent infection and there is no rationale for giving women specific instructions regarding them.

Key Points: Bladder Infections

- Uncomplicated cystitis should be treated for 3 days.
- Asymptomatic bacteriuria should be treated only in pregnant women and prior to urologic intervention.
- Recurrent UTIs due to bacterial persistence require urologic management; reinfections can be managed medically.

KIDNEY INFECTIONS

Renal Infection (Bacterial Nephritis)

Although renal infection is less prevalent than bladder infection it often is a more difficult problem for the patient and his or her physician because of its often varied and morbid presentation and course, the difficulty in establishing a firm microbiologic and pathologic diagnosis, and its potential for significantly impairing renal function. **Although the classic symptoms of acute onset of fever, chills, and flank pain are usually indicative of renal infection, some patients with these symptoms do not have renal infection. Conversely, significant renal infection may be associated with an insidious onset of nonspecific local or systemic symptoms or it may be entirely asymptomatic.** Therefore a high clinical index of suspicion and appropriate radiologic and laboratory studies are required to establish the diagnosis of renal infection.

Unfortunately, **the relationship between laboratory findings and the presence of renal infection often is poor. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside the collecting system.**

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Interstitial renal inflammation, once thought to be caused predominantly by bacterial infection, is now recognized as a nonspecific histopathologic change associated with a variety of immunologic, congenital, or chemical lesions that usually develop in the absence of bacterial infection. Infectious granulomatous diseases of the kidney often have either radiologic or pathologic characteristics that mimic renal cystic disease, neoplasia, or other renal inflammatory disease.

The effect of renal infection on renal function is varied. Acute or chronic pyelonephritis may transiently or permanently alter renal function, but nonobstructive pyelonephritis is no longer recognized as a major cause of renal failure (Baldassarre and Kaye, 1991; Fraser et al, 1995). However, pyelonephritis, when associated with urinary tract obstruction or granulomatous renal infection, may lead rapidly to significant inflammatory complications, renal failure, or even death.

Pathology

The opportunity for pathologic confirmation of acute bacterial nephritis is rare. The kidney may be edematous. Focal acute suppurative bacterial nephritis caused by hematogenous dissemination of bacteria to the renal cortex is characterized by multiple focal areas of suppuration on the surface of the kidney (Fig. 10–15). Histologic examination of the renal cortex shows focal suppurative destruction of glomeruli and tubules. Adjacent cortical structures and the medulla are not involved in the inflammatory reaction. Acute ascending pyelonephritis is characterized by linear bands of inflammation extending from the medulla to the renal capsule (Fig. 10–16). Histologic examination usually reveals a focal wedge-shaped area of acute interstitial inflammation with the apex of the wedge in the renal medulla. Polymorphonuclear leukocytes or a predominantly lymphocytic and plasma cell response are seen. Bacteria also may be present.

The changes that appear to be most specific for chronic pyelonephritis are evident on careful gross examination of the kidney and consist of a cortical scar associated with retraction of the corresponding renal papilla (Hodson, 1965a, 1965b; Heptinstall, 1974; Freedman, 1979). The kidney shows evidence of patchy involvement with numerous chronic inflammatory foci mainly confined to the cortex but also involving the medulla (Fig. 10–17).

The scars may be separated by intervening zones of normal parenchyma, causing a grossly irregular renal outline. The microscopic appearance, as with most chronic interstitial disease, includes the presence of lymphocytes and plasma cells. Although glomeruli within scars may be surrounded by a cuff of fibrosis or be partially or completely hyalinized, glomeruli outside these severely scarred zones are relatively normal. Vascular involvement is variable, but in patients with hypertension, nephrosclerosis may be found. Papillary abnormalities include deformity, sclerosis, and sometimes necrosis. Studies in animals have clearly indicated the critical role of the papilla in the initiation of pyelonephritis (Freedman and Beeson, 1958). However, these changes are not necessarily specific for bacterial infection and may occur in the absence of infection as a result of other disorders such as analgesic abuse, diabetes, and sickle cell disease.

Acute Pyelonephritis

Although pyelonephritis is defined as inflammation of the kidney and renal pelvis, the diagnosis is clinical. True infection of the "upper urinary tract" can be proved by catheterization tests (ureteral catheterization or bladder washout) as described in this chapter, but these are impractical and unnecessary in most patients with acute pyelonephritis. None of the noninvasive tests that have been developed to determine infection in the kidney or bladder is totally reliable.

Clinical Presentation. **The clinical spectrum ranges from gram-negative sepsis to cystitis with mild flank pain** (Stamm and Hooton, 1993). **The classic presentation is an abrupt onset of chills, fever (100° F or greater), and unilateral or bilateral flank or costovertebral angle pain and/or tenderness. These so-called upper tract signs are often accompanied by dysuria, increased urinary frequency, and urgency.**

Although some authors regard loin pain and fever in combination with significant bacteriuria as diagnostic of acute pyelonephritis, it is clear from localization studies using ureteral catheterization (Stamey and Pfau, 1963) or the bladder washout technique (Fairley et al, 1967) that **clinical symptoms correlate poorly with the site of infection** (Stamey et al, 1965; Eykyn et al, 1972; Fairley, 1972; Smeets and Gower, 1973).

In a large study of 201 women and 12 men with recurrent UTIs, Busch and Huland (1984) **showed that fever and flank pain are no more diagnostic of pyelonephritis than**

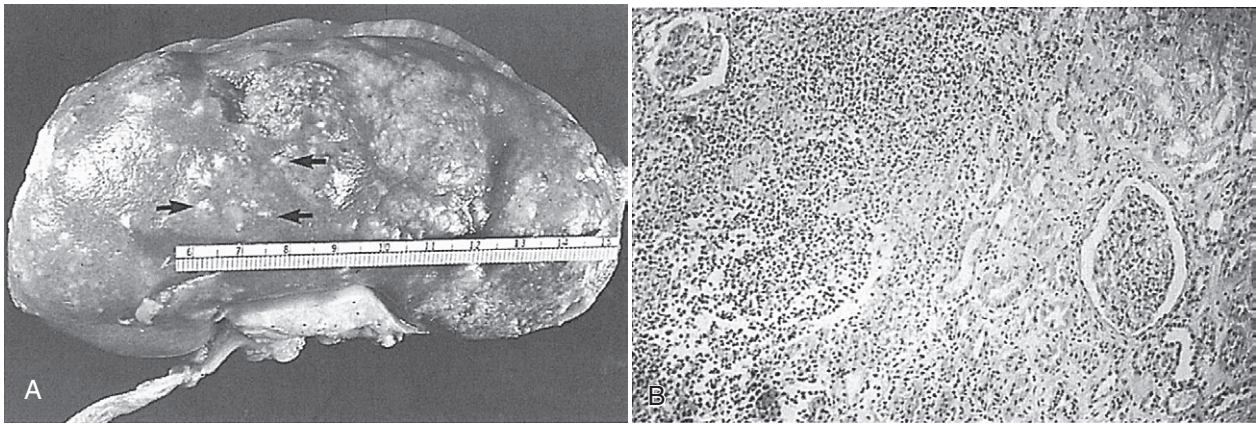

Figure 10–15. Acute focal suppurative bacterial nephritis. **A,** Surface of kidney. *Arrows* indicate focal areas of suppuration. **B,** Renal cortex showing focal suppuration destruction of glomeruli and tubules. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

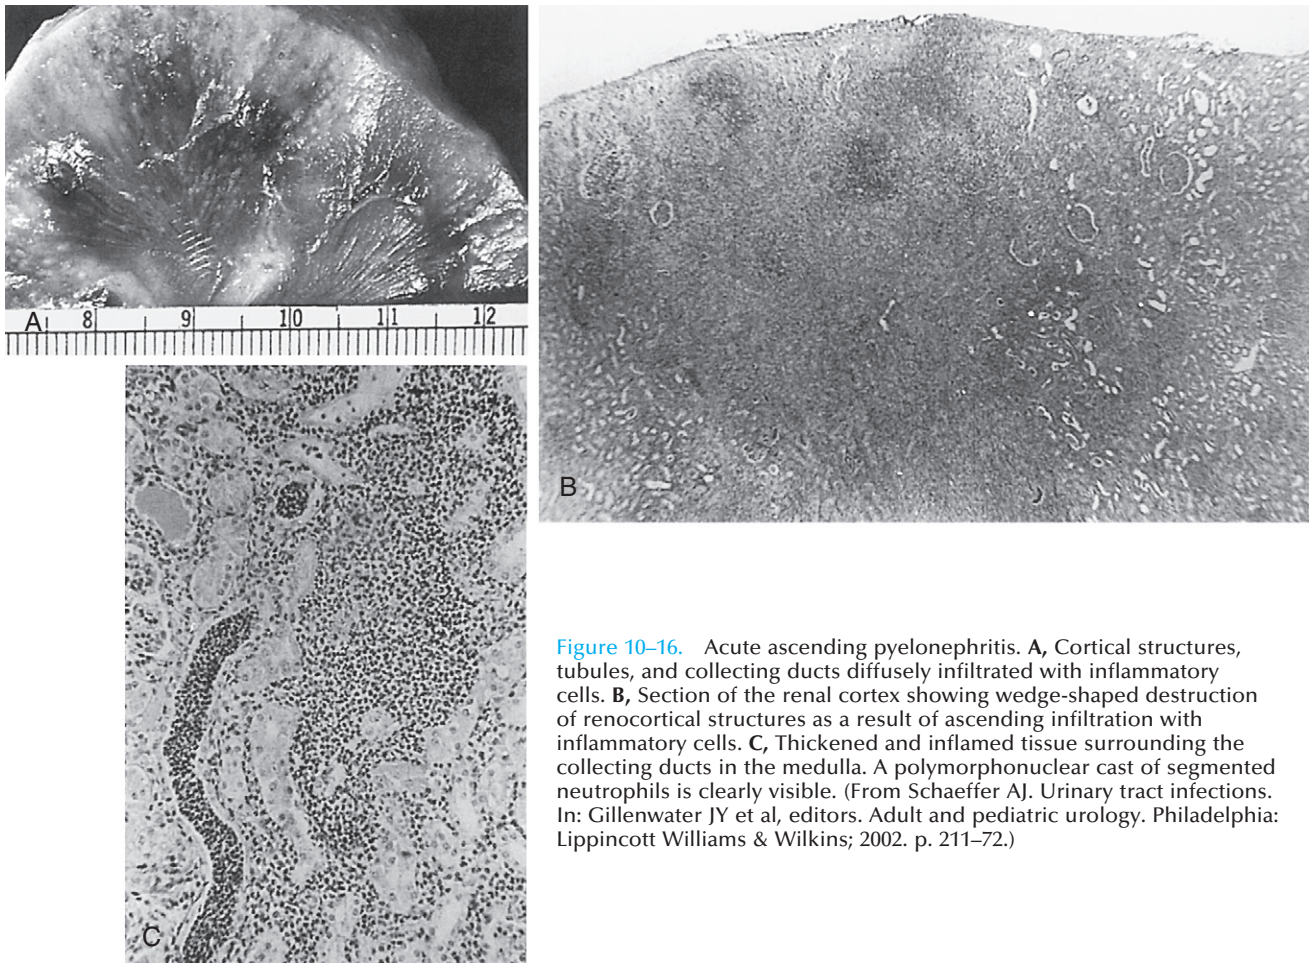

Figure 10–16. Acute ascending pyelonephritis. **A,** Cortical structures, tubules, and collecting ducts diffusely infiltrated with inflammatory cells. **B,** Section of the renal cortex showing wedge-shaped destruction of renocortical structures as a result of ascending infiltration with inflammatory cells. **C,** Thickened and inflamed tissue surrounding the collecting ducts in the medulla. A polymorphonuclear cast of segmented neutrophils is clearly visible. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

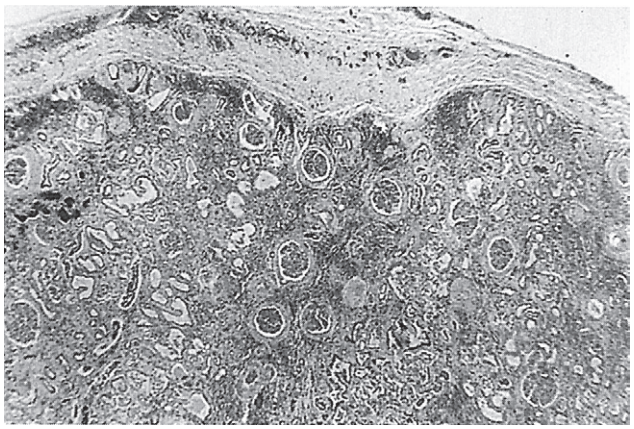

Figure 10–17. Chronic pyelonephritis. The renal cortex shows thickened fibrous capsule and focal retracted scar on surface of kidney. Focal destruction of tubules in center of picture is accompanied by periglomerular fibrosis and scarring. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

they are of cystitis. Of patients with flank pain and/or fever, over 50% had lower tract bacteriuria. Conversely, patients with bladder symptoms or no symptoms frequently had upper tract bacteriuria. Approximately 75% of patients give a history of previous lower UTIs.

On physical examination there often is tenderness to deep palpation in the costovertebral angle. Variations of this clinical presentation have been recognized. Acute pyelonephritis may also simulate gastrointestinal tract abnormalities with abdominal pain, nausea, vomiting, and diarrhea. Asymptomatic progression of acute pyelonephritis to chronic pyelonephritis, particularly in compromised hosts, may occur in the absence of overt symptoms. Acute renal failure may be present in the rare case (Richet and Mayaud, 1978; Olsson et al, 1980).

Laboratory Diagnosis. The patient may have leukocytosis with predominance of neutrophils. **Urinalysis usually reveals numerous WBCs, often in clumps, and bacterial rods or chains of cocci.** Leukocytes exhibiting brownian motion in the cytoplasm (glitter cells) may be present if the urine is hypotonic, but they are not in themselves diagnostic of pyelonephritis. **The presence of large amounts of granular or leukocyte casts in the urinary sediment is suggestive of acute pyelonephritis.** A specific type of urinary cast characterized by the presence of bacteria in its matrix has been demonstrated in the urine of patients who have had acute pyelonephritis (Fig. 10–18) (Lindner et al, 1980). Bacteria in the casts were not easily distinguished by simple brightfield microscopy without special staining of the sediment. Staining of the sediment with a basic dye such as dilute toluidine blue or KOVA stain (I.C.L. Scientific, Fountain Valley, CA) demonstrated the bacteria in casts without difficulty. Blood tests may show leukocytosis with a predominance of neutrophils, increased erythrocyte sedimentation rate, elevated C-reactive protein levels, and elevated creatinine levels if renal

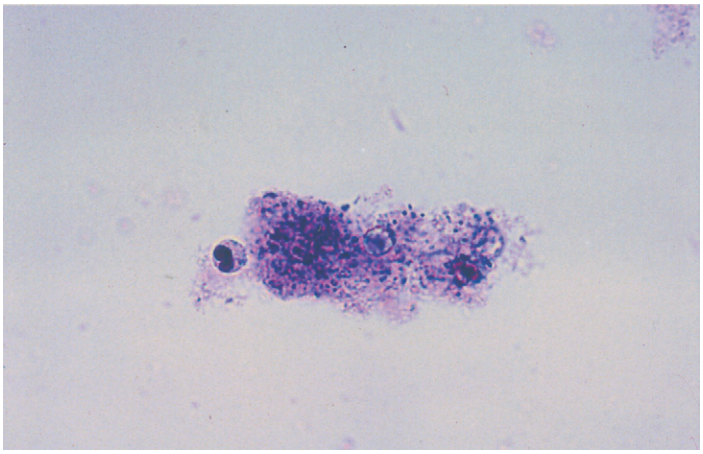

Figure 10–18. Brightfield micrograph of a mixed bacterial leukocyte cast from patient with acute pyelonephritis. Only the bacteria and the nucleus of a leukocyte stain strongly. Many bacteria are clearly demonstrated by through-focusing (toluidine blue O, ×640). (From Lindner LE, Jones RN, Haber MH. A specific urinary cast in acute pyelonephritis. Am J Clin Pathol 1980;73:809–11.)

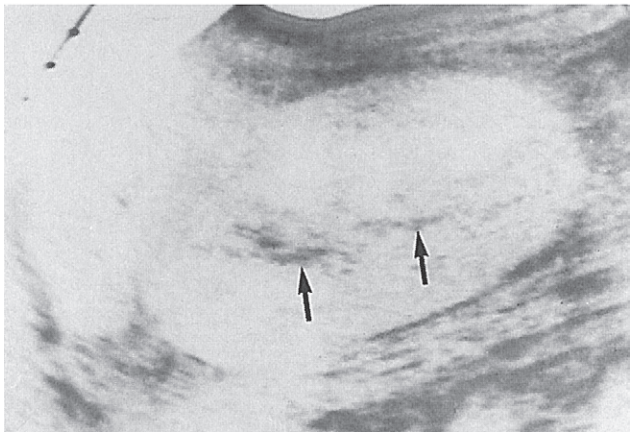

Figure 10–19. Acute pyelonephritis. Ultrasound image of the right kidney demonstrates renal enlargement, hypoechoic parenchyma, and compressed central collecting complex *(arrows)*. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott William & Wilkins; 2002. p. 211–72.)

failure is present. In addition, creatinine clearance may be decreased. Blood cultures may be positive.

Bacteriology. **Urine cultures are positive, but about 20% of patients have urine cultures with fewer than 10^5 cfu/mL and, therefore, negative results on Gram staining of the urine** (Rubin et al, 1992).

***E. coli*, which constitutes a unique subgroup that possesses special virulence factors, accounts for 80% of cases.** If vesicoureteral reflux is absent, a patient bearing the P blood group phenotype may have special susceptibility to recurrent pyelonephritis caused by *E. coli* that have P pili and bind to the P blood group antigen receptors (Lomberg et al, 1983). Bacterial K antigens and endotoxins also may contribute to pathogenicity (Kaijser et al, 1977). Many cases of community-acquired pyelonephritis are caused by a limited number of multiple-antimicrobial–resistant clonal groups (Manges et al, 2004).

More resistant species, such as *Proteus, Klebsiella, Pseudomonas, Serratia, Enterobacter,* or *Citrobacter* should be suspected in patients who have recurrent UTIs, are hospitalized, or have indwelling catheters, as well as in those who required recent urinary tract instrumentation. Except for *E. faecalis, S. epidermidis,* and *S. aureus,* gram-positive bacteria rarely cause pyelonephritis.

Blood cultures are positive in about 25% of cases of uncomplicated pyelonephritis in women, and the majority replicate the urine culture and do not influence decisions regarding therapy. Therefore blood cultures should not be routinely obtained for the evaluation of uncomplicated pyelonephritis in women. **However, they should be performed in men and women with systemic toxicity or in those requiring hospitalization or with risk factors such as pregnancy** (Velasco et al, 2003).

Renal Ultrasonography and Computed Tomography. These studies are commonly used to evaluate patients initially for complicated UTIs or factors or to reevaluate patients who do not respond after 72 hours of therapy (see later). Ultrasonography (Fig. 10–19) and CT show renal enlargement, hypoechoic or attenuated parenchyma, and a compressed collecting system. They also may delineate focal bacterial nephritis and obstruction. When parenchymal destruction becomes pronounced, a more disorganized parenchyma and abscess formation associated with complicated renal and perirenal infections may be identified (Soulen et al, 1989).

Differential Diagnosis. **Acute appendicitis, diverticulitis, and pancreatitis can cause a similar degree of pain, but the location of the pain often is different.** Results of the urine examination are usually normal. Herpes zoster can cause superficial pain in the region of the kidney but is not associated with symptoms of UTI; the diagnosis will be apparent when shingles appear.

Management

Initial Management. Infection in patients with acute pyelonephritis can be subdivided into (1) uncomplicated infection that does not warrant hospitalization, (2) uncomplicated infection in patients with normal urinary tracts who are ill enough to warrant hospitalization for parenteral therapy, and (3) complicated infection associated with hospitalization, catheterization, urologic surgery, or urinary tract abnormalities (Fig. 10–20).

It is critical to determine whether the patient has an uncomplicated or complicated UTI because significant abnormalities have been found in 16% of patients with acute pyelonephritis (Shen and Brown, 2004). In patients with presumed uncomplicated pyelonephritis that will be managed as outpatients, initial radiologic evaluation can usually be deferred. **However, if there is any reason to suspect a problem or if the patient will not have reasonable access to imaging if there should be no change in condition, we prefer renal ultrasound evaluation to rule out stones or obstruction.** In patients with known or suspected complicated pyelonephritis, CT provides excellent assessment of the status of the urinary tract and the severity and extent of the infection.

For patients who will be managed as outpatients, single-drug oral therapy with a fluoroquinolone is more effective than TMP-SMX for patients with domiciliary infections (Talan et al, 2000). Many physicians administer a single parenteral dose of an antimicrobial agent (ceftriaxone, gentamicin, or a fluoroquinolone) before initiating oral therapy (Israel et al, 1991; Pinson et al, 1994). If a gram-positive organism is suspected, amoxicillin or amoxicillin/clavulanic acid is recommended (Warren et al, 1999).

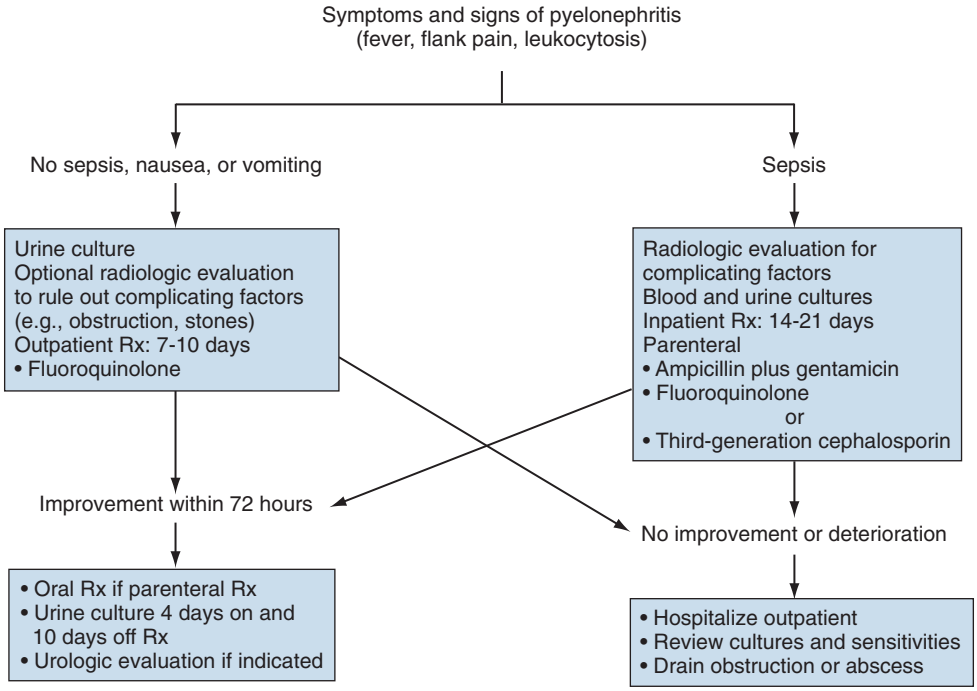

Figure 10–20. Management of acute pyelonephritis.

Table 10–23.

Treatment Regimens for Acute Complicated and Uncomplicated Pyelonephritis in Women

CIRCUMSTANCES	ROUTE	DRUG	DOSAGE	FREQUENCY PER DOSE	DURATION (DAYS)
Outpatient—moderately ill, no nausea or vomiting	Oral	TMP-SMX	160-800 mg	bid	10-14
		Ciprofloxacin	500 mg	bid	
		Levofloxacin	500 mg	qd	
		Norfloxacin	400 mg	bid	
Inpatient—severely ill, possible sepsis	Parenteral	TMP-SMX	160-800 mg	bid	14
		Ampicillin and gentamicin	1 g	qid	
			1.5 mg/kg	tid	
		Ciprofloxacin	400 mg	bid	
		Levofloxacin	500 mg	qd	
		Ceftriaxone	1 to 2g	qd	Take until afebrile, then take oral
		TMP-SMX or fluoroquinolone			
Pregnant	Parenteral	Ceftriaxone	1-2 g	qd	14
		Ampicillin and gentamicin	1 g	qid	
			1 mg/kg	tid	
		Aztreonam	1 g	tid-qid	Take until afebrile, then take oral
	Oral	Cephalexin	500 mg	bid	

TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Stamm WE, Hooton TM. Management of urinary tract infections in adults. N Engl J Med 1993;329:1328–34. Copyright 1993, Massachusetts Medical Society. All rights reserved.

If a patient has an uncomplicated infection but is sufficiently ill to require hospitalization (high fever, high WBC count, vomiting, dehydration, evidence of sepsis), has complicated pyelonephritis, or fails to improve during the initial outpatient treatment period, a parenteral fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside is recommended (Warren et al, 1999) (Table 10–23). If gram-positive cocci are causative, ampicillin/sulbactam with or without an aminoglycoside is recommended.

Hospitalization, initially with complete bed rest, intravenous fluids, and antipyretics, is required.

An obstructed kidney has difficulty concentrating and excreting antimicrobial agents. Any substantial obstruction must be relieved expediently by the safest and simplest means.

A Gram stain of the urine sediment is helpful to guide the selection of the initial empirical antimicrobial therapy. In all cases, antimicrobial therapy should be active against potential uropathogens and achieve antimicrobial levels in renal tissue as well as urine.

Subsequent Management. Even though the urine usually becomes sterile within a few hours of starting antimicrobial therapy,

patients with acute uncomplicated pyelonephritis may continue to have fever, chills, and flank pain for several more days after initiation of successful antimicrobial therapy (Behr et al, 1996). They should be observed.

Ambulatory patients should be treated with a fluoroquinolone for 7 days (Talan et al, 2000). Fluoroquinolone therapy is associated with greater bacteriologic and clinical cure rates than 14-day TMP-SMX therapy (Talan et al, 2000). Alterations in antimicrobial therapy may be made depending on the patient's clinical response and the results of the culture and susceptibility tests. Susceptibility tests should also be used to replace potentially toxic drugs, such as aminoglycosides, with less toxic drugs, such as the fluoroquinolones, aztreonam, and cephalosporins.

Patients with complicated pyelonephritis and positive blood cultures should be treated with parenteral therapy until clinically stable. If blood cultures are negative, 2- to 3-day parenteral therapy is sufficient. Following parenteral therapy, an appropriate oral antimicrobial drug (fluoroquinolone, TMP, TMP-SMX, or amoxicillin or amoxicillin/clavulanic acid for gram-positive organisms) should be continued in full dosage for an additional 10 to 14 days.

Unfavorable Response to Therapy. When the response to therapy is slow or the urine continues to show infection, an immediate reevaluation is mandatory. Urine and blood cultures must be repeated and appropriate alterations in antimicrobial therapy made on the basis of susceptibility testing. CT is indicated to attempt to identify unsuspected obstructive uropathy, urolithiasis, or underlying anatomic abnormalities that may have predisposed the patient to infection, prevented a rapid therapeutic response, or caused complications of the infectious process, such as renal or perinephric abscess. **In patients with fever lasting longer than 72 hours, CT is most helpful for ruling out obstruction and identifying renal and perirenal infections** (Soulen et al, 1989). Radionuclide imaging may be useful to demonstrate functional changes associated with acute pyelonephritis (decrease in renal blood flow, delay in peak function, and delay in excretion of the radionuclide) (Fischman and Roberts, 1982) and cortical defects associated with vesicoureteral reflux.

Follow-Up. **Repeat urine cultures should be performed on the fifth to the seventh day of therapy and 10 to 14 days after discontinuing antimicrobial therapy to ensure that the urinary tract remains free of infections. Between 10% and 30% of individuals with acute pyelonephritis relapse after a 14-day course of therapy. Patients who experience relapse usually are cured by a second 14-day course of therapy, but occasionally a 6-week course is necessary** (Tolkoff-Rubin et al, 1984; Johnson and Stamm, 1987).

Depending on the clinical presentation and response and initial urologic evaluation, some patients may require additional evaluation (e.g., voiding cystourethrogram, cystoscopy, bacterial localization studies) and correction of an underlying abnormality of the urinary tract. Raz and colleagues (2003) evaluated the long-term impact of acute pyelonephritis in women. Scanning with ^{99m}Tc-dimercaptosuccinic acid (^{99m}Tc-DMSA) 10 to 20 years after acute pyelonephritis revealed scars in approximately 50% of the patients but changes in renal function were minimal and not associated with renal scarring.

Acute Focal or Multifocal Bacterial Nephritis

Acute focal or multifocal bacterial nephritis is an uncommon, severe form of acute renal infection in which a heavy leukocyte infiltrate is confined to a single renal lobe (focal) or multiple lobes (multifocal).

Clinical Presentation. **The clinical presentation of patients with acute bacterial nephritis is similar to that of patients with acute pyelonephritis but usually is more severe. About half of the patients are diabetic, and sepsis is common.** Generally, leukocytosis and UTI resulting from gram-negative organisms are found; more than 50% of the patients are bacteremic (Wicks and Thornbury, 1979).

Radiologic Findings. The diagnosis must be made by radiologic examination. The mass has slightly less nephrographic density than the surrounding normal renal parenchyma.

Ultrasonography and CT establish the diagnosis. On ultrasonography the lesion is typically poorly marginated and relatively sonolucent with occasional low-amplitude echoes that disrupt the cortical medullary junction (Corriere and Sandler, 1982) (Fig. 10–21A). **Enhancement with a contrast agent is necessary with CT studies because the lesion is difficult to visualize on the unenhanced study** (see Fig. 10–21B). **Wedge-shaped areas of decreased enhancement are seen.** No definite wall is evident, and frank liquefaction is absent. Conversely, abscesses tend to have liquid centers, are usually round, and are present both before and after contrast medium enhancement. More chronic abscesses may also show a ring-shaped area of increased enhancement surrounding the lesion (Corriere and Sandler, 1982). Gallium scanning reveals uptake that is in the region of and larger than the previously demonstrated mass (Rosenfield et al, 1979). In patients with multifocal disease the findings are similar but multiple lobes are involved.

Management. Acute bacterial nephritis probably represents a relatively early phase of frank abscess formation. In a series of cases reported by Lee and coworkers (1980) a patient with acute focal bacterial nephritis progressed to abscess formation. **Treatment includes hydration and intravenous antimicrobial agents for at least 7 days, followed by 7 days of oral antimicrobial therapy.** Patients with bacterial nephritis typically respond to medical therapy, and follow-up studies will show resolution of the wedge-shaped zones of diminished attenuation. **Failure to respond to antimicrobial therapy is an indication for appropriate studies to rule out obstructive uropathy, renal or perirenal abscess, renal carcinoma, or acute renal vein thrombosis.** Long-term follow-up studies performed in a few patients with multifocal disease have demonstrated a decrease in renal size and focal calyceal deformities suggestive of papillary necrosis (Davidson and Talner, 1978).

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a urologic emergency characterized by an acute necrotizing parenchymal and perirenal infection caused by gas-forming uropathogens. The pathogenesis is poorly understood. **Because the condition usually occurs in diabetic patients, it has been postulated that the high tissue glucose levels provide the substrate for microorganisms such as *E. coli*, which are able to produce carbon dioxide by the fermentation of sugar** (Schainuck et al, 1968). Although glucose fermentation may be a factor, the explanation does not account for the rarity of emphysematous pyelonephritis despite the high frequency of gram-negative UTI in diabetic patients, nor does it explain the rare occurrence of the condition in nondiabetic patients.

In addition to diabetes, many patients have urinary tract obstruction associated with urinary calculi or papillary necrosis and significant renal functional

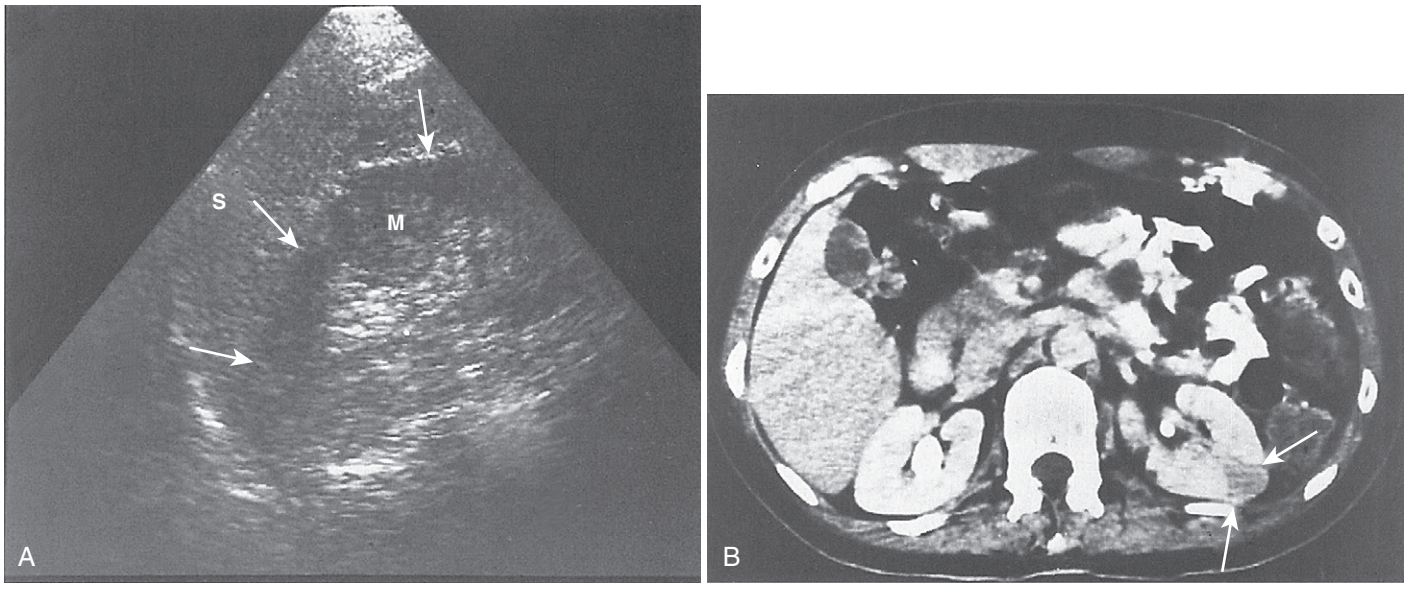

Figure 10–21. Acute focal bacterial nephritis. **A,** Ultrasound image: longitudinal view of the left kidney demonstrates spleen (S) and left kidney *(arrows)*. Note irregular midpole mass (M) of slightly higher echo texture than surrounding normal renal parenchyma. **B,** Contrast medium–enhanced CT scan demonstrates a wedge-shaped area of low density *(arrows)* in the middle portion of the left kidney. The findings resolved after antimicrobial therapy. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

impairment. The overall mortality rate has been reported to be between 43% (Freiha et al, 1979) and 19% (Huang and Tseng, 2000).

Clinical Presentation. **All of the documented cases of emphysematous pyelonephritis have occurred in adults** (Hawes, 1983). Juvenile diabetic patients do not appear to be at risk. Women are affected more often than men.

The usual clinical presentation is severe, acute pyelonephritis, although in some instances a chronic infection precedes the acute attack. **Almost all patients display the classic triad of fever, vomiting, and flank pain** (Schainuck et al, 1968). Pneumaturia is absent unless the infection involves the collecting system. Results of urine cultures are invariably positive. *E. coli* is most commonly identified. *Klebsiella* and *Proteus* are less common.

Radiologic Findings. **The diagnosis is established radiographically. Tissue gas that is distributed in the parenchyma may appear on abdominal radiographs as mottled gas shadows over the involved kidney** (Fig. 10–22). This finding is often mistaken for bowel gas. A crescentic collection of gas over the upper pole of the kidney is more distinctive. As the infection progresses, gas extends to the perinephric space and retroperitoneum. This distribution of gas should not be confused with cases of emphysematous pyelitis in which air is in the collecting system of the kidney. Emphysematous pyelitis is secondary to a gas-forming bacterial UTI, often occurs in nondiabetic patients, is less serious, and usually responds to antimicrobial therapy.

Ultrasonography usually demonstrates strong focal echoes suggesting the presence of intraparenchymal gas (Brenbridge et al, 1979; Conrad et al, 1979). **CT is the imaging procedure of choice in defining the extent of the emphysematous process and guiding management** (Figs. 10–23 and 10–24). **An absence of fluid in CT images or the presence of streaky or mottled gas with or without bubbly and loculated gas appears to be associated with rapid destruction of renal parenchyma and a 50% to 60% mortality rate** (Wan et al, 1996; Best et al, 1999). The presence of renal or perirenal fluid, the presence of bubbly or loculated gas or gas in the collecting system, and the absence of streaky or mottled gas patterns is associated with a less than 20% mortality rate. Obstruction is demonstrated in approximately 25% of the cases. A nuclear renal scan should be performed to assess the degree of renal function impairment in the involved kidney and the status of the contralateral kidney.

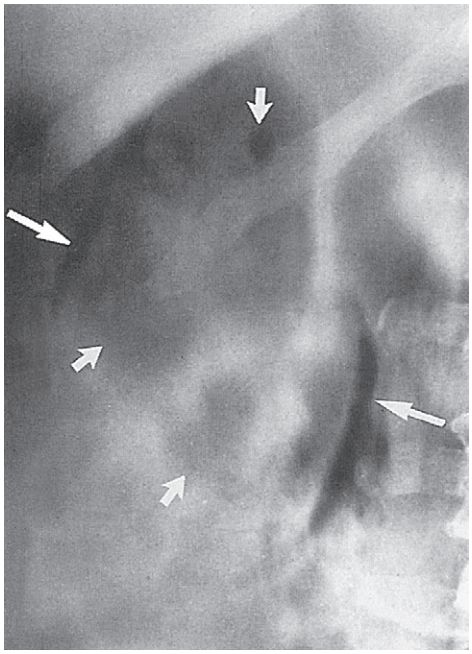

Figure 10–22. Emphysematous pyelonephritis; plain film. Extensive perinephric *(long arrows)* and intraparenchymal *(short arrows)* gas secondary to acute bacterial pyelonephritis. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott William & Wilkins; 2002. p. 211–72.)

Management. **Emphysematous pyelonephritis is a surgical emergency. Most patients are septic, and fluid**

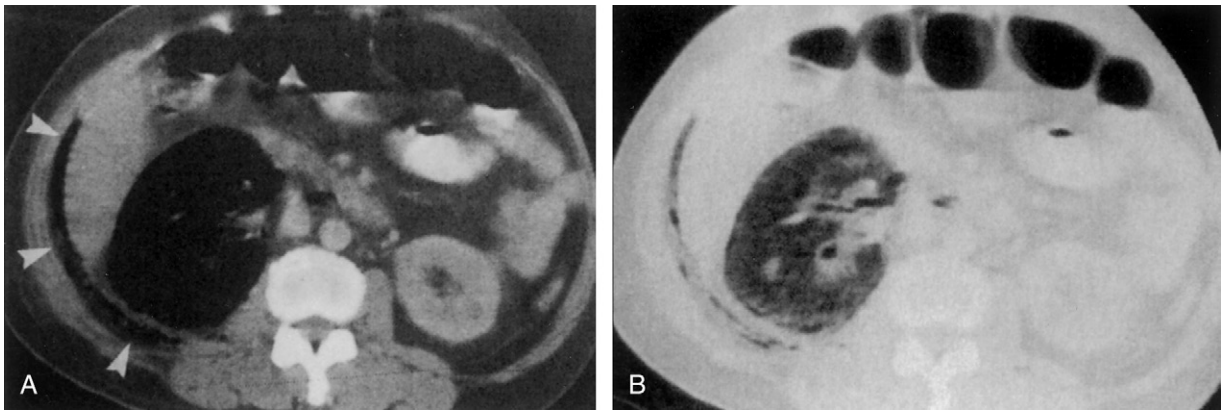

Figure 10–23. Type I emphysematous pyelonephritis with complete renal destruction in a 49-year-old woman. **A,** CT scan of the right kidney shows complete destruction with gas *(arrowheads)* extending beyond the renal fascia. **B,** CT scan with a modified lung window display shows the characteristic streaky gas in the completely destroyed kidney. The patient died on arrival in the emergency department. (**A** and **B,** From Wan YL, Lee TY, Bullard MJ, Tsai CC. Acute gas-producing bacterial renal infection: correlation between imaging findings and clinical outcome. Radiology 1996;198:433–8.)

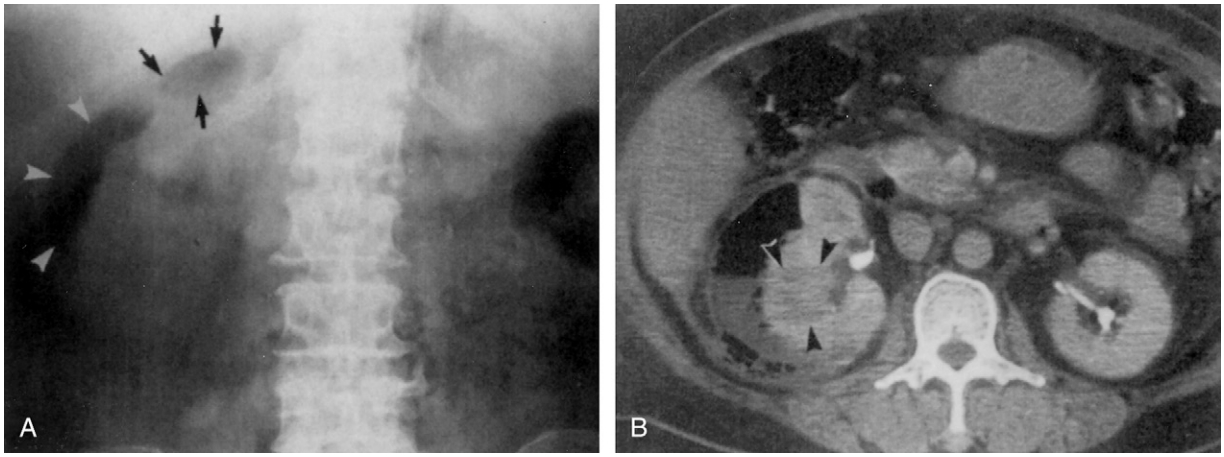

Figure 10–24. Type II emphysematous pyelonephritis in a 57-year-old woman. **A,** Radiograph shows crescent-shaped *(arrowheads)* and loculated *(arrows)* gas in the right renal area. **B,** CT scan obtained after administration of contrast material shows a low-attenuation area *(arrowheads)* in the right kidney due to acute pyelonephritis as well as a subcapsular abscess with fluid and bubbly and loculated gas. The patient survived after percutaneous drainage was performed. (**A** and **B,** From Wan YL, Lee TY, Bullard MJ, Tsai CC. Acute gas-producing bacterial renal infection: correlation between imaging findings and clinical outcome. Radiology 1996;198:433–8.)

resuscitation and broad-spectrum antimicrobial therapy are essential. If the kidney is functioning, medical therapy can be considered (Wan et al, 1996; Best et al, 1999). Nephrectomy is recommended for patients who do not improve after a few days of therapy (Malek and Elder, 1978). If the affected kidney is nonfunctioning and not obstructed, nephrectomy should be performed because medical treatment alone is usually lethal. If a kidney is obstructed, catheter drainage must be instituted. If the patient's condition improves, nephrectomy may be deferred pending a complete urologic evaluation. Although there are isolated case reports of retention of renal function after medical therapy combined with relief of obstruction, most patients require nephrectomy (Hudson et al, 1986).

Renal Abscess

Renal abscess or carbuncle is a collection of purulent material confined to the renal parenchyma. Before the antimicrobial era, 80% of renal abscesses were attributed to hematogenous seeding by staphylococci (Campbell, 1930). Although experimental and clinical data document the facility for abscess formation in normal kidneys after hematogenous inoculation with staphylococci, widespread use of antimicrobial agents since about 1950 appears to have diminished the propensity for gram-positive abscess formation (DeNavasquez, 1950; Cotran, 1969).

Since about 1970, gram-negative organisms have been implicated in the majority of adults with renal abscesses. Hematogenous renal seeding by gram-negative organisms may occur, but this is not likely to be the primary pathway for gram-negative abscess formation. Clinically there is no evidence that gram-negative septicemia antedates most lesions. Furthermore, gram-negative hematogenous pyelonephritis is virtually impossible to produce in animals unless the kidney is traumatized or completely obstructed (Cotran, 1969; Timmons and Perlmutter, 1976). The partially obstructed kidney rejects blood borne gram-negative inocula as well as a normal kidney. Thus ascending infection associated with tubular obstruction from prior infections or calculi appears to be the primary pathway for the establishment of gram-negative abscesses. Two-thirds of gram-negative abscesses in adults are associated with renal calculi or damaged kidneys (Salvatierra et al, 1967). Although the association of pyelonephritis with vesicoureteral reflux is well established, the association of renal abscess with vesicoureteral reflux has been infrequently

noted (Segura and Kelalis, 1973). More recent observations, however, indicate that reflux is frequently associated with renal abscesses and persists long after sterilization of the urinary tract (Timmons and Perlmutter, 1976).

Clinical Presentation. **The patient may present with fever, chills, abdominal or flank pain, and occasionally with weight loss and malaise.** Symptoms of cystitis may occur. Occasionally these symptoms may be vague and delay diagnosis until surgical exploration or, in more severe cases, autopsy (Anderson and McAninch, 1980). **A thorough history may reveal a gram-positive source of infection 1 to 8 weeks before the onset of urinary tract symptoms. The infection may have occurred in any area of the body.** Multiple skin carbuncles and intravenous drug abuse introduce gram-positive organisms into the bloodstream. Other common sites are the mouth, lungs, and bladder (Lyons et al, 1972). Complicated UTIs associated with stasis, calculi, pregnancy, neurogenic bladder, and diabetes mellitus also appear to predispose the patient to abscess formation (Anderson and McAninch, 1980).

Laboratory Diagnosis. **The patient typically has marked leukocytosis.** The blood cultures are usually positive. Pyuria and bacteriuria may not be evident unless the abscess communicates with the collecting system. **Because gram-positive organisms are most commonly blood borne, urine cultures in these cases typically show no growth or a microorganism different from that isolated from the abscess.** When the abscess contains gram-negative organisms, the urine culture usually demonstrates the same organism isolated from the abscess.

Ultrasonography and CT distinguish abscess from other inflammatory renal diseases. **Ultrasonography is the quickest and least expensive method to demonstrate a renal abscess. An echo-free or low-echodensity space-occupying lesion with increased transmission is found on the ultrasound image** (Fig. 10–25). The margins of an abscess are indistinguishable in the acute phase, but the structure contains a few echoes and the surrounding renal parenchyma is edematous (Fiegler, 1983). Subsequently, the appearance tends to be that of a well-defined mass. The internal appearance, however, may vary from a virtually solid lucent mass to one with large numbers of low-level internal echoes (Schneider et al, 1976). The number of echoes depends on the amount of cellular debris within the abscess. The presence of air results in a strong echo with a shadow. Differentiation between an abscess and a tumor is impossible in many cases. Arteriography is used infrequently to demonstrate abscesses. The center of the mass tends to be hypervascular or avascular, with increased vascularity at the cortical margins and lack of vascular displacement and neovascularity.

CT appears to be the diagnostic procedure of choice for renal abscesses, because it provides excellent delineation of the tissue. On CT, abscesses are characteristically well defined both before and after contrast agent enhancement. The findings depend in part on the age and severity of the abscess (Baumgarten and Baumgartner, 1997). Initially, CT shows renal enlargement and focal, rounded areas of decreased attenuation (Fig. 10–26). After several days of the onset of the infection, a thick fibrotic wall begins to form around the abscess. An echo-free or slightly echogenic mass due to the presence of necrotic debris is seen. CT of a chronic abscess shows obliteration of adjacent tissue planes, thickening of the Gerota fascia, a round or oval parenchymal mass of low attenuation, and a surrounding inflammatory wall of slightly higher attenuation that forms a ring when the scan is enhanced with contrast material (Fig. 10–27). The ring sign is caused by the increased vascularity of the abscess wall (Callen, 1979; Gerzof and Gale, 1982).

Radionuclide imaging with gallium or indium is sometimes useful in evaluating patients with renal abscesses (see earlier sections in this chapter and Chapter 4).

Management. **Although the classic treatment for an abscess has been percutaneous or open incision and drainage there is good evidence that the intravenous use of antimicrobial agents and careful observation of a small abscess less than 3 cm in diameter, if begun early enough in the course of the process, may obviate surgical procedures** (Hoverman et al, 1980; Levin et al, 1984; Shu et al,

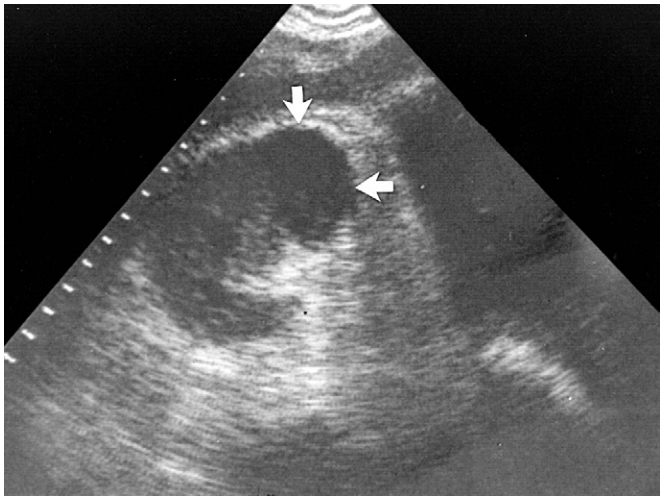

Figure 10–25. Acute renal abscess. Transverse ultrasound image of the right kidney demonstrates a poorly marginated rounded focal hypoechoic mass *(arrows)* in the anterior portion of the kidney.

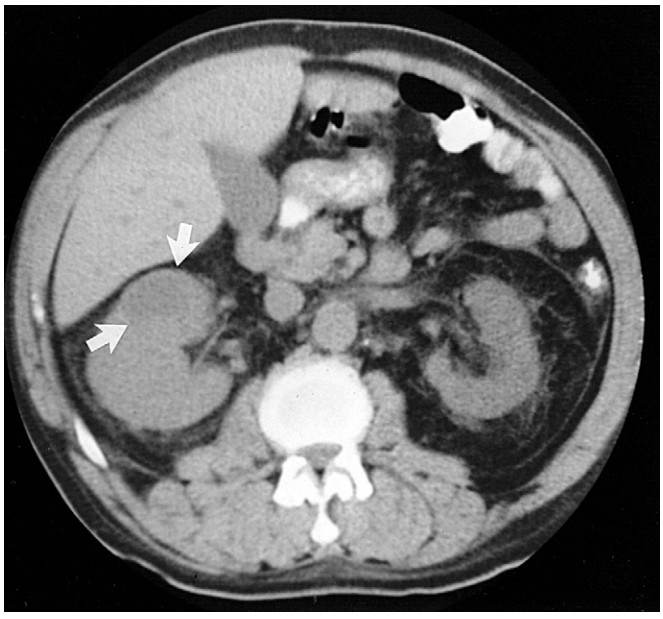

Figure 10–26. Acute renal abscess. Nonenhanced CT scan through the mid pole of the right kidney demonstrates right renal enlargement and an area of decreased attenuation *(arrows)*. After antimicrobial therapy, a follow-up scan showed complete regression of these findings.

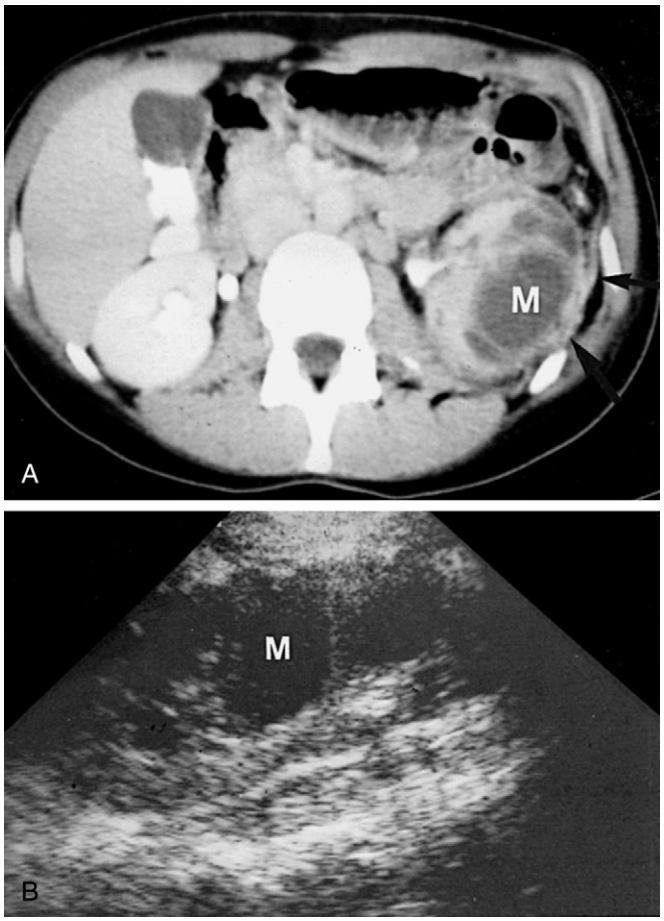

Figure 10–27. Chronic renal abscess. **A,** Enhanced CT scan shows an irregular septated low-density mass (M) extensively involving the left kidney. Note thickening of perinephric fascia *(arrowheads)* and extensive compression of the renal collecting system. Findings are typical of renal abscess. **B,** Ultrasound longitudinal image demonstrates a septated hypoechoic mass (M) occupying much of the renal parenchymal volume.

2004). **CT- or ultrasound-guided needle aspiration may be necessary to differentiate an abscess from a hypervascular tumor.** Aspirated material should be cultured and appropriate antimicrobial therapy instituted on the basis of the findings.

The selection of empirical antimicrobial therapy is dependent on the presumed source of the infection and the resistance patterns within the hospital. When hematogenous dissemination is suspected, the pathogenic organism most frequently is penicillin-resistant *Staphylococcus,* and the antimicrobial of choice therefore is a penicillinase-resistant penicillin (Schiff et al, 1977). If a history of penicillin hypersensitivity is present, the recommended drug is vancomycin. Cortical abscesses that occur in the abnormal urinary tract are associated with more typical gram-negative pathogens and should be treated empirically with intravenous third-generation cephalosporins, antipseudomonal penicillins, or aminoglycosides until specific therapy can be instituted. Patients should have serial examinations with ultrasonography or CT until the abscess resolves. A clinical course contrary to this should lead to the suspicion of misdiagnosis or an uncontrolled infection with the development of perinephric abscess or infection with an organism resistant to the antimicrobial agents used in therapy.

Abscesses 3 to 5 cm in diameter and smaller abscesses in immunocompromised hosts or those that do not respond to antimicrobial therapy should be drained percutaneously (Fernandez et al, 1985; Fowler and Perkins, 1994; Siegel et al, 1996). Surgical drainage, however, currently remains the procedure of choice for most renal abscesses greater than 5 cm in diameter.

Figure 10–28. Pyonephrosis: gross specimen. The kidney shows marked thinning of the renal cortex and medulla, suppurative destruction of the parenchyma *(arrows),* and distention of the pelvis and calyces. Previous incision released a large quantity of purulent material. The ureter showed obstruction distal to the point of section.

Infected Hydronephrosis and Pyonephrosis

***Infected hydronephrosis* is bacterial infection in a hydronephrotic kidney. The term *pyonephrosis* refers to infected hydronephrosis associated with suppurative destruction of the parenchyma of the kidney, in which there is total or nearly total loss of renal function** (Fig. 10–28). Where infected hydronephrosis ends and pyonephrosis begins is difficult to determine clinically. Rapid diagnosis and treatment of pyonephrosis are essential to avoid permanent loss of renal function and to prevent sepsis.

Clinical Presentation. **The patient is usually very ill, with high fever, chills, flank pain, and tenderness.** Occasionally, however, a patient may have only an elevated temperature and a complaint of vague gastrointestinal discomfort. A previous history of urinary tract calculi, infection, or surgery is common. **Bacteriuria may not be present if the ureter is completely obstructed.**

Radiologic Findings. The ultrasonographic diagnosis of infected hydronephrosis depends on demonstration of internal echoes within the dependent portion of a dilated pyelocalyceal system. CT is nonspecific but may show thickening of the renal pelvis, stranding of the perirenal fat, and a striated nephrogram. Ultrasonography demonstrates hydronephrosis and fluid debris levels within the dilated collecting system (Corriere and Sandler, 1982) (Fig. 10–29A). The diagnosis of pyonephrosis is suggested if focal areas of decreased echogenicity are seen within the hydronephrotic parenchyma.

