Figure 91–19. Mean changes for symptom **(A)** and peak flow rate **(B)** in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study study stratified by baseline serum prostate-specific antigen (PSA) levels. (From Roehrborn CG, Boyle P, et al. Serum prostate-specific antigen (PSA) is a reliable surrogate for prostate volume. Urology 1999;53:581–9.)

42 to 57 mL, 58 to 150 mL). The PLESS study also assessed periodically bother due to urinary symptoms, disease-specific quality of life, aspects of sexual function, and sense of well-being. Surprisingly, serum PSA at baseline also predicts after an initial placebo response the rate of deterioration of bother, quality of life, and certain aspects of sexual function (Bruskewitz et al, 1999) (Fig. 91–20).

The Medical Therapy of Prostatic Symptoms (MTOPS) study followed 3045 men treated with either placebo versus doxazosin (Cardura) versus finasteride versus combination therapy for 4 to 5 years and was designed as a progression study (Bautista et al, 2003; McConnell et al, 2003). The composite end point captured either a worsening of 4 points or more on the IPSS score verified twice within 4 weeks, AUR, socially unacceptable incontinence, recurrent urinary tract infection, or renal insufficiency due to BPH (Table 91–13). The worsening of 4 points or more was chosen to reflect a clinically meaningful worsening of LUTS symptomatology. Despite an overall numerical improvement in the IPSS by –4.9 points in the placebo group (intention to treat cohort), about 14% of placebo-treated patients experienced a verified worsening by 4 points or more over the course of the study for an incidence of 3.6/100 patient-years.

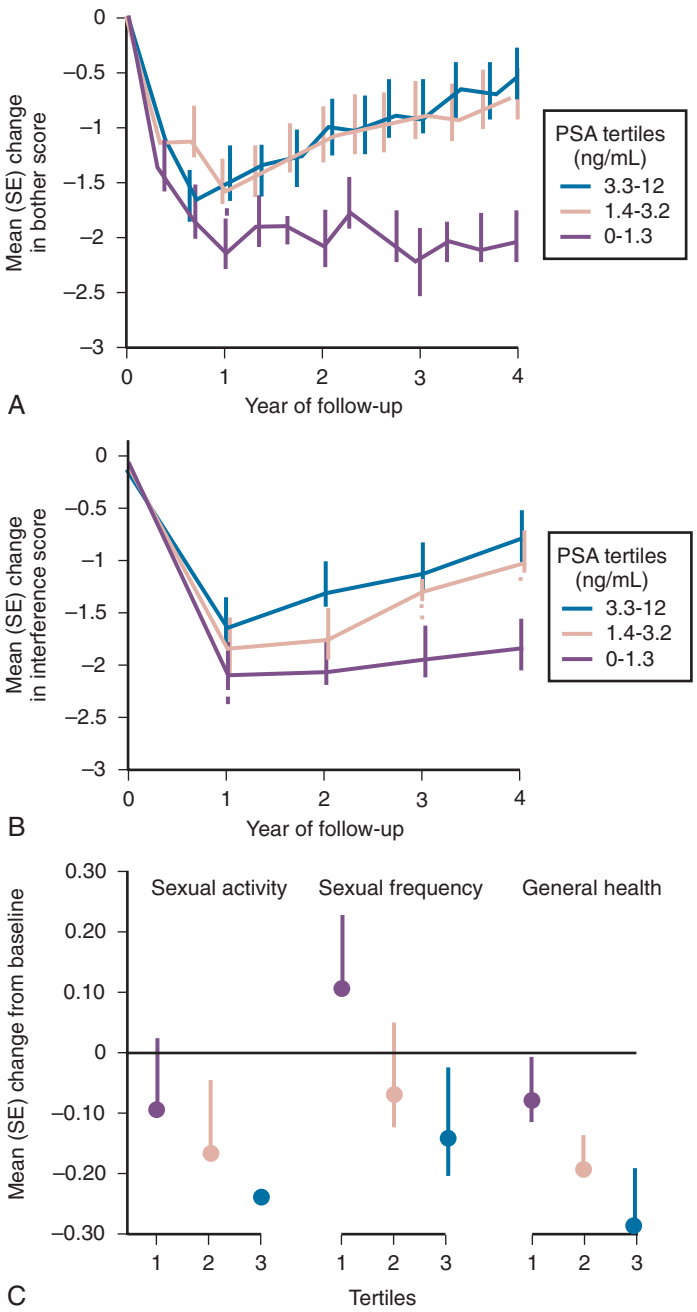

Figure 91–20. Mean changes for bother (**A**), interference with activities of daily living (**B**), and for sexual activity, frequency, and perception of general health (**C**) in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study study stratified by baseline serum prostate-specific antigen (PSA). SE, standard error. (From Bruskewitz R, Girman CJ, et al. Effect of finasteride on bother and other health-related quality of life aspects associated with benign prostatic hyperplasia. PLESS Study Group. Proscar Long-term Efficacy and Safety Study. Urology 1999;54[4]:670–8.)

The PLESS study and its placebo-control group allowed the study of natural history and disease progression in a cohort selected for moderate symptoms and other evidence of disease (in contrast to a population-based study) on the background of the initial combined placebo responses. In MTOPS, approximately 14% of placebo-treated patients experienced a worsening of 4 or more points in the IPSS over 4 years of follow-up.

Relationship between Placebo/Sham Effect and Perception of Improvement

Barry and colleagues (1995d) **reported an important observation by assessing the relationship between changes in the AUASI score and patients' global rating of improvement in over 1200 men treated in a medical treatment trial for BPH. They noted that a mean decrease in AUASI score of 3.1 points was associated with a slight improvement; however, this relationship was strictly dependent of the baseline value. For patients to perceive a slight, moderate, or marked improvement, increasing drops in the AUASI score were required with increasing baseline symptom severity.** For patients starting with a lower

Table 91–13.

Clinical Progression of BPH in Placebo-Treated Patients in MTOPS

EVENT	RATE OVER DURATION OF STUDY	CUMULATIVE NUMBERS OF EVENTS AT 4 YEARS	CUMULATIVE INCIDENCE (95% CI) AT 4 YEARS
Clinical progression overall	4.5	122	17 (14-20)
≥4 points IPSS increase	3.6	97	14 (11-17)
Acute urinary retention	0.6	18	2 (1-4)
Socially unacceptable incontinence	0.3	6	<1 (0-1)
Urinary tract infections	0.1	1	<1 (0-1)
Renal insufficiency due to BPH	0.0	0	0
Invasive therapy due to BPH	1.3	37	5 (3-7)

BPH, benign prostatic hyperplasia; CI, confidence interval; MTOPS, Medical Therapy of Prostatic Symptoms.

From McConnell J, Roehrborn CG, et al. The long-term effects of doxazosin, finasteride and the combination on the clinical progression of benign prostatic hyperplasia. N Engl J Med 2003;349(25):2385–96.

versus higher baseline score, the drop had to be –7.4 versus –15.3 points, respectively, to perceive a marked improvement, –4.0 versus –8.7 for a moderate improvement, –1.9 versus –6.1 for a slight improvement, –0.2 vs –2.0 for no improvement, and +3.3 versus +1.2 for worsening to be perceived.

Longitudinal Population-Based Studies

Diokno and coworkers (1992) **provided estimates of the prevalence, incidence, and remission of LUTS in 803 community-dwelling men 60 years or older.** The annual incidence of prostate surgery was 2.6% and 3.3% during years 1 and 2 of follow-up. The prevalence of at least one symptom was 35%, with annual incidence rates during years 1 and 2 of follow-up as 16.4% and 16.1%. Remission was also noted in that 22.9% of those having severe symptoms at baseline were asymptomatic at follow-up. Table 91–14 details the changes in symptom severity from one survey to the next. **The tendency for fluctuation and spontaneous remission of symptoms as well as the regression to the mean become evident from an analysis of these data.**

Garraway and coworkers conducted a study of LUTS in four villages in the Forth Valley in Scotland in men 40 to 79 years old, defining BPH as a prostate volume of over 20 mL by TRUS and a maximum flow rate of less than 15 mL/sec and applying a lower threshold to the symptom severity (Garraway et al, 1993a, 1993b; Guess CG et al, 1993; Tsang and Garraway, 1993). By this definition the prevalence of BPH increased at baseline from 14% in men in their 40s to 43% in men in their 60s, and about one half of men reported interference with activities of daily living due to LUTS and BPH. One- and 3-year follow-up data have been reported (Lee et al, 1996). **From baseline to 3 years the proportion of men with moderate symptoms increased from 34% to 45% and significant increases in symptom level occurred for 8 of 12 symptoms queried as well as for the AUASI (increase from 6.37 to 7.88 from baseline to year 3, *P* < .0001)** (Lee et al, 1996). **Parallel to symptom frequency and severity, bothersomeness of symptoms increased over time** (Fig. 91–21) **and the proportion of men reporting interference with two or more activities increased from 26% to 41%, with three or more activities from 18% to 27%, and with four or more activities from 15% to 18%. This study clearly demonstrated LUTS and BPH being a progressive disease, albeit with a very flat slope of progression.**

The most informative natural history study to date is the Olmsted County Study of Urinary Symptoms and Health Status Among Men, which has given us much information about prevalence and severity of urinary symptoms, bother, worry and embarrassment, quality of life due to symptoms, and the relationship between symptoms and other parameters such as flow rates, prostate volume, and PSA (Oesterling et al, 1993; Girman et al, 1994, 1995; Guess et al, 1995; Jacobsen et al, 2003; Sarma et al, 2003; Rule et al, 2005).

With continued follow-up of this cohort, data have emerged regarding the longitudinal changes in symptoms and flow rate over time in this population-based study. Of 904 men reporting none to mild symptoms (AUASI, 0 to 7 points) at baseline, 118 reported moderate to severe symptoms (AUASI, > 7 points) at 18 months and 196 did so at 42 months follow-up (Jacobsen et al, 1995a). However, 47 men who had developed moderate to severe symptoms at 18 months had none to mild symptoms at 42 months. At 42 months of follow-up an average increase in the IPSS of 0.18 (95% CI 0.13 to 0.24) points per year of follow-up was recorded. **The average annual symptom score slope and variability in slope increased with patient age at baseline from a mean of 0.05 ± 1.06 (standard deviation) per year among men in their 40s to 0.44 ± 1.35 per year for men in their 60s and decreased to 0.14 ± 1.42 per year for men in their 70s** (Jacobsen et al, 1996). **More recently, 92-month data showed an annual change of 0.34 point/yr, with 31% of all men reporting at least a 3-point increase. The greatest annualized increase was observed in men in their 60s with 0.6 point/yr** (Rhodes et al, 2000).

In addition, 6-year follow-up data on peak flow rate measurements in a subset of about 500 men showed a median peak urinary flow rate slope decrease of –2.1% per year (25th percentile –4.0, 75th percentile –0.6). Peak urinary flow rate declined more rapidly with decreasing baseline rate and increasing baseline age, prostate volume, and symptom severity (all *P* = .001). When the variables were simultaneously adjusted for each other, a rapid decline (negative slope 4.5% or greater per year) was more likely in men 70 years old or older and those with a rate less than 10 mL/sec at baseline compared with those 40 to 49 years old and those with a rate of 15 mL/sec or greater, respectively. Prostate volume and symptom severity were not statistically significant predictors of a rapid decline in peak urinary flow rate when variables were considered simultaneously (Roberts et al, 2000).

Based on TRUS the growth of the prostate in these men 40 to 79 years old was estimated to be about 0.6 mL per year or 6 mL per decade of life. However, prostate growth followed an exponential growth pattern with a slope estimate of 0.4 mL per year for men aged 40 to 59 years at baseline and of 1.2 mL per year for those 60 to 79 years at baseline (Rhodes et al, 1995, 1999). An updated analysis revealed a median growth rate of about 1.9% per year independent of age and symptoms. However, a higher baseline serum PSA and larger prostate volume predicted greater annualized volume increases.

Table 91–14.

Changes in Status of Symptom Severity from One Survey to the Next

SEVERITY	YEAR	NO. PATIENTS	Severity in Following Year (%) NONE	MILD	MODERATE	SEVERE
None	Baseline	293	83.6	12.3	2.7	1.4
	Year 1	223	83.9	9.0	2.2	4.9
Mild	Baseline	88	18.2	55.7	11.4	14.8
	Year 1	84	33.3	52.4	8.3	6.0
Moderate	Baseline	38	7.9	31.6	26.3	34.2
	Year 1	27	3.7	33.3	22.2	40.7
Severe	Baseline	35	22.9	17.1	11.4	48.6
	Year 1	31	9.7	22.6	12.9	54.8

Patients who underwent prostatectomy in preceding year were excluded from next survey.

Modified from Diokno AC, Brown MB, Goldstein N, Herzog AR. Epidemiology of bladder emptying symptoms in elderly men. J Urol 1992;148(6):1817–21.

Complications

Many of the complications of progressive BPH are rare, and much of the knowledge comes from studies of men

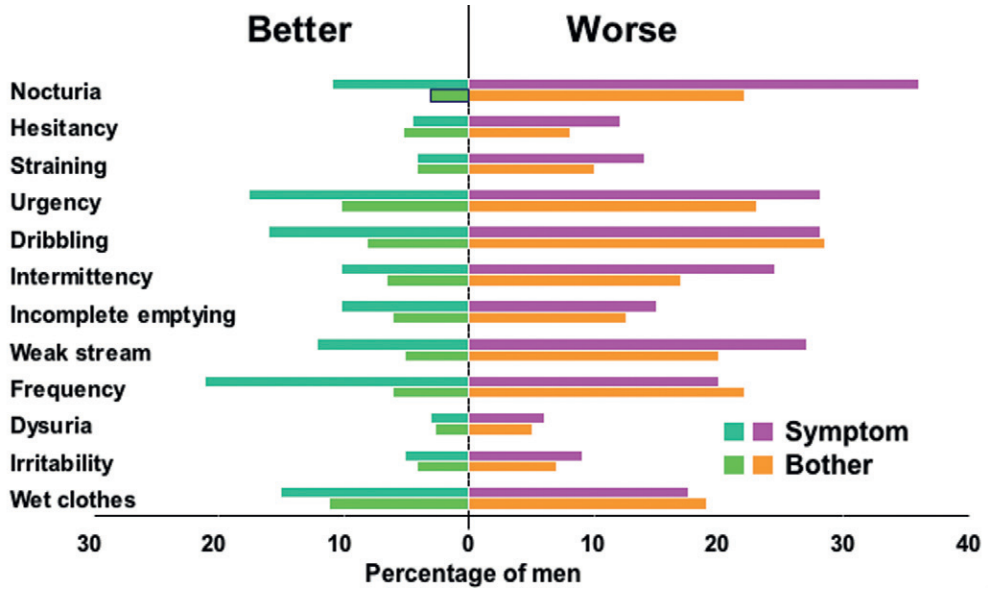

Figure 91–21. Changes in urinary symptoms and bothersomeness status between baseline and 3 years in a Scottish population-based study. (From Lee AJ, Russell EB, et al. Three-year follow-up of a community-based cohort of men with untreated benign prostatic hyperplasia. Eur Urol 1996;30[1]:11–7.)

presenting with such complications for treatment (i.e., cases) rather than observing cohorts of men for the development of complications.

Mortality

Between 1950 and 1954, 17 of 24 countries reported mortality rates of greater than 10 per 100,000, whereas between 1985 and 1989 data were available for 61 countries, only one reporting a greater than 10/100,000 mortality rate (Boyle et al, 1996). **If the mortality rates from 1950 were applied to 1990, 13,681 fewer deaths occurred in the United States alone than expected, a major but unheralded health care achievement.**

Bladder Stones

In a large autopsy study the prevalence of bladder stones was 8 times higher in men with a histologic diagnosis of BPH (3.4%) compared with controls (0.4%) but no increased incidence of ureteral or kidney stones was found (Grosse, 1990). In a study comparing watchful waiting and TURP in men with moderate symptoms, only 1 of 276 patients assigned to watchful waiting developed a bladder stone in 3 years of follow-up (Wasson et al, 1995). The self-reported rate of a bladder stone in a cross-sectional study in 2002 Spanish men was 0.7% (Hunter et al, 1996).

In clinical practice the risk of bladder stone development is small and screening only indicated if clinical circumstances warrant it (e.g., hematuria, stuttering of urination).

Urinary Tract Infections

In older surgical series UTIs constitute the main indication for surgical intervention in about 12% (Holtgrewe et al, 1989; Mebust et al, 1989). **Although one might intuitively assume that increased amounts of residual urine would predispose to the development of UTIs, clear evidence is lacking.** Hunter and colleagues (1996) quoted a rate of 5.2% self-reported episodes of UTI in a cross-sectional survey of 2002 men in Madrid, Spain. The best data to date come from the MTOPS study, in which the incidence of UTIs in the placebo-treated patients was only 0.1/100 patient-years (McConnell et al, 2003).

Bladder Decompensation

Urologists search for a progression from a normal mucosa to advancing trabeculation, development of cellules, and diverticula with ultimate detrusor muscle failure in mind when evaluating the bladder in men with BPH endoscopically. However, when the process starts, whether it really is related to BPH and obstruction, and when an intervention is necessary to prevent decompensation with resultant inability to void is unclear.

Biopsy samples from trabeculated, obstructed bladders show dense connective tissue deposition, a finding similar to that seen in animals experimentally obstructed (Gosling and Dixon, 1980; Levin et al, 1990, 2000; Chapple et al, 1991). However, bladder fibrosis is seen in both sexes with advancing age and may be a normal consequence of aging (Lepor et al, 1992a).

The critical question is whether delayed intervention might lead to progressive irreversible loss of bladder function and misses a window for cure. There is no direct evidence for this from longitudinal population or clinic patient studies. However, in the Veterans Affairs cooperative study comparing watchful waiting with TURP, those patients who crossed over from the conservative arm to TURP later in the trial had not as significant an improvement in symptoms and flow rate compared with those who underwent TURP at the beginning after randomization (Flanigan et al, 1998).

Urinary Incontinence

Incontinence is one of the most feared complications from surgical intervention for BPH. Although it may be the result of BPH secondary to overdistention of the bladder (overflow incontinence) or to detrusor instability estimated to affect up to one half or more of all obstructed patients (urge incontinence) (McConnell et al, 1994), it also is associated with aging; and in a community study an incidence of incontinence of 24% and 49% of incontinence in men and women older than 50 years was reported

(Roberts et al, 1998). In the Veterans Affairs cooperative study a 4% incidence of incontinence in both the surgical and conservative treatment arms was reported (Wasson et al, 1995). The self-reported rate of incontinence in a cross-sectional study in 2002 Spanish men was 6.1% (Hunter et al, 1996). In MTOPS the rate of socially unacceptable incontinence was 0.3/100 patient-years (McConnell et al, 2003).

Upper Urinary Tract Deterioration and Azotemia

The Agency for Health Care Policy and Research BPH guidelines reported a mean of 13.6% (range 0.3% to 30%) of patients presenting for TURP with evidence of renal failure based on predominantly older studies (McConnell et al, 1994). Patients in renal failure have an increased risk for complication after TURP compared with patients with normal renal function (25% vs. 17%) (Holtgrewe et al, 1989; Mebust et al, 1989) whereas the mortality increases up to 6-fold (Holtgrewe and Valk, 1962; Melchior et al, 1974a, 1974b). In the large database of patients who had upper tract imaging before surgery, 7.6% of 6102 patients in 25 series had evidence of hydronephrosis, of whom one third had renal insufficiency (McConnell et al, 1994).

The term *silent obstruction* or *silent prostatism* has been used to describe the constellation of asymptomatic patients who eventually develop renal failure resulting from bladder outlet obstruction, a case both rare and important (Mukamel et al, 1979). In the Veterans Affairs cooperative study, only 3 of 280 surgically treated patients and 1 or 276 patients in the watchful waiting arm developed renal azotemia, defined as a doubling of the serum creatinine concentration from baseline (Wasson et al, 1995). In none of the cohort or population-based studies have cases of renal failure been reported clearly attributable to BPH. However, the self-reported rate of an episode of renal failure in a cross-sectional study in 2002 Spanish men was 2.4% (Hunter et al, 1996).

In MTOPS there was not a single case of renal insufficiency due to BPH in over 3000 men observed for more than 4 years (McConnell et al, 2003). One has to be, however, careful not to overinterpret these findings. Participants in MTOPS were screened at baseline, and one might argue that some at higher risk for developing renal failure were excluded from participation.

Hematuria

It has always been recognized that patients with BPH might develop gross hematuria and form clots with no other cause being identifiable. Recent evidence suggests that in those patients predisposed to hematuria the microvessel density is higher compared with controls. Some renewed interest in the issue of BPH-related hematuria stems from the observation that finasteride appears to be a reasonable first-line therapy apparently influencing the expression of vascular endothelial growth factor (DiPaola et al, 2001). The self-reported rate of hematuria in a cross-sectional study in 2002 Spanish men was 2.5% (Hunter et al, 1996). Precise population estimates and incidence rates are not available, and the clinical management is dictated by the circumstances.

Acute Urinary Retention

AUR is for several reasons one of the most significant complications or long-term outcomes resulting from BPH. It has in the past represented an immediate indication for surgery. Between 25% and 30% of men who underwent TURP had AUR as their main indication in older series (Holtgrewe et al, 1989; Mebust et al, 1989), **and today most patients failing to void after an attempt of catheter removal still undergo surgery. For this reason alone, AUR is both from an economic viewpoint as well as from the viewpoint of the patient an important and feared event.** For the patient it presents as the inability to urinate with increasing pain, eventually a visit to the emergency department, catheterization, follow-up visits to the physicians, an attempt at catheter removal, and either recovery of spontaneous voiding or surgery, both painful and time-consuming processes. In older literature the risk of recurrent AUR was cited as being 56% to 64% within 1 week of the first episode and as occurring in 76% to 83% in men with diagnosed BPH (Breum et al, 1982; Klarskov et al, 1987; Hastie et al, 1990).

The etiology of AUR is poorly understood and obstructive, myogenic, and neurogenic causes all may play a role (Kaplan et al, 2008). **Prostate infection, bladder overdistention** (Powell et al, 1980), **excessive fluid intake, alcohol consumption, sexual activity, debility, and bed rest have all been mentioned** (Stimson and Fihn, 1990). **Prostatic infarction has been suggested as being an underlying event causing AUR** (Graversen et al, 1989). **Spiro and associates** (1976) **found evidence for infarction in 85% of prostates removed for AUR versus 3% in prostates of men having surgery for symptoms only.** In contrast, there was no evidence of infarction in six prostatectomy specimens removed from men who had surgery for AUR (Jacobsen et al, 1997). Anjum and associates (1998) found fundamentally similar rates of infarction in 35 men each in AUR versus no AUR (1.9% vs. 3.0%).

From a clinical and prognostic point of view, spontaneous AUR should be separated from precipitated AUR, although this is by no means consistently done in the literature. Precipitated AUR refers to the inability to urinate after a triggering event such as non–prostate-related surgery, catheterization, anesthesia, ingestion of medications with sympathomimetic or anticholinergic effects or antihistamines, or others. All other AUR episodes are classified as spontaneous (Roehrborn et al, 2000a). The importance of differentiating the two types of AUR becomes clear when evaluating the ultimate outcomes of patients. After spontaneous AUR, 15% of patients had another episode of spontaneous AUR and a total of 75% underwent surgery, whereas after precipitated AUR only 9% had an episode of spontaneous AUR, and 26% underwent surgery (Roehrborn et al, 2000a).

Descriptive Epidemiology

Older estimates of occurrence of AUR range from 4 to 15 to as high as 130 per 1000 patient-years (calculated by Jacobsen et al, 1997, based on studies by Craigen et al, 1969; Birkhoff et al, 1976; Ball et al, 1981), which leads to 10-year cumulative incidence rates ranging from 4% to 73% (Table 91–15). The self-reported rate of AUR in a cross-sectional study in 2002 Spanish men was 5.1% (Hunter et al, 1996).

More recent data from carefully controlled studies in better defined population shed additional light on the incidence rates in community-dwelling men and clinical BPH populations. AUR occurred in the Veterans Affairs cooperative study over 3 years in 1 man after TURP and in 8 of 276 men in the watchful waiting arm for an incidence rate of 9.6/1000 patient-years (Wasson et al, 1995). Barry and associates (1997a) reported outcomes of 500 men diagnosed by urologists with BPH who were candidates for prostatectomy by established criteria but elected to be followed conservatively. In 1574 patient-years 40 episodes of AUR occurred at a constant rate throughout the 4 years of follow-up for an incidence rate of 25/1000 patient-years.

BPH, benign prostatic hyperplasia; CI, confidence interval; IR, incidence rate; PLESS, Proscar Long-Term Efficacy and Safety Study; TURP, transurethral resection of the prostate.

During 15,851 patient-years of follow-up in the Physicians Health Study 82 men reported an episode of AUR for an incidence rate of 4.5/1000 patient-years (95% CI 3.1 to 6.2) (Meigs et al, 1999). Of the 2115 men aged 40 to 79 years in the Olmsted County study, 57 had a first episode of AUR during 8344 patient-years of follow-up (incidence 6.8/1000 patient-years, 95% CI 5.2, 8.9) (Jacobsen et al, 1997).

The first excellent data from men diagnosed with BPH stem from PLESS (McConnell et al, 1998). **In PLESS, 1,376 placebo-treated men with enlarged prostates and moderate symptoms had complete follow-up over 4 years, of which 99 experienced an episode of AUR for a calculated incidence rate of 1.8/100 patient-years. The placebo treatment groups from three 2-year studies with a similar patient population were meta-analyzed by Boyle and associates** (1998). **Of 2109 patients, 57 experienced AUR over the 2 years with a constant hazard for an incidence rate of 14/1000 patient-years. In the MTOPS placebo group the incidence rate was 0.6/100 patient-years for a cumulative incidence of 2%.**

Analytical Epidemiology

Age. **Several well-controlled studies provided considerable insights into the risk factors for AUR. Perhaps the most significant of these risk factors is age.** Studies from European countries and the United States demonstrate a nearly linear increase in the age-specific incidence of AUR for men ranging in age from 40 to older than 80 years (Jacobsen et al, 1997; Meigs et al, 1999; Verhamme et al, 2005; Cathcart et al, 2006) (Fig. 91–22).

LUTS. **Increased symptom severity is associated with increased risk of AUR in several large population-based or cohort studies** (Table 91–16). In the Physician's Health Study in men with mild symptoms the incidence of AUR increased from 0.4/1000 patient-years for those 45 to 49 years old to 7.9/1000 patient-years for those 70 to 83 years old. In men with an AUASI score of 8 to 35, rates increased from 3.3/1000 patient-years for those 45 to 49 years old to 11.3/1000 patient-years for those 70 to 83 years old. Men with a clinical diagnosis of BPH and an AUASI score of 8 or greater had the highest rates (age-adjusted incidence 13.7/1000 patient-years). All seven LUTS comprising the AUASI individually predicted AUR. The sensation of incomplete bladder emptying, having to void again after less than 2 hours, and a weak urinary stream were the best independent symptom predictors. Use of medications with adrenergic or anticholinergic side effects also predicted AUR (Meigs et al, 1999).

The Olmsted County study focused on age, symptom severity, maximum flow rate, and prostate volume (Jacobsen et al, 1997). **Incidence rates per 1000 patient-years increased from 2.6 to 9.3 for men in their 40s to their 70s if they had mild symptoms and from 3.0 to 34.7 if they had more than mild symptoms** (see Table 91–16).

Urodynamic Parameters. **The relative risk increased for older men, men with moderate to severe symptoms (3.2×), those with a flow rate under 12 mL/sec (3.9 times) and those with a prostate volume greater than 30 mL by TRUS (3.0 times), all compared with a baseline risk of 1.0 time for the corresponding groups** (Fig. 91–23). The highest relative risk by proportional hazard models exists for 60- to 69-year-old men with more than mild symptoms and a flow rate of less than 12 mL/sec (10.3 times), and for 70- to 79-year-old men except if they had mild symptoms and a flow rate over 12 mL/sec. All other stratification of men older than age 70 years had a relative risk ranging from 12.9 to 14.8 times (all compared with men 40 to 49 years old with mild symptoms and a flow rate over 12 mL/sec for which the base risk is 1.0 time).

Prostate Volume and Serum PSA. Although age in community-dwelling men is an important risk factor, in the BPH trial population of men who already are diagnosed with BPH, other factors can be analyzed. In the placebo groups of three 2-year studies (Marberger et al, 2000) and a 4-year study (PLESS) (McConnell et al, 1998; Kaplan et al, 2000; Roehrborn et al, 2000a), prostate volume, serum PSA, and symptom severity all were predictors of AUR episodes.

The incidence increased from 5.6% to 7.7% in men with a serum PSA of less than 1.4 ng/mL from mild to severe symptoms and from 7.8% to 10.2% for those with a serum PSA of more than 1.4 ng/mL over 4 years in PLESS (Kaplan et al, 2000). In the 2-year studies the rate of AUR was 8-fold higher in those with a serum PSA of over 1.4 ng/mL

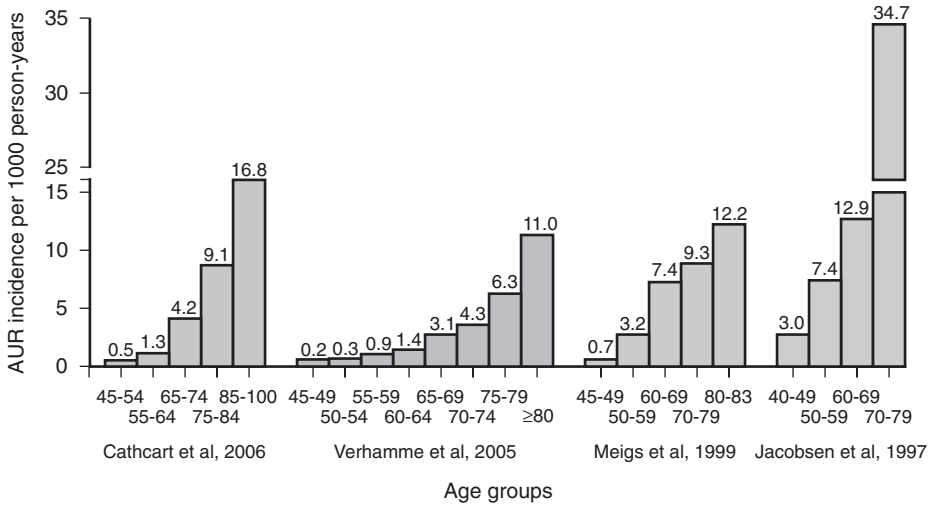

Figure 91–22. Increase in incidence of acute urinary retention (AUR) with age in four large studies. (From Kaplan SA, Wein AJ, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. J Urol 2008;180[1]:47–54.)

†Total of 57 AUR episodes in 2115 men with an overall incidence of 6.8/1000 patient-years (95% CI 5.2-8.9) in 8344 patient-years of follow-up.

AUASI, American Urological Association Symptom Index; AUR, acute urinary retention; CI, confidence interval.

From Kaplan SA, Wein AJ, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. J Urol 2008;180(1):47–54.

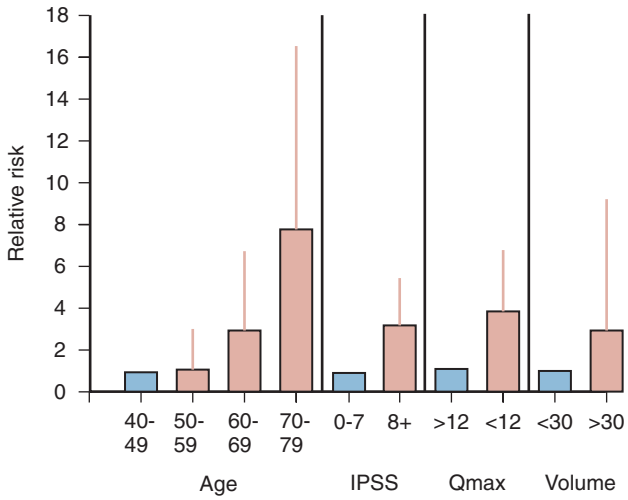

Figure 91–23. Relative risk of acute urinary retention in Olmsted County Study of Urinary Symptoms and Health Status Among Men by age, symptom severity, peak flow rate, and prostate volume. The shaded column represents the baseline and a relative risk of 1.0; the vertical line represents the 95% confidence interval. IPSS, International Prostate Symptom Score. (Data from Jacobsen SJ, Jacobson DJ, et al. Natural history of prostatism: risk factors for acute urinary retention. J Urol 1997;158[2]:481–7.)

(0.4% vs. 3.9%) and threefold higher if the prostate volume was over 40 mL (1.6% vs. 4.2%) (Marberger et al, 2000; Roehrborn et al, 2001). **A detailed analysis showed a near linear increase in risk for AUR with increasing thresholds of serum PSA** (Fig. 91–24) **in PLESS, an observation that applies to both spontaneous and precipitated AUR** (Roehrborn et al, 1999d). **The risk for both types of AUR increases with increasing serum PSA as well as prostate volume stratified by tertiles** (Fig. 91–25). Similar observations were made in MTOPS, in which the risk for AUR increased with increasing prostate volume as well as increasing baseline serum PSA (Fig. 91–26), **as well as in the 2-year phase III studies comparing dutasteride with placebo** (Roehrborn et al, 2002). **An analysis of over 100 possible outcome predictors alone or in combination revealed a combination of serum PSA, urinating more than every 2 hours, symptom problem index, maximum urinary flow rate, and hesitancy as being only slightly superior to PSA alone in predicting AUR episodes** (Roehrborn et al, 2001).

Surgery for Benign Prostatic Hyperplasia

Both surgery and AUR represent distinct end points in the disease progression of BPH. There are, however, distinct differences. AUR is an outcome mandating management, and surgery is one of the commonly employed management styles. AUR is probably one of the clearer indications for surgery, leaving the treating physician little choice in a patient who failed a trial without catheterization. However, most patients undergo surgery not for AUR but for symptoms (Holtgrewe et al, 1989).

Depending on local practice pattern, AUR accounts for 5% to over 30% of the indications for surgery. AUR can be compared with a bone fracture. It is impossible for the physician in his or her interaction with the patient to increase or decrease the probability for that outcome to occur. Furthermore, once it has occurred, no interaction or consultation can undo it. In contrast, it is easy to see how patients can be influenced in their decision to undergo surgery by the consultation with the physician. The interaction style, the quoted probabilities of beneficial and harmful outcomes to occur, and many other factors cause considerable variability in the incidence rates of prostate-related surgery, an observation that caused the Agency for Health Care Policy and Research to develop guidelines for the treatment of BPH (Wennberg et al, 1988). This situation is similar to myocardial infarction and coronary artery bypass grafting (CABG). The analytical epidemiology of myocardial infarctions is well understood, and risk factors are characterized. Not all myocardial infarctions result in CABG, and, in fact, CABG is frequently performed for other indications than a recent infarction. Consequently, there is abundant literature focusing on the geographic variation in the usage of CABG. From this brief discussion it becomes clear that surgery for BPH is a softer end point from an epidemiologic point of view than AUR, and data on rates of prostatectomy need to be interpreted in light of variation in its use, from provider to provider, region to region, health care plan to health care plan, and over time.

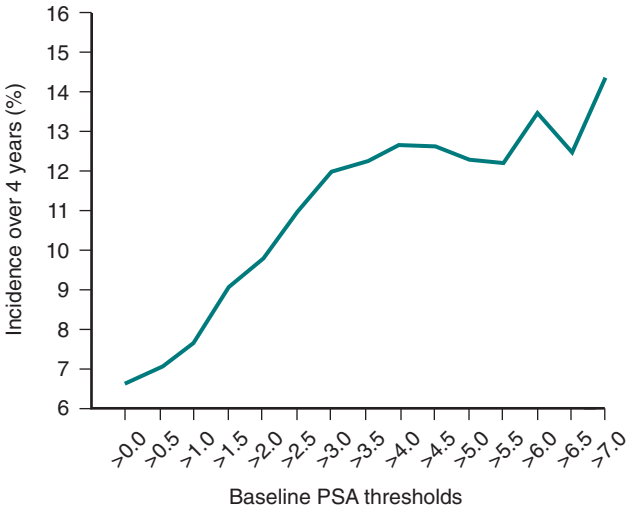

Figure 91–24. Incidence of spontaneous or precipitated acute urinary retention in the Proscar Long-Term Efficacy and Safety Study over 4 years stratified by increasing thresholds of serum prostate-specific antigen (PSA) at baseline. (From Roehrborn CG, McConnell JD, Lieber M, et al. Serum prostate-specific antigen concentration is a powerful predictor of acute urinary retention and need for surgery in men with clinical benign prostatic hyperplasia. PLESS Study Group. Urology 1999;53[3]:473–80.)

Of all prostate surgeries, TURP and laser ablation of the prostate are still clearly the most common procedures and the best studied. Cross-sectional descriptive data on incidence rates are available from the Medicare database. While in 1962 TURP constituted over 50% of all major surgeries performed by American urologists, this number had dropped to 38% by 1986 (Holtgrewe et al, 1989; Mebust et al, 1989). Although the number of TURPs performed on Medicare patients declined from an all time peak of 258,000 in 1987 to 168,000 in 1993—a reduction by 34%—it remains second only to cataract surgery on the list of Medicare's most costly surgical procedures. A 20% sample of Medicare beneficiaries was examined to further specify rates of TURP in the United States. In 1990

the rates of TURP (including all indications) were approximately 25, 19, and 13 per 1000 for men older than the age of 75, 70 to 74, and 65 to 69, respectively. The 30-day mortality after TURP for the treatment of BPH decreased from 1.20% in 1984 to 0.77% in 1990 (Lu-Yao et al, 1994). **Compared with the period 1984 to 1990, age-adjusted rates of TURP for BPH during 1991 to 1997 declined further by approximately 50% for white (14.6 to 6.72/1000) and 40% for black (11.8 to 6.58/1000) men** (Wasson et al, 2000). Medicare databases are only relevant

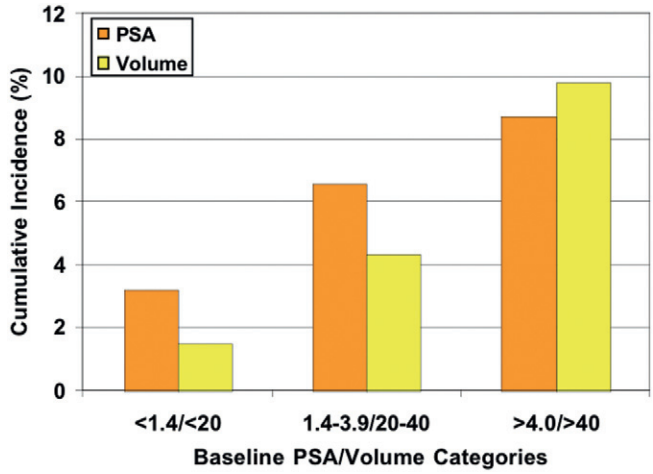

Figure 91–28. Cumulative incidence of invasive therapy (surgery) for benign prostatic hyperplasia in placebo-treated patients in the Medical Therapy of Prostatic Symptoms study stratified by baseline prostate volume *(yellow)* and baseline serum prostate-specific antigen (PSA) *(orange)*. (From Roehrborn CG, McConnell JD, Lieber M, et al. to those men older than age 65 years enrolled in Medicare and therefore are less interesting from a longitudinal epidemiologic point of view.

Older series of the natural history of BPH such as the one reported by Craigen and coworkers (1969) projected somewhat unrealistic estimates of 35% incidence of prostatectomy at 1 year and 45% at 7 years. Diokno and colleagues (1992) reported an annual incidence rate of 2.6% and 3.3% for years 1 and 2 in their cohort of men followed longitudinally (1992). Frequency, hesitancy, straining, and an interrupted stream were all associated with an increased risk.

The first study of substantial quality reporting on incidence rates and risk factors of prostate surgery was the Baltimore Longitudinal Study of Aging (BLSA) (Arrighi et al, 1990, 1991; Guess et al, 1990). Over 1000 men were observed for 30 years with yearly symptom assessments, questionnaires, and examinations. **Age, incomplete emptying, change in size, and force of stream were all independently associated with the risk of prostate surgery, as was a reportedly enlarged prostate by DRE.** Of 464 men without risk factors, only 3% required surgery during follow-up. For men with one risk factor the cumulative incidence was 9%, with two risk factors 16%, and with three risk factors even 37%. In a similar study, namely, the Veterans Affairs Normative Aging Study, nocturia and hesitancy emerged as independent predictors of surgery in 1868 men aged 49 to 68 observed for more than 20 years (Hindley et al, 2001). Age and five LUTS (dysuria, incontinence, trouble initiating flow, nocturia, and slow stream) were associated with the risk of surgery in 16,219 men over 40 years enrolled in the Kaiser Permanente Health Plan in California, of whom 1027 men underwent prostatectomy over 12 years of follow-up (Sidney et al, 1991a, 1991b).

In the Veterans Affairs cooperative trial comparing surgery with watchful waiting, 65 of 276 (24%) patients assigned to watchful waiting crossed over to surgery within 3 years of follow-up, of which 20 met predefined end points (azotemia, high residual urine volumes, incontinence, or

Key Points: Epidemiology and Natural History

- There is no globally accepted epidemiologic definition of BPH, and thus prevalence and incidence rates must be viewed in the context of the definitions chosen by the investigator reporting the data.
- Despite the significantly different proportion of men admitting to moderate to severe symptoms, a clear trend toward an increase in symptom scores with advancing age is noticeable in all reported studies.
- In general, in all cross-sectional studies prostate volume as assessed by TRUS has been found to increase slowly but steadily with advancing age.
- Analytical epidemiologic data suggest a limited role of classical determinants of the disease such as religion, socioeconomic factors, sexual activity, alcohol intake, hypertension, dietary factors, and others. There is conflicting evidence regarding smoking and some evidence suggesting dietary factors, obesity, and increased BMI as determinants of disease severity.
- All relevant parameters such as symptom severity and frequency, bother, interference, disease-specific HRQOL, maximum flow rate, and prostate volume tend to worsen with advancing age. However, reported correlations between these parameters as well as urodynamic pressure-flow studies are in general weak, with some exceptions. Strong correlations exist between measures of symptom severity and frequency (IPSS), bother, disease-specific HRQOL, and interference scores.
- The natural history of the disease has been studied in many longitudinal population-based studies as well as in placebo and sham control groups of treatment trials of men diagnosed with the condition. These studies suggest, in general, a worsening of LUTS and BPH with time. There are several key baseline parameters allowing a stratification of patients according to the risk of progression. Age, symptom severity, flow rate, prostate size, and serum PSA are useful predictors of the risk of progression.
- Complications of LUTS and BPH such as mortality, urinary tract infections, bladder decompensation, bladder stones, hematuria, urinary incontinence, upper urinary tract deterioration with renal insufficiency, and others are, in general, rare in properly supervised patients.
- The two most significant progression events are AUR and the need for BPH-related surgery. Although not exceedingly common, there is a significant baseline incidence rate and the risk is cumulative; that is, with increasing time of observation the incidence rate increases linearly.
- The risk of AUR and need for surgery is to some degree predictable from baseline parameters with advancing age, increased prostate size, and higher serum PSA levels representing the most significant risk factors.

high AUASI scores). High baseline bother score was a strong predictor of requiring surgery (Wasson et al, 1995).

The probability of undergoing surgery over 4 years increased from 10% in those men diagnosed with BPH who had mild symptoms to 24% in those with moderate and 39% in those with severe symptoms at baseline as reported in a natural history and observation study by Barry and colleagues (1997a).

The Olmsted County study and the placebo-treated patients from PLESS provide additional insights into the risk factors for undergoing prostate surgery in either community-dwelling men or men enrolled in a BPH treatment trial.

In the Olmsted County study during more than 10,000 patient-years of follow-up 167 men were treated, yielding an overall incidence of 16.0/1000 patient-years. There was a strong age-related increase in risk of any treatment from 3.3/1000 patient-years for men 40 to 49 years old to more than 30/1000 patient-years for those 70 years old or older. Men with moderate to severe symptoms, depressed peak urinary flow rates (<12 mL/sec), enlarged prostate (>30 mL), or elevated serum PSA (≥1.4 ng/mL) had about four times the risk of BPH treatment than those who did not. After adjustment for all measures simultaneously an enlarged prostate (hazard ratio 2.3, 95% CI 1.1 to 4.7), depressed peak flow rate (hazard ratio 2.7, 95% CI 1.4 to 5.3), and moderate to severe symptoms (hazard ratio 5.3, 95% CI 2.5 to 11.1) at baseline each independently predicted subsequent treatment. Overall nearly 1 in 4 men received treatment in the eighth decade of life. **These data suggest that men with moderate to severe LUTS, impaired flow rates, or enlarged prostates are more likely to undergo treatment, with increases in risk of similar magnitude to those associated with adverse outcomes, such as AUR** (Jacobsen et al, 1999).

Over 1500 patients with moderate LUTS and enlarged prostate glands were followed in PLESS on placebo for 4 years. Of these, 10% or 2.5% per year underwent surgery for BPH (McConnell et al, 1998). Whereas the hazard of undergoing surgery was linear, that is, it remained constant throughout the duration of the study, it was different when patients were stratified by either prostate volume or serum PSA in tertiles at the beginning of the study (Fig. 91–27). **Similar to the incidence of AUR, the rates of surgery increased from 6.2% to 14.6% for patients in the lowest to the highest PSA tertile and from 6.7% to 14.0% from the lowest to the highest prostate volume tertile.** In MTOPS the incidence of invasive therapy for BPH in the placebo group increased equally nearly linearly when stratifying by baseline serum PSA or prostate volume (Fig. 91–28) (McConnell et al, 2003).

Diagnosis

Assessing the Effectiveness and Safety of Medical Therapy

Nonsurgical Therapy

Medical Therapy

Future Strategies

The term ***benign prostatic hyperplasia*** (BPH) has very different connotations to the pathologist, radiologist, urodynamicist, practicing urologist, and patient. BPH to the pathologist is a microscopic diagnosis characterized by cellular proliferation of the stromal and epithelial elements of the prostate. The radiologist confirms the diagnosis of BPH on the basis of an enlarged prostate either with ultrasound or three-dimensional diagnostic imaging studies of the male pelvis (Haas and Resnick, 2000). The hallmark of BPH to the urodynamicist is the synchronous observation of elevated voiding pressure and a low urinary flow rate in the absence of other disease processes that cause bladder outlet obstruction (BOO) (Nitti, 2000). BPH to the practicing urologist represents a constellation of signs and symptoms that develop in the male population in association with aging and prostatic enlargement presumably caused by BOO (Shapiro and Lepor, 1995), together with ultrasound imaging. The patient is typically concerned about the impact of BPH on quality of life rather than about the presence of cellular proliferation, prostatic enlargement, or elevated voiding pressures.

Because of the diverse connotations of the term, it seems sensible to define BPH as microscopic BPH, macroscopic BPH, or clinical BPH. **Microscopic BPH** represents histologic evidence of cellular proliferation of the prostate. **Macroscopic BPH** refers to enlargement of the prostate resulting from microscopic BPH. **Clinical BPH** represents the **lower urinary tract symptoms (LUTS),** bladder dysfunction, hematuria, and urinary tract infection (UTI) resulting from macroscopic BPH. Abrams (1994) has suggested using the more clinically descriptive terms *benign prostatic enlargement* (BPE), *bladder outlet obstruction* (BOO), and *lower urinary tract symptoms* to replace BPH, but the time-honored, although limited, original terminology persists.

Microscopic BPH describes a proliferative process of the stromal and epithelial elements of the prostate (Bartsch et al, 1979). The proliferative process originates in the transition zone and the periurethral glands (McNeal, 1978). It is rarely identified in men younger than 40 years of age (Berry et al, 1984). The autopsy incidence of BPH is age dependent, the proliferative process being present in approximately 70% and 90% of men in their seventh and ninth decades of life, respectively. The development of microscopic BPH requires aging and the testes as the source of androgens (Walsh, 1984). Androgens play a passive role in the proliferative process. The specific molecular events that initiate and promote microscopic BPH have yet to be identified and characterized. Growth factors, such as epidermal growth factor (EGF), are involved through autocrine and paracrine stromal-epithelial interactions (Steiner, 2000).

Macroscopic BPH describes an "enlarged" prostate. Digital rectal examination (DRE) provides a relatively crude estimate of prostate size when compared with measurements using transrectal ultrasonography or magnetic resonance imaging (Roehrborn et al, 1997). Knowledge of prostate size may be clinically relevant in terms of selecting appropriate medical or surgical therapy. A strong correlation exists between serum prostate-specific antigen (PSA) levels and prostate volume (Roehrborn et al, 1999), and, as a consequence, in the absence of adenocarcinoma, the PSA value may be used as a surrogate for prostate volume (Roehrborn et al, 2001). The transition zone (inner gland) accounts for the majority of BPH tissue. The transition zone volume can be quantified using transrectal ultrasonography (Lepor et al, 1994) or magnetic resonance imaging (Tempany et al, 1993). There is no consensus regarding the extent of enlargement required to establish the diagnosis of macroscopic BPH; however, prostate volume of approximately 20 mL may be regarded as normal (Garraway et al, 1991) before BPH develops, and volumes of 100 mL or greater are encountered clinically.

The clinical manifestations of BPH include LUTS, poor bladder emptying, urinary retention, an overactive bladder, UTI, hematuria, and renal insufficiency (Jepsen

and Bruskewitz, 2000). Historically, the pathophysiology of clinical BPH was attributed to BOO secondary to macroscopic enlargement of the prostate gland (Lepor, 2000). This hypothesis was supported by epidemiologic data suggesting that the prevalence of microscopic BPH, macroscopic BPH, and clinical BPH is age dependent and therefore causally related (Isaacs and Coffey, 1989). This rather oversimplistic concept of the pathophysiology of BPH has been challenged by more recent reports demonstrating only weak relationships between prostate size, severity of BOO, and severity of symptoms (Barry et al, 1993; Bosch et al, 1995; Girman et al, 1995; Yalla et al, 1995). However, there are numerous epidemiologic data to confirm that BPH is a slowly progressive disease and that men with a larger prostate (or higher PSA) are at significantly greater risk of LUTS, impaired quality of life, and complications such as acute urinary retention (AUR) (Roehrborn et al, 2001) (see Chapter 91).

DIAGNOSIS

The complex of symptoms now commonly referred to as "LUTS" is not specific for BPH. Aging men with a variety of lower urinary tract pathologic processes may exhibit similar, if not identical, symptoms. The initial diagnostic challenge in these patients is to establish that the symptoms are, in fact, a result of BPH. This is the primary focus of initial evaluation and diagnostic testing. Fortunately, nonprostatic causes of symptoms can be excluded in a significant majority of patients on the basis of history, physical examination, and urinalysis. Additional diagnostic testing is necessary in patients in whom the diagnosis is still unclear after initial evaluation. These tests may also have a modest (but still unproven) value in predicting the response to treatment. The following recommendations concerning the initial evaluation of men presenting with LUTS reflect the consensus opinion for several independent groups. The American Urological Association (AUA) BPH guidelines were presented in 1994 and 2003, were updated in 2010 (McVary et al, 2010), and are available at www.auanet.org/content/guidelines-and-quality-care/clinical-guidelines.cfm?sub=bph. The European Association of Urology (EAU) has published guidelines on "Assessment, Therapy and Follow-Up of Men with Lower Urinary Tract Symptoms Suggestive of Benign Prostatic Obstruction (BPH Guidelines)" (Madersbacher et al, 2004), and in 2009 a Sixth International Consensus document was published (Abrams et al, 2009). Algorithms for the management of LUTS/BPH are shown in Figures 92–1 to 92–3.

Initial Evaluation

Medical History

A detailed medical history should be obtained to identify other causes of voiding dysfunction or cormorbidities that may complicate treatment. Specific additional areas to discuss when taking the history of a man with BPH symptoms include a history of hematuria, UTI, diabetes, nervous system disease (e.g., Parkinson disease or stroke), urethral stricture disease, urinary retention, and aggravation of symptoms by cold or sinus medication. Current use of prescription and over-the-counter medications should be discussed to determine whether the patient is taking drugs that impair bladder contractility (anticholinergic agents) or that increase outflow resistance (α-sympathomimetic agents). A history of prior lower urinary tract surgery raises the possibility of urethral or bladder neck stricture. Use of a voiding diary (recording times and volume) may help identify patients with polyuria or other nonprostatic disorders.

Physical Examination

A DRE and a focused neurologic examination should usually be performed. In addition, examination of the external genitalia is indicated to exclude meatal stenosis or a palpable urethral mass and an abdominal examination is necessary to exclude an overdistended, palpable bladder. The DRE and focused neurologic examination are performed to detect prostate or rectal malignancy, to evaluate anal sphincter tone, and to rule out any neurologic problems that may cause the presenting symptoms. The presence of induration is as important a finding as the presence of a nodule and should be correlated with a serum PSA value so that the need for prostatic biopsy can be assessed and acted upon.

DRE establishes the approximate size of the prostate gland. Estimation of prostate size is important to select the most appropriate pharmacologic or technical approach. DRE provides a sufficiently accurate measurement in most cases. The size of the prostate is not critical in deciding whether active treatment is required. Prostate size does not correlate precisely with symptom severity, degree of urodynamic obstruction, or treatment outcomes (Roehrborn et al, 1986; Simonsen et al, 1987). If a more accurate measurement of prostate volume is needed to determine whether to perform open prostatectomy rather than transurethral resection of the prostate (TURP), or some other procedure such as laser vaporization, ultrasonography (transabdominal or transrectal) is more accurate than cystourethroscopy. It is now established that a larger gland, and consequently a higher PSA, is associated with a greater risk of BPH progression (Roehrborn et al, 2001).

Urinalysis

A urinalysis should be done either by using a dipstick test or microscopic examination of the spun sediment to rule out UTI and hematuria, either of which strongly suggest a non-BPH pathologic process as a cause of symptoms. Because serious urinary tract disorders are relatively uncommon, the positive predictive value of screening for them is low and the effectiveness of early detection and intervention is unproven. **However, in older men with BPH and a higher prevalence of these disorders the benefits of an innocuous test such as urinalysis clearly outweigh the harms involved.** The test permits the selective use of renal imaging and endoscopy for patients with the greatest chance of benefiting from them. More importantly, urinalysis assists in distinguishing UTIs and bladder cancer from BPH. These conditions may produce urinary tract symptoms (e.g., frequency and urgency) that mimic BPH. If a dipstick approach is used, a test that includes leukocyte esterase and nitrite tests for the detection of pyuria and bacteriuria should be used.

The positive predictive value of urinalysis for cancer or other urologic diseases is around 4% to 26%, depending on the patients screened and the rigor of follow-up studies (Mohr et al, 1986, 1987; Messing et al, 1987). **Urine cytology should always be requested in men with severe irritable symptoms and dysuria, especially if they have a smoking history.** Carcinoma in-situ of the bladder is a diagnosis that may have serious consequences if overlooked.

Serum Creatinine Measurement

Although the measurement of the serum creatinine concentration was recommended in the initial evaluation of all patients with

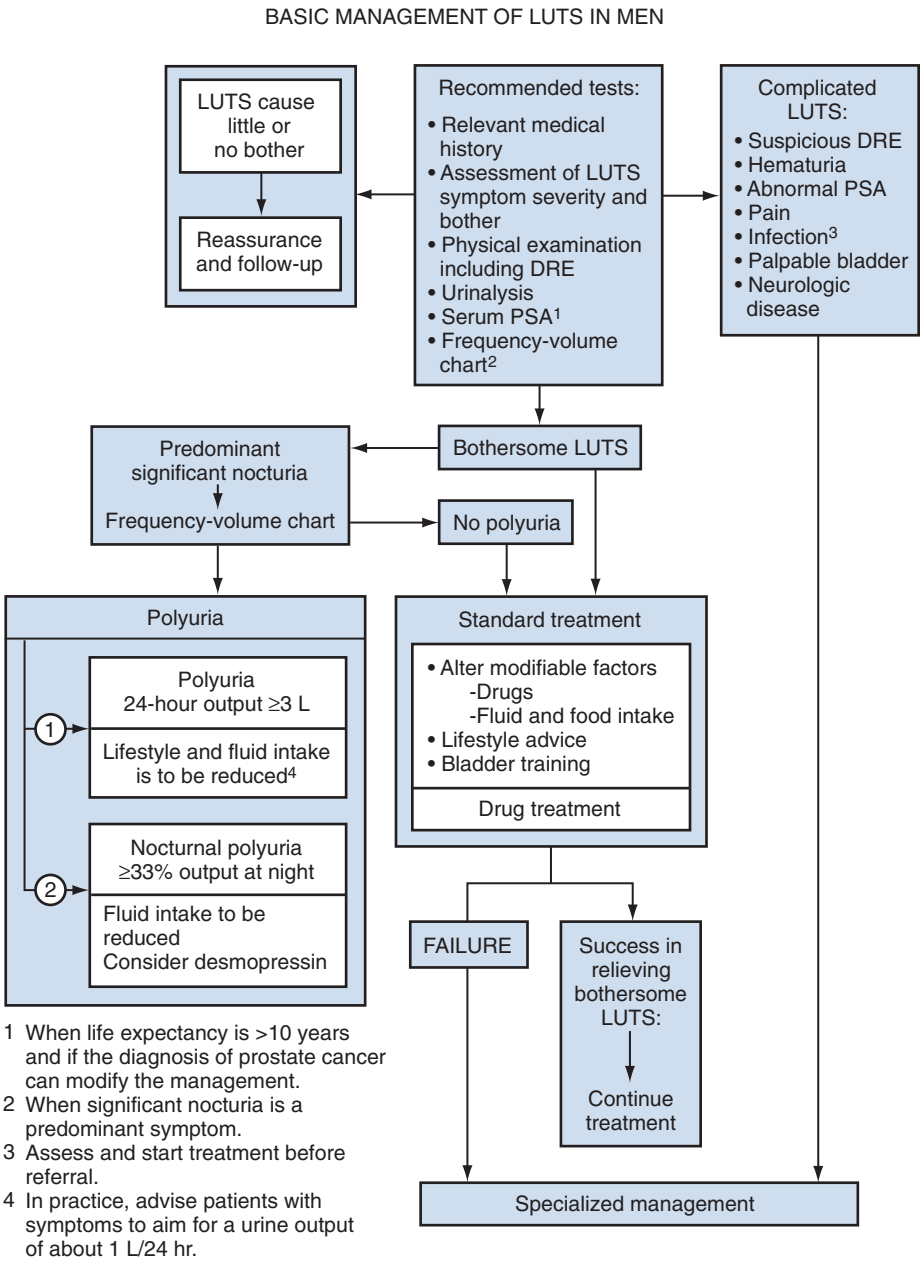

Figure 92–1. International Consensus guideline algorithm for management of lower urinary tract symptoms (2009): Basic management. DRE, digital rectal examination; PSA, prostate-specific antigen. (From Abrams P, Chapple C, Khoury S, et al. Evaluation and treatment of lower urinary tract symptoms in older men. J Urol 2009;181[4]:1779–87.)

symptoms of LUTS to exclude renal insufficiency caused by the presence of obstructive uropathy (McConnell et al, 1994; Denis et al, 1998), at the Fifth International Consultation on BPH it was suggested that serum creatinine determination should be optional or secondary. **The AUA guidelines on BPH and the Sixth International Consensus report no longer recommend routine creatinine measurement in the standard patient.** However, it is well established that BPH patients with renal insufficiency have increased risk for postoperative complications. The risk is 25% for patients with renal insufficiency, compared with 17% for patients without the condition (Mebust et al, 1989). Moreover, the mortality increases up to sixfold for BPH patients treated surgically if they have renal insufficiency (Holtgrewe and Valk, 1962; Melchior et al, 1974). Of 6102 patients evaluated in 25 studies by intravenous urography (IVU) before prostate surgery, 7.6% had evidence of hydronephrosis (McConnell et al, 1994). Of these patients, 33.6% had associated renal insufficiency. **Elevated serum creatinine levels in a patient with BPH is an indication for imaging studies (usually ultrasonography) to evaluate the upper urinary tract.** In a retrospective analysis of 345 patients who had undergone prostatectomy, 1.7% (n = 6) had occult and progressive renal damage (Mukamel et al, 1979). These patients had minimal or no urinary symptoms and presumably fit the category of patients with "silent prostatism." Measurement of the serum creatinine concentration is one means to identify such "at risk" patients.

Serum Prostate-Specific Antigen

Prostate cancer can lead to LUTS by producing bladder outflow obstruction similar to BPH. Moreover, localized prostate cancer commonly coexists with BPH. In most men with a 10-year or longer life span the knowledge of concomitant prostate cancer may well alter management of the BPH component. The detection of a large nodular prostate cancer on DRE would no doubt alter therapy; however, the "early detection" of small volume prostate cancer in an 80-year-old man is unlikely to increase life

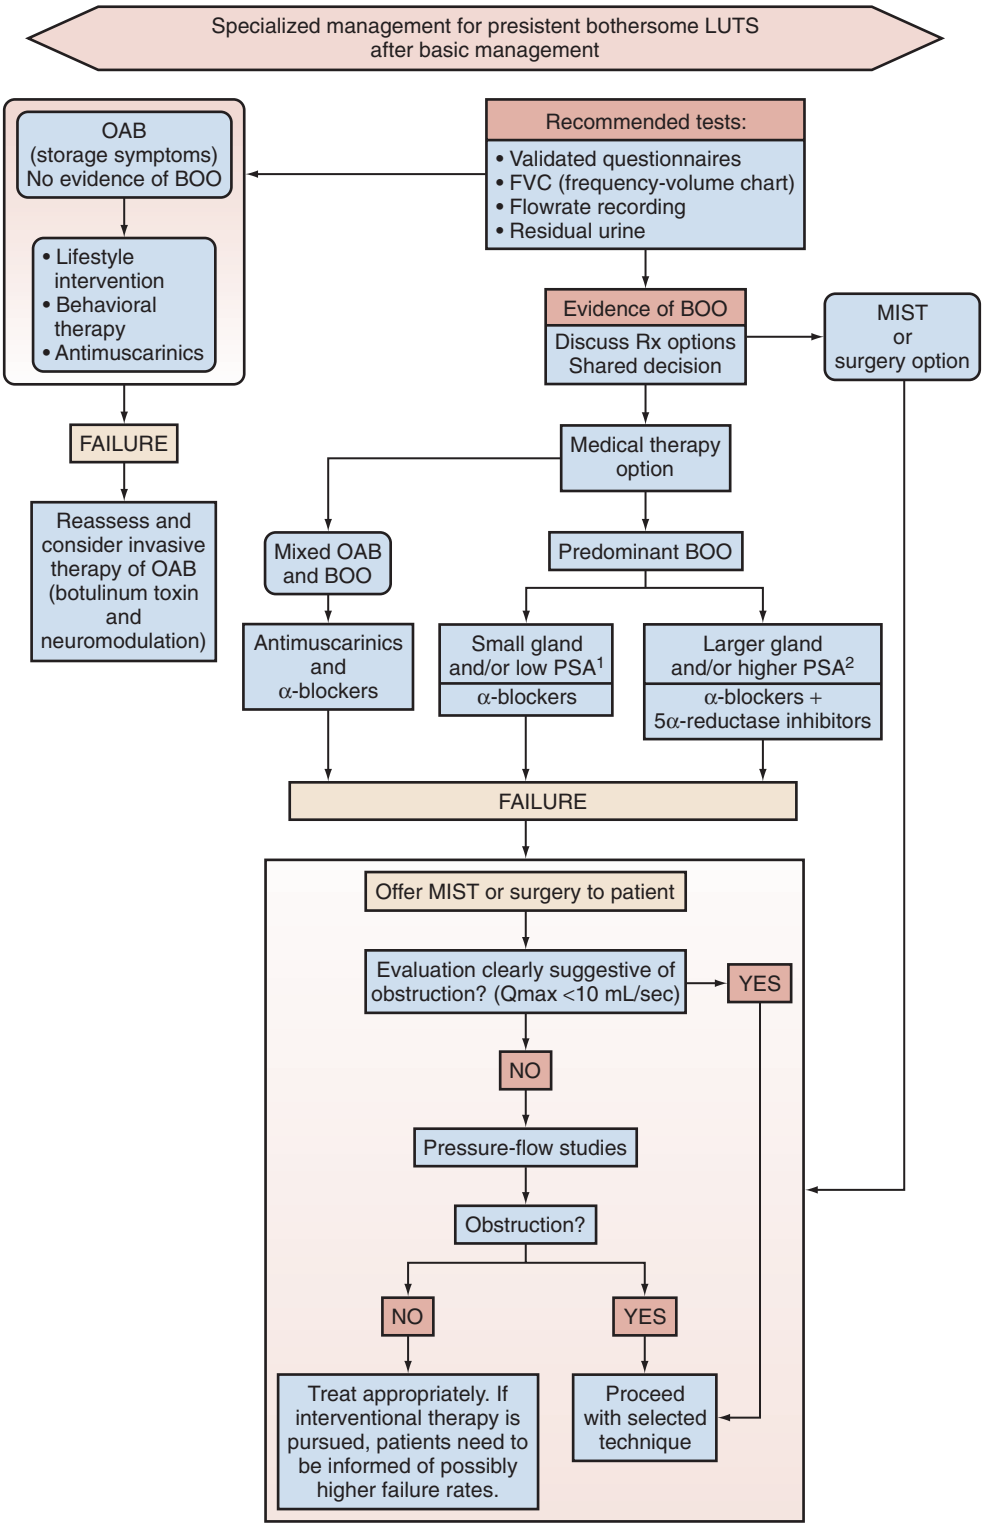

Figure 92–2. International Consensus guideline algorithm for management of lower urinary tract symptoms (LUTS) (2009): Specialized management. [1]PSA <1.5 ng; [2]PSA >1.5 ng; BOO, bladder outlet obstruction; MIST, minimally invasive surgical treatment; OAB, overactive bladder; PSA, prostate-specific antigen. (From Abrams P, Chapple C, Khoury S, et al. Evaluation and treatment of lower urinary tract symptoms in older men. J Urol 2009;181[4]:1779–87.)

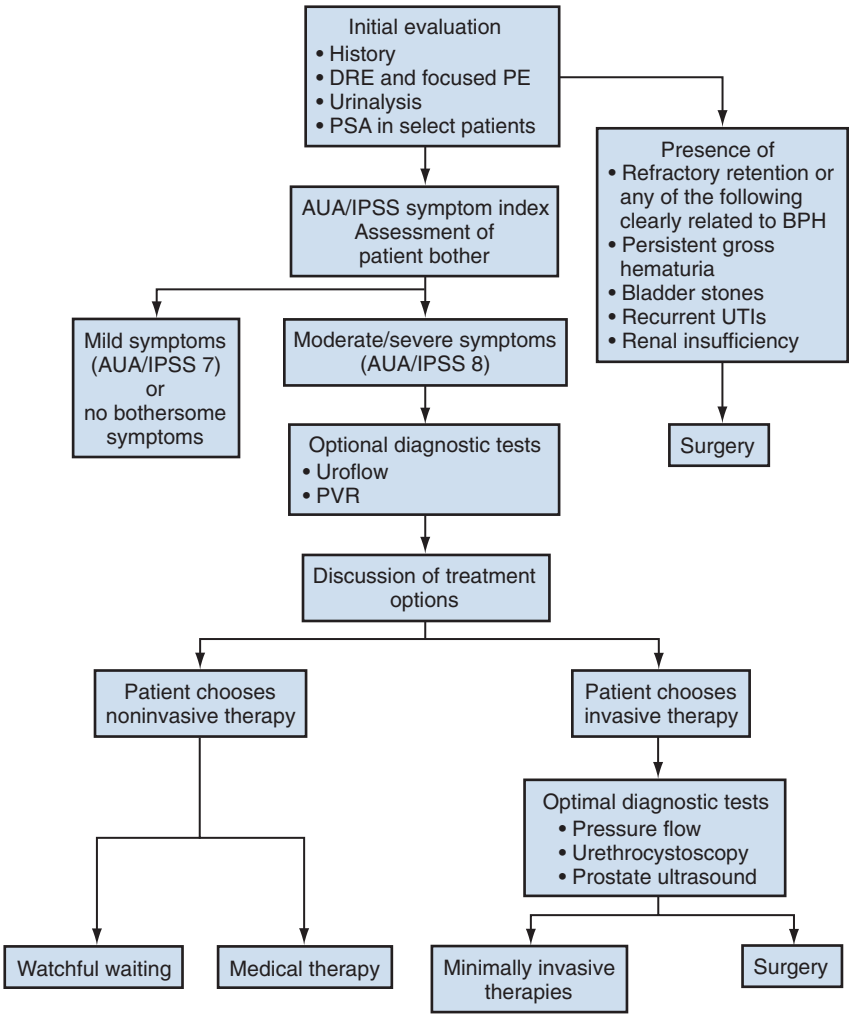

Figure 92–3. American Urological Association (AUA) guideline algorithm for management of benign prostatic hyperplasia (updated 2006). DRE, digital rectal examination; IPSS, International Prostate Symptom Score; PE, physical examination; PSA, prostate-specific antigen; PVR, postvoid residual. (From Kaplan SA. Update on the American Urological Association guidelines for the treatment of benign prostatic hyperplasia. Rev Urol 2006;8[Suppl. 4]:S10–7.)

expectancy. A PSA test and DRE increase the detection rate of prostate cancer over DRE alone. **Therefore measurement of the serum PSA value should be performed in patients in whom the identification of cancer would clearly alter BPH management** (Madersbacher et al, 2004; Kaplan et al, 2006; Abrams et al, 2009). There is significant overlap between the serum PSA values of men with BPH and men with clinically localized prostate cancer. Twenty-eight percent of men with histologically proven BPH have a serum PSA value greater than 4.0 ng/mL (McConnell et al, 1994). Serum PSA trends over time (PSA velocity), measurement of free versus complexed PSA, and PSA density may help to improve the specificity of PSA in men with BPH. Newer markers such as the PCA-3 test can also help to differentiate BPH from prostate cancer.

In the absence of prostate cancer the PSA value provides both a guide to prostate volume and also an indication of the likelihood of response to therapy with 5α-reductase inhibitors. However, in men with BPH already treated with a 5α-reductase inhibitor (e.g., finasteride [Proscar] or dutasteride [Avodart]) serum PSA is reduced 40% to 50% after 6 months of treatment. Failure to establish a baseline (pretreatment) PSA level may therefore complicate interpretation of future PSA values. Men who are taking these agents should have their PSA value doubled to correctly assess their risk of harboring a prostatic adenocarcinoma. Provided that this is done, recent evidence suggests that 5α-reductase therapy actually increases the sensitivity of PSA as a detector of cancer.

Symptom Assessment

The International Prostate Symptom Score (IPSS) is recommended as the symptom scoring instrument to be used for the baseline assessment of symptom severity in men presenting with LUTS (Kaplan et al, 2006; Abrams et al, 2009). When the IPSS system is used, symptoms can be classified as mild (0 to 7), moderate (8 to 19), or severe (20 to 35). The IPSS should also be the primary determinant of treatment response or disease progression in the follow-up period. Although other symptom score questionnaires are used, the IPSS is now the U.S. and international standard.

However, the IPSS cannot be used to establish the diagnosis of BPH. Men (and women) with a variety of lower urinary tract disorders (e.g., infection, tumor, neurogenic bladder disease) will have a high IPSS. Nonetheless, **the IPSS is the ideal instrument to grade baseline symptom severity, assess the response to therapy, and detect symptom progression in those men managed by watchful waiting.** Optimal treatment decisions in individual patients will also need to take into account how a given level of symptoms affects each man's quality of life (degree of bothersomeness).

The IPSS was developed from the AUA Symptom Index (AUASI) developed by the Measurement Committee of the AUA (Barry et al, 1992a, 1992b). Each question on the IPSS can yield 0 to 5 points, producing a total symptom score that can range from 0 to 35. This seven-question set is internally consistent (Cronbach alpha, 0.85) and reliable (test-retest correlation, 0.93). The index correlates strongly with patients' global ratings of their urinary difficulties (r = 0.78) and is sensitive to treatment response.

Johnson and associates (2009) showed that patients with a low education status are more likely to misunderstand the IPSS whether they are managed in public hospital or university practice. They tend to misrepresent their symptoms and therefore may receive inappropriate treatment. Eight percent of university hospital and almost 25% of public hospital patients under-reported their moderate symptoms as mild, and 33% of university hospital and 16% of public hospital patients over-reported their mild symptoms as moderate. When administered by a medical professional, many of the inaccuracies disappear even though the questionnaire is recommended as "self-administered." The use of the additional bother score or quality of life question may be useful in guiding appropriate treatment.

Although the IPSS correlates well with quality of life measures (Sagnier et al, 1995), there is still a need for sensitive BPH-specific quality of life instruments. Furthermore, because storage symptoms often predominate there is a need for better methods of quantifying urgency, frequency, and recording any incontinence. The standardization subcommittee of the International Continence Society has usefully categorized the range of likely symptoms into three groups: storage, voiding, and postmicturition (Abrams et al, 2003). Subdividing the IPSS into the four obstructive and three storage questions may also be useful. Other systems such as the Kings Score may be more sensitive to changes in storage symptoms. A voiding diary with frequency and volume recordings also may be helpful.

Clearly, symptom scores alone do not capture the complete picture of a prostate problem as perceived by the individual patient. Symptom impact on a patient's lifestyle must be considered as well. An intervention may make more sense for a moderately symptomatic patient who finds his symptoms very bothersome than for a severely symptomatic patient who finds his symptoms tolerable.

Additional Diagnostic Tests

Additional testing should be considered after the initial evaluation if there is a significant chance the patient's LUTS may not be due to BPH. Patients with a normal initial evaluation and only mild symptomatology on the IPSS (scores 0 to 7), or even more moderate symptoms but minimal bother, do not need additional diagnostic evaluation and can be considered for an active surveillance program and observed (Kaplan, 2006). Men who have developed serious complications of BPH should be treated surgically in most cases. Urinary flow rate, postvoid residual (PVR) urine volume, and pressure-flow urodynamic studies are appropriate tests to consider in the evaluation of men with moderate to severe symptoms (IPSS 8 to 35). The value of pressure-flow studies is debated, especially in men who elect watchful waiting or medical therapy as their management option. **Cystoscopy should not be done routinely** but is optional during later evaluation if invasive treatment is strongly considered. Urinary flow rate and PVR are generally recommended tests (Madersbacher et al, 2004; Kaplan, 2006; Abrams et al, 2009), and frequency-volume chart recordings are recommended by most clinicians (Madersbacher et al, 2004; Abrams et al, 2009).

It may be appropriate for the physician to offer treatment alternatives to the patient without performing any further diagnostic tests. Especially if the patient chooses watchful waiting or noninvasive therapy, invasive diagnostic tests may not be necessary. Conversely, if the patient elects an invasive treatment option, it may be appropriate for the physician to consider further evaluation.

Diagnostic Tests in Men Who Require Surgery for Benign Prostatic Hyperplasia

Surgery is generally recommended if the patient has refractory urinary retention (failing at least one attempt of catheter removal) or any of the following conditions clearly secondary to BPH: recurrent UTI, recurrent gross hematuria (resistant to 5α-reductase inhibitor therapy), bladder stones, renal insufficiency, or large bladder diverticula (McConnell et al, 1994; Denis et al, 1998; Kaplan et al, 2006; Abrams et al 2009). If there is reason to suspect that the patient's urinary retention may be due to detrusor hypocontractility, then urodynamic studies (e.g., filling cystometry) may be helpful. Pressure-flow urodynamic studies are not informative if the patient cannot urinate. Cystoscopy is appropriate to consider before the operative procedure to help plan the most prudent approach. The presence of infection and hematuria in patients should prompt appropriate evaluation and therapy for these conditions before treatment of BPH.

Uroflowmetry

Uroflowmetry is either generally recommended (by the AUA [Kaplan, 2006]), recommended for specialist investigation (Sixth International Consultation [Abrams et al, 2009]), or recommended generally and required before invasive treatment (EAU [Madersbacher et al, 2004]). Uroflowmetry involves the electronic recording of the urinary flow rate throughout the course of micturition. It is a common, noninvasive urodynamic test used in the diagnostic evaluation of patients presenting with symptoms of BOO. The results of uroflowmetry are nonspecific for causes of the symptoms. For example, an abnormally low flow rate may be caused by an obstruction (e.g., hyperplastic prostate, urethral stricture, meatal stenosis) or by detrusor hypocontractility. **The AHCPR Guideline Panel reached the following conclusions regarding uroflowmetry** (McConnell et al, 1994), which still apply:

- **Flow rate measurements are inaccurate if the voided volume is less than 125 to 150 mL.**
- **Flow rate recording is the single best noninvasive urodynamic test to detect lower urinary tract obstruction. Current evidence, however, is insufficient to recommend a given "cutoff" value to document the appropriateness of therapy.**
- **The peak flow rate (PFR; Qmax) more specifically identifies patients with BPH than does the average flow rate (Qave).**
- **Although PFR decreases with advancing age and decreasing voided volume, no age or volume correction is currently recommended for clinical practice.**

- **Although considerable uncertainty exists, patients with a PFR greater than 15 mL/sec appear to have somewhat poorer treatment outcomes after prostatectomy than patients with a PFR of less than 15 mL/sec.**
- **A PFR of less than 15 mL/sec does not differentiate between obstruction and bladder decompensation.**

The Fourth International Consultation on BPH concluded that flow rate measurement represents a reproducible way to quantify the strength of the urinary stream and, when used in combination with symptom scores for a small subset of patients (20%), has a high probability of correctly characterizing whether there is BOO (Denis et al, 1998).

Despite its limitations, flow rate recording has demonstrated some sensitivity in identifying BOO due to BPH. Scott and coworkers (1967) and Shoukry and associates (1975) found that PFR correlated better than symptoms with the presence or absence of obstruction as determined by pressure-flow studies. Siroky and coworkers (1979) concluded that uroflowmetry was able to separate physiologically unobstructed and obstructed patients. Gleason and colleagues (1982) found that PFR distinguished between normal men and patients with BPH, urethral stricture, or prostatitis. However, they also noted that a subgroup of patients with a decompensated detrusor muscle could not be separated from the obstructed men on the basis of PFR alone.

Chancellor and colleagues (1991) **found that flow rate recording cannot distinguish between BOO and impaired detrusor contractility as the cause for a low PFR.** None of eight measured, noninvasive urodynamic parameters was significantly different for 31 patients with outlet obstruction than for 14 patients with impaired detrusor contractility. Abrams and associates (1977, 1979) studied the value of uroflowmetry before prostatectomy. Failure rates for surgery were found to decrease with the addition of flow rate measurement to symptom assessment in preoperative evaluation.

PFR appears to predict surgical outcome in some studies. In one study reported by Jensen and coworkers (1984), 53 patients underwent prostatectomy based on clinical indication alone. All three groups according to level of PFR experienced improvements in their symptom score after surgery, but the group with a PFR less than 10 mL/sec before treatment had a better overall subjective outcome as assessed by global subjective judgment.

In another study, which included men studied with flow rates before and 6 months after prostatectomy (Jensen et al, 1988a), subjective evaluation revealed an overall symptomatic improvement rate of 80% after surgery. The difference in success rates for men falling above or below the cutoff value of PFR = 10 mL/sec was not significant ($P = .2$). When a PFR cutoff of 15 mL/sec was used, success rates for men above or below the cutoff value differed significantly.

McLoughlin and coworkers (1990), using urodynamic testing and a cutoff value of 12 mL/sec, evaluated 108 men with clinical BPH before and 1 year after surgery and determined that if using a PFR less than 12 mL/sec as an indicator for obstruction then only 3% of patients would have been subjected to an unnecessary TURP. These authors believed that the routine pressure-flow studies or cystometrograms were not indicated but that the screening of flow rates followed by further urodynamic testing in patients with a PFR of greater than 12 mL/sec should be considered. Very low rates do not appear to portend poor treatment outcome. In one study of 84 patients undergoing surgery for symptomatic BPH (Donkervoort et al, 1975), patients with a preoperative PFR less than 7 mL/sec improved symptomatically as much as patients with a PFR greater than 7 mL/sec.

Neither subjectively assessed symptoms nor quantified symptom score analysis correlates strongly with uroflowmetry measurements but each is an independent assessment. Patients with a PFR greater than 15 mL/sec may have somewhat poorer outcomes after surgery than those with a PFR less than 15 mL/sec (although the majority of patients still improve). Other investigators report similar findings for different PFR cutoff values (e.g., 12 mL/sec). Patients with very bothersome symptoms suggestive of clinical BPH but having a PFR greater than 15 mL/sec may benefit from further urodynamic testing (i.e., pressure-flow studies) to reduce the number of surgical treatment failures. A PFR less than 15 mL/sec does not differentiate between outflow obstruction and detrusor impairment. No minimal threshold of PFR reliably diagnoses detrusor failure or predicts a poor surgical outcome.

Postvoid Residual Urine Volume

Postvoid residual urine volume is the amount of fluid remaining in the bladder immediately after the completion of micturition. Studies indicate that PVR urine volume normally ranges from 0.09 to 2.24 mL, with the mean being 0.53 mL (Hinman and Cox, 1967). Seventy-eight percent of normal men have PVR volumes of less than 5 mL, and 100% have volumes of less than 12 mL (DiMare et al, 1963). The Agency for Health Care and Policy Research BPH Guideline Panel reached the following conclusions regarding PVR urine volume (McConnell et al, 1994):

- PVR urine volume measurement has significant intraindividual variability that limits its clinical usefulness.
- PVR urine volume does not correlate well with other signs or symptoms of clinical BPH.
- Large PVR urine volumes may predict a slightly higher failure rate with a strategy of watchful waiting. However, the threshold volume defining a poorer outcome is uncertain.
- It is uncertain whether PVR urine volume predicts the outcome of surgical treatment.
- It is uncertain whether PVR urine volume indicates impending bladder or renal damage.
- PVR urine volume can be measured with sufficient accuracy noninvasively by transabdominal ultrasonography. The measurement variation caused by the method is less than the biologic range of PVR variation.

The Fourth International Consultation initially recommended PVR volume determination in the initial assessment and during monitoring of patients under watchful waiting or other conservative treatment regimens (Denis et al, 1998).

PVR urine volume measurement can be performed by noninvasive (ultrasound) and invasive (catheterization) methods. Invasive techniques are accurate if performed correctly but carry a small, but clinically significant, risk of discomfort, urethral injury, UTI, and transient bacteremia. Small portable and less expensive devices can be used to measure the PVR urine volume with reported accuracy and are comparable to more expensive ultrasound units and catheterization. Birch and coworkers (1988) reported that of 30 men with BPH, 66% had wide variations in PVR urine volume when three measurements were done on the same day. In 34% of patients there was no difference among the three measurements. In 58%, at least two volumes were significantly different. In 8% of patients, all three were different. In most patients, two measurements were statistically similar whereas the third one yielded quite different results. Bruskewitz and colleagues

(1982) found similarly wide variations of the measured amount when they performed repetitive measurements of PVR urine volume (repeated two to five times) by in-and-out catheterization on 47 men before prostatectomy. They also found no correlation between the amount of residual urine and any cystoscopic or urodynamic findings, symptoms, or the presence or absence of a history of UTIs. Most clinical studies demonstrate minimal correlation between PVR urine volume and baseline measurements of symptoms, flow rate, or urodynamic measures of obstruction (Griffiths and Castro, 1970; Shoukry et al, 1975; Abrams and Griffiths, 1979). However, Neal and associates (1987) found a significant association in 253 men between PVR urine volume, age, "below normal" PFR, and high urethral resistance. Low voiding pressure, however, did not correlate well with the PVR amount. The authors concluded that outflow obstruction is related to the development of increasing amounts of PVR urine. In the AUA Outcome Study, Barry and colleagues (1993) found a significant correlation between high PVR urine volumes and low flow rates but no correlation with IPSS.

Traditionally, urologists have assumed that increasing amounts of PVR urine denote BPH progression and are thus an "indication" for surgery. This concept underlies the common inclusion of PVR urine volume in each individual government's appropriateness criteria. Unfortunately, data are lacking to support the predictive value of PVR urine volume. Andersen (1982) studied 104 men with BPH and reported two patterns of BPH progression. The slow course was characterized by the development of high levels of PVR urine that resulted in decompensation of the detrusor muscle and eventually led to urinary retention. The fast course was associated with uninhibited detrusor contractions. The amount of PVR urine, the presence of uninhibited detrusor contractions, and symptoms correlated poorly in the study. Nevertheless, Andersen recommended the PVR urine volume as a safety parameter when measured longitudinally throughout the clinical course of a patient with prostatism.

Data from the Veterans Affairs (VA) cooperative study group randomized trial comparing TURP with watchful waiting demonstrated that PVR urine volume does not predict the outcome of surgery, and there was little evidence to support criteria that require a certain amount of PVR urine before surgery is justified. Additionally, a high PVR urine volume did predict a slightly higher failure rate for watchful waiting. However, the majority of men with large PVR urine volume did not require surgery during the 3-year duration of the trial. In summary, **PVR urine volume is best viewed as a "safety parameter." Men with significant PVR amounts should certainly be monitored more closely if they elect nonsurgical therapy, particularly if antimuscarinic therapy is chosen.**

Pressure-Flow Studies

If the initial evaluation, flow rate, and PVR urine volume are not sufficiently suggestive of BOO, further urodynamic assessment by pressure-flow studies should be considered, especially if an invasive treatment is considered (i.e., surgery) or if surgical treatment has failed (McConnell et al, 1994; Denis et al, 1998; Kaplan et al, 2006; Abrams et al, 2009). **Pressure-flow studies differentiate between patients with a low PFR secondary to obstruction and those whose low PFR is caused by impaired detrusor contractility.** These studies should be performed when the distinction between the two will affect therapeutic decisions. Patients with a history of neurologic diseases known to affect bladder or sphincteric functions, as well as patients with normal flow rates (PFR > 15 mL/sec) but bothersome symptoms, may also benefit from urodynamic evaluation and especially if surgical therapy is contemplated.

The value of pressure-flow measurement in predicting treatment outcome is uncertain. In a study by Abrams and colleagues (1979), the inclusion of pressure-flow data in the preoperative evaluation and indication for surgery reduced the subjective failure rate to 12%, down from 28% when patients were certified as candidates for surgery without the urodynamic data. However, a 28% failure rate is significantly higher than that reported in other TURP series (McConnell et al, 1994). Jensen and Andersen (1990) recommended invasive urodynamic testing for patients with a PFR greater than 15 mL/sec. For the population in their study this would have resulted in an additional 9% of patients being excluded from surgery and a decrease in failure rate to 8.3%. The support for this recommendation has to be questioned, however, in light of an earlier study by Jensen and coworkers (1988b, 1988c) that found most unsatisfied patients are incorrectly classified preoperatively even with urodynamic testing.

Pressure-flow studies do permit more accurate categorization of patients. Abrams and associates (1979) used pressure-flow plots in addition to flow rate measurement. The study found that in about half the cases the patients with LUTS could be correctly classified as obstructed or nonobstructed by PFR alone but that the addition of the detrusor pressure (Pdet) at PFR allowed correct classification in two thirds of the group. The remaining one third of the patients were assessed by pressure-flow plot. In many of these patients, both Pdet and PFR were low, indicating a decompensating detrusor muscle as the source for the low PFR.

Pressure-flow studies provide much more specific insight into detrusor function and the etiology of voiding dysfunction than do flow rate measurements. However, a number of outcome-based investigations demonstrate a modest additional value of pressure-flow studies over symptom and flow rate evaluation. **Discussion of treatment options and the nature of the investigation with the patient is recommended before pressure-flow testing is organized.**

Filling Cystometry (Cystometrography)

Filling cystometry adds limited information to the evaluation of most men with LUTS and is not recommended in routine cases. The test may have value in the evaluation of patients with known or suspected neurologic lesions and LUTS, but pressure-flow studies provide more specific information.

Urethrocystoscopy

Urethrocystoscopy is not recommended to determine the need for treatment. Although the linkage between the endoscopic appearance of the lower urinary tract and the treatment outcome is poorly documented, available information suggests that the relationship is minimal (McConnell et al, 1994). The test is recommended for men with LUTS who have a history of microscopic or gross hematuria, urethral stricture disease (or risk factors such as history of urethritis or urethral injury), bladder cancer or suspicion of carcinoma in-situ, or prior lower urinary tract surgery (especially prior TURP). Urethrocystoscopy may be considered in men with moderate to severe symptoms who have chosen (or require) surgical or other invasive therapy to help the surgeon determine the most appropriate technical approach.

For example, if urethrocystoscopy reveals a large middle lobe, transurethral incision of the prostate (TUIP) is unlikely to be successful. The decision to perform an open prostatectomy or laser vaporization may be appropriately influenced by the shape of the

gland, as well as its size. Urethroscopy is therefore performed to select (or rule out) specific techniques, not to determine the need for treatment.

Imaging of the Upper Urinary Tract

Upper urinary tract imaging is not recommended in the routine evaluation of men with LUTS unless they also have one or more of the following: hematuria, UTI, renal insufficiency (ultrasonography recommended), history of urolithiasis, or history of urinary tract surgery (McConnell et al, 1994; Denis et al, 1998; Kaplan et al, 2006; Abrams et al, 2009). Intravenous urography before BPH treatment was performed by 73.4% of urologists in the United States in the late 1980s (Holtgrewe et al, 1989) and is associated with a 0.1% incidence of significant adverse events. Generally, ultrasound imaging is now preferred but is unnecessary in the uncomplicated case.

The presence or history of hematuria, renal insufficiency, UTI, and/or history of stones or prior urinary tract surgery increases the likelihood that imaging will demonstrate clinically significant findings (Juul et al, 1989; Andrews et al, 2002). Although there are no conclusive data on the combined incidence of the important clinical predictors just listed, approximately one third of all men with BPH have one or another indication for urinary tract imaging.

ASSESSING THE EFFECTIVENESS AND SAFETY OF MEDICAL THERAPY

The role of treatment for any disease process depends on the magnitude of the clinical effect and the incidence and severity of treatment-related morbidity. Assessing the effectiveness of medical therapies for BPH requires defining clinically relevant end points, identifying quantitative and reliable clinical outcome measures, eliminating investigator and patient bias, accounting for the placebo response, and enrolling the proper number of subjects so that only clinically significant changes are statistically significant. Assessing the safety of medical therapies requires a rigorous effort to identify all treatment-related clinical, biochemical, teratogenic, and mutagenic adverse effects associated with drug treatment.

Clinical End Points

The clinical consequences of BPH includes LUTS and associated reduction of quality of life, detrusor dysfunction characterized by detrusor acontractility, detrusor instability, and detrusor fibrosis; incomplete bladder emptying; acute and chronic urinary retention; UTI; renal insufficiency; and hematuria (Shapiro and Lepor, 1995). **The goals of treatment for BPH include relieving LUTS, decreasing BOO, improving bladder emptying, ameliorating detrusor instability, reversing renal insufficiency, and preventing disease progression, which may include a deterioration of symptoms, future episodes of gross hematuria, UTI, AUR, or the need for surgical intervention.**

Quantitative Outcome Measures

Symptoms

The primary objective of the AUASI (now IPSS) was to provide a universally accepted instrument to quantify the impact of BPH therapies on LUTS (Barry et al, 1992a, 1992b). There is no standardized format for reporting changes in the AUASI or other quantitative indices of symptom severity after treatment. Symptom response has been reported as a percentage of patients achieving a threshold response or as group mean changes in a symptom score. The literature typically reports the percentage of men achieving between a 30% and a 50% reduction in the symptom score. Expressing the symptom response as a single threshold response does not discriminate the overall magnitude of the clinical effect. When the baseline symptom scores are mild to moderate, small and clinically insignificant changes correspond to large percentage changes. When baseline symptom scores are severe, relatively large absolute changes may not be clinically significant. Symptom outcome should be expressed both as a percentage of patients achieving a threshold reduction response and as group mean changes in the symptom score.

The clinical significance of changes in the AUASI score were reported by Barry and colleagues (1995). There were 1165 subjects who participated in a randomized double-blind placebo-controlled study of medical therapy and completed the AUASI at baseline and after 3 months of treatment. The absolute and percentage changes in AUASI and BPH Impact Index scores were correlated with five global ratings of symptom improvement. The group mean changes in AUASI for subjects rating their improvement as markedly, moderately, or slightly improved, unchanged, or worse were –8.8, –5.1, –3.0, –0.7, and +2.7, respectively. The relationship between the patients' global ratings of improvement and the AUASI and BPH Impact Index changes were dependent on the baseline AUASI score. This important study provides the data required to determine sample sizes and interpret the clinical significance of symptom improvement in BPH clinical trials. A 3-point change appears perceptible to symptomatic men.

Bladder Outlet Obstruction

Experimental animal models of BOO have demonstrated profound changes in bladder ultrastructure, cellular composition, metabolism, and function resulting from BOO (Levin et al, 2000). These experimental observations must be cautiously extrapolated to man, because the response to BOO depends on the species and the severity and duration of obstruction. Animal studies demonstrate that under experimental conditions BOO causes alterations likely to adversely affect bladder function. The justification for measuring and treating BOO in men with BPH is to reverse or prevent these deleterious consequences of BOO.

Because synchronous pressure-flow urodynamic measurements do not correlate with severity of bladder dysfunction, severity of symptoms, or response to therapy, it is difficult to require these studies when evaluating the effectiveness of medical therapy for BPH. Long-term studies are needed to determine whether urodynamic measurements predict disease progression. At the present time the primary use of urodynamic testing is to discriminate the differential diagnosis of men presenting with multiple potential causes for LUTS.

Uroflowmetry represents a noninvasive and inexpensive but indirect indicator of urinary performances measure of BOO (Siroky, 1990). The reporting of PFR has been standardized (Abrams et al, 2003). At the lower spectrum of PFR a relatively small absolute change (i.e., 4 to 6 mL/sec) corresponds to a relatively high percentage change, whereas at the higher end of PFR a relatively large absolute change (i.e., 12 to 17 mL/sec) corresponds to a relatively modest percent change. The clinical significance of the changes in PFR cannot be defined, owing to

the lack of correlations with relevant clinical, physiologic, or biochemical outcomes.

Bladder Emptying

The clinical significance of PVR urine volume measurement is controversial. Barry and colleagues (1993) reported no correlation between AUASI score and PVR amount. It has been suggested that the PVR urine volume may predispose to UTI and irreversible bladder dysfunction secondary to stasis and overdistention. **There are no data clearly documenting that the incidence of UTI is related to the PVR urine volume.** Another limitation of PVR urine measurements is variability over short intervals of time (Bruskewitz et al, 1982). It is imperative to measure the PVR volume on several occasions if this parameter will influence treatment decisions.

There is no standardization for reporting changes in PVR urine volume. Typically, the data are presented as absolute group mean changes. The majority of BPH clinical trials exclude subjects with high baseline PVR amount (>300 mL) because of the potential risks of randomization to a placebo or ineffective treatment group. **Therefore the majority of subjects enrolled in clinical trials have clinically insignificant baseline PVR urine volumes, potentially undermining the relevance of most trials to "real world" practice.**

Bladder Overactivity

The definition of bladder overactivity (detrusor instability) is the development of a detrusor contraction exceeding 15 cm H_2O at a bladder volume less than 300 mL (Jepsen and Bruskewitz, 2000). The clinical significance of an overactive bladder (OAB) in men with BPH is unresolved. There is no evidence that men with detrusor instability electing watchful waiting are predisposed to develop disease progression. The presence of an OAB does not reliably predict response to medical or surgical treatment. **Therefore improvement of an OAB is not a standard outcome measure in clinical trials.**

Urinary Tract Infection, Renal Insufficiency, and Hematuria

Unlike other manifestations of BPH, the diagnosis of UTI, renal insufficiency, and hematuria is not controversial and the requirements for measurement are noninvasive and inexpensive. Because these events are not disease or gender specific, one must be cautious in assuming a causal relationship to BPH. There is no convincing evidence that UTI in the aging male population is associated with either PVR urine or BOO. It is reasonable to assume that renal insufficiency occurs secondary to urinary retention if renal failure is reversed after catheter drainage. Hematuria may be associated with prostatic vascularity and may sometimes respond to medical therapy with a 5α-reductase inhibitor.

Because the incidences of UTI, renal insufficiency, and hematuria are relatively uncommon and non–disease-specific events in the aging male population, it would be extremely difficult to design a prospective study to determine whether any BPH treatment prevents these events in an unselected cohort of men.

Eliminating Bias

***Bias* may be defined as a systematic error or difference between the true value and that actually attained from all causes other than sampling ability. The only mechanism to ensure that the potential bias of the subject and the investigator does not influence the outcome is a randomized, placebo-controlled, double-blind design.** Because subjects are typically randomized to receive a drug or its matching placebo, any effect of the investigators' bias would occur equally in the intervention and control groups.

The importance of eliminating bias cannot be overemphasized in BPH clinical trials. Some patients are very enthusiastic about receiving the "new" treatment. In the absence of a blinded randomization, these patients may be disproportionately directed into the active treatment groups. A subject receiving a known placebo would be reluctant to report any adverse events or clinical response. An investigator may be inclined to censor various outcomes if treatment group assignment is known. Although subjective outcome measures such as symptoms are more likely to be influenced by the placebo response, quantitative outcome measurements such as the PVR urine volume and PFR are also subject to a placebo response.

The placebo effect can be substantial in trials of drug treatment of BPH. **Trials should therefore include a placebo run-in period before recording baseline values.** Therefore these baseline values have already incorporated the placebo effect before any comparison is made. Ideally a 4-week placebo run-in period before initiation of treatment should be included in any trial design.

Similarly, the statistical concept of "regression toward mean" should also be taken into account in trial design. If measuring urinary symptom scores or PFRs, for instance, then in any population there will be some individuals whose values will be recorded at the extremes of the range for that population. These individuals, when followed up with sequential measurements of the same parameters, will tend to produce values that are less extreme and closer to the mean for the population being studied. Again, incorporating a placebo run-in period will allow this process to occur, at least to a degree, so that subsequent measurements from the baseline values determined after the placebo run-in period are more likely to be in response to a true treatment effect rather than to these two potentially confounding and misleading processes.

Sample Size

It is a general misconception that the validity of a clinical trial is directly proportional to the number of subjects enrolled. One of the objectives of a clinical trial is to determine whether the difference observed between two different treatment groups is clinically relevant. If the sample size of the clinical trial is properly determined in the early planning phase, a statistically significant outcome represents a clinically significant outcome. Calculation of sample size with provisions for adequate levels of significance and power is an essential part of planning a trial. Enrolling an excessive number of subjects may result in an overpowered study; that is, a small and clinically insignificant difference may be statistically significant. Conversely, enrolling insufficient numbers of subjects may result in an underpowered study; that is, a large and clinically significant difference may not be statistically significant. The larger the number of subjects enrolled in a study, the smaller is the change that is required to achieve statistical significance. Therefore the reader must examine the magnitude of the between-group difference and make a judgment about clinical significance.

Adverse Events

For a drug to enter into clinical investigation in humans it must be shown to elicit no significant chemical, behavioral, physiologic, teratogenic, mutagenic, or carcinogenic effects in at least two animal models. **The typical untoward or adverse events captured in a clinical trial include physical findings, laboratory results, and complaints.** A comprehensive physical examination and a battery of general laboratory tests are obtained at baseline and at the completion of the trial to capture any untoward events. The subjects' complaints are typically captured at each study visit. The adverse clinical effects may be expected or unexpected.

Complaints may be elicited by means of a checklist or by the subjects' unsolicited recall of an event. **Adverse clinical events are typically greater with a checklist.** The assessment of adverse events should determine the frequency and severity of the events and whether an event was severe enough to terminate participation in the study. The majority of clinical trials are powered based on outcome measures and not adverse events. **There is a tendency for studies to be underpowered to detect** serious adverse events that may therefore only show up later in postmarketing surveillance studies.

NONSURGICAL THERAPY

Watchful Waiting or "Self-Help"

A significant proportion of men with LUTS will not choose medical or surgical intervention because the symptoms are not bothersome, the complications of treatment are perceived to be greater than the inconvenience of the symptoms, and there is a reluctance to take a daily pill owing to side effects and/or the cost of treatment. Reassured that the symptoms are not caused by cancer or other serious genitourinary pathology, or that the delay in treatment will not have irreversible consequences, watchful waiting is often the patient-driven treatment of choice in the absence of absolute indications for intervention. Of 670 consecutive men with BPH referred to 39 urologists in the Netherlands, 41% elected watchful waiting (Stoevelaar et al, 1999). It is unreasonable to discourage an informed patient with severe symptoms and no other consequences of BPH from pursuing watchful waiting despite the safety and effectiveness of medical therapy. Watchful waiting does not imply the total absence of intervention. The severity and bother due to symptoms may be improved by simple measures such as decreasing total fluid intake especially before bedtime, moderating the intake of alcohol- and caffeine-containing products, and maintaining timed voiding schedules.

The impact of watchful waiting was examined in a study of 556 subjects with moderate symptoms of BPH randomized to TURP versus watchful waiting (Wasson et al, 1995). The changes in all outcome measures were significantly greater in the TURP group. A relevant outcome for patients selecting watchful waiting is disease progression. During 3 years of follow-up, treatment failure was observed in 23 (8.2%) and 47 (17%) of subjects randomized to TURP and watchful waiting, respectively. Treatment failure in the watchful waiting group was most often the result of increasing PVR volume or symptom score. Significant renal impairment was not seen.

Brown and associates (2007) evaluated the effectiveness of self-management as a first-line intervention for men with LUTS in a randomized controlled trial set in a teaching hospital and a district general hospital in London. One hundred forty men were randomized between standard care and "self-management," which comprised three small group sessions of relevant urinary education and lifestyle advice. Self-management significantly reduced the frequency of treatment failure and reduced urinary symptoms. Because of the large observed benefit of self-management, these investigators suggested a large multicenter trial to confirm whether self-management could be considered as first-line treatment for men with LUTS.

MEDICAL THERAPY

Medical therapies extensively investigated for BPH include α-adrenergic blockers, 5α-reductase inhibitors, aromatase inhibitors, and numerous plant extracts. Newer therapies include antimuscarinic drugs and phosphodiesterase inhibitors (PDEIs) and several combinations of these agents. α-Adrenergic blockers and 5α-reductase inhibitors, and the combination of both of these, are emphasized in this chapter because the safety and efficacy of drugs in these classes have been critically examined and these drugs are widely prescribed for the treatment of BPH. Aromatase inhibitors are briefly reviewed for historical interest. Plant extracts are also reviewed, because these agents are widely used in some parts of the world, despite the lack of properly designed clinical trials. Because plant extracts are not classified as drugs, the marketing and claims are not critically scrutinized by regulatory agencies.

The Impact of Medical Therapy

Prior to the 1980s, prostatectomy was the only widely accepted intervention for BPH. **The enthusiasm for medical therapy has been supported in part by the limitations of prostatectomy, which include the morbidity of the surgical procedure, failure to invariably achieve a successful outcome, and a small but significant re-treatment rate** (Lepor, 1993). Although medical therapies do not achieve the same level of efficacy as prostatectomy, the attractive features of medical therapy relative to prostatectomy are that clinically significant outcomes are obtained with fewer, less serious, and reversible side effects (Lepor, 1993). Because the indication for intervention in the overwhelming majority of patients with BPH is to improve quality of life by relieving symptoms (Emberton et al, 2008), the lower morbidity of medical therapy is of paramount importance in patient-driven treatment decisions.

In 1990, TURP was second only to cataract surgery in terms of expenditures paid by the U.S. Medicare program. **Medical therapy is currently considered the preferred treatment alternative for those individuals who lack absolute indications for surgery. Because the overwhelming majority of men undergoing TURP lack absolute indications for intervention** (Mebust et al, 1989) and prefer nonsurgical options (Emberton et al, 2008), the number of prostatectomies performed throughout the world has decreased significantly. A survey of the U.S. Medicare database also revealed that the absolute number of prostatectomies decreased from 250,000 in 1987 to 116,000 in 1996 to 88,000 in 2000 (Wasson, 2000) and stabilized since then. This 55% reduction in TURP has occurred despite the progressively increasing number of men enrolled in the Medicare program and overall increase in U.S. spending on BPH (Wei et al, 2005). Similar

reductions in TURPs have been reported from France, Canada, Denmark, and Germany.

Approximately 30% of American men older than 50 years have moderate to severe symptoms (Chute et al, 1993; Lepor and Machi, 1993). **Based on the demographics of the U.S. population, 6.5 to 8.7 million men are eligible to discuss BPH treatment options** (Wei et al, 2005; Jacobsen et al, 1995). The overwhelming majority of these men would not elect prostatectomy, owing to the risks associated with surgical intervention. These individuals are potential candidates for medical therapy.

Selecting Candidates for Medical Therapy

The ideal candidate for medical therapy should have symptoms that are bothersome and negatively affect quality of life so that the patient is willing to make a lifetime commitment to medical therapy, providing the drug is effective and adverse experiences are either nonexistent or minimal. There are currently no scientific data to support offering medical therapy to individuals presenting with absolute indications for intervention. Individuals presenting with recurrent urinary retention, recurrent UTIs, renal insufficiency, bladder calculi, and recurrent gross hematuria may develop life-threatening consequences from their BPH if it is not managed surgically. **Until properly controlled clinical studies unequivocally demonstrate favorable outcomes, patients presenting with absolute indications for intervention should be discouraged from selecting medical therapy.** If informed patients are willing to accept potential risks, medical therapy may be offered with a proviso for careful follow-up and future prostatectomy if medical therapy proves ineffective.

Preventing Benign Prostatic Hyperplasia with Medical Therapy

A potential role of medical therapy is to prevent the development of BPH or its progression. There are several factors limiting the enthusiasm for preventing the development of BPH. The clinical manifestations of BPH are rarely life threatening. Preventative intervention would have to be initiated before the fifth decade of life coinciding with the development of BPH (Partin, 2000). The long-term exposure to drug-induced adverse events and the prohibitive costs are the primary limitations of prevention therapy. In addition, effective medical and surgical therapy exists when BPH ultimately does becomes clinically evident. Because there are no clinical, biochemical, or genetic predictors of BPH development or progression, every man is potentially at risk. The ability to identify those individuals who are predisposed to develop clinical BPH refractory to medical therapy would provide a more compelling rationale for prophylaxis. There is good evidence that men with very large prostates (and usually higher PSA values) are at greater risk for developing urinary retention (Jacobsen et al, 1997) and that medical therapy (finasteride or dutasteride) can significantly decrease this risk of developing urinary retention (McConnell et al, 1998; Roehrborn et al, 2004). The decision to offer preventative therapy for urinary retention depends on the risk of the events, cost associated with treatment, and patient preferences for intervention.

Therapy with α-Adrenergic Blockers

Rationale

The rationale for α-adrenergic blockers in the treatment of BPH is based on the hypothesis that the pathophysiology of clinical BPH is in part caused by BOO, which is mediated by α_1-adrenergic receptors associated with prostatic smooth muscle (Caine, 1986) (Fig. 92–4). The importance of this dynamic obstruction was supported by morphometric studies demonstrating that smooth muscle is one of the dominant cellular constituents of BPH, accounting for 40% of the area density of the hyperplastic prostate (Shapiro et al, 1992). Caine and coworkers (1975) reported that the human prostate contracts in the presence of the α-adrenergic agonist norepinephrine. Several investigators subsequently demonstrated that the tension of prostate smooth muscle is mediated by the α_1 receptor (Hieble et al, 1985; Lepor et al, 1988; Gup et al, 1989). Lepor and colleagues (1988) were the first investigators to characterize the α_1 receptor in the human prostate using radioligand binding studies. These investigators subsequently reported that 98% of the α_1 receptors are localized to the prostatic stroma (Kobayashi et al, 1994). The importance of the adrenergic innervation of the prostate was further supported by the observation of high levels of norepinephrine in the human prostate (Lepor et al, 1990). Although the finding of high levels of smooth muscle α_1 receptors and norepinephrine in the human prostate suggests an important role of the adrenergic innervation in prostatic function, it cannot be assumed that these factors are directly responsible for clinical BPH. Lepor and associates (1990) reported no significant differences between norepinephrine levels, α_1 receptor density, or isometric contractile responses to phenylephrine (Gup et al, 1989) in BPH tissues obtained from men with symptomatic and asymptomatic BPH. Other investigators have shown α_1 receptor levels are higher in prostatic adenoma relative to prostatic capsule (Yamada et al, 1987; Kawabe et al, 1990). These observations simply show regional differences of α_1 receptors in the prostate and do not prove that clinical BPH is caused by upregulation of the α_1 receptor.

The most definitive evidence that blockade of prostate α_1 receptors relieves BOO was the observed direct relationship between the area density of prostate smooth muscle and the change in the PFR

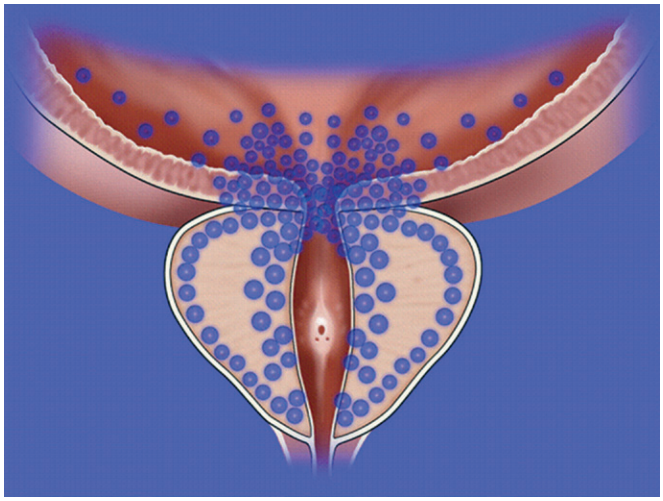

Figure 92–4. Distribution of α_1-adrenergic receptors in the lower urinary tract.

in 26 subjects undergoing prostatic biopsy before initiating α-adrenergic blocker therapy with terazosin (Hytrin) (Shapiro et al, 1992). Although the prostates of those subjects achieving symptom improvement had a significantly greater group mean area density of smooth muscle compared with those of nonresponders, a direct relationship between prostate smooth muscle area density and change in symptom scores was not observed. These observations suggest that nonprostate smooth muscle–mediated α_1 receptor events may also be responsible for the effectiveness of α-adrenergic blockade and that α_1 receptor–mediated symptom improvement and decreases in BOO are mediated by different mechanisms.

Classification of α-Adrenergic Blockers

α-Adrenergic blockers may be classified according to α receptor selectivity and serum elimination half-life (Table 92–1)

Phenoxybenzamine, a nonselective α blocker, was shown to be highly effective for BPH (Caine et al, 1976, 1978). The limitation of phenoxybenzamine was the high incidence and severity of adverse clinical events. Berthelsen and Pettinger (1977) described two subtypes of the α receptor (α_1 and α_2). Prazosin was one of the first α_1 receptor antagonists to be investigated for the treatment of BPH (Hedlund et al, 1983). **The efficacy of phenoxybenzamine and prazosin are comparable; however, prazosin is better tolerated, implying that efficacy and toxicity are mediated primarily by the α_1 and α_2 receptors, respectively** (Lepor, 1989). Prazosin and other α_1 antagonists, including intermediate-release (IR) alfuzosin (Jardin et al, 1991) and indoramin (Ramsay et al, 1985), require at least twice-daily dosing, owing to the relatively short serum elimination half-lives. **The next advance in the development of α-adrenergic blockers was the development of advanced drugs with serum elimination half-lives that allowed for once-a-day dosing.** Terazosin (Hytrin) (Lepor et al, 1992) and doxazosin (Cardura) (Gillenwater et al, 1995), tamsulosin (Flomax) (Chapple et al, 1997; Narayan and Tewari, 1998; Wilt et al, 2002b), and extended-release alfuzosin (UroXatral) (McNeill et al, 2005; van Kerrebroeck et al, 2000) are long-acting α-adrenergic blockers that have been shown to be safe and effective for the treatment of BPH.

Molecular cloning studies have identified three subtypes of the α_1 receptor (Andersson et al, 1997). Price and coworkers (1993) reported that the mRNA encoding the α_{1A} receptor is predominant in the human prostate. The fact that the α_{1A} mRNA is translated does not mean the encoded protein is translated. Lepor and associates reported that using autoradiographic (Kobayashi et al, 1994) and immunohistochemical (Walden et al, 1997) techniques, the α_{1A} and α_{1B} receptors are predominant in the human stroma and epithelium, respectively. Prostate smooth muscle tension has been shown to be mediated by the α_{1A} receptor (Forray et al, 1994).

Tamsulosin is a once-daily administered α_1 antagonist that exhibits some modest degree of selectivity for the α_{1A} versus the α_{1B} receptor and no selectivity for the α_{1A} versus the α_{1D} receptor (Foglar et al, 1995). The pharmaceutical industry has developed α_1 antagonists that are 1000-fold selective for the α_{1A} receptor versus α_{1B}/α_{1D} (Forray et al, 1994). Recently, silodosin (Rapaflo) has been introduced. This agent shows 162:1 selectivity for α_{1A} versus α_{1B} adrenoceptors and is achieving promising results.

Table 92–1.

Classification of α-Adrenergic Blockers and Recommended Doses

CLASS OF α-ADRENERGIC BLOCKER	DOSE
Nonselective	
Phenoxybenzamine	10 mg bid
α_1	
Prazosin	2 mg bid
IR Alfuzosin	2.5 mg tid
Indoramin	20 mg bid
Long-Acting α_1	
Terazosin	5 or 10 mg qd
Doxazosin	4 or 8 mg qd
Alfuzosin SR	10 mg qd
Subtype Selective	
Tamsulosin	0.4 mg qd
Silodosin	8 mg qd

Interpreting the α-Adrenergic Blocker Literature

Meta-analyses derived from the α-adrenergic blocker literature are often misleading because all of the data for a given drug are combined independent of dose and study design.

Study Designs. Four study designs have been used to investigate α-adrenergic blockers for BPH: titration to fixed dose, titration to response, titration to maximal dose, and randomized dose withdrawal.

Subjects enrolled in **titration to fixed dose** studies receive one of several predetermined final doses independent of clinical response unless significant adverse effects are encountered. An advantage of this study design is that dose-dependent efficacy and safety of different doses are determined. A disadvantage is the requirement for a large sample size to identify statistically significant differences between placebo and all of the treatment groups.

Titration to response design allows the investigators to titrate the dose to a threshold response or maximal dose. An advantage of this design is a smaller sample size because all subjects receiving active treatment are analyzed as a composite group independent of final dose. A disadvantage of this design is that the maximal therapeutic effect may be underestimated if the titration is not to maximal response. The data are also misleading if expressed in terms of group mean changes according to final dose because all nonresponders are titrated to the maximal dose in the absence of toxicity.

A randomized dose withdrawal design begins with an open-label dose titration. All responders are randomized to active drug or placebo. An advantage of this design is the enrichment of responders. A disadvantage is that the results are not generalizable to untreated patients.

A titration to maximal dose design, like titration to response, requires a relatively small sample size because there is only one active treatment group. This study design defines maximal clinical response achievable in practice, providing the maximal dose is also the most efficacious tolerable dose.

Dose Response. Multicenter, randomized, placebo-controlled studies have consistently shown that symptom and flow improvement is dependent on the dose of the α_1 blockers. **The differences between the effectiveness of different doses were often not statistically significant because these dose-ranging studies were not adequately powered to show significant differences between dose groups.** MacDiarmid and coworkers (1999) have provided the most compelling evidence for a positive correlation relationship between dose and effectiveness of α_1 blockers in the treatment of BPH. Responders to 4 mg of doxazosin were randomized in a double-blind manner

Table 92–2.

Efficacy of Terazosin in Benign Prostatic Hyperplasia

STUDY	ENROLLED (No.)	RANDOMIZED TREATMENT (mo)	DOSE (mg)	Group Mean Difference from Placebo	
				PFR (mL/sec)	Symptom Score

to receive 4 mg or 8 mg of doxazosin. The improvement observed in the 8-mg group was 3.7 symptom units greater than in the 4-mg group ($P = .03$). In phase 3 trials, the impact of dose observed in the responders is diluted by the lack of effect in the nonresponders. In clinical practice, nonresponders are withdrawn from treatment.

Review of the Literature

Several reviews have summarized the extensive clinical experiences with α-adrenergic blockade in BPH (Chapple, 1998; Djavan and Marberger, 1999; Lowe, 1999; Lepor, 2000; Roehrborn et al, 2004; Kaplan, 2008). Nonselective and short-acting α_1 antagonists are used less commonly in clinical practice, owing to tolerance and the requirement for multiple daily dose. Randomized, double-blind, placebo-controlled studies have reported the safety and efficacy of phenoxybenzamine (Caine et al, 1978; Abrams et al, 1982), prazosin (Hedlund et al, 1983; Kirby et al, 1987; LeDuc et al, 1990; Ruutu et al, 1991; Chapple et al, 1992), indoramin (Iacovou and Dunn, 1987; Chow et al, 1990; Stott and Abrams, 1991), and IR alfuzosin (Ramsay et al, 1985; Carbin et al, 1991; Jardin et al, 1991; Hansen et al, 1994). With the exception of alfuzosin, these studies typically enrolled relatively small numbers of subjects into short-term single-dose studies without quantitative assessment of symptom improvement. **Multicenter, randomized, double-blind, placebo-controlled studies have examined the safety and efficacy of the long-acting α-adrenergic blockers terazosin, doxazosin, tamsulosin, and slow-release (SR) alfuzosin. Subjects enrolled in these studies generally presented with moderate to severe symptoms, PVR less than 300 mL, and no absolute indications for surgical intervention.** Representative studies are reviewed to illustrate the safety, efficacy, and most effective use of α-adrenergic blockers in BPH. The reader is referred to the original articles for more comprehensive outcome assessments.

Terazosin. Randomized, double-blind, multicenter, placebo-controlled studies have consistently demonstrated the efficacy and safety of terazosin for BPH (Di Silverio, 1992; Lepor et al, 1992; Lloyd et al, 1992; Brawer et al, 1993; Elhilali et al, 1996; Lepor et al, 1996; Roehrborn et al, 1996) (Table 92–2). **The multicenter, double-blind, parallel-group, randomized, placebo-controlled study of once-a-day administration of terazosin to patients with symptomatic BPH reported by Lepor and associates** (1992) **is representative of the expectations of terazosin therapy.** Two hundred eighty-five patients entered the double-blind treatment receiving either placebo or 2, 5, or 10 mg of terazosin once daily. Statistically significant decreases from baseline obstructive, irritative, and total symptom scores were observed for all terazosin treatment groups. The level of improvements in the symptom scores were dose dependent. The 10-mg terazosin treatment group exhibited significantly greater decreases in mean irritative and total symptom scores relative to the placebo group. The 5- and 10-mg terazosin treatment groups exhibited a significantly greater mean decrease in obstructive scores relative to the placebo group. The percentages of patients experiencing a greater than 30% improvement in the total symptom scores for the placebo, 2-, 5-, and 10-mg treatment groups were 40%, 51%, 57%, and 69%, respectively (Fig. 92–5).

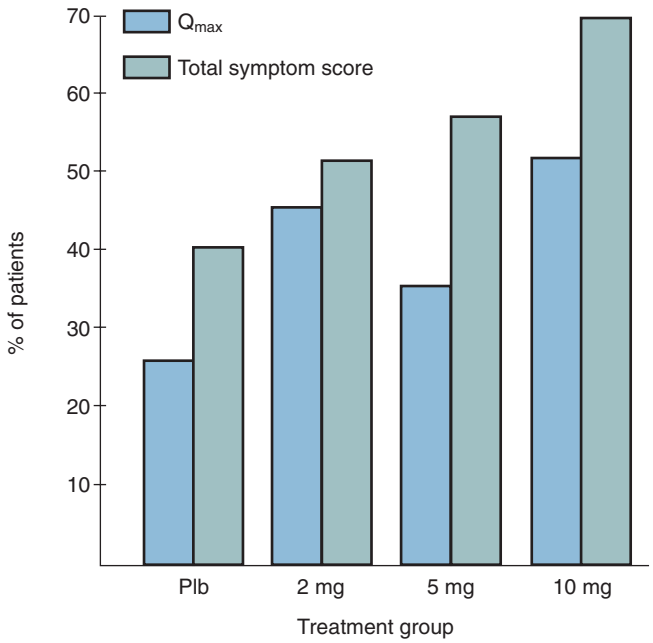

Figure 92–5. Two hundred eighty-five patients were enrolled in a randomized double-blind study comparing placebo (Plb) and 2 mg, 5 mg, and 10 mg terazosin administered once daily. Percentages of patients experiencing more than 30% improvement in total symptom scores and peak urinary flow rates are shown. (From Lepor H. Medical therapy for benign prostatic hyperplasia. Urology 1993;42:483–501.)

The percentage of patients experiencing greater than 30% improvement in total symptom score in the 10-mg treatment groups was significantly greater than that of the placebo group.

A statistically significant improvement from baseline was seen in the peak and mean urinary flow rates for all the treatment groups. The effect of terazosin on PFR was also dose dependent. The 10-mg treatment group exhibited a significantly greater increase from baseline in peak and mean urinary flow rates relative to the placebo group. The percentages of patients experiencing a greater than 30% increase in PFR in the placebo, 2-, 5-, and 10-mg treatment groups were 26%, 40%, 35%, and 52%, respectively. A significantly greater proportion of patients in the 10-mg terazosin treatment group exhibited a greater than 30% improvement in PFR compared with the placebo group. **Overall, the adverse events in the four treatment groups were minor and reversible.** Although a higher incidence of asthenia, flu syndrome, and dizziness were observed in the terazosin treatment groups, the differences from placebo were not statistically significant. There was a significantly greater incidence of postural hypotension in the 5-mg terazosin group than in the placebo group. The incidence of syncope for all terazosin-treated patients was less than 0.5%.

The relationships between percentage change in total symptom score and PFR versus baseline age, prostate size, PFR, PVR, and total symptom score were examined to identify clinical or urodynamic factors that predicted response to terazosin therapy. **No significant association was observed between treatment effect and any of these baseline factors.**

There is legitimate concern whether the results of multicenter studies conducted primarily at tertiary medical centers is generalizable to community practice. Roehrborn and coworkers (1996) **reported the results of the Hytrin Community Assessment Trial (HYCAT), which enrolled 2084 men into a 1-year randomized double-blind study comparing the safety and effectiveness of terazosin versus placebo.** The overwhelming majority of the subjects were enrolled by urologists in community practice. The daily dose of terazosin was titrated up to 10 mg based on the discretion of the principal investigators. The symptom scores in the placebo and terazosin group throughout the study are shown in (Fig. 92–6). The treatment-related improvement (terazosin minus placebo) in the AUASI score and in urinary PFR was 1.4 mL/sec and 3.9 symptom units, respectively. The treatment-related incidences of dizziness, asthenia, and peripheral edema were 5.9%, 4.6%, and 3.1%, respectively.

Lepor (1995) **presented an interim report of 494 patients entered into an open-label extension study demonstrating the durable clinical response of terazosin.** Durations of follow-up ranged from 3 to 42 months. The percentage of patients on final terazosin doses of 1, 2, 5, 10, and 20 mg were 7%, 12%, 26%, 34%, and 21%, respectively. Of the 494 patients, 213 (43.1%) withdrew prematurely: 55 (11%) because of therapeutic failure, 96 (19%) because of adverse events, and 62 (13%) because of administrative reasons.

At all follow-up visits the group mean PFRs were significantly higher than baseline values (Fig. 92–7). At baseline, PFR was 10.0 mL/sec. From 3 to 42 months, improvement ranged from 2.3 to 4.0 mL/sec. Between months 3 and 42, at least a 30% improvement in PFR from baseline was observed in 40% to 59% of the patients. At all follow-up intervals, the group mean Boyarsky symptom scores were significantly lower than at baseline; this was true of obstructive, irritative, and total scores (Fig. 92–8). From 3 months onward, improvement ranged from 4.0 to 5.4 points. Between months 3 and 42, at least a 30% improvement in total symptom score from baseline was observed in 62.4% to 77.1% of the patients.

Kirby (1998b) **has examined the mean changes in blood pressure according to whether subjects were normotensive or hypertensive at baseline** (Table 92–3). In normotensive patients, small, clinically insignificant decreases in blood pressure were generally noted. Untreated hypertensive men had larger and clinically significant decreases in blood pressure. In men with medically controlled hypertension, terazosin had no clinically significant effect on blood pressure, whereas in men with poorly controlled medically treated hypertension, terazosin significantly lowered blood pressure. In all clinical circumstances, terazosin's effect on blood pressure was consistently physiologically desirable. The ability to treat two common coexisting conditions (BPH and hypertension) is a potentially desirable feature of the drug.

Doxazosin. The half-life of doxazosin is longer than that of terazosin (22 vs. 12 hours). The efficacy, safety, and durability of clinical response of doxazosin has been demonstrated in multicenter, randomized, double-blind, placebo-controlled studies (Chapple et al, 1994; Fawzy et al, 1995; Gillenwater et al, 1995) (Table 92–4) and a long-term open-label extension study (Lepor, 1995). **Fawzy and associates** (1995) **reported a 16-week multicenter, randomized, double-blind, placebo-controlled titration to response study in 100 normotensive subjects with BPH.** Of the 41 evaluable subjects receiving doxazosin, 88% underwent titration to the maximal dose (8 mg). The group mean changes in PFR and symptom score were significantly greater in the doxazosin group compared with the placebo group (see Table 92–4). The magnitudes of these treatment-related effects are similar to those of terazosin. The systolic blood pressure changes in normotensive subjects are greater than those with terazosin. The treatment-related incidences of dizziness, fatigue, headache, somnolence, hypotension, and nausea were 20%, 8%, 8%, 6%, 8%, and 8%, respectively. The percentages of subjects withdrawing because of an adverse event were 14% and 2.1% in the doxazosin and placebo groups, respectively. The treatment-related incidence of adverse clinical events in this doxazosin study appears slightly higher than that of terazosin and may be a result of its greater effect on blood pressure.

Gillenwater and coworkers (1995) **reported a multicenter, randomized, double-blind, placebo-controlled titration to fixed dose study comparing placebo versus 2, 4, 8, and 12 mg of doxazosin in 248 men with mild to moderate essential hypertension.** The group mean changes in PFR and Boyarsky symptom score are summarized in Table 92–4 according to treatment groups. Because relatively small numbers

Table 92–3.

Effect of Terazosin on Blood Pressure in Normotensive and Hypertensive Men

	Treatment-Related Changes in Systolic Blood Pressure/Diastolic Blood Pressure (mm Hg)	
	Normotensives	Hypertensives
No antihypertensive treatment	–3.1/–1.7	–13.7/–10.7
Antihypertensive treatment	–2.8/–0.2	–12.6/–11.5

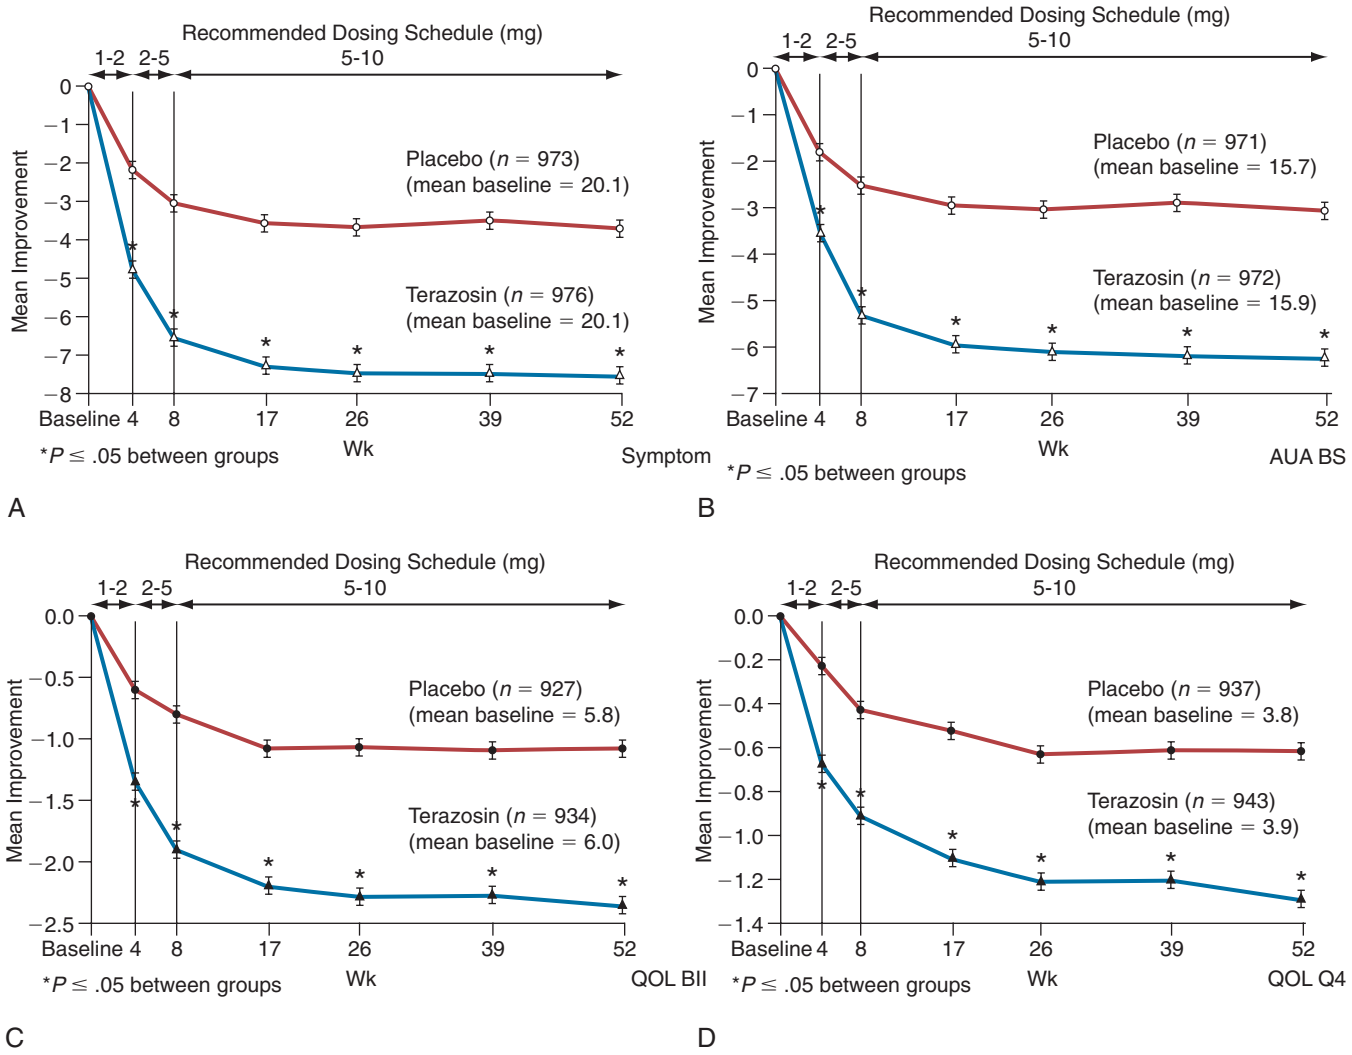

Figure 92–6. Time course of improvements in the American Urological Association (AUA) Symptom Index **(A)**, the AUA Bothersome Score (AUA BS) **(B)**, BPH Impact Index (QOL BII) **(C)**, and Quality of Life question (QOL Q4) **(D)** for placebo and terazosin treatment groups. A lowering of the score represents clinical improvement. Weeks 1 to 2 and 2 to 5 are the mandatory titration periods for 1 and 2 mg of terazosin (and placebo), respectively. (**A** to **D,** redrawn from Roehrborn CG. Effectiveness and safety of terazosin versus placebo in the treatment of men with symptomatic benign prostatic hyperplasia in the HYCAT study. Urology 1996;47:159–68.)

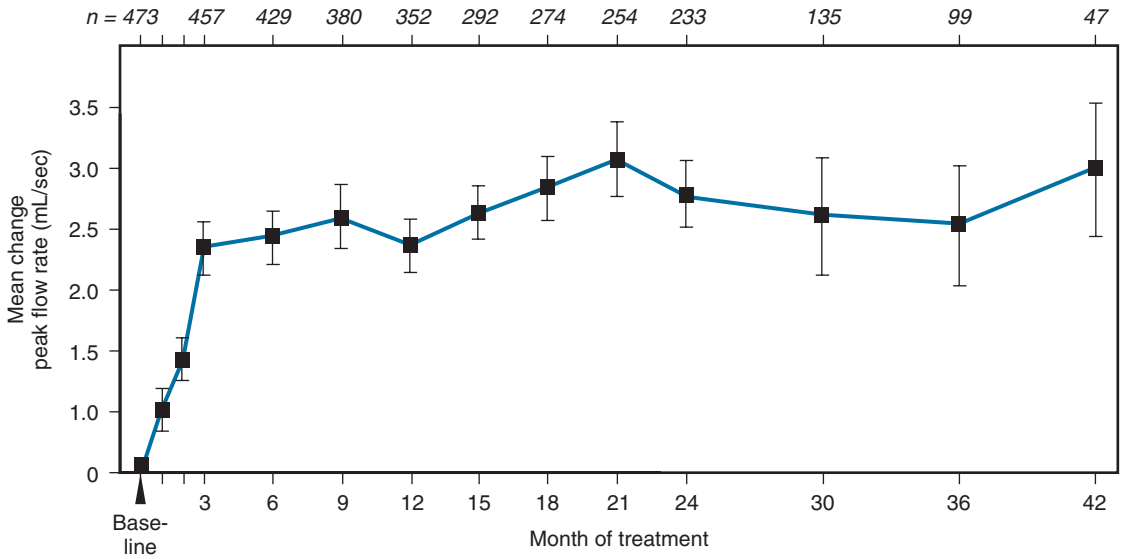

Figure 92–7. Mean change in peak flow rate between baseline and 42 months in terazosin-treated patients. The numbers across the top of the graph indicate the number of patients available at each time interval. All data points were significantly different from baseline at the $P \leq .05$ level. (From Lepor H and the Multicenter Study Group. Long-term efficacy and safety of terazosin in patients with benign prostatic hyperplasia. Urology 1995;45:406–13.)

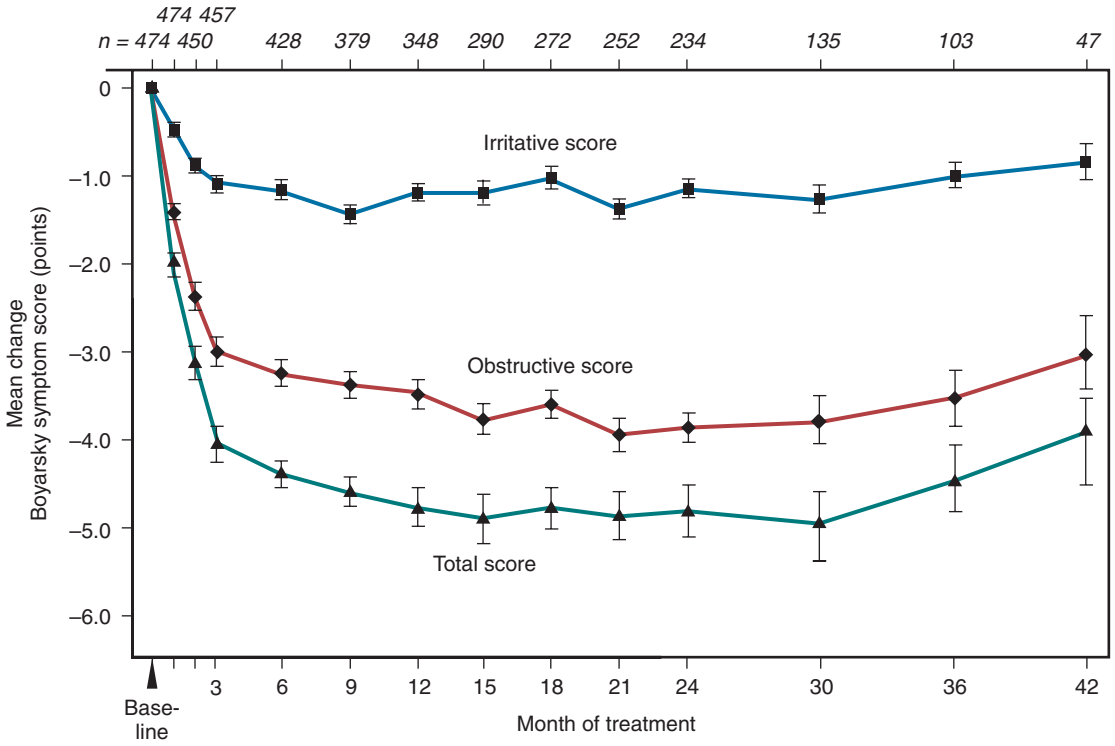

Figure 92–8. Mean change in Boyarsky symptom scores from baseline to 42 months. Baseline scores were 10.5 for total score, 6.2 for obstructive scores, and 4.3 for irritative scores. The numbers across the top of the graph indicate number of patients available at each time interval. All changes were significant at the $P \leq .05$ level. (From Lepor H and the Multicenter Study Group. Long-term efficacy and safety of terazosin in patients with benign prostatic hyperplasia. Urology 1995;45:406–13.)

of subjects were randomized into the individual treatment groups the failure to demonstrate statistical significance between placebo and some of the active treatment groups reflects the small sample size. The group mean improvement in PFR was dose dependent and statistically significant relative to placebo for all active treatment groups. The mean improvements in symptom scores relative to placebo for the group were statistically significant for the 4- and 8-mg doxazosin groups. Statistically and clinically significant changes in systolic blood pressure were observed between the placebo and the 4-, 8-, and 12-mg doxazosin groups. Lowering of blood pressure was a desirable outcome in these hypertensive patients. The overall treatment-related incidence of dizziness and fatigue was 15% and 10%, respectively. The percentages of subjects withdrawing because of an adverse event in the doxazosin versus placebo groups were 11.1% and 4.1%, respectively. Statistically significant changes in symptom scores and PFR relative to baseline have been reported in a long-term open-label doxazosin extension study (Lepor, 1995). The initial improvements in symptom scores and PFR in 450 subjects were maintained for up to 42 months. Kirby (1995) summarized the effects of doxazosin on blood pressure in normotensive and hypertensive men enrolled into two double-blind, placebo-controlled trials (Fawzy et al, 1995; Gillenwater et al, 1995). The treatment-related group mean reductions in sitting systolic blood pressure in the normotensive and hypertensive subjects were 3 and 17 mm Hg, respectively. The treatment-related group mean reductions in sitting diastolic blood pressure

in the normotensive and hypertensive subjects were 4 and 3 mm Hg, respectively.

With the standard preparation of doxazosin, multiple titration steps are used to obtain optimal therapeutic response. Often doxazosin standard is started at 1 mg/day and titrated through 2 and 4 mg/day to 8 mg/day to obtain the optimal response. The controlled release gastrointestinal therapeutic system (GITS) formulation of doxazosin reduces the plasma peak-to-trough ratio to minimize the need for titration. To compare the two formulations in 795 men with BPH, doxazosin standard was initiated at 1 mg/day, titrated to 2 mg/day after 1 week to 4 mg/day at 3 weeks and 8 mg/day at 7 weeks if indicated. This regimen was compared with doxazosin GITS initiated at 4 mg once daily and titrated to 8 mg once daily after 7 weeks if indicated and to a placebo group over 13 weeks. The symptoms of BPH were measured with the IPSS, which has seven questions (covering frequency, nocturia, weak urinary stream, hesitancy, intermittence, incomplete emptying, and urgency) scored 0 (absent) to 5 (severe). On the IPSS there was an improvement of –8.4 and –8.0 with doxazosin standard and GITS, respectively, compared with –6.0 in the placebo group. Doxazosin standard and GITS produced clinically comparable increases in mean PFR, compared with placebo, with a greater improvement observed earlier following treatment with doxazosin GITS than with doxazosin standard. A similar number of patients in both doxazosin groups was titrated to the maximum dose of 8 mg for both formulations. The incidence of adverse effects was slightly higher with doxazosin standard than doxazosin GITS and placebo, which caused a similar incidence.

The previous study and another with 680 men were combined to further analyze the comparison between doxazosin standard and GITS (Kirby et al, 2003). In addition to confirming the results given earlier, in a subgroup reporting sexual dysfunction at baseline there was a modest clinical improvement in sexual function with both preparations of doxazosin.. Treatment-related adverse events occurred in 16.1% of patients on doxazosin GITS, 25.3% of patients on doxazosin standard, and 7.7% of placebo patients. Headache and dizziness occurred in 6.0% and 5.3% of doxazosin GITS patients, compared with 5.1% and 9.1% of doxazosin standard patients, respectively (placebo, 4.5% and 1.9%, respectively). Fewer patients on doxazosin GITS (5.7%) or placebo (2.6%) discontinued treatment because of adverse events than on doxazosin standard (7.2%). The reduction in blood pressure was not clinically significant in the normotensive patients, but there were clinically significant reductions in blood pressure with both preparations of doxazosin (placebo, 3.9/5.0; doxazosin standard, 7.4/6.1; doxazosin GITS, 9.4/6.8). A comparison of the nonconcurrent multicenter, randomized, double-blind, placebo-controlled studies of terazosin (see Table 92–2) and doxazosin (see Table 92–4) shows similar efficacy. Studies of doxazosin versus tamsulosin (Kirby et al, 2003) and doxazosin versus alfuzosin (de Reijke and Klarskov, 2004) revealed only minor differences in safety and efficacy.

α-Adrenergic blockers such as doxazosin may influence smooth muscle growth in the prostate. In BPH patients treated with α_1-adrenoceptor antagonists there is a decreased expression of myosin heavy chain messenger RNA, a functional marker for the smooth muscle phenotype (Lin et al, 2001).

Biopsy and prostatectomy specimens from untreated and doxazosin-treated BPH patients suggest that doxazosin may induce apoptosis in both the epithelial and stromal cells with little effect on cell proliferation. The apoptosis was associated with a decrease in smooth muscle α-actin expression and stromal regression. Another study showed that the mean pretreatment baseline apoptosis was 1.9% and 1.0% for the epithelial and stromal prostate components. The mean apoptotic indexes increased after 3 months of doxazosin treatment for BPH to 6% in the glandular epithelial and 12% in the smooth muscle cells. By 12 months after treatment, epithelial apoptosis had decreased to constitutive levels while the apoptotic index of prostatic stromal cells remained high (Kyprianou et al, 1998).

In primary cultures of human prostate stroma cells, doxazosin increased apoptosis and decreased cell numbers. Transforming growth factor (TGF)-β_1 also decreased cell numbers, and because doxazosin increased the levels of TGF-β_1 in the cells it was suggested that the effect of doxazosin may be mediated through TGF-β_1 (Ilio et al, 2001).

The ability of doxazosin to induce apoptosis may be shared with the other quinazoline-based α_1-adrenergic receptor antagonists terazosin and prazosin, although it seems unlikely that this effect is α_1-adrenergic receptor mediated (Gonzalez-Juanatey et al, 2003). The apoptotic effects of the quinazoline-based α_1 antagonists may be linked to their ability to inhibit HERG potassium channels, which has been demonstrated using cloned channels expressed in *Xenopus* oocytes (Thomas et al, 2004).

Recent data also suggest that doxazosin may have a mildly beneficial impact on sexual function in men suffering from BPH (Kirby et al, 2005). The mechanism for this effect is uncertain but may be the result of a vasodilatory action within the corpora cavernosa.

Tamsulosin. **Tamsulosin is currently the most widely employed α_1 antagonist investigated for BPH** (Foglar et al, 1995). One of the features of tamsulosin is that it exhibits some degree of specificity for the α_{1A}-adrenergic receptor (Foglar et al, 1995). The efficacy and safety of tamsulosin has been investigated in four multicenter, randomized, double-blind, placebo-controlled studies (Kawabe et al, 1990; Abrams et al, 1995, Lepor et al, 1998; Narayan and Tewari, 1998) (Table 92–5).

Lepor and coworkers (1998) reported a multicenter, randomized, double-blind, placebo-controlled study of 756 American men with clinical BPH randomized to receive placebo or 0.4 or 0.8 mg of tamsulosin for 13 weeks. The mean changes in AUASI score, PFR, and adverse events are summarized in Table 92–5. The symptom score improvements were significantly greater in the 0.8-mg tamsulosin group compared with the 0.4-mg group. The treatment-related incidences of dizziness, asthenia, rhinitis, and abnormal ejaculation in the 4-mg group were 5%, 3%, 3%, and 6%, respectively, and in the 0.8-mg group they were 6%, 3%, 9%, and 18%, respectively. The mean changes in systolic and diastolic blood pressure in the placebo and tamsulosin groups were not significantly different for both hypertensive and normotensive subjects. In the subjects who were hypertensive and those whose blood pressure was uncontrolled, the systolic blood pressure changes in the placebo, 0.4-mg, and 0.8-mg groups were –8.4, –7.2, and –10.2 mm Hg, respectively. The advantage of not lowering blood pressure in men who are hypertensive at baseline is controversial.

Of the 618 subjects who completed the 13-week randomized study reported by Lepor and coworkers (1998), 418 (68%) continued into the 40-week extension study on the same double-blind medication and dose. **The symptom and flow rate improvements observed at the end of the 13-week study were maintained throughout the 40-week extension study.**

Narayan and associates (1998) **reported the results of a randomized, double-blind, placebo-controlled trial comparing the safety and effectiveness of 0.4 and 0.8 mg of tamsulosin versus placebo.** Seven hundred thirty-five men were randomized in the study. The active treatment was 13 weeks.

The treatment-related improvements in the AUASI score and PFR were comparable with those reported by Lepor and coworkers (1998). The differences between 0.4 mg and 0.8 mg were not statistically significant; however, the study lacked statistical power to show clinically significant differences between the active treatment groups. The treatment-related incidences of asthenia, dizziness, rhinitis, and abnormal ejaculation observed for the 0.4-mg tamsulosin group were 2%, 5%, 3%, and 11%, respectively; and for the 0.8-mg tamsulosin group they were 3%, 8%, 9%, and 18%, respectively. The incidences of retrograde ejaculation and rhinitis were significantly greater in the 0.8-mg group compared with the 0.4-mg group. No statistically or clinically significant differences were observed for systolic blood pressure between any of the treatment groups.

A systematic review of tamsulosin therapy for BPH has been published (Wilt et al, 2002b). This included 14 studies with a total of 4122 patients. The mean change in symptom score was 12% for the 0.4-mg dosage and 16% with the 0.8-mg dosage. Improvements in flow rate were 1.1 mL/sec for both dosages. Adverse events were generally mild and included dizziness, rhinitis, and abnormal ejaculation. These increased in a dose-dependent manner with discontinuations due to such effects similar to placebo at 0.2 mg but increasing to 16% with the 0.8-mg/day dosage.

Alfuzosin. **Jardin and colleagues** (1991) **reported the first large-scale, multicenter, randomized, placebo-controlled trial demonstrating that alfuzosin was safe and effective for the treatment of BPH** (Table 92–6). A long-term open-label extension study showed that the effectiveness of alfuzosin was durable up to 30 months (Jardin et al, 1994). The primary limitation of alfuzosin was a requirement for multiple daily doses (2.5 mg three times a day or 5 mg twice a day). In the absence of any demonstrable advantage over the once-a-day drugs like terazosin, doxazosin, and tamsulosin there was no compelling reason to prescribe alfuzosin.