Management. **Once the diagnosis of pyonephrosis is made, treatment is initiated with appropriate antimicrobial drugs and drainage of the infected pelvis.** A ureteral catheter can be passed to drain the kidney, but if the obstruction prevents this, a percutaneous nephrostomy tube

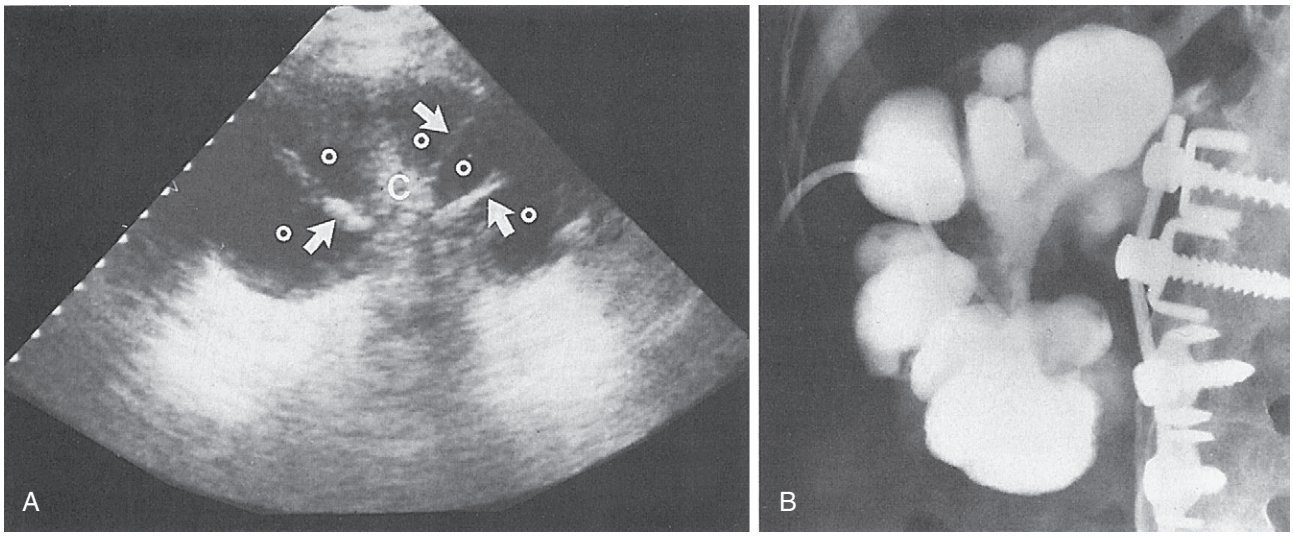

Figure 10–29. Pyonephrosis. **A,** Longitudinal ultrasound image of the right kidney demonstrates echogenic central collecting complex (C) with radiating echogenic septa *(arrows)* and thinned hypoechoic parenchyma. Multiple dilated calyces (o) with diffuse low-level echoes are seen. **B,** Antegrade pyelogram performed through a percutaneous nephrostomy catheter correlates well with the ultrasound image. Dilated pus-filled calyces are demonstrated. The renal pelvis is obliterated by chronic scarring and stone disease. The kidney did not regain function. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

should be placed (Camunez et al, 1989) (see Fig. 10–29B). When the patient becomes hemodynamically stable, other procedures are usually needed to identify and treat the source of the obstruction.

Perinephric Abscess

Perinephric abscess usually results from rupture of an acute cortical abscess into the perinephric space or from hematogenous seeding from sites of infection. Patients with pyonephrosis, particularly when a calculus is present in the kidney, are susceptible to perinephric abscess formation. Diabetes mellitus is present in approximately one third of patients with perinephric abscess (Thorley et al, 1974; Edelstein and McCabe, 1988). In about one third of the cases, perinephric abscess is caused by hematogenous spread, usually from sites of skin infection. A perirenal hematoma can become secondarily infected by the hematogenous route or by direct extension of a primary renal infection. When a perinephric infection ruptures through the Gerota fascia into the pararenal space, the abscess becomes paranephric. Paranephric abscesses may also result from infectious disorders of the bowel, pancreas, or pleural cavity. Conversely, perinephric or psoas abscess may be the result of bowel perforation, Crohn disease, or spread of osteomyelitis from the thoracolumbar spine. *E. coli, Proteus,* and *S. aureus* account for most infections.

Clinical Presentation. The onset of symptoms is typically insidious. Symptoms are present for more than 5 days in most patients with perinephric abscess compared with only about 10% of patients with pyelonephritis. The clinical presentation may be similar to that of pyelonephritis; however, more than one third of patients may be afebrile. An abdominal or flank mass can be felt in about half of the cases. Psoas abscess should be suspected if the patient has a limp and flexion and external rotation of the ipsilateral hip. Laboratory features include leukocytosis, elevated levels of serum creatinine, and pyuria in more than 75% of cases. Edelstein and McCabe (1988) showed that results of urine cultures predicted perinephric abscess isolates in only 37% of cases; a blood culture, particularly with multiple organisms, was often indicative of perinephric abscess but identified all organisms in only 42% of cases. **Therefore therapy based on the results of urine and blood cultures often may be inadequate. Pyelonephritis usually responds within 4 to 5 days of appropriate antimicrobial therapy; perinephric abscess does not. Thus perinephric abscess should be suspected in a patient with UTI and abdominal or flank mass or persistent fever after 4 days of antimicrobial therapy.**

CT is particularly valuable for demonstrating the primary abscess. In some cases, the abscess is confined to the perinephric space; however, extension to the flank or psoas muscle may occur (Fig. 10–30). CT is able to show with exquisite anatomic detail the route of spread of infection into the surrounding tissues (Fig. 10–31). This information may be helpful in planning the approach for surgical drainage. Ultrasonography demonstrates a diverse appearance ranging from a nearly anechoic mass displacing the kidney to an echogenic collection that tends to blend with normally echogenic fat within the Gerota fascia (Corriere and Sandler, 1982). Occasionally a retroperitoneal or subdiaphragmatic infection may spread to the paranephric fat that is outside this fascia. The clinical symptoms of insidious onset of fever, flank mass, and tenderness are indistinguishable from those associated with perinephric abscess. UTI, however, is absent. Ultrasonography and CT can usually delineate the abscess outside the Gerota fascia.

Management. Although antimicrobial agents are useful to control sepsis and to prevent spread of infection, the primary treatment for perinephric abscess is drainage; reports of successful treatment by antimicrobial agents alone are unusual (Herlitz et al, 1981). A detailed analysis of 52 perinephric abscess patients by Thorley and colleagues (1974) supports this tenet. In this study, half the patients were admitted to medical services and the other half to surgical services; 65% of those admitted to medical services died, whereas 23% of those admitted to surgical services died. These mortality rates reflect differences in the population of patients. Those admitted to the

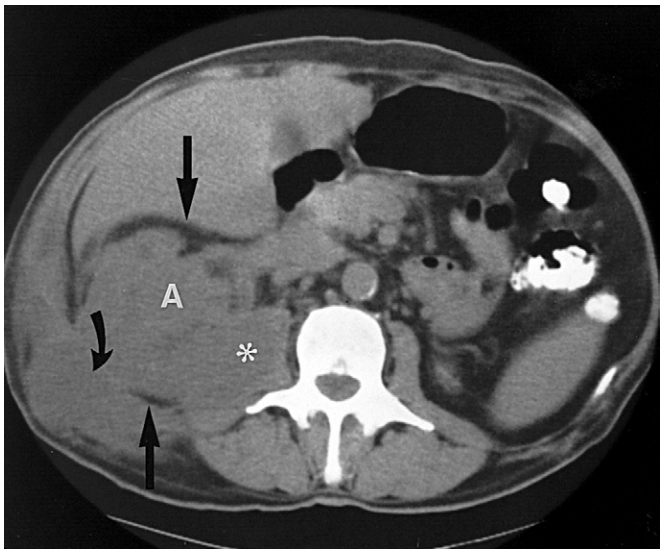

Figure 10–30. Nonenhanced CT scan through the lower pole of the right kidney (previous left nephrectomy) shows extensive perinephric abscess. Extensive abscess (A) distorts and enlarges the renal contour, infiltrates perinephric fat *(straight arrows),* and also extends into the psoas muscle *(asterisk)* and the soft tissues of the flank *(curved arrow)*. Also note that normal renal collecting system fat has been obliterated by the process.

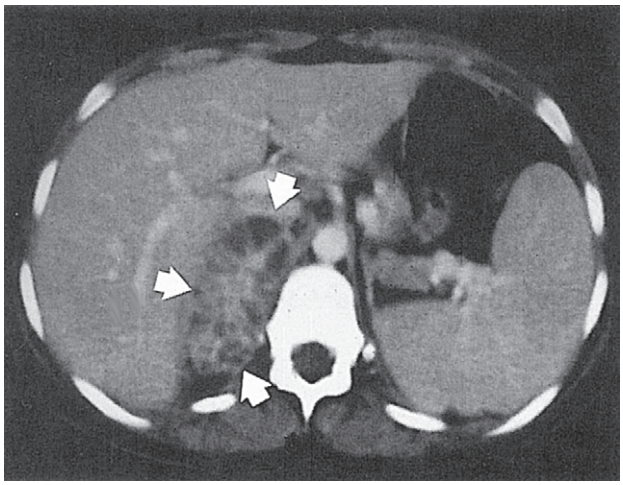

Figure 10–31. Perinephric abscess involving the right adrenal gland. CT scan shows large right pararenal mass *(arrows)* with multiple low-density areas within. At surgery, a large pararenal abscess with extensive involvement of the right adrenal was found. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

medical services were usually sicker and had higher temperatures, more underlying diseases, and vaguer symptoms. More importantly, none of those admitted to medical wards had an admission diagnosis of perinephric abscess, whereas 73% of those admitted to surgical wards did. Although 71% of all the patients had eventual surgical treatment of their perinephric abscesses, the diagnostic delay of those patients admitted to medical services postponed definitive treatment and consequently caused higher mortality.

Although surgical drainage, or nephrectomy if the kidney is nonfunctioning or severely infected, is the classic treatment for perinephric abscesses, renal ultrasonography and CT make percutaneous aspiration and drainage of small perirenal collections possible (Haaga and Weinstein, 1980; Elyaderani et al, 1981; Edelstein and McCabe, 1988). Haaga and Weinstein (1980), however, consider percutaneous drainage to be contraindicated in large abscess cavities filled with thick, purulent fluid.

Gram stain identifies the pathogenesis and guides antimicrobial therapy. An aminoglycoside together with an antistaphylococcal agent, such as methicillin or oxacillin, should be started immediately. If the patient has a penicillin hypersensitivity, cephalothin or vancomycin may be used.

Once the perinephric abscess has been drained, the underlying problem must be dealt with. Some conditions such as renal cortical abscess or enteric communication require prompt attention. Nephrectomy for pyonephrosis may be performed concurrent with drainage of the perinephric abscess if the patient's condition is good. In other instances it is best to drain the perinephric abscess first and correct the underlying problem or perform a nephrectomy when the patient's condition has improved.

Perinephric Abscess versus Acute Pyelonephritis. It has already been emphasized that the greatest obstacle to the treatment of perinephric abscess is the delay in diagnosis. **In the series of** Thorley and colleagues (1974) **a common misdiagnosis was acute pyelonephritis. In their review they found that two factors differentiated perinephric abscess and acute pyelonephritis: (1) most patients with uncomplicated pyelonephritis were symptomatic for less than 5 days before hospitalization, whereas most with perinephric abscesses were symptomatic for longer than 5 days; and (2) no patient with acute pyelonephritis remained febrile for longer than 4 days once appropriate antimicrobial agents were started. All patients with perinephric abscesses had a fever for at least 5 days, with a median of 7 days. Similar results were noted by** Fowler and Perkins (1994).

Patients with polycystic renal disease who undergo hemodialysis may be particularly susceptible to the progression from acute UTIs to perinephric abscess. Of 445 patients undergoing chronic hemodialysis at the Regional Kidney Disease Program in Minneapolis, 5.4% had polycystic kidney disease and 33.3% of these patients developed symptomatic UTIs (Sweet and Keane, 1979). Eight (62.5%) developed perinephric abscesses, and 3 of these patients died. According to the investigators, all UTIs, even those that progressed to perinephric abscesses, were promptly treated with appropriate antimicrobial agents, and all patients in this group became afebrile and asymptomatic when the agents were stopped. Yet later, after various times, symptoms attributable to perinephric abscess developed in 8 of the patients. The mechanism of this process is not clear, but the limited bioavailability of some antimicrobial agents in cysts is variable and could contribute to the progression of renal infection.

Chronic Pyelonephritis

In patients without underlying renal or urinary tract disease, chronic pyelonephritis secondary to UTI is a rare disease and an even more rare cause of chronic renal failure. In patients with underlying functional or structural urinary tract abnormalities, however, chronic renal infection can cause significant renal impairment. Thus it is essential that appropriate studies be used to diagnose, localize, and treat chronic renal infection.

The prevalence of chronic pyelonephritis has also been assessed in patients undergoing dialysis for end-stage renal disease. Despite

a 2% to 5% prevalence of bacteriuria in women, pyelonephritis uncomplicated by obstruction or urinary tract malformation does not cause end-stage renal disease. Schechter and colleagues (1971) analyzed the cause for renal failure in 170 patients referred to them for dialysis. Chronic pyelonephritis was the primary cause of end-stage renal disease in 22 (13%) but was usually associated with an underlying structural defect. Unequivocal nonobstructive chronic pyelonephritis was not found. The authors also observed that symptomatic infections tended to occur before the onset of azotemia in most patients with chronic pyelonephritis. Similarly, Huland and Busch (1982) evaluated 161 patients with end-stage renal disease and found that 42 had chronic pyelonephritis. However, in addition to a history of UTIs, these 42 patients had complicating defects, such as vesicoureteral reflux, analgesic abuse, nephrolithiasis, or obstruction. Nonobstructive uncomplicated UTI alone was never found to be the cause of renal insufficiency. Thus, using end-stage renal disease seen at autopsy or at the dialysis clinic as an indicator, the prevalence of uncomplicated chronic bacterial pyelonephritis is rare.

In addition, the role of bacterial infection in development of chronic renal disease can be assessed in patients with renal interstitial and tubular damage similar to that which has classically been called chronic pyelonephritis. The frequency with which various potential causes of interstitial damage are operative in patients with interstitial nephritis was assessed by Murray and Goldberg (1975). These investigators not only concluded that UTI is rarely the sole cause of chronic renal disease in the adult but also observed that 89% of their azotemic patients had a readily identifiable primary cause of their interstitial nephritis. Thus, when patients with a clinical diagnosis of chronic interstitial nephritis are selected as the starting point, it is easy to associate many factors with this disease but UTI does not seem to be one of them.

Clinical Presentation. **There are no symptoms of chronic pyelonephritis until it produces renal insufficiency, and then the symptoms are similar to those of any other form of chronic renal failure.** If a patient's chronic pyelonephritis is thought to be an end result of many episodes of acute pyelonephritis, a history of intermittent symptoms of fever, flank pain, and dysuria may be elicited. Similarly, urinary findings and the presence of renal infection correlate poorly. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Asscher (1980) has tabulated eight long-term follow-up studies from the literature on kidneys of adults with UTIs. The data from these reports on 901 patients show that bacteriuria present in otherwise healthy adults for long periods may be associated with nonexistent or extremely minimal evidence of kidney damage. Conversely, patients who have chronic pyelonephritis may have negative urine cultures.

Radiologic Findings. **The diagnosis of chronic pyelonephritis can be made with the greatest confidence on the basis of pyelographic findings. The essential features are asymmetry and irregularity of the kidney outlines, blunting and dilation of one or more calyces, and cortical scars at the corresponding site** (Fig. 10–32). In the absence of stones, obstruction, and tuberculosis, and with the single exception of analgesic nephritis with papillary necrosis (which can be readily excluded by history), chronic pyelonephritis is virtually the only disease that produces a localized scar over a deformed calyx (Stamey, 1980). In advanced pyelonephritis, calyceal distortion and irregularity together with cortical scars complete the picture. Hodson (1965a) pointed out that renal infarction, an extremely rare condition, may closely resemble pyelonephritic scars but that the renal pyramid remains with renal infarction in contradistinction to pyelonephritis.

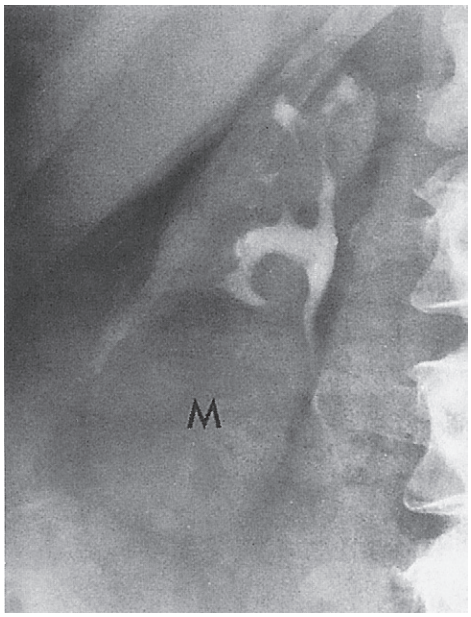

Figure 10–32. Chronic pyelonephritis. Ten-minute excretory urogram demonstrates irregular renal outline with upper pole parenchymal atrophy. Note significant loss of renal cortical thickness over blunted and dilated calyces. Lower pole mass (M) is a simple cyst. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

Pathology. **In chronic pyelonephritis, the gross kidney is often diffusely contracted, scarred, and pitted.** The scars are Y-shaped, flat, broad-based depressions with red-brown granular bases. The scarring is often polar with underlying calyceal blunting. The parenchyma is thin, and the corticomedullary demarcation is lost. **Histologic changes are patchy.** There is usually an interstitial infiltrate of lymphocytes, plasma cells, and occasional polymorphonuclear cells. Portions of the parenchyma may be replaced by fibrosis, and, although glomeruli may be preserved, periglomerular fibrosis is often seen. In some affected areas, glomeruli may be completely fibrosed and tubules atrophied. Leukocyte and hyaline casts are sometimes present in the tubules; the latter may cause resemblance to the thyroid colloid, hence the description *renal thyroidization* (Braude, 1973). In general, the changes are nonspecific; they also may be seen in toxic exposures, postobstructive atrophy, hematologic disorders, postirradiation nephritis, ischemic renal disease, and nephrosclerosis.

Management. **Management of radiographic evidence of pyelonephritis should be directed at treating infection, if present; preventing future infections; and monitoring and preserving renal function.** The treatment of existing infection must be based on careful antimicrobial susceptibility tests and selection of drugs that can achieve bactericidal concentrations in the urine and yet are not nephrotoxic. Achievement of acceptable bactericidal levels of a drug in the urine of a patient with chronic pyelonephritis may be difficult because the diminished concentrating ability of pyelonephritis may impair excretion

and concentration of the antimicrobial agent. The duration of antimicrobial therapy is often prolonged to maximize the chance of cure. With patients in whom renal damage develops or progresses in the presence of UTI, the working hypothesis should be that there is an underlying renal, usually papillary, lesion or underlying urologic condition, such as obstruction or calculus, that has increased susceptibility to renal damage. Appropriate nephrologic and urologic evaluation should be undertaken to identify and, if possible, correct these abnormalities.

Bacterial "Relapse" from a Normal Kidney

The concept that bacteria persist in the renal parenchyma between bacteriuric episodes and cause "relapsing" UTIs was based on a study by Turck and colleagues (1968) that suggested that bacterial persistence could be recognized by simply identifying two consecutive recurrent infections with the same organism. Unfortunately this study did not indicate whether the urine was cultured during therapy to ensure that the original infection had actually been eradicated. It is possible that some of these so-called relapses were in fact unresolved initial infections and that ureteral edema associated with catheterization may have impeded clearance of the initial infecting strain.

Subsequent studies summarized by Stamey (1980) **and** Forland and associates (1977) **have shown that in a normal urinary tract recurrent infections are not caused by relapse from bacterial persistence in the kidney.** With ureteral catheterization techniques, Cattell (1973) localized the site of bacteriuria in 42 patients who had follow-up for 6 months after therapy. He analyzed the response to antimicrobial therapy of 2 weeks' duration. Of the 26 patients who were cured of their initial infection, 16 had recurrence with the same organism, 8 had upper tract infections, and 8 had bladder bacteriuria.

Most of the changes of chronic pyelonephritis seem to occur in infancy, probably because the growing kidney is most susceptible to scarring. In a review that examined the long-term effect of UTIs in adults it was concluded that renal damage is rare in nonobstructive UTIs (Stamey, 1980) but that it does occur (Bailey et al, 1969; Davies et al, 1972; Davidson and Talner, 1973; Feldberg, 1982).

The association between hypertension and the pyelonephritic kidney has been addressed by Pfau and Rosenmann (1978), who concluded that the association of chronic pyelonephritis and hypertension is usually coincidental. Their conclusion agrees with that of a study by Parker and Kunin (1973) that examined 74 women who had been admitted to the hospital 10 to 20 years previously for pyelonephritis. Only 14.5% of these women had hypertension, a rate similar to that found in a random female population of the same age.

Infectious Granulomatous Nephritis

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a rare, severe, chronic renal infection typically resulting in diffuse renal destruction. Most cases are unilateral and result in a nonfunctioning, enlarged kidney associated with obstructive uropathy secondary to nephrolithiasis. Xanthogranulomatous pyelonephritis is characterized by accumulation of lipid-laden foamy macrophages. It begins within the pelvis and calyces and subsequently extends into and destroys renal parenchymal and adjacent tissues. It has been known to imitate virtually every other inflammatory disease of the kidney, as well as renal cell carcinoma, on radiographic examination (Malek and Elder, 1978; Tolia et al, 1980). In addition, the microscopic appearance of xanthogranulomatous pyelonephritis has been confused with clear cell adenocarcinoma of the kidney on frozen section and has led to radical nephrectomy (Anhalt et al, 1971; Malek and Elder, 1978; Flynn et al, 1979; Lorentzen and Nielsen, 1980; Tolia et al, 1980). The entity is uncommon and is found in only about 0.6% (Malek et al, 1972) to 1.4% (Ghosh, 1955) of patients with renal inflammation who are evaluated pathologically.

Pathogenesis. **The primary factors involved in the pathogenesis of xanthogranulomatous pyelonephritis are nephrolithiasis, obstruction, and infection** (Gregg et al, 1999). Nephrolithiasis has been noted in as many as 83% of the patients in various series; approximately half of the renal stones have been of the staghorn type (Parsons et al, 1983; Chuang et al, 1992; Nataluk et al, 1995). It has been proposed clinically and demonstrated experimentally that primary obstruction followed by infection with *E. coli* can lead to tissue destruction and collections of lipid material by macrophages (Povysil and Konickova, 1972). These macrophages (xanthoma cells) are distributed in sheets around parenchymal abscesses and calyces and are intermixed with lymphocytes, giant cells, and plasma cells. The bacteria appear to be of low virulence because spontaneous bacteremia has rarely been described. Other possible interrelated factors include venous occlusion and hemorrhage, abnormal lipid metabolism, lymphatic blockage, failure of antimicrobial therapy in UTI, altered immunologic competence, and renal ischemia (Friedenberg and Spjut, 1963; Mering et al, 1973; Goodman et al, 1979; McDonald, 1981; Tolia et al, 1981). The concept that xanthogranulomatous pyelonephritis is related to incomplete bacterial degradation and altered host response has received mixed support (Nielsen and Lorentzen, 1981; Khalyl-Mawad et al, 1982). Thus it appears that there is probably no single factor that is instrumental in the pathogenesis of this disease. Rather, there is an inadequate host acute inflammatory response within an obstructed, ischemic, or necrotic kidney.

Pathology. **The kidney is usually massively enlarged and has a normal contour.** Xanthogranulomatous pyelonephritis may be diffuse, as in approximately 80% of the patients, or segmental. In the diffuse form of the disease the entire kidney is involved, whereas in segmental xanthogranulomatous pyelonephritis only the parenchyma surrounding one or more calyces or one pole of a duplicated collecting system is involved. On sectioning, the kidney usually demonstrates nephrolithiasis and peripelvic fibrosis. The calyces are dilated and filled with purulent material, but fibrosis surrounding the pelvis usually prevents dilation. The papillae are often destroyed by papillary necrosis (Goodman et al, 1979). In advanced stages of the disease, multiple parenchymal abscesses are filled with viscous pus and lined by yellowish tissue (Fig. 10–33A). The cortex is often thin and replaced by xanthogranulomatous tissue. The capsule is often thickened, and extension of the inflammatory process into the perinephric or paranephric space is common (Goodman et al, 1979; McDonald, 1981; Gregg et al, 1999).

On microscopic examination the yellowish nodules that line the calyces and surround the parenchymal abscesses contain dark sheets of lipid-laden macrophages (foamy histiocytes with small, dark nuclei and clear cytoplasm) intermixed with lymphocytes, giant cells, and plasma cells (see Fig. 10–33B). Xanthogranulomatous cells are not specific to xanthogranulomatous pyelonephritis but may be present anywhere inflammation or obstruction

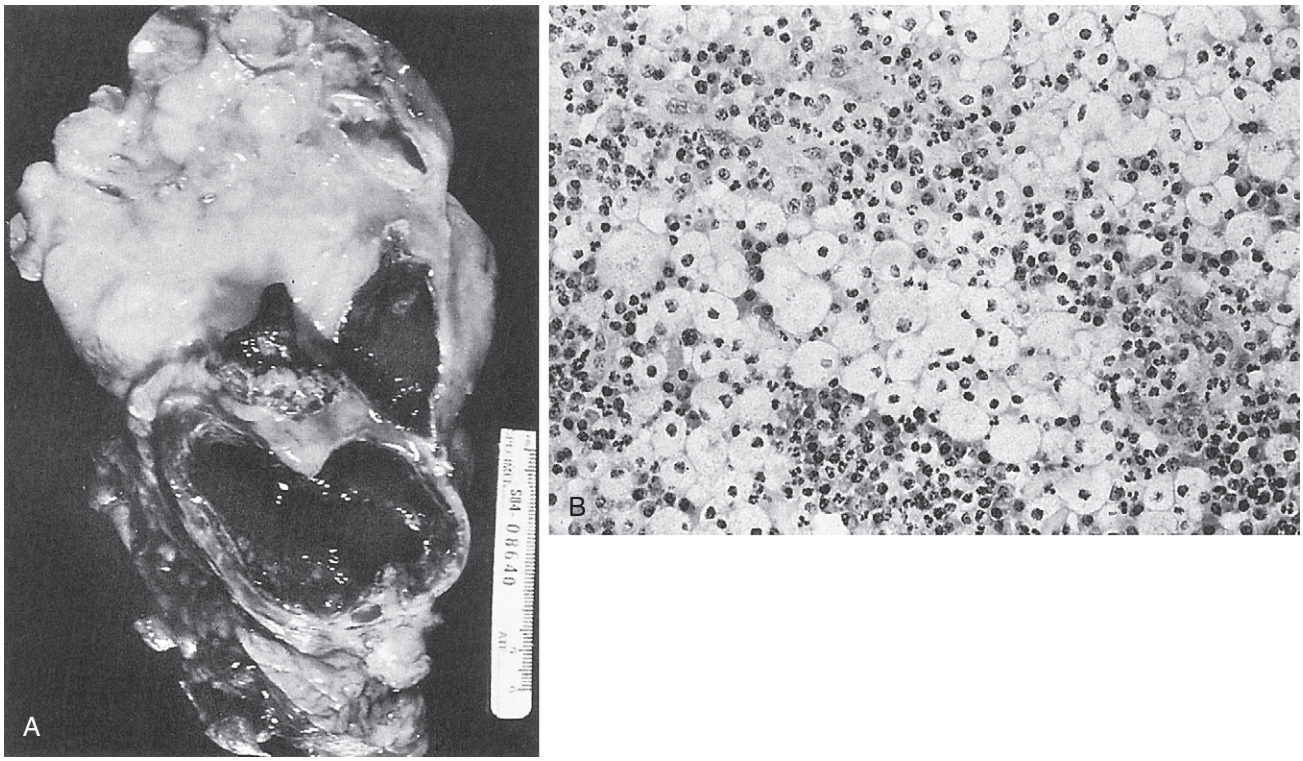

Figure 10–33. Xanthogranulomatous pyelonephritis. **A,** Gross specimen. Kidney is massively enlarged, measuring 23 × 12 cm; the normal architecture is replaced by a shaggy yellow upper pole mass corresponding to xanthogranulomatous inflammation and numerous distorted and dilated calyces. **B,** Microscopically, the shaggy yellow tissue is composed primarily of lipid-laden histiocytes mixed with other inflammatory cells. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

coexists. The origin of the fatty substance is disputed. Cholesterol esters that make up a part of the lipid might be derived from lysis of erythrocytes after hemorrhage (Saeed and Fine, 1963).

Clinical Presentation. **Xanthogranulomatous pyelonephritis should be suspected in patients with UTIs and a unilateral enlarged nonfunctioning or poorly functioning kidney with a stone or a mass lesion indistinguishable from malignant tumor. Most patients present with flank pain (69%), fever and chills (69%), and persistent bacteriuria (46%)** (Malek and Elder, 1978). **Additional vague symptoms, such as malaise, may be present. On physical examination, 62% of the patients had a flank mass and 35% had previous calculi** (Malek and Elder, 1978). Less commonly, hypertension, hematuria, or hepatomegaly is the presenting complaint. The medical history is often positive for UTIs and urologic instrumentation (Malek and Elder, 1978; Flynn et al, 1979; Goodman et al, 1979; Grainger et al, 1982; Yazaki et al, 1982; Petronic et al, 1989; Eastham et al, 1994; Nataluk et al, 1995). Diabetics also appear to be at greater risk of developing the disease (Eastham et al, 1994). Although it may occur at any age, the peak incidence of xanthogranulomatous pyelonephritis is in the fifth to the seventh decade. Women are more commonly affected than men. There is no predilection for either kidney.

Bacteriology and Laboratory Diagnosis. **Although review of the literature shows *Proteus* to be the most common organism involved with xanthogranulomatous pyelonephritis** (Anhalt et al, 1971; Tolia et al, 1981), ***E. coli* is also common.** The prevalence of *Proteus* organisms may reflect their association with stone formation and subsequent chronic obstruction and irritation. Malek and Elder (1978), in their analysis of 26 cases, found that renal tissue cultures grew bacteria in 22 of 23 cases. Anaerobes also have been cultured (Malek and Elder, 1978).

Approximately 10% of patients have mixed cultures. About one third of patients have no growth in their urine, probably because many patients have recently taken or are taking antimicrobial agents when cultures are obtained. The infecting organism may be revealed only by tissue cultures obtained during surgery. Urinalysis usually shows pus and protein. In addition, blood tests often reveal anemia and may show hepatic dysfunction in up to 50% of the patients (Malek and Elder, 1978).

Xanthogranulomatous pyelonephritis is almost always unilateral; therefore azotemia or frank renal failure is uncommon (Goodman et al, 1979; Gregg et al, 1999).

CT is probably the most useful radiologic technique in evaluating patients with xanthogranulomatous pyelonephritis (Fig. 10–34). **Fifty to 80 percent of patients show the classic triad of unilateral renal enlargement with little or no function and a large calculus in the renal pelvis** (Elder, 1984). **CT usually demonstrates a large, reniform mass with the renal pelvis tightly surrounding a central calcification but without pelvic dilatation** (Solomon et al, 1983; Goldman et al, 1984; Hartman, 1985). Renal parenchyma is replaced by multiple water-density masses representing dilated calyces and abscess cavities filled with varied amounts of pus and debris. On enhanced scans the walls of these cavities demonstrate a prominent blush owing to the abundant vascularity within the granulation tissue. The cavities themselves, however, fail to enhance, whereas tumors and other inflammatory lesions usually do. The CT scan is particularly helpful in demonstrating the extent of renal involvement and may indicate whether

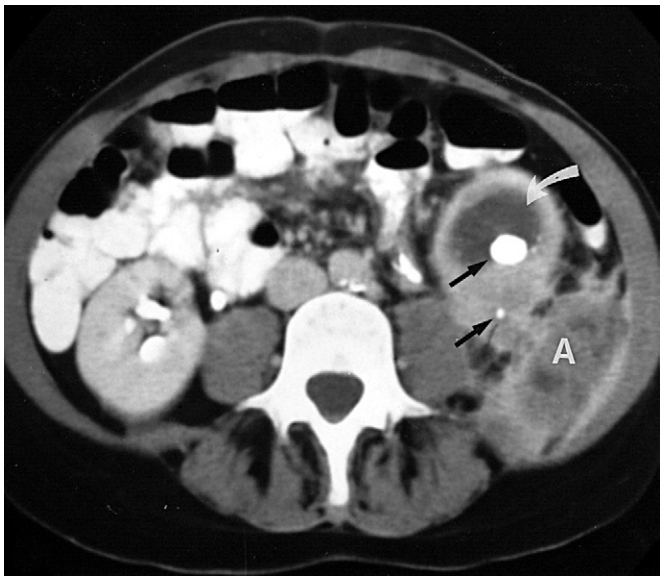

Figure 10–34. Xanthogranulomatous pyelonephritis. Enhanced CT scan shows collecting system and parenchymal calculi *(straight arrows)* with lower pole pyonephrosis *(curved arrow)* and an irregular, predominantly low-density perinephric abscess (A) extending into the soft tissues of the flank.

adjacent organs or the abdominal wall are involved by xanthogranulomatous pyelonephritis (Eastham et al, 1994; Kaplan et al, 1997).

Ultrasonography usually demonstrates global enlargement of the kidney (Merenich and Popky, 1991). The normal renal architecture is replaced by multiple hypoechoic fluid-filled masses that correspond to debris-filled, dilated calyces or foci of parenchymal destruction (Fagerholm, 1983; Hartman et al, 1984). With focal involvement, a solid mass involving a segment of the kidney is demonstrated with an associated calculus in the collecting system or ureter. Renal cell carcinoma and other solid renal lesions must be considered in the differential diagnosis (Elder, 1984).

Radionuclide renal scanning using ^{99m}Tc-DMSA is used to confirm and quantify the differential lack of function in the involved kidney (Gregg et al, 1999). MRI has not yet superseded CT in the evaluation of renal inflammation but it provides some advantages in delineating extrarenal extension of inflammation (Soler et al, 1997). Lesions of xanthogranulomatous pyelonephritis may appear as cystic foci of intermediate signal intensity on T1-weighted images and of hyperintensity on T2-weighted images. Arteriography shows hypervascular areas, but there may be some hypovascular areas (Malek and Elder, 1978; Van Kirk et al, 1980; Tolia et al, 1981). Therefore radiologic studies, although distinctive, often cannot be used to differentiate between xanthogranulomatous pyelonephritis and renal cell carcinoma.

Differential Diagnosis. Diagnosis of segmental xanthogranulomatous pyelonephritis without calculi may be difficult. Xanthogranulomatous pyelonephritis in association with massive pelvic dilation cannot be distinguished from pyonephrosis. When xanthogranulomatous pyelonephritis occurs within a small contracted kidney, the radiographic findings are nonspecific and nondiagnostic. Renal parenchymal malacoplakia may show renal enlargement and multiple inflammatory masses replacing the normal renal parenchyma, but calculi are usually not present. Renal lymphoma may be associated with multiple hypoechoic masses surrounding the contracted, nondilated pelvis, but lymphoma is usually clinically obvious, and renal involvement is usually bilateral and not associated with calculi (Hartman, 1985).

Management. The primary obstacle to the correct treatment of xanthogranulomatous pyelonephritis is incorrect diagnosis. Today, with CT technology, the diagnosis of xanthogranulomatous pyelonephritis is made preoperatively nearly 90% of the time (Eastham et al, 1994; Nataluk et al, 1995). Antimicrobial therapy may be necessary to stabilize the patient preoperatively, and, occasionally, long-term antimicrobial therapy will eradicate the infection and restore renal function (Mollier et al, 1995). Because the renal abnormality may be diagnosed preoperatively as a renal tumor and/or is diffuse, nephrectomy is usually performed. If localized xanthogranulomatous pyelonephritis is diagnosed preoperatively or at exploration, it is amenable to partial nephrectomy (Malek and Elder, 1978; Tolia et al, 1980; Osca et al, 1997).

The lipid-laden macrophages associated with xanthogranulomatous pyelonephritis, however, closely resemble clear cell adenocarcinoma and may be difficult to distinguish solely on the basis of frozen section. Furthermore, xanthogranulomatous pyelonephritis has been associated with renal cell carcinoma, papillary transitional cell carcinoma of the pelvis or bladder, and infiltrating squamous cell carcinoma of the pelvis (Schoborg et al, 1980; Pitts et al, 1981; Tolia et al, 1981); thus if malignant renal tumor cannot be excluded, nephrectomy should be performed. When diffuse and extensive disease into the retroperitoneum exists, removal of the kidney and perinephric fat may be needed. Under these circumstances the surgery may be difficult and may involve dissection of granulomatous tissue from the diaphragm, great vessels, and bowel (Malek and Elder, 1978; Flynn et al, 1979). It is important to remove the entire inflammatory mass because in nearly three fourths of patients xanthogranulomatous tissue is infected. If incision and drainage alone are performed rather than nephrectomy the patient may continue to suffer from protracted debilitating illness and may develop a renal cutaneous fistula; an even more difficult nephrectomy will then be necessary. In one early case-matched series of laparoscopic nephrectomies performed for xanthogranulomatous pyelonephritis it was concluded that the benefits of laparoscopic surgery do not extend to the treatment of this disease (Bercowsky et al, 1999); however, a larger review of a modern xanthogranulomatous pyelonephritis experience suggests that laparoscopic nephrectomy is a reasonable treatment approach.

Malacoplakia

Malacoplakia, from the Greek word meaning "soft plaque," is an unusual inflammatory disease that was originally described to affect the bladder but has been found to affect the genitourinary and gastrointestinal tracts, skin, lungs, bones, and mesenteric lymph nodes. It is an inflammatory lesion described originally by Michaelis and Gutmann (1902). It was characterized by von Hansemann (1903) as soft, yellow-brown plaques with granulomatous lesions in which the histiocytes contain distinct basophilic lysosomal inclusion bodies or Michaelis-Gutmann bodies. Although its exact pathogenesis is unknown, malacoplakia probably results from abnormal macrophage function in response to a bacterial infection, which is most often due to *E. coli*.

Pathogenesis. The pathogenesis is unknown, but several theories are popular. In 93 patients who had cultures of urine, diseased tissue, or blood, 89.4% had coliform infections (Stanton and Maxted, 1981). Moreover, 40% of the patients in this review had

an immunodeficiency syndrome, autoimmune disease, carcinoma, or another systemic disorder. This association of coliform infections and compromised health status in patients with malacoplakia is well recognized.

It is hypothesized that bacteria or bacterial fragments form the nidus for the calcium phosphate crystals that laminate the Michaelis-Gutmann bodies. Most investigations into the pathogenesis of this disease support theories that a defect in intraphagosomal bacterial digestion accounts for the unusual immunologic response that causes malacoplakia.

Pathology. **The diagnosis is made by biopsy. The lesion is characterized by large histiocytes, known as *von Hansemann cells,* and small basophilic, extracytoplasmic, or intracytoplasmic calculospherules called Michaelis-Gutmann bodies, which are pathognomonic** (Fig. 10–35). Electron microscopy has revealed intact coliform bacteria and bacterial fragments within phagolysosomes of the foamy-appearing malacoplakic histiocytes (Lewin et al, 1976; Stanton and Maxted, 1981). In their review of the subject, Stanton and Maxted (1981) and Esparza and associates (1989) emphasized that, although pathognomonic for the disease, Michaelis-Gutmann bodies may be absent in early malacoplakia and are not necessary for the diagnosis.

It has been shown that macrophages in malacoplakia involving the kidney and bladder contain large amounts of immunoreactive α_1-antitrypsin (Callea et al, 1982). The amount of α_1-antitrypsin remains unchanged during the morphogenetic stages of the pathologic process. Macrophages from other pathologic processes, closely resembling malacoplakia but without Michaelis-Gutmann bodies, do not contain α_1-antitrypsin except for a few macrophages in tuberculosis and xanthogranulomatous pyelonephritis. **Therefore immunohistochemical staining for α_1-antitrypsin may be a useful test for an early and accurate differential diagnosis of malacoplakia.**

Clinical Presentation. **Most patients are older than 50 years.** The ratio of females to males with malacoplakia within the urinary tract is 4:1, but this disparity does not occur in other body tissues (Stanton and Maxted, 1981). The patients often are debilitated, are immunosuppressed, and have other chronic diseases. The symptoms of bladder malacoplakia are bladder irritability and hematuria. Cystoscopy reveals mucosal plaques or nodules. As these lesions progress they may become fungating, firm, sessile masses that cause filling defects of the bladder, ureter, or pelvis on excretory urograms. The distal ureter may become strictured or stenotic and cause subsequent renal obstruction or nonfunction (Sexton et al, 1982). A typical patient with renal parenchymal disease may have one or more radiographic masses and chronic

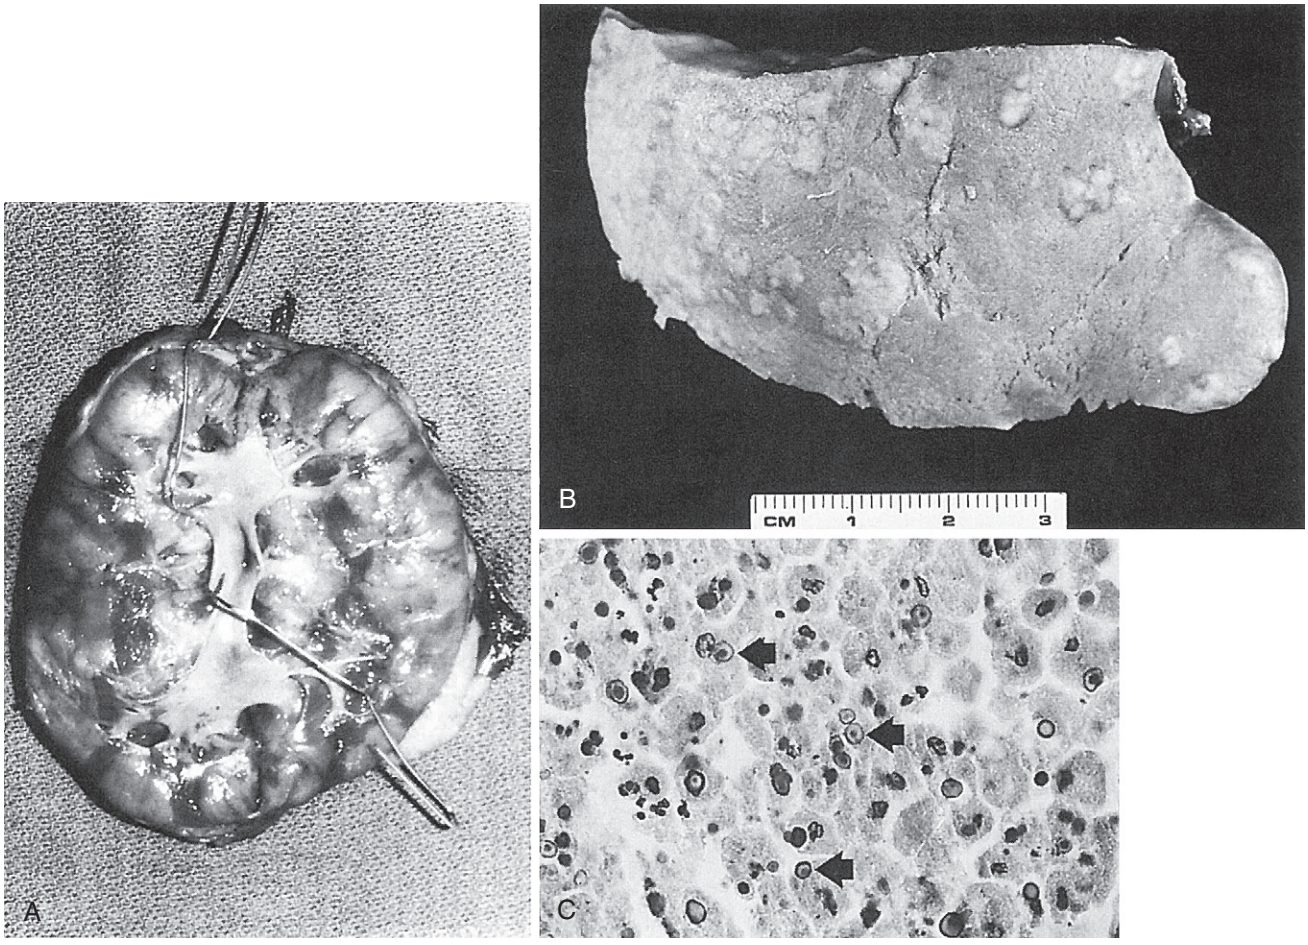

Figure 10–35. Renal parenchymal malacoplakia. **A,** Cut surface demonstrates extensive cortical and upper medullary replacement by multifocal, confluent, tumor-like masses. **B,** Cortical surface exhibits multiple, firm, plaquelike lesions. **C,** Hallmark of malacoplakia is demonstration of the Michaelis-Gutmann body *(arrows),* which represents incompletely destroyed bacteria surrounded by lipoprotein membrane (hematoxylin-eosin stain). (From Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: I and II. Monogr Urol 1985;6:3.)

E. coli infections. Renal parenchymal malacoplakia may be complicated by renal vein thrombosis and inferior vena cava thrombosis (McClure, 1983). When malacoplakia involves the testis, epididymo-orchitis is present. Malacoplakia of the prostate is rare, but, when it occurs, it may be confused with carcinoma clinically (Shimizu et al, 1981). Mortality can exceed 50%, and the morbidity can be substantial (Stanton and Maxted, 1981).

Radiologic Findings. **Multifocal malacoplakia on excretory urography typically presents as enlarged kidneys with multiple filling defects.** Renal calcification, lithiasis, and hydronephrosis are absent. The multifocal nature is best appreciated by using ultrasonography, CT, or arteriography. Ultrasound examination may demonstrate renal enlargement and distortion of the central echo complex. The masses are often confluent, resulting in an overall increase in the echogenicity of the renal parenchyma (Hartman et al, 1980). On CT the foci of malacoplakia are less dense than the surrounding enhanced parenchyma (Hartman, 1985). Arteriography typically reveals a hypovascular mass without peripheral neovascularity (Cavins and Goldstein, 1977; Trillo et al, 1977).

Unifocal malacoplakia on excretory urography appears as a noncalcified mass that is indistinguishable from other inflammatory or neoplastic lesions. Ultrasonography and CT may demonstrate a solid or cystic structure, depending on the degree of internal necrosis. Angiography may demonstrate neovascularity (Trillo et al, 1977). Extension beyond the kidney, which can occur with either multifocal or uniform malacoplakia, is best demonstrated by CT.

Differential Diagnosis. The differential diagnosis includes renal cystic disease, neoplasia, and renal inflammatory disease (Hartman, 1985). Malacoplakia should be considered when one or more renal masses are observed, particularly in female patients with recurrent UTIs with *E. coli,* altered immune response syndromes, or cystoscopic evidence of malacoplakia or filling defects in the collecting system (Charboneau, 1980). Malacoplakia should also be suspected when these radiographic findings occur in a renal transplant patient who has persistent UTI despite appropriate antimicrobial therapy. Cystic disease generally can be excluded by careful ultrasound and CT evaluations. Renal involvement with metastatic disease or lymphomas usually occurs late in the course of the disease, which is well established. Multifocal renal cell carcinoma is most often seen in the context of von Hippel-Lindau disease with its other clinical manifestations. Patients with xanthogranulomatous pyelonephritis usually have signs and symptoms of UTI. As with malacoplakia, the involved kidney is enlarged but renal calculi and obstruction are common. Multiple renal abscesses are often associated with hematogenous dissemination resulting from cardiac disease.

Management. **Management of malacoplakia should be directed at control of the UTIs, which should stabilize the disease process.** This subject is well reviewed by Stanton and Maxted (1981). Although multiple long-term antimicrobial agents, including many antituberculosis agents, have been used, the sulfonamides, rifampin, doxycycline, and TMP are thought to be especially useful because of their intracellular bactericidal activity (Maderazo et al, 1979). Fluoroquinolones are taken up by macrophages directly and have also proven effective in the management of malacoplakia (Vallorosi et al, 1999). Other investigators have used ascorbic acid and cholinergic agents such as bethanechol in conjunction with antimicrobial therapy and have reported good results (Abdou et al, 1977; Zornow et al, 1979; Stanton et al, 1983). Both agents are thought to increase intracellular cyclic guanosine monophosphate levels, which have been postulated as the biologic defect causing macrophage dysfunction. Surgical intervention, however, may be necessary if the disease progresses in spite of antimicrobial treatment. Nephrectomy is usually performed for the treatment of symptomatic unilateral renal lesions.

The long-term prognosis appears to be related to the extent of the disease. When parenchymal renal malacoplakia is bilateral or occurs in the transplanted kidney, death usually occurs within 6 months (Bowers and Cathey, 1971; Deridder et al, 1977). Patients with unilateral disease usually have a long-term survival after nephrectomy.

Renal Echinococcosis

Echinococcosis is a parasitic infection caused by the larval stage of the tapeworm *Echinococcus granulosus*. The disease is prevalent in dogs, sheep, cattle, and humans in South Africa, Australia, New Zealand, Mediterranean countries (especially Greece), and some parts of the former Soviet Union. In the United States the disease is rare, but it is found in immigrants from Eastern Europe or other foreign endemic areas or as an indigenous infection among American Indians in the Southwest and in Eskimos (Plorde, 1977).

Pathogenesis and Pathology. **Echinococcosis is produced by the larval form of the tapeworm, which in its adult form resides in the intestine of the dog, the definitive host.** The adult worm is 3 to 9 mm long. The ova in the feces of the dog contaminate grass and farmlands and are ingested by sheep, pigs, or humans, the intermediate hosts. Larvae hatch, penetrate venules in the wall of the duodenum, and are carried by the bloodstream to the liver. Those larvae that escape the liver are next filtered by the lungs. Approximately 3% of the organisms that escape entrapment in the liver and lungs may then enter the systemic circulation and infect the kidneys. The larvae undergo vesiculation, and the resultant hydatid cyst gradually develops at a rate of about 1 cm/yr. Thus the cyst may take 5 to 10 years to reach pathologic size.

Echinococcosis cysts of the kidney are usually single and located in the cortex (Nabizadeh et al, 1983). The wall of the hydatid cyst has three zones: a peripheral zone of fibroblasts derived from tissues of the host becomes the adventitia and may calcify; an intermediate laminated layer becomes hyalinized; and a single inner layer is composed of nucleated epithelium and is called the *germinal layer.* The germinal layer gives rise to brood capsules that increase in number, become vacuolated, and remain attached to the germinal membrane by a pedicle. New larvae (scoleces) develop in large numbers from the germinal layer within the brood capsule (Fig. 10–36). The hydatid cyst is also filled with fluid. When brood capsules detach, they enlarge and move freely in the fluid and are then called daughter cysts. Hydatid sand is composed of free larvae and daughter cysts.

Clinical Presentation. **The symptoms of echinococcosis are those of a slowly growing tumor. Most patients are asymptomatic or have a flank mass, dull pain, or hematuria** (Gilsanz et al, 1980; Nabizadeh et al, 1983). Because the cyst is focal, it rarely affects renal function. Rarely, the cyst ruptures into the collecting system, and the patient may experience severe colic and passage of debris resembling grape skins in the urine (hydatiduria). The cyst may also rupture into an adjacent viscus or the peritoneal cavity. The fluid is extremely antigenic (Hartman, 1985).

Laboratory Diagnosis. **If cyst rupture occurs, the definitive diagnosis can be established by identifying daughter cysts in the urine or by identifying the laminated wall of the cyst** (Sparks et al, 1976). Fewer than half of the patients

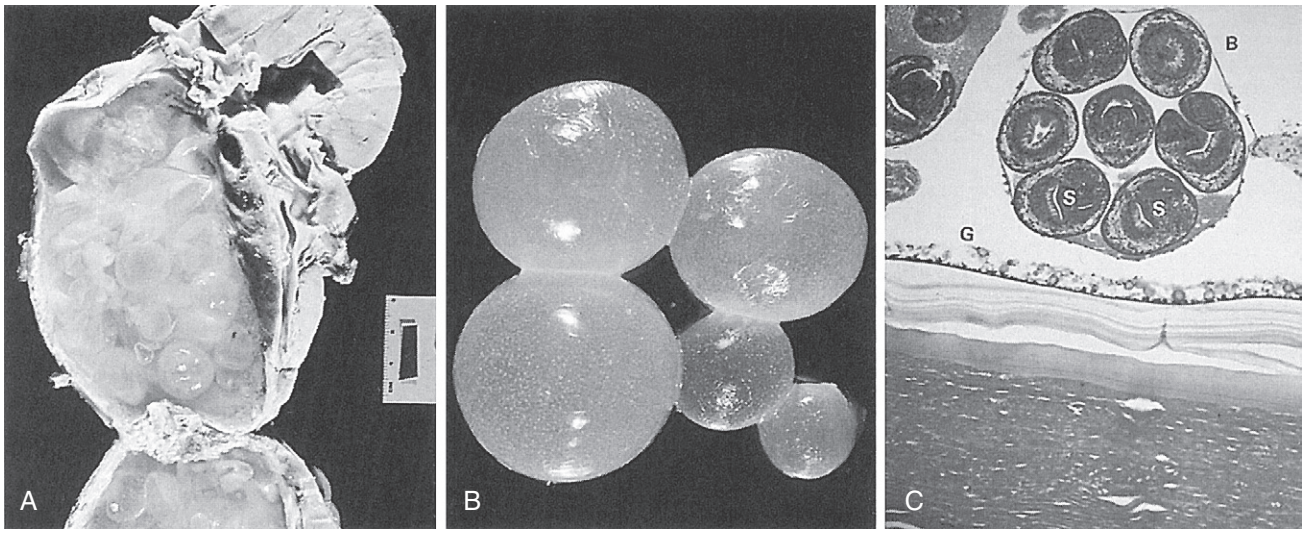

Figure 10–36. Echinococcosis. **A,** Gross specimen. A cystic mass measuring 7 × 11 cm in the lower pole. Smaller daughter cysts are identified within the larger cystic mass. **B,** Gross specimen. Daughter cysts represent brood capsules that have detached and move freely. **C,** Photomicrograph. Brood capsules (B) arising from the germinal layer (G) contain viable and degenerating scoleces (S). (From Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: III and IV. Monogr Urol 1985;6:26.)

have eosinophilia. The most reliable diagnostic test uses partially purified hydatid arc 5 antigens in a double-diffusion test (Coltorti and Varela-Diaz, 1978). Complement fixation, HA, and the Casoni intradermal skin tests are less reliable but, when combined, are positive in about 90% of patients (Sparks et al, 1976).

Radiologic Findings. **Excretory urography typically shows a thick-walled cystic mass, occasionally calcified** (Buckley et al, 1985). If the cyst ruptures into the collecting system, daughter cysts may be outlined in the pelvis as an irregular mass or as multiple solitary lesions (Gilsanz et al, 1980). Occasionally, direct filling of the cyst with contrast medium occurs.

Ultrasonography and CT are useful in characterizing the mass. Ultrasonography usually demonstrates a multicystic or multiloculated mass. A sudden change in position may demonstrate bright falling echoes corresponding to hydatid sand, which can be observed during real-time evaluation of hydatid cysts (Saint Martin and Chiesa, 1984).

On CT several patterns of renal echinococcosis may be recognized. The most specific is a cystic mass with discrete, round daughter cysts and a well-defined enhancing membrane (Martorana et al, 1981). The less-specific pattern is that of a thick-walled multiloculated cystic mass (Gilsanz et al, 1980). The presence of daughter cysts within the mother cyst differentiates the lesion from a simple renal cyst and from renal abscesses, infected cysts, and necrotic neoplasm.

Both CT and ultrasonography are useful in evaluating the liver. Angiography is seldom required. **Diagnostic aspiration should not be performed because of the danger of rupture and spillage of the highly antigenic cyst contents and risk of fatal anaphylaxis.** Nevertheless, Baijal and coworkers (1995) described a percutaneous management of renal hydatidosis as a minimally invasive diagnostic and therapeutic option.

Management. **The prognosis of echinococcosis is good but depends on the site and size of the cysts.** Medical treatment with benzimidazole compounds such as mebendazole or albendazole has shown limited success with significant side effects (Nabizadeh et al, 1983).

Surgery remains the mainstay of treatment of renal echinococcosis (Poulios, 1991). The cyst should be removed without rupture to reduce the chance of seeding and recurrence. If the cyst wall is calcified, the larvae are probably dead and the risk of seeding is low, although a daughter cyst may be viable. If the cyst ruptures or cannot be removed and marsupialization is required, then the contents of the cyst initially should be aspirated and filled with a scolicidal agent such as 30% sodium chloride, 0.5% silver nitrate, 2% formalin, or 1% iodine for approximately 5 minutes to kill the germinal portion (Sparks et al, 1976; Nabizadeh et al, 1983; Shetty et al, 1992).

Key Points: Kidney Infections

- Acute pyelonephritis classically presents as the abrupt onset of chills, fever, and flank or costovertebral angle tenderness but can present as symptoms as mild as cystitis or as severe as sepsis.
- Emphysematous pyelonephritis is a life-threatening infection diagnosed radiographically by the presence of gas in the parenchyma or collecting system and managed surgically.
- Renal abscesses are well delineated by CT and are classically managed with intravenous antimicrobial agents and drainage.
- Pyonephrosis is a bacterial infection in a hydronephrotic kidney. Prompt diagnosis is critical; treatment entails intravenous antimicrobial agents and drainage of the obstructed renal unit.
- Xanthogranulomatous pyelonephritis is a chronic renal infection that is often found in poorly functioning renal units obstructed secondary to nephrolithiasis. Xanthogranulomatous pyelonephritis can be mistaken for renal tumors.
- Malacoplakia is an unusual inflammatory disease thought to result from abnormal macrophage function. Michaelis-Gutmann bodies are lysosomal inclusion bodies that characterize this disease microscopically.

BACTEREMIA, SEPSIS, AND SEPTIC SHOCK

Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occur in response to an infection. A typical host response to infection involves localized containment and elimination of bacteria and repair of damaged tissue. This process is facilitated by macrophages and dendritic cells and orchestrated by CD4+ T helper cells via the release of both proinflammatory and anti-inflammatory molecules (cytokines, chemokines, interferons). Sepsis occurs when a local infectious process becomes an uncontrolled systemic blood-borne inflammatory response resulting in damage to tissues or organs remote from the initial site of infection or injury.

Definitions

Bacteremia: the presence of viable bacteria in the blood.