Extended-release or slow-release (SR) alfuzosin is a new formulation that allows for a once-daily dosing regimen without dose titration. Buzelin and coworkers (1997b) reported the first randomized, multicenter, placebo-controlled trial evaluating the safety and effectiveness of SR alfuzosin for the treatment of BPH. Three hundred and ninety subjects were randomized to once-daily 5 mg alfuzosin versus placebo for 12 weeks. The treatment-related improvements in the IPSS and PFR were –1.6 symptom unit and 1.3 mL/sec, respectively. The incidence of dropouts because of adverse events was 4.6% and 7.1% in the SR alfuzosin and placebo groups, respectively. The 2-mm Hg change in systolic and diastolic blood pressure was not significantly different from that in the placebo group. The incidences of dizziness and asthenia were similar in the SR alfuzosin and placebo groups.

SR alfuzosin (10 mg once a day) has been compared with IR alfuzosin (2.5 mg three times daily) and placebo (van Kerrebroeck et al, 2000). After a 1-month placebo lead-in, 447 patients were randomly assigned in equal proportions to the three

treatment groups for 3 months. The improvement in the IPSS was 6.9, 6.4, and 4.9 in the alfuzosin 10-mg/day, alfuzosin 2.5-mg three times a day, and placebo groups, respectively. The symptom improvement observed in both active treatment groups was significantly greater than that in the placebo group. The improvements in the filling and voiding subscores and quality of life index were also significantly greater in the active treatment group relative to the placebo group. The improvement in the PFR was 2.3 mL/sec, 3.2 mL/sec, and 1.4 mL/sec in the SR alfuzosin, IR alfuzosin, and placebo groups, respectively. The modest improvements in the PFR were significantly greater in both active treatment groups compared with placebo. The incidences of dizziness were 2.1%, 4.7%, and 1.3%; and those for asthenia were 3.5%, 0.7%, and 2.6% in the SR alfuzosin, IR alfuzosin, and placebo groups, respectively. No sexual dysfunction was reported in the 10-mg/day alfuzosin group. There were no statistically or clinically significant treatment-related effects on blood pressure in normotensive or hypertensive subjects. Of those men who were hypertensive at baseline, the mean reductions in the standing blood pressure were 8.1, 8.6, and 5.8 mm Hg, respectively, in the SR alfuzosin, IR alfuzosin, and placebo groups.

Alfuzosin has been shown to have a beneficial effect on the quality of life of men suffering from BPH. In the ALFUS study (Roehrborn et al, 2001) the quality of life index improved by 18% in both active groups compared with 8% in the placebo study arm ($P = .002$). In an open extension of the ALFORTI trial there was a 35% improvement from baseline of quality of life (van Kerrebroeck et al, 2002). Some part of this effect may be the result of a mildly beneficial impact on sexual function (van Moorselaar et al, 2005).

Because of the lack of adverse effects and blood pressure changes, alfuzosin has been described as a uroselective drug (Kirby, 1998a). SR alfuzosin exhibits no pharmacologic uroselectivity for any of the α_1 subtypes (Andersson et al, 1997). In-vivo studies in the conscious rat have shown that alfuzosin reduces urethral pressure without significantly altering blood pressure (Martin et al, 1995). This experimental observation does not prove clinical uroselectivity because terazosin and doxazosin do not alter blood pressure in normotensive subjects. Another explanation for the lack of adverse events has been the low penetration of alfuzosin into the brain (Rouquier et al, 1994). It is also important to consider that the better tolerance may simply be related to a lower level of α_1 blockade because the treatment-related improvement of the 10 mg of alfuzosin appears to be less than that achieved with 10 mg of terazosin and 8 mg of doxazosin.

The long-term effectiveness of IR alfuzosin 2.5 mg three times a day is supported by an open-label prospective 3-year trial involving 3228 men with clinical BPH (Lukacs et al, 2000). **The improvements in symptom score in BPH-specific health-related quality of life index observed at the 3-month visit were maintained throughout the 36 months of follow-up.** A total of 20.1% of the men withdrew from the study. Only 4.2% of the men discontinued therapy because of an adverse event. The other reasons for withdrawal were death, 7.6%; loss of follow-up, 1.7%; lack of efficacy, 1.8%; study withdrawal owing to personal reasons, 0.8%; concomitant disease, 0.7%; and other reasons, 3.3%. Only 0.3% of men experienced AUR.

Silodosin. In Japan, silodosin, a selective α_1-adrenergic receptor antagonist, is the BPH market leader and received U.S. Food and Drug Administration (FDA) approval in October 2008 (Watson Pharmaceuticals, Inc). In two phase 3 studies, 8 mg once-daily silodosin taken for 12 weeks resulted in significant and rapid improvement of the IPSS compared with placebo. Silodosin was shown to increase urine flow in 2 to 6 hours after the initial dose. Improvement of symptoms was realized in 3 to 4 days, with the majority of patients, including men on concomitant cardiovascular medications, achieving at least a 3-point improvement in IPSS score, regardless of age or severity of symptoms. It was associated with a low incidence of orthostatic hypotension and syncope, fainting, and dizziness. As the newest agent available silodosin has had to satisfy more rigorous cardiovascular requirements by the FDA than other, older agents. Silodosin demonstrated minimal effects on the cardiovascular system, without any meaningful prolongation of the QT interval. The most common drug-related side effect was retrograde ejaculation (better described as anejaculation). Rates of discontinuing therapy due to retrograde ejaculation were low. The second most commonly reported adverse event was dizziness, the rate of which being only slightly higher than in placebo-treated patients. There were no reported events of symptomatic orthostatic hypotension or dizziness when administered with a single dose of medications for erectile dysfunction (ED) in healthy male subjects.

A randomized, double-blind, placebo-controlled study comparing silodosin to tamsulosin or placebo study was conducted at 88 centers in Japan (Kawabe et al, 2006). Men aged 50 years or older with an IPSS of 8 or higher, a quality of life score of 3 or more, a PFR of less than 15 mL/sec, a prostate volume of 20 mL or more, and a PVR urine volume of less than 100 mL were eligible for enrollment. Patients were randomized to receive silodosin 4 mg twice daily, tamsulosin 0.2 mg once daily (i.e., a lower dose than used in the United States or Europe), or placebo, for 12 weeks: 457 men were randomized (silodosin, 176; tamsulosin, 192; and placebo, 89). The change in the total IPSS from baseline in the silodosin, tamsulosin, and placebo groups was –8.3, –6.8, and –5.3, respectively. There was a significant decrease in the IPSS versus placebo in the silodosin group from 1 week. In the early-stage comparison, silodosin showed a significant decrease in IPSS versus tamsulosin at 2 weeks. The change in quality of life score from baseline was –1.7, –1.4, and –1.1 in the silodosin, tamsulosin, and placebo groups, respectively. Silodosin showed a significant improvement in quality of life score versus placebo. In the subgroup of patients with severe symptoms (IPSS ≥ 20) silodosin also gave a significantly better improvement than placebo (–12.4 vs. –8.7). The incidence rates of adverse events and drug-related adverse events were, respectively, 88.6%, 82.3%, and 71.6% and 69.7%, 47.4%, and 36.4%, respectively. The most common adverse event in the silodosin group was abnormal ejaculation, which occurred more often in the silodosin than in the tamsulosin group (22.3% vs. 1.6%). However, only 5 men (2.9%) discontinued treatment for abnormal ejaculation. It is unclear how men in other populations will respond to this effect. Measurement by Noguchi and colleagues (2008) of intraurethral pressure in the prostatic urethra and intraluminal pressure in the vas deferens in anesthetized male dogs given the α_1-adrenergic receptor agonist phenylephrine and then a series of α_1-adrenergic receptor antagonists showed that silodosin had the highest selectivity for the vas deferens (7.5-fold), followed by naftopidil (4.3-fold), alfuzosin (3.8-fold), tamsulosin (2.6-fold), and prazosin (2.5-fold). These results suggest that high tissue selectivity for the vas deferens over the urethra may contribute to the incidence of abnormal ejaculation. These results (and U.S. data presented at the AUA meeting in 2009) do, however, suggest that silodosin is clinically useful for treating LUTS associated with BPH.

Naftopidil. Naftopidil, a relative selective α_{1D}-adrenergic receptor antagonist, seems more effective for patients showing a dominant expression of the α_{1D}-adrenergic receptor subtype. The α_1

adrenergic receptor antagonists tamsulosin and naftopidil were administered to 96 patients with BPH for 8 weeks in a crossover study. With the administration of both drugs, the IPSS significantly decreased and the maximum urinary flow significantly increased. Whereas naftopidil monotherapy decreased the IPSS for storage symptoms, tamsulosin monotherapy decreased the IPSS for voiding symptoms (Ikemoto et al, 2003). It remains to be seen how clinically important this new agent will turn out to be.

Effects of α-Adrenergic Blockers on Bladder Outlet Obstruction

The primary objective of medical therapy is to improve urinary symptoms. The relevance of urodynamic studies for assessing the clinical use of medical therapy for BPH is controversial. A drug that improves urodynamic parameters of BOO without relieving LUTS would be of limited clinical utility. Conversely, a drug that relieves LUTS without improving urodynamic parameters of BOO would be of great clinical importance. There are relatively few randomized, placebo-controlled studies examining the effects of α-adrenergic blockers on pressure-flow parameters. One of the limitations to designing these urodynamic studies is the definition of a clinically significant outcome.

Martorana and colleagues (1997) reported a randomized, double-blind, placebo-controlled study examining the effect of 1 month of alfuzosin, 2.5 mg three times a day, on pressure-flow urodynamic parameters. The changes in Pdet at maximum flow, detrusor opening pressure, and maximum Pdet were significantly greater in the alfuzosin-treatment group compared with the placebo group. There were no significant differences between the effects of alfuzosin and those of placebo on PFR.

α-Adrenergic Blockers and Sexual Function and Sexual Side Effects

Sexual function is complex and includes multiple domains such as sexual desire (libido), erectile function, and ejaculatory function. Erectile and ejaculatory functions are frequently reduced in patients with LUTS/BPH and can impact on their quality of life. Therefore the treatment of BPH should aim to maintain or even restore sexual function. α_1-Adrenergic receptor antagonists lack major effects on sexual desire in placebo-controlled studies (van Dijk et al, 2006). Reports on erectile function are inconsistent, with both beneficial and adverse effects being reported, but ED can occur in some patients without clear differences between drugs. Ejaculatory dysfunction during treatment may represent (relative) anejaculation. It occurs more frequently with tamsulosin and even more so for silodosin than with other drugs of this class.

α-Adrenergic Blockers in the Elderly

The adverse events associated with α-adrenergic blockers that may be particularly problematic in the elderly are dizziness and orthostatic hypertension. Kaplan and colleagues (1997) reviewed a personal series of 36 men with BPH older than age 80 years treated with terazosin or doxazosin. α-Adrenergic blockers were well tolerated, and no serious adverse events were observed. This experience was not of adequate size to address the incidence of falls. Pooled analysis of multicenter, randomized, placebo-controlled studies of terazosin (Zhang and Manski, 1998), doxazosin (Kaplan and D'Alisera, 1998), and tamsulosin (Chapple et al, 1997) have reported that the incidences of adverse events are not age dependent. It is important to emphasize that men enrolled into these studies were highly selected and so the tolerability and safety findings are not generalizable to all elderly men.

Data from population studies such as the 5872 participants in the Osteoporotic Fractures in Men study and a population-based case-control study using data from a managed care organization in southern California with more than 3 million members suggest that **moderate and severe LUTS independently increase the 1-year risk of falls, particularly recurrent falls, in community-dwelling older men** (Parsons et al, 2009) **and that there was a modest increase in risk associated with exposure to α-adrenergic blockers that requires further investigation** (Jacobsen et al, 2008).

α-Adrenergic Blocker Therapy and Coexisting Hypertension

The α-adrenergic blockers terazosin and doxazosin are established agents for the treatment of hypertension. The overwhelming clinical evidence demonstrates that terazosin and doxazosin lower blood pressure primarily in hypertensive men and that the blood pressure lowering is clinically significant (Fawzy et al, 1995; Gillenwater et al, 1995; Kirby, 1995, 1998b; Lepor et al, 1997; Lowe et al, 1999). **Approximately 30% of men treated for BPH have coexisting hypertension** (Boyle and Napalkov, 1995). It is reasonable to advocate the use of α-adrenergic blockers as the treatment of choice for men with hypertension and BPH.

An interim analysis of the Anti-Hypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) questioned the use of doxazosin in men at risk for developing congestive heart failure (ALLHAT Collaborative Research Group, 2000). In this study of 24,335 subjects with hypertension and at least one other coronary risk factor, men were randomized to chlorthalidone, doxazosin, amlodipine, or lisinopril. A significant increased risk of congestive heart failure in the doxazosin group relative to the chlorthalidone group was the basis for the decision to discontinue the doxazosin arm of the antihypertensive trial. There was no significant increase in congestive heart failure between doxazosin and the other antihypertensive agents. It is interesting that comparable levels of blood pressure reduction were achieved by both drugs. **The ALLHAT study questions the role of doxazosin as first-line therapy for the treatment of hypertension. The study does not assess the relative risks and benefits of doxazosin in men with BPH and hypertension, nor does it have any bearing on the use of doxazosin in combination with other antihypertensive agents.** Doxazosin remains an acceptable agent to treat BPH that coexists with hypertension. It should be the discretion of the physician managing the hypertension to add additional agents for treating the hypertension.

Mechanism of Adverse Events Associated with α-Adrenergic Blockade

Dizziness and asthenia are the adverse events most commonly associated with α-adrenergic blocker therapy. Elucidating the mechanism of action for these adverse events is essential for α_1 subtype drug development programs. It has been assumed that dizziness and possibly asthenia were caused by cardiovascular effects. Lepor and colleagues (2000) correlated the incidence of adverse events associated with terazosin relative to blood pressure changes. Men experiencing dizziness and asthenia did not exhibit greater changes in blood pressure while on terazosin therapy. Only postural hypotension was associated with greater changes in blood

pressure. α_1-Adrenergic-mediated dizziness and asthenia are likely due to effects at the level of the central nervous system. Therefore it cannot be assumed that developing an α-adrenergic blocker that eliminates effects on blood pressure will significantly improve the tolerability of α-adrenergic blockers.

α-Adrenergic Blockers and Intraoperative Floppy Iris Syndrome

Intraoperative floppy iris syndrome (IFIS) complicates approximately 2% of cataract surgery cases. The clinical manifestations of IFIS are poor preoperative pupil dilation, iris billowing and prolapse, and progressive intraoperative miosis. Surgical complications are increased when IFIS is not anticipated or recognized by the surgeon. Since IFIS was first described in 2005 (Chang et al, 2005), its association with the α_1-adrenergic antagonist tamsulosin has become well established. It appears that α_{1A} is the predominant receptor subtype in the iris dilator muscle as well. The persistence of IFIS long after the discontinuation of tamsulosin suggests a semipermanent muscular atrophy and loss of tone. It is not clear how long one must take tamsulosin before experiencing these chronic muscular changes. Anecdotal reports suggest that IFIS does not occur until patients have been on tamsulosin therapy for 4 to 6 months. IFIS can also occur up to several years after discontinuation of tamsulosin. IFIS has also been reported but less commonly with non–subtype-specific α_1-adrenergic antagonists, such as terazosin, doxazosin, and alfuzosin. According to an online survey, most members of the American Society of Cataract and Refractive Surgery believe that tamsulosin makes cataract surgery more difficult (95%) and increases the risks of surgery (77%).

Being able to elicit a prior history of tamsulosin use now enables cataract surgeons to anticipate IFIS and to employ alternative methods of managing the complication. Prevention of IFIS by withdrawing tamsulosin preoperatively has not shown consistent benefit. Therefore, in a patient with a known diagnosis of cataract, prescribing physicians may wish to consider involving the patient's cataract surgeon before initiating tamsulosin or α-adrenergic blocker treatment. **Patients should also be encouraged to report any prior or current history of α_1 antagonist use to their ophthalmic surgeon before undergoing any eye surgery.**

Comparison of α-Adrenergic Blockers

Because the therapeutic effect and adverse events associated with α blockers are both dose dependent, the effectiveness and tolerability of two different α blockers can be determined only in a randomized, double-blind, placebo-controlled trial. It is imperative that these studies be appropriately powered to show statistically significant effects for effectiveness and tolerability.

Buzelin and coworkers (1997a) reported a randomized, placebo-controlled study comparing α blockers (IR alfuzosin, 2.5 mg three times a day, vs. tamsulosin, 0.4 mg/day). The improvements in Boyarsky symptom score and PFR and the incidences of dizziness and asthenia were not significantly different between the two treatment groups. The effects of alfuzosin and tamsulosin on systolic and diastolic supine or standing blood pressures in the hypertensive patients were also not significantly different. This study suggests that IR alfuzosin and tamsulosin have equivalent effectiveness and tolerability. The obvious benefit of tamsulosin is that the dose does not have to be titrated.

The recommended daily doses of terazosin, doxazosin, tamsulosin, and SR alfuzosin are 10 mg, 8 mg, 0.4 mg, and 10 mg, respectively. The clinical data suggest that terazosin, 10 mg, and doxazosin, 8 mg, are more effective than tamsulosin, 0.4 mg, and alfuzosin, 10 mg (see Tables 92–2 and 92–4 to 92–6). The incidences of asthenia and dizziness appear to be higher for terazosin and doxazosin. **The apparent better tolerability of tamsulosin and SR alfuzosin may simply be because of degree of α_1 blockade and not uroselectivity.** Assessing the relative efficacy and tolerability of daily terazosin, 10 mg, or doxazosin, 8 mg, versus tamsulosin, 0.4 mg, or SR alfuzosin, 10 mg, would address this issue. In the absence of these studies, nonconcurrent studies can be compared, recognizing the potential impact of differences in study design, patient selection, recording of adverse events, and dosing.

Terazosin and doxazosin exhibit very similar pharmacologic and pharmacokinetic properties. It is therefore not surprising that the effectiveness and tolerability of these two agents are also comparable. The effectiveness of terazosin and doxazosin are both dose dependent, with the greatest recorded improvements in symptom scores observed at the 10-mg and 8-mg daily doses, respectively. These doses have both been shown to be significantly more effective than lower doses. Although the incidence of adverse events is dose dependent, the 10-mg and 8-mg doses of terazosin and doxazosin are generally well tolerated.

Terazosin is unit priced so that there is no financial disincentive to titrate up to the 10-mg dose. There is no significant cost advantage between 10 mg of terazosin and 8 mg of doxazosin. **Thus, until data from randomized, double-blind comparative trials demonstrate the contrary, 10 mg of terazosin and 8 mg of doxazosin should be considered equivalent.** Although the price of doxazosin therapy can be reduced by dividing the 8-mg tablet, this comes at the expense of significant loss of effectiveness.

Tamsulosin and SR alfuzosin have been positioned as uroselective α_1 blockers. Randomized studies have shown that 0.8 mg of tamsulosin is significantly more effective at relieving symptoms than the 0.4-mg dose (Lepor et al, 1998). No dose-ranging studies have been performed with SR alfuzosin. Unfortunately, an 0.8-mg tamsulosin dose has not been manufactured. Whereas the 0.8-mg tamsulosin dose appears to have less asthenia than terazosin and doxazosin, the incidence of dizziness is comparable and rhinitis and abnormal ejaculation are markedly greater. **The most appropriate dose of tamsulosin is 0.4 mg, owing to the cost and adverse events associated with the 0.8-mg dosage.** The advantage of 0.4 mg of tamsulosin is that this clinically effective dose can be administered without dose titration.

The major advantage of 0.4 mg of tamsulosin and SR alfuzosin is the lack of requirement for dose titration. For men presenting in urinary retention, tamsulosin and SR alfuzosin will likely decrease the time to voiding trial because of the lack of titration to an effective dose. The data suggest that tamsulosin and SR alfuzosin exhibit less effect on blood pressure in hypertensive men compared with terazosin and doxazosin.

Summary

Multicenter, randomized, double-blind, placebo-controlled studies have unequivocally demonstrated the safety and efficacy of α-adrenergic blockers for the treatment of BPH. The clinical response is rapid and dose dependent. Long-term open-label studies have demonstrated

that the clinical response is durable. The long-acting α_1 blockers are well tolerated. The blockers are safe in the elderly, diminish BOO, and reduce the risk of urinary retention. Their effect on falling needs further research. Terazosin and doxazosin significantly lower blood pressure only in hypertensive subjects, allowing treatment of coexisting BPH and hypertension. Direct comparison studies of the α-adrenergic blockers are sparse and involve small numbers of patients; therefore any claims of superiority cannot be justified.

Androgen Manipulation

Rationale

The rationale for androgen suppression is based on the observation that the embryonic development of the prostate is dependent on the androgen dihydrotestosterone (DHT) (Shapiro, 1990). Testosterone is converted to DHT by the enzyme 5α-reductase. The genetic deficiency of 5α-reductase in men results in a rudimentary prostate and in feminized external genitalia (Walsh et al, 1974). The development of BPH is also an androgen-dependent process (Coffey and Walsh, 1990). Castration and pharmacologic agents suppressing testosterone and DHT synthesis or action have been shown to reduce prostate volume in men with established BPH (McConnell, 1990). Peters and Walsh (1987) demonstrated that androgen suppression causes regression primarily of the epithelial elements of the prostate. Reducing prostate volume is thought to decrease the static component of BOO resulting from BPH. The primary limitation of the androgen suppression hypothesis is that the pathophysiology of clinical BPH and LUTS are not sufficiently dependent on prostate size.

Classification of Pharmacologic Agents

Surgical castration was reported to be an effective treatment for enlarged prostates in the 1890s (White, 1895; Cabot, 1896). Scott and Wade (1969) reported the first study investigating androgen suppression (medical castration) for BPH. Cyproterone acetate, an antiandrogen, was reported to decrease symptoms and increase PFR in the majority of treated subjects. The pharmacologic strategies of androgen suppression that have been investigated for BPH over the past 3 decades are summarized in Table 92–7.

Caveats Related to Interpreting Androgen Manipulation Studies

The efficacy of androgen suppression in BPH is presumed to be mediated by reduction of prostate volume. **Maximal reduction of prostate volume after initiation of androgen suppression is achieved within 6 months** (Peters and Walsh, 1987; Gormley et al, 1992). Therefore randomized treatment must be at least 6 months to capture maximal therapeutic effect.

Because the mechanism of action is by means of reduction of prostate volume, it is reasonable to assume that subjects with larger prostates achieve the greatest therapeutic benefit. **The majority of randomized, double-blind, placebo-controlled clinical trials evaluating androgen suppression enrolled subjects with larger prostates** (Gormley et al, 1992 [finasteride]; Eri and Tveter, 1993a [Casodex], 1993b [leuprolide]; McConnell et al, 1998 [finasteride], and Roehrborn et al, 2008b [dutasteride]). The results of studies enrolling a disproportionate number of men with large prostates may not be generalizable to the "typical" patient with clinical BPH.

Review of the Literature

Several excellent reviews of androgen suppression for BPH have been published (Vaughan and Lepor, 1996; McConnell, 1998). The overwhelming majority of drug studies evaluating androgen suppression were not randomized, enrolled small numbers of subjects, and utilized qualitative outcome measures. This section reviews only multicenter, randomized, double-blind, placebo-controlled trials. **Finasteride, a type 2 5α-reductase inhibitor, and dutasteride, a dual inhibitor of both type 1 and type 2 5α-reductase, represent the paradigm for androgen suppression and are emphasized in this section.**

Finasteride. **Finasteride is a competitive inhibitor of the enzyme 5α-reductase** (Vermeulen et al, 1989). Finasteride lowers serum and intraprostatic DHT levels. At least two isozymes (types 1 and 2) of 5α-reductase exist (Jenkins et al, 1992). Finasteride is a selective inhibitor of the type 2 isozyme. Finasteride does not reduce DHT levels to castrate levels because circulating testosterone is converted to DHT by type 1 isozymes that exist in skin and liver (Thigpen et al, 1993). **Gormley and coworkers** (1992) **reported the first multicenter, randomized, double-blind, placebo-controlled trial investigating the safety and efficacy of finasteride in 895 men with BPH.** The subjects were randomized to receive placebo or 1 or 5 mg of finasteride for 1 year. This study is often referred to as the North American Finasteride Trial.

The mean baseline prostate volumes in the placebo and 1- and 5-mg finasteride groups were 61, 61, and 59 cm^3, respectively. The primary outcome measures were group mean changes in a modified Boyarsky symptom score (maximum score, 36) and PFR (Figs. 92–9 and 92–10). The group mean changes in symptom score, PFR, and prostate volume are shown in Table 92–8. The group mean percentage changes in symptom score at 12 months in the placebo and 1- and 5-mg finasteride groups were –2%, 9%, and 21%, respectively. The mean percentage changes in PFR were 8%, 23%, and 22% in the placebo and 1- and 5-mg finasteride groups, respectively. The mean percentage changes in prostate volume were –3%, –18%, and –19% in the placebo and 1- and 5-mg finasteride groups, respectively. The difference between the mean changes in PFR and prostate volume was statistically significant for both the 1- and the 5-mg finasteride groups versus the placebo group. The difference between the mean changes in symptom scores was statistically significant only for placebo versus 5 mg of finasteride. The dose-dependent symptom response was not associated with a dose-dependent prostate volume or PFR response. The changes in prostate volume were not directly related to the magnitude of the clinical response to finasteride. These observations suggest that the efficacy of finasteride may not be mediated exclusively by reduction of prostate volume. The incidences of decreased libido, ejaculatory disorder, and impotence were significantly greater in the finasteride groups compared with the placebo group. The treatment-related incidences of decreased libido, ejaculatory disorder, and impotence in the 1- and 5-mg treatment groups were 4.7%, 2.7%, and 3.7%, respectively, and 3.4%, 2.7%, and 1.7%, respectively. The percentage of subjects withdrawing because of an adverse clinical event was equivalent in the three treatment groups. **Prostate volume regression was maximal at 6 months.** The greatest change in symptom

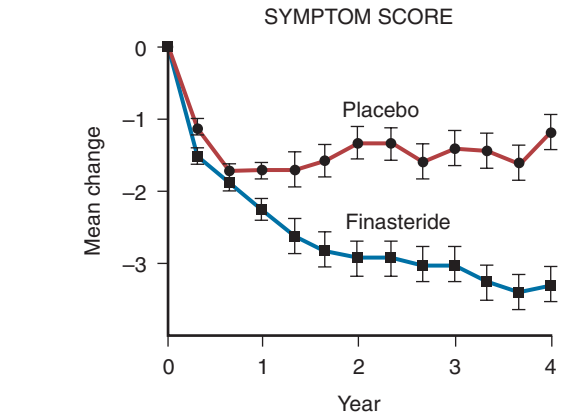
scores and PFR occurred within the first 2 months of initiating active treatment.

The Finasteride Study Group (1993) **reported another multicenter, randomized, double-blind, placebo-control led clinical trial that is referred to as the International Finasteride Study. The effect of finasteride on symptom scores, PFR, and prostate volume is in agreement with the findings of the North American Finasteride Trial.** Andersen and associates (1995) reported the results of a multicenter, randomized, double-blind, placebo-controlled study investigating the safety and efficiency of finasteride in 707 Scandinavian subjects maintained on randomized treatment for 2 years. The mean baseline prostate volumes in the placebo and finasteride groups were 41.7 and 40.6 cm^3, respectively. A selection bias for enrolling large prostates did not exist in this study. A modified Boyarsky symptom score was used to capture changes in symptom score. The differences in the group mean changes in the symptom score and PFR between finasteride and placebo after 12 and 24 months on active treatment are summarized in Table 92–8. **The difference between the group mean changes in symptom scores and PFR after 1 year of randomized treatment is slightly less than that in the North American Finasteride trial? This may be attributed to the smaller baseline prostate volumes.**

Although the proportion of subjects experiencing any adverse clinical event and the number of withdrawals from adverse clinical events were similar to those in the finasteride and placebo groups there were more patients with sexual dysfunction in the finasteride versus placebo groups (19% vs. 10%). The time-dependent symptom score changes demonstrate that the placebo response returns to baseline between 1 to 2 years whereas the finasteride response remains stable. The authors interpret this to show that finasteride halts or alters the natural history of the disease. The mean differences between the symptom scores at 12 and 24 months in the finasteride and placebo groups were only –0.3 and 0.6 symptom unit, respectively.

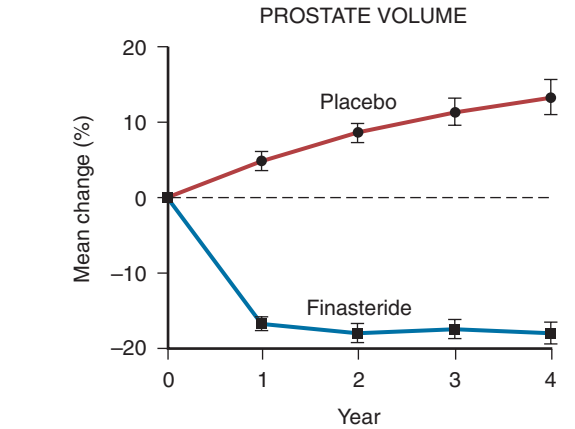
Marberger and coworkers (1998) **reported the results of a 2-year randomized, placebo-controlled trial of 3270 men receiving finasteride versus placebo that are comparable with those from the report of Andersen and associates** (1995). The mean baseline prostate volumes in the placebo and finasteride groups were 39.2 and 38.7 cm^3, respectively. The baseline prostate volume is the lowest of all the finasteride trials. The treatment-related improvements in the quasi-AUASI at 1 and 2 years were 1.0 and 1.7 symptom units, respectively. The incidences of AUR were 1.0% and 2.5% in the finasteride and placebo groups, respectively.

Stoner and associates (1994) **reported on the safety and efficacy of 3 years of therapy with finasteride.** Subjects participating in the North American Finasteride Study and International Finasteride Study were offered the opportunity to participate in an open-label extension study after completing 1 year of randomized therapy. The long-term (3 years) efficacy and safety analysis was limited to the 543 subjects randomized to 5 mg. Of the 543 subjects, 297 (55%) completed 3 years of treatment and were evaluable. Of the 246 unevaluable patients, 178 were dropouts and 68 were placed in a category indicating insufficient data. Inspection of the group mean changes in outcome measures reveals that the most precipitous changes in symptom scores, PFR, and prostate volume occurred between the 12- and the 18-month assessment, which coincides with transferring from blinded to unblinded treatment. After 18 months the time-dependent changes were stable, suggesting durability of response. A subsequent report of the open-label extension study demonstrated the durability of finasteride effective up to 5 years (Hudson et al, 1999).



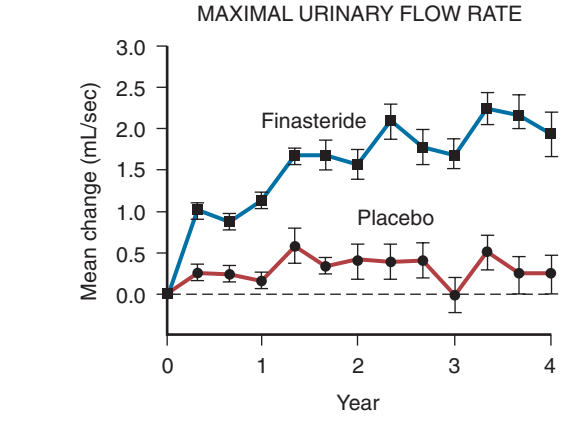
Boyle and coworkers (1996) reported a meta-analysis of six randomized, placebo-controlled clinical trials with finasteride. The mean group changes in symptom scores and PFR correlated with the mean baseline prostate volume. This observation accounts for the variability of treatment effect observed in the different studies.

The Proscar Long-Term Efficacy and Safety Study (PLESS) represented at the time the longest-duration multicenter, randomized, double-blind, placebo-con trolled study reported in the medical therapy of BPH literature (McConnell et al, 1998). The 3040 men with moderate to severe urinary symptoms were randomized to receive daily finasteride, 5 mg, versus placebo for 4 years. A quasi-AUASI was used. The baseline prostate volume in the study population was approximately 55 cm^3, indicating a bias for enrolling men with markedly enlarged prostates. The mean group changes in symptom score, PFR, and prostate volume throughout the study are shown for the finasteride and placebo in Figure 92–11. The treatment-related effects of finasteride on symptom score, PFR, and prostate volume were 2.0 symptom units, 1.7 mL/sec, and 32% size reduction for those subjects on active treatment at the end of the study. The symptom and PFR improvement was modest and consistent with findings of prior finasteride trials. The PLESS demonstrated the durability of symptom and flow improvements by finasteride and very modest progression of these end points in the placebo group.



The unique findings of the PLESS were related to incidences of both AUR and surgical intervention for BPH (Fig. 92–12). The cumulative incidences of AUR at 4 years in the finasteride and placebo groups were 7% and 3%, respectively (57% risk reduction). The cumulative risk of undergoing BPH-related surgery was 10% and 5% in the placebo and finasteride groups, respectively (55% risk reduction). In those men with prostate volumes greater than 55 cm^3, the risk reduction of AUR and/or surgical intervention for finasteride was 70%. The risk reduction of AUR and BPH-related surgery was clinically relevant, especially in men with very large prostates. Men with significantly enlarged prostates and LUTS should therefore be advised of their significant risk of urinary retention and the beneficial effects of finasteride.

The PLESS study also provided insights into the impact of finasteride on the detection of prostate cancer. The decision to pursue the diagnosis of prostate cancer in the study was left at the discretion of the principal investigator and therefore represents standard practice. **The detection of prostate cancer was not significantly different in the placebo and finasteride group, suggesting that finasteride does not mask the diagnosis of prostate cancer** (Andriole et al, 1998).



Tammela and Kontturi (1993) **reported a randomized, double-blind, placebo-controlled study examining the effects of finasteride on BOO in 36 men on a routine waiting list for prostatectomy.** The mean prostate volumes in the finasteride and placebo study groups were 50 and 48 cm^3, respectively. The mean baseline Pdet at maximum PFR in the placebo and finasteride groups were 115 and 126 cm H_2O, respectively, indicating that the subjects were severely obstructed. The group mean changes in Pdet at PFR was +3 and –39 cm H_2O in the placebo and finasteride groups, respectively. Although the difference between placebo and finasteride was highly statistically significant, the overwhelming majority of the finasteride-treated subjects remained obstructed after treatment. The marked

Figure 92–12. Probability of undergoing surgery for benign prostatic hyperplasia or the development of acute urinary retention during the 4-year study period in the placebo and finasteride groups. The figure shows life-table analyses of the proportion of men with each outcome. The numbers of events shown below the graphs are those that occurred during each 1-year interval. The numbers of men at risk are those at the beginning of the respective 1-year intervals. Data on men who died, were given a diagnosis of prostate cancer, or were lost to follow-up were censored at the time of death, diagnosis of prostate cancer, or discontinuation of therapy. (From McConnell JD, Bruskewitz R, Walsh P, et al. The effect of finasteride on the risk of acute urinary retention and the need for surgical treatment among men with benign prostatic hyperplasia. N Engl J Med 1998;338:557–63. Copyright © 1998 Massachusetts Medical Society.)

treatment-related changes in Pdet were not associated with statistically significant changes in symptom scores. The authors did not comment on whether the changes in Pdet correlated with changes in prostate volume. Of the subjects participating in the randomized, double-blind study, 27 completed a 4-year open-label extension study (Tammela and Kontturi, 1995). The Pdet at PFR showed further improvements over time.

PSA has become widely accepted as a screening instrument for prostate cancer (Tchetgen and Oesterling, 1995). An elevated or significantly rising PSA value is often an indication for prostatic biopsy. Finasteride reduces group mean serum PSA levels approximately 50% (Guess et al, 1993). The effect of finasteride on individual serum PSA levels is highly variable. **Because of the variable effect on PSA, men who are candidates for early detection of prostate cancer should have their PSA level determined before beginning finasteride therapy.** A biopsy should be performed if the PSA level is elevated. A repeat biopsy should be performed for progressively rising PSA levels after initiation of therapy.

The Prostate Cancer Prevention Trial (PCPT) (Thompson et al, 2003) showed that finasteride reduced the incidence of diagnosed prostate cancer (vs. placebo). There was an increased incidence of high-grade disease, probably owing to technical pathologic reasons.

Gross hematuria is a relatively rare, yet troublesome, manifestation of BPH. Puchner and Miller (1995) reported an uncontrolled personal experience of 18 BPH patients treated with finasteride for refractory gross hematuria secondary to BPH. In the 18 reported cases, 12 of the patients had undergone a prior prostatectomy. Finasteride was very effective in relieving the postprostatectomy-associated gross hematuria. Miller and Puchner (1998) reported a follow-up series that demonstrated the long-term effectiveness of finasteride for the treatment of hematuria from BPH. Carlin and coworkers (1997) reported resolution of gross hematuria in 12 men treated with finasteride. **These preliminary observations have been confirmed by a randomized, double-blind, placebo-controlled study by Foley and associates** (2000) **demonstrating that finasteride prevents recurrent gross hematuria secondary to BPH.** Gross refractory hematuria recurred within 1 year for 63% and 14% of men randomized to placebo and finasteride, respectively.

Dutasteride. **Dutasteride is a dual inhibitor of 5α-reductase types 1 and 2 and therefore has a greater impact on suppressing serum DHT levels** (Clark et al, 2004). In a randomized controlled trial of 4325 men (2951 completed) Roehrborn and colleagues (2002) reported that serum DHT was reduced by 90.2%. The symptom score was improved by 4.5 points (21.4%) ($P < .001$), and the maximal flow rate improved significantly by 2.2 mL/sec ($P < .001$) at 24 months. The risk reduction of AUR was 57% and the risk reduction of BPH-related surgery was 48% compared with placebo. Debruyne and coworkers (2004) reported the pooled results of a 2-year open-label extension study in which both dutasteride- and placebo-treated groups received dutasteride 0.5 mg/day. Significant improvements in symptom scores and PFRs were observed in both study groups. It was concluded that long-term treatment with dutasteride results in continuing improvements in both symptoms and PFR and that the risk reduction of AUR and BPH-related surgery was durable over 4 years. Similar to finasteride, the principal side effects were loss of libido and ED, but these were most frequently seen at the start of therapy and declined over time with treatment. Roehrborn and associates (2004) reported similar results and confirmed 93% suppression of DHT at 4 years. Recently, the results of the REDUCE study of dutasteride versus placebo in terms of their ability to prevent prostate cancer have been reported by Andriole and associates (2009). A 23% reduction in prostate cancer was seen in the dutasteride study arm, with no increase in less well-differentiated cancers in the dutasteride arm. Beneficial effects on symptoms, PFR, and risk of progression were also seen in this group of men at high risk for BPH progression as well as for a prostate cancer diagnosis. Further re-analysis has suggested some risk of high-grade cancers, and in December 2010 the FDA Oncologic Drugs Advisory Committee voted against use of dutasteride for reduction in the risk of prostate cancer. The manufacturer has withdrawn this application.

Zanoterone. **Zanoterone is a steroidal competitive androgen receptor antagonist** (Juniewicz et al, 1993). Berger and coworkers (1995) reported a multicenter, randomized, double-blind, placebo-controlled study in 463 subjects receiving placebo and 100, 200, 400, or 800 mg of zanoterone for 6 months. The group mean changes in AUASI score were not reported; however, the differences between placebo and all of the zanoterone groups were not statistically significant. The mean baseline prostate volumes ranged between 37.7 and 42.2 cm^3 in the five treatment groups. The differences between the percent group mean changes in prostate volume in the placebo (–6%) and active treatment groups (–4% to –8%) were not significantly different. Interestingly, the differences between the percent group mean changes in serum PSA in all of the active treatment groups were significantly greater than those in the placebo group, despite the lack of an apparent drug effect on prostate volume. The difference between the group mean changes in PFR for placebo and the 200-mg dose was 0.7 mL/sec. Fifty-six percent and 22% of all zanoterone subjects reported breast pain and gynecomastia, respectively. The incidence and severity of adverse clinical events and the equivocal efficacy precluded further development of this drug for BPH.

Flutamide. **Flutamide is an orally administered nonsteroidal antiandrogen that inhibits the binding of androgen to its receptor** (Sufrin and Coffey, 1973). The first reported randomized, double-blind, placebo-controlled trial in BPH examined the safety and efficacy of flutamide in 31 men with symptomatic BPH (Caine et al, 1975). Statistically significant differences were not observed between placebo and 300 mg of flutamide for symptoms, prostate size, PVR, and PFR. **Stone** (1989) **reported a multicenter, randomized, double-blind study comparing flutamide and placebo in men with BPH.** Eighty-four patients were randomized to receive 24 weeks of either flutamide, 250 mg three times a day, or placebo. Of the 84 patients, 58 (69%) and 12 (14%) were evaluable 12 and 24 weeks on double-blind treatment. The small sample size at 24 weeks precludes any meaningful conclusions. The between-group comparisons of group mean changes from baseline for placebo versus flutamide were not statistically significant at any time point. The incidences of breast tenderness and diarrhea in the flutamide group were 53% and 11%, respectively. Although the interim analysis was reported in 1989, a subsequent report of the multicenter study has not been published.

Cetrorelix. Cetrorelix is a gonadotropin-releasing hormone antagonist that has been investigated for BPH. **A potential advantage of a gonadotropin-releasing hormone antagonist over the luteinizing hormone–releasing hormone agonists in the treatment of BPH is the ability to titrate the level of androgen suppression.** This would be clinically relevant if different levels of androgen suppression mediate prostate size reduction and adverse events (hot flashes, decreased libido, ED). An open-label study of 11 men demonstrated that

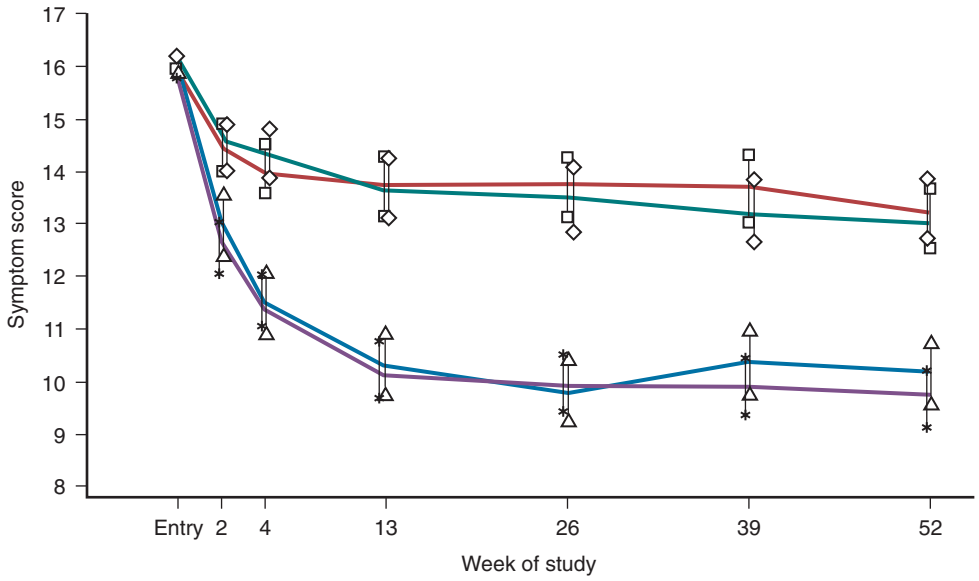
cetrorelix reduced prostate volume and improved LUTS without significant adverse events. Lepor and coworkers (1997) reported a proof of concept randomized, double-blind, placebo-controlled study of cetrorelix in men with BPH. After an 8-day placebo lead in, men received daily subcutaneous injections of placebo or 1 mg of cetrorelix (group C01) for 27 days. One group received loading doses of 10 mg of cetrorelix on the first 4 days of active treatment (group C10). Maximal lowering of testosterone was observed within 24 hours. The testosterone level was reduced to castrate levels in the C10 group and to intermediate testosterone suppression level in the non–loading-dose group (C01) (approximately 20 ng/dL). Men exhibiting a clinical effect were observed for 1 year. In the C10 and C01 groups, the treatment-related improvement in AUASI score was 3.0 and 2.0 symptom units, respectively. In both the C10 and the C01 groups the treatment-related improvement in PFR was 2.0 mL/sec. The treatment-related reductions of prostate volume were 5.5 and 3.0 cm^3, respectively. The treatment-related incidence of hot flashes and sexual dysfunction in the C01 group was negligible. During the open-label extension, prostate volume did not return to baseline, suggesting a prolonged effect on the disease. Because of problems with the drug formulation, phase 3 studies with cetrorelix were not pursued until recently (Debruyne et al, 2008).

In this dose-finding study three dosing regimens were explored: one or two injections weekly for 4 weeks. In all groups a rapid improvement in mean IPSS was obtained, with a peak effect of –5.4 to –5.9 (placebo: –2.8). Changes from baseline and differences to placebo were statistically significant up to week 20. Placebo response was less sustained than usually seen with oral preparations.

The primary disadvantage of cetrorelix and other gonadotropin-releasing hormone antagonists will be the requirement for an injection and the cost. If single-injection therapy provides desirable clinical response (over, for example, 6 months) with minimal adverse events there may exist a role for these antagonists in the treatment of BPH.

Aromatase Inhibitors. **The rationale for aromatase inhibition is that estrogens may be involved in the pathogenesis of BPH.** The estrogenic effect most likely mediates stromal-epithelial interactions that regulate the proliferative activity of the prostate. Several observations support the role of stroma in the development of BPH and the influence of estrogens on prostatic stroma. The inductive potential of prostatic mesenchyme (stroma) is supported by the observation of Cunha and colleagues (1980) in a mouse embryonic animal model. Coffey and Walsh (1990) reported that estrogen treatment of castrated beagles produced a threefold to fourfold increase in the total amount of prostatic stroma. Estrogens also greatly enhanced the ability of androgens to induce BPH in a canine model (Walsh and Wilson, 1976; DeKlerk et al, 1979). This synergistic effect may be mediated by the ability of estrogens to upregulate prostatic androgen receptor content. Stromal hyperplasia can be induced in the prostates of dogs and monkeys treated with aromatizable androgens and prevented by aromatase inhibitors such as atamestane (Habenicht et al, 1987; Habenicht and El Etreby, 1989).

Atamestane is a highly selective aromatase inhibitor that lowers both serum and intraprostatic levels of estradiol and estrone (El Etreby et al, 1991). **Gingell and coworkers** (1995) **reported a multicenter, randomized, double-blind, placebo-controlled study comparing placebo and 400 mg of atamestane** in 160 subjects with clinical BPH. Atamestane resulted in a statistically significant decrease in serum estradiol and estrone levels and a statistically significant increase in serum testosterone. No statistically significant group mean differences were observed for changes in Boyarsky symptom score, PFR, or prostate volume between the atamestane and the placebo groups. One of the explanations contributing to the failure of atamestane to achieve clinical efficacy was the increase in testosterone. The development of atamestane for BPH was suspended because of these negative clinical findings. The failure to demonstrate that atamestane causes regression of established BPH or clinical improvement does not negate the influence of estrogens in the pathogenesis of BPH.



Finasteride and dutasteride are the only drugs available that achieve androgen suppression with acceptable tolerability. Both symptoms and flow rates are improved, especially in men with larger glands. Impotence and decreased ejaculatory volume are the primary treatment-related adverse experiences. The literature also suggests finasteride and dutasteride may be offered to men with hematuria secondary to friable prostatic tissue and in those men with LUTS and enlarged prostates who elect to reduce their risk of developing urinary retention.

Summary

Finasteride represents the androgen suppression drug that has been most extensively characterized in BPH. Multicenter, randomized, double-blind, placebo-control led studies support its role in the treatment of BPH. Finasteride reduces prostate volume approximately 20%. The overall treatment-related improvements in symptom score (approximately 1.0 symptom unit) and PFR (approximately 1.5 mL/sec) relative to placebo are modest. Long-term safety and durability of efficacy has been demonstrated for finasteride. The adverse clinical events associated with finasteride are minimal and are related primarily to sexual function. Finasteride is effective in the management of gross hematuria associated with BPH, especially in the presence of friable prostate tissue. Dutasteride is an inhibitor of both type 1 and type 2 5α-reductase and has similar efficacy and side effects to finasteride. Finasteride and dutasteride alter the natural history of urinary retention in men with LUTS and enlarged prostates. In the recently reported REDUCE study, dutasteride reduced the incidence of prostate cancer by 23%. Antiandrogens have also been investigated for BPH. These studies failed to demonstrate statistically significant treatment-related efficacy. The equivocal efficacy and problematic toxicity of antiandrogens limited the enthusiasm for marketing these drugs for the treatment of BPH. The role of gonadotropin-releasing hormone antagonists requires further study.

Combination Therapy with α-Adrenergic Blockers and 5α-Reductase Inhibitors

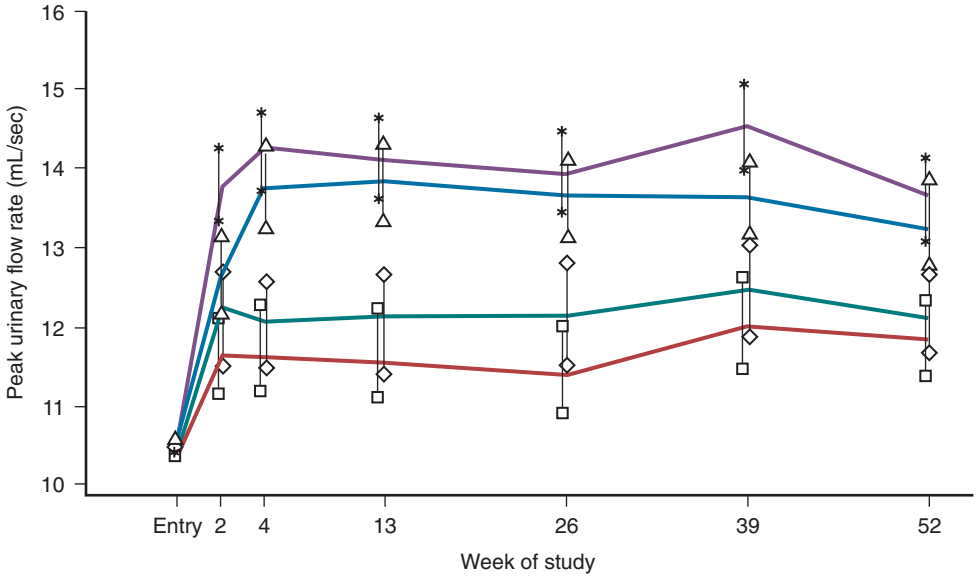
Lepor and coworkers (1996) **reported the first multicenter, randomized, double-blind trial comparing placebo, finasteride, terazosin, and combination therapy (finasteride and + terazosin) in 1229 U.S. veterans with clinical BPH.** All subjects randomized to finasteride received a daily dose of 5 mg. The dose of terazosin was titrated in all patients up to 10 mg, providing adverse clinical events were not encountered. The dose of terazosin was reduced at the discretion of the investigators to 5 mg for adverse events. Of the 1229 subjects

No. of men							
Placebo	(□)	305 297 294	290	280	263	265
Finasteride	(◇)	310 304 302	290	279	261	260
Terazosin	(△)	305 301 296	291	288	275	275
Combination	(∗)	309 305 299	292	288	280	278

Figure 92–13. AUA Symptom Index in men with benign prostatic hyperplasia, according to treatment group. Scores are expressed as adjusted means and 95% confidence intervals. The results of primary pairwise comparisons (with Bonferroni's adjustment) are as follows: finasteride and terazosin, $P < .001$; finasteride and combination therapy, $P < .001$; and terazosin and combination therapy, $P = 1.00$. The results of secondary pairwise treatment comparisons are as follows: finasteride and placebo, $P = .63$; terazosin and placebo, $P < .001$; and combination therapy and placebo, $P < .001$. (From Lepor H, Williford WO, Barry MJ, et al. The efficacy of terazosin, finasteride or both in benign prostatic hypertrophy. N Engl J Med 1996;335:533–9. Copyright © 1996 Massachusetts Medical Society.)

randomized, 1007 (81.9%) completed the 1-year randomized treatment on assigned study medication.

The AUASI score (Fig. 92–13) and PFRs (Fig. 92–14) are shown for the four treatment groups throughout the study. The group mean changes between baseline and final study visit for the relevant primary and secondary outcome measures are summarized in Table 92–9. The mean group differences between finasteride and placebo were not statistically significant for AUASI, Symptom Problem Index, and BPH Impact Index scores and PFR. The mean group differences between terazosin versus placebo and terazosin versus finasteride for all of the outcome measures other than prostate volume were highly statistically significant. The group mean differences between combination therapy and terazosin for all of the outcome measures other than prostate volume were not statistically significant, owing to the lack of treatment-related efficacy of finasteride. The Veterans Affairs study demonstrated the superiority of α-adrenergic blockade over androgen suppression for the treatment of clinical BPH over a 1-year interval. Prostate volume decreased approximately 20% in the finasteride and combination groups. The numbers of subjects withdrawing from the study because of adverse clinical events in the finasteride, terazosin, and combination groups were similar.



A multicenter, randomized, double-blind, placebo-controlled study comparing placebo, doxazosin, finasteride, and combination therapy confirmed the findings of the Veterans Affairs cooperative study (Kirby et al, 2003). In the Prospective European Doxazosin and Combination Therapy Trial (PREDICT), 1089 men were randomized in equal proportions to one of the just discussed four treatment groups for 1 year. The daily dose of doxazosin was titrated up to 8 mg. The baseline prostate volume was approximately 36 cm^3. The group mean improvement of AUASI score and PFR and change in prostate volume between baseline and final study visit are shown in Table 92–10.

A multicenter, double-blind study compared SR alfuzosin (5 mg), finasteride (5 mg), and combination therapy in 1051 men receiving active treatment for 6 months (Debruyne et al, 1998). The improvement in IPSS was not significantly different in the alfuzosin versus combination groups. At 6 months there were no significant differences between PFR among any of the treatment groups.

Medical Therapy of Prostatic Symptoms (MTOPS) Trial

The results of all three large-scale studies just described appear to suggest that the role of 5α-reductase inhibitors as generalized monotherapy for LUTS may be somewhat limited, a finding at variance with some of the original studies on finasteride. An additional, longer-term trial, which has been progressing in parallel to these studies, has generated important new information on both the clinical potential of 5α-reductase inhibitors as monotherapy and the potential of drug combinations. The MTOPS trial, a prospective, randomized, double-blind, multicenter, placebo-controlled trial, was established to determine whether medical therapy can prevent or delay the progression of BPH in the long term. Further elucidation of the natural history of BPH, determining baseline factors associated with more rapid disease progression, was a secondary aim of the study.

In 18 academic centers across the United States a total of 3047 patients were recruited and randomized to receive doxazosin, finasteride, a combination of both, or placebo. Mean age of

No. of men							
Placebo	(□)	305	296	294	290	279	258	264

participants was 62.6 years, most were white (82.6%), with 8.8% black and 7.2% Hispanic participants. The inclusion/exclusion criteria allowed men with all prostate sizes to be enrolled, as long as the serum PSA value was less than 10 ng/mL. This resulted in a wide distribution of prostate sizes and serum PSA values, allowing for stratified analyses of subsets based on these criteria (McConnell et al, 2003).

Disease progression was defined as a worsening of BPH symptoms according to the AUASI. Progression was deemed to have occurred in the case of one of the following: a 4-point rise in the AUASI score, confirmed by a second visit within 4 weeks; a 50% increase in creatinine relative to baseline levels; AUR; two or more UTIs within 1 year or a single episode of urosepsis due to BOO; and socially unacceptable incontinence. The first occurrence of any of these events indicated BPH progression. Progression as an end point represented a novel concept at the time of the initiation of the MTOPS study, although the PLESS as well as the dutasteride

studies later on utilized AUR and surgery as end points in their study designs (McConnell et al, 1998; Roehrborn et al, 2002). Entirely novel was the concept of utilizing a threshold to define symptom progression. Based on data from the Veterans Affairs cooperative study, in which men perceived general improvement in their symptom status once the AUASI score improved by more than 3 points, a threshold of 4 points was chosen—to be confirmed within 4 weeks—to indicate global subjective worsening of symptom status.

To assess the natural history of BPH, PFR, prostate volume, sexual function, and quality of life were regularly recorded with respect to BPH symptoms. Transrectal ultrasonography and DRE were used to evaluate prostate volume, the Sexual Function Inventory Questionnaire evaluated sexuality, and the Short Form-36 Health Survey instrument recorded quality of life scores. Prostatic biopsies were obtained at baseline and at 5 years (or at primary end point) in 37% of study participants who volunteered to take part in a biopsy substudy. Patients were randomized to receive 5 mg finasteride and doxazosin placebo, 5 mg finasteride and doxazosin titrated to up to 8 mg, titrated doxazosin and finasteride placebo, or two placebo drugs.

The results of the MTOPS trial suggest that the combination of doxazosin and finasteride exerts a clinically relevant, positive effect on rates of disease progression. Men who received combination therapy were significantly less likely to experience BPH progression than those receiving either monotherapy or placebo, with risk reduction rates of 39% for doxazosin, 34% for finasteride, and 67% for combination therapy compared with placebo.

Invasive therapy and AUR risk were significantly reduced by finasteride and combination therapy (by 69% and 64%, and by 79% and 67%, respectively), whereas all treatment regimens (placebo, doxazosin, finasteride, and combination) brought about a significant improvement in AUASI score (4.0, 6.0, 5.0, and 7.0, respectively) and PFR (1.4, 2.5, 2.2, and 3.7 mL/sec, respectively) at 4 years. **AUASI score and PFR improved significantly more in the combination therapy group compared with the monotherapy groups,** whereas adverse events were similar to previously reported studies.

In addition to indicating the potential benefits of combination therapy, MTOPS provided important data regarding the natural history of untreated BPH and the prediction of BPH patients who will respond most effectively to medical treatment. Although the patients receiving finasteride alone or in combination experienced the expected decrease in prostate volume, patients on placebo or doxazosin alone experienced an increase in prostate volume from a baseline of 34.0 mL by 9.3 (30.3%) (placebo) and from 36.4 mL by 9.9 (31.4%) (doxazosin), respectively. Stratified by PSA quartiles**, total prostate volume in both placebo and doxazosin-treated patients increased from 4.9 mL (24.9%) to 16.2 mL (34.5%) from the lowest to the highest quartile for an annualized growth of 1.1 to 3.6 mL/yr.** These findings suggest that doxazosin, despite its apoptotic effect (Glassman et al, 2001), does not interfere with the natural growth tendency of the prostate gland and that baseline **PSA is a useful predictor of future prostate growth in men with LUTS and BPH.**

Examination of baseline measures and the disease outcomes of 737 patients treated with placebo revealed that PSA, PFR, PVR, and prostate volume at baseline correlated with clinical progression of the disease and the need for BPH-related surgery ($P = .03$ to $< .001$). Age was linked to clinical progression ($P < .001$) and AUASI score correlated with need for surgery ($P = .002$). Baseline PSA and prostate volume correlated with risk of AUR ($P = .03$ to $.003$). Risk of progression, BPH-related surgery, and AUR increased alongside levels of serum PSA. In medically treated patients, however, baseline values were variably predictive of BPH outcome. In doxazosin-treated patients, for example, PSA, PFR, and prostate volume were predictive of outcome; however, this was not true of patients treated with finasteride alone or combined therapy.

The number needed to treat (NNT) to prevent a case of BPH progression as defined in MTOPS in the overall population was 8.4 for the combination therapy group and 13.7 and 15.0, respectively, for the doxazosin- and finasteride-treated patients. For those men treated with combination therapy who had a baseline PSA of more than 4.0 ng/mL, however, the NNT was 4.7, and for those with a prostate volume over 40 mL it was 4.9, suggesting that combination therapy becomes an economically stronger option in patients at higher risk for progression.

The link between sexual dysfunction and severity of LUTS was also confirmed by the MTOPS data. A correlation was observed between LUTS and five domains of sexual dysfunction (libido, sexual function, ejaculatory function, the patient's assessment of his sexual problems, and overall satisfaction). In addition, men with larger prostates were more likely to have low libido, low overall sexual functioning, reduced ejaculatory function, and greater sexual problems.

Another study of combination therapy in BPH employing dutasteride and tamsulosin has been reported by Barkin and colleagues (2003). Three hundred twenty-seven patients were treated with both drugs for 24 weeks and then the α-adrenergic blocker was withdrawn for a further 12 weeks; of those patients with an IPSS less than 20, 84% continued without noticeable deterioration of their symptoms. In contrast, in the 27% of patients with more severe symptoms (IPSS > 20), 42.7% reported a worsening of their symptoms compared with 14% of those who remained on combination therapy. It was concluded that a 5α-reductase inhibitor can be used in combination with an α-adrenergic blocker to achieve rapid onset of symptom relief in patients at risk of underlying disease progression and the α-adrenergic blocker can then be discontinued. In patients with severe symptoms, combination therapy should be continued for a longer term.

Combination versus Avodart or Tamsulosin (CombAT) Trial

Recently, Roehrborn and colleagues (2008b) have reported the 2-year results of the CombAT study. In these men with a pretreatment PSA between 1.5 and 10 ng/mL, combination of dutasteride and tamsulosin was more effective than either drug alone. Interestingly, in men with larger prostates, although the tamsulosin effect was rapid, over time dutasteride was the more effective agent. Superiority of combination therapy versus dutasteride was seen from month 3 and versus tamsulosin from month 9 and was maintained for the study duration ($P < .001$).

The full 4-year data will be published soon and are important because longer-term studies are clearly needed to fully evaluate the efficacy of 5α-reductase inhibitor therapy in BPH.

Anticholinergic (Antimuscarinic) Receptor Blockers

There is an overlap between symptoms traditionally regarded as being due to BPH and those ascribed to the syndrome of OAB. OAB

symptoms may coexist with BPH or BOO and may be either secondary to that obstruction or unrelated. Telephone surveys in the United States (Stewart et al, 2003) and in Europe (Milsom et al, 2001) show that 12% to 16% of the adult population admit to OAB symptoms. In Europe 60% of those with symptoms had consulted a medical practitioner about the symptoms and two thirds reported that they had an effect on daily living. Traditionally, in the treatment of OAB symptoms the use of antimuscarinic (commonly called anticholinergic) agents is often employed in women. However, in men there is always anxiety that these antimuscarinic agents decrease detrusor contractility and could, in theory, increase the risk of urinary retention, particularly in a man with significant obstruction. If not leading to AUR, then the risk of increasing PVR might lead to other complications, such as infection.

There have been small studies and anecdotal evidence showing that antimuscarinic agents can be used judiciously with efficacy and with minimal side effects. More recently, newer antimuscarinic agents have been introduced. Tolterodine studies have shown symptomatic benefit without increased AUR in men with OAB with proven BOO (Abrams et al, 2006) and suggest that antimuscarinic agents can be safely administered in men with BOO. Abrams and associates (2006) investigated a total of 222 men older than age 40 years with BOO and detrusor overactivity confirmed by pressure-flow studies who were enrolled and were randomized to tolterodine (2 mg twice daily in 149) or placebo (in 72) for 12 weeks: 87% completed the trial. Primary end points were PFR and Pdet at PFR. Median treatment differences in PFR (–0.7 mL/sec, 95% CI –1.6 to 0.4) and Pdet at PFR (–7 cm H_2O, 95% CI –3 to 11) were comparable. Tolterodine significantly reduced the BOO index versus placebo (–9 vs. 0, $P < .02$), although the urodynamic significance of these changes has been questioned. There were significant treatment differences in volume to first detrusor contraction (+59 mL, 95% CI 19 to 100) and maximum cystometric capacity (+67 mL, 95% CI 35 to 103), favoring tolterodine over placebo ($P < .003$). Change in PVR was significantly greater among patients treated with tolterodine (+25 mL) than placebo (0 mL, $P < .004$). But there were no significant between-group differences in the incidence of adverse events. Urinary retention was reported by 1 patient treated with placebo. Tolterodine did not appear to adversely affect urinary function in men with OAB and BOO. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. Tolterodine was also well tolerated. **These results suggest that antimuscarinic agents could be safely administered in men with BOO.**

Blake-James and coworkers (2007) performed a systematic review of the available literature then and, when data were sufficient, performed a meta-analysis to assess the safety and efficacy of antimuscarinic therapy in men with LUTS suggestive of BPH. They analyzed 5 randomized controlled trials and 15 observational studies of good quality (Table 92–11). Minimal changes were reported in PFR or IPSS overall, although storage symptoms scores did appear to improve in 1 trial. PVR did increase, but minimally, and there was no convincing increase in AUR rates. The authors concluded that, although antimuscarinic therapy was safe, more studies were required to define the efficacy of this therapy for men with LUTS/BPH.

Combination Therapy: α-Adrenergic Blockers and Anticholinergic (Antimuscarinic) Receptor Blockers

Response of the OAB symptoms seen in men with LUTS/BPH raises the possibility that a combination with α-adrenergic blocker therapy could both reduce the risk of retention or deteriorating

Table 92–11.

Summary of Outcomes of Randomized Controlled Trials of Antimuscarinic (Anticholinergic) Treatment

	Study				
OUTCOME	Abrams et al, 2006	Lee et al, 2005	Athanasopoulos et al, 2003	Saitoh et al, 1999	Dahm et al, 1995
No. of subjects	221	228	50	134	70

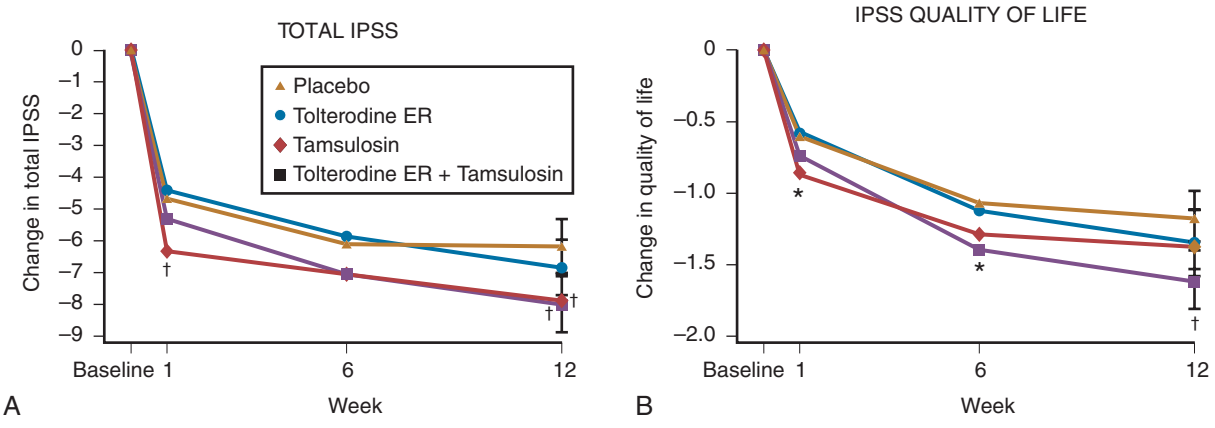
IPSS, International Prostate Symptom Score; MC, mean capacity; PFR, peak flow rate; PVR, postvoid residual volume; VFC, volume at first contraction.
Change is intervention arm versus change in control; statistical significance between groups $P < .05$; NS, not significant.
From Blake-James BT, Rashidian A, Ikeda Y, Emberton M. The role of anticholinergics in men with lower urinary tract symptoms suggestive of benign prostatic hyperplasia: a systematic review and meta-analysis. BJU Int 2007;99:85–96.



bladder function and also add to the treatment of the remaining obstructive symptoms of LUTS/BPH.

In a Korean randomized study (Lee et al, 2005), 211 men with OAB symptoms and urodynamically proven BOO were randomized (1:2) into two groups; one group was given doxazosin (4 mg once daily) only and the other was given propiverine (20 mg once daily) plus doxazosin for an 8-week trial. Significant improvements were noted in each group after treatment in urinary frequency, maximum flow rate, average micturition volume, and IPSS. Improvement in urinary frequency (23.5% vs. 14.3%, $P = .004$), average micturition volume (32.3% vs. 19.2%, $P = .004$), and storage (41.3% vs. 32.6%, $P = .029$) and urgency ($P = .019$) symptoms were more significant in group 2 given propiverine plus doxazosin. PVR urine was found to be significantly increased only in group 2, but this was not accompanied by urinary retention. Patient satisfaction rates were found to be significantly higher in group 2 than in group 1 ($P = .002$). Overall adverse event rates were higher in group 2 ($P = .002$), although discontinuation rates and discontinuation rates due to adverse events were not different between the two groups, suggesting that combination therapy consisting of α_1-adrenoceptor antagonists with antimuscarinic agents represents an effective and relatively safe treatment modality in select patients with OAB coexisting with benign prostatic obstruction.

Kaplan and coworkers (2006) in a double-blind placebo-controlled trial in 95 centers in the United States enrolled 879 men with the usual LUTS/BPH parameters often found in trials but who also had proven frequency (minimum 8 times a day) and urgency (at least three episodes per 24 hours as recorded in voiding diaries) and randomized them between tolterodine 4 mg daily, tamsulosin 0.4 mg daily, a combination of tolterodine and tamsulosin, and placebo over a 12-week period. The combination group showed a significant benefit over placebo in response to a patient-reported single-item question determining the perception of benefit (80% vs. 62%). This was the primary end point. Data supplied suggest an NNT (number needed to treat) of 5, which is reasonable. Interestingly, neither drug used alone was significantly better than placebo in terms of patient perception of benefit, although the tamsulosin study arm showed IPSS improvement (Fig. 92–15). There were only minor adverse events, which were equally distributed in the groups.

The data suggest that in this population of men with LUTS but enriched by recruiting men with OAB symptoms (24% reported episodes of incontinence at baseline, for instance) that a treatment strategy targeting both the bladder and the prostate was needed to achieve maximal benefit. They postulate that the best candidates for this form of combination therapy might be those men not immediately responding adequately to α-adrenergic blocker therapy alone.

Once again, the added expenses of combination therapy need to be considered, although the NNT rate is encouraging. **There is minimal available evidence on the long-term outcome of medical therapy of mixed OAB and BOO due to BPH. The short-term data suggest that combination of antimuscarinic and α-adrenergic blocker therapy is safe with minimal risk of retention or AUR in carefully selected men.** It would seem advisable to avoid treating men with a substantial residual urine (200 mL or more in the study), and men on this therapy who are reporting increased hesitancy or showing signs of increasing PVR or clinical evidence of retention should be warned to stop the antimuscarinic element of the combination therapy immediately. **Men with significant obstruction and large, persistent residual urine volumes should be considered for surgical therapy rather than the addition of antimuscarinic agents.**

No. of patients						
Placebo	215 208	213	213	215 210	213	213
Tolterodine ER	210 203	206	206	210 206	206	206
Tamsulosin	209 196	197	197	206 198	198	198
Tolterodine ER + Tamsulosin	217 200	203	203	217 204	205	205

Values are adjusted means (i.e., least-squares means). ER indicates extended release; IPSS, International Prostate Symptom Score.
*$P < .05$.
†$P < .01$ vs placebo.

Figure 92–15. **A** and **B,** Response of lower urinary tract symptoms to tolterodine, tamsulosin, or combination vs placebo. (From Kaplan SA, Roehrborn CG, et al. Tolterodine and tamsulosin for treatment of men with lower urinary tract symptoms and overactive bladder: a randomized controlled trial. JAMA 2006;296[19]:2319–28.)

Key Points: Antimuscarinic Therapy

- Short-term trial data suggest antimuscarinic agents can be safely given to carefully selected men with OAB/storage symptoms and BPH.
- The combination of antimuscarinic agents and α-adrenergic blocker therapy may improve both storage and voiding symptoms.
- It is advisable to avoid treating men with large PVR urine volumes (≥200 mL) with antimuscarinic agents.
- Men with significant obstruction and large persistent residual urine volumes should be considered for surgical therapy.
- Long-term data are not available.

Phosphodiesterase Inhibitors

The rationale for the use of PDEIs in the treatment of LUTS/BPH was initially based on demographic data showing the frequent occurrence of both ED and LUTS in men as they age (Table 92–12). This raised the possibility of a common underlying mechanism at least contributing to both processes. This, in turn, raised the possibility of new treatment options that might impact on both processes.

After the first clinical report in 2002 of improvement in LUTS in men given sildenafil (Viagra) for their ED (Sairam et al, 2002) there has been an explosion of interest in the role of PDEIs as treatments for LUTS and, in particular, for the management of the many men with both conditions whom we commonly see in clinics. The scientific basis is rapidly becoming stronger and **there is now good level 1 evidence from (currently) four clinical trials clearly showing improvement of LUTS after**

Table 92–12.

Summary of Epidemiologic Studies Associating LUTS with Erectile Dysfunction

STUDY	STUDY DESIGN/NAME	NO.	FINDINGS
Braun et al, 2000	Cologne Male Survey	4000	LUTS in 72.2% of patients with ED vs. 37.7% without ED; prevalence risk highly significant
Blanker et al, 2001	Krimpen Community Cohort	3924	ED RR: 1.8-7.5 for increasing urinary complaints; risk of ED greater with LUTS than with smoking or cardiac symptoms
Moreira et al, 2003	Brazilian Cohort Study	428	ED incidence RR: 3.67 if self-reported BPH—2-yr follow-up; addresses temporality of BPH → ED
Boyle et al, 2003	UrEpik Study	4800	IPSS > 7 showed odds ratio of 1.39 of having ED in a weighted multiple regression model, including age; similar odds ratios: heart attack, hypertension, and smoking
Vallancien et al, 2003	Cross-sectional European Survey	1274	55% of patients with mild LUTS had ED vs. 70% with severe LUTS; significance maintained after multiple regression analyses
Rosen et al, 2003	Multinational Survey of the Aging Male	12815	RR 3.7-7.6; IPSS correlated with IIEF, sexual activity, and ejaculatory parameters; controlled for age and comorbidities; older men still sexually active
Braun et al, 2003	Cologne Male Survey	4489	Prevalence of LUTS in men suffering from ED was about 72.2% (n = 621) vs. 37.7% (n = 1367) in men with normal erections; the odds ratio was 2.11, even after controlling for age
Chung et al, 2004	Cross-sectional Community Survey	2115	LUTS correlated with ED; sexual satisfaction and libido inversely correlated with LUTS
Ponholzer et al, 2004	Austrian Study	2858	RR for ED in men with LUTS (IPSS > 7) was 2.2; controlled for age, vascular risk factors, and predominance of obstructive or irritative symptoms
Hansen et al, 2004	Danish Study	3442	LUTS predicted ED after multiple regression; RR 2.3-3.4; overall LUTS prevalence 39% and ED prevalence 29%
Elliott et al, 2004	U.S. Veterans Affairs Survey	181	ED correlated with obstructive LUTS after controlling for age, depression, hypertension, and coronary artery disease on multivariate analysis
Terai et al, 2004	Japanese Cross-sectional Survey	2084	RR: 1.5; ED correlated with LUTS (IIEF vs. IPSS); correlation remained after controlling for age
McVary et al, 2004	MTOPS Secondary Analysis	3000	AUASI score correlated with ED and other domains; included correlation with maximum flow rate (multivariate analysis controlled for confounders)
Shiri et al, 2005	Finish Cohort Study	1126	RR of ED incidence with DAN-PSS score 7-11 was 2.7, RR was 3.1 for DAN-PSS > 12 over a 5-yr period; addresses temporality of BPH → ED
Paick et al, 2005	PLESS Study and Questionnaire	2981	2% increase in ED risk for unit increase in PLESS LUTS survey, significant after controlling for age
Brookes et al, 2008	BACH Study Subset Analysis	2301	Multivariable regression model of ED found strong association of AUASI score and ED independent of age; nocturia, incontinence, and prostatitis strongest factors; no differences found across race or ethnicity

AUASI, American Urological Association Symptom Index; BACH, Boston Area Community Health Survey; BPH, benign prostatic hyperplasia; DAN-PSS, Danish Prognostic Symptom Score; ED, erectile dysfunction; IIEF, International Index of Erectile Function; IPSS, International Prostate Symptom Score; LUTS, lower urinary tract symptoms; MTOPS, Medical Therapy of Prostatic Symptoms trial; PLESS, Proscar Long-Term Efficacy and Safety Study; RR, relative risk.

treatment with PDEIs (McVary et al, 2007a, 2007b; Roehrborn et al, 2008b; Stief et al, 2008) (Table 92–13).

However, in the studies so far available to us there are no significant changes in PFR, suggesting that the effects of PDEIs may be either more focused on bladder muscle function than on prostatic tissue or are more profound on storage symptoms than on bladder outflow obstruction itself. The relationship between the management of LUTS and ED has been well reviewed (Kohler and McVary, 2009).

ED is commonly found in the male population who are at risk for LUTS. This association is found throughout the Western world as well as in Asian studies. The pathophysiologic link between these conditions is not yet clear, but several theories have been described with various levels of supporting data (Fig. 92–16). It is likely that there is an overlap between the roles of each of these candidate mechanisms, and an ultimate effect leading to smooth muscle relaxation in prostatic, bladder neck, or erectile tissues appears to be crucial. The candidate mechanisms include the following:

1. Pelvic atherosclerosis
2. Autonomic hyperactivity
3. The calcium-independent Rho-kinase activation pathway
4. Reduced nitric oxide (NO) levels, which is probably the best explored process so far

The pelvic atherosclerosis theory suggests that just as penile ischemia leads to smooth muscle loss in the penis so smooth muscle damage in the bladder would decrease compliance and predispose to replacement of bladder smooth muscle with collagen and fibrosis. Reduced nitric oxide synthase (NOS) expression is seen with ischemia. Furthermore, conditions promoting pelvic atherosclerosis such as hypertension, smoking, hypocholesterolemia, and diabetes mellitus are implicated in both ED and LUTS.

Autonomic hyperactivity and particularly increased sympathetic tone are seen in various components of the metabolic syndrome and have been implicated in the development of LUTS (McVary, 2005).

Abnormal activation of the Rho/Rho-kinase pathway is involved in the pathogenesis of hypertension, vasospasm, and arteriosclerosis and is a potent target of new therapies for these diseases. RhoA/Rho-kinase may suppress endothelial nitric oxide synthase (eNOS). Rho-kinase appears to play a key role in the regulation of force and velocity of actomyosin cross-bridging in smooth muscle by inhibiting myosin phosphatase–mediated dephosphorylation of the regulatory chain of myosin II. This calcium-independent pathway leads to smooth muscle contraction, probably by creating mediators of α-adrenergic (norepinephrine) and endothelin-1 (ET-1) promoted smooth muscle contraction. Abnormal Rho-kinase activation or upregulation contributes to a lack of smooth muscle relaxation in the urinary tract and thus to changes in bladder compliance and to LUTS.

Nitric oxide is a nonadrenergic noncholinergic mediator of smooth muscle activity. Burnett and coworkers (1995) reported NOS activity in the prostate. Takeda and associates (1995) showed that prostate smooth muscle tension is mediated by NO.

NO activates soluble guanylate cyclase of smooth muscle, cells, which in turn increases cyclic guanosine monophosphate (cGMP) levels. That, in turn, is responsible for smooth muscle cell relaxation and penile erection, for instance. This process is most likely to involve activation of potassium channels by cGMP, leading to hyperpolarization and closure of voltage-dependent calcium channels. Intracellular levels of calcium are reduced with an effect on myosin and its detachment from actin and muscle relaxation.

Clinical investigation really began in 2000 with a study of 112 men being investigated for their response to sildenafil but whose urinary symptoms were also prospectively assessed by IPSS and measurement of PFR over a 3-month period (Sairam et al, 2002). This open-label descriptive study was the first study to measure parameters of both ED and urinary symptoms and showed an improvement in LUTS as well as ED in response to sildenafil. Similar smaller studies were followed by four randomized, placebo-controlled studies using sildenafil, tadalafil (Cialis), and vardenafil (Levitra) (McVary et al, 2007a, 2007b; Roehrborn et al, 2008b; Stief et al, 2008). These trials are summarized in Table 92–13.

The first randomized controlled trial published to elucidate the impact of PDEIs on LUTS was by McVary and coworkers (2007a). This was the first proper randomized controlled study and was a 12-week double-blind, placebo-controlled investigation performed in 41 centers in the United States between March 2004 and May 2005. Men with both ED (scoring < 25 on the International Index of Erectile Function [IIEF]) and LUTS (scoring > 12 on IPSS) with no evidence of prostate cancer were enrolled: 369 men in total were randomized between sildenafil (189 men) and placebo (180 men). They were assessed according to a range of other parameters (BPH Impact Index, quality of life score, self-esteem and relationship questionnaire, etc) and, as expected, men's ED improved. However, their IPSS and other urinary symptoms scores improved as well. IPSS improved by 6.32 points compared with 1.93 for placebo. The BPH Impact Index improved by 2 points compared with 0.9 for placebo, and the quality of life score improved by 0.97 compared with 0.29 for placebo. Interestingly, men with more severe LUTS improved more (by 8.6 compared with 2.4 in the less severely symptomatic men). **There was no significant difference in PFR, which led the authors to suggest that possibly other mechanisms were involved than simply smooth muscle relaxation in the bladder and prostate.** They pointed out that other phosphodiesterases were present in the prostate, particularly types 4 and 11, and that these may have a role to play.

In answer to questions raised about their study, more information was subsequently provided regarding baseline IPSS scores. These data showed baseline IPSS scores of 20.76 (±5.6) for those randomized to sildenafil and 20.55 (±5.5) for those randomized to placebo. The sildenafil group improved by 6.32 points compared with 1.93 for the placebo study arm. The subsequent data also indicated that the improvement in IPSS score was greater in those men whose ED also responded, that is, an IPSS improvement of 7 versus 3.2 in those whose ED did not respond ($P < .0001$).

The second randomized controlled trial (McVary et al, 2007b) investigated tadalafil. This was designed to establish a proof of principle prior to larger and more definitive trials. It was a double-blind, placebo-controlled, randomized multicenter study in 21 centers in the United States. It included first a 4-week washout phase but also a 4-week single-blinded placebo run-in period before determination of baseline values and compliance to reduce the placebo effect and the reversion to the mean phenomenon. Then followed the double-blind phase randomizing men between tadalafil and placebo. Men in this study were chosen on the basis of their urinary symptoms (men older than 45 with LUTS by IPSS of 13 and higher and a PFR of 4 to 15 mL/sec, PSA < 10, and PVR of < 200 mL). They were randomized between placebo or tadalafil at 5 mg for 6 weeks, after which the dose was escalated to 20 mg daily for a total of 12 weeks. The study ran between November 2004 and July 2005. As before, a range of parameters were measured. Of 281 men, 138 were randomized to tadalafil and 143 to placebo. There was a moderate response at 6 weeks but a greater

Table 92–13.

Clinical Trials Showing Improvement of LUTS after Treatment with PDEIs: Summary of Level 1 Evidence from Four Randomized Controlled Trials Investigating PDEIs (Sildenafil, Vardenafil, and Tadalafil)

STUDY	AGENT AND DOSE DURATION	NO. TREATED	INCLUSION	EXCLUSION	PLACEBO RUN-IN	IPSS Δ: PDEI vs. PLACEBO (*P* value)	OTHER FINDINGS
McVary et al, 2007	Sildenafil 50-100 mg/day for 12 wk	369 189	Age ≥ 45, history of ED: ≤25 IIEF (EF domain), IPSS ≥12	PCa (or suspected); urinary symptom from causes other than BPH, hypotension, retinitis pigmentosa, hepatic/liver failure, use of 5α-reductase inhibitor within 6 mo; use of α-adrenergic blocker/PDEI within last month	No	6.3 vs. 1.9 ($P < .0001$)	No change in PFR; IIEF, BII, mean IPSS QoL score, and GAQ all significantly improved
Stief et al, 2008	Vardenafil 10 mg bid for 8 wk	222 109	Age 45-64, IPSS ≥12, no history of ED required	Vardenafil contrainidications: spinal cord injury, prostatitis, history of stricture, urinary retention, bladder or prostate cancer, history of cancer with ≤3-yr life expectancy; use of nitrates, androgens, anticoagulants, ED treatments, or α-blocker use during the study	No	5.9 vs. 3.6 ($P = .0013$)	No change in Qmax or PVR; IIEF, QoL, irritative and obstructive IPSS subscores all significantly improved
McVary et al, 2007b	Tadalafil 5 mg → 20 mg/day 4-wk run-in + 12 wk (6 → 6)	281 138	Age ≥45, IPSS ≥12 from BPH for 6 mo, no history of ED required	Elevated PSA, recent 5α-reductase inhibitor use, BPH medication use during the study, history of pelvic surgery, hepatic/liver failure, causes of LUTS other than from BPH, uncontrolled diabetes, nitrate use, chemotherapy	Yes	5 mg 2.8 vs. 1.2 ($P = .003$) **20 mg 3.8 vs. 1.7 ($P < .001$)** 7.1 vs. 4.5 ($P < .001$): includes run-in	No change in PFR; IIEF, irritative and obstructive IPSS subscores, mean IPSS QoL score all significantly improved
Roehrborn et al, 2008	Tadalafil 2.5, 5, 10, 20 mg/day 4-wk run-in +12 wk	1058 ~212/group	Age ≥45, IPSS >12 from BPH for 6 mo, PFR: 4-15 mL/sec	Elevated PSA, recent 5α-reductase inhibitor use, BPH medication use during the study, history of pelvic surgery, hepatic/liver failure, causes of LUTS other than from BPH, uncontrolled diabetes, nitrate use, chemotherapy	Yes	2.5 mg 3.9 vs. 2.3 ($P < .05$) **5 mg 4.9 vs. 1.8 ($P < .05$)** 10 mg 5.2 vs. 4.5 ($P < .05$) 20 mg 5.3 vs. 4.5 ($P < .05$)	No change in Qmax; IIEF, mean IPSS QoL score, BII, LUTS GAQ all significantly improved (≥5 mg); dose > 5 mg minimal Δ improvement but ↑ side effects

difference between the 2 arms by 12 weeks. Baseline IPSS scores in the tadalafil arm improved from 17.5 to 13.3, that is, by 3.8 points, whereas the placebo arm baseline IPSS of 18.3 improved to 16.1 (or 1.7 points; $P < .001$), thus indicating a net improvement of 2.1 points for the active study arm. Whether a 2-point change is clinically significant or easily perceived by men is uncertain, but it is comparable to the response to α-adrenergic blocker treatment in the meta-analysis performed by the AUA BPH guideline update panel (American Urological Association, 2006). If the placebo run-in period is included, then the active study arm response of 7.1 points on IPSS (±0.6) is similar to that in the sildenafil study (6.32 points). More convincingly, **men in the tadalafil group were more likely to show a 3-point or greater improvement in IPSS by 12 weeks than men in the placebo group (60.9% vs. 42.7%), indicating an NNT of 5.5,** which is seen as reasonable and representing effective therapy (Bandolier, 2011).

Roehrborn and colleagues (2008a) built on this proof of principle experience with a "dose finding study" in a larger study of 1058 men, performed in 92 centers in 10 countries. Men were randomized between placebo and either a 2.5-, 5-, 10-, or 20-mg tadalafil once-daily dose. This randomized, double-blind, placebo-controlled 12-week study also included a 4-week single-blind placebo run-in period (during which period 67 men's IPSS "improved" from the "moderate/severe" range to the "mild" category) and generally similar inclusion criteria and outcome assessments, with the IPSS response to the 5-mg dose of tadalafil being the primary outcome.

Daily dosing with 5 mg of tadalafil led to a statistically significant net improvement of 2.6 points in IPSS compared with placebo (4.87 vs. 2.27), again similar to responses to α-adrenergic blockers. Most of the response was seen by 8 weeks, and there was minimal further improvement at the higher doses (Fig. 92–17). There was no significant change to PFR at any dose, nor changes to PSA or PVR.

Stief and associates (2008) investigated vardenafil in a similar fashion in a randomized, double-blind, placebo-controlled phase 2b study undertaken in 16 centers in Germany between October 2005 and June 2006. Men were randomized between vardenafil 10 mg twice daily (109 men) and placebo (113 men) and assessed at 4 and 8 weeks. This was another proof of concept study and did not include a placebo run-in period. Eventually, 105 men took vardenafil and 110 took a placebo. **Vardenafil was associated with a significant improvement in IPSS versus placebo.** IPSS score improved from 16.8 to 11 (or by approximately 5.9) on vardenafil compared with 16.8 to 13.2 (3.6) on placebo, that is, a mean difference of 2.3 points, again similar to an α-adrenergic blocker response to alfuzosin or tamsulosin. There were small but not significant improvements in PFR (15.9 mL/sec to 17.5). This was a relatively young cohort and had reasonable PFR values at baseline, so a study with older men and lower flow rates might

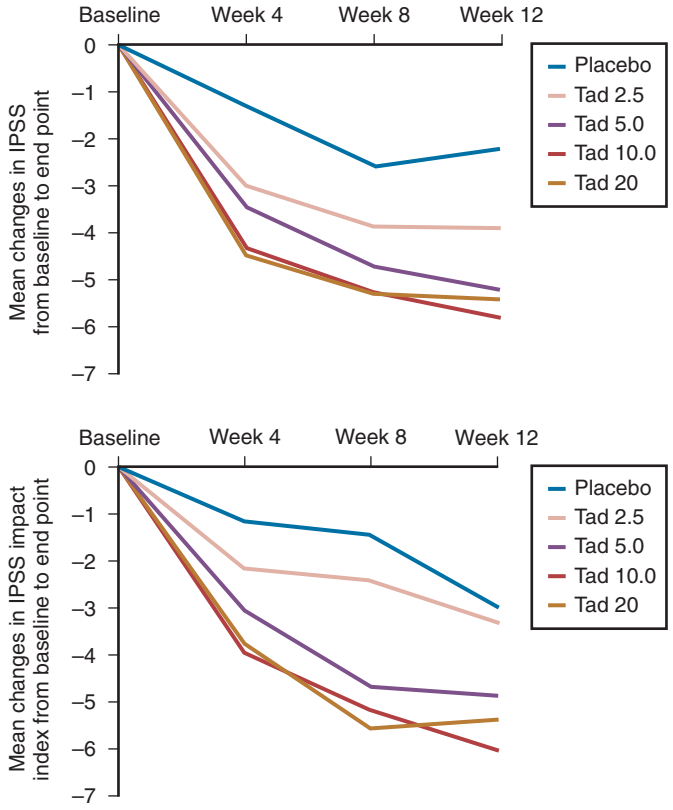

Figure 92–17. Response of lower urinary tract symptoms to tadalafil. Mean change in IPSS and BPH impact index after treatment with placebo or tadalafil (Tad) at 5, 10, and 20 mg/day. (From Roehrborn CG, McVary KT, Elion-Mboussa A, Viktrup L. Tadalafil administered once daily for lower urinary tract symptoms secondary to benign prostatic hyperplasia: a dose finding study. J Urol 2008a;180[4]:1228–34.)

more readily assess whether there is any effect of PDEIs on the flow aspects of BPH/LUTS.

Combination Therapy: α-Adrenergic Blockers and Phosphodiesterase Inhibitors

Most recently there is published evidence that PDEIs and α-adrenergic blockers in combination reduce adrenergic tone in both prostate and cavernosal smooth muscle tissue in organ bath studies (Oger et al, 2009). It is logical to consider combining PDEIs and α-adrenergic blocker medication. α-Adrenergic blockers are established treatments, and from the previous discussion it is likely that PDEIs are effective at reducing LUTS (although not by altering flow rate) and are likely to become more important options for the management of men with BPH/LUTS and ED in future.

So far evidence for combination therapy with α-adrenergic blockers and PDEIs is limited. Kaplan and coworkers (2007) in a 12-week open-label single-center pilot study randomized 62 men between 25 mg of sildenafil (21 men), 10 mg of alfuzosin (20 men), and a combination of both agents (21 men). IPSS improved by 11.8% on sildenafil (i.e., decreased from 16.9 to 14.9), by 15.6% on alfuzosin, and by 24.1% on a combination of sildenafil and alfuzosin, suggesting that there may be a synergistic benefit from the use of both agents.

Improvement in PFR was observed in all groups, but patients receiving combination therapy had greater improvement (29.6%) than patients receiving either only alfuzosin (21.7%) or only tadalafil (9.5%). IPSS was significantly improved in the alfuzosin group (27.2%) and was more marked in the combination therapy group (41.6%). There was a small nonsignificant increase in IPSS in the tadalafil-only group (8.4%).

Liguori and colleagues (2009) in a randomized, open-label, three-arm study gave 66 men complaining of ED and LUTS tadalafil or alfuzosin or tadalafil and alfuzosin and found that the IIEF sexual function scores did improve with alfuzosin alone (+15%). As expected, sexual function scores were more obviously improved with tadalafil alone (+36.3%) but the greatest improvement was experienced with combination therapy (+37.6%).

Improvement in PFR was observed in all groups, but patients receiving combination therapy had greater improvement (29.6%) than patients receiving either only alfuzosin (21.7%) or only tadalafil (9.5%). IPSS was significantly improved in the alfuzosin group (27.2%) and was more marked with the combination therapy (41.6%), and a small increase, although not statistically significant, was also observed with tadalafil (8.4%).

Finally, a new PDEI agent, udenafil (Zydena), has been administered to 120 men with BPH and ED. Men whose conditions were stable on α-adrenergic blocker therapy for their LUTS/BPH were given 100 mg of udenafil for 8 weeks. LUTS and ED improved significantly compared with baseline (IPSS improved from 14.3 to 11.5 and IIEF improved from 11.95 to 18.32). No significant change in blood pressure or heart rate was reported in this study. This is an important issue because **the concomitant use of α-adrenergic blockers and PDEIs may lead to symptomatic hypotension in some patients because both are vasodilators.**

It seems reasonable to suggest that concomitant treatment with PDEIs should only be initiated once the patient's condition has been stabilized on α-adrenergic blocker therapy**. In these patients PDEIs should be initiated at the lowest recommended starting dose. In those men already taking an optimized dose of a PDEI, α-adrenergic blocker therapy should be initiated at the lowest dose.** Any stepwise increase in α-blocker dose may be associated with further lowering of blood pressure in patients taking PDEIs.

Studies so far suggest that vardenafil may be administered at any time with tamsulosin whereas **men given vardenafil and terazosin at the same time were more prone to hypotension.** This effect was minimized by giving vardenafil and terazosin at doses separated by a time interval of 6 hours. **The coadministration of doxazosin (4 and 8 mg daily) and tadalafil (5 mg/day or 20 mg as a single dose intermittently) leads to further lowering of blood pressure, and this combination is not recommended by the manufacturers.**

Summary

PDEIs may well have a role in therapy for BPH/LUTS. There is now good level 1 evidence of a beneficial effect of PDEIs on urinary symptoms. The mechanisms of effect are still unclear but the subject of extensive research because so many other body systems are also affected. **It is likely that PDEI treatment will be of value, especially for men with LUTS and significant ED.** Because recent U.S. data indicate the proportion of men reporting moderate to severe LUTS ranges from 8% in those 30 to 39 years old to 26% in those 70 to 79 years old and the prevalence of ED is also high and increases dramatically with age with 10% of 30- to 39-year-old and 59% of 70- to 79-year-old men reporting mild to moderate or moderate to severe symptoms, this is clearly a substantial number of men who may request treatment (Brookes et al, 2008).

Further data on safety and cost-effectiveness, especially for combination therapy, will be needed. Currently, PDEIs are more expensive than α-adrenergic blockerr or 5α-reductase inhibitors, which are now off patent protection in many countries and health care systems. Studies are needed to determine if costs may be reduced by using combination therapy initially followed by later withdrawal of the more expensive agent.

Key Points: PDEIs

- There is an as yet undetermined link between LUTS/BPH and ED.
- PDEIs improve urinary symptoms scores.
- PDEIs do not improve flow rates.
- The combination of α-adrenergic blockers and PDEIs may lead to a synergistic benefit, thereby improving LUTS.
- The combination of α-adrenergic blockers and PDEIs may lead to symptomatic hypotension.
- PDEIs or a combination of α-adrenergic blockers and PDEIs may be of value in therapy for men with both ED and LUTS.

Phytotherapy

The pharmacologic use of plants and herbs (phytotherapy) for the treatment of LUTS associated with BPH is common. **Phytotherapeutic agents for LUTS/BPH have gained widespread use since about 1990** (Lowe and Fagelman, 1999). These agents are popular in Europe, particularly in France, Austria, and Germany, where they are often prescribed and their costs reimbursed (Lowe et al, 1998). Recent **European data** (Fourcade et al, 2008) **show that although α-adrenergic blocker monotherapy was the most frequently prescribed treatment (62.5% overall, 87.1% in Germany, 46.1% in France), phytotherapy was very popular (23.5%), followed by 5α-reductase inhibitor monotherapy (3.75%).** Combination therapy was rare. Treatment varied according to the severity of the symptoms ($P = .008$), with phytotherapy being given to patients with the lowest IPSS and combination therapy given to those with the highest IPSS. However, use in the United States has escalated. It has been estimated that over $1 billion was spent in the United States alone for these products (Lowe and Fagelman, 1999). These agents have been marketed to "promote prostatic health," and therefore it is not surprising that many men try them. Additional factors that contribute to their widespread use include being "natural" products (not "medications"), presumed safety, ease of accessibility (no prescription necessary), avoidance of prostate surgery, and prevention of prostate cancer (falsely assumed). The widespread availability of these products in health food stores, vitamin shops, traditional pharmacies, and supermarkets, as well as at numerous websites on the Internet, has contributed to their use and reflects the demand for these phytotherapeutic agents.

Origin of Phytotherapeutic Agents

Phytotherapeutic products are not the actual plant but are extracts derived from either the roots, the seeds, the bark, or the fruits of the various plants used (Table 92–14). Although monopreparations (single plant only) are available, many companies manufacture combination products (two or more plant extracts) in an attempt to provide "enhanced" efficacy (never proven), to improve marketability, and to provide their own "unique" product that can be registered because there is no patent protection for these products. However, to determine mechanisms of action and efficacy, only the monopreparations are evaluated and reviewed here.

Table 92–14.
Origin of Plant Extracts

SPECIES	COMMON NAME
Serenoa repens, Sabal serrulata	Saw palmetto berry/American dwarf palm
Hypoxis rooperi	South African star grass
Pygeum africanum	African plum tree
Urtica dioica	Stinging nettle
Secale cereale	Rye pollen
Cucurbita pepo	Pumpkin seed
Opuntia	Cactus flower
Pinus	Pine flower
Picea	Spruce

Components of Plant Extracts

PHYTOSTEROLS	PHYTOESTROGENS	TERPENOIDS
β-Sitosterol	Coumestrol	Lectins
Δ5-Sterol	Genistein (isoflavone)	Polysaccharides
Δ7-Sterol	Flavonoids	Aliphatic alcohols
Stigmasterol	Fatty acids	Plant oils
Campesterol	Free	
	Esterified	

Composition of the Phytotherapy Extracts

The composition of plant extracts is very complex. They contain a wide variety of chemical compounds, which include phytosterols, plant oils, fatty acids, and phytoestrogens (Table 92–15). Which of these is the exact "active" component is not definitely known. Both the free fatty acids and the sitosterols have been thought to be the active components.

Most of the plant extracts are unique. First, the plants are not identical, owing to natural variability. Second, the extraction processes used by the various manufacturers are frequently different and use various substrates for the process. Thus, even if the phytotherapeutic compounds produced by two different companies contain the same plant, the exact composition of the final products is probably different and the content of the "active" component in each preparation may also be different. For example, analysis by the National Consumer Lab of free fatty acid content in 27 different saw palmetto products showed variability from 0% to 95%, with only 17 containing more than the presumed standard amount of 85% (http://www.ConsumerLab.com, March 2000).

Mechanism of Action

The mechanisms of action of the phytotherapeutic agents are generally unknown (Lowe et al, 1998). Many in-vitro experimental studies have been undertaken to elucidate this; thus there are numerous proposed mechanisms of action (Table 92–16). Almost all these studies use supraphysiologic doses that are many times higher than the standard doses used clinically. The biologic effects are typically examined in tissue culture, which might not be an accurate reflection of in-vivo effects (Lowe and Ku, 1996). The three mechanisms of action that have received the

Table 92–16.

Suggested Mechanisms of Action of Plant Extracts

Action on α-adrenergic receptors
Free radical scavenger
Alteration of lipid peroxidation
Modulation of prolactin-induced prostatic growth
Protection of bladder and detrusor function
Placebo effect

greatest attention are anti-inflammatory effects, 5α-reductase inhibition, and growth factor alteration.

The anti-inflammatory effects are modulated by effects on prostaglandin synthesis. Plant flavonoids are inhibitors of both cyclooxygenase and lipoxygenase enzymes (Bach, 1982; Buck, 1996). Flavone, a phytoestrogen commonly found in plants and herbs, has been shown to be a strong inhibitor of cyclooxygenase (Mower et al, 1984; Alcaraz and Ferrandiz, 1987). *Serenoa repens* (Permixon) has been shown to inhibit phospholipase A_2 activity, thereby decreasing arachidonic acid metabolites and prostaglandin E_2 synthesis (Plosker and Brogden, 1996). Additionally, in two different studies, Paubert-Braquet and colleagues (1994, 1997) demonstrated inhibition of the production of lipoxygenase metabolites and leukotrienes by neutrophils by *S. repens* and *Pygeum africanum* (Tadenan).

The most widely suggested mechanism of action of *S. repens* is as a 5α-reductase inhibitor (Plosker and Brogden, 1996), thus reducing the conversion of testosterone to DHT and potentially leading to reduction of prostate volume (Gormley et al, 1992).

Although inhibition of 5α-reductase activity by *S. repens* was found in experimental models using foreskin fibroblasts (Sultan et al, 1984), transfected Sf9 insect cells (Iehle et al, 1995), DU145 cancer cell line (Delos et al, 1994), primary cultures of human BPH and adenocarcinoma epithelial and fibroblast cells (Delos et al, 1995), and cocultures of human epithelial and fibroblast cells (Scaglione et al 2008), other in-vitro and in-vivo data have not confirmed this effect (Rhodes et al, 1993; Weisser et al, 1996).

Two ex-vivo experiments have demonstrated conflicting results. Pretreatment with *S. repens* for 3 months before suprapubic prostatectomy demonstrated a decrease in prostatic DHT and an increase in prostatic testosterone concentrations compared with controls, which suggests inhibition of 5α-reductase activity (DiSilverio et al, 1998). In a similar pretreatment study using *Sabal serrulata* (IDS-89) for 3 months, prostate tissue levels of 5α-reductase, 3α-hydroxysteroid, and 3β-hydroxysteroid oxidoreductase were not different compared with placebo (Weisser et al, 1996). An in-vivo experiment of healthy male volunteers demonstrated a reduction of serum DHT levels with finasteride but not with *S. repens* (Strauch et al, 1994). Clinically, in a large multicenter trial comparing *S. repens* with finasteride, no effect on PSA levels and only 6% reduction in prostate volume were noted for *S. repens*–treated patients, whereas the finasteride-treated patients had reduction of PSA levels by 41% and prostate volume by 18% (Carraro et al, 1996).

It has been subsequently postulated that *S. repens* inhibits intracellular 5α-reductase while having little or no effect on other androgen-dependent processes (e.g., PSA production) that rely on binding of androgens to their receptor. *S. repens* causes disruption of nuclear membrane in cell culture but has no effect on the integrity of the cell membrane (Bayne et al, 1999); therefore, the intracellular theory has been promulgated. Whether this supraphysiologic cell culture experiment actually reflects what is happening in vivo is uncertain and unproved.

Plant extracts are also thought to act by altering growth factor–induced growth and proliferation. In-vitro studies with *P. africanum* demonstrated an inhibitory effect on both basic fibroblastic growth factor (bFGF)– and epidermal growth factor (EGF)–induced human and rat prostate fibroblast proliferation (Paubert-Braquet et al, 1994; Yablonsky et al, 1997). Subsequent experiments with *S. repens* have also shown inhibition of bFGF- and EGF-induced proliferation of human BPH prostate cells from biopsy specimens (Paubert-Braquet et al, 1998). Additionally, an ex-vivo experiment in men treated with *S. repens* before prostatectomy demonstrated reduced levels of tissue EGF, particularly in periurethral tissue (DiSilverio et al, 1998).

Although experimental data have suggested numerous possible mechanisms of actions for the phytotherapeutic agents it is uncertain which, if any, of these proposed mechanisms is responsible for the clinical responses.

***Serenoa Repens* (Saw Palmetto Berry).** The extract of the berry of the American saw palmetto, or dwarf palm plant, *Serenoa repens* (also known by its botanical name of *Sabal serrulatum*), is the most popular phytotherapeutic agent available for the treatment of BPH. Although numerous clinical trials with saw palmetto berry extracts have been published, many were uncontrolled open-label studies, thus providing little useful information in determining the efficacy of these phytotherapies. Even though placebo-controlled studies have been published (Table 92–17), most of them are flawed and few of them would meet the generally accepted criteria developed by the International Consultation on BPH for assessing treatment results in men with LUTS (McConnell, 1998). The studies are of limited value because of their small numbers of patients, short duration (only 1 to 3 months), and lack of use of standardized symptoms scores.

For example, nocturia was the only symptom available for analysis in all the studies reviewed in two meta-analyses (Wilt et al, 1998; Boyle et al, 2000). In the Wilt and colleagues (1998) meta-analysis of 18 trials involving 2939 patients using various *S. repens* single and combination preparations, the mean weighted difference for nocturia between patients and subjects taking a placebo was –0.76 times per evening (–1.22 to –0.32) for 10 trials. In the Boyle and coworkers (2000) meta-analysis of 13 trials involving 2859 patients using only the Permixon brand of *S. repens,* the attributable reduction of nocturnal urinations was 0.50 (±0.01) times per night. Wilt and coworkers conducted a systematic review, first published in 1998 and updated in 2002 and again in 2009, to evaluate the efficacy and adverse events of *S. repens* (Tacklind et al, 2009). Initially their analysis was mildly supportive of the efficacy of *S. repens*. In this update 9 new trials involving 2053 additional men (a 64.8% increase) were included. For the main comparison—*S. repens* versus placebo—3 trials were added with 419 subjects and three end points (IPSS, peak urine flow, prostate size). Overall, 5222 subjects from 30 randomized trials lasting from 4 to 60 weeks were assessed. Twenty-six trials were double blinded, and treatment allocation concealment was adequate in 18 studies. With these extra data and especially the double-blind, placebo-controlled trial reported by Bent and associates (2006), they

Table 92–17.

Placebo-Controlled Trials of *Serenoa repens* (Permixon)

TRIAL	PATIENTS RANDOMIZED (N)	DURATION (mo)	SIGNIFICANT IMPROVEMENT IN SYMPTOMS VS. PLACEBO	SIGNIFICANT IMPROVEMENT IN PEAK URINARY FLOW RATE
Descotes, 1996	176	1	Yes	$P < .05$

Heterogeneity of the studies
Inclusion/exclusion criteria
Study designs
Assessments of efficacy
Variable placebo response rates
Study duration

concluded that *S. repens* was not superior to placebo in improving IPSS or PFR or for reducing prostate size. For nocturia, *S. repens* was significantly better than placebo (weighted mean difference –0.78 nocturnal visits, 95% CI –1.34 to –0.22, $P < 0.05$; 9 trials), but with the caveat of significant heterogeneity within studies. A sensitivity analysis, utilizing higher-quality, larger trials demonstrated no significant difference. *S. repens* was also not superior to finasteride or to tamsulosin. Overall, it was concluded that ***S. repens* was not more effective than placebo for treatment of urinary symptoms consistent with BPH.**

Despite inherent weaknesses in meta-analyses (Table 92–18) these analyses attempt to maximize the information available from clinical trials using *S. repens* in the treatment of symptomatic BPH/LUTS and to provide the best information available until the appropriate placebo-controlled, randomized clinical studies are conducted. However, approximately 35% of the prior meta-analyses performed are not accurately predicted by the subsequent randomized controlled trials (LeLorier et al, 1997). **Therefore, whereas the efficacy of *S. repens* has not been completely determined, current meta-analysis suggests that *S. repens* is not more effective than placebo for treatment of urinary symptoms consistent with BPH.**

***Pygeum africanum* (African Plum).** In addition to the proposed mechanisms of actions previously discussed, *P. africanum* (Tadenan) has been postulated to have additional beneficial effects on LUTS by having a protective effect on the obstructed bladder. Using a rabbit model with partial BOO, Levin and associates (1996) demonstrated that changes in bladder mass, decrease in compliance, and alterations in contractile response to various forms of stimulation could be tempered by pretreatment with *P. africanum*.

A review of the published experience with *P. africanum* identified 2262 patients treated with this extract: 1810 in open-label studies and 452 in comparative trials (Andro and Riffaud, 1995). Twelve double-blind, placebo-controlled studies were completed between 1972 and 1990. Only one study enrolled more than 100 subjects, and none was longer than 12 weeks or used standardized symptom scores. In a 2-month open-label study (Breza et al, 1998) and a 2-month comparison trial of 50 mg twice daily versus 100 mg daily (Chatelain et al, 1999) both trials demonstrated a reduction in IPSS score of approximately 40% (5.7 and 6.4 units) and an improvement in PFRs of approximately 18% (2.1 and 1.7 mL/sec) over baseline. However, without a placebo study arm, the actual magnitude of drug effect cannot be determined. Thus, without at least the data from the Tadenan-IPSS study, the efficacy of *P. africanum* cannot be determined. Additionally, there are few other significant data available with regard to any of the other *P. africanum* extracts.

Thus none of those trials meets the guidelines recommended by the International Consultation Conferences on BPH. Another meta-analysis for the Cochrane collaboration (Wilt et al, 2002a) concluded that an effect was possible but not proven. **Therefore the data concerning the efficacy of *P. africanum* are not conclusive.**

***Hypoxis rooperi* (South African Star Grass).** *Hypoxis rooperi* (Harzol) has been studied in both a 6-month double-blind, placebo-controlled trial of 200 patients (Berges et al, 1995) and, subsequently, an open-label follow-up (Berges et al, 2000). In the initial study, statistically significant improvements were documented for symptom scores (IPSS), quality of life, PFRs, and PVRs (Berges et al, 1995). The placebo group showed appropriate mild improvement in these parameters. The IPSS improved by 7.4 units for β-sitosterol patients and 2.3 units for placebo. Similarly, peak urinary flow rates improved by 5.2 mL/sec for treated patients compared with 1.1 mL/sec for placebo. **This magnitude of improvement has not been observed with any other medical therapy previously evaluated for BPH.**

During the follow-up study, patients were able to remain on or switch over to Harzol therapy. For those 38 patients who continued Harzol therapy, IPSS improvements were maintained. The 27 patients who received placebo initially and were then treated with Harzol demonstrated similar levels of improvement in IPSS scores and PFRs. Surprisingly, the 14 patients who stopped therapy still maintained similar levels of improvement over the next 12 months. This suggests that intermittent therapy could be an option.

Another product (Azuprostat) contains primarily β-sitosterols from *H. rooperi* as well as from *Pinus* (pine) and *Picea* (spruce). Although this is a combination preparation of extracts, its proposed active ingredient β-sitosterol is common to all three. This product (Azuprostat) was evaluated in a 6-month randomized,

placebo-controlled trial with 177 patients (Klippel et al, 1997). Significant improvements in IPSS scores, PFRs, and PVRs were found. IPSS scores improved by 8.2 units for treated patients and 2.8 units for placebo. PFRs improved by 8.9 mL/sec for treated patients and 4.4 mL/sec for placebo. This magnitude of improvement has not been reported for any type of medical therapy for BPH. It is hard to believe these results in which the mean post-treatment PFRs are 19.4 mL/sec, which is a normal value for younger men and not for the typical age of men in the study. If these results are reproducible, they would rival surgical intervention.

Wilt and associates (1999) also produced a meta-analysis for β-sitosterol products. It included four trials (two mentioned earlier and two earlier suboptimal ones) encompassing three different products: Harzol, Azuprostat, and WA184, all of which have different amounts of β-sitosterol. WA184 did not improve PFR (Kadow et al, 1986). Again, this meta-analysis is tempered by the same factors mentioned previously. Their conclusion was that **β-sitosterol does improve urologic symptoms and urinary flow rates, but its long-term effectiveness, safety, and ability to prevent the complications of BPH are unknown** (Wilt et al, 1999).

Other Extracts. The other extracts listed in Table 92–14—*Urtica dioica, Cucurbita pepo, Secale cereale,* and *Opuntia*—have even fewer relevant clinical studies published than the aforementioned ones. Of these extracts, *Secale cereale* (Cernilton) had two placebo-controlled trials published over a decade ago that did not have standardized scores, used different dosages of the preparation, lasted 12 and 24 weeks, and enrolled only 103 and 60 subjects (Buck et al, 1990). Wilt and associates (1999) in a systematic review and meta-analysis of Cernilton concluded that it modestly improves overall urologic symptoms including nocturia, but additional trials are needed to evaluate clinical effectiveness. More recently Zhang and coworkers (2008) have reported a randomized, double-blind, placebo-controlled clinical trial of a flaxseed lignan extract containing 33% secoisolariciresinol diglucoside (SDG). SDG was evaluated for its ability to alleviate LUTS in 87 subjects with BPH with repeated measurements conducted over a 4-month period using treatment dosages of 0 (placebo), 300, or 600 mg/day SDG. After 4 months of treatment, 78 of the 87 subjects completed the study. For the 0, 300, and 600 mg/day SDG groups, respectively, the IPSS decreased –3.67 ± 1.56, –7.33 ± 1.18, and –6.88 ± 1.43 (mean ± SE, $P = .100$, $< .001$, and $< .001$ compared with baseline), the quality of life score improved by –0.71 ± 0.23, –1.48 ± 0.24, and –1.75 ± 0.25 (mean ± SE, $P = .163$ and .012 compared with placebo and $P = .103$, $< .001$, and $< .001$ compared with baseline), and the number of subjects whose LUTS grade changed from "moderate to severe" to "mild" increased by 3, 6, and 10 ($P = .188$, .032, and .012 compared with baseline). PFR insignificantly increased 0.43 ± 1.57, 1.86 ± 1.08, and 2.7 ± 1.93 mL/sec (mean ± SE, no statistical significance reached), and postvoid urine volume decreased insignificantly by –29.4 ± 20.46, –19.2 ± 16.91, and –55.62 ± 36.45 mL (mean ± SE, no statistical significance reached). The observed decreases in IPSS and quality of life score were correlated with the concentrations of plasma total lignans. It was concluded that dietary flaxseed lignan extract appreciably improved LUTS in BPH subjects and that the therapeutic efficacy appeared comparable to that of α_1-adrenergic receptor blockers and 5α-reductase inhibitors.

Summary

Most phytotherapeutic preparations are plant extracts with different components manufactured by different extraction procedures, which prevents comparison of the preparations. Although numerous in-vitro experiments have been conducted to determine their possible mechanisms of pharmaceutical action, it is uncertain which of the actions demonstrated in vitro might be responsible for clinical responses in vivo. **Appropriate randomized placebo-controlled clinical trials monitored by an outside agency are needed to ascertain and to confirm the efficacy of these products. Phytotherapies for BPH should be scrutinized and subjected to trials just as are all regulated drugs.**

Acute Urinary Retention

Acute urinary retention is the most common urologic emergency managed by most urologists worldwide. Furthermore, it will be encountered by most physicians whatever their specialty and is commonly witnessed on surgical and elderly care wards. AUR may be "spontaneous" where it is usually associated with previous LUTS suggestive of BPH. Alternatively, it may be "precipitated" by some other factor, such as the effects of various medications, particularly anticholinergic or sympathicomimetic agents, which are commonly found in cough and cold remedies. Urinary infection, excessive fluid intake, and the consequences of surgery (postoperative pain or the effects of anesthesia or analgesia or loss of mobility) may precipitate AUR. Obviously there can be an overlap between these two rather artificial divisions and AUR in a man with symptomatic or silently progressing BPH may well be precipitated by one of these other factors.

Population-based cohort studies from the United States (Jacobsen et al, 1997; Meigs et al, 1999), from Holland (Verhamme et al, 2005), and also from the United Kingdom (Cathcart et al, 2006) defined the incidence, although it varies among populations. Verhamme and coworkers (2005), in a study based on Dutch general practitioner records covering essentially the whole male population of Holland, reported an incidence of 2.2 AUR events per thousand man-years, of which 40% were precipitated (Fig. 92–18). AUR was the first symptom of BPH in 49% of men designated as suffering from LUTS/BPH, and in this group the risk of AUR was 11 times higher (18.3 per 1000 man-years). They concluded that AUR was of low incidence in the general population but substantial in the LUTS/BPH population. Cathcart and colleagues (2006), reviewing national figures from the United Kingdom, reported 3.1 AUR episodes per 1000 man-years.

These figures are lower than the two U.S. cohort studies. Jacobsen and associates (1997) found an incidence of 6.8 events per 1000 man-years in the Olmsted County Study of Urinary Symptoms and Health Status Among Men, and the Health Professionals Follow-up Study (Meigs et al, 1999) reported a rate of 4.5 per 1000 man-years. There may be selection bias here because the prevalence of BPH/LUTS in these U.S. studies is much higher than in the European studies (33% of the Olmsted County men had an IPSS of greater than 8, 30% of the men in the Health Professionals Follow-up Study had a diagnosis of BPH/LUTS compared with just 8% in the Dutch men. **Analysis of the placebo arms of a series of large studies such as the PLESS evaluation of finasteride, MTOPS, and the CombAT study indicate that increasing age, the presence of LUTS, a low PFR, and prostatic enlargement and/or raised PSA increase the risk of AUR.**

When AUR develops, most men are catheterized for a period or taught intermittent self-catheterization. At some variable point the catheter will usually be removed and a trial without catheter performed (Emberton and Fitzpatrick, 2008). **It is reasonable to**

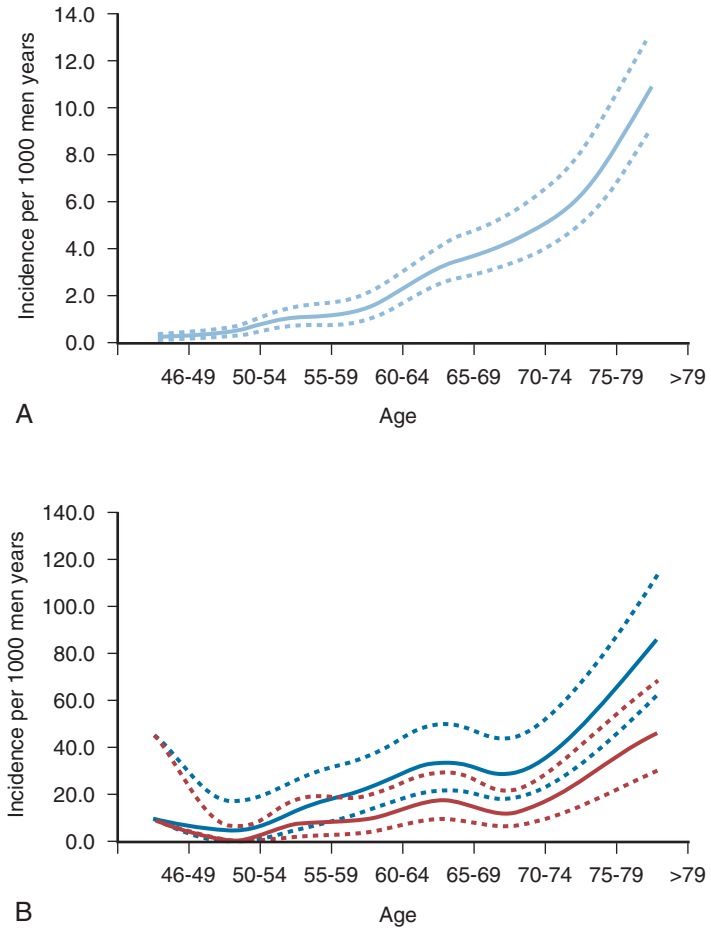

Figure 92–18. Incidence of acute urinary retention in the general population of Dutch men **(A)** and in the lower urinary tract symptom/benign prostatic hyperplasia population **(B)**. (From Verhamme KM, Dieleman JP, van Wijk MA, et al: Low incidence of acute urinary retention in the general male population: the triumph project. Eur Urol 2005;47[4]:494–8.)

speculate that urinary retention is caused in part by dynamic as opposed to static outflow obstruction because a significant proportion of men void spontaneously after catheter placement (Taube and Gajraj, 1989). If urinary retention is caused by increased sympathetic activity at the level of the prostatic smooth muscle, an α-adrenergic blocker should increase the likelihood of spontaneous voiding after catheter removal.

The chance of successful voiding after a period of AUR was improved by the use of alfuzosin (McNeill et al, 2005) and tamsulosin (Lucas et al, 2005). In a multicenter study a total of 360 men with AUR underwent emergency catheterization and were blindly randomized to alfuzosin 10 mg/day or placebo for 3 days (first phase). All patients with successful trial without catheterization, regardless of treatment, were then again blindly randomized to alfuzosin 10 mg/day or placebo for 6 months (second phase). Alfuzosin significantly increased the successful trial without catheterization rate (146 of 236, 61.9%) compared with placebo (58 of 121, 47.9%; $P = .012$). In the second phase, 14 (17.1%) of the 82 alfuzosin-treated patients versus 20 (24.1%) of the 83 placebo-treated patients required BPH surgery, 5 (36%) of 14 versus 13 (65%) of 20 within 1 month, and 8 (57%) of 14 versus 17 (85%) of 20 within 3 months of treatment. Emergency surgery because of AUR relapse was the main cause of failure in both groups (11 [78.6%] of 14 in the alfuzosin group and 16 [80.0%] of 20 in the placebo group). Compared with placebo, alfuzosin improved the Kaplan-Meier survival rates by 9.6% ($P = .04$), 11.4% ($P = .04$), and 8.3% ($P = .20$), with surgical risk reductions of 61%, 52%, and 29% at 1, 3, and 6 months of treatment, respectively. High PSA values and the residual urine volume after the trial without catheterization significantly increased the risk of AUR relapse and BPH surgery (McNeill et al, 2005).

An economic analysis (Annemans et al, 2005) suggests that treatment with alfuzosin before and after a successful trial without catheterization reduces treatment costs in the first 6 months. **Unfortunately, even those who succeed will have a high rate of subsequent failure to void and 80% of those who will experience this failure do so within 6 months** (Cathcart et al, 2006). **At that point surgery and/or pressure-flow studies are indicated.**

Medical Therapy for the Prevention of Acute Urinary Retention

Large-scale, randomized, double-blind, placebo-controlled trials of long-term duration are necessary to determine whether a medical therapy prevents a relatively uncommon event such as AUR. **In the MTOPS trial, finasteride or combination therapy of finasteride with doxazosin, but not doxazosin alone, reduced the incidence of AUR** (McConnell et al, 2003). **Debruyne and associates** (2004) **reported data for dutasteride suggesting similar results.** Because men with large prostates have on average a threefold greater chance of developing urinary retention (Jacobsen et al, 1997), enrolling men with large prostates would enhance the probability of observing an effect on AUR. **The 3-year open-label prospective study of alfuzosin supported a 0.3% risk of retention** (Lukacs et al, 2000). This is markedly lower than the predicted risk of developing urinary retention in an age-matched cohort of men (Jacobsen et al, 1997) but may be more a delay rather than prevention. **The trial data suggest a role for 5α-reductase drugs in the prevention of AUR.**

FUTURE STRATEGIES

Medical therapies provide improvement over watchful waiting for most patients (Hutchison et al 2007). The therapeutic response to medical therapy is less than that of prostatectomy. As Clifford and Farmer (2000) noted in a meta-analysis of α-adrenergic blocker and finasteride studies, "neither finasteride nor α-blockers approach the efficacy of prostatic surgery in terms of improvement in either symptoms or flow rates…." Therefore opportunities exist to develop novel strategies that may be more effective than existing therapies. The development of "pharmacogenetics" and molecular biologic testing may allow "personalized" medication so that α_{1A}-adrenergic receptor–predominant men get tamsulosin and α_{1D}-adrenergic receptor–predominant men get naftopidil, for instance. Developing different classes of drugs to relax smooth muscle and further targeting nonprostatic factors are further potential opportunities.

Endothelins are potent vasoconstrictors. Langenstroer and associates (1993) reported that human prostate contains endogenous endothelin and that **endothelin elicits a very potent contraction in the human prostate.** The contractile response elicited by endothelin in the human prostate is not abolished by pretreatment with selective α_1-adrenergic blockers. These observations suggest that relaxation of prostatic smooth muscle in BPH may also be achieved by endothelin antagonists. The

pharmaceutical industry is actively engaged in efforts to synthesize selective endothelin antagonists. Kobayashi and colleagues (1994) have characterized the binding properties of endothelin receptor subtypes in the human prostate. Both endothelin-A and endothelin-B receptors are present in the human prostate. These receptors are localized primarily in the stroma and glandular epithelium, respectively. Preliminary studies suggest that both types of endothelin receptors mediate the tension of prostate smooth muscle. Endothelin antagonists may emerge as another treatment for BPH.

It is generally assumed that the clinical manifestations of BPH are the result of BOO. Therefore pharmacologic strategies have been directed toward reducing BOO. **Several observations suggest that nonprostatic factors may also contribute to clinical BPH.** The severity of clinical prostatism as captured by symptom scores is poorly correlated with measurement of BOO. In addition, the changes in symptom scores after therapy for BPH are poorly correlated with changes in PFR and obstruction grade. The discordance between symptom severity and measures of obstruction suggests that nonprostatic factors may be contributing to clinical BPH. Clearly several factors including aging, the hormonal milieu, nonurologic diseases, and prostatic growth affect bladder morphometry, neurologic innervation, BOO, and renal function, and these factors collectively contribute to clinical BPH. Our present understanding of the pathophysiology of clinical BPH is rudimentary. It is therefore imperative to develop a more comprehensive understanding of the pathophysiology of symptoms. This knowledge will result in more effective use of existing therapies and will provide the rationale for the next generation of therapeutic modalities.

Key Points: Evaluation and Nonsurgical Management of Benign Prostatic Hyperplasia

- Benign prostatic hyperplasia (BPH) is the most common cause of lower urinary tract symptoms (LUTS) in men beyond middle age.
- Evaluation requires a history and symptom score (IPSS) and a careful physical examination including a digital rectal examination.
- Uroflowmetry and ultrasound estimation of PVR urine volume are often helpful, and determination of the PSA level is requested when a diagnosis of prostate cancer would alter the management of the individual patient.
- Medical therapy is now the usual first-line management of uncomplicated BPH with either an α-adrenergic receptor blocker or (if the prostate is large) a 5α-reductase inhibitor.
- Combination therapy with both an α-adrenergic receptor blocker and a 5α-reductase inhibitor has been demonstrated to be the most effective means of preventing disease progression and seems likely to become the standard of care in appropriate cases.
- Antimuscarinic agents and PDEIs are useful adjuncts for men with "storage" symptoms or ED. Their true importance will become clearer with time.

Summary

The prostate continues to be central to urologic practice in terms of the volume of cases that arise involving a disorder of that organ, be it benign, malignant, or inflammatory. Because of this, the amount of money available from grant-giving authorities for research into prostatic diseases is probably the highest for any research on the genitourinary tract, and so inevitably our interest in and understanding of the pathogenesis of problems relating to prostatic conditions have increased greatly. This has led to increasingly effective therapies for some prostatic abnormalities, but after the initial advances in the management of benign prostatic hyperplasia (BPH) of 10 to 12 years ago, how far have things moved forward? And, although groups of patients are continually being identified who would benefit from individual or combined medical treatments, can we say that the same has been happening in our development of minimally invasive therapies?

One thing that is certain is that in our investigation of medical therapy of BPH the identification of groups of patients who would best respond to different drugs has taken many large trials with long-term follow-up and careful statistical powering to demonstrate equivalence or a predefined difference. One always has the feeling that drug trials keep moving forward, leading to a greater understanding of the condition itself and of the ideal treatment for BPH. It can be said with some degree of confidence that the advent of medical management has reduced greatly the indications for and the number of patients undergoing transurethral resection of the prostate (TURP) and has also strongly influenced the wish of patients to have TURP, in that they would now prefer to try most other types of treatment before agreeing to undergo this procedure.

As the pharmacologic management of BPH was flourishing, many new minimally invasive therapies were being introduced. The huge success that greeted the development of technologic innovations in the management of renal calculous disease with percutaneous nephrolithotomy and extracorporeal shockwave lithotripsy prompted most of us to believe that the same could be achieved with BPH.

The yardstick against which the new minimally invasive therapies were measured was, of course, TURP. This was a very significant technologic innovation when it was introduced, and it went through a considerable amount of evolution before it reached the high levels of excellence that it has reached today. We know that it does not seem to produce as good results as the open prostatectomy, but it is not far behind. This statement is made without there having been a randomized trial between the two procedures, and comments on the safety and efficacy of one against the other are not evidence based. However, TURP can be viewed as a highly effective treatment with an acceptable complication rate, so much so that it is now accepted as the "gold standard," that is, the standard against which other minimally invasive therapies must be measured and the standard that it is hoped they can achieve.

One of the slightly disappointing things is that although many of these therapies have been introduced, in spite of the fact that they were originally welcomed as a significant advance in the treatment of BPH, in the longer term they have not turned out to be so. In many cases, the conclusion that they were of value was based on a series of poorly constructed short-term trials in which intention-to-treat analysis of the results may not have been rigidly adhered to. However, the demise of some of the earlier technologies has led to strengthening and evolution of the newer ones, all of which has been beneficial for patients with BPH.

It should also be remembered why it is that the new minimally invasive techniques have been introduced. Ideally, they have been popularized and developed in the hope that they will have less complications than TURP, less requirement for anesthesia, and a shorter hospital stay and if possible will be less expensive. If the treatment is as effective as TURP, it should be ahead on one of these counts, and if it is not as efficacious, a rationale for its use

should be devised, in addition to attempts at the identification of the patients most likely to benefit from it. Its exact therapeutic positioning in the management of BPH should be found.

The discussion presented here focuses on the current approach to the minimally invasive and endoscopic management of BPH. The literature has been critically and fairly reviewed, and the information outlined has relied heavily on evidence-based principles. When level I evidence is available, such as a meta-analysis or systematic literature review, the reader's attention will be drawn to it. The purpose of all of this is to present the data so that readers will be able to make a valued judgment on the various treatment options, thus helping in their urologic practice.

INTRAPROSTATIC STENTS

One of the earliest attempts to find less traumatic methods of treating symptomatic BPH was the introduction of either temporary or permanent intraprostatic stents, and, to a degree, they are still being used. They were first introduced as a method of treating certain cardiovascular conditions; and since the work of Dotter (1969), they have also been part of the treatment for peripheral vascular disease. They have since been used to treat stenosis of the coronary, femoral, and renal arteries (Maass et al, 1982; Dotter et al, 1983; Wright et al, 1985; Palmaz et al, 1987). Other types of obstruction have also been treated by the placement of stents: vena caval obstruction (Furui et al, 1990), bronchial obstruction (Mair et al, 1990), and tracheal stenosis (Skapshay et al, 1989). Even cervical stenosis (Luesley et al, 1990) and lacrimal duct obstruction (Hurwitz, 1989) have been treated in this manner. It is clear that stents have a role to play in treating obstruction in different parts of the body, but the exact role needs to be defined accurately. In the case of coronary artery disease, for example, a trial comparing stents with coronary artery bypass grafting is still awaited. In the case of the prostate, it took some time before it was realized that the role of stents was rather a limited one and that they would not replace TURP in every patient.

One of the few innovations that have occurred has been the introduction of a new temporary prostatic stent, which is based on a modification of the Foley catheter. This is described in detail later.

The idea of using stents for splinting the lobes of the prostate was derived from their original use in the cardiovascular system, where they are used to prevent arterial restenosis after angioplasty. Fabian (1980) first described the use of stents in urology when he suggested their usefulness in the treatment of outlet obstruction secondary to enlargement of the prostate. At some time after this the use of stents was advocated in the treatment of urethral strictures, and, subsequent to this, the use of prostatic stents became widespread, with the introduction of many different types: stents are now available in different lengths, diameters, materials, and designs.

As mentioned earlier, when stents were introduced as a treatment for symptomatic BPH, their exact role was uncertain and tended to be overstated as perhaps something that could be used in virtually every case. **Eventually it became clear that their major role was likely to be found in the management of patients who were unfit for surgery, in either the short or the long term, in which the alternative would have been months or, indeed, a lifetime of indwelling urethral catheterization.**

Along with these changes in the indications for the use of stents have emerged two basic types of stent: that which is put in for a short time and can be removed with ease and that which is placed as a permanent type of treatment and can be removed only with much greater difficulty.

Temporary Stents

Temporary stents are tubular devices that are made of either **a nonabsorbable or a biodegradable material.** They remain in the prostatic urethra for a limited period of time; they neither become covered by the urethral epithelium nor become incorporated into the urethral wall. The nonabsorbable stents need to be removed every 6 to 36 months, depending on which type of material is used. They can usually be removed, and, if necessary, replaced, without difficulty with the patient under topical anesthesia with sedation.

Temporary stents are designed for short-term use, to relieve bladder outlet obstruction (BOO), and to act as an alternative to an indwelling urethral or suprapubic catheter in high-risk patients considered unfit for surgery. In such patients these temporary stents permit normal micturition with an acceptable side effect profile. Success rates have been reported in the range of 50% to 90%. They are easy to reposition or replace, but catheterization or cystoscopy cannot be performed while the stent is in place. Complications such as encrustation, migration, breakage, stress incontinence, and bacteriuria have been reported in varying degrees of frequency.

Spiral Stents

First-Generation Stents. The Urospiral (Porges) and the Prosta Kath (Pharma-Plast) are examples of spiral stents. The former is made of 21-Fr stainless steel and varies between 40 and 80 mm in length. The latter is also made of 21-Fr stainless steel but is gold plated in an attempt to prevent encrustation. It varies in length between 35 and 95 mm. Neither stent should remain in the prostatic urethra for longer than 12 months.

A spiral stent should be inserted with a 21-Fr panendoscope using either a 30-degree or a 0-degree lens under direct vision and with the aid of a grasping forceps. It may also be inserted over a catheter guide under ultrasound visualization (Nordling et al, 1989).

In the original series reported by Nordling and colleagues (1989), the Prosta Kath was inserted under topical anesthesia in 45 patients with acute or chronic retention. Ultrasonography was used in 35 patients and endoscopy in 6 to facilitate stent placement. **Retention was relieved in 41 of the 45 patients, leading the authors to advocate its use in high-risk patients.**

Ozgur and coworkers (1993) reported re-establishment of voiding with the Urospiral with good results after 4 months of follow-up in 31 patients who were unfit for surgery. The Urospiral was also used in 10 patients with advanced prostate cancer (Anson et al, 1993). All had retention or severe obstruction. The patients were started on antiandrogens after stent insertion. The stent was removed 3 months later, and all patients were reported as voiding satisfactorily, although one patient subsequently required a limited TURP. In another report, 18 high-risk patients with BPH had a Urospiral inserted (Karaoglau et al, 1992). **All voided without difficulty and with complete bladder emptying. However, the complications were rather high: hematuria in 2, migration in 1, and infection in 8.**

In 87 patients declared unfit for TURP, Thomas and colleagues (1993) reported an experience extending over 4 years using the Prosta Kath. Sixty-four patients presented with acute urinary retention, and, after treatment, 57 voided successfully whereas 7

failed to void. A further 14 patients presented with chronic urinary retention; 5 of these voided satisfactorily, but 9 required alternative therapy. **Complications included hematuria with clot retention (5%), stent migration (15%), recurrent urinary tract infections (10%), and encrustation (4%).** These findings of relatively high complications are also reported by other authors (Nordling et al, 1989; Harrison and De Souza, 1990). Braf and coworkers (1996) observed 55 men for between 12 and 16 months, 32 of whom were treated with the Prosta Kath and 23 with the Urospiral. Ten patients failed in the Prosta Kath group, and 8 patients failed in the Urospiral group. Complications in both groups include encrustation, urinary tract infection, migration, stricture formation, and failure to void. In the largest number of patients reported from one center Nordling and associates reported on the use of the Prosta Kath in 318 patients. They divided the complications into none, moderate, and severe. In the patients who were described as having severe complications, stress or urgency incontinence occurred in 63, emptying problems in 8, and frequency or nocturia (more than three times per night) or both in 57.

Second-Generation Stents. Other spiral stents have been developed as second-generation models in an attempt to overcome the problems of the first-generation stents just described while maintaining the efficacy and ease of insertion. These are the Memokath and the Prosta Coil.

The Memokath (Engineers and Doctors A/S, Copenhagen, Denmark) is made of nitinol, a nickel-titanium alloy, which has the property of shape memory. It is malleable and heat expandable at a temperature of 45° C to 50° C. Like other temporary stents, it is easy to insert and maintains its expanded position in the prostatic urethra. With the earlier model of the Memokath, epithelial hyperplasia at the apex of the prostate was reported in some cases, but modifications have since been made. The later model ensured close contact of the wires even in the expanded position, thus reducing the possibility of hyperplastic growth of the urethral epithelium through the gaps in the expanded spiral. The Memokath is soft and malleable when cooled, returning to its original shape when heated to the preceding temperatures. Of 22-Fr caliber, it has a length of 35 to 95 mm. It permits the passage of a flexible cystoscope and may be left in place for up to 36 months.

The Prosta Coil is a self-expanding and self-retaining stent made of a nickel-titanium alloy (Instent, Minneapolis, MN). It is inserted by being mounted on a 17-Fr delivery catheter under fluoroscopy; once released from the mounting it takes the form of a wave-shaped tube whose diameter varies from 24 to 30 Fr. Its length is from 40 to 80 mm, and it can be left in position for up to 36 months.

The Memokath was reported as being used in **30 patients who were unfit for surgery or who refused it; the success rate was 80%. Normal voiding is described as having occurred in all patients.** The peak urinary flow rate (PFR, also Qmax) reached a mean of 16 mL/sec immediately after insertion (Poulsen et al, 1993). However, there was a wide range of PFRs, from 4 to 25 mL/sec. Unfortunately, 3 patients later developed urinary retention at 5 days, 2.5 months, and 5 months, respectively, after insertion. Two more stents needed to be removed because of hyperplastic growth of the epithelium. A total of 24 stents were still in place at 3 months. Nordling (1996) updated these authors' experience after inserting 64 of the modified Memokath stents. Similar successful voiding was reported. The complications that patients described as severe were few, with urgency incontinence being the most common (10 patients). However, moderate symptoms were relatively more common.

Results are available from a long-term study conducted in the United Kingdom. The Memokath was inserted in men who were either permanently or temporarily unfit for TURP, in most cases because of severe respiratory or cardiovascular disease. **In this study, 211 men had 217 stents inserted over an 8-year period. In the same time frame, 1511 TURPs were performed. The mean age of patients having stents was 80.2 years, and in the TURP group it was 70.2 years. The patients who had stents fitted experienced an improvement in the mean International Prostate Symptom Score (IPSS) from 20.3 to 8.2 in just 3 months, with results being maintained for 7 years. However, these results must be viewed in the light of the fact that 38% died with stents in place, 34% remain alive with their stents, and 23% had stent removal because of failure. Migration occurred in 13%, and 16% required repositioning. This study suggests that long-term success can be achievable using the Memokath but that failure can also be anticipated in a significant minority** (Perry et al, 2002).

The Prosta Coil has been used in a small series of patients with short follow-up (Yachia et al, 1994). The mean follow-up was 14 months, with a range of 2 to 28 months. There were initial irritative urinary symptoms that were reported as having disappeared within 1 month. **The mean PFR at the most recent follow-up was 21.3 mL/sec (with a range of 15 to 36 mL/sec) and the mean IPSS was 9 (with a range of 6 to 12).**

Thus spiral stents were among the earliest type of temporary stents to be introduced, and they have developed to a large degree from the original designs. New models have reduced such complications as encrustation and urothelial hyperplasia, but stress incontinence and urgency incontinence still occur, as does displacement of the stent. However, they are easy to insert and do not require general anesthesia. Although the follow-up is relatively short term, in most of the reported series, good success rates are reported. The place of spiral stents is clearly that of a nontraumatic therapy for urinary retention in patients unfit for surgery, and they have a reasonable chance of a successful outcome.

It is hard to predict whether further design changes will take place. The earlier type of spiral stents had the advantage of being less expensive. The newer models are made of compounds aimed to reduce complications or prevent stent migration but are all more expensive than the earlier models. With a limited market and with a restricted acceptability, further developments in this type of stent are unlikely.

Polyurethane Stents

Polyurethane stents are also known as intraurethral catheters. There are three types: the intraurethral catheter (Angiomed, Germany), the Barnes stent (CR Bard, Covington, GA), and the trestle stent (Microvasive, Boston Scientific, Natick, MA).

Intraurethral Catheter. The intraurethral catheter, the first to be introduced, was reported initially by Nissenkorn (1991). It is made of a type of polyurethane known as Puroflex and has a fixed 16-Fr caliber. Its length varies from 40 to 60 mm, and it can be left in place for up to 6 months. It has a double device at its proximal end shaped like the head of a de Pezzer or Malecot catheter. It has a nylon string at its distal end and a flared split end proximally, which sits in the bladder. It is inserted under topical anesthesia using a 22-Fr cystoscope. The nylon string is cut after placement, and any positional adjustment required can be performed by the use of a grasping forceps. **Eighty-five devices were inserted into 73 patients, and, of these, 60 patients had an indwelling catheter for 1 week to 3 years before insertion.**

Nissenkorn (1991) described a successful outcome in 63 patients who believed that their quality of life was considerably better than it had been when they had an indwelling catheter. He therefore believed that this was suitable for use in such patients, with a high likelihood of success.

A later study reported the use of the Nissenkorn intraurethral catheter in 43 patients (Sassine and Schulman, 1994). Once again, the patients treated had developed urinary retention and were unfit for surgery but also had a short life expectancy. Thirty-six of the 43 patients were able to void satisfactorily after stent insertion. The intraurethral catheter should not be inserted in the presence of bladder stones or anything else likely to block or have a ball-valve effect on the device.

One of the potential uses of temporary prostatic stents is as an expedient to overcome the early retentive effects of heat treatment to the prostate. Clearly, an objection to this might be that such a therapeutic strategy effectively doubles the cost of the treatment and so makes it less attractive. However, it is an attractive way of overcoming an early complication of heat treatment, which might have been seen by some as a significant limitation of heat treatment. The Barnes stent and the trestle stent may have such an application.

Barnes Stent. What has been called the Barnes stent is made of polyurethane, has a 16-Fr caliber, and is of a single length. It also has a de Pezzer end proximally, but this time a single one. It is thus a modification of the original intraurethral catheter. It was used in 25 patients who underwent endoscopic laser ablation of the prostate (ELAP). Twenty-two of the 25 voided immediately. Early stent migration occurred in 1 patient, but late migration did not occur. The stent was inserted with ease, could be removed with ease at 12 weeks, and was inexpensive. PFRs improved from 8 mL/sec before ELAP to 16.5 mL/sec at 6 weeks with the stent in place (Barnes et al, 1996). The Nissenkorn catheter has also been used safely and with equal success after laser therapy (Nissenkorn et al, 1996).

Trestle Stent. The trestle stent or prostatic bridge catheter has been described and consists of two tubes and an interconnecting thread. The tube that lies in the prostate has a 22-Fr diameter and has a 30-degree angulation. The length is 75 mm, and it has a smooth tip: It is to be used in prostates with a volume of less than 80 mL. The connecting thread is 25 mm, which passes through the distal sphincteric mechanism. The second tube lies in the bulbar urethra and is 35 mm long. It is inserted with the patient under topical anesthesia using a delivery system comprising a positioning stylet, an inflatable balloon with injection cannula, and an outer pusher tube. The technique is described in detail by Djavan and colleagues (1999).

In a report from Devonec and Dahlstrand (1998) the results of its use **in 52 patients after high-energy transurethral microwave therapy (TUMT) were described. Tolerance was good in 32 patients, acceptable in 13, and poor in 6. Retrograde ejaculation occurred in eight. PFRs reached 14.6 mL/sec on the day of removal of the device. The device was left in place for 1 month, but the improvement in PFR was maintained at 1 year.** Djavan and colleagues (1999) also described its use in 54 patients who had received high-energy TUMT. The device was left in place for up to 1 month, and it was found that the incidence of post-treatment retention was prevented, with concurrent early but significantly improved symptom scores and PFRs. Toleration was high, with 48 of 54 devices remaining in place for 1 month. Early removal was required because of urinary retention in 3 and migration in 3.

The intraurethral catheter or its more recent variations are being used in a rather different context than the spiral stents. They have been used successfully, albeit in a small number of nonrandomized short-term studies, with few problems related to tolerance. A further cost-efficacy evaluation is required, in addition to larger multicenter randomized controlled comparative trials.

The Spanner. The spanner has a design very similar to the proximal 4 to 6 cm of a Foley catheter. It includes a balloon to prevent displacement, a port for urine drainage that lies proximal to the balloon, and a reinforced stent of varying length that spans most of the prostatic urethra (Fig. 93–1).

In the first study using this device, the stent was inserted under topical anesthesia in 30 patients (Corica et al, 2004), **of whom 5 had been in urinary retention. The stents remained in place for a mean of 57 days. The mean PFR improved by 42% from 8.2 to 11.6 mL/sec. The overall mean IPSS decreased from 22.3 to 7.1, a 68% difference. The adverse events were few, and the device was found to be stable and patent at the end of the study.**

This article describes an early open study designed to test the efficacy, safety, and stability of the device. It could be criticized in that it was composed of a group of patients whose characteristics were not adequately described, with no entry criteria defined. It is, however, an interesting new device that may well be important for many patients as a temporary method of bypassing prostatic obstruction.

Biodegradable Stents

The concept of stents that can be put in place after a procedure that has a high incidence of secondary and temporary obstruction has been mentioned earlier in the context of stents being inserted after laser or high-energy TUMT. These stents are removed some weeks later. With the biodegradable stent the concept is brought one step further; the stents do not need to be removed, and eventually they disappear by biodegrading. This interesting idea was first introduced in urology when Kemppainen and colleagues (1993) used a biodegradable stent in rabbits after urethrotomy. The idea has now been extended to the ureter (Schlick and Planz, 1998; Lumiaho et al, 1999; Clayman, 2000), after endoscopic urethroplasty (Oosterlinck and Talja, 2000), and in coronary artery disease (Tamai et al, 2000).

Figure 93–1. Pro Vu device used for transurethral needle ablation of the prostate. (Courtesy of Neo Vitalis Ltd, Southport, UK.)

Further experimental studies have shown that biodegradable stents can potentially be used as a bridge across the prostate after minimally invasive procedures, without the necessity of having to remove them later (Petas et al, 1997a, 1998; Laaksovirta et al, 2002; Vaajanen et al, 2003).

In addition, clinical studies have been performed that examine the use of biodegradable stents after various procedures (Talja et al, 1995; Dahlstrand et al, 1997; Petas et al, 1997b). The benefit is that these stents prevent the development of obstruction that can occur after laser procedures; however, the use of the second procedure in association with, for example, laser prostatectomy takes away a great deal from the value of the first procedure, not least in terms of cost-effectiveness. There are three types of biodegradable stents.