Systemic inflammatory response syndrome (SIRS): a clinical syndrome characterized by the 2001 International Sepsis Definitions Conference (Levy et al, 2003) as extremes of body temperature, heart rate, ventilation, and immune response. A detailed list of diagnostic criteria is presented in Table 10–24. **SIRS can occur in response to multiple insults including systemic infection, trauma, thermal injury, or a sterile inflammation.**

Sepsis: SIRS and infection either documented or strongly suspected.

Septic shock: an extreme form of sepsis complicated by organ dysfunction and persistent circulatory failure despite fluid and pharmacologic resuscitation.

Table 10–24.

Characteristics of Sepsis

General
Fever (core temperature >38.3° C)
Hypothermia (core temperature <36° C)
Heart rate >90 min, 1 or 2 SD above the normal value for age
Tachypnea
Altered mental status
Significant edema or positive fluid balance (20 mL/kg/24 hr)
Hyperglycemia (plasma glucose >120 mg/dL or 7.7 mol/L) in the absence of diabetes
Inflammatory
Leukocytosis (WBC count >12,000/μL)
Leukopenia (WBC count <4000/μL)
Normal WBC count with >10% immature forms
Organ Dysfunction
Arterial hypoxemia (PaO_2/FIO_2 >300)
Acute oliguria (urine output 0.5 mL/kg in 1 hr for at least 2 hr)
Creatinine increase of 0.5 mg/dL
Coagulation abnormalities (INR 1.5 or aPTT >60 sec)
Ileus (absent bowel sounds)
Thrombocytopenia (platelet count <100,000/μL)
Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)
Tissue Perfusion
Hyperlactatemia (>1 mmol/L)
Decreased capillary refill or mottling

INR, international normalized ratio; aPTT, activated partial thromboplastin time.
From Levy MM, Fink MP, Marshall JC, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. Crit Care Med 2003;31:1250–6.

Pathophysiology

Initial studies of pathophysiologic features of septic shock concentrated on the interactions of lipopolysaccharides (LPS) from the gram-negative bacterial cell wall with various innate immune system pathways. More recent investigations now focus on understanding the activation and regulation of both the innate and acquired immune systems and the array of cytokines that are released during localized and systemic inflammatory responses.

Bacterial Cell Wall Components in Septic Shock

The exotoxins produced by some bacteria (e.g., exotoxin A produced by *P. aeruginosa*) can initiate septic shock. **However, the bacteria themselves, and in particular their cell wall components, are primarily responsible for the development of septic shock. These components activate numerous innate immunologic pathways, including macrophages, neutrophils, and dendritic cells and the complement system. The prime initiator of gram-negative bacterial septic shock is endotoxin, an LPS component of the bacterial outer membrane.** Endotoxin can directly activate the coagulation, complement, and fibrinolytic systems, leading to the release of small molecules that cause vasodilation and increased endothelial permeability (Tapper and Herwald, 2000).

Cytokine Network

Monocytic cells appear to have a pivotal role in mediation of the biologic effects of SIRS and septic shock. Monocytes can remove and detoxify LPS and be beneficial to the host. However, LPS-stimulated monocytes produce cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-1. The intravascular activation of inflammatory systems involved in septic shock is mainly the consequence of an overproduction of these and other cytokines. Production of these cytokines is modulated by CD4+ T helper cells. Type 1 CD4+ T helper cells release proinflammatory cytokines including TNF-α, interferon-γ, and IL-2. These cytokines are also produced by macrophages, endothelial cells, and other cells stimulated by microbial products. The systemic release of large amounts of the cytokine TNF is associated with death from septic shock in humans (Waage et al, 1987; Calandra et al, 1988; Girardin et al, 1988). However, despite the fact that TNF is classically regarded as a central mediator of pathophysiologic changes associated with sepsis, the role of attenuation of this and other proinflammatory cytokines remains unclear. For example, in one animal model of peritonitis, survival was worsened by the administration of antibodies blocking TNF (Eskandari et al, 1992). Also, patients suffering from rheumatoid arthritis treated with TNF-α agents remain susceptible to the development of septic shock. Lastly, a meta-analysis of clinical trials utilizing anti-inflammatory agents in sepsis suggested these agents were generally harmful in all but a small subset of patients (Hotchkiss and Karl, 2003). More recently, anti-inflammatory cytokines, including IL-4 and IL-10, released by type II CD4+ T helper cells, have also been noted to be elevated in sepsis, further illustrating the complex regulation of the both proinflammatory and anti-inflammatory cytokines in a septic patient. In summary, both proinflammatory and anti-inflammatory cytokines are elements

of early sepsis; however, the role of cytokine modulation in the treatment of sepsis remains unclear.

Clinical Presentation and Diagnosis

Early signs of the systemic inflammatory response syndrome include temperature extremes (>38° C [100.4° F] or <36° C [96.8° F]), tachycardia (heart rate >90 beats per minute), tachypnea, and altered mental status. The classic bedside findings differentiating septic shock from other types of shock include a warm patient, brisk capillary refill, and a bounding pulse reflecting pyrexia, peripheral vasodilation, and decreased systemic vascular resistance. Other diagnostic criteria include evidence of organ dysfunction such as hypotension, oliguria, or ileus and laboratory abnormalities including leukocytosis or leukopenia, hyperbilirubinemia, hyperlactatemia, hyperglycemia, coagulation abnormalities, and elevated C-reactive protein and procalcitonin (see Table 10–24 for complete list of Consensus Conference criteria). The classic clinical presentation of fever and chills followed by hypotension is manifest only in about 30% of patients with gram-negative bacteremia (McClure, 1983). Even before temperature extremes and the onset of chills, bacteremic patients often begin to hyperventilate. Thus the earliest metabolic change in septicemia is a resultant respiratory alkalosis. In critically ill patients, the sudden onset of hyperventilation should lead to blood drawing for culture and careful evaluation of the patient. Changes in mental status can also be important clinical clues. Although the most common pattern is lethargy or obtundation, an occasional patient may become excited, agitated, or combative. Cutaneous manifestations such as the bull's-eye lesion associated with *P. aeruginosa* may be identified.

Metastatic infections secondary to genitourinary tract bacteremia have been described (Siroky et al, 1976). In this review of 137 patients who developed metastatic infections from bacteremia with a genitourinary source, 79% had undergone prior urologic instrumentation, 59% developed skeletal infections, mainly of the spine; and 29% developed endocarditis, most commonly caused by *E. faecalis*.

Bacteriology

In classic studies of sepsis syndrome and septic shock, gram-negative bacteria were predominant organisms isolated in 30% to 80% of cases and gram-positive bacteria in 5% to 24% (Ispahani et al, 1987; Calandra et al, 1988; Bone, 1991). Although *E. coli* is the most common organism causing gram-negative bacteremia, many nosocomial catheter-associated infections are caused by highly resistant gram-negative organisms: *P. aeruginosa*, *Proteus*, *Providencia*, and *Serratia*. *Acinetobacter* and *Enterobacter* are also emerging as important nosocomial pathogens. In a large series, *E. coli* caused about one third of the cases; the *Klebsiella-Enterobacter-Serratia* family, approximately 20%; and *Pseudomonas*, *Proteus, Providencia,* and anaerobic species, approximately 10% each (Kreger et al, 1980). Anaerobic organisms may cause bacteremia when the source is a postsurgical intra-abdominal abscess or transrectal prostatic biopsy. More recent studies suggest the incidence of sepsis caused by both gram-positive bacterial and fungal organisms is increasing (Martin et al, 2003) and reinforce the need for initial broad-spectrum antimicrobial coverage.

Management

The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection (Dellinger et al, 2004; Sessler et al, 2004). Although the identification and early intervention of sepsis by the urologist is important, the use of expert consultants is also recommended because management of sepsis and the critically ill patient is complex and always evolving.

Principles of resuscitation include support of the airway and breathing and optimization of perfusion. Intubation and mechanical ventilation may be required in patients who are obtunded and are unable to protect their airway. Supplemental oxygen may be instituted, but supranormal oxygen delivery is no longer considered a goal of therapy (Dellinger et al, 2004). Tissue perfusion should first be optimized with fluid resuscitation to restore mean circulating filling pressures. If additional blood pressure support is needed, vasoactive agents including phenylephrine, norepinephrine, and dopamine can be instituted; however, low-dose dopamine administration for renal protection is no longer recommended by critical care experts. Other principles of resuscitation and supportive care include optimization of oxygen delivery, the use of stress-dose corticosteroid therapy, correction of coagulopathies if clinically significant, maintenance of blood glucose levels below 150 mg/dL, and implementation of hemofiltration as needed.

Identification of the presumptive source of infection and cultures from corresponding fluids and blood should be obtained before the initiation of antimicrobial therapy. Multiple blood cultures for aerobic and anaerobic organisms should be obtained. In addition, all potential sources of bacteremia must be cultured (i.e., urine, sputum, and wounds). Careful attempts to identify the source of infection should be made, because the choice of appropriate antimicrobial coverage depends on the organisms that are thought most likely to cause the infection. The severity of the underlying disease and the possibility of synergistic interactions are also important considerations. If the urinary tract is the most likely portal of entry, a broad-spectrum antimicrobial agent either alone or in combination with an aminoglycoside should be administered. **Three clinical factors have been predictive of the subsequent isolation of a resistant pathogen: (1) the use of an antimicrobial drug in the last month, (2) advanced age, and (3) male sex** (Leibovici et al, 1992). If the infection is hospital acquired, or if the patient has had multiple infections or is immunocompromised or severely ill, an aminoglycoside and anti-*Pseudomonas* β-lactam or a third-generation cephalosporin should be used. When identification and drug susceptibilities of the offending organism are known, antimicrobial therapy should be changed to use the lowest cost, least toxic antimicrobial with the narrowest antimicrobial coverage. Antimicrobial treatment should be continued until the patient has been afebrile for 3 to 4 days and is clinically stable. Local infections that may have provided the focus for the bacteremia should be treated individually as appropriate.

Early studies suggested that recombinant human activated protein C (drotrecogin alfa), an inhibitor of multiple inflammatory and coagulation pathway components, could be used to lower mortality in sepsis (Bernard et al, 2001). However, meta-analysis of two large randomized trials raised doubt about the clinical usefulness of activated protein C in reducing mortality in sepsis (Wiedermann and Kaneider, 2005).

Key Points: Bacteremia, Sepsis, and Septic Shock

- Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occurs in response to an infection.
- The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection.

BACTERIURIA IN PREGNANCY

Asymptomatic bacteriuria is one of the most common infectious complications of pregnancy. The prevalence of bacteriuria does not change initially with the occurrence of pregnancy and ranges from 2% to 7% (Hooton et al, 2000). The risk of acquiring bacteriuria during pregnancy increases with the progression of pregnancy (Norden and Kass, 1968; Campbell-Brown et al, 1987; Stenqvist et al, 1989), lower socioeconomic class, multiparity, and sickle cell traits (Patterson and Andriole, 1987; Stenqvist et al, 1989).

The site of bacteriuria in pregnant female patients probably also reflects the situation before conception. In two studies that localized the origin of the bacteriuria, one using the Stamey ureteral catheterization technique and the other the Fairley bladder washout, upper tract infections were found in 44% and 24.5% of pregnant female patients, respectively (Fairley et al, 1966; Heineman and Lee, 1973). In nonpregnant females with recurrent bacteriuria, Stamey (1980) has reported about a 50% probability that the origin is in the upper tract. With other techniques, which may reflect the severity of tissue infection rather than the location of infection, the results are similar; approximately 50% of women with screening bacteriuria of pregnancy are fluorescent antibody-positive (Fa^+) and thus have evidence of upper tract infection (Harris et al, 1976). Fairley and his group (1973) found that the site of infection is unrelated to the likelihood that pyelonephritis will develop during pregnancy.

Spontaneous resolution of bacteriuria in pregnant women is unlikely unless treated. Nonpregnant patients often clear their asymptomatic bacteriuria (Hooton et al, 2000), **but pregnant women become symptomatic more frequently and tend to remain bacteriuric** (Elder et al, 1971).

Pyelonephritis develops in 1% to 4% of all pregnant women (Sweet, 1977) **and in 20% to 40% of pregnant women with untreated bacteriuria** (Pedler and Bint, 1987; Wright et al, 1993). **Of the women who develop pyelonephritis during pregnancy, 60% to 75% acquire it during the third trimester** (Cunningham et al, 1973), **when hydronephrosis and stasis in the urinary tract are most pronounced. From 10% to 20% of pregnant women who get pyelonephritis develop it again before or just after the delivery** (Cunningham et al, 1973; Gilstrap et al, 1981). Moreover, a third of pregnant women who develop pyelonephritis have a documented prior history of pyelonephritis (Gilstrap et al, 1981). Treatment of screening bacteriuria of pregnancy decreases the incidence of acute pyelonephritis during pregnancy from a range of 13.5% to 65% to a range of 0% to 5.3% (Sweet, 1977).

In Sweet's excellent review (1977) of bacteriuria and pyelonephritis during pregnancy, he suggests that patients with a renal source of bacteriuria are more likely to have persistent postpartum bacteriuria than those with cystitis alone. In addition, those women with persistent bacteriuria may have an increased incidence of impaired creatinine clearance and urinary concentrating ability and an increased incidence of radiographic changes compatible with chronic pyelonephritis. His review of 12 studies revealed that follow-up excretory urograms in pregnant women with bacteriuria showed an 8% to 33% incidence of radiologic changes compatible with chronic pyelonephritis; the incidence of all urinary tract abnormalities in this group was 18% to 80%.

Zinner and Kass (1971) estimated that approximately 10% of bacteriuric pregnant females have pyelographic evidence of pyelonephritis, and, in their study, these abnormalities were most common in women who had bacteriuria 10 to 14 years after pregnancy. The highest incidence of radiographic changes of pyelonephritis was found in women who had their infections localized to the upper urinary tract (Fairley et al, 1966). In this study, abbreviated excretory urograms were performed within a few days of localization of the infection by ureteral catheterization. Six women (30%) with upper UTIs revealed radiographic renal abnormalities compatible with chronic pyelonephritis on the side to which the infection was localized, and two (10%) had nonexcretion of one kidney with infection in the contralateral one. No patient with an infection localized to the bladder showed radiographic evidence of pyelonephritis.

In their evaluation of renal function, Zinner and Kass (1971) found that women who had had bacteriuria during pregnancy and had it again 10 to 14 years later on follow-up showed significantly lower mean maximal urine osmolalities than those who were not bacteriuric on follow-up. Others have found evidence of decreased creatinine clearance and concentrating ability in bacteriuric women post partum (Sweet, 1977). It is unlikely, however, that uncomplicated bacteriuria in pregnant women produces changes in kidney appearance or function different from those found in nonpregnant bacteriuric women. After observing 40 bacteriuric women during pregnancy, Kincaid-Smith (1978) stated that there was no difference in renal size or function between 6 months and 4 years after delivery. Pregnancy, therefore, may provide the opportunity for bacteriuria to be discovered, but this bacteriuria probably reflects only a susceptibility to UTI that was present at conception. **The increased likelihood that bacteriuria may progress to acute pyelonephritis during pregnancy alters the morbidity of bacteriuria for this group.** Treatment of asymptomatic bacteriuria found early in pregnancy has been shown to decrease the prevalence of subsequent acute pyelonephritis from 28% to less than 3% (Sweet, 1977).

Pathogenesis

The anatomic and physiologic changes induced by the gravid state significantly alter the natural history of bacteriuria (Patterson and Andriole, 1987). **These changes may cause pregnant women to be more susceptible to pyelonephritis and may require alteration of therapy.** These changes have been well summarized in several reviews (Davidson and Talner, 1978; Waltzer, 1981).

Anatomic and Physiologic Changes during Pregnancy

Increase in Renal Size

Renal length increases approximately 1 cm during normal pregnancy. It is thought that this does not represent true hypertrophy

but is the result of increased renal vascular and interstitial volume. No histologic changes have been identified in renal biopsy specimens (Waltzer, 1981).

Smooth Muscle Atony of the Collecting System and Bladder

The collecting system, especially the ureters, undergoes decreased peristalsis during pregnancy, and most women in their third trimester show significant ureteral dilatation (Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981) (Fig. 10–37). This hydroureter has been attributed both to the muscle-relaxing effects of increased progesterone during pregnancy and to mechanical obstruction of the ureters by the enlarging uterus at the pelvic brim. Progesterone-induced smooth muscle relaxation also may cause an increased bladder capacity (Waltzer, 1981). Later in pregnancy, the dilation may be the result of the obstructive effect of the enlarging uterus (Poole and Thorsen, 1999).

Bladder Changes

The enlarging uterus displaces the bladder superiorly and anteriorly. The bladder becomes hyperemic and may appear congested endoscopically (Waltzer, 1981). Estrogen stimulation probably causes bladder hypertrophy as well as squamous changes of the urethra (Waltzer, 1981).

Augmented Renal Function

The transient increases in glomerular filtration rate and renal plasma flow during pregnancy have been well summarized by several authors and are probably secondary to the increase in cardiac output (Zacur and Mitch, 1977; Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981). Glomerular filtration increases by 30% to 50%, and urinary protein excretion increases. **The significance of these physiologic changes is apparent when the normal serum creatinine and urea nitrogen values for pregnant women are surveyed** (Table 10–25). **Values considered normal in nonpregnant women may represent renal insufficiency during pregnancy.**

Davison and Lindheimer (1978) recommend that pregnant patients with serum creatinine levels greater than 0.8 mg/dL or urea nitrogen levels greater than 13 mg/dL undergo further evaluation of renal function. Similarly, **urinary protein in pregnancy is not considered abnormal until greater than 300 mg of protein in 24 hours is excreted.**

These significant physiologic changes in pregnancy, which may develop as early as the first trimester, lead to urinary stasis and

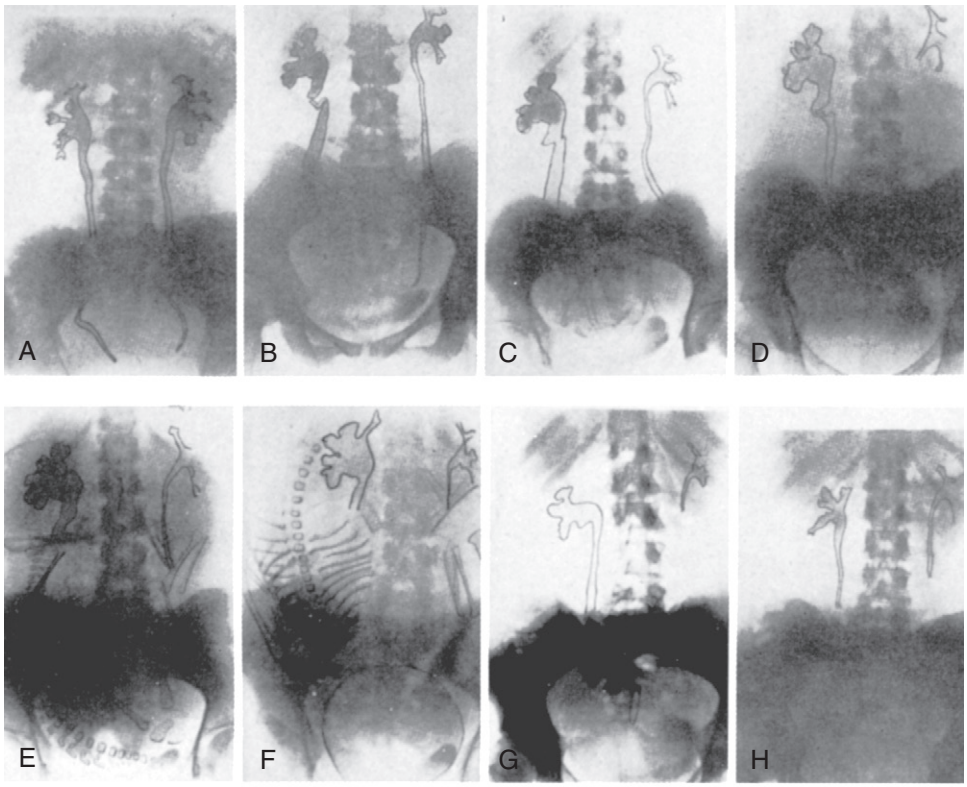

Figure 10–37. Progressive hydroureter and hydronephrosis observed on IVGs during a normal pregnancy. **A,** 15 weeks; **B,** 18 weeks; **C,** 22 weeks; **D,** 26 weeks; **E,** 34 weeks; **F,** 39 weeks; **G,** 1 week post partum; **H,** 6 weeks post partum. Bilateral hydroureter and hydronephrosis are shown as early as 15 weeks (**A**). **B** to **H,** Successive urograms are from one patient during a normal pregnancy. Dilation occurs mainly on the right side, and both urinary tracts are normal by 6 weeks after delivery. (**A** to **H,** From Hundley JM, Walton HJ, Hibbits JT, et al. Physiologic changes occurring in the urinary tract during pregnancy. Am J Obstet Gynecol 1935;30:625–49.)

mild hydroureteronephrosis, and contribute to development of pyelonephritis.

Recent studies of *E. coli* adhesins and their respective specific tissue receptors have established an adhesin-based mechanism of pyelonephritis-induced preterm births and low birth weights in mice (Kaul et al, 1999). There is a higher incidence of *E. coli*-bearing Dr adhesins during the third trimester of pregnancy in women with gestational pyelonephritis (Nowicki et al, 1994) and an upregulation of Dr adhesin in the kidney, endometrium, and placenta during the third trimester of pregnancy (Martens et al, 1993). When infected intravesically with *E. coli*-bearing Dr adhesin, nearly 90% of mice that were hyporesponsive to bacterial lipopolysaccharide and had a deficient immune response delivered preterm, compared with 10% of mice infected with *E. coli* without Dr adhesin. Also, there was a significant reduction in fetal birth weight in the Dr adhesin-infected group. Bacterial tissue culture showed systemic spread of the *E. coli*-bearing Dr adhesins to the placentae and fetuses.

Complications Associated with Bacteriuria during Pregnancy

Prematurity and Prenatal Mortality

In the preantimicrobial era, pregnant women with symptomatic UTIs and bacterial pyelonephritis were reported to have a high incidence of prematurity, low birth weight, and death (Gilstrap et al, 1981). The relationship between asymptomatic bacteriuria and prematurity is less clear. Gilstrap and colleagues (1981) found no difference in pregnancy among patients treated for asymptomatic bacteriuria as compared with nonbacteriuric controls. **However, because women with asymptomatic bacteriuria are at higher risk for developing a symptomatic UTI that results in adverse fetal sequelae, complications associated with bacteriuria during pregnancy, and pyelonephritis and its possible sequelae, such as sepsis in the mother, all women with asymptomatic bacteriuria should be treated** (Smaill, 2001).

Maternal Anemia

Although several studies suggest that bacteriuria untreated during pregnancy is associated with maternal anemia, not all studies support this. Some difficulties in interpreting the results of these surveys have been caused by inadequate documentation of bacteriuria. In one survey in which urine cultures were obtained by suprapubic aspiration, the data suggest that pregnant patients requiring three or more treatments for bacteriuria have lower levels of serum hemoglobin and folate than controls (McFadyen et al, 1973). In another study from England, investigators showed a statistically significant difference in the incidence of anemia between 410 bacteriuric pregnant women and 409 control pregnant women (Williams et al, 1973). In this survey, 14.6% of bacteriuric women and 10% of control women were anemic at the first prenatal visit. This separation increased during the third trimester (32 weeks), when 25% of women treated with placebo alone had anemia but only 16.8% of those women treated with antimicrobial agents had anemia. Furthermore, in the 31 untreated (placebo-treated) bacteriuric women who subsequently developed pyelonephritis, the incidence of anemia was 45.2%. These investigators concluded that "untreated bacteriuria increases the likelihood of developing anemia during pregnancy and that this risk is enhanced by the development of acute pyelonephritis, even if it is treated promptly."

Laboratory Diagnosis

Significant false-negative rates occur if screening is conducted by urinalysis or reagent strip testing (Preston et al, 1999; McNair et al, 2000). **Therefore an initial screening culture should be performed in all pregnant women during the first trimester** (Stenqvist et al, 1989). If the culture shows no growth, repeat cultures are generally unnecessary because patients who have no growth in their urine early in their pregnancy are unlikely to develop bacteriuria later (Norden and Kass, 1968; McFadyen et al, 1973). Pregnant women with a history of recurrent UTI or vesicoureteral reflux may benefit from antimicrobial prophylaxis (Bukowski et al, 1998).

Management

Selection of an antimicrobial agent to treat the bacteriuria must be made, however, with special considerations given to maternal and fetal toxicity. The physiologic changes of pregnancy may decrease tissue and serum drug concentrations. Maternal expanded fluid volume, the distribution of the drug in the fetus, increased renal blood flow, and increased glomerular filtration decrease the serum drug concentration. If the culture is positive, special consideration must be given to the selection of antimicrobial agents chosen to treat infection to prevent fetal toxicity. The pathogens are similar to those seen in nonpregnant women (MacDonald et al, 1983). Table 10–26 lists the antimicrobial agents and dosing for use in pregnancy. The aminopenicillins and cephalosporins are considered safe and generally effective throughout pregnancy. In patients with penicillin allergy, nitrofurantoin is a reasonable alternative. It may be used safely during the first two trimesters in patients without glucose-6-phosphate dehydrogenase deficiency. Given the low efficacy of short-course β-lactam therapy in nonpregnant women, it is prudent to describe a full 3- to 7-day course of therapy in pregnant women. Follow-up cultures should be obtained to document absence of infection. If the culture is positive, the cause of bacteriuria must be determined to be lack of resolution, bacterial persistence, or reinfection. If the infection is unresolved, proper selection and administration of another drug probably will solve the problem. If the problem is bacterial persistence or rapid reinfection, antimicrobial suppression of infection or prophylaxis (Pfau and Sacks, 1992) throughout the remainder of the pregnancy should be considered.

Pregnant women with acute pyelonephritis should be hospitalized and treated initially with parenteral antimicrobial agents. More than 95% of these patients respond within 24 hours using ampicillin and an aminoglycoside (Cunningham et al, 1973) or cephalosporins (Sanchez-Ramos et al, 1995). Appropriate oral agents should then be given for at least 14 days (Faro et al, 1984). After the treatment course is completed, low-dose prophylaxis with nitrofurantoin, amoxicillin, or cephalexin has been shown to be effective in preventing reinfection (Van Dorsten et al, 1987; Sandberg and Brorson, 1991). The efficacy of postcoital prophylaxis with either cephalexin (250 mg) or nitrofurantoin (50 mg) has been reported (Pfau and Sacks, 1992).

Drugs that are relatively contraindicated during pregnancy include the fluoroquinolones, TMP, chloramphenicol, erythromycin, tetracycline, sulfonamides, and sometimes nitrofurantoin (Nicolle, 1987). Fluoroquinolones are contraindicated because of their effects on immature cartilage. TMP may have teratogenic effects and should be avoided, especially in the first trimester. The "gray baby" syndrome is a toxic effect of chloramphenicol on neonates resulting from the inability of the infant to metabolize

Table 10–26.

Oral Antimicrobial Agents Used in Pregnancy

DRUG	DOSAGE	COMMENTS
Agents Considered Safe		
Penicillins		
Ampicillin	500 mg qid	Extensively used
Amoxicillin	250 mg tid	Safe and effective
Penicillin V	500 mg qid	Used less frequently but achieves excellent urinary levels
Cephalosporins		
Cephalexin	500 mg qid	Extensively used
Cefaclor	500 mg qid	Somewhat more effective against gram-negative organisms
Nitrofurantoin	100 mg qid	May be used during the first two trimesters; may result in hemolytic anemia in patients with G6PD deficiency
Sulfasoxazole	1 g, followed by 500 mg qid	May cause kernicterus in the newborn; also may cause hemolytic anemia when G6PD deficiency is present; especially avoid in last few weeks of gestation
Agents That Should Be Avoided		
Fluoroquinolones		Possible damage to immature cartilage
Chloramphenicol		Associated with "gray baby" syndrome
Trimethoprim		May cause megaloblastic anemia because of anti–folic acid action
Erythromycin		Associated with maternal cholestatic jaundice
Tetracyclines		May cause acute liver decompensation in the mother and inhibition of new bone growth in the fetus

G6PD, glucose-6-phosphate dehydrogenase.

or excrete the drug. Erythromycin may cause cholestatic jaundice in the mother. Tetracycline may cause fetal malformations and maternal liver decompensation. Sulfonamides may cause kernicterus and neonatal hyperbilirubinemia and should be avoided in the third trimester. As mentioned earlier, nitrofurantoin can cause hemolytic anemia in both mother and child when glucose-6-phosphate dehydrogenase deficiency is present (Nicolle, 1987).

Pregnancy in Women with Renal Insufficiency

With current management of recurrent UTIs, infections alone are no contraindication to pregnancy. In patients who have renal insufficiency with or without UTIs, Davison and Lindheimer (1978) emphasize that renal function should be carefully evaluated by both serum creatinine levels and creatinine clearance before a woman is counseled about conceiving or continuing a pregnancy. Although little is known about the outcome of pregnancies with differing degrees of renal insufficiency, it is known that normal pregnancy is rare if the preconception serum creatinine level exceeds 3 mg/dL (about 30 mL/min clearance).

Table 10–27.

Bacteriuria in Two Population Surveys

AGE (yr)	MEN (%)	WOMEN (%)
65-70	2-3	20-21
>80	21-22	23-50

Data from Brocklehurst JC, Dillane JB, Griffiths L, et al. Prevalence and symptomatology of urinary infection in an aged population. Gerontol Clin 1968;10:242–53; and Sourander LB. Urinary tract infections in the aged: an epidemiological study. Ann Med Intern Fenn 1966;55(Suppl. 45):7–55.

The degree of renal function impairment is the major determinant for pregnancy outcome. The fetal survivors of pregnant women with mild or moderate renal disease (serum creatinine <1.4 mg/dL and from 1.4 mg/dL to 2.4 to 2.8 mg/dL, respectively) is only slightly diminished, and irreversible deterioration of maternal renal function is uncommon. However, the perinatal mortality is approximately four times higher with severe disease. The rate of perinatal morbidity due to low birth weight or prematurity doubles from mild to moderate renal disease, and again from moderate to severe disease (Vidaeff et al, 2008).

Key Points: Bacteriuria in Pregnancy

- Screening for bacteriuria with a culture should be performed in all pregnant women during the first trimester.
- The prevalence of bacteriuria does not change with the occurrence of pregnancy; however, unlike in nonpregnant women, spontaneous resolution of bacteriuria in pregnant women is unlikely.
- All pregnant women with bacteriuria should be treated.
- Bacteriuria more commonly progresses to acute pyelonephritis during pregnancy.
- Pyelonephritis develops in 1% to 4% of all pregnant women (Sweet, 1977) and in 20% to 40% of pregnant women with untreated bacteriuria.
- Pregnant women with acute pyelonephritis should be hospitalized and treated initially with parenteral antimicrobial agents.

BACTERIURIA IN THE ELDERLY

UTIs in the elderly are a common and expanding health problem (Kaye, 1980). In 2003 there were almost 34 million Americans older than 65 years (U.S. Census Bureau, 2003). As the life expectancy increases, the diagnosis, treatment, morbidity, and mortality of UTIs in the elderly will assume increasing importance.

Epidemiology

At least 20% of women and 10% of men older than 65 years have bacteriuria (Boscia and Kaye, 1987). In contrast to young adults, in whom bacteriuria is 30 times more prevalent in women than in men, the ratio in women to men with bacteriuria progressively decreases to 2:1. Most elderly patients with bacteriuria are asymptomatic; estimates among women living in nursing homes range from 17% to 55%, as compared with 15% to 31% for their male cohorts (Nicolle, 1994). The prevalence of bacteriuria in the elderly increases with age (Table 10–27) (Sourander, 1966; Brocklehurst et al, 1968) and concurrent disease (Fig. 10–38) and may exceed 50% in selective groups (Boscia and Kaye, 1987;

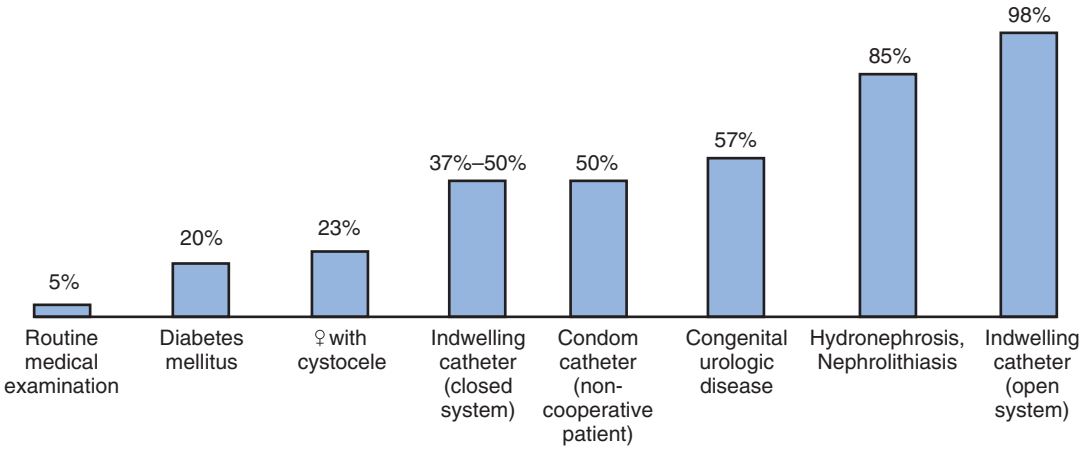

Figure 10–38. Frequency of significant bacteriuria related to underlying disease. (Adapted from Jackson GG, Arana-Sialer JA, Andersen BR. Profiles of pyelonephritis. Arch Intern Med 1962;110:663–75.)

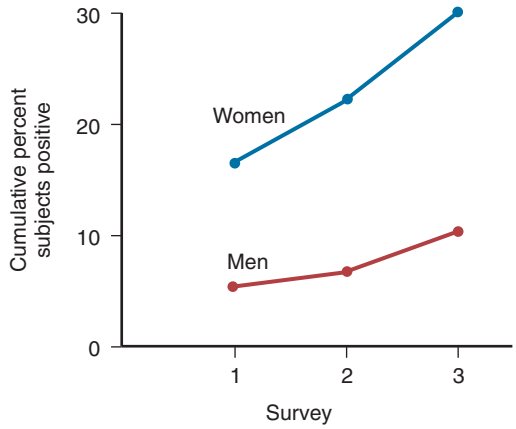

Figure 10–39. Cumulative percentage of subjects (age = 65 years) with at least one positive urine culture survey result over three surveys performed at 6-month intervals. (From Boscia JA, Kobasa WD, Knight RA, et al. Epidemiology of bacteriuria in an elderly ambulatory population. Am J Med 1986;80:208.)

Schaeffer, 1991). Risk factors can be compounded. In a study of 373 women and 150 men older than 68 years, 24% of functionally impaired nursing home residents had bacteriuria compared with 12% of healthy domiciliary subjects (Boscia et al, 1986). Longitudinal studies have clarified the dynamic aspect of bacteriuria in the elderly with frequent, spontaneous alteration between positive and negative urine cultures (Monane et al, 1995) (Fig. 10–39). There is only a small pool of elderly patients with persistent bacteriuria (Kaye, 1980). The incidence of asymptomatic bacteriuria is much more common than is apparent from a single survey, implying that most elderly will eventually have episodes of bacteriuria (Boscia et al, 1986).

Pathogenesis

The pathophysiology of increased susceptibility is multifactorial and poorly understood. **Age-related changes include decline in cell-mediated immunity, neurogenic bladder dysfunction, increased perineal soiling as a result of fecal and urinary incontinence, increased incidence of urethral catheter placement, and, in women, changes in the vaginal environment associated with estrogen depletion** (Schaeffer, 1991; Raz and Stamm, 1993). Increased receptivity of uroepithelial cells (Reid et al, 1984) and a decrease in prostatic and vaginal antimicrobial factors associated with changes in pH and levels of zinc and hormones have been observed (Boscia et al, 1986). Bacteriologic characteristics of infection in the elderly differ from those in younger patients (Baldassarre and Kaye, 1991). *E. coli* remains the most common uropathogen, causing 75% of these infections. There is a significant increase in the incidence of *Proteus, Klebsiella, Enterobacter, Serratia,* and *Pseudomonas* species, as well as enterococci. Bacteriuria due to gram-positive bacteria is much more common in elderly men than in elderly women (Jackson et al, 1962). *S. saprophyticus* is not seen in this population. Polymicrobial bacteriuria is more common among the elderly (Nicolle et al, 1987). The shift in the pattern of uropathogens, the high frequency of polymicrobial infections, and antimicrobial resistance in UTIs in the elderly are due in large part to the high frequency of institutionalization and hospitalization, catheterization, and antimicrobial usage in this population (Fig. 10–40).

Laboratory Diagnosis

Diagnosis of bacteriuria and UTIs in the elderly can be difficult. **Urinary tract symptoms are often absent, and concomitant disease can mask or mimic UTI. Even severe upper tract infections may not be associated with fever or leukocytosis** (Baldassarre and Kaye, 1991). Therefore a high index of suspicion is warranted, and diagnosis should rely on the results of a carefully obtained urinalysis and culture. The presence of greater than 10^5 cfu/mL of urine remains the standard for diagnosis in these patients. However, counts of 10^2 or more bacteria are clinically significant in catheterized specimens (Kunin, 1987; Nicolle et al, 2005).

Pyuria alone is not a good predictor nor an indication for antimicrobial treatment of bacteriuria in this population (Ouslander et al, 1996; Nicolle et al, 2005). Boscia and associates (1989) reported that more than 60% of women with pyuria of 10 WBCs/mm^3 or greater (noted in midstream specimens) did not have a concurrent bacteriuria. However, the absence of pyuria was a good predictor of the absence of bacteriuria.

Because urinary tract abnormalities can often predispose and complicate bacteriuria in the elderly, a thorough urologic evaluation is warranted. Renal dysfunction, calculi, hydronephrosis, urinary retention, neurogenic bladder dysfunction, and other abnormalities should be identified by serum creatinine measurement, excretory urography, CT, ultrasonography, urodynamics,

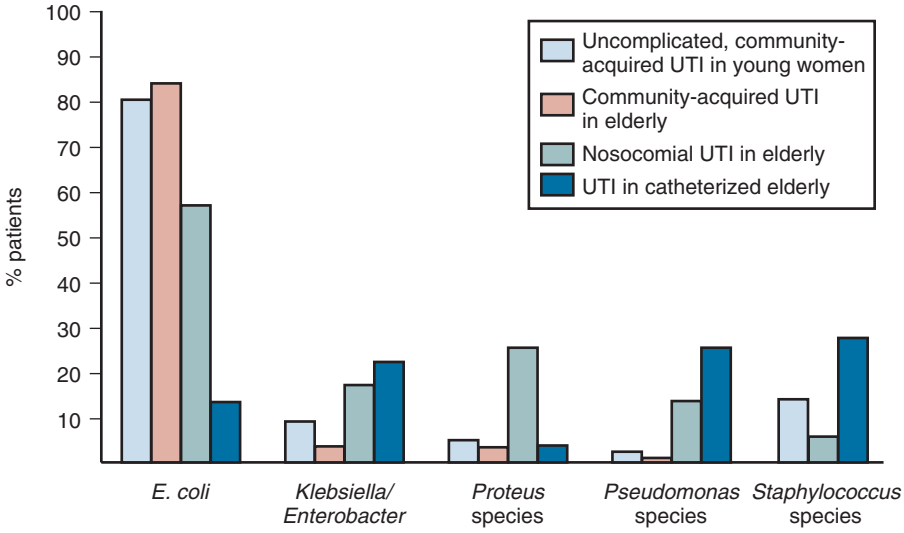

Figure 10–40. Microbiology of urinary tract infections. (Data compiled from Stark RP, Maki DG. Bacteriuria in the catheterized patient: what quantitative level of bacteriuria is relevant? N Engl J Med 1984;311:560–4; Kunin CM. Detection, prevention, and management of urinary tract infections. 4th ed. Philadelphia: Lea & Febiger; 1987. p. xiii; Nicolle LE, Bjornson J, Harding GKM. Bacteriuria in elderly institutionalized men. N Engl J Med 1983;309:1420–5; Krieger JN, Kaiser DL, Wenzel RP. Urinary tract etiology of bloodstream infections in hospitalized patients. J Infect Dis 1983;148:57–62.)

and/or cystoscopy. The timing and sequence of these tests should be dictated by the clinical setting.

Significance of Screening Bacteriuria

Screening for asymptomatic bacteriuria in elderly residents in the community or long-term care facilities is not recommended (Nicolle et al, 1983; Nordenstam et al, 1986; Boscia et al, 1987; Abutryn et al, 1994). **There is no documented relationship between asymptomatic bacteriuria and uncomplicated UTIs and worsening renal function in this population.** The treatment of asymptomatic bacteriuria to improve incontinence has not been justified (Baldassarre and Kaye, 1991; Ouslander et al, 1995). Although studies have demonstrated decreased survival in bacteriuric patients compared with nonbacteriuric control subjects, it is unclear whether increased mortality rates and bacteriuria are causally related (Baldassarre and Kaye, 1991; Abutryn et al, 1994).

Studies that have found a significantly increased mortality among persons with bacteriuria have looked at populations that were heterogeneous in terms of age and underlying disease (Dontas et al, 1981; Latham et al, 1985). An age difference of only 2 years increases mortality by 20% (Dontas et al, 1968). Therefore, in the studies mentioned previously (Dontas et al, 1968) and others (Abutryn et al, 1994), it is not clear how much of the observed association between bacteriuria and mortality was due to differences in age between the bacteriuric and the abacteriuric groups. In a study of bacteriuria and mortality in a homogeneous 70-year-old population, the association between bacteriuria and mortality was weaker and linked to fatal diseases not attributable to bacteriuria (Dontas et al, 1968). Nicolle and associates (1987) randomized institutionalized women with bacteriuria to treatment or observation and followed these patients for more than 1 year. Treatment did not result in improved survival and was associated with a number of adverse effects.

Bacteriuria that leads to UTIs in elderly subjects in the presence of underlying structural urinary tract abnormalities (e.g., obstruction with hydronephrosis) or systemic conditions (e.g., severe diabetes mellitus) are clinically significant, can lead to renal failure, and require prompt therapy. In addition, UTIs caused by urea-splitting bacteria, such as *Proteus* or *Klebsiella* species that cause formation of infection stones, may also lead to severe renal damage.

Sepsis and its sequelae (sepsis syndrome and septic shock) are increasingly common in the elderly. This is in part due to the aggressive use of catheters (Kunin et al, 1992) and other invasive equipment, implantation of prosthetic devices, and the administration of chemotherapy to cancer patients or corticosteroids in other immunosuppressed patients with organ transplants or inflammatory diseases. In addition, modern medical care has given longer life spans to the elderly and patients with metabolic, neoplastic, or immunodeficiency disorders, who remain at increased risk for infection.

Management

Prospective randomized comparative trials of antimicrobial or no therapy in elderly male and female nursing home residents with asymptomatic bacteriuria consistently document no benefit of antimicrobial therapy. There was no decrease in symptomatic episodes and no improvement in survival. In fact, treatment with antimicrobial therapy increases the occurrence of adverse drug effects and reinfection with resistant organisms and increases the cost of treatment. **Therefore asymptomatic bacteriuria in elderly residents of long-term care facilities should not be treated with antimicrobial agents.**

If patients present with lower tract symptoms, 7 days of therapy is recommended. For individuals presenting with fever or more severe systemic infection 10 to 14 days of therapy is recommended. The goal in this population is to eliminate symptoms but not sterilize the urine (McMurdo and Gillespie, 2000).

The 10% to 15% decrease in susceptibility of uropathogens to β-lactams, TMP-SMX, and fluoroquinolones in isolates from nursing home residents is disturbing and most likely due to a pattern of empirical prescribing in the nursing homes. In contrast, the susceptibility of isolates from patients with acute uncomplicated UTI in an outpatient setting has not changed appreciably in 10 years. The difference in susceptibility between the isolates from the outpatient and nursing home settings can be attributed to the presence of additional risk factors for antimicrobial resistance in the latter group. These risk factors include frequent antimicrobial

usage, overcrowding, underlying pathology, and the presence of catheters and other invasive devices. Antimicrobial use needs to be guided by current surveillance studies of targeted uropathogenic bacteria and implemented (Vromen et al, 1999).

The elderly population is more susceptible than young patients to the toxic and adverse effects of antimicrobial agents (Grieco, 1980; Carty et al, 1981; Boscia et al, 1986) because the metabolism and excretion of antimicrobial agents may be impaired and the resulting increased serum levels can further damage renal function. Interactions with other medications can occur (Stahlmann and Lode, 2003). The safety margin between therapeutic and toxic doses is significantly narrowed. Therefore antimicrobial agents must be used judiciously, and dosing and drug levels should be carefully monitored.

The fluoroquinolones are effective in this population, and the side effects are not more apparent than in a younger population. However, fluoroquinolones can cause QT interval prolongation; therefore they should be avoided in patients with known prolongation of the QT interval, patients with uncorrected hypokalemia or hypomagnesemia, and patients receiving some antiarrhythmic agents (Stahlmann and Lode, 2003).

Chondrotoxicity of fluoroquinolones has led to restricted use in pediatric patients, but there is no indication that similar effects could occur in joint cartilage of adults. Tendinitis and tendon ruptures have occurred in rare cases. Chronic renal diseases, concomitant use of corticosteroids, and age older than 60 years have been recognized as risk factors for fluoroquinolone-induced tendon disorders (Stahlmann and Lode, 2003).

Key Points: Bacteriuria in the Elderly

- Bacteriuria is very common in both elderly women and men.
- Screening for bacteriuria is not recommended in elderly patients because there is no relationship between asymptomatic bacteriuria and uncomplicated UTIs or deteriorating renal function; asymptomatic bacteriuria should not be treated.
- Infections of the urinary tract may present as subtle signs, and a high index of suspicion is often required for diagnosis.
- Treatment of symptomatic UTI requires modifications for physiologic and pathophysiologic conditions of the elderly.

CATHETER-ASSOCIATED BACTERIURIA

Catheter-associated bacteriuria is the most common hospital-acquired infection, accounting for up to 40% of such infections and more than 1 million per year (Haley et al, 1985; Stamm, 1991). **The development of bacteriuria in the presence of an indwelling catheter is inevitable and occurs at an incidence of approximately 10% per day of catheterization. Sterile and clean intermittent catheterization has been associated with rates of bacteriuria ranging from 1% to 3% per catheterization** (Warren, 1997). The most important risk factors associated with increased likelihood of developing catheter-associated bacteriuria are duration of catheterization, female gender, absence of systemic antimicrobial agents, and catheter-care violations (Stamm, 1991). Most catheter-associated UTIs are asymptomatic. In patients with short-term catheter placement, only 10% to 30% of bacteriuric episodes produce typical symptoms of acute infection (Haley et al, 1981; Hartstein et al, 1981). Similarly, although patients with long-term catheters are bacteriuric, the incidence of febrile episodes occurs at a rate of only 1 per 100 days of catheterization (Warren, 1991). The extra direct cost associated with catheter-associated UTIs is about $600 per year per patient. The nosocomial costs for *E. coli* infections with relatively susceptible strains are considerably lower than for those caused by resistant gram-negative bacteria, which often require expensive parenteral antimicrobial therapy (Tambyah et al, 2002). Recently, the Center for Medicare Services (CMS) announced that they will no longer reimburse hospitals for the extra costs resulting from catheter-associated UTIs.

Pathogenesis

Bacteria enter the urinary tract of a catheterized patient by several routes. Bacteria can be introduced at the time of initial catheter placement by either mechanical inoculation of urethral bacteria or contamination from poor technique. Subsequently the bacteria most commonly gain access via a periurethral or intraluminal route (Stamm, 1991). In women, periurethral entry is the most prevalent. Daifuku and Stamm (1984) found that among 18 women who developed catheter-associated bacteriuria, 12 had antecedent urethral colonization with the infecting strain. Bacteria may also enter the drainage bag and follow the intraluminal route to the bladder. This route is particularly common in patients who are clustered among other patients with indwelling catheters (Maizels and Schaeffer, 1980; Tambyah et al, 1999).

The urinary catheter system provides a unique environment that allows for two distinct populations of bacteria: those that grow within the urine and another population that grows on the catheter surface. A biofilm represents a microbial environment of bacteria embedded in an extracellular matrix of bacterial products and host proteins that often lead to catheter encrustation (Stamm, 1991; Bonadio et al, 2001). Certain bacteria, particularly of the *Pseudomonas* and *Proteus* species, are adept at biofilm growth, which may explain their higher incidence in this clinical setting (Mobley and Warren, 1987). The uropathogens isolated from the catheterized urinary tract often differ from those found in noncatheterized ambulatory patients. *E. coli* is still the most common organism isolated, but *Pseudomonas, Proteus,* and *Enterococcus* species are very prevalent (Warren, 1991). In patients with long-term catheterization of more than 30 days, the bacteriuria is usually polymicrobial and the presence of four or five pathogens is not uncommon (Warren et al, 1982). Although certain species may persist for long periods, the bacterial populations in these patients tend to be dynamic.

Clinical Presentation

Most patients are asymptomatic. Suprapubic discomfort and development of fever, chills, or flank pain may indicate a symptomatic UTI.

Laboratory Diagnosis

Significant bacteriuria in patients with catheters is present when greater than 100 cfu/mL is present because even this low level progresses to greater than 10^5 cfu/mL in almost all patients (Maizels and Schaeffer, 1980; Stark and Maki, 1984). Pyuria is not a discriminate indicator of infection in this population.

Management

Careful aseptic insertion of the catheter and maintenance of a closed dependent drainage system are essential to minimize development of bacteriuria. The catheter-meatal junction should be cleaned daily with water, but antimicrobial agents should be avoided because they lead to colonization with resistant pathogens, such as *Pseudomonas*.

Incorporation of silver oxide (Schaeffer et al, 1988) or silver alloy (Saint et al, 1998) into the catheter and hydrogen peroxide into the drainage bag has been reported to decrease the incidence of bacteriuria in some studies (Schaeffer et al, 1988) but not in other populations (Stamm, 1991). The major benefit of silver alloy is in decreasing the likelihood of bacteriuria in hospitalized adults catheterized for the short-term (Saint et al, 2000; Newton et al, 2002; Brosnahan et al, 2004). If an asymptomatic catheterized patient has had an indwelling catheter for 3 or more days, and will have the catheter removed, a dipstick test can be used to rule out bacteriuria (Tissot et al, 2001). **Concurrent administration of systemic antimicrobial agents transiently decreases the incidence of bacteriuria associated with short-term catheterization, but after 3 to 4 days the incidence of bacteriuria is similar to the rate in catheterized patients not taking systemic antimicrobials agents, and the prevalence of resistant bacteria and side effects is substantial.** The concept of instilling nonvirulent bacteria into the bladder to completely block colonization and infection by pathogens has been tested in patients with spinal cord injuries (Hull et al, 2000). Patients successfully colonized with the nonvirulent strain had reduced symptomatic UTI and a subjective improvement in quality of life.

Patients with indwelling catheters should be treated only if they become symptomatic (e.g., febrile). Urine cultures should be performed before initiating antimicrobial therapy. The antimicrobial agent should be discontinued within 48 hours of resolution of the infection. If the catheter has been indwelling for several weeks, encrustation may shelter bacteria from the antimicrobial agent; therefore the catheter should be changed.

When a catheter is to be removed and there is a high probability of bacteriuria or the dipstick test is positive, a culture should be obtained 24 hours before removal (Tissot et al, 2001). **If the probability is low or the dipstick is negative, a culture may not be necessary. The patient should be started on empirical antimicrobial therapy such as TMP-SMX or a fluoroquinolone just before decatheterization and maintained on therapy for 2 days. A post-therapy culture should be obtained 7 to 10 days later to confirm the eradication of the bacteriuria.**

Key Points: Catheter-Associated Bacteriuria

- Careful aseptic insertion of the catheter and maintenance of a closed dependent drainage system are essential to minimize development of bacteriuria.
- The development of catheter-associated bacteriuria is inevitable.
- If bacteriuria is suspected in a catheterized patient, a culture should be obtained and antimicrobial therapy initiated before decatheterization.
- Only symptomatic catheter-associated UTIs require treatment.
- Antimicrobial therapy should be continued for 2 to 3 days and a post-therapy culture obtained 7 to 10 days later.

MANAGEMENT OF UTI IN PATIENTS WITH SPINAL CORD INJURY

Patients with spinal cord injury have unique concerns that affect the risk, diagnosis, and management of UTIs, which are all considered complicated.

Epidemiology

UTIs are among the most common urologic complications of spinal cord injury. It has been estimated that approximately 33% of spinal cord-injured patients have bacteriuria at any time (Stover et al, 1989) and that eventually almost all of spinal cord-injured patients will become bacteriuric and many will suffer significant morbidity and mortality. One prospective study of patients on intermittent catheterization or condom catheterization reported an incidence of significant bacteriuria of 18 episodes per person per year and an annual incidence of febrile UTIs of 1.8 per person per year (Waites et al, 1993). In addition, UTI is the most common cause of fever in the spinal cord–injured patient (Beraldo et al, 1993). **The 1992 National Institute on Disability and Rehabilitation Research Consensus Conference (1993) examined the problems associated with UTIs in spinal cord–injured patients. Among the risk factors identified were impaired voiding, overdistention of the bladder, elevated intravesical pressure, increased risk of urinary obstruction, vesicoureteral reflux, instrumentation, and increased incidence of stones. Other factors that have been implicated are decreased fluid intake, poor hygiene, perineal colonization, decubiti and other evidence of local tissue trauma, and reduced host defense associated with chronic illness** (Gilmore et al, 1992; Waites et al, 1993).

Pathogenesis

The method of bladder management has profound impact on UTI. The National Institute on Disability and Rehabilitation Research Consensus Conference (1993) noted that indwelling catheters were most likely to lead to UTI and that the vast majority of patients with an indwelling catheter for 30 days are bacteriuric. Suprapubic catheters and indwelling urethral catheters eventually have an equivalent infection rate (Kunin et al, 1987; Tambyah and Maki, 2000; Biering-Sorensen, 2002). However, the onset of bacteriuria may be delayed using a suprapubic catheter compared with a urethral catheter. During a 2-year period, 170 patients with spinal cord injury were evaluated regarding type of urinary drainage and infection (Warren et al, 1982). In patients using indwelling urethral catheters, all urine cultures were positive. The corresponding values for the suprapubic catheter group were 44%. Condom drainage systems are also associated with an incidence of bacteriuria from 63% (Dukes, 1928) to almost 100% (Pyrah et al, 1955).

Since its introduction by Lapides and colleagues (1972), clean (but not sterile) intermittent catheterization (CIC) has earned general recognition in the management of spinal cord injury patients (National Institute on Disability and Rehabilitation Research, 1993). **Although never rigorously compared with indwelling urethral catheterization, CIC has been shown**

to decrease lower tract complications by maintaining low intravesical pressure and reducing the incidence of stones (Stover et al, 1989). CIC also appears to reduce complications associated with an indwelling catheter, such as UTI, fever, bacteremia, and local infections such as epididymitis and prostatitis. Weld and Dmochowski (2000) followed 316 patients with spinal cord injury with different bladder management for a mean of 18.3 years and recorded all complications. The CIC group had statistically significantly lower complication rates compared with the urethral catheterization group and no significantly higher complication rates relative to all other management methods for each type of complication studied. Thus it is generally agreed that CIC places patients with spinal cord injury at the lowest risk for significant long-term urinary tract complications (Stamm, 1975).

There is conflicting evidence over the value of sterile versus nonsterile or "no touch" methods of CIC. Some studies have reported a lower incidence of infection in patients treated with sterile techniques (Foley, 1929), whereas others have not (Pyrah et al, 1955; Nyren et al, 1981). Bennett and coworkers (1997) reported on a sterile method of CIC that uses an introducer tip to bypass the distal 1.5 cm of the urethra and showed a significant decrease in UTI with the use of the urethral introducer tip. Different types of catheters have been used for CIC. The low-friction catheters might be less traumatic for the urethra (Casewell and Phillips, 1977; Garibaldi et al, 1980), but their impact on bacteriuria and UTI has to be studied.

Clinical Presentation

The majority of patients with spinal cord injury with bacteriuria are asymptomatic. Because of a loss of sensation, patients usually do not experience frequency, urgency, or dysuria. More often they complain of flank, back, or abdominal discomfort, leakage between catheterizations, increased spasticity, malaise, lethargy, and/or cloudy, malodorous urine. UTI is the most common cause of fever in spinal cord–injured patients (Beraldo et al, 1993).

Bacteriology and Laboratory Diagnosis

Urinalysis will show bacteriuria and pyuria. Pyuria is not diagnostic of infections, because it may occur from the irritative effects of the catheter. The National Institute on Disability and Rehabilitation Research Consensus Statement (1993) recommended the following criteria for the diagnosis of significant bacteriuria in spinal cord–injured patients. Any detectable bacteria from indwelling or suprapubic catheter aspirates was considered significant because the vast majority of patients with an indwelling catheter and low-level bacteriuria showed an increase to greater than 10^5 cfu/mL within a short period of time (Cardenas and Hooton, 1995). For patients on CIC, greater than or equal to 10^2 cfu/mL was considered significant. For catheter-free males, a clean voided specimen showing greater than or equal to 10^4 cfu/mL was considered significant.

Bacteriuria in patients with spinal cord injury differs from that in patients with intact spinal cords in its etiology, complexity, and antimicrobial susceptibility and is influenced by the type and duration of catheterization. *E. coli* is isolated in approximately 20% of patients. Enterococci, *P. mirabilis*, and *Pseudomonas* are more common among spinal cord–injured patients than patients with intact spinal cords. Other common organisms are *Klebsiella* species, *Serratia* species, *Staphylococcus*, and *Candida* species. Most bacteriuria in short-term catheterization is of a single organism, whereas patients catheterized for longer than a month will usually demonstrate a polymicrobial flora caused by a wide range of gram-negative and gram-positive bacterial species (Edwards et al, 1983). Such specimens commonly have two to four bacterial species, each at concentrations of 10^5 cfu/mL or more (Monson and Kunin, 1974; Nickel et al, 1987). Some may have up to six to eight species at that concentration (Monson and Kunin, 1974). This phenomenon is due to an incidence of new episodes of bacteriuria approximately every 2 weeks and the ability of these strains to persist for weeks and months in the catheterized urinary tract (Edwards et al, 1983; Gabriel et al, 1996). Two of the most persistent species are *E. coli* and *Providencia stuartii*. *P. stuartii* is rarely found outside the long-term catheterized urinary tract and may use the catheter itself as a niche (Lindberg et al, 1975; Hockstra, 1999).

Management

Because of the diverse flora and high probability of bacterial resistance, a urine culture must be obtained before initiating empirical therapy. For afebrile patients, an oral fluoroquinolone is the agent of choice (Cardenas and Hooton, 1995). β-Lactams, TMP-SMX, and nitrofurantoin are not recommended because of the high prevalence of bacterial resistance to these drugs. An indwelling catheter should be changed to ensure maximal drainage and eliminate bacterial foci in catheter encrustations. **Spinal cord–injured patients with fever or chills are usually admitted and treated with a parenteral aminoglycoside and a penicillin or a third-generation cephalosporin** (Cardenas and Hooton, 1995). In this patient population, consultation with a physician with expertise in antimicrobial management may be necessary, especially in a patient with recurrent infections.

If clinical improvement does not occur within 24 to 48 hours, reculture and adjustment of antimicrobial therapy based on the initial culture and susceptibility should be performed. Imaging studies should be obtained to rule out obstruction, stones, and abscess. The duration of therapy is not established, but 4 to 5 days is recommended for the mildly symptomatic patient and 10 to 14 days for sicker patients (Cardenas and Hooton, 1995). Post-therapy cultures are usually not necessary because asymptomatic recolonization is common and not clinically significant. However, if a urea-splitting bacterium is identified, a follow-up culture should be obtained to ensure its eradication. Spinal cord–injured patients with recurrent symptomatic UTIs should undergo urinary tract imaging and urodynamic testing and a review of their bladder management program with particular attention to catheter drainage, intermittent catheterization techniques, and frequency of intermittent catheterization or voiding schedule (Cardenas and Hooton, 1995).

Antimicrobial prophylaxis is not supported for most patients who have neurogenic bladder caused by spinal cord injury (Morton et al, 2002). Antimicrobial prophylaxis did not significantly decrease symptomatic UTIs and resulted in an approximately twofold increase in antimicrobial-resistant bacteria.

Recurrent UTIs may be associated with high storage pressures, and intervention to decrease storage pressure may decrease the incidence of symptomatic UTI. Evidence from studies in spinal cord–injured patients suggests that bladder catheterization for longer than 10 years is associated with an increased risk of carcinoma of the bladder. West and colleagues (1999) examined two databases with more than 33,000 spinal

cord–injured patients and identified 130 patients with bladder cancer (0.4%) during a 5-year period. Several risk factors for bladder cancer have been proposed. Vereczky and associates (cited in Weyrauch and Bassett, 1951) tested different risk factors based on the outcome of 153 spinal cord-injured patients in which 7 were diagnosed with bladder cancer. Of a total of 31 possible predictors, only duration of catheterization was significant. **Chronic infection and inflammation of the bladder mucosa could be the carcinogenic stimulus in these patients** (Pyrah et al, 1955). **Nitrosamines produced in infected urine have also been implicated** (Najenson et al, 1969).

For further discussion of spinal cord injury and urinary infection, see Chapter 65.

Key Points: Management of UTI in Patients with Spinal Cord Injury

- UTI in patients with spinal cord injury commonly presents as fever; flank, back, or abdominal discomfort; leakage between catheterizations; increased spasticity; malaise; lethargy; and/or cloudy, malodorous urine.
- The majority of spinal cord–injured patients with bacteriuria are asymptomatic.
- Only symptomatic patients require therapy.
- Urine culture before the initiation of empirical therapy is essential because spinal cord–injured patients often culture diverse flora with a high probability of bacterial resistance.
- Clean intermittent catheterization places patients with spinal cord injury at the lowest risk for significant long-term urinary tract complications.
- Chronic infection can be carcinogenic.

OTHER INFECTIONS

Fournier Gangrene

Fournier gangrene is a potentially life-threatening form of necrotizing fasciitis involving the male genitalia. It is also known as idiopathic gangrene of the scrotum, streptococcal scrotal gangrene, perineal phlegmon, and spontaneous fulminant gangrene of the scrotum (Fournier, 1883, 1884). As originally reported by Baurienne in 1764, and by Fournier in 1883, it was characterized by an abrupt onset of a rapidly fulminating genital gangrene of idiopathic origin in previously healthy young patients that resulted in gangrenous destruction of the genitalia. The disease now differs from these descriptions in that it involves a broader age range, including older patients (Bejanga, 1979; Wolach et al, 1989), follows a more indolent course, and has a less abrupt onset; and, in approximately 95% of the cases, a source can now be identified (Macrea, 1945; Burpee and Edwards, 1972; Kearney and Carling, 1983; Jamieson et al, 1984; Spirnak et al, 1984).

Infection most commonly arises from the skin, urethra, or rectal regions. An association between urethral obstruction associated with strictures and extravasation and instrumentation has been well documented. **Predisposing factors include diabetes mellitus, local trauma, paraphimosis, periurethral extravasation or urine, perirectal or perianal infections, and surgery such as circumcision or herniorrhaphy. In cases originating in the genitalia the infecting bacteria probably pass through the Buck fascia of the penis and spread along the dartos fascia of the scrotum and penis, the Colles fascia of the perineum, and the Scarpa fascia of the anterior abdominal wall.** In view of the typical foul odor associated with this condition, a major role for anaerobic bacteria is likely. **Wound cultures generally yield multiple organisms, implicating anaerobic-aerobic synergy** (Meleney, 1933; Miller, 1983; Cohen, 1986). Mixed cultures containing facultative organisms (*E. coli*, *Klebsiella,* enterococci) along with anaerobes (*Bacteroides, Fusobacterium, Clostridium,* microaerophilic streptococci) have been obtained from the lesions.

Clinical Presentation

Patients frequently have a history of recent perineal trauma, instrumentation, urethral stricture associated with sexually transmitted disease, or urethral cutaneous fistula. Pain, rectal bleeding, and a history of anal fissures suggest a rectal source of infection. Dermal sources are suggested by history of acute and chronic infections of the scrotum and spreading recurrent hidradenitis suppurativa or balanitis.

The infection commonly starts as cellulitis adjacent to the portal of entry. Early on, the involved area is swollen, erythematous, and tender as the infection begins to involve the deep fascia. Pain is prominent, and fever and systemic toxicity are marked (Paty and Smith, 1992). The swelling and crepitus of the scrotum quickly increase, and dark purple areas develop and progress to extensive gangrene. If the abdominal wall becomes involved in an obese patient with diabetes, the process can spread very rapidly. Specific genitourinary symptoms associated with the condition include dysuria, urethral discharge, and obstructed voiding. Alterations in mental status, tachypnea, tachycardia, and temperature greater than 38.3° C (101° F) or less than 35.6° C (96° F) suggest gram-negative sepsis.

Laboratory Diagnosis and Radiologic Findings

Anemia occurs secondary to a decreased functioning erythrocyte mass caused by thrombosis and ecchymosis coupled with decreased production secondary to sepsis (Miller, 1983). Elevated serum creatinine levels, hyponatremia, and hypocalcemia are common. Hypocalcemia is believed to be secondary to bacterial lipases that destroy triglycerides and release free fatty acids that chelate calcium in its ionized form.

Because crepitus is often an early finding, a plain film of the abdomen may be helpful in identifying air. Scrotal ultrasonography is also useful in this regard. Biopsy of the base of an ulcer is characterized by superficially intact epidermis, dermal necrosis, and vascular thrombosis and polymorphonuclear leukocyte invasion with subcutaneous tissue necrosis. Stamenkovic and Lew (1984) noted that the use of frozen sections within 21 hours after the onset of symptoms could confirm a diagnosis earlier and lead to early institution of appropriate treatment.

Management

Prompt diagnosis is critical because of the rapidity with which the process can progress. The clinical differentiation of necrotizing fasciitis from cellulitis may be difficult because the initial signs including pain, edema, and erythema are not distinctive. However, the presence of marked systemic toxicity out of proportion to the local finding should alert the clinician. Intravenous hydration and antimicrobial therapy are indicated in preparation for surgical debridement. Antimicrobial regimens include combinations of ampicillin plus sulbactam or a parenteral third-generation cephalosporin such as ceftriaxone, gentamicin, and clindamycin. If there is no response to clindamycin, chloramphenicol may be used.

Immediate debridement is essential. In the patient in whom diagnosis is clearly suspected on clinical grounds (deep pain with patchy areas of surface hypoesthesia or crepitation, or bullae and skin necrosis), direct operative intervention is indicated. **Extensive incision should be made through the skin and subcutaneous tissues, going beyond the areas of involvement until normal fascia is found. Necrotic fat and fascia should be excised, and the wound should be left open. A second procedure 24 to 48 hours later is indicated if there is any question about the adequacy of initial debridement.** Orchiectomy is almost never required, because the testes have their own blood supply independent of the compromised fascial and cutaneous circulation to the scrotum. Suprapubic diversion should be performed in cases in which urethral trauma or extravasation is suspected. Colostomy should be performed if there is colonic or rectal perforation. Hyperbaric oxygen therapy has shown some promise in shortening hospital stays, increasing wound healing, and decreasing the gangrenous spread when used in conjunction with debridement and antimicrobial agents (Paty and Smith, 1992). Once wound healing is complete, reconstruction, for example, using myocutaneous flaps, improves cosmetic results.

Outcome

The mortality rate averages approximately 20% (Cohen, 1986; Baskin et al, 1990; Clayton et al, 1990) but ranges from 7% to 75%. Higher mortality rates are found in diabetics, alcoholics, and those with colorectal sources of infection who often have a less typical presentation, greater delay in diagnosis, and more widespread extension. Regardless of the presentation, **Fournier gangrene is a true urologic emergency that demands early recognition, aggressive treatment with antimicrobial agents, and surgical debridement to reduce morbidity and mortality.**

Periurethral Abscess

Periurethral abscess is a life-threatening infection of the male urethra and periurethral tissues. Initially, the area of involvement can be small and localized by Buck fascia. However, when Buck fascia is penetrated there can be extensive necrosis of the subcutaneous tissue and fascia. Fasciitis can spread as far as the buttocks posteriorly and the clavicle superiorly. Rapid diagnosis and treatment are essential to reduce the morbidity and high mortality historically associated with this disease.

Pathogenesis

Periurethral abscess is frequently a sequela of gonorrhea, urethral stricture disease, or urethral catheterization. Frequent instrumentation is also associated with periurethral abscess formation. The source of the infecting organism is the urine. Gram-negative rods, enterococci, and anaerobes are most frequently identified. The presence of multiple organisms is common. Anaerobes, normal residents of the male urethra, are also frequently found in wound cultures.

Clinical Presentation

Presenting signs and symptoms include scrotal swelling in 94% of patients, fever (70%), acute urinary retention (19%), spontaneously drained abscess (11%), and dysuria or urethral discharge (5% to 8%). The average interval between initial symptoms and presentation is 21 days. Urinalysis of the first glass specimen reveals pyuria and bacteriuria.

Management

Treatment consists of immediate suprapubic urinary drainage and wide debridement. Antimicrobial therapy with an aminoglycoside and a cephalosporin is usually adequate for empirical coverage. More selective antimicrobial therapy can be instituted when the antimicrobial susceptibility of the organisms is available. Perineal urethrostomy or chronic suprapubic diversion occasionally has been helpful to prevent recurrences, and it should be considered in patients with diffuse stricture disease. The presence of a malignancy is unusual, but biopsy is important.

Key Points: Other Infections

- Fournier gangrene is necrotizing fasciitis arising from the perineal skin, scrotum, urethra, or rectum.
- Emergent surgical debridement and broad-spectrum antimicrobial agents are the essentials of treatment of Fournier gangrene.
- Periurethral abscess can occur secondarily to urethral stricture or catheterization; treatment entails surgical debridement, suprapubic urinary drainage, and antimicrobial agents.

Prostatitis and Related Conditions, Orchitis, and Epididymitis

J. Curtis Nickel, MD, FRCSC

Prostatitis and Related Conditions

Orchitis

Epididymitis

PROSTATITIS AND RELATED CONDITIONS

Historical Aspects

Modern descriptions of the clinical presentation, pathology, and microscopic evaluation of prostate-specific specimens of prostatitis patients were firmly established by Young, Gereghty, and Stevens (1906) by the turn of the 20th century. Bacterial and cytologic localization studies of the lower urinary tract were described shortly thereafter (Hitchens and Brown, 1913) and standardized by 1930 (Von Lackum, 1927, 1928; Nickel, 1930, 1999a). **The primary form of therapy for prostatitis during most of the 20th century was repetitive prostate massage** (Farman, 1930; O'Conor, 1936; Henline, 1943; Campbell, 1957). With the introduction of sulfanilamide in the 1930s, antimicrobial therapy became the main therapeutic approach (Ritter and Lippow, 1938). However, even in the 1950s and 1960s, the significance of inflammatory cells and bacteria in the expressed prostatic secretion (EPS) was questioned (O'Shaughnessy et al, 1956; Bowers and Thomas, 1958; Bourne and Frishette, 1967), and it was even recognized that, in many cases, antibiotics were performing little better than placebo in the treatment of prostatitis (Gonder, 1963).

The next era of prostatitis management began in the 1960s with Meares and Stamey's (1968) description of the four-glass lower urinary tract segmented localization study. Prostatic massage as the mainstay of prostatitis therapy was abandoned, and antimicrobial therapy was rationalized for the very small percentage of patients with bacteria localized to prostate-specific specimens. Unfortunately the vast majority of patients who were diagnosed with a nonbacterial cause continued to suffer the indignities of dismal urologic management (Nickel, 1998a). The establishment of new definitions and a classification system, better understanding of the etiopathogenesis, completion of randomized placebo-controlled trials with validated outcome indices, and the evolving insight that patients with prostatitis have variable clinical phenotypes has radically changed the way this condition is managed.

Epidemiology

Prostatitis is the most common urologic diagnosis in men younger than age 50 years and the third most common urologic diagnosis in men older than age 50 years after benign prostatic hyperplasia (BPH) and prostate cancer (McNaughton Collins et al, 1998). There were almost 2 million U.S. physician visits annually from 1990 to 1994 with prostatitis listed as the diagnosis (McNaughton Collins et al, 1998), Approximately 5% of visits to U.S. urologists were reported to be for inflammatory diseases of the prostate (Schappert, 1994). In the mid 1990s urologists in Wisconsin in the United States saw an average of 173 patients with prostatitis per year (Moon, 1997) whereas Canadian urologists reported an average of 264 patients with prostatitis per year, with 38% of whom newly diagnosed (Nickel et al, 1998a). Based on both a physician survey study in Dane County, Wisconsin (Moon, 1997), and a survey of younger men from a Wisconsin National Guard unit (Moon et al, 1997), it was estimated that 5% of men (aged 20 to 50 years) have a history of prostatitis. In the Netherlands, de la Rosette and colleagues (1992a) noted that 4% of respondents reported a history of prostatitis, whereas researchers in Finland reported a 14% overall lifetime prevalence in that country (Mehik et al, 2000). McNaughton Collins and colleagues (2002) noted that 16% of health care professionals in the United States report either a previous or current diagnosis of prostatitis. Roberts and associates (1998) reviewed the medical records of 2113 men from July 1992 through February 1996 (a median of 50 months' follow-up) in the Olmsted County community-based cohort in Minnesota and found the overall prevalence of a physician's diagnosis of prostatitis was 9%.

Many of these epidemiologic studies are limited by physicians' or patients' long-term recollection and the unreliability of a physician's coding or diagnosis of prostatitis. **Population-based studies employing the validated National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI)** (Litwin et al, 1999) **to determine the prevalence of prostatitis-like symptoms in the general population of men showed widely variant results** (**12.2% in Nigeria** [Ejike and Ezeanyika, 2008], **8.0% in Malaysia** [Cheah et al,

2003], **6.6% in Canada** [Nickel et al, 2001b], **2.7% in Singapore** [Tan et al, 2002], **and approximately 2.2% in older men in Olmsted County** [Roberts et al, 2002]). Employing NIH-CPSI definitions of prostatitis-like symptoms in a managed care population, Clemens and colleagues (2006) estimated that between 5.9% and 11.2% have prostatitis-like symptoms depending on the specific definition. Whereas retrospective billing data studies have indicated that up to 8% of U.S. male patients seen in urologic outpatient practice have a diagnosis of prostatitis (McNaughton Collins et al, 1998), prospective practice audit studies have shown that as many as 12% of men presenting to Italian urologists are diagnosed with prostatitis (Rizzo et al, 2003), whereas only 2.8% of men had a clinical diagnosis of prostatitis in a similar study carried out in Canada (Nickel et al, 2005c). Symptoms of prostatitis wax and wane, with approximately one third to one half of patients experiencing relief of symptoms over a 1-year period (Nickel et al, 2002b; Turner et al, 2004b, Propert et al, 2006b).

It has traditionally been believed that prostatitis is a disease of younger men (e.g., aged 35 to 50 years). Epidemiologic studies described in this section confirm that prostatitis affects men of all ages, unlike BPH and prostate cancer, which are predominantly diseases of older men. Compared with men aged 66 years and older, a diagnosis of prostatitis is 1.6-, 2.6-, and 2.1-fold greater in men aged 18 to 35, 36 to 50, and 51 to 65 years, respectively, in the Olmsted County study (Roberts et al, 1998). The age-specific prevalence of a physician-assigned diagnosis of prostatitis was highest in patients between the ages of 20 and 49 years and increased again in those older than 70 years. The cumulative probability of having a diagnosis of prostatitis (acute or chronic) by 85 years of age was 26%. In the Canadian prevalence study (Nickel et al, 2001b) there was no significant difference in the prevalence of prostatitis-like symptoms in men younger than 50 years (11.5% reported at least mild symptoms over the previous week) compared with men older than 50 years (8.5% reported at least mild symptoms over the previous week). As many as 20% of men diagnosed with BPH also report prostatitis-like symptoms (Nickel 2005a). Interestingly, although prostatitis symptoms appear to be as prevalent in older versus younger males they are reported to be less distressing with age (Hedelin and Jonsson, 2007).

Chronic prostatitis is associated with substantial costs and significant predicted resource consumption (Calhoun et al, 2004; Turner et al, 2004a; Duloy et al, 2007). Overall spending in the United States for the diagnosis and management of prostatitis, exclusive of pharmaceutical spending, totaled 84 million dollars in 2000 and appears to be increasing (Pontari et al, 2007). This economic factor needs increased attention when evaluating the incidence and treatment of this prevalent condition.

Histopathology

For the pathologist, prostatitis is defined as an increased number of inflammatory cells within the prostatic parenchyma (Cotran et al, 1999). **Prostatic inflammation may or may not be noted in patients with a diagnosis of prostatitis** (True et al, 1999), **BPH** (Nickel et al, 1999c), **or prostate cancer** (Zhang et al, 2000) **and is noted in autopsy series in as many as 44% of prostate tissue samples from men without any definitive prostate disease** (McNeal, 1968).

A consistent description of fairly distinct, although often coexisting, patterns of chronic inflammation can be found in the prostate gland of patients with or without prostate disease. **The most common pattern of inflammation is a lymphocytic infiltrate in the stroma immediately adjacent to the prostatic acini** (Kohnen and Drach, 1979; Nickel et al, 1999b). The intensity of the inflammatory process varies considerably from only scattered lymphocytes to dense lymphoid nodules. Stromal lymphocytic infiltrates frequently coexist with periglandular inflammation. Sheets, clusters, and occasional nodules of lymphocytes and scattered plasma cells are seen within the fibromuscular stroma with no apparent relationship to the ducts and acini. Infiltrates of inflammatory cells restricted to the glandular epithelium and lumen are found in association with prostatitis and BPH but can be found in asymptomatic patients. The intraepithelial inflammatory cells may be neutrophils, lymphocytes, or macrophages, or all of these, whereas neutrophils and macrophages are typically found in the lumen. Figure 11–1 illustrates the various inflammatory patterns seen in a prostate specimen of a patient with chronic prostatitis.

Corpora amylacea, which may develop from the deposition of prostatic secretions around a sloughed epithelial cell or other irritant, are not usually associated with inflammation unless they become large enough to distend or obstruct the prostatic gland (Attah, 1975). Prostatic calculi may contribute to prostatic inflammation by obstructing central prostate ducts and thus preventing drainage or providing a nidus in which bacteria can survive host defenses and antibiotics (Meares, 1974; Roberts et al, 1997).

Granulomatous prostatitis presents a nonspecific and variable histologic pattern typified by heavy lobular, mixed, inflammatory infiltrates that include abundant histiocytes, lymphocytes, and plasma cells. Small, discrete granulomas may be present, or the pattern may be typified by well-defined granulomas. Granulomatous prostatic inflammation is a common consequence of

Key Points: Epidemiology

- Two percent to 12% of men older than age 20 years currently experience prostatitis-like symptoms.
- Nine percent to 16% of men have had a diagnosis of prostatitis.
- Prostatitis represents 3% to 12% of male outpatient visits to urologists.

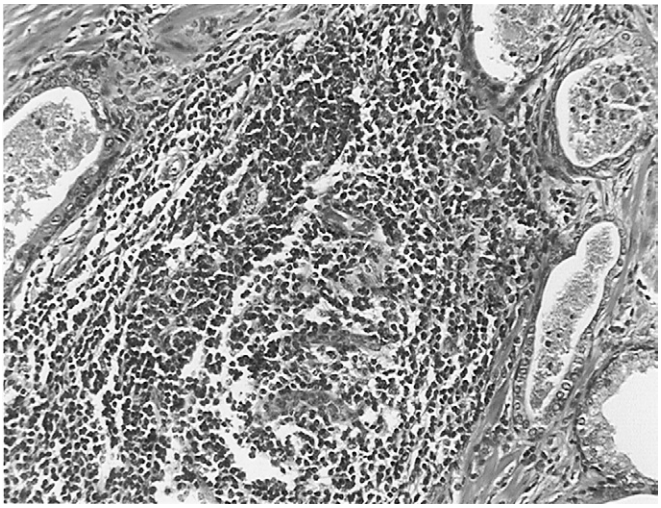

Figure 11–1. Histologic preparation of a prostate specimen demonstrating areas of glandular, periglandular, and stromal inflammation (×400). (Courtesy of Dr. Alexander Boag.)

surgery (Eyre et al, 1986) or therapy with bacillus Calmette-Guérin (BCG) (Lafontaine et al, 1997) and a rare event in patients with systemic tuberculosis (Saw et al, 1993).

A consensus group of urologists and pathologists have developed a classification system to describe histologic inflammatory patterns in the prostate (Nickel et al, 2001d), but it is only useful for comparative research purposes.

Etiology

Microbiologic

Gram-Negative Uropathogens. **Acute bacterial prostatitis is a generalized infection of the prostate gland and is associated with both lower urinary tract infection (UTI) and generalized sepsis. Chronic bacterial prostatitis is associated with recurrent lower UTIs (i.e., cystitis) secondary to areas of focal uropathogenic bacteria residing in the prostate gland. The most common cause of bacterial prostatitis is the Enterobacteriaceae family of gram-negative bacteria, which originate in the gastrointestinal flora.** The most common organisms are strains of *Escherichia coli,* which are identified in 65% to 80% of infections (Stamey, 1980; Lopez-Plaza and Bostwick, 1990; Weidner et al, 1991b; Schneider et al, 2003). *Pseudomonas aeruginosa, Serratia* species, *Klebsiella* species, and *Enterobacter aerogenes* are identified in a further 10% to 15% (Meares, 1987; Weidner et al, 1991b). **However, in acute bacterial prostatitis, the organisms that result from previous manipulation of the lower urinary tract show different patterns of virulence and resistance (e.g., to ciprofloxacin and cephalosporins) compared with the organisms associated with spontaneous acute prostatitis** (Millan-Rodriquez et al, 2006; Ha et al, 2008).

Urovirulence factors play a significant role in the pathogenesis of bacterial prostatitis (Ruiz et al, 2002; Johnson et al, 2005). For instance, bacterial P-fimbria (or pili) bind to the urothelial receptors, and this subsequently facilitates ascent into the urinary tract as well as establishing deep infections in the prostate gland itself (Dilworth et al, 1990; Neal et al, 1990; Andreu et al, 1997). Colonization of the lower urinary tract by *E. coli* is also facilitated by the presence of the type 1 fimbria, also known as mannose-sensitive fimbria. The receptor is a common moiety of the uroepithelial uromucoid; this association has been shown to be important in the development of cystitis in humans, and its presence in prostatitis has also been documented (Correll et al, 1996). Phase variation of type 1 pili during the establishment of acute bacterial prostatitis may occur in the setting of prostatitis (Schaeffer, 1991). Multiple virulence factors appear to be necessary to produce prostatitis (Mitsumori et al, 1999; Ruiz et al, 2002). Bacteria reside deep in the ducts of the prostate gland and when threatened, with host defense and antimicrobial therapy, tend to form aggregates (also called biofilms), which appears to be a protective mechanism allowing bacteria to persist in the prostate gland even when the cystitis is treated with antibiotics (Nickel and Costerton, 1993; Nickel et al, 1994). Hemolysin appears to be a virulence factor associated with *E. coli* acute prostatitis, but hemolysin may also be associated with increased ability of certain strains of *E. coli* to persist in the prostate as biofilms in patients with chronic bacterial prostatitis (Soto et al, 2007).

Gram-Positive Bacteria. Enterococci are believed to account for 5% to 10% of documented prostate infections (Drach, 1974a; Meares, 1987; Bergman, 1994). The role of other gram-positive organisms, which are also commensal organisms in the anterior urethra, is controversial (Jimenez-Cruz et al, 1984; Fowler and Mariano, 1984b, Krieger et al, 2002). An etiologic role for gram-positive organisms such as *Staphylococcus saprophyticus,* hemolytic streptococci, *Staphylococcus aureus,* and other coagulase-negative staphylococci has been suggested by a number of authors (Drach, 1974a, 1986; Bergman, 1994). Nickel and Costerton (1992) have shown coagulase-negative *Staphylococcus* to be present in the EPS as well as transperineal prostate biopsy tissue of men with chronic prostatitis (microscopy and culture). Although this and other studies (Carson et al, 1982; Pfau, 1983; Bergman et al, 1989; Wedren, 1989) suggested that coagulase-negative staphylococci are involved in the pathogenesis of chronic prostatitis, these studies did not conclusively demonstrate that these bacteria were actually causing the inflammation and symptom-complex rather than simply colonizing the prostate (Krieger et al, 2002). However, eradication of gram-positive bacteria in the prostate of men experiencing recent onset of prostatitis symptoms resulted in similar clinical results compared with men with gram-negative uropathogens localizing to the prostate (Magri et al, 2007a; Nickel and Xiang, 2008). In both cases, eradication of the bacteria localized to the prostate was strongly correlated with a good clinical outcome. However, the inconsistent localization of gram-positive bacteria in prostate-specific specimens from patients with chronic prostatitis suggests that this relationship may not be as strong as suggested (e.g., Krieger et al, 2005).

Anaerobic Bacteria. In studies in which the prostate-specific specimens were cultured anaerobically, anaerobic bacteria could be identified in a small number of patients (Nielsen and Justesen, 1974; Mardh and Colleen, 1975; Szoke et al, 1998). This has not been a consistent finding, and the role of anaerobic bacteria is essentially unknown.

***Corynebacterium* Infection.** *Corynebacterium* species have usually been acknowledged as prostate nonpathogens but have been suggested as potential etiologic agents in this disease (Riegel et al, 1995; Domingue, 1998). Domingue and colleagues (1997) suggested that these difficult-to-culture coryneforms could be missed by routine culturing of EPS. Direct Gram staining of the EPS showed gram-variable pleomorphic coccobacillary rods that do not usually grow on routine media. The presence of these pleomorphic swollen rods was also shown by fluorescent acridine orange staining. Tanner and associates (1999), using polymerase chain reaction (PCR) techniques, were able to identify a bacterial signal (phylogenetically gram-positive organisms with predominance of *Corynebacterium* species) in 65% of 17 patients with chronic prostatitis. Approximately half of these patients tended to respond to antimicrobial therapy, whereas patients in whom molecular signals for these bacteria could not be identified did not.

Chlamydial Infection. **The evidence supporting the role of *Chlamydia trachomatis* as an etiologic agent in chronic prostatic inflammation is both confusing and conflicting.** Mardh and Colleen (1972) found that one third of men with chronic prostatitis had antibodies to *C. trachomatis* compared with 3% of controls. Shortliffe and coworkers (1992) found that 20% of patients with nonbacterial prostatitis had antichlamydial antibody titers in the prostatic fluid. Koroku and associates (1995) detected *C. trachomatis*–specific immunoglobulin A (IgA) in 29% of men with chronic nonbacterial prostatitis. Bruce and colleagues (1981) found that 56% of patients with "subacute or chronic prostatitis" were infected with *C. trachomatis* (after examining early morning urine, prostatic fluid, or semen specimens). In a follow-up study, Bruce and Reid (1989) found that 6 of 55 men with abacterial prostatitis, including 31 believed to have chlamydial prostatitis, met strict criteria for positive diagnosis for

chlamydial prostatitis based on identification of the organisms by culturing or immunofluorescence. Kuroda and colleagues (1989) identified *C. trachomatis* in the urethras of 20% of men with prostatitis. Other investigators have come to similar conclusions (Nilsson et al, 1981; Weidner et al, 1983). *Chlamydia* has also been isolated in prostate tissue specimens. Poletti and coworkers (1985) isolated *C. trachomatis* from prostate samples obtained by transrectal aspiration biopsy of men with "nonacute abacterial prostatitis." Abdelatif and colleagues (1991) identified intracellular *Chlamydia* employing "in-situ hybridization techniques" in transurethral prostate chips from 30% of men with histologic evidence of "chronic abacterial prostatitis." Shurbaji and associates (1998) identified *C. trachomatis* in paraffin-embedded secretions in 31% of men with histologic evidence of prostatitis compared with none in patients with BPH without inflammation.

Although Mardh and Colleen (1972) suggested that *C. trachomatis* may be implicated in as many as one third of men with chronic prostatitis, their follow-up studies employing culturing and serologic tests could not confirm *C. trachomatis* as an etiologic agent in idiopathic prostatitis (Mardh and Colleen, 1975; Mardh et al, 1978). Shortliffe and Wehner (1986) came to a similar conclusion when her group evaluated antichlamydial antibody titers in prostatic fluid. Twelve percent of controls (compared with 20% of patients with nonbacterial prostatitis) had detectable antibodies. Berger and coworkers (1989) could not culture *C. trachomatis* from the urethras in men with chronic prostatitis nor did they find a serologic or local immune response to *C. trachomatis* in such patients. Doble and associates (1989b) were not able to culture or detect by immunofluorescence *Chlamydia* in transperineal biopsy specimens of abnormal areas of the prostate in men with chronic abacterial prostatitis. Krieger and colleagues (1996b) were only able to find *Chlamydia* in 1% of prostate tissue biopsy specimens in men with chronic prostatitis. A further localization and culture series by Krieger and associates (2000) also failed to culture *Chlamydia* from either urethral or prostate specimens. Further elucidation of the role of chlamydial etiology of prostate infection is required to make any definitive statement on the association between isolation of this organism and its prostatic origin and effect (Weidner et al, 2002).

***Ureaplasma* Infection.** *Ureaplasma urealyticum* is a common organism isolated from the urethra of both asymptomatic men and men with nonspecific urethritis. Weidner and colleagues (1980) found high *U. urealyticum* concentrations in prostate-specific specimens in patients with signs and symptoms of abacterial prostatitis. Isaacs (1993) cultured *U. urealyticum* from prostate secretion in 8% of patients with chronic nonbacterial prostatitis. Fish and Danziger (1993) found significant *U. urealyticum* concentrations in 13% of patients with prostatitis. Treatment with specific antimicrobial therapy cleared the organisms in all cases. Ohkawa and associates (1993a) isolated *U. urealyticum* cells from the prostates of 18 of 143 patients with chronic prostatitis. Antibiotics eradicated the organism in all, improved the symptoms in 10, and cleared the leukocytes in the EPS in 4 (Ohkawa et al, 1993b).

Other investigators (Mardh and Colleen, 1975), employing similar techniques, were unable to implicate *U. urealyticum* in patients with nonbacterial prostatitis. The problems encountered in all these studies include the absence of controls and the fact that it was difficult to account for possible urethral contamination in collecting specific prostate specimens.

Other Microorganisms. *Candida* (Golz and Mendling, 1991; Indudhara et al, 1992) and other mycotic infections such as aspergillosis and coccidioidomycosis (Schwarz, 1982; Chen and Schijj, 1985; Campbell et al, 1992; Truett and Crum, 2004) have been implicated in prostatic inflammation. However, in most cases it was usually an isolated finding in immunosuppressed patients or those with systemic fungal infection. Viruses (Doble et al, 1991; Benson and Smith, 1992) have also been implicated in prostatic inflammation, but no systematic evaluation of the role of these agents in prostatitis has been undertaken. *Trichomonas* has been described in the prostate glands of patients complaining of prostatitis-like symptoms (Kuberski, 1980; Gardner et al, 1996; Skerk et al, 2002a).

Nonculturable Microorganisms. There are significant limitations to the culture techniques employed to attempt to identify etiologic microorganisms associated with prostatitis (Lowentritt et al, 1995; Domingue et al, 1997; Domingue, 1998). Bacteria may exist in aggregated biofilms adherent to the prostatic ductal walls or within the obstructed ducts in the prostate (Nickel and MacLean, 1998). Nickel and Costerton (1993) observed that 60% of patients with previously diagnosed chronic bacterial prostatitis who progressed to sterile EPS cultures but continued to have symptoms despite antimicrobial therapy had positive cultures in prostate biopsy specimens showing an organism similar to the initial organism. As discussed earlier, such organisms appear to persist in small aggregates or biofilms in the ducts and acini of the prostate gland.

Berger and associates (1997) cultured urine specimens and transperineal prostate biopsy specimens specifically for commensal and fastidious organisms. These investigators demonstrated that, in prostate biopsy cultures, men with evidence of inflammation in EPS are more likely to have bacteria isolated, positive cultures for anaerobic bacteria, higher total bacterial counts, and more bacterial species isolated than men without EPS inflammation. Krieger and colleagues (1996b), Riley and coworkers (1998), and Tanner and associates (1999) used a combination of clinical, culture, and molecular biologic methods (i.e., PCR) and found a strong correlation between inflammation and EPS and the detection of bacteria-specific 16S rRNA (gram-negative and gram-positive organisms) in the prostate tissue. But other researchers did not show any association between culture and PCR findings in men with nonbacterial prostatitis compared with men with prostatitis symptoms (Keay et al, 1999; Lee et al, 2003; Leskinen et al, 2003b). Nanobacteria are intriguing organisms that are difficult to isolate and culture but may be implicated in some chronic urologic conditions, including chronic prostatitis (Wood and Shoskes, 2006). A number of investigators (Shoskes et al, 2005; Short et al, 2008) have demonstrated the possibility that nanobacteria associated with and without prostatic calculi may be implicated in some cases of chronic prostatitis.

It has been estimated that less than 10% of all environmental bacteria have been identified (Domingue, 1998), so it is possible that fastidious and nonculturable microorganisms might be present in the prostate gland and that such organisms might be involved in the inflammatory process and subsequent development of symptoms.

Altered Prostatic Host Defense

Risk factors that allow bacterial colonization or infection of the prostate with potentially pathogenic bacteria include intraprostatic ductal reflux (Kirby et al, 1982); **phimosis** (VanHowe, 1998); **specific blood groups** (Lomberg et al, 1986); **unprotected penetrative anal rectal intercourse; UTI; acute epididymitis** (Berger et al, 1987); **indwelling urethral catheters and condom catheter drainage** (Meares, 1998); **and transurethral surgery, especially in men who**

have untreated, infected urine (Meares, 1989). Secretory dysfunction of the prostate characterized by an alteration in the composition of prostatic secretions can be diagnostic of patients with prostatitis: there is a decrease in the levels of fructose; citric acid; acid phosphatase; the cations zinc, magnesium, and calcium; and the zinc-containing prostatic antibacterial factor; but pH, the ratio of isoenzymes lactate dehydrogenase-5 to lactate dehydrogenase-1, levels of inflammatory proteins such as ceruloplasmin, and complement C3 are increased (Meares, 1989). These defined alterations in the prostate secretory function have also been blamed for adversely affecting the normal antibacterial nature of prostatic secretions. A decrease in prostatic antibacterial factor may reduce the intrinsic antibacterial activity of the prostatic fluid (Fair et al, 1976), whereas the alkaline pH may hamper diffusion of certain basic antimicrobial drugs into the prostatic tissue and fluid (Fair and Cordonnier, 1978). However, caution is warranted because it is not known whether these compositional changes are a cause or a consequence of inflammation.

Dysfunctional Voiding

Anatomic or neurophysiologic obstruction resulting in high-pressure dysfunctional flow patterns has been implicated in the pathogenesis of the prostatitis syndrome. Blacklock (1974, 1991) demonstrated that bladder neck, prostatic, and urethral anatomic abnormalities predisposed some men to developing prostatitis. Urodynamic studies confirm that many patients, particularly those with prostatodynia, have decreased maximal urinary flow rates and obstructive-appearing flow patterns (Barbalias et al, 1983; Ghobish, 2002). On videourodynamic studies, many patients with prostatitis syndromes show incomplete funneling of the bladder neck as well as vesicourethral dyssynergic patterns (Kaplan et al, 1994, 1997; Hruz et al, 2003). Investigators (Dellabella et al, 2006) have described ultrasound alterations of the preprostatic sphincter in men with chronic prostatitis. In a study of 48 treatment refractory chronic prostatitis patients with no associated infection, Hruz and associates (2003) determined that 29 (60%) had bladder neck hypertrophy diagnosed by endoscopic and urodynamic criteria. This dyssynergic voiding may lead to an autonomic overstimulation of the perineal-pelvic neural system with subsequent development of a chronic neuropathic pain state. Alternatively, this high-pressure, dysfunctional voiding may result in intraprostatic ductal reflux in susceptible individuals (see the next section).

Intraprostatic Ductal Reflux

Reflux of urine and possibly bacteria into the prostatic ducts has been postulated as one of the most important etiologic mechanisms involved in the pathogenesis of chronic bacterial and nonbacterial prostatic inflammation. Anatomically, the ductal drainage of the peripheral zone is more susceptible than other prostatic zones to intraprostatic ductal reflux (Blacklock, 1974, 1991). Kirby and associates (1982) instilled a carbon particle solution into the bladders of men diagnosed with nonbacterial prostatitis. Carbon particles were found in the EPS macrophages and prostatic acini and ductal system after surgery in men with nonbacterial prostatitis. Persson and Ronquist (1996) noted high levels of urate and creatinine in EPS, which they postulated was caused by urine reflux into the prostatic ducts. Terai and coworkers (2000) provided molecular epidemiologic evidence for ascending infection in acute bacterial prostatitis.

Prostatic calculi are composed of substances found only in urine, not in prostatic secretions (Sutor and Wooley, 1974; Ramiraz et al, 1980), **further evidence that urinary intraprostatic reflux occurs and likely contributes to the formation of prostatic calculi. If pathogenic bacteria reflux into the prostate gland, they may exist in protected aggregates within prostatic calculi themselves.** High culture counts of pathogens encrusted in prostatic calculi have been demonstrated by Eykyn and colleagues (1974). This type of bacterial colonization in protective bacterial aggregates or biofilms associated with prostatic calculi may lead to recalcitrant chronic prostatitis and subsequent recurrent UTIs despite what seems to be adequate antibiotic therapy. Ludwig and coworkers (1994), employing transrectal ultrasonography, showed that men with chronic inflammatory prostatitis had a significantly increased frequency of prostatic calculi compared with men without prostate inflammation (prostatodynia). It appears that prostatic calcification is common in patients with nonbacterial chronic prostatitis and is associated with greater inflammation, bacterial colonization, pelvic floor spasm, and symptom duration (Shoskes et al, 2007). The inflammation resulting from chemical, bacterial, or immunologic stimulation has been shown to possibly cause an increase in intraprostatic pressures, measurable with transperineally inserted pressure transducers (Mehik et al, 2002).

Immunologic Alterations

The local prostatic immune system is activated by infection in bacterial prostatitis. In acute bacterial prostatitis, serum and prostatic fluid antigen-specific (i.e., bacterial antigen) IgG and IgA can be detected immediately after the onset of infection, and after successful antibiotic therapy they decline to normal levels over the next 6 to 12 months (Fowler and Mariano, 1984a; Meares, 1977, 1998; Kumon, 1992). **Prostate-specific antigen (PSA) levels can be markedly elevated during an acute episode of bacterial prostatitis** (Dalton, 1989; Moon et al, 1992; Neal et al, 1992) **and slowly resolve to normal levels over the course of 6 weeks, provided there is no recrudescence of the infection.** In chronic bacterial prostatitis, no serum immunoglobulin elevation is detected, whereas prostatic fluid IgA and IgG levels are both increased (Shortliffe and Wehner, 1986; Kumon, 1992). After successful antibiotic therapy, IgG levels return to normal after several months but the IgA (particularly secretory IgA) levels remain elevated for almost 2 years (Shortliffe et al, 1981a, 1981b; Fowler and Mariano, 1984a). Antibody-coated bacteria detected in urine, EPS, and semen is another prominent feature of chronic bacterial prostatitis (Riedasch et al, 1984, 1991).

Noninfectious inflammation (nonbacterial prostatitis) might also be secondary to immunologically mediated inflammation due to some unknown antigen or perhaps even related to an autoimmune process. IgA and IgM antibody levels (not microorganism-specific) are elevated (Shortliffe and Wehner, 1986; Shortliffe et al, 1989, 1992), and similar antibodies as well as fibrinogen and complement C3 (Vinje et al, 1983; Doble et al, 1990) have been identified in prostatic biopsy specimens from patients with chronic prostatitis. Both animal model studies (Donadio et al, 1998; Ceri et al, 1999; Lang et al, 2000) and human studies (Alexander et al, 1997; Batstone et al, 2002; Maake et al, 2003; Motrich et al, 2007) have suggested that prostatitis may be an autoimmune process. A number of candidates have been suggested for the self-antigen, including PSA (Ponniah et al, 2000). Other specific immunologic and neuroendocrine alterations such as cytokine production (Alexander et al, 1998; Jang et al, 2003) and nerve growth factor (Miller et al, 2002) have a subsequent role to play in the process of inflammation. Specifically, interleukin-10 has been implicated in the etiology and

clinical manifestations in chronic prostatitis (Miller et al, 2002; Shoskes et al, 2002) but other cytokines such as interleukin (IL)-1β and tumor necrosis factor-α have also been implicated (Nadler et al, 2000). IL-8 is the most common cytokine localized to the semen in men with chronic prostatitis (Khadra et al, 2006; Penna et al, 2007). There may be a genetic phenotype that promotes specific immunologic parameters that predispose to immunologically induced prostatic inflammation (Riley et al, 2002; Shoskes et al, 2002). These immunophenotypic patterns have even been observed in noninflammatory category IIIB chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (Barghorn et al, 2001). Whatever the initiating event, the immunologic cascade appears to have an important role in the development of prostatitis in those patients who develop prostatic inflammation (Moon, 1998; Kumon, 1999).

Chemically Induced Inflammation

Investigators have demonstrated that urine and its metabolites (e.g., urate) are present in the prostatic secretion of patients with chronic prostatitis (Persson and Ronquist, 1996). These investigators have hypothesized that the prostatic inflammation and subsequent symptoms may be simply due to a chemically induced inflammation secondary to the noxious substances in the urine that have refluxed into the prostatic duct.

Pelvic Floor Muscle Abnormalities

Some investigators (Zermann et al, 1999) **propose that the sensory or motor disturbances or both consistent with neural dysregulation of the lower urinary tract may be a consequence of acquired abnormalities in the central nervous system.** Certainly, extraprostatic tenderness is identified in many patients with chronic prostatitis (Berger et al, 2007; Shoskes et al, 2008). Zermann and Schmidt (1999) describe 103 patients with chronic pelvic pain whom they evaluated at a specialized neurourologic unit. They showed that a majority of the men had insufficient conscious control of their somatically innervated striated pelvic floor muscles. The patients showed various levels of identity with their pelvic floor muscles, but none was able to demonstrate the full range of pelvic floor contraction and relaxation repetitively and effortlessly. This was true whether or not there was evidence of inflammation. They conclude that their findings reflect a functional disassociation between the central nervous system and the peripheral target, the pelvic floor muscles.

Other clinicians (Anderson, 1999; Potts, 2003) believe that the source of the pain is specifically at the pelvic musculature attachment area at the sacrum, coccyx, ischial tuberosity, pubic rami, and endopelvic fascia. These areas are immediately adjacent to the prostate and bladder and can be recognized by the demonstration of a hyperirritable spot or myofascial trigger point that is painful on compression. It is hypothesized that the formation of myofascial trigger points in this area results from mechanical abnormalities in the hip and lower extremities, chronic holding patterns such as those that occur during toilet training, sexual abuse, repetitive minor trauma and constipation, sports that create chronic pelvic stimulation, trauma or unusual sexual activity, recurrent infections, and surgery (Anderson, 1999). More recently, it has been hypothesized that the pain experienced in some men with CPPS may be explained by pudendal nerve entrapment, which causes subsequent neuropathic pain (Antolak et al, 2002). Unfortunately, all these studies examining pelvic floor muscle abnormalities did not compare findings to a control group (a criticism that can apply to many of the studies cited in this etiology section).

Neuroendocrine Mechanisms

The pain associated with the chronic prostatitis syndromes is similar in many respects to neuropathic pain. **Objective autonomic nervous system changes can be observed in men with a chronic prostatitis, suggesting that altered autonomic nervous system responses may be responsible for the pain associated with this chronic pelvic pain syndrome** (Yilmaz et al, 2007). Pain that may have originated in the prostate or pelvic floor muscles, through mechanisms of cross-sensitization, may have spread to adjacent organs and/or structures. We are only recently beginning to understand the complexity of overlapping neuropathways and possible mechanisms underlying pelvic organ crosstalk (Malykhina, 2007).

It has been shown that **men with chronic prostatitis showed evidence of dysfunctional hypothalamic-pituitary-adrenal axis function** reflected in augmented awakening cortisol responses (Anderson et al, 2008). Another study evaluating the adrenocortical hormone abnormalities in men with chronic prostatitis suggested that some men with this condition may even meet the diagnostic criteria for nonclassic congenital hyperplasia (Dimitrakov et al, 2008).

Psychological Factors

Psychological factors have always been considered to play an important role in the development or exacerbation of the chronic prostatitis syndromes. Some researchers who have investigated the psychopathology in these patients concluded that this syndrome should be viewed as a psychosomatic disorder (Mendlewich et al, 1971; Mellan et al, 1973; Keltikangas-Jarvinen et al, 1982). De la Rosette and associates (1993b) compared a group of 50 patients with chronic prostatitis with a group of 50 patients seen for vasectomy and showed that, although there were significant statistical differences between the groups (with patients with chronic prostatitis scoring consistently higher personality disorder scores), these differences in scores were quite small compared with those between patients with prostatitis and psychiatric patients. Berghuis and coworkers (1996) compared 51 prostatitis patients with a group of 34 men without any chronic pain condition and concluded that depression and psychological disturbances are common among prostatitis patients. Egan and Krieger (1994) compared prostatitis patients with those seeking treatment for chronic low back pain. Major depression was more common in prostatitis patients, but back pain caused more somatically focused depression and anxiety. Ku and coworkers (2002) suggested that depression and weak masculine identity may be associated with an early stage of chronic prostatitis. A large case-control study confirmed that depression and panic disorders are significantly more common in men with chronic pelvic pain conditions than in control subjects (Clemens et al, 2008). These more recent studies demonstrate that psychological factors are involved in the disease, but it seems unjustified to label this group of patients as neurotic or as having a psychopathologic condition. However, recent analyses of the large prostatitis cohorts showed that psychological variables, such as depression, maladaptive coping techniques (e.g., pain catastrophizing and pain contingent resting), poor social support, and stress are important in chronic prostatitis outcomes (Tripp et al, 2004, 2005, 2006; Ulrich et al, 2005; Nickel et al, 2008b). Factors such as catastrophizing are particularly important because they have been found to be stronger predictors of patient pain reports than depression (Tripp et al, 2006), indicating that negative cognitive appraisals of pain experience may be a primary target for psychosocial interventions. This

may be especially important given the strong association that pain catastrophizing has shown with elevations in depression, disability, and lower quality of life manifest in patients with chronic prostatitis (Tripp et al, 2005, 2006; Nickel et al, 2008b).

Association with Interstitial Cystitis (Painful Bladder Syndrome)

Interstitial cystitis, now referred to many as painful bladder syndrome or bladder pain syndrome, is an ill-defined CPPS occurring primarily in females, and a number of investigators have hypothesized that chronic nonbacterial prostatitis may have a similar cause (Pontari, 2006; Forrest et al, 2007). Unfortunately the cause of interstitial cystitis remains unknown, but the pathogenic mechanisms are theorized to be very similar to those that cause chronic prostatitis in men (Sant and Nickel, 1999; Eisenberg et al, 2003; Parsons 2003). Some researchers have proposed that in some patients diagnosed with prostatitis, a bladder-orientated interstitial cystitis mechanism actually accounts for the symptoms and that the prostate is only indirectly involved (Sant and Kominski, 1997). Certainly, the pain and voiding symptoms of interstitial cystitis and chronic prostatitis overlap to some extent (Miller et al, 1995; Novicki et al, 1998; Sant and Nickel, 1999; Forrest and Schmidt, 2004), and men with prostatitis diagnoses have findings on cystoscopic (Berger et al, 1998), urodynamic (Siroky et al, 1981), and potassium sensitivity testing (Parsons et al, 2002, 2005) very similar to those of patients with interstitial cystitis. However, Yilmaz and associates (2004) did not confirm positive potassium sensitivity testing in prostatitis patients and Keay and colleagues (2004) have shown that men diagnosed with chronic prostatitis (pain only) have normal antiproliferative factor activity whereas men diagnosed with interstitial cystitis (pain and irritative voiding symptoms) have detectable levels of urine antiproliferative factor.

An Interrelated, Pluricausal, Multifactorial Etiology

It is likely that the nonbacterial prostatitis syndromes have a multifactorial etiology, either a spectrum of etiologic mechanisms or, more likely, a progression or cascade of events after some initiating factor. In an important review on mechanisms involved in the pathogenesis of chronic prostatitis, Pontari and Ruggieri (2004) concluded that, "the symptoms of chronic prostatitis/chronic pelvic pain syndrome appear to result from an interplay between psychological factors and dysfunction in the immune, neurological and endocrine systems." Figure 11–2 describes a hypothetical scenario that could potentially involve most of the proposed and interrelated causes described in this section.

Key Points: Etiology

- Gram-negative Enterobacteriaceae and enterococci are responsible for most cases of bacterial prostatitis.
- Nonbacterial prostatitis syndromes are caused by an interrelated cascade of inflammatory, immunologic, neuroendocrine, and neuropathic mechanisms that begins with an initiator in a genetically or anatomically susceptible man.

Definition and Classification

Traditional Classification

The traditional classification system is based on the landmark paper by Meares and Stamey (1968) describing the differential diagnosis of the prostatitis syndromes. This classic paper described in great details the serial cultures (and treatment) in four patients with chronic prostatitis and introduced the so-called Meares-Stamey four-glass test. This localization test, which segmentally assesses inflammation and cultures of the male lower urinary tract, is described later in this chapter (see Lower Urinary Tract Evaluation). **Based on 10 years of clinical experience with this test, a classification system describing four categories of prostatitis was described by** Drach and colleagues in 1978**. Differentiation of the four categories depended on an analysis of prostatic fluid, which included microscopy (examination for white blood cells [WBCs], inflammatory cell clumps, mucus debris, oval fat bodies, and macrophages) and culturing (identifying traditional uropathogens).**

Acute bacterial prostatitis was diagnosed when prostatic fluid was clinically purulent, systemic signs of infectious disease were present, and bacteria were cultured from prostatic fluid. **Chronic bacterial prostatitis** was diagnosed when pathogenic bacteria were recovered in significant numbers from a purulent prostatic fluid in the absence of a concomitant UTI or significant systemic signs. **Nonbacterial prostatitis** was diagnosed when significant numbers of bacteria could not be cultured from prostatic fluid but the fluid consistently revealed microscopic

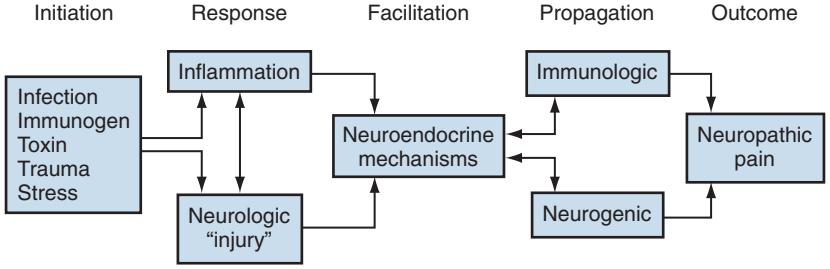

Figure 11–2. It is very likely that the etiology and pathogenesis of chronic prostatitis/chronic pelvic pain syndrome (category III CPPS) involves a pluricausal, multifactorial mechanism. An initiating stimulus such as infection, reflux of some "toxic" or "immunogenic" urine substance, perineal/pelvic "trauma," and/or psychological stress starts a cascade of events in an anatomically or genetically susceptible man, resulting in a local response of either inflammation or neurogenic injury (or both). Further immunologic or neuropathic (possibly interrelated) mechanisms mediated by neuroendocrine pathways propagate or sustain the chronicity of the initial (or ongoing) event. The final outcome is the clinical manifestation of chronic perineal/pelvic pain–associated symptoms associated with local and central neuropathic mechanisms.

Table 11–1.
Classification System for the Prostatitis Syndromes

TRADITIONAL	NATIONAL INSTITUTES OF HEALTH	DESCRIPTION
Acute bacterial prostatitis	Category I	Acute infection of the prostate gland
Chronic bacterial prostatitis	Category II	Chronic infection of the prostate gland
N/A	Category III chronic pelvic pain syndrome (CPPS)	Chronic genitourinary pain in the absence of uropathogenic bacteria localized to the prostate gland employing standard methodology
Nonbacterial prostatitis	Category IIIA (inflammatory CPPS)	Significant number of white blood cells in expressed prostatic secretions, post–prostatic massage urine sediment (VB3) or semen
Prostatodynia	Category IIIB (noninflammatory CPPS)	Insignificant number of white blood cells in expressed prostatic secretions, post–prostatic massage urine sediment (VB3) or semen
N/A	Asymptomatic inflammatory prostatitis (AIP)	White blood cells (and/or bacteria) in expressed prostatic secretions, post–prostatic massage urine sediment (VB3), semen or histologic specimens of prostate gland

purulence. **Prostatodynia** was diagnosed in the remaining patients who had persistent pain and voiding complaints as in the previous two categories but who had no significant bacteria or purulence in the prostatic fluid. This clinical differentiation of the prostatitis syndromes is now referred to as the "traditional" classification system (Table 11–1).

The significant limitations of this classification system included the abandonment by most physicians of the rigorous Meares-Stamey four-glass test (Moon, 1997; Nickel et al, 1998a; McNaughton Collins et al, 1999, 2000a), the realization that only the very rare patient would be subsequently diagnosed with chronic bacterial prostatitis, the perception that patients responded to specific therapy (e.g., antibiotics) independent of this classification system, and the dawning realization that, in many cases, patients presenting with prostatitis syndromes were not easily classified into one of these categories (e.g., patients in whom specific cultures were negative because of previous antibiotic therapy or those thought to have a cause other than the prostate gland) (Nickel, 1998a).

National Institutes of Health Classification

The limitations of the traditional diagnostic algorithm and traditional classification system led to the development of the National Institutes of Health (NIH) classification system (see Table 11–1) (Krieger et al, 1999). The new definition recognized that pain is the main symptom in "abacterial chronic prostatitis" (with variable voiding and sexual dysfunction), and it was the optimal criterion to differentiate chronic prostatitis patients from control patients or patients experiencing other genitourinary problems (e.g., BPH). **This classification differed from the traditional system in two main areas: the descriptions of category III CP/CPPS and category IV asymptomatic inflammatory prostatitis.**

Category I is identical to the acute bacterial prostatitis category of the traditional classification system. **Category II** is identical to the traditional chronic bacterial prostatitis classification, except that it now usually refers to patients with recurrent lower urinary tract infections (with a prostate nidus of infection) (Schaeffer, 2006). **Category III** is defined as the "presence of genitourinary pain in the absence of uropathogenic bacteria detected by standard microbiologic methodology." This syndrome is further categorized into **category IIIA,** or inflammatory CP/CPPS (based on the presence of excessive leukocytes in EPSs or post–prostatic massage urine or semen), and **category IIIB,** or noninflammatory CP/CPPS (no significant leukocytes in similar specimens). Category IV, or asymptomatic inflammatory prostatitis, addressed one of the major problems and omissions of the traditional classification system. Patients are classified as having **category IV** prostatitis by the presence of significant leukocytes (or bacteria or both) in prostate-specific specimens (EPS, semen, and tissue biopsies) in the absence of typical chronic pelvic pain.