A randomized study (Petas et al, 1997b) **compared self-reinforced polyglycolic acid biodegradable spiral stents (group 1), no device (group 2), or an indwelling catheter (group 3) after visual laser ablation of the prostate. The procedure was performed on 72 men, and 27 were in group 1, 23 in group 2, and 22 in group 3. Voiding began at a median of 1 day in group 1 and a median of 6 days in group 2; the indwelling catheter was required for an average of 6.5 days in group 3, and voiding commenced a median of 6 days after this.** The authors found, as they had in previous in-vitro studies, that the stent degraded into small fragments of polymer debris that were passed out in the urine. They commented that voiding became more obstructed at 3 to 4 weeks postoperatively, presumably from degradation and sloughing of the stent, but they found that this was only a transient effect.

In another study, Dahlstrand and colleagues (1997) evaluated the same polyglycolic acid stent after high-energy TUMT with the Prostasoft 2.5. They compared the use of the stent in 15 patients against a further 15 patients in whom a standard 16-Fr urethral catheter was inserted. The mean duration of catheterization was 14.1 days, with a standard deviation of 4.1 days; this was obviously prevented by the stent, which did not cause problems, even when it was degrading.

In a rather innovative way, Knutson and colleagues (2003) described the use of a biodegradable polyglycolic acid stent to assess the risk of post-TURP incontinence in patients with combined BOO and overactive bladder. In 37 patients with severe overactive bladder and moderate to severe BOO this biodegradable stent was inserted into the prostatic urethra; 25 noticed either no leakage or minor leakage and 19 have had TURP with good results. Twelve of the 37 had a major problem with incontinence after the insertion of the stent. There was a small complication rate related to stent insertion.

These stents are definitely of interest for the future, but their exact place in the treatment of BPH needs to be established, with larger and longer-term studies. In addition, the problem related to the overall cost must be defined accurately; otherwise, the value of the primary procedure will be questioned.

Permanent Stents

With permanent stenting of the prostate, the urologist is attempting to treat definitively and permanently patients who present with symptomatic BPH. To be of proven value this type of treatment, like any other, must be shown to be at least comparable to TURP. The initial enthusiasm for permanent stents has been replaced by relative silence in the literature at present. Permanent stents were initially introduced as treatment for recurrent urethral strictures and were subsequently used in patients with lower urinary tract symptoms (LUTS). In urologic terms, permanent stents are being used preferentially for the treatment of detrusor-sphincter dyssynergia (Chancellor et al, 1999; Chartier-Kastler et al, 2000; Gajewski et al, 2000), postbrachytherapy BOO (Konety et al, 2000), anastomotic strictures and urinary incontinence after radical prostatectomy (Meulen et al, 1991), and complex urethral strictures (Tillem et al, 1997). There have been no reports in the recent literature that relate to the long-term follow-up of the patients originally treated with permanent stents, and there has been no indication of new interest in their use.

UroLume

The UroLume endourethral prosthesis (American Medical Systems, Minnetonka, MN) is a woven tubular mesh that maintains its position in the urethra by outward external pressure, thus maintaining the patency of the prostatic urethra. The original 42-Fr device was made of metal superalloy and varied in length from 1.5 to 4.0 cm. It is inserted with a special 21-Fr deployment tool using a 0-degree panendoscope. Gradually, epithelialization occurs, ideally in a smooth manner, covering the individual wires of the mesh. The stent can be removed by securing about 5 mm of the distal aspect in the jaws of a grasping forceps and then pulling the distal end inside a resectoscope sheath to minimize any possibility of urethral trauma while removing it.

The original stent tended to shorten while it expanded outward, leading to its replacement by a stent less likely to do so. However, this stent tended to migrate more easily, and a further modification was required. In addition to these changes the delivery tool was modified, leading to the present, more satisfactory model.

Chapple and colleagues (1990) reported on the initial experience with the UroLume. **Twelve patients who were considered to be a poor risk for surgery presented with LUTS; 9 of the 12 patients presented with urinary retention. The results were encouraging, with 11 of 12 voiding satisfactorily for a mean follow-up of 8.2 months. The mean PFR after the procedure was 13.6 mL/sec.** Further encouragement came from the low complication rate, consisting mainly of short-term irritative voiding symptoms, with only 1 of the 12 being dissatisfied because of severe urgency and frequency (the patient was subsequently found to have detrusor instability). A further study in a similar group of unfit patients was performed by McLoughlin and colleagues (1990). All 19 patients in their study group presented in urinary retention, and all voided satisfactorily after the stent was inserted under local anesthesia.

In a larger, multicenter open trial from the United States, Oesterling and colleagues (1994) reported on 126 men who presented either with moderate or severe LUTS (95 men) or with urinary retention (31 men). There were strict inclusion and exclusion criteria in the trial design, but fitness for surgery was not among them. **In the nonretention group, 80 of 95 were evaluable at 12 months and 52 at 24 months; the Madsen symptom score decreased from 14.0 to 5.9 and 5.4, respectively. In the retention group, 24 of the 31 patients evaluable at 12 months had a mean symptom score of 6.1. In the nonretention group, the PFR increased from 9.1 to 13.0 and 13.1 mL/sec, respectively, with the retention group having a mean PFR of 11.7 mL/sec at 12 months.** Difficulties with insertion were experienced in 16% of cases; irritative voiding symptoms occurred in 10%.

Guazzoni and coworkers (1994) described a European study using the modified UroLume stent (the so-called less shortening variety described earlier). Once again, the strict inclusion and

exclusion criteria did not refer to fitness for surgery, and at this time the stent was being presented as a proposed therapy for prostatic obstruction, not necessarily only for unfit patients. In this multicenter study, 135 healthy patients (91 with LUTS, 44 with urinary retention) were treated. In the nonretention group, 74 of 91 patients were evaluable at 12 months. The mean Madsen-Iversen symptom score had decreased from 14.1 to 6.4, but the tight standard deviations of the mean observed in the U.S. study (0.4) were not seen in this study (5.1); the PFR improved from 9.3 to 15.7 mL/sec at 12 months (with a very wide standard deviation of 6.5, unlike that in the U.S. study). In the retention group, 34 of 44 were evaluable at 12 months; the mean symptom score was 4.5 and the mean PFR was 13.1 mL/sec. The complications were well described but were found to be significant in the long term.

In a British study (Bajoria et al, 1995), 44 men fit for TURP accepted as an alternative a second-generation UroLume stent. The stent was inserted in 44 patients, who either were in urinary retention or had urodynamically proven outflow obstruction. The results achieved were similar to those reported by Guazzoni and colleagues (1994), but there was also a relatively high complication rate. Both sets of authors noted **epithelial hyperplasia and migration of the stent in addition to irritative urinary symptoms and painful ejaculation. The second-generation less shortening stent was not recommended for general use,** and a third-generation stent was then produced. However, Bajoria and colleagues (1995) strongly suggested that permanent stents should still be considered as being under evaluation rather than for general use.

In a multicenter study of 96 men who were unfit for prostatic surgery, 73 presented in acute urinary retention and 11 in chronic retention. **All but 6 were able to void immediately after stent insertion; 2 required a second stent, and 4 required a period of suprapubic catheter drainage. At 12 months, the PFR was 15 mL/sec in the retention group and 18.1 in the nonretention group. Severe irritative symptoms were seen in the majority of patients for up to 3 months, and encrustation was encountered in 15 of 27 patients who underwent cystoscopy** (Williams et al, 1993).

The results of a long-term analysis of the UroLume Wallstent have been published by Masood and coworkers (2004). The stent was inserted in 62 patients with moderate or severe LUTS secondary to BPH. The 5- and 12-year follow-up was completed by 22 and 11 patients, respectively. Death occurred in 21 patients (34%), and the stent was removed in 29 patients (47%), the vast majority of these removals occurring in the first 2 years. The authors concluded that this is a safe treatment but that cases must be carefully selected and that it should be performed only by experienced hands.

The use of the UroLume stent can be seen to have some application in patients with prostatic obstruction, particularly if they are unfit. However, interest in this type of stent seems to have waned somewhat because of the use of other types of less invasive treatments, which appear more satisfactory to patient and urologist alike.

Memotherm

The Memotherm (Angiomed, Germany) is a stent of nickel-titanium alloy that is expandable to 42 Fr with heat. When it is cooled, it can easily be compressed and distorted, but when warmed to body temperature it expands to a flexible cylinder and does not shorten. It is made from a woven single wire, which makes it easy to remove; traction unravels the wire. It is manufactured in lengths varying between 1.5 and 8.0 cm and is available in a prepacked sterile delivery service. It is inserted under direct vision with a 0-degree telescope.

Williams and White (1995) reported on 48 men with LUTS and urodynamic findings suggestive of bladder outflow obstruction. The results were disappointing. **Only 37 patients were able to void immediately after stent insertion, the others requiring a suprapubic catheter for up to 8 weeks. Symptomatic improvement occurred in many, but complications, including stent migration, were relatively high. Thirteen of the 48 patients required removal of their stents.** These authors suggested that the results were not appropriate to encourage marketing of the device.

Gesenberg and Sintermann (1998) used the Memotherm in 123 patients considered to be at high risk for prostatic surgery; 46 of these presented in urinary retention. Of the 123 patients, only 52 were evaluable at 12 months. The mean PFR increased from 7.4 to 13.0 mL/sec (with a standard deviation of 6.2), and the IPSS improved from 24.0 to 8.8 (SD 6.2). **The authors noted a considerable improvement in quality of life. However, the complication rate was relatively high, with recurrent infections and urgency symptoms in 56%, urothelial hyperplasia in 34%, and urethral stricture in 10%. There was a high number of re-treatments,** and the authors suggested that there may be an additional role for medical treatment in some of these patients.

These results have not appeared to be convincing large numbers of urologists to use these stents on patients with symptomatic BPH, but modifications may occur. Heat-expandable stents are widely used in cardiovascular conditions and in biliary stenosis.

Other Permanent Stents

The ASI stent (Advanced Surgical Instruments) was evaluated in several centers (Kirby et al, 1992; Kaplan et al, 1995). It was introduced on a balloon, which was then inflated, thus expanding the stent. The early results suggested an improvement in symptom score (44%) and PFR (22%), but complications also occurred that made it less attractive for general use. It has since been withdrawn from production.

The Ultraflex stent (Boston Scientific, Natick, MA) is made of nickel-titanium alloy that also has a capacity to expand to a caliber of 42 French when exposed to body heat. It is available in lengths varying from 2 to 6 cm. There have been reports of its use in patients with prostatic obstruction, but it has been studied in a group of patients with detrusor-sphincter dyssynergia (Chartier-Kastler et al, 2000), and the incidence of epithelial hyperplasia and migration was encouragingly low.

Summary

Originally, permanent prostatic stents were introduced as a definitive treatment for prostatic obstruction, particularly (but not in every study) for patients unfit for prostatic surgery who presented with urinary retention. Patients were able to void satisfactorily in most cases, but complications were relatively high. One stent has been removed from the market, one has not yet been reported on as a treatment for prostatic problems, variable results have been reported on another, and the most frequently investigated, the UroLume, has not received recent attention in the literature as a specific treatment for BPH.

Temporary stents are receiving widespread attention, but the original idea that they should be used as a temporary expedient to overcome outflow problems in the

medically unfit population is being modified. The newer stents, whether biodegradable or not, are being viewed as possible methods of overcoming the temporary retention that can occur secondary to treatments such as laser therapy or high-energy TUMT.

TRANSURETHRAL NEEDLE ABLATION OF THE PROSTATE

Heat treatment of whatever kind to the prostate is intended to reduce outflow resistance and the volume of the obstruction by increasing the temperature within the prostate and inducing necrosis of prostatic tissue. The aim is to increase prostatic temperature to in excess of 60° C. Transurethral needle ablation of the prostate (TUNA) uses low-level radiofrequency (RF) energy that is delivered by needles into the prostate and that produces localized necrotic lesions in the hyperplastic tissue. It has previously been used to ablate cardiac nerve bundles in the Wolff-Parkinson-White syndrome (Calkins et al, 1992) and to destroy malignant tissue (Rossi et al, 1995; Zlotta et al, 1995). It has also been used to treat chronic cervical zygapophyseal joint pain (Lord et al, 1996). The advantage of TUNA is that it can be delivered under topical anesthesia to patients with symptomatic BPH, causing very precise and reproducible lesions within the prostate.

Delivery of Radiofrequency Energy

The TUNA system (Medtronic, Inc, Minneapolis, MN) consists of a special catheter attached to a generator. At the end of the catheter are two adjustable needles that are withdrawn into two adjustable shields made from Teflon. The needles are advanced into the prostatic tissue and can be placed accurately into the required position.

The generator produces a monopolar RF signal of 490 kHz, which allows excellent penetration and uniform tissue distribution. The patient has a grounding pad placed over the sacrum, and the current passes toward this through the prostatic tissue. In other words, tissue heating is created because of tissue resistance to the current as it flows from the active to the return electrode. The active electrode has a small surface area, with the RF current being concentrated in an area immediately surrounding it. The return electrode is large, and so the diffusion of the RF current is greater. This arrangement allows heat to be concentrated near the active electrode early, thus accurately controlling the tissue effect. The size of the lesion caused by RF relates to the position and depth of insertion of the electrode as well as the power used and the duration of the treatment.

RF produces molecular or ionic agitation with collision of particles that relates to the frequency of the energy, and this results in a central hot core inside the prostate and away from the urethra (Schulman et al, 1993). The limited distance dissipation reinforces the safety of the procedure because RF can be applied to tissue only by direct contact, with heat being generated proportional to one over the fourth power of the radius. If the power generated is too high, the prostate rapidly desiccates with a rise in tissue impedance, preventing the desired heating effect. Therefore the appropriate energy level required to produce the localized necrotic lesion must be found, preventing the increase in tissue impedance resulting in prostatic charring around the needle caused by excessive generation of energy (Schulman et al, 1993). Interestingly, heat is lost by convection, and so increased vascularity can have an effect on the degree of localization of the lesion. RF is very much affected by blood flow and has almost no effect on vessels larger than 2 to 3 mm in diameter (Organ, 1976).

There is a difference in the method of tissue heating brought about by RF and, for example, microwave application. Microwaves treat a broad area and can penetrate tissue more deeply than RF. The central temperature is therefore lower than with RF to maintain safe heat levels at the treatment rim. Therefore treatment with microwaves takes longer than RF to produce coagulative necrosis. **RF, however, has a much hotter central area with a very quick decline in temperature as the distance increases from the treatment needle.** This results in faster generation of the necrotic lesion but of a smaller area (Perlmutter et al, 1993).

Experimental Studies

In a series of preliminary studies on animals and ex-vivo human prostates it has been shown that **the TUNA system can create 1-cm necrotic lesions without difficulty in the prostate with no damage to rectum, bladder base, or distal prostatic urethra** (Goldwasser et al, 1993; Ramon et al, 1993). Other studies showed that the lesions are accurate with sharp delineation from the untreated areas (Schulman et al, 1993). These authors also showed that the lesion appeared first as a hemorrhagic lesion along the needle path, with slight discoloration in the surrounding area. Necrosis was maximal at 7 days, with fibrosis having developed by 15 days.

In an elegant neurohistochemical study, Zlotta and colleagues (1997) removed prostates from patients scheduled for prostatectomy 1 to 46 days after TUNA. Immunohistochemistry was used with anti–S-100 protein and neuron-specific enolase for nerve staining and anti–prostate-specific antigen and antidesmin for glandular and muscle cells. They showed that the maximal lesion size ranged from 10×7 to 20×10 mm^2 and that there was destruction of all tissue components. The lesions were accurately positioned 0.3 to 1.0 cm from the urethra, which remained undamaged. **In the treated area there was an absence of staining for prostate-specific antigen, smooth muscle actin, and α-adrenergic neural tissue. Even in specimens removed 24 hours after TUNA, no positively staining nerve cells were seen in the treated areas.**

It has also been shown (Issa et al, 1996) that there may be sequential damage to different types of nerve endings. **Nitric oxide synthase receptors were found to be most vulnerable to thermal damage, which occurred earliest, with damage to the α-adrenergic receptors maximal at 1 to 2 weeks.**

The temperatures achieved in the largest area have been studied by Rasor and coworkers (1993) using an infrared temperature monitor in an ex-vivo animal model. They showed that the central core of the lesion around the tip of the lesion reached 90° to 100° C. Treatment times of 5 to 7 minutes were required to produce coagulation necrosis in the treatment zone. Dosimetry studies have shown that the temperatures at the edge of the zone were 50° C.

Instruments

The generator produces low-level monopolar RF waves of about 490 kHz, which produce temperatures of about 100° C in the target area. The RF generator is connected to the TUNA catheter, which has changed somewhat in design since it was first manufactured.

The TUNA catheter is, in fact, a specifically designed endoscopic instrument. This has evolved from what was a device through which a panendoscope lens could be inserted. A number of other changes have also been made. The most up-to-date version of the TUNA catheter is called the Pro Vu system, and part of this device is reusable, unlike previous models (Fig. 93–2; see also Fig. 93–1). The new system also contains a markedly improved optical system. Previously, the needles were introduced either blindly or under transrectal ultrasound (TRUS) guidance, which had the advantage in the latter case of seeing how close to the surrounding tissues the needles lay. However, an adequate visualization of the needle entering the prostate tissue gives the urologist a better idea of the treatment area. The final change concerns the angle between the catheter and the needles, which is at present not fixed. This means that a high bladder neck that is hypertrophied or a genuine median lobe enlargement can now be treated easily by this technique.

The configuration of the needles within their protective sheath ensures that the treatment area is deep inside the prostatic lobes, and this ensures that the prostatic urethra is spared. Because there is a limited number of nerve endings in the prostatic glandular tissue and because the higher concentration of nerve endings immediately underlying the urethral epithelium remains undisturbed, topical anesthesia can be used with the patient experiencing only moderate discomfort. In addition, postprocedural irritative urinary symptoms are kept to a minimum.

Treatment

The patient is placed in the lithotomy position and topical anesthesia with 2% intraurethral lidocaine (Xylocaine) is achieved. The best result is attained by applying a penile clamp for 10 minutes and by giving intravenous sedation if required. There is a variation from institution to institution as to the optimum form of anesthesia; for many, what is described previously is satisfactory, but some prefer spinal or even general anesthesia, particularly for their initial experience with the technique. In other cases, a local prostatic block, either transperineally or transrectally, may be the method of choice.

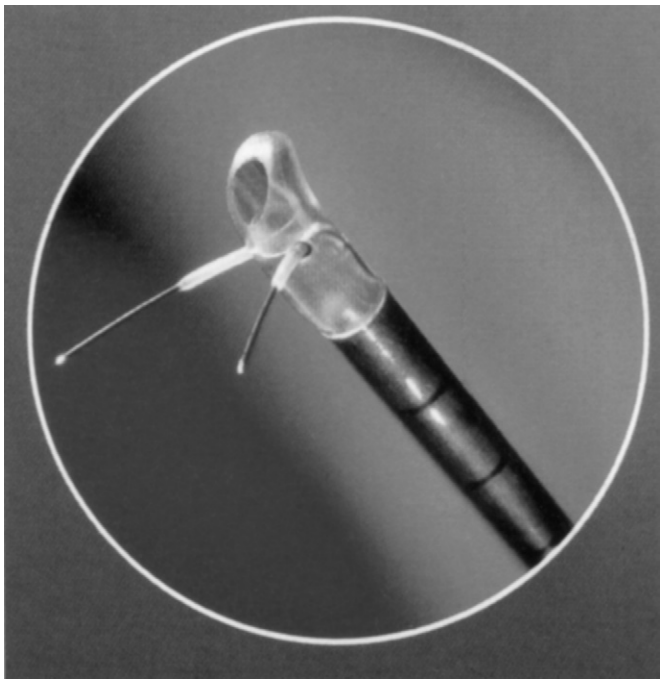

Figure 93–2. Deployment of radiofrequency needles in transurethral needle ablation of the prostate. (Courtesy of Neo Vitalis Ltd, Southport, UK.)

With the new modifications **the TUNA catheter is advanced under vision with the 0-degree fiberoptic telescope, which also allows the urologist to see the needles being advanced accurately into the prostate. The exact position within the prostate of the needle tip can be visualized by TRUS.** Preprocedural assessment of the size of the prostate by this method allows calculation of the length of deployment of the needle within the prostate; this can also be done at the beginning of the procedure, as described earlier, with the ultrasound showing the exact position of the needle tip. It is important to remember that the thermal lesion may extend for up to 5 to 6 mm beyond the position of needle deployment with lesions measuring up to 20 × 10 mm. When the position is deemed satisfactory, the Teflon shield on the proximal part of the needle is advanced to protect the urethral epithelium and the underlying tissue. Therefore the tip of the needle should not lie within 5 to 6 mm of the outer rim of the prostate, and the urethra is protected by the shields that extend from 5 to 6 mm from the TUNA catheter itself.

The number of lesions depends on the size of the prostate, but because there are two needles each time power is switched on in the generator two lesions are produced. It is usually advised that one pair of lesions should be used to treat 20 g of prostate tissue; it can also be expressed in terms of length, with one pair of lesions, or treatment plane, being used for less than 3 cm of prostatic urethral length, two planes for 3 to 4 cm, and one extra plane of treatment for every extra centimeter of urethral length. The procedure is then repeated in the opposite lobe.

The RF power that is delivered is 2 to 15 W for 5 minutes per lesion. In earlier models the treatment was begun at a low power, but now the whole thermal process is automated, with temperature levels at treatment areas preset. The temperature at the tip of the needle varies from 80° C to 100° C. The urethral temperature is kept below 46° C, and the temperature in the lesion is sustained for the treatment period.

At the end of the procedure, some urologists like to leave a urethral catheter in overnight; others do not put in a catheter and allow the patients to go home after they have voided and feel that they are emptying their bladder.

Clinical Results

Table 93–1 shows the results of the total world experience in the use of TUNA. There is a wide variety in the number of patients in each series and in the length of follow-up. Of note is that most are open series, with a minority of randomized studies (Issa and Oesterling, 2000). Although the inclusion and exclusion criteria are the same in most series, they are not exactly the same and are not as strict as those in studies testing α-adrenergic blockers and 5α-reductase inhibitors. The size of the studies varies from 12 to 130 patients, and, in many cases, the number of patients observed for the longest period of time consists of less than 50% of the original sample, which makes it difficult to draw definite conclusions. However, when looking at them all together, a number of points can be considered.

A total of 546 patients have been observed for 12 months, with an increase in the mean PFR by an average of 6 mL/sec, representing an average improvement of

Table 93–1.

Studies of Transurethral Needle Ablation with 12-Month Follow-up

77%. The mean symptom score decreased by an average of 13.1 symptom units, which is an average improvement of 58%. Although there was consistency of the general improvements, there was a range. The greatest improvement in the mean PFR was 9.2 mL/sec (Giannakopoulos et al, 1996), and in the mean symptom score it was 15.4 symptom units (Steele and Sleep, 1997). The least improvement in mean PFR was 2.7 mL/sec (Rosario et al, 1997) and in symptom score it was 10.8 (Millard et al, 1996). Although the numbers in patients observed for longer are less (176 for 24 months and 88 for 36 months), the mean improvements appear to be maintained (Issa and Oesterling, 2000).

In the U.S. randomized trial comparing TUNA with TURP, 65 patients were treated by TUNA and 56 by TURP (Bruskewitz et al, 1998). At 1 year, 59 of the TUNA group (90%) and 47 of the TURP group (84%) were available for evaluation. **In the TUNA group the symptom score improved from 24.7 to 11.1 (13.6 symptom units) and the PFR from 8.7 to 15.0 mL/sec (6.3 mL/sec). In the TURP group, the symptom score improved from 23.3 to 8.3 (15.0 symptom units) and the PFR improved from 8.4 to 20.8 mL/sec (12.4 mL/sec).** The reasons for patients being lost to follow-up are clearly stated, but it was because of ineffectiveness in only 2 patients (3.1%) of the TUNA group and none of the patients treated by TURP. The treatment was found to be effective and safe. The complication rate of TUNA was low, in both the short and the long term; the most commonly reported adverse events were bleeding (32.3%), urinary tract infection (7.7%), and urethral stricture (1.5%). There was no adverse effect of any kind on sexual function in patients treated by TUNA.

There are some additional long-term studies that are of interest. Zlotta and coworkers (2003) entered 188 consecutive patients into a study; there were 5-year data on 121 of these. At the 5-year assessment, 41 of the 176 patients who were evaluable (2 dead, 10 lost to follow-up) required additional treatment after TUNA (23.3%). Although there were 5-year data on 121 patients, and this was defined as a 5-year follow-up, the 10 patients on whom there were only 4-year data were also included, giving a total of 131 patients**. The mean IPSS decreased from 20.9 to 8.7, with tight standard deviations but a range at long-term follow-up of 2 to 20. The PFR improved from 8.6 to 12.1 mL/sec with a range at long-term follow-up of 6.5 to 19.2 mL/sec, once again giving the impression of quite a wide scatter of results. Although the drop in the mean IPSS is 12.2, which is an impressive decrease, the improvement in PFR is a less impressive decrease, being 3.5 mL/sec and comparable to that achieved by medical management at the same time point.**

In another study from the United States (Hill et al, 2004), 121 men were enrolled in a prospective, randomized, multicenter clinical trial; 65 (54%) were randomly selected to receive TUNA and 56 (46%) were selected to receive TURP. It was reported that 9 of the 65 men (14%) required further intervention in the TUNA cohort, compared with 1 of the 56 men (2%) in the TURP cohort. The requirement for additional medical management in the TUNA cohort was not stated, presumably explaining the difference observed between this study and that described in the previous paragraph. Although this was reported as a 5-year study, only 18 of the 65 men in the TUNA group (28%) and 22 of the 56 (39%) in the TURP were evaluable at 5 years. This makes the 5-year data difficult to interpret despite the highly significant statistical differences described by the authors. At 3 years, the mean IPSS had decreased from 24.0 to 15.2 in the TUNA group and from 24.1 to 10.1 in the TURP group. The mean PFR had improved from 8.8 to 13.0 mL/sec in the TUNA group and from 8.8 to 19.1 mL/sec in the TURP group.

A cost comparison of medical management and TUNA for treating BPH over a 5-year period was performed by Naslund and colleagues (2005). They constructed a cost analysis model using published costs for tamsulosin, finasteride, TUNA, and TURP. They found that over the 5 years tamsulosin was less expensive than TUNA and that finasteride cost the same as TUNA. Combination therapy was more expensive, reaching a break-even point at 2 years and 7 months of treatment. The authors also calculated that TURP is more expensive than TUNA for achieving improvements in IPSS but less expensive for improving PFR.

A meta-analysis of trials of TUNA for treating symptomatic BPH has been reported (Boyle et al, 2004). Meta-analyses are dependent on the data that are put into them. In the case of TUNA, the trials analyzed were often poorly constructed, with inadequate numbers, and not randomized. **In fact, there were 2 randomized trials, 2 nonrandomized observational protocols, and 10 single-aim observational studies. One thing that was consistent, however, was that in all studies the patients had severe LUTS, the mean IPSS at entry being greater than 20. The effect of TUNA was to halve the mean IPSS at 1 year. The shortage of long-term studies makes it difficult to draw specific conclusions, but although there was a tendency for the IPSS to increase in the long term the 50% decrease was maintained. The PFR increased by about 70% from baseline to 1 year. It tended to decline over time, but a 50% or greater improvement was maintained.** One question has not been answered: although the mechanism of action of TUNA is an adequate explanation for the early improvements, how can it explain any positive long-term effect?

Pressure-Flow Studies

There have been six studies that examined relief of urodynamically proven obstruction as an end point, and these are summarized in Table 93–2. The number of patients in each group varies considerably (from 12 to 108), as does the length of follow-up. The largest number of patients are evaluable at 3 months (253), with smaller numbers having been observed to 12 months (140)

Table 93–2.

Pressure-Flow Studies after Transurethral Needle Ablation with 12-Month Follow-up

STUDY	NO. PATIENTS	Detrusor Pressure at Maximum Flow	
		Preop.	Postop.
Campo et al, 1997	72	85.3	63.7
Steele and Sleep, 1997	29	92.4	72.9
Rosario et al, 1997	39	97.0	84.0
Millard et al, 1996	20	70.7	59.9

or even longer. All patients had pressure-flow studies performed before and after treatment by TUNA.

At 3 months the average detrusor pressure (Pdet) at PFR was 85.4 cm H_2O, which 3 months after treatment had decreased to an average of 64.8 cm H_2O (average decrease of 20%). The range at 3 months was 53.2 to 79.0 cm H_2O. It is difficult to draw too many conclusions from these average figures because of the variability in each series, but they do point to the fact that there is a decrease in the Pdet at PFR in most series, if not quite relieving obstruction reliably in every case. At 12 months the average Pdet at PFR was 91.6 before treatment and 73.5 after treatment. In each series there was a small decrease in the difference that had been observed at 3 months.

In another urodynamic study (Minardi et al, 2001), a small number of patients (24) were observed to 24 months. The authors showed that there was initially no change in the prostatic volume or the prostate-specific antigen levels and that pressure-flow studies showed a reduction in the mean opening pressure and Pdet at PFR. **This led them to speculate that the ideal patient for TUNA was a man younger than 70 years with a prostatic volume of less than 6 mL, with a pretreatment Pdet at PFR of less than 60 cm H_2O and residual volume of less than 100 mL.**

Adverse Effects

The adverse effects that occurred in the U.S. randomized study (Bruskewitz et al, 1998) have been alluded to earlier. **By far the most common complication reported, however, is post-treatment urinary retention, occurring at a rate between 13.3% and 41.6%.** It can be expected that within the first 24 hours about 40% of patients experience urinary retention. The second most common adverse event reported is that of irritative voiding symptoms, occurring in about 40% of patients in the early period after treatment. Given the mechanism of the TUNA treatment, this high rate is surprising, but the symptoms are usually mild, lasting between 1 and 7 days.

Urinary tract infection was not commented on in every series, but it was reported in up to 3.1% of patients. It is advisable to give a prophylactic antibiotic to cover the treatment, using whatever regimen the particular urologic department uses for other endoscopic procedures. In this way symptomatic infections leading to epididymo-orchitis or significant sepsis can be completely prevented. Urethral strictures are uncommon, with the highest rate reported as being 1.5%. Hematuria occurs in a large number of treated patients but is almost always mild and short lasting. Patients who are taking aspirin, in whatever dosage, should be advised to refrain from taking it for 7 days before the procedure.

Sexual dysfunction is rare after TUNA. Urinary incontinence has not been reported in any series.

Reoperation

The reoperation rate must be compared with that of TURP. **Although a 14% requirement for reoperation because of lack of efficacy of the primary treatment with TUNA may seem low, it occurred in less than 2 years** (Schulman and Zlotta, 1995). In addition, the 12.7% incidence reported by Steele and Sleep (1997) occurred inside a 2-year period. In the multicenter study reported by Ramon and colleagues (1997), 9 of 76 patients were deemed to have experienced failure of the procedure because of an absence of improvement in PFR. Eight of these patients had no symptomatic improvement, but 5 had an improvement in quality of life.

Indications

The patient most likely to benefit from TUNA would be one who had lateral lobe enlargement and a prostate of 60 g or less (Naslund, 1997). Larger glands can be treated, but more time has to be spent treating each 1-cm segment. Patients with larger prostates, purely bladder neck hypertrophy, or median lobe enlargement are not ideal patients to be treated in this way, but they can be treated; for example, median lobe enlargement can be treated by rotating the TUNA catheter so that the needles point posteriorly, with special care being taken in assessing the depth of their penetration into the prostate.

Summary

The TUNA procedure is simple to perform, and the technology is improving all the time. As long as it is performed carefully, with special emphasis on placement of needles and awareness of the depth of their penetration, complications can be kept to a minimum. With the combination of improved endoscopic visualization of the needles and placement using TRUS, efficacy can be high, with **an average improvement in the mean symptom score of 13.1 symptom units and in the mean PFR of 6 mL/sec to be expected at 12 months. A treatment by some other modality can be expected in 12.7% to 14% of patients within 2 years. TUNA can be given with the patient under topical anesthesia or local prostatic or perineal block, and so it is useful in poor-risk cases also. About 40% of patients have retention within the first 24 hours. The long-term efficacy of the treatment has not been clearly evaluated, with no large series of patients having long-term follow-up.**

TRANSURETHRAL MICROWAVE THERAPY

Transurethral microwave therapy has been much evaluated in the past decade and has been widely used. Many urologists have a high regard for its usefulness in treating patients with LUTS, but, for many others, it has no place in the therapeutic line-up. TUMT has been examined clinically in many centers throughout the world, although the very large number of patients who have been entered into open noncomparative studies may surprise some urologists. The rationale for its effect on symptoms has also been studied carefully by authors from different centers, which is unlike that of many of the other so-called minimally invasive treatment modalities. In addition there has been an evolution in the

Figure 93–3. The Prostatron device. (Courtesy of Urologix, Inc, Minneapolis, MN.)

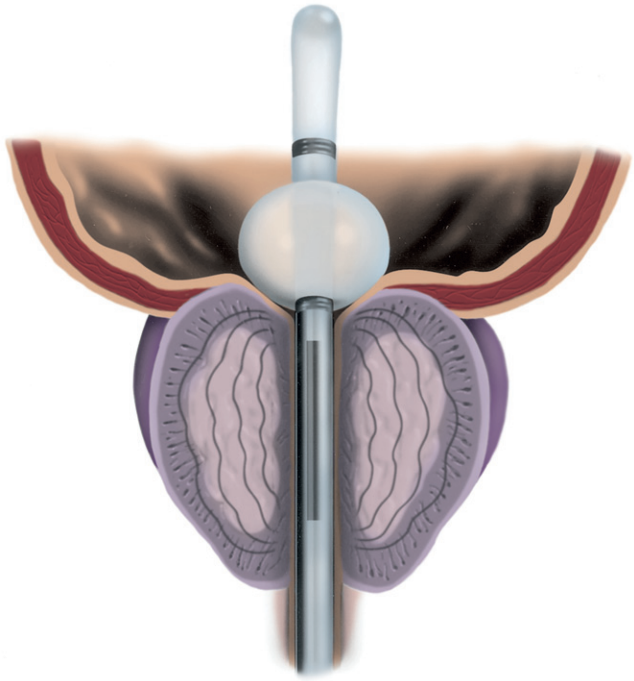

Figure 93–4. The Prostatron antenna, treating the prostatic transition zone. (Courtesy of Urologix, Inc, Minneapolis, MN.)

technology of TUMT (Figs. 93–3 and 93–4), from low-energy to high-energy application, perhaps indicating that this technique has a future in the treatment of LUTS.

The current transurethral method has developed from the early transrectal devices that supplied heat ranging from 42° C to 44° C. The results with this early form of treatment were rather disappointing, and transurethral catheters were developed that would allow higher temperatures to be used while cooling the urethral mucosa. In one of these devices currently used, the Prostatron, the cooling fluid in the catheter maintains the urethral temperature at about 44° C or lower while producing temperatures within the prostate of up to 70° C. The early experimental studies (Magin et al, 1980; Harada et al, 1985; Leib et al, 1986) showed that microwave energy could create high temperatures in the prostate of laboratory animals without damaging the surrounding structures.

Early clinical results using transrectal probes suggested some efficacy (Yerushalmi et al, 1985; Servadio et al, 1987), but overall results were disappointing when tested against sham controls and did not demonstrate that further use of this type of treatment would be beneficial to patients (Zerbib et al, 1992). Later changes resulted in the transurethral method of applying microwave treatment, and this has been further developed, leading ultimately to the sophisticated machines that are being used today. The two most commonly used are the Prostatron and the Targis, but there are several others, all producing similar effects. The Prostatron has three different types of software programs, ranging from relatively low to higher energy: the Prostasoft 2.0, 2.5, and, more recently, 3.5.

Method of Action

The effect of TUMT on prostatic tissue has been studied widely, and a number of different theories, none mutually exclusive, have been presented. These cover heat changes and differential blood flow in the prostate, damage to the sympathetic nerve endings, and induction of apoptosis.

Temperature and Blood Flow

Several studies have been performed that described the interstitial thermal mapping in canine and human subjects (Astrahan et al, 1991; Kaplan et al, 1992; Roehrborn et al, 1992; Devonec et al, 1993). These have all shown that **the temperature varies in the prostatic adenoma, with the area around the urethra being relatively spared from high temperatures and with surrounding tissues such as the rectum also being unaffected.** Some of these studies involved a limited number of measurement sites, the use of periodic rather than continuous temperature monitoring, and difficulties with positioning of the temperature probes.

In an extensive study involving careful and accurate placement of probes, Larson and Collins (1995a) measured temperature gradients within the prostate. Their interstitial thermal mapping method involved the placement of thermosensors using a biplane ultrasound imaging system; this allowed accurate needle

placement in both the anteroposterior and the longitudinal dimensions. In their study they increased the microwave power by 5 W, reaching a maximum of 36 W in 11 minutes and then maintaining an average power of 31.4 W. **In one representative patient, urethral temperature reached a nadir of 21.7° C,** then rose progressively to 40.1° C, and remained between 38.7° C and 41.1° C for the duration of the treatment. Rectal temperature did not show an initial decline but remained at 37.7° C to 39.1° C throughout. Prostatic temperature at a distance of 5 mm radially from the urethra reached 62.4° C about 7 minutes after the initial power maximum and remained between 60.9° C and 68.7° C. At 10 mm radially from the urethra, the average temperature was 50.5° C, whereas at 15 mm it was indistinguishable from urethral or rectal temperature (Larson and Collins, 1995a; Larson et al, 1998b).

Osman and colleagues (2000) performed a study in 13 patients in which they recorded maximum mean peak temperatures of 66.8° ± 13° C at 4 mm from the urethra using the Targis device. No temperature higher than 45° C was recorded beyond 15 mm on either side of the urethra anteroposteriorly or beyond 16 mm on either side of the urethra transversely. **Using gadolinium-enhanced magnetic resonance imaging (MRI), they found postprocedural perfusion defects with means of 28.1% ± 2.1% of the total gland and 63.6% ± 34% of the transition zone volume.**

Histopathologic changes were found to be related to the temperature rises in different parts of the prostate (Larson et al, 1996). **They showed that tissue exposed to a minimum of 45° C** for about 60 minutes suffered hemorrhagic necrosis with uniform extirpation of tissue. The border between viable and necrotic tissue was sharply defined. The histologic changes were related to temperature rises within the prostate, and it was also believed that differences in the thermal sensitivity between stromal and epithelial elements appeared unlikely to account for differences in treatment outcomes. However, there has been some disagreement about these findings. In an evaluation with MRI, Nordenstam and coworkers (1996) did not find that there was significant necrosis in the prostate. Similarly, D'Ancona and colleagues (1999), using the high-energy Prostasoft hardware (Larson and colleagues used the Targis T3), found that histologic parameters were moderately predictive of response; large prostates and prostates with a high epithelium to stroma ratio responded better to high-energy TUMT.

With the use of color Doppler ultrasonography, blood flow changes were estimated during microwave treatment in 2 patients with BPH (Larson and Collins, 1995b). At rest, a comparatively low level of blood flow was seen. **As heat energy was delivered, the blood flow rose in a marked and sustained manner. This increase was seen in the posterior half of the prostate, including the peripheral zone and the posterior half of the transition zone. Marked recruitment of posterior and periurethral vessels was noted. It was also believed that peripheral resistance within the prostatic vessels was reduced.** Therefore these authors in a series of studies linked temperature changes to histologic and blood flow findings. However, the blood flow alterations were performed in only 2 patients, and experimental confirmation with more accurate methods of blood flow estimation is required.

In another study, Larson and coworkers (1998a) **showed that in terms of heating patterns, the Targis antenna (operating at a frequency of 902 to 1928 MHz) gave a more efficient delivery of thermal energy than the Prostatron antenna (operating at a frequency of 1296 MHz).**

Sympathetic Nerve Degeneration

In a histologic study, 10 patients underwent TUMT and some days later had an open prostatectomy (Perachino et al, 1993). Multiple prostatic samples were taken for examination from the periurethral prostatic tissue to a depth of 2.5 cm. The samples were stained with hematoxylin and eosin and with S-100, neuron-specific enolase, and vimentin. The authors found microabscesses, epithelial necrosis, and vasculitis in the prostate. **Compared with controls, it was found that nerve fibers were disrupted, with axons rarely being seen. This study suggested that thermal damage to the adrenergic fibers was behind the improvement in symptoms after TUMT.** The authors did not attempt to quantify their findings. They also believed that the variable response sometimes noted was due to the variable numbers of nerve endings seen in different parts of the prostate.

Support for this theory came from an investigation into human prostatic α_1-adrenergic receptor density after TUMT. Radioligand-binding assays using ^{3}H-prazosin were performed on prostatic tissue from 25 patients, 10 of whom had received TUMT. Binding was saturable, and a single class of high-affinity binding sites was identified in all cases. **In the controls (untreated by TUMT), the mean α_1-adrenergic receptor density** was 96.4 fmol/mg compared with 71.3 fmol/mg in those who had undergone TUMT, a statistically significant difference. The mean dissociation constants were 0.56 in both groups (Bdesha et al, 1996). These results suggested that there was a significant reduction in prostatic α_1-adrenergic receptor density in the region of the prostate that had been subjected to maximal heating.

Another study has been performed to test this hypothesis, but using a different methodology. Ten patients had TUMT 1 week before scheduled TURP. Biopsy samples were taken, 5 to 6 mm deep, and stained with hematoxylin and eosin and with anti–PGP 9.5, which is a nonspecific neural marker gene product that is immunoreactive to all neurons. With this method, nerve fibers were found in the urethral epithelial layer, lamina propria, and smooth muscle layer of controls. **Almost all of the TUMT biopsy samples had nerve fibers in the epithelial layer and the lamina propria, but there were no nerve fibers in the smooth muscle layer in virtually all of the specimens** (Brehmer et al, 2000).

Induction of Apoptosis

Seven patients, all with glands weighing more than 100 g, were selected for open prostatectomy, and all had TUMT with the ECP (Comair, Sweden) 915-MHz equipment 2 hours to 1 week before surgery. Specimens were stained with hematoxylin and eosin, and apoptosis was verified by the terminal deoxynucleotidyl nick-end labeling (TUNEL) technique in sections showing histologic changes suggestive of apoptosis, such as pyknotic nuclei and chromatin segregation. Necrotic areas were frequently seen in the prostate to a depth of 4 to 5 cm. Outside these necrotic areas, normal and apoptotic areas were interspersed, the latter confirmed by TUNEL. The author found that **the area of tissue damage seen after TUMT was relatively small compared with the volume of the prostate** (Brehmer, 1997). The heat was implicated as the cause of the apoptosis, but there was no speculation about the exact mechanism whereby it brought this about.

In another study, Brehmer and Svensson (2000) performed culture of prostatic stromal cells from patients undergoing TURP. These were then stained for several cytoskeletal proteins and assessed for apoptosis by light microscopy of cells stained with the

Giemsa nuclear stain, by transmission electron microscopy, and by measurement of caspase-3–like activity, the latter being one of the main effects of apoptosis. The cell cultures were exposed to moderate hyperthermia (47° C). **Twenty-four hours after heat exposure, 76% of the cells were apoptotic, with only 14% of the cells being necrotic.** The caspase activity (indicating increased apoptosis) had increased to about sixfold by 24 hours after heat treatment. The application of moderate heat for a longer period was found to be the most effective way of inducing apoptosis. Higher temperatures for shorter times resulted in a greater degree of necrosis. It was believed that, in vivo, other factors might modify the apoptotic result, such as stromal-epithelial interactions or heat dissipation by increased blood flow.

Thus these studies have shown that there may be several factors involved in the mode of action of TUMT. High temperatures cause necrosis of prostatic cells, whereas lower temperatures for longer periods of application induce programmed cell death or apoptosis. It is possible that the greater prostatic blood flow that has been found during treatment may be an attempt to dissipate the heat and that this may modify the induction of apoptosis. There is also evidence that TUMT causes disruption of α_1-adrenergic receptor nerves in the smooth muscle of the prostate, another possible cause of the beneficial effect of TUMT, but this effect depends on the number of nerve endings in the treated area of the prostate. A further study investigating the combination of these findings and assessing the relative contribution of many of them was reported by Bolmsjo and coworkers (1996).

Clinical Results

The literature on TUMT is characterized by a large number of open studies, much more than any other technology-based treatment for BPH. In addition, many of them are short-term studies; some of those that purport to be longer term have in fact only a small percentage of patients who have reached what might be called long-term follow-up. However, there are also many carefully performed comparative studies, both against sham treatment and against TURP. The lesson that can be learned from these studies about TUMT is that machines delivering higher power yield better results than those delivering lower power. At the same time it might be said that this use of higher energy makes the procedure more complicated in that there is a greater requirement for sedation or analgesia.

Two of the earliest reports investigated, in a small number of patients, the use of the lower energy Prostatron device. In the first of these, **37 patients were treated and at 3 months had an improvement in Boyarsky symptom score from 12 to 8 and an increase in the PFR from 8.4 to 10.8 mL/sec** (Devonec et al, 1991). These results were statistically significant if perhaps not quite so clinically impressive. In another study, 19 patients with LUTS who were not in retention were treated (Carter et al, 1991), but, at 12 weeks, only 9 of these patients were evaluable. The mean symptom score had improved from 12.0 to 2.8 and the mean PFR from 8.2 to 14.3 mL/sec. However, this study could be criticized for the fact that fewer than half of the patients were evaluable at 12 weeks and that the standard deviations of the mean PFRs were very large. The results were elegantly presented in terms of histopathology and technique and spurred many urologists to assess the TUMT in their own departments.

At this stage in the development of the technique the concept was specifically that heat treatment even with lower energy caused necrosis of prostatic tissue. The other ideas about sympathetic nerve damage and apoptosis were introduced later.

Open Studies

In an attempt to find medium- to long-term efficacy results, only studies with a follow-up of 1 year or greater are reviewed. A study performed with the Prostatron 2.0 software (Blute et al, 1993) evaluated 150 patients; 44% of these required oral or intravenous sedation. There were 150 patients, and results were presented from 118 who had Madsen symptom scores before treatment and at 12 months and from 104 who had PFRs. **The American Urological Association (AUA) Symptom Index** (AUA-7 or AUASI, equivalent to the IPSS) **score improved from a mean of 13.7 to 5.4 and the PFR improved from 8.5 to 11.3 mL/sec. A total of 43 patients (36%) required catheterization for urinary retention; 63% required catheterization for 1 week or less, but it was necessary for more than 30 days in 4 patients.** In another study with the same device, 30 patients were treated and 20 of these were evaluable at 1 year. The mean symptom score improvement was from 16.5 to 6.9, and the PFR improved from 7.2 to 10.7 mL/sec (Homma and Aso, 1993). The study reported in 1996 by Baba and coworkers entered 135 patients into treatment with the same device, and although they refer to "durability of response," it can be seen that less than 20% of the total are followed to 2 years and less than 50% for 12 months. They noted that by 2 years 61 patients had been lost to follow-up. The same 3 mL/sec improvement as just mentioned was noted in those evaluable at 1 year.

A 4-year open study observed 187 patients treated with the Prostatron software 2.0 (Hallin and Berlin, 1998). At the end of the 4-year period, 56 were evaluable, although only 9 were truly lost to follow-up because the fate of all the rest was known. A total of 97 patients had needed further treatment for their LUTS. The satisfaction rate was 62% at 1 year, 34% at 2 years, and 23% at 4 years, with 66% having required further treatment and 11% being dissatisfied at the same time point. The authors believed that the patients who would respond best to this treatment were those with a PFR of 10 mL/sec or more or those with an initial irritative score in the lower range. The fact that many patients do not respond to TUMT treatment but that some do for long periods of time was commented on. The patterns of treatment after the introduction of TUMT in Sweden were reported on by Blomqvist and coworkers (1997), who found that the number of TUMT procedures performed in Sweden increased rapidly after the technique was introduced but then decreased equally rapidly. Three years after the introduction of drugs for BPH, the number of men receiving drug treatment was greater than the number of men having both TURP and TUMT annually.

Pressure-flow analysis has also been performed on patients being treated by the lower-energy TUMT (De la Rosette et al, 1995; Tubaro et al, 1995). These authors found that **there was no noticeable change in the Pdet at PFR at 6 months but that there was a marginally greater improvement (although not statistically better) in those with constrictive obstruction as opposed to those with compressive obstruction.** Finally, a series of patients being treated with the Prostatron 2.0 were observed to 5 years (Keijzers et al, 1998). Of the 231 patients treated, only 89 patients reached 5 years without requiring further treatment for BPH. The total number of patients treated in six European centers was 1092. Overall, the improvement in PFR was between 2 and 3 mL/sec and the re-treatment rate relatively high (Francisca et al, 1999).

It was thought that by increasing the energy the results achieved with TUMT could be improved. Of 85 patients treated with the Prostasoft 2.5 protocol, 74 were evaluable at 1 year (De Wildt et al,

1996a). **The mean Madsen symptom score improved from 13.9 to 5.8, and the mean PFR increased from 9.4 to 14.9 mL/sec. The Pdet at PFR improved from a mean of 63.6 to a mean of 38.9 cm H_2O** at 26 weeks. A further study of 116 patients using the same protocol was reported by a European group (De la Rosette et al, 1996), with 67 patients having reached 52 weeks of observation. The Madsen score improved from 13.6 to 4.9 and the PFR from 9.6 to 14.5 mL/sec. More recently, the Prostasoft 3.5 protocol has been introduced and has been found to be well tolerated (Francisca et al, 2000b). Early results of its use in a small number of patients in urinary retention have indicated some value (Floratos et al, 2000).

A large open study was performed into the use of the 30-minute algorithm for high-energy TUMT with the Prostasoft 3.5 protocol (De La Rosette et al, 2000). Of 108 men treated, 86 were evaluable at 6 months (with only 41 at 1 year). At 6 months, the IPSS had improved from 20.0 to 9.3 and the PFR improved from 9.5 to 14.6 mL/sec. The Pdet at PFR decreased from 58.7 cm H_2O at baseline to 46.9 cm H_2O at 6 months. As reflected on the Abrams-Griffiths nomogram, this represented a shift from the obstructed to the equivocal zone for most patients. The mean duration of catheterization after treatment was 17.9 days, with a range of 6 to 62 days. The authors commented that at 3 months all treatment-related complications had disappeared. It was noted that the faster treatment was an improvement on previous methods from the viewpoint of tolerability to patients but had the same subjective and objective improvement as the Prostasoft 2.5 protocol.

In a study using the high-energy T3 Urologix device it was found that at 1 year there was a 63% improvement in symptom score and a 64% improvement in PFR. Urodynamic analysis showed that there was a better improvement in patients with marginal obstruction rather than unequivocal obstruction (Javlé et al, 1996).

A full urodynamic evaluation of the Prostalund Compact Device was carried out by Alivizatos and coworkers (2005). **In this study 38 patients were evaluated, 19 of whom had an indwelling catheter. The treatment lasted a mean of 43.1 minutes, and the maximum intraprostatic temperature achieved was 58.7° C; a mean of 18.4 ± 14.3 g of prostatic tissue was destroyed. All of the urodynamic parameters improved in the patients without a pretreatment catheter. The mean changes were IPSS from 21.5 to 6.5, PFR from 7.2 to 18.1 mL/sec, and Pdet at PFR from 87.5 to 48.4 cm H_2O. In those who had a pretreatment catheter, the PFR at 3 months was 13.2 mL/sec. This is a small series, but the results are encouraging.**

To complete the equipment types the Core Therm–monitored feedback TUMT was used in 102 patients, but only early results were presented, and, of note, the median catheter time was 8.5 days (David et al, 2004). The results of the Cooled Thermo Cath (Urologix) have been published in abstract form (Roehrborn et al, 2005), and again in a small relatively short-term study it is hard to draw too many conclusions, although at 6 months the symptom score improved from a mean of 21.0 to 8.3, with a less encouraging improvement in PFR, from 7.8 to 12.5 mL/sec.

In a prospective cohort study, 31 patients with acute urinary retention were treated with the Targis machine (Djavan et al, 1999a). **By 4 weeks, 29 of the 31 were able to void, with a median time to spontaneous voiding being 3.0 weeks. The flow rate gradually improved to a maximum at 12 weeks.** The authors suggested that this type of treatment is helpful in patients who present with acute urinary retention but are unsuitable for surgical treatment.

A further study attempted to determine the efficacy of high-energy TUMT in treating patients with medically refractory urinary retention secondary to BPH (Kellner et al, 2004). This was a relatively small series of 39 patients, all of whom received treatment. The mean prostate volume was quite large (75.2 mL), but the standard deviation was 57.6. The treatment was unsuccessful in 18%. **Of the 32 patients (82%) in whom success was achieved there was a mean of 1.6 voiding trials, and these patients required a catheter for a mean period of 4.1 weeks after treatment. Only 6 patients (15%) were able to stop their medication for BPH. The follow-up for this study was relatively short, 18 ± 10.2 months.**

Berger and colleagues (2003) evaluated the use of TUMT in a similar but larger group of patients. A total of 78 patients in poor general health presented with acute urinary retention secondary to BPH with a mean prostatic volume of 53.9 mL. The mean follow-up was 34 months (range 6 to 42 months), with 38.5% lost to follow-up (30 patients), but early results in these were evaluable. Three months after the procedure, 68 (87.1%) were able to urinate spontaneously. Of the 68, 5 (7.3%) developed a further episode of retention within 2 years. The catheter was in place for a mean of 21 days, with 6 patients requiring prolonged catheterization. **It can be seen therefore that treating patients in acute urinary retention with TUMT is a possibility, but the requirement for maintaining medical therapy is a cost burden that may limit its acceptability.**

Long-term results are becoming available. Trock and colleagues (2004) reported the long-term pooled analysis of results using the Targis cooled thermotherapy system. Although the article is entitled results of 3 months to 4 years, only 171 of 540 patients had symptoms evaluable at 4 years and only 67 of 524 had a PFR result. In fact, there is no parallel between the number of patients who had a symptom score result or a PFR result at any given time point with a significant dropoff in the number of flow rate results occurring at 2 years. The 4-year results must be viewed with some caution; the mean symptom score fell from 20.91 to 11.54, and the mean PFR rose from 7.91 to 10.94 mL/sec. It was not possible to conclude how many patients dropped out of the study because of lack of efficacy or how many required alternative treatment. In another study using the same technology Miller and colleagues (2003) reported on 5-year data. Of note was that they previously reported on their 1-year and 3-year results in separate publications, but even in this report only 132 of 150 were evaluable at 1 year, 90 of 150 at 3 years, and 59 of 150 at 5 years. The results are similar to those of the multicenter trial mentioned earlier. Other long-term results have been published by Ohigashi and colleagues (2002), showing that in their experience using the Prostatron the durability of successful results was limited.

In another 2-year study (Thalmann et al, 2002), 200 patients with urodynamically proven outflow obstruction were found to have derived benefit from TUMT. However, as observed clearly by the authors, 13 (6.5%) were lost to follow-up, 15 (7.5%) had died, and 43 (21.5%) required a second or third treatment (TUMT or TURP). Of the 10 patients who required a repeated TUMT, only 4 voided successfully without obstruction and without requiring another intervention.

TUMT versus Sham Procedure

A short-term, 3-month study compared TUMT (21 patients) with the Prostasoft 2.0 to a sham procedure (19 patients) (Ogden et al, 1993). The mean Madsen score changed from 14.2 to 12.8 in the sham group and 14.5 to 4.3 in the TUMT group. The PFR changed

from 8.6 to 9.2 mL/sec in the sham group and from 8.5 to 13.0 mL/sec in the TUMT group. A further study was performed in which 50 patients were randomly assigned to TUMT or sham treatment (De la Rosette et al, 1994). Twenty-four of the 25 patients in each group were evaluable at 12 weeks. In the sham group, the mean Madsen score had changed from 12.1 to 8.2 and in the TUMT group it changed from 13.2 to 5.9. The PFR had changed from 9.7 to 9.5 mL/sec in the sham group and from 9.6 to 13.0 mL/sec in the TUMT group. **In a U.S. study, 110 patients were randomly assigned to sham treatment (35 patients) or TUMT (75 patients)** (Blute et al, 1996). At 3 months the sham-treated patients had changed their symptom score from 14.9 to 10.8 and the TUMT patients' scores had changed from 13.9 to 6.3. The PFR had changed in the sham group from 7.4 to 9.4 mL/sec and in the TUMT group from 7.2 to 11.5 mL/sec.

A randomized controlled trial compared TUMT with the Prostatron 2.0 to a sham procedure (Nawrocki et al, 1997). There were three groups: group 1 received standard TUMT; group 2, a sham treatment; and group 3, no treatment. Patients were observed for 6 months after treatment. In group 1, the AUASI score improved from 19 to 9.5, in group 2 from 17.5 to 9.5, and in group 3 from 18 to 17. The PFR changed from 8.83 to 9.94 mL/sec in group 1, from 9.44 to 9.49 in group 2, and from 8.79 to 8.47 mL/sec in group 3. That is, there was no difference in the degree of improvement in PFR whether the patient had the machine switched on or off or had no treatment. However, the symptomatic improvement was greater than with no treatment, but once again it did not matter whether the machine was on or off.

In a further study, using the Dornier microwave, 147 patients received TUMT and 73 received a sham procedure (Roehrborn et al, 1998). The AUASI score changed from 23.9 to 18.0 in the sham group and from 23.6 to 12.7 in the TUMT group. PFR changed from 8.1 to 9.8 mL/sec in the sham group and from 7.7 to 10.7 mL/sec in the TUMT group, all observations being made at 6 months. Using the T3 Targis, 125 were treated with TUMT and 44 with a sham procedure and results reviewed at 6 months (Larson et al, 1998b). **The sham group showed a symptom score improvement from 21.3 to 14.3 and the TUMT group improved from 20.8 to 10.5. The PFR increased from 7.8 to 9.8 mL/sec in the sham group and to 11.8 mL/sec in the TUMT group.**

A further sham-controlled study was performed using the ECP system (Brehmer et al, 1999). In this study, patients' results were reviewed at 1 year, and a PFR improvement of 3.6 mL/sec was noted in the TUMT group, with a change of 0.4 mL/sec in the sham group. The changes in symptom score were similar in that there was a relatively smaller improvement in the sham group.

Finally, it is appropriate to include the results of a study in which α-adrenergic blockers were given either adjuvantly or neoadjuvantly in addition to TUMT with the Targis machine. It was found that the use of this treatment improved the early results achieved in the treatment of LUTS (Djavan et al, 1999b).

Sham-controlled studies are helpful in assessing whether the improvement noted after a specific treatment is merely a placebo effect. They are sometimes difficult to justify in that they involve a nontreatment arm, but several have been performed in the treatment of LUTS. In one, results were reviewed at 3 months; and those patients who had had a sham treatment and were not improved were given definitive TUMT (De Wildt et al, 1996b). Virtually all of the sham-controlled studies showed a greater improvement in the TUMT group except one (Nawrocki et al, 1997), in which the results suggested a placebo improvement only. In a further study, in which TUMT was compared with urethral catheterization the changes in symptom score and PFR were no different at 3 months (Mulvin et al, 1994).

TUMT versus TURP

Comparative studies between TUMT and TURP can help to define the exact place TUMT occupies in the management of BPH. For example, the weight of evidence was that it had a therapeutic benefit when compared with sham treatment or when viewed singly. However, it was unlikely that it would compete realistically with TURP in terms of symptomatic or flow rate improvement, and a more valuable approach might have been to concede the battle in terms of efficacy and concentrate almost entirely on post-treatment morbidity.

The earliest comparative trial against TURP randomly assigned 39 patients to TUMT and 40 patients to TURP (Dahlstrand et al, 1993). **One-year follow-up was possible in 25 and 22 patients, respectively. The mean Madsen symptom score improved from 11.2 to 2.7 in the TUMT group and from 13.3 to 0.9 in the TURP group. The PFR improved from 8.0 to 12.3 mL/sec in the TUMT group and from 7.9 to 17.7 mL/sec in the TURP group.** Both of these differences are statistically significant in favor of TURP-treated patients. Retrograde ejaculation occurred in 25% of the sexually active patients treated by TURP and in none of those treated by TUMT. In addition, the urethral stricture rate was 7.5% in the TURP group but zero in the TUMT group. The authors concluded that the improvements were not as great as with TURP but that the complication rate was much lower, although a detailed evaluation of all the complications would have been interesting.

In a follow-up study the results achieved by these treatments in 69 patients were evaluated at 2 years (Dahlstrand et al, 1997). There were 31 patients treated by TUMT and 30 treated by TURP who had reached 2 years of follow-up. In the TUMT group the Madsen-Iversen score had improved from 12.1 to 2.3 and in the TURP group from 13.6 to 1.2. The PFR increased from 8.6 to 12.3 mL/sec in the TUMT group and from 8.6 to 17.6 mL/sec in the TURP group. The authors carried out pressure-flow studies 6 months after treatment and found that the decrease in infravesical outflow resistance was greater after TURP than after TUMT. However, they also found that when the obstruction was calculated in terms of urethral resistance there was a statistically significant decrease in both groups. This is in keeping with other observations on pressure-flow and urethral resistance changes after TUMT, when previous studies had suggested that TUMT induced a change from constrictive to compressive obstruction, with an increased elasticity in the prostatic urethra (Höfner et al, 1993). The long-term complications were not discussed.

The higher-energy Prostatron 2.5 was also evaluated against TURP in a 6-month study (Ahmed et al, 1997). After TUMT the AUASI score changed from 18.5 to 5.3, and, after TURP, it changed from 18.4 to 5.2. The PFR actually worsened slightly from 10.1 to 9.1 mL/sec after TUMT and improved from 9.5 to 14.6 mL/sec after TURP. Pressure-flow studies showed a change from 98.5 to 105.6 cm H_2O in the TUMT group and from 96.7 to 48.8 mL/sec in the TURP group. Obviously, in this study not only did TUMT not relieve obstruction but it also was associated with a marginal worsening of flow rate. However, in spite of this, the improvement in symptom score was exactly comparable to the symptom score of TURP at 6 months. **Complications were higher in the TURP group, but prolonged catheter time (either clean intermittent or indwelling) was more marked in the TUMT group.**

A further comparative study was performed using the Prostatron 2.5 device and comparing results with those of TURP in a prospective randomized trial (D'Ancona et al, 1997). A total of 31 patients underwent TUMT and 21 underwent TURP, of whom 26 and 18, respectively, were evaluable at 12 months. **The Madsen symptom score improved from 13.3 to 4.2 in the TUMT group and from 13.8 to 2.8 in the TURP group. The PFR improved from 10.0 to 16.9 mL/sec in the TUMT group and from 9.3 to 18.6 mL/sec in the TURP group. Pressure-flow studies showed that whereas 62% of the TUMT group and 76% of the TURP group were obstructed before their respective treatments, at 6 months 40% and 15%, respectively, were still considered to be obstructed.** All of the TUMT procedures were done as day cases, and the average number of days in hospital for patients having TURP was 4.1. The length of catheterization was 4.1 days for TURP with a range of 4 to 5 days and was 12.7 days for TUMT with a range of 6 to 35 days. The incidence of urinary tract infections was 4% and 16%, respectively. Irritative voiding symptoms were present in 19% of those who underwent TURP and 29% of those who were treated by TUMT.

Later evaluation of these results took place at a mean of 2.4 years, although 17 of 31 patients who had TUMT and 12 of 21 who had TURP were all who remained in the study. Eight of the original 31 TUMT patients and 1 of the 21 who had TURP required alternative treatment. The Madsen score improved from 13.3 to 5.8 in the TUMT group and from 13.8 to 3.6 in the TURP group. The PFR increased from 9.3 to 15.1 mL/sec in the TUMT group and from 9.3 to 19.1 mL/sec in the TURP group (D'Ancona et al, 1998).

A full quality of life study was performed on 147 patients randomly assigned to either TUMT with the Prostasoft 2.5 protocol or TURP. It was found that both treatments had a positive effect on various aspects of quality of life. The areas of perception of urinary difficulties and daily activities particularly were improved. However, TURP caused a greater improvement in both quality of life and clinical outcome, with neither treatment influencing sexual function (Francisca et al, 2000a).

Overall, the main complication, particularly with the higher energy TUMT, was prolonged catheterization and, with it, urinary infection. It would seem that sexual side effects such as erectile dysfunction and retrograde ejaculation were significantly less common than after TURP.

There have been two systematic reviews of the literature, which give level I evidence concerning the value of this technique. It must be remembered that these reviews are only as good as they are allowed to be by the data put into them. One of the issues characterizing the entire technology in BPH literature is the large number of poorly constructed trials that have been performed.

The first of these systematic reviews came from an Australian group attached to the Royal Australian College of Surgeons (Wheelahan et al, 2000) and covers trials performed up to 1999. **It found that TUMT offered less morbidity than TURP but was not as effective as TURP in improving symptoms or reducing BOO. TUMT was associated with a lengthy period of catheterization after treatment, thus causing the higher rates of urinary tract infection and urinary retention. The durability of TUMT, which showed that 23% of patients remained satisfied with a single such treatment after 4 years, was not particularly convincing. The authors concluded that it was not possible to determine the safety and efficacy of TUMT because of the poor-quality evidence base.**

The second systematic review came from the United States and included all the trials from the previous review up to 1999 but added four other papers up to 2002 (Hoffman et al, 2004). The authors were specific in including only randomized trials of TUMT and TURP and found that this meant only 6 of 26 possible trials could be reviewed, with 540 participants (322 TUMT, 218 TURP). Without being directly critical of the standard of these trials, the authors outlined clearly the shortcomings of each of them, showing a lack of uniformity that makes it difficult to draw definite conclusions. **The pooled mean PFR increased from 7.9 to 13.5 mL/sec after TUMT and from 8.6 to 18.7 mL/sec after TURP. Only two studies reported a mean PFR after TUMT that had reached 15 mL/sec or greater.** The authors were unable to find statistically significant differences between low-energy and high-energy systems. Only four studies provided a follow-up of 12 months or greater with 85% to 93% of patients available for follow-up. There was an absence of comprehensive reporting of adverse perioperative events in most of the trials, but the findings of previous systematic reviews in this regard appeared to remain the same. **The very definite conclusion once again was that TURP produced greater improvement in symptom scores and PFR and that fewer men required re-treatment for BPH than with TUMT. The recommendation was that further research was required to evaluate the long-term efficacy and safety of TUMT.**

Summary

TUMT is not as effective as TURP in improving the objective signs of outflow obstruction, in terms of either PFR or Pdet at PFR. However, it does seem to have a measurable effect on the prostate because the elasticity of the urethra is increased after treatment.

The symptomatic improvement that occurs after TUMT seems to be energy related. However, the surprising finding is that even when no objective signs of improvement are seen in comparative trials, the improvement in symptom score caused by TUMT can be considerable. Whether this is a placebo effect or not is unclear because in the two trials in which it occurred the results are given only from the 6-month time point, at which the placebo effect would be at its maximum. Long-term results from these two trials are needed.

Complications are less than with TURP, with prolonged catheterization and infection being the most common. However, the fact that the procedure can be performed as a day case with the patient under mild sedation is an important positive side of the procedure. **The success associated with this treatment cannot be guaranteed in every patient, as can be seen from the relatively high number of nonresponders in many series.** Why this should be is unclear, but several possible explanations have been given and were outlined earlier.

It would seem that the higher-energy devices will be used preferentially to those producing lower energy, but long-term studies, particularly multicenter studies, would be particularly helpful in being able to assess them fully. Because it is clear that TUMT does not outperform TURP, it is to be hoped that trials will be aimed specifically at assessing the exact place of TUMT in the treatment of symptomatic BPH and that the standard of trials will improve.

LASERS

The introduction of the laser as a treatment option for BPH was greeted by urologists and patients with a high degree of expectancy. However, as with other types of minimally invasive therapy, an initial excess of optimism gave way to realism, with the development of a clearer view of the indications for this type of treatment and, indeed, of its limitations. Newer modifications have taken place, allowing even an endoscopic "enucleation" to be performed. When the original laser techniques were introduced, it was hard to predict this being possible, and so it is reasonable to suggest that with technologic advances happening at an increasingly fast rate the laser may well play a greater role in the management of BPH in the future. However, although TURP is now recognized as the gold standard, it was not always the case; in fact, it took TURP several decades to achieve this exalted status. It may be that the absence of randomized clinical trials delayed the ultimate recognition of TURP as the treatment against which all others must be compared. For this reason, large multicenter randomized clinical trials comparing the laser with other modalities are needed for this technology to achieve widespread acceptance; these must be adequately statistically powered and have a sufficiently long follow-up time. In addition, it would probably be a more satisfactory approach if the authors of these trials tried to find the exact role of the laser in the treatment of BPH rather than suggesting that it is a method that will supplant TURP. It is likely that both methods of treatment will have a role to play, but that of the laser still needs to be accurately defined (Fitzpatrick, 1998, 2000).

The volume of papers in the literature on lasers has increased beyond all expectations in the past decade. This reflects a continuing interest in the technology and a belief on the part of urologists that the laser will be the way that symptomatic BPH should be treated. Many of the older technologies are now of no interest to urologists, but it is to be hoped that the somewhat uncritical approach that was taken toward the earlier lasers will not be taken toward the new favorites, the holmium laser and the photoselective KTP laser.

Types of Laser

As is well known, "laser" stands for light amplification by the stimulated emission of radiation. The mechanism of the operating principle of lasers is a process known as stimulated emission of radiation (Nau et al, 2000). In the laser, a flashlamp gives out high-intensity light, which then bombards a resonator cavity with photons. These excite electrons in the resonator cavity to higher energy status. Most of the photons that come from the flashlamp to the resonator cavity are wasted in the form of heat, with less than 5% being absorbed. For this reason, lasers used in the treatment of BPH require rather elaborate cooling devices.

The electrons in the resonator cavity, which are excited by the bombardment of photons, are caused to jump to higher or "excited state" orbitals. Because of the instability of these excited state orbitals there is a very rapid decay of the electrons, which emit a photon. This process is known as spontaneous emission of radiation. However, the emitted photon has the energy required to interact with other excited state atoms. If this interaction happens, further electron orbital decay and photon emission are induced. This photon has the same characteristics and travels in the same direction as the incident photon. This is known as stimulated emission of radiation and, as stated earlier, is the operating principle of lasers. These photons leave the resonator cavity as a coherent laser beam.

There are four types of laser that can be used to treat the prostate.

Neodymium:Yttrium-Aluminum-Garnet Laser

The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser emits light at a wavelength of 1064 nm, and its active medium consists of neodymium atoms in an yttrium-aluminum-garnet rod. Because this light is poorly absorbed by water and body pigments it can penetrate tissues relatively deeply. This poor absorption in a fluid medium causes thermal coagulation of the surface tissue and of areas just under the surface. The tissue that has been coagulated becomes white, and hemostasis is total. Subsequently, the coagulated tissue sloughs, and this may occur over a period of some weeks. It may take up to 3 months to achieve complete healing.

One of the more recent modifications of laser application is the process of tissue vaporization and desiccation, and this can be achieved with the Nd:YAG laser. This technique requires a higher energy density for a longer period of time, and surface carbonization occurs, leading to increased laser light absorption superficially and a limitation of the depth of penetration, further increasing the energy density.

Potassium-Titanyl-Phosphate Laser

The potassium-titanyl-phosphate (KTP) laser uses a KTP crystal to double the frequency of an Nd:YAG laser and produces a 532-nm wavelength. This provides an intermediate level of coagulation and vaporization. Only half the depth of tissue penetration is reached compared with that of the Nd:YAG laser. However, the consequent higher energy per unit tissue volume produced may increase tissue vaporization and desiccation. This may be used as an advantage in that the prostate and bladder neck may be incised with the KTP laser.

Holmium:Yttrium-Aluminum-Garnet Laser

The holmium:yttrium-aluminum-garnet (Ho:YAG) laser emits light at a frequency of 2100 nm. The energy is emitted in a series of rapid pulses over a few milliseconds, the Q-switched laser. This is unlike the continuous wave of the Nd:YAG or KTP lasers. Whereas the same type of standard optical fiber can be used for the Nd:YAG or the KTP laser, a different flexible optical fiber is required for the Ho:YAG laser. Because it produces a cutting effect by vaporization of the tissue water, its hemostatic properties are less than those of the continuous wave lasers.

Diode Laser

With conventional lasers, less than 5% of the electrical input is converted into laser light, and this inefficiency means that conventional lasers require high-energy cooling devices and radiators, thus increasing the size of the machine. The high gain of the diode laser allows the more efficient use of the photons that are generated. Thus the available diode lasers used for medical purposes are small and portable, and special connections are not required.

Methods of Delivery

The energy from lasers can be delivered as follows:

End firing
- Bare tip
- Sculptured tip
- Sapphire tip

Side firing
- Metal or glass reflector
- Prismatic internal reflector

Interstitial
- Bare tip
- Diffuser tip
- Diffuser tip with temperature transducer

Energy levels can be varied, depending on the type of laser, to allow coagulation or evaporation to occur, as alluded to earlier. As with any form of heat treatment, an increase in the temperature of the tissue being treated has different effects, and it is important to be able to control and localize this temperature rise. When the temperature is between 45° C and 50° C, desiccation of tissue occurs, and then, as the temperature increases from 50° C to 100° C, coagulation begins and becomes irreversible. When the temperature exceeds 100° C, the tissue boils and there is resultant carbonization and vaporization.

Coagulation alone may make the procedure imprecise, with danger to neighboring tissue such as the distal sphincter mechanism. During the process of vaporization, tissue water is converted to steam and miniexplosions occur within tissues, increasing the mechanical rupture. The vaporization is determined by the intensity of laser application to tissue rather than its duration. Once the cells become coagulated, laser energy penetrates through them less well, halting the forward process of ablation and increasing backscatter and surrounding coagulation (Stein and Narayan, 2000).

Delivery Systems and Laser Techniques

The laser experience has shown that it is possible to adapt a technique and then evolve it almost completely into something new while still using the same basic form of energy. For example, the evolution from the transurethral ultrasound–guided laser-induced prostatectomy (TULIP) device (Intrasonic, Burlington, MA) to the currently used interstitial and contact devices has been relatively quick but demonstrates clearly the wish on the part of investigators to remove imperfections and to improve results. The aim to find a truly minimally invasive technique is encapsulated in this evolution.

There are two ways in which lasers can have an effect on the prostate, either by coagulation or by vaporization. In the first of these coagulation is achieved at temperatures of 70° C to 90° C. The Nd:YAG laser supplies a wide scatter of power over a relatively large surface area with deep penetration. The second way is by vaporization, which raises the temperature to several hundred degrees Celsius. The power density is high, delivered by a narrow beam. Vaporization can be achieved by using a laser tip that increases the absorption of power by the prostate. **Therefore the factors determining whether coagulation or vaporization occurs are essentially the power density of the laser beam itself, the total energy delivered, and the time for which it is applied.**

The TULIP device was one of the earliest laser systems and consisted of a characteristic balloon, which maintained the distance between the laser beam and the prostate. Also contained in the tip was a 7.5-MHz ultrasonic transducer and an Nd:YAG laser. The probe was moved from the bladder neck to the verumontanum and was then moved to another position, so that, in this longitudinal manner, the entire circumference of the prostate could be treated. The TULIP device has not withstood the test of time in spite of many improvements made to the original model. It is likely that the reason is that urologists prefer being able to visualize a technique directly rather than indirectly by ultrasonography.

Side-Firing Laser

Probably the first study of the side-firing laser was performed by Costello and colleagues (1992) using a canine model. **The energy used was 60 W for a duration of 60 seconds in four quadrants of the prostate, which caused coagulative necrosis.** The canine prostate is different from the human prostate, but it served as an indicator to how the procedure could be performed in humans. Considerable improvements have been made since that time in terms of the laser fibers, the formula for dosimetry, and the technique used.

A large volume of work has been performed on the side-firing laser systems, and this has up to now dominated the literature. **The fiber bends the laser beam at various angles, and this is accomplished by reflection or refraction, depending on the fiber used.**

Reflective systems use a gold-plated mirror or solid gold tip to deflect the beam. The angle of reflection varies from 45 to 105 degrees, with 90 degrees being the most common. There is a further divergence depending on the design of the reflector mechanism that also is variable. This is important because it determines the power density by establishing the size of the laser spot on the prostate. Reflective systems tend to absorb more energy than refractive systems. At present, this type of system is more suited to tissue coagulation. Refractive systems either are glass capped or use a quartz tip to deflect the beam. The angle of divergence is narrow, allowing either coagulation or vaporization.

The most popular method using the side-firing laser is that of coagulation. Some surface vaporization occurs, but most of the tissue is coagulated, followed later by sloughing, which lasts for some weeks. The power settings have been recommended as 40 to 60 W for 60 seconds or even 90 W for 60 seconds. This latter higher power may cause mainly vaporization. In this situation the lack of coagulative necrosis means an absence of tissue sloughing. A hybrid procedure has also been described that combines coagulation of the prostate with contact incision through the prostate.

The technique has also varied in description. One method is the use of a quadrant spot application, or even a sextant approach for larger glands, extending every 1 to 2 cm along the prostate from bladder neck to verumontanum (Kabalin, 1993; Norris et al, 1993; Kabalin et al, 1995). The beam is applied until the treated area becomes white. It is then moved onto a normally colored area, which is then treated until the entire surface of the prostate gland has been rendered white. After an initial increase in prostate size from edema, sloughing of the tissue takes place, with the tissue being passed urethrally.

Another technique has been described (Nau et al, 2000). The treatment begins proximal or distal to the bladder neck, dependent on whether retrograde ejaculation is a factor of importance. If the procedure is begun 1 cm distal to the bladder neck, it can reduce the incidence of this complication from up to 15% to zero, according to these authors. They scan the laser beam either longitudinally or radially. That is, from the beginning of their treatment in the region of the bladder neck, the fiber is scanned distally at a rate of 1 mm/sec to the level of the verumontanum; it is then returned to the starting point and rotated slightly so that the next line of tissue that is coagulated is immediately beside the previously treated line. This is continued until the entire prostate appears white.

Alternatively, a radial scanning technique can be used. With this method, the probe is rotated through 360 degrees at a speed of 1 mm/sec, starting in the region of the bladder neck. The fiber

is then withdrawn 5 mm distally and the circumferential treatment continued. This is repeated at 5-mm distances until the level of the verumontanum is reached.

Contact Laser

Although the technique of the side-firing laser is well described and the results are well known, a number of possible criticisms have led to further evolution of the laser technique. For example, there is difficulty in controlling the distribution of energy and predicting the eventual result; the side effects of post-treatment retention and urethral discomfort with irritable bladder symptoms have also deterred many urologists from using it. These criticisms have led to the evolution of other methods, one of which is the use of the contact laser, which removes some tissue immediately, thereby decreasing post-treatment voiding difficulties (McNicholas and Singh, 2000).

Contact laser tips are made of synthetic sapphire and can be made in different shapes, either conventionally round or in the shape of a wedge. Initially, the size of the tips was 1.5 mm (Watson et al, 1994). The success of these led to the introduction of tips of 5 mm (Bartsch et al, 1994) and most recently to tips of 10 mm (McNicholas and Hines, 2000). A removable side-firing contact probe has been introduced. This allows the surgeon to remove the contact tip and replace it with a side-firing free-beam device.

Because the size of the contact tip exceeds the size of the instrument channel of the cystoscope, it is usual to advance the fiber until it protrudes through the end of the instrument and then to attach the contact tip. It is then advanced along the length of the urethra. Special instruments to facilitate the passage of this type of laser have been designed (Press and Smith, 1995).

Once in position, the contact tip should be placed just above the verumontanum and 20 W power applied at this level. After allowing this power to raise the temperature at the treatment position and visually obvious tissue contraction to occur, the tip is advanced proximally in the curve of the prostate to the bladder neck, taking care not to undermine it. This procedure is then repeated, from verumontanum to bladder neck, by rotating the instrument so that a further channel can be cut adjacent to the previous one. At the end of the procedure, a bladder neck incision can be performed if required (McNicholas and Hines, 2000).

Interstitial Laser

The purpose of this method of applying laser energy is to reduce post-treatment voiding difficulty and urethral obstruction because the integrity of the prostatic urethra can be preserved. A small fiber is introduced into the prostate, usually transurethrally, and energy from either the Nd:YAG or the diode laser at low power heats the prostate and induces coagulative necrosis. **The necrotic tissue is removed by the process of tissue repair and is not sloughed off and passed urethrally as with other methods.**

The laser energy is applied to the prostate by one of three possible fibers: (1) a bare fiber, (2) a bare fiber within a cannula with saline solution irrigation, and (3) a fiber with a distal diffusor tip.

In a study by McNicholas and colleagues (1993) **it was shown that the size of the intraprostatic lesion is dependent on the power applied, the duration of treatment, and the vascularity of the tissue.** In addition, the ratio of fibrovascular to epithelial tissue is important. The aim of interstitial treatment is to create spherical lesions of 1 to 2 cm diameter within the prostate. The prostate should be heated slowly to avoid carbonization, which limits the effect of the treatment and prevents further coagulative necrosis.

Two types of laser generators are used for interstitial laser therapy. The Dornier ITT system (Dornier, Germering, Germany, and Kennesaw, GA) uses the Nd:YAG laser to generate 1064-nm energy with a power range of 2 to 100 W. The other generator is the Indigo LASEROPTIC system (Indigo Medical, Johnson & Johnson, Cincinnati, OH). This generator is portable, weighing about one eighth as much as the Dornier system. It is a diode laser generator, which uses a diode pump source and gallium-aluminum-arsenide to generate a 830-nm wavelength with a power range of 2 to 20 W.

The laser fiber is inserted through a standard cystoscope and is passed transurethrally into the prostatic adenoma. With the use of the Nd:YAG interstitial laser, it is left in each position for 10 minutes at 5 to 7 W. The diode laser requires a 3-minute treatment session at each location. The length of the procedure depends on the size of the gland and the type of laser system being used.

The position of the laser tip within the prostate can be visualized by the use of TRUS. It is possible that conventionally positioning the fiber under vision will place it too close to the prostatic urethra, risking urethral damage and edema with resultant post-treatment voiding problems. Issa and colleagues (1998) have modified this using the Indigo laser so that the fiber can enter the prostate at a greater angle, thus keeping it away from the prostatic urethra.

There is no definite agreement about how much tissue should be ablated, with some investigators using a lower number of treatment sites, paying particular attention to the position of the tip of the fiber. Others suggest a more aggressive approach, such as one lesion per 5 to 7 mm^3 (Arai et al, 1996).

Prostatectomy with Holmium Laser

The vaporization techniques described earlier using the Nd:YAG laser with high-energy-density beams at high power (60 to 100 W) at a wavelength of 1064 nm have been effective in removing small amounts of tissue immediately during the procedure. However, it is a relatively inefficient way to do this because of the high power required. The Ho:YAG laser beam is absorbed by water (unlike the Nd:YAG beam) at a wavelength of 2140 nm and causes considerable tissue vaporization.

This technique was first evaluated in canine experiments in 1992 (Johnson et al, 1992) and subsequently with improved technology in 1996 by Kabalin. In the latter study the mean transverse diameter of the defect was almost 2 cm. A surrounding rim of 2 mm of tissue coagulation was also produced.

The methods of using the Ho:YAG laser have evolved because of several modifications in both technology and methodology (Webb et al, 1993; Dennstedt et al, 1995; Gilling et al, 1995, 1996, 1999). The technique has passed through simple vaporization to combined endoscopic laser ablation of the prostate (CELAP) and is now used to resect large pieces of prostatic tissue.

The dual-wavelength Versa Pulse Select laser (Coherent, Inc., Santa Clara, CA) was used, and a maximal power of 60 W in a pulsed mode was used to resect tissue. A 26-Fr continuous-flow resectoscope was modified, and an end-firing bare fiber was passed through it; its position was stabilized by passing it through a 6-Fr ureteral catheter. **The median lobe was first resected by initial bilateral bladder neck incisions and then with a transverse incision just proximal to the verumontanum. The median lobe was then undermined to the bladder neck and detached back into the bladder. The lateral lobes were removed by making incisions at 1 and 5 o'clock and then at 7 and 11 o'clock and then beginning distally and undermining proximally by detaching them**

backward into the bladder. If the lobes were large, they could be cut into smaller pieces. They were retrieved from the bladder with a modified grasping forceps, or more recently using a morcellator, and by irrigation (Fig. 93–5).

Clinical Results

Part of the difficulty with trials using surgical instruments such as the laser is that a placebo-based randomized controlled trial cannot be performed. This effectively means that to test efficacy the laser must be compared against what is accepted as the best method to treat LUTS endoscopically, which is recognized as TURP. Unfortunately, and particularly with the laser (whose name implies modernity and success in the public's mind), this does not exclude a pre-existing bias that might be present toward the laser. In addition, and this is similar to the other technologies for treating BPH, none of the comparative trials is as carefully statistically powered as those testing medical management of BPH. It might be said that a large number of the open studies are too large and that a comparative study should have been introduced at an earlier stage. However, there have been many trials, both open and comparative, and a large amount of relevant information is available.

Transurethral Ultrasound-Guided Laser-Induced Prostatectomy

TULIP has ceased to be used by urologists, but because it was the first to be introduced and is currently out of favor because it has been surpassed by instruments that are easier to use rather than because of its lack of efficacy, it is worth looking briefly at the results achieved with its use.

The initial results came from the TULIP National Human Cooperative Study Group (McCullough et al, 1993; McCullough, 1994). These showed that in a small subset observed for 6 months only (68 of 242 patients) there was a 78% improvement in PFR (6.7 to 11.8 mL/sec), although, as can be seen, the final mean PFR is still rather low, in spite of treatment. There was also a 68% improvement in symptom score. However, 4% of the patients underwent TURP, and irritative symptoms and urgency lasted for 2 to 3 months in a high percentage of patients. When patients were observed up to 1 year, it could be seen that the incidence of post-treatment retention was 22%, with a stricture rate of 5% and bladder neck contractures in 1%.

Schulze and coworkers (1995) carried out the procedure in 89 patients who were observed for a maximum of 1 year. **The mean PFR increased from 7 to 15 mL/sec but was reported as**

exceeding 20 mL/sec in about half. The modified Boyarsky symptom score decreased from 17 to 5 at 1 year. Although it was efficacious in this group, the patients were chosen only as candidates for TURP rather than having strict inclusion and exclusion criteria.

Chatzopoulos and colleagues (1996) evaluated 38 patients with a maximal follow-up of 30 months after the TULIP procedure. **The authors pointed out that the mean symptom score decreased by 54% and PFR increased by 112%. However, an improvement in symptom score was seen in 43.6% and in the PFR in 41%, but in only 28.2% was there an improvement in both.** In addition, reoperation was required in 16% and the incidence of complications was considered high.

In a further study (Horninger et al, 1997) it was found that the efficacy of TULIP, contact laser, and interstitial laser was similar. However, because simpler machines were becoming available, interest waned in the TULIP and techniques with an improved side effect profile were sought.

Side-Firing Laser

The side-firing laser has several advantages over the TULIP technique, related to the ease with which it can be used. The fact that it can be passed through an endoscope and the effect that the procedure is having can be visualized (at least on the urethral surface) make it especially attractive to the urologist. When viewing the results achieved with this technology, the reader must remember that ultimately it should be compared with TURP in terms of efficacy and side effects, to say nothing of cost-effectiveness.

The initial study (Costello et al, 1992), looking at 6-week results in 17 patients, found an increase in the PFR from 5 to 9 mL/sec and an improvement in the Madsen-Iversen symptom score from 15 to 4. Costello and coworkers (1994) reported on 33 patients observed for 3 months. They showed that the PFR increased from 8.5 to 15.2 mL/sec and that the AUASI score improved from 21.5 to 9.5. That the short-term results were encouraging was also supported by a further study (Norris et al, 1993). One hundred eight patients were observed for a maximum of 6 months; the PFR increased from 7.6 to 12 mL/sec, and the AUASI score improved from 22.3 to 9.2. These studies were noncomparative and were performed essentially to find out whether the technique might be submitted to trials against TURP. It can be seen that there is a variation to the PFR improvement in the important series just cited.

However, the longer-term study of Kabalin (1996) suggested that the results could be maintained. **In 227 patients the PFR was 7.3 mL/sec before treatment and the improvement to 15.2 mL/sec at 3 months was still attained through 1 year (17 mL/sec), 2 years (18.3 mL/sec), and 3 years (18.5 mL/sec). The AUASI score decreased from 20.3 to 10 at 3 months and to 5.7 in those who had been observed to 3 years.** Therefore, although a symptom score of 10 after treatment might have appeared disappointing because it is still in the moderately symptomatic range, the fact that it had further decreased to 8 at 1 year and 8.6 at 2 years, with a further drop to 5.7 at 3 years, showed the benefit of long-term follow-up.

The efficacy of visual laser ablation of the prostate (VLAP) has been subjected to urodynamic analysis. James and colleagues (1995) reported on 79 patients waiting for TURP who were treated by VLAP as an alternative treatment. They had preoperative symptom scores and urodynamic evaluation, and these were repeated 3 months after treatment. The AUASI score decreased from 21.4 to 9.4, and the PFR increased from 6.5 to 10.6 mL/sec. **The Pdet at PFR decreased from 74 to 54.2 cm H_2O.** In another carefully performed urodynamic study (Te Slaa et al, 1995), results were assessed preoperatively and at 6 months after the procedure. The IPSS decreased from 21.3 to 5.3, and the PFR increased from 7.9 to 17.8 mL/sec. The percentage of patients demonstrating urodynamically proven obstruction decreased from 80% before treatment to 5% at 6 months after treatment.

All of these were, of course, open studies, but they did lead to a number of comparative studies, in each case against TURP. In 60 patients observed for 6 months it was found that VLAP gave a significantly better result in terms of symptom score than TURP but that TURP gave a significantly greater improvement in PFR (Sengor et al, 1996). However, in a multicenter trial in the United States at six investigational sites, a longer follow-up took place (Cowles et al, 1995). In this study, 115 men who did not have urinary retention were randomly assigned to TURP (59 patients) or VLAP (56 patients); initially, all of these men were observed for 1 year after treatment. The authors showed that VLAP required less operating time (23.4 against 45.2 minutes) and a shorter hospitalization (1.8 against 3.1 days). The AUASI score improved by 13.3 in the TURP group and by 9.0 in the VLAP group, and the PFR improved by 7.0 mL/sec in the TURP group and by 5.3 mL/sec in the VLAP group. The IPSS improvement was statistically significantly better in the patients who had TURP. The authors noted a quality of life improvement in 93.0% of the patients who had TURP and in 78.2% of those who had VLAP.

A further comparative study showed 1-year results in 151 patients (Anson et al, 1995). In this trial, **75 patients were randomly assigned to TURP and 76 to VLAP. In 1 year, the AUASI score had improved from 18.2 to 5.1 in the TURP group and from 18.1 to 7.7 in the VLAP group; the PFR increased from 10.0 to 21.8 mL/sec (improvement of 11.8) in the TURP group and from 9.5 to 15.4 mL/sec (improvement of 5.9) in the VLAP group.** These authors and those of the previously mentioned trials concluded on the evidence described that VLAP was a safe and viable or useful alternative therapy to TURP.

However, the last-mentioned study has been re-evaluated at 5 years (McAllister et al, 2000). **Of the original 151 patients, 109 could be traced; of these, 69 patients had not required further treatment.** In those in whom further treatment was not required and who had not been lost to follow-up, VLAP had produced results comparable with those of TURP. Unfortunately, because this was less than 50% of the original sample, it is difficult to be absolutely certain which patients respond better than others to VLAP. Of the original group treated, 26 patients had required further surgical treatment: 8 of 51 (16%) TURP patients and 18 of 47 (38%) VLAP patients. These authors then admitted that the figures did not support their original conclusion that VLAP could be offered to every patient with BPH.

A urodynamic study was performed on 90 patients having VLAP and 43 having TURP (Jung et al, 1996). This suggested that TURP eliminated obstruction in all patients but that the grade of obstruction was lowered to normal in those treated by VLAP having prostate sizes of 50 mL or less.

The complication rates vary from center to center. The figures related to blood loss and blood transfusion are absolutely clear. Neither the U.K. study (Anson et al, 1995) nor the U.S. study (Cowles et al, 1995) had any patient treated with VLAP requiring a blood transfusion. In fact, two studies have shown that **VLAP can be performed on patients either on full anticoagulation therapy or having abnormal coagulation indices because of hematologic disorders** (Costello and Crowe, 1994;

Kingston et al, 1995). It is also certain that VLAP causes neither "TURP syndrome" nor any particular effect on serum sodium levels (Cummings et al, 1995).

The retrograde ejaculation rate varies from 27% to 33%, urethral stricture rate varies from 0% to 1.8%, and bladder neck contracture occurs in 4.4% (Anson et al, 1995; Cowles et al, 1995). The U.K. study showed a higher incidence of post-treatment dysuria (15% at 3 months) and bacteriuria (28 of 76 patients). The development of post-treatment urinary retention was 30.4% in the patients treated by VLAP by Cowles and colleagues (1995). This has led them and other authors to recommend catheterization after VLAP for 4 to 7 days.

The incidence of post-treatment retention has led some urologists to advocate a "hybrid" technique, in which a side-firing laser is first used to coagulate the adenoma and then a contact laser is introduced to perform bladder neck incisions, usually with a KTP:YAG laser for the latter procedure. Carter and coworkers (1999) found that this technique gave statistically similar improvements in both symptom score and PFRs at 1 year to TURP in a randomized study involving 204 patients. These results were still maintained when viewed at 18 months (Pearcy et al, 1999). In a further but smaller study of 45 patients, TURP was found to be more effective than the hybrid treatment in prostates larger than 40 mL; 38% of patients who had received the hybrid treatment were discharged with a suprapubic catheter, whereas all TURP patients were able to void at the time of discharge from hospital (Tuhkanen et al, 1999).

Contact Laser

In a study performed in the United States (Narayan et al, 1995), **100 patients were treated by transurethral evaporation of the prostate (TUEP) using the Nd:YAG laser and were stratified according to gland size: in 41 it was less than 40 mL, in 39 it was 41 to 80 mL, and in 20 it was greater than 80 mL. The mean improvement of PFR at 6 months was 9.9 mL/sec in the first group and 9.2 mL/sec in the third group;** the mean improvement in AUASI score was 14.6 in the first group and 16.2 in the third group at the same time. The authors believe that the efficacy of the treatment was independent of the size of the prostate gland and also showed that it was effective in patients who presented in acute urinary retention. In this and in another study (Fournier et al, 1996), the length of time that patients required indwelling catheters after treatment was 2.9 to 4.7 days.

In a urodynamic study comparing contact laser vaporization of the prostate with TURP, patients with prostate glands smaller than 40 mL were evaluated before treatment and at 6 months. There was a similar statistical improvement in both symptom scores and PFRs in both groups. The authors also found that both treatments were equally effective in relieving obstruction; the mean Pdet at PFR was 38.3 cm H_2O in the contact laser vaporization group and 31.3 cm H_2O in the TURP group (Tuhkanen et al, 1999).

The Oxford Laser Prostate Trial was first reported on by Keoghane and colleagues in 1996. A total of 148 patients were randomly assigned to contact laser (72 patients) or to TURP (76 patients). **At 3 months the AUASI score had improved by 7.3 in the laser arm and by 11.9 in the TURP arm, a statistically significant difference in favor of TURP.** However, the authors also found that at 3 months there was an equal distribution in bothersome score in both groups. They also found an equal effect on loss of sexual function in both groups (Keoghane et al, 1996). At 3 years the improvement in the mean symptom score was 11.0 for the laser patients and 12.0 for the TURP patients. These improvements were virtually the same as had been noticed at 1 year, indicating that patients had a symptom improvement roughly equal to that of TURP and equally maintained for 3 years. The improvement in mean PFR in the two groups showed a different trend: at 1 year it was 9.4 for TURP and 6.2 for laser, at 2 years it was 4.9 for TURP and 5.2 for laser, and at 3 years it was 2.1 for TURP and 1.8 for laser. That is, the pre-laser PFR was 11.8 mL/sec and at 3 years this was 13.4, having been 17.1 at 1 year. The same downward trend was noticed in PFRs after TURP, which also reached a maximum at 1 year. In spite of a gradual but obvious decrease in PFR after both types of treatment there was no such decrease in symptom scores. At 3 years, 18% of the laser patients and 9% of the TURP patients required reoperation (Keoghane et al, 2000).

Interstitial Laser

McNicholas and colleagues introduced the topic of interstitial lasers with a description of their use in an experimental study (1993). Further experimental results were described by Muschter and coworkers, and, in addition, the first large clinical experience was described (1994). **They had 221 patients with LUTS treated with interstitial laser and observed for 12 months. The results were encouraging, with a mean AUASI score improvement from 25.4 before treatment to 6.1 at 12 months. In addition, the PFR increased from 7.7 to 17.8 mL/sec.** The authors found that the prostate volume (measured by TRUS) decreased by 40%. A further large open study confirmed these results; sexual side effects were few, but irritative symptoms occurred in 12.6% and urethral strictures in 4% (Muschter and Hofstetter, 1995). A further but much smaller study reported 3-month results in 16 patients; the AUASI score decreased from 16.5 to 5.8 and the PFR increased from 8.8 to 11.9 mL/sec (Orovan and Whelan, 1994). A short-term open study on 61 patients revealed a similarly low improvement in the PFR at 3 months, from 6.7 to 10.0 mL/sec, whereas the AUASI score improved from 18.9 to 7.7 (Arai et al, 1996).

All of these open studies show that, at 3 months, the improvements in PFR are less than might have been expected, demonstrating the importance of longer-term studies and the relative lack of value of short-term studies; they also show that large numbers of patients can be treated safely with this technique with a good side effect record, considerably improving on previous laser techniques. However, the results of a comparative trial, against TURP or TUNA, would make interesting reading and would also give valuable clinical information.

In an excellent summary of the procedure, Muschter (1999) reviewed the reported literature, indicating that the interstitial laser technique had been performed on a total of 785 patients. **The length of follow-up was very variable, but improvement in symptom score for 70% was noted overall (range, 32% to 92%). The average improvement in PFR was 98% (range, 35.2% to 203%). The decrease in prostate volume ranged from 8.3% to 41.6%, and the re-treatment rate at 12 months ranged from 0% to 15.4%.**

All of these results are with the interstitial Nd:YAG laser, and results with the more recently introduced diode interstitial laser have not been reported as frequently. Although comparative trials with the diode laser are ongoing, short-term results of small open studies indicate a safe and reliable technology. At 3 months, 25 patients thus treated had an improvement in symptom score from 20.6 to 6.9; the PFR increased from 9.1 to 20.3 mL/sec (De la Rosette et al, 1997). A further open study reported on results in 104 patients reviewed at 1 year (Conn et al, 1999). The AUASI

score showed a mean improvement from 22.4 to 8.3 and the PFR from 8.6 to 14.2 mL/sec. The mean catheterization time after treatment was 4.8 days.

Transurethral interstitial laser coagulation (TUILC) was compared in a small randomized trial with TUMT and TURP (Norby et al, 2002) and was found to be effective but associated with a relatively high morbidity (64%), principally urinary tract infection. In another small noncomparative trial, TUILC combined with minimal TURP was assessed in 41 patients with BOO caused by BPH (Corvin et al, 2002). The authors believed that this combination could reduce the morbidity associated with TURP, which was irrigation fluid absorption and blood loss. The case was not made particularly strongly, because of the absence of a comparator group, that there was an unacceptably high morbidity associated with TURP.

Kursh and coworkers (2003) **described a randomized multicenter trial comparing TUILC and TURP with a 2-year follow-up. They found that TUILC performed well, and although the authors concluded that TUILC was an acceptable alternative to TURP it was noted that 16% of the TUILC group required TURP within the first year. In another small randomized trial, Liedberg and colleagues** (2003) **randomly assigned 20 to a TUILC group and 11 to a TURP group. These authors found a significantly greater improvement in symptom score and PFR in the TURP group and a greater morbidity rate in the TUILC group. Urinary infections occurred in 13 TUILC patients (65%) as against 1 TURP patient. Post-treatment catheterization was required for 24 days after TUILC and 2 days after TURP. In a small study of 28 patients in acute urinary retention, TUILC was performed with urinary infection in 2 and a mean catheterization time after TUILC of 6.3 days** (Nishizawa et al, 2003). **The mean prostatic volume decreased by 19.4% at 6 months, and the IPSS and PFR were 8.0 and 11.2 mL/sec, respectively, at 3 months. In a study of 82 patients observed for a mean of 48.4 months, 29 (35%) were re-treated, 18 (22%) had TURP, and 11 (13%) had additional pharmacotherapy** (Terada et al, 2004).

Holmium:Yttrium-Aluminum-Garnet Laser

The Ho:YAG laser was introduced for use in a number of urologic conditions (Webb et al, 1993) and was then used in combination with the Nd:YAG laser in the treatment of BPH (Gilling et al, 1995).

Prostate resection with the Ho:YAG laser was first reported on 84 patients with a mean follow-up of 4.3 months (range, 1.5 to 9); the mean prostate volume was 50 mL, and the mean resection time was 35.1 minutes (Gilling et al, 1996). Recatheterization was required in 2 patients before they left the hospital and in a further 2 within the first week but was in every case short term. The side effects were minimal, with irritative symptoms and dysuria being negligible. The mean AUASI score improved from 21.3 to 4.1 at 3 months, and the PFR increased from 7.5 to 19.3 mL/sec at 3 months.

A combined review of data in a single center in New Zealand and a single center in the United Kingdom showed that the procedure had been safely performed in 967 patients (Mackey et al, 1998). Of these, 503 had been observed to 3 months, and the mean AUASI score had improved from 20.6 to 7.0 and the PFR increased from 8.8 to 21.1 mL/sec. Because only 33% of the total number had been observed to 6 months, it is difficult to draw conclusions from the results, but the improvements were being maintained (AUASI score, 4.8; PFR, 22.3 mL/sec).

These encouraging results from large open studies led to a comparative trial between two centers in New Zealand and the United States. Patients were randomly assigned to TURP (59 patients) or Ho:YAG prostatic resection (61 patients). In a well-described study, 102 patients were observed to 1 year. The AUASI score improved from 21.9 to 4.2 in the Ho:YAG group and from 23.0 to 4.3 in the TURP group at 1 year. At the time point, the PFR had increased from 8.9 to 25.2 mL/sec in the holmium group and from 9.1 to 20.4 mL/sec in the TURP group. All cases were urodynamically studied; the mean Pdet at PFR decreased from 75.9 to 35.2 cm H_2O at 6 months in the holmium group and from 83.4 to 39.2 cm H_2O in the TURP group. Complications were low and were equal in both groups. Prolonged catheterization was not required in either group (Gilling et al, 1999).

This type of treatment can also be applied to large prostates. A total of 43 patients with prostates larger than 100 g were treated by Ho:YAG prostate resection. The mean catheter time was 19.7 hours, and the mean hospitalization time was 28.4 hours. At 6 months follow-up the AUASI score had improved from 23.5 to 2.8 and the PFR increased from 9.0 to 24.8 mL/sec.

The Ho:YAG laser has been used in both smaller and larger prostates. These are several descriptions of holmium laser enucleation of the prostate (HoLEP) in this context. Thirty-eight men with a mean prostatic volume of less than 60 mL were treated as day cases (Larner et al, 2003). This treatment was found to be safe and effective with outcomes equivalent to those expected from TURP, but it must be remembered that this was not a comparative trial. In another study, Ho:YAG laser bladder neck incision was compared with HoLEP as an outpatient procedure (Aho et al, 2005). HoLEP was superior in producing relief of obstruction, and fewer patients required recatheterization or reoperation. Catheter time, hospital stay, and postoperative morbidity were found to be similar. Both techniques were believed to be effective, but the bladder neck incision was quicker to perform. Using the slightly older holmium technology, holmium laser ablation of the prostate (HoLAP), there was a 7-year follow-up from a study of 79 patients (Tan et al, 2003a). Only 43% of the sample were available for follow-up, the mean AUA score of the remainder was 10.0, and the mean PFR was 16.8 mL/sec. The reoperation rate was 15%.

There have been a number of studies of the use of HoLEP in large prostates. The definition of a large prostate varies, as does the type of trial. Two studies from the same unit in the United States evaluated HoLEP in patients with prostates weighing more than 75 g and more than 125 g, respectively (Kuo et al, 2003; Matlaga et al, 2006). **Of note was the tissue retrieval rate of 1.09 g/min for this technique, with an operative time of 94.7 minutes, a range of 27 to 263 minutes for enucleation, and a further mean of 33.4 minutes for morcellation. If the long operating time was a negative, the fact that the mean postoperative catheterization was 15.1 hours and the mean length of hospitalization was 26.0 hours was a strong positive.**

A number of randomized trials comparing HoLEP with TURP have been performed. The statistical powering of these studies was not commented on in many cases, leading the reader to question the outcomes of the studies. However, the comments of the authors were all clearly in favor of the value of HoLEP to patients with LUTS. Tan and colleagues (2003b) found that HoLEP was superior to TURP in terms of time of catheterization, hospital stay, and amount of tissue removed, but it took almost twice as long

as TURP to perform. It was also superior to TURP in relieving urodynamically proven obstruction at 6 months, but there was no significant difference in the improvement in AUASI score and PFR. Exactly the same findings were produced in other randomized trials (Kuntz et al, 2004a, 2004b; Montorsi et al, 2004). The most recent holmium laser technology, holmium laser resection of the prostate (HoLRP), was subjected to a randomized trial against TURP (Westenberg et al, 2004). There were 120 patients, of whom 73 completed a 48-month assessment. The authors found no difference between the two techniques in terms of urodynamic indices, potency, continence, and symptom scores. As in the other studies, HoLRP took much longer to perform than TURP but was associated with less perioperative morbidity, catheter time, and hospital stay.

There have been three systematic literature reviews, one specifically of holmium laser prostatectomy (Tooher et al, 2004) **and two of laser prostatectomy in general** (Wheelahan et al, 2000; Hoffman et al, 2004). **These reviews showed that there were three randomized controlled trials comparing HoLRP and TURP and two comparing HoLEP and TURP. As with the other minimally invasive procedures, the majority of the studies were nonrandomized comparative studies or case series. The quality of the available evidence was found to be poor in most cases; most studies were lacking information on statistical powering, methods of randomization, allocation concealment, and blinding; had short follow-up periods; and had significant losses to follow-up. All three studies suggested that it was impossible to draw any long-term conclusions but that the laser techniques offered an option other than TURP for treating symptomatic BPH. However, the report of Wheelahan and colleagues** (2000), **which did not look at holmium laser therapy, photoselective vaporization of the prostate, or interstitial laser therapy, stated that safety or efficacy could not be determined owing to an incomplete and poor evidence base.**

Photoselective KTP Laser

Photoselective vaporization of the prostate (PVP) using a high-power 80-W KTP laser (Greenlight PV Laser System, Laserscope, San Jose, CA) has produced an alternative laser technology seen by many as an exciting new advance. KTP/532 laser energy is delivered by a side-firing glass fiber through a 27-Fr continuous-flow resectoscope. Sterile water irrigation is used, and the procedure is performed with the use of spinal anesthesia. The end point of the procedure is the production of a TURP-like cavity that has resulted from complete vaporization of the prostatic adenoma.

The only comparative trial thus far reported is an experimental one using a porcine kidney model, where ex-vivo blood-perfused kidneys were used to verify the hemostatic effect of KTP laser vaporization against TURP-like tissue resection. The laser technique was associated with highly significantly decreased bleeding with larger coagulation zones (Reich et al, 2004).

The remainder of the reported literature indicates a low level of evidence on which to base clinical decision-making. Kumar (2005) treated 18 patients and found a mean 51% reduction in prostate volume, but the follow-up was only 2.8 months. Sulser and coworkers (2004) described their early experience with PVP in 65 patients. The mean operating time was 57 minutes and the mean prostatic volume before treatment was 49 mL. All patients were catheter free by 1 month, but this was only a short-term 3-month observational study. PFR increased from a mean of 7.7 to 18.2 mL/sec, and IPSS decreased from 18.5 to 7.2. There were no major complications. Hai and Malek (2003) reported on only 10 patients who had a mean prostate volume decrease of 27%. There was a significant improvement in PFR and AUASI.

There has been a prospective clinical trial from six American medical centers on 139 men with symptomatic BOO related to BPH, and the 1-year efficacy and safety data have been reported (Te et al, 2004). The mean symptom score had decreased at 1 year from 23.9 to 4.3 and the mean PFR increased from 7.8 to 22.6 mL/sec. No significant complications were noted. The authors conceded that although the results were encouraging, long-term follow-up data were required.

PVP has been performed in 64 men with symptomatic BPH who had large-volume prostates (>60 mL). The mean operative time was over 2 hours (123 minutes), and 62 of the 64 patients were discharged within 23 hours. At 12 months the mean IPSS had decreased from 18.4 to 6.7 and the mean PFR had improved from 7.9 to 18.9 mL/sec (Sandhu et al, 2004). There has also been a report of PVP being performed in 66 high-risk patients, who had an American Society of Anesthesiologists score of 3 or greater; 29 patients were treated with ongoing oral anticoagulants or had severe bleeding disorders (Reich et al, 2005). No major complications occurred, nor was blood transfusion required. The average catheterization time was 1.8 days. The mean IPSS improved from 20.2 to 6.5 at 1 year, and the mean PFR improved from 6.7 to 21.6 mL/sec at 1 year.

Summary

The use of the laser to treat symptomatic BPH has evolved from the relatively cumbersome TULIP technique to other methods that require smaller pieces of equipment or that can treat a wider range of prostates. The difficulties in treating large prostates have been overcome using the newer technology. The minimal invasiveness of the laser has been improved, and the complications, particularly prolonged catheterization, bacteriuria, and urethral strictures, have been lowered very considerably. Cost-effectiveness still remains a question in urologists' minds, but it would appear that quality of life improvement is as good as that achieved with TURP (Arai et al, 2000). Further long-term results from comparative studies are required from multicenter groups, which it is hoped would also answer the question of a higher reoperation rate seen in some long-term laser studies.

Recently, a systematic literature review assessed the evidence presented between 2006 and 2008 for the 532-nm photoselective laser vaporization and holmium laser enucleation of the prostate (Naspro et al, 2009). Although the authors suggested that both of these techniques are promising alternatives to both TURP and open prostatectomy, the quality of the trials was not universally high and the follow-up relatively short in many of them, particularly in the case of the KTP laser. More high-quality randomized controlled trials with adequate follow-up are required.

TRANSURETHRAL RESECTION OF THE PROSTATE

History

TURP, as we know it today, was developed in the United States in the 1920s and 1930s. Nesbit (1975) pointed out that there were several significant factors important in its development: (1) the invention of the incandescent lamp by Edison in 1879; (2) the

cystoscope, developed independently by Nitze and Lieter in 1887; and (3) the development of the fenestrated tube by Hugh Hampton-Young, which allowed the obstructing tissue to be sheared off blindly. Other important factors were the invention of the vacuum tube in 1908 by De Forest, which allowed the constant production of high-frequency electrical current that could be used in resecting tissue. In 1926, Bumpus combined the cystoscope and the tubular punch. Also, at that time, Stearns developed the tungsten loop that could be used for the resection. This was put together by McCarthy in 1932, using a foroblique lens so that he could resect the tissue under direct vision using a wire loop.

In the 1970s the development of the fiberoptic lighting system, together with the Hopkins (1976) rod lens wide-angle system, significantly improved visualization for endoscopic surgery. Previously, the optical system was a series of small lenses placed in a rigid tube. In the Hopkins rod lens wide-angle system the air spaces were replaced by solid glass rods. The spacer tubes were shorter, resulting in minimal obstruction and increased admission of light.

Over the years, TURP, as a treatment modality for obstructing BPH, gained popularity throughout the world. It is now considered the gold standard for the surgical management of BPH. In the 1986 National Health Survey, 96% of patients had TURP when they had surgery done for BPH. It was estimated that 350,000 Medicare patients had TURP that year. However, today there are many medical and surgical alternatives to transurethral prostatectomy, and the number of TURPs has fallen to less than 200,000 per year in the Medicare age group.

Another factor that may have influenced the incidence of transurethral prostatectomy was the formal development of care guidelines for patients with BPH (McConnell et al, 1994). In 1989, the Omnibus Budget Reconciliation Act created the Federal Agency for Health Care Policy and Research (AHCPR). Patient care guidelines were demanded by Congress, and two of the first selected were the diagnosis and management of BPH. **It was the BPH Guideline Panel's recommendation that patients with minimal symptoms should undergo watchful waiting and that if intervention was to be considered in patients who were more symptomatic the patient should be informed of the harms and benefits of each therapeutic modality and participate actively in making the decision, not only whether to intervene but which treatment modality would be his choice.** Many patients opted for a less invasive procedure, although less effective than TURP.

Indications

In 1968, Lytton and coworkers (1968) estimated that the chance of a 40-year-old man having a prostatectomy in his lifetime was approximately 10%. However, Glynn and colleagues in 1985 raised the estimate to 29%. Arrighi and associates (1991), in reviewing the Baltimore Longitudinal Study on Aging (BLSA), believed that men older than 60 years had a 39% risk of requiring surgery in the next 20 years; men 50 to 59 years of age, a 24% chance; and men 40 to 49 years of age, a 13% chance.

There are very few studies of the natural history of patients who are seen initially because of modest symptoms of prostatism without an absolute indication for intervention (i.e., acute refractory urinary retention, recurrent infections). Ball and coworkers (1981) observed 97 patients for 5 years and found that the patients' symptoms were essentially the same in 52% and worse in only 16.5%. The urodynamic studies revealed little change in that group, and only 1.6% of the patients developed retention. Conversely, Birkhoff and associates (1976) observed 26 patients for 3 years and found a 50% to 70% worsening of the patients' subjective symptoms and 71% deterioration in objective criteria. Furthermore, acute retention was unpredictable.

The most common reasons for recommending intervention in a patient with symptoms of BOO and irritability are that the symptoms are moderate to severe, bothersome, and interfere with the patient's quality of life. Mebust and colleagues (1989) noted that 90% of patients undergoing TURP had symptoms of prostatism but 70% had another indication as well (e.g., acute urinary retention, occurring in 27%).

In 1989, the AUA initiated the Guideline Panel for Diagnosis and Management of Benign Prostatic Hyperplasia. Recognizing the significance of assessing the patients' symptoms, a system score was developed by the AUA's Measurement Committee, Winston Mebust, Chairman. Barry (1992) was the senior author of this questionnaire, which came to be known as the AUA-7 Symptom Index (shortened to AUASI and now also known as the IPSS) (Table 93–3). Other scoring systems have been developed, such as those by Madsen and Iversen (1983), Boyarsky and associates (1977), and the International Continence Society Study on BPH. However, the AUASI was validated as to its clarity, test-retest reliability, internal consistency, and criteria validity. The AHCPR took over the AUA BPH Guideline Panel in 1990. The Guideline Panel subsequently recommended a formal assessment of the patients' symptoms, using any scoring system but preferring the AUASI. Patients with mild symptoms (with a score of 0 to 7) were assigned to watchful waiting; those with moderate (8 to 19) or severe (20 to 35) symptoms would undergo further testing or treatment, or both. **The AUASI is not disease specific.** The questionnaire has been given to older women, who obviously do not have a prostate but may have bladder dysfunction, resulting in a significant score. The AUASI was considered to be part of the patient's initial evaluation but did not make the diagnosis of BPH.

The AUASI was adopted at the World Health Organization Consultation on BPH in Paris in 1991 (Mebust et al, 1991). In addition to the AUASI, one global quality of life question was added—"If you were to spend the rest of your life with your urinary condition, just the way it is now, how would you feel about it?" Responses ranged from "delighted" to "terrible." Therefore, not only should the patient's severity of symptoms be considered in deciding whether intervention is warranted, but also how much the patient is being bothered by his symptoms and how they affect his overall quality of life. It should be pointed out that patients having symptoms secondary to an obstructing prostate may have a variation in their symptoms over time. Ball and Smith (1982) noted that 31% of the patients they were observing had improvements in their symptoms. More recently there have been efforts to develop a concise questionnaire to evaluate further the degree to which the condition is bothersome or the impact on quality of life of patients with symptoms from BPH. Such an example is the BPH Impact Index (Barry et al, 1995) (Table 93–4).

Although symptoms constitute the primary reason for recommending intervention, in patients with an obstructing prostate there are some absolute indications. These are acute urinary retention, recurrent infection, recurrent hematuria, and azotemia. A postvoid residual urine has been used by some urologists as an indication, but, as pointed out by Bruskewitz and coworkers (1982), there can be extreme variability within a given patient as to the amount of postvoid residual when this factor is assessed repetitively over

Table 93–3.

American Urological Association (AUA) Symptom Index for Benign Prostatic Hyperplasia

	NOT AT ALL	LESS THAN 1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	None	1 time	2 times	3 times	4 times	5 or more times

AUA Symptom Score = sum of questions A1 to A7 = _____

Modified from McConnell, JD, Barry MJ, et al. Benign prostatic hyperplasia: diagnosis and treatment. Clinical practice guideline no. 8. Rockville (MD): U.S. Department of Health and Human Services, Agency for Health Care Policy and Research, Public Health Service; 1994. p. 1–17.

Table 93–4.

Benign Prostatic Hyperplasia (BPH) Impact Index

1. Over the past month, now much physical discomfort did any urinary problems cause you?	None	Only a little	Some	A lot
2. Over the past month, how much did you worry about your health because of urinary problems?	None	Only a little	Some	A lot
3. Overall, how bothersome has any trouble with urination been during the past month?	Not at all bothersome	Bothers me a little	Bothers me some	Bothers me a lot
4. Over the past month, how much of the time has any urinary problem kept you from doing the kinds of things you would usually do?	None of the time	A little of the time	Most of the time	All of the time

BPH Impact Index = sum of questions B1 to B4 = _____

a period of time. Furthermore, there is no information on the amount of postvoid residual urine that represents the point "that if nothing is done, irreparable damage to the bladder will occur." It was believed by the AHCPR BPH Panel (McConnell et al, 1994) that it might be of some use in following patients who are assigned to watchful waiting. In the AHCPR BPH Guideline, the patient's history is taken with focus on the urinary tract. Many of these patients have other comorbidity problems, and Mebust and colleagues (1989) noted that only 23% did not have a significant medical problem before surgery. The most common were pulmonary disorders (14.5%), gastrointestinal disorders (13.2%), myocardial infarction (12.5%), arrhythmia (12.4%), and renal insufficiency (4.5%). Therefore, a general medical evaluation is warranted.

A urinalysis is also recommended to be sure that the patient's symptoms are not related to infection. A digital rectal examination should be done, taking into consideration the consistency of the prostate, to help the urologist in determining whether the patient has cancer, and also for an estimate of size. The size of the prostate might be important in selecting what type of surgical therapy would be warranted (e.g., transurethral incision of the prostate or, in the very large prostate, an open prostatectomy). A serum creatinine value is also to be obtained. It was noted by Mebust and colleagues (1989) that patients with a serum creatinine level greater than 1.5% had a 25% incidence of postoperative complications versus 17% in those who had a normal creatinine level.

A number of tests are considered to be optional for the urologist in evaluating the patient with moderate to severe symptoms from BPH. Many consider uroflowmetry to be the single best noninvasive urodynamic test to detect lower tract obstruction. However, it should be pointed out that the patient's obstructive symptoms, when evaluated with a formal questionnaire, correlate poorly with uroflowmetry measurements. Furthermore, there is no specific cutoff point at which one can state that the patient is definitely obstructed. **A PFR less than 15 mL/sec does not differentiate between outflow obstruction and detrusor impairment.** Pressure-flow studies are recommended as an optional test.

This is one of the best ways to evaluate a patient's degree of obstruction and detrusor function, particularly when the diagnosis is unclear. However, it is invasive, is uncomfortable for the patient, requires expensive equipment, and requires considerable experience in performing so that the results are reproducible.

A number of tests are not recommended, such as a filling cystometrogram. Although this test can demonstrate uninhibited bladder contractions, it is invasive and does not give much more information than can be obtained from the patient's history of bladder irritability symptoms. **Cystoscopy, done routinely in the physician's office as a diagnostic procedure, is not recommended.** The only reason for performing cystoscopy in the urologist's office is if the urologist needs to know the size of the prostate and its configuration in making a recommendation about the type of therapy that would be useful for the patient (e.g., transurethral incision if a small prostate or an open prostatectomy if a very large prostate). If it is critical for the urologist to know the exact size when deciding whether the patient should have an open prostatectomy, TRUS is more precise than cystoscopy. Upper tract imaging is also not recommended to be performed routinely. Rather, it should be reserved for patients with hematuria or renal insufficiency or for those with a history of urinary infection, urinary tract surgery, or stones.

Anesthesia

Transurethral surgery of the prostate is usually performed with the use of a general or spinal anesthetic. However, Sinha and associates (1986) have reported doing TURP with the patient under local anesthesia. Birch and colleagues (1991) have recommended performing TURP using sedation and local anesthesia. However, they pointed out that the gland size should be less than 40 g. Nielsen and associates (1981) noted no difference in blood loss when the surgery was done with either an epidural or a general anesthetic. McGowan and Smith (1980) evaluated spinal anesthesia versus general anesthesia and found no difference in blood loss, postoperative morbidity, or mortality.

Use of an anesthetic should be individualized. During the procedure, the anesthetist should monitor the patient's tissue oxygen saturation, electrocardiogram, and, if warranted, a serum sodium level, in addition to the usual parameters.

Perioperative Antibiotics

Urinary tract infections can be found in 8% to 24% of BPH patients preoperatively. The infection should be treated before surgery. Prophylactic use of antibiotics, usually a single dose just before the start of surgery, has become the norm; and postoperative sepsis has been kept to a minimum in this way. In patients who have preoperative bacteriuria or a catheter in situ before surgery, the antibiotics should be continued until the catheter at time of surgery is removed. **It is recommended that patients should be given a first-generation cephalosporin in combination with gentamicin before the initiation of surgery.**

Monopolar versus Bipolar Techniques

Traditionally, TURP has been performed using monopolar technology with 1.5% glycine or mannitol as nonhemolytic fluids for irrigation. This technique has been used for a very long time with considerable success, but concerns about TUR syndrome have led to the introduction of bipolar TURP.

The standard monopolar TURP is now being challenged by the use of bipolar resection (Gyrus PlasmaKinetic System, Gyrus Medical, Maple Grove, MD). The rationale for the introduction of this system is that the complications of standard monopolar TURP need to be reduced to improve acceptability by patients. There has been a series of studies with the Gyrus system (Botto et al, 2001; Dunsmuir et al, 2003) and with the Vista CTR system (ACMI Corp.) (Singh et al, 2005). In a small retrospective study, 18 patients had conventional monopolar TURP, and 26 had bipolar TURP. The point was made by the authors that there have been few innovations in TURP technique in recent years and that this latest change has allowed earlier removal of the catheter and earlier discharge from hospital. The fact that all of these studies are short term, nonrandomized, and in some cases retrospective means that the observations on relative complication rates must be taken with some caution. However, this new technology may have something to offer. The Gyrus bipolar system consists of a generator with 200-W capability, an RF range of 320 to 450 kHz, and a voltage range of 254 to 350 V. There is a plasmakinetic resectoscope with a TUR loop of 80/20 platinum/iridium alloy electrode with the active and return electrode on the same axis (axipolar) separated by a ceramic insulator (Botto et al, 2001; Patel and Adshead, 2004).

In a systematic review of the literature and meta-analysis of randomized controlled trials, Mamoulakis and colleagues (2009) compared the two techniques. They found 16 randomized controlled trials with 1406 patients involved. Unfortunately, the overall trial quality was poor. A lack of information about allocation concealment and blinding outcome assessors was very frequently observed and the absence of prevention of statistical errors of bias because of underpowered studies was also commonly noted. Long-term efficacy evaluation of bipolar TURP was not possible and although the numbers of TUR syndrome and postoperative clot retention were significantly less than in monopolar TURP, owing to the relatively small patient volume in each treatment arm, in absolute numbers there was not a great deal of difference between the two techniques. Bipolar TURP may well turn out to be the technology of the future, but it is hoped there will be a number of well-designed multicenter randomized controlled trials with a longer follow-up and a cost analysis to prove this.

Surgical Technique

The surgical technique employed has been described in detail in previous editions of this textbook (Fitzpatrick and Mebust, 2002). It is not necessary to describe the technique in detail, but it is appropriate to show the diagrams of the technique described (Figs. 93-6 to 93-12).

Various surgical techniques have been developed by urologists for removing the adenoma. Every surgical technique employs the principle that the resection should be performed in a routine step-by-step manner. Another technique is demonstrated in Figures 93-13 to 93-15.

Management of Intraoperative Problems

Hemostasis

The amount of intraoperative bleeding depends on the size of the prostate, the length of time required to resect the adenoma, and, to a degree, the surgeon's skill. Arterial bleeding is controlled by electrocoagulation. This should be done as one completes each

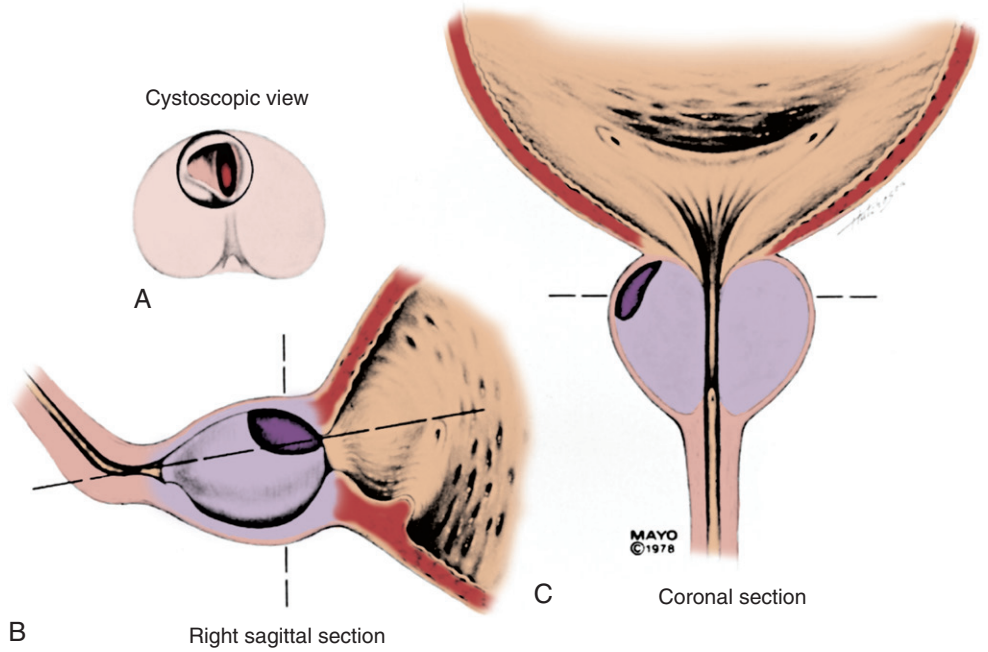

Figure 93–6. **A** to **C,** First stage of resection of the prostate. The resection is begun at the 12-o'clock position, and the tissue at the bladder neck and the adjacent adenoma are resected in quadrants. (©1978, the Mayo Foundation.)

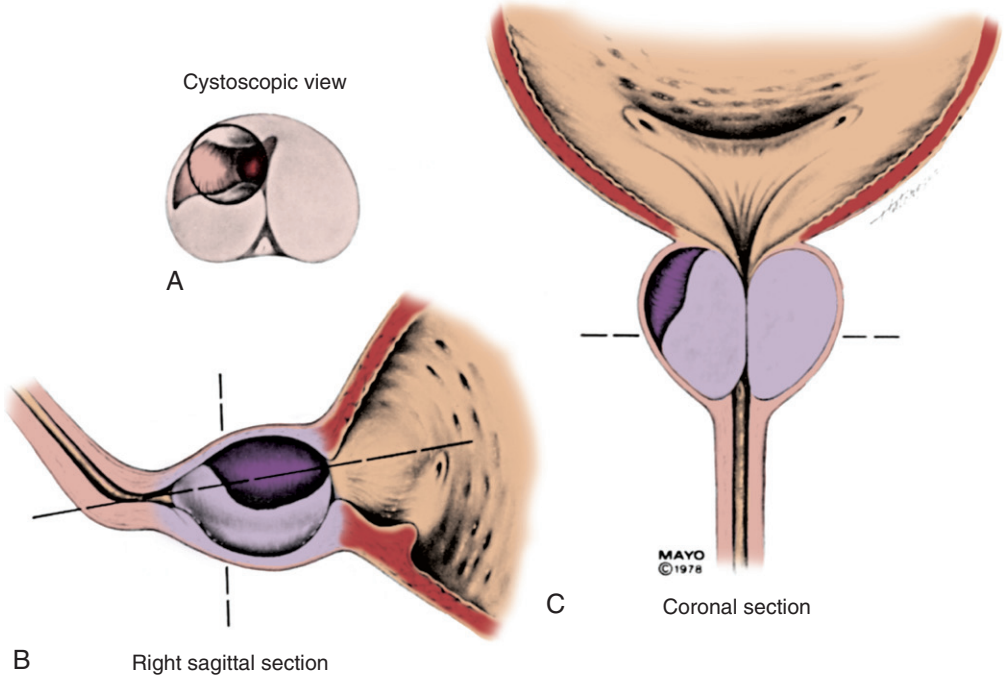

Figure 93–7. **A,** The midportion of the gland is resected starting at the 12-o'clock position and carrying it down to the 9-o'clock position. **B** and **C,** The sagittal and coronal section views are shown. (©1978, the Mayo Foundation.)

stage of the resection, before moving on to the next stage. **After the catheter is inserted, at the end of the surgical procedure, the irrigation fluid should be light pink.** If the irrigation fluid has a continued red color, one should suspect arterial bleeding. The surgeon should reinsert the resectoscope and coagulate the arterial bleeding. Venous bleeding is apparent at the end of the procedure, when on irrigating the catheter the return is initially clear but then dark blood later oozes from the catheter. Venous bleeding can be controlled by filling the bladder with 100 mL of irrigating fluid and placing the catheter on traction for 7 minutes at the operating table. The balloon of the catheter is overinflated to 50 mL of fluid.

Extravasation, or perforation of the prostatic capsule, occurs in about 2% of patients. The symptoms of extravasation are restlessness, nausea, vomiting, and abdominal pain, despite spinal anesthesia. Pain is usually localized to the lower abdomen and back.

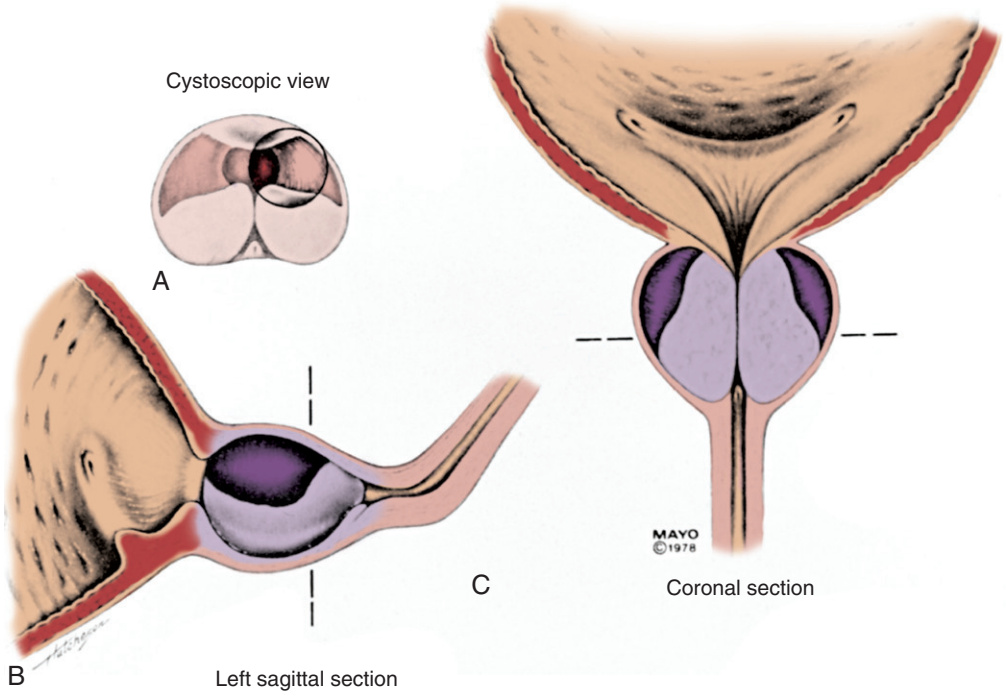

Figure 93–8. **A,** The resection is now begun at the 12-o'clock position, and the left side of the patient's gland in the midfossa is resected down to the 3-o'clock position. **B** and **C,** Sagittal and coronal sections are shown. (©1978, the Mayo Foundation.)

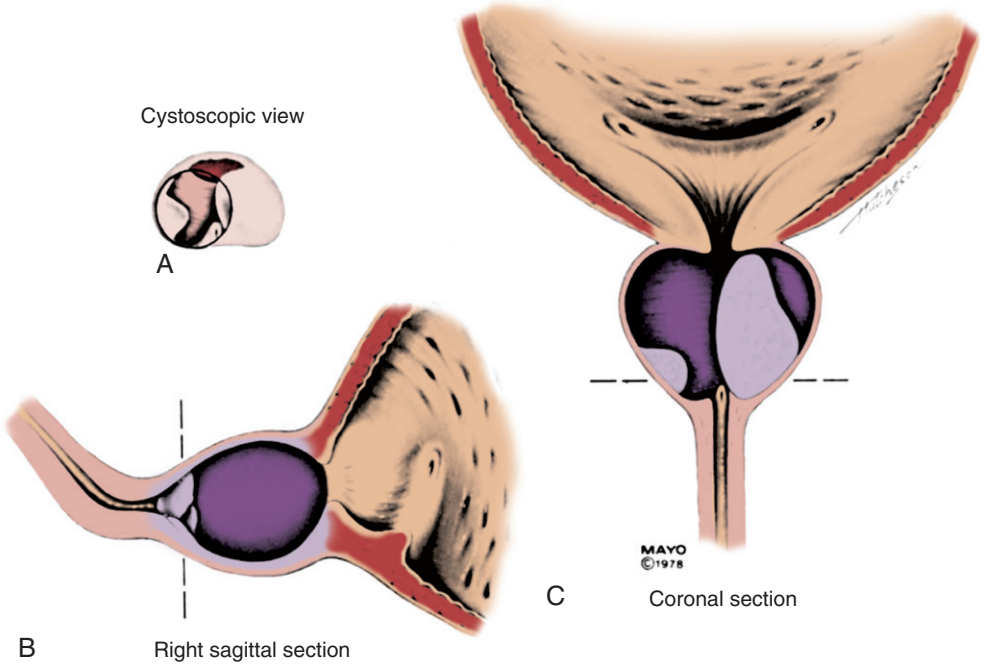

Figure 93–9. **A,** The midportion of the gland is resected farther down from the 9-o'clock position to the 6-o'clock position. **B** and **C,** Sagittal views. (©1978, the Mayo Foundation.)

If extravasation is suspected, the operation should be terminated as rapidly as possible but hemostasis must be secured. Bleeding must be controlled, even as the extravasation is increased, because simultaneous postoperative management of extravasation and hemorrhage is difficult. Cystography may provide information about the diagnosis and, to some degree, the extent of the extravasation. Over 90% of these patients can be managed simply by urethral catheter drainage and cessation of the operative procedure. If there is extensive extravasation and concern about infecting the perivesical tissue, suprapubic drainage should be instituted.

Transurethral Resection Syndrome

In the AUA cooperative study (Mebust et al, 1989), TUR syndrome occurred in 2% of the patients. The syndrome was characterized by mental confusion, nausea, vomiting, hypertension,

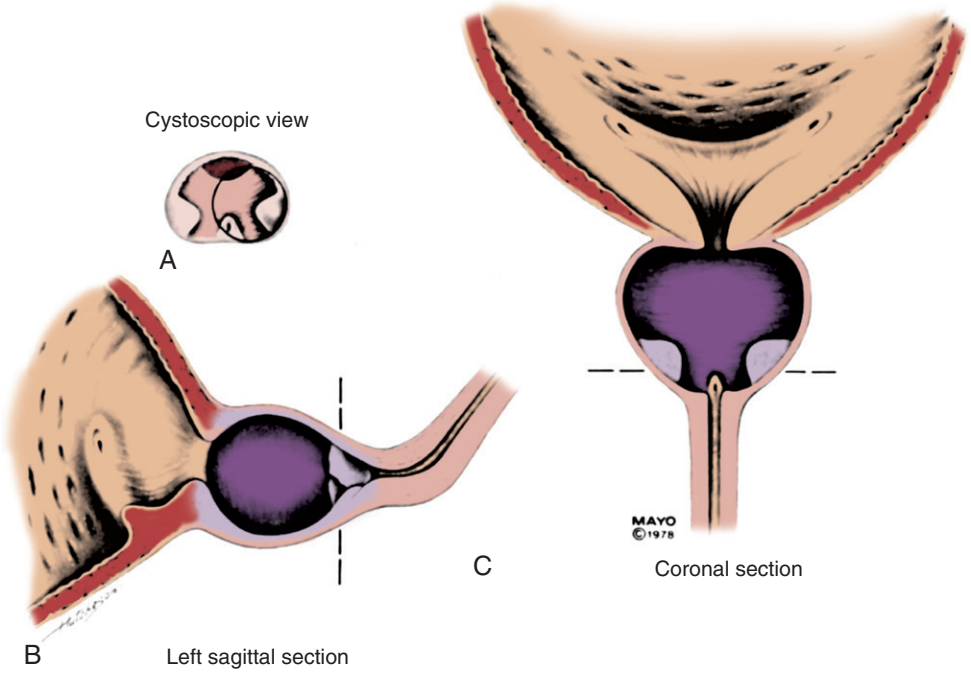

Figure 93–10. **A** to **C,** The tissue remaining at the apex is now resected. It is begun by initiating the resection next to the verumontanum and carrying it toward the 12-o'clock position. (©1978, the Mayo Foundation.)

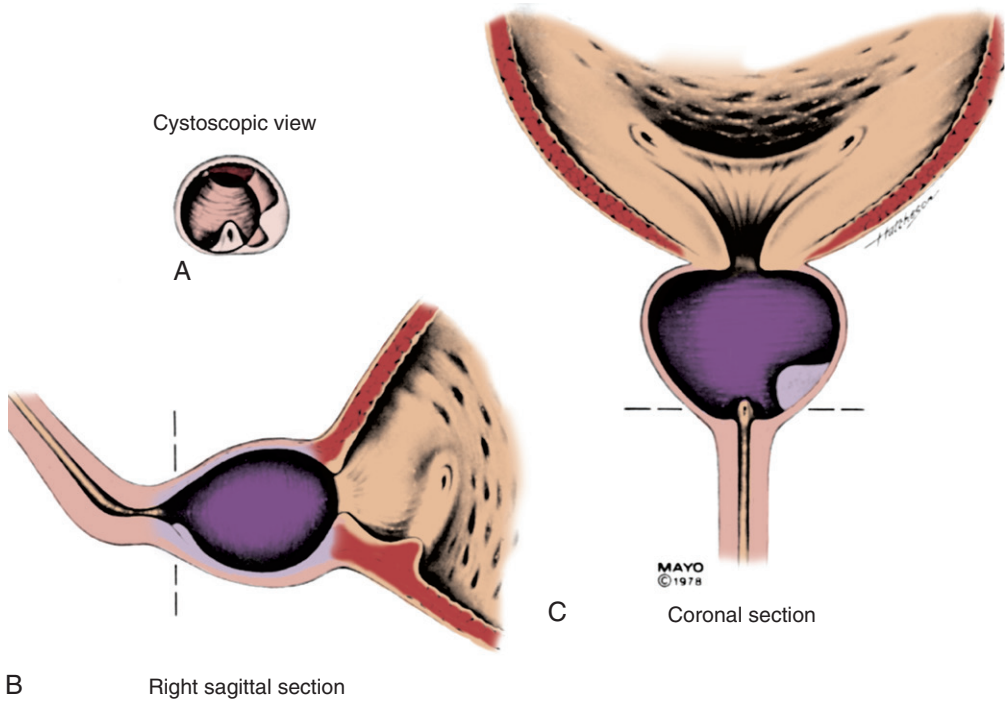

Figure 93–11. **A** to **C,** Residual tissue is carefully cleared on the patient's right side. (©1978, the Mayo Foundation.)

bradycardia, and visual disturbance. Usually, the patients do not become symptomatic until the serum sodium concentration reaches 125 mEq/dL. The risk is increased if the gland is larger than 45 g and the resection time is longer than 90 minutes.

In 1950, several studies were undertaken to determine the amount of fluid absorbed during TURP. Hagstrom (1955) weighed patients preoperatively and postoperatively and calculated that approximately 20 mL/min of fluid was absorbed by the patient. However, there was significant variation in patients. Oester and Madsen (1969), using a double-isotope technique, demonstrated that the average amount of fluid absorbed by the patient was 1000 mL and that one third of this fluid was absorbed intravenously. Madsen and Naber (1973) demonstrated that pressure in the prostatic fossa and the amount of fluid absorbed were dependent on the height of the fluid by the patient. They noted that when the height of the fluid was changed from 60 to 70 cm, fluid absorption was greater than twofold. They also reported that approximately 300 mL/min of fluid was needed for a good vision

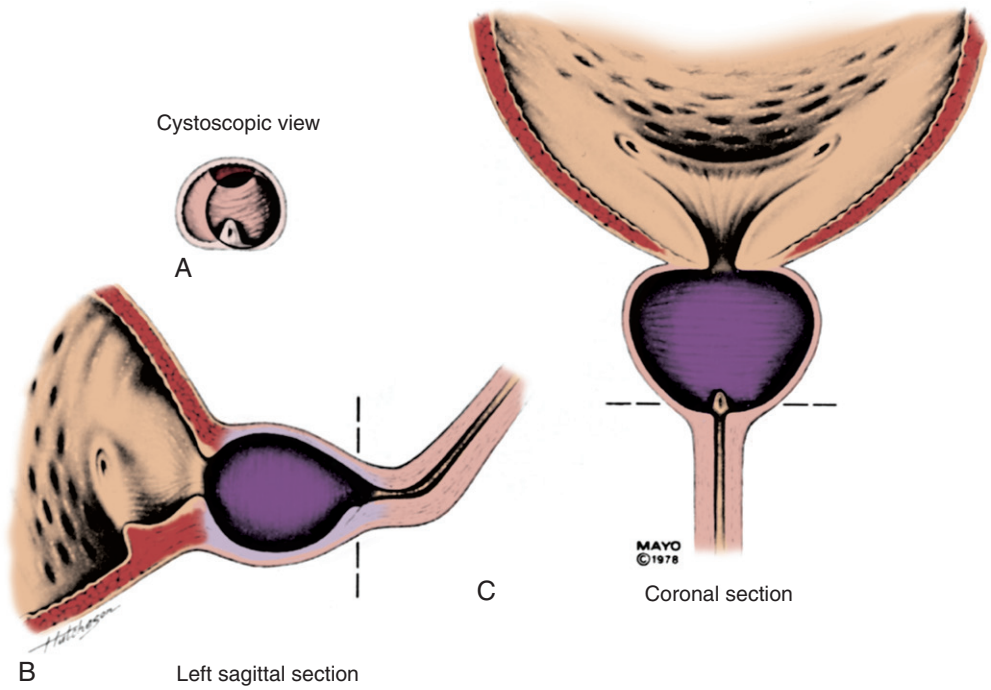

Figure 93–12. **A** to **C,** The remaining residual tissue is cleared from the patient's left side, leaving an unobstructed view from the verumontanum through the bladder neck into the bladder. (©1978, the Mayo Foundation.)