The NIH International Prostatitis Collaborative Network met in Washington in 1998 and confirmed the value of this classification system, not only in clinical research studies but also in clinical practice (Nickel et al, 1999c).

Key Point: Classification

- The NIH classification of the prostatitis syndromes has now become recognized as the best system for research and clinical practice.

Clinical Presentation

Category I: Acute Bacterial Prostatitis

Acute bacterial prostatitis, category I, is a rare but important lower urinary tract infectious disease. It is characterized by an acute onset of pain combined with irritative and obstructive voiding symptoms in a patient with manifestations of a systemic febrile illness. The patient typically complains of urinary frequency, urgency, and dysuria. Obstructive voiding complaints including hesitancy, poor interrupted stream, strangury, and even acute urinary retention are common. The patient complains of perineal and suprapubic pain and may have associated pain or discomfort of the external genitalia. In addition, there are usually significant systemic symptoms including fever, chills, malaise, nausea and vomiting, and even frank septicemia with hypotension. The combination and severity of symptoms in category I, acute bacterial prostatitis, vary from patient to patient. Approximately 5% of patients with acute bacterial prostatitis may progress to chronic bacterial prostatitis (Cho et al, 2005).

Category II: Chronic Bacterial Prostatitis

The most important clue in the diagnosis of category II, chronic bacterial prostatitis, is a history of documented recurrent UTIs. From 25% to 43% of patients diagnosed with chronic bacterial

prostatitis employing a four-glass test had a history of recurrent UTIs (Weidner and Ludwig, 1994; Wright et al, 1994). Patients may be relatively asymptomatic between acute episodes, or they may present with a long history of a CPPS, which is described extensively in the next section. The prevalence of bacterial prostatitis ranges from 5% to 15% of prostatitis cases (Schaeffer et al, 1981; Krieger and Egan, 1991; Weidner and Ludwig, 1994). In one of the largest and most comprehensive clinical series, Weidner and associates (1991b) found significant bacteriuria (with uropathogenic organisms) in 4.4% of patients with symptoms of chronic prostatitis.

Category III: CP/CPPS

The presenting symptoms of inflammatory category IIIA CP/CPPS (similar to the previous category of chronic nonbacterial prostatitis) are indistinguishable from those of patients with noninflammatory category IIIB disease (previously referred to as prostatodynia). The symptoms experienced by patients with CP/CPPS have been studied extensively by Krieger and colleagues (1996a). They evaluated 50 patients with CP/CPPS seen in a prostatitis clinic (compared with 75 control patients). Alexander and Trissel (1996) surveyed a cohort of 163 prostatitis patients on the Internet. These symptoms were best defined in the development of prostatitis symptom scores by Neal and Moon (1994), Krieger and colleagues (1996a), Nickel and Sorensen (1996b), and Brahler and coworkers (1997). **The predominant symptom in all these studies was pain, which was most commonly localized to the perineum, suprapubic area, and penis but can also occur in the testes, groin, or low back. Pain during or after ejaculation is one of the most prominent, important, and bothersome features in many patients** (Shoskes et al, 2004). Irritative and obstructive voiding symptoms including urgency, frequency, hesitancy, and poor interrupted flow are associated with this syndrome in many patients. Erectile dysfunction and sexual disturbances have been reported in patients with CPPS (Mehik et al, 2001; Liang et al, 2004; Zaslau et al, 2005; Muller and Mulhall, 2006; Marzalek et al, 2007; Smith et al, 2007a, 2007b; Lee et al, 2008a) but are not pathognomonic features of this syndrome. The best description of the CP/CPPS patient was provided by the NIH Chronic Prostatitis Cohort Study (Schaeffer et al, 2002). A detailed description of 488 men with CP/CPPS noted that the most frequently reported pain/discomfort was in the perineum, followed by pain/discomfort in the suprapubic area. Over half of the men had pain/discomfort during or after sexual climax (ejaculatory pain may be the most discriminatory symptom).

By definition, the syndrome becomes chronic after 3 months' duration. The symptoms tend to wax and wane over time; approximately one third of patients improve over 1 year (usually patients with shorter duration and fewer symptoms) (Nickel et al, 2002; Turner et al, 2004; Propert et al, 2006). An age-matched case-control study of risk factors in men with CP/CPPS (Pontari et al, 2005) showed that compared with asymptomatic controls, men with CP/CPPS reported a significantly greater life time prevalence of nonspecific urethritis (12% vs. 4%), cardiovascular disease (11% vs. 2%), neurologic disease (41% vs. 14%), psychiatric conditions (29% vs. 11%), and blood or infectious disease (41% vs. 20%).

The impact of this condition on health status is significant. The quality of life of many patients diagnosed with CP/CPPS is greatly diminished. Wenninger and associates (1996), employing a generic health status measure, the Sickness Impact Profile, showed that the mean scores were within the range of scores reported in the literature for patients with a history of myocardial infarction, angina, or Crohn disease. McNaughton Collins and coworkers (2001b) employed similar quality of life assessment instruments in the NIH Chronic Prostatitis Cohort Study of almost 300 patients and confirmed this finding. These investigators noted that the mental health component was affected more than the physical component of the quality of life assessment. CP/CPPS patients' quality of life was lower than those observed in the most severe subgroups of men with congestive heart failure and diabetes mellitus. This significant impact on quality of life has also been reported in a cohort of CP/CPPS men evaluated in a primary care setting (Turner et al, 2002). Patients with a diagnosis of CP/CPPS may present with depression (Tripp et al, 2005, 2006), stress (Ulrich et al, 2005), or a history of abuse (sexual, physical, or emotional) (Hu et al, 2007). Depression, maladaptive coping techniques (e.g., catastrophizing and pain contingent resting) and poor social support are associated with a poorer quality of life (Nickel et al, 2008b).

Category IV: Asymptomatic Inflammatory Prostatitis

Category IV, asymptomatic inflammatory prostatitis, by definition, does not cause symptoms. The patients present with BPH, an elevated PSA level, prostate cancer, or infertility. Subsequent microscopy of EPS or semen and/or histologic examination of BPH chips, prostate cancer specimens, or prostate biopsy specimens disclose evidence of prostatic inflammation.

Symptom Assessment

In a syndrome such as CP/CPPS, in which the objective parameters of the disease are unknown, controversial, or not validated, evaluation outcomes become of critical importance. In a syndrome defined primarily by its symptom-complex, analysis of specific prostatitis-like symptoms, the quality of life, the patient's functional status, and the patient's satisfaction with medical care will result in not only better evaluation of the prostatitis patient but also improved therapeutic follow-up. Scientifically validated symptom indices not only improve the care of patients but also optimize clinical decision making in terms of comparing clinical trial outcomes. Since the early 1990s, several different symptom indices have been described in clinical research (Neal and Moon, 1994; Krieger et al, 1996a; Nickel and Sorensen, 1996b; Brahler et al, 1997; Chiang et al, 1997) and have been sporadically employed in clinical practice (McNaughton Collins and O'Leary, 1999). Although each of these symptom indices was successful at the time it was developed for the specific purpose or study, none was believed to be ideal for use in general research or clinical practice because they were not validated according to the rigorous standards that now must be met for an accepted urologic disease-specific index (O'Leary et al, 1992).

The NIH Chronic Prostatitis Collaborative Research Network (CPCRN) developed a reproducible and valid instrument to measure the symptoms and quality of life of patients with chronic prostatitis for use in research protocols as well as clinical practice (Litwin et al, 1999). The steps followed in the development of the NIH-CPSI included a systematic literature review, focus groups, cognitive testing, an expert panel review, a validation test, and psychometric analyses. **The final index consists of nine questions that address the three most important domains of the chronic prostatitis experience. Pain (which is the primary symptom of CP/CPPS) was captured in four questions that focused on its location, severity, and**

frequency. Urinary function, the second most important component of patients' symptoms, was captured in two questions, one concerning irritative, and the other obstructive, function. The quality of life or impact was captured in three additional questions that asked about the effect of symptoms on daily activities. The NIH-CPSI (Fig. 11–3) **has now been accepted by the international prostatitis research community as an accepted outcome measure** (Nickel et al, 1999c) **and has shown validity and responsiveness in primary care samples** (Turner et al, 2003) **and clinical trials** (Propert et al, 2006). It has been translated and validated in many languages other than English (Collins et al, 2001; Kunishima et al, 2002; Leskinen et al, 2003a; Schneider et al, 2004; Karakiewicz et al, 2005). The symptom index has also proved its usefulness in the evaluation and follow-up of patients in general clinical urologic practice (Nickel, 1999b, 2001c).

NIH-Chronic Prostatitis Symptom Index (NIH-CPSI)

Pain or Discomfort

1. In the last week, have you experienced any pain or discomfort in the following areas?

	Yes	No
a. Area between rectum and testicles (perineum)	❑ 1	❑ 0
b. Testicles	❑ 1	❑ 0
c. Tip of the penis (not related to urination)	❑ 1	❑ 0
d. Below your waist, in your pubic or bladder area	❑ 1	❑ 0

2. In the last week, have you experienced:

	Yes	No
a. Pain or burning during urination?	❑ 1	❑ 0
b. Pain or discomfort during or after sexual climax (ejaculation)?	❑ 1	❑ 0

3. How often have you had pain or discomfort in any of these areas over the last week?

❑ 0 Never
❑ 1 Rarely
❑ 2 Sometimes
❑ 3 Often
❑ 4 Usually
❑ 5 Always

4. Which number best describes your AVERAGE pain or discomfort on the days that you had it, over the last week?

❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑
0	1	2	3	4	5	6	7	8	9	10
NO PAIN									PAIN AS BAD AS YOU CAN IMAGINE	

Urination

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

Impact of Symptoms

7. How much have your symptoms kept you from doing the kinds of things you would usually do, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

8. How much did you think about your symptoms, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

Quality of Life

9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that?

❑ 0 Delighted
❑ 1 Pleased
❑ 2 Mostly satisfied
❑ 3 Mixed (about equally satisfied and dissatisfied)
❑ 4 Mostly dissatisfied
❑ 5 Unhappy
❑ 6 Terrible

Scoring the NIH-Chronic Prostatitis Symptom Index Domains

Pain: Total of items 1a, 1b, 1c, 1d, 2a, 2b, 3, and 4 = ____

***Urinary Symptoms*:** Total of items 5 and 6 = ____

Quality of Life Impact: Total of items 7, 8, and 9 = ____

Figure 11–3. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) captures the three most important domains of the prostatitis experience: pain (location, frequency, and severity), voiding (irritative and obstructive symptoms), and quality of life (including impact). This index is useful in research studies and clinical practice. (Reprinted with permission from Litwin MS, McNaughton Collins M, Fowler FJ, et al. The NIH Chronic Prostatitis Symptom Index [NIH-CPSI]: development and validation of a new outcome measure. J Urol 1999;162:369–375.)

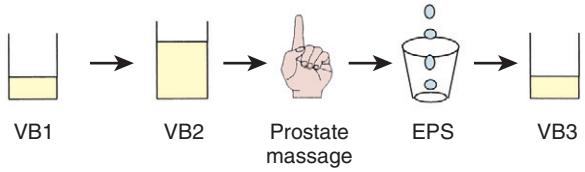
Key Point: Symptom Assessment

- The validated NIH-CPSI is a useful research and clinical tool for evaluating CP/CPPS patients.

Lower Urinary Tract Evaluation

Physical Examination

Physical examination is an important part of the evaluation of a patient with prostatitis, but it is usually not helpful in making a definitive diagnosis or further classifying the disorder. It assists in ruling out other perineal, anal, neurologic, pelvic, or prostate abnormalities and is an integral part of the lower urinary tract evaluation by providing prostate-specific specimens.



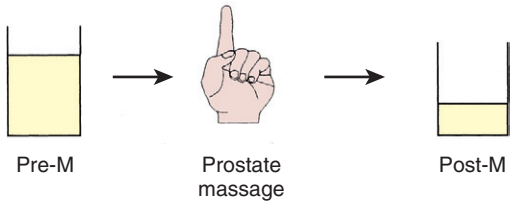
In category I, acute bacterial prostatitis, the patient may be systemically toxic, that is, flushed, febrile, tachycardic, tachypneic, and even hypotensive. The patient usually has suprapubic discomfort and perhaps has clinically detectable acute urinary retention. Perineal pain and anal sphincter spasm may complicate the digital rectal examination. The prostate itself is usually described as hot, boggy, and exquisitely tender. The expression of prostatic fluid is believed to be totally unnecessary and perhaps even harmful.

The physical examination of a patient with category II, chronic bacterial prostatitis and category III CPPS is usually unremarkable (except for pain). Careful examination and palpation of external genitalia, groin, perineum, coccyx, external anal sphincter (tone), and internal pelvic floor and side walls may pinpoint prominent areas of pain or discomfort. **The digital rectal examination should be performed after the patient has produced pre-prostatic massage urine specimens (see later). The prostate may be normal in size and consistency, and it has also been described as enlarged and boggy (loosely defined by the author as softer than normal). The degree of elicited pain during prostatic palpation is variable and is unhelpful in differentiating a prostatitis syndrome.** The prostate should be carefully checked for prostatic nodules before a vigorous prostatic massage is performed to produce prostate-specific specimens (EPS and post–prostatic massage urine sample).

Lower Urinary Tract Cytologic Examination and Culture Techniques

In patients presenting with category I, acute bacterial prostatitis, a urine culture is the only laboratory evaluation of the lower urinary tract required. It has been suggested that the vigorous prostatic massage necessary to produce EPS can exacerbate the clinical situation, although such fears have never been substantiated in the literature. A midstream urine specimen will show significant leukocytosis and bacteriuria microscopically, and culturing usually discloses typical uropathogens. Blood cultures may show the same organism.

In 1968, Meares and Stamey described the classic four-glass urine collection technique to distinguish urethral, bladder, and prostate infections in men with chronic prostatitis, and for 3 decades this has remained the "gold standard" for the evaluation of this lower urinary tract syndrome. The voided bladder-1 (VB1) specimen includes the first 10 mL of urine and represents the urethral specimen. The voided bladder-2 (VB2) specimen is similar to a midstream urine collection and represents the bladder urine. EPS should be collected directly into a sterile container during prostatic massage. The voided bladder-3 (VB3) specimen, the first 10 mL of urine voided after prostatic massage, includes any EPS trapped in the prostatic urethra. The three urine specimens are centrifuged for 5 minutes and the sediment examined under high power for leukocytes (including aggregates of leukocytes), macrophages, oval fat bodies, erythrocytes, bacteria, and fungal hyphae. A wet mount of a drop of EPS can be examined under a coverslip in a similar manner. Some researchers (Muller et al, 2001; Krieger et al, 2003) point out that quantitative determination of the EPS WBC concentration by a counting chamber method is superior to the standard wet mount method but probably only indicated in research studies. In fact, the NIH Chronic Prostatitis Cohort Study (Schaeffer et al, 2002; Nickel et al, 2003a) suggested that leukocyte determination did not appear to add significant clinical information to the assessment of a patient with CP/CPPS. All four specimens are sent to the laboratory for quantitative culturing. Figure 11–4 illustrates the technique and interpretation of the four-glass test.



4-Glass Test (Meares-Stamey Test)

Classification	Specimen	VB1	VB2	EPS	VB3
CAT II	WBC	–	+/–*	+	+
	Culture	–	+/–*	+	+
CAT IIIA	WBC	–	–	+	+
	Culture	–	–	–	–
CAT IIIB	WBC	–	–	–	–
	Culture	–	–	–	–

Figure 11–4. Technique and interpretation of the Meares-Stamey four-glass lower urinary tract localization test for CP/CPPS.

Category II, chronic bacterial prostatitis, is diagnosed if there is a 10-fold increase in bacteria in the EPS or VB3 specimen compared with the VB1 and VB2 specimens. In a patient who has acute cystitis this localization is impossible, and in this case the patient can be treated with a short course (1 to 3 days) of therapy with an antibiotic such as nitrofurantoin, which penetrates the prostate poorly but eradicates the bladder bacteriuria. Subsequent localization of bacteria in the post–prostatic massage urine or EPS is then diagnostic of category II prostatitis. Category IIIA CP/CPPS is diagnosed when no uropathogenic bacteria are cultured, but excessive leukocytosis (usually defined as more than 5 to 10 WBCs/high-power field [hpf]) is noted in the prostate-specific specimens (EPS or VB3 or both). Category IIIB CP/CPPS is diagnosed when no uropathogenic bacteria are cultured and there is no significant leukocytosis noted on microscopic examination of EPS or the sediment of VB3.

Although the four-glass test remains the gold standard diagnostic evaluation of prostatitis patients, numerous surveys (Moon, 1997; Nickel et al, 1998a; McNaughton Collins et al, 1999, 2000a) have confirmed that clinicians have more or less abandoned this time-consuming and expensive rigorous evaluation. **The pre-massage and post-massage test (or two-glass test), originally suggested by** Weidner and Ebner (1985) **and popularized**

2-Glass Test (PPMT)

Classification	Specimen	Pre-M	Post-M
CAT II	WBC	+/–*	+
	Culture	+/–*	+
CAT IIIA	WBC	–	+
	Culture	–	–
CAT IIIB	WBC	–	–
	Culture	–	–

Figure 11–5. Technique and interpretation of the pre- and post-massage two-glass lower urinary tract localization test for CP/CPPS.

by Nickel (1995, 1996, 1997a), **is a simple, cost-effective screen to categorize patients with chronic prostatitis.** The patient provides a midstream pre-massage urine specimen and a urine specimen (initial 10 mL) after prostatic massage. Microscopy (sediment) and culturing of these two screening urine specimens allows categorization of the majority of patients presenting with a chronic prostatitis syndrome. Figure 11–5 illustrates the technique and interpretation of the two-glass pre-massage and post-massage test.

In a retrospective personal series and a review of series in the literature, Nickel (1997a) noted that this test had 91% sensitivity and specificity compared with the gold standard Meares-Stamey test. Its limitations were thought to be due to the exclusion of the urethral and EPS specimen. However, in patients without clinical urethritis, Krieger and associates (2000) demonstrated that urethral swabs are more efficient in picking up urethral inflammation than the VB1 specimen. But in this series of 235 patients only 3% had more than 1 WBC/hpf. Therefore the urethral specimens rarely detected significant urethral inflammation, and in this series rarely did cultured organisms change the direction of clinical therapy in patients with prostatitis (without clinical urethritis). In the same study (Krieger et al, 2000) comparing EPS with post–prostatic massage urine, the investigators demonstrated that EPS examination detected 76%, whereas post-massage urine examination detected 82% of the patients who had inflammation on one or both tests. Ludwig and associates (2000), in a series of 328 patients in whom both EPS and a VB3 specimen were obtained, demonstrated that VB3 is almost as accurate as EPS (92% sensitivity; 99% specificity) in detecting prostate-specific inflammation. Seiler and associates (2003) came to the same conclusion in their study of 143 chronic prostatitis patients. Nickel and colleagues from the NIH CPCRN (2006) examined a cohort of 353 CP/CPPS men with complete four-glass data and noted that the two-glass test predicted a positive four-glass result with clinically acceptable accuracy (over 95% of men would have had the same diagnosis if the four-glass test was performed). This test, however, is only a screening test, and in patients in whom it is important to localize bacteria to the prostate versus the urethra (e.g., patients with recurrent UTIs, suspicion of urethral abnormality), a follow-up VB1 specimen or urethral swab may be very helpful. If typical urethral organisms are localized to the prostate when the pre-massage and post-massage test is used and the clinician is inclined to consider them pathogenic and subsequently treat the patients, urethral and EPS specimens to definitively localize the specific bacteria to the prostate are appropriate. As a general rule, it is always best to examine the EPS (if obtainable) microscopically.

Key Point: Lower Urinary Tract Culture Technique

- The two-glass pre- and post-massage test is a simple, useful screen for inflammation and infection of the lower urinary tract in patients presenting with chronic prostatitis.

Microbiologic Considerations. Both the traditional and the NIH classification systems depend on culturing for standard uropathogens. The Enterobacteriaceae (e.g., *E. coli, Serratia, Klebsiella, Proteus, Pseudomonas*) represent the most common uropathogens, followed by gram-positive enterococci. However, as discussed earlier in the section on etiology, other gram-positive organisms that typically colonize the urethra (*Staphylococcus epidermidis, Staphylococcus saprophyticus, Streptococcus* species, *Corynebacterium,* and *Bacteroides*) can be localized to the prostate specimens, including semen (>10-fold colony-forming unit count in prostate-specific specimens compared with pre–prostatic massage specimens), and their association with the prostatic inflammation symptom-complex remains unclear. At this time, these patients are still considered as having category III CP/CPPS, but as more research results become available this may change as our understanding of bacterial pathogenicity in the prostate gland evolves (Nickel and Moon, 2005; Nickel and Xiang, 2008).

Cytologic Considerations. The differentiation of the two subtypes of category III CP/CPPS depend on cytologic examination of the urine or EPS or both. The urine specimens are centrifuged for 5 minutes, and the sediment is resuspended under a coverslip and examined at high power (×300 to ×400) while the wet mount of a drop of EPS is examined under a coverslip at the same power. WBCs have traditionally been reported as numbers of leukocytes per high-power field (Fig. 11–6). **There is no validated cutoff point for the level of WBCs per high-power field that is required to differentiate an inflammatory from a noninflammatory CP/CPPS. Although the suggested limits have ranged from as low as 2** (Anderson and Weller, 1979) **to as high as 20** (Blacklock and Beavis, 1978) **the consensus appears to favor 5 to 10 WBCs/hpf in EPS as the upper level of normal** (Meares and Stamey, 1968; Pfau et al, 1978; Schaeffer et al, 1981). But inflammatory cells in the EPS fluctuate over time (Anderson and Weller, 1979; Schaeffer et al, 1981) and with the frequency of ejaculation (Jameson, 1967; Yavascaoglu et al, 1999). A disadvantage of looking at a drop of prostatic fluid or urine sediment is that the cells may clump or aggregate, which renders quantifying them virtually impossible. Also, an unstained specimen does not allow differentiation of the type of WBC present (e.g., polymorphonuclear leukocytes, lymphocytes, monocytes, macrophages). If accuracy is required (i.e., research), then the WBCs can be counted in a glass hemacytometer (so they may be quantified as cells per square millimeter) and subsequently stained to differentiate the inflammatory cell subtype (Anderson and Weller, 1979).

The clinical relevance of adding cytologic examination of semen specimens (which is difficult without special staining techniques) is unknown. Certainly, semen examination increases the percentage of patients identified as inflammatory category IIIA CP/CPPS (Krieger et al, 2000).

Nickel and colleagues (2003a) compared the number of WBCs in the EPS in patients with CP/CPPS to EPS specimens from normal

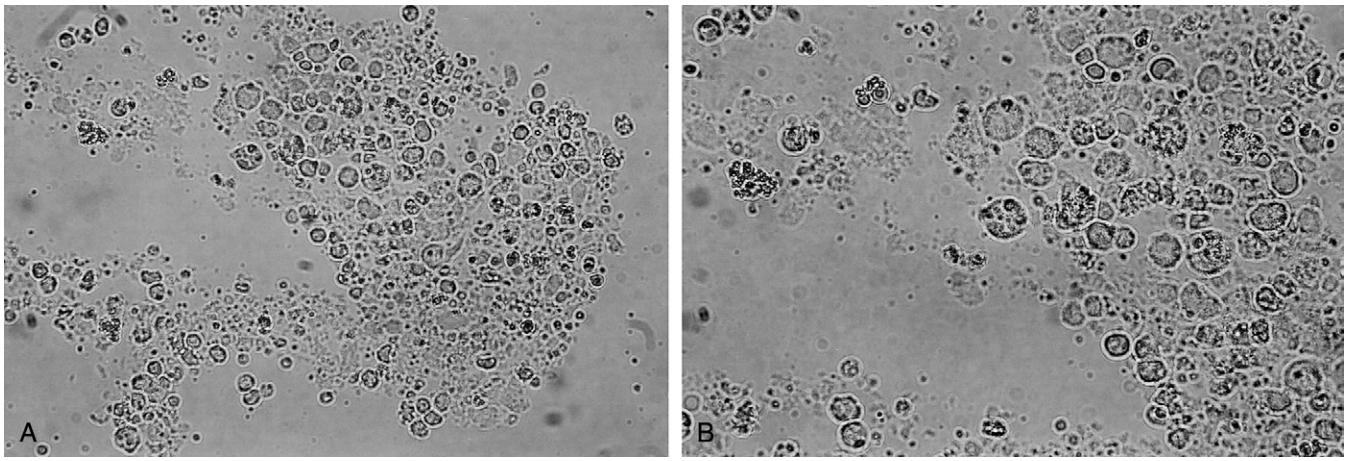


Figure 11–6. **A** and **B,** Unstained photomicrographs showing individual white blood cells, clumps of white blood cells, and lipid-laden macrophages in the expressed prostatic secretion (EPS) of a patient with category IIIA CPPS (**A,** ×250; **B,** ×400).

asymptomatic control men and noted that while there was a statistically significant difference in WBC counts in the CP/CPPS men the clinical significance was not apparent (e.g., 50% of CPPS men had >5 WBCs/hpf compared with 40% of control men). The relevance of examining urine and EPS for white cells in routine clinical practice has been challenged (Nickel et al, 2003a). In fact, **we have not been able to confirm the association between histologically proven prostate inflammation and prostatitis symptoms** (Nickel et al, 2007), **further confusing the issue of whether we really need to determine prostate-specific specimen inflammation,** which is really just a surrogate for prostate inflammation. However, some investigators (Nickel, 2002d) have recommended that urine cytology (for malignant cells) become a standard diagnostic test for men presenting with prostatitis-like symptoms, particularly if the symptom-complex includes irritative voiding symptoms, dysuria, and/or suprapubic/bladder pain.

Urodynamics

Pain is the dominant symptom in patients presenting with CP/CPPS, but a wide constellation of irritative and obstructive voiding symptoms are associated with this syndrome. Proposed causes to account for the persistent irritative and obstructive voiding symptoms include detrusor vesical neck or external sphincter dyssynergia, proximal or distal urethral obstruction, and fibrosis or hypertrophy of the vesical neck (Blacklock, 1974, 1986; Bates et al, 1975; Orland et al, 1985; Theodorou et al, 1999). These abnormalities can often be clarified and diagnosed by urodynamics, particularly video-urodynamics. Others have suggested that men with defined primary voiding dysfunction have been misdiagnosed with chronic prostatitis (Webster et al, 1980; Siroky et al, 1981; Murnaghan and Millard, 1984). Siroky and associates (1981) noted that urodynamics revealed that 50% of 47 men with recurrent voiding symptoms, perigenital pain, or both previously diagnosed as chronic prostatitis had bladder acontractility during a study with nonrelaxing perineal floor (striated muscle spasm) and that another 36% had detrusor overactivity with appropriate striated sphincter relaxation. Barbalias (1990) and Barbalias and colleagues (1983) noted decreased peak and mean urinary flow rates, a significantly elevated maximal urethral closing pressure, and incomplete funneling of the bladder neck accompanied by urethral narrowing at the level of the external urinary sphincter during voiding with urodynamic evaluation of men diagnosed with chronic prostatitis. Hellstrom and colleagues (1987) also noted elevated urethral pressures, "hyperreflexia" of the external urethral sphincter, and intraprostatic reflux in three patients with unremitting symptoms of chronic nonbacterial prostatitis.

Kaplan and associates (1994, 1996, 1997) postulated that chronic lower urinary tract symptoms in young men are often misdiagnosed as chronic nonbacterial prostatitis when in fact they indicate a cohort of men with undiagnosed chronic voiding dysfunction. This conclusion is based on the video-urodynamic studies of 137 consecutive men 50 years of age or younger diagnosed with chronic prostatitis (Kaplan et al, 1996). These researchers demonstrated a variety of urodynamic abnormalities, including 54% of patients with primary vesical neck obstruction, 24% with functional obstruction localized to the membranous urethra (pseudodyssynergia), 17% with impaired bladder contractility, and 5% with an acontractile bladder. They noted detrusor overactivity in 49% of the men. Simple documentation of uroflowmetry and residual urine bladder scan abnormalities may suggest proceeding to more sophisticated urodynamics (Ghobish, 2000). Other groups dispute the benefits of urodynamics and have noted very few urodynamic abnormalities in patients presenting with classic chronic prostatitis symptoms (Mayo et al, 1998).

Endoscopy

Clinical experience (rather than controlled clinical studies) suggests that lower urinary tract endoscopy (i.e., cystoscopy) is not indicated in the majority of men presenting with CP/CPPS. However, cystoscopy is indicated in patients in whom the history (e.g., hematuria), lower urinary tract evaluation (e.g., VB1 urinalysis), or ancillary studies (e.g., urodynamics) indicate the possibility of a diagnosis other than CP/CPPS. In these patients, occasionally lower urinary tract malignancy, stones, urethral strictures, bladder neck abnormalities, and so forth that can be surgically corrected are discovered. Cystoscopy can probably be justified in men refractory to standard therapy.

Transrectal Ultrasonography

Transrectal ultrasonography has become one of the best radiologic methods to evaluate prostate disease and has become an especially helpful clinical tool for the assessment of prostate volume and ultrasound guidance of biopsy needles. **The diagnostic value of ultrasonography in differentiating benign from malignant prostate disease is controversial, and the**

further differentiation of the various benign conditions of the prostate is even more so. Di Trapani and colleagues (1988) described inhomogeneous echo structures, constant dilatation of periprostatic venous plexus, elongated seminal vesicles, and thickening of the inner septa in patients with prostatitis. Doble and Carter (1989) described seven ultrasound signs associated with the presence of symptoms of chronic prostatitis compared with controls, and although the sensitivity increased with higher leukocyte counts the signs were not sufficiently specific to differentiate clinical groups.

Peeling and Griffiths (1984) describe the heterogeneity of the echo pattern and prostatic calculi as ultrasound features related to prostatitis. Ludwig and coworkers (1994) described the ultrasound features such as prostatic calcifications and seminal vesicle abnormalities that appear to be indicative of signs of inflammation but not proof of the presence of chronic prostatitis. Harada and associates (1980) concluded that the presence of stones is not related to a specific prostate disease process. De la Rosette and colleagues (1992b) performed ultrasonography in 22 patients with nonbacterial prostatitis and compared the results with those of a control group of 22 patients without lower urinary tract symptoms. This study indicated that there were no significant differences in ultrasound patterns of patients with nonbacterial prostatitis and the control group. Others have employed color Doppler ultrasonography (Veneziano et al, 1995) and automated computer analysis (de la Rosette et al, 1995) in an attempt to improve the value of transrectal ultrasonography in the evaluation of prostatitis patients; however, the results are not conclusive enough to indicate that this is a clinically useful tool.

Transrectal ultrasonography can be valuable in diagnosing medial prostatic cysts in patients with prostatitis-like symptoms (Dik et al, 1996), **diagnosing and draining prostatic abscesses** (Granados et al, 1992), **or diagnosing and draining obstructed seminal vesicles** (Littrup et al, 1988). It is not required in all cases of acute bacterial prostatitis but rather only in those patients who are failing appropriate antimicrobial therapy (Horcajada et al, 2003).

Prostate Biopsy

Occasionally, because of an elevated PSA level or abnormal digital rectal examination, prostate biopsy is indicated (Kawakami et al, 2004). Some clinicians will consider starting patients with elevated screening PSA levels and a history of prostatitis or symptoms of CPPS on antibiotics, but this practice is really only rational in patients with acute or chronic bacterial prostatitis (Nickel, 2002c), conditions that invariably lead to elevated PSA levels. The diagnosis of CP/CPPS should be used only as a reason against a prostate biopsy if the clinician is looking for an excuse not to biopsy (Nickel, 2002c). A comprehensive review on PSA and prostatitis is available (Kawakami et al, 2004).

Out of desperation, urologists sometimes resort to prostate biopsy in an attempt either to demonstrate histologic evidence of prostatic inflammation or to culture an organism that cannot be cultured employing the standard approach. The importance and interpretation of prostate biopsies in prostatitis performed for reasons other than prostate cancer screening is unclear. Doble and associates (1990) demonstrated immune complexes in the prostate of patients with prostatitis but found culture of the prostatic tissue unhelpful (Doble et al, 1989a). Nickel and Costerton (1993) were able to confirm the presence of potentially uropathogenic bacteria in patients with a documented history of chronic bacterial prostatitis in whom EPS cultures became sterile after antibiotic therapy. Berger and associates (1997) also confirmed the presence of potential uropathogenic bacteria in prostate biopsy specimens (which correlated to some extent with prostatic inflammation in EPS) in patients in whom the same bacteria did not grow standard prostatic specimens (e.g., EPS). Krieger and colleagues (1996b) demonstrated the possible presence of microorganisms in the prostate gland of a majority of men with chronic prostatitis syndrome using the molecular biologic technique of polymerase chain reaction. **At this time, histologic, culture, and molecular biologic evaluations of prostate biopsy specimens in patients with CP/CPPS remain research tools only.**

Seminal Vesiculitis

Occasionally, seminal vesiculitis can occur as a consequence of local bacterial infection in acute and chronic bacterial prostatitis (Zeitlin, 1999) and patients can present with seminal vesicle abscesses (Stearns, 1963; Kennelly and Oesterling, 1989). Seminal vesicle abscesses were traditionally diagnosed clinically by a positive ejaculate culture and seminal vesiculography (Dunnick et al, 1982; Baert et al, 1986) but is now imaged with computed tomography (Patel and Wilbur, 1987), transrectal ultrasonography (Littrup et al, 1988), magnetic resonance imaging (Sue et al, 1989) or recently with technetium-99m ciprofloxacin radioisotope scan (Choe et al, 2003).

Other Possible Markers

Wishnow and associates (1982) found that control patients (10 patients) and men with chronic abacterial prostatitis (4 patients) had no antibodies to gram-negative bacterial antigens, in contrast to men with bacterial prostatitis (6 patients). They hypothesized that immunologic analysis may provide a better diagnostic tool than culturing and microscopy. Shortliffe and coworkers (1981a, 1981b, 1986, 1989, 1992) found that the total IgA and IgG levels in the prostatic fluid in men with chronic abacterial prostatitis were higher than those of controls. They also discovered that prostatic fluid from control or abacterial prostatitis patients did not contain specific antibodies to gram-negative urinary pathogens (in contrast to men with bacterial prostatitis). Nickel and colleagues (2001a) used a similar antibody screening procedure in evaluation of 102 men with CP/CPPS who were subsequently treated with quinolone antibiotics. However, "antibody-positive" patients did not have a better response to antibiotic therapy than "antibody-negative" patients after 12 weeks of therapy. Li and associates (2001) demonstrated increased endotoxin concentrations in EPS and VB3 of men with bacterial prostatitis and inflammatory category IIIA CPPS and suggested that endotoxin levels might be used to identify these categories of patients with chronic prostatitis.

Alexander and colleagues (1998) discovered that men with chronic abacterial prostatitis had higher mean levels of the proinflammatory cytokines IL-1α and TNF-α in seminal plasma compared with controls. Ruggieri and coworkers (2000) noted that levels of both IL-1α and IL-8 were significantly higher in semen in category IIIA patients (leukocytes) than in category IIIB patients, but there was no statistically significant difference in levels of TNF-α, IL-1α, or IL-6. This group found no correlation between cytokine levels and the number of leukocytes in EPS. The increased IL-8 levels in the semen of patients with prostatitis symptoms has recently been confirmed by Khadra and coworkers (2006) and Penna and associates (2007), suggesting that this could be a surrogate marker for CP/CPPS. Nadler and colleagues (2000) found that mean levels of IL-1α in EPS were higher in men with inflammatory chronic abacterial prostatitis and noninflammatory

chronic bacterial prostatitis compared with controls. Hochreiter and associates (2000a) did find a direct significant correlation between the number of leukocytes in EPS and IL-1α levels in EPS. **One of the most intriguing possible biomarkers includes monocyte chemoattractant protein-1 and macrophage inflammatory protein-1α detected in EPS. Both of these chemokines are elevated in category IIIA and IIIB CP/CPPS, whereas macrophage inflammatory protein-1α may be a further marker for clinical pain in these patients** (Desireddi et al, 2008). The sensitivity, specificity, and, more importantly, the clinical applicability of all these immunologic tests is really unknown and none of them is yet indicated in clinical practice.

Marmar and associates (1980) hypothesized that zinc levels in EPS would be a useful marker for prostatitis and found that, indeed, zinc levels in men with chronic abacterial prostatitis and bacterial prostatitis were significantly lower than zinc levels in control patients and men with prostatodynia. However, Zaichick and colleagues (1996) found no differences in zinc levels between patients with chronic abacterial prostatitis, BPH, and controls. At this time the measurement of zinc levels in prostatic or semen specimens is clinically unhelpful.

Tanner and associates (1999) detected positive signals (rRNA-based molecular technique with prostatic fluid) in 65% of patients with chronic prostatitis. Seven of 11 patients with bacterial signals but none of 6 patients without bacterial signals was improved on antibiotic therapy. The same group (Shoskes and Shahed, 2000) subsequently confirmed this finding with a larger cohort of patients. These results are intriguing, and controlled studies evaluating the potential clinical significance of differentiating patients based on molecular biologic techniques are required.

An Approach to Diagnosis and Classification

A diagnostic algorithm that provides a practical approach to the workup of the majority of men presenting with CP/CPPS is shown in Figure 11–7. Table 11–2 shows the tests recommended by the NIH Third International Prostatitis Collaborative Network (Nickel, 2003).

Key Points: Lower Urinary Tract Evaluation

- Mandatory evaluation includes history-taking, physical examination, urinalysis, and urine culture.
- Recommended evaluation includes lower urinary tract localization test (culture), NIH-CPSI, flow rate, residual urine determination, and urine cytology.

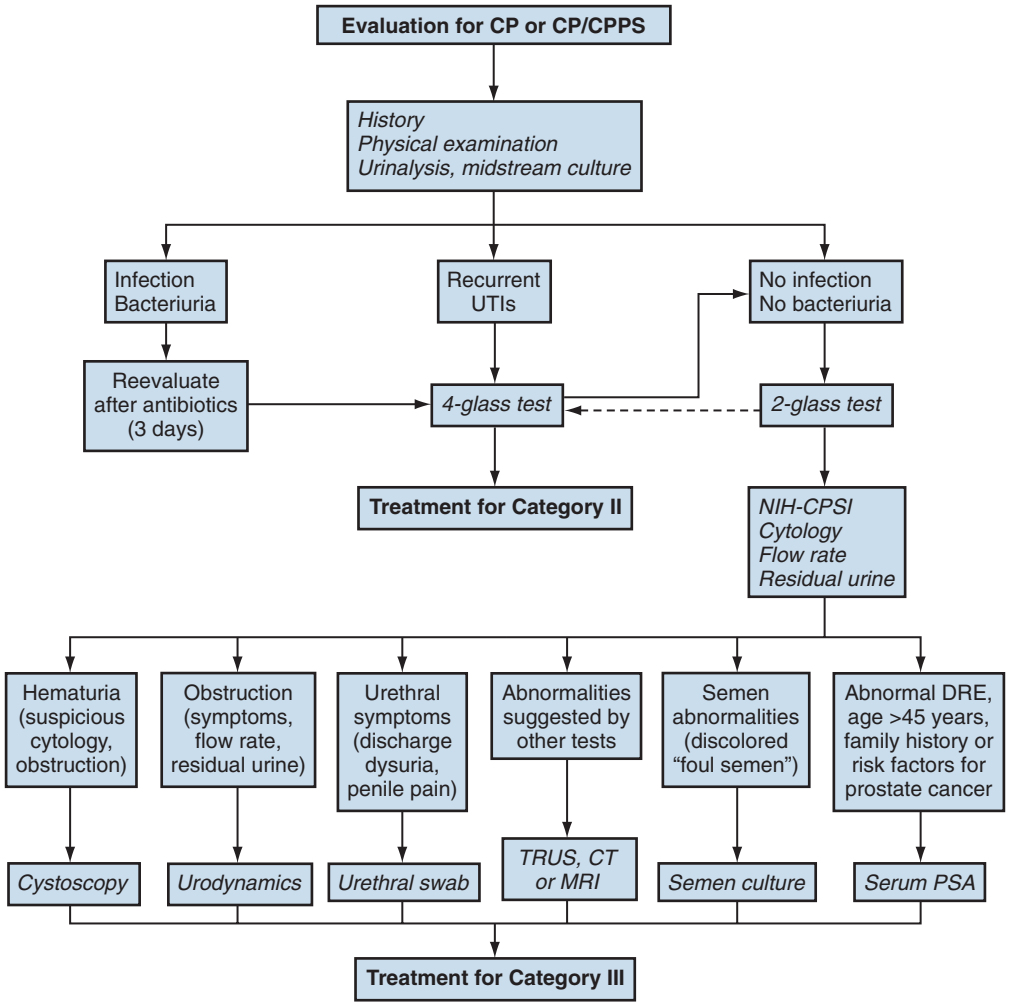

Figure 11–7. A suggested diagnostic algorithm for the evaluation of patients presenting with CP/CPPS. UTIs, urinary tract infections; TRUS, transrectal ultrasonography; CT, computed tomography; MRI, magnetic resonance imaging; DRE, digital rectal examination; PSA, prostate-specific antigen.

Table 11–2.

Suggested Evaluation of a Man with Chronic Pelvic Pain Syndrome*

Mandatory
History
Physical examination, including digital rectal examination
Urinalysis and urine culture
Recommended
Lower urinary tract localization test
Symptom inventory or index (NIH-CPSI)
Flow rate
Residual urine determination
Urine cytology
Optional
Semen analysis and culture
Urethral swab for culture
Pressure-flow studies
Video-urodynamics (including flow-electromyography)
Cystoscopy
Transrectal ultrasonography
Pelvic imaging (ultrasonography, CT, MRI)
Prostate-specific antigen

*See text for explanation, rationale, and description of each test.

Treatment

In this section the rationale for each of the various treatments advocated for the prostatitis syndromes is presented followed by a review of the clinical trial data that support (or not) the use of those specific therapeutic modalities in clinical practice. Recent rigorous prospective studies in chronic bacterial prostatitis and randomized placebo-controlled trials employing standardized definitions and validated outcomes in CP/CPPS have allowed us to develop a best-evidence-based treatment strategies in a therapeutic field that used to be based on poor clinical data, dogma, and anecdotal experience (McNaughton Collins et al, 2000b, 2001a; Nickel, 2002a, 2002b, 2004; Schaeffer, 2006; Nickel, 2008b).

Antimicrobial Agents

Rationale. It is generally accepted that acute and chronic bacterial prostatitis are etiologically secondary to bacterial infection of the prostate gland. Many urologists further believe that, although bacteria are cultured in only 5% to 10% of cases of prostatitis, bacteria may be the cause of prostatitis in a significant percentage of patients presenting with this syndrome. **Antimicrobial therapy is the most commonly prescribed treatment for the chronic prostatitis syndromes** (Moon, 1997; Nickel et al, 1998a; McNaughton Collins et al, 2000b, 2001a), independent of culture status.

Pharmacology and Pharmacokinetics. Most antimicrobial pharmacokinetic studies were performed in animal models (dogs and rats) (Madsen et al, 1978; Nickel, 1997b). Stamey (1980) and Stamey and associates (1970) found that acid antibiotic drugs can be detected in prostatic secretions only in very low concentrations, even when plasma concentrations of the drug are very high. Alkaline antibiotic drugs are found in concentrations greater than the simultaneous plasma levels. In dogs, this was explained by the presence of a pH gradient across the prostate epithelium. This phenomenon of ion trapping, and the fact that drug penetration was believed to be a passive transport mechanism based on diffusion and concentration, suggested that drug penetration is dependent on the lipid solubility, degree of ionization, degree of protein binding, and size and shape of the antimicrobial molecule. In dogs, the pH of plasma was found to be 7.4, whereas that of prostatic secretion is 6.4. Therefore, in this model, weak acids (low pKa) concentrate on the plasma side whereas antibiotics with a higher pKa (weak bases) concentrate in the prostatic secretion.

Because infection may alter the local prostatic environment, thus changing the pharmacokinetic parameters, animal models were developed that introduced infection into the process (Baumueller and Madsen, 1977; Madsen et al, 1994; Nickel et al, 1995). All these animal studies (with and without infection) showed that trimethoprim concentrates in prostatic secretion and prostatic interstitial fluid (exceeding plasma levels), whereas sulfamethoxazole and ampicillin do not. The fluoroquinolones, which are neither pure acids nor bases but have characteristics of both, being zwitterionic drugs (e.g., those that have two pKa values) (Gasser et al, 1986), should allow drug concentration in the prostate at various pH ranges. In the dog model, ciprofloxacin and norfloxacin did not concentrate in prostatic secretion as predicted, and this may be accounted for by their lipid solubility and protein-binding characteristics. Carbenicillin, which for years was the only antibiotic approved by the U.S. Food and Drug Administration for the treatment of bacterial prostatitis, could not be detected in prostatic secretion at all. Aminoglycosides did not concentrate in prostatic secretion and for unknown reasons may not follow the rules of nonionic diffusion of drugs across biologic membranes.

It is difficult to extrapolate the animal pharmacokinetic studies to humans (Sharer and Fair, 1982). Fair and Cordonnier (1978) found that the prostatic secretion of normal men is slightly alkaline (pH ~ 7.3) but also that the pH of prostatic secretion in men with prostatic infection is markedly increased (pH ~ 8.3). This has been confirmed in other studies (Anderson and Fair, 1976; Blacklock and Beavis, 1978; Pfau et al, 1978), and because the pH gradation is crucial to ion trapping we should not apply the results from animal studies directly to humans. Unfortunately, drug diffusion studies are difficult to perform in humans and most studies determine antibiotic concentrations in transurethrally resected BPH adenomas. These studies are further complicated because the high drug concentrations in urine can substantially alter the results. Employing a method to reduce urine contamination, Naber and Madsen (1999) demonstrated that for most fluoroquinolones the ratio of concentrations in prostatic fluid to concentrations in plasma is less than 1 (norfloxacin ratio 0.12, ciprofloxacin ratio 0.18 to 0.26, lomefloxacin ratio 0.48). Concentrations in seminal fluid usually exceed corresponding plasma concentrations of ciprofloxacin and ofloxacin, with ciprofloxacin demonstrating the highest ratio of seminal fluid to plasma (Naber, 1999). The numerous studies evaluating fluoroquinolone concentrations in prostatic tissue demonstrated that the fluoroquinolone concentration in the adenoma tissue is usually higher than that in plasma.

Clinical Trial Data. Unless the patient has a significant anatomic abnormality of the lower urinary tract or develops a prostate abscess, antimicrobial therapy is universally successful in eradicating the bacteria and curing the patient presenting with acute bacterial prostatitis (Nickel and Moon, 2005). **In the acutely inflamed prostate gland the pharmacokinetic considerations described in the previous section probably do not play a significant role in antibiotic penetration,** and it is believed that most antibiotics achieve reasonable intraprostatic concentrations in the acute phase of the disease. Although prospective clinical trial data are unavailable, **most experts suggest therapy initially with parenteral antibiotics (depending on the seriousness of the infection) followed by oral**

antibiotics with wide-spectrum antimicrobial activity (Becopoulos et al, 1990). The most common drugs suggested for initial therapy (Neal, 1999; Ludwig, 2008; Benway and Moon, 2008) are a combination of penicillin (i.e., ampicillin) and an aminoglycoside (i.e., gentamicin), second- or third-generation cephalosporins, or one of the fluoroquinolones. **Once the acute infection has settled down, therapy should be continued with one of the oral antimicrobial agents appropriate for the treatment of chronic bacterial prostatitis (e.g., trimethoprim or fluoroquinolones). The duration of optimal therapy is unknown; between 2 and 4 weeks has been suggested** (Nickel, 1998b; Bjerklund-Johansen et al, 1998; Wagenlehner et al, 2007; Ludwig, 2008).

In the 1970s to 1990s the most commonly used antimicrobial agent in the treatment of chronic prostatitis was trimethoprim-sulfamethoxazole (co-trimoxazole) (Moon, 1997; Nickel et al, 1998a) **and, to a lesser extent, trimethoprim alone.** In patients with chronic bacterial prostatitis, eradication of pathogens (the only objective measurement in most chronic prostatitis studies) with trimethoprim-sulfamethoxazole or trimethoprim alone ranged from a low of 0% (Smith et al, 1979) to a high of 67% (Paulson and White, 1978), with most studies demonstrating an efficacy rate of between 30% and 50% (Meares, 1973, 1975, 1978; Drach, 1974b; McGuire and Lytton, 1976). It appears that longer-duration therapy (90 days) provides the best clinical results. **Trimethoprim-sulfamethoxazole is less effective both in bacterial eradication and cost-effectiveness when compared with the newer fluoroquinolones** (Kurzer and Kaplan, 2002).

Except for the well-studied fluoroquinolones, most antibiotics (including minocycline, cephalexin, and carbenicillin) do not demonstrate significant clinical efficacy in clinical studies in which patients were observed for sufficient time (Paulson and White, 1978; Oliveri et al, 1979; Mobley, 1981). One notable exception has been the macrolides, erythromycin (Mobley, 1974), azithromycin (Skerk et al, 2003), and clarithromycin (Skerk et al, 2002b), particularly when *C. trachomatis* is implicated.

The fluoroquinolones have demonstrated improved therapeutic results, especially in prostatitis caused by *E. coli* and other members of the Enterobacteriaceae but not necessarily in prostatitis due to *P. aeruginosa* or enterococci. Naber (1999) analyzed the many studies available in the literature evaluating fluoroquinolones in the treatment of chronic prostatitis and found eight comparable studies in which the diagnosis was obtained by localization studies and in which the patients were observed for a sufficient time after completion of therapy (Weidner et al, 1987; Pust et al, 1989; Schaeffer and Darras, 1990; Heidler, 1990; Weidner et al, 1991a; Pfau, 1991; Ramirez et al, 1994; Koff, 1996); in these studies the researchers evaluated norfloxacin, ciprofloxacin, ofloxacin, and lomefloxacin. In 2005 Naber (reported at the Sixth International Consultation on New Developments in Prostate Cancer and Prostate Disease, Paris, June, 2005) added three more recent studies that met these strict criteria (Naber et al, 2000, 2002; Bundrick et al, 2003). These studies are outlined in Table 11–3. A subsequent study has suggested that levofloxacin may also be effective in treating chronic bacterial prostatitis (Naber et al, 2008). For chronic prostatitis caused by *E. coli,* treatment duration of 1 month for the fluoroquinolones seems to be superior to the usual 3-month treatment with trimethoprim-sulfamethoxazole. It has been suggested that antibiotics should be continued only for 4 to 6 weeks if pretreatment cultures are positive and/or the patient has reported positive effects from treatment (Wagenlehner et al, 2007). Some clinicians have observed that as many as 20% of patients who fail an initial treatment period could be rescued with a second cycle of treatment with another antibiotic (Magri et al, 2007). In microbiologically diagnosed chronic bacterial prostatitis, eradication of bacteria is associated with both short-term and long-term clinical success (Nickel and Xiang, 2008). This appears to be true in men with recent onset of prostatitis associated with bacterial localization

Table 11–3.

Clinical Trials of Fluoroquinolone Treatment of Chronic Bacterial Prostatitis*

ANTIBIOTIC	DOSE	DURATION OF THERAPY (days)	NO. OF PATIENTS	BACTERIOLOGIC CURE (%)	FOLLOW-UP (mo)	REFERENCE
Norfloxacin	400 mg bid	28	14	64	6	Schaeffer and Darras, 1990
Norfloxacin	400 mg bid	174	42	60	8	Petrikkos et al, 1991
Ciprofloxacin	500 mg bid	14	15	60	12	Weidner et al, 1987

Ciprofloxacin/Levofloxacin	500 mg bid	28	125	56 (clinical†)	6	Bundrick et al, 2003
	500 mg qd	28	136	53 (clinical†)	6	
Levofloxacin	500 mg qd	28	117	91	6	Naber et al, 2008

*Naber (1999) reviewed the world literature in respect to clinical trials of fluoroquinolone treatment of chronic bacterial prostatitis and noted only eight studies in which the diagnosis of prostatitis was obtained by localization studies and in which the patients were observed for at least 6 months. Naber has subsequently expanded his list of suitable available trials in 2005 (reported at the 6th International Consultation on New Developments in Prostate Cancer and Prostate Disease, Paris, June, 2005).

†Clinical success at 6 months: bacterial eradication post therapy was 75% for levofloxacin and 77% for ciprofloxacin.

with the traditional uropathogens (gram-negative uropathogens and enterococci species) as well as nontraditional bacteria (gram-positive such as coagulase-negative staphylococcal and streptococcal species) (Magri et al, 2007; Nickel and Xiang, 2008). A number of investigators (Baert and Leonard, 1988; Jimenez-Cruz et al, 1988; Yamamoto et al, 1996; Guercini et al, 2005b) have advocated direct injection of antibiotics into the prostate gland, but this method has never been rigorously evaluated or become popular among urologists.

Many studies evaluating physicians' practice patterns in prostatitis syndromes (de la Rosette et al, 1992a; Moon, 1997; Nickel et al, 1998a; McNaughton Collins et al, 1998, 2000a) have confirmed that most patients diagnosed with chronic prostatitis, irrespective of culture results, are treated with antimicrobial therapy. Older studies have generally indicated that approximately 40% of patients with nonbacterial chronic prostatitis have some symptomatic improvement with antimicrobial therapy (Berger et al, 1989; Weidner, 1992; de la Rosette et al, 1993a; Ohkawa et al, 1993b; Bergman, 1994; Bjerklund-Johansen et al, 1998; Tanner et al, 1999; Nickel et al, 2001a). Antibiotic therapy may benefit CP/CPPS patients by three different mechanisms: a strong placebo effect, the eradication or suppression of noncultured microorganisms (Nickel et al, 2001a), or the independent anti-inflammatory effect of some antibiotics (Yoshimura et al, 1996; Galley et al, 1997). It has been suggested by a European consensus group evaluating the role of antibiotics in the treatment of chronic prostatitis (Bjerklund-Johansen et al, 1998) that antibiotics should be considered empirical treatment for category IIIA CP/CPPS but the benefits should be appraised after a minimum of 2 to 4 weeks of therapy. The antibiotics could be continued for 4 to 6 weeks if the patient has reported positive effects from treatment (Wagenlehner et al, 2007). These recommendations remain controversial, particularly because new data appear to provide conflicting interpretations. Two multicenter randomized placebo controlled studies have assessed the efficacy of 6 weeks of levofloxacin (Nickel et al, 2003b) and ciprofloxacin (Alexander et al, 2004) in men with CP/CPPS. In these trials the participants had chronic symptoms for a long duration (many years) and had been heavily treated (including treatment with antibiotics). In the study by Nickel and associates (2003b), 80 patients were randomized to levofloxacin or placebo whereas in the NIH-sponsored study reported by Alexander and colleagues (2004) 196 men with CP/CPPS were randomized in a 2×2 factorial design to ciprofloxacin, tamsulosin, the combination of ciprofloxacin and tamsulosin, or placebo. In both of these prospective-designed controlled multicenter trials, no significant difference was reported between the fluoroquinolone and placebo in terms of symptom amelioration. **Antibiotics should not be prescribed for previously treated men with CP/CPPS of long duration.** However, two recent prospective trials comparing the effect of 4 to 6 weeks of antibiotics (Magri et al, 2007; Nickel and Xiang, 2008) in men with localization of both traditional uropathogens and organisms not usually believed to be uropathogenic (and therefore classified as category III CP/CPPS) showed similar eradication and clinical success rates (75% to 80%). Furthermore, in the study by Nickel and Xiang (2008), the eradication of those organisms, whether or not they were considered to be uropathogens, correlated with both short- and long-term clinical success. Because the majority of patients in Nickel and Xiang's study (2008) had a short history of prostatitis and were antibiotic naive for that episode, it was concluded **that antibiotic treatment may be considered for antibiotic-naive patients with recent diagnosis of prostatitis, regardless of culture status.**

α-Adrenergic Blocker Therapy

Rationale. Patients with CP/CPPS have significant lower urinary tract symptoms, which appear to be related to poor relaxation of the bladder neck during voiding (Barbalias et al, 1983; Murnaghan and Millard, 1984; Blacklock, 1986; Hellstrom et al, 1987; Barbalias, 1990; Kaplan et al, 1997). The subsequent turbulent "dysfunctional" voiding may predispose the patient to reflux of urine into the prostatic ducts, causing intraprostatic inflammation and subsequently pain (Kirby et al, 1982). **The bladder neck and prostate are rich in a receptors, and it is hypothesized that α-adrenergic blockade may improve outflow obstruction, improving urinary flow and perhaps diminishing intraprostatic ductal reflux.**

Clinical Trial Data. A number of older clinical trials suggested that the α-adrenergic blockers diphenoxybenzamine (Dunzendorfer et al, 1981), phenoxybenzamine (Osborn et al, 1981), alfuzosin (de la Rosette et al, 1992c; Barbalias et al, 1998), terazosin (Neal and Moon, 1994; Barbalias et al, 1998; Lacquaniti et al, 1999; Gül et al, 2001), doxazosin (Evliyaoglu and Burgut, 2002) and tamsulosin (Lacquaniti et al, 1999) resulted in significant symptomatic improvement of prostatitis-related symptoms; however, these trials were small, most were uncontrolled, and outcome measures were not validated. The study by Barbalias and associates (1998) further seemed to indicate that the combination of antibiotics and α-adrenergic blockers improved the clinical result in patients with chronic bacterial prostatitis.