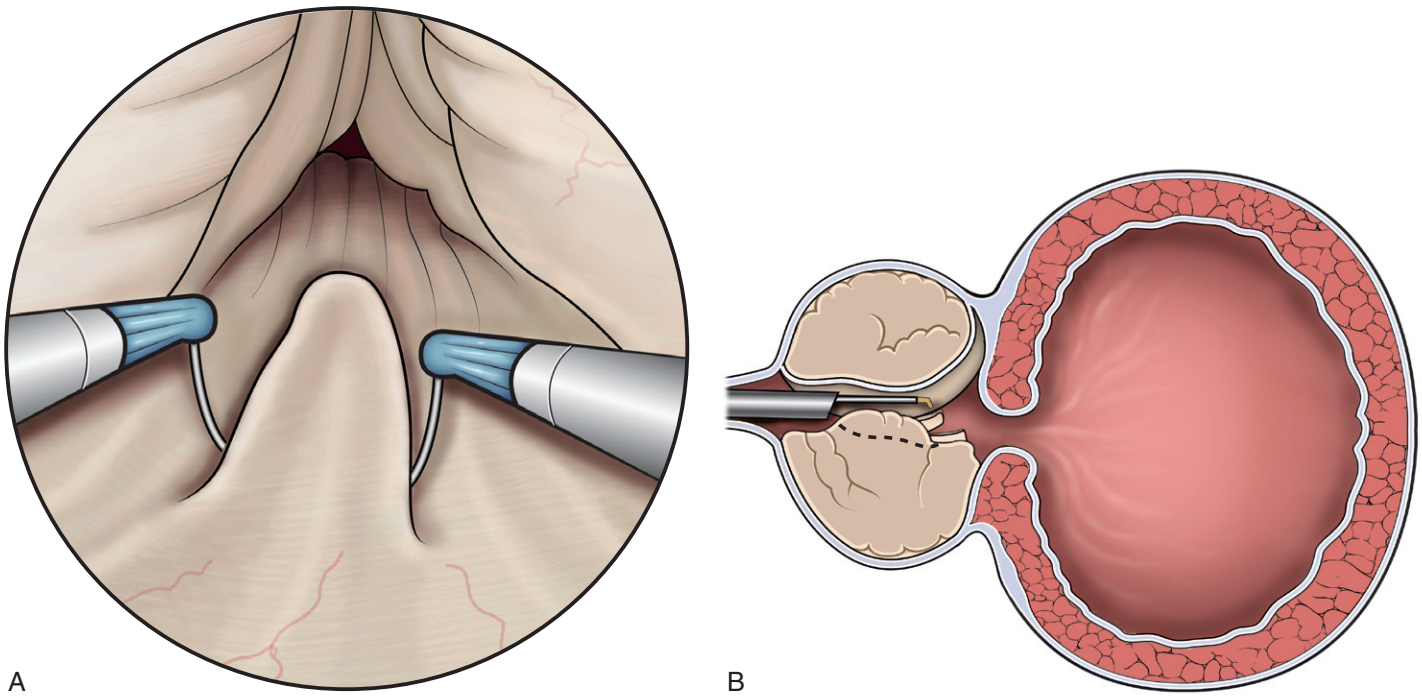

Figure 93-13. **A** and **B,** Resection usually begins at the proximal portion of the middle lobe at the 6-o'clock position. The resectoscope is placed just proximal to the verumontanum and the resection performed always controlling the end point of each cut. It is necessary to be aware of the position of the verumontanum to see that the lower part of the cut is not extending below this level or otherwise damage to the sphincter mechanism may occur. (Modified from May F, Hartung R. Surgical atlas: transurethral resection of the prostate. BJU Int 2006;98:921–34.)

field. This could not be achieved when the fluid level was below 60 cm H_2O. Harrison and colleagues (1956) believed that the TUR syndrome was related to dilutional hyponatremia. Certainly, the syndrome can be reduced by the administration of 3% saline solution. However, other factors have been suggested as a possible cause. Glycine is metabolized to glycolic acid and ammonium. Ammonium intoxication has been suggested as a possible cause of the TUR syndrome or direct toxic effect of the glycine. **Nevertheless, it is our belief that the TUR syndrome is secondary to dilutional hyponatremia.** This can be corrected by

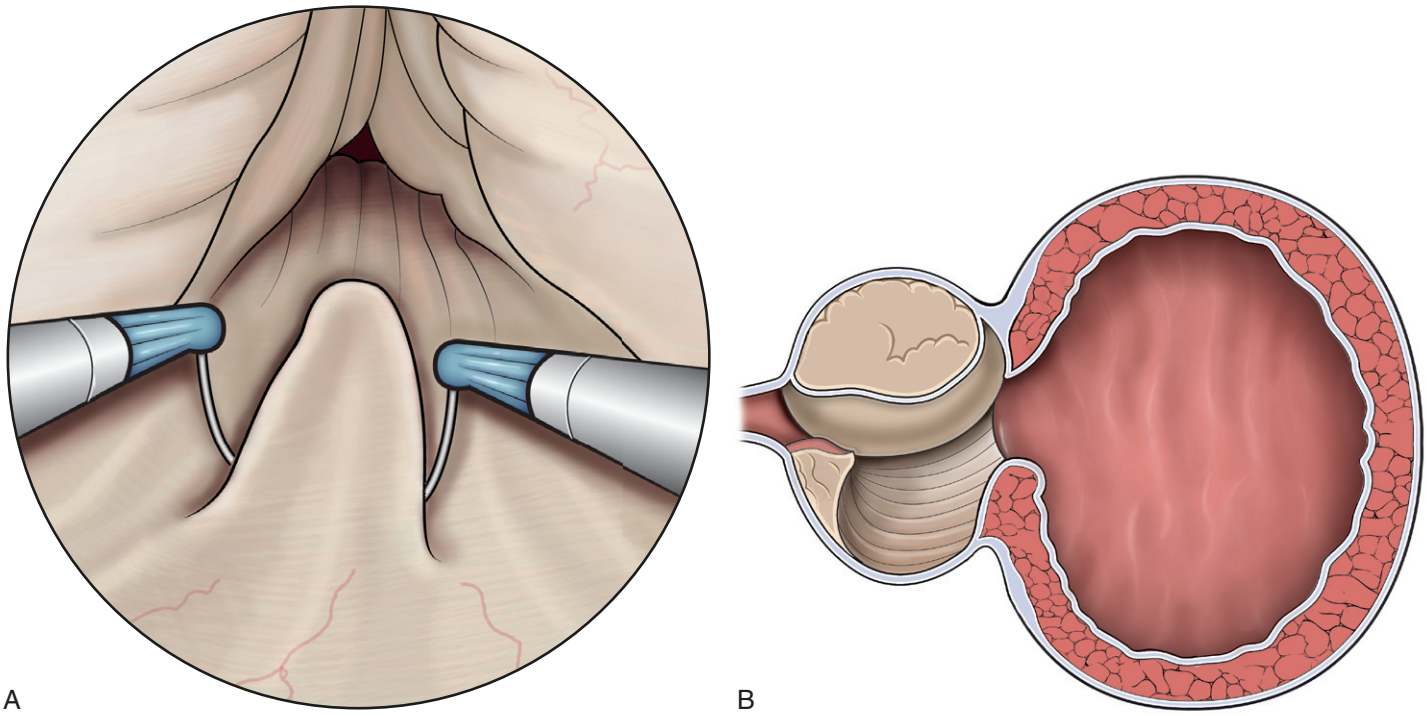

Figure 93-14. **A** and **B,** Resection should be performed with long cuts toward the verumontanum. A large overhanging middle lobe should be resected with special care. It is important to make short cuts in the region of the bladder neck, because the surgeon might not be aware that he or she is cutting down the trigone toward the ureteral orifices. Subsequent cuts are made down to the peripheral tissue, which is recognized as a rather fibrous structure compared with the granular appearance of the prostatic adenoma. (Modified from May F, Hartung R. Surgical atlas: transurethral resection of the prostate. BJU Int 2006;98:921–34).

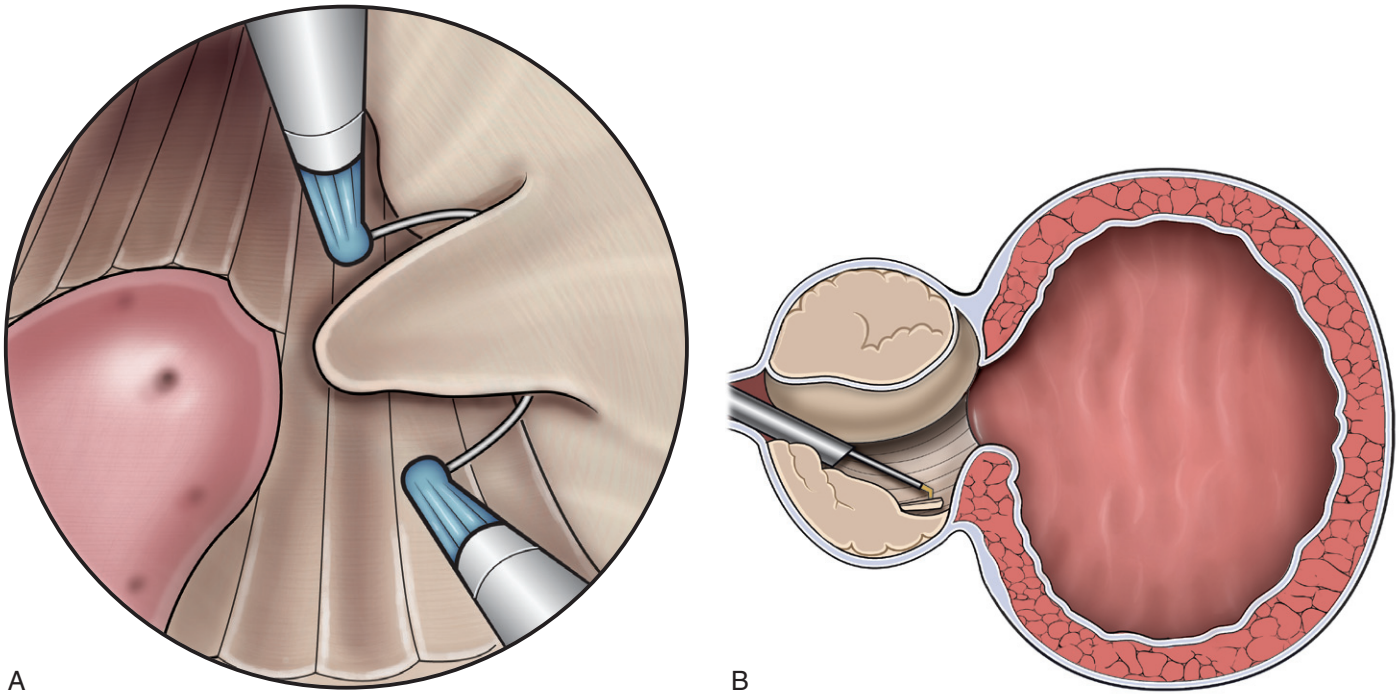

Figure 93-15. **A** and **B,** Resection in smaller adenomas is now carried directly to the side lobe. It depends on the preference of the surgeon whether to begin on the left and then to resect the other side or vice versa. (Modified from May F, Hartung R. Surgical atlas: transurethral resection of the prostate. BJU Int 2006;98:921–34).

giving the patient 200 mL of 3% saline solution very slowly over a period of time.

Conversely, one can attempt to calculate the amount of water overload by determining the serum sodium preoperatively and postoperatively, knowing the patient's weight, and determining the amount of extracellular fluid. Stalberg and coworkers (1992), in patients undergoing TURP with general anesthesia, tagged the irrigating fluid with 1% ethanol and measured the amount of ethanol excreted in the breath. This is believed to be a very effective and quick way of determining which patients are becoming

overloaded with fluid. In patients who have a large gland or when the operating time is being prolonged, a serum sodium value is routinely obtained, although the patient is still undergoing surgery. When patients demonstrate a drop in serum sodium level, diuretics (e.g., furosemide [Lasix]) are administered. The serum sodium concentration is measured in the postoperative recovery area, and, if need be, a further dose of diuretic is administered.

Intraoperative Priapism

During the surgical procedure a penile erection may occur, which may obviate the surgery unless a penile urethrostomy is performed. This has usually been managed by injecting an α-adrenergic agent directly into the corpora cavernosa. The solution of ephedrine or phenylephrine is usually diluted (e.g., 0.3 mL 1% phenylephrine diluted to 3 mL with normal saline solution for 100 μg/1 mL) (Lee et al, 1995).

Outcomes

Patients' Symptoms

In developing the guideline for the diagnosis and management of BPH, the AHCPR Guideline Panel (McConnell et al, 1994) asked patients what was the most significant factor they considered in deciding what type of therapy should be used in treating their BOO secondary to BPH. The foremost factor was relief of symptoms.

In reviewing the literature, the AHCPR Guideline Panel used meta-analysis to combine the various clinical studies. They noted that the chance of improvement of patients' symptoms after TURP was 70% to 96% confidence interval (CI), with a mean of 88%. The magnitude of reduction in symptom score was 85%. **This was significantly better than with less invasive procedures.**

Mortality

Over the past 50 to 60 years there has been a gradual reduction in the immediate postoperative mortality rate associated with TURP. Perrin and colleagues (1976) found a mortality rate of 5%, reported in the 1930s. Holtgrewe and Valk (1962) reported 2.5%; Melchior and associates (1974), 1.3%; and Mebust and coworkers (1989), 0.2%. This was the mortality rate noted at 30 days. The number of patients noted in each of these three studies was well over 2000.

Roos and colleagues (1989), using insurance claim data from England, Denmark, and Manitoba, Canada, noted that the death rate at 90 days was significantly higher compared with an open prostatectomy. They noted an early postoperative death rate of 2.9% in a study involving almost 40,000 patients. A meta-analysis of other series showed a mortality rate of 1.18%. However, including the study by Roos and colleagues with other reports, the mean estimate was 1.5% (90% CI, 0.5% to 0.3%).

In more recent studies, Ala-Opas and colleagues (1993) found no immediate mortality in a series of over 400 patients undergoing TURP. Chute and associates (1991), in an epidemiologic study, compared patients who had TURP with those who did not have TURP and found that the mortality rate over time was identical. Montorsi and coworkers (1993) compared a group of patients who underwent either TURP or open prostatectomy and found the mortality rate in each group was identical. Concato and colleagues (1992) compared a group of patients retrospectively, undergoing TURP or prostatectomy; and, when corrected for comorbidity, the mortality rate was the same for both groups. However, a chart review had been conducted by Malenka and associates (1990) looking at comorbidity factors in the Canadian population. They could not identify comorbidity factors to account for the apparent difference in mortality rate between TURP and open prostatectomy.

Fuglsig and coworkers (1994) age matched a group of patients who had undergone TURP with those who had not, and the mortality rate for the two groups was identical. The mortality rate could not be influenced by many factors, such as the type of hospital where the surgery was performed, the skill of the surgeon, the size of the gland, the operating time, or, again, comorbidity factors.

In reviewing the cause of death in the Canadian series it was found to be secondary to cardiac disease. In the patients who were studied in Denmark, death resulted from pulmonary complications. **This suggests that the observation by Roos and associates** (1989) **was truly related to comorbidity being significant in those undergoing TURP as opposed to those who underwent an open prostatectomy.**

The immediate morbidity rate after TURP was reported by Mebust and coworkers (1989) as 18%. This was similar to the rates reported by Holtgrewe and Valk (1962) and Melchior and associates (1974). Although the incidence was unchanged, in the Mebust report the incidence of significant complications (e.g., acute pyelonephritis) was not as high as that noted in the previous studies. The most common complications in the immediate postoperative period were failing to void (6.5%), bleeding requiring transfusion (3.9%), and clot retention (3.3%). The AHCPR BPH Guideline Panel (McConnell et al, 1994) found a mean immediate postoperative complication rate of 14.95% with a 90% CI of 5.2% to 30.7%. In more recent studies, the immediate postoperative complication rate has been noted by Plentka and associates (1991) (3.1%), Estey and colleagues (1993) (7.8%), and Chute and coworkers (1991) (4.2%). However, these are all retrospective studies.

Wasson and associates (1995) reported on a prospective randomized study in which patients were assigned to either watchful waiting or TURP. **Ninety-one percent of the men had no complication during the first 30 days after surgery. Specifically, there was no difference between either group in the incidence of urinary incontinence or impotence.** The most frequent complications noted were a need for replacement of urinary catheter (4%), perforation of the prostatic capsule (2%), and hemorrhage requiring transfusion (1%). At the end of 3 years of follow-up, the mortality rate was the same for each group. Twenty-three patients in the treatment group were considered treatment failures, and 47 patients were in the watchful waiting group. The failure rate in the watchful waiting group was 6.1 per 100 man-years of follow-up compared with 3 per 100 man-years of follow-up in the surgery group ($P = .002$). The higher rate in the watchful waiting group was largely attributed to a higher incidence of three outcomes: (1) intractable urinary retention (2.9% vs. 0.9%), (2) a high volume of residual urine (5% vs. 1.1%), and (3) a high urinary symptom score (4.3% vs. 0.4%). In those undergoing surgery there was improvement in PFR, reduction in the severity of symptoms, and reduction in the degree to which the symptoms bothered the patient. The authors noted that the outcomes of surgery were best for the men who were most bothered by urinary symptoms at baseline. This study refutes the uncontrolled observations in prior retrospective series that TUR frequently leads to incontinence and impotence, and it confirms that the incidence of short-term complications and re-treatment after surgery is low.

There are few data on the long-term outcomes of patients undergoing TURP. In the study conducted by Wasson and colleagues of 280 men undergoing surgery, at 3-year follow-up, 9 men had vesical neck contracture requiring endoscopic surgery, 9 had a urethral stricture that required dilatation, and 8 underwent a second TUR, 4 because of adenocarcinoma. Bruskewitz and coworkers (1986), in observing a series of patients over 3 years, noted that at 1 year most patients' symptoms improved (84%) and 10% remained approximately the same. At 3 years, 75% had improved and 13% remained the same. The change in symptomatology was the development of urge incontinence occurring in those patients several years after surgery. Only 1 of the 84 patients required a repeated resection, resulting in an incidence of 2%. However, 10% of the patients developed a vesical neck contracture.

Meyhoff and Nordling (1986) noted that 90% of their patients were considered to have satisfactory results at 5 years after TURP. Flow rates were improved from preoperative values, although there had been a slight decline in flow rates over the 5-year period. They did note an 8% re-resection rate, but all patients were noted to have especially small glands, suggesting that these might have been postoperative vesical neck contractures, as had been noted in the prior studies.

Ala-Opas and associates (1993) found that 92% of the patients were satisfied with the results of their surgery 6.5 years after the procedure had been done. Montorsi and associates (1993), in a group of patients observed for 5 years, found that 95% of the patients were unobstructed and subjectively satisfied about their urinary status.

In a large U.K. study, entitled The National Prostatectomy Audit (Emberton et al, 1995, 1996; Neal, 1997), 5361 patients who had undergone prostatectomy were reviewed by questionnaire. The findings were significant because of the large number of patients who responded, representing 89% of all those who had undergone the operation in four health regions of the United Kingdom. It was found that patients who were most bothered by their symptoms had the best response to surgery. The degree of preoperative evaluation varied greatly from urologist to urologist. Men who waited longer for surgery had worse symptoms by the time of their operation. Older men and those of a higher social class were more likely to undergo prostatectomy with fewer symptoms. Twelve percent of men throughout the study were undergoing surgery for the second time, and the clinical course of men having a second operation differed considerably from that of men having a first procedure.

A large study from Australia assessed the mortality and prostate cancer risk in 19,598 men after surgery for BPH. This was a population-based cohort of men in Western Australia operated on over a 17-year period (Holman et al, 1999). It was found that at 10 years the relative survival was 116.5% in patients who had TURP and 123.5% in patients after open prostatectomy. However, the relative risk of 1.20 fell to 1.10 (0.99 to 1.23) after adjustment for comorbidity. It was concluded that any excess mortality risk from TURP was small and clinically unimportant.

Another study found that just looking at mortality after TURP without attention to other issues could be misleading (Hargreave et al, 1996). A total of 81,997 men underwent prostatectomy in Scotland between 1968 and 1989. Although the study confirmed the increased risk of late mortality after TURP compared with open prostatectomy, it was found that limitations in the coding of the comorbidities and the absence of coding of more subtle aspects of the condition of the patient that may influence the choice between different types of prostatectomy mean that the differential mortality after the two procedures could reflect preoperative selection rather than the effects of the procedure itself.

Finally, in a review of 166 patients older than 80 years who had undergone TURP, with a mean follow-up of 60 months, it was found that 88.5% had an American Society of Anesthesiologists operative risk classification of III or IV, indicating a poor risk. All patients had at least one serious associated medical disease. Early complications occurred in 25.9%, late complications in 13.2%, and reoperation in 4.2%. The mortality rate within 30 days of operation was 1.2%, and 43 patients died during the follow-up period. The authors compared the Kaplan-Meier survival curves of the group under review with the expected survival rate of the age-matched population and found no statistical difference (Matani et al, 1996).

Summary

TURP was introduced as a method of treatment that was less invasive than open prostatectomy. Although evidence-based medicine now considers it imperative that a new treatment should be compared in a randomized fashion against a known standard, this did not happen with TURP. Thus it took at least 50 years for it to be accepted as the established treatment and it took even longer for its exact role in the therapeutic armamentarium to be found. Although comparative trials evaluating minimally invasive treatments against TURP in terms of efficacy have lost that particular battle in the majority of cases, the complication rate after TURP has not been thus compared. When looked at without the benefit of comparison in a randomized trial, TURP is still an incomparable treatment for BPH, particularly if the patient has a high "bother" score, has recurrent urinary tract infections caused by incomplete bladder emptying, or has outflow obstruction when measured by pressure-flow urodynamic studies.

TRANSURETHRAL VAPORIZATION OF THE PROSTATE

Whereas TURP removes tissue by resection of prostatic tissue and causes hemostasis by fulguration, transurethral vaporization of the prostate (TUVP) is brought about by combining the concepts of vaporization and desiccation. Desiccation is the drawing out of water from tissue, by drying out, rather than vaporizing the cells. This concept was introduced by Mebust and coworkers (1972, 1977) using a transurethral probe with direct-vision capabilities to heat and desiccate the prostate. TUVP was first described by Kaplan and Te (1995a, 1995b).

Mechanism of Action

With TUVP, two electrosurgical effects are combined: vaporization and desiccation. Vaporization steams tissue away using high heat, and coagulation uses lower heat to dry out tissue. Other factors are also involved that modify the delivery of electrical energy. These include the voltage production by the generator, the current density of the surface area of contact of the electrode, and the electrical resistance of the tissue being treated (Kaplan et al, 1998).

In the case of TUVP the electrode's leading edge is the point at which maximal efficiency for vaporization occurs, as well as that of current density delivery. At the point of the trailing edge of the electrode there is a decrease in the delivery of current, lowering the power and permitting tissue desiccation to occur.

Therefore vaporization occurs at the leading edge and desiccation occurs at the trailing edge (Kaplan et al, 1998).

The power of the generator determines whether vaporization occurs at the leading edge of the electrode. The electricity that is transmitted to the cell is converted to heat, resulting in the cell exploding or drying out. This is dependent on the conduction of electricity by the cell or the tissue resistance encountered by the current. In simple terms, the well-hydrated cell conducts electricity well, whereas the drier the tissue, the greater the electrical resistance. Clearly, a higher power is required to overcome this resistance, which may lead to poor vaporization if the power cannot be varied.

The type of generator used is also important in deciding the effectiveness of the vaporization. Older machines do not have a method of modulating delivery of power to the tissues depending on the degree of resistance encountered. Usually, therefore, the power is switched high to overcome this problem. The balance then is in some cases controlled by the limitation of the amount of current required to maintain a constant power. This safety feature prevents the delivery of an ever-increasing voltage that would compensate for the increase in resistance associated with the drying out of tissue that would occur with vaporization. This could potentially lead to unwanted damage both to the local tissues and to other areas such as the urethra. For this reason, modern generators specifically designed for TUVP can vary the delivery of power by reading tissue resistance. In addition, the safety feature described earlier whereby power can be limited is set at a higher level, thus making TUVP more efficient.

For TUVP, the cutting current power should be set to a maximum of 75% higher power than for a standard TURP, but the power used need not always be as high as this. In fact, it has been estimated that a minimal power delivery of 150 W is required for TUVP (van Swol et al, 1999).

Electrode Design

The *rollerball,* which is traditionally used for fulgurating the base of superficial bladder tumors, can be used for TUVP. However, it should not be used for prostates that are particularly large. In the study by Juma (1996), it was most effective in patients with glands whose mean volume as estimated by TRUS was 31.9 mL. The effectiveness in larger glands is probably limited by the shape of the rollerball, where the most satisfactory vaporization takes place at the middle part of the leading edge, assuming an equal distribution of contact pressure.

A *grooved rollerbar* has been widely used and consists of a bar that is 3 mm wide and 3 mm in diameter, which is composed of nickel-silver and insulated with Teflon (Vapor Trode, Circon-ACMI, Stamford, CT). The design is superior to the standard rollerball because the grooved design increases the number of leading edges at which electrovaporization takes place, and this allows increased efficiency of vaporization to a wide contact area and thus to a larger volume of tissue (Narayan et al, 1996; Reis et al, 1999). A similar grooved electrode has also been produced (Richard Wolf, Germany), known as the EVAP.

New second-generation vaporizing electrodes have been manufactured and evaluated. They have the aim of both vaporizing and resecting prostatic tissue simultaneously and have been termed *vaporizing loops* by some. The technique has been given several possible names in the literature, all amounting to the same thing: transurethral vaporization-resection of the prostate (TUVRP), thick-loop TURP, vapor-cut electrovaporization-resection (Cabelin et al, 2000).

Some examples of these are testament to the inventiveness of many of the instrument companies in relation to design. The Vapor Tome (Circon-ACMI, Stamford, CT) is a thick loop with grooves, giving a thin leading edge for vaporization and a thick trailing edge for desiccation. The Wedge (Microvasive, Natick, MA) is a smooth loop with the same edge configuration, made of stainless steel, tungsten, and chromium. The Wing EVAP (Richard Wolf, Germany) is a semicircular gold-plated wide loop that is wider and thicker than the standard TURP loop (Cabelin et al, 2000). Other modifications are under investigation, in which not only new electrodes but also specific electrosurgical generators are being developed, the aim of which is to reduce side effects while maintaining efficacy and also decreasing the potential risks of high-voltage power to the tissues surrounding the prostate.

Clinical Experience with Electrovaporization

The first report of TUVP was from Kaplan and Te (1995a), using the Vapor Trode. They reported on 25 men with moderate LUTS with a mean prostatic size of 57.6 mL. **There was an improvement in AUASI from 17.8 to 4.2 at 3 months and in PFR from 7.4 to 17.3 mL/sec at the same time.** The most encouraging findings were that all of the patients had their catheters removed within 24 hours (mean, 14.6), but by 3 months 1 patient had developed a distal urethral stricture. In the study by Juma (1996) using the standard rollerball in a study of 20 patients for 3 months, the results were similar, although 1 patient developed a bladder neck stenosis and 1 required repeated TURP.

Other pilot studies also suggested that a comparative trial would be appropriate because of the efficacy and safety that had been demonstrated. Galluci and his colleagues (1996) treated 35 patients with the Vapor Trode and found that improvements at 28 days were as encouraging as those at 3 months in other studies (PFR, 9.8 to 20.74 mL/sec; AUASI score, 18.2 to 10.4), but of note was that the standard deviation of the mean in both cases was very wide. Stewart and colleagues (1995) with the same electrode treated 34 patients, 20 of whom were in urinary retention; 33 of 34 were voiding satisfactorily. In a study of 22 patients subjected to pressure-flow analysis at 6 months, the mean Pdet at PFR decreased from 108 to 39 cm H_2O (Okada et al, 1998). Similar results related to relief of obstruction in 91 patients were reported by Matos Ferreira and Varregoso (1997).

Comparative Studies

All of the pilot studies were short term, none longer than 6 months, but comparative studies were indicated, and several of these compare TUVP with TURP. Patel and colleagues (2000) have carefully reviewed five of these in which different types of electrode were used (Galluci et al, 1996; Patel et al, 1997; Shokeir et al, 1997; Hammadeh et al, 1998; McAllister et al, 1998). **A total of 270 patients had TURP, whereas 262 patients had TUVP. A comparison of complications shows that postoperative irritative symptoms, urinary infection, 1-year reoperation rate, and urethral stricture were the same in both groups. However, catheter duration postoperatively, hematuria, transfusion rate, and retrograde ejaculation were lower in the TUVP group, as was hospital stay.** Operating time, postoperative urinary retention, impotence, and urinary incontinence were higher in the TUVP group. Again, these

were all short-term studies, with follow-up to a maximum of 1 year. In some cases, the numbers of patients who had actually reached 1-year follow-up were not stated. In addition, the range on either side of the mean was quite wide. All of the studies showed significant improvements in symptom score and PFR, which were maintained to the time of maximal follow-up in the study reported.

In most studies the size of the prostate gland operated on was 60 mL or less as measured by TRUS. The follow-up period for these studies needs to be much longer than 1 year so that the comment "TUVP is an acceptable alternative to TURP" can be sustained. In addition, the complication rates in some studies are rather high; for example, the study by De Sautel and colleagues (1998) shows that in a relatively small number of cases TUVP is as effective as TURP in relieving urodynamically proven outflow obstruction, but the overall complication rate for TUVP was 17.5%.

There has been a somewhat longer randomized trial comparing TUVP with TURP (McAllister et al, 2003). In this study, 235 patients with symptomatic BPH were randomly assigned to the two treatment options and it was a multicenter trial from four study centers in the United Kingdom. Forty-five of the 235 presented with acute urinary retention, and for the remainder a reduction in IPSS of 5 or more points was defined as success; statistically, and using this definition of success, 220 patients were required in the study to be able to detect a 15% difference in treatment outcome with 80% power at the 5% level. The mean reduction in prostate volume was the same in both groups, as were the operating time, hospital stay, and the improvement in symptom score, PFR, and postvoid residual volume. The transfusion rate was higher in the TURP group. At 6 months, 9% of the TURP group had become impotent, compared with 17% in the TUVP group, but this difference was not statistically significant.

A meta-analysis was performed comparing the efficacy and safety of TUVP and TURP for symptomatic BOO secondary to BPH. From a total of 25 randomized controlled trials, 20 met the predefined inclusion criteria and were subjected to a formal analysis. A total of 1489 patients were randomly assigned to TUVP (708) or TURP (781). There was a considerable variation in the follow-up, but the median was 12 months. The meta-analysis found a considerable limitation to most of the studies, particularly pertaining to the justification of sample size, randomization, the procedure for concealing treatment allocation, and the appropriate handling of study withdrawals to maintain the principle of intention-to-treat analysis. None of the studies estimated the sample size before starting the study as part of their calculation of statistical power, and only two described how the random allocation sequence was generated. There was also a considerable variation in the method of reporting the outcomes of the individual studies. Once again, this meta-analysis, as others related to other minimally invasive treatments have shown, demonstrates a poor database for drawing meaningful conclusions. However, it did suggest that TURP and TUVP provide comparable improvements in AUASI score and PFR for up to 1 year of follow-up (Poulakis et al, 2004).

Vaporization-Resection

A number of relatively short-term pilot studies using the Wing, Wedge, and Vapor Cut electrodes have been published and have been summarized by Cabelin and colleagues (2000). They have shown that the efficacy and complication rates are the same as with the standard Vapor Trode. The number of patients treated varied from 31 to 91, and the size of the gland ranged from 39 to 59.6 mL. The operating time was long (49.3 to 56.7 minutes), but the AUASI score decreased from 24.3 to 4.1 with the Wing and from 19.0 to 7.2 with the Vapor Cut. The PFR improved from 5.2 and 8.9 to 16.0 and 18.4 mL/sec, respectively (Perlmutter and Schulsinger, 1998; Küpeli et al, 1999; Perlmutter and Vallencien, 1999; Talic, 1999).

A comparative study between TUVRP and TURP has been reported by Talic and coworkers (2000). The Wing resection electrode was used in the TUVRP group. All patients were observed for about 9 months, with a range of 6 to 15 months. At 6 months the TUVRP group had improvements in AUASI score (24.9 to 4 ± 3.4) and PFR (7.5 to 19 ± 6.5 mL/sec); the TURP group had comparable improvements in symptom score (20.1 to 5.6 ± 3.1) and PFR (9.1 to 15.2 ± 10 mL/sec). Of particular note is the very wide range on either side of the mean values.

Summary

TUVP and TUVRP are technologic innovations based on an idea that has been present for some years. Modifications are being made in the equipment that will make this even safer and that will prevent some of the potential problems associated with the delivery of high power to tissues. **Efficacy appears similar to that of TURP, but the studies are short-term evaluations and the glands operated on are relatively small. The short-term complication profile appears to be better than with TURP, but further studies are required to prove this because there is a certain variability in the rate of occurrence of some of them.** In general, although the catheterization time is shorter than with TURP, the operating time is longer. Before this can be accepted as a technique that will replace TURP, long-term multicenter randomized trials are required. However, the technologic improvements and the consistently similar short-term improvements in AUASI score and PFR are encouraging.

TRANSURETHRAL INCISION OF THE PROSTATE

If a poll were to be taken among urologists as to how many would favor a transurethral incision of the prostate (TUIP) as treatment for symptomatic BPH, it is likely that the number would be very small. However, TUIP has been available since the 19th century. Edwards and colleagues (1985) credit Bottini with describing the technique in 1887, but Hedlund and Ek (1985) credit Guthrie in 1834. Guthrie's technique was to disrupt the bladder neck, whereas Bottini used diathermy to divide it. However, in 1973, Orandi published the first significant series on TUIP. The procedure seemed to be most useful in those who had a small prostate and who had obstructive bladder outflow symptoms. Classically, the patient was a younger man when compared with those having TURP (Orandi, 1973).

Technique

The surgical technique is relatively simple. With a Collings knife, an incision is made at the 5- and 7-o'clock positions or on one side of the midline only. It starts just distal to the ureteral orifice and ends just proximal to the verumontanum (Fig. 93–16). The incision depth should be

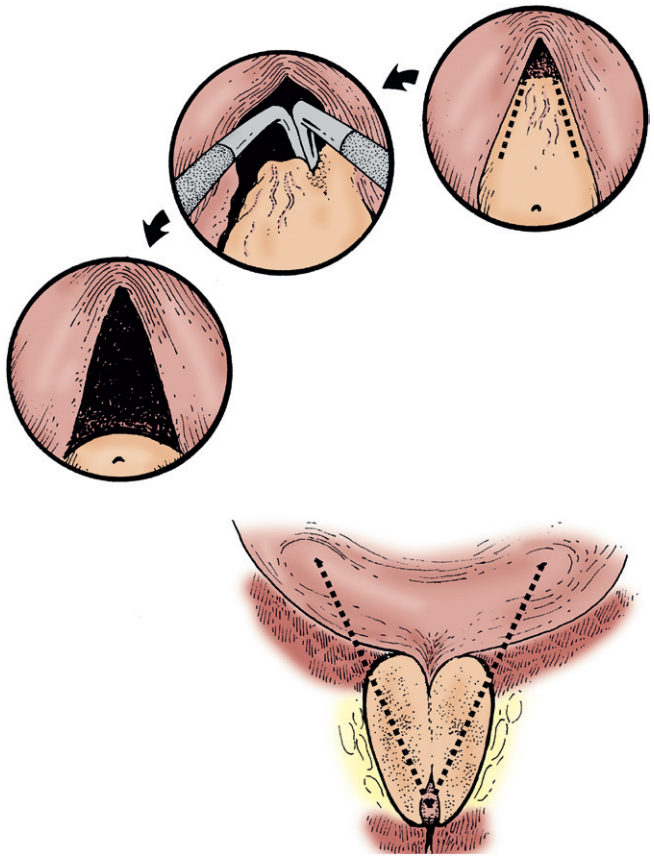

Figure 93–16. Transurethral incision of the prostate. The incision is started at the ureteral orifice and carried through the bladder neck up to the verumontanum. This procedure is done bilaterally. (From Mebust WK. A review of TURP complications and the National Cooperative Study, lesson 24, volume VIII. 1989. p. 189–90.)

to the point at which fine filaments of the external capsule are seen. Care must be taken not to incise too deeply because extravasation of irrigation fluid or rectal injury may occur. With completion of the incisions and with the scope in the more distal urethra there should be no visible obstruction to the bladder outflow.

Complications

The advantage of TUIP is that it is quick, technically easier, and associated with less morbidity and a decrease in retrograde ejaculation compared with TURP. The incidence of retrograde ejaculation after TURP ranges from 50% to 95%; but after TUIP it has been reported as occurring in 0% to 37% of cases. Turner-Warwick (1979) noted that with one incision the incidence of retrograde ejaculation was less than 5% but with two incisions it was 15%. Hedlund and Ek (1985) reported no difference between this incidence with one and with two incisions.

Clinical Efficacy

The procedure has been assessed by some open studies using strict urodynamic criteria for evaluation. Edwards and Powell (1982) found a significant reduction in voiding pressure after TUIP. Kelly and colleagues (1989) used pressure-flow curves and showed a significant fall in voiding pressure, with shift of the Pdet at PFR from the obstructive to the equivocal range on the Abrams-Griffiths nomogram. They found it to be less effective than TURP in relieving obstruction. Katz and colleagues (1990) noted a satisfaction rating of up to 94% with a significant improvement in symptoms and PFR after TUIP.

Sirls and colleagues (1993) reviewed 41 men (mean age, 63.4 years) for a mean follow-up of 53 months. **The Boyarsky symptom score decreased from 12.5 to 6.9, and the PFR improved from 10.3 to 15.3 mL/sec. The postvoid residual urine volume decreased from 179.8 to 99.4.** The Pdet at PFR decreased from 84.5 to 44.5 cm H_2O, all of which indicated an excellent response to TUIP, particularly if the prostate gland weighed 30 g or less.

In the largest series, Orandi (1985) reported on 646 patients whom he had observed from 3 months to 15 years, finding a reoperation rate of 9.6%.

Comparative Studies

Orandi (1973), in a prospective study over a 2-year period of 132 patients managed with TURP or TUIP, found that the results and complications did favor TUIP but there was no statistically significant difference between the two treatments. The only apparent difference was the higher incidence of bladder neck contraction after TURP.

Miller and associates (1992) reported on 108 patients who underwent a bladder neck incision and compared them with a similar group undergoing TURP. They believed that bladder neck incision was better than TURP in terms of a shorter operative time and shorter duration of catheterization. No other perioperative differences were found. For the 10-year follow-up there was no difference in reoperation rates between the two groups, with an equally high approval by patients after both procedures. In another comparative study, Soonawalla and Pardanini (1992) found that the PFR increased from 8 to 19 mL/sec after TUIP and from 8 to 21 mL/sec after TURP.

Dorflinger and coworkers (1992) randomly assigned 60 patients to either TURP or TUIP. They found that both operations significantly improved AUASI score and PFR, but the improvement in PFR was better for the TURP group. Neither operation caused any significant change in sexual activity or erectile function postoperatively. Retrograde ejaculation was a more common occurrence in patients treated by TURP. Riehmann and colleagues (1995) randomly assigned 56 patients to TURP and 61 to TUIP, and there was a mean follow-up of 34 months. Differences in PFR improvement were significant statistically at 3 months and 24 months only and not at any other time. Retrograde ejaculation was twice as common in the TURP group. Reoperation was required in slightly more patients in the TUIP group, but the difference was not statistically significant. The AHCPR BPH Guideline Panel (McConnell et al, 1994) performed a meta-analysis of the various studies, and the results are noted in Table 93–5. There is a slightly better chance of improvement of symptoms of patients treated by TURP, as there is in the degree of that improvement.

Summary

TUIP is effective in treating patients with LUTS caused by BOO. It has been shown to have an important role in the management of younger patients, especially if the prostate is smaller than 30 g. The efficacy is comparable in such patients with TURP, and the results are maintained in the long term. The technique is simple, and the morbidity is low.

Table 93–5.

Treatment Outcomes Balance Sheet

OUTCOME	TUIP	TURP
Chance of symptom improvement	78%-83% (80)	75%-96% (88)
Degree of symptom improvement	73%	85%
Morbidity (20% significant)	2.2%-33% (14)	5.2%-30.7% (16)
Mortality (30-90 days)	0.2%-1.5%	0.53%-3.31%
Incontinence (total)	0.061%-1.1%	0.68%-1.4%
Operative treatment for surgical complications	1.34%-2.65%	0.68%-10%
Impotence	3.9%-24.5%	3.3%-34.8%
Retrograde ejaculation	6%-55%	25%-99%

TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

OTHER TECHNOLOGIES

There are some other approaches that have not been previously mentioned in this chapter but they are included only to complete the picture. There is no significant evidence available to support any of these as having a future in the treatment of symptomatic BPH. The literature mainly consists of open studies, which in many cases would correspond to phase 1 trials or very small phase 2 trials.

Water-Induced Thermotherapy

Water-induced thermotherapy is another treatment introduced to treat LUTS and to reduce BOO secondary to BPH. An early article (Corica et al, 2000) assessed its effect on prostatic tissue, using it in both benign and malignant prostates, in 27 patients. The patients were awake, with local anesthetic gel inserted urethrally. The discomfort experienced by patients was recorded as mild. Pathologic examination of the removed prostate consistently showed periurethral hemorrhagic necrosis extending up to 11 mm from the urethra, focal or extensive urothelial denudation, and mild inflammation.

The same group of authors subsequently developed a novel rapid high-temperature, liquid-filled, flexible balloon thermotherapy system (Corica et al, 2003). The same anesthesia as previously was used in 17 patients, and a full histologic study was performed. Again, consistent findings were recorded, including periurethral hemorrhagic necrosis, extensive denudation, and varying degrees of inflammation. The mean depth of necrosis was 0.9 cm, involving a mean of 16% of the prostatic adenoma. In the prostates examined later, the necrotic tissue had been replaced by scar tissue (fibrosis and hyalinization) with a mean depth of 0.13 cm.

In a small open study, two slightly different temperatures were used in two groups of patients (Breda and Isgro, 2002). Because of the small numbers the results are somewhat difficult in that the temperature did not matter and that previously catheter-dependent patients were able to void with a PFR of 10.7 to 11.5 mL/sec in 73% to 88% of patients.

There has been a prospective multicenter trial performed involving 125 patients (Muschter et al, 2000). **Improvement was noted at 3 months, extending to 12 months. The IPSS at 12 months had improved by a median of 12.5 symptom units and the PFR improved by 6.4 mL/sec over baseline. This was not a comparative study. Side effects were minimal. The authors concluded that the treatment held promise as a useful and cost-effective option for management of BPH. In a later review of the topic, the failure rate and rate of subsequent TURP were reported as 5.6% after 12 months, 9.6% after 24 months, and 11.2% after 36 months** (Muschter, 2003).

Transurethral Ethanol Ablation of the Prostate

This technique has not been subjected to a great deal of in-depth study. It was initially introduced as a transperineal injection, with phenol being the agent injected (Talwar and Pande, 1966; Angell, 1969). There was clear evidence from several early studies that the agent injected leaked extraprostatically, with consequently a relatively high incidence of significant adverse events. The development of a transurethral method of injecting ethanol has been seen as a safer approach (Goya et al, 1999; Ditrolio et al, 2002). A detailed description of the injection technique is to be found in these articles and in the study presented by Plante and colleagues (2003), who also describe the histologic findings observed in the canine prostate. They found a considerable lobular volume of necrosis (mean of 42.6%); and although the findings were not absolutely consistent, they found that the prostate capsule always acted as a relative barrier to ethanol diffusion after transurethral injection.

A European multicenter study has been performed in 115 symptomatic BPH patients using transurethral ethanol ablation of the prostate (Grise et al, 2004), **and 94 of these patients were observed for 12 months. An average reduction in prostate volume of 16% was found, with a small adverse event rate and a requirement for TURP in 7% of patients in that time period. Relatively modest improvements in IPSS and PFR were reported, with 98% of patients voiding spontaneously 4 days after treatment.**

Rotoresection of the Prostate

This technique has not been widely reported, but early studies, both experimental and clinical, have been published. It has been designed for conventional transurethral application, with an axially adjustable actively rotating crank with a milling-head spiked electrode fitting into a specifically designed working element instead of a loop electrode. It is driven by a micromotor, which transmits rotation to the electrode by an angled drill handle. The first use of this system was reported by Michel and coworkers in 1996. In an experimental porcine model these researchers found a rate of time ablation comparable to that of a standard resection loop (5.5 to 6.0 g/min) and more than twice that of electrovaporization (1.7 to 2.0 g/min). The rate of bleeding was significantly better than for either, and the depth of tissue coagulation was 1.5 mm, compared with 0.4 mm with TURP.

There have been three clinical studies. Michel and coworkers (2003) used the rotoresect system in 84 patients and evaluated them for up to 4 years. They found no change in hemoglobin or serum sodium values. The mean duration of catheterization was 1.4 days. There was an early significant improvement in IPSS and PFR, which lasted to the 4-year evaluation.

A prospective study was carried out, and results at 12 months (Wadie et al, 2003) **and 24 months** (Wadie et al, 2005) **have been published. In the latter report the results of 23 of the original 24 patients have been evaluable. The AUASI score decreased from 20.5 ± 3.8 to 1.12 ± 1.56, and the PFR rose from 8.7 ± 2.1 to 21.8 ± 8.5 mL/sec, results comparable to those reported earlier. Again, the complication rate was found to be low.**

SUMMARY

Since the previous edition of this book there is very little new apart from the explosion of interest in the newer types of laser therapy. Many of the recent papers on thermotherapy describe newer techniques but once again fail to get to the "meat" of the subject, which is to answer the question as to the exact position of thermotherapy in the management of BPH. Even in the case of the laser therapies, the authors do not tell the reader if they consider that they will actually overtake TURP and supplant it in the future. In addition, the standard of trials has not improved greatly, with many still being open label studies with no comparator group; some of the comparative studies have group sizes that do not give the impression of having been powered statistically to show either equivalence or a specifically stated difference. There have been several new meta-analyses or systematic literature reviews, which may help the reader to make a more balanced, evidence-based decision.

There has been much discussion as to which of these therapies is better than TURP. At present, it would seem that TURP is either equivalent to the best of the minimally invasive therapies or better than most in terms of improvement of subjective and objective indices. As was stated in the introduction, however, it is not only the efficacy of the treatment that must be compared with TURP. The adverse event profile, the requirement for intravenous sedation, length of hospitalization, and cost also are all very important.

The vast majority of trials that have been reported compare a treatment with TURP only against efficacy, whereas it would be of benefit to the urologist if trials could view the comparison of the other factors in a prospective way, perhaps even excluding efficacy. This has been done by some authors, but a major multicenter approach would give the best information. In this way, it would be clear which is the best way to treat BPH.

However, the view could be taken that it is not necessary to find a minimally invasive treatment that is better than TURP. For example, none of the drug treatments has even come close to the efficacy of TURP, but they have been demonstrated to be of lasting value in management and have found a very specific place in the treatment armamentarium of BPH. In that case, the questions just posed would need to be answered very carefully.

It might be considered controversial to state that perhaps patients should be allowed to have sequential treatments. It is known that some patients do not respond well to specific minimally invasive treatments, so perhaps they might have a second treatment with the same modality, even a relatively short time after the first. There may be cost implications that would have the hospital managers shaking their heads, but it would certainly lower hospital bed requirements if it proved successful. In the same way, if a treatment proved efficacious for a 3-year period and then the symptoms returned, it is conceivable that a further treatment might return the patient to symptomatic well-being, even if a further full evaluation was required.

What is definitely necessary is that the exact place for each treatment modality should be found. Some may well have a small but well-defined role in the management of BPH, and, in the case of others, this role may be larger. One of the problems with extracorporeal shockwave lithotripsy was that it took a long time to find exactly how it should be used to treat, for example, staghorn renal calculi; no comparative trial was performed. In the same way, TURP was introduced without a comparative trial; and although it is recognized now as the gold standard, it took several decades before this happened. Minimally invasive treatments are in most cases pitted against TURP, but with many of them this has been a wasted exercise because in the preliminary open studies they could have clearly been seen not to be as efficacious. Commercial necessity requires comparison against a recognized treatment, but often this is not in the patients' best interests. It may be that the treatment has a lesser, but equally important, role to play.

At the International Consultation on BPH, held in July 2000, the committee that discussed "International Therapy for Benign Prostatic Hyperplasia" prepared a report (Debruyne et al, 2001). In it was outlined final recommendations on the use of such treatments, which were defined as acceptable, acceptable with restriction, investigational, or unacceptable. This decision was based on several meetings between the members of the panel and is rather a suggestion than an instruction to urologists.

The panel found that a number of treatments for BPH were unacceptable: balloon dilatation, hyperthermia, and high-intensity focused ultrasonography. It is widely accepted that this is so, and these treatments have not been dealt with in this discussion because it is unlikely that they will have a role in the future in their present form. Prostatic stents are deemed acceptable with restriction, which once again is not controversial because that restriction has been clearly described in the large number of original and review articles related to them.

Key Points

- Intraprostatic stents are confined to alternative therapy for BPH for patients unfit for TURP.
- Transurethral needle ablation has been modified several times and has a significant beneficial effect on PFR and IPSS. Not enough long-term studies are available.
- The literature base for TUMT is inconsistent, and it is not possible to draw conclusions on long-term efficacy. It also improves PFR and IPSS.
- The holmium laser and the high-power PVP laser are the most popular instruments in this technology section and are efficacious in improving PFR and IPSS, probably in a way that is comparable to TURP. Long-term studies are required.
- TUVP and TUIP are also effective, particularly for small prostates, but have not overtaken TURP as the chosen method to treat obstructive BPH.
- In well-trained hands, TURP is a safe and effective way of treating BPH, with an acceptable side effect profile.
- Other means of prostatic resection, such as rotoresection of the prostate, are under evaluation, without long-term multicenter trials as yet. The efficacy of water-induced thermotherapy and ethanol injection of the prostate remains unproved.

Rather more interesting is the list of treatments described as being acceptable, presumably without restriction in the minds of the panel: TUMT, transurethral needle ablation, interstitial laser coagulation, laser-vaporization, and transurethral electrovaporization (naturally, TURP and open prostatectomy are also included). It may be that these newer treatments are acceptable, but it is absolutely necessary to define in what way and to remember that, in most of these treatments, the results are short term. In some cases, they may be considered as possible replacements for TURP, but, in that case, a large amount of further information is required related to the points previously discussed and to long-term efficacy. In the case of those being considered as alternative treatments for BPH not necessarily as good as TURP, their exact role needs to be defined.

It is very likely that some day TURP will be replaced as the ideal interventional treatment for BPH. It took a considerable amount of time for TURP to achieve its exalted position, but it could happen soon that some other treatment will occupy that position.

Retropubic and Suprapubic Open Prostatectomy

Misop Han, MD, MS • Alan W. Partin, MD, PhD

Indications for Open Prostatectomy
Preoperative Evaluation
Operating Day Preparation
Surgical Technique
Postoperative Management
Complications
Summary

The treatment options for bladder outlet obstruction due to benign prostatic hyperplasia have been expanded dramatically over the past 2 decades with the development of medical and minimally invasive therapies. The current medical therapies for lower urinary tract symptoms (LUTS) include selective long-acting α_1-adrenergic antagonists, such as terazosin (Hytrin [Lepor et al, 1992; Roehrborn et al, 1996]), doxazosin (Cardura [Gillenwater et al, 1995]), and tamsulosin (Flomax [Abrams et al, 1995]), and the 5α-reductase blockers, such as finasteride (Proscar [Gormley et al, 1992; Andersen et al, 1995; Lepor et al, 1996]) and dutasteride (Avodart [Roehrborn et al, 2002, 2004]). Minimally invasive procedures include visual laser ablation of the prostate (VLAP [Cowles et al, 1995]), transurethral electrovaporization of the prostate (TVP [Kaplan et al, 1996]), transurethral needle ablation (TUNA [Schulman et al, 1993; Campo et al, 1997]), transurethral microwave thermotherapy (TUMT [Ogden et al, 1993; Javle et al, 1996]), interstitial laser coagulation (ILC [Muschter and Hofstetter, 1995]) and transurethral incision of the prostate (TUIP [Cornford et al, 1997]). However, these approaches are usually reserved for men with moderate symptoms and a small to medium-sized prostate gland (Reich et al, 2006). For larger prostate glands, open prostatectomy has been frequently performed. Lately, holmium laser enucleation of the prostate (HoLEP) with the holmium:yttrium-aluminum-garnet (Ho:YAG) laser has been performed as a minimally invasive alternative to open surgery (Gilling et al, 1998). Most recently, as urologists gain experience in minimally invasive therapy, a simple prostatectomy has been performed using a laparoscopic or robotic approach (Sotelo et al, 2005, 2008; Mariano et al, 2006).

For patients with acute urinary retention, persistent or recurrent urinary tract infections, severe hemorrhage from the prostate, bladder calculi, severe symptoms unresponsive to medical therapy, and/or renal insufficiency as a result of chronic bladder outlet obstruction, transurethral resection of the prostate (TURP) or open prostatectomy is indicated. **When compared with TURP, open prostatectomy offers the advantages of lower re-treatment rate and more complete removal of the prostatic adenoma under direct vision and avoids the risk of dilutional hyponatremia (the TUR syndrome) that occurs in approximately 2% of patients undergoing TURP** (Mebust et al, 1989; Roos et al, 1989). Several contemporary series have demonstrated objective improvement in urinary symptoms after open prostatectomy (Tubaro et al, 2001; Gacci et al, 2003; Varkarakis et al, 2004). **The disadvantages of open prostatectomy, as compared with TURP, include the need for a lower midline incision and a resultant longer hospitalization and convalescence period. There also may be an increased potential for perioperative hemorrhage** (Serretta et al, 2002).

Open prostatectomy can be performed by either the retropubic or the suprapubic approach. **In retropubic prostatectomy the enucleation of the hyperplastic prostatic adenoma is achieved through a direct incision of the anterior prostatic capsule.** This approach to open prostatectomy was popularized by Terrence Millin, who reported the results of the procedure on 20 patients in *Lancet* in 1945 (Millin, 1945). **The advantages of this procedure over the suprapubic approach are (1) excellent anatomic exposure of the prostate, (2) direct visualization of the prostatic adenoma during enucleation to ensure complete removal, (3) precise transection of the urethra distally to preserve urinary continence, (4) clear and immediate visualization of the prostatic fossa after enucleation to control bleeding, and (5) minimal to no surgical trauma to the urinary bladder. The disadvantage of the retropubic approach, as compared with the suprapubic prostatectomy, is that direct access to the bladder is not achieved.** This may be important when one considers excising a concomitant bladder diverticulum or removing bladder calculi. The suprapubic approach also may be the preferred method when the obstructive prostatic enlargement includes a large intravesical median lobe.

Suprapubic prostatectomy, or transvesical prostatectomy, consists of the enucleation of the hyperplastic prostatic adenoma through an extraperitoneal incision of the lower anterior bladder wall. This approach to open prostatectomy was first performed by Eugene Fuller in New York in 1894; it was later popularized by Peter Freyer in London, England, who described the procedure in 1900 and later reported the results of his first 1000 patients in 1912 (Freyer, 1912). The major advantage of this suprapubic procedure over the retropubic

approach is that it allows direct visualization of the bladder neck and bladder mucosa. As a result, **this operation is ideally suited for patients with (1) a large median lobe protruding into the bladder, (2) a clinically significant bladder diverticulum, or (3) large bladder calculi. It also may be preferable for obese men, in whom it is difficult to gain direct access to the prostatic capsule and dorsal vein complex** (Culp, 1975). **The disadvantage, as compared with the retropubic approach, is that direct visualization of the apical prostatic adenoma is reduced. As a result, the apical enucleation is less precise and this factor may affect postoperative urinary continence. Furthermore, hemostasis may be more difficult because of inadequate visualization of the entire prostatic fossa after enucleation.**

INDICATIONS FOR OPEN PROSTATECTOMY

The indications for prostatectomy, by either open approach or transurethral resection, include (1) acute urinary retention; (2) recurrent or persistent urinary tract infections; (3) significant symptoms from bladder outlet obstruction not responsive to medical therapy; (4) recurrent gross hematuria of prostatic origin; (5) pathophysiologic changes of the kidneys, ureters, or bladder secondary to prostatic obstruction; and (6) bladder calculi secondary to obstruction.

Open prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g. If sizable bladder diverticula justify removal, suprapubic prostatectomy and diverticulectomy should be performed concurrently. If the prostatectomy is performed without the diverticulectomy, incomplete emptying of the bladder diverticulum and subsequent, persistent infection may occur. Large bladder calculi that are not amenable to easy transurethral fragmentation may also be removed during the open procedure. Open prostatectomy should also be considered when a patient presents with ankylosis of the hip or other orthopedic conditions that prevent proper positioning for TURP. Also, it may be wise to perform an open prostatectomy in men with recurrent or complex urethral conditions, such as urethral stricture or previous hypospadias repair, to avoid the urethral trauma associated with TURP. Finally, the association of an inguinal hernia with an enlarged prostate suggests an open procedure, because the hernia may be repaired via the same lower abdominal incision (Schlegel and Walsh, 1987; Brunocilla et al, 2005).

Contraindications to open prostatectomy include a small fibrous gland, the presence of prostate cancer, and previous prostatectomy or pelvic surgery that may obliterate access to the prostate gland.

PREOPERATIVE EVALUATION

In deciding whether to perform an open prostatectomy for symptomatic obstruction due to benign prostatic hyperplasia, it may be necessary to consider the upper and lower urinary tracts. Usually the patient will have already completed the International Prostate Symptom Score (IPSS) questionnaire and had a peak urinary flow rate determination. The postvoid residual urine volume also may have been verified with abdominal ultrasonography. **A cystoscopic examination is not indicated in the routine evaluation of a patient with obstructive voiding symptoms** (McConnell et al, 1994). **However, cystoscopy should be performed in men with hematuria, suspected urethral stricture, and bladder calculus or diverticulum.** It also can be helpful in confirming the presence of a large median lobe or in assessing the length of the prostatic urethra. For this indication it is most ideal to perform the cystoscopic examination with the patient under anesthesia just before surgery, when the pelvic floor musculature is relaxed.

Before performing an open prostatectomy the presence of prostate cancer should be excluded. All men should undergo a digital rectal examination and have a serum prostate-specific antigen determination. If the digital rectal examination detects induration or nodularity, or the serum prostate-specific antigen level is elevated, a transrectal ultrasound-guided biopsy of the prostate gland should be performed. Transrectal ultrasonography, by itself, is not indicated as a first-line diagnostic test for evaluating the prostate gland to detect early, curable prostate cancer. However, it can be useful in determining prostate size.

The upper urinary tracts should be evaluated preoperatively in men with known renal disease, abnormal renal function, recurrent urinary tract infection, or hematuria. This can be accomplished by an intravenous pyelogram with a postvoid drainage film, by computed tomography in patients with normal renal function, or by renal ultrasonography in men with compromised renal function. Magnetic resonance imaging is not commonly indicated.

Before surgery the patient should undergo a complete medical evaluation consisting of a detailed history, thorough physical examination, and appropriate laboratory assessment. Most patients will be of an age with an increased risk for cardiovascular and pulmonary disease, hypertension, diabetes mellitus and other medical conditions. All abnormalities uncovered in this evaluation should be addressed. The patient's medications should be reviewed and attention should be given to the agents such as aspirin and nonsteroidal anti-inflammatory agents that can contribute to perioperative bleeding. **These medications should be discontinued and therapeutic anticoagulation reversed before surgery.** In addition, a chest radiograph, electrocardiogram, routine electrolyte studies, coagulation studies, and a complete blood cell count are usually required for these patients before surgery.

Men in urinary retention should have an evaluation of renal function. If the serum creatinine value is elevated, surgery should be delayed until this parameter stabilizes. Urinalysis is performed to rule out a urinary tract infection; and, if an infection is suspected, a urine specimen should be sent for culture and sensitivity. If an infection is present, appropriate antimicrobial therapy must be instituted before surgery to prevent urinary sepsis (Serretta et al, 2002).

Historically, 3% to 10% of men undergoing an open prostatectomy will require one or more units of blood in the perioperative period (Serretta et al, 2002; Varkarakis et al, 2004; Zargooshi, 2007). Thus **it may be prudent to have one or two units of blood available intraoperatively.** Patients who are concerned about infectious processes associated with blood transfusion can donate one to two units of autologous blood before surgery so that it is available at the time of the procedure. The preferred autologous donation schedule is one unit per week, with the last donation 2 weeks before surgery. During this process, the patient

should receive oral iron supplementation (ferrous sulfate or ferrous gluconate).

Lastly, the patient must be informed of the benefits and risks associated with open prostatectomy and written informed consent should be obtained. The benefit to be achieved is improved urination. **Potential risks include urinary incontinence, erectile dysfunction, retrograde ejaculation, urinary tract infection, bladder neck contracture, urethral stricture, and the need for a blood transfusion. Other potential untoward effects include deep vein thrombosis and pulmonary embolus.**

OPERATING DAY PREPARATION

The patient is kept without oral intake after midnight and self-administers a Fleet enema the morning of surgery. The type of the anesthesia to be used and the risks associated with it are discussed and finalized with the patient and his family in conjunction with the anesthesiologist. One dose of a second-generation cephalosporin is administered before making the incision.

SURGICAL TECHNIQUE

Anesthesia

The preferred anesthesia is spinal or epidural. Regional anesthesia may reduce intraoperative blood loss and the frequency of postoperative deep vein thrombosis and pulmonary embolus (Peters and Walsh, 1985). **General anesthesia is utilized when there is a medical or anatomic contraindication to regional anesthesia or when the patient simply prefers general anesthesia.**

Retropubic Prostatectomy

Proper Positioning of the Patient

Once anesthesia has been induced the patient is positioned on the operating table in a supine position. If a cystoscopic examination is to be performed, the patient is prepped and draped in the usual manner for a transurethral diagnostic procedure. Flexible cystoscopy, in this situation, will obviate major repositioning of the patient. After the cystoscopy the table is placed in a mild Trendelenburg position without extension.

Incision and Exposure of the Prostate

The suprapubic area is shaved, prepped, and draped in the usual sterile manner. A 22-Fr urethral catheter with a 30-mL balloon is passed into the bladder and connected to a sterile closed drainage system, and the balloon is inflated with 30 mL of saline. A lower midline incision from the umbilicus to the pubic symphysis is made. It is deepened through the subcutaneous tissue. **The linea alba is incised, allowing the rectus abdominis muscles to be separated in the midline. The transversalis fascia is incised sharply to expose the space of Retzius.** At the superior aspect of the wound the posterior rectus abdominis fascia is incised above the semicircular line to the level of the umbilicus and the peritoneum is mobilized cephalad starting at the pubic symphysis and swept anterolaterally. The pelvis is inspected for any abnormalities, and the inguinal area is examined for hernias. If a hernia is identified, it can be repaired using the preperitoneal approach described by Schlegel and Walsh (1987). A self-retaining Balfour retractor is placed in the incision and widened. A well-padded, malleable blade is connected to the retractor and used to displace the bladder posteriorly and superiorly. Unlike an anatomic radical retropubic prostatectomy, the balloon of the catheter is not positioned beneath the malleable blade. Instead it is allowed to rest at the level of the bladder neck and aids in identifying the prostatovesical junction later in the operation. The anterior surface of the bladder and prostate are exposed. With the use of DeBakey forceps and Metzenbaum scissors, the preprostatic adipose tissue is gently removed to expose the superficial branch of the dorsal vein complex and the puboprostatic ligaments (Fig. 94–1).

Hemostatic Maneuvers

Before proceeding with enucleation of the prostatic adenoma it is important to achieve complete control of the dorsal vein complex as well as the lateral pedicles at the bladder neck (the main arterial blood supply to the prostate gland) (Walsh and Oesterling, 1990). To accomplish this task the endopelvic fascia is incised laterally and the puboprostatic ligaments are partially transected, similar to the maneuver in an anatomic radical retropubic prostatectomy (Reiner and Walsh, 1979). In patients with marked prostatic enlargement this maneuver can be easier because the enlarged prostate gland protrudes out from beneath the pubic symphysis. A 3-0 Monocryl suture on a ⅝-inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate and tied (Fig. 94–2A). The superficial branch of the dorsal vein at the bladder should be coagulated or ligated.

At this point attention is focused on securing the lateral pedicles at the prostatovesical junction. The 30-mL balloon of the catheter is used to identify the junction between the bladder and the prostate. The balloon is then deflated and 2-0 chromic suture material on a large CTX needle is used to place a figure-of-eight suture deep into the prostatovesical junction at the level where the seminal vesicles approach the prostate gland bilaterally (see Fig. 94–2B). With this maneuver, the main arterial blood supply to the prostate

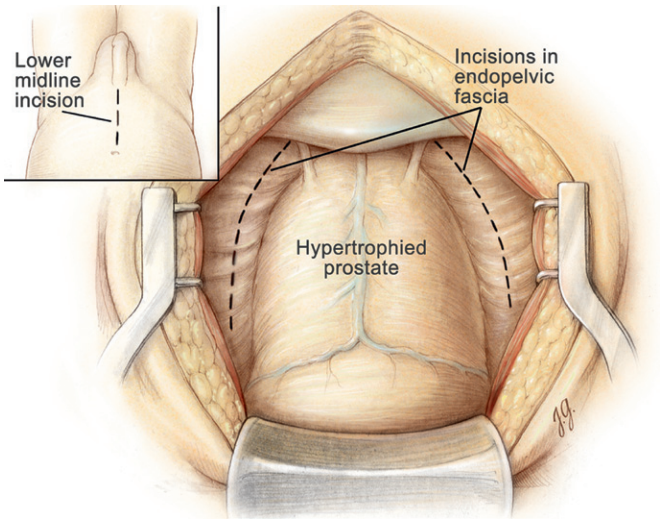

Figure 94–1. Retropubic prostatectomy. The space of Retzius has been opened and the periprostatic adipose tissue has been dissected free from the superficial branch of the dorsal vein complex. The endopelvic fascia is incised bilaterally *(dotted lines)*, and the puboprostatic ligaments are transected bilaterally. (© Brady Urological Institute.)

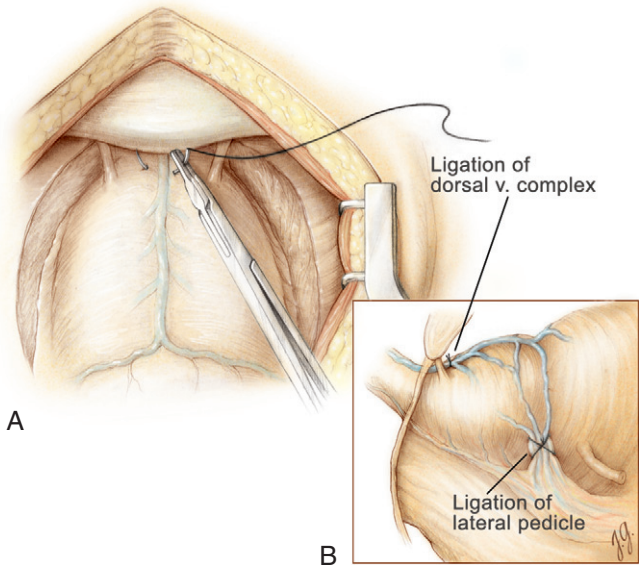

Figure 94–2. Retropubic prostatectomy. **A,** A 2-0 chromic suture on a ⅜-inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate. A tie is grasped and tied around the dorsal vein complex. **B,** With 2-0 chromic suture material on a CTX needle, a figure-of-eight suture is placed through the prostatovesicular junction just above the level of the seminal vesicles to control the main arterial blood supply to the prostate gland. When placing this suture, care must be taken to avoid entrapment of the neurovascular bundles located posteriorly and slightly laterally. (© Brady Urological Institute.)

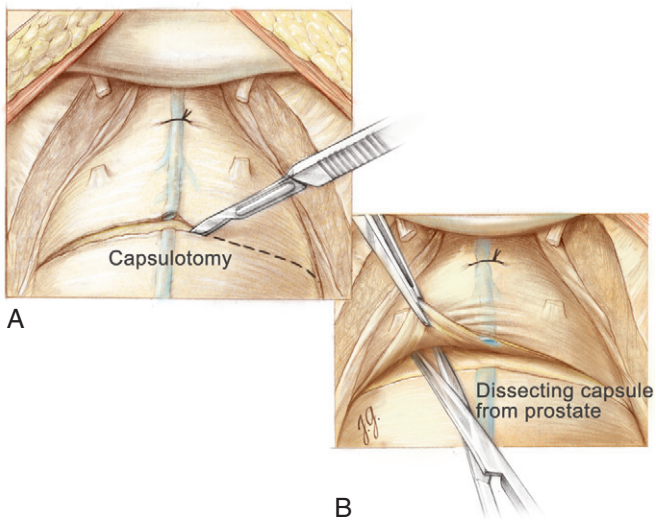

Figure 94–3. Retropubic prostatectomy. **A,** With the superficial branch of the dorsal vein complex secured proximally and distally, a No. 15 blade on a long handle is used to make the transverse capsulotomy. **B,** Metzenbaum scissors are used to develop the plane anteriorly between the prostatic adenoma and the prostatic capsule. (© Brady Urological Institute.)

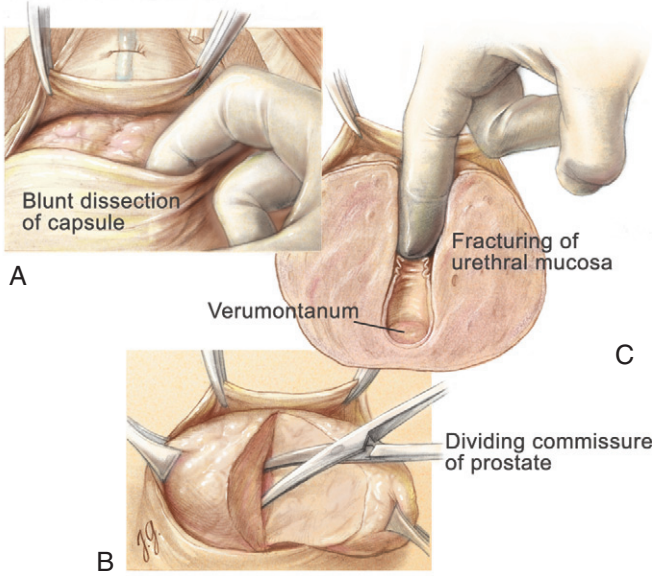

Figure 94–4. Retropubic prostatectomy. **A,** With blunt dissection with the index finger, the prostatic adenoma is dissected free laterally and posteriorly. **B,** Metzenbaum scissors are used to divide the anterior commissure to visualize the posterior urethra and verumontanum. **C,** The index finger is then used to fracture the urethral mucosa at the level of the verumontanum. With this last maneuver, extreme care is taken not to injure the external sphincteric mechanism. (© Brady Urological Institute.)

adenoma is controlled. Having secured the dorsal vein complex earlier, the major sources of hemorrhage for this operation have been eliminated.

Enucleation of the Adenoma

With a sponge stick on the bladder neck to depress the bladder posteriorly, a No. 15 blade on a long handle is used to make a transverse capsulotomy in the prostate 1.5 to 2.0 cm distal to the bladder neck (Fig. 94–3). The superficial branch of the dorsal vein complex is transected as the transverse capsulotomy is made. It does not bleed because hemostasis of the dorsal vein complex has previously been controlled both proximally and distally. The incision is deepened to the level of the adenoma and extended sufficiently lateral in each direction to permit complete enucleation. A pair of Metzenbaum scissors is used to dissect the overlying prostatic capsule from the underlying prostatic adenoma. Once a well-defined plane is sufficiently developed, the index finger can be inserted between the prostatic adenoma and the capsule to further develop the plane laterally and posteriorly (Fig. 94–4). A pair of Metzenbaum scissors is then used to incise the anterior commissure from the bladder neck to the apex separating the lateral lobes of the prostate anteriorly. The posterior prostatic urethra is exposed, and the index finger is inserted down to the verumontanum. The mucosa of the urethra overlying the left lateral lobe is divided sharply at the level of the apex under direct vision without injury to the external urinary sphincter. With the aid of a Babcock clamp, the left lateral lobe is removed safely. This maneuver is then repeated for the right lateral lobe. If a median lobe is present, the overlying mucosa is incised at the level of the bladder neck and this lobe is removed (Fig. 94–5). In this manner the entire prostatic adenoma is removed with preservation of a strip of posterior prostatic urethra. Because the capsulotomy was a transverse rather than longitudinal incision there is little risk that the incision will

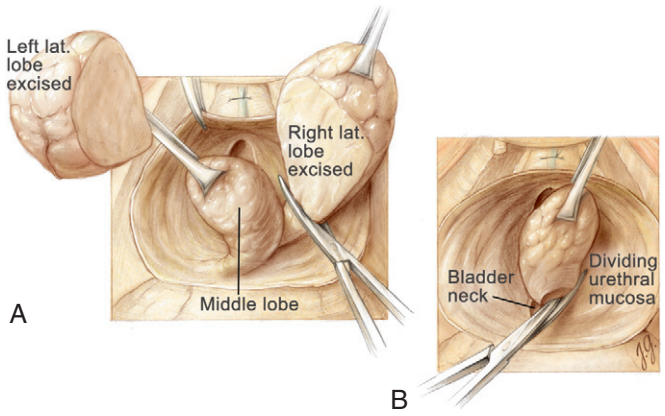

Figure 94–5. Retropubic prostatectomy. **A,** After removal of the left lateral lobe of the prostate, the right lateral lobe is excised with the aid of a tenaculum and Metzenbaum scissors. **B,** Lastly, the median lobe is removed under direct vision. (© Brady Urological Institute.)

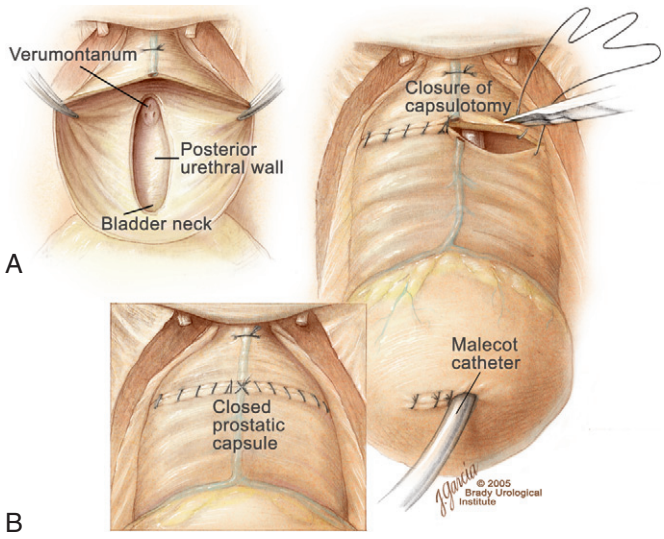

Figure 94–6. Retropubic prostatectomy. **A,** View of the prostatic fossa and posterior urethra after enucleation of all the prostatic adenoma. Note that the verumontanum and a strip of posterior urethra remain intact. **B,** After placement of a urethral catheter and, if needed, a Malecot suprapubic tube, the transverse capsulotomy is closed with two running 2-0 chromic sutures. The two sutures are tied first to themselves and then to each other across the midline to create a watertight closure of the prostatic capsule. (© Brady Urological Institute.)

be inadvertently extended into the sphincteric mechanism during the enucleation process, which would compromise subsequent urinary continence.

The prostatic fossa is now carefully inspected to ensure that all of the adenoma has been removed and that hemostasis is complete. **If hemorrhage is persistent, 4-0 chromic suture material can be used to place a figure-of-eight suture in the bladder neck at the 5- and 7-o'clock positions as in suprapubic prostatectomy** (see Fig. 94–11). **When placing these sutures it is necessary to visualize the ureteral orifices so that they are not incorporated.** Indigo carmine dye may be given intravenously to aid in the visualization of the ureteral orifices if necessary. If the bladder neck appears obstructive at the completion of the operation, it may be appropriate to perform a wedge resection at the 6-o'clock position and advance the bladder mucosa into the prostatic fossa. The maneuver helps prevent the development of a bladder neck contracture.

Closure

After inspecting the bladder for complete adenoma removal and hemostasis, a 22-Fr, three-way Foley catheter with a 30-mL balloon is inserted through the anterior urethra and prostatic fossa into the bladder. With the urethral catheter in place, the prostatic capsule is closed (Fig. 94–6). Then 2-0 chromic suture material on a ⅝-inch circle-tapered needle is used to create two running sutures. These sutures begin laterally and meet in the midline; they are first tied separately and then together to create a watertight closure. Fifty milliliters of water is then placed in the balloon to ensure that the catheter balloon remains in the bladder and does not retract into the prostatic fossa. The bladder is then irrigated with saline to ensure continued hemostasis and to test the capsular closure for leakage. A small, closed-suction drain is placed via a separate stab incision lateral to the prostate and bladder on one side to prevent hematoma and urinoma formation. The pelvis is irrigated with copious amounts of normal saline solution, and the rectus fascia is reapproximated with a size 1 PDS suture on a TPI needle in a running fashion. The skin is closed with skin staples. The drain is secured to the abdominal wall, and the urethral catheter is secured to the lower extremity.

Suprapubic Prostatectomy

Proper Positioning of the Patient

After anesthesia has been induced, the patient is positioned on the operating table in a supine position. Cystoscopy, if clinically indicated, is performed as previously described. **The table is placed in a mild Trendelenburg position without extension.** The patient's suprapubic area is shaved. **After the lower abdomen and external genital area are prepped and draped in the usual sterile manner, a 22-Fr catheter is inserted into the bladder. After residual urine is drained, 250 mL of saline is instilled into the bladder and the catheter is clamped.**

Incision and Exposure of the Prostate

A lower midline incision is made from the umbilicus to the pubic symphysis (Fig. 94–7). It is deepened through the subcutaneous tissue. The linea alba is incised, allowing the rectus abdominis muscles to be separated in the midline. The transversalis fascia is incised sharply to expose the space of Retzius. At the superior aspect of the wound the posterior rectus abdominis fascia is incised above the semicircular line to the level of the umbilicus and the peritoneum is then swept cephalad to develop the prevesical space. A self-retaining Balfour retractor is placed in the incision to retract the rectus muscles laterally. The anterior bladder wall is identified, and two 3-0 Vicryl stitches are placed on each side of the midline below the peritoneal reflection. **A vertical cystotomy is made with an electrocautery. With the use of a pair of Metzenbaum scissors, a cystotomy is then extended cephalad and caudally to within 1 cm of the bladder neck** (Fig. 94–8). **Several pairs of stay sutures are placed using 3-0 Vicryl on each side of the midline to facilitate exposure. A figure-of-eight suture using 3-0 Vicryl is placed and tied at the most caudal position of**

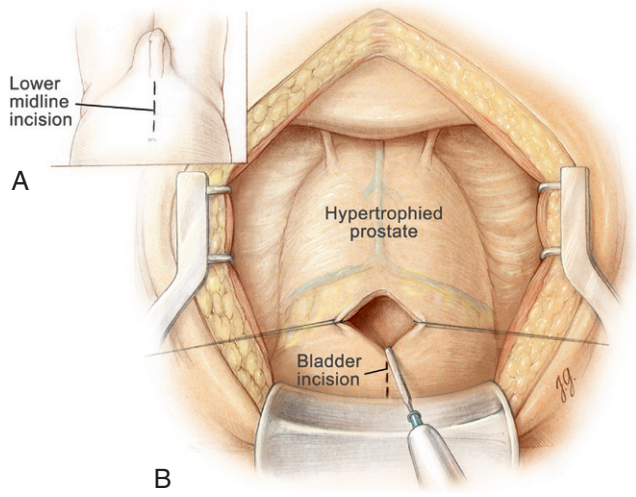

Figure 94–7. Suprapubic prostatectomy. **A,** A lower midline incision is made from the umbilicus to the pubic symphysis. **B,** After developing the prevesical space, a small, longitudinal cystotomy is made with an electrocautery. (© Brady Urological Institute.)

the cystotomy to prevent further extension of the cystotomy incision during blunt finger dissection of the adenoma. Alternatively, a transverse bladder incision can be utilized. After inspecting the bladder, a well-padded, malleable blade is placed in the bladder, connected to the Balfour retractor, and used to retract the bladder cephalad. The bladder neck and prostate gland now can be visualized. A narrow Deaver retractor can be placed over the bladder neck and used to further expose the trigone. **Indigo carmine dye may be given intravenously to aid in the visualization of the ureteral orifices if necessary.**

Enucleation of the Adenoma

An electrocautery is used to create a circular incision in the bladder mucosa distal to the trigone (see Fig. 94–8). Care is taken not to injure the ureteral orifices. With the use of a pair of Metzenbaum scissors, the plane between the prostatic adenoma and prostatic capsule is developed at the 6-o'clock position (Fig. 94–9). Once a well-established plane is created posteriorly, the prostatic adenoma is dissected circumferentially and inferiorly toward the apex, using blunt dissection (Fig. 94–10). At the apex the prostatic urethra is transected using a pinch action of the two fingertips and avoiding excessive traction so as not to avulse the urethra and injure the sphincteric mechanism. At this point the prostatic adenoma, either as one unit or separate lobes, can be removed from the prostatic fossa.

Hemostatic Maneuvers

After enucleation of the adenoma the prostatic fossa is inspected for residual tissue. If found, these nodules are removed by sharp

or blunt dissection. **The prostatic fossa also must be examined for discrete bleeding sites that frequently can be controlled with an electrocautery or 4-0 chromic suture ligatures. In addition, a 0-chromic suture is used to place two figure-of-eight sutures to advance the bladder mucosa into the prostatic fossa at the 5-o'clock and 7-o'clock positions at the prostatovesical junction to ensure control of the main arterial blood supply to the prostate** (Fig. 94–11). With this maneuver, hemostasis is usually complete.

If hemorrhage remains pronounced despite the hemostatic sutures, a size 2 nylon purse-string suture can be placed around the vesical neck, brought out through the skin, and tied firmly, as described by Malament (1965). This maneuver closes the bladder neck and tamponades the prostatic fossa. The nylon suture is removed by cutting it at the skin and applying gentle traction on postoperative day 2 or 3. Plicating sutures can be placed transversely in the posterior prostatic capsule to prevent further bleeding, as described by O'Conor (1982).

Closure

A 22-Fr urethral catheter with a 30-mL balloon is passed through the urethra into the bladder. In addition, a 20- to 24-Fr Malecot suprapubic tube is placed into the dome of the bladder and secured with a 4-0 chromic purse-string suture. The suprapubic tube exits the bladder via a separate stab incision at the lateral aspect of the dome, avoiding the peritoneal cavity (Fig. 94–12). Next, **the cystotomy incision is closed in two layers.** The first layer of closure is performed using a 2-0 Vicryl to create two running sutures. Care is taken to get a small amount of bladder mucosa in the suture. The two sutures begin cephalad and caudally and meet in the midbladder where they are first tied separately and then together. Previously placed 3-0 Vicryl stay-sutures are tied over the first layer of closure to complete the two-layer closure. With this approach the bladder closure is watertight and completed in a timely manner. Fifty milliliters of saline is placed in the balloon to ensure that the catheter balloon remains in the bladder and does not retract into the prostatic fossa. The urethral catheter and suprapubic tube are irrigated to confirm a watertight closure and to verify that hemorrhage is minimal. A small, closed-suction drain is placed via a separate stab incision lateral to the bladder. The drain exits the skin on the opposite side of the suprapubic tube. The pelvis is irrigated with copious amounts of normal saline solution, and the rectus fascia is closed with a size 1 PDS suture on a TPI needle in a running fashion. The skin is closed with skin staples. Next, the suprapubic tube and drain are secured to the abdominal wall, and the urethral catheter is anchored to the lower extremity.

POSTOPERATIVE MANAGEMENT

In the recovery area the outputs from the pelvic drain, suprapubic tube, and urethral catheter are monitored. In addition, it is routine to verify the hematocrit. **If significant hemorrhage is noted, the urethral catheter may be placed on traction so that the balloon containing 50 mL of saline can compress the bladder neck and prostatic fossa. Constant and reliable traction can be maintained by securing the catheter to the abdomen. In addition, continuous bladder irrigation should be initiated to prevent clot formation. For maximal effect the inflow should be through the urethral catheter and the outflow through the suprapubic tube.** For most patients these measures are adequate and effective. **However, if excessive bleeding persists after these measures, the urethral catheter can be removed in the operating suite and a cystoscopic inspection of the prostatic fossa and bladder neck can be performed to identify and fulgurate discrete bleeding sites. If marked hemorrhage should continue to persist, open re-exploration should be strongly considered.**

On the evening of the day of surgery the patient is asked to perform the dorsiflexion and plantarflexion exercises 100 times per hour while awake and to perform pulmonary exercises.

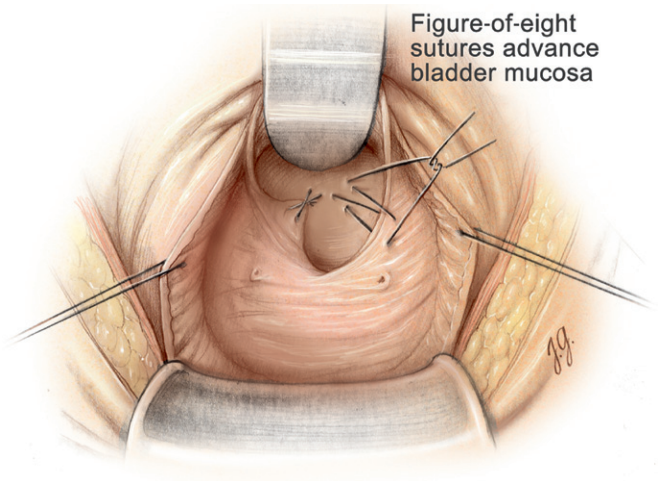

Figure 94–11. Suprapubic prostatectomy. After enucleation of the entire prostatic adenoma, a 0-chromic suture is used to place two figure-of-eight sutures to advance bladder mucosa into the prostatic fossa at the 5- and 7-o'clock positions at the prostatovesicular junction to ensure control of the main arterial blood supply to the prostate. (© Brady Urological Institute.)

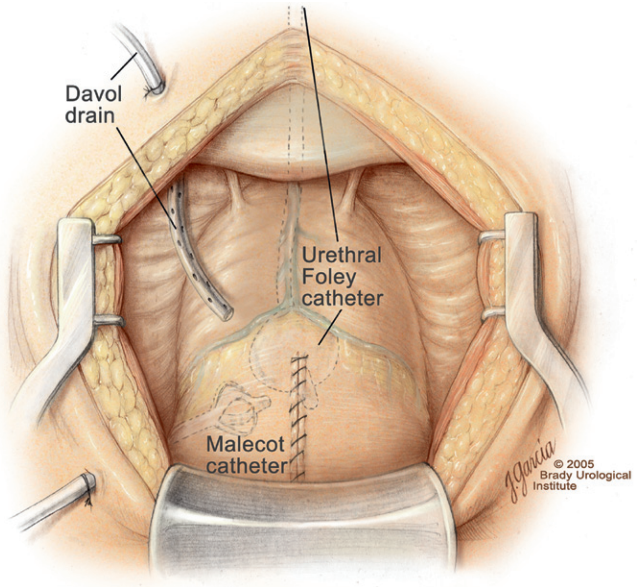

Figure 94–12. Suprapubic prostatectomy. After placement of a urethral catheter and a Malecot suprapubic tube, the cystotomy is closed in two layers using a running 2-0 Vicryl suture, enforced by tying of multiple interrupted 3-0 Vicryl stay sutures. A closed Davol suction drain is placed on one side of the bladder and exits via a separate stab incision. (© Brady Urological Institute.)

Effective pain management consists of intravenous morphine sulfate on an as-needed basis via a patient-controlled analgesic pump.

On the first postoperative day the patient is started on a clear liquid diet and asked to ambulate four times per day. Pulmonary exercises are continued. **If the hematuria is resolved, continuous bladder irrigation can be discontinued with both urethral catheter and suprapubic tube placed to gravity drainage. Also, the balloon in the urethral catheter is partially deflated to 30 mL of saline and residual clots are removed by irrigation.**

On the second postoperative day, if urine is clear, the urethral catheter may be removed and the suprapubic tube is clamped to allow a voiding trial. The patient is encouraged to ambulate and continue pulmonary exercises. **When the patient tolerates a regular diet, oral analgesics can be given and parenteral narcotics discontinued.** Appropriate discharge instructions are reviewed with the patient at this time in preparation for discharge on the third day after surgery. **On the third postoperative day the pelvic drain is removed if the drainage is less than 75 mL/24 hr.** The skin staples are removed and replaced with Steri-strips in nonobese men. The pathologic examination of the enucleated prostatic adenoma should be performed to confirm the absence of adenocarcinoma of the prostate.

On discharge from the hospital the patient is encouraged to gradually increase his activity. If the patient voids well with a minimal postvoid residual urine volume, the suprapubic tube is then removed in the clinic on the fifth day after surgery. The patient should be able to resume full activity 4 to 6 weeks postoperatively with outpatient visits at 6 weeks and 3 months.

COMPLICATIONS

The overall rate of morbidity and mortality associated with open prostatectomy is extremely low. Historically, excessive hemorrhage had been a major concern. But with modern surgical techniques, blood loss is now minimal and the need for a blood transfusion is uncommon (Zargooshi, 2007). In retropubic open prostatectomy, controlling the dorsal vein complex distal to the apex of the prostate and ligating the lateral pedicles to the prostate at the prostatovesical junction markedly reduces venous and arterial bleeding, respectively. Nevertheless, it may still be prudent to have one to two units of autologous blood available at the time of open prostatectomy.

Urinary extravasation can also be of concern in the immediate postoperative period; this most likely results from an incomplete closure of the prostatic capsulotomy in retropubic prostatectomy or the cystotomy in suprapubic prostatectomy. This will usually resolve spontaneously with continued catheter drainage. The drain should be left in place until urinary extravasation ceases.

After an open prostatectomy, urgency and urgency incontinence may be present for several weeks to several months, depending on the preoperative bladder status. If the condition is severe, the patient may be given an anticholinergic agent such as oxybutynin (Ditropan). Stress incontinence and total incontinence are rare. With a precise enucleation of the prostatic adenoma, risk of injury to the external sphincter mechanism is minimal. If stress incontinence does result after the procedure, the patient may benefit from transurethral collagen injections for a mild condition or an artificial urinary external sphincter when the situation is more severe.

Late urologic complications are not common. Acute cystitis rarely occurs as long as the patient voids to completion. Acute epididymitis can occur occasionally if infected urine refluxes into the ejaculatory ducts.

Erectile dysfunction occurs in 3% to 5% of patients undergoing an open prostatectomy; it is more common in older men than in younger men. Retrograde ejaculation occurs in 80% to 90% of patients after surgery. The risk of this adverse effect is reduced if the bladder neck is preserved at the time of surgery. Also, 2% to 5% of patients will develop a bladder neck contracture 6 to 12 weeks after an open prostatectomy (Tubaro et al, 2001; Varkarakis et al, 2004). This commonly occurs in men who have a relatively small opening at the bladder neck at the end of the operation. As stated earlier, for these men it may be appropriate to perform a wedge resection at the 6 o'clock position and advance the bladder mucosa into the prostatic fossa in the retropubic prostatectomy. However, if a bladder neck contracture does develop, the initial management should be dilatation with urethral sounds or a direct vision incision of the bladder neck using a Collings knife to create a 22-Fr opening.

The most common nonurologic adverse effects include deep vein thrombosis, pulmonary embolus, myocardial infarction, and a cerebrovascular event. The incidence of any one of these complications is less than 1% and the overall mortality rate resulting from this operation should approach zero (Varkarakis et al, 2004).

SUMMARY

Open prostatectomy, whether performed via a retropubic approach or a suprapubic approach, is an excellent treatment option for (1) men with symptomatic bladder outlet obstruction due to benign prostatic hyperplasia causing a markedly enlarged prostate gland, (2) individuals with a concomitant bladder condition, such as a bladder diverticulum or large bladder calculi,

Key Points

- Open prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g or sizable bladder diverticular or calculi exist.
- Before performing an open prostatectomy, the presence of prostate cancer should be excluded.
- Potential risks of open prostatectomy include urinary incontinence, erectile dysfunction, retrograde ejaculation, urinary tract infection, bladder neck contracture, urethral stricture, deep vein thrombosis, pulmonary embolus, and the need for blood transfusion.
- Advantages of open prostatectomy over TURP are a lower re-treatment rate, more complete removal of the prostatic adenoma under direct vision, and no risk of TUR syndrome.
- Disadvantages of open prostatectomy over TURP are a lower midline incision, longer hospitalization, and increased potential for perioperative hemorrhage.
- Two approaches to open prostatectomy are retropubic and suprapubic.
- Suprapubic prostatectomy is ideal for men with a large median lobe, clinically significant bladder diverticulum, or large bladder calculi.

and (3) patients who cannot be placed in the dorsal lithotomy position for TURP. With improved surgical technique these procedures can be routinely performed in a precise manner with minimal hemorrhage. Efficacy, in terms of durable improvement in symptom score and peak urinary flow rate, is superior than other treatment options available for the obstructing prostate gland, including TURP. Meanwhile, complications are minimal and the length of hospitalization has been markedly reduced. For most patients, the length of hospital stay is 3 days or less. Thus, for the properly selected individual, an open prostatectomy is a highly effective and well-tolerated operation.

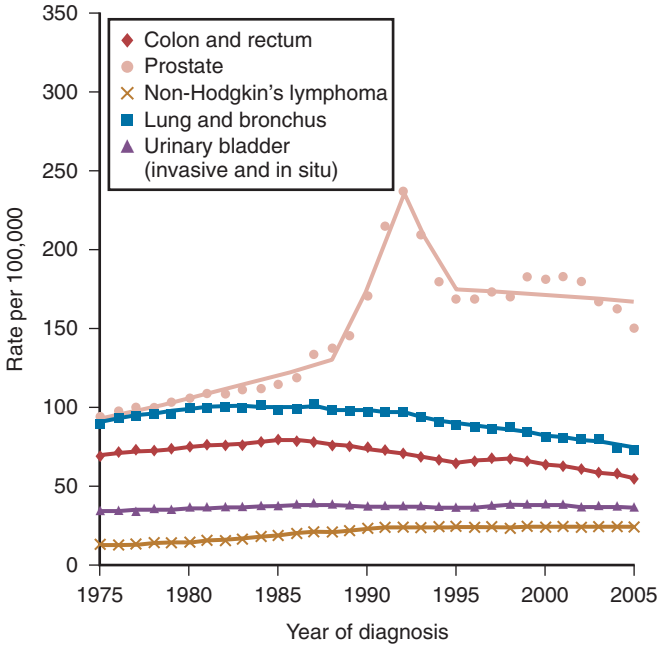
EPIDEMIOLOGY

Incidence and Mortality Trends

Incidence

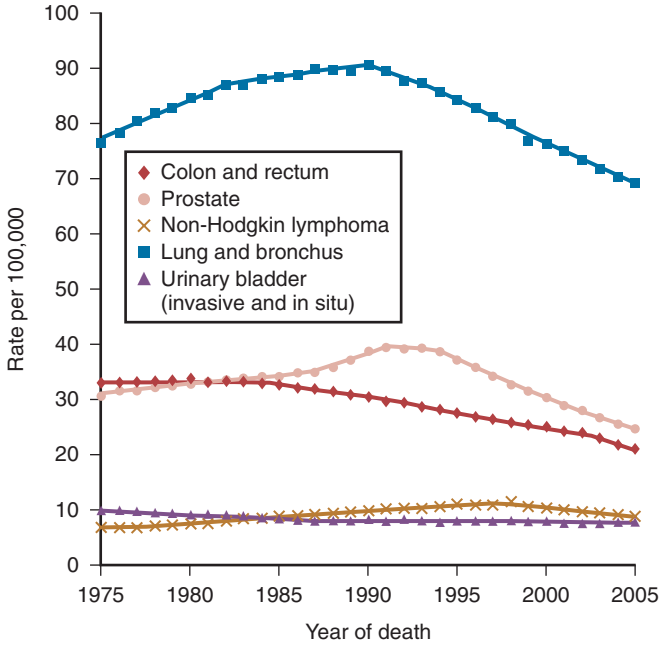
Prostate cancer has been the most common noncutaneous malignancy in U.S. men since 1984, now accounting for one quarter of all such cancers (American Cancer Society, 2008)**. The estimated lifetime risk of disease is 16.72%, with a lifetime risk of death at 2.57%.** Prostate cancer incidence varies by race/ethnicity, with African-Americans at highest risk (Table 95–1). The incidence of prostate cancer peaked in 1992 (approximately 5 years after introduction of the prostate-specific antigen [PSA] screening test), fell precipitously until 1995, increased slowly until 1995 at a slope similar to that observed prior to the PSA era, and has decreased again in recent years (Fig. 95–1). The years in which peak rates were observed can be differentiated by race: 1992 for whites (237.8 per 100,000 men) and 1993 for African-Americans in (343.1 per 100,000). **The decrease in incidence between 1992 and 1995 has been attributed to the "cull effect" of identifying previously unknown cancers in the population by the use of the PSA test, followed by a return to baseline where fewer cases were detected in previously screened individuals** (Stephenson et al, 1996). For 2008, the American Cancer Society estimated 186,320 new cases of prostate cancer in the United States (American Cancer Society, 2008).



Mortality

Prostate cancer mortality rates in the United States rose slowly between 1973 and 1990 (Fig. 95–2). This may have resulted from a gradual increase in the number of biologically lethal cancers or a decreasing use or effectiveness of therapy during this interval. In the early 1990s, an abrupt rise in mortality was observed. This increase may have been caused by an increase in attribution bias occurring when the National Center for Health Statistics made a change from manual to automated methods for assignment of cause of death (Feuer et al, 1999). **Subsequent to 1991, the peak mortality year, steady declines in prostate cancer mortality were reported. The magnitude of this decline is nearly 2.5 times larger than the increase in mortality seen as a result of attribution bias; thus it seems likely that the declines in prostate cancer mortality in the United States since 1991 are real and clinically significant** (Stephenson, 2005). In 2008, the American Cancer Society estimated 28,660 prostate cancer–related deaths in the United States, for an approximate annual rate of 23.3 per 100,000 population, representing a 41% decrease from the peak in 1991 (American Cancer Society, 2008). **Furthermore, the mortality rate for prostate cancer in white men in the United States has declined to a level lower than that observed prior to the introduction of PSA-based screening in 1987** (Tarone et al, 2000).

The observed decline in mortality since 1991 is unlikely to be explained by PSA screening alone. Based on our current beliefs concerning lead time, the decline would have occurred too soon after the initiation of screening (Etzioni et al, 1999). **One hypothesis is that it is the result of the more aggressive treatment of prostate cancer that began in the 1980s** (Walsh, 2000)**.** Rates of both radical prostatectomy (RP) and radiation therapy rose steadily through the 1980s (pre-PSA era), whereas hormone therapy and no-treatment rates remained stable (Stephenson, 2005). Outcomes for patients treated in the 1980s should be reflected in the mortality data of the 1990s, while outcomes for patients treated in the PSA era (the 1990s) have had less time to affect recent mortality data. **Given the long natural history of low-stage cancers detected in the PSA era, their treatment would not be expected to have a substantial effect on mortality statistics for another 5 to 10 years. Additional observation time is necessary to determine if screening, PSA-induced stage migration, and more aggressive use of therapy have contributed to declining mortality.**



Racial Differences

Although anthropologists accept that there are subtle biologic differences among populations, commonly used categories, such as African-American, white, and Hispanic, are social and cultural descriptors that have no defined biologic basis. **Observed disease-related differences between groups defined in this fashion may therefore be more reflective of common environmental exposure, diet, lifestyle, and attitudes**

Figure 95–2. Age-adjusted cancer death rates for men, United States, 1975-2005. (From Surveillance, Epidemiology, and End Results Program, 1975-2001, Division of Cancer Control and Population Sciences, National Cancer Institute, 2008.)

Table 95–1.

Prostate Cancer Incidence and Mortality by Race/Ethnicity, United States, 2000–2004

	INCIDENCE*	MORTALITY*
White	161.4	25.6
African-American	255.5	62.3
Hispanic/Latino	140.8	21.2
Asian-American and Pacific Islander	96.5	11.3
American Indian and Alaska Native	68.2	21.5

*Per 100,000, age adjusted to the 2000 U.S. standard population.
Data from American Cancer Society. Cancer facts and figures 2008. <http://www.cancer.org/acs/groups/content/@nho/documents/document/2008cafffinalsecuredpdf.pdf>; 2008 [accessed 06.04.11].

toward health care than of differences in genetic structure or function. Recognizing these caveats, it is noteworthy that African-American men have the highest reported incidence of prostate cancer in the world, with a relative incidence of 1.6 compared with white men in the United States (American Cancer Society, 2008). **Although African-Americans have experienced a greater decline in mortality than white men since the early 1990s, their death rates remain more than 2.4 times higher than whites.** A recent meta-analysis quantifies this difference, demonstrating a higher risk of biochemical recurrence (risk ratio = 1.34, 95% confidence interval [CI] = 1.23 to 1.46), prostate cancer–specific death (risk ratio = 1.29, 95% CI = 1.13 to 1.47), and all-cause mortality (risk ratio = 1.35, 95% CI = 1.23 to 1.48) (Evans et al, 2008). These differences were not fully explained by differences in comorbidity, PSA screening, or access to health care. One study that analyzed Medicare data found shorter survival intervals for African-Americans: 1.8 years shorter with localized disease treated by RP, 0.7 years shorter after radiation, and 1 year shorter in those choosing watchful waiting, findings that persist after adjusting for other covariates, including education and income levels (Godley et al, 2003).

Many biologic, environmental, and social hypotheses have been advanced to explain these differences, ranging from postulated differences in genetic predisposition; differences in mechanisms of tumor initiation, promotion, and/or progression; higher fat diets, higher serum testosterone levels, or higher body mass index; structural, financial, and cultural barriers to screening, early detection, and aggressive therapy; and physician bias. Differences in screening rates between whites and African-Americans may play a role in explaining the differences in mortality, although the 2005 National Health Interview Survey demonstrated that among men ages 40 to 49 years, African-American men were more likely to have had a PSA test than white men, and there were no significant differences in PSA screening rates by race/ethnicity in men ages 50 to 79 years (Ross et al, 2008). Studies have consistently shown that African-American men are more likely to receive androgen-deprivation therapy, expectant management or external beam radiation therapy, and are less likely to undergo radical

prostatectomy compared with white men (Underwood et al, 2005). Even among those treated with "watchful waiting," African-American men may receive less intensive follow-up (Shavers et al, 2004). **There are currently no data that clearly indicate any of these hypotheses are the determinants of the observed differences in incidence or mortality, and it seems likely that the source of the disparity is multifactorial.** Recent observations suggest that the incidence of organ-confined disease at diagnosis among African-Americans is increasing, that the disparity in mortality is lessening in the PSA era, and that those with organ-confined disease can be cured at a high rate regardless of race (Powell et al, 2004; American Cancer Society, 2008).

The incidence of prostate cancer in other ethnic groups is lower than that of whites and African-Americans. Comparative data for prostate cancer–related incidence and mortality are now available for these groups (see Table 95–1).

Worldwide Incidence and Mortality

Incidence rates show that prostate cancer is the fifth most common malignancy worldwide and the second most common in men (Parkin et al, 2005). **Prostate cancer makes up 11.7% of new cancer cases overall, 19% in developed countries, and 5.3% in developing countries. Its incidence varies widely between countries and ethnic populations, with disease rates differing by more than 100-fold. The lowest yearly incidence rates occur in Asia (1.9 cases per 100,000 in China) and the highest in North America and Scandinavia, especially in African-Americans (249 cases per 100,000)** (Parkin et al, 2005; American Cancer Society, 2008). As in the United States, prostate cancer incidence has increased in many countries since the early 1990s, with the largest increases in high-risk countries (Hsing et al, 2000). Although much of the increase can be correlated with the introduction of PSA, some of the increase predates screening and is perhaps partly due to the increasing diagnosis of latent cancers following transurethral resection of the prostate (Potosky et al, 1990; Oliver et al, 2001). Large increases have also been noted in low-risk countries between 1973 and 1992 (e.g., 104% among Chinese in Singapore and 84% in Miyagi, Japan) (Hsing et al, 2000). **Mortality also varies widely among countries, being highest in the Caribbean (28 per 100,000 per year) and lowest in Southeast Asia, China, and North Africa (<5 per 100,000 per year)** (Parkin et al, 2005). Mortality rates increased slowly for most countries between 1985 and 1995 (Quinn and Babb, 2002). The CONCORD study, a worldwide population-based analysis of cancer survival in five continents, recently analyzed international differences in survival for breast, colorectal, and prostate cancer (Coleman et al, 2008). **Using data from cancer registries, age-standardized 5-year survival rates were found to vary greatly, ranging from 80% or higher in the United States (92%), Australia, and Canada, to less than 40% in Denmark, Poland, and Algeria.**

There are multiple potential explanations for the worldwide and ethnic variations in prostate cancer incidence and mortality. Access to and quality of health care, the accuracy of cancer registries, and the penetrance of PSA screening all affect how rates of disease are reported. Before reliable data were available from African countries, rates of prostate cancer in Africa were thought to be much the same as those in Asia. However, in Uganda and Nigeria, prostate cancer is very common, and in Nigeria it is the most common cancer in men (Gronberg, 2003). Interestingly, there has been a more marked decline in prostate cancer mortality in countries with a higher uptake of PSA screening when compared with countries where routine screening is not widely performed (Collin et al, 2008). Possible explanations for the observed mortality differences include international variability in treatment approaches and bias related to the misattribution of cause of death.

Environment also plays an important role in modulating prostate cancer risk around the world. Japanese and Chinese men in the United States have a higher risk of developing and dying from prostate cancer than do their relatives in Japan and China (Muir et al, 1991; Shimizu et al, 1991). Likewise, prostate cancer incidence and mortality have increased in Japan as the country has become more Westernized (Hsing et al, 2000). It is important to note, however, that Asian-Americans have a lower prostate cancer incidence than white or African-American men, indicating that genetics still plays a role in determining prostate cancer predisposition.

Age at Diagnosis

Prostate cancer is rarely diagnosed in men younger than 50 years old, accounting for only 2% of all cases (Jani et al, 2008). **The median age at diagnosis is 68 years, with 63% diagnosed after age 65** (Ries et al, 2011). At 85 years of age, the cumulative risk of clinically diagnosed prostate cancer ranges from 0.5% to 20% worldwide, despite autopsy evidence of microscopic lesions in approximately 30% of men in the fourth decade, 50% of men in the sixth decade, and more than 75% of men older than 85 years (Sakr et al, 1993; Gronberg, 2003). PSA-based screening has induced an important age migration effect; the incidence of prostate cancer in men 50 to 59 years of age has increased by 50% between 1989 and 1992 (Hankey et al, 1999), with important implications for deciding on the need for, type of, and complications after therapy.

Stage at Diagnosis

In addition to changes in prostate cancer incidence and mortality over the last several decades, there has been a substantial shift to more favorable stage at presentation in men with newly diagnosed disease. **This clinical stage migration is largely if not exclusively accounted for by PSA screening** (Catalona et al, 1993; Mettlin et al, 1993). **Since the introduction of PSA testing, the incidence of local-regional disease has increased, whereas the incidence of metastatic disease has decreased** (Newcomer et al, 1997). Nonpalpable cancers (American Joint Committee on Cancer [AJCC] clinical stage T1c) now account for 60% to 75% of newly diagnosed disease (Derweesh et al, 2004; Gallina et al, 2008). Clinical stage migration has also been associated with improvements in 5- and 10-year disease-specific survival, which for all stages combined now are 99% and 91%, respectively (American Cancer Society, 2008).

The use of PSA has also resulted in a substantial downward pathologic stage migration as evidenced by an increase in the proportion of patients with organ-confined disease (Catalona et al, 1993; Jhaveri et al, 1999; Derweesh et al, 2004;) **and a decrease in the proportion with seminal vesicle involvement** (Gallina et al, 2008). These observations have been consistent across the United States and Europe (Noldus et al, 2000; Gallina et al, 2008). Since 1995, however, a slowing in this trend has been observed, suggesting a diminishing effect of PSA screening on pathologic stage migration (Fig. 95–3) (Dong et al, 2007b). The improvement in pathologic stage has been seen for clinical stages T1-T3 tumors and all tumor grades (Fig. 95–4) and has resulted in improved cancer-specific

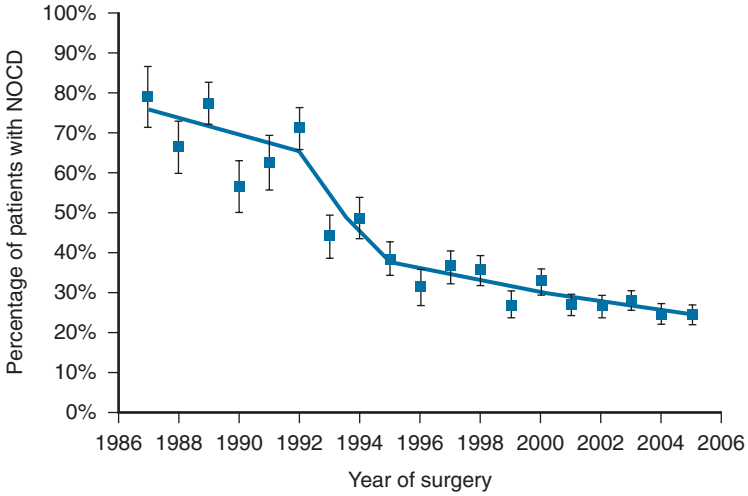

Figure 95–3. Declining rate of extracapsular extension (resulting in increased rate of organ-confined disease) on radical prostatectomy specimens at the Cleveland Clinic, 1987-2005. Trends in pathologic stage migration with joinpoint regression analysis. Annual change: 1987 to 1992: –2.9%; 1992 to 1995: –16.9%; 1995 to 2005: –4.2%. NOCD, non–organ-confined disease.

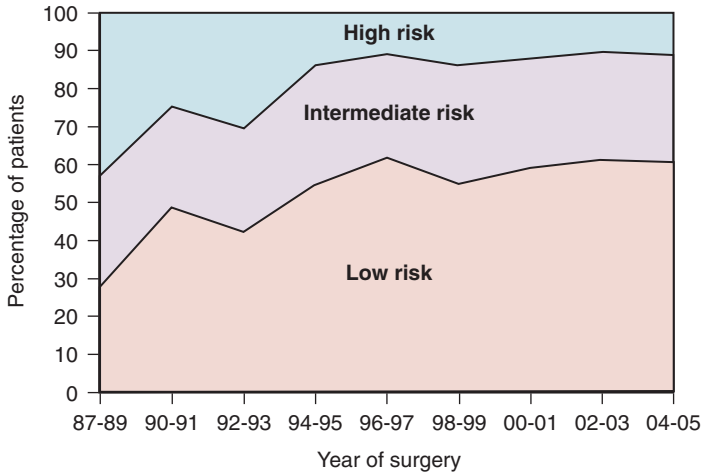

Figure 95–4. Risk stratification of surgical population over time. Low risk: prostate-specific antigen (PSA) less than 10, and stage T1 or T2a, and biopsy Gleason score = 6 or lower. Intermediate risk: PSA 10 to 20, or stage T2b or T2c, or biopsy Gleason score = 7. High risk: PSA more than 20, or stage T3, or biopsy Gleason score = 8 or higher, or any two or more intermediate risk factors.

survival after external radiation or surgery for patients treated late in the PSA era (Jhaveri et al, 1999; Derweesh et al, 2004; Kupelian et al; 2005).

Effect of Screening on Mortality

Recently, the results of two large randomized trials assessing the effect of PSA screening on prostate cancer mortality were published. **The first examined results from the Prostate, Lung, Colorectal, and Ovarian (PLCO) cancer screening trial and reported on 76,693 men aged 55 to 74 years at 10 U.S. centers receiving either annual screening or usual care** (Andriole et al, 2009). **After 7 years of follow-up, no difference in prostate cancer mortality was detected between the groups, with an incidence of 2.0 deaths per 10,000 person-years (50 deaths) in the screening group and 1.7 deaths per 10,000 person-years (44 deaths) in the control group (rate ratio = 1.13, 95% CI = 1.16 to 1.29). However, the trial has been criticized for its relatively short follow-up, given the long natural history for prostate cancer and because more than half the men in the control arm actually had a PSA test done outside of the trial. The second trial, the European Randomized Study of Screening for Prostate Cancer (ERSPC), included 162,243 men between the ages of 55 and 69 years randomized to either PSA screening every 4 years or no screening** (Schroder et al, 2009). **After a median follow-up of 9 years, screening reduced the rate of death from prostate cancer by 20% (rate ratio = 0.80, 95% CI = 0.65 to 0.98). However, they estimated that to prevent one prostate cancer death, one would need to screen 1410 men (95% CI = 1142 to 1721), and treat 48 additional cases of prostate cancer.**

The results of these trials highlight two important points. First, overall, prostate cancer is an indolent disease with a very low cause-specific death rate and will only impact life expectancy in a minority of men. Second, the morbidity of treatment needs to be strongly considered when evaluating population screening. Prior to the release of the above-mentioned studies, an evidence update for the U.S. Preventative Task Force on the benefits and harms of PSA screening concluded that false-positive PSA test results cause psychologic adverse effects for up to 1 year and that the benefits of screening remain uncertain (Lin et al, 2008). On the other hand,

Key Points: Epidemiology

- In the United States, prostate cancer:
  - Is the most common visceral malignancy in men.
  - Is the second leading cause of cancer-related deaths.
  - Incidence peaked in 1992 approximately 5 years after the introduction of PSA as a screening test, declined until 1995, subsequently increased at a rate similar to that observed in the pre-PSA era, and is declining again in recent years.
  - Mortality has declined since 1991 and for whites is now lower than before PSA was introduced.
- Worldwide, prostate cancer incidence and mortality rates:
  - Vary significantly between countries and regions.
  - Are highest in African-American men.
- PSA has induced a significant downward migration in age and stage (both clinical and pathologic) at diagnosis.
- PSA screening may have a beneficial effect on prostate cancer mortality; however, the absolute effect is small relative to the number needed to screen and treat to cure a single individual.

in 2009 the American Urological Association (AUA) released a Best Practice Statement suggesting that early detection of and risk assessment for prostate cancer should continue to be offered to asymptomatic men 40 years of age or older who have a life expectancy of at least 10 years (American Urological Association, 2009).

RISK FACTORS

Although the specific causes of prostate cancer initiation and progression are not yet known, considerable evidence suggests that **both genetics and environment play a role in the origin and evolution of this disease.** Traditional and molecular epidemiology have identified a number of potential risk factors associated with the development of prostate cancer.

Familial and Genetic Influences

Ample epidemiologic evidence suggests that prostate cancer has both a familial and genetic component. The first reports of a familial clustering were published in the mid-20th century and suggested that the risk of developing prostate cancer was higher in those with an affected first-degree relative (Woolf, 1960). Subsequent case control and cohort studies have confirmed this observation (Eeles et al, 1997). Twin studies have also suggested a genetic component, with higher rates of concordance for monozygotic than dizygotic brothers (Gronberg et al, 1994; Ahlbom et al, 1997; Page et al, 1997). **Results of a meta-analysis demonstrate that relative risk increases according to the number of affected family members, their degree of relatedness, and the age at which they were affected** (Table 95–2) (Zeegers et al, 2003). A consistent finding is the increased risk when a brother is affected compared with when a father is affected. This is consistent with either X-linked or recessive genetic components (Monroe et al, 1995). However, the bias associated with the fact that brothers of affected men are more likely to seek prostate cancer screening may also explain the differential association.

For investigative purposes, prostate cancer may be conveniently divided into three phenotypes: sporadic, familial, and hereditary. Sporadic cancers occur in individuals with a negative family history. Familial prostate cancer is defined as cancer in a man with more than one affected relative. Hereditary prostate cancer is a subset of the familial form and has been operationally defined as nuclear families with more than three affected members, prostate cancer in three successive generations, or two affected individuals diagnosed with cancer before age 55 (Carter et al, 1993). **Although most prostate cancer is likely to be polygenic in origin, the existence of true hereditary prostate cancer is suggested by three epidemiologic observations: (1) relatives of patients < 55 years old are at higher risk of getting prostate cancer than those with older affected relatives; (2) there is stronger familial clustering in families with early onset prostate cancer; and (3) the number of affected family members and their age at onset are the most important determinants of risk among relatives.** Sporadic cancers account for about 85% of all prostate cancers and about 15% are familial and/or hereditary. Hereditary prostate cancer accounts for 43% of early onset disease (55 years of age or younger) but only 9% of all cancers that occur by 85 years of age (Carter et al, 1992).

Table 95–2.

Family History and Risk of Prostate Cancer

FAMILY HISTORY	RELATIVE RISK	95% CONFIDENCE INTERVAL
None	1	
Father affected	2.17	1.90-2.49
Brother affected	3.37	2.97-3.83
First-degree family member affected, age less than 65 years at diagnosis	3.34	2.64-4.23
Greater than two first-degree relatives affected	5.08	3.31-7.79
Second-degree relative affected	1.68	1.07-2.64

Data derived from meta-analysis assessing risk of prostate cancer for relatives of patients with prostate carcinoma (Zeegers, Jellema A, Ostrer H. Empiric risk of prostate carcinoma for relatives of patients with prostate carcinoma: a meta-analysis. Cancer 2003;97:1894–03).

A number of studies have suggested a familial coaggregation of prostate cancer with breast cancer (Thiessen, 1974; Tulinius et al, 1992; Goldgar et al, 1994). The two major susceptibility genes in breast cancer, *BRCA1* (17q21) and *BRCA2* (13q12), have also been studied in prostate cancer. Two large epidemiologic studies have estimated the risk of prostate cancer in men who are carriers of specific *BRCA1* founder mutations to be double that of noncarriers, with a cumulative risk of 30% by 80 years of age (Struewing et al, 1997; Warner et al, 1999). Moreover, the *BRCA2* gene has provided consistent association with an increased risk of prostate cancer, estimated at 5- to 7-fold, and may play a more important role in early onset disease (Breast Cancer Linkage Consortium, 1999; Edwards et al, 2003). However, due to their rarity, these mutations only contribute to a small fraction of hereditary prostate cancer cases.

Linkage studies have identified a number of **candidate prostate cancer susceptibility genes, including *RNaseL* (hereditary prostate cancer-1 [*HPC1*] region, 1q23-25)** (Carpten et al, 2002)**, *ELAC2* (*HPC2* region, 17p)** (Tavtigian et al, 2001), **and *MSR1* (8p22-23)** (Xu et al, 2002). Segregation studies have also suggested the existence of prostate cancer susceptibility loci on chromosomes 1q42.2-43 (*PCAP*) (Berthon et al, 1998), 1p36 (*CAPB*, also linked to brain tumors) (Gibbs et al, 1999), and Xq27-28 (Xu et al, 1998), but the gene or genes linked to these regions have not been identified. Many other genetic loci and prostate cancer susceptibility genes have been more recently identified, and the list is continually growing (Online Mendelian Inheritance in Man, 2009).

More recently, genome-wide association studies (GWAS) have emerged as a new approach to indentify alleles associated with prostate cancer without prior knowledge of position or function (Wellcome Trust Case Control Consortium, 2007). Genotype frequencies are compared among cases and controls at DNA sequence variations called single nucleotide polymorphisms (SNPs). Using this technique, studies have demonstrated SNPs on 8q24 and 17q, as well as on chromosomes 3, 6, 7, 10, 11, 19, and X, to be associated with prostate cancer risk (Amundadottir et al, 2006; Gudmundsson et al, 2007; Eeles et al, 2008). A worldwide consortium of 13 groups was recently formed to compile the large series necessary to provide accurate estimates of the risks associated with genetic variants and to evaluate the combined association of these variants (Kote-Jarai et al, 2008). The combined risks associated with each pair of SNPs were found to be consistent with a multiplicative risk model. In total, they determined that the 15 susceptibility variants studied only explained 16% of the familial risk of prostate cancer. **This indicates that, to date, only a small piece of the prostate cancer genetic puzzle has been**

discovered, and with the continued improvement in genetic technology, it is likely that the number of known susceptibility genes will increase. A commercially available genetic test, which assesses nine genetic variants associated with prostate cancer risk, is currently offered to the general public (deCODE Genetics, Reykjavík, Iceland). Although the test is being marketed as a preventative tool, its clinical utility in the general population requires further study.

Of the known susceptibility genes, *HPC1* is the best characterized. The existence of *HPC1* was suggested by a genome-wide scan of families with hereditary prostate cancer (Smith et al, 1996) and later confirmed by linkage studies (Cooney et al, 1997; Eeles et al, 1998). A recent genome-wide association screen also identified an association between this locus and sporadic prostate cancer (Nam et al, 2008). ***HPC1* was mapped to the human gene that encodes for the antiviral and pro-apoptotic enzyme RNaseL** (Carpten et al, 2002). RNaseL is part of the innate immune system that responds to a pathogen-associated molecular pattern (PAMP) to induce degradation of viral and cellular RNAs, thereby blocking viral infections (Klein and Silverman, 2008). It is the terminal enzyme of the 2-5A synthetase family, an RNA degradation pathway that plays an important role in mediating the biologic effects of interferons, especially in response to viral infection. **2-5A binds with high affinity to RNaseL, converting it from its inactive form as a monomer to a potent dimer that degrades single-stranded RNA, thus preventing viral replication, interfering with protein synthesis, and causing caspase-mediated apoptosis** (Fig. 95–5) (Silverman, 2003). *RNaseL* knockout mice are more prone to viral infections (Silverman, 2003).

A variety of inactivating and missense mutations of *RNaseL* have been identified in families with hereditary prostate cancer (Xiang et al, 2003). **Of these, SNP R462Q, resulting from an arginine to glutamine substitution, has been shown to be associated with an increased risk of prostate cancer** (Casey et al, 2002); **men and cell lines with this allelic variant have been shown to have reduced RNaseL activity leading to deficient apoptosis** (Carpten et al, 2002; Xiang et al, 2003; Malathi et al, 2004), **presumed to lead to an accumulation of genetic defects ultimately resulting in cancer formation.**

The epidemiologic data suggest that *HPC1* is a rare autosomal dominant gene that has high penetrance, meaning that while it does not account for many prostate cancers, an individual carrier is highly likely to be affected by prostate cancer. Although cancers with specific mutations of the *HPC1/RNaseL* gene have been reported to present with higher-grade and more advanced stages (Gronberg et al, 1997; Goode et al, 2001; Rennert et al, 2005), other mutations have not shown such an association (Larson et al, 2008).

The biologic functions of the other known susceptibility genes fall into several classes. As with other malignancies, these genes include mediators of inflammation (e.g., *MIC1, MSR1*), antioxidant enzymes (e.g., *MSR1, PON1*), DNA repair (e.g., *OGG, CHEK2,* and *BRCA2*), susceptibility to infection (e.g., *MSR1, RNaseL,* and *TLR4*), and apoptosis (e.g., *RNaseL*).

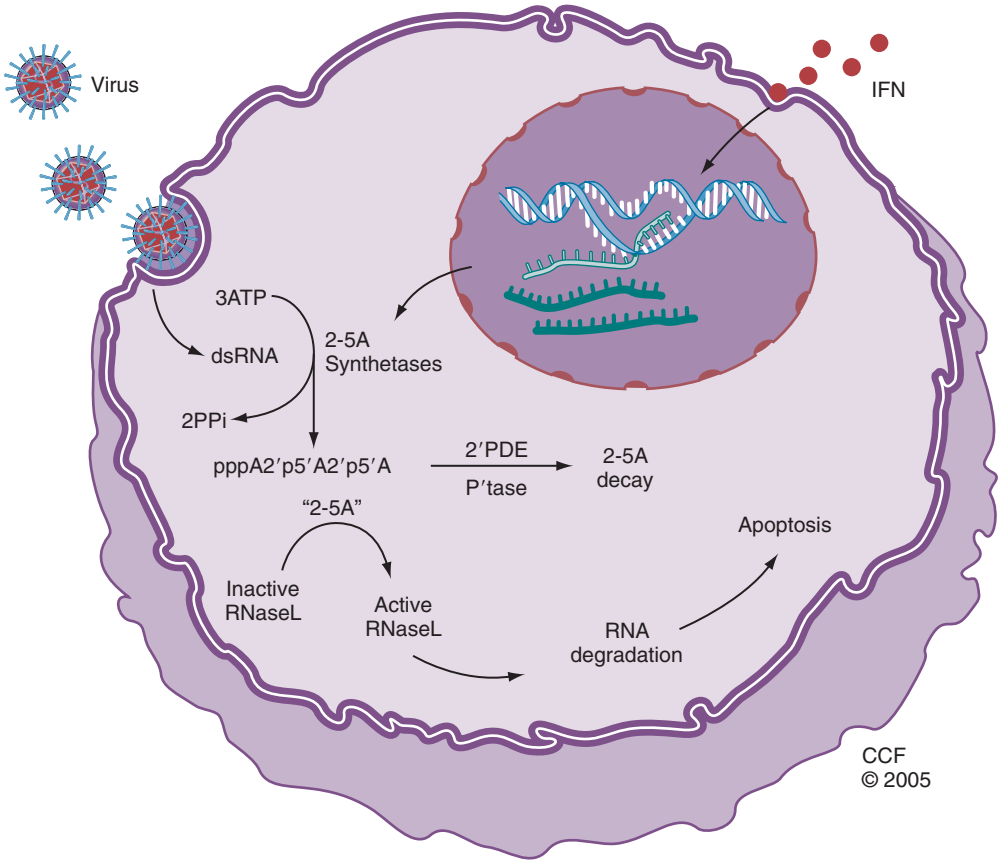

Figure 95–5. Cellular effects of RNaseL. In response to interferon (IFN) and viral infection, a family of oligoadenylate synthetases are activated, resulting in the conversion of ATP to a series of short 2′- to 5′- linked oligoadenylates (2-5A). 2-5A binds with high affinity to RNaseL, converting it from its inactive form as a monomer to a potent dimer that degrades ssRNA and causes caspase-mediated apoptosis of the host cell. Prostate cancer cells deficient in RNaseL are resistant to apoptosis. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2011. All Rights Reserved.)

Key Points: Risk Factors

- Both genetics and environment are important in the origin and evolution of prostate cancer.
- Most prostate cancer is polygenic, but some hereditary forms may be determined by variants in a single or relatively few genes.
- *HPC1* is an autosomal-dominant gene with high penetrance and encodes for the enzyme RNaseL, which has both antiviral and pro-apoptotic activity.
- Commonly observed variants in *RNaseL* result in reduced enzymatic activity and have been associated with an increased risk of prostate cancer.
- Infectious agents, both viruses and bacteria, may be important in the genesis of prostate cancer.
- Other prostate cancer susceptibility genes are mediators of inflammation, DNA repair, and defenses against oxidative stress.

Inflammation, Infection, and Genetic Susceptibility

It is estimated that infections cause almost 20% of all cancers worldwide (American Cancer Society, 2008). **Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue contributes to the development of infection-associated cancers of the colon, esophagus, stomach, bladder, and liver** (Coussens and Werb, 2002; De Marzo et al, 2007). **Accumulating epidemiologic, histologic, and genetic evidence suggests that a similar process may underlie the development of prostate cancer.**

Some evidence suggests that prostate cancer may have an infectious etiology. Two meta-analyses examining 34 case-control studies reported statistically significant associations of prostate cancer with a history of sexually transmitted infection (RR = 1.4) or prostatitis (OR = 1.57) (Dennis et al, 2002b; Dennis and Dawson, 2002). Supportive evidence is provided by studies demonstrating positive associations of antibodies against syphilis, human papillomavirus (HPV), and human herpesvirus-8 (HHV-8) with prostate cancer (De Marzo et al, 2007). Case-only or case-control studies have also reported higher plasma concentrations of acute-phase reactants and proinflammatory cytokines in men with prostate cancer (De Marzo et al, 2007). Two studies have demonstrated evidence of viral pathogens in human prostate tissue, including HPV, human herpes simplex virus type 2 (HSV2), cytomegalovirus (CMV), and HHV-8 (Strickler and Goedert, 2001; Zambrano et al, 2002; Samanta et al, 2003).

However, recent studies assessing the association between infection and prostate cancer have shown mixed results. In the Health Professionals Follow-up Study (Sutcliffe et al, 2006), a prospective study of 51,529 American male health professionals aged 40 to 75 years, no association was found between a self-reported history of gonorrhea or syphilis and prostate cancer, although the incidence of sexually transmitted infections was very low in this population. In addition, no overall correlation between prostate cancer and clinical prostatitis was found. Similarly in this cohort, no associations were observed between *Chlamydia trachomatis*, HPV-16, HPV-18, and HPV-33 antibody seropositivity and prostate cancer (Sutcliffe et al, 2007a). Conversely, in a small case-control study in African-American men (Sarma et al, 2006), a history of gonorrhea or prostatitis increased the odds of prostate cancer by 1.78-fold (95% CI = 1.13 to 2.79) and 4.93-fold (95% CI = 2.79 to 8.74), respectively, even after adjusting for potential confounders. Furthermore, men reporting 25 or more sexual partners had 2.80 times the odds of being diagnosed with cancer (95% CI = 1.29 to 6.09) compared with men with five or fewer partners.

Inflammatory infiltrates and the histologic lesion called proliferative inflammatory atrophy (PIA) are frequent in clinical prostate specimens (De Marzo et al, 1999). **PIA is a spectrum of lesions characterized by epithelial atrophy, low apoptotic index, and an increased proliferative index usually associated with inflammatory infiltrates** (Putzi and De Marzo, 2000). Inflammation in PIA may include mononuclear infiltrates in the stroma and macrophages and/or neutrophils in the glandular lumen or epithelium. Macrophages activated by interferon-γ secrete proinflammatory cytokines and reactive nitrogen species (e.g., nitric oxide). Inducible nitric oxide synthase, which catalyzes the generation of nitric oxide, is overexpressed in macrophages in PIA but not in normal epithelium (Nelson et al, 2003). **PIA appears to be a regenerative lesion appearing as a consequence of infection or cell trauma resulting from oxidant damage, hypoxia, infection, or autoimmunity, and its hyperproliferative state may lead to cancer.** PIA is often found adjacent to high-grade prostatic intraepithelial neoplasia (HGPIN) or early cancer (Putzi and De Marzo, 2000), and there is an identifiable genetic pathway between PIA, HGPIN, and cancer (Shah et al, 2001; Nakayama et al, 2003; Nelson et al, 2003).

The previously described genetic and histologic observations in prostate cancer strongly suggest that compromised cellular defenses against inflammatory oxidants may initiate and/or perpetuate prostatic carcinogenesis. Oxidative stress is mediated by reactive oxygen and nitrogen species that bind DNA and cause mutations, and oxidant stresses from exogenous and endogenous sources are implicated in the accumulation of DNA damage that occurs with aging and subsequently leads to malignant change (Coussens and Werb, 2002). Cellular defense mechanisms against this process include frontline antioxidant enzymes, which scavenge reactive oxygen and nitrogen species and prevent mutations; DNA repair enzymes; and the ability to undergo apoptosis if the DNA damage is too severe to repair. **A recent model proposes that inherited and acquired defects in cellular defense mechanisms against infection and oxidative stress allow prostate cancer to develop.** This model suggests that, as in other inflammatory-mediated cancers, persistent infection leads to chronic inflammation, and that defects in antioxidant enzymes, DNA repair mechanisms, and apoptosis lead to cancer. Subsequent expression by tumor cells of α-methylacyl-CoA racemase (Kumar-Sinha et al, 2004), an enzyme that oxidizes branched-chain fatty acids from dietary sources, results in generation of hydrogen peroxide, which may contribute to continued oxidative stress, and tumor growth. This model is illustrated in Figure 95–6. **In addition to providing a framework for further experimental study, this model gives a theoretical rationale for the use of antioxidants as chemopreventative agents (see later).**

Like cervical cancer, which is characterized by viral infection coincident with the onset of sexual activity, histologic evidence of preinvasive lesions, and a latency period of 15 to 20 years before the development of invasive cancer, **the accumulating**

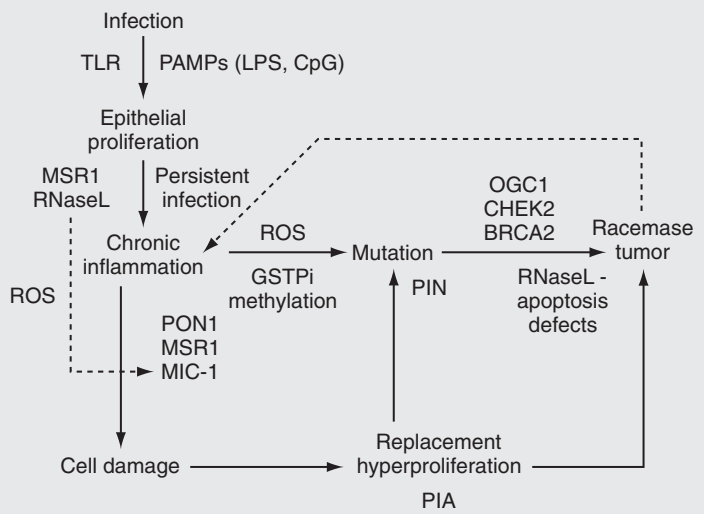

Figure 95–6. Model of prostate cancer pathogenesis related to infection, chronic inflammation, and defects in cellular defense against oxidative stress. Defects in Toll-like receptor (TLR) genes lead to immortalization of benign prostatic epithelium, and allelic variants of *RNaseL* and *MSR1* allow persistent infection, leading to a proinflammatory cellular microenvironment. Defects in genes that control the intensity of the inflammatory response (*MSR1* and *MIC1,* the latter of which is regulated by *RNaseL*) permit a robust inflammatory response. Defects in cellular defenses against the resultant oxidative stress, including deficiencies in antioxidant enzymes (allelic variants in *PON1,* methylation of *GSTP1*), DNA repair (*OGG1, CHEK2, BRCA2*), and apoptotic defects (*RNaseL*), lead to cancer through the histologic intermediates proliferative inflammatory atrophy (PIA) and prostatic intraepithelial neoplasia (PIN). Established tumors make racemase, an enzyme that converts fatty acids to free radicals, creating an autocrine growth loop based on perpetuation of oxidative stress. CpG, DNA CpG island repeats (representing viral genomes in this context); LPS, bacterial lipopolysaccarhide; PAMP, pathogen-associated molecular profile; ROS, reactive oxygen species.

histologic, epidemiologic, and genetic evidence suggests the possibility that at least some prostate cancer cases have a viral pathogenesis. The epidemiologic data linking prostate cancer risk to prior infections and the association of a functionally important mutation in the antiviral *HPC1/RNaseL* gene support this hypothesis. Recently reported studies have identified a previously undescribed γ-retrovirus, xenotropic murine leukemia–related virus (XMRV), from prostate cancer tissue in men with the R462Q allelic variant of *HPC1/RNaseL*. The initial experiment demonstrated the presence of viral genomes for XMRV in prostate tumors in 8 of 20 patients with the R462Q SNP in *RNaseL*, but in only 1 of 62 wild-type or heterozygous patients (Urisman et al, 2006). XMRV infections were visualized by immunohistochemistry and fluorescence in-situ hybridizations in prostatic stromal cells adjacent to the tumor. A full-length, replication-competent, and infectious viral molecular clone of XMRV was subsequently cloned from prostate tissue cDNA and has been used for in-vitro studies (Dong et al, 2007a). In addition, XMRV integration sites have been mapped in host chromosomal DNA (Kim et al, 2008), suggesting that modulation of cancer-related gene function by XMRV could be important. The presence of XMRV in prostate tissue has been recently confirmed by two other groups, including evidence of expression of XMRV proteins in malignant prostatic epithelium using a rabbit polyclonal antibody (Fischer et al, 2008; Singh Laboratory, 2010). **Together these observations suggest that XMRV infects and persists in the prostate when there is a deficiency in RNaseL activity, providing a proposed mechanism by which XMRV could be oncogenic in genetically susceptible individuals.**

Other infectious agents have also been implicated in prostate cancer. BK virus (BKV), a member of the polyomavirus family, infects almost 90% of the human population by early childhood and resides in a subclinical persistent state in the urinary tracts of healthy individuals. BKV transforms rodent cells in culture, causes kidney tumors in transgenic mice, and immortalizes primary human cells alone or in the presence of other oncogenes such as c-*RAS* and adenovirus *E1A* (Das et al, 2008). The occurrence of mutations in *TP53* and *RB1* in the early stages of prostate cancer is relatively low, suggesting the possibility that a virus, such as BKV (encoding tumor antigens that inactivate these tumor suppressors), may play a role in the etiology of prostate cancer. BKV DNA has been demonstrated in epithelial cells of benign and PIA ducts of cancerous prostate specimens, and BKV large tumor antigen (Tag) expression has been observed specifically in atrophic epithelial cells, PIA, and prostatic intraepithelial neoplasia (PIN) but not in cancer nor in the epithelium of normal prostates (Das et al, 2004, 2008). These observations suggest a role for BKV in PIA and the early development of prostate cancer. Furthermore, in a study examining the bacterial flora of prostate cancer, Sfanos and Isaacs (2008) demonstrated the presence of 83 distinct microorganisms by sequencing bacterial 16S rDNA in core samples of 30 prostate cancers, most of which were not found by routine culture methods. If XMRV, BKV, or specific bacteria are proven to be oncogenic, their effects may be preventable by development of a protective vaccine.

Key Points: Inflammation, Infection, and Genetic Susceptibility

- Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue contributes to the development of infection-associated cancers, possibly including prostate cancer.
- Some epidemiologic data suggests that a history of sexually transmitted infection or prostatitis is associated with a higher risk of prostate cancer.
- Histologic evidence of inflammation, as manifested by proliferative inflammatory atrophy, is common in prostate cancer and may represent a key pathobiologic process in its development.
- Both genetic and histologic observations suggest that compromised cellular defenses against inflammatory oxidants are important in prostate cancer initiation and promotion.

Molecular Epidemiology

Molecular epidemiologic approaches have identified many biomarkers of exposure measured in blood or other tissues and evaluated them in relation to incidence or mortality. These biomarkers capture aspects of diet, environmental contaminants, and factors for which concentrations are partly genetically determined. A brief

survey of major molecular epidemiologic studies relating to prostate cancer is presented.

Gene Fusions

Gene fusions resulting from chromosomal translocations are the most common genetic alteration in human cancers (Futreal et al, 2004). These were previously thought to be the oncogenic mechanism exclusively limited to hematologic malignancies and sarcomas, as exemplified by the BCR-ABL1 fusion protein in chronic myeloid leukemia. **In 2005, recurrent genomic rearrangements in prostate cancer were identified, resulting in the fusion of the 5′ untranslated end of *TMPRSS2* (21q22.2, an androgen-responsive, prostate-specific, transmembrane serine protease gene) to members of the *ETS* family of oncogenic transcription factors** (Tomlins et al, 2005). **In over two dozen published reports using PSA-screened patient cohorts, the most common fusion identified in localized prostate cancer involves *TMPRSS2* fused to *ERG* (*ETS*-related gene, 21q22.3) in approximately 50% of patients** (Kumar-Sinha et al, 2008). However, this gene fusion may be less common (15%) in population-based cohorts (Demichelis et al, 2007). Gene fusions involving other members of the *ETS* family, most commonly *ETV1* (*ETS* variant gene 1, 7q21.2), but also *ETV4* and *ETV5,* are likely present in less than 10% of prostate cancer samples collectively (Kumar-Sinha et al, 2008).

The *TMPRSS2* gene is prostate specific, and is expressed in both benign and malignant prostatic epithelium. *TMPRSS2* expression has been shown to be induced by androgens in hormone-responsive prostate cancer cell lines (Lin et al, 1999). Therefore it is hypothesized that *TMPRSS2* drives *ETS* gene overexpression in prostate cancers positive for *TMPRSS2-ETS* gene fusions (Fig. 95–7) (Kumar-Sinha et al, 2008). Although some studies have demonstrated an association between *TMPRSS2-ERG* with high pathologic stage (Mehra et al, 2007), higher recurrence rates (Nam et al, 2007), and prostate cancer–specific death (Demichelis et al, 2007), others have failed to report such clinical correlations. It is notable, however, that the presence of *TRMPSS-ETS* gene fusion was associated with a markedly higher risk of death in men managed by watchful waiting in one Swedish cohort (Demichelis et al, 2007).

Currently, the clinical application of this discovery is uncertain. Given that *ETS*-positive and *ETS*-negative tumors have distinct morphologic features, expression signatures, and potentially different clinical outcomes, some have proposed classifying prostate cancer as two categories: *ETS* gene fusion–positive and *ETS* gene fusion–negative disease (Kumar-Sinha et al, 2008). Because these gene fusions do not occur in benign prostate tissue, a sensitive and specific screening test based on their presence could be developed for the detection of prostate cancer. Eventually, gene fusion status may be used to decide the need for initial or repeat biopsy, for enrollment in therapeutic trials, or for surveillance after therapy. It also follows that targeting ERG activity in fusion-positive prostate cancers may provide an effective therapeutic approach for this subset of patients. Presently, attempts at identifying small molecular inhibitors of the ERG pathway that could serve as therapeutic agents are underway. **At this time, the emerging consensus suggests that *TRMPSS*-related gene fusions are highly specific for the presence of prostate cancer, but their utility as prognostic markers requires further study.**

Androgens

Androgens influence the development, maturation, and maintenance of the prostate, affecting both proliferation and differentiation of the luminal epithelium. There is little doubt that exposure of the prostate at key developmental times to androgens plays an important role in prostate carcinogenesis. Androgens are also important in the maintenance of established cancers, as supported by the historical observation that the majority of prostate cancers initially respond to androgen-deprivation therapy, and more recently by results of the Prostate Cancer Prevention Trial, which indicated that inhibition of the conversion of testosterone to the more potent dihydrotestosterone by finasteride reduces the incidence of prostate cancer by approximately 25% (Thompson et al, 2003). In addition, genetic polymorphisms of the androgen receptor (AR) (Balic et al, 2002; Taplin et al, 2003), the 5α-reductase type 2 isoenzyme (Makridakis and Reichardt, 2004), and the genes involved in biosynthesis of testosterone have also been implicated in prostate carcinogenesis (Chang et al, 2002).

High serum androgen levels have long been hypothesized to be a risk factor for prostate cancer. However, studies examining this association have been inconsistent, with some studies finding an association between specific hormones and prostate cancer risk. Recently, a collaborative group performed a pooled analysis of 18 prospective studies assessing this association using data from 3886 men with prostate cancer and 6438 control subjects (Endogenous Hormones, Prostate Cancer Collaborative Group, 2008). **The collaborative analysis failed to detect an association between the risk of prostate cancer and serum concentrations of testosterone, calculated free testosterone, dihydrotestosterone, dehydroepiandrostenedione sulfate, androstenedione, androstanediol glucuronide, estradiol, or calculated free estradiol.** The only positive finding in this study was a modest inverse association between prostate cancer risk and serum concentration of sex-hormone binding globulin. **This study suggests that one-time**

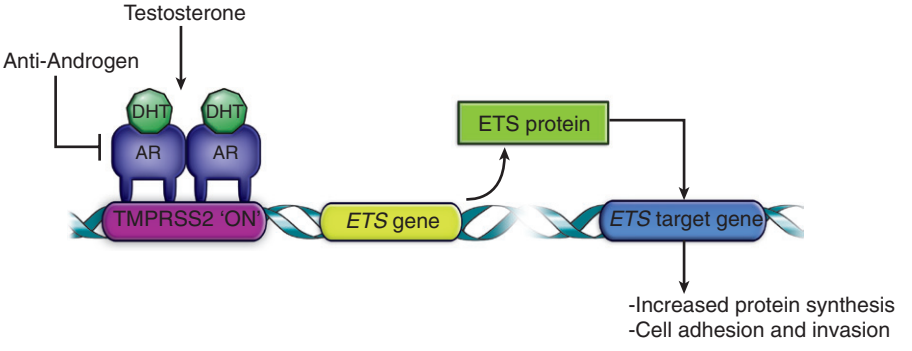

Figure 95–7. Role of gene fusion in prostate cancer. Androgen-mediated upregulation of *ETS* genes (for example, ERG or *ETV1*) leads to the activation of *ETS* target genes involved in increased protein synthesis, and cell adhesion and invasion. DHT, dihydrotestosterone.

measurements of serum sex hormones in adulthood are not a good measure of prostate cancer risk.

Estrogens

Estrogens have both direct and indirect effects on prostatic growth and development and have been postulated to play a role in prostate cancer initiation and progression. **Traditionally, estrogens have been considered protective against prostate cancer and have been used as a treatment for advanced disease.** This treatment effect is primarily through a negative feedback on the hypothalamo-pituitary-gonadal axis, and also through a direct inhibitory effect of estrogens on prostate epithelial cell growth. **However, there is increasing evidence from animal studies that estrogens may act as procarcinogens in the prostate** (Leav et al, 1988). Aromatase-knockout mice cannot produce 17β-estradiol locally in the prostate, and despite elevated testosterone and dihydrotestosterone, they do not develop prostate cancer (McPherson et al, 2001). There is evidence across multiple species that estrogens acting through stromal estrogen receptor (ER) α may contribute to prostate carcinogenesis and cancer progression (Prins and Korach, 2008). ERα expression is silenced in early prostate cancers, and re-emerges with disease progression. Prostate epithelial ERβ may play an important role in initiation of prostate cancer, with loss of ERβ potentially contributing to disease progression in organ-confined disease (Prins and Korach, 2008). In addition, the re-emergence of ERβ expression in metastatic prostate cancer also suggests a potential role in progression to castrate-resistant disease. Age-related prostatic disease parallels increases in serum estrogen levels, and there is a low incidence of prostate cancer in cultures with diets rich in phytoestrogens (Denis et al, 1999). However, the data on serum estrogen levels and prostate cancer risk are mixed (Barrett-Connor et al, 1990; Gann et al, 1996; Chen et al, 2003). Complicating interpretation of serum measurements is the fact that estradiol can be produced from testosterone by intraprostatic aromatase (Risbridger et al, 2003).

Insulin-Like Growth Factor Axis

Insulin-like growth factor (IGF)-1 is a peptide hormone that promotes growth in adolescence and childhood and is correlated with adult lean body mass (Severson et al, 1988). **IGF-1 promotes proliferation and inhibits apoptosis in normal prostate and tumor cells in vitro** (Cohen et al, 1991; Cohen et al, 1994). IGF-1 circulates bound to binding proteins, the most prevalent of which is insulin-like growth factor binding protein (IGFBP)-3. In the prostate IGFBP-3 promotes apoptosis and may mediate growth inhibition by 1,25-dihydroxyvitamin D (Boyle et al, 2001). IGFBP-3 can be cleaved by PSA, reducing its pro-apoptotic activity (Koistinen et al, 2002).

Results of epidemiologic studies suggest an association between IGFs and their associated binding proteins (IGFBPs) with prostate cancer risk. A recent combined analysis of individual patient data from 12 studies attempted to quantify the magnitude of the association (Roddam et al, 2008). The study included data on 3700 men with prostate cancer and 5200 control subjects. They found a **positive correlation between serum concentration of IGF-1 and subsequent prostate cancer risk.** The OR in the highest versus lowest quintile was 1.38 (95% CI = 1.19 to 1.60). Serum IGFBP-3 concentration was not found to be independently associated with prostate cancer risk; the observed association was secondary to its association with IGF-1 levels. Neither IGF-2 nor IGFBP-2 concentrations were associated with prostate cancer risk.

Leptin

Leptin, a peptide hormone produced by adipocytes, contributes to the control of body weight by appetite suppression and modulating energy use (Friedman, 2002). Obese men become leptin resistant and exhibit elevated plasma leptin (Chu et al, 2001). **Epidemiologic studies assessing the association between circulating leptin concentrations with prostate cancer have yielded mixed results** (Chung and Leibel, 2006). A genetic study found that prostate cancer patients were almost 5 times more likely to carry a polymorphism that results in increased leptin expression compared with controls (Ribeiro et al, 2004). **There is significant evidence, however, suggesting that leptin plays a role in the development of advanced prostate cancer** (Ribeiro et al, 2006). Leptin has been shown to stimulate proliferation of the androgen-independent prostate cancer cell lines DU145 and PC-3 (Somasundar et al, 2004; Deo et al, 2008). In addition, leptin appears to induce expression of vascular endothelial growth factor (VEGF) and basal fibroblast growth factor (BFGF), and stimulate cell migration (Frankenberry et al, 2004). Energy imbalance, perhaps mediated by leptin, is emerging as a possible contributor to the progression of prostate cancer to metastasis and death (Calle et al, 2003; Platz et al, 2003).

Vitamin D, Vitamin D Receptor, and Calcium

Vitamin D (1,25 dihydroxyvitamin D_3) is an essential vitamin that is a part of the steroid hormone superfamily. Human sources include both dietary intake and conversion from an inactive to active vitamin D in the skin through sunlight exposure. Interest in vitamin D as a determinant of prostate cancer risk comes from several epidemiologic observations (Peehl et al, 2003):

1. Men living in northern latitudes with less exposure to sunlight-derived ultraviolet exposure have a higher mortality rate from prostate cancer.
2. Prostate cancer occurs more frequently in older men, in whom vitamin D deficiency is more common both because of less ultraviolet exposure and age-related declines in the hydroxylases responsible for synthesis of active vitamin D.
3. African-Americans, whose skin melanin blocks ultraviolet radiation and inhibits activation of vitamin D, have the highest worldwide incidence and mortality rates for prostate cancer.
4. Dietary intake of dairy products rich in calcium, which depresses serum levels of vitamin D, is associated with a higher risk of prostate cancer.
5. Native Japanese, whose diet is rich in vitamin D derived from fish, have a low incidence of prostate cancer.

In addition, prostate cancer cells express the vitamin D receptor, and several studies have demonstrated an antiproliferative effect of vitamin D on prostate cancer cell lines by inducing cell cycle arrest (Krishnan et al, 2003).

Many studies show no or a weak association between vitamin D levels and prostate cancer risk (Chan and Giovannucci, 2001; Freedman et al, 2002; Jacobs et al, 2004; Ahn J et al, 2008). The Cancer Prevention Study II Nutrition Cohort, a prospective cohort of 65,321 men demonstrated a modestly increased relative risk of 1.2 for total calcium intake (dietary and with supplements) and 1.6 for high dietary calcium intake alone (≥2000 vs. <700 mg/day), but not for dairy intake (Rodriguez et al, 2003). The results suggest that very high calcium intake, above daily recommendation, may modestly increase risk. **These conflicting results regarding vitamin D, calcium, and prostate cancer risk may be explained by variants in the**

vitamin D receptor (VDR). Polymorphisms resulting in a VDR with lower activity have been associated with increased risk for prostate cancer, as well as with increased risk of biochemical recurrence following radical prostatectomy (Oakley-Girvan et al, 2004; Williams et al, 2004; John et al, 2005).

Other Influences

Sexual Activity/Sexually Transmitted Diseases

Sexual activity has been hypothesized to expose the prostate to infectious agents, which may increase the risk of prostate cancer, akin to the causal relationship between HPV and cervical cancer in women. **Some studies have found a link between sexually transmissible infections (STIs) and prostate cancer risk** (Fernandez et al, 2005; Sarma et al, 2006), **although not consistently** (Patel et al, 2005; Huang et al, 2008). A meta-analysis of 6022 cases of prostate cancer and 7,320 controls found significant associations between prostate cancer and any STI (odds ratio [OR] = 1.48, 95% CI = 1.26 to 1.73), gonorrhea (OR = 1.35, 95% CI = 1.05 to 1.83), and human papillomavirus (OR = 1.39, 95% CI = 1.12 to 2.06) but not for syphilis (Taylor et al, 2005). Studies have also suggested a protective association between prostate cancer and frequency of ejaculation, with RR ranging from 0.66 to 0.89 (Giles et al, 2003; Leitzmann et al, 2004). In the Giles study, the protective effect was seen in men in their 20s, who reported greater than 5 ejaculations per week; the large prospective cohort study by Leitzmann demonstrated a protective effect for men in their 20s and 40s, reporting greater than or equal to 21 ejaculations per month in the previous year and as a lifetime average. The biologic basis for this effect is not known.

Vasectomy

A relationship between vasectomy and prostate cancer risk was initially suggested in 1993 with a relative risk of 1.6 based on two large cohort studies (Giovannucci et al, 1993a, 1993b). Risk increased with time so that men who underwent vasectomy at an early age had a higher risk. A recent meta-analysis reported a pooled relative risk of 1.37, with a linear trend suggesting a 10% increase for each additional 10 years since vasectomy (Dennis et al, 2002a). On the other hand a large, population-based, case-control study found no association between prostate cancer and vasectomy, nor with time since vasectomy (Cox et al, 2002). The biologic mechanism by which vasectomy might predispose to cancer is unknown, although presence of antisperm antibodies, and decreased seminal androgen concentrations or secretory activity have been proposed. The magnitude of the relative risk is small enough to potentially be explained by inadequate selection of controls and/or selection bias, because men who have undergone vasectomy may be more likely to seek follow-up with a urologist. After excluding studies that were likely biased, one analysis found that the association became nonsignificant (Millard, 1999).

Smoking

Cigarette smoke may be a risk factor for prostate cancer, because it is a source of cadmium exposure, increases circulating androgen levels, and causes significant cellular oxidative stress. Both case-control and cohort studies have produced conflicting results and none have demonstrated a clear dose-response relationship, although some recent studies have suggested an association with more advanced stage at diagnosis and increased prostate cancer–related mortality (Bostwick et al, 2004).

Diet

Descriptive epidemiologic studies of migrants, geographic variations, and temporal studies suggest that dietary factors may contribute to prostate cancer development (Bostwick et al, 2004). The incidence of latent prostate cancers is similar around the world, but the incidence of clinically manifest cancers differs, with Asians having the lowest rates of clinical prostate cancer. Thus the most convincing evidence for the role of the diet and other environmental factors in modulating prostate cancer risk comes from migration studies showing an increased incidence of prostate cancer in first-generation immigrants to the United States from Japan and China (Muir et al, 1991; Shimizu et al, 1991). These observations suggest that diet may play a role in converting latent tumors into clinically manifest ones. A strong positive correlation exists between prostate cancer incidence and the corresponding rates of several other diet-related cancers, including breast and colon cancers (Bostwick et al, 2004).

Dietary Fat

Prostate cancer incidence and mortality rates around the world correlate highly with the average level of fat consumption, especially for polyunsaturated fats (Bostwick et al, 2004). Potential mechanisms of action include fat-induced changes in the hormonal milieu, induction of oxidative stress, and/or insulin-like growth factor-1 (IGF-1). High levels of dietary fat stimulate proliferation of prostate cancer cells both in vitro and in vivo, and animal models have shown that a fat-free diet can reduce the growth of androgen-dependent tumors in the Dunning model (Clinton et al, 1988; Wang et al, 1995; Aronson et al, 1999).

Epidemiologic studies have suggested a moderate to strong association between total and specific fats and the risk of developing prostate cancer (Chan et al, 2005). However, results from large prospective studies showed no association between dietary fat intake and prostate cancer risk (Park et al, 2007; Wallstrom et al, 2007; Crowe et al, 2008). **A meta-analysis of observational studies demonstrated only a weak association between higher intake of total fat and risk of prostate cancer (RR = 1.2, 95% CI = 1.1 to 1.3), and noted a large degree of heterogeneity between studies** (Dennis et al, 2004). Observations on the association of dietary fat and risk may have alternative explanations. Diets high in meats, which are sources of fat, are also usually low in vegetables containing nutrients that may protect against prostate cancer. Furthermore, meats and dairy products contain other constituents, such as zinc (Zn) and calcium (Ca), that may affect prostate cancer risk.

Obesity

Obesity as measured by body mass index (BMI) has been suggested as a risk factor for prostate cancer, because of their common occurrence in middle-aged men and clear links to colon and breast cancer risk (Giovannucci, 1995; Madigan et al, 1998). White fat in mammals serves not only as an important energy reservoir but also as an endocrine organ, with secretion of cytokines and agents with cytokine-like activity (tumor necrosis factor [TNF]-α, interleukin [IL]-1β, IL-6, IL-8, IL-10, transforming growth factor [TGF]-β), as well as their soluble receptors (Trayhurn and Wood, 2004). Several studies have shown that BMI and waist circumference show significant positive correlation with markers of oxidative stress (Keaney et al, 2003; Furukawa et al, 2004). Treatment of obesity through reduction in fat intake and increased exercise has been shown to reduce oxidative stress, suggesting that lifestyle

modification could be important in reducing the risk of prostate cancer (Roberts et al, 2002).

Studies examining the association between adult body mass index and the risk of prostate cancer have yielded conflicting results. **Two recent meta-analyses of observational studies have estimated the RR of prostate cancer to be 1.05 (95% CI = 1.01 to 1.08) and 1.03 (95% CI = 1.00 to 1.07) per 5 kg/m² increment in BMI** (MacInnis and English, 2006; Renehan et al, 2008). **Recently, three large prospective studies, examining the association between obesity and prostate cancer risk by stage and/or grade at diagnosis, suggested that obesity was associated with a lower risk of low-grade disease but a greater risk of high-grade disease** (Gong et al, 2006; Rodriguez et al, 2007; Wright et al, 2007). Potential explanations for the latter observation include the association of obesity with higher serum estradiol, insulin, free IGF-1, and leptin levels, and lower free testosterone and adiponectin levels, which have also been associated with more aggressive prostate cancer (Buschemeyer and Freedland, 2007). Another possible explanation is detection bias. Higher BMI has been shown to be associated with lower serum PSA (Baillargeon et al, 2005), which in obese men could lead to fewer prostate biopsies. However, given that the association between obesity and high-grade disease was also observed in the Prostate Cancer Prevention Trial, a study in which all men underwent biopsy, it is unlikely that detection bias is solely responsible for this finding (Gong et al, 2006).

Alcohol Consumption

Alcohol consumption and risk of prostate cancer is of interest because of its association with other cancers, its effect on estrogen and testosterone, and the high content of polyphenolic compounds with antioxidant activity in red wine. Although initial studies suggested an association between alcohol intake and prostate cancer risk (Sesso et al, 2001; Velicer et al, 2006), and a possible protective effect of red wine (Schoonen et al, 2005), recent large studies have failed to detect an association between total alcohol intake and the incidence of prostate cancer (Schoonen et al, 2005; Baglietto et al, 2006; Sutcliffe et al, 2007b; Rohrmann et al, 2008), suggesting that alcohol does not contribute appreciably to the etiology of this disease.

Key Points: Molecular Epidemiology

- Androgen exposure of the prostate plays an important but incompletely defined role in prostate carcinogenesis.
- Long-term absence of androgen exposure to the prostate appears to protect against the development of cancer, but a dose-response relationship between androgen levels and cancer risk has not been established.
- Polymorphisms in genes encoding for the androgen receptor and various enzymes related to androgen metabolism may be important determinants of prostate cancer risk.
- Estrogen is also important in prostate cancer development and may have varying effects depending upon local tissue activity of ERα and ERβ.
- Elevated serum levels of IGF-1 have been associated with prostate cancer risk.
- Dietary factors, including saturated fat consumption, may also be important in prostate cancer risk.

ETIOLOGY AND MOLECULAR GENETICS

Prostate cancer is unique among solid tumors in that it exists in two forms: a histologic or clinically occult form, which can be identified in approximately 30% of men greater than 50 years old and 60% to 70% of men greater than 80 years old, and a clinically evident form, which affects approximately one of six U.S. men. Latent prostate cancer is believed to have a similar prevalence worldwide and among all ethnicities, whereas the incidence of clinical prostate cancer varies dramatically between and within different countries. For this reason, an understanding of prostate cancer etiology must encompass the steps leading to both the ***initiation*** of histologic cancer and ***progression*** to clinically evident disease. **The exact molecular relationship between latent and clinical cancers is not known, and it is likely that the progression from latent to clinically evident cancer is a biologic continuum with overlap in the associated molecular events.** Mutations, downregulation by promoter methylation and other mechanisms, and protein modification have all been implicated in progression of prostate cancer (Fig. 95–8).

The Influence of Androgens

As previously discussed, androgens play an important role in prostate carcinogenesis. **The primary androgen of the prostate is dihydrotestosterone (DHT), irreversibly catalyzed from testosterone by 5α-reductase. DHT binds to intracytoplasmic AR with much greater affinity than testosterone, and binding of DHT to the AR enhances translocation of the steroid-receptor complex into the nucleus and activation of androgen response elements** (Steers, 2001). There are two isoenzymes of 5α-reductase, the products of two separate genes. **Type 1 5α-reductase is expressed primarily in the skin and liver and, to a lesser extent, in the prostate, while the type 2 enzyme is expressed predominantly in prostate epithelium and other genital tissues** (Andriole et al, 2004b).

Functional type 2 5α-reductase is a prerequisite for normal development of the prostate and external genitalia in males, and insufficient exposure of the prostate to DHT appears to protect against the development of prostate cancer. Transrectal ultrasonography (TRUS) in males with inherited 5α-reductase deficiency demonstrates miniscule prostatic tissue, and biopsies demonstrate stroma but no epithelium (Imperato-McGinley and Zhu, 2002). **In addition to the lack of enzyme activity, a lack of testosterone may also protect against the development of prostate cancer, as evidenced by the atrophic prostates seen in men after surgical castration** (Wilson and Roehrborn, 1999).

Although exposure of the prostate to androgens seems to be prerequisite for later development of prostate cancer, the duration and magnitude of androgen exposure needed to set the stage for carcinogenesis is unknown. As mentioned above, studies assessing the association between serum testosterone or sex hormone–binding globulin (SHBG) and prostate cancer have been inconsistent. Single measures of serum testosterone levels may not accurately reflect the amount of bioavailable testosterone; furthermore, they do not accurately quantify the testosterone exposure in the individual over the years it takes to develop prostate cancer. Future research

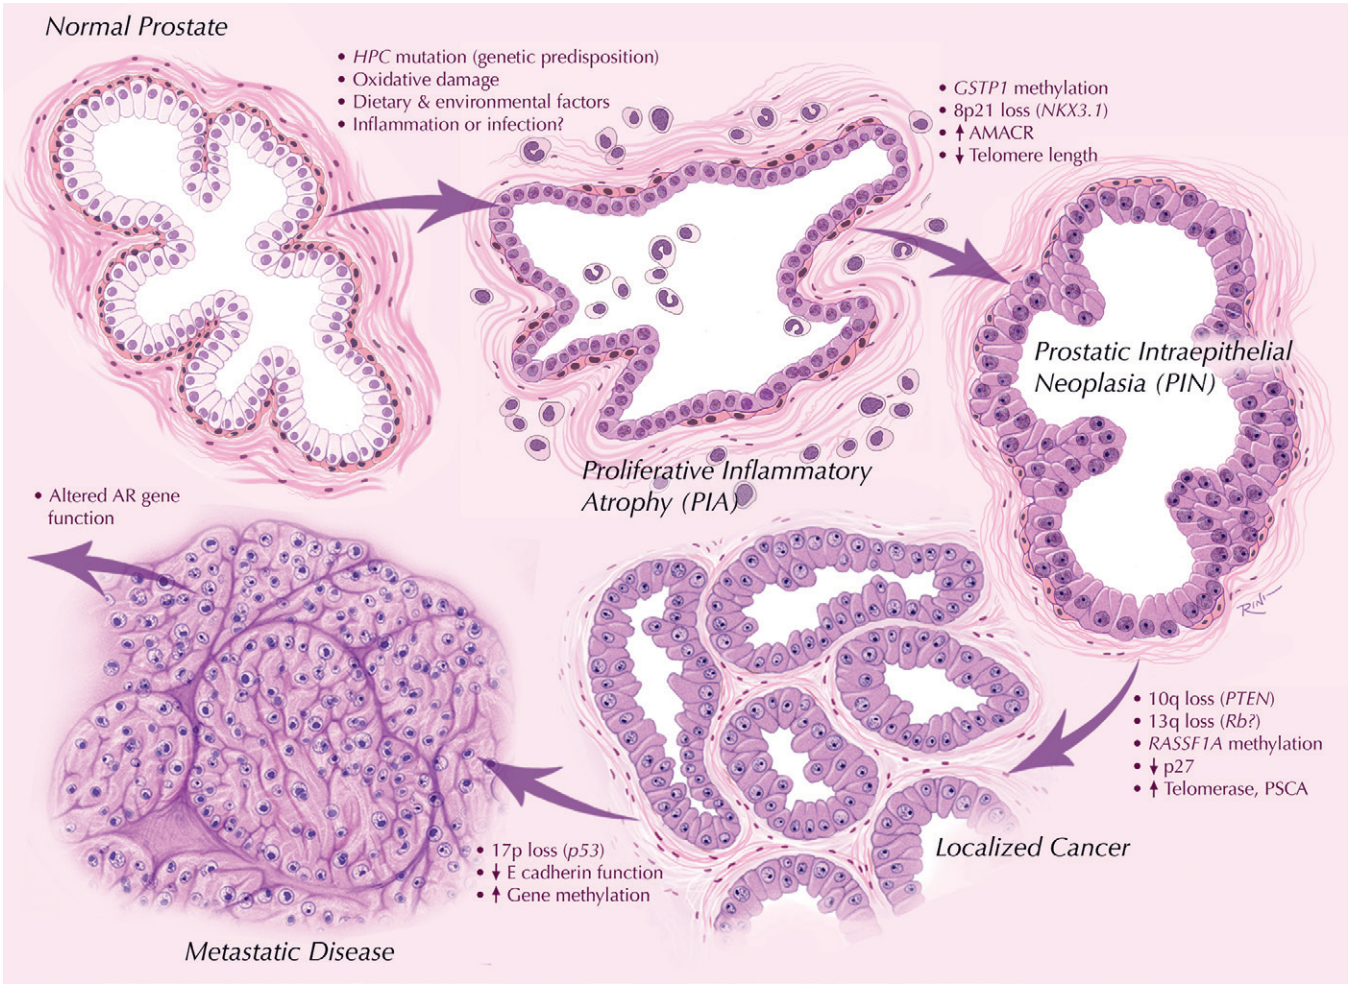

Figure 95–8. Contemporary model of prostate cancer progression. Genetic predisposition, oxidative damage, and inflammatory changes are associated with earliest steps of prostate cancer development. Downregulation of caretaker genes, such as *GSTP1,* by aberrant promoter methylation may increase potential for neoplastic transformation. Chromosomal loss and telomere shortening may also contribute to genetic instability and progression to invasive disease. Further methylation changes, loss of tumor suppressor gene function and additional mutational events are associated with metastases and androgen independence. (From Gonzalgo ML, Isaacs WB. Molecular pathways to prostate cancer. J Urol 2003;170:2444–52.)

will likely improve our understanding of the factors that may affect tissue concentrations of androgen at the biochemical and molecular level.

Stem Cells

Stem cells are required for the maintenance of high-cell turnover–tissues where cells continually need to be replaced, and like most epithelial organs, the prostate is believed to contain stem cells capable of multilineage differentiation. The existence of prostatic stem cells is suggested by studies demonstrating the ability of prostate epithelium to regenerate when androgen is administered to castrated rodents (Isaacs and Coffey, 1989; Bui and Reiter, 1998; Tsujimura et al, 2002). Supportive evidence includes observations that (1) basal and luminal cells of prostate glands have distinct phenotypes as measured by immunohistochemical marker expression, especially for various forms of keratin; (2) cell culture experiments demonstrate that some prostate cancer cells are self-replicating while others are not; and (3) stem cell–enriched populations of cells can produce three-dimensional structures with basal cells and fully differentiated luminal cells in nude mice (Taylor and Risbridger, 2008). These observations led to the development of a stem cell theory for prostate cancer that postulated that an androgen-independent stem cell produces androgen-independent transit-amplifying (TA) cells that, in turn, give rise to androgen-dependent, fully differentiated luminal secretory cells (Isaacs and Coffey, 1989). Although it was originally believed that prostatic stem cells reside within the basal epithelium, recent models have challenged this notion (Tsujimura et al, 2002). A recent study has suggested that *TROP2* may be a marker for a subpopulation of basal cells with stem cell characteristics (Goldstein et al, 2008). **Once their biology is fully understood, stem cells are likely to be an attractive target for both prevention and therapy.**

Epigenetic Changes

Epigenetic events affect gene expression without altering the actual sequence of DNA. Known mechanisms include DNA hyper- and hypomethylation, chromatin remodeling, histone modification, and RNA interference (Dobosy et al, 2007). **A variety of genes implicated in prostate cancer initiation and progression are affected by these processes,** including hypermethylation of hormonal response genes (*ERαA, ERβ,* and *RARβ*), genes controlling the cell cycle (*CYCLIND2, 14-3-3σ*), tumor cell invasion/tumor architecture genes (*CD44*), DNA repair genes

(*GSTpi, GPX3,* and *GSTM1*), tumor suppressor genes (*APC, RASSF1α, DKK3, TP16^{INK4α}, E-cadherin,* and *TP57^{WAF1}*), signal transduction genes (*EDNRB* and *SFRP1*), and inflammatory response genes (*PTGS/COX2*); hypomethylation of *CAGE, HPSE,* and *PLAU;* histone hypoacetylation of *CAR, CPA3, RARB,* and *VDR;* and histone methylation of *GSTP1* and *PSA* (Li et al, 2005). **Clinical studies have shown that quantitative methylation analysis of the *GSTpi, APC, PTGS2, RASSF1α, MDR1, TP16,* and *MGMT* genes can improve sensitivity and specificity for the diagnosis of cancer, and efforts to develop global gene methylation profiles in serum, urine, and tissue as an adjunct to predicting risk of cancer, determining the need for rebiopsy, and tumor aggressiveness are underway** (Dobosy et al, 2007). Furthermore, agents that can inhibit or reverse the effects of DNA methyl transferases (DNMTs) and histone deacetylases (HDACs) and restore normal gene expression are under study for both prevention and therapy.

Cyclooxygenase

Inflammatory cells in the prostate produce a variety of compounds designed to eradicate infectious microorganisms, many of which have potential to cause oxidative DNA damage. These compounds include superoxide, hydrogen peroxide, oxygen free radicals, and peroxynitrite (Potts and Pasqualotto, 2003). The inflammatory response stimulates the production of prostaglandins that are part of the eicosanoid family, which includes long-chain polyunsaturated fatty acids. Cyclooxygenase (COX) enzymes catalyze the rate-limiting step of prostaglandin synthesis, converting arachidonic acid to the intermediate prostaglandin G2 (Zha et al, 2004). Two isoforms of COX (COX-1 and COX-2) have been identified (DeWitt and Smith; 1988, Hla and Neilson, 1992). COX-1 is constitutively expressed in many tissues and cell types and helps mediate normal cellular physiologic functions. **COX-2 is an inducible enzyme that mediates acute and chronic inflammation, pain, and cellular repair mechanisms.** COX-2 expression is rapidly induced in response to inflammatory or mitogenic stimuli, cytokines, tumor promoters, and growth factors (Zha et al, 2004; Patel et al, 2008). Prostaglandins resulting from COX-2 expression mediate a variety of responses to tissue injury and hypoxia that promote tumor formation, including inhibition of apoptosis, promotion of cellular proliferation, and angiogenesis (Patel et al, 2008). **Most studies suggest increased COX-2 expression in prostate cancer and HGPIN compared with benign prostatic epithelium** (Patel et al, 2008). **Epidemiologic studies and clinical observations suggest that nonsteroidal anti-inflammatory drugs (NSAIDs) and certain selective COX-2 inhibitors may reduce the risk of prostate cancer** (Aparicio Gallego et al, 2007). However, the recent observation of increased cardiovascular morbidity associated with long-term COX-2 inhibitor use led to the early closure of a drug sponsored prostate cancer prevention trial in 2004. **Further clinical trials of COX-2 inhibitors may be difficult to complete, and the expected benefit must be weighed against the potential risks of the drug in the target population.**

Somatic Mutations Associated with Tumor Initiation and Progression

A number of somatic mutations in tumor DNA are acquired during clonal expansion of nascent tumors as a result of mitotic errors, defects in DNA repair mechanisms, loss of apoptotic ability, and other mechanisms. A variety of genes are so affected in prostate cancer.

Androgen Receptor

As discussed earlier, polymorphisms of the AR are linked epidemiologically to prostate cancer risk. There is also growing evidence that the AR itself may in fact be oncogenic under certain circumstances (Scher and Sawyers, 2005). **Alterations in AR signaling can occur at various levels, all of which could potentially contribute to the development and/or progression of prostate cancer. These include (1) changes in ligand concentration in tumor cells (e.g., intracrine mechanism)** (Labrie et al, 1993), **(2) increased AR protein expression (e.g., this has been detected in castrate-resistant disease, leading to increased sensitivity to low ligand levels)** (Bubendorf et al, 1999), **(3) mutations leading to altered structure and function (shown to be present in 50% of prostate cancers)** (Bostwick et al, 2004)**, (4) changes in coregulatory molecules (e.g., coactivator proteins such as ARA54 and ARA70 can selectively enhance the activity of AR to alternative or low concentrations of ligand, or lead to independent activation)** (Scher and Sawyers, 2005), **and (5) factors leading to activation of the receptor independent of the ligand (e.g., many of the growth factors and tyrosine kinases implicated in prostate cancer initiation and progression may exert their effects by cross talk with the AR**) (Culig et al, 1994; Craft et al, 1999). A recent study shows that knockout of AR causes regression of even castrate-resistant prostate cancer, suggesting that AR is biologically and clinically important even after androgen deprivation (Snoek et al, 2009).

NKX3-1

***NKX3-1* is an androgen-regulated and prostate-specific gene located on chromosome 8p21** and belongs to the homeobox gene family (He et al, 1997; Prescott et al, 1998). Mice deficient in *NKX3.1* show defects in prostate ductal morphogenesis and secretory protein production and with age develop dysplasia, PIN, and cancer (Bhatia-Gaur et al, 1999; Tanaka et al, 2000; Abdulkadir et al, 2002). Loss of either one or both *NKX3-1* alleles becomes increasingly common in prostate lesions as they progress from PIN to local, metastatic, and androgen-independent tumors (Bowen et al, 2000).

PTEN

PTEN on chromosome 10q23 is among the best studied tumor suppressor genes in prostate cancer. Genetic, functional, and molecular studies suggest a role of *PTEN* in both initiation and progression of prostate cancer (Dong, 2006). *PTEN* deletion has been shown to induce prostate cancer in mice (Wang et al, 2003). Loss of *PTEN* function is seen in PIN and is associated with a high Gleason score and advanced stage (Rubin et al, 2000).

Classical Oncogenes

Genetic alterations in the tumor suppressor genes *RB1* and *TP53* are commonly present in metastatic or hormone-refractory disease, suggesting a role in tumor progression. Alterations in c-*MYC,* c-*ERBB2,* and *BCL-2* have also been observed in advanced and hormone-refractory prostate cancer but not commonly in lower-stage and -grade cancers, suggesting that mutations of proto-oncogenes usually occur as secondary events associated with tumor progression (Gurumurthy et al, 2001; Fossa et al, 2002; Qian et al, 2002).

Telomerase

Eukaryotic chromosomes have telomeres on their ends that consist of repeating units of 6 base pairs (TTAGGG) that protect the chromosomal ends from inappropriate recombination. **Normal cellular aging is characterized by the progressive loss of these repeated elements, and consequently telomere length decreases successively with every cell replication.** Critical telomere shortening leads to chromosomal instability, further leading to an increased incidence of cancers due to chromosomal fusions, breakage, and rearrangements (Blasco et al, 1997). There is increasing evidence that telomere shortening during cell division and oxidative cell damage, possibly as a result of chronic inflammation, may play a role in prostate carcinogenesis (Meeker, 2006). Prostate cancer and high-grade PIN appear to result in an activation of the telomerase enzyme, a reverse transcriptase that maintains or increases telomere length (Meeker et al, 2002; Meeker, 2006). In addition to prostate cancer causation, telomeres may also play a role in disease progression, and studies suggest that telomerase suppression may contribute to the emergence of androgen-independent disease (Meeker, 2006).

Glutathione-*S*-Transferase

Reactive oxygen species are inactivated by a host of protective enzymes, including glutathione-*S*-transferase (GST), glutathione peroxidase, and superoxide dismutase. **The expression of one of these enzymes, GSTP1, is absent in approximately 70% of PIN and virtually all cases of prostate cancer, making it the most common genetic alteration in this malignancy** (Nelson et al, 2003). This loss of expression results from hypermethylation of CpG islands in the *GSTP1* promoter and causes a defect in cellular defense against oxidant stress, leading to a higher mutation rate. Additionally, *GSTP1* hypermethylation has been identified in prostate biopsies with histologic findings of PIN (Nakayama et al, 2004). DNA methylation assays that may soon be used in diagnostic testing of serum and tissue for prostate cancer are under development.

TP27

TP27 belongs to the CIP/KIP family of cyclin-dependent kinase (CDK) inhibitors and regulates progression of the cell cycle from G1 to S phase. Loss of TP27 may accelerate tumorigenesis by enabling cells to progress unregulated through the cell cycle. Mice deficient in TP27 develop prostate hyperplasia, and mice deficient in both TP27 and PTEN have a high incidence of prostate cancer (Cordon-Cardo et al, 1998; Di Cristofano et al, 2001). Studies in humans have found loss of heterozygosity for TP27 in 50% of patients with metastatic prostate cancer (Kibel et al, 2000). Studies of patients undergoing RP have found an association between loss of TP27 expression and increased risk of biochemical recurrence (Guo et al, 1997; Cordon-Cardo et al, 1998).

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF), which is an important mediator of tumor angiogenesis, is expressed in a majority of prostate cancers, and increased expression has been associated with disease progression and survival (Green et al, 2007; Peyromaure et al, 2007). VEGF is regulated by androgen, suggesting a potential pathway by which androgen regulates prostate cancer growth (Joseph and Isaacs, 1997). Several SNPs in the *VEGF* gene have been associated with protein expression; however to date, studies examining the influence of these polymorphisms on prostate cancer risk have been inconsistent (Langsenlehner et al, 2008). Therapeutic inhibition of the VEGF receptor signaling pathway is currently being investigated in the treatment of prostate cancer.

E-Cadherin

The *E-cadherin* gene, which is located on chromosome 16q22.1, encodes a transmembrane glycoprotein that mediates intercellular adhesion as well as cell signaling (Takeichi, 1991). **E-cadherin expression is reduced in a significant percentage of prostate cancers, particularly in poorly differentiated tumors, and E-cadherin expression in prostate cancer correlates inversely with grade, stage, metastasis, recurrence, and survival** (Umbas et al, 1992; Bostwick et al, 2004). However, studies of the association between SNPs of E-cadherin and prostate cancer risk have yielded conflicting results.

α-Methylacyl-CoA Racemase (AMACR)

AMACR (racemase) is an enzyme that plays a critical role in the metabolism of branched-chain fatty acids. AMACR expression has been shown to decrease in metastatic prostate cancer compared with localized disease, and is associated with cancer-specific survival (Rubin et al, 2005). In addition, studies suggest that polymorphisms within the *AMACR* gene may be associated with prostate cancer risk (Levin et al, 2007), although further experimental studies are needed to better characterize this association.

Prostate-Specific Membrane Antigen

Prostate-specific membrane antigen (PSMA) is a transmembrane glycoprotein that is expressed by prostate cancer epithelium and on the neovasculature of other solid tumors (Ghosh et al, 2005). **Overexpression of PSMA is observed after androgen withdrawal and in hormone-refractory disease, and is the basis of clinical imaging studies using anti-PSMA monoclonal antibodies.** Because of its restricted tissue expression, PSMA is being actively investigated as an immunotherapeutic target (Schulke et al, 2003).

Epidermal Growth Factor and Epidermal Growth Factor Receptor

There is substantial evidence that epidermal growth factor (EGF) signaling through the epidermal growth factor receptor (EGFR) is important in prostate cancer. EGF levels are frequently elevated, and EGFR is commonly

Key Points: Etiology and Molecular Genetics

- The primary androgen of the prostate is dihydrotestosterone (DHT), formed by the action of 5α-reductase on testosterone.
- Epigenetic regulation of gene expression by promoter methylation and histone acetylation has been implicated in the progression of prostate cancer.
- *TMPRSS2-ETS* gene fusions have been identified in most prostate cancers, and their role in disease detection and prognosis is currently being investigated.
- Somatic mutations in a variety of genes with diverse biological functions have been implicated in prostate cancer development and progression.
- Mutations, amplification, and ligand promiscuity of the AR are important determinants of progressive castrate-resistant prostate cancer.

overexpressed in prostate cancer cells (Vicentini et al, 2003). In addition, EGFR expression increases as the disease progresses to hormone resistance (Di Lorenzo et al, 2002). A genetic polymorphism in the *EGF* gene has been shown to be associated with progression-free survival in patients on androgen-deprivation therapy, identifying a potential therapeutic target in these patients (Teixeira et al, 2008).

EZH2

EZH2 is a histone-lysine methyltransferase with activity dependent on its association with other components of the polycomb repressive complexes 2 (PRC2). EZH2 levels are increasingly elevated during prostate cancer progression (LaTulippe et al, 2002). EZH2 expression in localized prostate cancer has also been shown to be associated with poor prognosis and disease recurrence (Varambally et al, 2002; van Leenders et al, 2007).

CHEMOPREVENTION

Rationale

Prevention is so much better than cure, because it saves the labor of being sick.

—Thomas Adams, 1618

As previously discussed, prostate carcinogenesis is a multistep molecular process induced by genetic and epigenetic changes that disrupt pathways controlling the balance between cell proliferation, apoptosis, differentiation, and senescence. **The presence of precursor lesions that represent intermediate stages between normal and malignant cells—as long as 20 years before the appearance of cancer, coupled with the age-dependent incidence of most cancers—suggests that carcinogenesis occurs slowly during a protracted interval. In theory, this provides the opportunity to intervene before a malignancy is established, using lifestyle changes (dietary alterations, smoking cessation, exercise) or by chemoprevention, defined as the use of natural or synthetic agents that reverse, inhibit, or prevent the development of cancer. The goal of primary chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality. Effective chemoprevention requires the use of nontoxic agents that inhibit specific molecular steps in the carcinogenic pathway.**

Prostate cancer is an attractive and appropriate target for primary prevention because of its incidence, prevalence, and disease-related mortality (see Table 95–1). The burden of prostate cancer can also be measured in other terms. A recent study of complications after surgical therapy for localized disease in an unselected population-based cohort reported that, at greater than 18 months following RP, 8.4% of men were incontinent, and 41.9% reported that their sexual performance was a moderate-to-large problem (Stanford et al, 2000). In a prospective cohort study comparing outcomes 5 years after radiation or surgery to age-matched controls, the authors concluded that "…declines in urinary and sexual function domains after diagnosis and treatment of localized cancer far exceeded any effects from aging…" (Hoffman et al, 2004). A large study assessing health-related quality of life after primary treatment for prostate cancer found that although each treatment modality was associated with a distinct pattern of change in quality-of-life domains, they all had a significant effect on urinary, sexual, bowel, and/or hormonal function (Sanda et al, 2008). Although many single-institution studies have reported better results in highly selected cohorts of treated patients, it is clear that the majority of men treated for localized disease in the community pay a substantial price to be cured, and fear of cancer recurrence remains substantial for as long as 2 years after treatment (Mehta et al, 2003). It seems self-evident that an effective prevention strategy would spare many men this burden of diagnosis and cure.

The molecular pathogenesis of prostate cancer also lends itself to a primary prevention strategy. Histologic lesions, including atypical small acinar proliferation (ASAP), PIA, and PIN contain both genetic and epigenetic changes intermediate between normal prostatic epithelium and prostate cancer. Clinically evident prostate cancer is rare in men younger than 50 years, whereas prostatic intraepithelial neoplasia is apparent at autopsy in men younger than 30 years. Furthermore, the prevalence of PIN is similar in populations at much different risks of developing clinically evident cancer, suggesting that external environmental influences are important and potentially modifiable.

Clinical Trial Design

Target populations appropriate for primary prevention studies can be subdivided into those with low, intermediate, and high risk of developing prostate cancer based on current epidemiologic evidence (Klein and Meyskens, 2001). Each group has its own clinical characteristics that lend advantages and disadvantages for trial design, end points, and statistical analysis (Table 95–3). Based on the hypothesis that the specific molecular mechanisms underlying the development and/or progression of disease in each risk group and model may be unique and that different agents may be useful for each situation, it seems apparent that multiple potential chemopreventative agents should be tried in all risk groups and clinical models to best define which agents appear promising for large-scale studies. Testing of potentially active agents for secondary prevention in clinical models of patients with active disease is also appropriate (Table 95–4). **The presurgical model allows for pre- and post-treatment tissue biopsies and is thus useful for proof-of-principle demonstrations that a given agent is affecting its intended molecular target.** The other models may yield useful strategies for the management of patients in specific clinical situations. **The molecular mechanisms that underlie disease progression is likely different for each primary and secondary target population, and it may not be possible to generalize the results from a particular trial to other clinical scenarios.**

Numerous observations in the epidemiologic literature suggest associations between various dietary, lifestyle, genetic, and nontraditional factors and the risk for developing prostate cancer. It is generally not practical to quantitate all of these factors in the course of a prevention trial, but if the trial is large enough, the effects of these factors are likely to be equally and randomly distributed across all study arms. Most trials are designed to collect data relevant to these factors for secondary analysis and analysis of potential confounds for unexpected results.

Prostate Cancer Prevention Trial

The most significant event in chemoprevention of prostate cancer occurred with the publication of the results

Table 95–3.

Target Populations for Primary Prevention

RISK GROUP	SPECIFIC POPULATION	ADVANTAGES	DISADVANTAGES
Low	General population	Easily definable	Rate of progression slow
		Readily available	Requires large study population and long follow-up interval
		Results widely applicable	Studies costly
Intermediate	African-Americans	Higher risk than general population	Difficult to define
			Difficult to recruit because of perceived bias
	Genetic:	Double or greater the risk of prostate cancer	Ascertainment bias
	Family history		Risk varies with number of affected family members, age of onset, and degree of relatedness
	HPC-1 linked	Genetically homogeneous	Likely to be genetically heterogeneous
			Identification invasive and costly
			Affected subjects rare
	Other genes	Genetically homogeneous	Identification invasive and costly
			Affected subjects rare
			Risk of progression undefined
High	High-grade PIN	Highest known risk	Sampling error
			Diagnosis subjective
			Uncommon

HPC, hereditary prostate cancer; PIN, prostatic intraepithelial neoplasia.

Table 95–4.

Models of Secondary Prevention

MODEL	ADVANTAGES	DISADVANTAGES
Presurgical	Early-stage disease	Treatment period short
	Readily available study population	
	Pre- and post-treatment tissue available for biologic study	
Elevated PSA/ negative biopsy	Well-defined histologic end point	Risk of progression undefined
		Sampling error
Adverse pathology after RP	High risk of progression	More advanced disease
		Clinical end point
Rising PSA after RP or RT	High risk of progression	Most advanced disease
		Clinical end point

PSA, prostate-specific antigen; RP, radical prostatectomy; RT, radiation therapy.

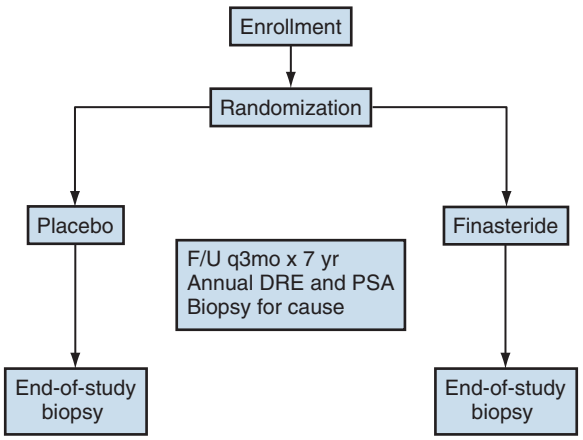

Figure 95–9. Design of the Prostate Cancer Prevention Trial. DRE, digital rectal examination; PSA, prostate-specific antigen.

of the Prostate Cancer Prevention Trial (PCPT) (Thompson et al, 2003). This landmark study, opened in 1993, was the first large-scale population-based trial to test a chemopreventative strategy in men at risk for prostate cancer. The PCPT was based on two observations: (1) Androgens are required for the development of prostate cancer and (2) men with congenital deficiency of type 2 5α-reductase are unaffected by benign prostatic hyperplasia (BPH) and prostate cancer. **The PCPT tested the hypothesis that treatment with finasteride, which induces an acquired deficiency of type 2 5α-reductase, would lower intraprostatic DHT levels and thereby prevent prostate cancer.** In the PCPT, 18,882 men greater than or equal to 55 years of age with a normal digital rectal examination (DRE) and a prostate-specific antigen (PSA) level of less than or equal to 3.0 ng/mL were randomly assigned to treatment with finasteride (5 mg/day) or a placebo for 7 years (Fig. 95–9). Prostate biopsy was recommended if the annual PSA level, adjusted for the effect of finasteride, exceeded 4.0 ng/mL or if the DRE was abnormal. The primary end point was the prevalence of prostate cancer during the 7 years of the study, as diagnosed by either for-cause biopsies (abnormal DRE or PSA) or by end-of-study biopsy. **The trial was stopped approximately 15 months early by an independent data safety and monitoring committee, because the primary end point of a 25% risk reduction on the finasteride arm was reached, and sensitivity analyses suggested that additional follow-up would not change that outcome.**

The main findings of the PCPT are as follows:

1. The prevalence of prostate cancer was reduced by 24.8% (hazard ratio [HR] = 0.75, 95% CI = 18.6 to 30.6) from 24.4% to 18.4% in those participants randomized to finasteride compared with placebo.
2. The prevalence of Gleason grade 7 to 10 tumors was higher in the finasteride group than the placebo group (6.4% versus 5.1%, HR = 1.27, 95% CI = 1.07 to 1.50).
3. The risk reduction associated with finasteride among risk groups defined by age, family history, race, and PSA were of the same general magnitude.

4. Sexual side effects were more common with finasteride, whereas urinary symptoms were more common with the placebo.

Additional important observations were as follows: (1) the risk reduction in the finasteride arm was seen in both clinically apparent tumors (those diagnosed "for cause" because of an elevated PSA or abnormal DRE) and end-of-study biopsies; (2) there were an equal number of deaths due to prostate cancer (five) in each study arm; (3) 98% of the tumors were clinically localized; and (4) finasteride-treated glands were 25% smaller than those in the placebo arm.

A number of relevant observations can be made about the results of the trial. Most surprising was the 24.4% prevalence of prostate cancer in the placebo arm, 4 times higher than the 6% assumed for the trial design. This discrepancy can be explained by the fact that the 6% assumption was based on Surveillance, Epidemiology, and End Results (SEER) incidence estimates, which are derived from clinically evident cases and not on the prevalence in men undergoing biopsy for no reason other than being on the trial. The incidence of clinically evident cancers detected "for cause" by elevations in PSA or abnormal PSA was 7.2% at 7 years, roughly what was estimated by use of the SEER data. Another observation was a marked effect of finasteride on the prevalence of Gleason sum 6 tumors, no effect on the prevalence of Gleason sum 7 tumors, and a slight increase in the prevalence of Gleason sum 8 to 10 tumors. The higher incidence of high-grade tumors was restricted to those men undergoing "for-cause" biopsy. Finally, **secondary analyses of the PCPT trial have demonstrated an overall improved sensitivity of DRE** (Thompson et al, 2007b), **as well as a higher sensitivity and area under the curve for PSA for the diagnosis of prostate cancer in the finasteride arm** (Thompson et al, 2006). However, given that the latter finding was demonstrated for all grades, the bias would lead to a greater detection of all grades of prostate cancer with finasteride.

There are two areas of continued debate over the results of the PCPT. The first is whether Gleason sum 6 cancers that were "prevented" are biologically significant, which can be defined as destined to metastasize or kill the host. A review of the pathologic characteristics of prostate biopsies from men in the placebo and finasteride groups of the PCPT found that 75% of all cancers and 62% of cancers with a Gleason score less than or equal to 6 met the accepted biopsy criteria for clinically significant tumors (Epstein et al, 1994; Lucia et al, 2008). Although the proportion of insignificant cancers was directly correlated with serum PSA, even at the lowest PSA values (0 to 1.0 ng/mL) almost half of the tumors met the definition of clinical significance. Moreover, an analysis of the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) found that of men with prostate cancer who met this definition, 91% choose some form of definitive therapy instead of watchful waiting (Barocas et al, 2008). **Viewed in the context of "clinical relevance" as defined by current urologic practice, preventing grade 6 tumors by finasteride also prevents the anxiety, cost, and morbidity associated with their treatment. From a public health perspective, preventing the "burden of cure" in newly diagnosed patients should be added as a positive to the 25% reduction in risk of diagnosis and significant reduction in urinary symptoms associated with finasteride use.**

The second question still under debate is whether the increased prevalence of higher-grade tumors is real or artifactual. Finasteride is known to change the appearance of prostatic epithelium in a way that could bias interpretation, and the Gleason grading system has never been validated on glands treated with antiandrogenic agents (Civantos et al, 1996). However, when this was examined in the PCPT, degenerative hormonal changes in high-grade biopsies were equivalent between the finasteride and placebo groups (Lucia et al, 2007). Another potential explanation for the observed increase in high-grade tumors in the finasteride group is ascertainment bias. As stated above, finasteride has been shown to increase the sensitivity of PSA and DRE, as well as decrease prostate volume by approximately 25%. Data suggest that having a smaller prostate results in more high-grade cancers diagnosed at biopsy (Kulkarni et al, 2006). This was demonstrated in the PCPT, where biopsy identified a greater proportion of patients with high-grade disease present at prostatectomy in the finasteride group than in the placebo group (Lucia et al, 2007). Therefore **when accounting for all biases, the adjusted prostate cancer rates were estimated to be 21.1% for the placebo group and 14.7% in the finasteride group, a 30% risk reduction for all cancers (relative risk [RR] = 0.70, 95% CI = 0.64 to 0.76), and a nonstatistically significant 14% increase in high-grade cancer** (Redman et al, 2008). **Using known predictive factors to estimate true tumor grade in those men who did not undergo end-of-study biopsy, and incorporating grading information from those who had radical prostatectomies, the rate of high-grade cancer was estimated to be 8.2% and 6.0% in the placebo and finasteride groups, respectively, suggesting that finasteride may in fact reduce the risk of high-grade disease (27% risk reduction [RR = 0.73, 95% CI = 0.56 to 0.96])** (Fig. 95–10). Using a different analysis methodology in an independent analysis, another study concurred that the rate of true high-grade disease may have been lower in the finasteride group compared with the placebo group (Pinsky et al, 2008). In March 2009, the American Urological Society and the American Society for Clinical Oncology jointly published guidelines based on expert review of the available evidence, stating that use of finasteride for the prevention of cancer should be discussed with at-risk men (Kramer et al, 2009).

Deciding whether or not the advantages of taking finasteride (Table 95–5) **outweigh the potential disadvantages is not a simple task.** An initial mathematical model suggested a baseline 5:1 benefit to risk ratio, as defined by the number of cancers prevented for each excess high-grade cancer in

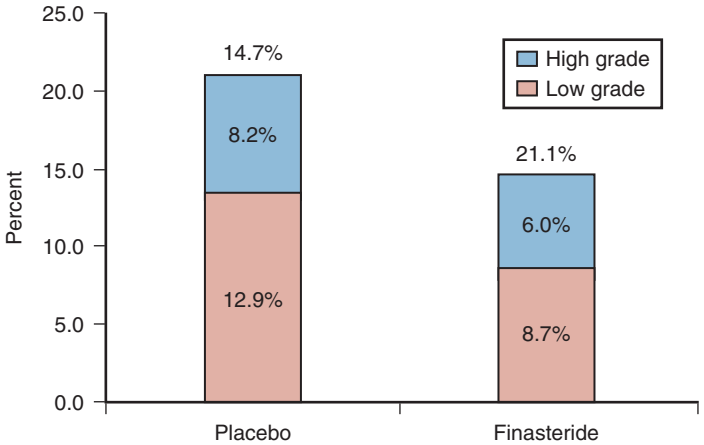

Figure 95–10. Estimated bias-adjusted fractions of total subjects with low-grade and high-grade prostate cancers in the finasteride and placebo arms of the Prostate Cancer Prevention Trial.

Table 95–5.

Benefits and Costs of Finasteride When Used to Prevent Prostate Cancer

Benefits
6.4% reduction in cancer prevalence
Fewer urinary symptoms and lower risk of acute urinary retention and need for surgical intervention for obstructive urinary symptoms
Avoids "burden of cure"
Costs
1.3% increase in high-grade tumors
Potential for more aggressive therapy
Potential excess mortality
Sexual side effects and cost of treatment
Cost of finasteride

those taking finasteride (Klein et al, 2005). Another study using a person-years–saved model estimated that the use of finasteride as a preventative could reduce the lifetime risk of prostate cancer for a U.S. man from 17% to 13%, while saving more than 250,000 lives every 10 years (Unger et al, 2004). However, more recently published decision-analytic models examining finasteride chemoprevention found that its widespread use is unlikely to be cost effective when considering the usually indolent natural history of treated prostate cancer (Zeliadt et al, 2005; Svatek et al, 2006, 2008). Nonetheless, they suggested that chemoprevention may be cost effective in high-risk populations.

In addition to the prevention of prostate cancer, 5α-reductase inhibitors (5ARIs) have other benefits that need to be considered. As mentioned earlier, finasteride improves the sensitivity of PSA (Thompson et al, 2006) and DRE (Thompson et al, 2007b) in prostate cancer screening, decreases the risk of high-grade prostatic intraepithelial neoplasia (HR = 0.79, 95% CI = 0.70 to 0.89) (Thompson et al, 2007a), and may be effective in the treatment and possibly prevention of chronic nonbacterial prostatitis (Nickel et al, 2004). Furthermore, benign prostatic hyperplasia (BPH) treatment trials in patients with moderate to severe lower urinary tract symptoms demonstrated: (1) a reduction in AUA symptom sores by 20% to 39% compared with 13% to 29% for the placebo, (2) a reduction in the risk of acute urinary retention by one half in long-term trials (RR = 0.51, 95% CI = 0.38 to 0.69; absolute risk reduction [ARR] = 2.2%), and (3) a reduction in the risk of surgical intervention due to BPH progression by one half (RR = 0.50, 95% CI = 0.43 to 0.58, ARR = 1.7%) (Wilt et al, 2008).

On the other hand, adverse effects that are more common with finasteride than with the placebo include impaired sexual or erectile function and endocrine effects. Pooled data from randomized trials indicate absolute differences of 2% (95% CI = 1 to 2) for gynecomastia, 3% (95% CI = 1 to 6) for decreased libido, 4% (95% CI = 1 to 8) for erectile dysfunction, and 4% (95% CI = 8 to 17) for reduced volume of ejaculate (Wilt et al, 2008). **Sexual dysfunction was also assessed in the PCPT participants during the 7-year trial period. As measured by the Sexual Activity Scale in a companion quality-of-life (QOL) study to the PCPT, comparing baseline scores over the course of 7 years, finasteride increased sexual dysfunction relative to the placebo by a mere 3.21 points (95% CI = 2.83 to 3.59 on a scale of 0 to 100), a clinically meaningless effect.**

Other 5α-Reductase Inhibitors

A second large-scale trial of another 5ARI, dutasteride, completed accrual in the spring of 2005. This agent inhibits both type 1 and type 2 forms of 5α-reductase, is antiandrogenic, and promotes death of prostate cancer cell lines (Lazier et al, 2004), **and has been shown to reduce the risk of prostate cancer in men treated for lower urinary tract symptoms related to benign prostatic enlargement when compared with the placebo** (Andriole et al, 2004c). The Eligibility for the Reduction by Dutasteride of Prostate Events (REDUCE) trial included men aged greater than or equal to 50 and less than or equal to 75 years who had PSA scores from 2.5 to 10 ng/mL, prostate volumes less than or equal to 80 cc, and one prior negative prostate biopsy within 6 months of enrollment, thus representing a group at high risk for cancer on subsequent biopsy (Andriole et al, 2004a). The primary end point of REDUCE is the prevalence of cancer on study-mandated prostate biopsies performed at 2 and 4 years after entry. The trial accrued 8231 men, of whom 6726 (82.6%) underwent at least one biopsy and 1516 (22.5%) were diagnosed with prostate cancer. Dutasteride reduced the risk of prostate cancer over 4 years by 23% (857 in the placebo arm vs. 659 in the dutasteride arm, $P < .0001$). Interestingly, no significant increase in Gleason sum 8 to 10 tumors was observed in the study (19 in the placebo arm vs. 29 in dutasteride arm, $P = .15$). Preliminary analyses also suggest that dutasteride enhanced the utility of PSA as a diagnostic test for prostate cancer, demonstrated beneficial effects on BPH outcomes (relative risk reductions of 77% for acute urinary retention and 73% for BPH-related surgery), and was generally well tolerated (15% drug-related adverse events in the placebo arm vs. 22% in dutasteride arm). The fact that the results of REDUCE were congruent with those of the PCPT with respect to the magnitude of risk reduction, benefits for BPH end points, minimal toxicity, and no issues related to tumor grade suggests a class effect for 5ARIs and that these agents should be used more liberally for prevention of prostate cancer.

Antioxidants and the Selenium and Vitamin E Cancer Prevention Trial (SELECT)

Selenium

Selenium (Se) is an essential trace element occurring in both organic and inorganic forms. The organic form is found predominantly in grains, fish, meat, poultry, eggs, and dairy products and enters the food chain through plant consumption. There is marked geographic variability of Se in food related to local soil content. **The strongest evidence for a protective effect of Se came from the Nutritional Prevention of Cancer Trial, a randomized study of oral selenized yeast in patients with nonmelanoma skin cancer, which showed a 65% reduction in the prostate cancer incidence when compared with the placebo** (Clark et al, 1996). In that trial, 1312 participants took the equivalent of 200 μg yeast per day versus the placebo, and with a mean follow-up of 4.5 years, the incidence of prostate cancer was reduced in the Se arm by 65% compared with the placebo. Of note, the effect was strongest for those with a PSA value less than 4 ng/mL and those with the lowest serum Se levels at study entry (Duffield-Lillico et al, 2003).

Vitamin E

Vitamin E is a family of naturally occurring, essential, fat-soluble vitamin compounds that functions as the major lipid-soluble antioxidant in cell membranes. The most active form of vitamin E is α-tocopherol; it is also among the most abundant, is widely distributed in nature, and is the predominant form in human tissues. Alpha-tocopherol may influence the development of cancer through several mechanisms, including induction of cell cycle arrest and through direct antiandrogen activity (Ni et al, 2003; Thompson and Wilding, 2003). **The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Trial (ATBC),** a randomized, placebo-controlled trial of α-tocopherol (50 mg/day) and beta-carotene (20 mg/day) alone or in combination in male smokers, with a primary end point of lung cancer incidence and mortality (Albanes et al, 1996), **on secondary analysis found a statistically significant 32% reduction in prostate cancer incidence and a 41% lower mortality in those receiving α-tocopherol** (Albanes et al, 1995).

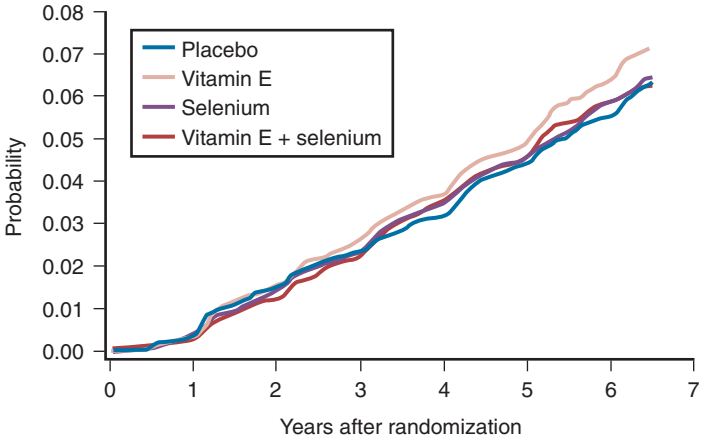

Figure 95–11. Cumulative incidence of prostate cancer detection over time by intervention group: results from the Selection and Vitamin E Cancer Prevention Trial. (From Lippman SM, Klein EA, Goodman PJ, et al. Effect of selenium and vitamin E on risk of prostate cancer and other cancers: the Selenium and Vitamin E Cancer Prevention Trial [SELECT]. JAMA 2009;301:39–51.)

Selenium and Vitamin E Cancer Prevention Trial (SELECT)

The accumulated epidemiologic and biologic evidence that Se and vitamin E may prevent prostate cancer led to the design and launch of SELECT, the Selenium and Vitamin E Cancer Prevention Trial (Klein et al, 2001; Lippman et al, 2005). **SELECT was a phase III, randomized, double-blind, placebo-controlled, population-based trial designed to test the efficacy of selenium and vitamin E alone and in combination in the prevention of prostate cancer.** It was the largest cancer prevention trial ever performed. Eligibility criteria include age greater than or equal to 50 years for African-Americans, greater than or equal to 55 years for whites, a DRE not suspicious for cancer, serum PSA less than or equal to 4 ng/mL, and normal blood pressure. Randomization was equally distributed among four study arms (selenium + placebo, vitamin E + placebo, selenium + vitamin E, and placebo + placebo). **Although the study duration was planned for 12 years, as a result of a planned interim analysis in August 2008, an independent data and safety monitoring committee recommended discontinuation of the study because the data convincingly demonstrated no effect on the risk of prostate cancer by either agent alone or in combination, and no chance of a beneficial effect of the hypothesized magnitude with continued supplementation** (Fig. 95–11) (Lippman et al, 2009). There were statistically nonsignificant increased risks of prostate cancer in the vitamin E group (HR = 1.13, 99% CI = 0.95 to 1.35, P = .06) and type 2 diabetes mellitus in the selenium group (RR = 1.07, 95% CI 0.94 to 1.22, P = .16). However, neither of these findings was observed in the combination group. Secondary analyses also showed no effect on the risks of lung, colorectal, or overall cancer incidence, no effect on cardiovascular events, and no effect on overall survival. **Null results for the effect of vitamin E on prostate cancer risk were also reported in the Physicians' Health Study II (PHS), a randomized trial of vitamins E (400 IU every other day) and C (500 mg daily) versus placebo in the prevention of prostate and other cancers** (Gaziano et al, 2009). **Together, these results suggest that neither selenium nor vitamin E should be used in the hope of preventing prostate or other cancers.**

Other Agents

Selective Estrogen Receptor Modulators (SERMs)

SERMs possess both agonistic and antagonistic estrogen-like activity and have been shown to repress prostate cancer growth in several transgenic mouse models. In the transgenic mouse model of prostate cancer (TRAMP), toremifene reduces the incidence of high-grade PIN and cancer in an estrogen-dependent, androgen-independent mechanism (Raghow et al, 2002). A randomized, double-blind, placebo-controlled trial is currently open to assess the activity of toremifene against high-grade PIN and prostate cancer incidence.

Soy

Legumes play an important role in the traditional diets of Asian countries, where prostate cancer incidence is low, but only a minor role in the West, where the incidence is the highest worldwide. Soybeans are unique among legumes because they are a concentrated source of isoflavones, which have weak estrogenic activity. **The major isoflavone components of soy, including genistein, daidzein, and their metabolites, inhibit benign and malignant prostatic epithelial cell growth, downregulate androgen-regulated genes, and reduce tumor growth in animal models** (Cohen et al, 2003; Hedlund et al, 2003; Yu et al, 2003). Migration studies and lower prostate cancer rates in Asian men with higher soy intake also support the role of soy as an anticancer agent (Severson et al, 1989). However, results from small clinical trials have not shown promise thus far. Dietary trials conducted in men prior to prostatectomy (Dalais et al, 2004), as well as in men on active surveillance (Kumar et al, 2004; Ornish et al, 2005), showed modest or no decrease in PSA values (the primary end point of these studies) with soy intake.

Lycopene

Lycopene is a red-orange carotenoid found primarily in tomatoes, tomato-derived products, and other red fruits and vegetables. Lycopene is a highly unsaturated acyclic isomer of β-carotene, is the predominant carotenoid in human plasma, and possesses

potent antioxidant activity. Lycopene has been shown to inhibit the growth of benign and malignant prostatic epithelial cells in vitro (Obermuller-Jevic et al, 2003). **There is mixed epidemiologic evidence that lycopene consumption is associated with a lower risk of prostate cancer** (Giovannucci and Clinton, 1999). A meta-analysis of observational studies reported a 23% reduction in prostate cancer risk with high tomato and lycopene intake (Etminan et al, 2004). However, a nested case-control study in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial prospectively examined the intake of more than 25 tomato-containing foods in 29,361 men and found no correlation with the incidence of prostate cancer (Peters et al, 2007). To date, results of initial clinical trials have demonstrated potential beneficial activity of lycopene in prostate cancer; however, treatment length has been relatively short, participants have included men at various stages of disease, and surrogate markers have been used rather than clinical meaningful end points (Bunker et al, 2007; Dahan et al, 2008). Currently, no phase III trials examining the role of lycopene in prostate cancer prevention are being conducted.

Green Tea (*Camellia sinensis*)

Green tea has been suggested as a prostate cancer preventative based on epidemiologic observations of a low incidence of prostate cancer among Asians with a high dietary intake. Previous work has focused on the effects of polyphenols (i.e., flavanols; also know as catechins), which accounts for 30% to 40% of extractable solids from dried green tea leaves. Prostate cancer cell culture experiments have demonstrated that the major polyphenolic constituent of green tea, (–)-epigallocatechin-3-gallate (EGCG), induces apoptosis, cell-growth inhibition, and cell-cycle dysregulation (Adhami et al, 2003). In the TRAMP model, oral infusion of a polyphenolic fraction isolated from green tea significantly inhibited tumor development and metastasis (Brusselmans et al, 2003; Hastak et al, 2003). A small randomized, double-blind, placebo controlled trial of green tea catechin tablets in 60 men with HGPIN demonstrated cancer at 1-year biopsy in 9 patients in the placebo group, compared with only 1 patient in the treatment group (Bettuzzi et al, 2006). Another small trial in men with hormone-refractory prostate cancer found only minimal clinical activity (Choan et al, 2005). Confirmatory trials are needed to better assess the role of green tea consumption in prostate cancer prevention.

Statins

Statins are widely used cholesterol-lowering drugs given for the treatment and prevention of atherosclerotic cardiovascular disease. They inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA), the rate-limiting enzyme in cholesterol biosynthesis. Statins are hypothesized to play a role in the prevention of cancer by inhibiting inflammation, angiogenesis, cell proliferation, migration/adhesion, invasion, and/or by preferentially promoting apoptosis in tumor cells (Hamilton and Freedland, 2008). Observational studies of statin use demonstrate high heterogeneity with mixed results for prostate cancer risk. **Statin users have been shown to have lower serum PSA levels than nonusers** (Cyrus-David et al, 2005; Hamilton et al, 2008), **suggesting an anticancer effect, but potentially leading to fewer prostate biopsies, and thus biasing results of epidemiologic and clinical studies. A meta-analysis of six randomized clinical trials, six cohort, and seven case-control studies found no association between statin use and overall prostate cancer incidence but did find a protective association with advanced prostate cancer (RR = 0.77, 95% CI = 0.64 to 0.93)** (Bonovas et al, 2008). Statin users tend to be healthier and more medically compliant than nonusers, making them more likely to undergo PSA screening and possibly resulting in earlier cancer detection. Further research is needed to help determine the role, if any, of statins in the prevention of prostate cancer.

Key Points: Chemoprevention

- The goal of primary chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality.
- Effective chemoprevention requires the use of nontoxic agents that inhibit specific molecular steps in the carcinogenic pathway.
- Prostate cancer is an attractive and appropriate target for primary prevention, because of its incidence, prevalence, and disease-related mortality.
- Target populations appropriate for primary prevention studies can be subdivided into those with low, intermediate, and high risk of developing prostate cancer. The molecular mechanisms that underlie disease progression are likely to be different for each target population, and it may not be possible to generalize the results from a particular trial to other clinical scenarios.
- The Prostate Cancer Prevention Trial demonstrated that finasteride reduces the period prevalence of prostate cancer by 25%. The apparent increase in high-grade disease in men on finasteride may be due to ascertainment bias induced by the effects of finasteride on PSA, DRE, and prostate volume.
- SELECT demonstrated that neither vitamin E nor selenium prevent prostate cancer. The lack of efficacy of vitamin E was confirmed by the SELECT Trial.
- 5α-Reductase inhibitors and other hormonal agents, antioxidants, and statins are among the many agents currently being investigated in prostate cancer chemoprevention.

CONCLUSION

It is clear that the process of prostate carcinogenesis is complex. The interplay of constitutional, behavioral, molecular, and environmental factors—against the backdrop of various processes occurring during aging—interact to set in motion a series of events that ultimately are manifest through the diagnosis of prostate cancer. The understanding of this process is complicated by the various confounds associated with the diagnosis of the disease in clinical trials, general populations, and epidemiologic studies. Additionally, the current inability to distinguish biologically significant from biologically insignificant disease complicates full understanding of the interaction of these factors.

Prostate cancer is an attractive target for chemoprevention, because of its ubiquity, treatment-related morbidity, long latency between premalignant lesions and clinically evident cancer, and defined molecular pathogenesis. The PCPT provides the first firm evidence that this cancer can be prevented by a relatively nontoxic oral agent. The current body of evidence argues against a routine recommendation of any dietary or nutritional supplement for the prevention of prostate cancer.

Pathology of Prostatic Neoplasia

Jonathan I. Epstein, MD

Prostatic Intraepithelial Neoplasia

Adenocarcinoma

Subtypes of Prostate Adenocarcinoma

This chapter covers the pathology of adenocarcinoma of the prostate from its precursor lesions to invasive carcinomas, from needle biopsies to radical prostatectomies. Other tumors involving the prostate are also discussed. In particular, practical points of pathology that are critical for urologists to know for the management of their patients are emphasized.

PROSTATIC INTRAEPITHELIAL NEOPLASIA

Prostatic intraepithelial neoplasia (PIN) consists of architecturally benign prostatic acini or ducts lined by cytologically atypical cells and is classified as low-grade and high-grade neoplasias (McNeal and Bostwick, 1986) (Fig. 96–1). **Diagnostic reports should not comment on low-grade PIN.** First, pathologists cannot reproducibly distinguish between low-grade PIN and benign prostate tissue (Epstein et al, 1995). Second, when low-grade PIN is diagnosed on needle biopsy, these patients are at no greater risk of having carcinoma on repeated biopsy than are men with a benign biopsy finding (Epstein and Herawi, 2006). Evidence that high-grade PIN (HGPIN) is a precursor to some prostate carcinomas includes the following: There is an increase in the size and number of high-grade PIN foci in prostates with cancer compared with prostates without carcinoma; with increasing amounts of high-grade PIN, there are a greater number of multifocal carcinomas; both high-grade PIN and carcinoma preferentially involve the peripheral zone; and biomarkers and molecular changes show similarity between high-grade PIN and carcinoma (Bostwick et al, 1996; Haggman et al, 1997). About 20% of high-grade PIN lesions harbor a *TMPRSS2-ERG* fusion gene, which is a common molecular abnormality detectable in about 50% of prostate cancers (Cerveira et al, 2006; Perner et al, 2007).

The incidence of high-grade PIN on biopsy averages 7.6% among 38 studies, with a median of 5.2%. There is a tremendous variation in the percentages reported, ranging from 0% to 25%, with no apparent correlation to number of cores sampled or whether the study was from an academic or community hospital setting (Epstein and Herawi, 2006). The most likely explanation accounting for this variation is interobserver threshold. The distinction between low-grade and high-grade PIN is based on the prominence of the nucleoli. This is a subjective exercise, and those pathologists with a lower threshold as to what defines prominent nucleoli will have a higher incidence of high-grade PIN. **The largest studies reported a 16% to 44.6% risk of cancer on subsequent biopsy. Of the 11 studies with at least 50 cases of high-grade PIN on needle biopsy with follow-up, the mean risk of cancer is 26.4%** (Epstein and Herawi, 2006). **In the majority of studies, serum prostate-specific antigen (PSA) levels, results of digital rectal examination, and transrectal ultrasonography findings do not enhance the prediction of who is more likely to have carcinoma on repeat biopsy.** PIN by itself does not give rise to elevated serum PSA values (Ronnett, et al, 1993). Of 8 studies in which the risk of cancer after a needle biopsy diagnosis of high-grade PIN was compared with the risk of cancer after a benign biopsy finding, 6 showed no difference between the groups (Epstein and Herawi, 2006). **For patients diagnosed with unifocal high-grade PIN on extended initial core sampling, a repeat biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer and in the absence of extensive high-grade PIN.** High-grade PIN on greater than or equal to two cores is associated with a sufficiently high risk of subsequent cancer that rebiopsy within a year of the initial PIN diagnosis is warranted (Abdel-Khalek et al, 2004; Netto and Epstein, 2006; Merrimen et al, 2009). Lefkowitz and colleagues (2002) described 31 men who had an initial diagnosis of high-grade PIN on 12-core biopsy with an interval to follow-up prostate biopsy of 3 years. The rate of cancer on repeat 12-core biopsy was 25.8% compared with their earlier study in which rebiopsy within 1 year of a diagnosis of high-grade PIN yielded cancer in only 2.3%. They hypothesized that the 3-year interval allowed unsampled small cancers that were associated with the high-grade PIN at the time of initial biopsy to grow to a size that was detectable on repeat biopsy, or alternatively, some of the high-grade PIN lesions progressed to cancer during the 3-year interval. **If a repeat prostate needle biopsy is performed, it should sample the entire prostate and not just the initial sextant site where the high-grade PIN was found** (Epstein and Herawi, 2006).

The significance of HGPIN on transurethral resection (TUR) is not clear, with conflicting data as to the risk for subsequent discovery of cancer (Gaudin et al, 1997; Pacelli and Bostwick, 1997). In an elderly patient with HGPIN on TUR, often no further workup is instituted. In a younger man, a more aggressive workup to rule out a clinically significant tumor is warranted. The one piece of evidence we have for premalignant lesions in other organs that is lacking in the prostate is the natural history of high-grade PIN. With the prostate, there is no capability to monitor a PIN focus to determine whether there is already infiltrating carcinoma at that site or whether infiltrating carcinoma has evolved in the immediate vicinity of the PIN focus. Because we do not know what

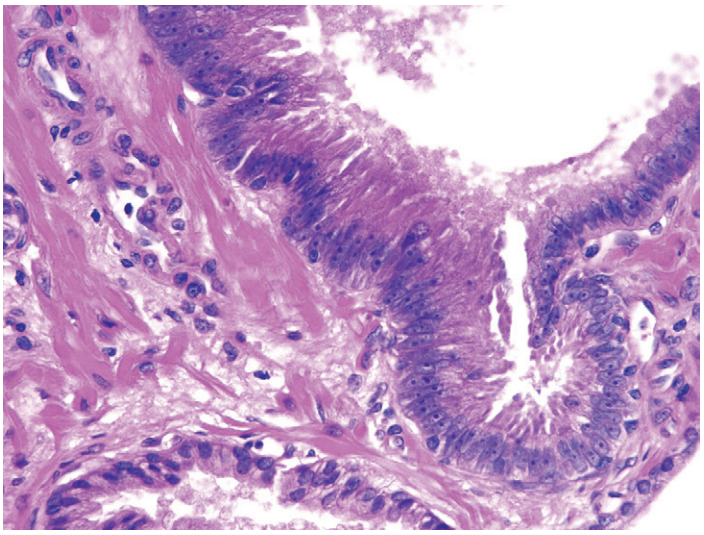

Figure 96–1. High-grade prostatic intraepithelial neoplasia. Note cytologically atypical cells with prominent nucleoli in an architecturally benign gland *(top)*, contrasted to a benign gland *(bottom)*.

percentage of patients develop infiltrating carcinoma during a given follow-up interval, when high-grade PIN is found on biopsy material, most authorities do not use the term *carcinoma in situ of the prostate*. **It appears that high-grade PIN is a precursor lesion to many peripheral intermediate- to high-grade adenocarcinomas of the prostate.** However, PIN need not be present for carcinoma to arise. Low-grade carcinomas, especially those present within the transition zone, are not closely related to high-grade PIN.

Intraductal carcinoma of the prostate (IDC-P) has, in several studies, been described in radical prostatectomy specimens (McNeal et al, 1986; McNeal and Yemoto, 1996; Rubin et al, 1998; Wilcox et al, 1998; Cohen et al, 2007; Robinson and Epstein, 2010). Rarely, IDC-P may be identified on biopsy material in the absence of infiltrating carcinoma (Guo and Epstein, 2006). IDC-P on prostate biopsies is frequently associated with high-grade cancer and poor prognostic parameters at radical prostatectomy, as well as potentially advanced disease following other therapies (Guo and Epstein, 2006). These findings support the idea that in most cases IDC-P represents intraductal spread of carcinoma within pre-existing ducts and acini and that IDC-P in the vast majority of cases should not be categorized as a preinvasive neoplastic condition. Consideration should be given to aggressively treating patients with IDC-P on biopsy, even in the absence of documented infiltrating cancer.

ADENOCARCINOMA

Location

In clinical stage T2 carcinomas and in 85% of nonpalpable tumors diagnosed on needle biopsy (stage T1c), the major tumor mass is peripheral in location (McNeal, 1969; Byar and Mostofi, 1972; Epstein et al, 1994b). In the remaining cases, tumors are predominantly located in the transition zone (i.e., periurethrally or anteriorly). Tumors that appear to be unilateral on rectal examination are bilateral in approximately 70% of cases when they are examined for pathology. Adenocarcinoma of the prostate is multifocal in more than 85% of cases (Byar and Mostofi, 1972). In many of these cases of bilateral or multifocal tumor, the other tumors are small, low grade, and clinically insignificant. Consequently, the distinction between pathologic stages T2a and T2b is meaningless (Freedland et al, 2004). In a highly selected population with limited unilateral biopsy cancer, the mean number of separate tumor nodules per radical prostatectomy is 2.9. A contralateral tumor to the positive biopsy side at radical prostatectomy is typically small. However, 20% have some contralateral adverse pathology in terms of size, extraprostatic extension, grade, or margins (Yoon et al, 2008).

Spread of Tumor

Because the prostate lacks a discrete histologic capsule, *extraprostatic extension* is preferable to "capsular penetration" as the term to describe a tumor that has extended out of the prostate into periprostatic soft tissue (Ayala et al, 1989). Some authors use the term *capsular invasion* when they believe that the "capsule" is infiltrated by a tumor but the tumor does not extend out of the prostate. Because there is no such entity as the prostatic capsule, "capsular invasion" makes no sense. Peripherally located adenocarcinomas of the prostate tend to extend out of the prostate through perineural space invasion (Villers et al, 1989). Perineural invasion by itself in radical prostatectomy specimens does not worsen prognosis, because perineural invasion merely represents extension of a tumor along a plane of decreased resistance and not invasion into lymphatics (Hassan and Maksem, 1980). In contrast, vascular invasion increases the risk of recurrence after radical prostatectomy (Baydar et al, 2008). Extraprostatic extension preferentially occurs posteriorly and posterolaterally, paralleling the location of most adenocarcinomas.

Further local spread of tumor may lead to seminal vesicle invasion, which is diagnosed when a tumor extends into the muscle wall of the seminal vesicle. The most common route of seminal vesicle invasion is by tumor penetration out of the prostate at the base of the gland, with growth and extension into the periseminal vesicle soft tissue and eventually into the seminal vesicles. Less commonly, there may be direct extension through the ejaculatory ducts into the seminal vesicles or direct extension from the base of the prostate into the wall of the seminal vesicles. Least commonly, there may be discrete metastases to the seminal vesicle (Fry et al, 1979; Ohori et al, 1993). Local spread of prostate cancer may also rarely involve the rectum, where it may be difficult to distinguish from a rectal primary tumor (Fry et al, 1979; Lane et al, 2008).

The most frequent sites of metastatic prostate carcinoma are lymph nodes and bone. Prostate cancer may present with metastases to the left supradiaphragmatic, typically the supraclavicular, lymph nodes (Cho and Epstein, 1987). Lung metastases from prostate carcinoma are extremely common at autopsy, and almost all cases have bone involvement as well (Varkarakis et al, 1974). Metastatic lesions usually take the form of multiple small nodules or diffuse lymphatic spread rather than large metastatic deposits. Clinically, prostate carcinoma metastatic to the lung is usually asymptomatic. In addition to lymph nodes, bones, and lung, the next most common regions of spread of prostate cancer at autopsy are bladder, liver, and adrenal gland (Hess et al, 2006).

Tumor Volume

In general, the size of a prostate cancer correlates with its stage. Extraprostatic extension is uncommon in tumors of less than 0.5 cm^3, and tumors that are less than 4 cm^3 uncommonly reveal lymph node metastases or seminal vesicle invasion (McNeal et al, 1990). Tumor volume is also proportional to grade (see following

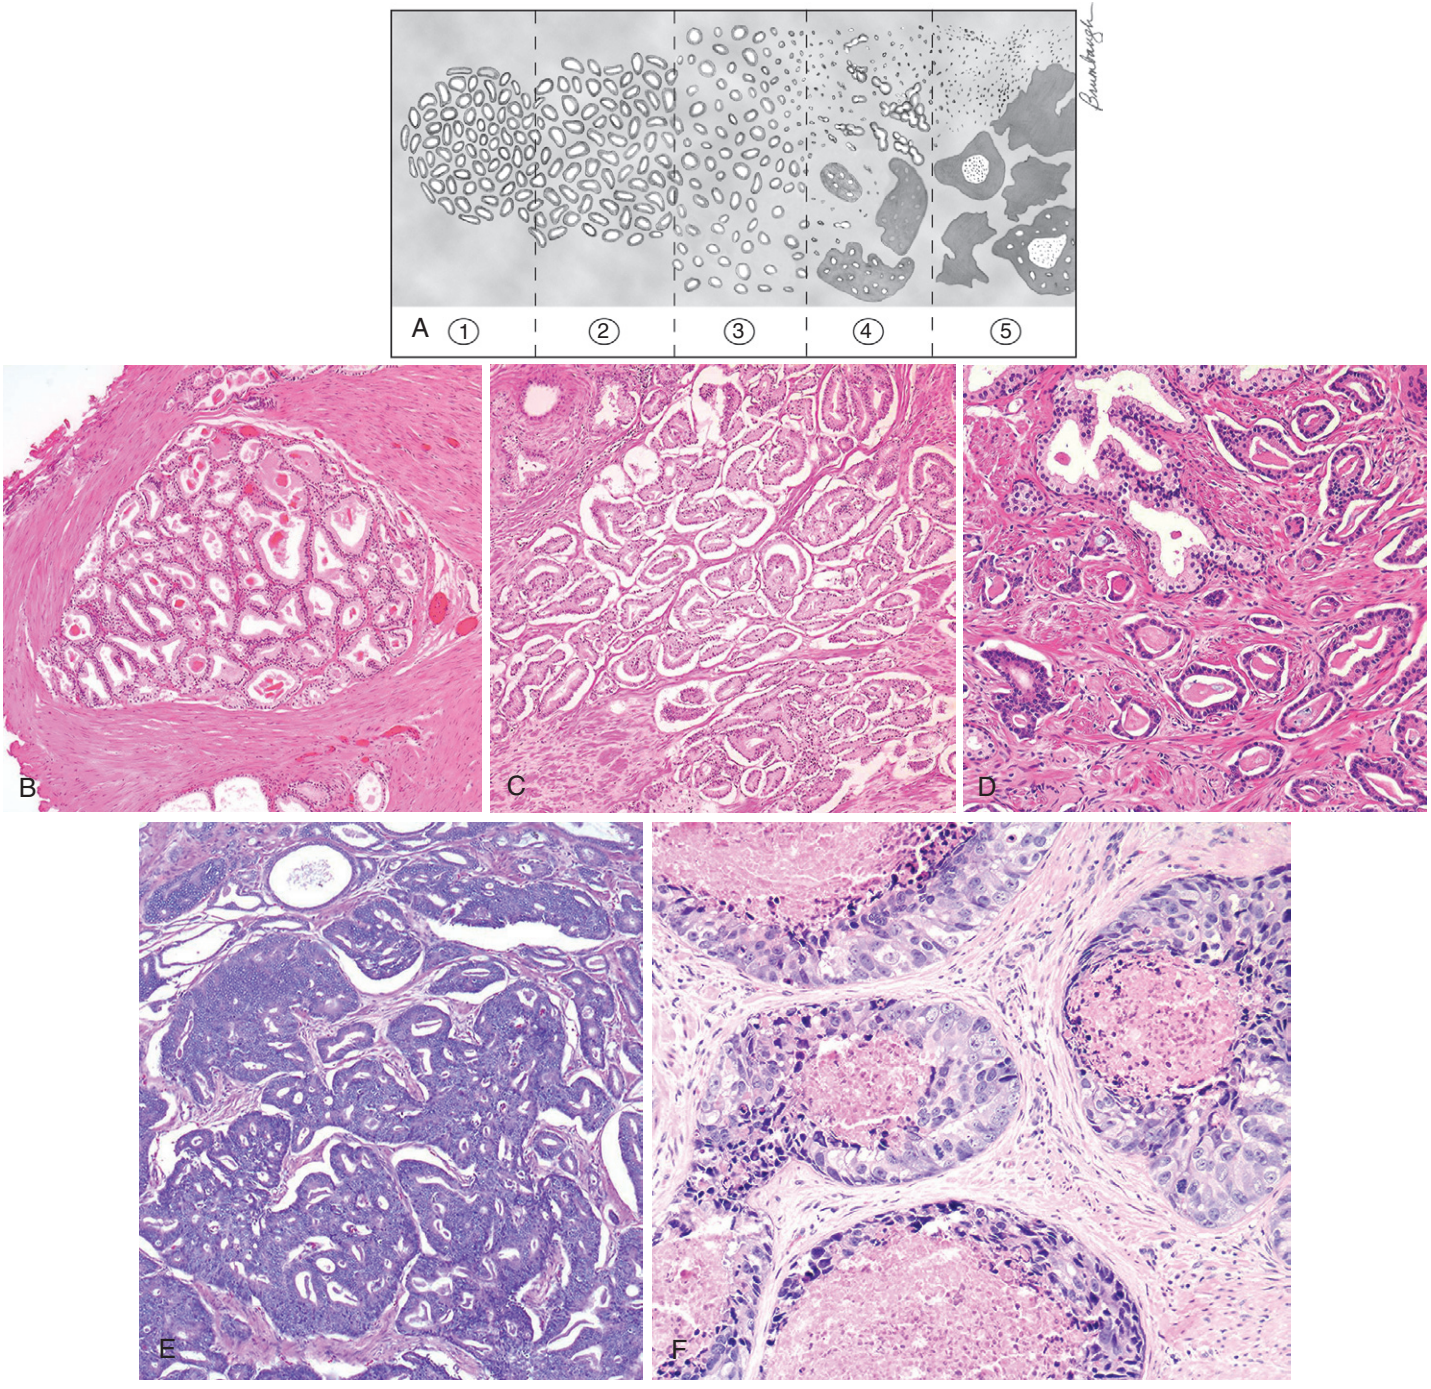

Figure 96–2. The Gleason grading system. **A,** Schematic diagram of the Gleason grading system. **B,** Gleason pattern 1: Well-circumscribed nodule of closely packed glands. **C,** Gleason pattern 2: nodule with more loosely arranged glands. **D,** Gleason pattern 3: small glands with an infiltrative pattern between benign glands. **E,** Gleason pattern 4: large irregular cribriform glands. **F,** Gleason pattern 5: solid nests of tumor with central comedonecrosis.

discussion). The location and grade of the tumor also modulate the effect of tumor volume (Christensen et al, 1990; McNeal et al, 1990; Greene et al, 1991). For example, **transition zone tumors extend out of the prostate at larger volumes than do peripheral zone tumors, because of their lower grade and greater distance from the edge of the gland.**

Grade

Although numerous grading systems exist for the evaluation of prostatic adenocarcinoma, the Gleason grading system is the most widely accepted (Gleason and Mellinger, 1974). The Gleason system is based on the glandular pattern of the tumor as identified at relatively low magnification (Fig. 96–2). Cytologic features play no role in the grade of the tumor. **Both the primary (predominant) and the secondary (second most prevalent) architectural patterns are identified and assigned a grade from 1 to 5, with 1 being the most differentiated and 5 being the least differentiated** (Table 96–1). **Because both the primary and the secondary patterns are influential in predicting prognosis, there is a Gleason sum or score obtained by the addition of the primary**

Table 96–1.

2005 International Society of Urological Pathology Modified Gleason System

Pattern 1

Circumscribed nodule of closely packed but separate, uniform, rounded to oval, medium-sized acini (larger glands than pattern 3)

Pattern 2

Like pattern 1, fairly circumscribed, yet at the edge of the tumor nodule there may be minimal infiltration

Glands are more loosely arranged and not quite as uniform as Gleason pattern 1

Pattern 3

Discrete glandular units

Typically smaller glands than seen in Gleason pattern 1 or 2

Infiltrates in and amongst non-neoplastic prostate acini

Marked variation in size and shape

Pattern 4

Fused microacinar glands

Ill-defined glands with poorly formed glandular lumina

Large cribriform glands

Cribriform glands

Hypernephromatoid

Pattern 5

Essentially no glandular differentiation, composed of solid sheets, cords, or single cells

Comedocarcinoma with central necrosis surrounded by papillary, cribriform, or solid masses

and secondary grades. If a tumor has only one histologic pattern, then for uniformity, the primary and secondary patterns are given the same grade. Gleason scores range from 2 (1 + 1 = 2), which represents tumors uniformly composed of Gleason pattern 1 tumor, to 10 (5 + 5 = 10), which represents totally undifferentiated tumors. This author prefers to assign both a primary and a secondary pattern even when presented with limited cancer so as to not to create any confusion. For example, cases that the pathologist signs out as only "Gleason grade 4" could be interpreted to mean Gleason pattern 4 (high-grade cancer) or Gleason score 4 (low-grade cancer). In radical prostatectomy specimens, it has been demonstrated that tertiary (third most common pattern) high-grade components adversely affect biologic behavior, yet are not always equivalent to the sum of the primary pattern and highest-grade pattern. It is recommended that in radical prostatectomy specimens, the routine Gleason score, consisting of the most prevalent and the second most prevalent architectural patterns, be recorded along with a note stating that there is a tertiary high-grade pattern (Pan et al, 2000; Trock et al, 2009). **There are a few exceptions to the Gleason system, as described above. For needle biopsy specimens in which the typical scenario includes tumors with patterns 3, 4, and 5 in various proportions, both the primary pattern and the highest grade should be added to derive the Gleason score. Any amount of high-grade tumor sampled on needle biopsy most likely indicates a more significant amount of high-grade tumor within the prostate because of the correlation of grade and volume and the problems inherent with needle biopsy sampling. In the setting of high-grade cancer, one should ignore lower-grade patterns if they occupy less than 5% of the area of the tumor. For example, a tumor composed of 98% Gleason pattern 4 and 2% Gleason pattern 3 should be diagnosed as Gleason score 4 + 4 = 8** (Epstein et al, 2005).

It is important to recognize Gleason pattern 4 tumors because tumors with this pattern have a significantly worse prognosis than those with pure Gleason pattern 3 (McNeal et al, 1990; Epstein et al, 1993b). It has also been demonstrated in radical prostatectomy specimens that tumors with Gleason score 4 + 3 = 7 have a worse prognosis than those with Gleason score 3 + 4 = 7 (Chan et al, 2000). **There is fairly good interobserver reproducibility of the Gleason system among uropathology experts and poorer reproducibility among practicing pathologists** (Allsbrook et al, 2001a, 2001b). It has been demonstrated that although current use of the Gleason grading system is not optimal, significant improvements can be made after participation in relatively brief educational programs, such as those available on websites (e.g., www.isuporg.org [International Society of Urological Pathology]).

The Gleason grade on biopsy material has also been shown to correlate fairly well with that of the subsequent prostatectomy specimen (Fine and Epstein, 2008). Several studies have demonstrated that there is better correlation between the biopsy and prostatectomy grade with extended as opposed to sextant needle biopsy sampling. In general, a Gleason score less than or equal to 6 or greater than or equal to 7 on biopsy corresponds to a Gleason score less than or equal to 6 or greater than or equal to 7 in the radical prostatectomy, respectively, in 80% of cases. An unavoidable cause of discordant grading between the biopsy and subsequent prostatectomy specimen(s) concerns sampling errors with the needle biopsy. One of the most frequent causes of discordant grading is grading of tumors that straddle two grades. One way the practice of Gleason scoring can be improved is by virtually never assigning Gleason score 2 to 4 for adenocarcinoma of the prostate on needle biopsy. The reasons for this approach are as follows: (1) most tumors graded as Gleason score 2 to 4 on needle biopsy are graded as Gleason score 5 to 6 or higher when reviewed by uropathology experts (Steinberg et al, 2005); (2) there is poor reproducibility in the diagnosis of Gleason score 2 to 4 on needle biopsy even among uropathology experts (Allsbrook et al, 2001b); and (3) most important, assigning Gleason score 2 to 4 to an adenocarcinoma on needle biopsy can adversely affect the patient's care, because clinicians may incorrectly assume that all low-grade cancers on needle biopsy do not need definitive therapy. Although low volume, Gleason score 2 to 4 adenocarcinoma of the prostate, on transurethral resection of the prostate, has a relatively indolent course; low-grade cancer on needle biopsy does not. Pathologists, in general, are less frequently overdiagnosing Gleason scores 2 to 4 on biopsy in recent years. In one study, 24% of pathologists rendered a diagnosis of Gleason score 2 to 4 on biopsy in 1991, which decreased to 2.4% in 2001 (Ghani et al, 2005).

The ultimate value of any grading system is its prognostic ability. Both Gleason's data with 2911 patients and subsequent studies with long-term follow-up have demonstrated a good correlation between the Gleason sum and prognosis (Mellinger, 1977; Sogani et al, 1985). When stage of disease is factored in with grade, prognostication is enhanced. Some men with low-grade cancers develop high-grade tumors after several years (Brawn, 1983). It is not clear whether the residual low-grade cancer progressed or whether there was a subsequent development of a multifocal, more aggressive tumor. Although, in general, larger tumors are high grade and small tumors are low grade, exceptions occur (Epstein et al, 1994a). There is a tendency to hypothesize that

Table 96–2.

Reasons to Submit Needle Cores in Separate Jars for Each Sextant Site

- In "atypical" cases, the atypical site can be preferentially targeted on repeated biopsy, in addition to other sites.
- More specific location of cancer helps pathologists target additional tissue or block sampling in cases with no cancer on initial sampling of radical prostatectomy.
- Knowledge of sextant site helps pathologists recognize certain diagnostic pitfalls (i.e., seminal vesicle tissue or central zone mimicking high-grade prostatic intraepithelial neoplasia at the base and Cowper's gland mimicking cancer at the apex).
- With brachytherapy, this helps target areas where extra seeds can be distributed.
- Having a maximum of two cores per block or slide preparation with complete visualization of cores helps prevent missing small foci of cancer that could be "buried" in the paraffin block.
- Maximum of two cores per block or slide helps prevent core fragmentation where one cannot determine the number of involved cores, their percentage involvement, and the highest grade of cancer in the case.

tumors begin as low-grade tumors and, on reaching a certain size, dedifferentiate into higher-grade lesions, accounting for the relationship between size and grade. Alternatively, high-grade tumors may be high grade at their inception but are detected at an advanced size because of their rapid growth. Similarly, low-grade tumors may evolve so slowly that they tend to be detected at lower volumes. During a 2- to 3-year period after biopsy, there is no evidence that prostate cancer grades worsen significantly (Sheridan et al, 2008).

Assessment of Needle Biopsy Specimens

Processing. **When biopsy specimens are taken from different areas of the prostate, they should be submitted to pathology in separate containers** (Table 96–2). As long as cores are submitted in separate containers or the cores are in the same container yet specified by the urologist as to their location (i.e., by different color inks), pathologists should assign individual Gleason scores to separate cores (Epstein et al, 2005). If cores are combined in a container, one can try to give separate scores for each core or can give an overall Gleason score. For example, in a case with Gleason score 4 + 4 = 8 on one core and with pattern 3 (3 + 3 = 6, 3 + 4 = 7, 4 + 3 = 7) on other cores in the same container, the overall score for that container, averaging all involved needle biopsy specimens together as if they were one long positive core, would be Gleason score 4 + 3 = 7 or 3 + 4 = 7, depending on whether pattern 4 or 3 predominated.

Differential Diagnosis. The underdiagnosis of limited adenocarcinoma of the prostate on needle biopsy is one of the most frequent problems in prostate pathology (Epstein, 2004). There are also numerous benign mimickers of adenocarcinoma of the prostate (Srigley, 2004). In some of these cases, the use of antibodies to high-molecular-weight cytokeratin and p63 may resolve the diagnosis (Wojno and Epstein, 1995). Benign glands contain basal cells and are labeled with these antibodies, whereas prostate cancer shows no staining. Immunohistochemistry with antibodies to α-methylacyl-CoA racemase, which preferentially labels prostatic carcinoma and high-grade PIN, can also be used as an adjunct in the diagnosis of limited cancer, yet pathologists must be careful because false-positive and false-negative staining with α-methylacyl-CoA racemase has been reported (Jiang et al, 2004).

In certain cases, there are findings suggestive of but not diagnostic of carcinoma. **The incidence of atypical needle biopsy specimens reported from the 39 studies in the literature averages 7.6% with a median of 5.2%** (Epstein and Herawi, 2006). **Pathologists should sign out atypical cases descriptively as "a focus of atypical glands" rather than use ambiguous terminology such as "atypical hyperplasia" or "atypical small acinar proliferation."** A comment should be added in the report describing why the focus is suggestive of cancer yet not diagnostic, with a recommendation for repeat biopsy. In this way, there is no confusion in the urologist's mind that he or she is dealing with a lesion likely to be infiltrating cancer but for which the pathologist is not comfortable establishing the diagnosis. **The likelihood of cancer after an atypical diagnosis is 42% or 49%, according to the two largest studies from the Mayo Clinic and Johns Hopkins Hospital, respectively** (Iczkowski et al, 1997; Chan and Epstein, 1999). **Surprisingly, in men with a prior atypical biopsy result, the level of serum PSA elevation or the results of digital rectal examination do not correlate with the risk of a subsequent biopsy specimen showing carcinoma. Regardless of the serum PSA level, all patients with an initial atypical diagnosis on needle biopsy should undergo a repeat biopsy.** In a series of second-opinion prostate needle biopsy cases that were patient- and urologist-driven, on expert review, only 36.8% of outside atypical diagnoses were confirmed; on review, 92 of the 204 (45.1%) outside atypical cases in one study were diagnosed as cancer and 33 (16.2%) as benign (Chan and Epstein, 2005). **Cases diagnosed as atypical have the highest likelihood of being changed on expert review, and urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy.**

Prognosis. Adverse findings on needle biopsy, in terms of Gleason grade and tumor extent, in general accurately predict adverse findings in the radical prostatectomy specimen. However, favorable findings on needle biopsy do not necessarily predict favorable findings in the radical prostatectomy specimen, as a result of sampling error. The ways in which cancer may be measured on needle biopsy include number of positive cores, total millimeters of cancer among all cores, percentage of cancer per core, and total percentage of cancer in the entire specimen. An equal number of studies claim superiority of one technique over the other, with no one technique adopted uniformly (Epstein, 2004). It is proposed that pathologists report the number of positive cores along with one other measurement of tumor extent. At the Johns Hopkins Hospital, the percentages of each involved core are reported, for example, as "adenocarcinoma of the prostate, Gleason grade 3 + 3 = 6, involving two cores (70%, 30%)." By combining needle biopsy grade with clinical stage and serum PSA values, the extent of cancer within the prostate can be more accurately predicted (Makarov et al, 2007).

Whether perineural invasion that is extensive enough to be sampled on needle biopsy signals an increased risk of extraprostatic extension of cancer is controversial. Harnden (2007), in a systematic review of the importance of perineural invasion on needle biopsy to predict recurrence following radiotherapy or surgery, concluded that the weight of the evidence in 21 studies showed it was a significant prognostic indicator, particularly in specific patient subgroups defined by serum PSA and Gleason

scores. Over two thirds of the studies using external beam radiotherapy but none using brachytherapy showed prognostic significance for perineural invasion. Given that perineural invasion is readily identifiable in most cases, that it is prognostic in some studies, although the data is conflicting, and that it is uncertain what factors an individual clinician may consider in treatment decisions, it is the opinion of these authors that perineural invasion should be noted on the biopsy pathology report.

One can also use information from needle biopsy pathology reports to help determine whether to sacrifice the neurovascular bundle on a given side in cases with a higher likelihood of extraprostatic extension (Shah et al, 2003; Ohori et al, 2004; Tsuzuki et al, 2005).

There is emerging data that atrophy and associated inflammation are linked with prostate carcinogenesis (DeMarzo et al, 2003). However, the hypothesis is that these factors are involved in the initiation of prostate cancer and are not proximately related to cancer by the time atrophy is identified on needle biopsy. Atrophy of all morphologic types are very common on needle biopsy and are not associated with an increased risk of cancer or PIN on subsequent biopsy (Postma et al, 2005).

Assessment of Transurethral Resection Specimens

Processing. The recommended system is based on the percentage of the specimen involved by tumor, with 5% being the cutoff between stage T1a and T1b (Cantrell et al, 1981). All stage T1b tumors are detected by processing of between 6 and 8 cassettes of a transurethral resection (TUR) specimen. By processing 8 to 10 cassettes, more than 90% of stage T1a lesions are identified (Newman et al, 1982; Murphy et al, 1986; Vollmer, 1986; Rohr, 1987). Depending on the institution, all TUR tissues may be examined in men younger than 65 years in whom aggressive therapy for stage T1a disease might be pursued. There are conflicting opinions as to whether the grade of the cancer should be factored into the staging system for limited cancer detected on transurethral prostatectomy. On the basis of data from the author's institution, cases with less than 5% of tumor detected on TUR and with Gleason scores below 7 are staged T1a; if the Gleason scores are above 7, they should be staged T1b (Larsen et al, 1991).

Differential Diagnosis. One of the most common lesions to be confused with low-grade adenocarcinoma is adenosis (atypical adenomatous hyperplasia) (Gaudin and Epstein, 1994). In the author's institution, 1.6% of benign TUR specimens and 0.8% of all needle biopsy specimens contain adenosis. It is characteristically found in the transition zone of the prostate, is frequently multifocal, and most often is an incidental finding in TURs performed for urinary obstruction. **Although adenosis mimics carcinoma, there is no conclusive evidence suggesting that patients with adenosis have an increased risk of harboring or developing adenocarcinoma of the prostate.**

Assessment of Radical Prostatectomy Specimens

Assessment. Within institutions that do not totally embed radical prostatectomy specimens, there are sampling techniques that provide accurate pathologic staging (Hall et al, 1992; Sehdev et al, 2001). **Whole-mount sectioning of the prostate provides more aesthetically pleasing sections for teaching and publication, yet the information obtained by routine sections is identical.** In a minority of cases, routinely processed thinly sliced sections allow identification of positive margins not identified with use of thicker slices of tissue, which are necessary for whole-mount processing.

It is recommended that pathologists assign a separate grade to each dominant tumor nodule. Most often, the dominant nodule is the largest tumor, which is also the tumor associated with the highest stage and highest grade. In the unusual occurrence of a nondominant nodule (i.e., smaller nodule) that is of higher stage, one should also assign a grade to that nodule. If one of the smaller nodules is the highest-grade focus within the prostate, the grade of this smaller nodule should also be recorded. In general, this will be the exception; in most cases, separate grades will be assigned to only one or at most two dominant nodules.

If the urologist plans on aborting radical prostatectomy when lymph nodes are positive, the pathologist should freeze representative nodes, because approximately two thirds of microscopic metastases can be identified with random frozen sections. For urologists who perform radical prostatectomy in the face of microscopic metastases for local control, it has been demonstrated that men with a Gleason score below 8 on needle biopsy have a relatively prolonged interval before distant metastases appear; the pathologist need not examine the nodes at frozen section in these cases, because the urologist will proceed with surgery even if nodal metastases are found (Sgrignoli et al, 1994). Preoperatively, the physician and patient should decide and agree on what to do if there is a positive lymph node when the biopsy grade is Gleason score 8 to 10. In patients with Gleason scores of 8 to 10 on needle biopsy, it has been shown that if the lymph nodes are involved, these men will not benefit from radical surgery, whereas if the nodes are free of tumor, cure after radical prostatectomy is possible (Sgrignoli et al, 1994). Current data support that in men with Gleason scores of 8 to 10 on biopsy, all the nodes should be examined at the time of surgery, and the urologist should abort the prostatectomy if the nodes are positive. Other features that have correlated with prognosis are extent, grade, and ploidy of nodal metastases (Boorjian et al, 2007).

Prognosis. Only 25% of men with seminal vesicle invasion and none with lymph node metastases are biochemically progression-free at 10 years after radical prostatectomy, with grade and, in some studies, margins of resection influencing prognosis (Epstein et al, 1993b; Salomon et al, 2003; Bloom et al, 2004; Johnson et al, 2004). There is some controversy as to the definition of seminal vesicle invasion. Some investigators recognize both an intraprostatic and an extraprostatic portion of the seminal vesicle, whereby one can have organ-confined disease and seminal vesicle invasion (Ohori et al, 1993; Wheeler et al, 1998). However, these studies have demonstrated that the finding of intraprostatic seminal vesicle invasion does not adversely affect prognosis beyond that of finding extraprostatic extension without seminal vesicle invasion. Consequently, the author diagnoses seminal vesicle invasion only when the tumor extends out of the prostate into the muscle coat of the seminal vesicle; with use of this definition, seminal vesicle invasion is associated with a markedly adverse prognosis (Epstein et al, 1993b). The presence of extraprostatic extension and its extent also influence progression. Pathologists frequently underdiagnose extraprostatic extension. When tumor extends out of the prostatic gland, it induces a dense desmoplastic response in the periprostatic adipose tissue, where it can be difficult to judge whether the tumor has extended out of the gland

or is within the fibrous tissue of the prostate. Posterior, posterolateral, and lateral regions account for 18%, 17%, and 4% of positive margins, respectively, in the author's material. These sites parallel the location of most stage T2 carcinomas. In particular, these sites are disproportionately involved toward the apex (Stamey et al, 1990; Epstein et al, 1993b). **Only approximately 50% of men with positive margins progress after radical prostatectomy** (Epstein et al, 1993b). A major source of this discrepancy is that even in cases in which margins histologically appear to be positive, additional tissue removed from the site does not always show tumor (Epstein, 1990). It has also been demonstrated that tumor close to the margins does not result in a higher risk of recurrence (Epstein, 1990; Epstein and Sauvageot, 1997). Artifactually positive margins relate to the scant tissue surrounding the prostate, which may easily be disrupted during surgery or pathologic evaluation of the gland. Positive margins also may arise as a result of the surgical transection of intraprostatic tumor (intraprostatic incision). The reported incidence of intraprostatic incision ranges from 1.3% to as high as 71%. In the author's opinion, much of this variation relates to the difficulties described in recognizing extraprostatic extension. If an extraprostatic tumor associated with a desmoplastic stromal response at a margin is misdiagnosed as organ-confined, it will be misclassified as a positive margin due to intraprostatic incision. At the apex of the prostate, the boundaries of the prostate are especially vague such that it can be difficult to determine whether a cancer with a positive margin is intraprostatic. The other relatively frequent site of intraprostatic incision is in the region of the neurovascular bundles, where the urologist tries to preserve the bundle(s) for potency, yet cuts into the prostate. This author diagnoses a positive margin as a result of intraprostatic incision only if both tumor and benign glands are transected in the same area and are present at the inked margin. **Intraprostatic incision is associated with an increased risk of postoperative progression equivalent to that associated with focal extraprostatic extension and a positive margin** (Chuang et al, 2007). Preliminary studies have not shown a difference in sites of positive margins between open surgery and robotic radical prostatectomy, with the apex being the most commonly affected region (Smith et al, 2007). **In a multivariate analysis, Gleason grade, extraprostatic extension, and margins of resection are strong independent predictors of progression (i.e., elevated postoperative serum PSA level).** A more refined prognostication is not needed for men with Gleason scores of 2 to 4, because these men are almost all invariably cured by surgery. Men with Gleason scores of 8 to 10 have a poor prognosis after prostatectomy, with nodal metastases as the major prognostic determinant. Of cases with negative seminal vesicles and lymph nodes, Gleason scores of 5 to 7 account for 88% of tumors removed by radical prostatectomy and have a prognosis that can be stratified by various clinical and pathologic parameters (Epstein, in press; Epstein et al, 1993b; Diblasio and Kattan, 2003; Stephenson et al, 2005).

Tumor volume correlates well with pathologic stage and Gleason grade in clinical stage T2 cancers (McNeal et al, 1990). **However, most studies have found that tumor volume does not independently predict postradical prostatectomy progression once grade, pathologic stage, and margins are taken into account** (Epstein et al, 1993a; Kikuchi et al, 2004). Consequently, it is not currently recommended that tumor volume be calculated for clinical purposes in radical prostatectomy specimens. Rather, there should be some overall subjective indication of tumor volume to identify those cases with a minute amount of tumor and an excellent prognosis versus those cases with extensive tumor and a worse prognosis.

The evaluation of ploidy on radical prostatectomy specimens is controversial (Shankey et al, 1993; Adolfsson, 1994). The strongest data to support the prognostic importance of ploidy are in patients undergoing radical prostatectomy with pelvic node metastases (Boorjian et al, 2007). This author does not recommend that ploidy be routinely evaluated on radical prostatectomy specimens.

Adenocarcinoma with Treatment Effect

The major effect of combination endocrine therapy on benign prostate tissue is the presence of atrophic changes with immature squamous metaplasia (Vailancourt et al, 1996). This therapy may result in three different histologic patterns in prostate cancer: (1) atrophic prostate cancer, (2) cells with pyknotic nuclei with abundant xanthomatous cytoplasm resembling histiocytes, and (3) individual tumor cells resembling lymphocytes (Vailancourt et al, 1996). One of the problems with evaluating carcinomas that have been treated with hormone therapy is that the grade often appears artifactually higher (Smith and Murphy, 1994). **Pathologists should not assign a Gleason score to carcinomas with treatment effect.** However, if other areas of the tumor do not show a pronounced hormone effect, these areas can be Gleason graded. It has been demonstrated that finasteride does not alter the histology of either benign or malignant tissue (Yang et al, 1999; Rubin et al, 2005).

Radiation-related changes in the prostate are usually seen in patients who have been irradiated for adenocarcinoma of the prostate. When carcinoma is present in a biopsy specimen obtained 12 to 18 months after radiotherapy, it is a powerful predictor of either local or distant postirradiation failure (Scardino et al, 1986). Some studies have demonstrated that the morphologic appearance of the cancer (whether or not the cancer appears altered by the radiation) correlates with prognosis (Crook et al, 1997). Radiation alters the histologic features of benign prostate tissue so that it may mimic prostate cancer (Bostwick et al, 1982). Radiation atypia in benign prostate glands may persist for a long time (up to 72 months) after the initial treatment, resulting in a significant pitfall in evaluating prostate biopsy specimens (Magi-Galluzzi et al, 2003). If clinicians are aware of such treatment, this information should be provided to the pathologist.

SUBTYPES OF PROSTATE ADENOCARCINOMA

Mucinous adenocarcinoma of the prostate gland is one of the least common morphologic variants of prostatic carcinoma (Epstein and Lieberman, 1985; Ro et al, 1990). They behave like nonmucinous prostate carcinomas, having a propensity to develop bone metastases with advanced disease. **Mucinous adenocarcinoma of the prostate treated by radical prostatectomy is not more aggressive than nonmucinous prostate cancer** (Osunkoya et al, 2008). Even in ordinary adenocarcinomas of the prostate without light microscopic evidence of neuroendocrine differentiation, almost half show neuroendocrine differentiation on evaluation with immunohistochemistry for multiple neuroendocrine markers (di Sant'Agnese, 1992). Most studies do not demonstrate a convincing relation between the extent of neuroendocrine differentiation in ordinary prostate cancer and prognosis. Small cell carcinomas of the prostate are identical to small cell

carcinomas of the lung (Tetu et al, 1987, 1989). In approximately 50% of the cases, the tumors are mixed small cell carcinoma and adenocarcinoma of the prostate. Although most small cell tumors of the prostate lack clinically evident hormone production, they account for the majority of prostatic tumors with clinically evident adrenocorticotropic hormone or antidiuretic hormone production. **The average survival of patients with small cell carcinoma of the prostate is less than a year.** There is no difference in prognosis between patients with pure small cell carcinoma and those with mixed glandular and small cell carcinomas. Small cell carcinomas are not assigned a Gleason grade.

Between 0.4% and 0.8% of prostatic adenocarcinomas arise from prostatic ducts (Epstein and Woodruff, 1986; Christensen et al, 1991). When prostatic duct adenocarcinomas arise in the large primary periurethral prostatic ducts, they may grow as an exophytic lesion into the urethra, most commonly in and around the verumontanum, and give rise to either obstructive symptoms or hematuria. Tumors arising in the more peripheral prostatic ducts may present like ordinary (acinar) adenocarcinoma of the prostate and may be diagnosed on needle biopsy (Brinker et al, 1999). Tumors are often underestimated clinically because rectal examination findings and serum PSA levels may be normal. **Most prostatic duct adenocarcinomas are advanced stage at presentation and have an aggressive course; they should be regarded as Gleason score 4 + 4 = 8, because of their shared cribriform morphologic features with acinar adenocarcinoma Gleason score 8 and similar prognosis** (Brinker et al, 1999). **Pure primary squamous carcinoma of the prostate is rare and is associated with poor survival** (Parwani et al, 2004). These tumors develop osteolytic metastases, do not respond to estrogen therapy, and do not develop elevated serum acid phosphatase levels with metastatic disease. More commonly, squamous differentiation occurs in the primary and metastatic deposits of adenocarcinomas that have been treated with estrogen therapy. Sarcomatoid carcinomas (carcinosarcomas) have also been reported within the prostate and have a dismal prognosis (Lauwers et al, 1993).

Mesenchymal Tumors

Sarcomas of the prostate account for 0.1% to 0.2% of all malignant prostatic tumors (Sexton et al, 2001). Rhabdomyosarcomas are the most frequent mesenchymal tumor within the prostate and are seen almost exclusively in childhood. Leiomyosarcomas are the most common sarcomas involving the prostate in adults (Cheville et al, 1995). A spindle cell lesion that can occur at any age can closely simulate a leiomyosarcoma. Inflammatory myofibroblastic tumors may occur soon after TUR or without a history of TUR (Montgomery et al, 2006). There are also mesenchymal tumors of the prostate arising from the unique prostatic specialized stroma. These lesions range from prostatic stromal tumors of uncertain malignant potential to prostatic sarcomas. On histologic examination, these lesions are variable; one subtype resembles a tumor seen in the breast and is termed *phyllodes tumor of the prostate* (Herawi and Epstein, 2006).

Urothelial Carcinoma

Primary urothelial carcinoma of the prostate without bladder involvement accounts for 1% to 4% of all prostate carcinomas (Sawczuk et al, 1985). Primary urothelial carcinomas of the prostate show a propensity to infiltrate the bladder neck and the surrounding soft tissue such that more than 50% of the patients present with stage T3 or T4 tumors (Greene et al, 1976). Twenty percent of the patients present with distant metastases, with bone (predominantly osteolytic), lung, and liver being the most common sites. Treatment of stage T3 disease with radiation results in a 5-year survival of approximately 34%. In the minority of cases with tumor localized to the prostate (T2), radical surgery has resulted in long-term disease-free survival in several patients.

More commonly, urothelial carcinoma involves prostatic ducts and acini in patients with a history of carcinoma in situ (CIS) of the bladder who have been treated for a period of months to years with intravesical topical chemotherapy (Schellhammer et al, 1977; Mahadevia et al, 1986; Wood et al, 1989; Njinou Ngninkeu et al, 2003). Between 35% and 45% of cystoprostatectomies performed for urothelial carcinoma contain prostatic involvement. However, this number is dependent on the amount of histologic sampling of the prostate tissue and may be much higher in completely mapped specimens. If cystoprostatectomy is performed and only intraductal urothelial carcinoma is present, the prostatic involvement does not worsen the prognosis, which is determined by the stage of the bladder tumor (Esrig et al, 1996). Intraductal urothelial carcinoma of the prostate appears to involve the prostate by direct extension from the overlying urethra, which is usually involved by CIS. Intraductal and infiltrating urothelial carcinoma involving the prostate tends to be seen in higher-stage bladder tumors, in which the patients have a poor prognosis attributable to either advanced bladder or prostatic disease. A minority of these cases will have low-stage bladder tumor and a poorer prognosis,

Key Points

- Low-grade PIN should not be commented on in diagnostic reports, because the diagnosis is not reproducible among pathologists and lacks clinical significance.
- For patients diagnosed with isolated high-grade PIN on extended initial core sampling, repeat biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer, because the risk of cancer on rebiopsy is similar to the risk associated with repeat biopsy after a benign diagnosis. Further studies are needed to determine whether biopsy should be routinely repeated several years after a high-grade PIN diagnosis, and, if so, how often and when.
- Regardless of the serum PSA level, all patients with an initial atypical diagnosis on needle biopsy should undergo repeat biopsy; the risk of cancer is approximately 40%, and clinical findings are not helpful in predicting who is more likely to have cancer.
- Cases diagnosed as atypical have the highest likelihood of being changed on expert review. Urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy.
- Tumor volume measured in the radical prostatectomy specimen does not independently predict postsurgical progression once grade, pathologic stage, and margins are taken into account and should not be required for routine pathologic analysis.
- Gleason grade, whether it is assessed on needle biopsy, transurethral resection, or radical prostatectomy specimens, remains one of the most influential prognostic factors.

demonstrating the adverse effect of prostatic stromal infiltration (Esrig et al, 1996). **Extensive sampling of the periurethral area in cystoprostatectomy specimens performed for urothelial carcinoma is necessary to identify and to evaluate the prostate for urothelial carcinoma.**

Finally, one may find direct invasion from bladder urothelial carcinoma into the stroma of the prostate. The distinction between poorly differentiated urothelial carcinoma and poorly differentiated adenocarcinoma of the prostate can be difficult. Approximately 95% of poorly differentiated prostatic adenocarcinomas show PSA staining, although it may be focal (Chuang et al, 2007). In some cases of poorly differentiated prostatic adenocarcinomas, there may be weak or negative PSA staining where the tumor reacts to a greater degree with newer prostate specific markers, including prostate specific membrane antigen (PSMA), p501S (Prostein), and NKX 3.1 (Chuang et al, 2007). However, the lack of immunoreactivity to prostate specific markers in a poorly differentiated tumor within the prostate, especially if present in limited amount, does not exclude the diagnosis of a poorly differentiated prostatic adenocarcinoma. Although CK7 and CK20 are more frequently seen in urothelial carcinoma as compared to adenocarcinoma of the prostate, they may also be positive in adenocarcinoma of the prostate. Markers that label urothelial carcinoma and not prostate carcinoma include uroplakin and thrombomodulin (49% to 69% sensitivity) and TP63 and high molecular weight cytokeratin (83% to 90% sensitivity) (Chuang et al, 2007).

Miscellaneous Malignant Tumors

Primary prostatic lymphoma without lymph node involvement appears to be much less common than secondary infiltration of the prostate (Bostwick and Mann, 1985). The most common form of leukemic involvement of the prostate is that of chronic lymphocytic leukemia, although monocytic, granulocytic, and lymphoblastic leukemias have also been found in the prostate (Dajani and Burke, 1976).

Deaths due to prostate cancer in the United States were estimated to be almost 29,000 in 2008, representing a 25% decrease in the mortality rate compared with a decade ago (Jemal et al, 2008). Although the reasons for this improvement are often debated, early prostate cancer detection programs have likely played a role. Early detection has benefited greatly from prostate-specific antigen (PSA) screening efforts, the introduction and refinement of systematic transrectal ultrasonography (TRUS)–guided prostate biopsy techniques, and increased public awareness about prostate cancer.

TRUS of the prostate, first described by Watanabe and colleagues (1968), **expanded to routine clinical use with improvements in ultrasound technology and the introduction of the TRUS-guided systematic sextant biopsy protocol by Hodge and associates** (Hodge et al, 1989a, 1989b). Concurrent with improved biopsy techniques, the use of PSA screening increased the number of men undergoing early prostate cancer screening and prostate biopsy, with estimates as high as 800,000 biopsies annually in the United States alone (Halpern and Strup, 2000). Given the prevalence of prostate cancer and the frequency with which TRUS-guided prostate biopsies are performed, significant efforts have been focused on determining the appropriate indications for biopsy and the ideal technique by which to image and biopsy the prostate.

TRUS technology has become a mainstay of many image-guided prostate interventions, including prostate biopsy, brachytherapy, cryotherapy, and high-intensity focused ultrasonography (HIFU), as well as being used in the evaluation of appropriate patients for treatment of benign prostatic hyperplasia (BPH) (Beerlage, 2003). Fiducial gold seeds are being placed under ultrasound guidance to verify and correct the position of the prostate during megavoltage irradiation (Linden et al, 2009). In this chapter our focus is primarily on the use of TRUS and biopsy techniques for the diagnosis of prostate cancer.

ULTRASONOGRAPHIC ANATOMY OF THE PROSTATE

The prostate lies between the bladder neck and the urogenital diaphragm, just anterior to the rectum, an ideal position to be imaged by TRUS. The prostate gland is traditionally described based on a pathologic zonal architecture. These divisions consist of the anterior fibromuscular stroma (AFS) that is devoid of glandular tissue, transition zone (TZ), central zone (CZ), periurethral zone, and peripheral zone (PZ). Unfortunately, these regions are not visible sonographically as distinct entities (Fig. 97–1).

However, the TZ may often be discernible from the PZ and CZ, particularly in glands with significant BPH. Located posteriorly, the normal CZ and PZ, from which a majority of adenocarcinomas arise, have a homogeneous echogenic appearance, whereas the anteriorly situated TZ is more heterogeneous. **Frequently, calcifications along the surgical capsule known as "corpora amylacea" highlight the plane between the PZ and TZ** (Halpern, 2002). **Small, multiple diffuse calcifications are a normal, often incidental ultrasonographic finding in the prostate and represent a result of age rather than a pathologic entity.** Larger prostatic calculi associated with symptoms may be related to underlying inflammation and require further evaluation and, possibly, treatment (Geramoutsos et al, 2004).

The prostatic urethra traverses the length of the gland in the midline and thus must be imaged in the sagittal plane to be simultaneously viewed along its entire course (Fig. 97–2A and B). The distended urethral lumen has a hypoechoic appearance, whereas periurethral calcifications may produce a thin echogenic outline. The smooth muscle of the internal sphincter extends from the bladder neck, encircling the urethra to the level of the verumontanum. These muscle fibers may be visualized sonographically as a hypoechoic ring around the upper prostatic urethra, giving it a funneled appearance proximally as it arises from the bladder neck. On reaching the verumontanum the urethra angles anteriorly and runs through the remainder of the gland to exit at the apex of the prostate. This angle gives the prostatic urethra an anteriorly concave appearance when viewed along its entire course in the sagittal plane.

The paired seminal vesicles (SVs) are positioned posteriorly at the base of the prostate (Fig. 97–2C). **They have a smooth, saccular appearance and should be symmetrical. The normal SV measures 4.5 to 5.5 cm in length and 2 cm in width.** A cystic SV mass is presumptively benign, whereas a solid lesion has a small probability of being malignant, especially if the patient

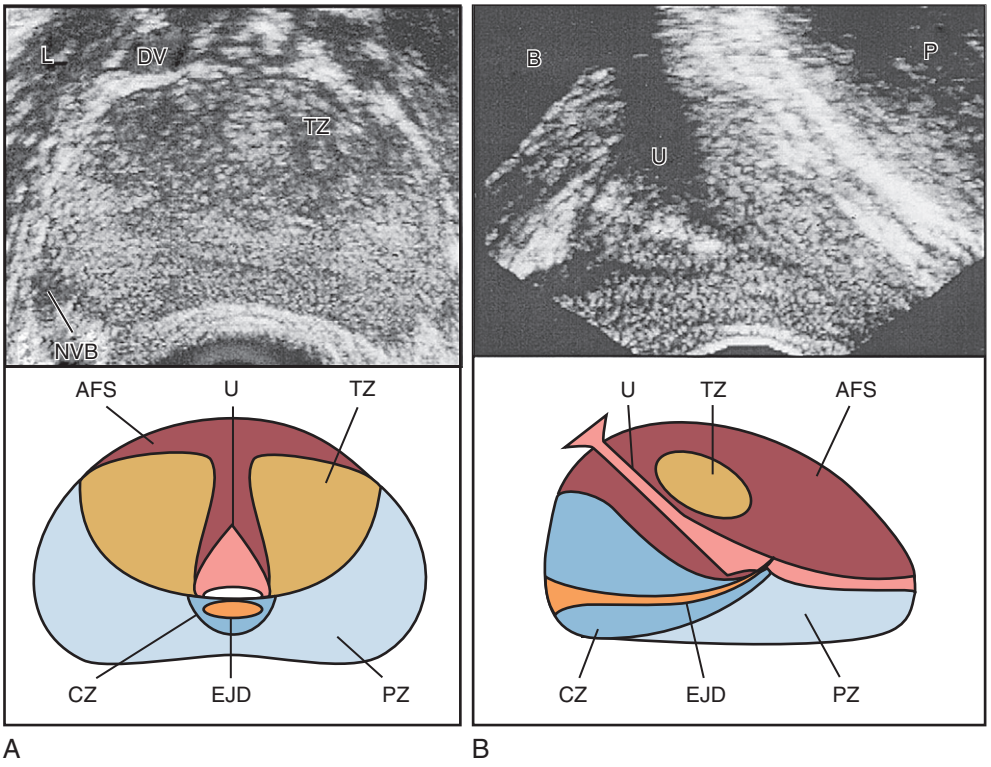

Figure 97–1. Normal prostate ultrasound images *(top)* with diagrams *(bottom)* at approximately the level of the verumontanum demonstrating zonal anatomy. **A,** Transverse view. **B,** Sagittal view. AFS, anterior fibromuscular stroma; CZ, central zone; DV, dorsal vein complex; EJD, ejaculatory ducts; NVB, neurovascular bundle; L, levator muscles; PZ, peripheral zone; TZ, transition zone; U, urethra.

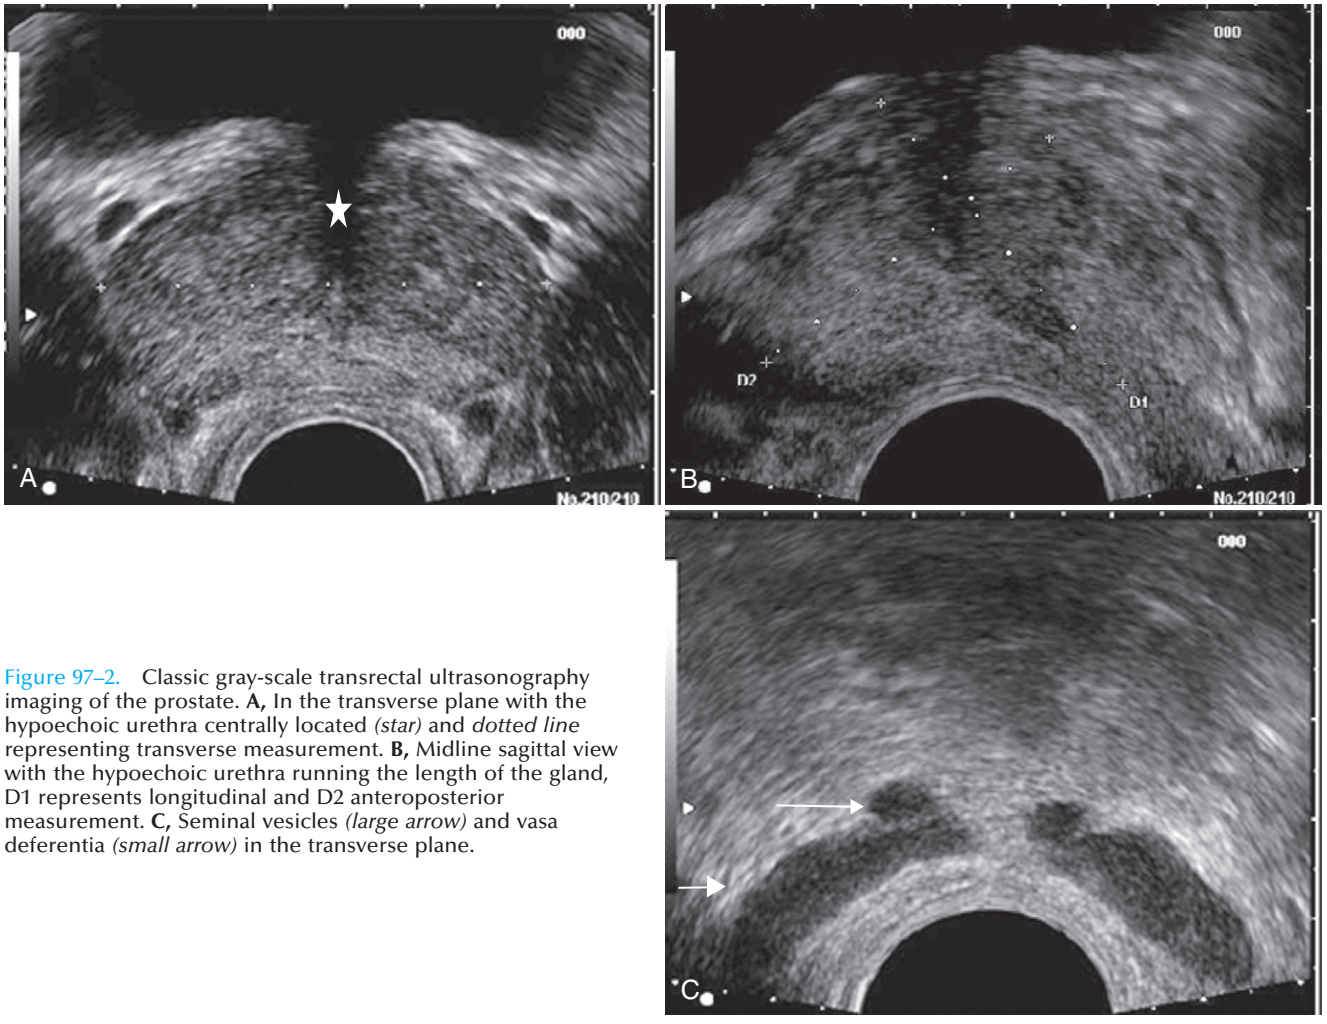

Figure 97–2. Classic gray-scale transrectal ultrasonography imaging of the prostate. **A,** In the transverse plane with the hypoechoic urethra centrally located *(star)* and *dotted line* representing transverse measurement. **B,** Midline sagittal view with the hypoechoic urethra running the length of the gland, D1 represents longitudinal and D2 anteroposterior measurement. **C,** Seminal vesicles *(large arrow)* and vasa deferentia *(small arrow)* in the transverse plane.

has a primary neoplasm elsewhere. Schistosomiasis should be considered when making a differential diagnosis in patients who live in areas where infestation is endemic with a solid SV mass (Al-Saeed et al, 2003). In the transverse plane, the vasa deferentia course just above their ipsilateral SV before diving caudally toward the prostate near the midline. Here they lie just medial to the tapering ipsilateral SV before the two structures fuse to form an ejaculatory duct. The ejaculatory ducts (occasionally seen as a hypoechoic structure) enter the gland posteriorly and empty into the urethra at the verumontanum (see Fig. 97–2C). Their course parallels that of the prostatic urethra distal to the verumontanum.

GRAY-SCALE TRANSRECTAL ULTRASONOGRAPHY (TRUS)

Gray-scale TRUS has become the most common imaging modality for the prostate. Most commonly used for prostate cancer detection, TRUS may also be used in the evaluation of other conditions such as infertility (see Chapter 21). Although the role of TRUS is expanding in directing the biopsy of prostate cancer, the role of staging localized prostate cancer using TRUS is very limited (Onur et al, 2004).

Commercially available endorectal probes are available in both side- and end-fire models and transmit frequencies of 6 to 10 MHz. Most modern ultrasound machines have optimized self-programming for TRUS and biopsy. Some newer biplane probes provide simultaneous sagittal and transverse imaging modes. Probes provide a scanning angle approaching 180 degrees to allow simultaneous visualization of the entire gland in both the transverse and sagittal planes. Increasing frequency yields increased resolution. As the frequency of the probe is increased, the portion of the image that is in focus (*focal range*) is closer to the transducer (Kossoff, 2000). The commonly used 7-MHz transducer produces a high-resolution image with a focal range from 1 to 4 cm from the transducer (best for PZ where most cancers arise). Lower-frequency transducers (e.g., older 4-MHz transducers) have a focal range from 2 to 8 cm but at lower resolution. Lower-frequency transducers improve anterior delineation of large glands, increasing the accuracy of volume measurements, but provide poor internal architecture visualization. **Acoustic properties of soft tissue are similar to those of water, but clinically useful ultrasound energy does not propagate through air. For this reason, a water-density substance, termed a *coupling medium*, is used.** The coupling medium, usually sonographic jelly or lubricant, is placed between the probe and the rectal surface. If the probe is covered with a protective condom, the coupling medium is placed between the probe and the condom, as well as between the condom and the rectal surface.

Techniques

The complete TRUS evaluation of the prostate includes scanning in both the sagittal and transverse planes to obtain a volume calculation. The CZ and PZ are inspected for hypoechoic lesions and contour abnormalities, and the SVs and vasa deferentia are fully visualized.

Machine Settings

The image magnification is adjusted so that most of the prostate is visible without the image being too small to allow detection of abnormalities. In general, the magnification is low during prostate measurements so that the entire gland is seen. During biopsies, magnification is maximal for visualization of needle passage. The ultrasonographer can manually alter the brightness (or gain) slightly with each new patient, and occasionally during imaging of different areas within the same prostate. **The optimal brightness setting results in a medium-gray image of the normal PZ. This gray tone serves as the reference point for judging lesions as hypoechoic (darker than the normal PZ), isoechoic (similar to the normal PZ), hyperechoic (lighter than the normal PZ), or anechoic (completely black).**

Probe Manipulation

Patients are typically scanned in the left lateral decubitus position (see Patient Positioning later). **TRUS should be performed in both the transverse and the sagittal planes.** There are two approaches to probe manipulation for transverse imaging (see Fig. 97–2A). With radial and some biplane probes, advancing the probe cephalad into the rectum images the prostate base, the SVs, and the bladder neck. Pulling the probe caudally toward the anal sphincter images the prostatic apex and proximal urethra. Transverse imaging with end-fire, side-fire, and some biplane probes is accomplished by angling the handle of the probe right or left using the anal sphincter as a fulcrum (see Fig. 97–2B). Angling the probe toward the scrotum produces more cephalad images, and angling the probe toward the sacrum produces more caudal images. There are also two approaches to probe manipulation for sagittal imaging. One method is rotation of the probe. Clockwise rotation yields images of the left side of the prostate, and counterclockwise rotation yields images of the right side. Alternatively, sagittal imaging can be accomplished by angling the probe up or down using the anal sphincter as a fulcrum. In the left lateral decubitus position, angling the handle of the probe down (toward the floor) images the right side of the prostate, and angling the handle of the probe up (toward the ceiling) images the left side. Urologists often prefer angling the probe because this method is similar to manipulation of a cystoscope and is less uncomfortable for the patient.

Volume Calculations

Prostate volume can be calculated through a variety of formulas. Volume calculation requires measurement of up to three prostate dimensions. In the axial plane, the transverse and anteroposterior (AP) dimensions are measured at the point of widest transverse diameter (see Fig. 97–2A and B). The longitudinal dimension is measured in the sagittal plane just off the midline, because the bladder neck may obscure the cephalad extent of the gland (see Fig. 97–2B). Most formulas assume that the gland conforms to an ideal geometric shape: either an ellipse ($\pi/6 \times$ transverse diameter $\times$ AP diameter $\times$ longitudinal diameter), sphere ($\pi/6 \times$ transverse diameter^3), or a prolate (egg-shaped) spheroid ($\pi/6 \times$ transverse diameter$^2 \times$ AP diameter). Despite the inherent inaccuracies that arise from these geometric assumptions, all formulas reliably estimate gland volume and weight, with correlation coefficients greater than 0.90 with radical prostatectomy specimen weights, because 1 cm^3 equals approximately 1 g of prostate tissue (Terris and Stamey, 1991). **The mature average prostate is between 20 and 25 g and remains relatively constant until about age 50, when the gland enlarges in many men** (Griffiths, 1996).

When a more accurate determination of gland volume is required, such as during brachytherapy, planimetry may be employed. With the patient in the lithotomy position, the probe is mounted to a stepping device, and serial transverse images are obtained at set intervals (e.g., 3 to 5 mm) through the entire length of the gland. The surface area of each serial image is determined, and the sum of these measurements is then multiplied by total gland length to yield the prostate volume.

Once gland volume has been obtained, one can calculate derivatives such as the PSA density (PSAD = serum PSA/gland volume). An elevated PSAD of the entire gland has been shown to have a sensitivity and specificity of 75% and 44%, respectively, for predicting a positive cancer diagnosis on repeat biopsy (Djavan et al, 2000). Unfortunately, there is high interoperator and intraoperator variability in PSAD determinations, and similar predictive information can now be obtained using serum free:total PSA (Djavan et al, 2003).

Cystic Lesions of the Prostate

Cystic prostatic structures are common on TRUS. Simple cysts have the same sonographic appearance as in any other part of the body: They are thin walled, anechoic, and show acoustic enhancement posterior to the cyst. Prostatic cysts may be congenital or acquired but are rarely clinically significant regardless of etiology.

Congenital prostatic cystic lesions may arise from either müllerian (müllerian duct cysts and prostatic utricles) or wolffian (ejaculatory duct and seminal vesicle cysts) structures. An enlarged prostatic utricle represents a diverticular projection from the posterior urethra at the level of the verumontanum (Cochlin, 2002) and appears as a midline anechoic structure. These are associated with genital anomalies, including hypospadias (most common), ambiguous genitalia, undescended testes, and congenital urethral polyps (Gregg and Sty, 1989). Müllerian duct cysts also appear as midline anechoic lesions that result from failure of the müllerian ducts to fuse with the urethra. They are generally ovoid to pear shaped with the cyst neck oriented toward the verumontanum. When müllerian duct cysts are present, men should be evaluated for unilateral renal agenesis (McDermott et al, 1993).

Lateral paraprostatic cystic structures include seminal vesicle and vas deferens cysts (wolffian in origin). Ejaculatory duct cysts are typically small, lie off of the midline, and may accompany ejaculatory duct obstruction/obliteration with azoospermia (Fig. 97–3A and B). Seminal vesicle cysts can be caused by congenital or acquired obstruction of the ejaculatory duct and are associated with cystic renal disease; up to two thirds of men with seminal vesicle cysts may also have renal agenesis (King et al, 1991). Acquired cysts of the TZ result from hemorrhagic degeneration of BPH nodules (Hamper et al, 1990), whereas those of the outer gland have no proven etiology.

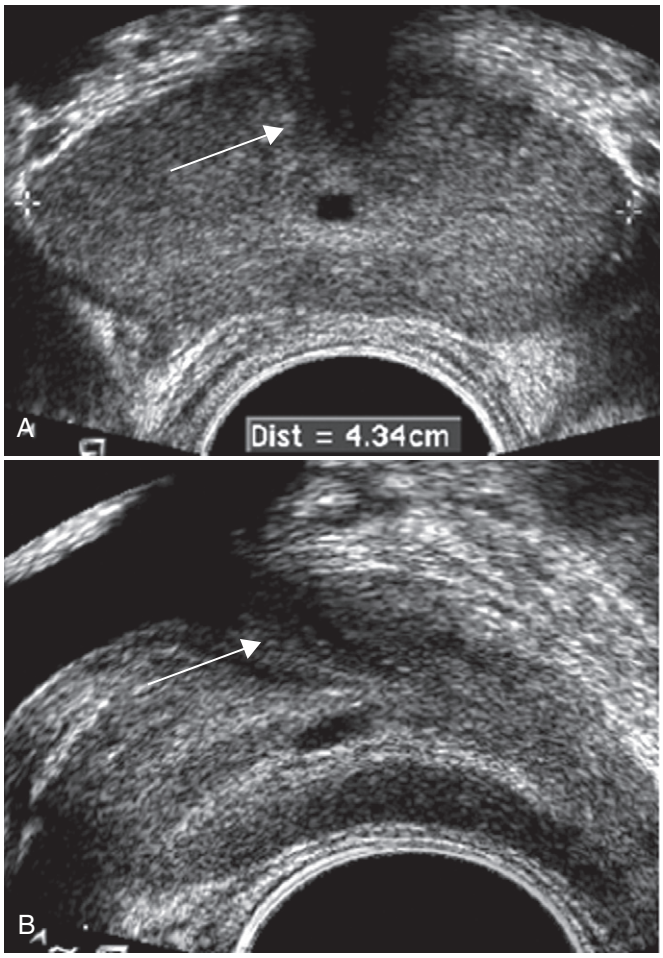

Figure 97–3. A hypoechoic midline cystic structure *(arrow)* arising from the ejaculatory duct is shown in the transverse **(A)** and sagittal **(B)** planes and demonstrates through-transmission classic for simple cysts.

Prostate Cancer Imaging on TRUS

All hypoechoic lesions within the PZ should be noted and included in the biopsy material (Fig. 97–4). The lack of a distinct hypoechoic focus does not preclude proceeding with biopsy, because 39% of all cancers are isoechoic and up to 1% of tumors may be hyperechoic on conventional gray-scale TRUS (Shinohara et al, 1989). Despite the higher prevalence of cancers discovered in prostates with hypoechoic areas, the hypoechoic lesion itself was not associated with increased cancer prevalence compared with biopsy cores

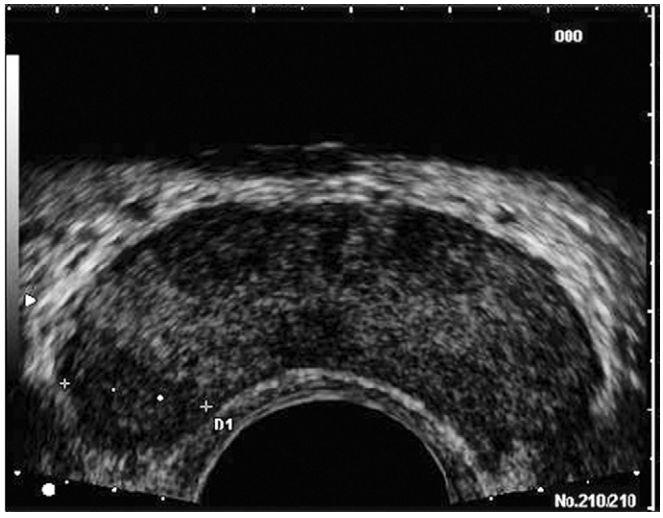

Figure 97–4. Classic hypoechoic peripheral zone (PZ) lesion *(dotted line)* in the right midgland that transrectal ultrasonography–guided biopsy proved to be a Gleason 3 + 3 = 6 adenocarcinoma.

from isoechoic areas in a contemporary series of almost 4000 patients (Onur et al, 2004). Furthermore, other disease processes, such as granulomatous prostatitis (Terris et al, 1997a), prostatic infarct (Purohit et al, 2003), and lymphoma (Varghese and Grossfeld, 2000), may all produce hypoechoic lesions. TZ BPH nodules are typically hypoechoic but may contain isoechoic or even hyperechoic foci. A hypoechoic lesion is malignant in 17% to 57% of cases (Frauscher et al, 2002), highlighting the need to biopsy these lesions but recognizing they are not pathognomonic for cancer as once thought.

Any focal contour abnormalities along the outer edge of the gland and any asymmetries in echotexture from the PZ of one lobe to that of the other are noted. **Extracapsular extension of prostate cancer, although not well visualized if present as a microfocus, is suggested by a focal loss of the typically bright white periprostatic fat.**

TRUS Appearance after Treatment

External-beam radiation therapy typically decreases volume by 6 months after treatment. Irradiated prostates are diffusely hypoechoic, with poorly defined anatomy. Large hypoechoic tumors, particularly those not responding to therapy, show little change in echogenicity once irradiated, but smaller foci responding well to therapy tend to become isoechoic (Egawa et al, 1991). In general, TRUS findings correlate poorly with pathologic findings and outcomes in irradiated prostates.

With interstitial brachytherapy, there is initial postimplantation edema followed by long-term changes as with external-beam radiation therapy (Whittington et al, 1999). With an ideal permanent implant, seeds should be distributed evenly throughout the gland. These seeds are hyperechoic and demonstrate posterior shadowing. The prostate volume declines significantly after treatment, with a 37% size reduction at 1 year after treatment and over 50% reduction 8 years after implantation (Stone and Stock, 2007). This decline is unaffected by neoadjuvant hormonal therapy.

Androgen ablation with luteinizing hormone–releasing hormone (LHRH) analogs will cause an average 30% volume decrease with androgen deprivation in prostates with and without cancer (Whittington et al, 1999). The decrease ranges up to 60% in large glands and as little as 10% in small glands. Volume decreases by approximately 21% at 6 months using agents such as finasteride (Marks et al, 1997).

Postradical prostatectomy TRUS is considered normal if there is smooth tapering of the bladder neck to the urethra (Kapoor et al, 1993). Many patients demonstrate a nodule of tissue anterior to the anastomosis, representing the ligated dorsal vein complex (Goldenberg et al, 1992). Any other hyperechoic or hypoechoic lesions or interruptions of the retroanastomotic fat plane are considered suspicious (Kapoor et al, 1993). Hypoechoic lesions have been reported in 75% to 95% of patients with locally recurrent cancer, and color Doppler has been used to improve cancer detection in the prostatic fossa (Sudakoff et al, 1996; Tamsel et al, 2006). Patients with detectable PSA who are candidates for salvage radiation therapy were once considered for routine biopsy of the anastomotic area. **Biopsy of the anastomotic region with PSA recurrence in the absence of a palpable nodule is not usually informative** (Scattoni et al, 2004). However, biopsy of an abnormality seen on TRUS, even with a normal digital rectal exam (DRE), can be diagnostic of locally recurrent disease (Naya et al, 2005).

TRUS and Other Malignancies

Prostatic involvement with transitional cell carcinoma (TCC) from the bladder is generally not detectable by TRUS, but 71% of prostatic stromal TCC lesions are hypoechoic. Prostatic TCC detected by TRUS must be confirmed by biopsy, because granulomas resulting from instillation of bacille Calmette-Guérin are common in TCC patients and are also hypoechoic (Terris et al, 1997a).

Extension to the prostate from the bladder, or urethral squamous cell carcinoma (SCC), is much more common than is primary prostatic SCC. Prostatic SCC appears as an irregular, anterior mass demonstrating relative hyperechogenicity (Terris, 1999).

Adenoid cystic/basal cell carcinoma of the prostate is rare but potentially fatal. Histologically, cribriform or adenoid cystic patterns predominate. Numerous cystic glands give this tumor an unusual appearance on TRUS, characterized by multiple, evenly distributed, small, anechoic cysts (Iczkowski et al, 2003).

Prostatic sarcoma is a rare complication of prostatic irradiation, and the TRUS appearance is typified by an irregular, hypoechoic mass with an anechoic area consistent with necrosis (Terris, 1998). Unlike radiation-induced sarcoma, the echogenicity of rhabdomyosarcoma is similar to that of normal prostate tissue.

Hematologic and lymphoid malignancies involving the prostate are generally not visualized with TRUS (Terris and Freiha, 1998). Biopsies may demonstrate a lymphocytic infiltrate, but this is often attributed to chronic inflammation if no suspicion of nonprostate malignancy exists.

PROSTATE BIOPSY TECHNIQUES AND OUTCOMES

Indications for Prostate Biopsy

Before TRUS improvements and serum PSA testing became widespread, clinicians relied mainly on digital rectal examination to establish a suspicion of prostate cancer and performed digitally

Key Points: Gray-Scale Transrectal Ultrasonography (TRUS)

- TRUS technology has become a mainstay of many image-guided prostate interventions, including prostate biopsy, brachytherapy, cryotherapy, and high-intensity focused ultrasonography (HIFU).
- The classic zonal anatomy of the prostate is not evident on TRUS, but the peripheral zone (PZ) may typically be distinguished from the transition zone (TZ), allowing biopsies to be reliably aimed toward the more commonly cancer-bearing PZ.
- Typically, benign cystic lesions of the prostate demonstrate thin-walled architecture with sonographic through-transmission and may become symptomatic if infected.
- Several formulas exist for determining prostate volume on TRUS. For highly accurate volume determinations, such as for brachytherapy, planimetry is required.
- Hypoechoic foci seen on gray-scale TRUS should be considered suggestive of adenocarcinoma of the prostate and included in the biopsy specimen. However, up to 39% of cancers are not visible on routine gray-scale ultrasound imaging.

directed lesional biopsies. **Today, PSA-based screening of asymptomatic men has resulted in the adaptation of TRUS biopsy as the standard of care for routine prostate biopsy.** The presence of focal nodules on digital rectal examination still will prompt a biopsy using the TRUS technique regardless of PSA levels. **TRUS-directed prostate needle biopsy remains the gold standard for diagnosis of prostate cancer.**

Early prostate cancer detection has been markedly improved by PSA-based screening programs. These initiatives have been shown to significantly increase the rate of organ-confined and potentially curable disease (Catalona et al, 1993). **Currently, most clinicians recommend biopsy once a patient's serum PSA rises above 4.0 ng/mL, although significant research efforts are ongoing to identify the optimal PSA threshold to recommend prostate biopsy in the asymptomatic patient.** Evidence for lowering the PSA threshold from work by Catalona's group showed higher rates of organ-confined disease at the time of radical retropubic prostatectomy in samples from PSAs in the 2.6- to 4.0-ng/mL range (Krumholtz et al, 2002). **These findings have led many urologists to now recommend prostate biopsy to men younger than 60 years of age once their PSA level rises above 2.5 ng/mL.** Despite this downward shift in the PSA cutoff for younger men, there remains a general trend toward allowing older men (70 years or older) to have slightly higher "normal" PSAs, in the range of 5.5 to 6.5 ng/mL, although this is not universally accepted (American Urological Association, 2000; Scardino, 2005). **Subsequent data from the Prostate Cancer Prevention Trial have shown that there is no safe PSA threshold that can rule out prostate cancer in any age range** (Thompson et al, 2005). When examining men whose serum PSA was less than or equal to 4.0, significant numbers of men were diagnosed with prostate cancer at all PSA levels, with an overall prostate cancer detection rate of 15% for all men with a value less than 4.0, and nearly 15% having a Gleason score of 7 or greater (Thompson et al, 2004).

Adjuncts to serum PSA testing have been advocated to improve the performance characteristics of PSA for prostate cancer detection, including measuring the free:total PSA, PSA velocity, PSA density (PSAD), and PSAD of the transition zone (PSAD-TZ) (Djavan et al, 2002). For patients with a serum PSA value between 4.0 and 10.0 ng/mL, using a percentage of free PSA threshold of less than 25% allowed detection of 95% of cancers while eliminating 20% unnecessary biopsies, and within this group the risk of prostate cancer increased dramatically as the percentage of free PSA level declined (Catalona et al, 1998).

Regardless of initial PSA value, a PSA velocity greater than 0.75 ng/mL/year is frequently associated with prostate cancer and warrants biopsy (Carter et al, 1992). Lower PSA velocity ranges, as low as 0.35 ng/mL/year, may be indicative of occult prostate cancer (Carter et al, 2006). The clinical utility of PSA velocity to detect clinically significant prostate cancer remains controversial, however, with a recent European Organization for Research and Treatment of Cancer (EORTC) study indicating the PSA velocity, on multivariable analysis, was not an independent predictor of detecting prostate cancer or clinically significant prostate cancer on transrectal biopsy (Wolters et al, 2009). An elevated PSAD and PSAD-TZ have both been shown to increase the likelihood of diagnosing prostate cancer on repeat biopsy (Djavan et al, 2000). The indications for TRUS and prostate biopsy are rapidly evolving and being continually refined (Table 97–1). Details concerning screening for prostate cancer and the role of prostate biopsy are discussed in Chapter 99.

Table 97–1.