Four randomized placebo controlled trials with clearly defined CP/CPPS patients (NIH classification) and employing the NIH-CPSI as the outcome parameter appear to have confirmed the efficacy of α-adrenergic blockers but only in men who have recent onset disease not those heavily pretreated and who are on therapy for longer than 6 weeks. Cheah and colleagues (2003) randomized 86 patients with chronic prostatitis to either terazosin or placebo for 14 weeks. Patients on terazosin had a 50% reduction in mean symptom score compared with 37% in the placebo-treated group. Terazosin resulted in modest but significant improvement in all domains of the NIH-CPSI. Mehik and colleagues (2003) followed 19 patients randomized to 6 months of alfuzosin treatment and 20 patients on 6 months of placebo therapy and both groups were followed for a further 6 months after discontinuing the active or placebo medication. Patients in the alfuzosin group had a significant amelioration of symptoms compared with the placebo therapy group that was evident at 4 months and became even more clinically significant by 6 months. At 6 months 65% of alfuzosin patients were rated as responders compared with 24% of placebo group. The beneficial effect appeared to wear off over the next 6 months after the alfuzosin was discontinued. Nickel and colleagues (2004b) randomized 57 men with CP/CPPS to tamsulosin, 0.4 mg, or placebo after a 2-week placebo run-in and observed the two groups for 6 weeks. Patients treated with tamsulosin had a statistically significant (but only modest clinically significant) treatment effect compared with patients taking a placebo. A significant treatment effect was not observed in patients who had mild symptoms, but patients with severe symptoms (75th percentile) had a statistically and clinically significant response compared with placebo. It appears that the response to α-adrenergic blockers is durable, for at least up to 24 to 38 weeks (Mehik et al, 2003; Cheah et al, 2004). Another study (Tugcu et al, 2007) included 90 treatment-naive patients with CP/CPPS randomized to receive doxazosin, 4 mg/day, alone or a triple therapy (doxazosin, 4 mg/day plus an anti-inflammatory agent—ibuprofen,

400 mg/day, and a myorelaxant-thiocolchicoside, 12 mg/day) or placebo. Over 6 months, the total NIH-CPSI score significantly improved in the doxazosin group (from 23.1 to 10.5 points) and triple-therapy groups (from 21.9 to 9.2) while it remained stable in the placebo group (from 22.9 to 21.9).

In contrast, the results from the NIH CPCRN randomized controlled trial (Alexander et al, 2004) **comparing 6 weeks of ciprofloxacin, tamsulosin, and the combination of ciprofloxacin and tamsulosin to placebo in very chronic and heavily pretreated patients failed to show any improvement in patients treated with tamsulosin (± ciprofloxacin) compared with patients treated with placebo.** A number of meta-analyses and comprehensive reviews of these data recommended that α-adrenergic blockers provided significant symptom amelioration only after more than 6 weeks of therapy in less heavily treated patients with recent onset of moderate to severe symptoms (Mishra et al, 2007; Yang et al, 2006; Nickel, 2008a). **To test this hypothesis, an NIH multicenter, randomized, double-blind, placebo-controlled trial was conducted to evaluate the efficacy of 12 weeks of alfuzosin or placebo to reduce symptoms in 272 randomized men with CP/CPPS diagnosed within 2 years previously and who had not been previously treated with an α-adrenergic blocker** (Nickel et al, 2008a). The rate of the primary outcome (reduction of at least 4 points in NIH-CPSI total score from baseline) was 49% in both treatment groups. The response rates at 12 weeks measured with a global response assessment were also similar, 34% and 35%, for the placebo and alfuzosin groups, respectively ($P = .90$). These important findings did not support the use of α-adrenergic blockers in recently diagnosed α-adrenergic blocker–naive men with CP/CPPS.

Anti-Inflammatory Agents and Immune Modulators

Rationale. Prostatic inflammation is associated with category IIIA CP/CPPS, and elevated cytokine levels are noted in the semen (Alexander et al, 1998; Ruggieri et al, 2000) and EPS (Nadler et al, 2000; Hochreiter et al, 2000b) of patients with inflammatory CPPS. **Nonsteroidal anti-inflammatory drugs, corticosteroids, and immunosuppressive drugs theoretically should improve the inflammatory parameters within the prostate and possibly result in a reduction of symptoms** (Pontari, 2002).

Clinical Trial Data. Canale and associates (1993a) found that nimesulide (a nonsteroidal anti-inflammatory drug) quickly reduced inflammatory-type symptoms such as dysuria, strangury, and painful ejaculation. A second study by Canale's group (1993b) found that, by the rectal route, ketoprofen was inferior to nimesulide (both drugs were used as suppositories). Prednisolone has been suggested as a potent anti-inflammatory for chronic prostatitis (Bates and Talbot, 2000) and a randomized study presented by Dimitrakov and associates (2004) indicates that high-dose methylprednisolone (followed by rapid tapering of dose) may have more efficacy than placebo, even after 12 months, but the side effect profile makes this type of therapy less attractive. A small randomized trial evaluating oral corticosteroids did not show superiority of the active therapy over placebo (Bates et al, 2007).

The new class of cyclooxygenase-2 inhibitors has proved successful for long-term treatment of other chronic inflammatory conditions such as rheumatoid arthritis and chronic osteoarthritis, and many urologists employed these medications for prostatitis patients with some anecdotal successes reported. The results of a North American randomized control trial comparing the cyclooxygenase-2 inhibitor rofecoxib to placebo indicated that many men with CPPS benefited (in terms of pain and quality of life) from rofecoxib therapy compared with placebo. In this study in which 161 patients were randomized to rofecoxib 25 mg, rofecoxib 50 mg, or placebo, only patients on the high dose showed any clinical improvement compared with the placebo. Very few patients, however, had complete resolution of their symptoms (Nickel et al, 2003c). Another study from China (Zeng et al, 2004) assessing the effectiveness of two doses of the cyclooxygenase-2 inhibitor celecoxib also demonstrated a dose-dependent response (200 mg twice a day for 6 weeks was more effective than 200 mg once a day). At this time, high-dose, long-duration therapy with cyclooxygenase-2 inhibitors is not recommended.

Because the clinical and pathologic characteristics are similar to those of interstitial cystitis, Wedren (1987) compared the efficacy of pentosan polysulfate, a glycosaminoglycan drug that has been used in the treatment of interstitial cystitis, with placebo. In this small study the treated group was noted to have a statistically significant improvement in symptoms but the major symptom that improved was nonspecific myalgias and arthralgias. An uncontrolled pilot study evaluating oral pentosan polysulfate in 32 men with CPPS demonstrated amelioration of symptoms and improvement in the quality of life in over 40% after treatment for 6 months (Nickel et al, 2000). The results of a multicenter, randomized, placebo-controlled trial that randomized 100 men to pentosan polysulfate, 900 mg/day (three times the usual dose), or placebo indicated this medication provided modest benefit for some men with CPPS (Nickel et al, 2005b).

Thalidomide, a cytokine modulating drug, was assessed in 30 men with chronic abacterial prostatitis and abnormal semen cytokine levels (IL-2, IL-6, IL-8, IL-10, and TNF-α) in a randomized placebo-controlled trial (Guercini et al, 2005). Despite a significant reduction in cytokine levels in semen, no difference in symptom relief was noted. A similar lack of efficacy was noted in a small placebo-controlled trial evaluating the leukotriene antagonist zafirlukast (Goldmeier et al, 2005).

The potential of various anti-inflammatory agents, immune modulators, and cytokine inhibitors makes these classes of drugs potentially useful as adjunctive therapy for the chronic prostatitis syndromes, but clinical trials suggest that they are not a useful monotherapy.

Muscle Relaxants

Rationale. Many investigators believe that CPPS is the ultimate reflection of a smooth and skeletal neuromuscular dysregulatory phenomenon in the perineum or pelvic floor (Osborn et al, 1981; Egan and Krieger, 1997; Anderson, 1999; Zermann and Schmidt, 1999). **The use of α-blockers to relax smooth muscle** (see earlier discussion of α-adrenergic blockers) **and skeletal muscle relaxants combined with adjuvant medical and physical therapies has been advocated and promoted** (Anderson, 1999; Zerman and Schmidt, 1999).

Clinical Trial Data. In one of the few studies to compare muscle relaxants to placebo, Osborn and associates (1981) conducted a prospective double-blind study comparing phenoxybenzamine, baclofen (a striated muscle relaxant), and placebo in 27 patients with prostatodynia (category IIIB). Patients were treated with each agent for 1 month in a crossover trial. Symptomatic improvement was seen in 37% of the patients treated with baclofen compared with 8% treated with placebo. Simmons and Thin (1985) compared diazepam with an antibiotic in patients with chronic abacterial prostatitis and found no difference in symptom improvement

between the diazepam group (8 of 11 men improved) and the antibiotic group (7 of 12 men improved). Unfortunately **these studies were hindered by a lack of controlled and defined entry criteria and no quantified measurement of patients' responses and therefore the role of muscle relaxants has yet to be determined.**

Hormone Therapy

Rationale. Prostate growth and function are influenced by the local hormonal milieu, especially by androgens. **Theoretically, antiandrogens (including 5α-reductase inhibitors) could result in regression of prostatic glandular tissue (inflammation is believed to begin at the level of the ductal epithelium), improved voiding parameters (especially in older patients with BPH and prostatitis), and reduced intraprostatic ductal reflux** (Nickel, 1999c).

Clinical Trial Data. Holm and Meyhoff (1996) were the first to note that the 5α-reductase inhibitor finasteride had potential in alleviating symptoms by observing the effect of finasteride therapy in 4 patients with chronic prostatitis or prostatodynia. Leskinen and colleagues (1999) randomized 41 patients with chronic idiopathic prostatitis (i.e., nonbacterial prostatitis and prostatodynia) to treatment with placebo (25%, or 10 patients) or finasteride (75%, or 31 patients) for 1 year. Compared with placebo, finasteride reduced prostatitis and BPH symptom scores; however, there was no statistically significant difference in pain between the two groups. The baseline characteristics of the two groups were not comparable, and the enrolled patients consisted of an unknown mixed population with inflammatory and non-inflammatory prostatitis syndromes. A randomized open label comparative trial in CP/CPPS men showed significantly more improvement in men treated for a year with finasteride compared with saw palmetto, an herbal therapy (Kaplan et al, 2004). A randomized controlled trial compared the reduction of NIH-CPSI in 64 men with CP/CPPS randomized to finasteride or placebo (Nickel et al, 2004c). Six months of finasteride resulted in a numerical but not statistically significant reduction in symptoms compared with the symptom reduction noted in the placebo group. **Finasteride cannot be recommended as a monotherapy except perhaps in men with associated BPH.**

Testosterone and dihydrotestosterone are not the only hormones with a possible effect on prostate inflammation; estrogens may also play a role. A number of small, poorly controlled studies (Cavallini, 2001; Saita et al, 2001) suggested that mepartricin (a drug that lowers estrogen levels in the prostate) may be useful in the treatment of CP/CPPS. A small prospectively designed trial randomized 26 men with CP/CPPS to 60 days therapy with mepartricin or placebo (De Rose et al, 2004). The study showed a statistical and perhaps clinically significant benefit (60% vs. 20% improvement, respectively) that should stimulate further research in the role of hormonal manipulation (in this case estrogens) in the treatment of CP/CPPS.

Phytotherapeutic Agents

Rationale. A number of plant extracts have been shown in many in-vitro experiments to have 5α-reductase activity, α-adrenergic blockade activity, effects on bladder contractility, and anti-inflammatory properties (Lowe and Fagelman, 1999; Shoskes, 2002).

Clinical Trial Data. Three specific phytotherapeutic agents have been tested in clinical trials, Cernilton, a pollen extract (Buck et al, 1989; Rugendorff et al, 1993), Quercetin, a natural bioflavonoid (Shoskes et al, 1999) and *Serenoa repens* (saw palmetto berry) extract (Kaplan et al, 2004; Reissigl et al, 2004). Rugendorff and coworkers (1993) noted that over half of 72 patients with chronic prostatitis without other lower urinary tract abnormalities had favorable improvements in pain and irritative voiding symptoms when treated with Cernilton, but no control group was included in this study. A randomized study of pollen extract (Cernilton) in 122 men with category IIIA showed that men on the active treatment had statistically significant improvements in the pain and quality-of-life components of the CPSI (Wagenlehner et al, 2009). A controlled, randomized study of a similar preparation, Prostat/Poltit (grass pollen extract, including rye pollen), in 60 patients showed greater improvement in patients on active therapy compared with placebo but no validated outcome index incorporated into the study design (Elist, 2006). Shoskes and associates (1999) randomized 15 patients to the bioflavonoid Quercetin and 13 patients to placebo for 1 month. Sixty-seven percent of the patients in the treatment group were considered responders compared with only 20% of the patients in the placebo arm. Kaplan and associates (2004) did not note any appreciable long-term improvement in any CP/CPPS parameters when compared with 12 months of finasteride in a randomized open-label comparative study. However, Reissigl and colleagues (2004) reported that there was a moderate/marked improvement in over 60% of 72 CP/CPPS patients after 12 months of therapy with *Serenoa repens* extract compared with less than 25% in the 70 men in the placebo-treated group. However, further follow-up did not support the durability of this therapy (Reissigl et al, 2005). **Phytotherapy for CP/CPPS may look promising but further multicenter randomized controlled trials with well-characterized, standardized, and stable herbal components should be considered to assess their role in therapy.**

Neuromodulator Therapy

Rationale. One proposed mechanism is that CP/CPPS, particularly in chronic cases of long standing, represents a neurogenic pain syndrome and that the subsequent pain is actually a neuropathic pain (Pontari and Ruggieri, 2004). Patients with CP/CPPS have a history of neurologic disease that is almost five times more likely among cases than control subjects (Pontari et al, 2005), and men with CP/CPPS have been found to have abnormalities of both the afferent and efferent autonomic nervous systems (Yang et al, 2003; Yilmaz et al, 2007). This type of neuropathic pain related to central nervous system sensitization responds to gabapentinoids in other chronic pain conditions (Rosenstock et al, 2004; Crofford et al, 2005).

Clinical Trial Data. A recent NIH CPCRN randomized placebo-controlled trial evaluated effect of the gabapentinoid pregabalin on symptoms of men with long-standing, treatment-refractory CP/CPPS (Pontari et al, 2010). Among the 103 men assigned to pregabalin, 47% reported at least a 6-point decrease in total NIH-CPSI score at 6 weeks (primary end point) compared with 35.8% of 106 men assigned to placebo (P = .072). The NIH-CPSI total score decreased by a mean of 6.6 and 4.2 points (of 43) in the pregabalin and placebo groups respectively (P = .008), whereas significantly more men in the pregabalin arm reported they were markedly or moderately improved compared with placebo (31% and 19%, respectively; P = .023). Although 6 weeks of pregabalin therapy was not superior to placebo for treating symptoms of CP/CPPS based on the primary end point, the impressive differences in secondary end points suggest that pregabalin may prove effective in some men with long-standing CP/CPPS.

Allopurinol

Rationale. Persson and Ronquist (1996) theorized that the intraprostatic ductal reflux of urine increases the concentration of metabolites containing purine and pyrimidine bases in the prostatic ducts, causing inflammation.

Clinical Trial Data. Persson and associates (1996) compared allopurinol therapy with placebo in a double-blind controlled study in 54 men. The allopurinol groups had lower levels of serum urate, urine urate, and EPS urate and xanthine. With variations in accepted statistical methodology, the investigators were able to show a difference in the mean patient-reported discomfort score between the study and the control groups at certain times in this trial with 330 days of follow-up. However, a re-examination of the data employing more standardized statistical analyses did not convince other groups that changes in the urine and prostatic secretion of purine and pyrimidine bases resulted in significant amelioration of symptoms in this particular trial (Nickel et al, 1996a). A follow-up randomized clinical trial further showed no advantage of allopurinol compared with placebo (Ziaee et al, 2006).

Prostatic Massage

Prostatic massage has been the principal therapy for prostatitis since the turn of the 20th century (O'Conor, 1936; Campbell, 1957). With the introduction of the scientific approach advocated by Meares and Stamey in 1968, prostatic massage became important only as a diagnostic tool, but as a therapy it was abandoned by urologists. Currently it is regaining some popularity, primarily because of the failure of standard medical therapy in patients with refractory symptoms of chronic prostatitis. Its benefits are believed to arise from draining theoretically occluded prostatic ducts and improving circulation and antibiotic penetration (Hennenfent and Feliciano, 1998). Independent but uncontrolled studies (Nickel et al, 1999a; Shoskes and Zeitlin, 1999) describe clinical benefits in one third to two thirds of patients treated with repetitive prostatic massage (two to three times per week) for 4 to 6 weeks along with antibiotic therapy. However, another trial indicated that prostatic massage does not significantly improve the response of men with CP/CPPS treated with antibiotics (Ateya et al, 2006). It appears that some patients may improve with prostatic massage, but a panel of North American "prostatitis experts" (Nickel et al, 1999) could not come to a consensus on the potential overall benefit or even the mechanism of achieving that benefit if it does occur. **A subsequent systematic review of the literature concluded that evidence for a role of repetitive prostatic massage as an adjunct in the management of chronic prostatitis is at most "soft" but could be considered as part of multimodal therapy in selected patients** (Mishra et al, 2008). Frequent ejaculation may achieve the same function as prostatic massage (Yavascaoglu et al, 1999).

Perineal or Pelvic Floor Massage and Myofascial Trigger Point Release

Most clinicians recognize that men with prostatitis syndromes, especially the noninflammatory category or prostatodynia, have specific anatomic areas that cause discomfort. Anderson (1999) believes that prolonged or chronic tension, distention, or distortion in the muscle bands (e.g., in the perineum) leads to a painful trigger point that is responsible for the pain. Predisposing factors leading to the formation of myofascial trigger points in the perineum or pelvis may include mechanical abnormalities in the hip and lower extremities, chronic urinary holding patterns (dysfunctional toilet training), sexual abuse, repetitive minor trauma, constipation, trauma, unusual sexual activity, recurrent infections or surgery, and perhaps stress and anxiety. Treatment of these trigger points includes heat therapy, physiotherapy massage, ischemic compression, stretching, anesthetic injections, acupuncture, electroneural modulation, and mind-body interactions such as progressive relaxation exercises, yoga, and hypnosis (Potts, 2003). Anderson and associates (2005) report that employing these techniques with a team consisting of a urologist, physiotherapist, and psychologist results in more than half of patients having or demonstrating a clinically detectable improvement. A case study analysis indicates that this may be an effective therapeutic approach in some patients (Anderson et al, 2005) and may result in improvement not just in pain but also in sexual function (Anderson et al, 2006). A recently reported NIH pilot study of men and women with chronic pelvic pain treated with either relaxation massage or specific pelvic massage therapy demonstrated improvement in women but could not corroborate these findings in men (Peters K, presented at AUA annual meeting, May 19, 2008).

Pudendal Nerve Entrapment Therapy

It has been hypothesized that the symptoms of CPPS could be caused by entrapment of the pudendal nerve, perhaps between the sacrotuberous and sacrospinous ligaments, in the canal of Alcock or by the falciform process of the sacrotuberous ligament (Robert et al, 1998). Pudendal nerve blocks (Thoumas et al, 1999; McDonald and Spigos, 2000; Peng and Tumber, 2008) and neurolysis surgery (Robert et al, 1993; Mauillon et al, 1999) have been suggested for treatment. The role of the pudendal nerve in chronic perineal pain deserves more scientific scrutiny.

Biofeedback

It is possible that the voiding and pain symptoms associated with CP/CPPS may be secondary to some form of pseudodyssynergia during voiding or repetitive perineal muscle spasm; biofeedback has the potential to improve this process. Kaplan and associates (1997), Nadler (2002), Ye and colleagues (2003), and Cornel and coworkers (2005) have demonstrated in small uncontrolled studies that biofeedback does ameliorate specific prostatitis-like symptoms in some men. Controlled clinical trials will be necessary to evaluate this mode of therapy.

Acupuncture

Acupuncture is an accepted traditional Chinese therapy for chronic pain, including prostatitis (Ge et al, 1988; Katai, 1992; Ikeuchi and Iguchi, 1994). Chen and Nickel (2003) determined in a pilot study of 12 treatment-refractory men that acupuncture was safe and provided effective and durable symptom improvement. A subsequent study comparing 10 weeks of acupuncture versus sham acupuncture treatment indicated that the active acupuncture proved to be almost twice as likely as sham treatment to improve CP/CPPS symptoms (Lee et al, 2008).

Psychological Support

Data from the NIH Prostatitis Cohort (Tripp et al, 2005, 2006; Nickel et al, 2008b) support a biopsychosocial model that associates the chronic pain and poor quality of life of CP/CPPS with depression and suggests that physicians may be able to advise patients to avoid certain pain coping strategies that can be associated with greater depression. Nickel and colleagues (2008) have developed an evidence-based cognitive behavioral treatment

program for men with CP/CPPS. This program specifically targets empirically supported biopsychosocial variables (e.g., pain catastrophizing, depressive thinking, social support) and encourages patients to critically evaluate their patterns of thinking and to entertain novel thinking and behavioral responses to their troublesome symptoms, with an end objective to improve overall quality of life.

Studies also show that the maladaptive pain coping technique of employing "pain contingent resting" (using rest rather than more active behaviors to control pain) is reported by CP/CPPS patients in response to their pain (Tripp et al, 2006; Nickel et al, 2008b). It was suggested by Tripp and coworkers (2006) that such sedentary behaviors in the presence of pain may be associated with elevated disability in men with CP/CPPS. A double-blind randomized study showed that men participating in aerobic exercise were significantly better than those who were randomized to stretching and motion exercise, suggesting that increased physical activity is a valid option in men with CP/CPPS (Giubilei et al, 2007). The results of a study examining perceived helpfulness of medical and self-management strategies suggested that clinicians may find it useful to support patients' use of safe, inexpensive, self-management approaches, such as warm baths, increased water intake, exercise, and avoidance of prolonged sitting (Turner et al, 2006).

Minimally Invasive Therapies

Balloon Dilatation. Lapatin and coworkers (1990) employed balloon dilatation in an uncontrolled trial of seven patients with nonbacterial prostatitis and prostatodynia and showed improvement in voiding symptoms during a 1- to 5-month follow-up. Pain and discomfort were not assessed. This treatment effect has never been substantiated, and balloon dilatation has not been routinely employed in clinical practice. Suzuki and coworkers (1995) combined the potential beneficial effects of balloon dilatation with prostatic hyperthermia in five men with CP/CPPS and demonstrated significant improvement in symptoms in one patient and partial improvement in three. Nickel and associates (1998b) were not able to duplicate this beneficial effect in a small pilot trial evaluating the "hot balloon" (heating by radiofrequency energy rather than laser energy).

Transurethral Needle Ablation. Chiang and associates (1997) employed transurethral needle ablation (TUNA) of the prostate in 7 patients with chronic nonbacterial prostatitis, assessed the patients before and after therapy (6 months of follow-up) employing a modification of the Symptom Severity Index (Nickel and Sorensen, 1996b), and reported favorable results in 4. A follow-up study by Chiang and Chiang (2004) showed significant improvement in symptoms in the majority of 32 patients treated with TUNA. But Leskinen and colleagues (2002) investigated the effectiveness and durability of TUNA in 25 patients randomized to TUNA and 8 patients randomized to sham treatment and they reported that the efficacy of TUNA in CP/CPPS is comparable to sham treatment and so could not recommend TUNA as therapy for CP/CPPS.

Other Minimally Invasive Surgeries. Serel and colleagues (1997) reported significantly meaningful beneficial effects in 30 patients with chronic abacterial prostatitis and prostatodynia employing the neodymium:yttrium-aluminum-garnet laser. Ruedi and associates (2003) suggested that high-frequency electrostimulation may be harnessed to treat chronic prostatitis. A number of other minimally invasive treatments have been examined in small pilot studies. These include pelvic and sacral electromagnetic therapy (Leippold et al, 2005; Rowe et al, 2005), extracorporeal shockwave therapy (Zimmerman et al, 2008), and injection of botulinum toxin directly into the prostate (Chuang and Chancellor, 2006).

Sham control trials will be required before minimally invasive surgery can be recommended as a treatment for CP/CPPS.

Microwave Hyperthermia and Thermotherapy. It is believed that the heat applied to the prostate gland by the microwave process could shorten the natural resolution of the inflammatory process, perhaps by accelerating the process of fibrosis or scar formation in the area of chronic inflammation. In addition, heat therapy, particularly with the higher temperatures achieved with transurethral microwave thermotherapy, could alter the afferent nerve fibers that convey the objective symptom of pain from the inflamed prostate gland (intraprostatic sympathectomy) (Perachino et al, 1993). It may even be possible that the microwave energy kills nonculturable or cryptic bacteria within the prostate gland (Sahin et al, 1998).

Although many uncontrolled trials employing heat therapy have shown benefit (Nickel, 1999d; Zeitlin, 2002), only three published studies have used sham controls. Vassily and associates (1999) noted symptom improvement in 75% of men in a transrectal microwave hyperthermia-treated group compared with 52% of men in the sham-treated group. Shaw and colleagues (1993) documented treatment success (defined as a greater than 50% improvement in symptoms) in 55% of the men in a transrectal microwave hyperthermia group (15 patients) compared with 10% of patients treated with sham therapy (13 patients) at 3 months. Nickel and Sorensen (1996b) examined the safety and efficacy of transurethral microwave thermotherapy in 20 men randomized to therapy or sham. At 3 months' follow-up, the transurethral microwave thermotherapy–treated patients had significantly improved symptom scores compared with sham-treated patients (7 of 10 men treated with transurethral microwave thermotherapy had a favorable result compared with 1 of 10 men treated with a sham therapy). A recently reported study in men with CP/CPPS treated with cooled transurethral microwave thermotherapy using the NIH-CPSI as an outcome (Kastner et al, 2004) again suggested that thermotherapy remains a promising treatment for intractable chronic prostatitis, particularly when it is associated with concomitant BPH. Although this prospective study showed a significant reduction in NIH-CPSI score compared with baseline in 35 men followed for 12 months, it was not a randomized sham controlled trial. **Heat therapy appears to be a promising therapeutic approach but, until larger-scale studies are performed, should be restricted to patients with refractory or end-stage symptoms.**

Surgery

In acute bacterial prostatitis (category I), urinary obstruction is a very common symptom. Traditionally, it has been suggested that the insertion of a suprapubic cystotomy tube is the optimal therapy because an indwelling Foley catheter may further obstruct urethral ducts, resulting in the potential to develop prostate abscesses (Dajani and O'Flynn, 1968; Pai and Baht, 1972; Weinberger et al, 1988). **In most patients, however, an in-and-out catheterization to relieve the initial obstruction or short-term (12 hours) indwelling catheterization with a small-caliber Foley catheter is appropriate. A developing prostate abscess, best detected with transrectal ultrasonography or computed tomography** (Rovik and Doehlin, 1989), **in patients who fail to respond quickly to antibiotics is optimally drained by the transurethral incision route** (Pai and Baht, 1972). **However, transperineal incision**

and drainage (Granados et al, 1992) **must be considered when the abscess has penetrated beyond the prostatic capsule or penetrated through the levator ani muscle. More recently it has been suggested that percutaneous drainage of the abscess is the most effective and less morbid procedure** (Varkarakis et al, 2004).

Surgery does not have an important role in the treatment of most chronic prostatitis syndromes unless a specific indication is discovered during the evaluation of the patient (Kirby, 1999). These indications are usually noted during specific and ancillary investigations such as cystoscopy, transrectal ultrasonography, urodynamics, or computed tomography/magnetic resonance imaging. Certainly, patients with urethral strictures benefit from surgical correction. Kaplan and associates (1994) have suggested that men with chronic nonbacterial prostatitis-like symptoms and urodynamic evidence of vesical neck obstruction benefit from endoscopic incision of the bladder neck.

Seminal vesicle abscesses can be managed with antibiotic therapy, transrectal aspiration, and, if necessary, an operation to remove the seminal vesicles. Traditionally seminal vesiculectomy was performed as a difficult open procedure, but recently laparoscopic excision of the seminal vesicles was reported to be the least morbid procedure (Nadler and Rubenstein, 2001).

Radical transurethral resection of the prostate (Barnes et al, 1982; Sant et al, 1984) has been advocated in patients who have either relapsing or refractory chronic bacterial prostatitis (category II) secondary to bacterial persistence within the prostate gland. Although prostatic calculi are not pathognomonic of prostatitis (Harada et al, 1980), it has been clearly shown that bacteria can persist in protective biofilms or aggregates within the interstices or on the surface of the calculus material (Meares, 1974; Nickel et al, 1994). Theoretically, removal of all the infected material, including potentially infected calculi, can be achieved (with appropriate intraoperative radiographs or ultrasound studies), but except for small anecdotal case series (Barnes et al, 1982; Sant et al, 1984) there is no substantial proof in the literature as to the efficacy of major prostate surgery in category II chronic prostatitis. Radical transurethral resection of the prostate has not been advocated for category III CP/CPPS, but open radical prostatectomy has been shown anecdotally to benefit a few patients with symptoms of nonbacterial prostatitis or prostatodynia or both (Davis and Weigel, 1990; Frazier et al, 1992). **No definitive clinical series or long-term follow-up has ever been presented, and this type of surgery should not be encouraged or recommended at this time.**

Treatment Summary

Acute bacterial prostatitis is relatively simple to treat; eradicate the bacteria with appropriate antibiotic therapy. The objective for chronic bacterial prostatitis is similar—eradication of bacteria, but long-term symptom amelioration sometimes eludes us. Our standard therapies for CP/CPPS, when used as monotherapy, offer only modest improvement in symptoms (Nickel et al, 2004a; Nickel, 2008b). Multimodal therapy employing multiple concurrent treatment strategies may offer the best results at this time (Shoskes et al, 2003; Shoskes and Katz, 2005). However, a number of well-controlled prospective studies did not demonstrate increased efficacy by combining α-adrenergic blockers and antibiotics (Alexander et al, 2004) or α-adrenergic blockers and anti-inflammatory agents (Batstone et al, 2005). The explanation for this difficulty in treating chronic prostatitis may be that the patients become peripherally and centrally sensitized and that treatment targeted to the initiators of the process may not work as well when the condition becomes chronic (Yang et al, 2003; Pontari and Ruggieri, 2004; Pontari, 2007). Table 11–4 is a list of the various standard medical therapies that are currently recommended. Further investigations should focus not only on the mechanisms inducing the symptoms, including the pain, but also on the mechanisms maintaining the pain.

To evaluate and compare the many clinical trials assessing the various therapies advocated for CP/CPPS it is important to clearly define and classify the patient population (NIH classification system), determine results by employing a standardized outcome index (NIH-CPSI), prospectively compare a treated group to a similar group randomized to placebo, and fulfill the requirements of peer review for publication in a reputable journal (Nickel et al, 1999c; Propert et al, 2002). **In the past several years the results of a significant number of such trials have been published** (Nickel, 2004, 2008a; Schaeffer, 2006), **allowing the reader to assess and compare the efficacy of antibiotics, α-adrenergic blockers, anti-inflammatory agents, phytotherapies, and hormonal agents in CP/CPPS** (Table 11–5). A suggested treatment algorithm based on these assessments is presented in Figure 11–8.

Key Points: Therapy

- The following medical therapies have been evaluated in standardized randomized placebo controlled trials in CPPS: antibiotics, α-adrenergic blockers, anti-inflammatory agents, hormonal therapies, phytotherapies, and pregabalin.
- The following medical therapies have shown benefits in placebo- or sham-controlled studies in CPPS: marked benefit—none; moderate benefit in some selected trials—α-adrenergic blockers and pregabalin; and modest benefit—anti-inflammatory agents and phytotherapies.

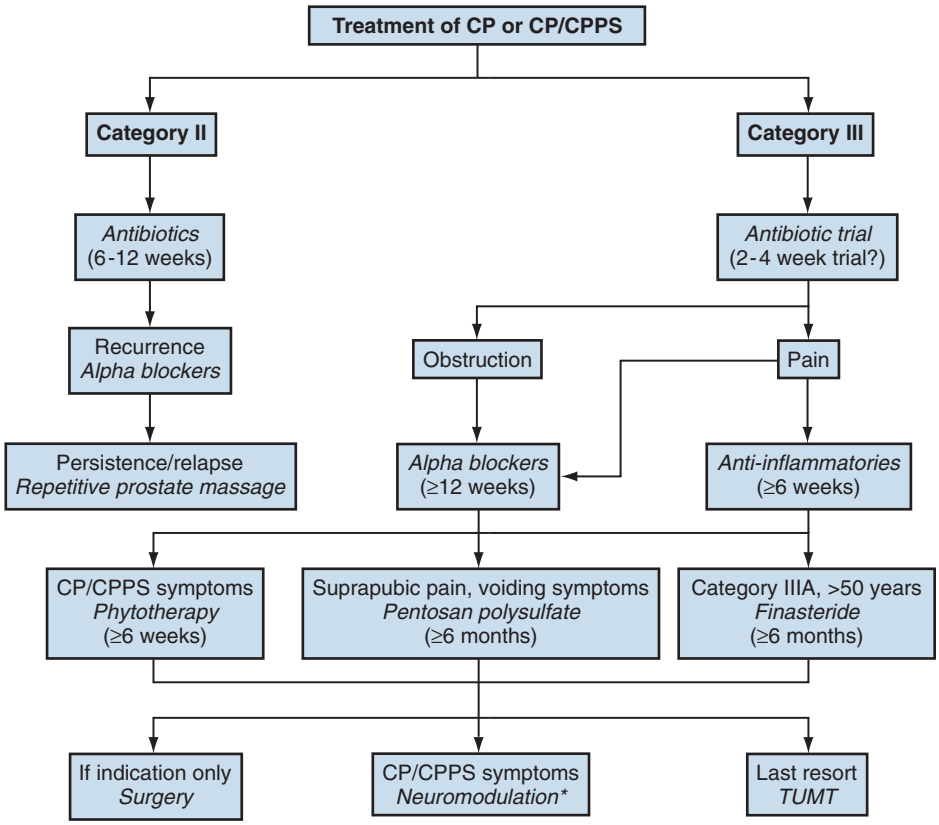
Phenotypic Approach to Pelvic Pain (PAPP): UPOINT Management of CP/CPPS

Many clinicians dedicated to practicing an evidence-based approach to managing patients with CP/CPPS have become frustrated. Many of the traditional and new promising therapies that appear to work in real-life clinical practice fail to show significant efficacy when subjected to large randomized placebo-controlled trials (Schaeffer, 2006; Nickel, 2008b). Only recently have we become aware that patients with urologic chronic pelvic pain syndromes, such as CP/CPPS, are not a homogeneous group of patients with identical etiologic mechanisms, genitourinary pain, voiding symptoms, and/or psychosexual problems but rather a heterogeneous group of individual patients with widely differing clinical phenotypes. This realization has led the NIH to fund the Multidisciplinary Approach to Pelvic Pain (MAPP) study group to explore basic science (particularly biomarker and etiologic studies) and epidemiology to better understand the differences in this very heterogeneous group of patients. It is hoped that "phenotyping" patients may explain our very inconsistent therapeutic results and that the concept eventually may be applicable to direct better management strategies.

Table 11–4.

Suggested Medical Therapy for CP/CPPS

DRUG CLASS	SPECIFIC THERAPY	DOSE	DURATION OF THERAPY (wk)	EVIDENCE
Antibiotics	TMP-SMX	160/800 mg bid	12	See Table 11–3 for summary of clinical trial data.
	Norfloxacin	400 mg bid	4-12	
	Ciprofloxacin	500 mg bid	4-12	
	Ofloxacin	300 mg bid	4-12	
	Lomefloxacin	400 mg qd	4-12	
	Levofloxacin	500 mg qd	4-12	
α-Adrenergic blockers	Terazosin	5 mg qd	>14	Cheah et al, 2003
	Alfuzosin	10 mg qd	>12	Mehik et al, 2003 Nickel et al, 2008a
	Tamsulosin	0.4 mg qd	>6	Nickel et al, 2004b Alexander et al, 2004
Phytotherapy	Pollen extract	1 tab tid	24	Buck et al, 1989 Rugendorff et al, 1993
	Quercetin	500 mg bid	4	Shoskes et al, 1999
	Saw palmetto	150 mg qd	24	Reissigl et al, 2004
Anti-inflammatory agents	Nimesulide	100 mg bid	2-4	Canale et al, 1993a
	Rofecoxib	25-50 mg qd	>6	Nickel et al, 2003
	Other NSAIDs Indomethacin Diclofenac Ibuprofen	Various	2-4	Evans, 1999
	Pentosan polysulfate	100 mg tid	24	Wedren, 1987 Nickel et al, 1999 Nickel et al, 2005
Hormonal agents	Finasteride	5 mg qd	24	Leskinen et al, 1999 Nickel et al, 2004
	Mepartricin	40 mg qd	8	De Rose et al, 2004
Gabapentinoids	Pregabalin	50-100 mg tid	6	Pontari et al, 2010



TMP-SMX, trimethoprim-sulfamethoxazole.

Table 11–5.

Clinical Trials Evaluating Therapy for CP/CPPS That Met the Evidence-Based Criteria Established by Nickel (see text)

			Patients (n)		Responders (%)		Change in NIH-CPSI		TREATMENT
ACTIVE AGENT	REFERENCE	DURATION	ACTIVE	PLACEBO	ACTIVE	PLACEBO	ACTIVE	PLACEBO	EFFECT
Levofloxacin	Nickel et al, 2003	6 wk	35	45	42	37	–5.4	–2.9	2.5
Terazosin	Cheah et al, 2003	14 wk	43	43	NK	NK	–14.3*	–10.2	4.1
Alfuzosin	Mehik et al, 2003	24 wk	17	20	65*	24	–9.9*	–3.8	6.1
Tamsulosin	Nickel et al, 2004a	6 wk	27	30	52	33	–9.1*	–5.5	3.6
Ciprofloxacin	Alexander et al, 2004	6 wk	49	49	22	22	–6.2	–3.4	2.8
Tamsulosin			49		24		–4.4		1.0
Tamsulosin + Ciprofloxacin			49		10		–4.1		0.7
Alfuzosin	Nickel et al, 2008b	12 wk	138	134	49.3† 34.8‡	49.3† 33.6‡	–7.1	–6.5	0.6
Rofecoxcib 25 mg	Nickel et al, 2003	6 wk	53	59	46	40	–4.9	–4.2	0.7
Rofecoxib 50 mg	Nickel et al, 2003	6 wk	49	59	63*	40	–6.2	–4.2	2.0
Pentosan polysulfate	Nickel et al, 2005	16 wk	51	49	37	18	–5.9	–3.2	2.7
Finasteride	Nickel et al, 2004	24 wk	33	31	33	16	–3.0	–0.8	2.2
Mepartricin	de Rose et al, 2004	8 wk	13	13	NK	NK	–15.0	–5.0	10.0
Quercetin	Shoskes et al, 1999	4 wk	15	13	67*	20	–7.9*	–1.4	6.5
Pregabalin	Pontari et al, 2010	6 wk	103	106	47.2† (31*)‡	35.8† (19)‡	–6.6*	–4.2	2.4

*Significant difference between active and placebo ($P < .05$).
†Primary end point (CPSI responders—see text).
‡Global Response Assessment responders.
NK, not known.

*Amitriptyline, gabapentin, biofeedback, massage therapy, acupuncture, neurostimulation.

Figure 11–8. A suggested therapeutic algorithm for the treatment of patients presenting with CP/CPPS. TUMT, transurethral microwave thermotherapy.

There are a number of reasons why the majority of randomized placebo-controlled trials reported in the literature and this chapter have been "negative," making it difficult to develop evidence-based management guidelines. The first reason is because treatments based on a single etiologic mechanism are doomed to fail when tested in the whole CP/CPPS population. As discussed earlier under Etiology, most of the mechanisms examined are based on sound scientific theory and all are associated with at least some confirmatory clinical data. We must accept that there is no one all encompassing etiologic mechanism responsible for all cases of CP/CPPS. In addition, we cannot be sure that the patients we routinely manage in clinical practice are the same patients who have been enrolled in clinical trials. In fact, the most rigorously designed NIH-sponsored randomized controlled trials (Alexander et al, 2004; Nickel et al, 2008a; Pontari et al, 2010) did not enroll over 90% of the CP/CPPS patients who were screened. Finally, were the negative trials reported in the literature and this chapter really negative? A reappraisal of the study results would suggest otherwise. Table 11–6 outlines such a reappraisal of results in "negative" studies in CPPS. Antibiotics tended to work better in less chronic heavily pretreated patients (marginally significant improvement in levofloxacin trial) (Nickel et al, 2003b) compared with ciprofloxacin trial (Alexander et al, 2004), further substantiated by the 75% improvement seen using ciprofloxacin or levofloxacin treatment in patients with very early (4 to 8 weeks of symptoms associated with that particular episode) presentation (Nickel and Xiang, 2008). Whereas large NIH-sponsored multicenter studies failed to confirm the benefits of α-adrenergic blockers in both chronic heavily pretreated (Alexander et al, 2004) and recently diagnosed α-adrenergic blocker–naive (Nickel et al, 2008a) CP/CPPS patients, at least four other randomized controlled trials (Cheah et al, 2003; Mehik et al, 2003; Nickel et al, 2004b; Tugcu et al, 2007) with less rigorous selection criteria did show significant efficacy with α-adrenergic blockers. Although trials examining anti-inflammatory agents (Nickel et al, 2004c), pentosan polysulfate (Nickel et al, 2005b), finasteride (Nickel et al, 2004c), and pregabalin (Pontari et al, 2010) were considered negative trials based on the primary end point analysis, these trials showed efficacy for many of the validated outcomes (including responder analyses employing the validated subjective global or global response assessment scale) of statistical (Nickel et al, 2003c; Nickel et al, 2005b; Pontari et al, 2010) or marginal significance (Nickel et al, 2004c) (see Table 11–6 for details). So what do all these seemingly negative trials mean to physicians treating CP/CPPS? It is very likely that we will never discover a single overall cure for all patients diagnosed with this condition. This reevaluation of trial results, however, strongly suggests that some patients do, in fact, respond to these various therapies. We must be able to identify patients who may respond to specific therapies.

A clinically practical phenotyping classification system for patients diagnosed with urologic chronic pelvic pain syndromes (CP/CPPS and Interstitial Cystitis) has been proposed (Shoskes et al, 2009a, 2009b). **UPOINT is a 6-point clinical classification system that categorizes the phenotype of patients with UCPPS into one or more of six clinically identifiable domains: *U*rinary, *P*sychosocial, *O*rgan-Specific, *I*nfection, *N*eurologic/Systemic, and *T*enderness (muscle)** (Fig. 11–9). It has been suggested that UPOINT will be a new clinical tool for urologists to use to direct individually based therapy. UPOINT has been evaluated and validated in female interstitial cystitis (Nickel et al, 2009) and male CP/CPPS (Shoskes et al, 2009). For both of these urologic chronic pelvic pain conditions

Table 11–6.

"Negative" Randomized Placebo-Controlled Treatment Trials in CP/CPPS*

INTERVENTION	REFERENCE	PRIMARY OUTCOME (*P* NONSIGNIFICANT)	ALTERNATIVE INTERPRETATION
Ciprofloxacin	Alexander et al, 2004	Mean NIH-CPSI score	2 × 2 factorial design has limitations Cohort was heavily pretreated and long duration Other studies show benefit†
Levofloxacin	Nickel et al, 2001	Mean NIH-CPSI score	Less heavily pretreated cohort Significant benefit at 3 wk Marginally significant benefit at 6 wk (*P* = .06) Other studies show benefit†
Rofecoxib	Nickel et al, 2004c	Pain severity (0-10 scale)	Significant benefit at 50-mg dose for secondary outcome (SGA)
Tamsulosin	Alexander et al, 2004	Mean NIH-CPSI score	2 × 2 factorial design has limitations Cohort was heavily pretreated and long duration Other trials show benefit‡
Alfuzosin	Nickel et al, 2008a	4-point decrease in NIH-CPSI	α-Adrenergic blocker nave, recently diagnosed Other trials show benefit‡
Finasteride	Nickel et al, 2004c	SGA	Marginally significant benefit (*P* = .06) for primary and secondary outcome
Pentosan polysulfate	Nickel et al, 2005b	SGA numeric score	Significant benefit for secondary outcome (percentage of SGA responders)
Pregabalin	Pontari et al, 2010	6-point decrease in NIH-CPSI	Significant benefit seen for all important secondary outcomes (GRA, total and subscore NIH-CPSI, pain questionnaire)

*An alternative interpretation that suggests there may be subgroups of patients who benefit from the tested intervention.
†Other studies showed benefit with earlier intervention (see text for details).
‡Four other trials with less rigorous enrollment criteria showed benefit (see text for details).
NIH-CPSI, National Institutes of Health Chronic Prostatitis Symptom Index; SGA, Subjective Global Assessment; GRA, Global Response Assessment. (SGA and GRA are essentially the same index.)

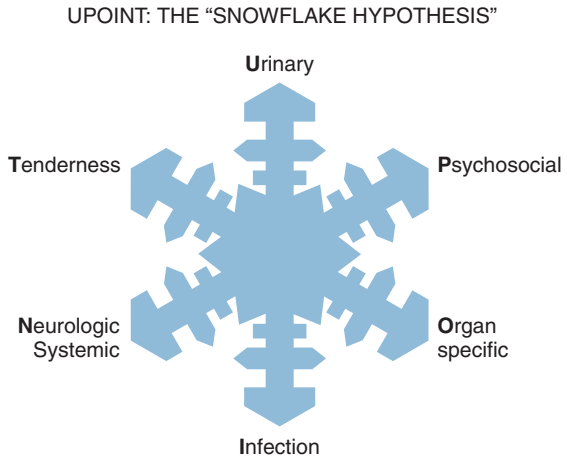


Figure 11–9. The UPOINT phenotypic classification system has six clinically defined domains (*U*rinary, *P*sychosocial, *O*rgan Specific, *I*nfection, *N*eurologic/Systemic, and *T*enderness). Because each individual patient presents with a unique phenotype, the six-point UPOINT system has been called the "snowflake hypothesis."

each domain has been clinically defined using standard clinical assessment, linked to specific mechanisms of symptom production or propagation, and associated with specific therapy (criteria for inclusion in the specific CP/CPPS domains are listed in Table 11–7).

In one study researchers determined the phenotype of a cohort of men with documented CP/CPPS using the UPOINT system and assessed the frequency of individual domains and their effect on symptom severity (Shoskes et al, 2009). The percentage of patients positive for each domain was 52%, 34%, 61%, 16%, 37%, and 53% for the urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness domains, respectively. Only 22% were positive for only one domain, and a significant stepwise increase was found in the total CPSI score as the number of positive domains increased (in other words, symptom severity was associated with the number of identified domains). As symptom duration increased, so did the number of positive domains (suggesting a phenotype progression). The domains with the most significant effect on symptoms included the urinary, psychosocial, organ-specific, and neurologic/systemic domains. For pain, the psychosocial, neurologic/systemic, and tenderness domains had significantly greater scores, whereas only the psychosocial and neurologic/systemic domains influenced the patients' quality of life. This suggests that domains active outside the pelvis may have the most profound effect on symptoms and quality of life. It is postulated that identifying and managing these phenotypic domains may result in more effective amelioration of CP/CPPS symptoms and greater improvement in quality of life. Based on best available evidence to date, suggested treatment regimens based on this new clinical phenotyping strategy are presented in Table 11–7. The author and his colleagues are currently developing and testing a specific questionnaire that will provide urologists with a clinical instrument to identify the six major phenotypes but also the subclassifications that will likely be relevant within each specific domain. A better understanding of etiology, mechanisms of disease, and disease progression and the discovery of specific biomarkers that will allow better phenotype identification will further improve management of CP/CPPS.

Table 11–7.

Phenotypic Approach to Pelvic Pain (PAPP): UPOINT Classification and Directed Therapy for CP/CPPS

UPOINT DOMAIN	CLINICAL CRITERIA	POSSIBLE THERAPY*
Urinary	Bothersome urgency, frequency, and/or nocturia Increased postvoid residual urine Dysuria	Diet modification α-Adrenergic blockers Pyridium Anticholinergic agents
Psychosocial	Depression Maladaptive coping Social dysfunction Stress Anxiety	Cognitive behavioral therapy Counseling Antidepressants Antianxiolytics
Organ specific	Specific prostate tenderness Leukocytosis in prostate specimens Hematospermia Extensive prostate calcification Lower urinary tract obstruction	Quercetin α-Adrenergic blockers Prostate massage Surgery
Infection	Exclude patients with clinical category I or II prostatitis† Gram-negative bacilli or enterococci in prostate-specific specimens History of previous resolution with antibiotics	Antibiotics
Neurologic/Systemic	Pain beyond abdomen and pelvis Associated medical conditions such as irritable bowel syndrome, fibromyalgia, etc.	Gabapentinoids Amitriptyline Neuromodulation
Tenderness (of skeletal muscles)	Palpable tenderness, painful spasm or trigger points in pelvis or abdomen	Physiotherapy Muscle relaxants Exercises

*Therapies listed are not necessarily evidence based but suggested on best-available evidence, interpretation of clinical trial data, and clinical experience. Therapies should be targeted against specific symptom or clinical assessment within a particular phenotype. Some treatments will be effective only in a subcategory of a specific phenotype and not effective in others.

†This category does not include category II chronic bacterial prostatitis patients, defined as men with recurrent urinary tract infections (usually same organism) with identical organism identified in prostate-specific specimens between episodes of infection (see text). These patients have the requirements for inclusion in the category III CP/CPPS: genitourinary and/or pelvic pain with no history of recurrent urinary tract infections.

Key Points: Phenotypic Management of CP/CPPS

- UPOINT classification of CP/CPPS patients allows better descriptions of individual phenotypes.
- Specific multimodal therapy directed at individual UPOINT phenotypes may result in better management outcomes.

ORCHITIS

Definition and Classification

By definition, orchitis is inflammation of the testis, but the term has been used to describe testicular pain localized to the testis without objective evidence of inflammation. Acute orchitis represents sudden occurrence of pain and swelling of the testis associated with acute inflammation of that testis. **Chronic orchitis** involves inflammation and pain in the testis, usually without swelling, persisting for more than 6 weeks. A classification (Nickel and Beiko, 2001) based on etiology is presented in Table 11–8.

Table 11–8.

Classification of Orchitis

Acute bacterial orchitis
Secondary to urinary tract infection
Secondary to sexually transmitted disease
Nonbacterial infectious orchitis
Viral
Fungal
Parasitic
Rickettsial
Noninfectious orchitis
Idiopathic
Traumatic
Autoimmune
Chronic orchitis
Chronic orchialgia

Pathogenesis and Etiology

Isolated orchitis is a relatively rare condition and is usually viral in origin. It spreads to the testis by a hematogenous route. Most cases of orchitis, particularly bacterial, occur secondary to local spread of an ipsilateral epididymitis and are referred to as *epididymo-orchitis*. UTIs are usually the underlying source in boys and elderly men. In young sexually active men, sexually transmitted diseases are often responsible (Berger, 1998). Truly noninfectious orchitis is often idiopathic or related to trauma, although autoimmune disease has rarely been implicated (Pannek and Haupt, 1997). It may be impossible to clinically distinguish chronic orchitis from chronic orchialgia.

Bacterial orchitis is usually associated with epididymitis and is therefore often caused by urinary pathogens, including *E. coli* and *Pseudomonas*. Less commonly, *Staphylococcus* species or

Streptococcus species are responsible. The most common sexually transmitted microorganisms responsible are *Neisseria gonorrhoeae, C. trachomatis,* and *Treponema pallidum*. Xanthogranulomatous orchitis, usually associated with *Proteus* and *E. coli*, is an extremely rare inflammatory destructive lesion of the testes that is treated with orchiectomy (Kang et al, 2007; Al-Said et al, 2007).

Mycobacterial infections, tuberculosis (Chen et al, 2004; Park et al, 2008), and bacillus Calmette-Guérin therapy (Hill et al, 2008) can also cause orchitis. The most common cause of **viral orchitis** is mumps (Jalal et al, 2004; Masarani et al, 2006; Emerson et al, 2007), but infectious mononucleosis has also been implicated (Weiner, 1997). **Fungal infections** occasionally involve the testis, with candidiasis, aspergillosis, histoplasmosis, coccidiomycosis, blastomycosis, and actinomycosis all having been reported as causes of orchitis (Wise, 1998). **Parasitic infections** rarely cause orchitis in the Western Hemisphere, but filariasis (Hazen Smith and von Lichtenberg, 1998) and trypanosomiasis (Ehrhardt et al, 2006) have been described in some endemic areas of Africa, Asia, and South America.

Diagnosis

In patients presenting with **acute infectious orchitis,** history discloses a recent onset of testicular pain, often associated with abdominal discomfort, nausea, and vomiting. These symptoms may be preceded by symptoms of parotitis in boys or young men, by UTIs in boys or elderly men, or alternatively by symptoms of a sexually transmitted disease in sexually active men. Although the process is usually unilateral, it is sometimes bilateral, especially if viral. Physical examination may reveal a toxic and febrile patient. The skin of the involved hemiscrotum is erythematous and edematous, and the testis is quite tender to palpation or can be associated with a transilluminating hydrocele. The patient should be clinically assessed for prostatitis and urethritis. For acute noninfectious orchitis the clinical picture resembles the just-presented description except that these patients lack the toxic appearance and fever.

For **chronic orchitis and orchialgia** there may have been a history of previous episodes of testicular pain, usually secondary to acute bacterial orchitis, trauma, or other causes. The patient has chronic testicular (and possibly epididymal) pain to a degree that could seriously affect his day-to-day functioning and quality of life. Patients with this diagnosis usually become very frustrated with this problem. On examination the patient does not appear toxic and does not have a fever. The scrotum is not usually erythematous, but the testis may be somewhat indurated and is almost always tender to palpation.

Laboratory tests employed to assist in the diagnosis include urinalysis, urine microscopy, and urine culture. For a patient in whom a sexually transmitted disease is suspected, a urethral swab should also be taken for culture. If the diagnosis is not evident from the history, physical examination, and these simple tests, scrotal ultrasonography should be performed (to rule out malignancy in patients with chronic orchitis/orchialgia). The most important differential diagnosis in young men and boys is testicular torsion. Testicular torsion is often difficult to differentiate from an acute inflammatory condition. Scrotal ultrasound evaluations (with use of Doppler imaging to determine testicular blood flow) are especially helpful in differential diagnosis (Mernagh et al, 2004; Gunther et al, 2006), but occasionally the diagnosis will be missed (particularly with intermittent or partial torsion) and the clinician should err in favor of the surgically correctable diagnosis of torsion.

Treatment

General principles of therapy include bed rest, scrotal support, hydration, antipyretics, anti-inflammatory agents, and analgesics. **Antibiotic therapy** (specific for UTI, prostatitis, or sexually transmitted diseases) should be employed for infectious orchitis and is ideally based on culture and sensitivity testing but may be based on microscopic or Gram stain results. There are no specific antiviral agents available to treat orchitis caused by mumps, and the previously mentioned supportive measures are important. If early testing is negative or results are unavailable, empirical treatment should be initiated, directed at the most likely pathogens based on the available clinical information: a fluoroquinolone would be the best agent in this scenario. Most patients can be readily managed on an outpatient basis. Surgical intervention is rarely indicated, unless testicular torsion (or rarely xanthogranulomatous orchitis) is suspected (as discussed previously). Spermatic cord blocks with injection of a local anesthetic may sometimes be needed to relieve the patient of severe pain. Abscess formation is rare, but if it does occur then percutaneous or open drainage is necessary.

Treatment of chronic orchitis/orchialgia is supportive. Anti-inflammatory agents, analgesics, support, heat therapies, and nerve blocks all have a role in ameliorating symptoms. It is generally believed that the condition is self-limited but could take years (and sometimes decades) to resolve. **Orchidectomy is indicated only in cases in which pain control is refractory to all other measures (and even this might not be successful in alleviating the chronic pain)** (Nariculam et al, 2007).

EPIDIDYMITIS

Definitions and Classification

Epididymitis by definition is inflammation of the epididymis. Acute epididymitis represents sudden occurrence of pain and swelling of the epididymis associated with acute inflammation of the epididymis (Nickel et al, 2002). **Chronic epididymitis** refers to inflammation and pain in the epididymis, usually without swelling (but with induration in long-standing cases), persisting for over 6 weeks (Nickel et al, 2002). Inflammation is not always clinically evident in many cases of localized epididymal pain. Approximately 1 man in 100 attending a North American urology clinic has a diagnosis of epididymitis (Nickel et al, 2005c). In the late 1990s the average cost per episode of epididymitis managed in the United States was 368 dollars (Gift and Ownes, 2006), a cost considerably less than that reported for men with a diagnosis of chronic prostatitis. A classification for epididymitis is presented in Table 11–9 (Nickel et al, 2002).

Pathogenesis and Etiology

Acute epididymitis usually results from the spread of infection from the bladder, urethra, or prostate via the ejaculatory ducts and vas deferens into the epididymis. The process starts in the tail of the epididymis and then spreads through the body of the structure to the head of the epididymis. In infants and boys, epididymitis is often related to a UTI and/or an underlying genitourinary congenital anomaly (Merlini et al, 1998) or even to the presence of a foreskin (Bennett et al, 1998). In elderly men, BPH and associated stasis, UTI, and catheterization is the most common cause of epididymitis. Bacterial prostatitis

Table 11–9.

Classification of Epididymitis

Acute bacterial epididymitis
Secondary to urinary tract infection
Secondary to sexually transmitted disease
Nonbacterial infectious epididymitis
Viral
Fungal
Parasitic
Noninfectious epididymitis
Idiopathic
Traumatic
Autoimmune
Amiodarone-induced
Associated with a known syndrome (e.g., Behçet disease)
Chronic epididymitis
Chronic epididymalgia

and/or seminal vesiculitis are associated with epididymal infection in postpubertal males of all ages (Furuya et al, 2004). In sexually active men younger than 35 years of age, epididymitis is commonly the result of a sexually transmitted infection (Berger, 1998). In most cases of acute epididymitis, the testis is also involved in the process and thus the condition is referred to as epididymo-orchitis.