Commonly Cited Recommendations for Transrectal Ultrasonography (TRUS) and/or Biopsy

TRUS without Biopsy

- Treatment planning volume measurements: brachytherapy, cryotherapy, benign prostatic hyperplasia therapy (e.g., transurethral microwave thermotherapy, radiofrequency ablation)
- Volume measurement during hormonal downsizing for external-beam radiation therapy or brachytherapy
- Placement of fiducial markers for external-beam radiation therapy
- Evaluation of azoospermia: ejaculatory duct cysts, seminal vesicle cysts, etc.
- Therapeutic aspiration or unroofing of prostatic cysts; drainage of prostatic abscess

TRUS-Directed Biopsy

- Diagnosis of suspected symptomatic prostate cancer (i.e., bone metastasis, cord compression)
- Screening for prostate cancer in asymptomatic patient > age 50 with > a 10-year life expectancy (if strong family history or if African-American, consider screening at age 45)
  Prostate nodule or significant prostate asymmetry regardless of PSA level
  PSA > 4.0 ng/dL regardless of age
  In men < age 60 to 65 years, consider biopsy if PSA > 2.5 ng/dL
  If PSA > 0.6 ng/dL at age 40
  Increased PSA velocity (>0.75 ng/dL/year)
  Free PSA in considering initial biopsy with PSA < 10 ng/mL: >25% no biopsy; >10% and <15%, consider biopsy; <10%, biopsy
- Prior to intervention in symptomatic benign prostatic hyperplasia (e.g., surgical therapy or initiation of 5α-reductase inhibitors)
- Prior to cystoprostatectomy or orthotopic urinary diversion
- To diagnose failed radiation therapy before use of second-line therapy
- Follow-up biopsy (3-6 months) after diagnosis of high-grade PIN or ASAP

ASAP, atypical small acinar proliferation; PIN, prostatic intraepithelial neoplasia; PSA, prostate-specific antigen.

Data from American Urological Association (AUA, 2000) and National Comprehensive Cancer Network (Scardino, 2005).

Prostate biopsy may also be indicated on the basis of the pathologic analysis of previous biopsy specimens. In men who have undergone prostate biopsy and are found to have only high-grade prostatic intraepithelial neoplasia (HGPIN) or atypical small acinar proliferation (ASAP), a follow-up biopsy should be performed. HGPIN represents a premalignant lesion and carries a 23% to 35% risk of diagnosing prostate cancer on subsequent biopsy (Davidson et al, 1995; Kronz et al, 2001). The natural history of ASAP is less well defined than that of HGPIN, but, if ASAP is present in the initial biopsy specimen, the risk of diagnosing prostate cancer on subsequent biopsy is significantly increased (Iczkowski et al, 1998; Ouyang et al, 2001). **Thus irrespective of follow-up PSA values, current recommendations are to rebiopsy all patients with either HGPIN or ASAP in their initial biopsy specimen within 3 to 6 months.**

Contraindications to Prostate Biopsy

Significant coagulopathy, painful anorectal conditions, severe immunosuppression, and acute prostatitis are all contraindications to prostate biopsy.

Preparing Patients for Biopsy

Patients should be informed of the risks and benefits of the procedure and provide informed consent. All anticoagulant therapy (warfarin, clopidogrel, aspirin/nonsteroidal anti-inflammatory drugs [NSAIDs], herbal supplements) should be stopped 7 to 10 days before prostate biopsy. For those patients with underlying coagulopathy or who are on warfarin, prostatic biopsy should not be performed until the international normalized ratio has been corrected below 1.5. A small amount of urine in the bladder can facilitate the examination.

Antibiotic Prophylaxis

A wide variety of prophylactic regimens have been studied using both oral and intravenous antibiotics, with widely varying opinions of the use of antibiotics and the choice of agents. **The American Urological Association Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis advocates antibiotic prophylaxis prior to transrectal prostate biopsy** (Wolf et al, 2008). Our current practice is to give patients a dose of an oral fluoroquinolone 30 to 60 minutes before biopsy and continue therapy for 2 to 3 days. By using similar protocols, recent large studies have reported minimal infectious complications, although bacteremia/sepsis still occurs in 0.1% to 0.5% of patients (Djavan et al, 2001b; Raaijmakers et al, 2002). The postbiopsy duration of antibiotics also remains controversial even in those who agree the antibiotics are indicated; single-dose oral fluoroquinolone prophylactic regimens demonstrated equivalent efficacy to 3-day regimens in preventing infections (Kapoor et al, 1998; Sabbagh et al, 2004; Wolf et al, 2008). For those patients at risk of developing endocarditis or infection of prosthetic joints, pacemakers, and automated implanted cardiac defibrillators, prophylaxis should consist of intravenous ampicillin (vancomycin, if penicillin allergic) and gentamicin preoperatively, followed by 2 to 3 days of an oral fluoroquinolone.

Cleansing Enema

We routinely have patients self-administer a cleansing enema at home before biopsy. **This practice decreases the amount of feces in the rectum, thereby producing a superior acoustic window for prostate imaging.** However, many clinicians may elect not to use an enema because this option may allow more spontaneous performance of a prostate biopsy. The enema's effect on reducing infections is debatable, but it seems logical that a cleansing enema and empty rectal vault may reduce bacterial seeding of the prostate.

Analgesia

Comments on periprocedural pain control using topical lidocaine jelly have been published (Issa et al, 2000; Obek et al, 2004); in our experience and in the literature, this provides only suboptimal analgesia. **Data now suggest that infiltration anesthesia around the nerve bundles with local anesthetic may provide excellent pain control, which is increasingly important when using extended biopsy techniques** (Berger et al, 2003; Trucchi et al, 2005). A local prostatic block is achieved using 2% lidocaine, a long spinal needle (7-inch, 22-gauge), and TRUS guidance along the biopsy channel of the transducer. Multiple variations exist for the infiltration of local anesthetic for transrectal biopsy (Nash et al, 1996; Soloway and Obek, 2000). We have found that injecting 5 mL of lidocaine at the level of the seminal vesicles near the bladder base, at the hyperechoic fat pad that demarcates the junction of the seminal vesicles and the prostate bilaterally, produces an excellent block. Other approaches include infiltration of 10 mL starting at the junction of the seminal vesicles and infiltration along the lateral aspect of the prostate from base to apex. **Direct infiltration into the prostate (intraprostatic injection) can augment the anesthetic benefit seen with periprostatic injection** (Lee et al, 2007; Cam et al, 2008). One must be cautious, however, to avoid direct intravascular injection, because of the risk of systemic lidocaine absorption. Local anesthesia for transperineal biopsies should include infiltration of the skin and subcutaneous tissues of the perineum initially. Ultrasound guidance may then be employed to aid infiltration of deeper tissues along the anticipated tracts of the biopsy needle. Postbiopsy analgesic regimens, if used, should avoid aspirin and NSAIDs because of increased risk of bleeding.

Patient Positioning

Patients are usually placed in the left lateral decubitus position with knees and hips flexed 90 degrees. An armboard attached parallel to the table and a pillow between the knees helps maintain this position. The buttocks should be flush with the end of the table to allow manipulation of the probe and biopsy gun without obstruction. If necessary, the right lateral decubitus or lithotomy position can be used. **The lithotomy position is used by some clinicians and is preferred for transperineal biopsies, brachytherapy treatment planning, or placement of fiducial gold markers for external-beam therapy** (Dehnad et al, 2003). Because the distribution of color Doppler flow within the prostate is dependent on patient position, the lithotomy position is preferred when color Doppler imaging is used to identify areas of hyperemia for targeted biopsy of the prostate (Halpern et al, 2002b).

Transrectal Prostate Biopsy Techniques

The prostate volume is assessed, and imaging of the prostate in both the transverse and sagittal planes is begun. The examination usually starts at the base of the gland and extends to the apex. Most modern ultrasound units are automatically set for optimal prostate visualization, and the TRUS gray-scale exam of the prostate is conducted as previously described, noting the location and characteristics of any lesions (i.e., hypoechoic, hyperechoic, calcifications, contour abnormalities, cystic structures).

A spring-driven, 18-gauge, needle core biopsy device or biopsy gun, which can be passed through the needle guide attached to the ultrasound probe, is most often used. Most ultrasound units provide best visualization of the biopsy needle path in the sagittal plane. Images are typically superimposed with a ruled puncture path that corresponds to the needle guide of the TRUS unit. The biopsy gun advances the needle 0.5 cm and samples the subsequent 1.5 cm of tissue with the tip extending 0.5 cm beyond the area sampled (Kaye, 1989). Therefore when sampling the PZ, the needle tip may be placed 0.5 cm posterior to the prostate capsule before firing; advancing the needle to or through the capsule can result in sampling of more anterior tissue, missing the most common location of cancers. Avoiding adjustment of the probe position while the biopsy needle is in contact with the rectal surface and applying pressure with the probe to compress the rectal mucosa before biopsy can help avoid rectal bleeding. Pressing the probe against the rectum also minimizes the discomfort of the biopsy needle traversing the rectal mucosa, similar to pulling the skin tight to minimize the discomfort of phlebotomy.

The biopsy sample is typically placed in 10% formalin or per local protocol. There is currently no uniformly accepted method for submission of the biopsy samples (e.g., all samples submitted individually or multiple samples placed in one container). Some pathologists believe strongly that each site should be specifically identified, because certain locations may be predisposed to cancer "look-alikes" (e.g., Cowper gland at the apex, seminal vesicles at the base) (Levin, 2004). At the very least, samples should be segregated into left- and right-sided containers or processed by local guidelines.

Sextant Biopsy

The original sextant biopsy scheme (one core, bilaterally, from the base, mid, and apex) significantly improved cancer detection for digital-directed biopsy of palpable nodules and ultrasound-guided biopsy of specific hypoechoic lesions (Hodge et al, 1989a, 1989b). Taken in the parasagittal plane, these cores sampled a portion of the PZ but also included a significant amount of tissue from the TZ, with subsequent studies of radical prostatectomy specimens demonstrating that the vast majority of adenocarcinomas arise in the posterolateral PZ (McNeal et al, 1988), thus explaining some of the false-negative results of standard sextant biopsy (Eskew et al, 1997).

Extended Core Biopsy Techniques

Modifications to the standard sextant biopsy scheme have focused on the importance of laterally directed cores (Terris et al, 1992). Numerous studies have shown improved cancer detection rates by incorporating additional laterally directed cores into the standard systematic sextant technique, ultimately taking anywhere from 8 to 13 cores (Eskew et al, 1997; Chang et al, 1998a; Levine et al, 1998; Babaian et al, 2000; Brossner et al, 2000; Presti et al, 2000; Durkan et al, 2002; Fink et al, 2003). Selected extended biopsy series are compared in Table 97–2. In a prospective study of 483 patients, Presti and colleagues (2000) found that adding laterally directed cores from the base and midgland bilaterally improved cancer detection from 80% with standard sextant to 96% with this 10-core scheme (only 4% of cancers were detected on the lesionally directed or TZ biopsy). **At present, 6 cores are considered inadequate for routine prostate biopsy for cancer detection.** Figure 97–5 depicts the originally proposed sextant technique and several common extended core biopsy strategies. TZ and SVs are not routinely sampled, because these regions have been shown to have consistently low yields for cancer detection at initial biopsy (Epstein et al, 1997; Terris et al, 1997b), but TZ and anteriorly directed biopsies may occasionally prove necessary to diagnose prostate cancer in those patients with persistently elevated PSA levels and prior negative biopsies (Mazal et al, 2001). **However, there may be a role for TZ biopsies in men with gland size of more than 50 mL, with an additional yield of 15% cancer detection in these larger prostates** (Chang et al, 1998b). Seminal vesicle biopsy is not routinely performed unless there is a palpable abnormality, with some authors recommending SV biopsy when the PSA value is greater than 30 or if brachytherapy is being considered (Gohji et al, 1995).

Table 97–2.

Increasing Prostate Cancer Detection Rates with Extended Core Biopsy Protocols

STUDY	NO. OF CORES	CANCER DETECTION RATE
Eskew et al, 1997	6	26.1%
	13	40.3%
Naughton et al, 2000	6	26%
	12	27%
Presti et al, 2000	6	33.5%
	8	39.7%
	10	40.2%
Babaian et al, 2000	6	20%
	11	30%

Repeat and Saturation Prostate Biopsy

Physicians are frequently presented with the dilemma of a patient who has had one or more negative prostate biopsies yet continues to have an elevated PSA value or abnormal digital rectal examination of concern for prostate cancer. Often these patients have undergone multiple biopsies despite the well-documented decline in cancer detection with each successive biopsy (Djavan et al, 2003). Keetch and coworkers (1994) reported an initial positive biopsy rate of 34% in 1136 men from their PSA-based prostate cancer screening program. Cancer detection rates then fell to 19%, 8%, and 7% on biopsy 2, 3, and 4, respectively. These findings were confirmed by results from the European Prostate Cancer Detection Study. **In this cohort of 1051 men with PSA values between 4.0 and 10.0 ng/mL, the initial cancer detection rate with sextant biopsy was 22%. Positive cores were then found in only 10%, 5%, and 4% of patients on subsequent biopsies 2, 3, and 4, respectively** (Djavan et al, 2001a).

These diminishing returns coupled with improved cancer detection rates on initial biopsy with extended core protocols have led some researchers to examine "saturation biopsy" techniques in this difficult subset of patients. In a study of 57 men with an average of two prior negative sextant biopsies, a cancer detection rate of 30% was obtained with an average of 22.5 cores per patient (Borboroglu et al, 2000). Similar protocols from the Mayo Clinic (Stewart et al, 2001) and Toronto (Fleshner and Klotz, 2002) demonstrated improved cancer detection rates. **A drawback to these techniques is that additional anesthetic requirements often require these "saturation"**

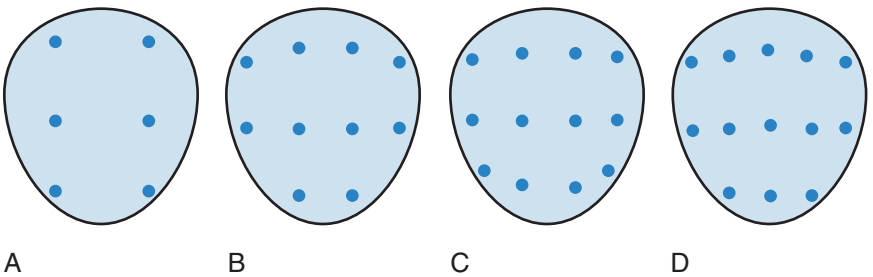

Figure 97–5. Various reported systematic biopsy schemes. **A,** Sextant biopsy scheme originally proposed by Hodge and associates (Hodge et al, 1989b). **B,** The 10-core biopsy of Presti and coworkers (2000). **C,** The 12-core, or double sextant, biopsy. **D,** The 13-core "5-region biopsy" of Eskew and colleagues (1997). Base is at the top of figure, apex is at bottom.

biopsies to be performed in a hospital setting. More recent reports question the benefit of a saturation biopsy scheme, considering the attendant increased cost and potential morbidity. In a reassessment of their previous work on saturation biopsy, investigators at the Mayo Clinic performed a large prospective study of standard systematic and saturation biopsy techniques and did not find a significant increase in prostate cancer detection (Ashley et al, 2008).

Our study suggests that equally improved cancer detection rates can be achieved in this setting using contrast medium–enhanced TRUS (CE-TRUS) and a targeted biopsy protocol of only 10 cores in an outpatient setting (Halpern et al, 2005), thereby minimizing the morbidity and costs associated with saturation biopsies. The use of the free and total PSA may also allow patient classifications of low probability or high probability of having prostate cancer with a PSA level less than 10 ng/mL and determine the need for additional prostate biopsy after an initial negative result (Catalona et al, 1998).

When should we stop ordering biopsies for the patient who has a high degree of suspicion for undiagnosed prostate cancer? Unfortunately there is no clear answer. By using available data from large series such as the European Prostate Cancer Detection Study, we can consider some reasonable recommendations to our patients. In this series of over 1000 men, despite differences in location and multifocality, pathologic and biochemical features of cancers detected on first and second biopsy were similar, suggesting similar biologic behavior. Cancers found on third and fourth biopsies had a lower grade, stage, and cancer volume compared with cancers on first and repeat biopsies. Morbidity of first and repeat biopsies was similar, whereas third and fourth biopsies had a slightly higher complication rate. **The use of a second prostate biopsy in all cases of a negative finding on initial biopsy appears justified. Third and fourth repeat biopsies, however, should only be obtained in selected patients with high suspicion of cancer and/or poor prognostic factors on the first or second biopsy** (Djavan et al, 2005).

Fine-Needle Aspiration Biopsy

The use of transrectal fine-needle aspiration (FNA) of palpable abnormalities of the prostate still is advocated in many countries outside the United States, because it is less expensive, faster, and easier to perform and results in lower morbidity than any other technique. High sensitivity, specificity, and efficacy depend on appropriate training in performing transrectal FNA of the prostate and in interpreting the smears (Perez-Guillermo et al, 2005). **Controversy exists as to whether FNA is as reliable as core biopsy for grading purposes** (Algaba et al, 1996).

Transperineal Prostate Biopsy

Transperineal biopsy offers an approach to the prostate in those patients lacking a rectum (e.g., surgical extirpation, congenital anomaly). The patient is positioned in dorsal lithotomy with the perineum shaved and prepared as for a sterile surgical procedure. An end-fire ultrasound transducer is used. Despite significant limitations in visualization using this technique compared with TRUS, the prostate can and should be imaged in both the coronal and sagittal planes with calculation of the gland volume. Focal PZ hypoechoic lesions are difficult to visualize through the transperineal window, as are the SVs. The urethra will appear as a hypoechoic midline structure and may be readily identified by following the corpus spongiosum proximally from the base of the penis. Once the boundaries of the gland have been clearly delineated in the coronal plane, six cores should be taken, three from either side of midline.

The diagnostic yield of transperineal ultrasound–guided prostate biopsy was compared with that of TRUS-guided biopsies in a routine biopsy setting (Vis et al, 2000). By using radical prostatectomy specimens with TRUS biopsy–detected prostate cancer, simulated transperineal biopsies were performed and transrectal biopsies were repeated. Significantly, 82.5% of the known tumors were detected with the longitudinal transperineal approach versus 72.5% of cancer detection with repeat transrectal biopsy. The authors postulate that the longitudinal orientation of their cores allows more efficient sampling of the PZ, thereby improving cancer detection. By using this approach in the repeat biopsy setting, researchers at Mayo Clinic in Jacksonville, Florida, obtained a mean of 21.2 cores (range, 12 to 41) in 210 men using a template perineal biopsy (Pinkstaff et al, 2005). The transperineal approach enhanced identification of transition zone cancers not detected by previous transrectal prostate biopsy in high-risk patients. **Conversely, in a recent Japanese randomized trial comparing transrectal and transperineal techniques for initial prostate biopsy, the cancer detection rate was similar for both, with higher complications noted in the transperineal approach** (Hara et al, 2008). Therefore the authors concluded that transrectal prostate biopsy should be the preferred technique for initial prostate biopsy.

Transurethral Prostate Biopsy

Transuretheral resection biopsy was once advocated for the diagnosis of TZ cancers or after negative TRUS sampling. In contemporary series, solitary TZ cancers, without concomitant peripheral zone tumors, are estimated to occur in less than 5% of prostate cancer patients (Pelzer et al, 2005). **With improved TRUS techniques including local anesthesia, the TZ can be adequately sampled, and the value of transurethral biopsy has been questioned for the vast majority of patients** (Bratt, 2006).

Risks and Complications of Prostate Biopsy

Postbiopsy Infections

Most infectious complications after TRUS biopsy are limited to symptomatic urinary tract infection and low-grade febrile illness, which can be readily treated with oral or intravenous antibiotics; however, rare case reports of fatal septicemia after prostate biopsy have been published (Breslin et al, 1978; Brewster et al, 1993; Bates et al, 1998; da Silva et al, 1999). Historical series prior to the routine use of antibiotic prophylaxis found bacteriuria in 32% to 36% of patients and bacteremia/febrile illness in 48% to 69% of patients undergoing TRUS biopsy (Brown et al, 1981; Crawford et al, 1982). **Recent studies show that 2% of patients will go on to develop a febrile urinary tract infection, bacteremia, or acute prostatitis and require hospitalization for intravenous antibiotics** (Kapoor et al, 1998; Lindert et al, 2000). Additional infections such as epididymitis have been reported infrequently (Donzella et al, 2004). **There is considerable concern, however, regarding the rising incidence of community-acquired antibiotic-resistant organisms resistant to standard fluoroquinolone prophylaxis** (Patel and Kirby, 2008).

Bleeding

Even with normal coagulation parameters, bleeding is the most common complication seen after prostate biopsy. As noted, any potential medications that can alter coagulation parameters, including herbal remedies, should be held for 5 to 7 days before biopsy and those on warfarin managed as noted. Two large European screening programs noted hematuria in 23% to 63% of men after sextant biopsy, with clot retention developing in 0.7% (Djavan et al, 2001b; Raaijmakers et al, 2002). Rectal bleeding is common and seen in 2.1% to 21.7% of patients (Enlund and Varenhorst, 1997; Djavan et al, 2001b). **Rectal bleeding is typically minor and readily controlled with direct pressure by the ultrasound probe or digitally; persistent brisk hematochezia may require anoscopic intervention for control.** Hematospermia, commonly seen postbiopsy, is of minimal clinical importance but can be cause for significant concern on the part of the patient if not discussed at the time of biopsy; 9.8% to 50.4% of men experience some blood in their ejaculate (Djavan et al, 2001b; Raaijmakers et al, 2002), which may persist for 4 to 6 weeks after prostate biopsy.

Other Complications

Excessive anxiety and discomfort from the endorectal probe may produce a moderate or severe vasovagal response in 1.4% to 5.3% of patients (Rodriguez and Terris, 1998; Djavan et al, 2001b) and may require termination of the procedure. Placing the patient in the Trendelenburg position and use of intravenous hydration usually resolve these symptoms, with further intervention as clinically indicated.

Acute urinary retention requiring temporary catheterization develops in 0.2% to 0.4% of patients after TRUS biopsy (Enlund and Varenhorst, 1997; Raaijmakers et al, 2002). Men with significantly enlarged glands and those with significant lower urinary tract symptoms (e.g., high International Prostate Symptoms Score), are more prone to develop retention (Rodriguez and Terris, 1998; Raaijmakers et al, 2002).

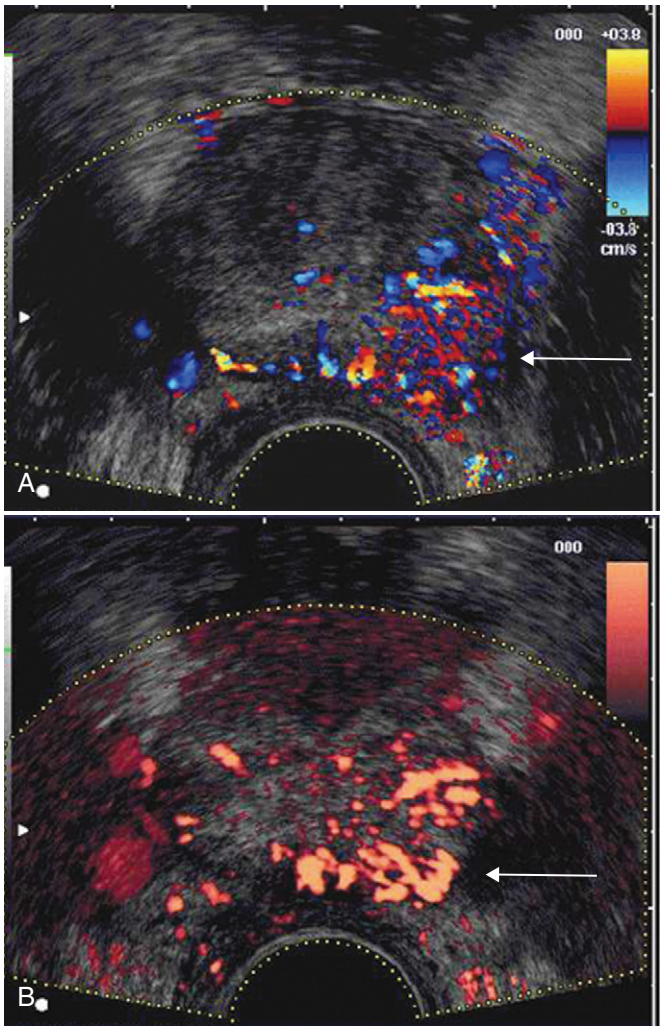

Figure 97–6. Color Doppler **(A)** transrectal ultrasonography (TRUS) and power Doppler **(B)** TRUS identify a Gleason 4 + 4 = 8 adenocarcinoma in the left midgland.

ADVANCED ULTRASONOGRAPHIC TECHNIQUES FOR PROSTATE IMAGING

Color and Power Doppler TRUS

Color Doppler imaging is based on the frequency shift in the reflected sound waves from the frequency of insonation and thus depicts the velocity of blood flow in a directionally dependent manner (Fig. 97–6A). **Color assignment is based on the direction of blood flow related to the orientation of the transducer receiving the signal; flow toward the transducer is depicted in shades of red and flow away in shades of blue; the color is not specific for arterial or venous flow.** Power Doppler imaging (also known as enhanced color Doppler, color amplitude imaging [CAI], or color angiography) uses amplitude shift to detect flow in a velocity and directionally independent manner (Bude and Rubin, 1996) (see Fig. 97–6B). The advantages of power Doppler imaging are its ability to detect slower flow and to have less reliance on the Doppler angle, making it more suitable for detection of prostate cancer neovascularity. Although power Doppler imaging offers improved sensitivity to small amounts of flow, neither modality has yet proved itself superior to the other for cancer detection. In 251 patients, Halpern and Strup (2000) found color Doppler sensitivity and specificity of 14.6% and 93.9%, respectively, to identify cancer. Whereas Doppler modes showed an improved diagnosis versus gray-scale TRUS, 45% of cancers still went unidentified by any sonographic modality. Others have shown increased cancer detection rates using Doppler-targeted biopsy strategies (Kelly et al, 1993; Rifkin et al, 1993; Newman et al, 1995; Sakarya et al, 1998; Cornud et al, 2000; Okihara et al, 2000; Shigeno et al, 2000), but none is sufficiently accurate to replace systematic biopsy (Halpern et al, 2002a). Enhancements in the technical aspects of color Doppler TRUS, including the use of contrast agents (see later), may provide the necessary improvements to specifically identify cancer sites in the future.

Multiple studies have shown that angioneogenesis and the resultant increase in microvessel density that occurs within foci of prostatic adenocarcinoma correlates with the presence of metastasis (Weidner et al, 1993), stage of disease (Fregene et al, 1993; Brawer et al, 1994; Bostwick et al, 1996), and disease-specific survival (Lissbrant et al, 1997; Borre et al, 1998). Interest in using color and power Doppler TRUS to aid in prostate cancer detection stems from studies of radical prostatectomy specimens demonstrating that foci of adenocarcinoma possess an increased density of microvessels compared with surrounding normal parenchyma (Bigler et al, 1993).

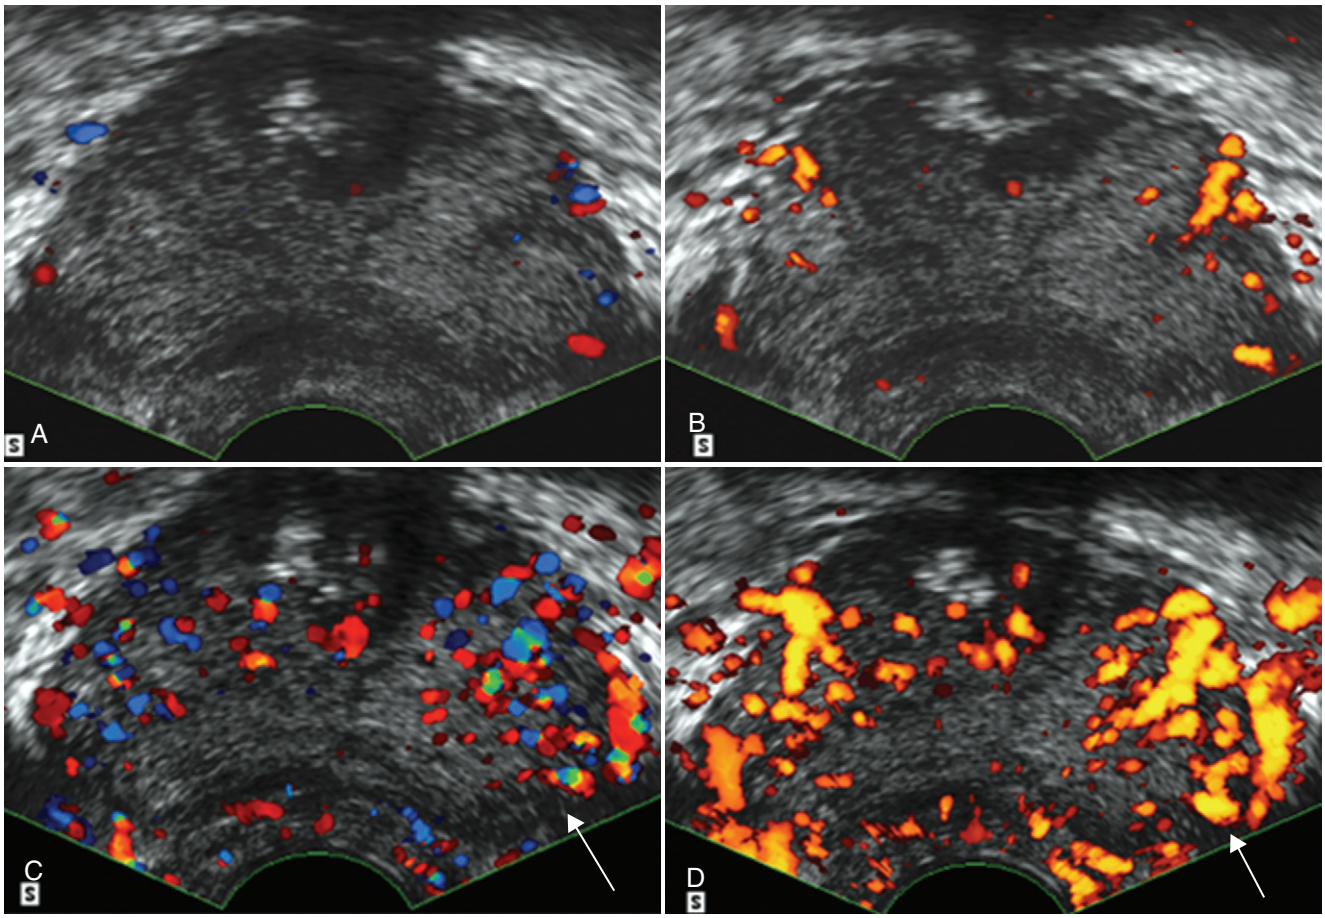

Figure 97–7. Unenhanced color **(A)** transrectal ultrasonography (TRUS) and power Doppler **(B)** TRUS fail to detect evidence of an underlying malignancy. After infusion of a microbubble contrast agent, color **(C)** TRUS and power Doppler **(D)** TRUS demonstrate an area of increased flow in the left midgland that proved to be a Gleason 3 + 4 = 7 adenocarcinoma on targeted biopsy *(arrows)*.

Patients with detectable color Doppler flow within their dominant tumor at the time of TRUS-guided biopsy are at a 10-fold increased risk for PSA recurrence after radical retropubic prostatectomy (Ismail et al, 1997). The presence of increased flow was also associated with a higher Gleason grade, increased incidence of SV invasion, and a lower biochemical disease-free (bNED) survival rate versus subjects without increased flow on preoperative TRUS (50% vs. 96% bNED at 31 months) (Ismail et al, 1997). Other investigators have also shown the association of power Doppler flow signals as an indicator of microvessel density with a higher Gleason score and have suggested a correlation with outcome (Wilson et al, 2004).

Current unenhanced Doppler modalities are not able to identify the microvessels of prostate cancer, which are typically 10 to 15 μm in diameter. The flow signals associated with malignant foci detected by unenhanced color and power Doppler imaging are due to detection of larger feeding vessels (Ismail and Gomella, 2001). Intravenous microbubble ultrasound contrast agents, similar to those currently approved and used in echocardiography, have been infused systemically during gray-scale and TRUS Doppler imaging to amplify flow signals within the microvasculature of prostate tumors, allowing selective visualization of malignant foci in clinical trials (Halpern et al, 2000; Ismail and Gomella, 2001). **These intravenous "bubble" contrast agents are constructed with air or higher-molecular-weight gas agents encapsulated (albumin or polymer hard shell, lipid- or surfactant-coated) for longevity and are generally 1 to 10 μm.**

Using contrast-enhanced TRUS (CE-TRUS) for prospective prostate cancer detection, Halpern and associates (Halpern et al, 2001) demonstrated an increase in sensitivity from 38% to 65% versus baseline unenhanced imaging, without significantly altering specificity. Subsequent studies by our group and others have improved sonographic detection of malignant foci using CE-TRUS and targeted biopsy of enhancing lesions (Frauscher et al, 2001; Halpern et al, 2002a; Roy et al, 2003; Halpern et al, 2005; Heijmink and Barentsz, 2007). In a multi-institutional trial involving several European centers, CE-TRUS has been recommended for routine care in prostate biopsy (Wink et al, 2008). Imaging using microbubble contrast agents combined with three-dimensional image reconstruction of enhanced power Doppler images also demonstrated increased diagnostic accuracy (Unal et al, 2000) (Fig. 97–7). Gray-scale harmonic imaging is a relatively newer method for imaging ultrasound contrast agents that provides better spatial and temporal resolution compared with color Doppler imaging. A variation on gray-scale harmonic imaging, flash-replenishment imaging, provides improved visualization of neovessels that are below the standard resolution of even gray-scale ultrasonography. Flash-replenishment imaging uses a combination of high-power flash pulses to destroy contrast microbubbles, followed by low-power pulses to demonstrate contrast replenishment. A composite image is constructed depicting the vascular architecture through maximum intensity capture of temporal data in consecutive

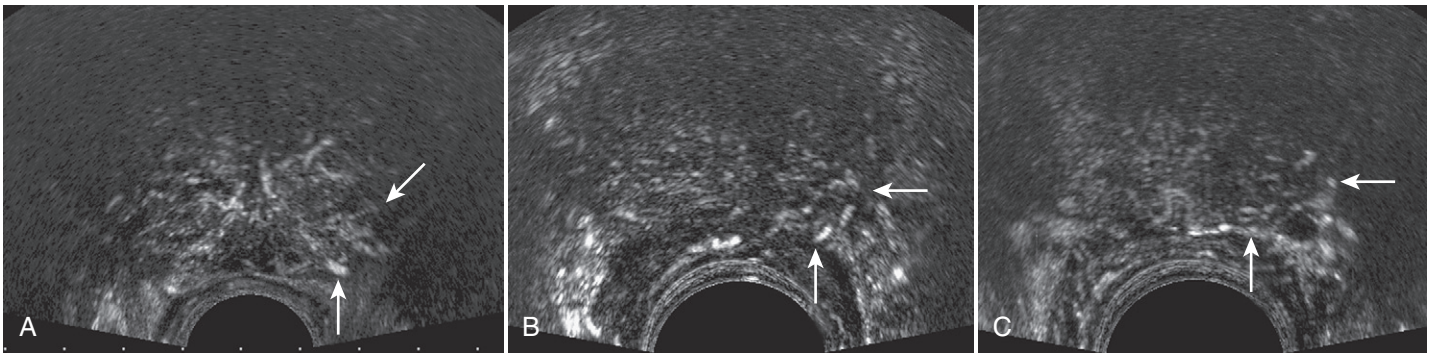

Figure 97–8. Flash-replenishment imaging demonstrating areas of increased and/or abnormal vascularity (*arrows*) to target for biopsy. **A,** Gleason 4 + 4 = 8 adenocarcinoma in the left base. **B,** Gleason 3 + 3 = 6 adenocarcinoma in left base and **(C)** left midgland.

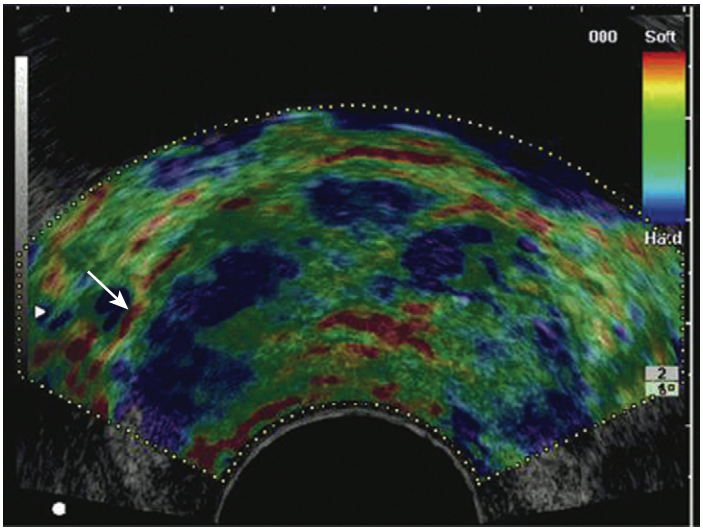

Figure 97–9. Elastography demonstrates an area of decreased compliance in the right base consistent with an underlying malignancy *(blue near arrow)*. Note color scale in upper right corner indicating relative tissue "firmness." Targeted biopsy of this region revealed a Gleason 4 + 4 = 8 adenocarcinoma.

low-power images, and it can be used for real-time targeted transrectal biopsy of areas of increased or abnormal vascularity. Using this technique, we have demonstrated much finer vascular detail for targeting biopsy, and targeted biopsy cores were significantly more likely to be cancerous than random systematic biopsy cores (Linden et al, 2007) (Fig. 97–8). Future developments in these and other imaging modalities that can selectively visualize prostate cancers based on the presence of angioneogenesis may ultimately allow more accurate localization of the sites of cancer.

Other Investigational Techniques

Artificial neural networks are another potential way to enhance TRUS images and identify malignant foci. Investigational automated image analysis, including pattern recognition and artificial neural networks applied to TRUS images, may successfully identify lesions that cannot be seen by the human eye (Loch et al, 1999).

A new sonographic technique known as elastography may prove to be superior to color Doppler imaging in the identification of malignant areas in the prostate (Nelson et al, 2007; Sumura et al, 2007). This technique employs real-time sonographic imaging of the prostate at baseline and under varying degrees of compression (Fig. 97–9). Through computerized calculations, differences in displacement between ultrasonic images from baseline and during compression may be visualized, and regions with decreased tissue elasticity may be tagged as suggestive of malignancy. In a preliminary study of 404 cases, with 151 cases positive for prostate cancer, the malignancy was found in 127 patients (84.1%) with real-time elastography directing the biopsy (Konig et al, 2005).

Endorectal magnetic resonance imaging (MRI) and MR spectroscopy as combined modalities might be able to guide and therefore limit the number of iterative biopsies and cores for patients (Amsellem-Ouazana et al, 2005). Use of MRI will require modifications in instrumentation and the technique of biopsy (Beyersdorff and Hamm, 2005). These MRI-directed biopsy techniques require expensive equipment that is not widely available for biopsy procedures.

New Doppler, contrast medium–enhanced, and other developing techniques have the potential to allow accurate localization and diagnosis of prostate cancer and minimize or eliminate the need for multiple biopsy sites to diagnose prostate cancer in the future. However, until these techniques are proved superior in

Key Points: Advanced Ultrasonographic Techniques for Prostate Imaging

- TRUS alone cannot diagnose prostate cancer without a tissue biopsy.
- Local prostate anesthesia is becoming commonplace and most useful when using extended core biopsy schemes.
- Patients undergoing TRUS-guided prostate biopsy require oral antibiotic prophylaxis for at least 24 hours perioperatively.
- Sextant biopsy of the prostate for prostate cancer detection is inadequate, and systematic biopsy procedures should include a minimum of 10 to 14 cores.
- In the future, investigational imaging modalities, such as contrast medium–enhanced TRUS and elastography, may allow more precise targeted biopsy protocols to replace extended core schemes by improved localization of malignant foci within the prostate.
- Color and power Doppler imaging modes improve cancer detection but do not reliably identify all malignant foci and thus cannot obviate the need for systematic biopsy at the present time.

the localization of prostate cancer, systemic TRUS gray-scale core needle biopsy will continue to be regarded as the gold standard for the diagnosis of prostate cancer.

Prostate Cancer Tumor Markers

Robert H. Getzenberg, PhD ● Alan W. Partin, MD, PhD

Tissue Biomarkers

Blood and Urine Biomarkers

Cellular Biomarkers

Molecular Biology

Summary

The discovery and use of tumor markers have positively affected early detection, diagnosis, and staging for many malignancies. By improving early detection, tumor markers contribute to improved curative success rates. Optimal treatment and cure depend not only on accurate and early diagnosis but also on reliable follow-up for efficient detection of clinical recurrence. The identification of new markers and the development of sensitive tools to measure them will contribute to improved cure rates.

Among urologic malignancies, prostate cancer has greatly benefited from the discovery and application of tumor markers. **Since its discovery in 1979 until clinical application in the late 1980s through 1990s, the prostate-specific antigen (PSA) has evolved into an invaluable tool for detecting, staging, and monitoring prostate cancer in men** (Sensabaugh, 1978; Wang et al, 1979, 1981; Papsidero et al, 1980; Kuriyama et al, 1981). The widespread use of PSA screening has generated greater awareness about prostate cancer. During the PSA era, cancers identified when confined to the prostate have improved cure rates using either radical prostatectomy or radiation therapy. **Whereas the majority of prostate cancers in the 1980s and early 1990s commonly arose through finding an abnormal digital rectal examination (DRE) or elevated PSA, or both, today most prostate cancer arises as clinically nonpalpable (stage T1c) disease with PSA levels between 2.5 and 10 ng/mL. The evolving demographics and natural history of prostate cancer have resulted in a stage migration to nonpalpable, clinically localized (stage T1c) disease and a parallel reduction in mortality** (Pound et al, 1997, 1999; Stephenson et al, 1997; Polascik et al, 1999). However, these PSA-detected T1c cancers are not homogeneous. Although PSA screening has improved survival, outcomes are not the same for all T1c-detected disease because some of these cancers may not pose a threat to survival (Gretzer et al, 2002). Methods for improved detection of clinically significant prostate cancer are needed.

Despite routine application of PSA assays, limitations of specificity for this marker remain. Although PSA is widely accepted as a prostate cancer tumor marker, it is organ specific and not disease specific. **Unfortunately, there is an overlap in the serum PSA levels among men with cancer and those with benign disease. Thus elevated serum PSA levels may reflect alterations within the prostate secondary to tissue architectural changes such as cancer, inflammation, or benign prostatic hyperplasia (BPH).** Currently, serum PSA levels as low as 2.6 ng/mL are used as a threshold to perform transrectal ultrasound-guided biopsy. **Although up to 30% of men presenting with an elevated PSA may be diagnosed following this invasive procedure, as many as 75% to 80% are not found to have cancer.** In some instances the biopsy needle may fail to sample representative areas, thus failing to detect present cancer. To this end, application of PSA derivatives such as PSA density, PSA velocity, age-adjusted values, and, more recently, molecular derivatives have attempted to improve the performance of PSA (Christensson et al, 1990; Benson et al, 1992a, 1992b; Carter et al, 1992a, 1992b; Oesterling et al, 1993a, 1993b, 1993c; Riehmann et al, 1993; Seaman et al, 1993; Bazinet et al, 1994; Rommel et al, 1994; McCormack et al, 1995; Morgan et al, 1996; Lilja, 1997).

We are in a midst of a PSA biomarker crisis because the specificities of PSA and its derivatives require supplementation to improve specificity and to differentiate cancer from benign diseases of the prostate. Research into the biochemistry of PSA is yielding advances that have the potential to contribute to the detection and management of prostate cancer. New understanding of the molecular biology of carcinogenesis and prostate cancer is beginning to yield a new era in prostate cancer tumor research. Exploiting the knowledge of molecular oncology and application of novel techniques has provided innovative tools for the discovery of new biomarkers. Application of these promising diagnostic tests may be instrumental not only for detection but also to aid in discrimination between aggressive and indolent cancers. This chapter reviews our currently used markers in tissue, blood and urine, as well as the cellular-based components, and describes some promising markers that may evolve from the improved knowledge and methods used to evaluate genomic alterations, epigenetic modifications, and protein expression.

TISSUE BIOMARKERS

Glutathione-*S*-Transferase Pi (GSTP1)

Changes in gene expression may occur as a result of alterations in DNA. Alterations known as epigenetic modifications include changes in DNA methylation and histone acetylation status. **Segments within the gene promoter that are composed of GC-rich regions are termed CpG islands. Alterations in the methylation status of these regions may affect gene expression and have been shown to play a role in**

carcinogenesis (Jones and Baylin, 2002). **Furthermore, cumulative effects of environmental exposures, such as diet and stress throughout life, may affect DNA methylation status and thus contribute to the risk of cancer development** (Li et al, 2004). Assays for detection of CpG island hypermethylation include Southern blotting, restriction endonuclease PCR (RE-PCR), bisulfite genomic sequencing (BCR), and methylation-specific (MSP) PCR. Although each assay is sensitive, technical limitations exist. Currently, MSP PCR is most commonly employed for the detection of methylated CpG islands (Jones, 2002). **The products of two hypermethylated genes that have been evaluated in prostate cancer development are glutathione-*S*-transferase P1 (GSTP1) and RAS association domain family protein isoform A (RASSF1A).**

GSTP1 belongs to a family of detoxifying enzymes that are involved in metabolic reduction of electrophilic carcinogens. These enzymes are thought to be involved in the development of prostate cancer. Elevated levels of *GSTP1* CpG hypermethylation have been detected in tissues from precancerous lesions (atypia and prostatic intraepithelial neoplasia [PIN]) and within ejaculates, urine, and plasma from men with prostate cancer (Nakayama et al, 2003). To date, many studies have evaluated these hypermethylated CpG islands as a prostate cancer tumor marker (Cairns et al, 2001; Goessl et al, 2001a, 2001b; Gonzalgo et al, 2003; Bastian et al, 2004). Cairns and coworkers (2001) have demonstrated the presence of elevated *GSTP1* hypermethylation in up to 79% of prostate cancer specimens. Using urine specimens obtained after prostate massage, Goessl and colleagues (2001a, 2001b) found elevated levels of this marker in 68% of men with organ-confined disease, 78% of men with locally advanced or metastatic disease, 29% of men with PIN, and 2% of men with BPH.

Gonzalgo and coworkers (2003) demonstrated elevated *GSTP1* hypermethylation in up to 50% of urine sediments taken from men immediately after transrectal prostate biopsy. Hypermethylation was also detected in 33% of men with negative biopsies and in up to 67% of men found to have PIN or atypia, suggesting that these patients may harbor occult prostate cancer and require more rigid follow-up with a low threshold for repeat biopsy. The use of MSP to measure *GSTP1* hypermethylation in body fluids represents an emerging tool that is feasible and has demonstrated reproducible results, and it is likely to become a valued screening modality for prostate cancer detection.

In addition to *GSTP1,* hypermethylation of *RASSF1A* has been noted to occur in up to 70% of prostate cancers (Kuzmin et al, 2002; Liu et al, 2002). Early findings have noted an association of this marker with more aggressive tumors, and it may aid in distinguishing between these cancers and more indolent cancers. Although early, this work is promising, and the subject remains under investigation.

Many men continue to undergo biopsy procedures even though only 10% to 36% of men having an initial negative biopsy are found to have cancer on second biopsy (Djavan et al, 2000; O'Dowd et al, 2000; Lopez-Corona et al, 2003; Singh et al, 2004; Eggener et al, 2005), and cancer detection decreases with each subsequent negative biopsy (Keetch et al, 1994). Improved methods are needed to identify men who can forgo a repeat biopsy, particularly if the trigger for initial biopsy or the initial biopsy histology indicates high-risk features. Therefore emphasis on achieving a high negative predictive value (NPV) and low false-negative rate has been championed following many biomarker evaluations. In initial studies of prostate cancer, DNA methylation markers have exhibited high sensitivity and specificity (Maruyama et al, 2002; Yegnasubramanian et al, 2004), and improved upon the sensitivity of histology alone by 15% (Harden et al, 2003a). We therefore conducted this study to evaluate whether DNA methylation markers could improve upon the NPV of histology alone in men without cancer on initial biopsy but with a high index of suspicion for a missed cancer.

The first tissue methylation-biomarker to be discovered was glutathione-*S*-transferase π (GSTP1). Glutathione *S*-transferases (GSTs) are a family of detoxification enzymes that conjugate reactive substrates with reduced glutathione. The enzymes are dimers classified into four groups: α, μ, π, and θ (Hayes et al, 1995). Li and coworkers (2004) noted that the glutathione-*S*-transferase π *(GSTP1)* gene was unmethylated in all normal human tissues and BPH but was hypermethylated in all 20 prostate cancer (CaP) specimens analyzed. Eighty-eight of 91 CaP specimens did not stain for GSTP1 protein. Harden and coworkers (2003a, 2003b) used PCR to detect hypermethylated *GSTP1* in prostate biopsy specimens. Twenty-nine (of 45 patients) were able to be evaluated using this method. *GSTP1* methylation was detected in 11 of 15 (73% sensitivity) CaP cases and in none of 14 (100% specificity) benign controls. Quantitation of *GSTP1* hypermethylation accurately detected CaP even in small, limited tissue samples. This would indicate that methylated *GSTP1* represents a marker useful for CaP screening.

Bastian and coworkers (2005) used a restriction endonuclease, QMSP (RE-MSP), to detect abnormalities in the CpG islands found in serum *GSTP1* DNA. No men with a negative biopsy had *GSTP1* DNA detected in their sera, compared with 12% of men with clinically localized CaP and 28% with metastatic disease.

Gene Fusions

With the landmark discovery of the presence of gene fusions in prostate cancer by Chinnaiyan and colleagues (Tomlins et al, 2005), considerable work has been performed to determine if assays can be developed that can accurately detect prostate cancer or provide prognostic information. The *TMPRSS2* and *ETS* transcription factor fusions have revealed novel biology about solid tumors with great potential implication (Tomlins et al, 2005). Because this discovery has such great potential, the concept has been to determine if we can detect these fusions in the urine of men with prostate cancer (Barry et al, 2007). A feasibility study that examined urine samples post-DRE, revealed that indeed the *TMPRSS2-ERG* fusion can indeed be found within the urine and has the potential to be an interesting marker (Laxman et al, 2008) with potential to aid in the detection of prostate cancer in men about to undergo a biopsy for the disease. In a larger follow-up study, investigators were able to determine that gene fusions are detectable in approximately 37% of the urine samples obtained from men with prostate cancer (Hessels et al, 2007). Using tissue samples, the presence of these gene fusions was observed in about half of the prostate cancer cases and was, in fact, observed in an even lower percentage of the more aggressive tumors (Perner et al, 2007; Mosquera et al, 2008). Several assays are being developed to detect these fusions in tissue and urine samples (Lu et al, 2008). Further delineation of the various splice variants that have been produced has the potential to add to the diagnostic utility of these fusions, indicating that the detection of a single fusion may not be sufficient (Hu et al, 2008). The clinical utility of the detection of a single gene fusion alone has been questioned recently with findings that the *TMPRSS2-ERG* fusion does not correlate with outcome in men undergoing prostatectomies (Gopalan et al, 2009). Moving toward the concept that single biomarkers will probably not answer the important clinical questions in prostate

cancer alone, many investigators have begun to multiplex markers, resulting in additive value. Combining both the prostate cancer–3 (PCA-3) test, that will be described later in the chapter, together with the detection of these gene fusions in urine resulted in increasing sensitivity to 73%, although it was not possible to determine the specificity of the combined tests in these clinical populations. Overall, the current data related to the use of urine-based gene fusions seems to indicate that, at best, they may add slightly to PSA or even PCA-3 detection of prostate cancer and does not appear to have the ability to distinguish aggressive from nonaggressive disease.

Gene and Androgen Receptor Polymorphisms

As the genetic alterations associated with disease states are mapped, novel information is being revealed related to the potential of these differences to serve as biomarkers for prostate cancer. These findings have been specifically associated with more advanced prostate cancer. Using arrays that can specifically analyze single nucleotide polymorphisms (SNPs), investigators have begun to perform large-scale genomic comparisons of genetic alterations associated with prostate cancer. Much of the initial work has been done on individuals who have family histories of prostate cancer. In work performed through a collaborative effort that examined large numbers of individuals who are part of these hereditary study cohorts, investigators have revealed SNP patterns that impart a higher risk for developing prostate cancer. Because these are genomic differences, a simple blood draw or cheek swab can be used to make such a determination (Sun et al, 2008). Although the data are quite dramatic, the question has been raised about how these data should be handled clinically. For example, if an individual is found to have a fivefold increase in their risk for prostate cancer, what should be done? Should they be screened more carefully or more frequently? Should they simply undergo a prostate biopsy or treatment? Certainly this seems like an application where some type of preventive strategy might work. Unfortunately, we have little, if anything available that has been used to effectively prevent the disease.

In an attempt to discern genomic polymorphisms that may be predictive of castrate-resistant prostate cancer, Luo and colleagues (Hu et al, 2009) have examined the androgen receptor to determine if there may be gene variants that are predictive of the ability of the tumor to continue to grow in the absence of androgens. The hypothesis is that there are distinct forms of the androgen receptor that may be active in the absence of ligands. This may permit the cancer cells to continue to grow even in a castrate environment. They have recently revealed the presence of several unique forms of the androgen receptor. One form, variant 7, is shown to be increased in men with advanced prostate cancers (Hu et al, 2009). Using an antibody being constructed, the researchers are proposing to develop a blood test that can be used to identify individuals with castrate- resistant prostate cancer.

BLOOD AND URINE BIOMARKERS

Prostate-Specific Membrane Antigen

The glycoprotein prostate-specific membrane antigen (PSMA) is a folate hydrolase and is found embedded within the cell membrane of all prostatic epithelial cells. The hydrophobic amino acids found on amino acid residues 20 to 43 suggest that this protein is a type II integral membrane protein with a small intracellular domain and a large extracellular domain (Israeli et al, 1997; Fair et al, 1997). The gene for PSMA has been cloned, fully sequenced, and localized to the short arm of chromosome 11 (11p11-p12). PSMA has been identified in the central nervous system, intestine, and prostate. In the brain, PSMA functions to metabolize the neurotransmitter *N*-acetyl-aspartyl-glutamate. In the intestine, PSMA has been localized to the proximal small bowel, where it works as a carboxypeptidase. Although isolated in these other tissues, PSMA is predominantly expressed in the prostate gland.

Of interest for diagnosis (Douglas et al, 1997), prognosis (Perner et al, 2007), and imaging (Wynant et al, 1991; reviewed by Abdel-Aziz et al, 2000) is the discovery of elevated expression of this protein in tissue from prostate cancer compared with normal prostate tissue (Silver et al, 1997; Chang et al, 1999a; Elgamal et al, 2000). More work has focused on use of PSMA in treatment strategies than for diagnostic tests (Elsässer-Beile et al, 2009). Multiple monoclonal antibodies have been designed to identify both the intracellular and extracellular domains of the PSMA protein; however, few have shown "diagnostic promise" immunohistochemically or as serum/urine assays (Horoszewicz et al, 1987; Douglas et al, 1997). However, PSMA mRNA expression among prostate cancers is highest in the hormone-deprived state (Henttu et al, 1992; Israeli et al, 1994). **During cancer progression, differentially expressed variants of PSMA have been identified. Of three alternatively spliced variants of PSMA, one, known as PSM′, is differentially expressed in normal tissue, BPH, and prostate cancer.** Su and colleagues (1995) demonstrated that the PSMA/PSM′ ratio is upregulated three- to sixfold in prostate cancer compared with BPH (0.76 to 1.6) and normal (0.075 to 0.45) tissue. Further reports to date have demonstrated the production of antibodies to PSMA. Horoszewicz and coworkers (1987) have found increased PSMA levels in 47% of prostate cancer patients (20 of 43) versus only 5% of noncancer patients (3 of 66) and negative results in 30 normal blood donors. Using the antibody produced by Horoszewicz and coworkers, Xiao and colleagues (2001) reported use of an immuno-SELDI (surface-enhanced laser desorption ionization) assay for PSMA. Applying the antibody to PSMA on a ProteinChip array, these authors were able to differentiate cases of prostate cancer from BPH. Perner and colleagues (2007) demonstrated marked differences, immunohistochemically, in the levels of PSMA in tissues from various prostate tumors that progressed after surgery (HR = 1.5, 95% CI = 1.1 to 2.8, P = .17) and suggested that PSMA might act independently as a prognostic biomarker of disease progression. The development of an accurate enzyme-linked immunosorbent assay (ELISA) for PSMA in serum/urine has potential significance for diagnostic and prognostic evaluation for prostate cancer. The clinical usefulness of PSMA for diagnosis, monitoring, and imaging continues to be promising and remains under investigation in many laboratories.

Human Kallikrein Gene Family

Another source of blood-based prostate cancer biomarkers has been identified among the protein products of the human kallikrein gene family (Fig. 98–1). Originally, only three genes of this family of genes were identified: the pancreatic/renal kallikrein *(hKLK1),* human kallikrein 2 *(hKLK2),* and PSA *(hKLK3)* genes (McCormack et al, 1995; Rittenhouse et al, 1998; Diamandis et al, 2000; Lilja, 1997). Since the identification of 12 other kallikrein genes, this family of proteases now consists of 15 members and is described with a distinct nomenclature (Diamandis et al, 2000; Yousef and Diamandis, 2001). Located on the long arm of

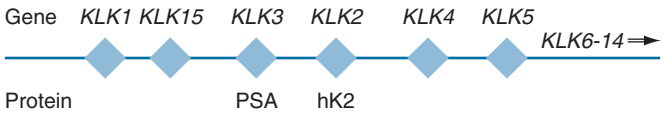

Figure 98–1. Human kallikrein gene map. Map of the human kallikrein locus and corresponding proteins as described by Yousef and Diamandis (2001).

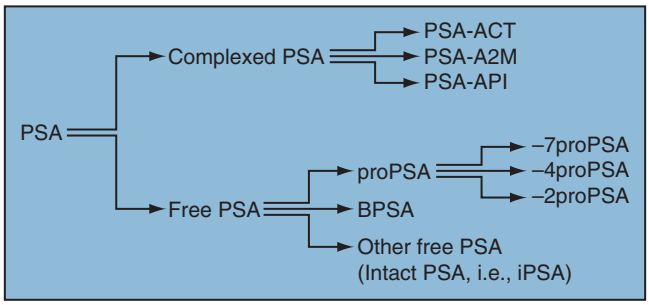

Figure 98–2. Molecular forms of prostate-specific antigen (PSA). Molecular derivatives of PSA include free PSA, such as proPSA (and the various clipped forms), BPSA (benign PSA), and other free PSA forms such as intact, inactivated PSA. Complexed PSA includes free PSA that is bound to proteases such as ACT (α_1-antichymotrypsin), API (α_1-protease inhibitor), and A2M (α_2-macroglobulin).

chromosome 19 within the region spanning q13.2-q13.4, these genes share similar structural similarities. The serine proteases encoded by the three originally described genes have been identified as hK1 or hPRK (*KLK1* gene), hK2 or hGK-1 (*KLK2* gene), and hK3 or PSA (*KLK3* gene). These serine proteases have similar amino acid sequences, with hK1 expressing 60% and hK2 expressing 78% homology with PSA (Schedlich et al, 1987; Clements, 1989). Both hK2 and hK3 are released in zymogen form from the prostatic epithelium and are found in seminal fluid as well as serum. Because they share structural homology, they can both form complexes with endogenous protease inhibitors such as α_2-macroglobulin and α_1-antichymotrypsin (ACT) (Young et al, 1995; Lilja, 1997; Rittenhouse et al, 1998). **hK2 has been shown to regulate PSA activity by cleaving a leader amino acid sequence from PSA (proPSA), thus activating PSA** (Kumar et al, 1997; Lovgren et al, 1997; Takayama et al, 1997). **Although PSA is less expressed in prostate cancer tissue, hK2 levels have been shown to be elevated in poorly differentiated prostate cancer** (Darson et al, 1997; Tremblay et al, 1997). Similar to PSA, hK2 has been shown to aid in the detection of prostate cancer (Kwiatkowski et al, 1998; Partin et al, 1999; Nam et al, 2000). It is likely that several other members of the kallikrein family of serine proteases will become useful tumor markers. Both hK6 and hK10 have been described as potential serum biomarkers for nonprostatic diseases, especially ovarian cancer (Luo et al, 2001; Yousef and Diamandis, 2001).

Prostate-Specific Antigen (PSA or hK3)

The most notable marker in the kallikrein family is hK3, also known as PSA. It was first identified and purified in the late 1970s, but widespread use in clinical urology did not occur for another decade (Ablin et al, 1970; Sensabaugh, 1978; Wang, 1979; Papsidero, 1980; Kuriyama, 1980, 1981; Wang, 1981; Seamonds, 1986; Chan et al, 1987; Stamey et al, 1987; Oesterling et al, 1988). PSA is a 33-kD glycoprotein that acts as a serine protease. The ectopic expression of PSA has been reported in smaller concentrations in the tissue of malignant breast tumors (Yu et al, 1994a, 1994b, 1994c), normal breast tissue (Monne et al, 1994; Yu et al, 1995), breast milk (Yu and Diamandis, 1995), female serum (Yu et al, 1995), and adrenal and renal carcinomas (Levesque et al, 1995a); however, for practical and clinical purposes, PSA is organ specific, primarily produced by the prostatic luminal epithelial cells (Yu et al, 1995; Levesque et al, 1995b; Diamandis et al, 2000). Although it is organ specific, PSA is not cancer specific, as demonstrated by the substantial overlap in values between men with benign versus malignant prostate disease (Oesterling et al, 1988; Partin et al, 1990).

The function of this androgen-regulated protease is to liquefy semen through its action on the gel-forming proteins semenogelin and fibronectin within the semen following ejaculation (Lilja and Laurell, 1984; Lilja, 1985; Lilja et al, 1987; McGee and Herr, 1988; Christensson et al, 1990). **PSA is normally found in low concentration in sera (ng/mL). Within sera, PSA circulates in both bound and unbound forms** (Fig. 98–2). **Most PSA in sera is bound or complexed to the antiproteases ACT and macroglobulin (MG)** (Christensson et al, 1990; Lilja et al, 1991; Stenman et al, 1991). Binding of free PSA to ACT inactivates the protease, but the complex PSA-ACT remains immunodetectable by current assays (Partin et al, 2003). Binding of PSA to MG still allows some proteolytic activity but renders the PSA-MG complex undetectable by most current assays (Christensson et al, 1990). **Free PSA without proteolytic activity is probably rendered inactive within the prostatic epithelial cell before release into the sera. This free inactive PSA does not form complexes with antiproteases, circulates unbound in sera, and is immunodetectable by current assays** (Lilja et al, 1991). The primary release of PSA into the seminal fluid results in 10^6-fold higher seminal concentrations than levels measured within serum (Sensabaugh, 1978; Wang et al, 1981; Lilja and Abrahamsson, 1988; McCormack et al, 1995). The concentrations found in seminal plasma range from 0.5 to 5.0 mg/mL, whereas the normal serum concentration in men aged 50 to 80 years without prostate disease ranges between 1.0 and 4.0 ng/mL (Catalona et al, 1991).

Prostate cancer cells do not necessarily make more PSA than do normal prostate cells, and elevated serum levels are probably a result of cancer progression and destabilization of the prostate histologic architecture (Stamey et al, 1987). Studies have demonstrated that **prostate cancer cells do not make more PSA but rather make less PSA than normal prostatic tissue** (Meng et al, 2002). **Evaluation of tissue from prostate cancer specimens has demonstrated up to 1.5-fold lower messenger RNA (mRNA) expression levels compared with normal prostate tissue** (Meng et al, 2002).

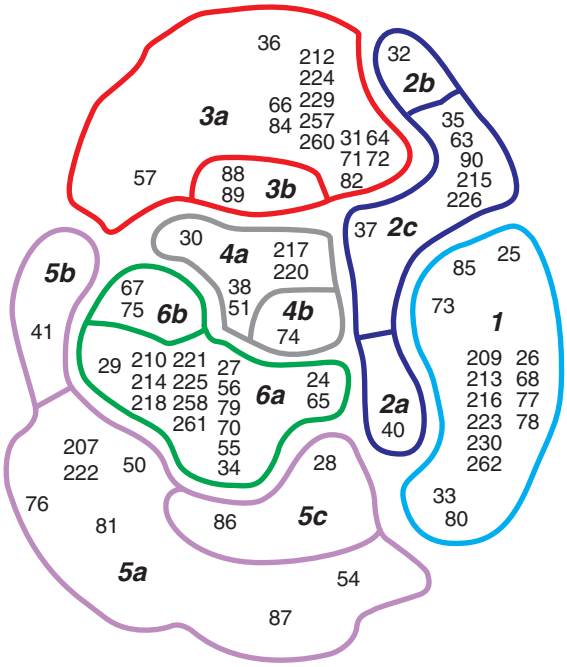
PSA expression is strongly influenced by androgens (Young et al, 1991; Henttu et al, 1992). Immunohistochemical detection of PSA within the prostate is characterized by bimodal peaks between 0 and 6 months and after 10 years, correlating directly with testosterone levels (Goldfarb, 1986). Serum PSA becomes detectable at puberty with increases in luteinizing hormone and testosterone (Vieira et al, 1994). **In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume.**

In men without BPH, the rate of change in PSA is 0.04 ng/mL per year (Carter et al, 1992b; Oesterling, 1993), compared with

0.07 to 0.27 ng/mL per year in men with BPH who are between the ages of 60 and 85 years (Carter et al, 1992b). Cross-sectional data suggest that PSA increases 4% per milliliter of prostate volume and that 30% and 5% of the variance in PSA can be accounted for by prostate volume and age, respectively (Oesterling et al, 1993a). Blacks without prostate cancer have higher PSA values than whites (Morgan et al, 1996; Fowler et al, 1999). Fowler and colleagues (1999) have demonstrated that, on a volume/volume basis, the benign prostatic tissue of black men contributes more PSA to sera than does the benign prostatic tissue of white men, a difference that increases with age.

Elevated serum PSA levels are probably a product of disruption of cellular architecture within the prostate gland (Stamey et al, 1987). **The loss of the barrier afforded by the basal layer and basement membranes within the normal gland is a likely site for the egress of PSA into the circulation. This can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (prostate massage, prostate biopsy)** (Stamey et al, 1987). Prostatic inflammation (acute and chronic) and urinary retention can cause PSA elevations to variable degrees (Armitage et al, 1988; Dalton, 1989; Nadler et al, 1995). PSA elevations may not be related to the histologic finding of inflammation in men without clinical prostatitis (Morote et al, 2000). **Prostatic trauma, such as occurs after prostatic biopsy, can result in a leak of PSA into the circulation that may require more than 4 weeks for return to baseline values** (Yuan et al, 1992). **DRE as performed in an outpatient setting can lead to increases in serum PSA** (Thompson and Zeidman, 1992). **However, the change in PSA after DRE does not appear to be clinically significant, because the change is within the error of the assay and rarely causes false-positive tests** (Chybowski et al, 1992; Crawford et al, 1992; Thompson and Zeidman, 1992).

Studies of the effect of ejaculation on serum PSA have shown both no significant change in PSA (Kirkali et al, 1995) and a significant decrease in serum PSA (Simak et al, 1993; Heidenreich et al, 1997) in men 30 to 40 years old or younger. However, in the age group in which PSA testing is primarily used for early detection of prostate cancer (50 years and older), ejaculation can lead to an increase in PSA that can result in a false-positive elevation (Tchetgen et al, 1996; Herschman et al, 1997). After 48 hours, this fractional increase in PSA would be expected to return to baseline levels in most men (Tchetgen et al, 1996). A history of sexual activity and a repeated PSA test after 48 hours of sexual abstinence may be helpful in the interpretation of serum PSA levels that are minimally elevated.



The presence of prostate disease (prostate cancer, BPH, and prostatitis) is the most important factor affecting serum levels of PSA (Wang et al, 1981; Ercole et al, 1987; Robles et al, 1988). **PSA elevations may indicate the presence of prostate disease, but not all men with prostate disease have elevated PSA levels. Furthermore, PSA elevations are not always specific for prostate cancer.**

Prostate-directed treatment (for both BPH and cancer) can lower serum PSA by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell. Manipulation of the hormonal environment for treatment of cancer and BPH with orchiectomy, luteinizing hormone–releasing hormone analogs, and 5α-reductase inhibition; radiotherapy; and surgery for BPH or cancer can all lead to reductions in serum PSA (Henttu and Vihko, 1992). **Finasteride (5 mg) and other 5α-reductase inhibitors (dutasteride) for treatment of BPH have been shown to lower PSA levels by an average of 50% after 6 months of treatment** (Guess, 1993). **Thus one can multiply the PSA level by two to obtain the "expected" PSA level of a patient who has been taking a 5α-reductase inhibitor—for 6 months or more. Men who are to be treated with a 5α-reductase inhibitor should have a baseline PSA measurement before initiation of treatment and should be observed with serial PSA measurements, because this drug may decrease PSA serum levels by up to 50%. If PSA does not decrease by 50% or if there is a rise in PSA when the patient is taking a 5α-reductase inhibitor, the patient should be suspected of having occult prostate cancer and undergo further testing.** Finasteride (1 mg), also marketed for the treatment of male baldness, may also lower PSA levels to a lesser extent than the 5-mg dosage. Other over-the-counter medications and neutraceutical use should always be documented. **Although saw palmetto has not been shown to affect PSA levels, these unregulated supplements may contain compounds that can alter PSA levels (e.g., PC-SPES, now off the market). Interpretation of PSA values should always take into account the presence of prostate disease, previous diagnostic procedures, and prostate-directed treatments.**

Molecular Derivatives of Prostate-Specific Antigen

One of the most exciting and clinically useful discoveries since the introduction of PSA testing has been the demonstration of different molecular forms of PSA in serum (Christensson and Lilja, 1994; Christensson et al, 1990, 1993; Lilja et al, 1991; Stenman et al, 1991; McCormack et al, 1995; Lilja et al, 1997; Polascik et al, 1999). Measurable PSA found circulating in the blood exists either complexed (bound, cPSA) to proteins or as a free (unbound) form (fPSA) (see Fig. 98–2). **Three proteins that are known to bind to PSA in the blood are ACT, α_2-macroglobulin (A2M), and α_1-protease inhibitor (API)** (Christensson et al, 1990, 1993, 1994; Lilja et al, 1991; McCormack et al, 1995; Tewari et al, 1996; Lilja, 1997). Figure 98–3 illustrates the molecular model of PSA and its epitope sites. **The majority of PSA that enters the serum is bound (70%) to these proteins.** When bound to A2M, all PSA epitope sites become masked, making this complex difficult to measure (Fig. 98–4). **Of the complexed PSA derivatives found in serum, PSA bound to ACT (PSA-ACT) is immunoreactive and found in the greatest concentration.** Although representing a lower proportion of total PSA in the blood, fPSA is also immunoreactive and therefore measurable. Development of new monoclonal antibodies specific for fPSA and cPSA has allowed more accurate measurement of the different molecular forms of PSA and their ratios in serum (Table 98–1) (Lilja et al, 1991; Stenman et al, 1991).

Free PSA and the Percent Free PSA. Although the majority of serum PSA is found complexed to the proteases (most to ACT), 5% to 35% of PSA exists as fPSA (McCormack et al, 1995; Tewari et al, 1996; Woodrum et al, 1998). **Although prostate cancer cells do not produce more PSA than benign prostate epithelium, the PSA produced from malignant cells appears to escape proteolytic processing. Thus men with prostate cancer have a greater fraction of serum PSA complexed to ACT and a lower percentage of total PSA that is free compared with men without prostate cancer** (Christensson et al, 1993; Leinonen et al, 1993; Lilja, 1993; Stenman et al, 1994; Catalona et al, 1997). Using this

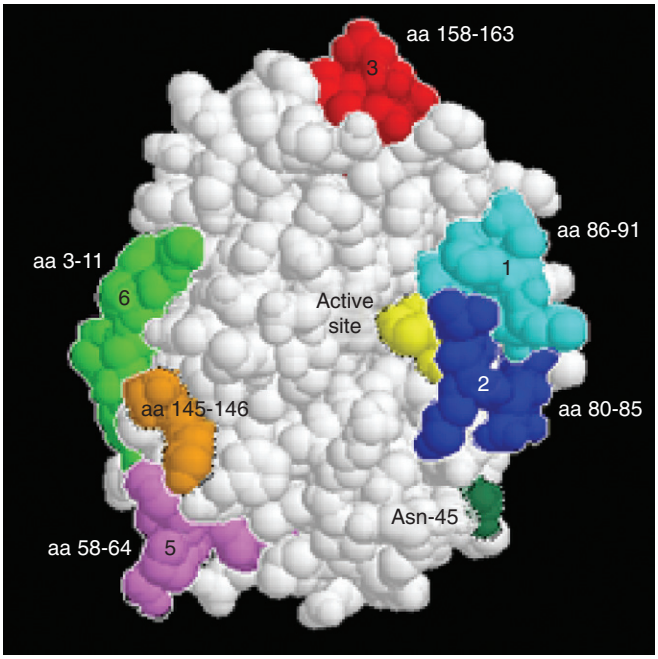


Figure 98–3. Molecular model of prostate-specific antigen demonstrating the available epitopes.

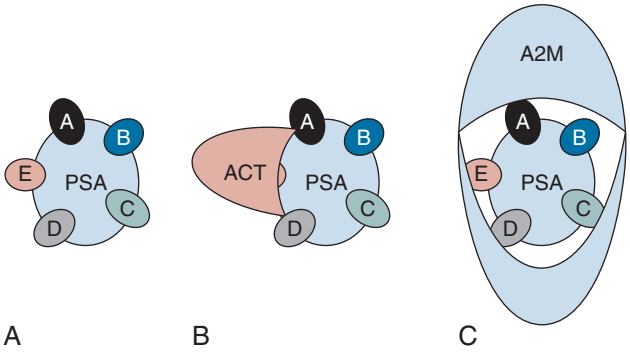

Figure 98–4. Prostate-specific antigen (PSA)–binding proteases. **A,** Free PSA with *A* to *E* representing immunoreactive epitopes of free PSA. **B,** α_1-Antichymotrypsin (ACT) blocks the E epitope during binding. **C,** α_2-Macroglobulin (A2M) blocks all immunoreactive sites on PSA, making this derivative difficult to measure in serum.

Table 98–1.

Molecular Derivatives of Prostate-Specific Antigen

PSA TYPE	% IN SERUM
Complexed PSA	60-95
PSA-ACT	60-90
PSA-API	1-5
PSA-A2M	10-20
Free PSA	5-40

ACT, α_1-antichymotrypsin; API, α_1-protease inhibitor; A2M, α_2-macroglobulin; PSA, prostate-specific antigen.

important observation led to the measurement of the percentage of the ratio of free to total PSA (%fPSA) and has since provided an additional degree of specificity for prostate cancer detection (Catalona et al, 1998; Partin et al, 1998). The difference in the ratio of free to total PSA (percentage of free PSA or %fPSA) is greatest when comparing men without prostate cancer who have prostate enlargement (BPH) with those with prostate cancer and no prostate enlargement. This difference may be due to differential expression of PSA isoforms by transition zone (zone of origin of BPH) tissue compared with peripheral zone (zone of most prostate cancer) tissue (Chen et al, 1997; Mikolajczyk et al, 2000). **The role for %fPSA is more applicable to PSA levels less than 10 ng/mL, because the positive predictive rate of total PSA above 10 to 20 ng/mL has been demonstrated to be as high as 80%. Currently, %fPSA is approved by the Food and Drug Administration (FDA) for use to aid PSA testing in men with benign DRE and minimal PSA elevations, within the diagnostic gray zone of 4 to 10 ng/mL.** If PSA levels are less than 4.0 ng/mL, more recent data have demonstrated the utility of %fPSA when deciding whether a patient requires an initial or repeat biopsy.

Christensson and coworkers (1993) measured free and total PSA fractions in men with and without prostate cancer and found that a free/total PSA cutoff of 0.18 (18% free/total PSA) significantly improved the ability to distinguish between subjects with and without cancer compared with use of total PSA alone. Other %fPSA cutoff values have also been identified to improve risk stratification. Catalona and colleagues (1995) have found that %fPSA provided independent predictive information regarding the presence or absence of cancer above that provided by other clinical indices, including age, total PSA, DRE results, and prostate size. As many as 20% to 65% of unnecessary biopsies may be avoided when using %fPSA cutoff values ranging between 14% and 28%, while maintaining sensitivity rates from 70% to 95% within the tPSA range of 4 to 10 ng/mL (Catalona et al, 1998; Partin et al, 1998; Veltri and Miller, 1999; Vessella et al, 2000;

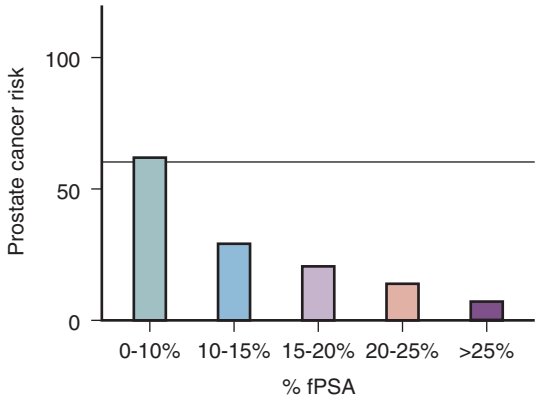

Figure 98–5. Prostate cancer risk stratification for men with prostate-specific antigen (PSA) values between 4 and 10 ng/mL (the diagnostic gray zone) based on percent free PSA (%fPSA). (From Catalona WJ, Partin AW, Slawin KM. Percentage of free PSA in black versus white men for detection and staging of prostate cancer: a prospective multicenter clinical trial. Urology 2000;55:372–6.)

Stephan et al, 2002). In a prospective, multi-institutional study of men 50 to 75 years old with PSA levels between 4 and 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% (biopsy less than 25%) detected 95% of cancers while avoiding 20% of unnecessary biopsies (Catalona et al, 1998). **These data confirm that the application of %fPSA can help counsel men with PSA elevation between 4 and 10 ng/mL regarding their risk of cancer and the need for further evaluation to rule out the disease** (Fig. 98–5).

A number of other studies have demonstrated the usefulness of %fPSA in prostate cancer detection (for reviews see Polascik et al, 1999; Karazanashvili et al, 2003). Increased use of PSA as a screening tool has led to increased interest in the evaluation of PSA levels below 4.0 ng/mL. Examination of cancers detected within the PSA range 2.5 to 4.0 ng/mL has shown numbers of cancers similar to those detected in the 4 to 10 ng/mL range and also that these cancers are clinically significant and may exhibit aggressive pathologic potential (Colberg et al, 1993; Smith et al, 1998; Schroder et al, 2000; Recker et al, 2001). Djavan and colleagues (1999) demonstrated that for men with PSA levels less than 4 ng/mL, a %fPSA cutoff value of 27% could detect up to 90% of cancers while preventing 18% of unnecessary biopsies. Furthermore, comparison against PSA derivatives, such as prostate-specific antigen density (PSAD), PSA velocity, and transition zone density favored %fPSA. Haese and coworkers (1997) demonstrated that %fPSA in the total PSA (tPSA) range of 2 to 4.0 ng/mL does not substantially increase the number of biopsies needed to detect clinically significant prostate cancer compared with that in the 4 to 10 ng/mL range. In this study, a %fPSA cutoff value of 18% to 20% detected almost half of cancers while sparing 73% of men from undergoing biopsy, with a biopsy-to-cancer ratio of 3:1 to 4:1.

One study has demonstrated that a %fPSA cutoff of 25% would lead to detection of 95% of prostate cancers in both white and black men (Catalona et al, 2000), suggesting that race may not be important when using %fPSA in cancer detection. **Free PSA and total PSA both decrease in men receiving finasteride. As both decline, the percentage of fPSA is not altered significantly by this medication** (Keetch et al, 1997; Pannek et al, 1998).

In addition to contributing to detection, %fPSA has been shown to provide prognostic information. Serial measurement of %fPSA within archival serum demonstrated early marked and sustained differences in aggressive and nonaggressive prostate cancers (Carter et al, 1997). This group identified a statistically significant difference in %fPSA in men with and without metastatic disease up to 10 years prior to the development of prostate cancer. For the same cohort of men, total PSA levels failed to differentiate aggressive from nonaggressive prostate cancer 10 years prior to diagnosis. This study suggests that the longitudinal measurement of %fPSA changes may aid in detection and contribute information regarding disease behavior, thus providing useful information for therapeutic decision making.

Despite these encouraging results, several important factors should be kept in mind with regard to interpretation of %fPSA in clinical practice for cancer detection (Meyer et al, 1997). Such factors include prostatic manipulation, specimen handling, and assay variation (Partin et al, 1996a, 1996b; Stephan et al, 1997; Roth et al, 1998; Woodrum et al, 1998). Prostatic manipulation and urethral instrumentation have been shown to affect the interpretation of the ratio of fPSA to total PSA. Although there may be marginal changes in total PSA, fPSA levels may fluctuate, affecting the %fPSA calculation. Furthermore, because fPSA is cleared more rapidly from serum than complexed PSA forms (i.e., total PSA), the resulting calculated %fPSA is directly affected. Thus it is recommended that PSA determinations be avoided for several weeks following prostatic manipulation (surgery, biopsy, cystoscopy) (Partin et al, 1996b; Lein et al, 1997; Bjork et al, 1998).

Prostate volume has also been shown to influence the serum ratio of free to total PSA (Catalona et al, 1995; Partin et al, 1996; Haese et al, 1997; Stephan et al, 1997; Woodrum et al, 1998). The cutoff for %fPSA that optimizes sensitivity and specificity for cancer detection depends on prostate size because overlap in %fPSA is greatest among men without cancer who have enlarged prostates and men with cancer in the setting of prostate enlargement (Catalona et al, 1995). This group demonstrated that using a %fPSA cut point of 23% in men with PSA levels between 4 and 10 ng/mL and a prostate volume of less than 40 cm^3 could yield 90% sensitivity. However, for men with larger prostates, the %fPSA cut point dropped to 14% in order to maintain this degree of sensitivity.

The recommended and FDA-approved use for %fPSA remains for men with PSA levels within the diagnostic gray zone of 4 to 10 ng/mL. However, many clinicians use this ratio to aid in the decision making process regarding repeat biopsy (Stephan et al, 1997; Hayek et al, 1999; Djavan et al, 2000). For an initial biopsy, %fPSA ranges of 18% to 25% are commonly suggested; however, a widely accepted cutoff value has yet to be determined. For a repeat biopsy, Stephan and colleagues (1997) reported a 5% cancer miss rate when using a %fPSA value of 21% to trigger rebiopsy. A study by Hayek and coworkers (1999) illustrated a 16% positive rebiopsy rate regardless of %fPSA and concluded that this derivative was unable to provide further risk stratification for men in their population. Djavan and colleagues concluded that %fPSA is an accurate predictor of prostate cancer at rebiopsy. This group identified a %fPSA of 30% as the most accurate predictor of cancer in repeat biopsy specimens. However, until more series mature, the aggressiveness of this application in screening and follow-up biopsies should be tailored on a case-by-case basis (Luderer et al, 1995; Catalona, 1996; Partin et al, 1996b; Stephan et al, 1997; Catalona et al, 1998; Hayek et al, 1999; Djavan et al, 2000).

Classification of free PSA isoforms can be done by assessing the presence or absence of internal cleavages, in which case the respective "forms" are termed "nicked" or "intact." **PSA originates with a 17–amino acid chain that is cleaved to yield**

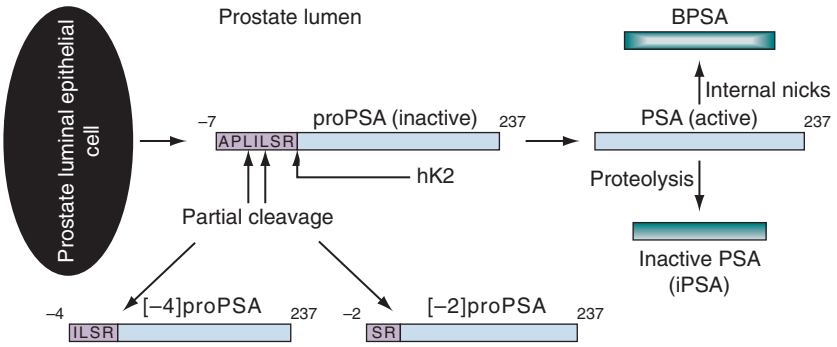

Figure 98–6. Differential cleavage and activation of pro–prostate-specific antigen (PSA). ProPSA is released from the prostate epithelial cell with a 7–amino acid leader sequence. hK2 cleaves the amino acid leader to activate PSA. Active PSA undergoes proteolysis to yield inactive PSA (iPSA) and may also undergo internal degradation to form benign PSA (BPSA). Partial cleavage of the 7–amino acid leader sequence yields inactive forms of proPSA (i.e., [–2]pPSA or [–4]pPSA).

a precursor inactive form of PSA termed proPSA (pPSA) (Zhang et al, 1995; Kumar et al, 1997, 2000; Mikolajczyk et al, 1997, 2001, 2002; Peter et al, 2001). As depicted in Figure 98–6, **the precursor form of PSA contains a 7–amino acid pro-leader peptide, in addition to the 237 constituent amino acids of mature PSA, and is termed [–7]pPSA.** Once released, the proleader amino acid chain is cleaved at the amino terminus by hK2, converting pPSA to its active 33-kD PSA form. In addition to hK2, pPSA may be activated to PSA by other prostate kallikreins, including hK4 (Takayama et al, 1997). Incomplete removal of the 7–amino acid leader chain has led to the identification of various other truncated or clipped forms of pPSA. These include pPSAs with 2, 4, and 5 leader amino acids ([–2]pPSA, [–4]pPSA, and [–5] pPSA) (Zhang et al, 1995; Kumar et al, 1997, 2000; Mikolajczyk et al, 1997, 2001, 2002; Peter et al, 2001). **With cellular disruption, these inactive forms circulate as free PSA and may constitute the majority of the circulating free PSA in patients with prostate cancer** (Mikolajczyk et al, 1997) (Fig. 98–7).

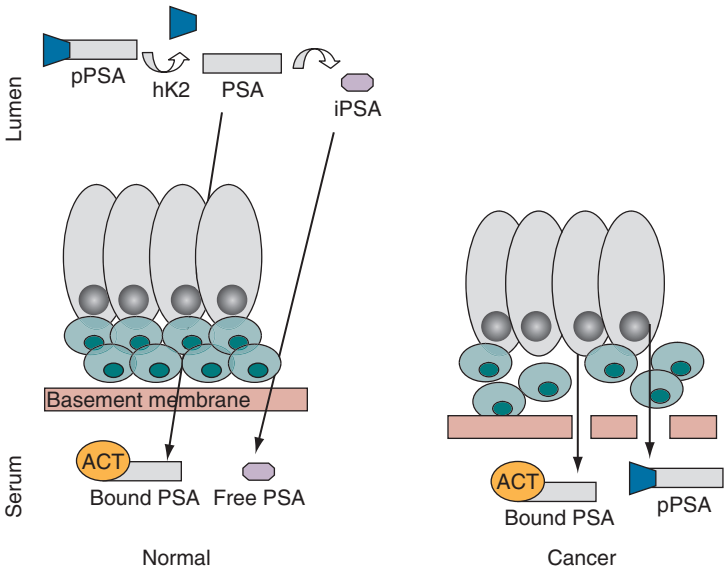

Figure 98–7. Prostate-specific antigen (PSA) synthesis in normal versus cancer tissue. ProPSA is secreted into the lumen, where the 7–amino acid leader sequence is cleaved by hK2 to yield active PSA. Some of the active PSA diffuses into the serum, where it is bound to proteases such as α_1-antichymotrypsin (ACT). The luminal active PSA undergoes proteolysis, and the resulting inactive PSA (iPSA) may also enter the circulation to circulate in the unbound or free state. In prostate cancer, loss of the tissue architecture may permit a relative increase in bound PSA and proPSA in serum.

Reports by Mikolajczyk and colleagues (2000, 2001) have revealed significantly elevated levels of these truncated forms of pPSA in prostate cancer tissue. Incomplete cleavage and processing of pPSA may contribute to the relative increase of these PSA isoforms identified in prostate cancer tissue. One of these clipped forms that is cleaved between leucine 5 and serine 6 of the propeptide has been termed [–2]pPSA. The decreased PSA processing in prostate cancer may result in a relative increase in pPSA and its cleaved forms, in particular [–2]pPSA. Immunohistochemical studies by Mikolajczyk and colleagues (2001) have demonstrated increased binding of monoclonal antibodies recognizing [–2]pPSA in prostate cancer tissue. Measuring the ratio of this clipped form of PSA to total PSA may serve as a strong discriminator between men with and without prostate cancer. These truncated forms in serum are being studied as potential prostate cancer markers.

From a clinical point of view, the present literature associates some isoforms with malignant prosate cells ([–2]proPSA) and others with BPH (BPSA) (Canto et al, 2004; Slawin et al, 2005). Two studies (Khan et al, 2003; Sokoll et al, 2003) support these findings regarding cancer detection and cancer "aggressiveness," demonstrating a positive diagnostic impact of pPSA in the early detection of prostate cancer in men with total PSA levels between 2.5 and 4 ng/mL and between 4 and 10 ng/mL. In the study by Sokoll and colleagues (2003), %pPSA detected up to 75% of cancers and avoided 59% of unnecessary biopsies (compared with 33% when %fPSA was applied) in men presenting with PSA levels between 2.5 and 4 ng/mL. In addition, studies by Catalona and colleagues (2003, 2004) showed an improved prostate cancer detection rate among men with total PSA between 2 and 4 ng/mL, where the ratio of proPSA ([–2]proPSA) to fPSA (%proPSA) spared nearly 20% of unnecessary biopsies while %fPSA only spared 10%. They also demonstrated—for PSA between 4 and 10 ng/mL—a 90% sensitivity and 31% specificity with %proPSA compared to only 20% (specificity) with %fPSA. Recently, in a multicenter validation effort sponsored by the National Cancer Institute (NCI) Early Detection Research Network (EDRN), Sokoll and colleagues (2008b) demonstrated excellent receiver operator characteristic (ROC) curves for the %[–2]proPSA assay for the diagnosis of prostate cancer. Likewise, a single institution study (Bangma et al, 2004) and a large multicenter study (Lein et al, 2005) showed no improvement in diagnostic accuracy when comparing [–5, –7] proPSA and the corresponding ratios with tPSA or f/tPSA. Further studies using other proPSA forms or tumor-associated proteins should be done.

Another isoform of fPSA, referred to as benign PSA or BPSA, represents a cleaved form of PSA that has been identified in tissue

from the nodular BPH transition zone tissue (Chen et al, 1997; Mikolajczyk et al, 2000; Wang et al, 2000; Canto et al, 2004; Slawin et al, 2005). In a study by Marks and colleagues (2001), BPSA discriminated men with symptomatic BPH from men without BPH. Although serum BPSA alone is unlikely to differentiate between hyperplasia and cancer, in combination with assays for pPSA, it may allow additional discrimination.

In addition to BPSA and pPSA, other isoforms of PSA have been identified in serum and have demonstrated promise as additional tools to aid in clinical detection of prostate cancer (Mikolajczyk et al, 2001, 2002; Peter et al, 2001). An additional form of pPSA that is found intact and inactive and that does not form a complex with ACT has been identified. This form of pPSA has been termed intact PSA and has been identified in human prostate cancer cells (Nurmikko et al, 2000, 2001; Steuber et al, 2002). It is likely that pPSA exists in various forms in tissue and serum from men with and without prostate cancer. Preliminary studies have demonstrated that the ratio of intact to free PSA may improve the accuracy of prostate cancer detection (Nurmikko et al, 2000, 2001; Steuber et al, 2002). Although encouraging, these studies using subfractions of fPSA await further scrutiny.

Human Kallikrein 2 (hK2)

The human kallikrein hK2 has been found to share many important properties with PSA and has demonstrated potential as another prostate cancer tumor marker (Young et al, 1992; Darson et al, 1997; Kumar et al, 1997; Rittenhouse et al, 1998; Lovgren et al, 1999; Becker et al, 2000; Yousef et al, 2001a). **Among many similarities, hK2 and PSA share 80% amino acid homology** (see Fig. 98–1), **exhibit similar specificity for prostate tissue, and are both hormonally regulated by androgens.** The exact function of hK2 remains under further study, but this protease has been shown to perform enzymatic activities, one of which is to activate the zymogen (pPSA) to the active PSA through cleavage of the amino acid presequence (see Fig. 98–7) (Young et al, 1992; Kumar et al, 1997; Yousef et al, 2001a).

The concentration of hK2 in samples of prostatic tissue, seminal fluid, and serum is many times lower than that of PSA (Young et al, 1992; Darson et al, 1997; Lovgren et al, 1999). In prostatic tissue, the hK2 mRNA concentration represents only 10% to 50% of PSA mRNA concentrations, and in semen and serum samples, the concentration of hK2 is 1% to 3% that of PSA (Young et al, 1992; Darson et al, 1997; Lovgren et al, 1999). Together with specificity issues, cross-reactivity with PSA and the detection limits of the available assays for these low hK2 concentrations challenged earlier analytic experiments. However, the development of hK2 purification techniques and more specific monoclonal antibodies has resulted in more reliable assays and thus increased study in the clinical setting (Piironen et al, 1996; Finlay et al, 1998; Klee et al, 1999; Becker et al, 2000).

Immunohistochemical studies revealed different tissue expression patterns for hK2 and PSA. In benign epithelium, PSA is intensely expressed compared with the minimal immunoreactivity of hK2 (Tremblay et al, 1997; Darson et al, 1999). **In contrast, in cancerous tissue hK2 is expressed more intensely.** Furthermore, hK2 immunohistochemically stains the different Gleason grades of prostate cancer differently than does PSA. This inverse staining relationship of hK2 is seen as intense staining in high-grade (Gleason primary grade 4 or 5) cancers and lymph node metastasis compared with minimal staining in low-grade (Gleason primary grade 1 to 3) cancers and even weaker association in benign tissue, in which PSA exhibits intense staining (Darson et al, 1997, 1999; Tremblay et al, 1997; Kwiatkowski et al, 1998).

The development of improved monoclonal antibodies for hK2 has minimized the previous cross-reactivity with PSA and permitted more accurate measurement of hK2 in serum samples (Finlay et al, 1998; Klee et al, 1999; Becker et al, 2000). Since the introduction of these assays, many researchers have demonstrated elevated levels of hK2 in men with prostate cancer compared with men without cancer (Becker, 2000). Furthermore, men with low-grade disease have lower concentrations of serum hK2 than men with more aggressive cancer (Darson et al, 1999; Becker et al, 2000). Application of the ratio of hK2 to free PSA (hK2/fPSA) allows discrimination between benign tissue and cancer (Kwiatkowski et al, 1998). For men with tPSA in the 4 to 10 ng/mL range, hK2/fPSA significantly differentiated prostate cancer from BPH, whereas hK2/tPSA did not (Becker et al, 2000). Data from a multicenter study demonstrated a statistically significant difference between men with biopsies positive for cancer, looking at hK2 alone and in combination with fPSA/tPSA (Kwiatkowski et al, 1998). Combining %fPSA and hK2/fPSA, Partin and associates (1999) demonstrated an increased cancer detection rate within the tPSA range of 2 to 10 ng/mL. Furthermore, this group was able to identify up to 40% of men with cancer in the 2 to 4 ng/mL range measuring hK2/fPSA.

Additional reports have demonstrated the ability of hK2 levels to predict pathologic outcome and to aid in repeat prostate biopsy decision making (Haese et al, 2000, 2003; Nam et al, 2001). Haese and colleagues (2000, 2003) evaluated the ability of hK2 levels to distinguish between pathologic organ-confined and non–organ-confined prostate cancer. In univariate ROC and multivariate logistic regression analyses, hK2 optimally predicted organ-confined disease. Nam and coworkers (2001) showed that men found to have cancer upon repeat biopsy had higher hK2 and hK2/fPSA levels than men with a negative biopsy, suggesting that hK2 may be helpful in improving the selection criteria for repeat biopsy. Recently, Vickers and coworkers (2008) used a large cohort of men to combine, within a multivariable model, hK2 with PSA and its isoforms to better predict prostate cancer detection. Although these results are encouraging, further evaluation is under way before recommending widespread application of hK2 to the clinical armamentarium of prostate cancer tumor markers.

Additional Kallikrein Tumor Markers

In addition to PSA (hK3) and hK2, 15 other kallikrein genes have been identified (reviewed in Paliouras et al, 2007). The expression products of these genes have demonstrated diagnostic potential as prostate cancer tumor markers. Many of these proteases have a highly conserved structural organization and have been shown to contribute to biologic events such as angiogenesis and growth factor release (Diamandis and Yousef, 2001). Study of these proteins suggests interaction among the kallikreins in pathways that affect normal physiologic and pathologic processes (Yousef and Diamandis, 2002). Among these genes, the studies have evaluated some of the potential of the expression products of *KLK4*, *KLK11*, *KLK14*, and *KLK15* as biomarkers for prostate cancer.

KLK4

The gene *KLK4* encodes hK4 and is predominantly expressed in basal cells of the normal prostate (Xi, 2004). Although its function and structure continue to be evaluated, current studies suggest that this peptide is not targeted for secretion and is predominantly localized to the nucleus (Xi et al, 2004). It was originally

demonstrated to be unique to prostatic expression, but improved reverse transcription polymerase chain reaction (PCR) techniques have identified *KLK4* mRNA expression in the testis, adrenal, uterus, and thyroid (Nelson et al, 1999). Although hK4 expression has been shown to occur in both normal and cancerous prostate tissue, *KLK4* mRNA was found to be expressed at higher levels in the majority of prostate cancer tissues compared with matched normal prostate tissues (Obiezu et al, 2002; Xi et al, 2004) and may represent a proliferative factor (Klokk et al, 2007). In ovarian cancer, hK4 is associated with advanced disease. Further evaluation is under way to explore the value of this kallikrein as a biomarker for prostate cancer.

KLK11

The gene *KLK11* encodes hK11, formally referred to as hippostasin or PRSS20 (Diamandis et al, 2002). It was initially found in the serum of cancer patients, but further studies have demonstrated that this protease may aid in differentiating prostate cancer patients from those with BPH, because immunofluorometric assays have displayed lower hK11 values in prostate cancer patients compared with men with BPH (Nakamura et al, 2003a, 2003b). Applying the ratio of hK11 to total PSA resulted in a further reduction in unnecessary biopsies. Nakamura and colleagues (2003a, 2003b) have demonstrated that at 90% sensitivity, the ratio of hK11 to total PSA has a specificity of 51.5%. Confirmatory studies are under way for this promising biomarker.

KLK14

Yousef and coworkers (2001b) have identified *KLK14* of the kallikrein gene family. Expression of this gene has been demonstrated in brain, spinal cord, prostate, thyroid, and testis. The expression of hK14 is similar to that of hK2 and PSA and has been noted in the secretory epithelial cells of the prostate (Hooper et al, 2001). Rabien and colleagues (2008) demonstrated the association of *KLK14* levels with biochemical progression after radical prostatectomy among men with prostate cancer. Elevated levels of this protein have been demonstrated in prostate cancer tissues compared with normal prostate tissues. Although it is still early in development, this marker may aid in prognosis because this protease appears to correlate with aggressiveness of disease (Yousef et al, 2003; Rabien et al, 2008).

KLK15

The gene *KLK15* encodes hK15. Although it is most notably expressed in the thyroid, lower levels of hK15 expression have also been measured from the prostate, salivary gland, adrenal, colon, testis, and kidney (Yousef et al, 2001). Using a human prostate cancer cell line, *KLK15* expression was found to be upregulated compared with normal prostate tissues (Yousef et al, 2001c). As with hK14, hK15 has shown an association with tumor aggressiveness and has potential as a diagnostic and prognostic prostate cancer biomarker (Stephan et al, 2003).

Proteomic Patterns

A number of years ago, the "holy grail" of cancer biomarkers was to develop protein signatures of the disease. The goal was to discern proteomic patterns that could serve as fingerprints that would not only identify the presence of cancers but also subclassify patients into groups that may have different prognoses or potential responses to therapy. Application of sensitive tools in the study of molecular biology is becoming essential for the discovery of novel tumor markers. Identifying unique genetic expression in cancer states compared with normal tissues will provide not only insight into the molecular etiology of disease but also novel methods for detection. In addition to identifying genes that are either on or off, identification of post-translational events that are unique to disease states will undoubtedly become invaluable in the discovery of cancer biomarkers. The identification of biomarkers from human serum and body fluids has been assessed by a variety of proteomic technologies. Much of the approach to develop such fingerprints came from the use of mass spectrometric (MS) analysis of blood and/or urine samples. The early MS studies used large machines with relatively low throughput. To increase the ability of this approach to analyze larger numbers of samples more rapidly, an approach known as surface-enhanced laser desorption ionization (SELDI) was developed. A large number of these instruments were placed in centers around the world. SELDI separates relatively small fragments of proteins (peptides) and uses these patterns to distinguish patients with cancer from those with benign diseases (Malik et al, 2007). Although in principle this approach is sound, it suffers from several significant drawbacks. These include the lack of ability to define the individual protein components and therefore the inability to produce more typical antibody-based tests. Also, while operating at single institutions, the instruments performed in a reasonably reproducible fashion, but the design of the instruments was such that no two instruments performed with sufficiently high levels of concordance. After extensive investigation, it was concluded that SELDI-based approaches to analyzing serum samples are not a reliable tool with which to diagnose prostate cancer, at least at this time (McLerran et al, 2008).

In order to address these limitations, MS approaches have been developed that reveal the identities of the components. Prior to applying these approaches, a significant amount of attention has been spent on standardizing protocols by which tissue, blood, and urine samples have been collected. The apparently subtle differences in collection techniques have been shown to result in somewhat major and therefore confounding differences in proteomic patterns (Diaz et al, 2008). Much progress has been made toward this end, and the more recent findings have demonstrated the ability of MS approaches to distinguish diseased and normal populations. These include the use of two-dimensional difference gel electrophoresis (2D-DIGE) as a means to identify serum markers for the differentiation of more aggressive prostate cancer (Byrne et al, 2009). Similar studies have been performed with urine samples to develop a "urine proteome" for the identification of prostate cancer (M'Koma et al, 2007). The idea of a fingerprint for the detection and classification of prostate cancer is still one that holds much promise but still needs further investigation and validation.

Endoglin

Endoglin is a transmembrane glycoprotein that is otherwise known as CD105. Although the expression of this protein is not prostate restrictive or even prostate cancer selective, it has been shown by a number of groups to be expressed in vascular endothelial cells and therefore found to be elevated in cancerous states. Investigators have examined the possibilities for detecting endoglin in the plasma as well as in the urine of men with prostate cancer. When examining the plasma levels of the protein, the investigators demonstrated that with approximately 3 years of follow-up, preoperative endoglin levels correlate with an increased risk for biochemical progression of

prostate cancer (Svatek et al, 2008). Similarly, when endoglin is used in combination with several other blood-based biomarkers, further discrimination regarding the risk for biochemical recurrence is provided (Svatek et al, 2009). Endoglin is also expressed in the urine of men with prostate cancer compared with those who are biopsy negative after each group received a DRE. These urinary levels correlate with tumor volume and appear to be more accurate than PSA in the discrimination of biopsy outcome (Fujita et al, 2009). These same investigators also examined the serum levels of endoglin and demonstrated that although the serum levels were not predictive of a diagnosis of prostate cancer, it was possible to distinguish between organ-confined and non–organ-confined disease. These initial studies have been intriguing and certainly will need validation in multi-institutional trials.

PCA-3

Using differential display and Northern blot analysis to compare normal and prostate cancer tissue, Bussemakers and colleagues (1999) identified the *DD3* prostate-specific gene on chromosome 9q21-22. Study of this gene has determined that it may function as noncoding RNA because it has been found to be alternatively spliced, contains a high density of stop codons, and lacks an open reading frame. **Expression of the DD3^{PCA-3} protein has been localized to prostatic tissue and has been found in 95% of prostate cancer and prostate metastasis specimens.** de Kok and colleagues (2002) developed a real-time quantitative reverse transcriptase PCR (QRT-PCR) assay for DD3 and showed **66-fold upregulation of this protein in cancerous tissues compared with normal control tissues. Furthermore, DD3 was detected from specimens containing as little as 10% cancer, indicating that this test was capable of finding cancer within a large background of normal cells.** Using this discovery, Hessels and coworkers (2003) developed a test to detect DD3 in urine specimens from men, following prostate massage and biopsy. Using QRT-PCR to analyze the urine from these men undergoing biopsy for serum PSA greater than 3 ng/mL, the test demonstrated 67% sensitivity and 83% specificity for men diagnosed with cancer after confirmatory biopsy. As also reported, a negative predictive value of 90% supports the potential of the test as a modality to reduce the number of invasive diagnostic procedures, such as transrectal ultrasonography (TRUS) biopsy. Several clinical studies and further assay development are currently under way for evaluation of DD3/PCA-3.

This urine-based biomarker has been investigated most extensively and will soon be evaluated by the FDA. After its identification in the prostate cancer tissue, investigators have been able to demonstrate its detection using RT-PCR within the urine of men with prostate cancer. To enhance the sensitivity of such assays, urine samples have been collected after an "attentive" digital rectal examination, which conceptually will loosen and shed the cells within the prostate and therefore enhance the chance of detection (Fig. 98–8). Using this approach, urine-based assays have been developed that can detect prostate cancer (Tinzl et al, 2004). Several clinical studies have been performed that evaluate the utility of PCA-3 to serve as a prostate cancer biomarker. Some studies have focused on the utility of this biomarker in the setting of individuals who have undergone at least one biopsy of their prostate for the determination of prostate cancer (Hessels et al, 2003; van Gils et al, 2008). Assaying PCA-3 has been shown to have some utility to discriminate among those who would benefit from a second biopsy in that these individuals end up with prostate cancer (Deras et al, 2008). PCA-3 has also been reported to be associated with Gleason score of men with the disease in that higher levels of the message appear to correlate with Gleason score. PCA-3 levels are reported as a ratio of PCA-3 message over PSA message within the urine. The levels of PSA message are therefore used as a means to normalize these levels. Interestingly, in a recent report, it was noted that urinary levels of PCA-3 do not appear to be elevated with increasing prostate size but do correlate with tumor volume (Whitman et al, 2008). Although this supports the concept that enlarged prostates would not by themselves result in higher PCA-3 levels, it is somewhat surprising because the PSA message is used as a normalization factor to evaluate PCA-3 levels. In men with enlarged prostates, one would expect to have an elevated level of PSA message in urine as a result of the increase in cells in the prostate. Also, a breakdown of architecture would result in more PSA message being released into the urine and therefore an actual decline in urine-based PCA-3 message. The investigators actually did not note any change in PCA-3 levels and do not provide an explanation for this result (Whitman et al, 2008).

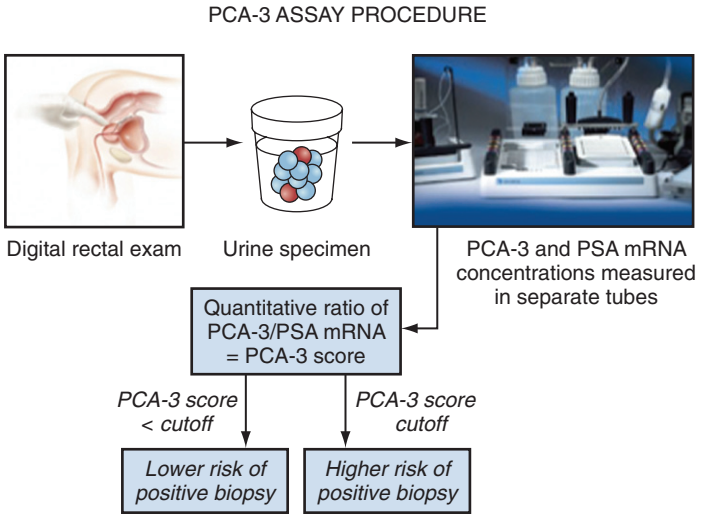

Figure 98–8. PCA-3 assay protocol. Following "attentive" digital rectal exam, urine is collected. RT-PCR determines the mRNA levels for PCA-3 and PSA. The ratio between PCA-3/PSA determines the PCA-3 score. Prostate cancer risk level suggests need for biopsy. (From Groskopf J, Aubin SM, Deras IL, et al. APTIMA PCA3 molecular urine test: development of a method to aid in the diagnosis of prostate cancer. Clin Chem 2006;52:1089–95.)

Recently, the PCA-3 diagnostic test has been standardized for whole urine, in an easy-to-use platform retaining the 69% sensitivity and 79% specificity (area under curve [AUC]-ROC = 0.746) in men undergoing prostate biopsy (Groskopf et al, 2006). However, the AUC-ROC was only 0.69 in a larger cohort of men (Deras et al, 2008). The molecular assay has been further evaluated in a multicenter trial in Holland (van Gils et al, 2007) and in the United States (Sokoll et al, 2008a), where the test has also been performed similarly. Although these results are promising, further validation is necessary to understand fully the potential clinical utility of this test. The U.S. FDA has not yet approved the PCA-3 diagnostic test, but several reference laboratories that run the test are available in the United States.

CELLULAR BIOMARKERS

Circulating Tumor Cells

There has been significant interest over the last several years in the development and evaluation of tests that can detect circulating tumor cells. The excitement in this area of research goes back fifteen years when investigators using polymerase chain reaction (PCR)–based approaches demonstrated PCR positivity for PSA among men with advanced prostate cancer (Katz et al, 1994). The problem with this approach was that PCR positivity was also found among men with localized prostate cancer, and even in men without prostate cancer (Sokoloff et al, 1996; Thiounn et al, 1997).

As described earlier in this chapter, one of the unmet needs in prostate cancer is the ability to use a marker that can predict the presence of disease that either has the ability to spread outside of the prostate or has already spread outside of the prostate. The concept behind using detection of epithelial cells in blood is that, if present, they might indicate the presence of tumor cells that have left the prostate and therefore perhaps metastatic disease.

Using a combination of antibodies that are designed to detect epithelial cells in blood, a system has now been developed that can be used with clinical samples. The CellSearch Circulating Tumor Cell Kit is now approved by the FDA for use in disease monitoring. This system is produced by Veridex (Raritan, NJ). The CellSearch system uses antibodies against CD45, EpCAM, and cytokeratins 8, 18, and/or 19. Positive cells are indicated by negative staining for CD45 and positive staining for EpCAM and the various cytokeratins. Using a magnetic core separation system, blood samples are analyzed using the disposable cartridges provided by the system. Men with prostate cancer can have samples taken before and after a therapeutic regimen. Response to therapy is then measured by alterations in the numbers of positive cells that are observed in the system. Based upon the studies performed using this system, a circulating tumor cell (CTC) count of 5 or more cells per 7.5 mL of blood at any time during the course of the disease has been associated with a poor prognosis (Shaffer et al, 2007). A principal limitation to this approach is that only cells that stain positively for EpCAM and the cytokeratins will be detected. Any degradation of cell surface molecules, or the cells themselves, will result in a failure to detect cells that may indeed to be present in blood. In a study of 422 patients with metastatic prostate cancer, using the Veridex platform, the investigators demonstrated that there was a difference between baseline numbers of cells and those present 2 to 5 weeks post-treatment (Fig. 98–9). For example, 57% of the patients had greater than 5 cells per 7.5 mL of blood before treatment, and 39% had greater than 5 cells per 7.5 mL after treatment (Shaffer et al, 2007).

Using a similar type of approach, investigators at the Harvard Medical School developed their own system to detect circulating tumor cells in blood. This microfluidic system has a number of advantages over the FDA-approved system. This "CTC-Chip" uses microposts that are embedded with anti-EpCAM antibody. The investigators have reported that they can detect 1 EpCAM-positive cell among one billion blood cells. This system provides the opportunity to subsequently isolate and therefore further study the circulating tumor cells (Nagrath et al, 2007).

In a more recent study, using the cutoff of greater than or equal to 5 CTCs per 7.5 mL of blood, patients were classified into populations that were considered to have either favorable or unfavorable responses. Among 276 men, they demonstrated that the group with the higher numbers of CTCs had a shorter overall survival and that this prediction was more accurate than the use of PSA (de Bono et al, 2008).

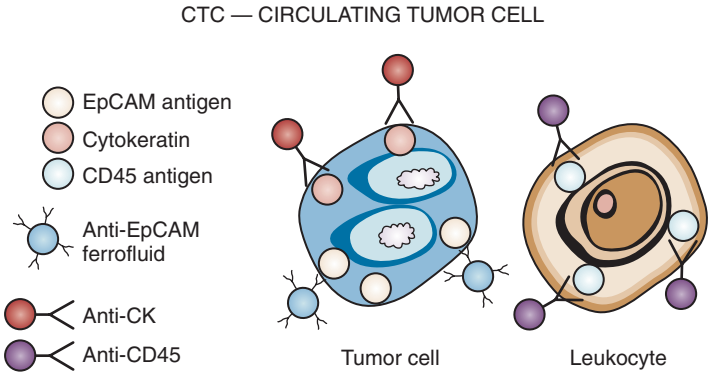

Figure 98–9. CellSearch CTC: Circulating Tumor Cell (Veridex) cell enumeration system. EpCAM, epithelial cell adhesion molecule; CK, cytokeratin; CD45, CD stands for "*cluster of differentiation,*" which was originally called *leukocyte common antigen*. The anti-EpCAM ferrofluid captures the cells, and they are then validated with cytokeratin-positive and CD45-negative staining.

In general, the potential use of CTCs as a measurement of prostate cancer cells appears to be promising. At the same time, we must realize that the markers being used to select cells from the blood can detect epithelial cells but are not tumor cell–associated. This may lead to the detection of cells that are not cancerous but actually represent normal epithelial cells in blood. On the other hand, the sensitivity of the currently used CTC assays may be somewhat limited in that tumor cells may exist at metastatic sites, such as in bones, without being easily detectable in blood. It is clear that the integration of more specific antibodies, as well as other approaches that can more accurately and sensitively detect tumor cells, may further enhance the utility of these types of assays.

Autoimmune Reponses

Although we classically think of biomarkers as substances that are abnormally expressed by the tumors and which are then detectable in a body fluid such as urine, blood, or prostatic fluids, this is not the only type of biomarkers that may be predictive. The response of the body to the presence of the cancer cell can itself be used as biomarkers. The immune response to the presence of a tumor can be predictive. Using a high-throughput approach, investigators at the University of Michigan were able to develop autoimmune profiles that could distinguish individuals with prostate cancer from those without the disease (Wang et al, 2005). Although the results appeared to be promising, further studies have not validated these findings. It is still likely that the immune response to tumors can indeed be used to detect tumors, or even the presence of metastases.

MOLECULAR BIOLOGY

New understanding of the molecular biology of carcinogenesis and prostate cancer is beginning to yield a new era in prostate cancer tumor research. Applications of sensitive tools are providing clinicians with improved methods for diagnosis and management of disease. These advances in molecular oncology have vastly improved our current understanding of prostate cancer etiology and molecular pathogenesis and have identified the

importance of genomic alterations, epigenetic modifications, and gene-protein expression that contribute to the development and progression of prostate cancer.

Future Directions in Prostate Cancer Biomarker Research

Gene Susceptibility Loci

The presence of a positive family history has been known to be a risk factor for the development of prostate cancer. A number of susceptibility loci probably involved in the risk of development of cancer have been identified (Lichtenstein et al, 2000) through studies of affected families with prostate cancer. Prostate cancer susceptibility genes have been located on chromosome 1q24-25 (*HPC1*), 1q42-2-q43 (*PCaP*), 1p36 (*CAPB*), 16q23.2, 17p11 (*ELAC2* or *HPC2*), 20q13 (*HPC20*), and Xq27-28 (*HPCX*) (Monroe et al, 1995; Lichtenstein et al, 2000; Nam et al, 2003; Simard et al, 2003). Key susceptibility genes that have been proposed to be involved in the inflammatory response are *MSR1* and *RNAEL* (DeMarzo et al, 2003).

Within these families, genetic polymorphisms are likely to occur at higher frequency and contribute to the increased risk of prostate cancer. **Polymorphic variants in genes encoding the androgen receptor (AR), CYP17, and 5α-reductase type 2 (SRD5A2) have been evaluated and suggest a role for infection and inflammation in the development of prostate cancer** (DeMarzo et al, 2003). Other polymorphic variants in genes encoding CYP3A, vitamin D receptor, PSA, GSTT1, GSTM1, GSTP1, IGF-1, and IGF-binding protein 3 have also been studied. Among these, GSTP1 and IGF have shown a correlation with the presence of cancer on biopsy of men with elevated PSA levels (Nam et al, 2003).

Although this information has aided and continues to contribute to the study of prostate cancer, familial susceptibility genes and polymorphisms are unlikely to account completely for the development of prostate cancer. Development of a large-scale test for these genes as a screening modality in the male population would probably not be very effective. Other factors such as diet, lifestyle, and chronic inflammation have also been implicated in the cause and progression of prostate cancer (Nelson et al, 2002; Foley et al, 2004; Montironi et al, 2004).

microRNAs

Based upon the realization that a majority of the DNA in the genome does not encode protein sequences, the utility of these sequences in the regulation of gene expression has been under intense investigation. Among the most important components of this regulation are microRNAs (miRNAs). These are small (usually less than 22-nucleotide (nt) sequences that are involved in the regulation of mRNA. With the association of a number of these miRNAs with cancer, the idea of using these nucleotides as markers of the disease has been attractive. A test has been developed to detect miRNAs in the plasma of men with prostate cancer. Although the study populations were small, the investigators demonstrated that detection of miR-141 has excellent potential for distinguishing men with prostate cancer from those without the disease (Mitchell et al, 2008). Additionally, microRNAs assays have been developed that can robustly detect even small amounts of these small RNAs in human tissues (Siva et al, 2009). Although these findings need to be expanded to larger populations of individuals, there is interesting data to demonstrate that this is an interesting family of potential markers.

α-Methylacyl Coenzyme A Racemase

The α-methylacyl coenzyme A racemase *(AMACR)* gene, located on chromosome 5, is upregulated in prostate cancer tissues (Luo et al, 2001; Rubin et al, 2002). AMACR functions as an enzyme responsible for the beta-oxidation of branched-chain fatty acids obtained in diets consisting of beef and dairy products. Upregulated AMACR mRNA levels have been identified using immunohistochemical analysis and Western blot assays in clinical prostate cancer tissue. Luo and colleagues (2002) demonstrated that 88% of prostate cancer cases and both untreated metastasis and hormone-refractory prostate cancers were strongly positive for AMACR. Rogers and colleagues (2004) measured AMACR levels in the voided urine from 26 men following transrectal prostate biopsy. Elevated AMACR levels were detected in 18 of 26 (69%) of the men and provided 100% sensitivity (12 of 12 positive biopsies) and 58% specificity. Immunohistochemical studies by Rubin and coworkers (2002) have shown that *AMACR* expression in biopsy tissue may provide 97% sensitivity and 100% specificity for prostate cancer detection. Furthermore, in combination with other markers, such as TP63, that aid in identifying basal cells absent in prostate cancer, measurement of AMACR has potential for the development of molecular probes to aid in the detection of prostate cancer.

However, there is new literature examining an expanded role for AMACR in noninvasive CaP screening. For example, Rogers and coworkers (2004) assessed the feasibility of a urine test for CaP based on measuring AMACR levels. They performed immunoblot analysis on voided urine from 26 men with suspected CaP following transrectal prostate biopsy. Elevated AMACR levels were detected in 18 of 26 (69%) of these patients. All 12 men with CaP demonstrated AMACR-positive urine (100% sensitivity), while 5 of 12 men without cancer had false-positive urine tests (58% specificity). Fifty percent of men with atypical biopsies were positive for AMACR as well. Zielie and coworkers (2004) developed an assay to detect CaP based on urine samples collected after prostatic massage. The researchers used polymerase chain reaction (PCR) to detect AMACR levels from total cellular RNA collected from the spun urine. When AMACR levels were normalized to cellular PSA mRNA levels, a diagnostic cutoff value of 2 SDs above the mean correctly identified all 9 cancer-free controls (100% specificity) and 7 of 10 (70% sensitivity) patients with CaP. Such assays for the detection of CaP from urine specimens show early promise but still require additional investigation.

Prostate Breast Overexpressed Gene1 *(PBOV1)* or *UROC28*

An and colleagues (2000) have cloned and characterized a novel gene, *UROC28,* found to be overexpressed in prostate, breast, and bladder carcinomas. This gene is on chromosome 6q23-24, and the expression protein product is measurable in serum. Early immunohistochemical studies have demonstrated differential expression and characterization between normal and cancerous tissues. This group has also identified and measured the protein UC28 in serum. Application of the antibody to a ProteinChip and SELDI analysis has provided encouraging results that correctly distinguish cancer specimens from normal and BPH specimens. This preliminary work remains under investigation.

Annexin A3

Among the potential urine-based proteins that can be used as biomarkers for prostate cancer is annexin A3. This protein is part

of a family of calcium and phospholipid binding proteins that have been shown to be altered in cancer (Wozny et al, 2007; Köllermann et al, 2008). Recently, using an immunoblot in which urine samples were blotted onto a membrane and probed for annexin A3 using an antibody, investigators were able to determine the potential clinical utility of urine-based annexin A3, either as a stand-alone biomarker or together with PSA. In a blinded study that consisted of training and evaluation sets of 243 and 264 men, respectively, the investigators were able to show that the addition of annexin A3 added to the ability of PSA to discriminate between these groups. Annexin A3 levels are inversely related to the presence of prostate cancer. Although this marker appears to have potential utility, further studies are certainly warranted to validate this work.

Hepsin

Complementary DNA (cDNA) microarray analysis has demonstrated overexpression of hepsin in prostate cancer compared with normal prostate and BPH tissues (Luo et al, 2001; Magee et al, 2001; Stamey et al, 2001). Hepsin is a type II transmembrane serine protease and was originally found as a cDNA clone in a human liver cDNA library (Leytus et al, 1988). Immunohistochemical studies have shown abundant staining of hepsin in tumor cell membranes. Stephan and coworkers (2004) have shown hepsin staining in 90% of all cases of prostate cancer. Furthermore, these authors demonstrated that in 53% of cases hepsin overexpression was more than 10-fold in cancerous tissue. In addition to providing a method for cancer detection, hepsin expression may provide prognostic information that may be used to assess prostate cancer aggressiveness.

NMP 48 (50.8 kD)

Using proteomic patterns based on surface-enhanced laser desorption ionization–time-of-flight (SELDI-TOF) mass spectroscopy, Hlavaty and colleagues (2003) discovered a unique 50.8-kD protein. This protein was subsequently characterized as a vitamin

Key Points

- Today, most prostate cancer arises as clinically nonpalpable (stage T1c) disease with PSA between 2.5 and 10 ng/mL. The evolving demographics and natural history of prostate cancer have resulted in stage migration to nonpalpable, clinically localized (stage T1c) disease and a parallel reduction in mortality.
- Although PSA is widely accepted as a prostate cancer tumor marker, it is organ specific and not disease specific.
- PSA is normally found in low concentration in serum (ng/mL). In serum, PSA circulates in both bound and unbound forms. Three proteins that are known to bind to PSA in blood are α_1-antichymotrypsin (ACT), α_2-macroglobulin (A2M), and α_1-protease inhibitor (API).
- Although prostate cancer cells do not produce more PSA than benign prostate epithelium, the PSA produced from malignant cells appears to escape proteolytic processing. Thus men with prostate cancer have a greater fraction of serum PSA complexed to ACT and a lower percentage of total PSA that is free compared with men without prostate cancer.
- The serum half-life of PSA, calculated after removal of all prostate tissue, is 2 to 3 days.
- Uncomplexed PSA is cleared from the serum within 2 to 3 hours.
- Finasteride (5 mg) and other 5α-reductase inhibitors used for treatment of BPH have been shown to lower PSA levels by an average of 50%.
- Although saw palmetto has not been shown to affect PSA levels, possible contaminants of these unregulated supplements may include compounds that can alter PSA levels (i.e., PC-SPES, now off the market). Interpretation of PSA values should always take into account the presence of prostate disease, previous diagnostic procedures, and prostate-directed treatments.
- The role for %fPSA is more applicable to PSA levels less than 10 ng/mL because the positive predictive rate of total PSA greater than 10 to 20 ng/mL has been demonstrated to be as high as 80%.
- PSA originates as a 17–amino acid chain that is cleaved to yield an inactive precursor form of termed proPSA (pPSA).
- The current clinically relevant immunodetectable complexed forms of PSA are bound to ACT and, to a lesser extent, to API. The sum of these and other presently unknown PSA complexes is represented by the term complexed PSA (cPSA).
- Immunohistochemical studies reveal different tissue expression patterns for hK2 and PSA. In benign epithelium, PSA is intensely expressed compared with the minimal immunoreactivity of hK2. In contrast, in cancerous tissue hK2 is expressed more intensely.
- Polymorphic variants in genes encoding the androgen receptor (AR), CYP17, and 5α-reductase type 2 (SRD5A2) have been evaluated and suggest a role for infection and inflammation in the development of prostate cancer. Notable among these are the AR variant 7, which has been shown to be associated with more aggressive disease.
- Segments within the gene promoter that are composed of GC-rich regions are termed CpG islands. Alterations in the methylation status of these regions may affect gene expression and have been shown to play a role in carcinogenesis.
- The products of two hypermethylated genes that have been evaluated in prostate cancer development are glutathione-*S*-transferase P1 (GSTP1) and RAS association domain family protein isoform A (RASSF1A).
- The *AMACR* gene, located on chromosome 5, has been found to be upregulated in prostate cancer tissues.
- Expression of the $DD3^{PCA-3}$ protein has been localized to prostate tissue and has been found in 95% of prostate cancer and prostate metastasis specimens. This message has been used to develop a urine-based test for the disease.
- Circulating tumor cells are being used as novel tools to correlate with response to therapy, as well as provide valuable resources with which to study metastatic disease.
- The discovery of the gene fusions associated with prostate cancer has revealed the potential to develop new tools with which to characterize the disease, although the clinical utility of these fusions must still be evaluated.
- Given the novel biomarkers that have been developed, multiparametric testing would seem to be a logical application with the currently existing PSA tests.

D binding protein using peptide mass fingerprinting. Using preprocessed serum samples from men with prostate cancer, BPH, and no cancer, this group was able to identify correctly vitamin D binding protein in the samples from men with cancer. SELDI-TOF identified the protein in 50 of 52 (96%) cancer cases, 5 of 20 (25%) biopsy-confirmed benign cases, 3 of 10 (30%) BPH cases, and 2 of 50 (4%) normal controls. Validation studies are under way for this potential prostate cancer tumor marker.

Metabolites

One of the characteristics of cancer cells are modifications in their metabolism. The cancer cell, in general, uses a less efficient source of generating energy and therefore surviving. Even with the explosion of molecular biology and the large amount of information that has been learned about cell cycle regulation, little attention has been given to the differences that exist between the metabolic processes of the cancer cell versus normal cells. Using a high-throughput approach that combines chromatography with mass spectroscopy, a number of potentially important differences in metabolomic profiles have been observed when comparing prostate cancer tissue with normal tissue. Among the molecules profiled, one of the differences appearing is with sarcosine, which has been demonstrated in the urine of men with prostate cancer (Sreekumar et al, 2009). Although the average levels of urine-based sarcosine are indeed different between men with prostate cancer and those without the disease, from the data provided, it seems that a cutoff able to separate these populations in a clinically robust fashion is unlikely. Despite this, there certainly is potential for the use of cancer metabolites to serve as markers of the disease, and this is an area of active investigation.

SUMMARY

Early detection when cancer remains confined to the prostate will not only improve cure rates but also decrease mortality from this disease. Although the discovery and application of PSA have revolutionized current prostate cancer detection and management, stage migration and changes in the natural history of this cancer have outrun the currently maximized application of this tumor marker. Application of various PSA derivatives, although improving sensitivity, risks impairing specificity. Discovery of molecular derivatives of PSA and new kallikrein markers has also improved prostate cancer detection.

Innovations and new understanding in the field of molecular oncology have provided a host of potential prostate cancer tumor markers. Because prostate cancer has been shown to be a heterogeneous disease, application of a panel of markers will probably ultimately provide added sensitivity and specificity for detection of the disease. Identification of hypermethylated regions, such as for *GSTP1*, and over- and underexpressed proteins and genes, such as PCA-3, provides greater diagnostic and prognostic potential to improve detection of prostate cancer. As these discoveries mature, development of these markers from research into clinically applicable tools will improve detection and management of prostate cancer.

Early Detection, Diagnosis, and Staging of Prostate Cancer

Stacy Loeb, MD ● Herbert Ballentine Carter, MD

Early Detection

Staging

Prostate cancer rarely causes symptoms at an early stage. The presence of symptoms suggests locally advanced or metastatic disease. Manifestations of locally advanced prostate cancer include urinary symptoms, ureteral obstruction causing renal failure, hematospermia or decreased ejaculate volume, and, rarely, impotence. Manifestations of metastatic disease include bone pain, pathologic fractures, anemia, and lower extremity edema, and, less commonly, malignant retroperitoneal fibrosis, paraneoplastic syndromes, and disseminated intravascular coagulation (DIC). Locally advanced and metastatic disease are uncommon presentations due to widespread screening with prostate-specific antigen (PSA) and digital rectal examination (DRE). A histologic diagnosis of prostate cancer is typically made by prostate needle biopsy using transrectal ultrasound guidance.

Following a diagnosis of prostate cancer, the goal of staging is the accurate determination of disease extent for management decisions and prognostication. In addition to PSA and DRE, the pathologic features of a prostate biopsy (grade and extent) help inform management decisions. Imaging studies are useful in specific situations.

This chapter will review diagnostic and staging modalities for prostate cancer.

EARLY DETECTION

Screening

General Concepts of Screening

Screening refers to testing for disease in healthy, asymptomatic populations, whereas diagnosis is the identification of disease among individuals with signs or symptoms. The principal goal of screening is to improve overall health outcomes by identifying and treating disease at an earlier stage. Despite the common misperception that early diagnosis through screening is invariably beneficial, it also has the potential for harm (Welch, 2004). There is strong evidence that prostate cancer screening reduces the rates of advanced disease (van der Cruijsen-Koeter et al, 2006; Aus et al, 2007), but controversy exists regarding the balance of benefit and harm (Barry, 2009).

From 1993 to 2003 after the onset of widespread PSA testing, the mortality rate from prostate cancer declined by 32.5% (Surveillance, Epidemiology, and End Results [SEER] Program), along with a 75% reduction in the proportion of advanced-stage disease at diagnosis. It was estimated that PSA screening could have accounted for 45% to 70% of this reduction in prostate cancer mortality in the United States (Etzioni et al, 2008). However, randomized trials comparing the disease-specific outcomes of men who are screened and those who are not represent the highest level of evidence for screening.

Randomized Trials

The Prostate, Lung, Colon, and Ovary (PLCO) trial of the National Cancer Institute (NCI) and the European Randomized Trial of Prostate Cancer Screening (ERSPC) were initiated in 1993 to compare prostate cancer–specific mortality (primary end point) between screened and unscreened arms (Auvinen et al, 1996; de Koning et al, 2002; Schroder, 2003; Andriole et al, 2004). Reductions in high-grade cancer and locally advanced/metastatic disease with serial screening were reported in the ERSPC (van der Cruijsen-Koeter et al, 2006; Aus et al, 2007), as well as a 20% reduction in prostate cancer–specific mortality among those screened compared with controls at a median follow-up of 9 years (Schroder et al, 2009). However, in the ERSPC, it was estimated that to prevent one prostate cancer death would require screening 1410 men and treating an additional 48 men. With longer follow-up, the Goteborg randomized population-based screening trial reported a greater mortality benefit with screening. By comparison, there was no difference in prostate cancer mortality between the screened and control arms of the PLCO at a median follow-up of 11 years (Andriole et al, 2009). Both trials reported results early when considering the long natural history of prostate cancer; and, with further follow-up, the findings could change. Further, the disparate findings between the studies may result from high rates of screening in the control arm of the PLCO (contamination) and lesser ability to detect a mortality difference given that the PLCO had approximately threefold fewer events than the ERSPC (Barry, 2009).

These randomized trials emphasize the potential for overdiagnosis (detection of cancers that would have otherwise remained undetected) and overtreatment of prostate cancer with screening. Overtreatment is especially concerning among older men (age greater than 65 years), for whom treatment was associated with minimal benefit in a randomized trial of surgery versus watchful waiting (Bill-Axelson et al, 2008). Given that the average age at diagnosis today is approximately 67 years, the risk of overtreatment is high.

Specialty Group Recommendations

Professional groups have published statements and guidelines on prostate cancer screening (National Comprehensive Cancer

Network, 2007; Lim and Sherin, 2008; Lin et al, 2008; U.S. Preventive Services Task Force, 2008). The U.S. Preventive Services Task Force (2008) concluded that the evidence is insufficient to assess the balance of benefit and harm of screening among men age 75 years or less, whereas screening is not recommended for men age 75 years or older. The American College of Preventive Medicine recommends against routine population screening with PSA and DRE (Lim and Sherin, 2008) and suggests shared decision making for men age 50 years or older with a life expectancy greater than 10 years. The American Cancer Society and the American Urological Association recommend annual prostate cancer screening beginning at age 50 years for average-risk men and earlier for higher-risk men (positive family history or black race). The National Comprehensive Cancer Network (2007) recommends offering baseline PSA screening at age 40 years with the frequency of follow-up testing based on PSA test results. The appropriate age to start and discontinue screening (Ross et al, 2005; Catalona et al, 2006; Schaeffer, 2009) and the appropriate interval between screens will continue to be a matter of debate (Carter et al, 1997; Ross et al, 2000; Hugosson et al, 2003b).

Despite the controversy associated with prostate cancer screening and disparate recommendations from professional organizations, opportunistic prostate cancer screening is highly prevalent in the United States (Lu-Yao et al, 2003; Sirovich et al, 2003; Ross et al, 2004; Schwartz et al, 2004; Chan et al, 2006; Walter et al, 2006). **Although prostate cancer screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test so that they can make an informed decision whether or not to be screened.**

Diagnostic Modalities

Digital Rectal Examination

Before the availability of PSA, physicians relied solely on DRE for early detection of prostate cancer (Cooner et al, 1990; Catalona et al, 1994; Ellis et al, 1994; Schroder et al, 1998; Vis et al, 2001; Okotie et al, 2007). DRE has only fair reproducibility in the hands of experienced examiners (Smith and Catalona, 1995) and misses a substantial proportion of early cancers (Cooner et al, 1990; Catalona et al, 1994; Ellis et al, 1994). It has been suggested that the value of DRE for screening at PSA levels less than 3.0 ng/mL is limited (Schroder et al, 1998; Vis et al, 2001). **Due to the risk of prostate cancer among men with abnormalities on DRE and the simplicity of the examination, most urologists use PSA and DRE together for prostate cancer detection.**

Further, **PSA improves the positive predictive value of DRE for cancer** (Schroder et al, 1998). The positive predictive value of DRE ranged from 4% to 11% in men with PSA levels of 0 to 2.9 ng/mL, and from 33% to 83% in men with PSA levels of 3 to 9.9 ng/mL or more (Schroder et al, 1998).

Overall, when DRE and PSA are used in prostate cancer screening, detection rates are higher with PSA than with DRE and highest with both tests together (Catalona et al, 1991). **Because DRE and PSA do not always detect the same cancers** (Okotie et al, 2007), **the tests are complementary and are recommended in combination as methods of assessing prostate cancer risk.**

Prostate-Specific Antigen (PSA)

PSA is a member of the human kallikrein gene family, is secreted in high concentrations (mg/mL) into seminal fluid, and circulates in bound (complexed) and unbound (free) forms that can be measured using assays approved by the U.S. Food and Drug Administration (FDA).

Factors Influencing PSA. Serum PSA levels vary with age, race, and prostate volume. Blacks without prostate cancer have higher PSA values than whites (Morgan et al, 1996; Fowler et al, 1999). PSA increases 4% per milliliter of prostate volume; and 30% and 5% of the variance in PSA can be accounted for by prostate volume and age, respectively (Oesterling et al, 1993).

PSA expression is strongly influenced by androgens (Young et al, 1991; Henttu et al, 1992). Serum PSA becomes detectable at puberty with increases in luteinizing hormone and testosterone (Vieira et al, 1994). In hypogonadal men with low testosterone levels, serum PSA may be low because of decreased expression and may not reflect the presence of prostate disease such as cancer (Morgentaler et al, 1996).

Metabolic factors can influence the serum PSA concentration. Obese men have slightly lower PSA levels than nonobese men (Baillargeon et al, 2005), possibly due to hemodilution (Banez et al, 2007). Statin use may reduce PSA levels by lowering lipids (Hamilton et al, 2008).

Overall, the presence of prostate disease (prostate cancer, benign prostatic hyperplasia [BPH], and prostatitis) is the most important factor affecting serum PSA levels (Wang et al, 1981; Ercole et al, 1987; Dalton, 1989; Nadler et al, 1995). **Although PSA elevations may indicate the presence of prostate disease, not all men with prostate disease have elevated PSA levels, and PSA elevations are not specific for cancer.**

It is postulated that serum PSA elevations occur from disruption of the normal prostatic architecture, allowing PSA to gain access to the circulation. This can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (e.g., prostate massage, prostate biopsy, transurethral resection) (Klein and Lowe, 1997). Although DRE can lead to slight increases in serum PSA, the resultant change in PSA falls within the error of the assay and rarely causes false-positive tests (Crawford et al, 1992).

Studies examining the effect of ejaculation on serum PSA have reported conflicting results (Simak et al, 1993; Kirkali et al, 1995; Tchetgen et al, 1996; Heidenreich et al, 1997; Herschman et al, 1997; Stenner et al, 1998; Yavascaoglu et al, 1998). A repeat PSA after 48 hours of sexual abstinence may be helpful for interpreting serum PSA levels that are minimally elevated.

Prostate-directed treatments (for BPH or prostate cancer) can lower serum PSA by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell (Shingleton et al, 2000).

5α-Reductase inhibitors that are used for BPH treatment have been shown to lower PSA levels, including both type 2 isoenzyme inhibitors (finasteride) and dual type 1 and 2 isoenzyme inhibitors (dutasteride) (Guess et al, 1993; Roehrborn et al, 2002). Finasteride 1 mg (trade name Propecia) used for male pattern hair loss (androgenic alopecia) results in the same decline in serum PSA levels as the 5-mg dosage (D'Amico and Roehrborn, 2007).

Men initiating treatment with 5α-reductase inhibitors should first have a baseline PSA measurement and should be followed with serial measurements. Although the PSA level is often multiplied by two to estimate the "true" PSA level of a patient who has been taking a 5α-reductase inhibitor for 12 months or more (Andriole et al, 1998), the PSA response to finasteride treatment can be highly variable (Marks et al, 2006). It has been suggested

that the PSA should instead be multiplied by a factor of 2.3 after 2 years and 2.5 after 7 years of treatment (Etzioni et al, 2005; Thompson et al, 2007; Walsh, 2008). Because this "moving target" can complicate the use of PSA in daily clinical practice, some have recommended using the PSA nadir on finasteride as the new baseline and performing a biopsy for subsequent PSA increases (Morgentaler, 2007).

Surgical therapy for BPH can lead to reductions in the serum PSA level (Shingleton et al, 2000) and "reset" the PSA baseline to a variable extent by removing the main contributor to PSA (transition zone).

Finally, prostate cancer treatments (medical or surgical), such as manipulation of the hormonal axis (e.g., luteinizing hormone–releasing hormone (LHRH) agonists, orchiectomy), radiation therapy, and radical prostatectomy lead to reductions in PSA.

The interpretation of PSA values should always take into account age, the presence of urinary tract infection or prostate disease, recent diagnostic procedures, and prostate-directed treatments.

Clinical Use for Diagnosis. The initial assays for PSA that were approved by the FDA in 1994 for early detection of prostate cancer detected both free PSA and PSA complexed to alpha 1 antichymotrypsin (ACT). Thus measurement of free and complexed PSA by these assays is generally referred to as the serum PSA level (Smith et al, 1996). Specific assays that detect free PSA alone and PSA complexed to ACT alone have been evaluated and approved for prostate cancer detection (see later).

It is now well-established that the use of PSA increases the detection of prostate cancers that are more likely to be organ-confined when compared with detection without PSA (Thompson et al, 1987; Mueller et al, 1988; Chodak et al, 1989; Rietbergen et al, 1999; Hoedemaeker et al, 2000). **Observational studies and randomized trials have shown that both the future risk of prostate cancer and the chance of finding cancer on a prostate biopsy increase incrementally with the serum PSA level** (Catalona et al, 1991, 1994; Brawer et al, 1992; Labrie et al, 1992; Gann et al, 1995; Fang et al, 2001; Thompson et al, 2004; Andriole et al, 2005; Whittemore et al, 2005; Loeb et al, 2006; Lilja et al, 2007).

Gann and associates (1995) were the first to demonstrate the association between the baseline PSA level and subsequent prostate cancer detection, which has been verified by others (Fang et al, 2001; Antenor et al, 2004; Whittemore et al, 2005; Loeb et al, 2006).

In addition to predicting future risk, PSA is directly associated with the present risk of prostate cancer. The probability of detecting prostate cancer on biopsy increases directly with PSA across the full spectrum of PSA levels (Table 99–1) (Thompson et al, 2004).

In summary, **both PSA and DRE are used to assess prostate cancer risk. The addition of PSA to DRE increases both the detection rate of prostate cancer and detection of cancers with a more favorable prognosis.**

Triggers for Biopsy. The choice of a PSA threshold for recommending a prostate biopsy is controversial (Catalona et al, 1994; Gann et al, 1995; Carter, 2004; Nadler et al, 2005; Thompson et al, 2005) and has recently been reviewed (Schroder et al, 2008). Gann (1995) pointed out that "dichotomization of PSA results into normal and abnormal obscures important information contained in levels below the usual cutoff." Data from the Prostate Cancer Prevention Trial clearly show that the risk of prostate cancer is continuous as PSA increases (Thompson et al, 2005). Some investigators have recommended against referring to PSA as "elevated" or "abnormal," and instead they advise using PSA together with other methods of risk assessment, such as family history, race, and DRE findings (Thompson et al, 2006). Nevertheless, most urologists continue to use total PSA thresholds for prostate biopsy decisions.

Table 99–1.

Prostate Cancer Detection as a Function of Serum Prostate-Specific Antigen (PSA) Level and Digital Rectal Examination (DRE) Findings in Contemporary Series

PSA LEVEL (ng/mL)	DRE FINDINGS*	CANCER DETECTION RATE (%)†	CANCER YIELD ON BIOPSY (%)‡	RATE OF HIGH-GRADE CANCER ON BIOPSY (%)§
0-1	–		8.8	0.9
1-2	–		17.0	2.0
0-2	–		12	1.4
		0.7	8	
2-4	–		15-25	5.2
		2	21	
4-10	+	11	17-32	4.1
		11-27	45-51	11.7
>10	–	41	43-65	19.4
	+	31-76	70-90	50.5
<4	–		15	2.3
	+	1-3	13-17	
>4	–	14	23-38	5.8
	+	14-38	55-63	20.6

Data in table extracted from the results of contemporary series: Crawford et al, 1996; Catalona et al, 1998; Schroder et al, 1998; Thompson et al, 2004; Andriole et al, 2005.

*DRE nonsuspicious for cancer (–); DRE suspicious for cancer (+).

†Cancer detection rate is the number of cancers found in those screened (total number of detected cancers divided by the total number of men screened).

‡Cancer yield is the total number of cancers detected divided by the total number of men undergoing a biopsy. For DRE (–) this indicates the positive predictive value of PSA at a specified level when the DRE is not suspicious for cancer; for DRE (+) it is the positive predictive value of a suspicious DRE when the PSA is at a specified level.

§Gleason score of 7 or more.

The use of higher PSA thresholds risks missing important cancers during the window for cure, whereas the use of lower thresholds increases the proportion of unnecessary biopsies and overdiagnosis. Although PSA was initially approved using 4 ng/mL as the upper limit of normal, many clinicians now use lower thresholds (2.5 to 3 ng/mL) to trigger a biopsy.

A PSA level that is considered suspicious for prostate cancer should be remeasured before performing a prostate biopsy, because of fluctuations in PSA that could create false-positive elevations (Eastham et al, 2003).

PSA Derivatives and Molecular Forms

Numerous variations on PSA-based screening have been proposed to improve test performance, including the adjustment of the PSA level for total prostate volume (PSA density) (Babaian et al, 1990; Veneziano et al, 1990; Littrup et al, 1991; Benson et al, 1992a, 1992b; Bazinet et al, 1994; Rommel et al, 1994; Catalona et al, 2000; Djavan et al, 2002; Egawa et al, 2002; Naya et al, 2002; Gjengsto et al, 2005) or transition zone volume (Djavan et al, 1999a, 1999b; Taneja et al, 2001; Singh et al, 2004; Gjengsto et al, 2005), and the evaluation of rate of change in PSA (PSA velocity) (Carter et al, 1992; Smith and Catalona, 1994; Fowler et al, 2000; Fang et al, 2002; D'Amico et al, 2004; Roobol et al, 2004; Berger

et al, 2005; D'Amico et al, 2005; Schroder et al, 2006; Berger et al, 2007; Loeb et al, 2007a, 2007b, 2008c; Eggener et al, 2008; Vickers et al, 2009). The discovery that PSA circulates in both bound (complexed) and unbound (free) forms and development of assays to measure these forms separately, have resulted in the investigation of their use for prostate cancer detection (McCormack et al, 1995; Lilja, 1997, 2003; Polascik et al, 1999; Gretzer and Partin, 2003) and this topic has recently been reviewed (Jansen et al, 2009).

Volume-Based PSA Parameters. Distinguishing between men with PSA elevations driven by BPH or cancer is difficult, because PSA is not specific for cancer and the prevalence of BPH is high. Volume-based PSA parameters (with prostate volume typically determined by ultrasonography) have been evaluated to reduce confounding from BPH. These include PSA density (PSAD, PSA divided by prostate volume), complexed PSA density (complexed PSA divided by prostate volume), and PSA transition zone density (PSA divided by transition zone volume) (Babaian et al, 1990; Veneziano et al, 1990; Littrup et al, 1991; Benson et al, 1992a, 1992b; Bazinet et al, 1994; Rommel et al, 1994; Djavan et al, 1999a, 1999b, 2002; Catalona et al, 2000; Naya et al, 2002; Gjengsto et al, 2005).

Benson and colleagues (1992a, 1992b) suggested that adjusting PSA for prostate size by dividing PSA by prostate volume (PSAD) could help distinguish between PSA elevations caused by BPH and those caused by prostate cancer. A direct relationship between PSAD and the chance of cancer has been documented (Seaman et al, 1993; Bazinet et al, 1994; Rommel et al, 1994), and a PSAD of 0.15 or greater was proposed for recommending prostate biopsy in men with PSA levels between 4 and 10 ng/mL and a normal DRE (Seaman et al, 1993; Bazinet et al, 1994). The usefulness of PSAD in prostate cancer detection has not been confirmed in all studies (Cooner, 1994; Taneja et al, 2001). An advantage of PSAD is that it has been directly associated with prostate cancer aggressiveness (Carter et al, 2002, 2007; Kundu et al, 2007).

PSA has been adjusted for the transition zone volume (Kalish et al, 1994), the prostatic region that is the major determinant of serum PSA in men without prostate cancer (Lepor et al, 1994). Djavan and associates (1999b) found that PSA transition zone volume was the parameter with the highest overall sensitivity and specificity for prostate cancer detection when PSA was between 4 to 10 ng/mL.

In general, although PSAD and its associated measures are imperfect predictors of cancer, they represent an additional method of risk assessment with potential utility for counseling men with intermediate PSA levels (4 to 10 ng/mL) regarding the need for prostate biopsy (Benson and Olsson, 1994) or repeat biopsy if PSA is persistently elevated (Keetch et al, 1996).

Prostate-Specific Antigen Velocity. Short-term fluctuations in PSA can occur between measurements in the presence or absence of prostate cancer, primarily due to physiologic variation (Carter et al, 1992, 1995; Riehmann et al, 1993; Prestigiacomo and Stamey, 1996; Eastham et al, 2003). However, the rate of change in PSA (PSA velocity, or PSAV)—PSA corrected for the elapsed time between measurements (Carter et al, 1992)—is associated with the risk of prostate cancer (Carter et al, 1992; Smith and Catalona, 1994; D'Amico et al, 2004, 2005; Roobol et al, 2004; Berger et al, 2005, 2007; Sengupta et al, 2005; Schroder et al, 2006; Loeb et al, 2007a, 2007b, 2008a; Eggener et al, 2008; Vickers et al, 2009). Using frozen sera to measure PSA years before diagnosis, Carter and colleagues (1992) showed that a PSAV more than 0.75 ng/mL per year was a specific marker for the presence of prostate cancer in men with PSA levels between 4 and 10 ng/mL. Other studies have demonstrated that men with prostate cancer have more rapid rises in PSA than men without prostate cancer (Smith and Catalona, 1994; Carter et al, 1995; Raaijmakers et al, 2004; Thompson et al, 2004; Loeb et al, 2008a). More recently, it has been shown that PSAV might be useful for prostate cancer detection among men with PSA levels less than 4.0 ng/mL (Carter et al, 2006; Loeb et al, 2007b). Some investigators have suggested the use of lower PSAV thresholds for men with lower total PSA levels (Loeb et al, 2007b; Moul et al, 2007).

Some studies have failed to demonstrate the value of PSAV for prostate cancer prediction beyond that of a single PSA measurement (Roobol et al, 2004; Vickers et al, 2009). Differences between studies could be due to the method of calculating PSAV (Yu et al, 2006; Connolly et al, 2007) and the point in the PSA history at which PSAV is calculated (Carter et al, 1992; D'Amico et al, 2004).

PSAV may play a role in the prediction of life-threatening prostate cancer (D'Amico et al, 2004, 2005; Carter et al, 2006; Loeb et al, 2008a, 2008b). A PSAV greater than 0.35 ng/mL/year 10 to 15 years prior to diagnosis was associated with a fivefold increased risk of life-threatening prostate cancer more than a decade later (Carter et al, 2006), while a PSAV greater than 2 ng/mL/year during the year prior to a prostate cancer diagnosis was associated with prostate cancer–specific mortality following radical prostatectomy or radiation therapy (D'Amico et al, 2004, 2005; Sengupta et al, 2005). However, a recent meta-analysis suggested that PSAV prior to treatment provides no additional information regarding prostate cancer outcome when compared with PSA alone (Vickers et al, 2009).

Free Prostate-Specific Antigen. Men with prostate cancer generally have a greater fraction of serum PSA that is complexed—and therefore a lower percentage of total PSA circulating in the free (unbound) form—than men without prostate cancer (Christensson et al, 1993; Leinonen et al, 1993; Lilja, 1993; Stenman et al, 1994; Catalona et al, 1995, 1998, 2000; Keetch et al, 1997; Pannek et al, 1998; Woodrum et al, 1998; Gann et al, 2002; Roehl et al, 2002; Hugosson et al, 2003a; Raaijmakers et al, 2004). This difference is thought to be due to differential expression of PSA isoforms by transition zone (zone of origin of BPH) tissue compared with peripheral zone tissue (where most prostate cancers arise) (Chen et al, 1997; Mikolajczyk et al, 1997, 2000a, 2000b).

Free PSA levels vary directly by age and prostate volume, and vary indirectly with the total PSA level (Woodrum et al, 1998). In addition, because assays differ in their ability to determine both free and total PSA, results may differ depending on the assay or combination of assays used (Woodrum et al, 1998). The percentage of free PSA (%fPSA) does not appear to be significantly altered by race (Catalona et al, 2000) or 5α-reductase inhibitors (Keetch et al, 1997; Pannek et al, 1998).

%fPSA has been shown to significantly improve the ability to distinguish between individuals with and without prostate cancer, compared with total PSA alone (Christensson et al, 1993). The %fPSA cutoff that optimizes sensitivity and specificity for cancer detection depends on prostate size, because overlap is greatest among men with enlarged prostates, with or without concomitant prostate cancer (Catalona et al, 1995).

%fPSA appears to be most useful in distinguishing between those with and without prostate cancer at intermediate total PSA levels. In men with PSA levels of 4 to 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% detected 95% of cancers while avoiding 20% of unnecessary biopsies (Catalona et al, 1998). The value of %fPSA to predict prostate cancer at levels less than 4.0 ng/mL is unclear (Gann et al, 2002; Roehl et al, 2002; Hugosson et al, 2003a; Raaijmakers et al, 2004).

%fPSA (at a cutoff of 25%) and PSAD (using a threshold of 0.078) have been shown to have comparable specificity (at a sensitivity of 95%) although %fPSA does not require transrectal ultrasonography (TRUS) (Catalona et al, 2000). Thus %fPSA can be used to counsel men with PSA elevations in the range 4 to 10 ng/mL regarding their risk of cancer.

Complexed Prostate-Specific Antigen. Because men with prostate cancer have a greater fraction of total PSA that is complexed to protease inhibitors than men without prostate cancer, measurement of complexed PSA (cPSA) has been studied as a marker for detection (Brawer et al, 2000, 2002; Okegawa et al, 2000; Parsons et al, 2004). When total PSA levels were between 4 and 10 ng/mL, cPSA provided improved specificity compared with total PSA, and similar specificity compared with the percentage of free PSA at a sensitivity of 95% (Brawer et al, 2000), findings that were subsequently confirmed (Okegawa et al, 2000). Similar results were reported in the 2.6 to 4.0 ng/mL PSA range (Parsons et al, 2004). **Overall, at a high sensitivity, cPSA provides higher specificity compared with total PSA and comparable specificity to %fPSA in prostate cancer detection.** A potential advantage of cPSA is the requirement for one assay.

PSA Isoforms. PSA is secreted from the prostatic luminal epithelium in a precursor form (pPSA or proPSA) (see Chapter 98) (Mikolajczyk et al, 2001, 2004; Peter et al, 2001; Catalona et al, 2003, 2004; Gretzer and Partin, 2003; Khan et al, 2003; Lilja, 2003; Canto et al, 2004; Lein et al, 2005; Makarov et al, 2009). Active free PSA can be further cleaved to BPSA or intact PSA (iPSA) that is inactive and not complexed. Research assays have been developed for measuring BPSA and pPSA (both native and truncated forms).

The relative concentration of these isoforms differs in the presence of prostatic disease. BPSA is found preferentially in nodular BPH tissue from the transition zone and can be considered a marker for BPH (Mikolajczyk et al, 2000b; Canto et al, 2004), whereas a larger relative proportion of proPSA has been associated with prostate cancer (Mikolajczyk et al, 1997, 2000a, 2001; Peter et al, 2001). Some studies have suggested that proPSA may improve the identification of prostate cancer among men with PSA levels of 2 to 4 ng/mL (Catalona et al, 2003, 2004), 4 to 10 ng/mL (Khan et al, 2003; Mikolajczyk et al, 2004), and 2 to 10 ng/mL (Catalona et al, 2003), while other studies have not shown incremental predictive value of specific subtypes beyond %fPSA (Lein et al, 2005).

hK2. hK2 is a closely related serine protease in the PSA/kallikrein gene family that has also been evaluated for prostate cancer detection (Kwiatkowski et al, 1998; Partin et al, 1999; Becker et al, 2000, 2003; Haese et al, 2003; Bangma et al, 2004; Steuber et al, 2005; Vickers et al, 2008). Expression of hK2 is higher in more poorly differentiated cancer tissues than in normal and benign tissues (Tremblay et al, 1997). Although some studies have suggested that the ratio of hK2 and free PSA might improve the ability of PSA to identify men with prostate cancer (Kwiatkowski et al, 1998; Partin et al, 1999; Becker et al, 2000; Vickers et al, 2008), other analyses have not (Becker et al, 2003; Bangma et al, 2004). hK2 does appear to correlate directly with grade and cancer volume and could be useful in patient assessment after diagnosis (Haese et al, 2003; Steuber et al, 2005).

Other Markers (see Chapter 98)

Prostate cancer gene 3 (*PCA-3*) is a noncoding prostate-specific mRNA overexpressed in prostate cancer tissue compared with benign tissue (Bussemakers et al, 1999; Marks et al, 2007; Deras et al, 2008; Haese et al, 2008; Nakanishi et al, 2008; Sokoll et al, 2008; van Gils et al, 2008; Whitman et al, 2008). Urine assays have been developed to measure PCA-3 mRNA (Sokoll et al, 2008), which is associated with the likelihood of a positive initial or repeat prostate biopsy (Marks et al, 2007; Deras et al, 2008; Haese et al, 2008). There are conflicting results on the association between *PCA-3* with prostate cancer aggressiveness (Nakanishi et al, 2008; van Gils et al, 2008; Whitman et al, 2008). In the future, it is likely that panels of biomarkers will be used in combination with standard measures of risk (age, family history, race) to selectively identify men who should undergo further evaluation for the presence of prostate cancer (Etzioni et al, 2003).

STAGING

General Concepts of Staging

The clinical staging of prostate cancer uses pretreatment parameters to predict the extent of disease, both for assessment of prognosis and to inform decisions regarding appropriate treatment. Available pretreatment modalities used to predict disease extent in men with prostate cancer include DRE (T stage), PSA and its derivatives, prostate cancer features on needle biopsy, and radiologic imaging. Because imaging modalities cannot reliably visualize microscopic disease, they are not helpful in most newly diagnosed cases. Pelvic lymph node biopsy is rarely performed prior to definitive therapy.

Clinical versus Pathologic Staging

Clinical staging is the assessment of disease extent using pretreatment parameters (DRE, PSA, needle biopsy findings, and radiologic imaging); whereas pathologic stage is determined after prostate removal and involves histologic analysis of the prostate, seminal vesicles, and pelvic lymph nodes if lymphadenectomy is performed. Pathologic staging more accurately estimates disease burden and is more useful than clinical staging for outcome prediction (Pound et al, 1997). Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease (Roehl et al, 2004). The most important pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement (Jewett, 1975; Walsh and Jewett, 1980; Epstein et al, 1990, 1993a, 1993b; Partin et al, 1993; Pound et al, 1997).

Classifications

The Whitmore and Jewett staging system is now of historical interest (Jewett 1956; Whitmore 1956). Today, clinical staging is based upon the tumor-node-metastases (TNM) classification system (Table 99–2). This system was first adopted in 1975 by the American Joint Committee on Cancer (AJCC) and has since undergone numerous modifications (Schroder et al, 1992). The most recent 1997 modification reduced the subdivision of T2 disease from three categories (T2a, T2b, and T2c) to two categories by combining single-lobe disease (T2a and T2b) into a single stage (Schroder et al, 1992). However, some believe that a distinction between stages T2a and T2b is clinically important (Iyer et al, 1999; Han et al, 2000). Also, a nonpalpable lesion identified by TRUS is considered T2 by the current TNM clinical staging system. However, TRUS findings do not predict tumor extent in PSA-detected nonpalpable lesions (Epstein et al, 1994; Ferguson et al, 1995) so that many urologists classify men with nonpalpable disease as T1c regardless of TRUS findings.

Table 99–2.

1997 and 1992 TNM Clinical Staging Systems for Prostate Cancer

1997	1992	DESCRIPTION
TX	TX	Primary tumor cannot be assessed
T0	T0	No evidence of primary tumor
T1	T1	Nonpalpable tumor—not evident by imaging
T1a	T1a	Tumor found in tissue removed at TUR; 5% or less is cancerous and histologic grade <7
T1b	T1b	Tumor found in tissue removed at TUR; >5% is cancerous or histologic grade >7
T1c	T1c	Tumor identified by prostate needle biopsy due to elevation in PSA
T2	T2	Palpable tumor confined to the prostate
T2a		Tumor involves one lobe or less
	T2a	Tumor involves less than half of one lobe by normal tissue on all sides
T2b		Tumor involves more than one lobe
	T2b	Tumor involves more than half of a lobe but not both lobes
None	T2c	Tumor involves more than one lobe
T3	T3	Palpable tumor beyond prostate
T3a	T3a	Unilateral extracapsular extension
T3b	T3b	Bilateral extracapsular extension
T3c	T3c	Tumor invades seminal vesicle(s)
T4	T4	Tumor is fixed or invades adjacent structures (not seminal vesicles)
T4a	T4a	Tumor invades bladder neck, external sphincter, and/or rectum
T4b	T4b	Tumor invades levator muscle and/or fixed to pelvic wall
N(+)	N(+)	Involvement of regional lymph nodes
NX	NX	Regional lymph nodes cannot be assessed
N0	N0	No lymph node metastases
N1	N1	Metastases in single regional lymph node, ≤2 cm in dimension
N2	N2	Metastases in single (>2 but ≤5 cm) or multiple with none >5 cm
N3	N3	Metastases in regional lymph node >5 cm in dimension
M(+)	M(+)	Distant metastatic spread
MX	MX	Distant metastases cannot be assessed
M0	M0	No evidence of distant metastases
M1	M1	Distant metastases
M1a	M1a	Involvement of nonregional lymph nodes
M1b	M1b	Involvement of bones
M1c	M1c	Involvement of other distant sites

TNM, tumor-node-metastasis; TUR, transurethral resection.

Prediction of Tumor Extent

Prostate-Specific Antigen

Despite controversy over its correlation with prostate cancer volume (Stamey et al, 2004), PSA is associated directly with pathologic stage and tumor extent (Stamey et al, 1987, 1989). PSA cannot be used alone to accurately predict disease extent for an individual patient due to significant overlap in PSA levels between stages, the variable contribution from BPH to PSA, and the fact that, on average, poorly differentiated tumors produce less PSA per gram of tumor (Partin et al, 1990). Despite these confounding factors, pathologic organ-confined disease is found in 80% of men with a PSA less than 4.0 ng/mL, 66% of those with PSA levels between 4.0 and 10.0 ng/mL, and fewer than 50% of men with PSA greater than 10.0 ng/mL (Catalona et al, 1997; Rietbergen et al, 1999). Also, 20% of men with PSA greater than 20 ng/mL and 75% of those with PSA greater than 50 ng/mL are found to have pelvic lymph node involvement.

In addition to the total PSA level, free PSA, hK2, proPSA, PSAD, and PSAV (see above) have been evaluated as predictors of prostate cancer grade and extent (Carter et al, 1997, 2006, 2007; Southwick et al, 1999; D'Amico et al, 2004, 2005; Kundu et al, 2007; Loeb et al, 2008b). Although prostatic acid phosphatase (PAP) has been associated with pathologic stage and progression following radical prostatectomy, (Moul et al, 1998; Han et al, 2001) the closer relationship between PSA and disease extent has virtually eliminated the clinical use of this parameter (Heller, 1987).

Digital Rectal Examination

DRE is used to determine whether a lesion is palpable and is associated with local disease extent (clinical T stage). Also, an abnormal DRE was associated with an increased risk of detecting high-grade (Gleason 8 to 10) prostate cancer in a screened population (Gosselaar et al, 2008).

However, because of its poor sensitivity and lack of reproducibility, DRE can both overestimate and underestimate the extent of disease (Turner and Belt, 1957; Byar and Mostofi, 1972; Walsh and Jewett, 1980). In one series of 565 men with presumed organ-confined disease based upon DRE, the sensitivity and specificity were 52% and 81%, respectively, for prediction of organ-confined disease (Partin et al, 1993). Nevertheless, DRE can be used in combination with other parameters to help predict tumor extent.

Prostate Needle Biopsy

Histologic grade is the most important information obtained from prostate needle biopsy and the Gleason grading system is the most commonly used (Gleason, 1966). At low-power magnification, the sum of a grade (1 to 5) assigned to the predominant pattern (occupying the largest area of the specimen) and the second most common pattern yields a score ranging from 2 to 10.

Recent studies have shown that tertiary Gleason patterns may affect prognosis (Patel et al, 2007), leading a 2005 consensus conference to recommend modification of the Gleason grading system (see Chapter 96). Accordingly, a biopsy Gleason score of 3 + 4 or 4 + 3 with a tertiary pattern 5 would be considered Gleason 3 + 5 and 4 + 5, respectively (Epstein et al, 2005).

Although a higher Gleason grade is associated with worse prognosis, it is not used alone for risk prediction (Stein et al, 1991; Epstein et al, 1993a, 1993b; Partin et al, 1993; Zincke et al, 1994). Other biopsy findings provide information regarding the extent of disease, including the number of positive cores, percentage of positive cores, and presence of perineural invasion (PNI). These features are associated with radical prostatectomy findings, and have been used to guide the selection of candidates for active surveillance programs (Egan and Bostwick, 1997; de la Taille et al, 1999a; Carter et al, 2002; O'Malley et al, 2002; Bismar et al, 2003).

Findings of seminal vesicle invasion or involvement of the periprostatic fat on prostate needle biopsy are associated with worse prognosis (Stone et al, 1998). Although some authors have recommended biopsy of the seminal vesicles and/or prostatic capsule to improve staging (Terris et al, 1993; Ravery et al, 1994; Vallancien et al, 1994; Stone et al, 1995, 1998), others suggest biopsy of these structures only when there is a large palpable tumor located at the base of the prostate (Guillonneau et al, 1997; Terris et al, 1997).

Combined Use of Pretreatment Parameters

Nomograms and algorithms have been developed to integrate multiple clinical parameters for improved staging. Considering the primary T stage based on DRE findings, serum PSA level, and Gleason grade, these algorithms/nomograms have been shown to more accurately predict both cancer extent and long-term outcomes after treatment compared with use of a single parameter (Humphrey et al, 1991; Kleer et al, 1993; Kleer and Oesterling, 1993; Partin et al, 1993, 1997, 2001; Bluestein et al, 1994; Kattan et al, 1998; Han et al, 2003; Stephenson et al, 2006; Makarov et al, 2007).

Several classification schemes have also been proposed that correlate with clinical outcomes. D'Amico demonstrated that stratification into low-risk (clinical stage T1 to 2a, PSA 10 ng/mL or less and Gleason score 6 or less), intermediate-risk (stage T2b, PSA greater than 10 but less than 20 ng/mL or Gleason score 7), and high-risk disease (stage T2c, PSA greater than 20 ng/mL or Gleason score 8 to 10) (D'Amico et al, 1998) was significantly associated with freedom from disease at 10 years after radical prostatectomy; 83% for low-risk, 46% for intermediate-risk, and 29% for high-risk disease (D'Amico et al, 2001). Other validated classification schemes have since been developed, including the Cancer of the Prostate Risk Assessment (CAPRA) score (Cooperberg et al, 2005, 2006; May et al, 2007). Pretreatment risk stratification using multiple parameters is useful for patient counseling.

Imaging

Numerous imaging modalities have been evaluated for staging prostate cancer. No technique is reliably sensitive to detect extraprostatic disease. The inability to image microscopic disease limits the accuracy of current modalities.

Radionuclide bone scan (bone scintigraphy) is the most sensitive modality for the detection of skeletal metastases (Terris et al, 1991). Bone survey films (skeletal radiography) have lower sensitivity for the identification of distant spread and are typically used only to confirm a positive bone scan in men at low risk for bone metastases. Because bone metastases at diagnosis are rare in asymptomatic men in the PSA era, the routine use of bone scans in this population may lead to false-positive results, unnecessary anxiety, and cost (Chybowski et al, 1991). Accordingly, recent guidelines recommend the use of bone scans for patients with a PSA greater than 20 ng/mL, a Gleason score of 8 to 10, clinical stage T3 or T4, or clinical symptoms (National Comprehensive Cancer Network, 2009).

The use of computed tomography (CT) and magnetic resonance imaging (MRI) to evaluate the local extent of disease and the possibility of nodal involvement is not routinely recommended due to low sensitivity (Rifkin, 1990; Tempany et al, 1994; Wolf et al, 1995). Cross-sectional imaging may be reserved for high-risk patients, such as those with clinical stage greater than or equal to T3 disease or greater than 20% nomogram probability of lymph node metastases. Given the rarity of lymph node involvement in contemporary screened populations, it appears that imaging is being overused (Kindrick et al, 1998; Cooperberg et al, 2002; Abraham et al, 2007).

Combined MRI and MRI spectroscopy have been evaluated for staging prostate cancer, but there is no evidence that these methods will overcome the current limitations of imaging microscopic disease (Yu et al, 1999; Kurhanewicz et al, 2000). Specialized techniques such as high-resolution MRI used in tandem with the intravenous administration of lymphotropic superparamagnetic nanoparticles may allow the detection of small and otherwise undetectable lymph node metastases in patients with prostate cancer (Harisinghani et al, 2003). These techniques, however, require further clinical evaluation before widespread use.

Advances in ultrasound imaging are also being studied for improving prostate cancer detection (Purohit et al, 2003). Color ultrasonography with power Doppler to evaluate the blood flow within prostate vessels and three-dimensional Doppler using contrast agents could improve the visualization of more subtle tissue alterations caused by cancer.

Finally, monoclonal antibody radioimmunoscintigraphy (radiolabeled monoclonal antibody scan) have been used for identification of microscopic cancer deposits in regional and distant sites. The ProstaScint scan (Cytogen, Princeton, NJ) uses this technology but has had limited accuracy in the detection of lymph node metastases because the antibody targets an intracellular epitope that is only exposed in dying or dead cells (Troyer et al, 1997; Chang et al, 1999). Future generations of this technology circumventing this limitation are under development.

Molecular Staging

Molecular staging has focused on the detection of circulating prostate cancer cells either directly through centrifugation/immunostaining methods or indirectly by identifying the genetic message (messenger RNA [mRNA]) for prostate-specific biomarkers (e.g., PSA) from circulating prostate cells (Moreno et al, 1992; Ts'o et al, 1997). Although these polymerase chain reaction (PCR)–based assays have been associated with pathologic stage, sensitivity for detecting circulating cancer cells is variable between studies (Cama et al, 1995; Israeli et al, 1995; de la Taille et al, 1999b). With the recent FDA approval of the semiautomated CellSearch system (Veridex, Raritan, NJ) for monitoring metastatic breast and prostate cancer, considerable investigation is underway to determine whether circulating tumor cells have a role in the staging of early disease (Davis et al, 2008; Helo et al, 2009).

Pelvic Lymphadenectomy

The presence of lymph node metastasis in men diagnosed with clinically localized prostate cancer portends a poor prognosis. Identification of patients harboring nodal metastases could have important implications for the initiation of adjuvant therapy. Although the prevalence of pelvic lymph node metastases correlates directly with T stage, serum PSA level, and biopsy grade, pelvic lymphadenectomy (PLND) remains the most accurate way to detect occult nodal involvement (Parker et al, 1999).

PSA screening has resulted in a steady decline in the rates of lymph node metastases from 20% to 40% in the 1970s and 1980s to less than 4% today (Partin et al, 1997; Parker et al, 1999). Currently, lymphadenectomy is often omitted before curative treatment (e.g., radical prostatectomy, radiation therapy) (Bishoff et al, 1995; Kawakami et al, 2006). Laparoscopic pelvic lymphadenectomy prior to treatment is typically reserved for patients with a Gleason score greater than 8, extraprostatic extension on DRE, PSA greater than 20 ng/mL, or suspicion of enlarged lymph nodes on radiologic evaluation.

Given the individual variation in prostatic lymphatic drainage patterns (Mattei et al, 2008), some investigators favor an extended pelvic lymphadenectomy in lieu of a limited dissection (Bader et al, 2002; Burkhard et al, 2006). Given the greater complication rates with a more extended PLND, risks may outweigh benefits for most men diagnosed with low-risk cancer today (Klein et al, 2008). Information regarding the therapeutic value of these strategies is confounded by stage migration and is difficult to evaluate without prospective trials.

Key Points

- Although the value of PSA screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test so that they can make an informed decision about the need for routine screening.
- The combination of DRE and serum PSA is the most useful first-line test for assessing the risk that prostate cancer is present. The presence of prostate disease (prostate cancer, BPH, and prostatitis) is the most important factor affecting serum levels of PSA.
- PSA increases detection rates of prostate cancer and leads to the detection of prostate cancers that are more likely to be confined when compared with detection without the use of PSA.
- The future risk of prostate cancer detection and the chance of finding cancer on a prostate biopsy increase incrementally with the serum PSA level.
- Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease.
- The most important pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, presence of extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement.
- The Gleason grading system is the most commonly used classification scheme for the histologic grading of prostate cancer.

Definitive Therapy for Localized Prostate Cancer: An Overview

William J. Catalona, MD ● Misop Han, MD, MS

Background
Conservative Management
Radical Prostatectomy
Radiation Therapy
Other Treatments
Recommendations for Treatment by Patient Risk Groups

The purpose of this chapter is to provide an overview of the definitive treatment of clinically localized prostate cancer. **In reporting differences in treatments, we have attempted to be objective but have included our editorial perspective. For balance, we have included in our suggested reading list several recent articles focusing on the relative advantages and disadvantages of the different management strategies, some expressing opinions contrary to ours.** We have grouped treatments into *established treatments,* such as radical prostatectomy and radiotherapy, for which abundant published information is available, and *other treatments,* including active surveillance, primary hormone therapy, cryoablation, radiofrequency ablation, and high-intensity focused ultrasound (HIFU), for which data are more limited for localized disease.

BACKGROUND

Prostate cancer is the most common nonskin cancer and the second-leading cause of death from cancer in men in the United States (Jemal et al, 2009). In 2009, it was estimated that more than 192,280 new cases would occur; for more than 27,000, it was predicted to be the cause of death (Jemal et al, 2009). Because prostate cancer is prevalent in many countries and exhibits a wide spectrum of aggressiveness, different methods of treatment have been developed, and the preferred methods for detection and treatment are controversial. The prevalence of prostate cancer increases strikingly with age. Autopsy studies have documented microscopic foci of prostate cancer in about one fourth to one third of men in the fourth and fifth decades of life and in more than three fourths in the ninth decade (Sakr et al, 1993; Yin et al, 2008). Yet, a disproportionately lower but still substantial number of men (about one in six) are diagnosed with prostate cancer during their lifetime (Jemal et al, 2009). **Because of effective treatment of some prostate cancers and the biologic indolence relative to life expectancy of others, only about 16% of men diagnosed with prostate cancer ultimately die of it. Prostate cancer is the cause of death in about 3% of the U.S. male population** (Jemal et al, 2009). An additional (unquantified) proportion suffers from prostate cancer but dies of other causes.

The marked disparity between prevalence and incidence rates of prostate cancer, on the one hand, and morbidity and mortality rates, on the other, has led some to conclude that many prostate cancers are harmless and perhaps would better be left undetected. Nevertheless, if the present trends of increasing life expectancy continue, given the current age-specific incidence, morbidity, and mortality rates of prostate cancer, this disease will become a far greater public health problem in the future.

Since the 1980s, the methods of diagnosis of clinically localized prostate cancer have changed. Widespread screening with serum prostate-specific antigen (PSA) and digital rectal examination (DRE) has allowed earlier detection (Catalona et al, 1991, 1993). Furthermore, with a remarkable stage migration, approximately 90% of cases are being detected in a clinically localized stage, whereas metastases at the time of diagnosis are now rare in the United States (Han et al, 2001a). The natural history of prostate cancer varies from indolent disease that might not cause symptoms during a patient's lifetime to highly aggressive cancer that metastasizes quickly and causes terrible suffering and untimely death. The challenge for the physician who treats patients with prostate cancer is to advise effective treatment in those for whom treatment is necessary. Selection of the appropriate treatment requires assessment of the tumor's potential aggressiveness and the general health, life expectancy, and quality of life preferences of the patient.

Patients whose tumor has a low malignant potential are predetermined to fare better with most treatments. Therefore the treatment outcomes in any patient series may be influenced by the malignant potential of the tumors as well as by the treatment used. Accordingly, it is difficult to compare the results of different reports because the populations of patients are usually heterogeneous and not strictly comparable. Furthermore, outcome measurements are not necessarily comparable between different forms of therapy (e.g., different definitions of biochemical progression for surgery and radiotherapy), confounding comparisons between them.

Characterization of the Primary Tumor

DRE and prostate ultrasound findings usually provide useful information about the extent of the primary tumor. The serum PSA data, including the total PSA level, the rate of change of PSA (PSA velocity and doubling time), the PSA density (serum PSA divided by prostate volume), and the percentage of PSA in the free or complexed isoforms, are significantly associated with prostate cancer aggressiveness (Benson et al, 1992; Carter et al, 1997; Catalona et al, 1998; D'Amico et al, 2004; Thompson et al, 2004; Kundu et al, 2007). The biopsy findings—Gleason score; the number of cores containing cancer; the distribution and volume of cancer in the biopsy cores; the presence of perineural space invasion, lymphovascular invasion, or ductal or neuroendocrine differentiation—also correlate with cancer aggressiveness and the likelihood of the cancer being organ confined. Prediction tables and algorithms have been developed to assist in this assessment (Partin et al, 1997, 2001). However, such statistical aids are more useful in *groups* of patients than in individual patients, and wide confidence intervals surrounding estimates of outcomes sometimes limit the usefulness of risk assessment for an individual patient. In this regard, it has been claimed that the simultaneous assessment of multiple variables in nomograms provides more accurate predictions than tables do for individual patients (Kattan, 2003).

Evaluation of the Patient

There is no general agreement about how extensive the initial staging workup should be. Some physicians believe that a radionuclide bone scan, abdominal-pelvic computed tomography (CT) scan, and magnetic resonance imaging (MRI) scan are not indicated if the tumor has a Gleason sum of less than 7, the serum PSA level is less than 10 ng/mL, and the biopsy findings do not reveal an extensive or highly aggressive cancer because the likelihood of finding metastases is quite low.

In patients contemplating surgical treatment, a more complete workup should be considered, including coagulation studies, baseline bone scan for future reference with confirmatory imaging studies, if necessary, and a CT or MRI scan of the abdomen and pelvis to evaluate the primary tumor and regional lymph nodes and to rule out other possibly important conditions that might need to be addressed at the time of surgery. However, tumor-selective imaging tests, such as monoclonal antibody scans, positron emission tomographic scans, magnetic resonance spectroscopy, and lymphotrophic MRI are not widely used, although they might prove more useful in the future. In this regard, with increasing availability of endorectal MRI technology, there is increasing use of endorectal MRI to evaluate the local extent of the tumor.

CONSERVATIVE MANAGEMENT

Active Surveillance or Watchful Waiting

Active surveillance and *watchful waiting* are almost unique to prostate cancer. There are different concepts of deferred treatment of prostate cancer. Watchful waiting refers to monitoring the patient until he develops metastases that require palliative treatment. Active surveillance or expectant management allows delayed primary treatment if there is biochemical or histologic evidence of cancer progression (Dall'Era et al, 2008). Active surveillance is a less established strategy in patients with a long life expectancy, because criteria for selecting candidates and trigger points for instituting treatment have yet to be defined and validated. Currently, treatment is frequently initiated because of the patient's anxiety from living with untreated cancer combined with a rising PSA level or biopsy findings that suggest an increase in the volume or Gleason grade of the cancer. Findings on DRE or transrectal ultrasonography are seldom the sole indications for intervention.

Traditionally, deferred treatment has been reserved for men with a life expectancy of less than 10 years and a low-grade (Gleason score 2 to 5) prostate cancer. However, active surveillance is now being evaluated as a management strategy in younger patients with low-volume, low- or intermediate-grade (up to Gleason score 3 + 4 = 7) tumors to avoid or to delay treatment that might not be immediately necessary. In one study, approximately 16% of patients with newly diagnosed prostate cancer would fulfill the criteria for active surveillance, about 10% chose surveillance, and an additional 4%, who did not meet all criteria, chose active surveillance (Barocas et al, 2008).

Statistical models have been generated in an attempt to predict which tumors can be observed without aggressive treatment. For example, Epstein and associates (1994, 1998) proposed a model involving preoperative clinical and pathologic features that would predict "insignificant tumors" (tumor volume less than 0.2 cc, Gleason score below 7, and organ-confined cancer). The preoperative features used in the model include no Gleason pattern 4 or 5 in the biopsy specimen, PSA density of 0.1 ng/mL/g or less, fewer than three biopsy cores involved (with a minimum of six total cores being obtained), and no core with more than 50% involvement or PSA density of 0.1 to 0.15 ng/mL/g and cancer smaller than 3 mm on only one prostate biopsy sample. Characteristically for statistical models, **this model was reported to have a predictive value of 95% for identifying a "significant" cancer but a predictive value of only 66% for identifying an "insignificant" cancer** (Epstein et al, 1994). Approximately 16% of the men in this series met criteria for an insignificant cancer (Epstein et al, 1994). Subsequently, Epstein and colleagues (1998) updated the model to include a free/total PSA ratio (≥0.15) and favorable needle biopsy findings (fewer than three cores involved, no core with more than 50% tumor, and Gleason score of 6 or lower).

Kattan and associates (2003) proposed another statistical model to predict small, moderately differentiated, organ-confined cancer on the basis of PSA, clinical stage, biopsy Gleason score, ultrasound-determined prostate volume, and variables derived from systematic biopsies. **They defined indolent cancer as being organ confined, having less than 0.5 cc tumor volume, and without poorly differentiated elements.** Approximately 20% of their patients treated with radical prostatectomy met the criteria for indolent tumors according to their prediction model.

Some authors have claimed that even patients who do not fulfill such criteria may be legitimate candidates for active surveillance (Eastham et al, 2003). **A potential untoward consequence of recommending active surveillance for all men without obviously aggressive, clinically localized disease is that only men with clearly aggressive and often incurable disease would be treated immediately, whereas a substantial proportion of those with curable disease destined to progress would be monitored, often with multiple extended biopsy procedures that could**

complicate subsequent attempts at nerve-sparing surgery or delay treatment until the window of opportunity for cure has closed.

All prostate cancer patients are at risk for progression. **In reports of deferred therapy for prostate cancer, patients are usually observed with semiannual PSA determinations, DRE, and annual biopsies** (Zietman et al, 2001; Choo et al, 2002; el-Geneidy et al, 2004; Klotz, 2004; Patel et al, 2004; Carter et al, 2007; Dall'Era et al, 2008). **Intervention is recommended if Gleason pattern 4 or 5 is present, more than two biopsy cores are involved, or more than 50% of a biopsy core is involved. Progression is more likely in patients who have cancer present on every biopsy procedure. The absence of cancer on repeated biopsy significantly decreases the likelihood of progression** (Carter et al, 2007). In this regard, biopsy criteria have been reported to be more accurate than PSA criteria in predicting progression. No study has found DRE or imaging studies to independently predict progression.

The percentage of patients with curable cancer at the time of progression has been reported to vary from 33% to 92%. **In most studies of active surveillance, approximately 25% to 50% of patients, depending on their individual risk factors, develop objective evidence of tumor progression within 5 years** (Neulander et al, 2000; Patel et al, 2004; Warlick et al, 2006). Carter and colleagues (2007) reported that 59% remained on surveillance, 25% underwent curative treatment, and 16% either withdrew, were lost to follow-up, or died of other causes. Although some studies suggest that patients with Gleason score 2 to 4 tumors do not suffer or die of prostate cancer with conservative management, those with higher Gleason score tumors have a substantial risk for morbidity and mortality (Albertsen et al, 1995, 2005; Johansson et al, 2004). Klotz and colleagues (2006) reported that of patients who underwent radical prostatectomy for evidence of cancer progression during active surveillance, 58% had tumor extension beyond the prostate and 8% had lymph node metastases.

A prospective, randomized clinical trial from Scandinavia reported that patients with clinically localized prostate cancer managed with watchful waiting have significantly higher rates of local cancer progression, metastases, and death from prostate cancer and a shorter cancer-specific (lower death rate from prostate cancer) and overall survival than those treated initially with radical prostatectomy (Bill-Axelson et al, 2008). Similarly, an observational study of Medicare patients treated with observation, radiation, or surgery showed a survival advantage for active treatment of men aged 65 to 80 years; however, the absolute difference in cancer-specific death at 12 years was small (Wong et al, 2006).

One rationale for active surveillance is the belief that there is substantial overdiagnosis of prostate cancer as a result of widespread PSA screening coupled with aggressive biopsy regimens. ***Overdiagnosis*** **often refers to a cancer detected by screening that would not be detected during the patient's lifetime without screening or would never cause disability or death. It is axiomatic that any effort to detect cancer early will involve detection of some cancers that would not have been otherwise detected. Therefore some overdiagnosis is necessary to reduce suffering and death from prostate cancer.**

There are two methods of estimating the extent of overdiagnosis. The epidemiologic method applies only to populations, not to individuals. With this method, statisticians look at population trends in prostate cancer cases and use statistical models to estimate whether more cases are being diagnosed than should be, considering past incidence rates of prostate cancer and prostate cancer deaths. Statisticians estimate lead time in prostate cancer diagnosis with PSA screening (3 to 12 years) and use the lead time to estimate overdiagnosis; however, statistical models have not accurately predicted the observed incidence of prostate cancer nor fully explained the observed decrease in advanced disease.

The second method of estimating overdiagnosis is for a pathologist to examine a surgically removed cancerous prostate gland and determine whether it contained only a tiny amount of cancer with no high Gleason pattern glands and that was completely encapsulated within the prostate gland. If so, they call it an overdiagnosed cancer.

Some reports have estimated that 50% or more of prostate cancer cases are overdiagnosed (Etzioni et al, 2002; Draisma et al, 2003). **However, recent studies suggest that epidemiologic estimates of overdiagnosis are exaggerated. Epidemiologic estimates based upon both statistical models and data from the United States yield a 23% to 28% incidence of possible overdiagnosis** (Draisma et al, 2009). **Estimates based upon clinicopathologic data range from 6% to 20%** (Graif et al, 2007; Pelzer et al, 2007).

Estimates of overdiagnosis derived from older men should not be generalized to younger men. Prostate cancers diagnosed in younger men are less likely to be harmless in the long term, and it is uncertain whether all cases labeled as overdiagnosed are clinically insignificant. Contrary evidence suggests that screening with low PSA thresholds for biopsy in young patients detects tumors that fulfill the criteria for insignificant cancer in only 12% of patients (Krumholtz et al, 2002). Even among those that do, some tumors are multifocal or do not have a diploid complement of chromosomes**. Presently, no tumor marker can identify indolent tumors with certainty.**

An accumulating body of increasingly compelling evidence shows that PSA screening can reduce prostate cancer deaths. First, there would be no point in trying to detect prostate cancer early if there were no effective treatment for early stage disease. The study on the long-term results of a Swedish randomized trial of radical prostatectomy versus watchful waiting for early prostate cancer showed that surgery can reduce the rates of metastases and prostate cancer deaths, and even increase overall survival (Bill-Axelson et al, 2011).

The "holy grail" of screening is the randomized trial. In the initial report from the European Randomized Study of Screening for Prostate Cancer (ERSPC), men randomized to screening had a 20% lower prostate cancer death rate. Not surprisingly, this mortality benefit was observed largely in men under age 70 (Schroder et al, 2009).

The initial report of the ERSPC contained the sobering estimate that 48 men had to be treated to prevent one prostate cancer death. This high number-needed-to-treat (NNT) raised many eyebrows, because it is shocking to think that 48 men would have to undergo surgery or radiation to prevent one man from dying of prostate cancer. However, because the risk of dying from prostate cancer is influenced by a patient's life expectancy, the NNT to save one life is also strongly influenced by a patient's age and health, and the length of follow-up of the trial. The NNT is lower in younger, healthier men and in trials that have longer follow-up. Subsequent studies have reported a far lower NNT to save one life.

The mortality curves of the screened and control groups from the ERSPC began to separate at 9 years of follow-up when the trial

was first reported. By 12 years follow-up, the NNT had decreased to 12 (Schröder FH, presented at the 2011 American Urological Association Meeting in Washington, DC).

In the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial (PLCO) (Andriole et al, 2009), the results were initially reported on the entire study group—young and old, healthy, and not so healthy. They concluded, "…we now know that prostate cancer screening provided **no** reduction in death rates at 7 years… ." Many authors summarized these two large screening trials as yielding conflicting results; however, this conclusion is not correct. From a subsequent data analysis of the healthier participants, a far different picture emerged. A follow-up analysis of PLCO data showed a striking mortality benefit in the roughly one third of PLCO participants with minimal or no co-morbidities (Crawford et al, 2010). This analysis showed the prostate cancer death rates of relatively healthy PLCO participants randomized to screening were 44% lower than in the control arm, and the NNT to save one life in these healthier men was reported to be only 5.

The Norrkoping Trial from Sweden (Sandblom et al, 2011) also was widely publicized as a negative screening trial. This trial has many limitations. First, it is a small study with only 85 screen-detected prostate cancer cases. Men were screened every 3 years, but the first two screens involved only digital rectal examination. There was no PSA screening until 6 and 9 years into the trial. Fine-needle aspiration cytology (rather than core needle biopsy) was used for diagnosing prostate cancer. The median age of the patients at diagnosis was nearly 70 years old, and the median follow-up of prostate cancer patients was only 6 years. Moreover, nearly half of the screen-detected patients were managed with watchful waiting, and only one third were treated with radical prostatectomy. Despite these limitations, the data actually provides considerable support for PSA screening. The screened patients had far fewer advanced tumors at diagnosis. There was a **strong** trend for better prostate cancer–specific survival in the screening arm that approached statistical significance, and there **was** a significantly lower risk ratio for prostate cancer death in the screening arm.

The Goteborg Screening Trial used perhaps the **best** methodology (Hugosson et al, 2010). It is a **population-based study of younger patients**—20,000 men aged 50 to 64. The contamination rate (i.e., opportunistic PSA screening of controls) was only 3% when the trial started versus an estimated 15% contamination rate in ERSPC and 40% to 50% in PLCO. Trial participants were screened every 2 years with **progressively lower** PSA cutoffs over time, beginning with a 3.4 ng/mL cutoff and ending with a cutoff of 2.5 ng/mL. Ninety-three percent of the men complied with the biopsy recommendation when they had an abnormal screening test, in contrast to PLCO, in which only 40% underwent prompt biopsies. Seventy-seven percent had 14 years of follow-up. The results showed that 41% fewer screened patients presented with advanced disease, and the screening arm had a 44% lower prostate cancer death rate. Moreover, the NNT was 12, which compares favorably with the NNT for breast cancer (NNT = 10 at 10 years of follow-up). The Gotebörg trial has not yet demonstrated a significant improvement in overall survival; however, overall survival benefit takes the longest time to demonstrate of any survival parameter.

Pound and colleagues (1999) reported that **the median time from PSA failure to the development of metastases after radical prostatectomy is 8 years, and the median time from metastases to death is 5 years** (Pound et al, 1999). **Thus the median time from diagnosis to death is more than 13 years.** The median follow-up time for patients in U.S. screening trial was only 5.2 years for controls and 6.3 years for cases—2 years before the expected metastases and 6 years before prostate cancer death. In the European trial, there also was no improvement in survival until after 7 years.

The United States trial has been portrayed as the underpinning for a proposed shift in the mind-set of physicians and patients that screening and treatment of prostate cancer do more harm than good. However, this trial was flawed at the beginning, is a mere snapshot taken halfway through the relevant follow-up period, and will never be informative of the true impact of screening on prostate cancer death of healthy men managed with intelligent screening, prompt biopsy, and effective treatment.

There is other compelling evidence to suggest that early diagnosis through PSA testing and prompt, effective, and high-quality treatment saves lives. This evidence comes largely from the cancer registries of the United States and World Health Organization databases. The percentage of men who have advanced prostate cancer at the time of diagnosis has decreased by 75% in the United States during the PSA era, and there has been a 40% decrease in the prostate cancer death rate during the PSA screening era (National Cancer Institute, 2010). **Statistical studies suggest that 45% to 70% of this decrease is due to PSA screening** (Etzioni et al, 2008).

Other studies have shown that in regions of the United States where more PSA testing is performed, there is a lower rate of advanced prostate cancer and prostate cancer death rates (Colli and Amling, 2008). In a population-based study, PSA screening reduced the prostate cancer-specific mortality rate by 62% (Agalliu et al, 2007; Kvale et al, 2007). **Globally, the death rate also has fallen in countries where PSA testing is practiced, while it continues to rise in countries where it is not** (Bouchardy et al, 2008).

The frequently cited decrease in prostate cancer mortality reported in the United Kingdom from 1992 to 2004 in the absence of widespread PSA screening is due largely to the method of attributing the cause of death in the United Kingdom databases during that time. Before the PSA era, if a man with metastatic prostate cancer died of pneumonia, the cause of death was attributed to prostate cancer, but during the early years of the PSA era, the cause of death was attributed to pneumonia. Thus there was a spurious decrease in the prostate cancer mortality rate in the PSA era in the absence of widespread PSA screening (Hussain et al, 2008).

The physician confronting the patient with newly diagnosed prostate cancer must decide on management based on the PSA level, the estimated tumor volume, and the Gleason score (up to one third of patients are upgraded on the basis of the radical prostatectomy specimen (Pinthus et al, 2006) to select patients for immediate treatment or active surveillance. Repeated biopsies are always subject to sampling errors (Harnden et al, 2008) and may induce fibrosis in and around the prostate gland that could compromise subsequent nerve-sparing surgery, rendering it impossible to perform in more than half of patients (Barzell and Melamed, 2007), as well as trigger inflammation leading to PSA fluctuations that are difficult to interpret.

Treatment is more likely to be successful if given earlier while the tumor is smaller and the prospects for potency-sparing surgery are greater. Deferred treatment is more appropriate for older patients with a limited life expectancy or comorbidities. Additional clinical and

laboratory research are needed to define the parameters for safe use of active surveillance in younger men, including the appropriate selection criteria, follow-up procedures, and trigger points for intervention (Carter et al, 2003; Allaf and Carter, 2004; Wilt, 2008). It will also be necessary to determine the proportion of patients that would still have curable disease when they are treated at the time of objective disease progression. In many instances, active surveillance delays the treatment by only a few years; however, Freedland and colleagues (2006) reported that delays of more than 6 months conferred a 2.73-fold increased risk of progression in patients with low-risk prostate cancer. Active surveillance frequently amounts to *delayed* treatment, and patients selected for active surveillance have cancers that are most curable with the fewest side effects. Some with curable disease would have surveillance until the window of opportunity for cure is closed, and it would be a mistake to treat only patients with incurable disease. **For the present, patients who opt for active surveillance should be evaluated with DRE and PSA testing quarterly or semiannually, and they should consider having repeated prostate biopsy procedures yearly or biennially.** In patients with a consistent PSA velocity of greater than 0.35 ng/mL/year, there is a fivefold increased risk of prostate cancer death in the next two to three decades (Carter et al, 2006). **Although it is assumed that quality of life should be largely preserved with active surveillance, studies have demonstrated significant decrements in quality of life with time, including waning erectile function, diminished urinary continence, and adverse psychologic effects from living with untreated cancer** (Penson et al, 2005). For example, in the Scandinavian study, men randomized to watchful waiting had a significantly worse quality of life than men randomized to radical prostatectomy (Johansson et al, 2008). This was especially true in men who received androgen deprivation (Johansson et al, 2008). **If the PSA level is rising, the DRE suggests tumor growth, or surveillance biopsy specimens show evidence of increased involvement by cancer, treatment should be instituted. Patients may change their minds about remaining on an active surveillance protocol; therefore the physician should review management options on follow-up visits.**

In patients with a long life expectancy, there is a certain risk associated with active surveillance. Clearly, it can avoid or delay treatment for some patients, but there will inevitably be those who will miss their opportunity for cure and, tragically, ultimately progress to metastases and death from prostate cancer. Favorable outcomes have been reported in potential candidates for active surveillance treated with prompt nerve-sparing radical prostatectomy (Loeb et al, 2008).

The ERSPC trial has provided an unequivocally affirmative answer to half of the often quoted aphorism of Willett Whitmore Jr. concerning prostate cancer—"Is cure possible when it is necessary?" To answer the second part, "Is cure necessary when it is possible?," will require more clinical research evaluating the trade-offs.

RADICAL PROSTATECTOMY

Radical prostatectomy was the first treatment used for prostate cancer and has been performed for more than 100 years (Kuchler, 1866; Young, 1905). It is a technically formidable operation, and as a result, simpler treatments have been sought for the treatment of early-stage disease. However, **no treatment has supplanted radical prostatectomy, and it still remains the gold standard because of the realization that hormone therapy and chemotherapy are never curative, and not all cancer cells can be eradicated consistently by radiation or other physical forms of energy, even if the tumor is contained within the prostate gland.**

Key Points: Conservative Management

- Prostate cancer treatment outcomes may be influenced by the malignant potential of the tumors as well as by the treatment used. Furthermore, outcome measurements are not necessarily comparable between different forms of therapy, confounding comparisons between them.
- Traditionally, deferred treatment has been reserved for men with a life expectancy of less than 10 years and a low-grade prostate cancer. Additional research is needed to define the parameters for safe use of active surveillance in younger men, including the appropriate selection criteria, follow-up procedures, and trigger points for intervention.
- A prospective, randomized clinical trial reported that patients with clinically localized prostate cancer managed with watchful waiting have significantly higher rates of local cancer progression, metastases, and death from prostate cancer than do those treated initially with radical prostatectomy and, as discussed above, a prospective, randomized screening trial reported that prostate cancer screening with PSA and DRE reduces prostate cancer-specific mortality by 20% to 27% with early follow-up. Because many of these patients were treated with radical prostatectomy, it may also be inferred to be evidence of the efficacy of radical prostatectomy for localized prostate cancer.

Innovations have led to the wider use of radical prostatectomy:

1. the development of the anatomic radical retropubic prostatectomy that allows the dissection to be performed with good visualization and preservation of the cavernous nerves responsible for erectile function and preservation of the external sphincter muscle that yields urinary continence rates in excess of 90% (Walsh and Donker, 1982);
2. the development of extended ultrasound-guided biopsy regimens, performed under local anesthesia as an office procedure (Arnold et al, 2001); and
3. the widespread use of PSA testing that has led to the majority of patients being diagnosed with clinically localized disease.

In recent years, the laparoscopic approach has been developed for performing the operation.

The main advantage of radical prostatectomy is that when skillfully performed, it offers the possibility of cure with minimal collateral damage to surrounding tissues (Han et al, 2001b; Hull et al, 2002). **Further, it provides more accurate tumor staging by pathologic examination of the surgical specimen. Also, treatment failure is more readily identified, and the postoperative course is much smoother than in the past.** Few patients require nonautologous blood transfusions. The hospital stay is usually 1 to 3 days, and operative mortality is rare in the modern era. Moreover, radical prostatectomy significantly reduces local progression and distant metastases and improves cancer-specific and overall survival rates compared with watchful waiting (Bill-Axelson et al,

2008). **Some patients with tumor recurrence after radical prostatectomy can be salvaged with potentially curative postoperative radiotherapy** (Stephenson et al, 2004b; Trock et al, 2008).

The potential disadvantages of radical prostatectomy are the necessary hospitalization and recovery period; a possibility of incomplete tumor resection, if the operation is not performed properly or if the tumor is not contained within the prostate gland; and a risk for erectile dysfunction and urinary incontinence. However, erectile dysfunction and rectal complications are less likely with nerve-sparing surgery than with radiotherapy, and good treatment options are available for both urinary incontinence and erectile dysfunction. Results reported from high-volume centers are more favorable than those from national surveys (Rabbani et al, 2000; Stanford et al, 2000, Kundu et al, 2004; Sanda et al, 2008).

Surgical Approaches to Radical Prostatectomy

Perineal. Total perineal prostateactomy is an acceptable surgical treatment when performed by a surgeon familiar with this approach (Scolieri and Resnick, 2001). It is usually associated with **less blood loss and a shorter operative time than the retropubic approach. The disadvantages are that it does not provide access for a pelvic lymph node dissection, there is a higher rate of rectal injury, and there is occasional postoperative fecal incontinence that does not occur commonly with other approaches** (Bishoff et al, 1998). It is more difficult to spare the cavernous nerves through the perineal approach.

Retropubic. The open retropubic approach is **preferred by many urologists because of their familiarity with the surgical anatomy, the lower risk for rectal injury and postoperative fecal incontinence, the wide exposure and ready access provided for pelvic lymphadenectomy and prostate excision with preservation of the neurovascular bundles, and the lower risk for positive surgical margins.**

Laparoscopic. The laparoscopic approach is the most daunting method of performing radical prostatectomy. It has been suggested that laparoscopic prostatectomy **may be associated with less bleeding, better visualization, less postoperative pain, and shorter convalescence than the standard open approach. However, the claimed advantages are not always realized with many surgeons and are usually less important to the patient than the cure of his cancer, the preservation of his potency, and the avoidance of other more serious complications. Laparoscopic prostatectomy can be performed through a transperitoneal or extraperitoneal approach, but the extraperitoneal approach poses logistical limitations, especially with the use of robotic assistance. The transperitoneal approach facilitates the lymphadenectomy but carries a higher risk of intestinal and vascular injury, urinary ascites, and postoperative intestinal obstruction.**

Furthermore, laparoscopic prostatectomy is associated with a higher risk for severe complications. Hemostasis in the neurovascular bundles is difficult to achieve without thermal injury to the neurovascular bundles because of the relative difficulty in rapidly placing hemostatic sutures or applying hemostatic clips laparoscopically. Heat from a harmonic scalpel or electrocautery can irreversibly damage the cavernous nerves. Although intraoperative blood loss is less with laparoscopic surgery, postoperative bleeding may occur after the release of positive pressure in the operative field. Rectal, ureteral, and vascular injuries and anastomotic leaks have also been more common with laparoscopic prostatectomy (Rassweiler et al, 2003).

When laparoscopic prostatectomy is performed by a skilled laparoscopic surgeon, reported incontinence and anastomotic stricture rates are comparable to those achieved with open surgery. It has been claimed that nerve sparing is equivalent or even better with laparoscopic surgery, but direct comparisons and validated results are lacking (Menon et al, 2007). **The early reported rates of positive surgical margins have been higher with laparoscopic prostatectomy, and the adequacy of cancer control is as yet uncertain because of lack of long-term results.**

Robotic. Remotely controlled laparoscopic surgery has recently been popularized because of its **greater technical ease for the surgeon, especially for tying sutures and performing the vesicourethral anastomosis.** It has been aggressively marketed as a less invasive, technologically more advanced method of performing the operation with less pain and a quicker recovery. **The availability of three-dimensional visualization is an advantage over standard laparoscopic techniques.** Early reported results are favorable but have not been validated (Menon et al, 2002, 2007). It is uncertain whether the results of laparoscopic prostatectomy are as good as those achieved with open prostatectomy (Smith, 2004; Webster et al, 2005; Hu et al, 2006; Rogers et al, 2006; Touijer and Guillonneau, 2006).

There has been a dramatic shift from open to robotic prostatectomy in the United States that has been driven largely by marketing. However, until recently, there has been little objective data to substantiate these claims (Smith et al, 2007; Weizer et al, 2007; Wood et al, 2007). **Recent reports based on comparative data have shown disadvantages in laparoscopic and robotic prostatectomy in tumor recurrence, urinary incontinence, and patient satisfaction.**

In performing a radical prostatectomy, the surgeon must dissect in the proper tissue plane to remove the prostate from between the neurovascular bundles without permanently damaging the nerves or cutting into the prostate, or worse, leaving part of the prostate behind.

Most prostate cancer patients have similar priorities. First, they want to survive; second, they want to remain continent; and third, they want to preserve their potency. These are their main priorities, but they want all three. This constellation of favorable outcomes is known as the "trifecta" (Eastham et al, 2008), and, understandably, patients want to achieve it as quickly and painlessly as possible. Often, patients with newly diagnosed prostate cancer would like to avoid any treatment, if possible, or, after realizing that treatment is necessary, seek the easiest way out. This frequently leads to consideration of options such as active surveillance, cryoablation, high-frequency ultrasound, or minimally invasive prostatectomy.

It is important to examine the claims concerning laparoscopic and robotic prostatectomy. Usually six incisions are made in laparoscopic surgery, and, in most cases, the procedure is performed within the peritoneal cavity, while for open surgery, one incision is made—4 to 5 inches in length and that does not enter the peritoneal cavity. **Comparative studies have shown that open prostatectomy has a similar recovery time and return to normal activity** (Weizer et al, 2007; Wood et al, 2007).

It is also more difficult to perform a lymph node dissection with laparoscopic approaches. Other factors come into play as well, such as lack of a sense of touch or tactile feedback. Furthermore, some surgeries that start out as laparoscopic must be converted to open, because of failure to progress or complications that cannot be handled laparoscopically. **Perhaps the most important consideration is that the laparoscopic approaches have no long-term track record of cancer control.** If small amounts of cancer are left behind, it may not become apparent for years.

A comparison of a sample of patients from the Medicare database who underwent minimally invasive or open prostatectomy between 2003 and 2005 revealed a lower rate of medical complications with the laparoscopic approaches; however, the men undergoing minimally invasive prostatectomy had more than a threefold higher rate of requiring salvage therapy for tumor recurrence within 6 months of surgery (Hu et al, 2008). In this study, the more experienced surgeons in minimally invasive radical prostatectomy had better results than less experienced surgeons; however, even the highest-volume laparoscopic surgeons had twice the rate of patients requiring salvage treatment for cancer recurrence when compared with all surgeons performing open radical prostatectomy. **Patients undergoing minimally invasive surgery also were 40% more likely to develop anastomotic strictures.**

Another study comparing the results of laparoscopic and open radical prostatectomy revealed that **the laparoscopic approach was associated with less blood loss, but, of more concern, had a higher rate of postoperative emergency room visits, readmissions to the hospital, and further surgery for complications** (Touijer et al, 2008). **Also, patients who underwent a laparoscopic radical prostatectomy were less likely to become continent than those treated with open prostatectomy.**

In a few studies including a small number of patients, potency rates have been reported to be similar with both techniques when experienced surgeons performed the operations (Menon et al, 2007). **However, in general, potency rates have not matched the best rates achieved by the most experienced surgeons performing open surgery.**

Schroeck and colleagues (2008) compared patient satisfaction and regret following radical prostatectomy**. Patients who underwent a robotic prostatectomy were more than four times more likely to regret their decision**. The authors suggested that these patients were more likely to be regretful and dissatisfied because of the higher expectations from an "innovative" procedure. These results raise concerns that patients are being misled about the true risks and benefits of minimally invasive procedures to treat prostate cancer.

Thus the outcomes of cancer control, potency, and continence are well documented for open prostatectomy, but the jury is still out with laparoscopic approaches.

Salvage Radical Prostatectomy

Radical prostatectomy can be performed in patients for whom other local treatments have failed (Pontes, 1994; Chen and Wood, 2003). **However, the rate of complications is far higher, and the complications are more serious and much more difficult to manage** (Stephenson et al, 2004a; Sanderson et al, 2006). **Moreover, the prospects for long-term disease-free survival are more limited for salvage prostatectomy than for primary radical prostatectomy.**

Most of the reported experience with salvage radical prostatectomy is from the pre-PSA era. Contemporary series of patients selected because of biochemical recurrence have lower morbidity and better cancer control rates (Stephenson et al, 2004a; Ward et al, 2005). **Nevertheless, postoperative incontinence rates are as high as 44% and bladder neck contracture rates as high as 22%** (Ward et al, 2005). The incontinence rate is even higher after brachytherapy, presumably because of the higher dose of radiation administered. **Long-term progression-free survival rates after salvage prostatectomy in the absence of hormone therapy have not been well documented.**

Selection of Patients for Radical Prostatectomy

An ideal candidate for radical prostatectomy is healthy and free of comorbidities that might make the operation unacceptably risky. He should have a life expectancy of at least 10 years, and his tumor should be deemed to be biologically significant and completely resectable. The generally accepted upper age limit for radical prostatectomy is about 75 years.

Because imaging studies are not accurate for staging prostate cancer, **preoperative clinical and pathologic parameters are often used to predict the pathologic stage and thus identify patients most likely to benefit from the operation** (Partin et al, 1997, 2001). These parameters are frequently used in tables and nomograms designed to predict pathologic tumor stage or post-treatment recurrence-free survival probabilities (Han et al, 2003; Kattan et al, 1998, 2000; Ross et al, 2001). New methods of predicting the outcome after radical prostatectomy that incorporate cellular and biologic features to improve accuracy have been reported (Donovan et al, 2009).

Patients with a low probability of resectable disease or a short life expectancy should not be advised to have surgery. Neoadjuvant hormone therapy does not enhance the resectability of prostate cancer and often increases the difficulty of performing nerve-sparing surgery (Soloway et al, 2002). **Similarly, neoadjuvant chemotherapy rarely produces pathologically complete responses** (Chi et al, 2008).

The surgeon should realistically counsel the patient on the nerve-sparing aspects of the operation. Nerve-sparing prostatectomy does not materially compromise cancer control in appropriately selected patients; however, it is inappropriate in men with advanced disease. **The feasibility of performing nerve-sparing surgery is questionable when there is extensive cancer in the biopsy specimens, palpable extraprostatic tumor extension, serum PSA level above 10 ng/mL, biopsy Gleason score higher than 7, poor-quality erections preoperatively, current and future lack of a sexual relationship, or other medical conditions that may adversely affect erections (e.g., diabetes mellitus, hypertension, psychiatric diseases, neurologic diseases, or medications that produce erectile dysfunction).**

Postoperative treatment of erectile dysfunction also should be discussed, including information on phosphodiesterase type 5 (PDE-5) inhibitors, intraurethral and intracorporeal administration of vasodilators, vacuum

erection devices, venous flow constrictors, and implantable penile prostheses. The discussion also should include the timing of the return of erections. The patient should be warned about the risk for development of Peyronie disease from injury to the penis during sexual activity without a rigid erection (Ciancio and Kim, 2000). He should also be informed that early postoperative use of intracavernosal injection therapy with vasodilating drugs allows most patients to have normal erections (with arterial blood) shortly after the catheter is removed. This protects against the occurrence of atrophic changes in the penis and allows the resumption of sexual activity early in the postoperative period. If erectile function is a high priority for the patient, he should be reassured that erections almost always can be restored, regardless of whether nerve-sparing surgery could be performed.

The preoperative evaluation should consider the likelihood of success in achieving all goals of surgery and in determining whether nerves can safely be spared. The surgeon should also discuss **the possibility of performing cutaneous nerve graft interposition if one or both cavernous nerves must be resected** (Kim et al, 1999; 2001; Quinlan et al, 1991; Secin et al, 2007). **There are limited data concerning the effectiveness of such grafts. In most patients with a tumor so advanced that one or both nerves must be resected, postoperative radiotherapy or hormone therapy is likely to be required, which could nullify the potential benefits of nerve grafting. Some studies question whether nerve grafting is effective** (Davis et al, 2008). The surgeon should also discuss the possible need for and potential side effects of adjuvant postoperative radiotherapy and/or hormone therapy, if the final pathology specimen reveals adverse prognostic features.

Surgical Technique

Radical prostatectomy involves complete removal of the prostate gland and seminal vesicles and usually includes a modified pelvic lymph node dissection as well. The key steps in performing anatomic nerve-sparing radical retropubic prostatectomy are as follows:

1. pelvic lymphadenectomy;
2. opening of the endopelvic fascia and limited incision of the puboprostatic ligaments;
3. suture ligation and transection of the Santorini dorsal venous complex;
4. dissection of the urethra at the apex of the prostate and transection of the urethra (sometimes the anastomotic sutures are placed at this point in the operation);
5. dissection of the prostate from the neurovascular bundles;
6. securing and transection of the prostatic pedicles;
7. transection and reconstruction of the bladder neck;
8. dissection of the seminal vesicles and ampullary portions of the vasa deferentia; and
9. performance of the vesicourethral anastomosis.

The surgeon should strive for complete apposition of the bladder neck and the urethra, with a watertight, tension-free closure.

Pelvic lymphadenectomy is optional in patients at low risk for lymph node metastases. Patients who elect to undergo lymphadenectomy should decide in advance whether they wish to proceed with the prostatectomy if there are nodal metastases. If they do not wish to proceed, the excised lymph nodes are sent for frozen-section examination during the operation. Otherwise, intraoperative frozen-section analysis of pelvic lymph nodes is unnecessary. Some have argued that a more extensive pelvic lymphadenectomy yields better outcomes, but compelling evidence for this is lacking (Weight et al, 2008), and more extensive lymphadenectomy carries a greater risk for postoperative genital and lower extremity lymphedema and lymphocele (Bader et al, 2002; Allaf et al, 2004; Musch et al, 2008). Thromboembolic events and reinterventions are more common in patients with symptomatic lymphocele (Musch et al, 2008).

The key to preserving urinary continence is to perform a meticulous dissection, avoiding injury to the external urinary sphincter. Preservation of the bladder neck is unnecessary to achieve good urinary continence. In patients with high-volume or high-grade tumors involving the base of the prostate, preservation of the bladder neck may risk positive surgical margins.

Meticulous dissection is required to preserve the neurovascular bundles. In performing nerve-sparing surgery, the neurovascular bundles are identified at the apex of the prostate (the dissection can also be performed in an antegrade fashion beginning at the base), and the bundles are dissected free of the posterolateral surface of the prostate gland. Hemostatic sutures or clips may be used to control bleeding from the neurovascular bundles. Use of electrocautery or a harmonic scalpel risks irreversible thermal injury to the neurovascular bundles.

The prostatic pedicles are suture ligated or hemoclipped and divided close to the gland, avoiding incision into the prostatic capsule. In performing the seminal vesicle dissection, care must be taken to avoid injury to the neurovascular bundles situated immediately lateral and posterior to them.

Postoperative Care

Patients should ambulate with assistance beginning on the afternoon or evening of surgery. **The catheter may be removed 3 to 21 days after surgery, depending on the integrity and the amount of tension on the vesicourethral anastomosis. Removal of the catheter before 7 days is associated with a 15% to 20% risk of urinary retention.**

After the catheter has been removed, Kegel exercises should be initiated. A protective pad is used until complete urinary control is achieved. The postoperative serum PSA level should be undetectable by 1 month after the operation. Ultrasensitive PSA measurements frequently falsely classify patients has having tumor recurrence (Taylor et al, 2006).

Cancer Control

The principal objective of radical prostatectomy is to completely excise the cancer. Important cancer control end points are pathologically organ-confined disease with clear surgical margins, biochemical recurrence (detectable serum PSA), local progression, metastases, cancer-specific survival, and overall survival. **As discussed above, depending on the Gleason score and the PSA doubling time, biochemical (PSA) evidence of recurrence usually precedes clinical metastases by a mean of about 8 years and cancer-specific mortality by about 13 years** (Pound et al, 1999).

Nonprogression rates vary with clinical and pathologic risk factors. Independent clinical prognostic factors are tumor stage, Gleason score, preoperative PSA level,

and calendar year of diagnosis and treatment. Adverse prognostic features include non–organ-confined disease, perineural or lymphovascular space invasion, extracapsular tumor extension, positive surgical margins, seminal vesicle invasion, and lymph node metastases (Grossfeld et al, 2000; Shariat et al, 2004). **In the PSA era, there has been a dramatic stage migration and improvement in prognostic features and treatment outcomes** (Han et al, 2001a; Moul et al, 2002).

A rising serum PSA level is usually the earliest evidence of tumor recurrence after radical prostatectomy (Pound et al, 1999). **Biochemical recurrence is frequently used as an intermediate end point for treatment outcomes; however, not all patients with biochemical recurrence ultimately develop metastases or die of prostate cancer. In rare instances with high-grade or neuroendocrine tumors that do not produce much PSA, there can be palpable evidence of recurrence despite an undetectable PSA level, indicating a role for DRE in monitoring of patients.**

In the first author's personal series, including more than 5000 open anatomic radical retropubic prostatectomies dating to 1983, the actuarial 10-year cancer progression-free survival probability was approximately 85% for patients with organ-confined disease, 65% for men with extracapsular tumor extension without cancerous surgical margins, 55% for men with extracapsular tumor extension and cancerous surgical margins, 25% for patients with seminal vesicle invasion, and 10% for patients with lymph node metastases. Patients treated in the PSA era have approximately five percentage points more favorable results within each pathologic category. Within these pathologic tumor stages, cancer progression rates also were strongly associated with other parameters. Case selection and the duration and frequency of follow-up monitoring are also important determinants of postoperative outcomes.

Radical prostatectomy also provides long-term cancer control in about half of highly selected men with clinical stage T3 disease (Freedland et al, 2007; Loeb et al, 2007).

Urinary Continence

Urinary continence after radical retropubic prostatectomy is generally good and varies according to the experience and skill of the surgeon. For high-volume radical prostatectomy surgeons, more than 90% of men recover complete urinary continence. **The return of urinary continence is associated with the patient's age:** approximately 95% of men younger than 60 years can attain pad-free urinary continence after surgery; 85% of men older than 70 years regain continence. **Few require implantation of an artificial urinary sphincter or a sling procedure for stress urinary incontinence.**

Erectile Function

Potency after radical prostatectomy is usually defined as the ability to maintain erections sufficiently rigid for penetration and sexual intercourse with or without the help of a PDE-5 inhibitor. Most patients with intact libido and erections wish to maintain these functions. Others with poor-quality erections usually wish to have erections that at least offer some rigidity to provide sensory satisfaction for both sexual partners. **The return of erectile function after radical retropubic prostatectomy correlates with the age of the patient, preoperative potency status, extent of nerve-sparing surgery, and era of surgery.** In the most favorable candidates in whom preoperative potency is normal and bilateral nerve-sparing surgery can be performed, up to 95% in their 40s, 85% in their 50s, 75% in their 60s, and 50% in their 70s can attain recovery of erections sufficient for penetration and intercourse. However, in most instances, erections are not as good as they were preoperatively.

In most patients, erections usually begin to return as partial erections 3 to 6 months after surgery and may continue to improve for up to 3 years or more (Burnett, 2005; Glickman et al, 2009). **Patients should be encouraged to use erectile aids postoperatively, including PDE-5 inhibitors, intraurethral suppositories, intracavernosal injections, or vacuum erection devices.** Erection rehabilitation programs using intracavernosal injection therapy or PDE-5 inhibitors might hasten the return of erections and increase the proportion of men who recover erections (Montorsi et al, 1997). However, it has been reported that on-demand, rather than nightly, dosing of PDE-5 inhibitors was efficacious in men with erectile dysfunction following bilateral nerve-sparing radical prostatectomy (Montorsi et al, 2008).

Complications

Anatomic nerve-sparing radical prostatectomy provides excellent cancer control with an acceptable complication rate in appropriately selected patients. The overall early complication rate after radical prostatectomy is less than 10% in experienced hands (Kundu et al, 2004). **With a careful selection of patients and performance of necessary preoperative cardiovascular evaluation, perioperative mortality has been largely avoided** (Mettlin et al, 1997; Kundu et al, 2004).

Early Complications

Early complications include hemorrhage; rectal, vascular, ureteral, or nerve injury; urinary leak or fistula; thromboembolic and cardiovascular events; urinary tract infection; lymphocele; and wound problems. It is advisable routinely to use support stockings and to ensure early ambulation. Prophylactic anticoagulation and sequential compression devices are advisable in patients at high risk for thromboembolic complications.

Inadvertent injury to the obturator nerve can occur during the pelvic lymphadenectomy. When a tension-free primary nerve repair is not feasible, nerve grafting can be performed by a cutaneous or genitofemoral nerve graft. However, even without a nerve repair, conservative management with physical therapy can compensate for the deficit, and therefore many patients do not have a significant thigh adductor deficit after the injury (Kirdi et al, 2000).

Ureteral injury is a rare complication. A minor injury or ligation can be managed with removal of the ligature and ureteral stenting. Mobilization of the distal ureter and reimplantation should be performed for more severe injuries.

Although uncommon, a rectal injury can occur and be repaired primarily by a multiple-layer closure (Lepor et al, 2001). However, a diverting colostomy should be considered in

men with a large rectal defect, a history of pelvic radiotherapy, or long-term preoperative glucocorticoid therapy.

Late Complications

The most common late complications of radical prostatectomy are erectile dysfunction, urinary incontinence, inguinal hernia, and urethral stricture. Early rehabilitation measures, including Kegel exercises to increase the strength and the bulk of the external sphincter muscle and the use of a PDE-5 inhibitor, vacuum erection device, and intraurethral or intracavernosal vasodilator appear to be helpful. Anastomotic or other urethral strictures should be managed initially with dilation, but internal incision and endoscopic injection of glucocorticoids may be required. For a long or persistent anastomotic stricture, a transurethral resection of the scar tissue cephalad to the external sphincter may be necessary. After the resection, an interval of catheter self-dilation of the anastomosis is usually required. Continued self-dilation or intermittent dilation by the urologist is required in difficult, persistent cases. Urethroplasty is rarely needed.

Key Points: Radical Prostatectomy

- Radical prostatectomy was the first treatment used for prostate cancer, and it still remains the gold standard. An ideal candidate for radical prostatectomy is a healthy man with a life expectancy of at least 10 years. Preoperative clinical and pathologic parameters are often used to predict the pathologic stage and thus to identify patients most likely to benefit from the operation.
- A rising serum PSA level is usually the earliest evidence of tumor recurrence after radical prostatectomy and is frequently an intermediate end point for treatment outcomes. However, not all patients with biochemical recurrence ultimately develop metastases or die of prostate cancer.
- The most common late complications of radical prostatectomy are erectile dysfunction, urinary incontinence, inguinal hernia, and urethral stricture. The return of erectile function after surgery correlates with age of the patient, preoperative potency status, extent of nerve-sparing surgery, and era of surgery; the return of urinary continence is associated with the patient's age.
- The relative safety and efficacy of laparoscopic radical prostatectomy in achieving the "trifecta" of cancer control, preservation of potency, and return of urinary continence is uncertain at this time.

RADIATION THERAPY

External Beam Radiotherapy (Three-Dimensional Conformal Radiotherapy)

External beam radiotherapy involves the use of beams of gamma radiation, usually photons, directed at the prostate and surrounding tissues through multiple fields. To minimize radiation injury to the bladder and rectum, three-dimensional conformal radiotherapy (3D-CRT), in which a computer alters the radiation beams to focus the radiation dose to the region of the prostate gland, was developed (Fraass, 1995). **The most sophisticated form of 3D-CRT, called intensity-modulated radiation therapy (IMRT), can provide localization of the radiation dose to geometrically complex fields** (Burren et al, 1999; Zelefsky et al, 2006). **Heavy-particle therapy that uses beams of high-energy protons** (Shipley et al, 1995; Rossi, 1999) **or neutrons** (Lawton et al, 1991; Russell et al, 1994) **has also been used to treat patients with prostate cancer. Heavy-particle therapy is another form of 3D-CRT in which the radiation beam can be virtually "stopped" within the tissue, allowing high doses of radiation to be delivered to a localized region. However, proton beam therapy is extremely expensive, and limited long-term results have been reported** (Brada et al, 2007).

A possible disadvantage of extreme conformal therapy with IMRT and heavy particles is that they can be too narrowly targeted so that movement of the prostate caused by differences in rectal or bladder filling could result in geographic miss of the tumor, especially in the important posterior peripheral region of the prostate.

Radiation therapy has been extensively studied for localized prostate cancer. **The outcomes of radiation therapy corrected for anatomic disease extent and other prognostic factors have been reported to be comparable to those of radical prostatectomy; however, this is misleading because the end points for determining treatment success or failure are different for radiotherapy and surgery** (Gretzer et al, 2002).

Radiation Dose and Field of Treatment

There is evidence from prospective, randomized trials that **dose escalation and three-dimensional definition improve results considerably** (Pollack et al, 2002). **Currently, doses of 76 to 80 Gy or more have been shown to improve cancer control** (Pollack et al, 2000; Dearnaley et al, 2007). **Low-risk patients are now frequently treated with 70 to 72 Gy, intermediate-risk patients with 75 to 76 Gy, and high-risk patients with 80 Gy or more. Doses above 75 Gy are now considered to be indicated; however, doses above 80 Gy have not been demonstrated to be beneficial.**

Image guidance for better target definition is crucial for dose escalation, and high radiation doses require protection of normal tissues. IMRT produces steep dose gradients where the gradient between 100% and 50% of dose can be as little as 1 to 1.5 cm. Radiation dose escalation requires precision in target definition and a high degree of accuracy in the daily placement of the radiation dose.

CT imaging is considered the standard imaging modality for 3D-CRT and 3D-IMRT, but CT is less precise than MRI. Therefore larger margins are required to accurately ensure that the entire prostate gland received the daily radiation dose. When CT imaging uses only the bone landmarks to localize the prostate gland, the daily radiation treatments might be directed inconsistently, and the rectum might receive increased doses of radiation. New technologies are being developed to accurately place the radiation beam before every treatment (Litzenberg et al, 2002, 2005, 2007; Cheng et al, 2003).

Radiation Side Effects

The main adverse side effects of radiation therapy are related to injury to the microvasculature of the bladder, rectum, striated sphincter muscle, and urethra. However,

urinary incontinence or radiation-induced complications requiring surgical correction are uncommon. **Approximately one third of patients experience acute symptoms of proctitis or cystitis during the course of radiotherapy, usually after the dose exceeds 50 Gy. In the great majority, symptoms subside after the completion of therapy. About 5% to 10% have permanent symptoms, such as irritable bowel syndrome and intermittent rectal bleeding or bladder irritability and intermittent gross hematuria.** In some cases, chronic symptoms develop years after treatment. Some patients require laser cauterization of radiation-induced telangiectasia for bleeding from the bladder or the rectum. External beam radiotherapy causes more rectal toxicity and less urinary toxicity than brachytherapy does.

A prior transurethral resection of the prostate is a relative contraindication to brachytherapy and external beam radiation therapy because the prostate does not hold the seeds well, and radiation after transurethral resection of the prostate is associated with an increased risk for urethral stricture. The presence of severe obstructive urinary symptoms is also a relative contraindication because of the risk for acute urinary retention, which is an even greater risk in patients treated with brachytherapy. Another relative contraindication is inflammatory bowel disease.

Approximately half of patients develop erectile dysfunction after radiotherapy for prostate cancer. This is caused by injury to the vasculature of the cavernous nerves and to the corpora cavernosa of the penis, usually beginning about 1 year after the completion of treatment. Younger patients with good baseline erectile function are more likely to retain adequate erections. PDE-5 inhibitors are useful in ameliorating the erectile dysfunction associated with radiotherapy (Merrick et al, 1999; Valicenti et al, 2001). Lower doses of radiation to the penile bulb have been investigated as a means of minimizing radiation-induced erectile dysfunction (Roach et al, 2004). The use of adjuvant hormone therapy also adversely affects erectile function.

Combined External Beam Radiation Therapy and Hormone Therapy for Locally Advanced Prostate Cancer

Randomized clinical trials have demonstrated that **patients with a high PSA, high Gleason score, or large-volume tumor benefit from androgen-deprivation therapy in conjunction with radiotherapy, whereas those with lower risk tumors do not.** For example, Bolla and colleagues (1997, 2002) reported that a 3-year adjuvant hormone therapy started concurrently with external beam radiation improved local tumor control and survival in patients with locally advanced prostate cancer. Hanks and associates (2003) explored the optimal duration of hormone therapy after radiation therapy. They showed that 28 months of hormone therapy before, during, and after radiation therapy, compared with 4 months of hormone therapy before and during the radiation therapy, provides significant improvement in all clinical end points, except for overall survival (Hanks et al, 2003). However, **the overall survival benefit of a longer course of hormone therapy was observed in patients with Gleason grade 8 to 10 disease.**

A Scandinavian trial comparing hormone therapy alone to hormones plus radiation in patients with locally advanced prostate cancer revealed clear and significant survival gains and no quality-of-life disadvantage for the radiation arm, indicating that **both the hormone and the radiation components contribute significantly to the therapeutic effect** (Widmark et al, 2009).

Concern has been expressed about the possible cardiovascular risks of hormone therapy, particularly the risk of fatal myocardial infarction. Although some studies have reported an increased rate of cardiovascular deaths (Tsai et al, 2007), two prospective trials revealed that although hormone therapy increases the risk of diabetes mellitus, heart disease, and myocardial infarction, there is no detectable increase in the risk of cardiovascular mortality (Van der Kwast et al, 2007; Efstathiou et al, 2008, 2009).

Radiation Therapy for Localized Prostate Cancer

High-Risk Localized Prostate Cancer (PSA greater than 20 ng/mL or Gleason score 8 to 10). No randomized trial has exclusively studied the additional benefit of hormone therapy in the high-risk patients receiving radiotherapy for localized prostate cancer. However, on the basis of the randomized trials involving locally advanced disease, long-term concurrent hormone therapy is advocated for the high-risk patients treated with radiotherapy for localized prostate cancer.

Intermediate-Risk Localized Prostate Cancer (PSA between 10 and 20 ng/mL, Gleason score 7, or clinical stage T2b). In a retrospective cohort study, D'Amico and coworkers (2000) demonstrated that 6 months of androgen-deprivation therapy (beginning 2 months before and continuing during and after radiation therapy) improved the PSA outcomes in intermediate- and high-risk patients but not in low-risk patients. In a subsequent randomized trial, D'Amico and colleagues (2008) confirmed that **6 months of hormone therapy improves outcomes, mostly in intermediate-risk patients**; hormone therapy was associated with an *earlier onset* of fatal myocardial infarcts in this study (D'Amico et al, 2007).

On the basis of these studies**, long-term hormone therapy is usually recommended along with external beam radiotherapy in patients with locally advanced disease or localized, high-risk disease. In patients with intermediate-risk, localized disease, short-term (6-month) hormone therapy is usually recommended.**

End Points for Treatment Success or Failure

Evaluation of the outcomes of radiotherapy is complicated because cancer cells are not killed immediately after exposure to ionizing radiation. Rather, they sustain lethal DNA damage but do not die until their next attempt to enter into cell division. Thus **the PSA level gradually decreases for up to 2 to 3 years after the completion of radiotherapy.** Accordingly, the PSA level is usually monitored at 6-month intervals until it reaches a nadir. In patients treated with external beam radiotherapy, the prostate gland is not completely ablated, and the remaining prostate epithelium continues to produce PSA. Also**, inflammation in the prostate gland can produce transient PSA elevations, called a PSA "bounce"** (Critz et al, 2000). **PSA bounce occurs in about 20% of patients, usually during the first 2 years after treatment and is less common with external beam therapy than with brachytherapy. Patients having PSA bounce are more likely to have biochemical failure, and a PSA bounce of greater that 1.4 ng/mL has been associated with biochemical failure, metastases, and prostate cancer death** (Feigenberg et al, 2006).

The biochemical end point used to determine treatment success after external beam radiation therapy is controversial. Until recently, the most frequently used

definition was the American Society of Therapeutic Radiology and Oncology (ASTRO) definition (Cox, 1997). **It requires three consecutive PSA increases measured 6 months apart and back-dates the time of cancer progression to halfway between the PSA nadir and the first rising PSA level. Thus it usually takes years to determine whether progression has occurred after radiotherapy.** Without long-term follow-up, the ASTRO definition yields progression-free survival estimates that appear 10% to 20% better than they actually are because it takes time for the PSA level to reach a nadir and even more time for three consecutive PSA increases to occur. Moreover, in clinical series, there are always more patients with shorter follow-up than with longer follow-up. Thus back-dating of the time of the recurrence moves the time of the recurrence event to a point in the series where the denominator is larger, and therefore the impact of the recurrence on the survival curve is diminished.

In recent years, the Phoenix definition was proposed to replace the ASTRO definition (Roach et al, 2006b). It eliminates back-dating but requires the PSA level to rise by 2 ng/mL before treatment failure is declared. Thus the time to recurrence is further prolonged after the PSA level begins to rise, and often it takes a considerably longer time for the PSA level to increase by 2 ng/mL. In some instances, adjuvant hormone therapy may be initiated before the PSA rises to 2 ng/mL. In practice, the Phoenix definition can yield results that are even more favorable than those obtained with the ASTRO definition. **Accordingly, it is not possible to make fair comparisons between radical prostatectomy and radiotherapy by use of these outcome measurements.**

Treatment Results of External Beam Radiotherapy

With conventional external beam radiotherapy, the 10-year cancer cure rates for patients with clinically localized prostate cancer were approximately 50% (Zietman et al, 2004). **Better results have been achieved with 3D-CRT and dose escalation. However, with dose escalation, there is not only a higher chance for cure, but also a higher risk of rectal morbidity** (Kuban et al, 2008). **High-risk patients are frequently treated with 2 to 3 years of androgen deprivation after radiotherapy** (Bolla et al, 1997; Pilepich et al, 1997). With this regimen, the 5-year progression-free probabilities have been reported to be 70% to 85% (Bolla et al, 1997; Kuban et al, 2008). There are limited data concerning the durable and favorable responses to radiation therapy, especially in young patients. A substantial proportion of patients who are unsuccessfully treated with radiotherapy have tumor recurrence within the radiation field, usually in the central part of the tumor.

High-dose proton or neutron beam therapy has been advocated as a more effective method of conformal radiotherapy, but there is no convincing evidence that treatment results are superior to those achieved with photons (Zietman et al, 2005).

In high-risk patients, external beam radiotherapy has also been combined with brachytherapy. The brachytherapy is usually given first, so that the external beam therapy can be discontinued if the patient begins to experience toxicity (Ragde et al, 1997, 1998; Critz et al, 1998).

Current research involves the use of magnetic resonance spectroscopy to guide radiation administration by directing higher doses to the metabolically active areas of the tumor. Similarly, imaging of hypoxic areas of the tumor with positron emission tomography is being evaluated to direct higher doses of radiation to hypoxic regions of the tumor.

Brachytherapy

With brachytherapy, radioactive sources (seeds or needles) are implanted directly into the prostate gland, and sometimes into the surrounding tissues, to deliver a high dose of radiation to the tumor while sparing, to the extent possible, the bladder and the rectum. Modern brachytherapy for prostate cancer was originally unsuccessful because freehand implantation of the seeds provided a poor radiation dose distribution; however, newer external template-based techniques provide more uniform implantation patterns.

Brachytherapy is relatively easy to perform and therefore has become popular for treatment of patients with clinically localized prostate cancer. It can be performed under general or regional anesthesia. The most commonly used permanent implants are iodine-125 or palladium-103 seeds. Theoretically, palladium offers a higher radiation dose rate that would be expected to be advantageous for treatment of poorly differentiated tumors that have a shorter cell cycle. However, in practice, **no significant advantage has been demonstrated for the use of palladium.** Although high-dose rate temporary implantation with iridium-192 wires has been used for more aggressive tumors, logistical considerations make it time-consuming, inconvenient, and impractical in many clinical settings.

Radiation Dose and Fields

After the implant has been completed, a post-treatment CT scan is routinely obtained to check the postimplant dosimetry. Dosimetry can be adversely affected by poor implantation or migration of the seeds after implantation. The radiation doses delivered to the prostate are approximately 145 Gy for iodine and 125 Gy for palladium, which are substantially higher than those with external beam radiotherapy. As with external beam radiotherapy, radiation dose is important with brachytherapy (Stone et al, 2007a; Kao et al, 2008). Biochemical recurrence is associated with dosimetry; however, it is unclear if dose-escalated brachytherapy produces better overall results. Randomized clinical trials are planned.

Direct comparisons of radiation doses between external beam radiotherapy and brachytherapy are not valid. **Although the prostate itself can tolerate high doses of radiation, the rectal toxicity limits the dose that can be given in brachytherapy.** Because of the much higher doses of radiation delivered, brachytherapy causes more ablation of the prostate gland than external beam radiotherapy does. In many patients treated with brachytherapy, post-treatment PSA levels decrease into the undetectable range. Despite this, **brachytherapy is seldom used for the treatment of high-volume, high-risk prostate cancers, because 3D-CRT is the preferred method for treatment of aggressive tumors.**

In patients who have an enlarged prostate gland, it can be technically challenging to implant the entire prostate volume, especially anteriorly. Accordingly, patients are often treated with androgen-deprivation therapy to shrink the prostate before brachytherapy is performed. Long-term androgen-deprivation therapy confounds assessment of the response to brachytherapy

because it delays PSA rises signaling tumor persistence or recurrence.

At present, transrectal ultrasound-guided brachytherapy is the standard approach. MRI is currently being investigated for use in preplanning and postplanning dosimetry with urethral sparing. MR-CT fusion scans have also been used for this purpose. Magnetic resonance spectroscopy–optimized implants are also under study to give higher doses to metabolically active regions of the tumor.

Results of Brachytherapy

Excellent short-term cancer control rates have been reported with brachytherapy. With the ASTRO failure criteria, 5- and 7-year progression-free survival estimates of 85% and 80%, respectively, have been reported for groups of largely low-risk patients (Ragde et al, 2001). Permanent brachytherapy alone also has been reported to be effective for intermediate-risk patients (Zelefsky et al, 2007). Obesity was reported to be associated with a higher prostate cancer–specific mortality rate (Efstathiou et al, 2007).

External beam radiotherapy combined with permanent-source brachytherapy has been reported to have an efficacy similar to high-dose external beam radiotherapy alone with possibly increased urinary toxicity (Lee et al, 2007).

Side Effects of Brachytherapy

Urinary symptoms are more common after brachytherapy than after external beam radiotherapy, especially in patients with prostatic hyperplasia. To avoid these problems, α-adrenergic blockers and hormone therapy are usually administered before treatment. Urinary retention occurs in up to 22% of patients. Approximately 10% of patients require transurethral resection of the prostate after brachytherapy. If an aggressive transurethral resection of the prostate is performed, there is a high rate of incontinence, occurring in 20% to 40% of patients. However, a more conservative, "channel" transurethral resection or laser prostatectomy can usually restore voiding function while preserving continence. Preservation of erectile function has been reported in 62% to 86% of patients treated with brachytherapy alone. **Impotence rates are higher when brachytherapy is combined with external beam radiotherapy. Furthermore, neoadjuvant hormone therapy frequently used before brachytherapy adversely affects postoperative erectile function. PDE-5 inhibitors may be helpful in restoring erections.**

Proctitis and rectal injury are less common with brachytherapy than with external beam therapy, whereas erectile dysfunction occurs more commonly with brachytherapy than with external beam radiation. Other complications associated with brachytherapy include seed migration and rectourethral fistula (Theodorescu et al, 2000; Di Muzio et al, 2003).

Stereotactic Radiotherapy ("Cyberknife")

"Cyberknife" radiotherapy involves a linear accelerator mounted on a robotic arm that gives large doses of radiation in a small number of fractions (hypofractionation). Limited results have been published in a small number of patients with low-risk disease. These results provide some evidence of short-term safety and evidence of PSA decline, but evidence of long-term safety and efficacy is lacking (King et al, 2009). More research is needed to put hypofractionated radiotherapy on a sound scientific basis (Kupelian et al, 2007; King et al, 2009).

Adjuvant Radiotherapy after Radical Prostatectomy

Patients with adverse findings in the radical prostatectomy specimen may benefit from adjuvant radiotherapy. Adjuvant radiotherapy is usually administered to the bed of the prostate gland, usually in doses in the range of 64 to 68 Gy. It is advisable to wait at least 3 to 4 months after surgery to allow complete wound healing and return of urinary continence. Radiation to the whole pelvis is usually discouraged, because of the higher risk for bowel complications. A long-term randomized trial reported that whole-pelvis radiation improves progression-free survival in men with greater than a 15% risk of pelvic node involvement (Roach et al, 2006a; Lawton et al, 2007). However, the preponderance of evidence suggests that pelvic radiation increases toxicity but has no proven effect on survival (Lawton et al, 2007; Pommier et al, 2007). Depending on the risk for recurrence, some patients do not opt for adjuvant radiotherapy but rather choose to monitor their PSA levels and avoid further treatment unless there is convincing biochemical (PSA) evidence of tumor progression.

Retrospective cohort studies have shown that postoperative radiotherapy reduces recurrence rates in patients with pathologic stage T3 disease and positive margins (Leibovich et al, 2000). Trock and colleagues (2008) reported on a retrospective study of men with PSA failure after radical prostatectomy that is unique because patients received either no treatment, salvage radiation therapy, or salvage radiation therapy with androgen-deprivation therapy. They **reported that salvage radiation was associated with a threefold reduction in prostate cancer mortality, and although the addition of hormone therapy provided no additional decrease in the risk for mortality, the patients who received hormone therapy had higher-risk disease. Therefore hormone therapy probably provided additional benefit for these high-risk patients. The benefit was strongest in those with the shortest PSA doubling times, but it is possible that with longer follow-up, a significant benefit also might become apparent in patients with less aggressive tumors. This study has changed the previous dogma that patients with the most aggressive tumors (i.e., rapid PSA recurrence, seminal vesicle invasion, rapid PSA doubling time) do not benefit from postoperative radiation.**

Randomized prospective trials have demonstrated the benefit of postoperative radiotherapy compared with observation in preventing tumor recurrence and increasing survival (Bolla et al, 2005; Swanson et al, 2007, 2008; Thompson et al, 2009). **However, there has not been a randomized trial that compared adjuvant postoperative radiotherapy with early salvage radiotherapy.** A European Organization for Research and Treatment of Cancer trial showed benefit not only in patients with positive surgical margins but also in those with extracapsular tumor extension and seminal vesicle invasion (Bolla et al, 2005). A Southwest Oncology Group trial

revealed benefits in reducing recurrence and PSA progression at 10 years with an overall significant survival advantage (Swanson et al, 2007). There was a lesser improvement but still a significant benefit for the subset with seminal vesicle involvement (Swanson et al, 2008).

A trial of adjuvant radiation after radical prostatectomy of men with stage pT3 prostate cancer or positive margins revealed that adjuvant radiation reduced the recurrence rate and that positive margins were the strongest predictor of benefit (Van der Kwast et al, 2007).

Adjuvant radiotherapy is most likely to benefit patients with positive surgical margins or extracapsular tumor extension without seminal vesicle invasion or lymph node involvement. However, not all patients with extracapsular tumor extension or positive margins have tumor recurrence without radiotherapy, and many patients with highly adverse findings have treatment failure with distant metastases despite adjuvant radiotherapy. Nevertheless, it is possible that some patients with seminal vesicle invasion or lymph node metastases might benefit from adjuvant radiotherapy (Cozzarini et al, 2004).

Side Effects of Adjuvant Radiotherapy

Side effects of adjuvant radiotherapy also include a 5% to 10% risk of radiation proctitis and a 50% probability that return of erectile function will be materially compromised. Radiotherapy also can compromise borderline postoperative urinary continence, but radiation-induced incontinence is relatively uncommon. Patients with highly unfavorable prognostic parameters who are more likely to fail with distant metastases probably derive benefit from postoperative androgen-deprivation therapy.

Adjuvant Hormone Therapy

In high-risk patients who opt for postoperative radiotherapy, it is uncertain whether they also should receive adjuvant hormone therapy. Clinical trials are under way to answer this question. The only disadvantages of adding hormone therapy in this setting are the expense and associated side effects of the hormone therapy. In patients with lymph node metastases, a prospective, randomized trial has demonstrated significantly improved survival in those treated with early androgen-deprivation therapy (Messing et al, 1999).

D'Amico and colleagues (2008) reported on a randomized trial of androgen suppression and radiation versus radiation alone for prostate cancer. There was a survival advantage of 6 months for patients receiving hormone therapy. However, all the benefit was observed in patients with no or minimal morbidity. Men with comorbidity fared worse with hormone therapy. Tsai and colleagues (2007) also reported an increased risk of cardiovascular death associated with hormone therapy. In contrast, Roach and colleagues (2008) found no difference in fatal cardiac events with 4 months of androgen-deprivation therapy. Despite the conflicting results, patients should have cardiac risk evaluation before beginning hormone therapy, particularly in patients with high-risk disease for whom 2 to 3 years of hormone therapy is considered standard.

Future Research

Future research will address issues about whether adjuvant radiotherapy offers an advantage over early salvage radiotherapy. Another issue being addressed in research is the definition of optimal target volume and mapping of postoperative recurrence patterns to ensure that the radiation addresses the right areas.

Comparison of Radiotherapy with Radical Prostatectomy

An important limitation of radiotherapy as a curative modality is tumor heterogeneity with respect to radiation sensitivity. Tumor persistence within the fields of radiation occurs in up to 40% of patients with clinically localized prostate cancer treated with radiation therapy (Stone et al, 2007b; Zelefsky et al, 2008; Crook et al, 2009). Thus in many patients, there are some tumor cells that are not eradicated by therapeutic doses of radiation (Kaplan et al, 2008). Accordingly, even if the tumor is confined to the prostate, radiotherapy might not cure it. Despite high-dose (>75 Gy) 3D-CRT, nearly half of patients had cancerous biopsy findings more than 2.5 years after treatment (Zelefsky et al, 1998). In addition, cancerous biopsy findings after treatment are usually associated with a poor prognosis (Scardino and Wheeler, 1985; Stone et al, 2007b; Zelefsky et al, 2008). The patterns of failure after surgery are different from those after radiotherapy. No modality affords 100% local control. Surgery is more likely to fail at the margins, and radiation therapy is more likely to fail in the center of the tumor. The strategies of dose escalation and better dose placement are designed to improve the central local control.

A study with a minimum follow-up of 23 years of men treated with radiotherapy for stage T1 to T3 prostate cancer revealed that more than two thirds developed recurrence, and more than half died of prostate cancer. Half of the recurrences occurred after 10 years, and some recurrences developed after 20 years; however, late recurrences might represent a new primary tumor (Swanson et al, 2004).

A systematic overview of radiotherapy for prostate cancer, involving more than 150,000 patients, reported that there are no randomized studies to compare the outcomes of radiotherapy with radical prostatectomy for patients with low-risk disease. Risk group comparisons of T stage, Gleason score, and PSA value have reported similar results between radiotherapy and surgery; however, different end points were used for treatment failure (Nilsson et al, 2004).

It is impossible to compare the results of surgery with those of radiotherapy because of the difference in the end points used for treatment failure, that is, undetectable PSA for surgery versus the ASTRO or Phoenix criteria for radiotherapy. For instance, applying the ASTRO criteria to patients treated with radical prostatectomy, the respective 5-, 10-, and 15-year progression-free rates improved from 85%, 77%, and 68% to 90%, 90%, and 90%, respectively (Gretzer et al, 2002).

In a study of conventional external beam radiotherapy in men with clinical stage T1-2 disease treated from 1991 to 1993, freedom from progression by use of the ASTRO criteria was 49% with back-dating the time of recurrence and 42% without back-dating (Zietman et al, 2004).

The use of PSA nadir of 0.2 ng/mL for patients treated with combined external beam therapy and brachytherapy has been recommended. Failure to achieve this nadir by 60 months almost always is associated with persistent disease (Critz, 2002). However, because external beam radiotherapy is more organ sparing than brachytherapy is, post-treatment PSA levels usually are higher in patients treated with external beam radiotherapy only and thus might not easily achieve a nadir of 0.2 ng/mL.

Valid comparisons of radiotherapy with current treatment methods are lacking. However, the available evidence suggests that radical prostatectomy is more effective in achieving long-term progression-free survival in patients with clinically localized prostate cancer. In a population-based study of long-term survival in nearly 60,000 patients with clinically localized prostate cancer from the U.S. Surveillance, Epidemiology, and End Results (SEER) cancer registry, radical prostatectomy yielded better results than radiotherapy (Lu-Yao and Yao, 1997). However, better results from both treatments would be expected in the PSA era and with recent technical advances.

A comparison of health-related quality of life after primary treatment of localized prostate cancer in patients and spouses from multiple centers from 0 to 2 years after radical prostatectomy, brachytherapy, or external beam radiation therapy revealed that **adjuvant hormone therapy with radiation was associated with worse quality of life outcomes. Patients receiving brachytherapy reported having more long-lasting urinary irritation, bowel, and sexual symptoms and transient problems with vitality or hormonal function. The adverse effects of prostatectomy on sexual function were mitigated by nerve-sparing procedures. After prostatectomy, urinary incontinence was observed, but urinary irritation and obstruction improved, particularly in patients with a large prostate gland. External beam radiation was associated with less urinary irritation and more rectal side effects. Each treatment is associated with a distinct pattern of change in quality of life domains related to urinary, sexual, bowel, and hormonal function. These changes influenced satisfaction with treatment outcomes among patients and their spouses or partners** (Sanda et al, 2008).

Concerns have been raised about highly aggressive second malignancies occurring after radiation therapy, that is, in 1 of 70 patients living more than 10 years after radiation therapy for prostate cancer, especially cancers of the bladder and rectum (Herr and Carver, 2008; Oh and Sandler, 2008).

Management of Postoperative Biochemical Recurrence

Patients with detectable PSA (>0.1 ng/mL) after radical prostatectomy usually have persistent cancer, although some have only retained benign prostate tissue causing the PSA elevation. In the latter case, the serum PSA level increases slowly. Of patients destined to have biochemical recurrence after radical prostatectomy, approximately 50% appear within 3 years, 80% within 5 years, and 99% within 10 years. Rarely, recurrences appear more than 15 years after radical prostatectomy.

The PSA velocity or doubling time, the interval from surgery to biochemical recurrence, and the Gleason score usually reflect how rapidly the tumor is likely to progress (Freedland et al, 2005). In many patients, progression occurs relatively slowly, and only about one third actually develop metastases (Pound et al, 1999; Ward et al, 2004). Numerous studies have demonstrated that patients with a rapidly rising PSA level after biochemical recurrence have a high risk of progression to metastases and prostate cancer-specific mortality (Albertsen et al, 2004; D'Amico et al, 2004). **In a study of men with a rising PSA level after radical prostatectomy who did not receive immediate radiation therapy, the median time to metastases was 8 years after PSA elevation, and only 34% of men developed clinically apparent metastases** (Pound et al, 1999).

If salvage radiotherapy is planned, it should be initiated before the PSA level rises much above 0.5 ng/mL (Cox et al, 1999). **Patients most likely to have favorable responses to salvage radiotherapy are those with PSA recurrence long after surgery, slowly rising PSA level, low-grade tumor, and no seminal vesicle invasion or lymph node metastases.** There is conflicting evidence concerning whether cancer at the surgical margins is a favorable or unfavorable parameter for predicting response to postoperative radiation therapy, although reports suggest that patients with positive margins have a more favorable response rate. In one study, a multivariate analysis revealed that PSA doubling time, pathologic grade, and PSA level at the time of salvage radiotherapy were independent predictors of clinical recurrence, whereas the interval from prostatectomy did not add independent predictive information (Ward et al, 2004).

A multi-institutional retrospective analysis reported that 50% of patients had disease progression at a median follow-up of 45 months after radiation therapy, 10% developed metastases, and 4% died of prostate cancer (Stephenson et al, 2004b). **The actuarial 4-year progression-free probability was about 45%. In this series, predictors of progression were Gleason grade of 8 or higher, preradiation PSA level above 2 ng/mL, negative surgical margins, and PSA doubling time of 10 months or less.**

As with adjuvant radiotherapy, the beneficial effects of salvage radiotherapy are controversial. Some patients fare well without it, whereas others will fail with distant metastases despite receiving it. Some patients with PSA recurrence are better managed with hormone therapy than with salvage radiotherapy. Although many men with biochemical failure are treated with hormone therapy, there are no data from prospective trials to address a possible progression-free or overall survival benefit. **The most appropriate PSA level at which to institute hormone therapy is unknown. Because of the substantial side effects associated with long-term, continuous hormone therapy (decreased libido, impotence, hot flashes, osteopenia with increased fracture risk, metabolic alterations, and changes in cognition and mood), delayed or intermittent hormone therapy is frequently used in patients who have biochemical recurrence, especially those with a slowly rising PSA level** (Sharifi et al, 2005).

The Veterans Administration Cooperative Urological Research Group trials conducted in the 1960s did not show a survival benefit in patients with metastases treated with early hormone therapy (Walsh et al, 2001). However, since then, other prospective, randomized clinical trials have suggested that early hormone therapy is more effective than delayed hormone therapy in patients with pelvic lymph node metastases (Messing et al, 1999) or those with locally advanced or asymptomatic metastatic disease (Immediate versus deferred treatment, 1997). Nevertheless, it is uncertain whether these studies can be extrapolated to patients who have biochemical recurrence after primary treatment. A retrospective study reported no difference in early clinical outcome between early and delayed hormone therapy in men with biochemical recurrence after radical prostatectomy (Moul et al, 2004). However, in high-risk patients, early hormone therapy delayed the time to bone metastases.

High-dose bicalutamide administration has been reported to delay disease progression and yield overall survival results equivalent to those of treatment with orchiectomy among patients with PSA recurrence (Wirth et al, 2004). A possible advantage of this form of early hormone therapy is that it is associated with less risk for sexual dysfunction and osteoporosis than other forms of androgen-deprivation therapy are. A disadvantage is a possible increased risk for cardiovascular complications and death associated with high-dose bicalutamide therapy.

Intermittent hormone therapy is a reasonable alternative to providing early androgen-deprivation therapy while limiting the adverse side effects and expense of continuous hormone therapy. There is accumulating evidence from prospective randomized trials that intermittent androgen deprivation is safe and has survival outcomes comparable to those of continuous hormone therapy (Lane et al, 2004; Da Silva et al, 2005a, 2005b).

OTHER TREATMENTS

Primary Hormone Therapy

Primary androgen-deprivation therapy may be appropriate for older men, those with significant medical comorbidities precluding the use of curative therapy, or those who do not wish to undergo curative therapy. There are limited published contemporary data of men treated with primary hormone therapy for clinically localized prostate cancer. Nevertheless, increasing numbers of patients are receiving primary androgen-deprivation therapy for the treatment of localized prostate cancer. In a large population-based Medicare cohort study, **primary hormone therapy did not improve survival among the majority of elderly with localized prostate cancer compared to conservative management** (Lu-Yao et al, 2008). **However, it could not be ruled out that in this study, men with higher-risk disease were more likely to have been treated with primary hormone therapy, so it is not possible to exclude a benefit.**

The American Society of Clinical Oncology practice guidelines did not make a strong recommendation for early hormone therapy, even in patients with positive lymph nodes, because the concern that any decrease in prostate cancer-specific mortality may be offset by an increased risk of nonprostate cancer mortality, with no overall survival benefit (Loblaw et al, 2007; Saigal et al, 2007).

Cryoablation

Cryoablation destroys prostate tissue through freezing. **Current technology uses argon gas circulating through hollow needles to freeze the prostate and helium gas to warm the urethra. Cryoablation has been used as primary treatment for salvage after radical prostatectomy or radiotherapy** (Babaian et al, 2008). A prior transurethral resection of the prostate is considered a relative contraindication to cryoablation. The initial results of cryoablation were poor with incomplete eradication of the tumor and high complication rates, including urinary retention, incontinence, urinary-intestinal fistula, stricture, chronic rectal or perineal pain, and nearly uniform loss of erections (Porter et al, 1997; Perrotte et al, 1999; Long et al, 2001). **With technical modifications, the complication rates have decreased, cancer control has improved somewhat, and the procedure is better tolerated** (Chang et al, 1994; Long et al, 2001; Onik, 2001, Cytron et al, 2003; Aus, 2006; Babaian et al, 2008).

Although a multicenter cryotherapy study has been published, **recurrence-free outcomes are difficult to interpret,**

Key Points: Radiation Therapy

- External beam radiotherapy uses gamma radiation beams directed at the prostate and surrounding tissues through multiple fields. To minimize radiation injury to the bladder and the rectum, three-dimensional conformal radiotherapy and intensity-modulated radiation therapy have been developed. Patients with a high PSA level, high Gleason score, or large-volume tumor benefit from androgen-deprivation therapy in conjunction with radiotherapy.
- Currently, the most frequently used definition to determine treatment success after radiation therapy is the Phoenix definition, which requires PSA increases of 2 ng/mL above the nadir PSA level.
- With brachytherapy, radioactive seeds or needles are implanted directly into the prostate gland to deliver a high dose of radiation to the tumor while possibly sparing the bladder and the rectum. Brachytherapy is relatively easy to perform and therefore has become popular for treatment of patients with clinically localized prostate cancer, but it is seldom used for the treatment of high-volume, high-risk prostate cancers. Urinary symptoms are more common after brachytherapy than after external beam radiotherapy, especially in patients with prostatic hyperplasia.
- Adjuvant radiotherapy shortly after surgery is most likely to benefit patients with positive surgical margins or extracapsular tumor extension without seminal vesicle invasion or lymph node involvement. Patients most likely to have favorable responses to salvage radiotherapy are those with PSA recurrence long after surgery, slowly rising PSA level, low-grade tumor, and no seminal vesicle invasion or lymph node metastases. However, mortality benefits have been demonstrated in patients with rapid PSA doubling times and high-risk tumors.
- It is unknown whether early adjuvant radiation is better than delayed salvage therapy in patients with adverse pathology findings after radical prostatectomy.

Key Points: Primary Hormone Therapy

- Primary androgen-deprivation therapy may be appropriate for older men, those with significant medical comorbidities precluding the use of curative therapy, and those who do not wish to undergo curative therapy; however, cardiovascular evaluation is prudent prior to treatment of men at risk for cardiovascular complications.
- Hormone therapy is never curative; nevertheless, many patients experience long-term remissions. Bilateral orchiectomy and estrogen administration have largely been replaced by luteinizing hormone–releasing hormone analogs. Antiandrogens produce less sexual dysfunction and osteoporosis but have a greater risk for adverse cardiovascular complications.

because no clear definition of recurrence after cryotherapy has been established (Long et al, 2001). In addition, many patients in the study received neoadjuvant hormone ablation. **An undetectable PSA level is seldom attainable after cryoablation. The ASTRO definition has been used for recurrence where biochemical progression rates have ranged from 91% for low-risk disease to 62% for high-risk disease. However, definitions of biochemical recurrence used for radiotherapy are not appropriate for ablative treatments such as cryoablation.**

Cryoablation has also been evaluated as a possible salvage therapy for men who have failed radiotherapy, but limited long-term data are available. One study reported undetectable PSA in 74% with 2 years of follow-up (Pisters et al, 1999). Reports from an Internet-based registry claim 5-year progression-free survival of 59% using ASTRO criteria and 55% using Phoenix criteria following salvage cryoablation (Pisters et al, 2008). However, 83% had PSA greater than 2 ng/mL after 5 years of follow-up, and 33% had positive biopsies. **Complications associated with salvage cryoablation were much more frequent than for primary treatment (**Bales et al, 1995; Perrotte et al, 1999; Pisters et al, 1999). Complications of salvage cryotherapy included 4.4% incontinence, 1.2% rectal fistula, and 3.2% requiring a transurethral resection of the prostate for obstruction (Pisters et al, 2008). The morbidity profile is improved with current argon-based technology, which dates to 2000. Rectal pain is reported in 17% to 37%, urethral sloughing and obstruction in 5% to 10%, and erectile dysfunction in more than 80%. A PSA nadir greater than 0.1 ng/mL is associated with tumor recurrence and short-term "cure" rates ranging from 34% to 74% have been reported (Babaian et al, 2008).

Potential advantages of cryoablation are that it is minimally invasive, it does not involve radiation exposure or surgical risk, repeated treatments are possible, and preservation of potency is possible but infrequent, even with cavernous nerve warming (Asterling and Greene, 2009). For salvage therapy, the main potential advantage of cryoablation may be that it could delay the need for hormone therapy (Ng et al, 2007). However, these advantages have yet to be documented or validated. In addition, **long-term unequivocal biochemical control and quality of life outcomes data for cryoablation are not yet available.**

Focal Cryoablation

Focal targeted therapy has been proposed as a potential treatment for localized prostate cancer in an attempt to reduce morbidity. **Subtotal cryoablation has also been proposed as a management strategy for patients managed with active surveillance, but there are no long-term results available. However, these modalities rely heavily on accurate tumor localization to achieve total tumor ablation. Extended pattern prostate biopsy fails to provide reliable localization of tumors to specific regions of the prostate** (Schulte et al, 2008).

In summary, there is no substantial evidence to support cryoablation over the other therapeutic treatment options, and there are insufficient data on subtotal cryoablation. Current cryoablation methods have a lower complication rate, but their effectiveness at achieving cancer control is not established. The reported results are inferior to those reported for salvage radical prostatectomy. In many studies, the PSA results are confounded by concomitant hormone therapy, and there remains concern about viable cancer cells near the warmed urethra.

Radiofrequency Interstitial Tumor Ablation

Heating prostate tissue to temperatures substantially above 38° C destroys it nonselectively, whereas it is claimed that *hyperthermia* at less elevated temperatures kills cancer cells selectively. **Radiofrequency interstitial tumor ablation-induced hyperthermia has been investigated as a treatment of the primary tumor, in combination with radiotherapy, and for salvage after radiotherapy failure** (Prionas et al, 1994; Zlotta et al, 1998; Shariat et al, 2005).

Like cryoablation, this office-based treatment can be repeated. Careful and constant monitoring is critical to limit the risk of damage to normal tissue (Shariat et al, 2005). Advantages claimed for hyperthermia are that it can be repeated and does not preclude the use of other therapies. However, **long-term data on complications and cancer control are not available** (Beerlage et al, 2000).

High-Intensity Focused Ultrasound (HIFU)

Acoustic energy can be used with ultrasound focusing to generate heat within the prostate gland, thus ablating focal lesions or the entire gland. Transrectally applied high-intensity focused ultrasound (HIFU) can elevate the tissue temperature of the prostate up to 100° C (Madersbacher et al, 1995). Within several seconds, a lesion develops with a sharp and predictable volume, leaving the surrounding tissue intact. Mechanisms of action of HIFU involve mechanical interaction of ultrasound waves with tissue, producing coagulating heat, high pressure, cavitation bubbles, and chemically active free radicals that ultimately induce tissue destruction by coagulation necrosis (Chapelon et al, 1999). **Days to months are required for necrosis and cavitation to occur.** Because HIFU energy is nonionizing, treatment can be repeated.

Treatment is performed under general or spinal anesthesia and takes 1 to 4 hours, depending on the prostate volume, which should not exceed 40 cc. The rectal mucosa is cooled (Blana et al, 2004), and a limited transurethral resection of the prostate or a bladder neck incision is often performed at the beginning of the procedure to reduce the risk of postoperative urinary retention (Chaussy and Thuroff, 2003). **Most patients require a urethral or suprapubic catheter for several days**.

One commercially available apparatus for HIFU has been tested in a multicenter trial and is available in Europe (Thuroff et al, 2003). Another is investigational with multicenter phase III trials under way (Uchida, 2005). Both devices are undergoing United States Food and Drug Administration phase II/III studies for efficacy.

The procedure is usually well tolerated; the most common side effect is acute urinary retention, occurring in about 20% of patients. **Other potential complications are urinary fistula, incontinence, urethral stricture, and perineal pain** (Blana et al, 2004). **Erectile dysfunction** has been reported in 27% to 61% (Blana et al, 2004; Pickles et al, 2005).

The initial results report a 70% progression-free survival rate with a mean follow-up of 23 months, which is insufficient to be clinically meaningful. The progression criteria used were any

*If there is more than a 20% probability of positive lymph nodes, AS, HT, ST + HT.

cancerous biopsy finding or a PSA rise of more than 0.4 ng/mL, but the durability of responses has not been documented (Blana et al, 2004). HIFU has also been used to treat radiation failures, but limited results have been reported (Gelet et al, 2004). Early outcomes reflect the risk characteristics of the tumors before radiation therapy. Adverse effects associated with salvage HIFU include rectourethral fistula in 6%, severe incontinence in 7%, and bladder neck contracture in 17% (Gelet et al, 2004).

Rebillard and colleagues (2008) reported negative biopsy rates in 64% to 93%, PSA less than 0.5 ng/mL in 55% to 84%, and 5-year progression-free survival of 60% to 70%. The most common complications are stress incontinence, infection, stricture, and erectile dysfunction. **Complication rates are lower than previously reported because of technical improvements and the frequent performance of transurethral resection of the prostate prior to HIFU** (Rebillard et al, 2008).

Overall, **there is insufficient information to recommend HIFU as a standard therapy. The preponderance of current evidence suggests that HIFU is not equivalent to cancer control obtained with surgery or radiation.** For instance, Koch and colleagues (2007) reported on a small series of patients treated in the United States with one commercially available device and no adjuvant hormone therapy. Ten percent of patients developed urinary retention following treatment, 20% were incontinent, and 5% had a rectal injury. Only 42% of patients achieved PSA less than 0.5 ng/mL and a negative biopsy. On the other hand, HIFU has been extensively studied in Europe where it is no longer considered experimental. The results with different machines may not be equivalent. The published reports from Europe are confounded by deficiencies in study design, inhomogeneous patient populations, undersampling of the prostate on biopsies, frequent use of transurethral resection of the prostate, and androgen ablation therapy. These limitations make it impossible to know the true safety or efficacy of HIFU (Koch et al, 2007).

RECOMMENDATIONS FOR TREATMENT BY PATIENT RISK GROUPS

The tumor is staged at the time of diagnosis and the patient evaluated for comorbidities. The legitimate treatment options and their associated risks and potential benefits are discussed in Tables 100–1 and 100–2. Choice of therapy for an individual patient depends on the availability of high-quality delivery.

Watchful Waiting versus Treatment
Active Surveillance
Identifying Men with "Low-Risk" Prostate Cancer
Current Results of Active Surveillance with Selective Delayed Definitive Therapy
Summary

The natural history of newly diagnosed prostate cancer is difficult to predict. Men with similar findings on digital rectal examination (DRE) and serum prostate-specific antigen (PSA) level (clinical stage), as well as histologic features on prostate biopsy (pathologic stage), can have markedly different outcomes. Whereas prostate cancer proves lethal in some patients, most men do die with, rather than of, their cancer. The ratio of approximately six newly diagnosed cases for every one death from prostate cancer each year—relatively constant during the past 30 years—is a result of the protracted natural history of the disease in most patients. Further highlighting the remarkable variation in behavior of this disease, autopsy studies have demonstrated that, on histologic examination, **cancer can be found at autopsy in the prostate of approximately 42% of American men 50 years or older who die of causes other than prostate cancer; yet the lifetime risk that an American man will be diagnosed with prostate cancer is estimated to be about 17% and the risk of dying of the disease only 3.6%** (Scardino et al, 1992; Sakr et al, 1993; Landis et al, 1999; Stanford et al, 1999) (Table 101–1). The challenge for physicians today is to identify the minority of men with aggressive localized prostate cancer that can be altered by definitive local therapy, while sparing the remainder of patients the morbidity of unnecessary treatment.

Epidemiologic data demonstrate a high incidence of prostate cancer relative to historical norms and a profound migration toward earlier-stage disease at the time of diagnosis. Implementation of large-scale screening programs and more extensive biopsy strategies are largely responsible for this increase. A retrospective analysis of the control group in the Prostate Cancer Prevention Trial (a phase 3, randomized, double-blind, placebo-controlled study sponsored by the National Cancer Institute) illustrates the potential for indiscriminant biopsy strategies to result in overdiagnosis of prostate cancer (Thompson et al, 2004). Among 2950 men with normal findings on DRE and PSA levels less than 4 ng/mL, 15.2% were found by biopsy to have prostate cancer, including 6.2% of men with PSA levels of 0.5 ng/mL or less (Table 101–2). As the serum PSA thresholds for recommending prostate biopsy decrease and more extensive biopsy strategies result in stage migration toward earlier disease, appropriate management of the disease requires careful assessment of risk: How likely is a given man's cancer to progress or metastasize during his remaining lifetime? What is the probability of success with treatment? What are the risks of side effects and complications with each treatment?

Although the clinical course of newly diagnosed prostate cancer cannot be predicted with certainty, most will turn out to be relatively slow growing, with doubling times for local tumors estimated at 2 to 4 years. **The majority of these cancers prove to be so small, low grade, and noninvasive that they appear to pose little risk to the life or health of the host.** Recent patient series suggest that 20% to 30% of men undergoing radical prostatectomy have pathologic features in the radical prostatectomy specimen consistent with an insignificant or indolent cancer that poses little immediate threat to life or health (e.g., organ-confined cancer < 0.5 mL, no Gleason grade 4 or 5 component). However, **the biologic potential of microscopically detectable cancer is difficult to characterize with certainty** and biopsy may underestimate the extent of cancer in the prostate. Consequently, most physicians recommend aggressive treatment even for small cancers detected by biopsy. Nevertheless, **conservative management (i.e., deferring definitive therapy until evidence that the cancer is sufficiently aggressive to warrant therapy) may be appropriate for many patients with a favorable (low-risk) cancer, and identification of such cancers before treatment would be a significant benefit to these patients.**

WATCHFUL WAITING VERSUS ACTIVE SURVEILLANCE WITH SELECTIVE DELAYED DEFINITIVE THERAPY

Traditionally, watchful waiting has meant that no active treatment is begun until a patient develops evidence of symptomatic disease progression, at which time

androgen deprivation therapy is initiated. The goal of this approach is to limit morbidity from either the disease or the therapy, not to administer potentially curative treatment (Table 101–3). The assumption is that definitive local therapy provides little or no benefit to the majority of men diagnosed with prostate cancer.

An alternative and more widely practiced strategy is to delay curative local therapy until the natural history and threat posed by the cancer can be more accurately characterized. **Active surveillance (AS) with selective delayed definitive therapy attempts to distinguish clinically insignificant cancers from life-threatening cancers while they are still localized and potentially curable.** This approach weighs the threat posed by the cancer within the patient's remaining lifespan and the risks of definitive, local therapy, continually reassessing the risk-benefit ratio at each evaluation. The assumption is that the risk posed by a given cancer can be assessed with some degree of certainty. **The goal is to avoid overtreating the majority of patients while administering curative therapy when needed in selected cases** (Table 101–3). The risks are the delayed therapy may be less effective or would need to be more intensive, with greater morbidity, to be as effective as immediate treatment.

WATCHFUL WAITING

Many clinicians recommend watchful waiting for the treatment of prostate cancer in elderly men with competing comorbidities. Several investigators have attempted to document the long-term risk of metastatic disease and death for men whose clinically localized prostate cancer was treated conservatively (Adolfsson et al, 1994; Chodak et al, 1994; Albertsen et al, 1995, 1998, 2005; Johansson et al, 1997, 2004; Cuzick et al, 2006). The impact of this slow-growing cancer depends on the life expectancy (age and comorbidities) of the patient and the clinical features (Gleason score, PSA) of the cancer (Table 101–4). **Those patients expected to live less than 5 years may develop local symptoms, but few patients will develop metastases or die of the disease.**

The risk of metastases or death from clinical stage T1 to T2 cancer managed conservatively was estimated in a meta-analysis of six watchful waiting series (Chodak et al, 1994). **The risk of metastasis at 10 years was 19% for well-differentiated cancers, 42% for moderately differentiated cancers, and 74% for poorly differentiated cancers.** Furthermore, if the primary tumor was not controlled, the risk for development of metastases persisted, even accelerated, after 10 years. These findings were confirmed by Johansson and colleagues (2004), who reported their long-term results among men with early-stage prostate cancer (T1-T2, NX, M0) or watchful waiting. They observed a consecutive sample of 223 men for a mean period of 21 years.

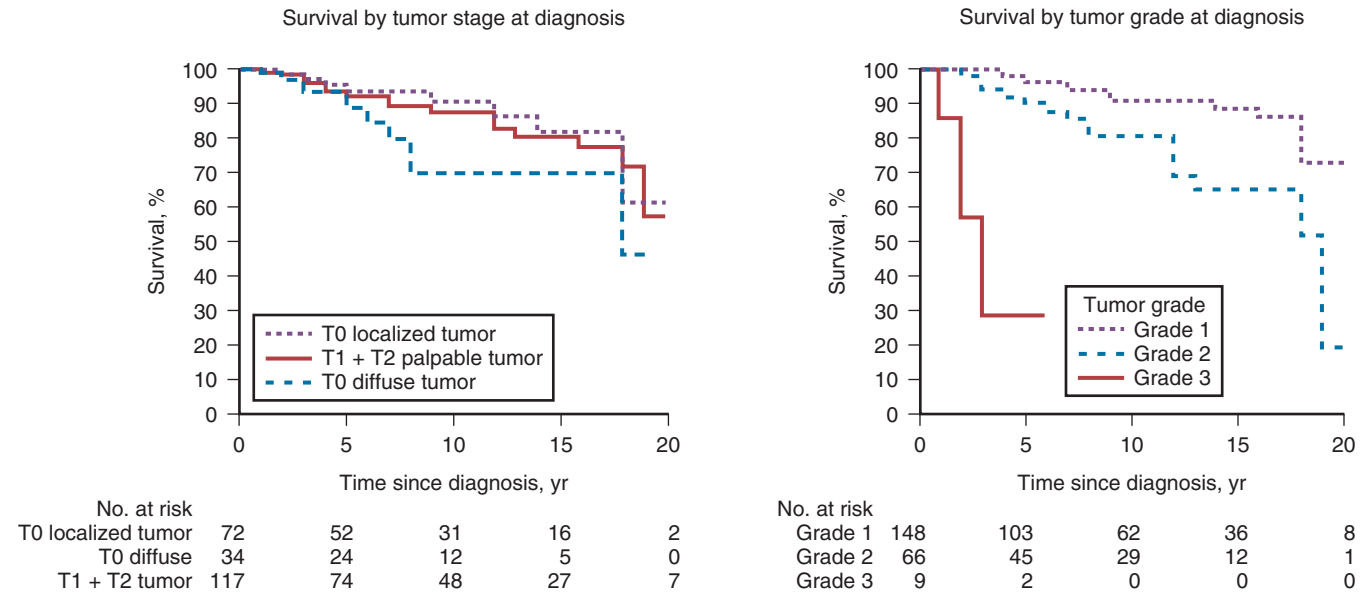

Figure 101–1. Cause-specific survival of men with prostate cancer managed conservatively, by stage of disease and tumor grade at diagnosis. Disease stages were T0 localized, T0 diffuse, and T1-T2. Grades were as follows: grade 1, highly differentiated; grade 2, moderately differentiated; and grade 3, poorly differentiated. (From Johansson JE, Andren O, Andersson SO, et al. Natural history of early, localized prostate cancer. JAMA 2004;291:2713–9.)

Most cancers had an indolent course during the first 10 to 15 years. However, further follow-up from 15 to 20 years revealed a substantial decrease in cumulative progression-free survival (from 45% at 15 years to 36% at 20 years), survival without metastases (from 77% to 51%), and prostate cancer-specific survival (from 79% to 54%) (Fig. 101–1). The authors concluded that **although most prostate cancers diagnosed at an early clinical stage have an indolent course, local tumor progression and aggressive metastatic disease may develop in the long term and early local treatment should be considered for men with a life expectancy exceeding 15 years.**

The impact on mortality was further documented in a large, population-based study (Albertsen et al, 1998, 2005). The probability of death from prostate cancer within 20 years of diagnosis depended on the Gleason sum of the cancer and the age of the patient at diagnosis. **Patients with a well-differentiated cancer (Gleason sum 2 to 4) had a low probability of death from cancer within 20 years (6 deaths per 1000 person-years; 95% confidence interval [CI], 2-11); higher-grade cancers took a substantial toll even among older men (Gleason score of 8 to 10, 121 deaths per 1000 person years; 95% CI, 90-156). In contrast to Johannsen, the Albertson cohort did not experience acceleration in the rate of metastases or death from cancer between 15 and 20 years.**

Kattan and colleagues (2008) reviewed United Kingdom cancer registry data to determine predictors of long-term outcomes for men with clinically localized prostate cancer managed without curative intent in the PSA era. The study included men who at the time of diagnosis were aged 30 to 75 years (inclusive), had a baseline serum PSA level of less than 100 ng/mL, had no evidence of metastatic disease, were not treated with curative intent, and were alive for at least 6 months after diagnosis of their disease. Diagnosis was by transurethral resection of the prostate in 1358 (56%) and needle biopsy in 1088 (44%). Most men were managed without initial treatment, while 30% were treated with hormone therapy within 6 months of diagnosis. In a competing risk analysis, 30% of the patients died of prostate cancer and 30% of other causes within 12 years. This was the first long-term watchful waiting study to include PSA at diagnosis and Gleason grade (reviewed centrally). Figure 101–2 shows the 10-year probability of death from prostate cancer and death from any cause by PSA and Gleason score at diagnosis (Cuzick et al, 2006). However, among men who did not die of another cause in this cohort, the probability of metastases, death from prostate cancer, or additional therapy within 12 years was 90%. These results suggest that localized prostate cancer detected clinically, in an unscreened population, results in a high rate of progression or secondary treatment within 12 years when managed with watchful waiting. **In these watchful waiting cohorts, age, Gleason grade, and PSA were able to identify men at increased risk for the development of metastatic disease and death from prostate cancer. Nevertheless, not all men with "adverse" features do poorly, nor do all men with favorable features do well.** Additional clinical and pathologic parameters are necessary to predict outcomes more accurately and to place expectant management of some patients on a sound basis.

WATCHFUL WAITING VERSUS TREATMENT

Perhaps the most compelling evidence that selected patients with prostate cancer benefit from active treatment compared with watchful waiting comes from the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4), which randomized 695 men with clinically localized prostate cancer to either radical prostatectomy or watchful waiting, with systemic treatment deferred until the development of symptomatic progression (Bill-Axelson et al, 2005, 2008). During a median of 10.8 years of follow-up, 47 of the 347 men (13.5%) who were randomly assigned to surgery died of prostate cancer, as did 68 of the 348 men (19.5%) assigned to watchful waiting (Fig. 101–3). **At 12 years, 12.5% of the surgery group and 17.9% of the watchful waiting group**

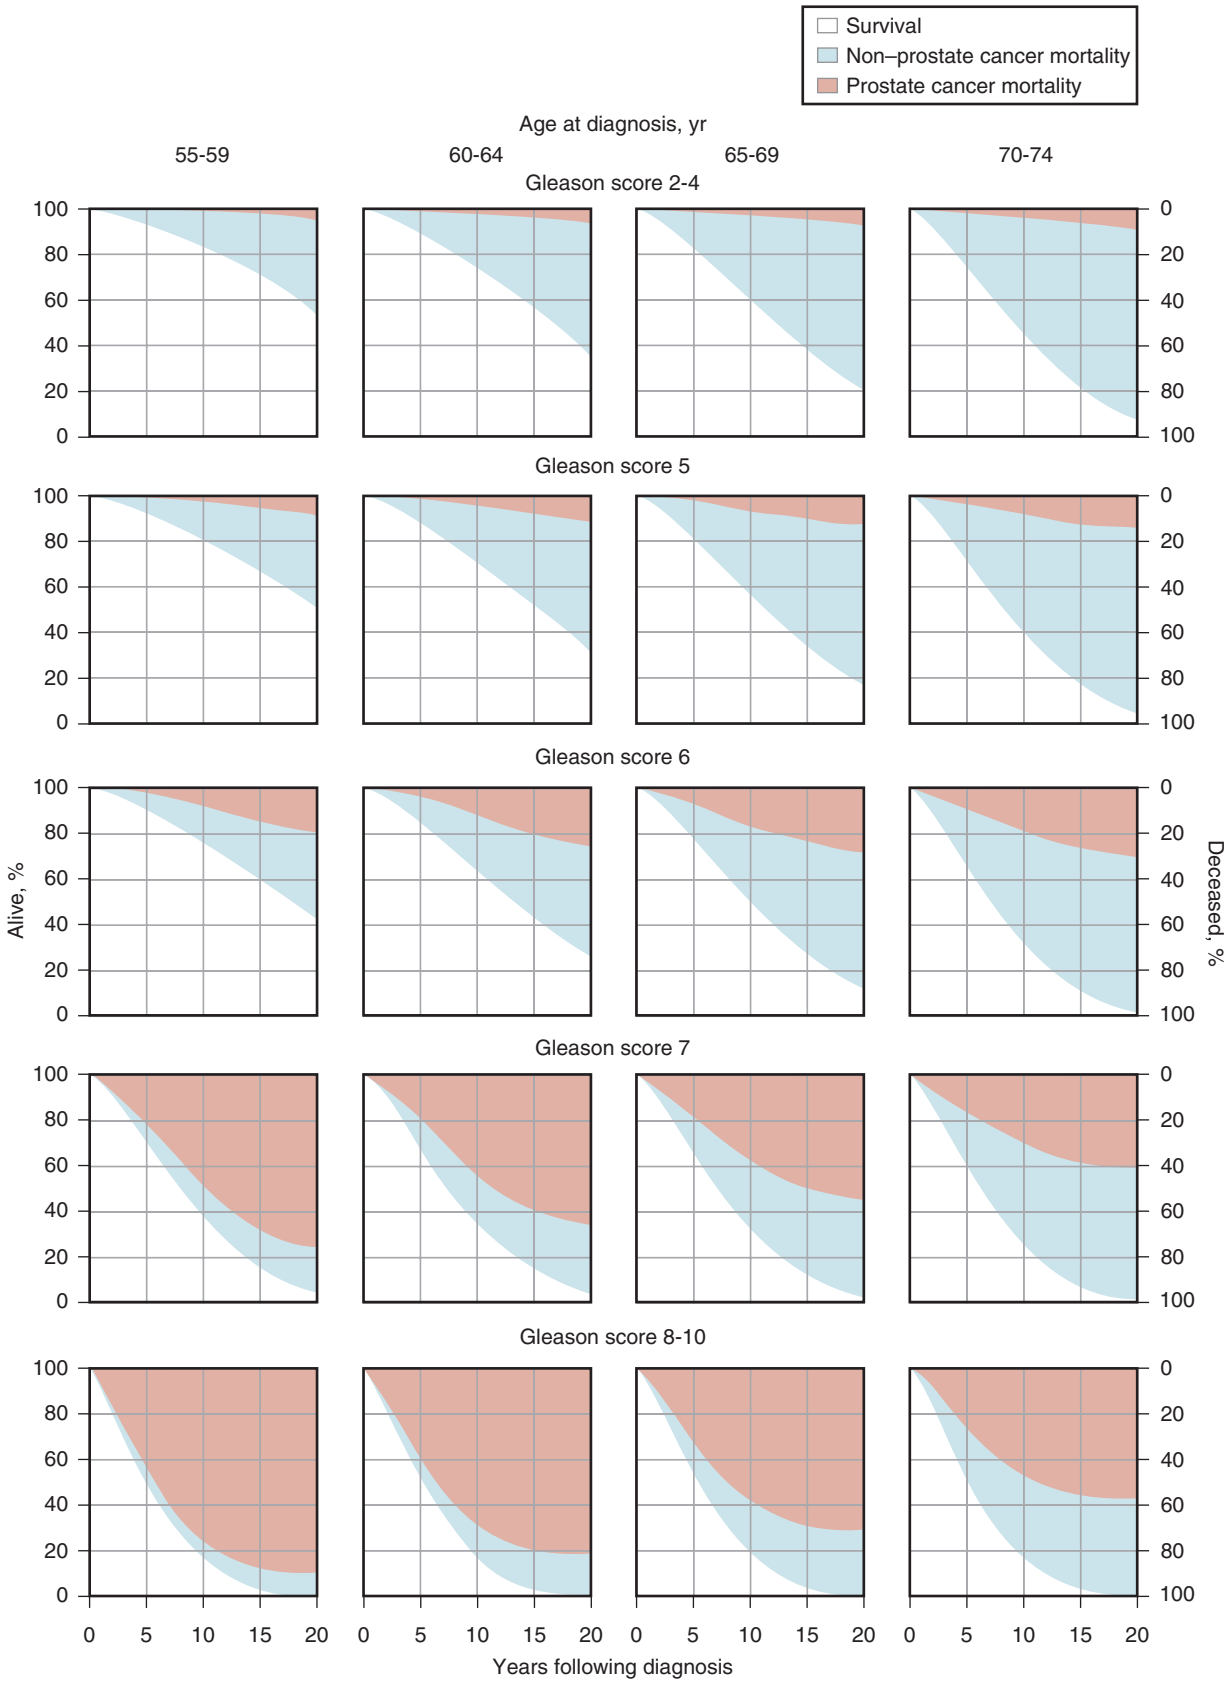

Figure 101–2. Proportion of patients dead from prostate cancer *(orange)*, dead from other causes *(blue)*, at different follow-up times up to 10 years, according to baseline PSA and Gleason score, separately for patients aged 70 years or younger at diagnosis and patients aged older than 70 years at diagnosis. (From Cuzick J, Fisher G, Kattan MW, et al. Long-term outcome among men with conservatively treated localized prostate cancer. Br J Cancer 2006;95(9):1186–94.)

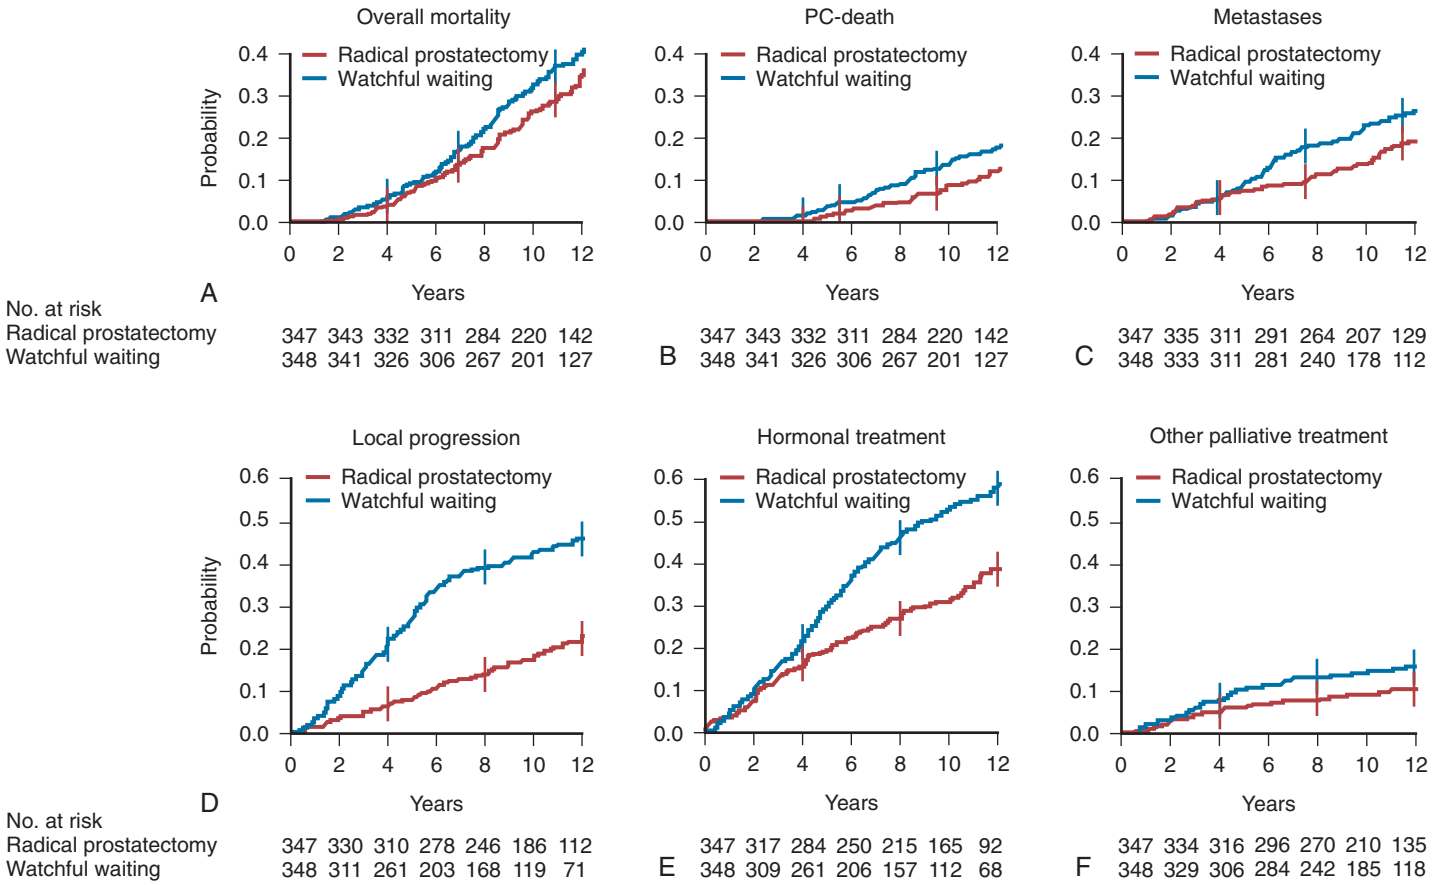

Figure 101–3. Scandinavian randomized trial comparing radical prostatectomy and watchful waiting for localized prostate cancer (PC) detected clinically in the absence of prostate-specific antigen screening. Surgical excision altered the natural history of prostate cancer, reducing cumulative incidence of **A,** overall mortality, **B,** prostate cancer death, **C,** metastases, **D,** local progression, **E,** hormonal treatment, and **F,** other palliative treatment. (From Bill-Axelson A, Holmberg L, Filen F, et al. Radical prostatectomy versus watchful waiting in localized prostate cancer: the Scandinavian prostate cancer group-4 randomized trial. J Natl Cancer Inst 2008;100(16):1144–54.)

had died of prostate cancer (difference = 5.4%, 95% CI, 0.2 to 11.1), for a relative risk of 0.65 (95% CI = 0.45 to 0.94; *P* = .03), and 19.3% in the surgery group and 26% in the watchful waiting group had distant metastases (difference = 6.7%, 95% CI = 0.2 to 13.2), for a relative risk of 0.65 (95% CI = 0.47 to 0.88; *P* = .006). This elegant study, which was carried out in a population not screened for prostate cancer with PSA, documents the overall benefit of radical prostatectomy for patients whose cancer is detected clinically. Because the estimated lead time for PSA screen–detected cancers is 6 to 8 years compared with clinically detected prostate cancers, the relevance of the Scandinavian study to the cancers detected by screening is uncertain.

Although the development of metastatic disease and death from prostate cancer are important adverse outcomes, local cancer progression and the need for treatment also have significant impact on quality of life (Fig. 101–3). For example, **the Scandinavian Prostate Cancer Group reported that fewer men in the radical prostatectomy group than in the watchful waiting group developed local recurrence or disease progression** (Steineck et al, 2002; Bill-Axelson et al, 2008). At 12 years, the cumulative incidence of local recurrence and/or progression was 21.7% in the surgery group and 45.6% in the watchful waiting group (difference = 23.9, 95% CI = 16.8 to 30.9). A total of 132 men in the radical prostatectomy group versus 205 in the watchful waiting group started hormonal therapy. The difference in cumulative incidence of hormonal therapy at 12 years was 19.3% (95% CI = 11.7 to 26.9), with **a lower probability of starting hormonal therapy in the radical prostatectomy group. All other palliative treatments (including radiation, treatment with cytotoxic drugs, and laminectomy) were also less common in the radical prostatectomy group.** The difference in the cumulative incidence of palliative treatment at 12 years was 5.2% (95% CI = 0.1 to 10.3). **Erectile dysfunction and incontinence were higher in men treated with radical prostatectomy, whereas men on watchful waiting experienced significantly more obstructive voiding complaints and bowel problems, resulting in similar levels of treatment-related distress** (Table 101–5).

ACTIVE SURVEILLANCE

Widespread use of PSA screening, combined with low thresholds for recommending prostate biopsy and more aggressive biopsy techniques (12 core, saturation), have resulted in a profound shift toward detection of prostate cancer earlier (Draisma et al, 2009). Furthermore, large randomized trials of PSA screening have shown a limited impact on cancer specific mortality (Andriole et al, 2009; Schroder et al, 2009). These studies suggest that a proportion, estimated in one study as 23% to 42% (Draisma et al, 2009), of prostate cancers are being detected by PSA screening that would

Table 101–5.

Comparison of Urinary Quality of Life (Function) between Radical Prostatectomy and Watchful Waiting in Patients from the Scandinavian Prostate Cancer Group

FUNCTION	RP	WW	RELATIVE RISK (95% CI)
Leak once per week or more often	49%	21%	2.3 (1.6-3.2)
Distress from leakage	29%	9%	3.0 (1.8-5.2)
Urinary obstruction	28%	44%	0.6 (0.5-0.9)
Low/moderate urinary quality of life	40%	45%	0.9 (0.7-1.2)

RP, radical prostatectomy; WW, watchful waiting.

never have been detected in the subjects' lifetime. These cancers are considered by some to be "overdetected," and this concept has led to wider acceptance of AS for low-risk prostate cancers.

AS refers to a systematic program of periodic monitoring of men diagnosed with a prostate cancer judged to pose little immediate threat to life or health. Such patients are offered AS as an alternative to immediate radical therapy. They return frequently for examination and PSA testing and periodically for prostate biopsy. Active intervention is delayed until there is clear evidence of progression of the cancer, although some patients become anxious and choose definitive therapy in the absence of progression. Although AS is now more widely accepted for very early, low-risk prostate cancer, the appropriate criteria for inclusion in an AS program and the definition of progression of the cancer are controversial, and the results of interim intervention and the long-term outcomes remain uncertain.

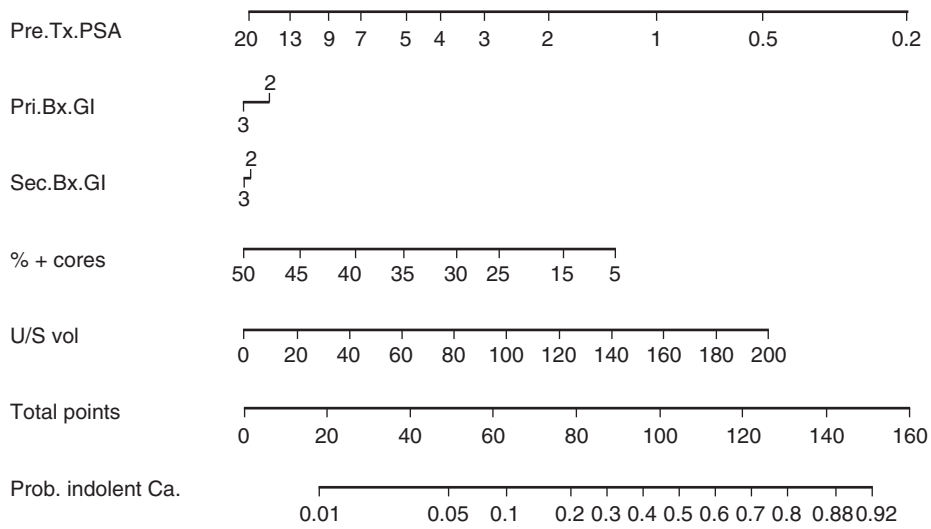
IDENTIFYING MEN WITH "LOW-RISK" PROSTATE CANCER

Many physicians and patients consider AS for selected low-risk prostate cancers. The difficulty is in defining "low risk." Initial clinical staging, when limited to digital rectal examination, PSA, and diagnostic biopsy results, has limited potential for accurately characterizing localized prostate cancers, although systematic needle biopsies, serial PSA determinations, and modern imaging are promising tools for more accurately assessing the size, grade, and extent of the cancer.