Chronic epididymitis may result from inadequately treated acute epididymitis, recurrent epididymitis, or some other cause including associations with other disease processes such as Behçet disease (Cho et al, 2003; Arromdee and Tanakitivirul, 2006; Pektas et al, 2008) or treatment with amiodarone (Nikolaou et al, 2007). The etiology of chronic epididymalgia is usually unclear. Certainly one of the best known and studied is the chronic epididymitis/epididymalgia that occurs in some men after a vasectomy. About 1 in 100 men describe severe pain 6 months after a vasectomy that noticeably affects their quality of life (up to 15% of men report some discomfort 6 months after the procedure) (Leslie et al, 2007).

The most common causative microorganisms in the pediatric and elderly age groups are the coliform organisms that cause bacteriuria (Berger et al, 1979). In men younger than the age of 35 who are sexually active with women, the most common offending organisms causing epididymitis are the usual bacteria that cause urethritis, namely *N. gonorrhoeae*, and *C. trachomatis*. In homosexual men practicing anal intercourse, *E. coli* and *Haemophilus influenzae* are most commonly responsible. Both tuberculosis (Lui et al, 2005; Tsili et al, 2008) and mycobacteria, such as bacillus Calmette-Guérin (Harada et al, 2006), can be associated with epididymitis. As with orchitis, viral, fungal, mycoplasmal, and parasitic microorganisms have all been implicated in epididymitis (Berger, 1998; Wise, 1998; Hazen Smith and von Lichtenberg, 1998; Scagni et al, 2008). Rarely, epididymitis as a complication of brucellosis has been described (Akinci et al, 2006; Queipo-Ortuno et al, 2006; Colmenero et al, 2007).

Diagnosis

Both acute infectious and acute noninfectious epididymitis present in much the same way as do acute infectious and acute noninfectious orchitis, respectively. Physical examination localizes the tenderness to the epididymis. However, in many cases the testis is also involved in the inflammatory process and subsequent pain and this is referred to as epididymo-orchitis. The spermatic cord is usually tender and swollen. Early on in the process, only the tail of the epididymis is tender, but the inflammation quickly spreads to the rest of the epididymis and if it continues to the testis then the swollen epididymis becomes indistinguishable from the testis.

There may be no clinical or etiologic differentiation between chronic epididymitis and epididymalgia. The patient usually presents with a long-standing history of pain (waxing and waning or constant) localized to the epididymis, and like chronic orchitis/orchialgia these symptoms may have a significant impact on the patient's quality of life (Nickel et al, 2002).

Laboratory tests should include Gram staining of a urethral smear and a midstream urine specimen. Gram-negative bacilli can usually be identified in patients with underlying cystitis. If the urethral smear reveals the presence of intracellular gram-negative diplococci, a diagnosis of infection with *N. gonorrhoeae* is established. If only WBCs are seen on the urethral smear, a diagnosis of *C. trachomatis* will be established two thirds of the time. A urethral swab and midstream urine specimen should be sent for culture and sensitivity testing. When an infant or young boy is diagnosed with epididymitis he should be further evaluated with abdominopelvic ultrasonography, voiding cystourethrography, and possibly cystoscopy (Shortliffe, 1998; Al-Taheini et al, 2008). If the diagnosis is uncertain, duplex Doppler scrotal ultrasonography to look for increased blood flow to the affected epididymis may be performed (also to rule out torsion as described under orchitis) (Mernagh et al, 2004). Ultrasonography can sometimes be helpful to rule out other epididymal and scrotal pathology (Lee et al, 2008).

Treatment

Management of acute infectious epididymitis depends on the likely cause and organism (Tracy et al, 2008). **The Centers for Disease Control and Prevention's 2006 guidelines for the treatment of infectious epididymitis includes ceftriaxone or doxycycline for men younger than age 35 years and levofloxacin or ofloxacin for men older than age 35 years** (Centers for Disease Control and Prevention et al, 2006).

For chronic epididymitis, a 4- to 6-week trial of antibiotics that would potentially be effective against possible bacterial pathogens and particularly *C. trachomatis* may be appropriate (Nickel, 2005). Anti-inflammatory agents, analgesics, scrotal support, and nerve blocks have all been recommended as empirical treatment (Nickel, 2005). It is generally believed that chronic epididymitis is a self-limited condition that will eventually "burn out," but this could take years (or even decades). **Surgical removal of the epididymis**

Key Points: Orchitis and Epididymitis

- Orchitis usually occurs with epididymitis (except for viral causation).
- Etiology of epididymitis and orchitis is usually related to the age of the patient.
- Acute presentation is usually related to infection or ischemia.
- In the young patient the most important differential diagnosis is torsion of the testis.
- Treatment of chronic epididymitis or epididymo-orchitis is difficult.

(epididymectomy) should be considered only when all conservative measures have been exhausted and the patient accepts that the operation will have at best a 50% chance of curing his pain (Padmore et al, 1996; Tracy et al, 2008). However, better surgical results (up to 70%) have been reported for epididymectomy for postvasectomy pain (Siu et al, 2007).

Bladder Pain Syndrome (Interstitial Cystitis) and Related Disorders

Philip M. Hanno, MD, MPH

Definition
Historical Perspective
Epidemiology
Etiology
Pathology
Diagnosis
Classification
Treatment
Principles of Management

Bladder pain syndrome/interstitial cystitis (BPS/IC) is a **condition diagnosed on a clinical basis** and requiring a high index of suspicion on the part of the clinician. Simply put, **it should be considered in the differential diagnosis of the patient presenting with chronic pelvic pain that is often exacerbated by bladder filling and associated with urinary frequency.** One can argue that it is a symptom-complex because it has a differential diagnosis that should be explored in a timely fashion before or at the time of initiation of empirical therapy (Blaivas, 2007). Once other conditions have been ruled out it can be considered a syndrome that generally responds to one of a variety of therapeutic approaches in the majority of cases. The perception that the original term *interstitial cystitis* was not at all descriptive of the clinical syndrome or even the pathologic findings in many cases has led to the current effort to reconsider the name of the disorder and even the way it is positioned in the medical spectrum (Hanno, 2008). What was originally considered a bladder disease is now considered a chronic pain syndrome (Janicki, 2003) that may begin as a pathologic process in the bladder in most but not all patients and eventually can develop into a disease that in a small subset of those affected even cystectomy may not benefit (Baskin and Tanagho, 1992). Its relationship to type III chronic pelvic pain syndrome (CPPS)/nonbacterial prostatitis is unclear (Chai, 2002; Hakenberg and Wirth, 2002). Its association with other chronic pain syndromes has taken on more importance recently as a promising clue to unlock the challenging etiologic and therapeutic puzzle of this condition.

BPS/IC encompasses a major portion of the "painful bladder" disease complex. "Painful bladder disorders" comprise a large group of patients with bladder and/or urethral and/or pelvic pain, irritative voiding symptoms (urgency, frequency, nocturia, dysuria), and sterile urine cultures. Painful bladder conditions with well-established causes include radiation cystitis, cystitis caused by microorganisms that are not detected by routine culture methodologies, and systemic disorders that affect the bladder. In addition, many gynecologic disorders can mimic BPS/IC (Kohli et al, 1997; Howard, 2003a, 2003b). BPS/IC has no easily discernible etiology.

The symptoms are allodynic, an exaggeration of normal sensations. There are no pathognomonic findings on pathologic examination, and even the finding of petechial hemorrhages on the bladder mucosa during cystoscopy after bladder hydrodistention under anesthesia is no longer considered the sine qua non of BPS/IC that it had been until a decade ago (Erickson, 1995; Waxman et al, 1998; Erickson et al, 2005). **BPS/IC is truly a diagnosis of exclusion.** It may have multiple causes and represent a final common reaction of the bladder to different types of insult.

DEFINITION

"It resembles a constellation of stars; its components are real enough but the pattern is in the eye of the beholder" (Makela and Heliovaara, 1991). This evocative description of fibromyalgia could equally apply to BPS/IC. Indeed, it has been argued, not necessarily convincingly, that each medical specialty has at least one somatic syndrome (irritable bowel syndrome, chronic pelvic pain, fibromyalgia, tension headache, noncardiac chest pain, hyperventilation syndrome) that might be better conceptualized as a part of a general functional somatic syndrome than with the symptom-based classification that we have now that may be more a reflection of professional specialization and access to care (Wessely and White, 2004).

BPS/IC is a clinical diagnosis based primarily on chronic symptoms of pain perceived by the patient to emanate from the bladder and/or pelvis associated with urinary urgency/frequency in the absence of other identified causes for the symptoms. It has been defined and redefined over the past century, and as the problem of definition

Table 12–1.

Definitions of Bladder Pain Syndrome/Painful Bladder Syndrome/Interstitial Cystitis Syndrome over the Past Century

YEAR	DEFINITION	SOURCE
1887	Skene: An inflammation that has destroyed the mucous membrane partly or wholly and extended to the muscular parietes	Skene, 1887
1915	Hunner: A peculiar form of bladder ulceration whose diagnosis depends ultimately on its resistance to all ordinary forms of treatment in patients with frequency and bladder symptoms (spasms)	Hunner, 1915
1951	Bourque: Patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate at all hours of the day and of the night suffering pains every time they void.	Bourque, 1951
1978	Messing and Stamey: Nonspecific and highly subjective symptoms of around-the-clock frequency, urgency, and pain somewhat relieved by voiding when associated with glomerulations upon bladder distention under anesthesia.	Messing and Stamey, 1978
1990	Revised NIDDK criteria: Pain associated with the bladder or urinary urgency, and glomerulations or Hunner ulcer on cystoscopy under anesthesia, in patients with 9 months or more of symptoms—at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350 mL	Wein et al, 1990
1997	NIDDK Interstitial Cystitis Database entry criteria: Unexplained urgency or frequency (7 or more voids per day) *or* pelvic pain of at least 6 months' duration in the absence of other definable causes.	Simon et al, 1997
2008	European Society for the Study of Interstitial Cystitis: Chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded.	Van de Merwe et al, 2008
2009	Japanese Urological Association: A disease of the urinary bladder diagnosed by three conditions: (1) lower urinary tract symptoms such as urinary frequency, bladder hypersensitivity and/or bladder pain; (2) bladder pathology proven endoscopically by Hunner ulcer and/or mucosal bleeding after overdistention; and (3) exclusion of confusable diseases such as infection, malignancy, or calculi of the urinary tract.	Homma et al, 2009
2009	Society for Urodynamics and Female Urology informal international dialogue consensus meeting: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks' duration, in the absence of infection or other identifiable causes.	Hanno and Dmochowski, 2009

Data from Hanno PM, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. Paris: Health Publication Ltd.; 2009. p. 1459–518.

has become more prominent lately so have the number of definitions and attempts to crystallize just what the diagnosis means (Table 12–1). **The International Continence Society (ICS) prefers the term *painful bladder syndrome* (PBS), defined as "the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology"** (Abrams et al, 2002). **The ICS reserves the diagnosis of IC to patients with "typical cystoscopic and histological features," without further specifying these. This definition may miss 36% of patients, primarily because it confines the pain to a suprapubic location and mandates a relationship of pain to bladder filling** (Warren et al, 2006).

In the absence of clear criteria for IC, this chapter will refer to BPS/IC and IC interchangeably, because all but recent literature terms the syndrome IC. The definition of the European Society for the Study of Interstitial Cystitis (ESSIC) is a clinically useful one, and changes made since its original iteration have likely made it more sensitive and inclusive (Mouracade et al, 2008). Minor modifications made at a meeting under the auspices of the Society for Urodynamics and Female Urology (SUFU) may be preferred by some clinicians. Perhaps more than for most diseases, how we arrived at this point is instructive and critical to an overall understanding of BPS/IC. The paradigm change that has resulted in morphing what was originally considered a bladder disease (aptly named interstitial cystitis) to a chronic pain syndrome (bladder pain syndrome) also merits discussion.

HISTORICAL PERSPECTIVE

Recent historical reviews confirm that IC was recognized as a pathologic entity during the 19th century (Christmas, 1997; Parsons and Parsons, 2004). Joseph Parrish, a Philadelphia surgeon, described three cases of severe lower urinary tract symptoms in the absence of a bladder stone in an 1836 text (Parrish, 1836) and termed the disorder *tic doloureux of the bladder.* Teichman and associates (2000) argue that this may represent the first description of IC. Fifty years later Skene (1887) used the term *interstitial cystitis* to describe an inflammation that has "destroyed the mucous membrane partly or wholly and extended to the muscular parietes."

Early in the 20th century, at a New England Section meeting of the American Urological Association, Guy Hunner (1915, 1918) reported on eight women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years. He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to have the pseudonym of Hunner ulcer. As Anthony Walsh (1978) observed, this has proven to be unfortunate. In the early part of the 20th century the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall he thought they were ulcers. For the next 60 years urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be focal rather than a pancystitis.

Hand (1949) authored the first comprehensive review about the disease, reporting 223 cases. In looking back, his paper was truly

a seminal one, years ahead of its time. Many of his epidemiologic findings have held up to this day. His description of the clinical findings bears repeating. "I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distention." He notes, "small, discrete, submucosal hemorrhages, showing variations in form … dot-like bleeding points … little or no restriction to bladder capacity." He portrays three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients had grade 1 disease, and only 13% had grade 3 disease.

Walsh (1978) later coined the term *glomerulations* to describe the petechial hemorrhages that Hand had described. But it was not until Messing and Stamey (1978) discussed the "early diagnosis" of IC that attention turned from looking for an ulcer to make the diagnosis to the concepts that (1) symptoms and glomerulations at the time of bladder distention under anesthesia were the disease hallmarks and (2) the diagnosis was primarily one of exclusion.

Bourque's *Aunt Minnie (she is hard to define, but you know her when you see her)* description of IC is over 50 years old and is worth recalling: "We have all met, at one time or another, patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate often, at all moments of the day and of the night, and suffering pains every time they void. We all know how these miserable patients are unhappy, and how those distressing bladder symptoms get finally to influence their general state of health physically at first, and mentally after a while" (Bourque, 1951).

Although memorable and right on the mark, this description and others like it were not suitable for defining this disease in a manner that would help physicians make the diagnosis and design research studies to learn more about the problem. Physician interest and government participation in research were sparked through the efforts of a group of frustrated patients led by Dr. Vicki Ratner, an orthopedic surgery resident in New York City, who founded the first patient advocacy group, the Interstitial Cystitis Association, in the living room of her small New York City apartment in 1984 (Ratner et al, 1992; Ratner and Slade, 1997). The first step was to develop a working definition of the disease. The modern history of PBS/IC is best viewed through the development of the modern definition.

Evolution of Definition

There are data to suggest that true urinary frequency in women can be defined as regularly having to void at intervals of less than 3 hours and 25% of women older than age 40 years have nocturia at least once (Glenning, 1985; Fitzgerald and Brubaker, 2003). Whereas bladder capacity tends to fall in women by the eighth and ninth decades of life, bladder volume at first desire to void tends to rise as women age (Collas and Malone-Lee, 1996). Based on a 90th percentile cut-off to determine the ranges of normality, the highest "normal" frequency ranges in the 4th decade range from 6 for men to 9 for women (Burgio et al, 1991). Large variation in the degree of bother with varying rates of frequency (Fitzgerald et al, 2002) makes a symptomatic diagnosis of PBS/IC based on an absolute number of voids subject to question, and frequency per volume of intake or even the concept of "perception of frequency" as a problem may be more accurate than an absolute number.

In an effort to define IC so that patients in different geographic areas, under the care of different physicians, could be compared, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) held a workshop in 1987 at which consensus criteria were established for the diagnosis of IC (Gillenwater and Wein, 1988). These criteria were not meant to define the disease but rather to ensure that groups of patients included in basic and clinical research studies would be relatively comparable. After pilot studies testing the criteria were performed, the criteria were revised at another NIDDK workshop a year later (Wein et al, 1990). These criteria are presented in Table 12–2.

Although meant initially to serve only as a research tool, the NIDDK "research definition" became a de facto definition of this disease, diagnosed by exclusion and colorfully termed a "hole in the air" by Hald (cited in George, 1986). Certain of the exclusion criteria serve mainly to make one wary of a diagnosis of IC but should by no means be used for categorical exclusion of such a diagnosis. However, because of the ambiguity involved, these patients should probably be eliminated from research studies or categorized separately. In particular, exclusion criteria 4, 5, 6, 8, 9, 11, 12, 17, and 18 are only relative. What percentage of patients with idiopathic sensory urgency has IC is unclear (Frazer et al,

Table 12–2.

National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Diagnostic Criteria for Interstitial Cystitis

To be diagnosed with interstitial cystitis, patients must have either glomerulations on cystoscopic examination or a classic Hunner ulcer, and they must have either pain associated with the bladder or urinary urgency. An examination for glomerulations should be undertaken after distention of the bladder under anesthesia to 80 to 100 cm H_2O for 1 to 2 minutes. The bladder may be distended up to two times before evaluation. The glomerulations must be diffuse—present in at least three quadrants of the bladder—and there must be at least 10 glomerulations per quadrant. The glomerulations must not be along the path of the cystoscope (to eliminate artifact from contact instrumentation). The presence of any one of the following excludes a diagnosis of interstitial cystitis:

- Bladder capacity of greater than 350 mL on awake cystometry using either a gas or liquid filling medium
- Absence of an intense urge to void with the bladder filled to 100 mL of gas or 150 mL of liquid filling medium
- The demonstration of phasic involuntary bladder contractions on cystometry using the fill rate just described
- Duration of symptoms less than 9 months
- Absence of nocturia
- Symptoms relieved by antimicrobial agents, urinary antiseptic agents, anticholinergic agents, or antispasmodic agents
- A frequency of urination while awake of less than 8 times per day
- A diagnosis of bacterial cystitis or prostatitis within a 3-month period
- Bladder or ureteral calculi
- Active genital herpes
- Uterine, cervical, vaginal, or urethral cancer
- Urethral diverticulum
- Cyclophosphamide or any type of chemical cystitis
- Tuberculous cystitis
- Radiation cystitis
- Benign or malignant bladder tumors
- Vaginitis
- Age younger than 18 years

From Wein AJ, Hanno PM, Gillenwater JY. Interstitial cystitis: an introduction to the problem. In: Hanno PM, Staskin DR, Krane RJ, Wein AJ, editors. Interstitial cystitis. London: Springer-Verlag; 1990. p. 13–5.

1990). **The specificity of the finding of bladder glomerulations has come into question** (Erickson, 1995; Waxman et al, 1998; Tomaszewski et al, 2001). Similarly, **the sensitivity of glomerulations is also unknown, but clearly patients with IC symptoms can demonstrate an absence of glomerulations under anesthesia** (Awad et al, 1992; Al Hadithi et al, 2002). **Bladder ulceration is extremely rare** and exists in less than 5% of patients in my experience and in the experience of others (Sant, 1991). A California series found 20% of patients to have ulceration (Koziol, 1994). Specific pathologic findings represent a glaring omission from the criteria, because **there is a lack of consensus as to which pathologic findings, if any, are required for, or even suggestive of, a tissue diagnosis** (Hanno et al, 1990, 2005a; Tomaszewski et al, 1999, 2001).

The unexpected use of the NIDDK research criteria by the medical community as a definition of IC led to concerns that many patients suffering from this syndrome might be misdiagnosed. The multicenter Interstitial Cystitis Database (ICDB) study through NIDDK accumulated data on 424 patients with IC, enrolling patients from May 1993 through December 1995. Entry criteria were much more symptom driven than those promulgated for research studies (Simon et al, 1997) and are noted in Table 12–3. In an analysis of the defining criteria (Hanno et al, 1999a, 1999b), it appeared the NIDDK research criteria fulfilled their mission. Fully 90% of expert clinicians agreed that patients diagnosed with IC by those criteria in the ICDB indeed had the disorder. However, 60% of patients deemed to have IC by these experienced clinicians would not have met NIDDK research criteria. **Thus, IC remains a clinical syndrome defined by some combination of chronic symptoms of urgency, frequency, and/or pain in the absence of other reasonable causation. Whereas IC symptom and problem indices have been developed and validated** (O'Leary et al, 1997; Goin et al, 1998), **these are not intended to diagnose or define IC but rather to measure the severity of symptomatology and monitor disease progression or regression** (Moldwin and Kushner, 2004).

Table 12–3.

Interstitial Cystitis Database (ICDB) Study Eligibility Criteria

1. Providing informed consent to participate in the study
2. Willing to undergo a cystoscopy under general or regional anesthesia when indicated during the course of the study
3. At least 18 years of age
4. Having symptoms of urinary urgency, frequency, or pain for more than 6 months
5. Urinating at least 7 times per day or having some urgency or pain (measured on linear analog scales)
6. No history of current genitourinary tuberculosis
7. No history of urethral cancer
8. No history of bladder malignancy, high-grade dysplasia, or carcinoma in situ
9. Males: no history of prostate cancer
10. Females: no occurrence of ovarian, vaginal, or cervical cancer in the previous 3 years
11. Females: no current vaginitis or clue cell, trichomonal, or yeast infections
12. No bacterial cystitis in the previous 3 months
13. No active herpes in the previous 3 months
14. No antimicrobials for urinary tract infections in previous 3 months
15. Never having been treated with cyclophosphamide
16. No radiation cystitis
17. No neurogenic bladder dysfunction (e.g., due to a spinal cord injury, stroke, Parkinson disease, multiple sclerosis, spina bifida, or diabetic cystopathy)
18. No bladder outlet obstruction (determined by urodynamic investigation)
19. Males: no bacterial prostatitis for previous 6 months
20. Absence of bladder, ureteral, or urethral calculi for previous 3 months
21. No urethritis for previous 3 months
22. Not having had a urethral dilation, cystometrogram, bladder cystoscopy under full anesthesia, or a bladder biopsy in previous 3 months
23. Never having had an augmentation cystoplasty, cystectomy, cystolysis, or neuroectomy
24. Not having a urethral stricture of less than 12 Fr

Nomenclature and Taxonomy

Recent international consultations have essentially agreed that the nomenclature of "interstitial cystitis" should be revised and I will use the terminology of the International Consultation on Incontinence of *bladder pain syndrome* but keep the term *interstitial cystitis* to facilitate recognition and understanding. This change implies that it is the symptoms that drive treatment, and **the question as to whether *interstitial cystitis* should refer to a distinct subgroup of the bladder pain syndrome is, as yet, unclear.**

The literature over the past 170 years has seen numerous changes in description and nomenclature of the disease. The syndrome has variously been referred to as tic douloureux of the bladder, IC, cystitis parenchymatosa, Hunner ulcer, panmural ulcerative cystitis, urethral syndrome, and painful bladder syndrome (Skene, 1887; Hunner, 1918; Powell and Powell, 1949; Bourque, 1951; Christmas, 1997; Teichman et al, 2000; Dell and Parsons, 2004). The term *interstitial cystitis,* which Skene is credited with coining and Hunner brought in to common usage, is a misnomer; in many cases not only is there no interstitial inflammation, but also, histopathologically, there may be no inflammation at all (Lynes et al, 1990a; Denson et al, 2000; Tomaszewski et al, 2001; Rosamilia et al, 2003). By literally focusing exclusively on the urinary bladder, the term *interstitial cystitis* furthermore does not do justice to the condition from both the physician's and the patient's perspective. The textual exclusiveness ignores the high comorbidity with various pelvic, extrapelvic, and nonurologic symptoms and associated disorders (Clauw et al, 1997) that frequently precede or develop after the onset of the bladder condition (Wu et al, 2006).

With the formal definition of the term *painful bladder syndrome* by the ICS in 2002, the terminology discussion became an intense international focal point (Abrams et al, 2002):

- In Kyoto at the International Consultation on Interstitial Cystitis Japan in March 2003, it was agreed that the term *interstitial cystitis* should be expanded to *interstitial cystitis/chronic pelvic pain syndrome* when pelvic pain is at least of 3 months' duration and associated with no obvious treatable condition/pathology (Ueda et al, 2003).
- The European Society for the Study of Interstitial Cystitis (ESSIC) held its first meeting in Copenhagen soon after the Kyoto meeting. Nomenclature was discussed, but no decision was reached because the participants concentrated on how to evaluate patients for diagnosis (Nordling et al, 2004).

- At the 2003 meeting of the NIDDK titled, "Research Insights into Interstitial Cystitis," it was concluded that "interstitial cystitis" will ultimately be replaced as a sole name for this syndrome. It will be a gradual process over several years. At the meeting it was referred to as "interstitial cystitis/painful bladder syndrome" in keeping with International Continence Society nomenclature (Hanno et al, 2005b).
- At the 2004 inaugural meeting of the Multinational Interstitial Cystitis Association in Rome it was concluded that the syndrome should be referred to as "painful bladder syndrome/interstitial cystitis" or "PBS/IC" to indicate an intellectual and taxonomical hierarchy within the acronym (Hanno et al, 2005b).
- The International Consultation on Incontinence in 2004, sponsored by both the ICS and the Société Internationale d'Urologie in association with the World Health Organization, included the syndrome as a part of its consultation. The chapter in the report was titled, "Painful Bladder Syndrome (including Interstitial Cystitis)," suggesting that the IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter, coauthored by nine committee members and five consultants from four continents, it was referred to as PBS/IC (one inclusive entity) (Hanno et al, 2005a). **IC may be a subgroup that encompasses those patients with typical histologic and cystoscopic features** (Peeker and Fall, 2002), **but what these features are is still controversial and somewhat vague.**
- In June 2006, Abrams and colleagues published an editorial focusing on the nomenclature problem (Abrams et al, 2006). They noted that "It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. Unfortunately, the latter is not the case for many of the pain syndromes suffered by patients seen at most pain, gynecological, and urological clinics. For the most part these 'diagnoses' describe syndromes that do not have recognized standard definitions, yet imply knowledge of a pathophysiologic cause for the symptoms. Unfortunately the terminology used to describe the condition may promote erroneous thinking about treatment on the part of physicians, surgeons and patients. These organ based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous." The editorial went on to note that a single pathologic descriptive term (*interstitial cystitis*) for a spectrum of symptom combinations ill serves patients. The umbrella term *painful bladder syndrome* was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS. It would fall within the rubric of chronic pelvic pain syndrome. Sufferers would be identified according to the primary organ that appears to be affected on clinical grounds. Pain not associated with an individual organ would be described in terms of the symptoms.

One can see in this the beginnings of a new paradigm that might be expected to change the emphasis of both clinical and basic science research and that removes the automatic presumption that the end organ in the name of the disease should necessarily be the sole or primary target of such research.

At the major biannual IC research conference in the fall of 2006, held by the NIDDK (Frontiers in Painful Bladder Syndrome/Interstitial Cystitis), the ESSIC group was given a block of time with which to present their thoughts and conclusions. Because (1) the term PBS did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, (2) as defined by the International Continence Society missed over a third of afflicted patients, and (3) is a term open to different interpretations, the ESSIC suggested that *painful bladder syndrome* be redesignated as bladder pain syndrome (BPS), followed by a type designation. BPS is indicated by two symbols, the first of which corresponds to cystoscopy with hydrodistention findings (1, 2, or 3 indicating increasing grade of severity) and the second to biopsy findings (A, B, and C indicating increasing grade of pathologic severity) (Table 12–4). Although neither cystoscopy with hydrodistention nor bladder biopsy was prescribed as an essential part of the evaluation, by categorizing patients as to whether either procedure was done and, if so, the results, it is possible to follow patients with similar findings and study each identified cohort to compare natural history, prognosis, and response to therapy (van de Merwe et al, 2008).

As Baranowski and associates (2008) conceived it, **BPS is defined as a pain syndrome with a collection of symptoms, the most important of which is pain perceived to be in the bladder. IC is distinguished as an end-organ, visceral-neural pain syndrome, whereas BPS can be considered a pain syndrome that involves the end-organ (bladder) and neurovisceral (myopathic) mechanisms. In IC, one expects an end-organ primary pathologic process. This is not necessarily the case in the broader BPS.**

A didactically very demonstrative way to conceptualize the dawning shift in conception of the condition is with the drawing of a target (Fig. 12–1). There may be many causes of chronic pelvic pain. When an etiology cannot be determined, it is characterized as pelvic pain syndrome. To the extent that it can be distinguished

as urologic, gynecologic, dermatologic, and the like, it is further categorized by organ system. A urologic pain syndrome can sometimes be further differentiated on the site of perceived pain. Bladder, prostate, testicular, and epididymal pain syndromes follow. Finally, types of BPS can be further defined as IC or simply categorized by ESSIC criteria. Patient groups have expressed their concerns with regard to any nomenclature change that potentially drops the term *interstitial cystitis* because the U.S. Social Security Administration and private insurances recognize IC but not the term BPS and benefits potentially could be adversely affected. Whether the term *interstitial cystitis,* as difficult as it is to define and as potentially misleading as it is with regard to etiology and end-organ involvement, should be maintained is a subject of ongoing controversy (Hanno and Dmochowski, 2009).

Key Points: Definition

- The *painful bladder disease complex* includes a large group of patients with bladder and/or urethral and/or pelvic pain, irritative voiding symptoms, and sterile urine cultures, many with specific identifiable causes.
- *Bladder pain syndrome* comprises a part of this complex and is a clinical diagnosis based primarily on chronic symptoms of pain perceived by the patient to emanate from the bladder and/or pelvis associated with urinary urgency/frequency *in the absence* of other identified etiology for the symptoms.
- The question as to whether the older term *interstitial cystitis* should refer to a distinct subgroup of the bladder pain syndrome is, as yet, unclear.

Urgency is a common complaint of this group of patients. **The ICS definition of urgency** (Abrams et al, 2002), "the complaint of a sudden compelling desire to pass urine, which is difficult to defer," **could be interpreted as compatible with either detrusor overactivity or BPS/IC depending on the weight one attaches to the word *sudden*.** There are those who see hypersensitivity or sensory urgency as bridging both overactive bladder and BPS/IC (Haylen et al, 2007; Yamaguchi et al, 2007), and the issue has been nicely addressed by Homma (2008). **Pain and pressure are more involved in the frequency of BPS/IC, and fear of incontinence seems the reason for the urgency of overactive bladder** (Abrams et al, 2005). Thus, urgency is not required to define BPS/IC, because it would tend to obfuscate the borders of overactive bladder and PBS/IC and is unnecessary for definition purposes. Figure 12–2 (Abrams et al, 2005) is a graphic depiction of one view of the relationship between these two, sometimes confused, conditions. The 14% incidence of urodynamic detrusor overactivity in the PBS/IC patients (Nigro et al, 1997) is probably close to what one might expect in the general population if studied urodynamically (Salavatore et al, 2003).

Still, there remains some ambiguity, and further research is necessary with regard to urgency. Studies are hampered by the fact that patients tend to use words to describe lower urinary tract symptoms but attribute meanings to the words different from physicians and researchers (Digesu et al, 2008). An analysis of urgency by the University of Maryland group reported that 65% of patients with BPS experienced an urge to urinate to relieve pain, with 46% agreeing that they had an urge to relieve pain and not to prevent incontinence. Still, 21% reported that urgency was for fear of impending incontinence and that this sensation was not present before the onset of BPS symptoms (Diggs et al, 2007). In some patients the term connotes an intensification of the normal urge to void, and in others it is a different sensation (Blaivas et al, 2009).

New efforts to phenotype the chronic urologic pain syndromes (BPS and chronic nonbacterial prostatitis/CPPS in men) are being explored (Nyberg et al, 2009; Shoskes et al, 2009a, 2009b). The hope is that looking at psychological, physical, and organ-specific parameters of afflicted patients, and specifically focusing on

Key Points: Urgency

- *Urgency* has been defined as the complaint of a sudden compelling desire to pass urine, which is difficult to defer.
- The cause the patient attributes to what precipitates the sensation is not a part of the definition and has resulted is some ambiguity. Fear of incontinence is more consistent with overactive bladder, whereas pressure, pain, or discomfort suggests bladder pain syndrome.

associated disorders, will aid in proper selection of therapeutic agents that may have selective specificity for different symptom constellations and also may improve productivity and results of research on etiology, prognosis, and new therapeutic agents.

EPIDEMIOLOGY

Prevalence

Epidemiology studies of PBS/IC are hampered by many problems (Bernardini et al, 1999). The lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology make much of the literature difficult to interpret. This is most apparent when one looks at the variation in **prevalence reports** in the United States and around the world (Table 12–5). These **range from 1.2 per 100,000 population and 4.5 per 100,000 females in Japan** (Ito et al, 2000), **to a questionnaire-based study that suggests a figure in American women of 20,000 per 100,000** (Parsons and Tatsis, 2004)!

It has been estimated that the prevalence of chronic pain due to benign causes in the population is at least 10% (Verhaak et al, 1998). Numerous case series have, until recently, formed the basis of epidemiologic information regarding PBS/IC. Farkas and associates (1977) discussed IC in adolescent girls. Hanash and Pool (1969) reviewed their experience with IC in men. Geist and Antolak (1970) reviewed and added to reports of disease occurring in childhood. **A childhood presentation is extremely rare and must be differentiated from the much more common and benign-behaving *extraordinary urinary frequency syndrome of childhood,*** a self-limited condition of unknown etiology (Koff and Byard, 1988; Robson and Leung, 1993). Nevertheless there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of PBS/IC. In Close and colleagues' review of 20 such children (1996) the median age at **onset was younger than 5 years and the vast majority of patients had long-term remissions with bladder distention.**

A study conducted at the Scripps Research Institute (Koziol et al, 1993) included 374 patients at Scripps as well as some members of the Interstitial Cystitis Association, the large patient support organization. A more recent, but similar study in England (Tincello and Walker, 2005) concurred with the Scripps findings of urgency, frequency, and pain in the vast majority of these patients, devastating effects on quality of life, and often unsuccessful attempts at therapy with a variety of treatments. Although such reviews provide some information, they would seem to be necessarily biased by virtue of their design.

Several population-based studies have been reported in the literature (Fig. 12–3), and these studies tend to support the reviews of selected patients or from individual clinics and the comprehensive follow-up case-control study by Koziol (1994). The first population-based study (Oravisto, 1975) included "almost all the patients with interstitial cystitis in the city of Helsinki." This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The prevalence of the disease in women was 18.1 per 100,000. The joint prevalence in both sexes was 10.6 cases per 100,000. The annual incidence of new female cases was 1.2 per 100,000. Severe cases accounted for about 10% of the total. Ten percent of cases were in men. The disease onset was generally subacute rather than insidious, and full development of the classic symptom-complex occurred over a relatively short time. IC does not progress continuously but usually reaches its final stage rapidly (within 5 years) in the Koziol study (1993) and then continues without significant change in symptomatology. Subsequent major deterioration was found by Oravisto to be unusual. The duration of symptoms before diagnosis was 3 to 5 years in the Finnish study. Analogous figures in a classic American paper a quarter of a century earlier were 7 to 12 years (Hand, 1949).

Another early population study, this one in the United States, first demonstrated the potential extent of what had been considered a very rare disease (Held et al, 1990). The following population groups were surveyed: (1) random survey of 127 board-certified urologists, (2) 64 IC patients selected by the surveyed urologists and divided between the last patient with IC seen and the last patient with IC diagnosed, (3) 904 female patients belonging to the Interstitial Cystitis Association, and (4) random phone survey of 119 persons from the U.S. population. This 1987 study reached the following conclusions:

1. There were 43,500 to 90,000 diagnosed cases of IC in the United States (twice the Finnish prevalence).
2. There was up to a fivefold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half million possible cases in the United States.

Table 12–5.

Prevalence of BPS/IC per 100,000 Women

STUDY	PREVALENCE
Oravisto, 1975 (Finland)	18
Jones, 1989 (USA)	500
Held et al, 1990 (USA)	30
Bade et al, 1995 (Netherlands)	12
Curhan et al, 1999 (USA)	60

Clemens, 2007b (USA)	197
Temml et al, 2007 (Austria)	306
Song et al, 2009 (China)	100
Berry et al, 2009 (USA)	2600

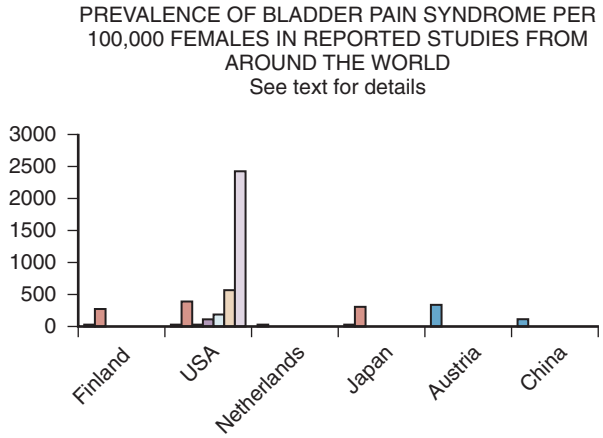

Figure 12–3. Prevalence of bladder pain syndrome per 100,000 females in reported studies from around the world. See text for details.

3. Median age at onset was 40 years.
4. Late deterioration in symptoms was unusual.
5. The temporary spontaneous remission rate was 50%, with mean duration of 8 months.
6. There was a 10 times higher incidence of childhood bladder problems in IC patients versus controls.
7. There was twice the incidence of a history of urinary tract infection versus controls.
8. Of IC patients 14% were Jewish (15% in the Koziol [1994] sample) versus 3% Jewish in a general population sample.
9. The study patients had a lower quality of life than dialysis patients.
10. Costs including lost economic production in 1987 totaled $427 million.

Other population studies followed. Jones and Nyberg (1997) obtained their data from self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey. The survey estimated that 0.5% of the population, or more than 1 million people in the United States, reported having a diagnosis of IC. There was no verification of this self-report by medical records. Bade and colleagues (1995) did a physician questionnaire-based survey in the Netherlands yielding an overall prevalence of 8 to 16/100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells. This prevalence in females compares to 4.5/100,000 in Japan (Ito et al, 2000).

The Nurses Health Study I and II (Curhan et al, 1999) showed a prevalence of IC between 52 and 67/100,000 in the United States, which was twice the prevalence in the study by Held and associates (1990) and threefold greater than the study by Bade and colleagues (1995) in The Netherlands. It improved on previous studies by using a large sample derived from a general population and careful ascertainment of the diagnosis. If the 6.4% confirmation rate of their study were applied to the Jones and colleagues' National Health Interview Survey data, the prevalence estimates of the two studies would be nearly identical.

Leppilahti and coworkers (2002, 2005) used the O'Leary-Sant IC symptom and problem index (never validated for making a diagnosis per se) to select women with IC symptoms from the Finnish population register. Of 1331 respondents, 32 had moderate or severe symptoms involving a suspicion of BPS/IC (symptom score 7 or higher). Of 21 who consented to clinical evaluation, 7 had probable or possible BPS/IC. Corrected estimates yielded a prevalence of 300/100,000 women. Similar studies without clinical confirmation suggested prevalence in Austrian women of 306/100,000 (Temml et al, 2007) and in Japanese women of 265/100,000 (Inoue et al, 2009). Using the Bristol Female Lower Urinary Tract Symptoms questionnaire, a 100/100,000 prevalence of BPS symptoms was reported in Fuzhou Chinese women (Song et al, 2009).

Roberts and coworkers (2003), using a physician diagnosis as the arbiter of IC, found annual incidence in Olmsted County, Minnesota, of 1.6 per 100,000 in women and 0.6 per 100,000 in men, a figure remarkably similar to that of Oravisto in Helsinki. The cumulative prevalence by age older than 80 years in the Minnesota study was 114 per 100,000, a figure comparable to that in the Nurses Health Study if one takes into account the younger age group in the Curhan data. Clemens and colleagues (2007b) calculated a prevalence of diagnosed disease in a managed care population of 197 per 100,000 women and 41 per 100,000 men, but when the diagnosis was tested by eliminating those who had not been evaluated with endoscopy or in whom exclusionary conditions existed, the numbers dropped considerably. The Boston Area Community Health Survey estimated a prevalence of painful bladder syndrome symptoms of 1% to 2% of the population depending on the definition used.

Looking at office visits to practices with an interest in urologic problems, 2.8% of patients in Canadian urologist offices had BPS/IC (Nickel et al, 2005) and probable BPS/IC was found in 0.57% in a primary care office in Michigan (Rosenberg and Hazzard, 2005).

An estimation of the prevalence at this time, recognizing that a consistent definition of the condition has not been used in epidemiologic studies, appears to be about 300/100,000 females and a male prevalence of 10% to 20% of the female estimate. A National Institutes of Health (NIH)-sponsored 5-year Rand Corporation epidemiology study is due to be completed in 2010 and may yield the most reliable data yet (Bogart et al, 2007). **Preliminary results reported at the annual American Urological Association meeting revealed that 2.5% to 2.7% of the population of U.S. women meet a high specificity symptom definition suggesting BPS/IC.** With the use of an epidemiologic definition with higher sensitivity, the prevalence was 6.5%. This translates to a prevalence in women older than 18 years of age in the United States who have symptoms by self-report compatible with BPS/IC of 3.4 to 7.9 million, significantly higher than most previous prevalence estimates (Berry et al, 2009).

Whether the considerable variability in prevalence in studies within the United States and around the world is related to methodology or true differences in incidence is an important question yet to be answered. It is clear that the prevalence of BPS/IC symptoms is much greater than the prevalence of a physician diagnosis of the disease (Clemens et al, 2007a). Familial occurrence of PBS/IC has been reported (Dimitrakov, 2001). **A hereditary aspect to incidence has been suggested** by Warren and associates (2001, 2004) in a pioneering study who found that adult female first-degree relatives of patients with IC may have a prevalence of IC 17 times that found in the general population. This, together with previously reported evidence showing a greater concordance of IC among monozygotic than dizygotic twins suggests, but does not prove, a genetic susceptibility to IC that could partially explain the discord in prevalence rates in different populations.

Key Point: Prevalence

- Prevalence studies show wide variation, but more modern studies tend to show higher values (see Table 12–5).

Characteristics and Natural History

Most studies show a female-to-male preponderance of 5:1 or greater (Clemens et al, 2005; Hanno et al, 2005a). In the absence of a validated marker it is often difficult to distinguish PBS/IC from CPPS (nonbacterial prostatitis, prostatodynia) that affects males (Forrest and Schmidt, 2004), and the percentage of men with PBS/IC may actually be higher (Miller et al, 1995, 1997; Novicki et al, 1998). **Men tend to be diagnosed at an older age and have a higher percentage of Hunner ulcer in the case series reported** (Novicki et al, 1998; Roberts et al, 2003). Costs of the disorder are not insignificant and can range from 4 to 7 thousand dollars a year not including lost wages, costs preceding diagnosis, alternative therapies, and costs attributable to misdiagnosis (Clemens et al, 2008c, 2009).

The Interstitial Cystitis Database Cohort (ICDB) of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys (Propert et al, 2000). Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. **Although all symptoms fluctuated there was no evidence of significant long-term change in overall disease severity. The data suggest that PBS/IC is a chronic disease, and no current treatments have a significant impact on symptoms over time in the majority of patients. Quality of life studies suggest that PBS/IC patients are six times more likely than individuals in the general population to cut down on work time owing to health problems but only half as likely to do so as patients with arthritis** (Shea-O'Malley and Sant, 1999). There is an associated high incidence of comorbidity, including depression, chronic pain, and anxiety and overall mental health issues (Michael et al, 2000; Rothrock et al, 2002; Hanno et al, 2005a). **There seems to be no effect on pregnancy outcomes** (Onwude and Selo-Ojeme, 2003).

Female patients with BPS/IC seem to report significant dyspareunia and other manifestations of sexual dysfunction. **All domains of female sexual function including sexually related distress, desire, and orgasm frequency can be affected** (Ottem et al, 2007; Peters et al, 2007b). Sexual function is an important predictor of physical quality of life and was the only strong predictor of mental quality of life in one recent study of patients with severe BPS/IC (Nickel et al, 2007).

The Boston Area Community Health Survey (BACH) (Link et al, 2008) **showed an overall prevalence of symptoms suggestive of BPS of 2% with twice as many women as men affected.** It was most common among middle-aged respondents with an earlier peak in women. It also was most common among minorities and those of lower socioeconomic status, and socioeconomic status seemed to overcome any effect due to race or ethnicity. **Emotional, sexual, and physical abuse was shown to be a risk factor in BACH** (Link and Lutfey, 2007), and this has been borne out in other studies. A Michigan study compared a control group of 464 women with 215 BPS/IC patients and found 22% of the control group having experienced abuse versus 37% of the patient group (Peters and Kalinowski, 2007). Those with a history of sexual abuse may present with more pain and fewer voiding symptoms (Seth and Teichman, 2008). How reliable these data are is not clear, and it would be wrong to jump to any conclusions about abuse in an individual patient. However, practitioners need to have sensitivity for the possibility of an abusive relationship history in all pain patients and in BPS patients in particular. When patients are found to have multiple diagnoses, the rate of previous abuse also increases, and these patients may need referral for further counseling at a traumatic stress center (Fenton et al, 2008).

Key Points: Natural History

- The female to male preponderance is 5:1.
- Symptoms tend to fluctuate, with the majority of patients showing no long-term deterioration.
- There is no deleterious effect on pregnancy outcomes.
- Men are diagnosed at an older age and have a higher prevalence of a Hunner lesion.

Associated Disorders

Knowledge of associated diseases is relevant for the clues it engenders with regard to etiology and possible treatment of this enigmatic pain syndrome. It is well known that patients with chronic pain syndromes including chronic fatigue syndrome, fibromyalgia, and temporomandibular disorder share key symptoms and can often develop overlapping conditions, including chronic pelvic pain (Aaron and Buchwald 2001; Aaron et al, 2001). In a case-control study Erickson found that **patients with IC had higher scores than controls for pelvic discomfort, backache, dizziness, chest pain, aches in joints, abdominal cramps, nausea, palpitations, and headache** (Erickson et al, 2001). Buffington theorizes that a common stress response pattern of increased sympathetic nervous system function in the absence of comparable activation of the hypothalamic-pituitary-adrenal axis may account for some of these related symptoms (Buffington, 2004). It has been suggested that panic disorder, a diagnosis associated with some BPS/IC patients (Clemens et al, 2008a), may sometimes be a part of a familial syndrome that includes IC, thyroid disorders, and other disorders of possible autonomic or neuromuscular control (Weissman et al, 2004). **Depression** has been associated with BPS/IC in both men and women (Hall et al, 2008; Clemens et al, 2008a), but whether this is an association or effect of the disorder is uncertain (Fitzgerald et al, 2007).

Newly diagnosed patients are most concerned with the possibility that BPS/IC could be a forerunner of bladder carcinoma. **No reports have ever documented a relationship to suggest that IC is a premalignant lesion.** Utz and Zincke (1973) discovered bladder cancer in 12 of 53 men treated for IC at the Mayo Clinic. Three of 224 women were eventually diagnosed with bladder cancer. Four years later additional cases were reported (Lamm and Gittes, 1977). Tissot and coworkers (2004) reported 1% of 600 patients previously diagnosed as having IC were found to have transitional cell carcinoma as the cause of symptoms. Somewhat ominously, 2 of these patients had no hematuria. In all patients, irritative symptoms resolved after treatment of the malignancy. From this experience has come the dictum that all patients with presumed IC should undergo cystoscopy, urine cytology, and bladder biopsy of any suspicious lesion to be sure that a bladder carcinoma is not masquerading as BPS/IC. It would seem that **in the absence of microhematuria, and with a negative cytology, the risk of missing a cancer is negligible but not zero. There is no evidence that BPS/IC itself is associated with a higher risk of bladder cancer or transitions to cancer over time** (Murphy et al, 1982).

A large-scale survey of 6783 individuals diagnosed by their physicians as having IC studied the incidence of associated disease in this population (Alagiri et al, 1997). Data from the 2405 responders was validated by comparison with 277 nonresponders (Fig. 12–4). **Allergies** were the most common association, with over 40% affected. Allergy was also the primary association in Hand's study (Hand, 1949). Thirty percent of patients had a diagnosis of **irritable bowel syndrome,** a finding confirming that of Koziol (1994). Altered visceral sensation has been implicated in irritable bowel syndrome in that these patients experience intestinal pain at intestinal gas volumes that are lower than those that cause pain in healthy persons (Lynn and Friedman, 1993), strikingly similar to the pain on bladder distention in IC.

Fibromyalgia, another disorder frequently considered functional because no specific structural or biochemical cause has been found, is also overrepresented in the BPS/IC population. This is a

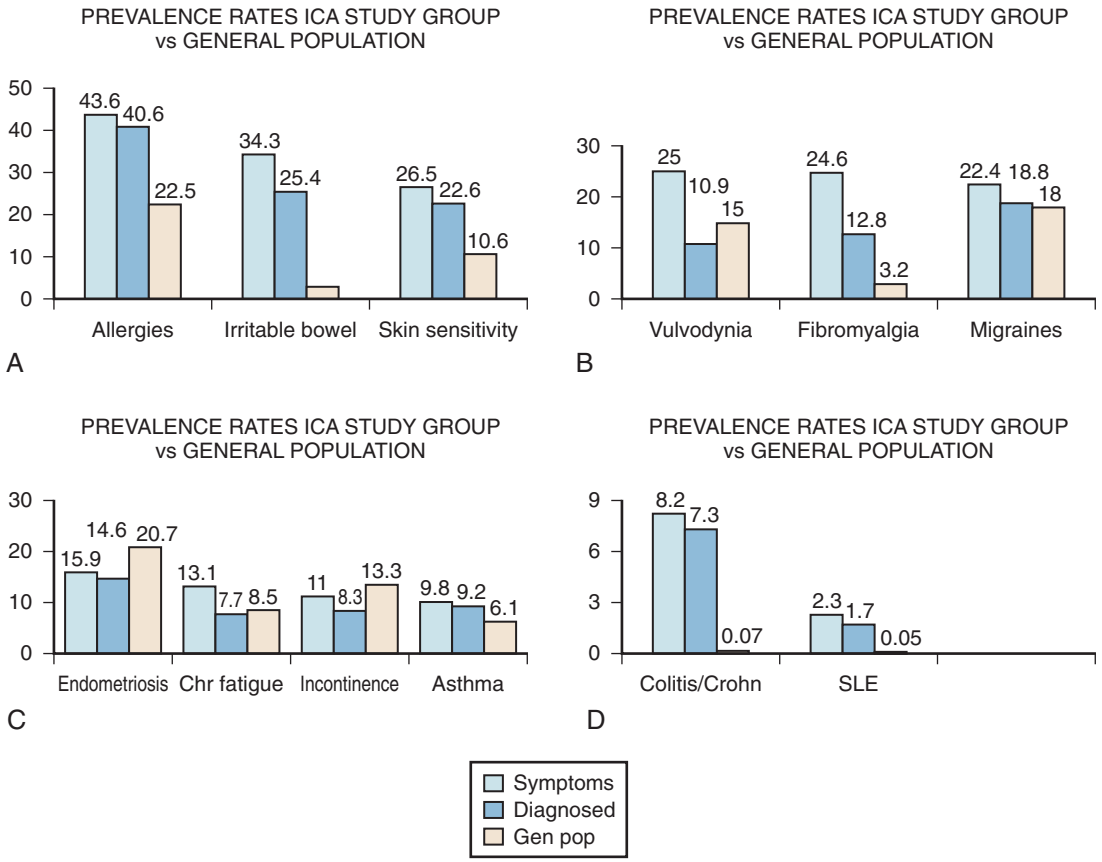

Figure 12–4. Comparison of disease prevalence rates between the Interstitial Cystitis Association (ICA) study group patients who report symptoms of a disorder, those who have been diagnosed with a disorder, and the general population. SLE, systemic lupus erythematosus. (From Alagiri M, Chottiner S, Ratner V, et al. Interstitial cystitis: unexplained associates with other chronic pain syndromes. Urology 1997;49[Suppl 5A]:52–7.)

painful, nonarticular condition predominantly involving muscles; it is the most common cause of chronic, widespread musculoskeletal pain. It is typically associated with persistent fatigue, nonrefreshing sleep, and generalized stiffness. As in BPS/IC, women are affected at least 10 times more often than men (Consensus document on fibromyalgia, 1993). The association is intriguing because both conditions have nearly identical demographic features, modulating factors, associated symptoms, and response to tricyclic antidepressants (Clauw et al, 1997).

Diagnosed **vulvodynia, migraine headaches, endometriosis, chronic fatigue syndrome, incontinence, and asthma had similar prevalence as in the general population.** Several publications have noted an association between BPS/IC and systemic lupus erythematosus (SLE) (Fister, 1938; Boye et al, 1979; De la Serna and Alarçon-Segovia, 1981; Weisman et al, 1981; Meulders et al, 1992). The question has always been as to whether the bladder symptoms represent an association of these two disease processes or rather are a manifestation of lupus involvement of the bladder (Yukawa et al, 2008) or even a myelopathy with involvement of the sacral cord in a small group of these patients (Sakakibara et al, 2003). The beneficial response of the cystitis of systemic lupus erythematosus to corticosteroids (Meulders et al, 1992) tends to support the latter view. No association with discoid lupus has been demonstrated (Jokinen et al, 1972b). Although the actual numbers are small, the Alagiri study demonstrated a 30 to 50 times greater incidence of systemic lupus erythematosus in the IC group compared with the general population. Overall, the incidence of collagen vascular disease in the IC population is low. Parsons (1990) found only 2 of 225 consecutive IC patients to have a history of an autoimmune disorder.

Inflammatory bowel disease was found in over 7% of the IC population Alagiri studied, a figure 100 times higher than in the general population. Although unexplained at this time, abnormal leukocyte activity has been implicated in both conditions (Bhone et al, 1962; Kontras et al, 1971).

The University of Maryland group sought antecedent nonbladder syndromes in 313 patients with incident BPS/IC and compared them to 313 matched controls (Warren et al, 2009). They found 11 antecedent syndromes were more often diagnosed in those with BPS/IC, and most syndromes appeared in clusters. The **most prominent cluster (45%) comprised fibromyalgia—chronic widespread pain, chronic fatigue syndrome, sicca syndrome, and/or irritable bowel syndrome.** Most of the other syndromes and identified clusters were associated with it. They found probable chronic fatigue syndrome in 20% of BPS/IC patients, probable fibromyalgia in 22%, and probable irritable bowel in 27% of the BPS patients. Far fewer had physician reported diagnoses of these syndromes, and odds ratios (OR) for BPS/IC versus controls were 2.5 to 2.9. Study of a managed care database in Portland Oregon revealed that patients coded for gastritis (OR = 12.2), child abuse (OR = 9.3), fibromyalgia (OR = 3.0), anxiety disorder (OR = 2.8), headache (OR = 2.5), and depression (OR = 2.0) were commonly diagnosed with BPS/IC (Clemens et al, 2008b).

A mysterious disorder that has been associated with IC is focal vulvitis. Vulvar vestibulitis syndrome is a

constellation of symptoms and findings involving and limited to the vulvar vestibule consisting of (1) severe pain on vestibular touch to attempted vaginal entry, (2) tenderness to pressure localized within the vulvar vestibule, and (3) physical findings confined to vulvar erythema of various degrees (Marinoff and Turner, 1991). McCormack (1990) reported on 36 patients with focal vulvitis, 11 of whom also had IC. Fitzpatrick and coworkers (1993) has added three more cases. The concordance of these noninfectious inflammatory syndromes involving the tissues derived from the embryonic urogenital sinus and the similarity of the demographics argue for a common etiology.

An association has been reported between IC and **Sjögren syndrome,** an autoimmune exocrinopathy with a female preponderance manifested by dry eyes, dry mouth, and arthritis but that can also include fever, dryness, and gastrointestinal and lung problems. Van de Merwe and colleagues (1993) investigated 10 IC patients for the presence of Sjögren syndrome. Two patients had both the keratoconjunctivitis sicca and focal lymphocytic sialoadenitis allowing a primary diagnosis of Sjögren syndrome. Only 2 patients had neither finding. These researchers later (2003) reported an incidence of 28% of Sjögren syndrome in patients with IC. The incidence of symptoms of PBS/IC in patients with Sjögren syndrome has been estimated to be up to 5% (Leppilahti et al, 2003).

A negative correlation with diabetes has been noted (Parsons, 1990; Koziol, 1994; Warren et al, 2009).

Further epidemiologic studies are warranted because the epidemiology of this disorder may ultimately yield as many clues to etiology and treatment as other avenues of research. The heterogeneity of causes and symptoms of CPPS suggests that proper clinical phenotyping could foster the development of better treatments for individual phenotypes and more successful treatments for all afflicted patients (Baranowski et al, 2008; Shoskes et al, 2009b).

Key Points: Associated Disorders

- Look for symptoms of the following disorders, which may be associated with some cases of BPS: depression, Sjögren syndrome, irritable bowel syndrome, allergies, fibromyalgia, chronic fatigue syndrome, inflammatory bowel disease, and focal vulvitis.
- No reports have ever documents a relationship to suggest that BPS is a premalignant condition.

ETIOLOGY

It is likely that PBS/IC has a multifactorial etiology that may act predominantly through one or more pathways resulting in the typical symptom-complex (Holm-Bentzen et al, 1990; Mulholland and Byrne, 1994; Erickson 1999; Levander, 2003; Keay et al, 2004b) (Fig. 12–5). There are numerous theories regarding its pathogenesis, but confirmatory evidence gleaned from clinical practice has proven sparse. Among numerous **proposals** that shall be further explored in this section are **"leaky epithelium," mast cell activation,** and **neurogenic inflammation,** or **some combination** of these and other **factors leading to a self-perpetuating process resulting in chronic bladder pain and voiding dysfunction** (Elbadawi, 1997). Irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, and various other chronic pain disorders may precede or follow the development of BPS/IC in some patients, but development of associated syndromes is not inevitable by any means, and their relationship to etiology is currently unknown (Warren et al, 2009; Nickel et al, 2010).

Animal Models

The problem with animal models is how accurately they mirror the human situation. A section on animal models appears in the electronic edition along with Figure 12–6 (see the Expert Consult website).

Infection

Often, a diagnosis of BPS/IC is made only after a patient has been seen by a number of physicians and treated with antibiotics for presumed urinary tract infection without resolution of symptoms (Held et al, 1990). The symptom-complex looks to the patient and physician like an infectious process (Porru et al, 2004). The epidemiology of urinary tract infection and its predominance in women mirror the BPS/IC data (Warren, 1994). The acute to subacute onset in many patients has fascinated clinicians who often associate an insidious onset with a chronic condition such as PBS/IC.

Reverse logic led some to suspect that antibiotics may be instrumental in causing IC (Holm-Bentzen et al, 1990). Most patients have been treated with antibiotics once or several times before the diagnosis is made. Numerous antibiotics, primarily in the penicillin family, can induce a cystitis (Bracis et al, 1977; Moller, 1978; Chudwin et al, 1979; Cook et al, 1979; Marx and Alpert, 1984), but no evidence has ever been documented that these antibiotics or the supposedly "surface active" nitrofurantoins or tetracyclines have any involvement in pathogenesis of IC (Ruggieri et al, 1987; Levin et al, 1988).

To determine whether there is an infectious cause of BPS certain procedures are necessary (Warren, 1994). Not just urine but bladder epithelium as well must be cultured for appropriate microorganisms, including bacteria, viruses, and fungi. Because some organisms might be culturable yet fastidious, special culture techniques should be used. Because some organisms in urine or tissue might be viable but nonculturable, specific nonculture techniques for discovery and identification should be employed. Most important, the same procedures must be carried out in a control population.

Attempts to show an infectious etiology go back to the dawn of the disease, but **the case has never been a strong one** (Duncan and Schaeffer, 1997). Hunner (1915) originally proposed that IC resulted from chronic bacterial infection of the bladder wall secondary to hematogenous dissemination. Harn and associates (1973) proposed a relationship between IC and streptococcal and post-streptococcal inflammation. They produced a progressive chronic inflammation in rabbit bladders by injecting small numbers of *Streptococcus pyogenes* in the bladder wall. The discovery that *Helicobacter pylori* is related to the pathogenesis of chronic atrophic gastritis and peptic ulcer disease and that antibiotic treatment can heal ulceration (Parsonnet et al, 1991; National Institutes of Health, Consensus Development Panel, 1994; Sung et al, 1995) has continued to focus attention of researchers in IC on the possibility that an infectious etiology is not only reasonable but will ultimately be found. Studies of *H. pylori* itself have failed to demonstrate an association with IC (English et al, 1998; Agarwal and Dixon 2003; Atug et al, 2004; Haq et al, 2004). Wilkins and colleagues (1989) found bacteria in catheterized urine specimens and/or bladder biopsy specimens in 12 of 20 patients with IC.

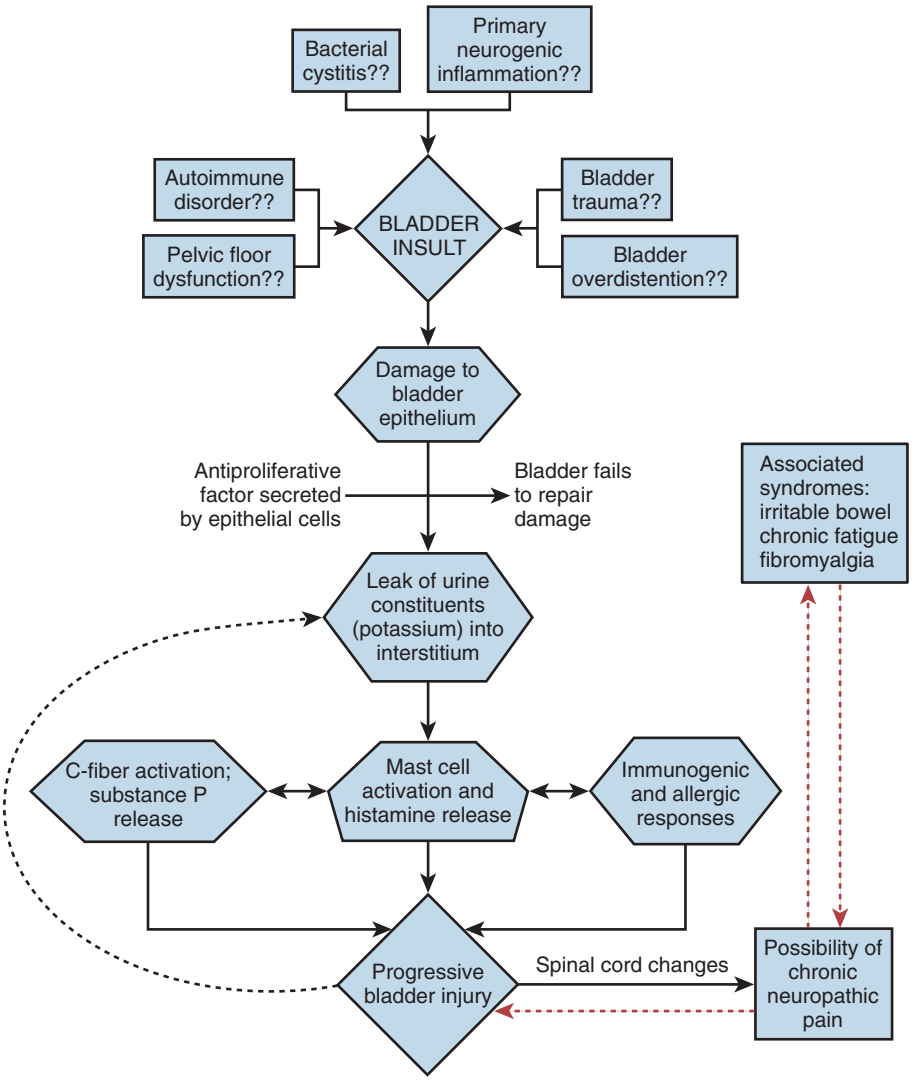

Figure 12–5. Hypothesis of etiologic cascade of bladder pain syndrome. (From Hanno P, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. Paris: Health Publication Ltd.; 2009. p. 1459–518.)

However, 8 of the isolates were fastidious bacteria, *Gardnerella vaginalis,* and *Lactobacillus* species and no controls were included in the study. Polyomaviruses have been reported to cause a BPS/IC-like syndrome that responds to cidofovir treatment (Eisen et al, 2009). These viruses are excreted intermittently in the urine of healthy, asymptomatic adults, making diagnosis of a true infection problematic.

Negative studies far outnumber the positive ones. Hanash and Pool (1970) performed viral, bacterial, and fungal studies on 30 IC patients and failed to substantiate an infectious cause. Hedelin and coworkers (1983) found only 3 of 19 IC patients to have urine cultures positive for *Ureaplasma urealyticum* and indirect hemagglutination antibodies to *Mycoplasma hominis* to be no greater than in controls. Potts and colleagues (2000) cultured *U. urealyticum* in 22 of 48 patients with "chronic urinary symptoms" and had great success in these patients (none of whom had established IC) with short courses of commonly prescribed antibiotics. Given the history of empirical use of antibiotics in the vast majority of IC patients, it is doubtful if this group represents even a small percentage of the IC diagnosed population. Nevertheless it illustrates that BPS/IC is a diagnosis of exclusion and that the urine culture is critical whereas an empirical short course of antibiotics is certainly reasonable if the patient has not already been treated for presumed infection. Empirical use of doxycycline has been successful in this situation (Burkhard et al, 2004).

The development of highly sensitive, rapid, and specific molecular methods of identifying infectious agents by the direct detection of DNA or RNA sequences unique to a particular organism (Naber, 1994) resulted in a flurry of activity into the search for a responsible virus or microorganism. Hampson and associates (1993) could find no evidence of mycobacterial involvement in 8 cases of BPS/IC using DNA probes. Haarala and colleagues (1996) confirmed an absence of bacterial DNA in the bladder of 11 BPS/IC patients with no documented history of urinary tract infection. Hukkanen and associates (1996) reported an absence of adenovirus and BK virus genomes in urinary bladder biopsy specimens of IC patients. Domingue and coworkers' (1995) provocative finding of the presence of bacterial 16S rRNA genes in bladder biopsy specimens from 29% of IC patients but not from control bladders, and his discovery of 0.22-μm filterable forms in culture of biopsy tissue from 14 of 14 IC patients and none of 15 controls has never been confirmed or repeated.

A preliminary study found a statistically significant increase in urine polymerase chain reaction studies to *Chlamydia pneumoniae* major outer membrane protein gene in patients with BPS/IC as compared with controls (Franke et al, 1999). Other studies have shown that similar percentages of both IC and control patient populations have nonculturable bacteria in their bladder on the basis of polymerase chain reaction studies of bladder biopsy specimens (Heritz et al, 1997; Keay et al, 1998a). The spirochete *Borrelia*

burgdorferi has been found in the bladder biopsy specimens and urine of patients with Lyme disease and can cause frequency, urgency, and nocturia. DNA studies have failed to show a role for *Borrelia* in IC (Haarala et al, 2000).

The role of infection in the pathogenesis of BPS/IC remains a mystery. **At this time there are little data to support the role of an infectious etiology** but investigators keep returning to an infectious theory. New insights into the mechanisms by which bacteria adhere, grow, and persist in association with host tissue and form intracellular pods capable of subverting host defense mechanisms and allowing replication within epithelial cells lay the foundation for a possible role of infection in initiating the BPS/IC pathologic cascade (Kau et al, 2005). The University of Maryland group proposes a model of BPS in which bladder epithelial damage such as that caused by bacterial cystitis may be the first step leading to a low-level inflammatory response we call BPS/IC (Keay and Warren, 1998). Domingue writes that "It is logical to suggest that even if organisms are not causative agents, their presence may lead to immune and host-cell responses that could initiate or exacerbate an inflammatory state" (Domingue and Ghoniem, 1997).

If infection does play a role it would be predicted that appropriate treatments to minimize microbial presence in the tissue would significantly improve the morbidity associated with BPS/IC. Durier's incredible series (1992) purporting to cure 27 of 27 IC patients with the use of up to five sequential antibiotics covering the anaerobic spectrum has never been duplicated. Warren and associates' (2000) prospective, double-blind, placebo-controlled, randomized trial of 50 patients may well prove the end of long-term empirical antibiotic treatment in established BPS/IC. Either a placebo or antibiotics (sequential doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin, and ciprofloxacin for 3 weeks each) were administered for 18 weeks. Most patients guessed the arm to which they were assigned. Of the 25 patients in the active arm, 80% had new nonurinary symptoms perceived as side effects. There was minimal improvement in some patients associated with the active arm of the study, but the conclusion that intensive antibiotics do not represent a major advance in therapy for IC seems well justified.

Although the concept that a urinary tract infection may trigger BPS in some patients is appealing (Elgavish et al, 1995; Elbadawi, 1997), **it is unlikely that active infection is involved in the ongoing pathologic process or that antibiotics have a role to play in treatment.**

Autoimmunity/Inflammation

Immune/neuroimmune mechanisms may have an important role in the pathogenesis of BPS/IC. Excessive release of sensory nerve neurotransmitters and mast cell inflammatory mediators is thought by some to be responsible for the development and propagation of symptoms (Luo, 2005). Inflammation results in altered nerve growth factor content of the bladder and in morphologic changes in sensory and motor neurons innervating the bladder. Such neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation subsides (Dupont et al, 2001). Up to one third of BPS/IC patients may have an acute urinary tract infection that immediately precedes the onset of chronic symptoms (Warren et al, 2008). However, abnormal differentiation in the urothelium with a loss of barrier function markers and altered differentiation markers may be independent and occur independently of inflammation (Hauser et al, 2008).

The role of inflammation may stem from inflammation originating in organs other than the bladder. Pain syndromes such as irritable bowel syndrome and BPS, which are associated with visceral hyperalgesia, are often comorbid with endometriosis and chronic pelvic pain. One of the possible explanations for this phenomenon is viscerovisceral cross-sensitization, in which increased nociceptive input from an inflamed pelvic organ sensitizes neurons that receive convergent input to the same dorsal root ganglion (DRG) from an unaffected visceral organ. Visceral sensory integration in the dorsal root ganglia has been demonstrated in a rodent model and may underlie the observed comorbidity of female pelvic pain syndromes (Li et al, 2008).

For many years the possibility that BPS may represent some type of autoimmune disorder has been considered. Narrowly defined, autoimmune diseases are clinical syndromes caused by the activation of T cells or B cells, or both, in the absence of an ongoing infection or other discernible cause (Davidson and Diamond, 2001). To establish a disease as autoimmune, three types of evidence can be considered: (1) direct evidence from transfer of pathogenic antibody or pathogenic T cells; (2) indirect evidence based on reproduction of the autoimmune disease in experimental animals; and (3) circumstantial evidence from clinical clues (Rose and Bona, 1993). Circumstantial evidence would include (1) association with other autoimmune diseases in the same individual or same family; (2) lymphocytic infiltration of target organ; (3) statistical association with a particular major histocompatibility complex haplotype; and (4) favorable response to immunosuppression.

Circumstantial evidence by itself cannot define an autoimmune disease, and **at this point the case for autoimmunity in BPS/IC is far from clear.** Three different possibilities exist: (1) BPS is caused by a direct autoimmune attack on the bladder, (2) some of the autoimmune symptoms and pathology of BPS arise indirectly as a result of tissue destruction and inflammation from other causes, and (3) autoimmune phenomena in BPS patients are coincident and unrelated to the disease (Ochs, 1997).

Silk (1970) found bladder antibodies in 9 of 20 IC patients and none in 35 pathologic or normal control patients. Gordon and associates (1973) found antibladder antibodies present in biopsy specimens from 6 of 8 IC patients and in 3 of 5 control patients. No control patient demonstrated antibodies in the muscle, whereas 3 of 5 IC patients with muscle in the biopsy did so. Jokinen and colleagues (1972a) looked at sera from 33 IC patients and found 28 with an antinuclear antibody titer of 1:10 or greater, but no bladder-specific antibodies were detected with immunofluorescence. There was poor correlation between antinuclear antibody titers and symptom severity. These researchers noted in a later study (Jokinen et al, 1973) that elevated antibody titers against cell nuclei and crude kidney homogenate decreased within 12 months after cystectomy in 3 IC patients. All of this provided hints that BPS/IC could fall into the autoimmune group of diseases.

Oravisto (1980) summarized the world literature on this idea in 1980, concluding that the chronic course of disease, the absence of infection, the pathologic findings, the occurrence of antinuclear antibodies, and the reported responses to corticosteroids at that time provided strong circumstantial evidence of autoimmunity. He discounted the paucity of activated lymphocytes that speak against an autoimmune process. Studies on autoantibodies in BPS/IC have shown that these mainly consist of antinuclear antibodies (Jokinen et al, 1972a) similar to the autoantibody profiles in some systemic diseases such as Sjögren syndrome, which is well known to be of autoimmune origin (Tan, 1989; Leppilahti et al, 2003). Mattila (1982) presented evidence of

immune deposits in the bladder vascular walls in 33 of 47 BPS/IC patients. Studying sera from 41 patients with IC, he concluded that the classical pathway activation of the complement system was involved, supporting the possibility that a chronic local immunologic process was indeed occurring (Mattila et al, 1983). The autoantibodies tested were found to be directed against cytoskeletal intermediate filaments. Because the autoantibodies have to gain access to intracellular structures to cause in-vivo deposits, primary tissue injury of unknown etiology has to be postulated (Mattila and Linder, 1984).

Anderson and colleagues (1989) studied 26 patients with BPS/IC and compared them to a control group of similar age and sex with other urologic complaints. They performed a standard autoimmune profile and looked for specific antibodies to normal human bladder in the serum. Sixty-five percent of IC patients and 36% of controls demonstrated non–organ-specific antibodies; 40% of IC patients had antinuclear antibodies; 75% of IC patients and 40% of controls had antibladder antibodies present in the serum. There was no increase in immunoglobulin deposition in the bladder epithelium in IC patients versus controls. Although IC patients demonstrated a nonspecific increase in antibody formation, this was not significantly different from a similar group of other urologic patients. The lack of specificity indicates the immunologic findings are likely secondary to inflammation rather than a primary etiology.

In a study looking for active immune cellular deposition in BPS/IC patients, no statistically significant difference between controls and nonulcerative IC patients was identified (Harrington et al, 1990). In contrast, the ulcerative BPS group had focal sheets of plasma cells, aggregates of T cells, B-cell nodules, a decreased or normal helper-to-suppressor cell ratio, and suppressor cytotoxic cells in germinal centers. Flow cytometry analysis of peripheral blood lymphocyte subsets showed increased numbers of secretory-Ig–positive B cells and activated lymphocytes in the nonulcerative group and increased numbers of secretory-Ig–positive cells and activated lymphocytes in the ulcerative group. These results may suggest a partial role for an immune mechanism in IC. Erickson and coworkers (1997a) have also noted a major difference in inflammatory cell types as well as clinical features in BPS/IC patients with severe inflammation, suggesting two different patient groups with two different underlying pathophysiologies.

Hanno and colleagues (1990) found CD4 cell predominance in all layers of the bladder in BPS/IC patients. Christmas (1994) reported increased numbers of CD4+ and CD8+ T cells in bladder biopsy specimens from patients with IC and bacterial cystitis as compared with controls. These T cells were present in the urothelium and submucosa but not in the detrusor. Control bladder tissue demonstrated only CD8 cells in the urothelium and both CD4+ and CD8+ cells in the submucosa. The number of plasma cells was significantly greater in IC patients than in normal controls and controls with bacterial cystitis.

MacDermott and colleagues (1991b) found a normal distribution of peripheral blood lymphocytes in IC patients, a finding not supportive of an autoimmune mechanism in the disease. The lamina propria showed a predominance of CD4 (helper T cells) lymphocytes over CD8 cells in both IC and other cystitis patients. The same pattern was seen in the epithelium of patients with bacterial or mechanical cystitis, but patients with IC had a predominance of CD8 lymphocytes in the urothelium, which was identical to that found in control subjects. The findings suggest that the urothelium is not involved in the inflammatory reaction, as is the lamina propria, making the urothelium an unlikely source for the initiating factor.

Miller and coworkers (1992) investigated the function of peripheral blood lymphocytes from nonulcerative IC patients, testing the proliferative response and cytokine production of T cells to nonspecific mitogenic stimulation and the proliferative response of T cells to urine components. Proliferation and cytokine production after mitogen stimulation were the same for controls and BPS/IC patients. Moreover, no immunologic response to IC urine by autologous peripheral blood lymphocytes in in-vitro assays was observed. Their findings cast doubt on theories suggesting that IC is an autoimmune disease.

Numerous inflammatory mediators have been studied with regard to their relation to BPS (Elgebaly et al, 1992; Felsen et al, 1994; Lotz et al, 1994; Steinert et al, 1994; Zuraw et al, 1994). Patients with BPS/IC exhibit varying degrees of inflammation that can separate them into clusters (Tomaszewski et al, 2001; Green et al, 2004). Bladder inflammation in IC is categorized by elevated urinary interleukin-6 (Erickson et al, 1997a) and activation of the kallikrein-kinin system (Rosamilia et al, 1999b). The absence of urinary interleukin-1β in IC argues against an immunologic or autoimmune etiology of the disorder (Martins et al, 1994). Neurogenic inflammation may play a role in the etiology, because long-term exposure of afferent nerve terminals to inflammatory mediators can alter ion channels and result in bladder hyperalgesia (Buffington and Wolfe, 1998; Yoshimura and de Groat, 1999). Substance P itself does not seem to be the single initiator of inflammation in the bladder, and its blockade does not protect the bladder in animal models from inflammatory responses (Luber-Narod et al, 1997). Urinary nitric oxide synthase (NOS) activity is known to be elevated in patients with urinary infection and thought to play a role in the bladder's response to infection and in the inflammatory process that follows infection. The finding that urinary NOS activity is decreased in BPS/IC patients has puzzled researchers but could explain the reduction in functional bladder capacity associated with the disorder (Smith et al, 1996; Foster et al, 1997).

Urothelial cell activation in IC may result in aberrant immune responses and immune activation within the bladder wall (Liebert et al, 1993) that could relate to pathogenesis of the disease but might not reflect initiating etiology (Ochs et al, 1994). It has been proposed that inflammatory and/or immune responses in IC could be exacerbated by persistent activation of the nuclear factor-kappa B (NF-κB) (Abdel-Mageed and Ghoniem, 1998; Abdel-Mageed, 2003). Angiogenic factors such as platelet-derived endothelial cell growth factor/thymidine phosphorylase and transforming growth factor-β may be involved in the inflammatory process to induce painful symptoms in patients with IC or bladder carcinoma (Ueda et al, 2002).

The exact role of autoimmunity in IC remains controversial (Ochs, 1997). Suplatast tosylate, a new immunoregulator,

Key Points: Autoimmunity and Inflammation

- Neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation subsides.
- Abnormal differentiation in the urothelium with a loss of barrier markers and altered differentiation markers may be independent and occur independently of inflammation.
- Visceral sensory integration may result in inflammation originating in organs other than the bladder causing symptoms identified with BPS.

has shown efficacy in a small, uncontrolled IC study in which improvements in symptoms and bladder capacity were correlated with changes in autoimmune parameters (Ueda et al, 2000). **Although the immune system remains a target for therapy, no clear indication of a primary role for autoimmunity as the cause of IC has been observed** (Liebert, 1997).

Mast Cell Involvement

Although mast cells are thought of primarily in the context of allergic disorders, and certain acute inflammatory responses, these cells have also been implicated in biologic responses as diverse as angiogenesis and wound healing, bone remodeling, peptic ulcer disease, atherosclerosis, and reactions to neoplasms (Galli, 1993). Mast cells remain one of the most enigmatic cells in the body. They secrete significant amounts of numerous proinflammatory mediators that contribute to a number of chronic inflammatory conditions, including stress-induced intestinal ulceration, rheumatoid arthritis, scleroderma, and Crohn disease. They have been described even among the lowest order of animals, having been discovered in the frog mesentery over 100 years ago. Their raison d'etre may be for initiating and coordinating the host's inflammatory and immune responses against microbial pathogens (Abraham and Malaviya, 1997). Recently they have been implicated in a range of neuroinflammatory diseases, especially those worsened by stress (Theoharides, 2004; Theoharides and Cochrane, 2004). These include multiple sclerosis, migraines, inflammatory arthritis, atopic dermatitis, coronary inflammation, irritable bowel syndrome, and BPS/IC. They may be activated through their Fc receptors by immunoglobulins other than IgE, as well as by anaphylatoxins, neuropeptides, and cytokines to secrete mediators selectively without overt degranulation.

Mast cells have frequently been reported to be associated with IC, both as a pathogenetic mechanism and as a pathognomonic marker (Simmons, 1961; Bhone et al, 1962; Smith and Dehner, 1972; Larsen et al, 1982; Hofmeister et al, 1997). The association of bladder mastocytosis, IC, and irritable bowel syndrome (Pang et al, 1996) and chronic urticaria (Sant et al, 1997) is intriguing. Evidence of their importance is mounting, suggesting that **they may serve as the final common pathway through which the symptomatic condition is expressed. Mast cells produce, among other compounds, histamine. Histamine release in tissue causes pain, hyperemia, and fibrosis, all notable features of IC.**

Simmons (1961) was the first to suggest mast cells as a cause of IC. Contribution of mast cells to the cellular infiltrate in IC (Fig. 12–7) has been shown to vary from about 20% in nonulcer IC patients to 65% in patients with ulceration (Sant et al, 1988; Enerback et al, 1989). Mast cells participate in allergic reactions (hypersensitivity type I) during which IgE antibody is synthesized in response to specific antigens. IgE binds to mast cell receptors, and antigen binds to the IgE, leading to degranulation (Lagunoff et al, 1983). Other triggers of mast cell secretion include acetylcholine, anaphylatoxins, cationic peptides such as substance P, chemicals, contrast agents, cytokines, opioids, antihistamines, exercise, hormones, viruses, and bacterial toxins (Sant and Theoharides, 1994). Mast cells promote infiltration of neutrophils, T and B lymphocytes, monocytes, and eosinophils. T lymphocytes secrete substances capable of activating mast cells, thus perpetuating the cycle of inflammation (Kaplan et al, 1985).

Since the presence of mast cells within the bladder wall was first recognized (Simmons and Bunce, 1958), numerous investigators have tried to determine whether there is an increase in the number of mast cells in the bladder of patients with IC or differences in their location or functional state (Larsen et al, 1982; Kastrup et al, 1983; Fall et al, 1987; Feltis et al, 1987; Lynes et al, 1987; Christmas and Rode, 1991). An increase in urothelial mast cells appears to be part of the generalized inflammatory cell reaction regardless of etiology, and not a specific feature of IC, whereas the presence of increased numbers of mast cells in the detrusor is more specific for IC. However, one study did report detrusor mastocytosis in 64% of IC patients and 80% of a control group with other urologic disease, with no statistically significant difference between the mean number of detrusor mast cells in the two groups (Hanno et al, 1990).

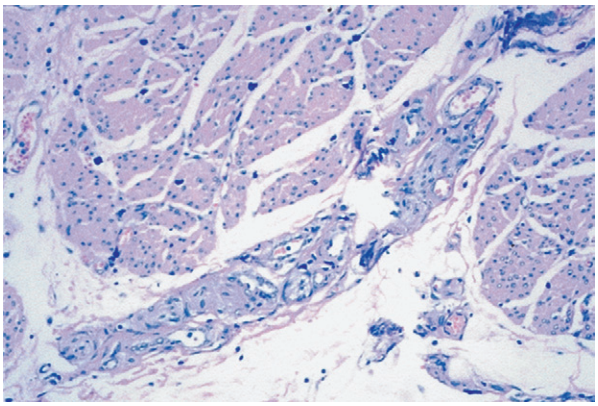

Figure 12–7. Giemsa stain shows detrusor mastocytosis and nerve hypertrophy in bladder pain syndrome (original magnification ×400). (Courtesy of John Tomaszewski, Hospital of the University of Pennsylvania, Department of Pathology.)

Aldenborg and associates (1986) reported that mast cells are found predominantly in the detrusor muscle in patients with classic IC, but there is also a secondary population of mast cells in the lamina propria and the bladder epithelium, with staining characteristics distinct from those in the detrusor. None of these epithelial mast cells was found in controls. These findings were interpreted to indicate a transepithelial migration of mast cells in patients with IC. This second population of mast cells does not appear to be involved in the nonulcer type of IC (Aldenborg et al, 1989). This mucosal population of mast cells can also differ from the mast cells found in deeper tissues in physiologic responses and release of secretory products (Sant, 1991). The "mucosal mast cells" are susceptible to aldehyde fixation and require special fixation and staining techniques for proper demonstration. Detrusor mast cells are not susceptible to fixation techniques. Recent studies have shown that although all human mast cells contain the proteinase tryptase there is a population of mast cells that also contain the proteinase chymase. The mast cell expansion in IC involves both types (Yamada et al, 2000). Mast cell activation is far more pronounced in the ulcerative form, which in addition displays prominent inflammation, in contrast to nonulcer IC in which it is sparse. Thus the basic pathologic processes may differ (Peeker et al, 2000b). Because activated mast cells lose their histologically identifiable granules once degranulation occurs, estimates of mast cell density using standard histologic techniques may underestimate mast cell numbers (Sant and Theoharides, 1994).

Electron microscopy has confirmed that mast cells in IC are more likely to be degranulated or activated than those found in other conditions (Larsen et al, 1982; Theoharides and Sant, 1991; Theoharides et al, 1995). In at least a subpopulation of IC patients

this may be explained by increased stimulation of mast cells by stem cell factor (Pang et al, 1998). A chronic exposure of detrusor muscle to histamine in IC patients is suggested by the finding that there is an impairment of the direct contractile response to histamine in detrusor muscle affected by IC in comparison to control detrusor, suggesting a receptor desensitization (Palea et al, 1993). The clinical relationship between an increased number of mast cells and symptoms of IC has not been definitively established. Some studies have found no correlation (Holm-Bentzen et al, 1987b; Lynes et al, 1987; Dondore et al, 1996). Although mast cell infiltration in intestinal segments used for augmentation has been associated with pain and failure of the procedure (Kisman et al, 1991), others have shown that mast cell infiltration in intestine used in the urinary tract is the norm and not pathologic (MacDermott et al, 1990).

Many of the substances that have been shown to induce mast cell secretion are released from neurons that innervate the organ containing the mast cells (Christmas et al, 1990). The capsaicin-sensitive sensory neurons that innervate the bladder are thought to have a dual "sensory-efferent" function, in which an axon reflex-induced release of neuropeptides results in local inflammation (Foreman, 1987; Barbanti et al, 1993). Hand (1949) reported an increase in the submucosal nerve density in IC, a phenomenon confirmed by Christmas and associates (1990), who showed an increase in nerve fiber proliferation in IC but not in patients with bacterial or lupus cystitis. Increased innervation by nerves releasing substances affecting mast cells could lead to increased mast cell secretion. Among these substances is acetylcholine. Mast cells can be stimulated by cholinergic agonists to secrete serotonin (Theoharides and Sant, 1991). Substance P–containing fibers have been found to be increased in bladders from IC patients and are found adjacent to mast cells (Pang et al, 1995b). In mice, mast cells modulate the inflammatory response of the bladder to substance P and to *Escherichia coli* lipopolysaccharide (Bjorling et al, 1999).

An increase in adrenergic but not cholinergic nerves in IC patients as compared with controls has been reported (Hohenfellner et al, 1992). These researchers also found increased numbers of neurons staining for vasoactive intestinal polypeptide and neuropeptide Y (NPY), both of which are associated with sympathetic nerves. Studies in rats have revealed that psychological stress can activate bladder mast cells through the action of sensory neuropeptides (Spanos et al, 1997; Alexacos et al, 1999). Diurnal cortical variations have been associated with symptom levels in PBS/IC (Lutgendorf et al, 2002), and the mast cell may represent a pathway for stress to be reflected in bladder symptomatology.

Mast cells can alter their environment by regulating tissue gene expression (Saban et al, 2001). The finding of increased synthesis of urinary leukotriene E4 in patients with IC and detrusor mastocytosis when compared with healthy controls suggests that cysteinyl containing leukotrienes are involved in the inflammatory reaction observed in the urinary bladder of patients with IC and may be produced from tissue mast cells in the bladder wall or macrophages (Bouchelouche et al, 2001a).

Could mast cell products be useful in diagnosing BPS/IC? They are not specific for BPS/IC and are increased in bladder carcinoma (Serel et al, 2004). Elevated histamine levels have been found in bladder biopsy specimens of IC patients (Kastrup et al, 1983; Lynes et al, 1987; Enerback et al, 1989) as well as from bladder washings (Lundeberg et al, 1993). Holm-Bentzen and colleagues (1987c) reported a significantly elevated urinary excretion of 1,4-methylimidazole acetic acid, the major metabolite of histamine. Others have found no differences between IC and controls in random spot tests of urinary histamine (Yun et al, 1992). Levels were elevated after hydrodistention in IC patients but not in control subjects, which is a possible consequence of hydrodistention and resultant mast cell degranulation. El Mansoury and coworkers (1994) found increased methylhistamine, a histamine metabolite, in spot and 24-hour urine samples from IC patients as compared with controls. Although such an increase could still be interpreted as indicating a systemic rather than a bladder syndrome, subsequent findings of elevated mast cell tryptase in the urine of IC patients could come only from the bladder (Boucher et al, 1995). Erickson and colleagues (2004) reported that urine methylhistamine is not useful as an objective marker of response to bladder distention or as a predictor of response to distention or as a substitute for bladder biopsy to determine mast cell counts.

The realization that mast cells are associated with the syndrome of BPS by no means diminishes the other multiple theories of causation. The poor clinical results with antihistamine therapy would argue against their being a primary factor. Their very presence could be related to injury from any of the proposed theories of etiology, and degranulation could likewise reflect a final common pathway resulting in pain and frequency from multiple causes. Rickard and Lagunoff (1995) proposed, based on results with mast cell granules and epithelial cells in tissue culture, that mast cells could contribute to failure of epithelialization of the bladder surface after injury by two potential mechanisms: (1) inhibition of epithelial cell replication and (2) interference with epithelial cell spreading, thus resulting in the "leaky epithelium" found in some patients. Mast cells may actually be the mediator through which female hormones play a role, accounting for the 10:1 female-to-male preponderance of the disease (Vliagoftis et al, 1992; Pang et al, 1995a; Patra et al, 1995; Bjorling and Wang, 2001). Estradiol augments the secretion of mast cell histamine in response to substance P. It has been proposed that the symptoms of BPS/IC may depend on an imbalance of the relative number of estrogen receptors to progesterone receptors on bladder mast cells (Letourneau et al, 1996).

To summarize, much important IC research has centered on the mast cell. These cells are strategically localized in the urinary bladder close to blood vessels, lymphatics, nerves, and detrusor smooth muscle (Saban et al, 1997). **Studies to date strongly suggest that BPS is a syndrome with neural, immune, and endocrine components in which activated mast cells play a central, although not primary, pathogenetic role in many patients** (Elbadawi and Light, 1996; Filippou et al, 1999). Studies in a mast cell–deficient mouse model demonstrate that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor, respectively, suggesting that pain is independent of pathology and inflammation and that histamine receptors may represent direct therapeutic targets for pain in BPS/IC (Rudick et al, 2008).

Key Points: Mast Cells and Histamine

- Mast cells may be a pathognomonic marker for BPS and also represent a pathogenetic mechanism of the syndrome. They could serve as a final common pathway through which the symptomatic condition is expressed.
- Histamine, produced by mast cells, may cause pain, hyperemia, and fibrosis, all notable features of BPS.

Bladder Glycosaminoglycan Layer and Epithelial Permeability

Until the early 1970s most investigators thought that the major barrier to free flow of urinary constituents was at the level of the epithelial cells. Tight junctions between urothelial cells, specialized "umbrella cells" lining the surface, and direct bactericidal activity of the vesical mucosa were thought capable of defense of the internal milieu from bacteria, molecules, and ions in the urine (Ratliff et al, 1994). Staehelin and colleagues (1972) proposed that lipid and other hydrophobically bonded materials were important in any barrier to permeability in the luminal membrane because permeants leaked through the interplaque regions if the particles alone limited transport. It has been shown that inflammation of the underlying muscle and lamina propria can disrupt the bladder permeability barrier by damaging tight junctions and apical membranes and causing sloughing of epithelial cells. Leakage of urinary constituents through the damaged epithelium may then exacerbate the inflammation in the underlying tissues (Lavelle et al, 1998, 2000).

It was Parsons and Hurst (1990) who hypothesized and popularized **the concept that IC in a subset of patients is the result of some defect in the epithelial permeability barrier of the bladder surface GAGs.** The major classes of GAGs include hyaluronic acid, heparin sulfate, heparin, chondroitin 4-sulfate and chondroitin 6-sulfate, dermatan sulfate, and keratan sulfate. These carbohydrate chains, coupled to protein cores, produce a diverse class macromolecules, the proteoglycans (Trelstad, 1985). GAGs exist as a continuous layer on the bladder urothelium (Dixon et al, 1986; Cornish et al, 1990). Except heparin, all the other types of GAGs have been found on the bladder surface (Ruoslahti, 1988). The GAG layer functions as a permeability and antiadherence barrier. When impaired, its functions can be duplicated by exogenous GAG (Hanno et al, 1978). In the absence of this protective layer in the urinary bladder its susceptibility to infection would increase, and the production of nitric oxide in the urothelial cells, and of substance P in the intraepithelial afferent C-fiber terminals, increases. Consequently, the permeability of both the urothelium and the blood vessels in the mucous membrane increases and the blood flow slows owing to vasodilatation (Hohlbrugger, 1999).

Parsons and Hurst (1990) reported a lower excretion of urinary uronic acid and GAGs in IC patients than in normal volunteers and hypothesized that a leaky transitional epithelium might be absorbing these substances to its surface. The data are interesting in that one might expect urinary GAG to increase with injury to the bladder and decrease with resolution (Uehling et al, 1988). The San Diego group (Lilly and Parsons, 1990; Parsons et al, 1990) went on to show experimentally that one can damage the GAG layer with protamine sulfate with resultant back-diffusion of urea through the bladder lumen, and that this urea loss can be prevented with a bladder instillation of exogenous GAG (heparin). By placing a solution of concentrated urea into the bladder of IC patients and measuring absorption versus controls, Parsons and associates (1991) found support for his theory in patients with IC. The rationale of the epithelial permeability school is nicely summarized in four publications (Parsons 1993, 1994; Hurst et al, 1997; Hohlbrugger and Riedl, 2000) and provides a comprehensive, if somewhat imperfect, theory of the disorder.

Support for an epithelial abnormality from a different perspective has come from Bushman and coworkers (1994), who found aneuploid DNA profiles on barbotage specimens from IC patients that may signal an underlying abnormality of the epithelial cell population in some patients with IC. Wilson and colleagues (1995) identified a loss of type IV collagen in the urothelial basement membrane in 5 of 11 IC patients. Hurst's group (1996) studied bladder biopsy specimens of IC patients and control subjects and concluded that there is a deficit of bladder luminal and basal proteoglycans associated with the disorder. The basal abnormality may reflect an altered urothelial differentiation program. In a later study, IC bladder biopsy specimens showed abnormalities in 24 of 27 patients when examined by immunohistochemical assessment of E-cadherin, ZO-1, uroplakin, and chondroitin sulfate (Slobodov et al, 2004). Erickson and coworkers (1996) measured a glycoprotein (epitectin) in the urine of IC patients and found a decrease compared with a control population, although a significant overlap was detected. Buffington and Woodworth (1997) gave 6 IC patients and 6 control subjects oral fluorescein dye. IC patients had higher levels of fluorescein in their plasma and lower urinary excretion of the dye, suggesting altered membrane permeability and increased fluorescein reabsorption in the bladder wall of IC patients. Erickson and colleagues (1998) compared urinary levels of hyaluronic acid in IC patients and control subjects, reporting higher urinary hyaluronic acid in the patient group, which possibly was accounted for by leakage of this GAG across the epithelium.

In feline IC, the only naturally occurring animal model of the disorder, the urothelium has been shown to have decreased transepithelial resistance and increased water and urea permeability compared with controls in response to hydrodistention (Lavelle et al, 2000). This indicates that barrier function is compromised, which could lead to the sensitization of sensory nerves by irritants from urine crossing into the muscle layer. Bladder strip studies have shown that bladders of cats with feline IC have significantly more spontaneous Ca^{2+} transients in the mucosal layer than control bladders. Coupled with increased sensitivity of muscarinic receptors in the mucosal layer, these bladders may manifest enhanced smooth muscle spontaneous contractions. This finding could play a contribution in the symptoms of BPS/IC (Ikeda et al, 2009). In fact, human cell culture studies comparing BPS/IC and normal bladder urothelial cells have shown greater sensitivity of IC bladder urothelial cells to carbachol, suggesting that BPS/IC pathobiology may also include alterations in muscarinic signaling (Gupta et al, 2009).

Further data for an abnormal surface mucin came from Moskowitz and colleagues (1994) who studied biopsy specimens from 23 IC patients with regard to the presence of a glycoprotein component of the surface mucin referred to as GP1 and compared the results to those in 11 normal controls. Qualitative GP1 changes in a majority of IC patients were identified. GP1 reactivity was noted in all controls but was absent in 35% of IC patients and diminished in 61%. This study may provide evidence of an abnormal bladder urothelium, but the effects of bladder distention in the IC group is unknown and may have contributed to the results. There were no pathologic controls used, and no attempt was made to correlate GP1 reactivity with IC symptoms (Messing, 1994). Castration in female rabbits is associated with bladder mucosal changes resulting in increased mucosal permeability (Parekh et al, 2004). Birder and colleagues have shown that feline IC results in increased baseline production of nitric oxide due to inducible nitric oxide synthase (iNOS) (Birder et al, 2005). These changes in transmitter release may have a role in altering mucosal barrier properties.

Vascular endothelial growth factor (VEGF) plays a key role in bladder inflammation and is closely associated with the vascular

alterations observed in patients with BPS/IC. VEGF and coreceptors (neuropilins [NRPs]) are strongly expressed in human bladder urothelium. NRP2 and VEGF-R1 are significantly downregulated in IC when compared with control subjects (Saban et al, 2008). GAG modification of NRPs plays a critical role in modulating VEGF/NRP signaling (Shintani et al, 2006), suggesting another possible mechanism in which a GAG deficiency could act by interfering with the functionality of this signaling system.

Some have cited the "potassium sensitivity test" as providing strong evidence for a population with mucosal leak (Parsons et al, 1994b). Parsons and colleagues placed water or 0.4 M potassium chloride (KCl) intravesically into normal volunteers and IC patients. Water did not provoke pain in either group, but KCl provoked the symptom in 4.5% of normal subjects and 70% of IC patients. Symptomatic responses were reduced in patients on heparinoid therapy. Similar findings occur in patients with radiation cystitis (100%) (Parsons et al, 1994c), urinary infection (100%) (Parsons et al, 1998), detrusor instability (25%) (Parsons et al, 1998), "urethral syndrome" (55%) (Parsons et al, 2001b), and more than 80% of women with endometriosis, vulvodynia, and pelvic pain (Parsons et al, 2001a, 2002b). Up to 33% of unselected Turkish women may test positive (Sahinkanat et al, 2008). Eighty-four percent of men with prostatitis also have a positive test (Parsons and Albo, 2002). **The poor specificity of the potassium test** suggests that it does not provide unequivocal evidence of a permeability dysfunction. **Because it is known that the normal bladder epithelium can never be absolutely tight, and there is always some leak, however small** (Hohlbrugger, 1997), **it is conceivable that the findings of pain with KCl are related to a hypersensitivity of the sensory nerves in this condition, rather than to pathologic epithelial permeability, at least in some patients.** In fact, KCl administered intravesically to cats with feline IC seems to *inhibit* afferent firing of peripheral Aδ fibers. Heightened sensitivity of afferent nerve fibers can explain KCl results without necessarily evoking increased permeability (Lutgendorf and Kreder, 2005; Roppolo et al, 2005). Intravesical administration of KCl has since been proposed as a diagnostic test for IC (Parsons et al, 1998) (see later).

How central abnormal epithelial permeability is to IC is, however, by no means clear. Tamm-Horsfall protein (THP), a high-molecular-weight glycoprotein synthesized exclusively by the ascending loop of Henle and the distal tubule of the kidney, has been studied as a potential marker of urothelial permeability. Fowler and associates (1988) provided graphic data that the urothelium might be leaky in IC. With immunohistochemical techniques this group assayed the bladder biopsy specimens of 14 IC patients and 10 normal control subjects for intraurothelial THP to assess indirectly the in-vivo permeability of the urothelium. Eight pathologic controls were also assessed. Ten of 14 IC patients versus 1 of 18 controls demonstrated intraurothelial THP. Serum THP autoantibody is higher in BPS/IC patients versus controls (Neal et al, 1991). It is known that excretion rates of THP vary widely, even in repeat samples taken from the same individual (Reinhart et al, 1990). Subsequent studies in IC have failed to show differences in the presence of intraurothelial THP in the IC population versus controls, nor in antibody reactivity to THP (Stone et al, 1992; Stein et al, 1993). Parsons and associates (2007) reported that the THP protein is qualitatively different in patients with IC than in controls, even if the urinary concentration of the protein is the same. Bade and coworkers (1996) failed to find THP in the bladder tissue from 10 IC patients. Others have suggested that when THP is seen in bladder tissue it is an incidental finding of no clinical significance. The finding of intraurothelial THP has not been shown to be a harbinger of IC or any other bladder disorder (Truong et al, 1994).

Finally, we must look at a body of literature that has failed to find GAG abnormality or hyperpermeability. Ultrastructural, biochemical, and functional studies of bladder GAGs have not supported this theory (Collan et al, 1976; Dixon et al, 1986; Johansson and Fall, 1990; Ruggieri et al, 1991). Nickel's group (Nickel et al, 1993) reported sophisticated electron micrography using a specific antimucus, antisera stabilization technique to study the ultrastructural morphologic appearance of the GAG layer. No significant difference in the morphologic appearance of the mucus or GAG layer was noted in IC versus control subjects. Urinary chondroitin sulfates, heparan sulfate, and total sulfated GAGs normalized to creatinine are not altered in IC (Erickson et al, 1997b). Although an increased ratio of total GAGs to sulfated GAGs in IC may indicate an altered GAG layer, whether it reflects a cause or is a result of the primary pathologic process(s) is unknown (Wei et al, 2000). That leaves one to postulate an as yet unknown functional abnormality, rather than GAG deficiency, to account for any increase in permeability.

Chelsky and coworkers (1994) measured bladder permeability in IC using direct measurement by transvesical absorption of technetium-99m–labeled diethylenetriaminepentaacetic acid (^{99mTc}-DTPA). Whereas some IC patients had a more permeable bladder than others, the same was true for normal volunteers. Increased permeability in the IC group could not be demonstrated. However, three IC patients had marked absorption of ^{99m}Tc-DTPA and may represent a subpopulation of patients with increased epithelial permeability. Intravesical instillation of 10% and 20% ethanol in rabbits was reported to be a reliable quantitative measure of bladder hyperpermeability by the San Diego group (Monga et al, 2001) and subsequently failed to demonstrate bladder permeability in humans with IC (Gordon et al, 2003).

Overall, it does seem that there is a population of BPS/IC patients with increased epithelial permeability but the issue is far from closed. Increased mucosal permeability is nonspecific and a consequence of bladder inflammation and also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis after intravesical challenge with antigen after sensitization (Engelmann et al, 1982; Kim et al, 1992). **It may also be a consequence of aging itself** (Jacob et al, 1978). **Whether this represents a primary cause of IC or merely reflects the result of an as yet unidentified source of inflammation is unclear.** Treatments that tend to damage the GAG layer, including transurethral resection and laser of ulcerated areas, bladder distention, and the administration of silver nitrate,

Key Points: Epithelial Permeability

- There is a population of BPS patients with increased epithelial permeability.
- Increased mucosal permeability is nonspecific and a consequence of bladder inflammation. It also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis after intravesical challenge with antigen after sensitization.
- Whether this represents a primary cause of BPS or merely reflects the result of an as yet unidentified source of inflammation is unclear.

oxychlorosene (Clorpactin), or the organic solvent dimethyl sulfoxide (DMSO) have all been used with varying results to treat IC.

One does not need increased permeability of the mucosa as a foundation of the many potential causes or contributing factors to BPS/IC. Enhanced adenosine triphosphate (ATP) release from the urothelium of patients with BPS/IC has been described (Kumar et al, 2007). This nonneuronal ATP may act as a sensory neurotransmitter. Increased purinergic activity may thus lead to a condition in which the bladder is oversensitive to distention.

Increased permeability and epithelial dysfunction must be only a part of the story.

Inhibition of Uroepithelial Cell Proliferation: Antiproliferative Factor

The finding that cells from the bladder lining of normal controls grow significantly more rapidly in culture than cells from BPS/IC patients led Keay and associates (1996) at the University of Maryland to the discovery of an **antiproliferative factor (APF) produced by the urothelium of IC patients.** Normal bladder cells were cultured in the presence of urine from patients with IC, asymptomatic controls, bacterial cystitis, and vulvovaginitis. Only urine from IC patients inhibited bladder cell proliferation (Keay et al, 1998b). **The presence of APF was found to be a sensitive and specific biomarker for IC** (Keay et al, 2001) (Table 12–6). It was found in bladder urine but not in renal pelvic urine of IC patients, indicating **production by the bladder urothelial cells** (Keay et al, 1999). Subsequent studies indicated **that APF is associated with decreased production of heparin-binding epidermal growth factor–like growth factor** (HB-EGF) (Keay et al, 2000, 2003b). **APF activity was related to increased production of epidermal growth factor (EGF), insulin-like growth factor-1, and insulin-like growth factor binding protein-3** by the bladder cells from IC patients but not by the cells from healthy bladders. Studies of IC patients and asymptomatic controls showed **urine levels of APF, HB-EGF, and EGF to reliably separate out IC from controls** (Keay et al, 2001; Erickson et al, 2002).

Table 12–6.

Prevalence of Urine Antiproliferative Factor Activity in Interstitial Cystitis Patients and Control Groups

GROUPS	NO. OF PATIENTS POSITIVE/TOTAL	% POSITIVE
Patients		
Interstitial cystitis	206/219	94
Controls		
Asymptomatic	10/113	9
Overactive bladder	2/32	6
Bacterial cystitis	7/58	12
Microscopic hematuria	2/19	10
Stress incontinence	1/10	10
Neurogenic bladder	0/11	0
Benign prostatic hyperplasia	1/14	7
Nonbacterial prostatitis	1/16	6
Vulvovaginitis	0/12	0
Miscellaneous	1/16	6

From Keay SK, Zhang CO, Shoenfelt J, et al. Sensitivity and specificity of antiproliferative factor, heparin-binding epidermal growth factor–like growth factor, and epidermal growth factor as urine markers for interstitial cystitis. Urology 2001;57:9.

APF levels in the urine were found to discriminate between men with IC versus those with CPPS or nonbacterial prostatitis (Keay et al, 2004a). APF activity dropped significantly in IC patients within 2 hours after hydrodistention (Chai et al, 2000b) and after 5 days of sacral neuromodulation (Chai et al, 2000a). Cell culture studies showed that APF actually caused decrease in HB-EGF and increase in EGF, mirroring the differences in urine levels of these growth factors between IC patients and controls and suggesting that APF is the primary abnormality (Keay et al, 2003b).

Whereas APF may prove to be a useful marker for BPS/IC, it may also unlock the etiology of the syndrome. It has been hypothesized by Keay and colleagues (2003a) **that BPS/IC may result from an inhibition of bladder epithelial cell proliferation caused by the APF, which is mediated by its regulation of growth factor production from bladder cells. Conceivably, any of a variety of injuries to the bladder (infection, trauma, and overdistention) in a susceptible individual may result in BPS/IC if APF is present and suppresses production of HB-EGF** (Keay and Warren, 1998). Theoretically, if production of APF could be "turned off" by genetic techniques, or its effects were nullified by exogenous HB-EGF, the clinical syndrome might be prevented. HB-EGF functionally antagonizes APF activity via a mitogen-activated protein kinase pathway activation (Kim et al, 2009a).

APF has been purified (Fig. 12–8) and proved to be **a frizzled 8 protein that belongs to a newly discovered family of proteins that seem to be important in the development of nerve tissues, skin, and the lining of organs** (Keay et al, 2004b). The frizzled family of receptors is critically involved in embryogenesis, and there is substantial evidence that members of this family also regulate tissue homeostasis in many different organs in the adult (Schulte and Bryja, 2007).

It appears that the cell cycle regulatory protein TP53 is an important mediator of APF-induced effects on bladder epithelial cells (Kim et al, 2007). APF treatment suppresses cell proliferation by cell cycle arrest of human bladder urothelial cells. Evidence shows that TP53 levels increase significantly after APF stimulation; TP53 downregulation enhances the suppressive effect of APF on cell growth; and overexpression of TP53 induces cell cycle arrest in the absence of APF. It is possible that targeting of TP53 could be a means of abrogating the pathologic effects of urinary APF and lead to new options for clinical therapy.

Studies are ongoing to confirm the research by Keay and colleagues and expand on its significance in diagnosis and development of a rational treatment approach (Rashid et al, 2004). The development of animal models with specific signaling abnormalities found in BPS/IC epithelial, endothelial, smooth muscle, neuronal, or immune cells to determine whether these animals develop a disease similar to the human disorder would be an extremely useful and potentially very productive pathway to learning more about potential therapeutic pathways (Keay, 2008).

Key Points: Antiproliferative Factor

- The frizzled 8 protein termed *antiproliferative factor* (APF) has been proposed as a marker to identify cases of BPS/IC.
- It is secreted by bladder epithelial cells of BPS patients and inhibits bladder epithelial cell proliferation through mediation of growth factor production. As such it could be a proximal cause of the syndrome in many patients.

Neurobiology

Neuropeptides present in primary afferents and the dorsal horn of the spinal cord have an important role in the mediation of nociceptive input under normal conditions. Under pathologic conditions, such as chronic inflammation or after peripheral nerve injury, the production of peptides and peptide receptors is dramatically altered, leading to a number of functional consequences (Wiesenfeld-Hallin and Xu, 2001). Inflammatory painful stimuli, especially if repeated, can chronically alter innervation, central pain-processing mechanisms, and tissue responses (Steers and Tuttle, 1997). It has been known for some time that the sensory nervous system can generate some of the manifestations of inflammation (Foreman, 1987; Dimitriadou et al, 1991, 1992). Activation of capsaicin-sensitive afferent neurons locally and centrally may be involved in stress-related pathologic changes in the rat bladder (Ercan et al, 2001). **Activation of sensory nerves, specifically pain fibers, is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related protein, and subsequent increase in vascular permeability, with leukocyte adhesion and tissue edema. The neuropeptide mediators have been shown to also cause degranulation of mast cells with release of additional potent mediators of inflammation and to lead to injury and increased permeability of epithelial surfaces** (Elbadawi and Light, 1996). An increase in nerve fibers within the suburothelium and detrusor muscle in ulcerative IC has been noted (Lundeberg et al, 1993). A correlation was found between the number of nerve fibers and numbers of mast cells as well as between the number of nerve fibers and the amount of histamine. **Consolidating the leaky urothelium theory and mast cell activation, neurogenic inflammation is an attractive proposal for etiology and can readily accommodate infectious, immunologic, and autoimmunologic mechanisms as factors** (Elbadawi and Light, 1996).

Harrison and colleagues (1990) proposed that small-diameter sensory nerves in the bladder wall may have a role in the transmission of the sensation of pain and in the triggering of inflammatory reactions rather than forming the afferent limb of the micturition reflex. Abelli and associates (1991) demonstrated in the rat urethra that mechanical irritation alone can cause neuropeptide release from peripheral capsaicin-sensitive primary afferent neurons, resulting in neurogenic inflammation. Extracellular ATP can act through the purinergic receptor subtype $P2X_3$ to transmit a pain signal to the central nervous system. These subunits expressed by cultured IC bladder urothelial cells are upregulated during in-vitro stretch and may phenotypically mimic sensory neurons (Sun and Chai, 2004).

Several pieces of additional information support a theory of neurogenic inflammation. Levels of nerve growth factor are elevated in bladder biopsy specimens of IC patients (Lowe et al, 1997). Studies in rats using pseudorabies virus clearly show that bladder inflammation can be induced from a somatic structure through a neural mechanism and that central nervous system dysfunction can bring about a peripheral inflammation (Doggweiler et al, 1998; Jasmin et al, 1998). Pelvic nerve stimulation in the rat increases urothelial permeability that is antagonized by capsaicin, indicating both an efferent effect of afferent nerves and afferent-mediated neuroepithelial interaction (Lavelle et al, 1999).

Numerous studies indicate increased sympathetic activity in IC. Hohenfellner and colleagues (1992) suggested that IC is associated with increased sympathetic outflow into the bladder and altered metabolism of vasoactive intestinal polypeptide and neuropeptide Y. Neuropeptide Y (NPY) inhibits bladder afferents and therefore may be involved in autonomic disturbances affecting the bladder. Elevation of urinary catecholamines in IC patients and plasma catecholamines in cats with feline IC has been observed (Stein et al, 1999; Buffington and Pacak, 2001a), as has an increased density and number of nerve fibers immunoreactive for tyrosine hydroxylase in IC patients (Peeker et al, 2000a). Whether these changes reflect a cause of IC or are merely the result of long-standing intense pain and a severely pathologic voiding pattern is unknown.

Galloway and associates (1991) proposed that the changes in IC may be explained by an increase in sympathetic discharge,

analogous to that seen in reflex sympathetic dystrophy (RSD) of limbs. The pathology in RSD is the development of abnormal synaptic activity between sensory afferent and sympathetic efferent neurons. Nerve cells in the spinal cord become hypersensitive to sensory input, and this sustains abnormal sympathetic outflow and corresponding vasomotor dysregulation. The excess sympathetic outflow leads to constriction of blood vessels and tissue ischemia, setting up further sensory changes and perpetuating the cycle. In RSD there is usually a trigger event leading to these changes. With the acute phase of RSD, regional signs of inflammation are evident in the affected extremity. One school of thought believes an inflammatory response to an injury initiates RSD. Increased capillary permeability is a direct result (Goris and Jan, 1998). Perhaps a urinary infection could trigger such a pathologic cycle in some IC patients?

Herbst and colleagues (1937) produced bladder lesions in a dog resembling the ulceration of IC by ligating the blood vessels to the posterior bladder wall and infecting the area with *Streptococcus viridans*. Studies using laser Doppler flowmetry have shown that when the bladder is distended under anesthesia the blood flow increases in control patients to a statistically significant degree as compared with IC patients (Irwin and Galloway, 1993; Pontari et al, 1999). Another study has purported to show that topical heparin therapy can normalize urothelial permeability and vesical blood flow in IC (Hohlbrugger et al, 1998). Decreased microvascular density has been described in the suburothelium but not in the deeper mucosa in bladder biopsy specimens of women with IC (Rosamilia et al, 1999a). Hyperbaric oxygen has been suggested to have a limited effectiveness for the treatment of BPS/IC (van Ophoven et al, 2004b, 2006; Tanaka et al, 2007) as well as radiation-induced cystitis (Weiss and Neville, 1989).

If lumbar sympathetic blocks can decrease the pain of IC, a role of the sympathetic nervous system in IC pathogenesis is a reasonable supposition (Irwin et al, 1993; Doi et al, 2001). An increase in sympathetic activity has been shown in cats with feline IC (Buffington and Pacak, 2001b; Buffington et al, 2002). Similar findings have been reported in a small study of IC patients (Dimitrakov et al, 2001), and sympathetic activity may be an underlying common denominator in many disorders associated with PBS/IC (Buffington, 2004).