Systematic Biopsy Results

In an attempt to identify patients who have low-risk cancer, Epstein and colleagues (1994) examined preoperative clinical and pathologic features in 157 men with clinical stage T1c prostate cancer (who later underwent radical prostatectomy) to find features that could predict "insignificant" cancer (pathologically organ-confined, < 0.2 mL, Gleason sum ≤ 6). Their **model for predicting an insignificant cancer included no Gleason grade 4 or 5 in the biopsy specimen and either:**

- PSA density of 0.1 ng/mL per gram or less, fewer than three biopsy cores involved with cancer (minimum of six cores obtained), and no core with more than 50% involvement; or
- PSA density of 0.15 ng/mL per gram or less and on only one (of six or more) biopsy cores with cancer smaller than 3 mm.



As a test for insignificant disease, this model had a negative predictive value of 95% and a positive predictive value of 66% in their own dataset.

Similarly, Goto and colleagues (1996) evaluated 170 patients who had six or more systematic needle biopsies and determined that a PSA density of less than 0.1 ng/mL, no Gleason grade 4 or 5 in the prostate biopsy specimen, and cancer smaller than 2 mm in a single biopsy core predicted a 75% probability of an unimportant or indolent cancer (<0.5 mL, organ confined, no Gleason grade 4 or 5) at radical prostatectomy. Epstein and colleagues (1998) evaluated 163 radical prostatectomy specimens of clinical stage T1c prostate cancer to determine whether free/total serum PSA ratios, which reflect prostate volume indirectly, combined with needle biopsy results would be more accurate. Using the same definition of indolent cancer that Goto and colleagues used, they determined that the best model to predict indolent tumor is a free/total serum PSA ratio of 0.15 or greater and favorable needle biopsy findings (defined as fewer than three cores involved, none of the cores with more than 50% tumor involvement, and Gleason sum < 6). This model had a 94% positive predictive value for significant cancer. None of these models, however, have been validated prospectively or on a separate cohort.

Because patient selection for deferred therapy is critically dependent on the results of the prostate biopsy (Gleason grade and amount of cancer), some investigators have suggested more extensive biopsy strategies to better assess the true extent of cancer within the prostate. Transrectal ultrasound-guided (TRUS) prostate biopsy has been shown to poorly reflect the grade and extent of a patient's cancer when compared with the radical prostatectomy specimens (Sved et al, 2004). Crawford and colleagues (2005), using computer simulations on 106 autopsy and radical prostatectomy specimens, suggested that transperineal prostate biopsies using a brachytherapy template, spaced at 5-mm intervals throughout the volume of the prostate, could determine grade and detect significant cancers with greater sensitivity. Onik and Barzell (2008) used a transperineal three-dimensional mapping method to restage 110 patients, all of whom had had unilateral prostate cancer diagnosed by TRUS biopsies. The median number of cores taken was 46 (SD ± 19). Bilateral cancer was found in 60 patients (55%), and the Gleason score was increased in 25 (23%). Complications were self-limited and included nine patients (8%) who required short-term catheterization and two (2%) with hematuria. Although this study was primarily designed to assess the role of transperineal biopsy in selecting men for focal therapy, the investigators hypothesized that 75% of patients thought to have low-risk cancers eligible for AS were found to have larger, higher-grade tumors better treated with definitive therapy. Although extensive biopsy strategies provide more information than a standard TRUS-guided biopsy does, their role in routinely evaluating a patient for AS is unclear. None of the commonly used guidelines for identifying candidates for AS have relied on extended prostate biopsy. Further information is necessary before a routine recommendation for this procedure is embraced.

Indolent Cancer Nomogram

To better counsel men diagnosed with prostate cancer, a statistical model to predict the presence of an indolent cancer was developed and validated from standard clinical variables (serum PSA level, prostate volume determined by TRUS examination, clinical stage, prostate biopsy Gleason grade, and systematic biopsy findings) (Kattan et al, 2003; Steyerberg et al, 2007). The biopsy features included number and percentage of biopsy cores involved with

Instructions for Physician: Locate the patient's PSA on the PreTx PSA axis. Draw a line straight upward to the Points axis to determine how many points toward having an indolent cancer the patient receives for his PSA. Repeat this process for the remaining axes, each time drawing straight upward to the Points axis. Sum the points achieved for each predictor and locate this sum on the Total Points axis. Draw a line straight down to find the patient's probability of having indolent cancer.

Instruction to Patient: "Mr. X, if we had 100 men exactly like you, we would expect <predicted probability from nomogram * 100> to have indolent cancer."

Figure 101–4. Nomogram for predicting an indolent prostate cancer from clinical data and systematic biopsy results (full model). Ca, cancer; Clin., clinical; Pre.Tx., pretreatment; Pri.Bx.Gl, primary biopsy Gleason grade; Prob., probability; Sec.Bx.Gl, secondary biopsy Gleason grade; U/S, ultrasound. (From Kattan MW, Eastham JA, Wheeler TM, et al. Counseling men with prostate cancer: a nomogram for predicting the presence of small, moderately differentiated, confined tumors. J Urol 2003;170:1792–7.)

cancer, total length of cancer in all cores, and total length of noncancerous tissue.

The analysis included men whose cancer was diagnosed after systematic needle biopsy that had features of a low-risk cancer (clinical stage T1c or T2a, biopsy Gleason patterns 2 or 3, PSA < 20 ng/mL). Analysis of the radical prostatectomy specimens found that 80 patients (20%) had an indolent cancer (as defined earlier). Logistic regression was used to construct prediction models of increasing complexity, from a base model that included only stage, grade, and PSA to a full model that added prostate volume, length of cancer, and length of noncancerous tissue in the cores. The nomograms predicted the presence of an indolent cancer with discrimination (area under the receiver operating characteristic curve) that increased from 0.64 for the base model to 0.79 for the full model (Fig. 101–4). Using such prognostic information, physicians can identify, with reasonable accuracy, patients with low tumor burden for whom initial aggressive management may not be indicated, especially in men who are older or with significant comorbidities.

Role of Imaging in Selecting Men for Active Surveillance

To improve the accuracy of gray-scale TRUS technology, a number of alternatives including color Doppler TRUS (CDUS), power Doppler imaging (PDI) with or without intravenous contrast administration, and elastography have been developed (Remzi et al, 2004; Halpern et al, 2005; Pelzer et al, 2005; Amiel and Slawin, 2006; Salomon et al, 2008). CDUS is based on the premise that increased microvascularity and abnormal blood flow patterns accompany cancer growth, whereas PDI is considered an improvement in CDUS because it has the advantage of increased sensitivity for detecting small, low-flow blood vessels. Ultrasound-based real-time elastography imaging visualizes differences in tissue strain produced by freehand compression, permitting the investigator to discriminate hard from soft tissue regions within the prostate. Studies examining CDUS and PDI have demonstrated varying degrees of benefit. Overall, the sensitivity of CDUS for the diagnosis of prostate cancer ranged between 49% and 87%, and specificity ranged between 38% and 93% (Amiel and Slawin, 2006). Some investigators have concluded that PDI offers no advantage over CDUS, whereas others have reported that PDI has a high negative predictive value and may help to reduce the number of unnecessary biopsies (Remzi et al, 2004; Halpern et al, 2005). Elastography has been reported to have a sensitivity and specificity of 75% and 77%, respectively, for detecting prostate cancer, with a positive predictive value, negative predictive value, and accuracy of 87.8%, 59%, and 76%, respectively (Salomon et al, 2008). However, this study was limited to selected patients with a diagnosis of prostate cancer who were scheduled for surgery.

Shukla-Dave and colleagues (2007) evaluated the utility of combining clinical data, biopsy data, and magnetic resonance imaging (MRI) with magnetic resonance spectroscopic imaging (MRSI) to predict the probability of insignificant prostate cancer in 220 patients with low-risk prostate cancer (defined as clinical stage T1c or T2a, PSA level < 20 ng/mL, biopsy Gleason score 6) undergoing radical prostatectomy. The probability of insignificant cancer was recorded retrospectively and separately for MRI and combined MRI/MRSI on a scale of 0 to 3 (0, definitely insignificant prostate cancer: no regions with abnormal T2-weighted signal; 1, probably insignificant: non-nodular decreased T2-weighted signal, smaller

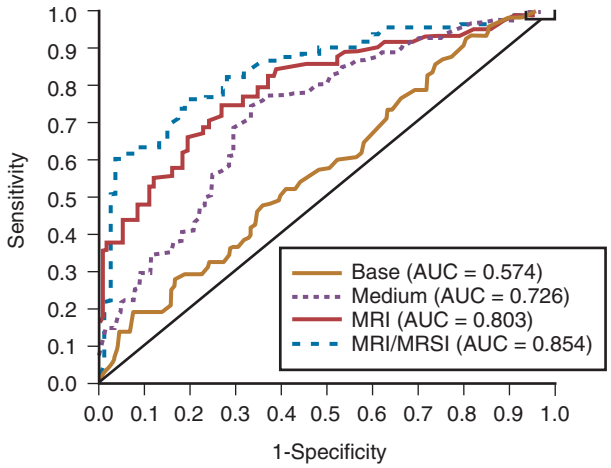


Figure 101–5. A comparison of receiver operating characteristic curves of models to predict the presence of an indolent cancer before radical prostatectomy. The base and medium models include clinical variables only, and the magnetic resonance imaging (MRI) and MRI/magnetic resonance spectroscopic imaging (MRSI) models add information from MRI and spectroscopy, respectively. The base model includes the serum PSA, primary and secondary biopsy Gleason grades, and clinical stage; the medium model adds percent biopsy cores positive and prostate volume on MRI. The MRI model adds the MRI score to the medium clinical model. MRI/MRSI adds the MRI/MRSI score to the MRI model. The P values for the differences between the models were base versus medium model, less than 0.001; base versus MRI model, less than 0.001; base versus MRI/MRSI model, less than 0.001; medium versus MRI model, less than 0.018; medium versus MRI/MRSI model, less than 0.001. (From Shukla-Dave A, Hricak H, Kattan MW, et al. The utility of magnetic resonance imaging and spectroscopy for predicting insignificant prostate cancer: an initial analysis. BJU Int 2007;99:786–93.)

than 0.5 cm^3; 2, indeterminate: non-nodular reduced T2-weighted signal, larger than 0.5 cm^3 or nodular but smaller than 0.5 cm^3; 3, definitely significant: nodular reduced T2-weighted signal, larger than 0.5 cm^3). At pathology, 41% of patients had insignificant cancer (organ-confined, ≤0.5 mL, no poorly differentiated elements in the prostatectomy specimen). Both MRI (AUC 0.803) and MRI/MRSI (AUC 0.854) models incorporating clinical, biopsy, and magnetic resonance data performed significantly better than models based on clinical data alone (Fig. 101–5). The addition of MRI and/or MRI/MRSI information to routinely collect clinical data may help in counseling patients who are considering deferred therapy.

CURRENT RESULTS OF ACTIVE SURVEILLANCE WITH SELECTIVE DELAYED DEFINITIVE THERAPY

AS with selective delayed definitive therapy, like watchful waiting, has the goal of avoiding unnecessary treatment of men with low-risk cancers, those that would seem to pose little risk to life or health during the next 5 to 10 years (Choo et al, 2001, 2002; Patel et al, 2004; Klotz, 2005; Carter et al, 2007; Soloway et al, 2008). The initial evaluation of a candidate for AS aims to reduce the chance that a large, aggressive cancer has been missed; subsequent evaluations aim to detect progression before the cancer metastasizes. Studies of watchful waiting (Adolfsson et al, 1994; Chodak et al, 1994; Albertsen et al, 1995, 1998, 2005; Johansson et al, 1997, 2004) suggest that the risk of progression *accelerates* over time, a pattern different from the risk of progression or recurrence after definitive therapy, which diminishes over time. Hence AS patients must accept frequent, regular, detailed evaluations of the status of their cancer for as long as they are healthy and young enough to be candidates for definitive therapy.

Outcomes of Active Surveillance

There are, as yet, few reports of outcomes of deferred definitive therapy for localized prostate cancer (Choo et al, 2001, 2002; Zietman et al, 2001; Carter et al, 2002, 2007; el-Geneidy et al, 2004; Klotz, 2004, 2007; Patel et al, 2004; Soloway et al, 2008). The University of Toronto conducted a prospective phase II study of AS, incorporating selective delayed intervention for the subset of patients with short PSA doubling time or grade progression on repeat biopsy (Choo et al, 2001, 2002; Klotz, 2004, 2007). The eligibility criteria for this study included patients with clinical stage T1c or T2a cancer, biopsy Gleason score of 6 or lower, and a serum PSA of 10 ng/mL or less. For patients older than the age of 70 years, these eligibility criteria were relaxed to include biopsy Gleason score 7 (3 + 4) or lower and/or PSA of 15 ng/mL or less. The core prospective cohort of 331 patients had a median follow-up of 8 years (range, 2 to 11). Patients were observed until they met one of three specific criteria defining rapid or clinically significant progression:

1. PSA progression, defined as a PSA doubling time (PSADT) of 3 years or less, based on multiple serum PSA determinations at 3-month intervals, calculated using a General Linear Mixed Model, which corrects for baseline PSA, grade, and age. This model is freely available at http://psakinetics.sunnybrook.ca.
2. Clinical progression, defined by meeting any of four conditions: more than a doubling of the product of the maximum perpendicular diameters of the primary lesion as measured by DRE, local progression of prostate cancer requiring transurethral resection of the prostate, development of ureteral obstruction, or radiologic or clinical evidence of distant metastasis.
3. Histologic progression (i.e., Gleason sum 4 + 3 or higher on repeat biopsy of the prostate).

Patients who had progression were offered radical intervention; those without progression were closely monitored. Biopsies were performed for cause at 1 year, then every 4 to 5 years. The median PSADT was 7 years; 42% had a PSADT longer than 10 years, suggesting an indolent course of disease in these patients. Twenty-two percent of patients had a PSADT of less than 3 years. With a median follow-up of 72 months, 34% of the patients had received radical treatment. Fifteen percent were treated because of a PSADT of less than 3 years; 7% because of histologic or clinical progression; and 12% because of patient preference. Ten percent have been treated with radical prostatectomy, and 36% of these had cancer outside of the prostate. The remainder has not required local or systemic therapy. Overall survival is 85% and disease-specific and metastasis-free survival is 99% at 8 years.

In a prospective, longitudinal surveillance program, Carter and colleagues (2007) observed a cohort of men (with clinical stage T1c prostate cancer suspected of harboring small-volume cancer based on needle biopsy findings and PSA density (Epstein et al, 1994). Median age was 65.7 years (range, 45.8 to 81.5), and median follow-up was 2.8 years (range, 0.4 to 12.5). Semiannual measurements of total and free PSA, a semiannual DRE, and an annual surveillance prostate biopsy examination were performed.

Treatment was recommended if there were findings of adverse pathologic features on an annual surveillance biopsy examination (any Gleason pattern 4 or 5, more than two cores that were positive for cancer, or more than 50% of any one core that was involved with cancer) or if a patient requested a change in management. Of 407 men, 239 (59%) remained on AS; 103 (25%) were treated definitively at a median of 2.2 years after diagnosis (range, 0.96 to 7.39); and 65 (16%) were lost to follow-up (12), withdrew from the program (45), or died of causes other than prostate cancer (8). Of the 103 men, 53 (51%) were treated with radical prostatectomy. Twenty percent of these men were considered to have noncurable disease, defined as pathologic stage T2 if Gleason score was 4 + 3 or greater, positive surgical margins of any grade, stage pT3aN0 (extraprostatic extension) if Gleason sum was 7 or greater and/or surgical margins were positive, any stage higher than pT3a regardless of grade or margin status, or any N+ stage. The investigators concluded that a program of careful selection and monitoring of older men who are likely to harbor small-volume, low-grade disease may be a rational alternative to immediate radical therapy for all.

Two hundred and seventy patients diagnosed in the Swedish arm of the European Randomized Study of Screening for Prostate Cancer have been managed with AS (Khatami et al, 2006). During a mean follow-up of 63 months, 104 (39%) received active treatment: 70 with radical prostatectomy, 24 with radiation, and 10 with endocrine treatment. There were no prostate cancer–related deaths. Those who received active treatment were significantly younger (62.6 vs. 65.5 years, $P < .0001$) and had a shorter PSADT (3.7 vs. 12 years, $P < .0001$). PSA relapse was observed in 9 (12%) of 70 of the radical prostatectomy patients during a mean follow-up of 37 months. Seven of these nine PSA relapses were in the patients with preoperative PSADT of less than 2 years. None of the 37 radical prostatectomy patients with a PSADT longer than 4 years had a PSA relapse. The investigators concluded that the optimal candidate for surveillance is a man with early, low-grade, low-stage cancer and a PSADT of longer than 4 years. In those with a PSADT less than 4 years, AS should be recommended with caution.

Patel and colleagues (2004) studied outcomes for patients with low-risk cancer who were eligible for definitive therapy but chose AS. This prospective study enrolled 88 patients with clinical stages T1-T2, N0 or NX, M0 prostate cancer, mean age of 65.3 years, and mean initial PSA value of 5.9 ng/mL. They were observed for a median of 44 months (range, 7 to 172). Follow-up involved DRE and serum PSA levels every 3 months for year 1 and every 6 months thereafter. Repeated TRUS-guided needle biopsy was recommended at baseline, 1 year later, and then every 2 to 3 years or sooner if DRE, TRUS (endorectal MRI was not available during this study), or PSA level indicated progression. Retrospectively reviewed data were used to develop criteria for "objective progression." Points were assigned for changes in Gleason score, PSA level, DRE/TRUS, and biopsy results (Table 101–6); patients with three or more points were classified as having objective progression. Progression criteria were met by 22 patients. The actuarial probability of progression was 36% at 5 years and 45% at 10 years (Fig. 101–6A). Of the 88 patients, 70 had a repeat biopsy within 6 months of diagnosis and 47 (47/70%) of these showed no cancer. In multivariable analysis, the result of the repeat biopsy was the most important predictor of progression (Fig. 101–6B). Only 36%

Table 101–7.
Likelihood of Prostate Cancer Remaining Untreated after Active Surveillance (AS)

SERIES	NO. OF PATIENTS	MEDIAN FOLLOW-UP, YR (RANGE)	REMAIN ON AS (%)
Klotz, 2008	331	8 (2-11)	65
Carter et al, 2007	407	2.8 (0.4-12.5)	59
Khatami et al, 2006	270	5.3 (0.9-10)	61
Patel et al, 2004	88	3.7 (0.6-14.3)	65
Soloway et al, 2008	99	3.8 (1-14.8)	92

of the patients showed objective progression within 5 years, whereas 44% were treated; patient preference accounted for the higher percentage of patients treated. Of the 31 patients with progression, 17 were treated with radical prostatectomy, 13 with radiation therapy, and 1 with androgen ablation. Seven men without objective progression were treated. Only one patient, who was treated with radiation therapy, had biochemical recurrence. The investigators concluded that AS is a feasible alternative to initial curative treatment in select patients with favorable, low-risk prostate cancer. About half of these patients remained free of progression at 10 years, and definitive treatment appeared effective in those with progression. Consistent with the study by Carter and colleagues (2002), the absence of cancer on repeated needle biopsy early after initial diagnosis identified cases unlikely to progress during 10 years.

These series confirm that in appropriately selected men, AS is associated with an extremely low rate of progression to metastatic disease and/or death and the majority of patients do not require intervention (Table 101–7). Further follow-up is necessary to determine the long-term risk of progression.

What Factors Predict Progression for Men on Active Surveillance?

One assumption about AS is that signs of progression can be identified while the cancer is still curable. Various clinical criteria have been investigated in an attempt to define those patients requiring definitive treatment and those still suitable for AS. Serial serum PSA testing including free and total levels has been examined by a number of investigators (Gerber et al, 1998; Choo et al, 2001, 2002; Do et al, 2002; Stephenson et al, 2002; de Vries et al, 2004; Klotz, 2004, 2008; Panagiotou et al, 2004). Gerber and colleagues (1998) examined changes in serum PSA levels in 49 men (mean age, 72 years) with untreated clinically localized prostate cancer. All patients had at least three PSA levels, which were measured at intervals of at least 6 months. **The investigators found significant variability in the rate of change of PSA with time.** They concluded that changes in PSA level may not be helpful in determining the need for therapy in men on AS. In men with small-volume cancers, the benign rather than malignant portion of the prostate drives the serum PSA level. Because PSA levels are highly variable in men with an untreated prostate gland (Eastham et al, 2003), reliance on PSA dynamics as inclusion or intervention criteria for the management of prostate cancer is problematic.

Numerous studies have examined the role of PSADT as a prognostic factor in men on AS, and the majority conclude that PSADT can be used a predictor of progression. Choo and colleagues (2002) observed 206 men with clinically localized prostate cancer who were managed with AS for a median of 29 months. PSADT was estimated from a linear regression of ln(PSA) on time, assuming a single exponential growth model. The median PSADT was 6.68 years, with 42% of patients having a PSADT of 10 years or longer. These investigators suggest that the definition of progression for men on AS should include a PSADT of less than 2 years on the basis of at least three separate measurements during a minimum of 6 months. This PSADT may, however, be too short, because six of nine men who underwent radical prostatectomy had extraprostatic disease. These results led the investigators at the University of Toronto to change their definition of progression to a PSADT of 3 years or less (Klotz, 2008). Further concern about PSADT as a predictor of progression for men on AS comes from studies examining PSADT before radical prostatectomy. Egawa and colleagues (2000) examined changes in PSA levels before radical prostatectomy and concluded that men with a PSADT of 3 years or less were more likely to have stage pT3 cancer at surgery, and 3 of 19 men with a PSADT longer than 6 years had pT3 cancer, 2 of them with positive nodes. D'Amico and colleagues (2004) studied 1095 men with localized prostate cancer to assess whether the rate of rise in PSA level—the PSA velocity—during the year before diagnosis, the PSA level at diagnosis, the Gleason score, and the clinical tumor stage could predict the time to death from prostate cancer and death from any cause after radical prostatectomy. An annual PSA velocity of more than 2.0 ng/mL was associated with a significantly shorter time to death from prostate cancer ($P < .001$) and death from any cause ($P = .01$). An increasing PSA level at diagnosis ($P = .01$), a Gleason score of 8, 9, or 10 ($P = .02$), and a clinical tumor stage of T2 ($P < .001$) also predicted the time to death from prostate cancer. The investigators concluded that men whose PSA level increases by more than 2 ng/mL during the year before the diagnosis of prostate cancer may have a relatively high risk of death from prostate cancer despite undergoing radical prostatectomy. Although these studies suggest that **PSA kinetics may be a useful predictor of cancer progression, the exact trigger point at which to recommend treatment requires further investigation. By the time the PSADT or PSAV is rapid, it is too late to successfully intervene with high probability of cure. More information is necessary to determine the performance characteristics of PSADT in identifying progression of localized prostate cancer up to but before the development of metastatic cancer.**

A number of other promising biomarkers identify patients at risk for cancer progression including PSA density, free versus total PSA ratio, and PCA3 (Do et al, 2002; Khan et al, 2003; Nakanishi et al, 2008). Genetic biomarkers may also allow better prediction of patient risk within the next decade. Although none of these has yet demonstrated benefit in routine practice, this remains an active area of research.

Although all AS studies have included periodic DRE as part of routine follow-up, none has found this to be an independent predictor of cancer progression. DRE is therefore unlikely to provide prognostic benefit if serial PSA measurements and prostate biopsy specimens are taken. In addition, DRE is subjective and there is significant interexaminer variation. **DRE remains important, however, not only as an indicator that a repeated prostate biopsy is warranted** but also in clinical staging and in the prediction of outcome if active treatment is recommended.

Serial imaging studies have also proven to be of limited value to patients on AS. In a prospective study of AS (Hruby

et al, 2001), the value of performing TRUS every 6 months was examined in 174 men. Findings on TRUS were scored as consistent with clinical progression if they demonstrated a new or enlarging hypoechoic peripheral zone lesion or a 30% or greater increase in overall prostate volume at the time of progression. The group of 28 men who progressed to require radical intervention underwent 83 TRUS examinations (median, 3 per patient). Of the 28, only 7 had changes on TRUS that were regarded as consistent with progression; in all 7, the change consisted of the growth of an existing nodule or the appearance of a new nodule. In only one case was this accompanied by an increase in gland volume of 30% or more. In the 136 men who underwent two or more serial TRUS examinations, there was no correlation between changes in either gland volume or the number of peripheral zone hypoechoic lesions and the rate of change of PSA. The investigators concluded that serial TRUS is of limited value as a determinant of disease progression in men with known but untreated prostate cancer.

The role of serial pelvic imaging with either computed tomography or endorectal MRI has not been investigated but is likely to be limited. These men are at low risk for macroscopic extraprostatic disease, so interval changes in any of these examinations are unlikely. Improvement in imaging tools to better characterize intraprostatic disease is necessary before serial imaging can be routinely recommended for men on AS.

Yap and colleagues (2003) assessed the role of serial bone scans in men being treated with AS at the University of Toronto. This aspect of their study included 244 eligible patients. Bone scintigraphy was repeated annually for the first 2 years, then every 2 years thereafter if the patient remained on AS. If the follow-up PSA level was above 15 ng/mL, the patient underwent annual bone scintigraphy. During follow-up (median, 30 months), 299 bone scans were taken. All 299 were negative for bone metastasis. The probability of a normal bone scan was estimated to be 88% to 100% (95% CI) when PSA level was below 15 ng/mL. The investigators concluded that bone scans are unnecessary for men on AS. The role of serial bone scintigraphy remains undefined even for men with a PSA level above 15 ng/mL.

Repeated prostate biopsies are considered an important aspect of continued evaluation of men managed with AS, not only to identify men with cancer progression but also to identify men whose disease is unlikely to progress. Virtually all AS studies have incorporated serial prostate biopsy in their follow-up regimen. The University of Toronto group advises performing a confirmatory biopsy at 1 year to identify high-risk features that might have been missed on the original biopsy (Klotz, 2008) and thereafter performing a prostate biopsy every 4 to 5 years or earlier if clinically indicated. Carter and colleagues (2007) recommend a first repeat biopsy at 1 year and then an annual prostate biopsy. Patel and colleagues (2004) performed a confirmatory biopsy in men with low-risk prostate cancer within 6 months of the diagnosing biopsy. This second biopsy showed no cancer in 61% of cases. Cancer in the second biopsy was the most significant prognostic factor for progression in their cohort of men on AS (Patel et al, 2004) (see Fig. 101–6B). Progression occurred in 5 of the 43 men (11%) who had a first repeat biopsy that was negative for cancer, compared with 12 of 27 (40%) who had an abnormal finding on first repeat biopsy. Actuarial progression-free probability at 5 years was 83% for patients with normal findings on repeat biopsy, compared with 43% for those with abnormal findings. An increase in Gleason sum was noted in 59% of patients with any prostate cancer on repeat biopsy. Patel and colleagues recommend performing an early (within 6 months) repeat prostate biopsy on men considering AS.

The National Cancer Institute of Canada together with four U.S.-based cooperative oncology trials groups (SWOG, CALGB, ECOG, and RTOG) and the United Kingdom Coordinating Committee on Cancer Research initiated a clinical trial entitled Surveillance Therapy Against Radical Treatment (START). This trial, which opened to 2007, will randomize 2100 patients between AS and the patient's choice of radical treatment (surgery or radiation). Eligible patients have histologically confirmed adenocarcinoma of the prostate diagnosed within 6 months before study randomization and must be suitable candidates for either surgery or radiotherapy (life expectancy of > 10 years and ECOG performance status 0, 1, or 2).

Patients are considered to have low-risk cancer defined as follows:

- Clinical stage T1b, T1c, T2a, or T2b at the time of diagnosis
- Clinical (diagnostic biopsy) Gleason score of 6 or lower
- PSA less than or equal to 10 ng/mL

To primary end point is to compare prostate cancer–specific survival of patients with favorable risk prostate cancer treated with radical prostatectomy or radical radiotherapy at the time of initial diagnosis versus AS and selective intervention based on prespecified biochemical, histologic, or clinical criteria.

Key Points

- Many prostate cancers pose little risk to life or health.
- Low-risk prostate cancer can be identified, with high probability, by any of several models on the basis of various combinations of biopsy Gleason grade, clinical stage, amount of cancer in biopsy cores, PSA level, prostate size, or ratio of free to total PSA.
- The goal of watchful waiting is to allow men with low-risk cancer to avoid treatment and the associated morbidity. Palliative treatment is offered only if symptoms develop.
- For patients with early-stage prostate cancer managed by watchful waiting, the probability of death from cancer is low for the first 10 years after diagnosis but may rise rapidly during the next 10 years if the cancer is not treated before it progresses to metastases.
- Watchful waiting is a reasonable option for patients with a life expectancy of less than 10 years and clinically localized, well-differentiated, or moderately differentiated prostate cancer.
- AS with selective delayed definitive therapy involves careful monitoring of men with prostate cancer. Definitive therapy is recommended for men who show clear signs of cancer progression.
- Men on AS should be monitored by periodic PSA measurements, DRE, and prostate biopsy.
- Increased Gleason sum or amount of cancer on repeated biopsy and decreased PSA doubling time indicate that definitive therapy may be warranted. Absence of cancer on repeated biopsy is a strong indicator that the cancer is unlikely to progress.
- Long-term outcomes for patients on AS are not yet available, but the majority of patients remain on AS and free of progression at 4 years after diagnosis. Definitive therapy appears to be effective in the majority of patients with signs of disease progression.

SUMMARY

Patients with a life expectancy (based on age and comorbidities) of less than 10 years and cancer with Gleason score of 6 or lower may be suitable for watchful waiting, especially if clinical stage and PSA values are favorable. Cancer progression and prostate cancer death are unlikely in this group of patients (see Fig. 101–2). Routine PSA testing is less important in the management of these patients, and follow-up radiographic studies or biopsies are not performed according to any predetermined schedule. Intervention is palliative and delayed until symptoms develop.

AS may be a safe alternative to immediate treatment in compliant men with a low risk of cancer progression, and it appears to be feasible in many men diagnosed with prostate cancer. Studies suggest that less than half of such patients have progression on long-term follow-up (see Table 101–7), and treatment appears to be effective in those whose cancer does progress. More detailed recommendations cannot be given at this point because of our current inability to predict the course of the disease with certainty. Major areas of future study include identifying appropriate baseline clinical parameters in selecting men for AS, defining the role of imaging in diagnosing low-risk prostate cancer, identifying additional circulating and tissue markers defining risk, and developing appropriate follow-up regimens and definitions of progression. Repeat prostate biopsy appears to be critical to defining progression, and PSADT has been widely employed, although its accuracy requires confirmation. With appropriate selection of patients, close follow-up, and selective use of local therapies in those with local cancer progression, AS is an acceptable choice for the management of selected patients with low-risk, early-stage prostate cancer.

Summary of Radical Perineal Prostatectomy

There is no better way to cure cancer that is confined to the prostate than total surgical removal. Radical prostatectomy is the only form of treatment for localized prostate cancer that has been shown in a randomized controlled trial to reduce progression to metastases and death from the disease (Holmberg et al, 2002; Bill-Axelson et al, 2008). Furthermore, on the basis of improved understanding of the periprostatic anatomy, today there is less bleeding and improved rates of postoperative continence and potency (Walsh, 1998, 2000; Nielsen et al, 2008).

The open surgical approach to radical prostatectomy has been challenged by advocates of laparoscopic and robotic techniques. It is the authors' opinion that the open procedure is still the "gold standard" providing the best outcomes in terms of cancer control and quality of life.

Technically, radical retropubic prostatectomy is one of the most difficult operations in the field of urology. **The three goals of surgery, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function.** Great skill and experience in the selection of surgical candidates and operative technique are necessary to achieve all three. This chapter summarizes the authors' experience with the hope that it will shorten the reader's learning curve. A video demonstrating a detailed description of the surgical technique is also available (Walsh and Garcia, 2004).

RADICAL RETROPUBIC PROSTATECTOMY: SURGICAL ANATOMY

Venous and Arterial Anatomy

The veins of the prostate drain into the Santorini plexus. It is necessary to have a complete understanding of these veins to avoid excessive bleeding and to ensure a bloodless field in exposing the membranous urethra and the apex of the prostate. **The deep dorsal vein leaves the penis under the Buck fascia between the corpora cavernosa and penetrates the urogenital diaphragm, dividing into three major branches: the superficial branch and the right and left lateral venous plexuses** (Reiner and Walsh, 1979) (Fig. 102–1). The superficial branch, which travels between the puboprostatic ligaments, is the centrally located vein overlying the bladder neck and prostate. This vein is easily visualized early in retropubic operations and has communicating branches over the bladder itself and into the endopelvic fascia. The superficial branch lies outside the anterior prostatic fascia.

The common trunk and lateral venous plexuses are covered and concealed by the prostatic and endopelvic fascia. The lateral

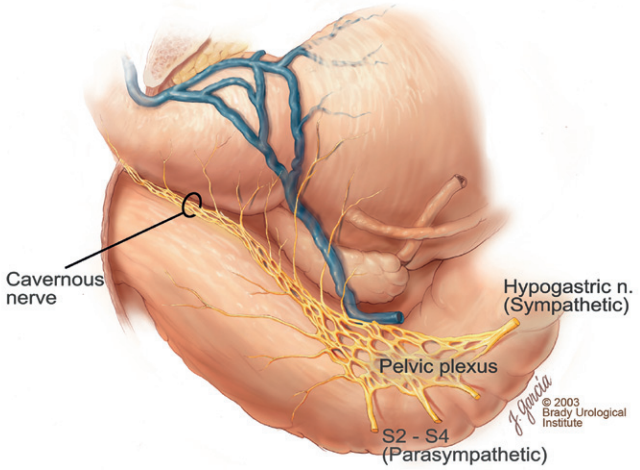

Figure 102–1. Location of the superficial and deep branches of the dorsal vein as they travel over the anterior and anterolateral surfaces of the prostate. Note the common trunk located immediately over the urethra. This is the site where the dorsal vein is transected. The pelvic plexus: The autonomic innervation of the pelvic organs arises from the pelvic plexus, which is formed by parasympathetic fibers that arise from the sacral center (S2 to S4) and sympathetic fibers via the hypogastric nerve from the thoracolumbar center. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. The branches that innervate the corpora cavernosa enter in a spraylike distribution 20 to 30 mm distal to the junction of the prostate and bladder, where they continue distally posterolateral to the prostate. (© Brady Urological Institute.)

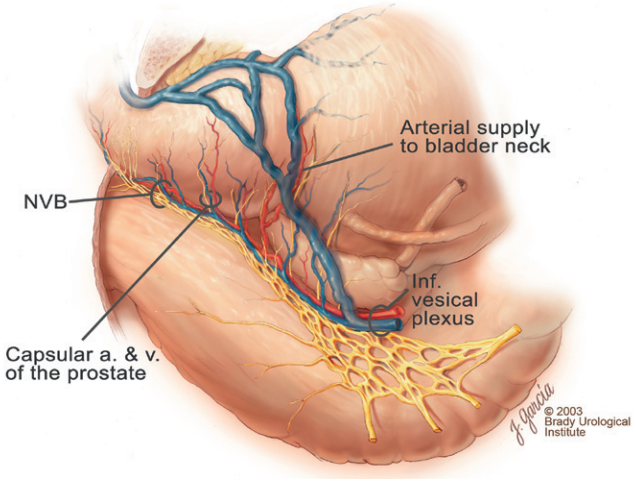

Figure 102–2. Arterial supply to the prostate. The inferior vesical artery terminates in two large groups of vessels. One group, called the urethral vessels, enters the prostate at the posterolateral vesicoprostatic junction to supply the bladder neck and periurethral portions of the gland. The second group, the capsular branches, runs along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. These capsular arteries and veins are intimately associated with the branches of the pelvic plexus forming the neurovascular bundle (NVB) that is used as the macroscopic landmark to aid in the identification of the microscopic branches of these nerves. Note at the apex that small branches of the nerves travel anteriorly away from the vessels. (© Brady Urological Institute.)

venous plexuses traverse posterolaterally and communicate freely with the pudendal, obturator, and vesical plexuses. Near the puboprostatic ligaments, small branches from the lateral plexus often penetrate the pelvic sidewall musculature and communicate with the internal pudendal vein. The lateral plexus interconnects with other venous systems to form the inferior vesical vein, which empties into the internal iliac vein. With the complex of veins and plexuses anastomosing freely, any laceration of these friable structures can lead to considerable blood loss.

The prostate receives arterial blood supply from the inferior vesical artery. According to Flocks (1937), **after the inferior vesical artery provides small branches to the seminal vesicle and the base of the bladder and prostate, the artery terminates in two large groups of prostatic vessels: the urethral and capsular groups** (Fig. 102–2). The urethral vessels enter the prostate at the posterolateral vesicoprostatic junction and supply the vesical neck and periurethral portion of the gland. The capsular branches run along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. The capsular vessels terminate as a small cluster of vessels that supply the pelvic floor. On histologic examination, the capsular arteries and veins are surrounded by an extensive network of nerves (Walsh and Donker, 1982; Walsh et al, 1983; Lue et al, 1984; Lepor et al, 1985). These capsular vessels provide the macroscopic landmark to aid in the identification of the microscopic branches of the pelvic plexus that innervate the corpora cavernosa.

The major arterial supply to the corpora cavernosa is derived from the internal pudendal artery. However, **pudendal arteries can arise from the obturator, inferior vesical, and superior vesical arteries. Because these aberrant branches travel along the lower part of the bladder and anterolateral surface of the prostate, they are divided during radical prostatectomy.** This may compromise arterial supply to the penis, especially in older patients with borderline penile blood flow (Breza et al, 1989; Polascik and Walsh, 1995; Rogers et al, 2004).

Pelvic Plexus

The autonomic innervation of the pelvic organs and external genitalia arises from the pelvic plexus, which is formed by parasympathetic, visceral, efferent, preganglionic fibers that arise from the sacral center (S2 to S4) and sympathetic fibers via the hypogastric nerve from the thoracolumbar center (Walsh and Donker, 1982; Lue et al, 1984; Lepor et al, 1985; Schlegel and Walsh, 1987; Walsh, 2007) (see Fig. 102–1). The pelvic plexus in men is located retroperitoneally beside the rectum 5 to 11 cm from the anal verge and forms a fenestrated rectangular plate that is in the sagittal plane with its midpoint at the level of the tip of the seminal vesicle.

The branches of the inferior vesical artery and vein that supply the bladder and prostate perforate the pelvic plexus. For this reason, ligation of the so-called *lateral pedicle* in its midportion not only interrupts the vessels but also transects the nerve supply to the prostate, urethra, and corpora cavernosa. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. In addition, branches that contain somatic motor axons travel through the pelvic plexus to supply the levator ani, coccygeus, and striated urethral musculature. **The nerves**

innervating the prostate travel outside the capsule of the prostate and Denonvilliers fascia until they perforate the capsule where they enter the prostate.

The branches to the membranous urethra and corpora cavernosa also travel outside the prostatic capsule in the lateral pelvic fascia dorsolaterally between the prostate and rectum (see Fig. 102–1). Although these nerves are microscopic, their anatomic location can be estimated intraoperatively by use of the capsular vessels as a landmark. This structure, which is referred to here as the neurovascular bundle, has been termed the *neurovascular bundle of Walsh* (Stedman's Medical Dictionary, 2000) (see Fig. 102–2). As emphasized by Takenaka and colleagues (2004) and Costello and colleagues (2004), the cavernous branches join the capsular arteries and veins in a spraylike distribution to form the neurovascular bundle 20 to 30 mm distal to the junction of the bladder and prostate (see Fig. 102–2). The neurovascular bundles are located in the lateral pelvic fascia *between* the prostatic fascia and the levator fascia. At the apex of the prostate, the branches of the nerves to the cavernous bodies and striated sphincter also have a spraylike distribution both anteriorly and posteriorly with wide variation (Costello et al, 2004; Takenaka et al, 2005a). After piercing the urogenital diaphragm, the nerve branches pass behind the dorsal penile artery and dorsal penile nerve before entering the corpora cavernosa (Walsh and Donker, 1982).

Striated Urethral Sphincter

The external sphincter, at the level of the membranous urethra, is often depicted as a "sandwich" of muscles in the horizontal plane. However, Oelrich (1980) demonstrated clearly that the striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. In utero, this sphincter extends without interruption from the bladder to the perineal membrane. As the prostate develops from the urethra, it invades and thins the sphincter muscle, causing a reduction or atrophy of some of the muscle (Fig. 102–3).

In the adult the fibers at the apex of the prostate are horseshoe shaped and form a tubular, striated sphincter surrounding the membranous urethra. Near the apex of the prostate, the edges fuse in the midline posteriorly (Fig. 102–4A). Thus as Myers (1987) has shown, the prostate does not rest on a flat, transverse urogenital diaphragm like an apple on a shelf, with no striated muscle proximal to the apex. Rather, the external striated sphincter is more tubular and has broad attachments over the fascia of the prostate near the apex. This has important implications in the apical dissection and reconstruction of the urethra for preservation of urinary control postoperatively (Walsh et al, 1990).

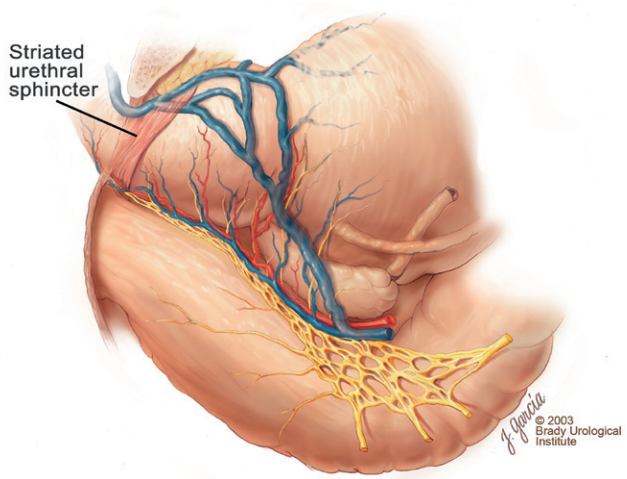

Figure 102–3. The striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. The dorsal vein complex travels through the sphincteric complex. (© Brady Urological Institute.)

The striated sphincter contains fatigue-resistant, slow-twitch fibers that are responsible for passive urinary control. Active continence is achieved by voluntary contraction of the levator ani musculature, which surrounds the apex of the prostate and membranous urethra. Some fibers of the levator ani (levator urethrae, pubourethralis) surround the proximal urethra and the apex of the prostate and insert into the perineal body in the midline posteriorly (Myers, 1991, 1994). **The pudendal nerve provides the major nerve supply to the striated sphincter and levator ani.** When patients are instructed to perform sphincter exercises postoperatively, they are actually contracting the levator ani musculature. However, because the striated urethral sphincter has similar innervation, patients are exercising this important muscle as well. Somatic motor nerves traveling through the pelvic plexus provide additional innervation to the pelvic floor musculature (Zvara et al, 1994; Costello et al, 2004, Takenaka et al, 2005a).

Pelvic Fascia

The prostate is covered with three distinct and separate fascial layers: Denonvilliers fascia, the prostatic fascia (also called the *capsule of the prostate*), and the levator fascia. Denonvilliers fascia is a filmy, delicate layer of connective tissue located between the anterior walls of the rectum and prostate (Fig. 102–4B). This fascial layer extends cranially to cover the posterior surface of the seminal vesicles and lies snugly against the posterior prostatic capsule. This fascia is most prominent and dense near the base of the prostate and the seminal vesicles and thins dramatically as it extends caudally to its termination at the striated urethral sphincter. On microscopic examination, it is impossible to discern "posterior" and "anterior" layers of this fascia (Jewett et al, 1972). For this reason, one must excise this fascia completely to obtain an adequate surgical margin.

In addition to Denonvilliers fascia, the prostate is also invested with the prostatic fascia and levator fascia. Anteriorly and anterolaterally, the prostatic fascia is in direct continuity with the parenchyma of the prostate. The major tributaries of the dorsal vein of the penis and Santorini plexus travel within the anterior prostatic fascia. Laterally, the prostatic fascia fuses with the levator fascia, which covers the pelvic musculature, to form the lateral pelvic fascia (Fig. 102–5) (Myers, 1991, 1994). Posterolaterally, the levator fascia separates from the prostate to travel immediately adjacent to the pelvic musculature surrounding the rectum. **The prostate receives its blood supply and autonomic innervation between the layers of the levator fascia and prostatic fascia** (see Figs. 102–4B and 102–5).

In an effort to avoid injury to the dorsal vein of the penis and Santorini plexus during radical perineal prostatectomy, the lateral and anterior pelvic fasciae are reflected off the prostate. This accounts for the reduced blood loss associated with radical

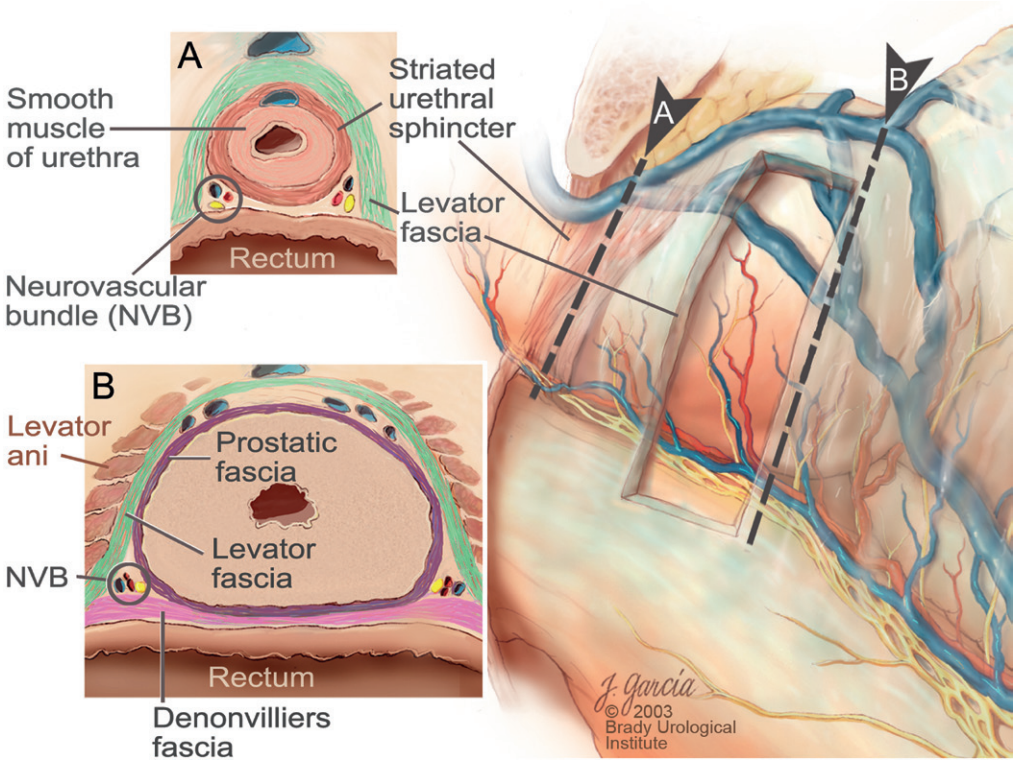

Figure 102–4. **A,** A cross section through the apex of the prostate demonstrating the relationship among the fascia surrounding the striated sphincter, striated sphincter, and smooth muscle of the urethra. Note that at this level, the striated sphincter circumferentially surrounds the urethra. Note that the neurovascular bundles are posterolateral to the circumferential striated sphincter. **B,** A cross section through the midportion of the prostate demonstrating the relationship between the levator fascia, Denonvilliers fascia, and prostatic fascia. Note that the neurovascular bundles are located between the layers of the levator fascia and prostatic fascia. In performing a proper nerve-sparing operation, the prostatic fascia must remain on the prostate. (© Brady Urological Institute.)

perineal prostatectomy. In performing radical retropubic prostatectomy, the prostate is approached from outside these fascial investments. For this reason, the dorsal vein complex must be ligated and the lateral pelvic fascia must be divided (Walsh et al, 1983).

SURGICAL TECHNIQUE

Preoperative Preparation

The preoperative assessment must include a focused review of systems; a complete medical, surgical, and anesthesia history; an inquiry of all prescription and nonprescription medications; a physical examination; and routine preoperative laboratory testing. Life-threatening complications associated with radical retropubic prostatectomy are rare and include myocardial infarction, cerebrovascular accident (stroke), cardiac arrhythmias, pulmonary embolus, hemorrhage, and anesthesia reactions. The preoperative assessment must identify those candidates who are at increased risk for these mortality events in order to intervene to attenuate these risks.

The preoperative assessment should identify factors that may add to the technical challenge of the surgical procedure including prior abdominal or pelvic surgery and irradiation, prior transurethral surgery, extensive prostate biopsies, history of significant inflammatory bowel disease, the prior use of mesh during inguinal or incisional hernia repairs, and the size of the prostate. Although none of these factors are contraindications for radical retropubic prostatectomy, a greater level of skill and experience may be required to minimize complications.

The observation that up to 15% to 20% of men develop an inguinal hernia following radical retropubic prostatectomy implied that this surgical procedure directly predisposes to the development of hernias (Regan, 1996; Lodding, 2001; Nielsen and Walsh,

2005). Approximately 15% of men undergoing radical prostatectomy will have a coexisting inguinal hernia detected if an appropriate inguinal examination is performed (Lepor and Robbins, 2007). In most of these cases, the inguinal hernias are asymptomatic. These observations suggest that a radical retropubic prostatectomy may transform an asymptomatic inguinal hernia into a symptomatic hernia. Therefore examination of the inguinal canal with Valsalva should be performed, enabling properitoneal hernia repairs at the time of the radical prostatectomy.

Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate. This delay enables inflammatory adhesions or hematomas to resolve so that the anatomic relationships between the prostate and the surrounding structures return to a nearly normal state before surgery. This is especially important if one hopes to preserve the neurovascular bundles intraoperatively and avoid rectal injury.

During this delay, patients may be offered the opportunity to donate autologous blood, although the utilization of autologous transfusions at our institutions has declined as continuous modifications to our technique have reduced blood loss. One of the limitations of autologous blood donation is that many donated units are not transfused if the hematocrit is higher than 30% (Goad et al, 1995). Therefore hemodilution and erythrocyte stimulating proteins have been recommended as alternative blood management strategies (Gilbert and Smith, 2000). Erythrocyte-stimulating proteins, which are not approved by the U.S. Food and Drug Administration, have been shown to raise the hematocrit on average percentage points, diminishing postprostatectomy anemia (Rosenblum et al, 2000). The relatively higher discharge hematocrit attributable to the use of erythrocyte stimulating proteins affects the pace of recovery because postoperative hematocrit has been shown to influence both time to work and return to activities (Sultan et al, 2006).

The American Urological Association recently published best practice guidelines for the use of prophylactic antibiotics for urologic surgical procedures (Wolf et al, 2008). The recommended prophylactic regimens for open or laparoscopic surgery involving entry into the urinary tract are a first- or second-generation cephalosporin or an aminoglycoside in combination with metronidazole or clindamycin. The duration of therapy should be no longer than 24 hours. The authors routinely use a first-generation cephalosporin alone and have an infection rate much less than 1%.

While donating blood and immediately before surgery, patients should avoid taking high doses of vitamin E, aspirin, nonsteroidal anti-inflammatory agents, omega-3 fish oils, and thienopyridines (Plavix and Ticlid), which interfere with platelet function. Products that are not medically indicated should be discontinued at least 1 week before surgery. **The preoperative management of anticoagulants and antiplatelet agents that are used for the treatment of specific medical conditions such as prosthetic valves, atrial fibrillation, and coronary artery stent implants should be performed in conjunction with the internist or cardiologist.** With nearly 1 million coronary interventions occurring every year and the majority including an implant of a drug-eluting stent, managing prescribed antiplatelet therapy can create a dilemma balancing the risk of stent stenosis and perioperative bleeding. In the majority of cases, stent thrombosis is a catastrophic event resulting in life-threatening complications (Cutlip et al, 2001). A reasonable compromise for men with drug-eluting stents undergoing a radical retropubic prostatectomy is to preoperatively discontinue the thienopyridine while continuing aspirin therapy and restarting the thienopyridine as soon as clinically indicated (Grines et al, 2007).

Patients are prescribed a clear liquid diet on the day before surgery, are requested to drink half a bottle of magnesium citrate in the evening, and have an enema on the morning of surgery. They are admitted to the hospital on that day.

Special Instruments

Unlike radical perineal or robot-assisted laparoscopic prostatectomy, radical retropubic prostatectomy requires few special instruments. A fiberoptic headlight is essential because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. A standard Balfour retractor with both narrow and wide malleable blades is useful during lymph node dissection and is necessary during radical prostatectomy to provide cranial and posterior retraction on the peritoneum and bladder. Coagulating forceps; small, fine, and regular right-angled clamps; Metzenbaum and Jamison scissors; and 2.5- to 4.5-power loupes are the only other specialized instruments that should be available.

Anesthesia, Incision, and Lymphadenectomy

A spinal or epidural anesthetic is preferable for this procedure. **Regional anesthesia is associated with less blood loss and a lower frequency of pulmonary emboli** (Peters and Walsh, 1985; Shir et al, 1995). The anesthesiologist is encouraged to maintain relative hypotension with systolic blood pressure of no more than 100 mm Hg and to limit the replacement of crystalloid to 1500 mL until the prostate is removed (Davies et al, 2004). The patient is placed in the supine position with the table flexed to increase the distance between the umbilicus and pubis.

The skin is prepared and draped in the usual way. A No. 16 Silastic Foley catheter is passed into the bladder, inflated with 20 mL of saline, and connected to sterile, closed, continuous drainage. The use of a 16-Fr catheter facilitates placement of sutures in the mucosa of the urethra. A right-handed surgeon always stands on the left side of the patient.

An 8-cm midline, extraperitoneal, lower abdominal incision is made extending from the pubis toward the umbilicus. Alternately, in thin patients, a transverse skin incision just above the pubis can be used. This short incision provides excellent exposure of the prostate because the rectus muscles are separated maximally by the retractor at the pubis. It also limits traction on the prostate and neurovascular bundles when using the sponge stick and malleable blade. For reasons that are not entirely clear, the authors have also noted a marked reduction in thromboembolic events since they began using this incision; none in 700 consecutive patients compared with 10 in the prior 700 ($P = .002$). The anterior fascia is incised down to the pubis, the rectus muscles are separated in the midline, and the transversalis fascia is opened sharply to expose Retzius space. Laterally, the peritoneum is mobilized off the external iliac vessels to the bifurcation of the common iliac artery. **Care is taken to preserve the soft tissue covering the external iliac artery that contains the lymphatics draining the lower extremity. Interruption of these lymphatics may lead to lower extremity edema and lymphocele formation.** This maneuver is accomplished without dividing the vas deferens. Next, a self-retaining Balfour retractor is placed. Exposure for the lymph node dissection is facilitated by placement

of a narrow, malleable blade attached to the Balfour retractor beneath the mobilized vas deferens to displace the peritoneum superiorly and a deep Deaver retractor to retract the bladder medially. Previously, when the vas deferens was routinely divided, some patients complained of persistent testicular pain that the authors attributed to excessive traction on the spermatic cord during this maneuver. However, if the vas deferens is not divided, the traction on the spermatic cord is absorbed by the vas deferens and persistent testalgia is rare.

The pelvic lymph node dissection is performed before the radical prostatectomy. The dissection is initiated on the ipsilateral side of the major tumor in the prostate by dividing the adventitia over the external iliac vein (Fig. 102–6). The lymphatics overlying the external iliac artery are preserved. The dissection proceeds beneath the external iliac vein out to the pelvic sidewall and then inferiorly to the femoral canal, where the lymphatic channels are ligated at a convenient point. There is no need to remove the Cloquet node. The dissection then proceeds superiorly along the pelvic sidewall to the bifurcation of the common iliac artery, where the lymph nodes in the angle between the external iliac and hypogastric arteries are removed. Next, the obturator lymph nodes are removed with care to avoid injury to the obturator nerve. The obturator artery and vein are skeletonized but are usually left undisturbed and are not ligated unless excessive bleeding occurs. The dissection then continues down to the pelvic floor, exposing the hypogastric veins. This extended dissection removes more lymph nodes than in a more limited dissection, improving staging and providing potential therapeutic benefit in some patients (Allaf et al, 2004; Palapattu et al, 2004). A similar procedure is performed on the opposite side. **If the patient has a well-differentiated to moderately well-differentiated tumor (Gleason grade < 8) and the lymph nodes are normal to palpation, frozen-section analysis is not performed** (Sgrignoli et al, 1994; Cadeddu et al, 1997).

Exposure

To expose the anterior surface of the prostate, it is necessary to displace the peritoneum superiorly. **The authors no longer place the balloon on the Foley catheter in the dome of the bladder beneath the malleable blade because they believe that excessive traction on the bladder can damage the detrusor musculature, thereby delaying recovery of urinary continence, and produce traction injury to the neurovascular bundle.** Also, the short incision limits the amount of traction. A malleable blade is used to retract the peritoneum superiorly and to gently displace the bladder posteriorly.

Incision in Endopelvic Fascia

The fibroadipose tissue covering the prostate is carefully dissected away to expose the pelvic fascia, puboprostatic ligaments, and superficial branch of the dorsal vein.

The endopelvic fascia is entered where it reflects over the pelvic sidewall, well away from its attachments to the bladder and prostate (Fig. 102–7). The point of incision is where the fascia is transparent, revealing the underlying levator ani musculature. After the fascia has been opened, one can usually visualize the bulging lateral venous plexus of Santorini, which is located medially. Therefore **an incision in the endopelvic fascia too close to the bladder or the prostate risks laceration of these veins, with potential severe blood loss.** Beneath this venous complex lie the prostatic arteries and the branches of the pelvic plexus that course toward the prostate, urethra, and corpora cavernosa.

The incision in the endopelvic fascia is then carefully extended in an anteromedial direction toward the puboprostatic ligaments. This allows the surgeon to palpate the lateral surface of the prostate. **At this point, one often encounters small arterial**

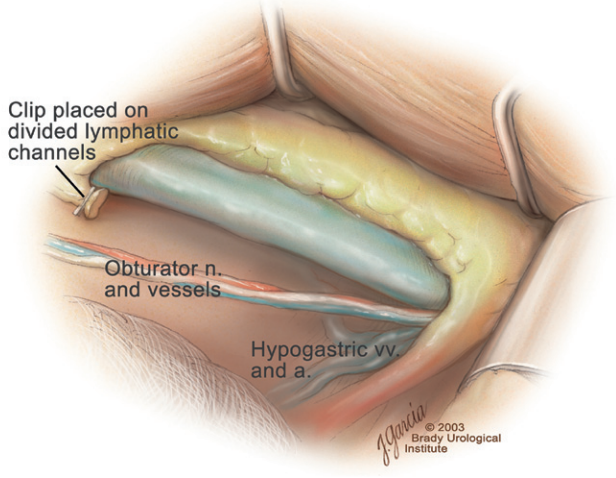

Figure 102–6. View of the right pelvis after completion of the staging pelvic lymph node dissection. Note that the fibroadipose tissue overlying the external iliac artery has not been disturbed and that the obturator nerve, obturator vessels, and hypogastric veins over the pelvic floor have been skeletonized. (© Brady Urological Institute.)

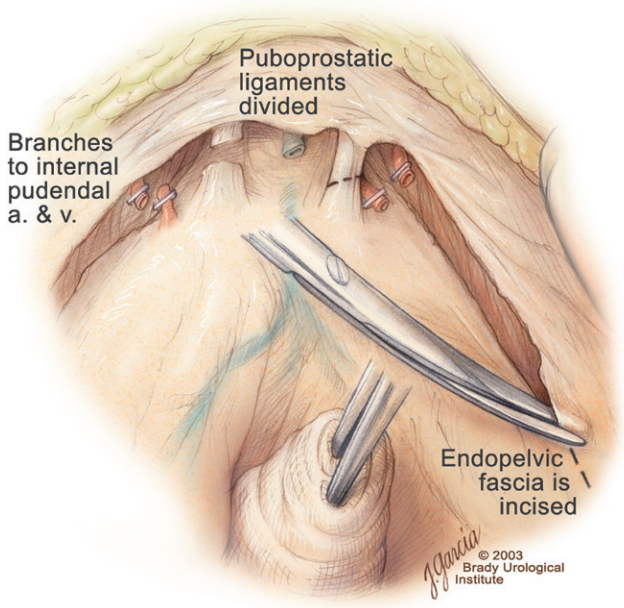

Figure 102–7. Incision in the endopelvic fascia and division of the puboprostatic ligaments. The incision in the endopelvic fascia is made at the juncture with the pelvic sidewall well away from the prostate and bladder. Anteriorly, near the puboprostatic ligaments, small arterial and venous branches from the internal pudendal vessels have been clipped and divided. The puboprostatic ligaments are divided superficially far enough down to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex. However, the pubourethral component of the complex is intact to preserve anterior fixation of the striated sphincter to the pubis. (© Brady Urological Institute.)

and venous branches from the pudendal vessels that perforate the pelvic musculature to supply the prostate. These vessels should be ligated with clips to avoid coagulation injury to the pudendal artery and nerve, which are located just deep to this muscle as they travel along the pubic ramus.

Division of the Puboprostatic Ligaments

The fibrofatty tissue covering the superficial branch of the dorsal vein and puboprostatic ligaments is gently teased away to prepare for division of the ligaments without injury to the superficial branch of the dorsal vein. After the superficial branch has been dissected away from the medial edge of the ligaments, it is coagulated and divided. After all fibrofatty tissue has been removed, a sponge stick is used to displace the prostate posteriorly, and scissors are used to divide each ligament (see Fig. 102–7).

The dissection should continue down far enough to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex at the point where it will be divided. The pubourethral component of the complex must remain intact to preserve the anterior fixation of the striated urethral sphincter to the pubis (Burnett and Mostwin, 1998).

Preservation of Accessory Pudendal Arteries

Arterial insufficiency is a factor contributing to erectile dysfunction in patients after nerve-sparing radical retropubic prostatectomy. One source for this insufficiency may arise from accessory pudendal arteries that travel over the anterolateral surface of the prostate. These arteries have been found in 70% of cadaveric dissections and in 7% of patients by selective internal pudendal angiography. In the authors' experience, large visible accessory pudendal arteries are present in 4% of men (Rogers et al, 2004).

Because release of accessory arteries may be associated with significant blood loss necessitating prompt ligation and division of the dorsal vein complex, it is useful to have the contralateral dissection completed before accessory vessels are released. For this reason, when these vessels appear to be prominent and are present unilaterally, the endopelvic fascia and puboprostatic ligament on the contralateral side should be divided first. The surgical technique for preservation of the arteries begins with division of the endopelvic fascia lateral to the vessels and division of the puboprostatic ligament (the vessels are beneath the puboprostatic ligament) (Rogers et al, 2004). Next, a vessel loop is used to elevate the artery and then with sharp dissection and a right-angled clamp, the accessory artery is released from its investing fascia (Fig. 102–8). As the dissection proceeds, venous tributaries are divided. At times, there may be substantial blood loss from the venous complex over the prostate; hemostasis, however, is usually easily obtained with a 2-0 running absorbable suture. The dissection must extend caudally beyond the site at which the dorsal vein complex will be divided.

Ligation of the Dorsal Vein Complex

The goal is to divide the complex with minimal blood loss while avoiding damage to the striated sphincter and inadvertent entry into the anterior apex of the prostate. With use of the sponge stick to push the prostate posteriorly, a 3-0 Monocryl suture is passed superficially through the dorsal vein complex just distal to the apex of the prostate (Fig. 102–9). In placing this stitch, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient. Next, the needle is reversed in the needle holder and the same suture is placed through the perichondrium of the pubic symphysis (Fig. 102–10). Once this horizontal mattress suture is tied, three important goals are accomplished: (1) control of much of the venous bleeding without a "bunching" effect—this flat surface is much easier to divide; (2) recapitulation of the puboprostatic ligaments to provide additional anterior support of the striated sphincter; and (3) fixation of the dorsal vein complex anteriorly. This enables the surgeon to visualize the plane on the anterior apex of the prostate during division of the dorsal vein complex. The suture is not cut; it will be used once the dorsal vein is divided to oversew bleeders. A figure-of-eight 2-0 chromic suture is next placed on the anterior surface of the prostate near the bladder neck to reduce bleeding from the proximal dorsal veins, which can be excessive in some patients who have incompetent venous valves (Fig. 102–11).

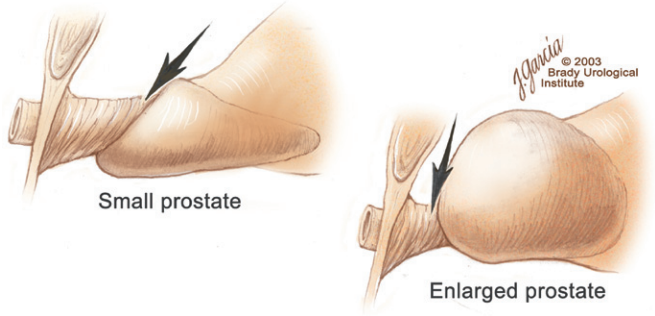

Figure 102–12. As Myers (1991) has pointed out, there is marked variability in the shape of the apex of the prostate. In patients with a small prostate it can have a gentle slope, whereas in patients with an enlarged prostate, there can be an abrupt 90-degree angle. Knowledge of this variability is important to avoid excising excessive amounts of the striated sphincter. (© Brady Urological Institute.)

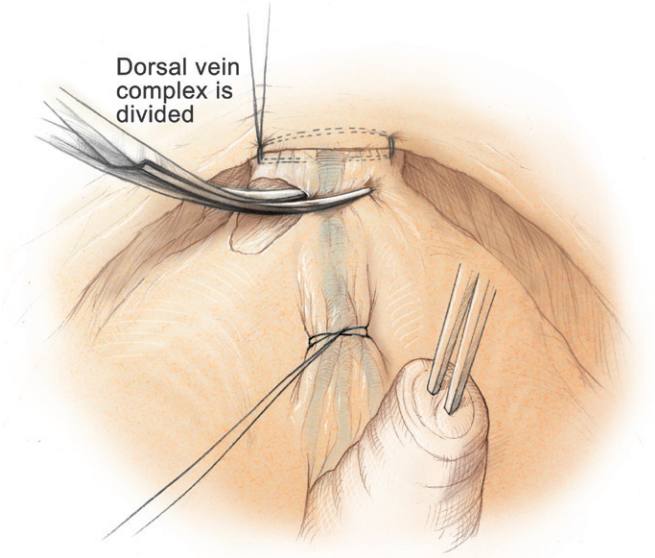

Figure 102–13. With a sponge stick depressing the prostate posteriorly, the dorsal vein complex is divided beginning at the left edge. (© Brady Urological Institute.)

Apical Dissection

The apical dissection is the most complex and important step in the operation. The striated sphincter and the surrounding dorsal vein must be divided with care to avoid inadvertent incision into the apex of the prostate, the most common site for positive margins. Bleeding from the dorsal vein complex must be controlled without injury to the surrounding striated sphincter, the continence mechanism responsible for passive urinary control. During these maneuvers, the apical neurovascular bundles must not be injured by excessive traction, cautery, or inadvertent transection.

The standard approach to division of the dorsal vein complex is presented first. This is a validated technique that maximizes the amount of soft tissue covering the apex of the prostate. As a consequence, in Walsh's hands, the probability of a positive surgical margin in a patient with organ-confined disease is only 1.3%.

With recognition that high release of the levator fascia at the apex can result in earlier recovery of potency in selected patients (Nielsen et al, 2008), **an alternative technique using high anterior release of the neurovascular bundle, before division of the dorsal vein, is also described.**

Standard Division of the Dorsal Vein Complex. As Myers (1991) has pointed out, there is marked variability in the shape of the apex of the prostate (Fig. 102–12). For this reason, it is not wise to pass an instrument bluntly through the complex blindly. Rather, the dissection should be approached by direct division and visual assessment of the landmarks. With the application of downward pressure on the anterior surface of the prostate with a sponge stick, Metzenbaum scissors are used to divide the complex. This is usually started on the left edge of the complex where the junction with the apex of the prostate can usually be seen well (Fig. 102–13). Because the distal complex is fixed anteriorly, with downward pressure on the sponge stick, the exact plane between the juncture of the anterior surface of the prostate and the striated musculature can be visualized. Here the 4.5-power loupes enable the surgeon to distinguish tissue textures and avoid positive margins. This is

the most common site for positive surgical margins because it can be difficult to identify the anterior apical surface of the prostate. It also helps to rest the scissors on the anterior apex to find the correct plane.

There is one important caveat in performing this maneuver. As the dissection proceeds posteriorly, **if the striated sphincter is divided too close to the apex of the prostate, there is risk that the neurovascular bundle may be damaged. As the neurovascular bundle approaches the apex of the prostate, it is often fixed medially beneath the striated sphincter by an apical vessel** (Walsh et al, 2000b). For this reason, the lateral edges of the sphincter along the urethra should be divided obliquely midway between the apex of the prostate and the pelvic floor. Absolute control of venous bleeding from the dorsal vein complex is mandatory so that the remainder of the procedure can be performed in a bloodless field. To achieve hemostasis, the 3-0 Monocryl suture on a ⅝-circle needle that was placed previously is used to oversew the superficial edges of the striated urethral sphincter–dorsal vein complex (Fig. 102–14). **In placing this running suture, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient.** If the needle driver is held loosely, the superficial edges of the complex can be easily approximated, forming a hood over the anterior urethra. Circumflex veins are often present at the posterior edge of the complex at the 5- and 7-o'clock positions; hemoclips are often used to control these bleeders. At the completion of this maneuver, hemostasis should be excellent.

Finally, to control back-bleeding from the anterior surface of the prostate, **the edges of the proximal dorsal vein complex on the anterior surface of the prostate are sewn in the shape of a V with a running 2-0 absorbable suture** (Fig. 102–15). **If one tries to pull these edges together in the midline, the neurovascular bundles can be advanced too far anteriorly on the prostate** (Walsh et al, 2000b). If one begins by placing a figure-of-eight suture at the bladder neck before dividing the dorsal vein complex and then uses the same suture to oversew the proximal dorsal vein, there is less back-bleeding.

Division of the Urethra and Placement of the Urethral Sutures. By gently displacing the prostate posteriorly with a sponge stick, the prostatourethral junction should be well visualized. The lateral bands of the striated musculature should be released as described earlier at their midpoint to free up as much of the urethra as possible. A right-angled clamp is then passed around the smooth musculature of the urethra near the apex of the prostate to ensure that the urethra is transected as close to the apex as possible (Fig. 102–16). With scissors, the anterior two thirds of the urethra is divided with care to avoid damage to the Foley catheter. This provides excellent exposure for placement of five sutures in the distal urethral segment at the 12-, 2-, 5-, 7-, and 10-o'clock positions. With 3-0 Monocryl on a ⅝-circle tapered needle, **the**

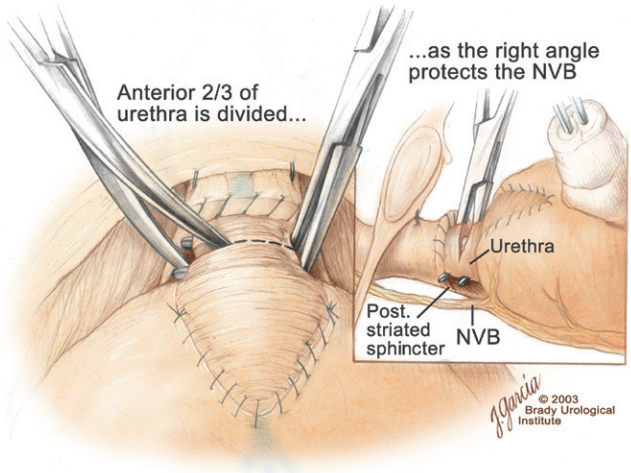

Figure 102–16. A right-angled clamp is placed around the smooth muscle of the urethra close to the apex of the prostate. Note in the inset that the neurovascular bundles (NVBs) are protected from injury by the posterior component of the striated sphincter, which is still intact. Also see Figure 102–5. (© Brady Urological Institute.)

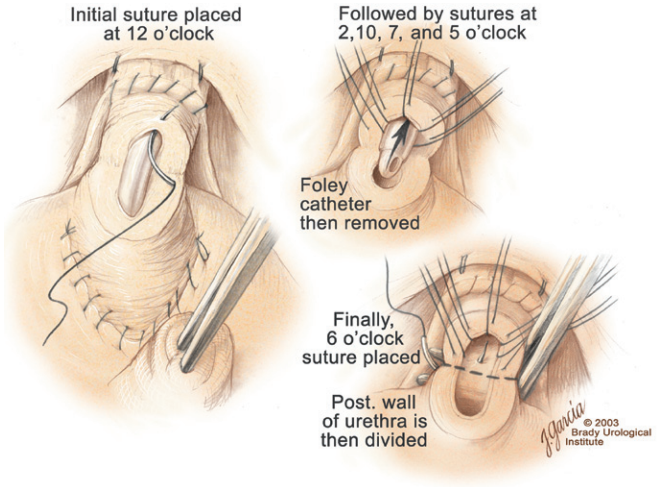

Figure 102–17. The 3-0 Monocryl sutures are placed in the distal urethral mucosa and submucosa at the 12-, 2-, 10-, 7-, and 5-o'clock positions. The Foley catheter is then removed, the 6-o'clock suture is placed, and the posterior wall of the urethra is divided. (© Brady Urological Institute.)

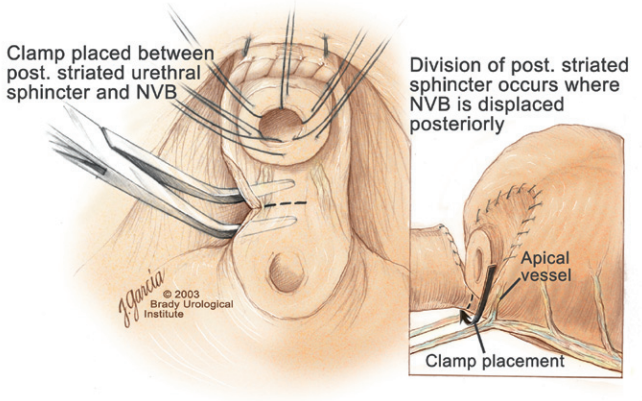

Figure 102–18. Division of the posterior component of the striated sphincter. A right-angled clamp is passed beneath the left edge of the striated sphincter midway between the apex of the prostate and urethra, at a site where the neurovascular bundles (NVBs) have fallen posteriorly. After the left edge of the complex is divided, a right-angled clamp is then passed along the right edge and the maneuver is repeated. (© Brady Urological Institute.)

needle should incorporate just the urethral mucosa and submucosa but not the smooth muscle (Fig. 102–17). As stated previously, the surgeon should face the head of the table to place these sutures and should hold the needle driver against the pubis perpendicular to the patient. The first suture is placed in the mucosa and submucosa of the urethra at the 12-o'clock position. By use of a 16-Fr catheter, the mucosa is easily identified. The smooth muscle should not be incorporated in this stitch because stitches in the smooth muscle delay the recovery of urinary control. If the urethral tissue appears flimsy, this suture should then be placed through the dorsal vein complex to improve tensile strength. Once the mucosa and submucosa have been elevated by the 12-o'clock stitch, the remaining sutures are more easily placed. For a right-handed surgeon, it is easiest to place the 7- and 10-o'clock sutures from the outside of the lumen to the inside. The other three sutures are more easily placed beginning on the luminal surface and then proceeding outside. In performing the final anastomosis, a French eye needle can be used to place these three sutures through the lumen of the bladder. The sutures are covered with towels to avoid inadvertent traction or displacement.

After the sutures are placed, the catheter is removed. The 6-o'clock suture is placed through the mucosa of the urethra, from the outside to the inside. The posterior band of urethra is now divided to expose the posterior portion of the striated urethral sphincter complex (see Fig. 102–17). The posterior wall of the striated sphincter complex is composed of skeletal muscle and fibrous tissue. **Identification and precise division of this complex are important in (1) obtaining adequate margins of resection for apical lesions, (2) identifying the correct plane on the anterior wall of the rectum to ensure that all layers of Denonvilliers fascia are excised, (3) avoiding blunt trauma to the neurovascular bundles that are located immediately posteriorly, and (4) preserving urinary continence.**

To divide the posterior portion of the sphincter safely, a right-angled clamp is passed immediately beneath the left edge of this complex (Fig. 102–18). The clamp should pass midway between the apex of the prostate and the urethra. If it is passed too close to the apex of the prostate, it may damage the neurovascular bundle. However, midway, the neurovascular bundle is located more posteriorly and is beneath the right-angled clamp (Walsh et al, 2000b) (see Fig. 102–5).

The left border of the complex is then divided with scissors. Next, the right-angled clamp is placed beneath the right edge of the complex and the complex is divided. It is necessary to divide the complex from each side because if one tries to divide the entire complex from one side, the contralateral neurovascular bundle may be damaged. Finally, the central component of the complex is divided.

High Anterior Release of the Neurovascular Bundles at the Apex before Division of the Dorsal Vein Complex. **The purpose of this approach is to speed up the recovery of sexual function and continence by reducing traction on the branches of the nerves to the cavernous bodies and striated sphincter or to avoid inadvertent transection of the small branches that travel anteriorly** (Costello et al, 2004; Takenaka et al, 2004, 2005a; Horninger et al, 2005; Menon et al, 2005; Montorsi et al, 2005). **However, because there is less soft tissue at the apex, the risk of positive surgical margins could be increased by this approach. The authors select candidates for this approach using** parameters that identify patients with a low risk of extraprostatic extension in the region of the neurovascular bundle (Tsuzuki et al, 2005), **and in the authors' hands, they have not noted an increased rate of positive surgical margins** (for a detailed discussion of Tsuzuki parameters, see later).

The procedure begins after the endopelvic fascia has been opened as previously described. The levator fascia over the anterior apex of the prostate is incised as suggested by Takenaka (2005b), and the incision is extended distally along the lateral edge of the dorsal vein complex on the anterolateral surface of the prostate, preserving the underlying prostatic fascia (Fig. 102–19A). The prostatic fascia is the glistening white fascia immediately below the veins that travel along the lateral surface of the prostate. **To identify the correct plane and to avoid inadvertent incision into the prostate, it is essential to have excellent visualization and magnification (4.5-power loupes).** In many patients, these venous tributaries must be

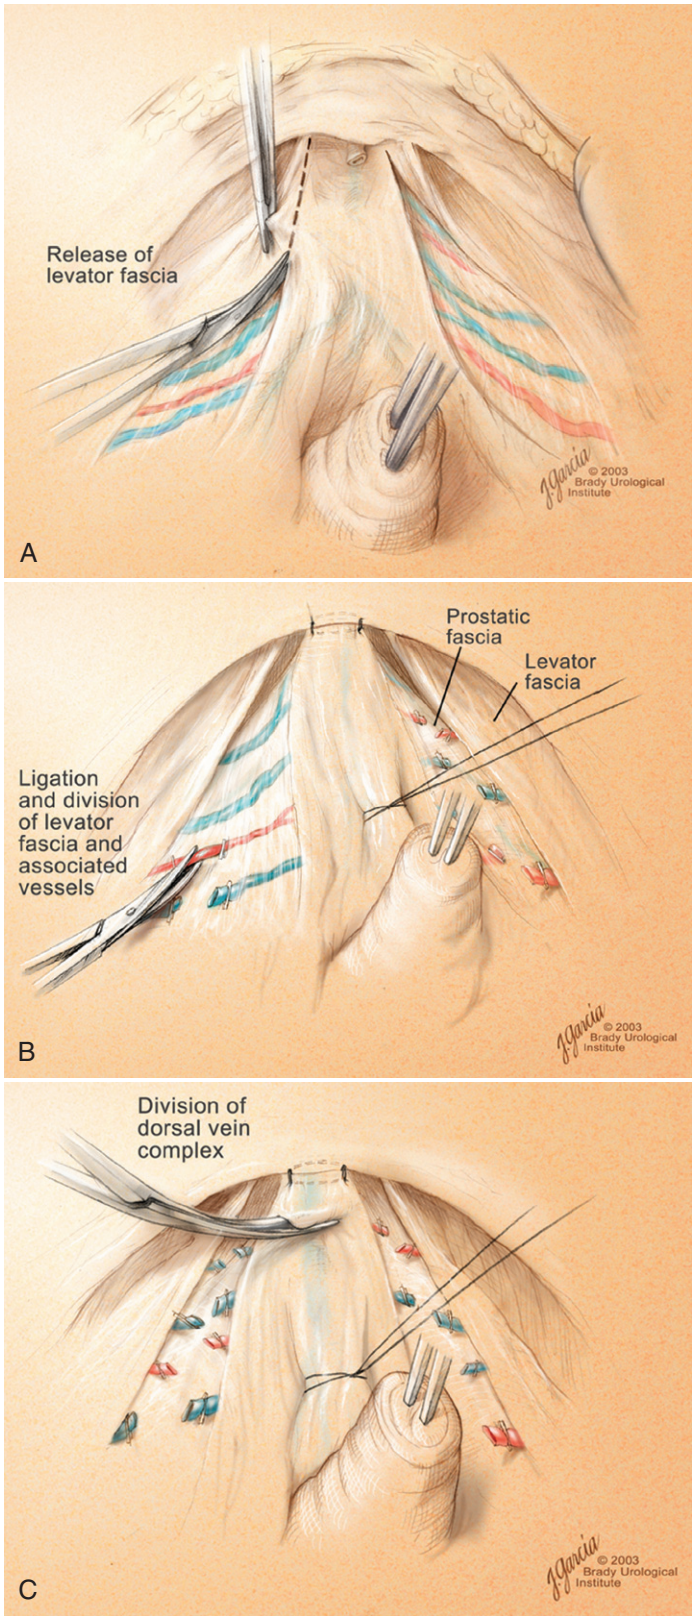

Figure 102–19. High anterior release of the levator fascia. **A,** The levator fascia over the anterior apex of the prostate is incised along the lateral edge of the dorsal vein complex, preserving the underlying prostatic fascia. **B,** The dissection extends distally beyond where the dorsal vein was ligated. Venous tributaries are controlled with clips. **C,** The dorsal vein complex is divided to the urethral between the two preplaced dorsal vein sutures. (© Brady Urological Institute.)

divided and controlled. Cautery should not be used. Instead, hemostasis should be achieved by use of small hemoclips. As the dissection proceeds distally, the levator fascia should be released from the lateral shoulders of the prostate, with care taken not to enter the underlying prostatic fascia. **Because the recovery of sexual function at 12 months following unilateral high release was the same as with bilateral high release, the authors now routinely perform it on only one side, the side with the most favorable pathology.** Once the dissection has extended distally beyond the apex of the prostate, the dorsal vein is ligated distally and proximally as described previously (Fig. 102–19B). Next, while the prostate is immobilized by the dorsal vein complex, the prostate is turned on the side using a sponge stick and the levator fascia and associated veins are released further from the prostatic fascia posterolaterally, exposing and releasing the neurovascular bundle. Next the dorsal vein complex, which has been skeletonized by these maneuvers, is ligated further with the Monocryl suture to reduce blood loss when it is divided. The prostate is then displaced posteriorly by the sponge stick, and the dorsal vein complex is divided between the two ties down to the urethra (Fig. 102–19C). Because the levator fascia has previously been released, prominent neurovascular bundles can usually be visualized lateral to the urethra. Bleeding from the distal dorsal vein complex is controlled with the 3-0 Monocryl suture. Residual back-bleeding from the proximal dorsal vein on the anterior surface of the prostate is controlled with the 2-0 chromic suture. Because less of the striated sphincter is excised by this technique, the bleeding edges can usually be brought together in the midline.

Next, the urethra is transected and the urethral sutures placed. The posterior component of the striated sphincter is transected. If high release of the levator fascia was only performed unilaterally, insert a right-angled clamp under the levator fascia at the apex on the side contralateral to the high release. This facilitates identification of the same dissection plane beneath the levator fascia as the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside (Fig. 102–20). At this point, as described by Masterson and colleagues (2008), the neurovascular bundle is released from the lateral surface of the prostate to just above the seminal vesicles. This approach avoids traction on the neurovascular bundles and makes the subsequent steps in preservation of the neurovascular bundles much easier (Fig. 102–21).

Identification and Preservation or Wide Excision of the Neurovascular Bundles

Today, in most men who are candidates for surgery, it is safe to preserve both neurovascular bundles and rarely necessary to excise both of them (Walsh, 2001). With improved surgical techniques and the availability of phosphodiesterase type 5 inhibitors, most healthy potent men younger than 65 years should be potent after surgery. As discussed earlier, **the neurovascular bundle is outside the prostate between layers of lateral pelvic fascia (the levator fascia and prostatic fascia). If nerve sparing is performed correctly, the prostatic fascia must remain on the prostate. This is called an *interfascial* dissection. Furthermore, when cancer extends through the capsule, it rarely penetrates more than 1 to 2 mm, and this much tissue is often present even when the neurovascular bundle is preserved** (Hernandez et al, 2005). As Costello and colleagues (2004) have shown, the cavernous branches are positioned posterior to the capsular vessels and the nerves immediately adjacent to the

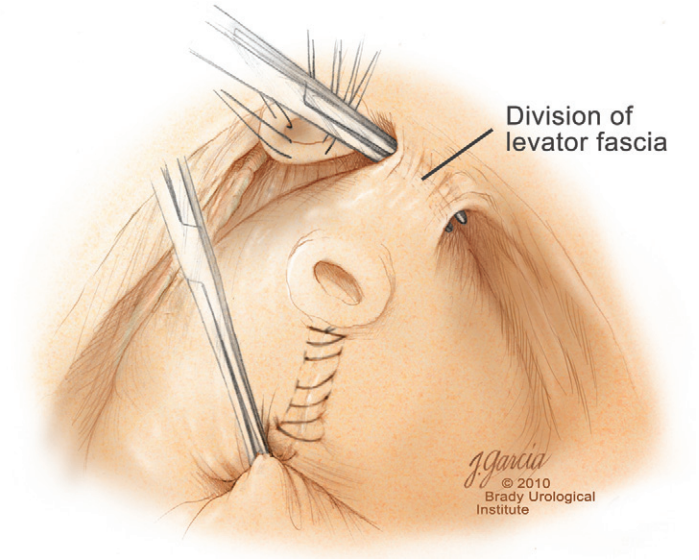

Figure 102–20. If high release of the levator fascia was only performed unilaterally, after the posterior component of the striated sphincter has been divided, insert a right-angled clamp under the levator fascia on the side contralateral to the high release at the apex. This facilitates identification of the same dissection plane beneath the levator fascia as the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside. (© Brady Urological Institute.)

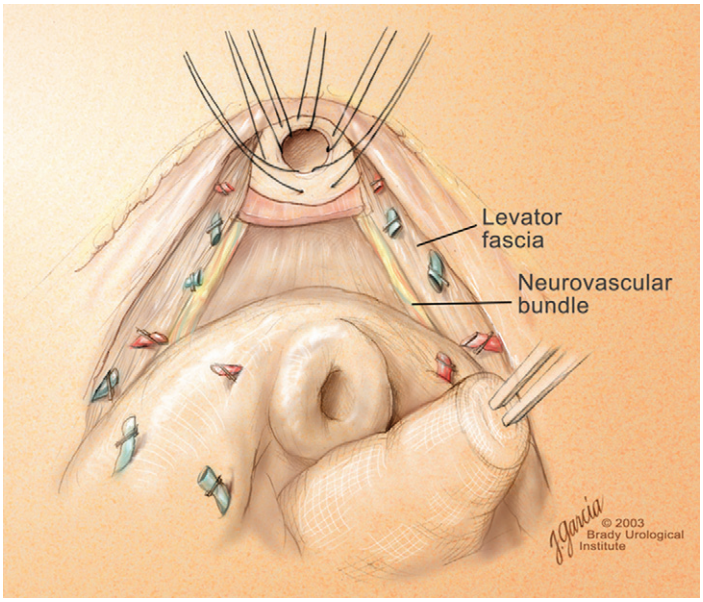

Figure 102–21. A view of the completed dissection. (© Brady Urological Institute.)

prostatic capsule are nerves going into the prostate, not the cavernous nerves.

To avoid bleeding from the capsular arteries and veins, some surgeons dissect beneath the prostatic fascia. This is called an *intrafascial* dissection. Because this plane is directly on the prostatic parenchyma, the risk of positive surgical margins is high. For this reason, this approach should never be used. Many well-meaning surgeons believe that if they excise the neurovascular bundle, they can avoid a positive surgical margin. Unfortunately, this is not the case because the neurovascular bundle is not the most common site for positive margins. Rather, the most common site is the apex, followed by posterior and then posterolateral. In 22% the positive margins are multiple. In multiple studies, it has been demonstrated that the rate of positive margins in nerve-sparing and non–nerve-sparing procedures is the same (Ward et al, 2004). In Walsh's hands, the neurovascular bundles are preserved bilaterally in 87% of patients; one neurovascular bundle is excised in 13%. This has resulted in an overall rate of positive surgical margins of approximately 5% (Epstein, 2001). The neurovascular bundles are rarely if ever excised bilaterally. The authors have always believed that if there is capsular penetration bilaterally to the point where it is necessary to excise both neurovascular bundles, the patient most likely has distant dissemination and is not curable. Between 1986 and 1999, only seven potent men had both neurovascular bundles excised. Four were not cured because they had positive lymph nodes, positive seminal vesicles, or positive surgical margins elsewhere. In the three other patients, it was not necessary to excise both neurovascular bundles because there was no capsular penetration on one side.

How does one decide when and where to excise the neurovascular bundle? Preoperatively, no definite decision is made. Consideration is given to the status of sexual function, but in impotent patients, the authors do not always excise the neurovascular bundles because there is evidence that the bundles provide both somatic and autonomic innervation to the continence mechanism and that patients who undergo excision of both neurovascular bundles have more incontinence than do patients in whom the neurovascular bundles are preserved (Nelson et al, 2003). Consideration is also given to other important factors such as the presence of a *palpable apical lesion* and a high probability of capsular penetration based on the Partin tables (Partin et al, 1997, 2001). **However, no final decision is made until the time of surgery. When the endopelvic fascia is opened, if induration is palpable in the lateral pelvic fascia, the neurovascular bundle on that side is widely excised. If there is no induration but the neurovascular bundle appears to be fixed to the prostate at the time it is being released, it is also excised. However, the final decision about preservation or wide excision of the neurovascular bundle does not need to be made until the prostate is removed. If there appears to be inadequate tissue over the posterolateral surface after the prostate has been removed, the neurovascular bundle can then be widely excised.** For surgeons who are not comfortable or experienced in using intraoperative findings, Tsuzuki and colleagues (2005) have defined preoperative parameters to identify patients with a higher likelihood of extraprostatic extension in the region of the neurovascular bundle. If patients have two or more of the following criteria, the risk of extraprostatic extension in the region of the neurovascular bundle on that side is greater than 10%: prostate-specific antigen (PSA) level above 10 ng/mL, Gleason score higher than 6, average percentage of biopsy core on the side involved greater than 20%, percentage of cores with tumor on that side greater than 33%, or an abnormal finding on digital rectal examination. **The authors use these parameters when selecting candidates for high anterior release of the neurovascular bundles.**

Identification and Preservation of the Neurovascular Bundle. This is where the tactile sensation provided by open surgery is so important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. Also, in gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be

preserved. Tactile sensation is muted with the laparoscopic technique, and with the robot, it is absent. When the neurovascular bundle is released, there should be no upward traction on the prostate. Rather, the prostate should be rolled from side to side. Also with the catheter out, the prostate is softer and it appears easier to identify the correct plane for release of the neurovascular bundle.

Recall that the lateral pelvic fascia is composed of two layers, the levator fascia and the prostatic fascia. The neurovascular bundle travels between these two layers (see Figs. 102–4B and 102–5). With a right-angled clamp, the superficial layers of levator pelvic fascia are released. The use of 4.5-power loupes is helpful during this maneuver to assure the surgeon that the prostatic fascia has not been violated. The magnification also facilitates a more gentle dissection with less traction on the neurovascular bundle. **A Babcock clamp, rather than a sponge stick, is used during release of the neurovascular bundle to manipulate the prostate. This clamp facilitates gentle elevation of the prostate during the release and results in less traction on neurovascular bundle because the prostate is released from the bundle rather than the bundle being released from the prostate.** This dissection should begin at the bladder neck, where this fascia forms a thick band (Fig. 102–22). When this band is divided, the prostate immediately becomes more mobile. The superficial fascia should be released from the bladder neck to the apex. This maneuver releases the bundle laterally, thus making it easier to perform the next step, in which the bundle is released posteriorly at the apex.

Once the superficial fascia has been released, the location of the neurovascular bundle can be identified by the presence of a subtle "groove" on the posterolateral edge of the prostate (Fig. 102–23). **By tracing this groove to the apex of the prostate, one can determine where the neurovascular bundle begins to travel caudally and laterally away from the prostatic apex toward the urethra. Once the medial border of the neurovascular bundle has been identified at the apex, the dissection in the midline can be safely carried posteriorly toward the rectum.**

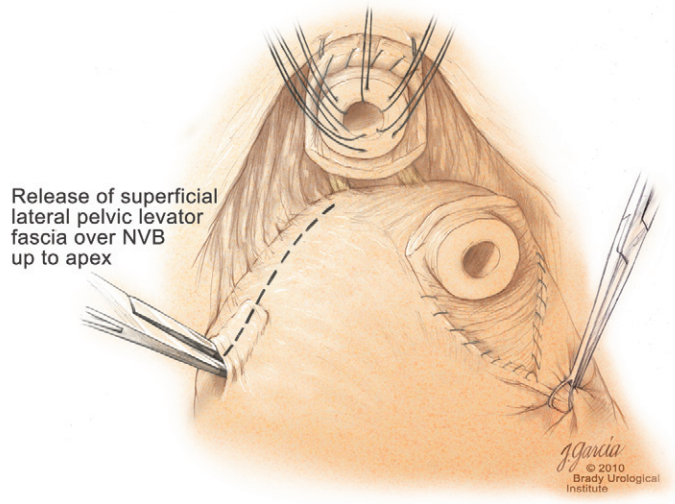

Figure 102–22. The lateral surface of the prostate is exposed by displacing the prostate on its side with use of a Babcock clamp. A right-angled clamp is then inserted under the superficial layer of the levator fascia, beginning at the bladder neck and continuing all the way out to the apex. NVB, neurovascular bundle. (© Brady Urological Institute.)

The plane between the rectum and prostate having been developed in the midline, it is now possible to release the neurovascular bundle from the prostate, beginning at the apex and moving toward the base, using the Babcock clamp to elevate and displace the prostate over on its side. **Beginning on the rectal surface, the bundle is released from the prostate by spreading a right-angled clamp gently.** At the apex, there are often prominent apical vessels. Because the prostate has been elevated on its side across the midline, this distorts the direction of the neurovascular bundle by kinking it (Fig. 102–24). If this artifact is not

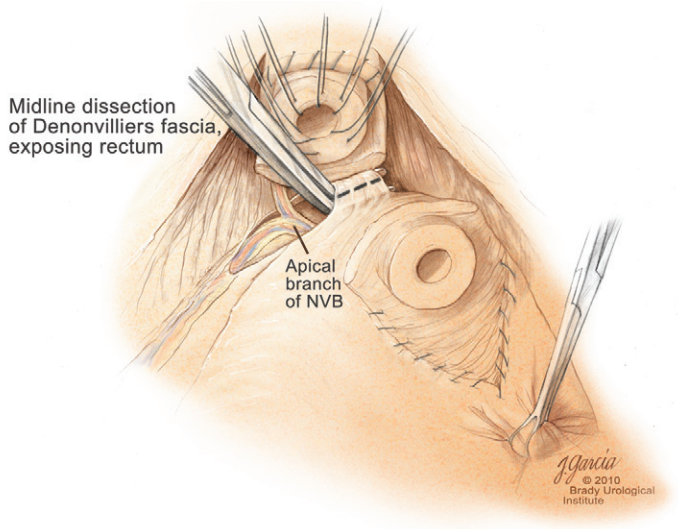

Figure 102–23. Once the levator fascia has been released, the neurovascular bundle (NVB) can be located by the presence of a subtle "groove" on the posterolateral edge of the prostate. This groove should be traced out to the apex of the prostate, and once the medial border has been identified, the dissection in the midline can be pursued, dividing residual layers of Denonvilliers fascia down to the rectum. (© Brady Urological Institute.)

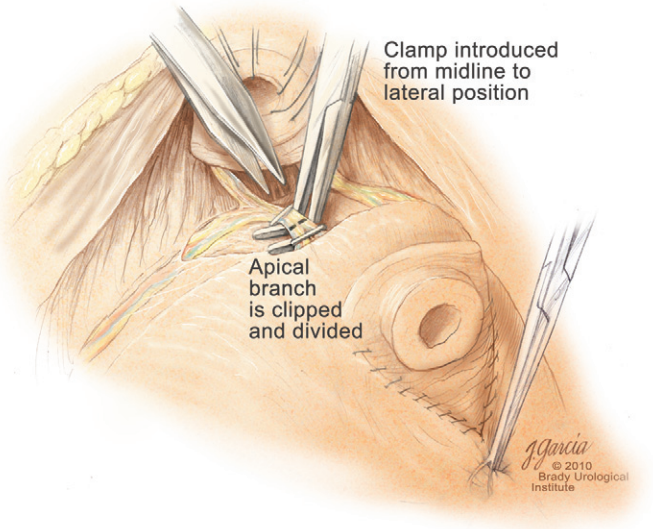

Figure 102–24. At the apex, there are often prominent apical vessels. Because the prostate has been elevated on its side across the midline, note that the neurovascular bundle appears to be kinked. If this artifact is not recognized, the neurovascular bundle can be inadvertently transected. Once these vessels are clipped and divided, the neurovascular bundle returns to its natural straight course. (© Brady Urological Institute.)

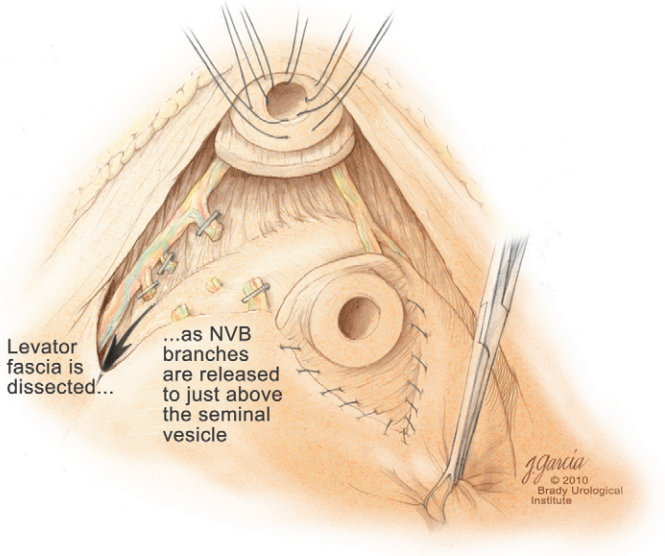

Figure 102–25. The neurovascular bundle (NVB) has been released to just above the seminal vesicle. (© Brady Urological Institute.)

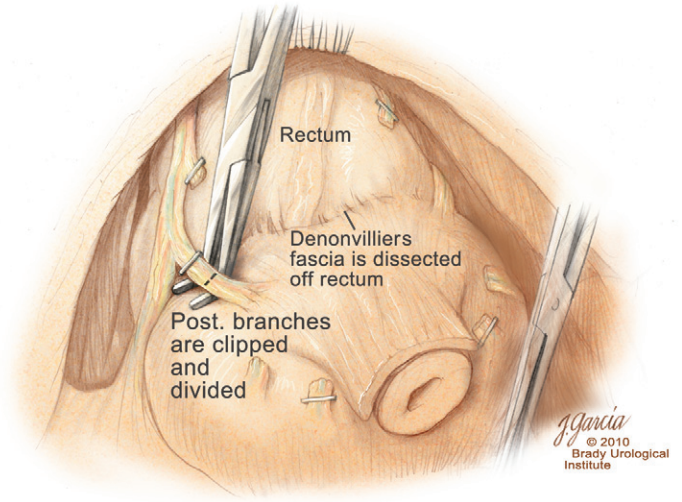

Figure 102–26. Posterior dissection. The attachment of Denonvilliers fascia to the rectum is released, maintaining all layers of Denonvilliers fascia over the posterior surface of the prostate and seminal vesicles. Prominent branches from the neurovascular bundle to the posterior surface of the prostate are identified at the posterolateral angle of the rectum. By dividing these posterior branches, the neurovascular bundle is free to fall away from the prostate posteriorly. (© Brady Urological Institute.)

recognized, the neurovascular bundle can be inadvertently transected. These vessels should be clipped and divided. Once the dissection has been initiated at the apex, it should proceed to the midpoint of the prostate. Because the superficial layers of the levator fascia have already been released, this dissection often proceeds easily. Furthermore, in using this plane, Denonvilliers fascia and the prostatic fascia remain on the prostate; only the residual fragments of the levator fascia are released from the prostate laterally. At this point in the procedure, the bundle should be released to the seminal vesicle (Fig. 102–25).

The vascular branches to the neurovascular bundles are best controlled by small hemoclips placed parallel to the bundle (see Fig. 102–24). **Thermal energy of any form (unipolar, bipolar, or harmonic scissors) should never be used on the neurovascular bundle or its branches** (Ong et al, 2004). There is usually no need to clip the prostatic side of these tiny vessels; fine scissors should be used to divide them. The number of arterial and venous branches is extremely variable. By starting at the apex, however, one can easily identify them prospectively. If the fixation of the bundle to the prostate cannot be explained by vascular branches, the neurovascular bundle should be excised. The surgeon should be aware that the bundle may travel more anteriorly in some patients. In these patients, one can confuse the groove with the potential space between the prostate and rectum. This is another good reason to release the bundle at the apex first. In addition, some patients have many veins on the lateral surface of the prostate that anastomose between Santorini's plexus anteriorly and the neurovascular bundle posteriorly. The apical approach to the bundle facilitates management of this condition as well.

Furthermore, to make certain that Denonvilliers fascia is maintained on the prostate, the neurovascular bundles should be released by dissecting from the rectal surface anteriorly. Using the principles described previously, positive surgical margins in patients with organ-confined disease that are caused by inadvertently cutting into the prostate are rare. Also, because the neurovascular bundle is more mobile, it is easier to interrogate the surgical field with tactile sensation and magnification to find the correct plane. For this reason, even in patients with extraprostatic extension in the region of the neurovascular bundle, it is possible to partially excise the bundle, preserve potency, and obtain negative margins of excision (Hernandez et al, 2005).

To avoid traction on the neurovascular bundle, this dissection should continue cephalad to the level of the seminal vesicles (Masterson et al, 2008). At this point, the surgeon should look for a prominent arterial branch traveling from the neurovascular bundle over the seminal vesicles to supply the base of the prostate (Fig. 102–26). This posterior vessel should be ligated on each side and divided. In doing so, the neurovascular bundles are no longer tethered to the prostate and fall posteriorly.

Wide Excision of the Neurovascular Bundle. **Before excision of the neurovascular bundle unilaterally, the contralateral neurovascular bundle should be freed from the prostate, starting at the apex.** This avoids traction injury, which can occur during wide excision of the contralateral bundle. The neurovascular bundle to be excised is identified at the apex, and a right-angled clamp is passed from medial to lateral, immediately on the anterior surface of the rectum (Fig. 102–27). The bundle is divided without ligation in an effort to excise as much soft tissue as possible. Later, if bleeding is troublesome, the distal end can be clipped. The dissection is continued by dividing the fascia on the lateral surface of the rectum from the apex to the base so that the neurovascular bundle and abundant fascial tissue are included in the specimen. This procedure is performed under direct vision, with the dissection terminating at the tip of the seminal vesicle, where the neurovascular bundle is ligated and divided. In this way, the neurovascular bundle and the lateral pelvic fascia are excised under direct vision in a more complete way than was previously possible (Fig. 102–28).

Posterior Dissection and Division of the Lateral Pedicles

Once the neurovascular bundles have been either preserved at the apex or widely excised and the prostate has been mobilized to the level of the seminal vesicles, the catheter is replaced, and with

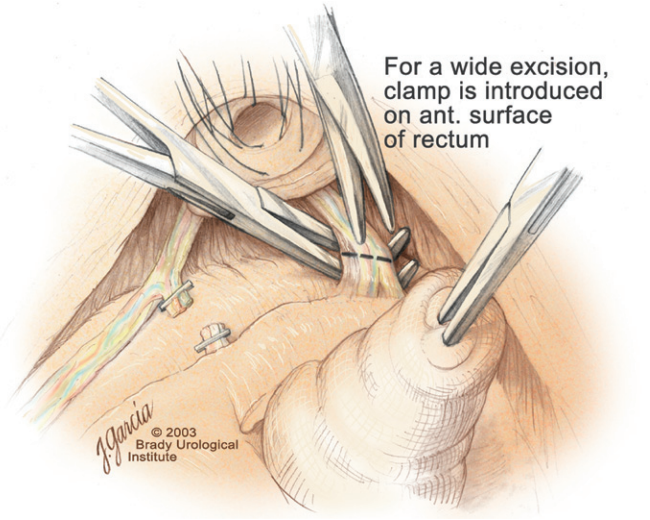

Figure 102–27. Wide excision of the neurovascular bundle. Once the contralateral neurovascular bundle has been released and residual attachments of the rectum to the prostate at the apex are freed up, a right-angled clamp is then passed directly on the anterior surface of the rectum from the midline laterally. If the right-angled clamp is passed lateral to medial, a rectal injury is more likely to occur. (© Brady Urological Institute.)

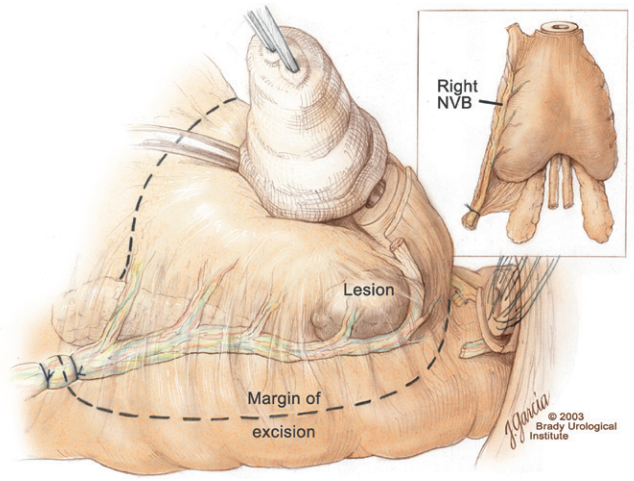

Figure 102–28. Extent of the division of the neurovascular bundle (NVB) from the apex laterally to the tip of the seminal vesicle, where the neurovascular bundle is ligated. This provides excellent soft tissue covering the primary lesion. (© Brady Urological Institute.)

light upward traction on the catheter, the attachment between the rectum and Denonvilliers fascia is divided in the midline posteriorly (Fig. 102–29). Because the neurovascular bundles have been freed up, one may now apply traction to the catheter to gain exposure to the base of the prostate and seminal vesicles. However, to improve exposure, the sponge stick should never be placed on the prostate itself because it may displace tissue, producing a false-positive margin. Instead, the sponge stick should be placed on the catheter. In developing this plane, all layers of Denonvilliers fascia should be left covering the seminal vesicles.

At this point the lateral pedicle can be divided safely on the lateral surface of the seminal vesicles without injury to the neurovascular bundle (see Fig. 102–29). **The lateral pedicles are thick, and therefore they need to be divided in a sequential way: superficial, middle, deep (next to the seminal vesicles). If one tries to divide them all at once, one risks cutting into the overlying prostate.**

Obvious arterial bleeders are simply controlled with hemoclips. With this approach, one can leave more soft tissue on the prostate and protect the neurovascular bundles from injury. The dissection proceeds superiorly onto the anterolateral surface of the junction between the bladder and the prostate. Finally, Denonvilliers fascia is divided over the tips of seminal vesicles to facilitate removal. At this point, many surgeons elect to divide the vasa deferentia and free up the seminal vesicles.

Division of the Bladder Neck and Excision of the Seminal Vesicles

The prostate has now been mobilized almost completely. The bladder neck is incised anteriorly at the prostatovesicular junction (Fig. 102–30). The incision is carried down to the mucosa, the mucosa is incised, the Foley balloon is deflated, and the two ends of the catheter are clamped together to provide traction. As the incision in the bladder neck is widened, branches running from the inferior vesical pedicle to the prostate are noted at 5- and 7-o'clock positions (Fig. 102–31). **After these pedicles are divided, it should be possible to visualize the plane between the anterior surface of the seminal vesicles and the posterior wall of the bladder. By scissor dissection hugging the anterior surface of the seminal vesicles, the posterior bladder neck can be divided safely while observing the location of the ureteral orifices** (Fig. 102–32).

After the posterior bladder wall is divided, the bladder neck is retracted with an Allis clamp, and the vasa deferentia are ligated with hemoclips and divided. The seminal vesicles are dissected free from surrounding structures (Fig. 102–33). Recall that the pelvic plexus is located on the lateral surface of the seminal vesicles. **To avoid injury to the pelvic plexus, the surgeon should perform this dissection with great care, especially laterally, and under direct vision should identify the small arterial branches that travel to the seminal vesicles and stay close to the seminal vesicles when these small vessels are ligated with small clips.** As the tips of the seminal vesicles are freed, small arterial branches at the tip of each seminal vesicle should be identified, ligated, and divided. Any residual attachments of Denonvilliers fascia are then divided, and the specimen is removed. The specimen is inspected carefully to identify any areas where the margin of resection is uncertain. If there is any concern about the margin on the posterolateral surface of the prostate, the neurovascular bundle on that side should be excised.

The operative site is inspected carefully for bleeding. **Small bleeding vessels near the neurovascular bundle should not be cauterized to avoid injury to the fine nerve fibers.** Bleeding from these small vessels should be controlled with small hemoclips. If not, the patient may develop a hematoma between the rectum and bladder. Inflammation surrounding the neurovascular bundles secondary to this hematoma may delay the return of sexual function (Walsh et al, 2000b). To avoid this adverse event, one can make a small opening in the peritoneum in the rectovesical cul-de-sac to facilitate decompression of a hematoma if it develops.

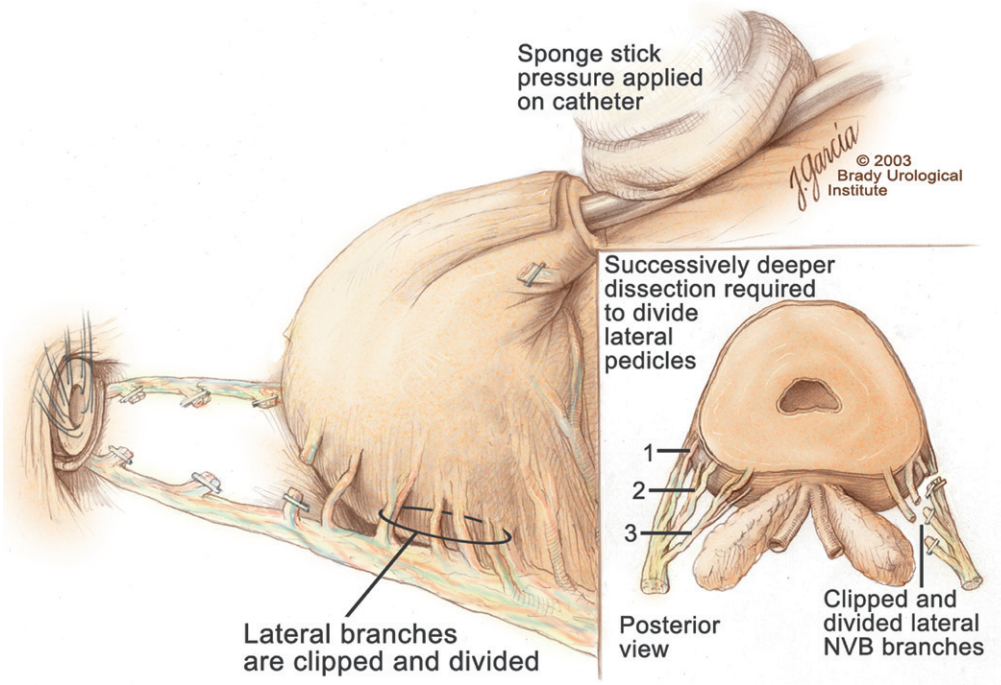

Figure 102–29. Lateral view demonstrating the location of the neurovascular bundle (NVB) after ligation of the posterior branch to the prostate. The site for division of the lateral pedicle is indicated. The lateral pedicle is thick and should be divided in layers: 1, superficially; 2, in the middle; and then 3, deep next to the seminal vesicle. If one tries to divide this thick pedicle all at once, one risks cutting into the overlying prostate. (© Brady Urological Institute.)

Bladder Neck Reconstruction and Anastomosis

The bladder neck is reconstructed with a running suture or interrupted 2-0 absorbable sutures to approximate full-thickness muscularis and mucosa, forming a tennis racquet closure (Fig. 102–34). At this point, it is useful to have previously injected indigo carmine to facilitate visualization of the ureteral orifices; ureteral catheters are not usually necessary. **By incorporating the mucosa in the closure, troublesome hematuria can be avoided.** The closure is initiated in the midline posteriorly and proceeds anteriorly until the bladder neck is narrowed to approximate the diameter of the urethra. Interrupted or running 4-0 absorbable sutures are used to advance the mucosa over the raw musculature of the bladder neck. In this way, a rosette of mucosa covers the bladder neck, facilitating a mucosa-to-mucosa urethrovesical anastomosis. The suture at the 6-o'clock position is left long to facilitate placement of the urethral sutures for the final anastomosis (see later).

At this point, the bladder neck can be anastomosed to the urethra, or buttressing sutures can be used to intussuscept the bladder neck (Walsh and Marschke, 2002). **These**

sutures prevent the bladder neck from pulling open as the bladder fills. The standard surgical technique described in this chapter emphasizes ample margins to ensure excellent cancer control, especially at the apex. Some surgeons preserve the puboprostatic ligaments and dissect beneath them closer to the apical prostate. Although this may preserve more of the striated sphincter, there is concern that it may lead to inadequate apical margins. The technique described herein may excise more striated musculature, and consequently it takes longer for some men to be pad free. Walsh has found that with intussusception of the bladder

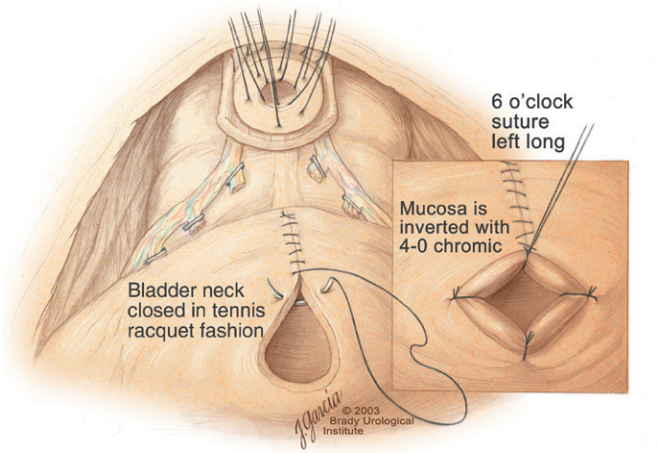

Figure 102–34. Tennis racquet closure of the bladder neck with a running 2-0 absorbable suture incorporating all layers of the bladder wall. The bladder mucosa is then advanced over the raw bladder edges with interrupted 4-0 absorbable suture material to ensure a mucosa-to-mucosa anastomosis. The posterior midline suture (at the 6-o'clock position) is left long. (© Brady Urological Institute.)

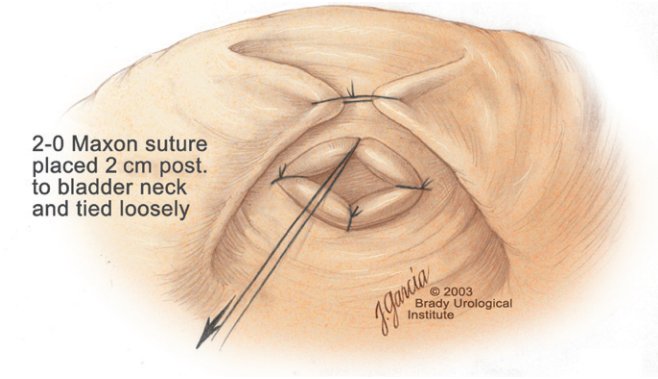

Figure 102–35. Intussusception of the bladder neck. A 2-0 Maxon suture is placed in the edges of the posterior bladder wall, where the bladder was previously attached to the prostate, about 2 cm from the reconstructed bladder neck and tied in the midline. (© Brady Urological Institute.)

neck, 80% of men are pad free at 3 months and 98% at 1 year (Parsons et al, 2004). A 2-0 Maxon suture is placed into the edges of the posterior bladder wall, where the bladder was previously attached to the prostate, about 2 cm from the reconstructed bladder neck (Fig. 102–35). If there are any hemoclips in this area, they should be removed because they may be folded into the bladder neck, causing a bladder neck contracture. The suture is tied in the midline. The next suture is placed more anteriorly. Before this suture is placed, it is wise to release tension on the anterior bladder wall by loosening the malleable blade. This will aid in identifying the loose perivesical tissue that should be incorporated into this stitch. A second figure-of-eight 2-0 Maxon suture is placed about 2 cm lateral to the bladder neck on each side (Fig. 102–36). At this point, the bladder neck should protrude beneath the anterior hood of tissue that was created by the anterior stitch, like a turtle that is poking its head outside its shell. When the bladder neck is filled with saline, it should be competent with little leakage. After this test is completed, the bladder should be emptied completely by placing a forceps through the bladder neck. The 6-o'clock suture should again be placed on traction to facilitate placement of the urethral sutures.

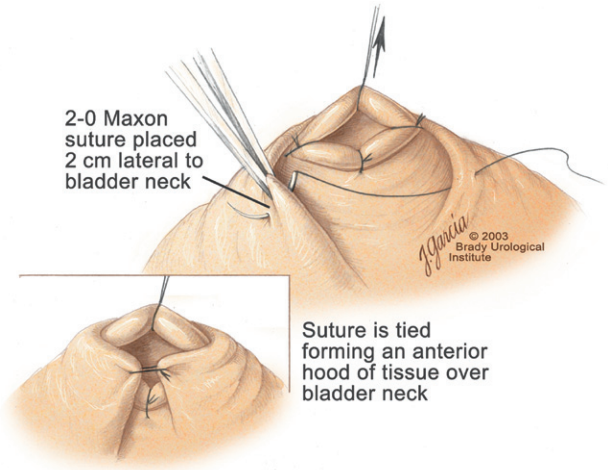

Figure 102–36. Intussusception of the bladder neck. A second figure-of-eight 2-0 Maxon suture is placed anteriorly about 2 cm lateral to the bladder neck on either side and tied. (© Brady Urological Institute.)

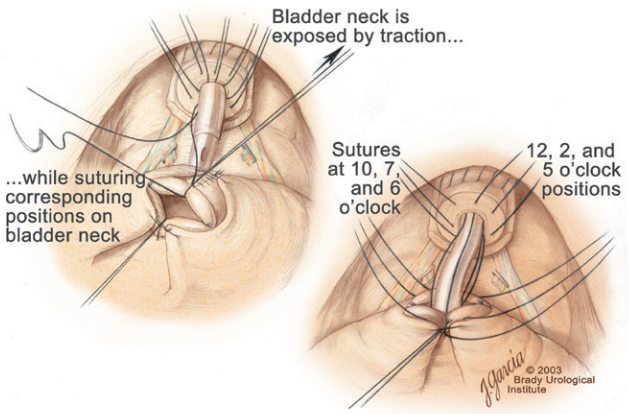

Figure 102–37. The bladder neck is exposed by placing traction on the 4-0 absorbable suture at the 6-o'clock position. The final anastomosis is performed by placing 3-0 Monocryl sutures at the 12-, 2-, 5-, 7-, and 10-o'clock positions. (© Brady Urological Institute.)

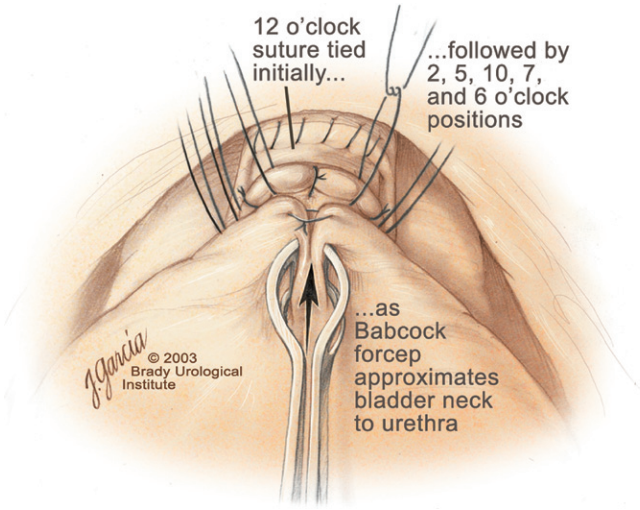

Figure 102–38. A Babcock clamp is used to displace the reconstructed bladder neck into the pelvis and is held in place until all sutures are tied. With this maneuver, one can be certain that there is excellent coaptation of the reconstructed bladder neck to the urethra while the sutures are being tied. (© Brady Urological Institute.)

The operative site is inspected carefully for bleeding. A new silicone Foley catheter (16-Fr, 5-mL balloon) is placed through the urethra into the pelvis. The six 3-0 Monocryl sutures that were previously placed in the distal urethra are now placed through the bladder neck in their corresponding positions from inside to outside (Fig. 102–37). Use of traction on the 4-0 suture that was placed at the 6-o'clock position to exteriorize the mucosa facilitates placement of the sutures. As mentioned previously, a French eye needle is used for placement of the 12-, 2-, and 5-o'clock sutures. The catheter is irrigated free of clots, the balloon is tested, and the catheter is placed through the bladder neck and inflated with 15 mL of saline. The catheter is no longer placed on traction while the sutures are tied. Instead, a Babcock clamp, which is placed on the anterior bladder wall close to the reconstructed bladder neck, is used to hold the bladder in place while the sutures are tied (Fig. 102–38). This ensures excellent coaptation of the mucosa to mucosa and has markedly reduced the probability of bladder neck contractures.

The anterior suture is tied initially. There should be no tension. If there is, the bladder should be released from the peritoneum. The 2-, 5-, 10-, 7-, and 6-o'clock sutures are tied sequentially. After all sutures are tied, the catheter is manipulated to make certain it is not caught in one of the sutures. The catheter is irrigated with saline to eliminate clots. After the operative site is irrigated vigorously with saline, a small suction drain is placed through the fascia (away from the midline) and directed into the operative site in the midline, between (not through) the rectus muscles. The incision is closed with a running No. 2 nylon suture and skin clips. The catheter is carefully taped to the thigh.

POSTOPERATIVE MANAGEMENT

The postoperative recovery of men who undergo radical retropubic prostatectomy is usually uneventful. Patients ambulate the morning after the procedure. Pain control is achieved by intravenous patient-controlled analgesia with morphine on the night of surgery; the next morning, intravenous ketorolac tromethamine is instituted. **This combination of analgesic agents reduces postoperative ileus.** Patients are fed a clear liquid diet on the night of surgery and a regular diet the next day. Closed-suction drains are left in place until they cease to function. Patients are discharged from the hospital on day 1 or 2 with a Foley catheter in place. The urinary catheter represents the source of significant bother (Lepor et al, 2001) and limits the return to activities and work (Sultan et al, 2006). Therefore the urinary catheter should be removed as soon as possible without compromising outcomes. Most would agree that removing the urinary catheter in the presence of significant extravasation would be unwise. Eighty percent of vesicourethral anastomosis exhibits no evidence of cystographic extravasation by the fourth postoperative day. Removal of the urinary catheter at this time is not recommended because of the high rate of acute urinary retention (Patel and Lepor, 2003). Approximately 10% of men will exhibit moderate extravasation on postoperative cystograms performed 1 week after surgery. Routinely performing cystography at 1 week allows "early" removal of the urinary catheter while also identifying the small subset of men who might benefit from longer bladder drainage. Alternatively, the urinary catheter may be removed between days 9 and 14 without a cystogram.

Bladder spasms arising from the indwelling urinary catheter can be a greater problem than incisional pain during hospitalization. Bladder spasms will generally spontaneously subside, and reassurance is often sufficient. In cases of severe bladder spasms, an oral anticholinergic agent or diazepam may be administered.

COMPLICATIONS

Radical retropubic prostatectomy is well tolerated, with minimal morbidity and low mortality (0.2%). Complications can be divided into those occurring intraoperatively and those occurring postoperatively.

Intraoperative Complications

The most common intraoperative problem is hemorrhage, usually arising from venous structures. Hemorrhage may occur during pelvic lymphadenectomy if one of the branches of the hypogastric vein is torn inadvertently. Venous injury like this can often be controlled by temporary packing. If this is not successful, it can be repaired with fine cardiovascular sutures. Hemorrhage can also occur during incision in the endopelvic fascia if the incision is made too close to the prostate, during division of the puboprostatic ligaments if the ligaments are not dissected free from the superficial branch of the dorsal vein or anterior prostatic fascia, and during exposure of the apex of the prostate with transection of the dorsal vein complex. If one understands fully the anatomy of the dorsal vein complex, this bleeding is usually satisfactorily controlled once the dorsal vein has been divided and ligated. **Consequently, if there is troublesome bleeding from the dorsal vein complex at any point, the surgeon should completely divide the dorsal vein complex over the urethra and oversew the end. This is the single best means to control bleeding from the dorsal vein complex. Any maneuver short of this only worsens the bleeding.** To gain exposure for the prostatectomy, one must put traction on the prostate. If the dorsal vein is not completely divided, traction opens the partially transected veins and usually worsens the bleeding. It is imperative to obtain excellent hemostasis before the apex of the prostate is approached so that the anatomy can be viewed in a bloodless field. With careful technique and a thorough knowledge of anatomy, the average blood loss during radical prostatectomy is 500 to 1000 mL. However, because substantial bleeding may occur unexpectedly, the surgeon should always be prepared by having adequate blood available from the blood bank.

Less common complications include obturator nerve injury during pelvic lymph node dissection, rectal injury, and ureteral injury. If the obturator nerve is inadvertently severed, an attempt should be made at reanastomosis with fine nonabsorbable sutures. Rectal injury is an infrequent but serious complication. In 3500 consecutive cases, 11 injuries to the rectum were experienced. They occur during apical dissection in attempting to develop the plane between the rectum and Denonvilliers fascia. If a rectal injury occurs, the prostatectomy should be completed, the bladder neck should be reconstructed, and hemostasis should be excellent. It is wise to interpose omentum between the rectal closure and the vesicourethral anastomosis to reduce the possibility of a rectourethral fistula. This maneuver can be accomplished simply by making a small opening in the peritoneum; finding the omentum and fashioning a slender, well-vascularized pedicle that will be long enough to reach the pelvic floor; dividing the peritoneum in the rectovesical cul-de-sac; and feeding the end of an omental pedicle through this opening. The anal sphincter is dilated widely by an assistant, and the rectal injury is clearly delineated. While there is excellent visualization, the edges of the wound are freshened and closed in two layers. The omental pedicle is immobilized over the repair, with absorbable sutures, and the vesicourethral anastomosis is performed. The wound should be copiously irrigated with antibiotic solution, and the patient should be maintained on broad-spectrum antibiotics for both aerobic and anaerobic bacteria. When this technique was used without a colostomy, all patients recovered without development of a wound infection, pelvic abscess, or rectourethral fistula (Borland and Walsh, 1992). However, if the patient has received prior radiotherapy, it is prudent to perform a diverting colostomy. Ureteral injury occurs secondary to inadvertent dissection within the layers of the trigone while attempting to identify the proper cleavage plane between the bladder and seminal vesicles. If this injury occurs, ureteral reimplantation should be undertaken.

Postoperative Complications

Delayed Bleeding

Life-threatening hemorrhage is a rare complication of radical retropubic prostatectomy with nonautologous transfusion rates of 1% at our institutions. Significant bleeding after radical prostatectomy is defined as postoperative hemorrhage requiring the acute transfusion of blood to support blood pressure. In 1350 consecutive radical prostatectomies, 7 cases (0.5%) met this criterion (Hedican and Walsh, 1994). Of these, four patients were explored for bleeding and three were managed expectantly. The mean blood product requirements for explored patients were comparable with those for patients managed conservatively, although total hospitalization was shorter in patients who underwent a secondary operation. In the three patients managed nonoperatively, the pelvic hematoma drained through the urethrovesical anastomosis, resulting in symptomatic bladder neck contractures in all three and long-term problems with urinary control in two. Only one of four patients explored (25%) experienced prolonged mild incontinence. **These results suggest that patients requiring acute transfusions for hypotension after radical prostatectomy should be explored to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.**

Thromboembolism

Thrombophlebitis with pulmonary embolism is the major cause of mortality after radical prostatectomy. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, use of intermittent compression devices, early ambulation, and a shorter incision. With an 8-cm incision, Walsh has not had a thromboembolic event in his most recent 700 cases, in contrast to a rate of 1.4% in the prior 700 cases. Although the precise mechanism behind this reduction is unknown, the authors believe that the lower and shorter incision reduces exposure, dehydration, and traction on the external iliac veins during the procedure. Minidose heparin or low-dose, low-molecular-weight heparin is used at some centers (but not the authors' centers).

Most important, patients should be informed of the signs and symptoms of this complication before they go home and should be instructed to call the physician immediately if they have any of the following symptoms: swelling or pain in the leg, especially in the calf; sudden chest pain that is worse on taking a deep breath; hemoptysis; shortness of breath; or the sudden onset of

weakness or fainting. The authors have found that the informed patient is the best way to reduce the morbidity and mortality from this complication. When patients develop thromboembolic events, twice-daily subcutaneous administration of low-molecular-weight heparin without monitoring of clotting factors appears to be at least as effective and safe as an adjusted-dose, intravenous administration of unfractionated heparin (Buller et al, 2003).

Bladder Neck Contracture

Bladder neck contractures occur in 0.5% to 10% of patients after radical prostatectomy. They arise from inadequate coaptation of the mucosal surfaces. This may be due to inadequate approximation at the time of surgery, urinary extravasation, or distraction of the bladder neck from a hematoma. The use of a Babcock clamp to approximate the bladder neck and urethra while the anastomotic sutures are tied has virtually eliminated bladder neck contractures in our practice. The diagnosis should be considered in any patient who complains of a poor urinary stream or in patients who have prolonged unexplained incontinence. If treatment with simple dilation fails, direct cold-knife incision of the bladder neck at 3-, 6-, and 9-o'clock followed by intermittent self-catheterization for a limited time usually corrects the problem. In patients with recalcitrant bladder neck contractures, the injection of triamcinolone acetonide (200 mg in 5 mL) after cold-knife incision may be useful.

Urinary Incontinence

After radical prostatectomy, incontinence is usually secondary to intrinsic sphincter deficiency. In some men, the striated sphincter may be poorly developed; in older men, it is thinner and contains more collagen (Burnett and Mostwin, 1998; Strasser et al, 1999). However, the predominant cause of this deficiency is injury during ligation and division of the dorsal vein complex. The smooth musculature of the urethra, which also contributes to continence, can be damaged by placement of large, deep sutures for the anastomosis or denervated by injury to the neurovascular bundles. Furthermore, the bladder neck must be supple, with a diameter that is not excessively large, because urinary continence can be hampered by the development of a bladder neck contracture or by a wide bladder neck (Horie et al, 1999; Groutz et al, 2000). To avoid these complications, as outlined previously, it is important to preserve the striated sphincter during the apical dissection, to avoid tension on the final anastomosis by releasing the bladder from the peritoneum if necessary, to reconstruct the bladder neck so that the opening is small and supple, and to accomplish a precise mucosa-to-mucosa anastomosis facilitated by use of a Babcock clamp. Buttressing sutures to intussuscept the bladder neck to prevent it from pulling open as the bladder fills have also proved useful (Walsh and Marschke, 2002). Finally, many men have detrusor hypertrophy and decreased bladder compliance from pre-existing bladder outlet obstruction. It takes these patients longer to achieve full urinary control. For this reason, it is important to avoid excessive traction on the bladder intraoperatively, which may aggravate this condition.

It is beyond the scope of this chapter to review all of the literature on urinary incontinence. In a population-based longitudinal cohort follow-up study up to 24 months, Stanford and colleagues (2000) reported that after radical prostatectomy, 8.4% of men had either frequent urinary leakage or no control. In contrast, in Walsh's patient-reported outcome study in which patients returned a validated questionnaire to an independent third party, 93% of the patients were wearing no pads at 1 year and 98% stated that they had no significant urinary problem (Walsh et al, 2000a). In a more recent study performed after introduction of the bladder neck intussusception, 98% of the patients were pad free at 1 year and no patient reported having a significant problem with urinary control (Parsons et al, 2004).

During their recovery, patients need constant encouragement and advice at regular intervals. The details of this program are reported elsewhere (Walsh and Worthington, 1995, 2001). Until urinary control has returned completely, patients are advised to reduce their fluid intake, avoid caffeinated beverages and alcohol, and stop α-adrenergic antagonists if they take them for the treatment of hypertension. Treatment with imipramine or α agonists in men who are not hypertensive can be helpful. In patients who have not developed a bladder neck contracture and who have not been treated with external beam radiotherapy, the postoperative injection of collagen into the submucosa adjacent to the bladder neck is helpful for many.

Erectile Dysfunction

Three factors are important in the recovery of erectile function after radical prostatectomy: age of the patient (younger than 65 years), status of potency preoperatively, and ability to preserve both neurovascular bundles. With use of the surgical technique described herein, recovery of sexual function was evaluated by a validated questionnaire that was sent to an independent third party (Walsh et al, 2000a). At 18 months, 86% of the patients were able to have unassisted intercourse with or without sildenafil citrate. Although a third of patients were taking sildenafil citrate, only 4% of men reported that they could not have intercourse without it. The recovery of sexual function occurred gradually: 38% were potent at 3 months, 54% at 6 months, 73% at 12 months, and 86% at 18 months. Recovery of sexual function also correlated with the age of the patient at the time of surgery: 100% in men 30 to 39 years, 88% in men 40 to 49 years, 90% of men 50 to 59 years, and 75% in men 60 to 67 years. These data were recently updated with a similar questionnaire (Parsons et al, 2004). At 3 months, 42% of the patients were potent; at 6 months, 49%; and at 1 year, 73%. In both series, most patients had both neurovascular bundles preserved. In patients in whom only one neurovascular bundle is preserved, 65% of patients are potent. In patients with an accessory pudendal artery, preservation was associated with a twofold increase in the likelihood of recovery of erections (Rogers et al, 2004).

High anterior release of the neurovascular bundle is associated with significantly earlier recovery and return to baseline sexual function. In potent men undergoing high anterior release, 93% were potent 12 months after surgery and 70% reported a return to their baseline erectile function. In men who preoperatively reported a frequency of intercourse more than once per week, 78% reported a return to their baseline sexual function at 12 months. Interestingly, this recovery and return to baseline function was noted in men who underwent either a unilateral or bilateral high release. This suggests that the improved sexual recovery associated with this technique is not likely due to preservation of anterior branches of the cavernous nerves but rather due to improved accuracy in the preservation of the nerves with less traction. **Other experienced surgeons have also noted improved recovery of sexual function using similar early nerve release techniques providing further merit to this technical modification** (Masterson et al, 2008).

In patients who are medically cleared, phosphodiesterase type 5 (PDE5) inhibitors augment sexual recovery after radical prostatectomy. Until recently, however, the best dosing schedule (nightly or on demand) for these medications was unclear. In a small study, Padma-Nathan reported improved recovery of sexual function in patients given nightly sildenafil versus patients given placebo (Padma-Nathan et al, 2008). However, men in the placebo arm never received any therapy. In 2008 Montorsi and colleagues reported on a multi-institution randomized, double-blinded study examining recovery of erectile function using either vardenafil "on demand," nightly, or placebo for 9 months. At the end of the blinded treatment period, vardenafil "on demand" was of greater benefit than nightly treatment. In a similarly devised trial, Pavlovich noted no difference in recovery of sexual function in patients using either "on-demand" or nightly sildenafil, with a trend toward improved recovery in the "on-demand" arm (Pavlovich et al, 2009). **Thus on-demand dosing of PDE5 inhibitors appears to be the most effective method to aid in recovery of sexual function.**

SURGICAL MODIFICATIONS TO CLASSIC ANATOMIC RADICAL PROSTATECTOMY

Since the initial report of the anatomic radical prostatectomy, refinements in the surgical technique have been made. Some modifications have minimized the short-term and long-term morbidity of the procedure or the oncologic outcome and have been incorporated into the classic operation (Walsh et al, 2000b; Walsh and Marschke, 2002; Rogers et al, 2004); others have demonstrated no or minimal measurable benefit or negative benefit and have been abandoned (Steiner et al, 1993; Parsons et al, 2004). Several modifications to the classic anatomic radical prostatectomy have been suggested to improve early return of urinary continence, erectile function, or both. These surgical modifications have focused on the function of the bladder neck in urinary control, dissection around the seminal vesicles, and placement of interposition nerve grafts when resection of the neurovascular bundles is required.

Bladder Neck (Sparing) Preservation

Investigators have proposed that preservation of as much of the bladder neck as possible at the time of removal of the prostate can hasten return of urinary control after radical retropubic prostatectomy (Klein, 1992; Licht et al, 1994; Braslis et al, 1995; Lowe, 1996; Shelfo et al, 1998; Poon et al, 2000; Soloway and Neulander, 2000; Srougi et al, 2001; Deliveliotis et al, 2002). Klein (1992) was the first to suggest that modification of the bladder neck resection and reconstruction at the time of radical retropubic prostatectomy might influence urinary control. The group at the University of Miami has reported on a large nonrandomized series of men who underwent radical retropubic prostatectomy with bladder neck preservation (Braslis et al, 1995; Soloway and Neulander, 2000). In 2000 they reported only a 1% bladder neck contracture rate and 1% positive margins at the bladder neck site only and suggested that "extensive" resection at the bladder neck did not add to the curative nature of the procedure yet did not elaborate in detail on the return of urinary control.

In 1996 Lowe compared bladder neck preservation with bladder neck resection (classic method) in a nonrandomized group of nearly 200 men divided between bladder neck preservation and excision. No difference was seen in positive margins, and bladder neck preservation hastened the return of urinary control but did not improve overall continence in the long term. Poon and colleagues (2000) and the group from Loma Linda also reported on a comparative study of 220 men divided into three groups: bladder neck preservation, classic tennis racquet closure, and anterior bladder tube reconstruction. Bladder neck contracture occurred in 10% overall and in 5%, 11%, and 18% by group, respectively. Urinary continence, ascertained by third-party telephone interview, demonstrated 12-month rates of 93%, 96%, and 97% by group, respectively (no difference). These authors concluded that there was no major difference between groups with respect to return of urinary control. Similarly, Deliveliotis and colleagues (2002) showed no difference in continence rates in the long term (1 year) but significant difference ($P < .05$) in the short term (3 to 6 months) when preservation of the bladder neck was exercised.

In several series, higher margins were seen with bladder neck preservation. Srougi and colleagues (2001) from São Paulo, Brazil, reported on a planned enrollment of 120 men in a truly randomized trial between bladder neck preservation and classic reconstruction. Enrollment was stopped because the rate of positive surgical margins in the preservation arm was 10-fold higher (10% vs. 0%) compared with the classic reconstruction arm. Within the group of 70 who finished the trial, the authors measured continence rates and found no difference concluding that the external sphincter appears to play a more important role than the bladder neck in continence after radical prostatectomy. Marcovich and colleagues (2000) also demonstrated that bladder neck–sparing surgery resulted in significantly higher rates of positive surgical margins at the bladder neck compared with standard radical retropubic prostatectomy (47% vs. 20%).

All would agree with the number one goal of anatomic radical prostatectomy, namely, cancer control. These studies seem to agree that there is little difference in the positive margin rates (bladder neck only) with this modification. **The randomized controlled trials suggest that there may be a small (question clinical significance) difference in the early (short-term, 3 to 6 months) return of urinary control with little or no difference in long-term (1-year) urinary control. Finally, the high rate of bladder neck contracture and positive margins in some studies makes this modification less than desirable. The risks need to be weighed against the benefits.**

The authors of this chapter do not perform bladder neck–sparing surgery.

Seminal Vesicle Sparing

The dramatic stage shift witnessed during the past 2 decades (Han et al, 2004), primarily brought about through early detection with PSA, has dramatically decreased the numbers of men presenting with regionally advanced disease (T3b) within the seminal vesicles (Han et al, 2001). Seminal vesicle involvement has been widely accepted as a poor prognostic feature; however, contemporary studies have demonstrated that few men (<8%) presenting with "localized" prostate cancer (near 0% in cT1c) have disease that has already spread to the seminal vesicle. Are we removing this tissue unnecessarily? Some investigators suggested that the close approximation of the seminal vesicles to the neurovascular bundle, pelvic plexus, and bladder base and neck blood supply may allow the dissection in this area to play a major role in postoperative urinary and erectile function and have developed algorithms to predict

seminal vesicle involvement before surgery (reviewed by Zlotta et al, 2004).

A modification to the classic anatomic radical prostatectomy has been proposed—seminal vesicle sparing. Korman and colleagues (1996) were the first to investigate the importance of complete resection of the seminal vesicle during radical retropubic prostatectomy. They investigated the incidence of histologic evidence of cancer within the distal 1 cm of seminal vesicle tissue in 71 consecutive radical retropubic prostatectomy specimens. Of 71 specimens, 12 had seminal vesicle invasion whereas 0 (0%) had disease in the distal 1 cm of the seminal vesicles bilaterally, which led the investigators (who advocated complete resection of the seminal vesicles at that time) to suggest that it is not necessary to remove the seminal vesicle in its entirety when the dissection is difficult. This might eliminate the potentially damaging dissection near other important anatomic structures.

In a follow-up study, Theodorescu and colleagues (1998) looked at the importance of complete seminal vesicle excision by comparing radical retropubic prostatectomy with radical perineal prostatectomy. In two similar groups (stage, race, age, PSA level, and grade), 64% underwent radical retropubic prostatectomy and 36% underwent radical perineal prostatectomy (seminal vesicles are not routinely removed). In the follow-up period, 45% of the men in the perineal prostatectomy group demonstrated biochemical (PSA) elevation (>0.2 ng/mL) compared with only 18% in the retropubic prostatectomy group. When they broke down the perineal prostatectomy group on the basis of no seminal vesicle excision or seminal vesicle excision, the PSA recurrence rate was 69% versus 20%, respectively. The authors concluded that complete excision of the seminal vesicle during radical prostatectomy is essential for cancer control.

John and Hauri (2000) investigated the influence of seminal vesicle preservation during radical retropubic prostatectomy on urinary continence. They observed 54 men, of whom 34 underwent radical retropubic prostatectomy with seminal vesicle removal and 20 with seminal vesicle preservation. A modified pad test at 6 weeks and 6 months postoperatively demonstrated continence rates of 60% at 6 weeks and 95% at 6 months for the seminal vesicle preservation group compared with 18% at 6 weeks and 82% at 6 months for the seminal vesicle resected group. They concluded that seminal vesicle preservation may preclude damage to the pelvic nerves and maintain urinary continence during radical retropubic prostatectomy. Clearly, a double-blinded (patient and third-party reviewer) randomized trial of this method must be performed to fully understand these results.

The authors of this chapter do not perform seminal vesicle–sparing surgery.

Interposition Nerve Grafting

Although wide resection of both neurovascular bundles is rarely indicated when curative intent is the desired effect for anatomic radical prostatectomy (Walsh and Worthington, 2001), investigators have suggested interposition sural nerve grafts after unilateral and bilateral neurovascular bundle resection during radical retropubic prostatectomy (Kim et al, 1999, 2001a, 2001b, 2001c; Scardino and Kim, 2001; Walsh, 2001; Singh et al, 2004). Early studies in the rat (Burgers et al, 1991; Quinlan et al, 1991b; Ball et al, 1992a, 1992b) provided experimental evidence documenting the beneficial effect of interposition nerve grafting after unilateral or bilateral cavernous nerve damage or resection. However, in man, as opposed to the rat, the cavernous nerves are composed of many fibers that are separated by as much as 3 cm (Costello et al, 2004; Takenaka et al, 2004). This raises the legitimate question of whether it is possible to perform a classic end-to-end nerve graft. The precise pathophysiologic mechanism of cavernous nerve regeneration has yet to be fully understood; however, basic science studies and human clinical testing have suggested that return of parasympathetic function can be demonstrated after interposition grafting of the brachial plexus, facial nerves, and peripheral nerves.

It is universally accepted that preservation of erectile function after radical prostatectomy is quantitatively related to preservation of the autonomic innervation and that, with resection of both neurovascular bundles, recovery of erectile function satisfactory for spontaneous erection and intercourse is limited (Quinlan et al, 1991a). Kim and colleagues (1999) first suggested interposition sural nerve grafting at the time of anatomic radical prostatectomy to replace resected cavernous nerves. This group later reported on 28 men with bilateral non–nerve-sparing radical prostatectomy who underwent bilateral sural nerve grafts with 12-month follow-up that 26% had unassisted erections sufficient for intercourse, 26% had partial erections, and 43% had erections sufficient for intercourse with the aid of sildenafil citrate (Kim et al, 2001a). Sexual function returned 5 months after grafting at the earliest time. Another group (Singh et al, 2004) investigated the return of urinary control with respect to sural nerve grafting. They reported a series of 111 men with purposeful unilateral nerve excision, 53 of whom underwent unilateral sural nerve graft after the prostatectomy. At 12 months, 95% of the grafted group reported "complete" urinary control (leakage of only a few drops) compared with only 53% of the nongrafted group ($P < .012$). The authors suggested that the cavernous nerves may play a role in return of continence. These findings have yet to be validated and should be viewed cautiously until a randomized study can be conducted.

Most urologists performing radical retropubic prostatectomy and neurovascular bundle excision require the participation of a plastic surgeon to perform the harvest and implantation of the nerve graft material. Kim and Seo (2001) suggest that with experience, the urologic oncologist performing the radical retropubic prostatectomy should feel comfortable with harvest of the nerve and placement of the graft with limited impact on surgical time and blood loss. Technically, the sural nerve (width of 1.5 to 3 mm, ovoid) graft is harvested with iris scissors through a 3-cm incision that is placed 1 cm inferior to the lateral malleolus. The saphenous vein will be encountered. Dissection should be carried out with loupe magnification. The nerve is divided at the distal end and the foot-side end fulgurated. A tendon stripper (6 mm in diameter) is used to strip the nerve proximally for about 20 cm toward the back of the calf, and a 1-cm incision is used to retrieve the proximal end. Fulguration of the proximal (leg) side of the nerve is also required. The graft is placed in cooled saline. The skin is closed, and compression stockings ensure decreased hematoma formation (Kim and Seo, 2001). The average length of nerve needed per side is 5 to 6.5 cm; however, 40-cm segments can be isolated for bilateral procedures with minimal sensory deficit (Kim and Seo, 2001). The nerve graft is reversed, and the distal nerve is attached to the proximal cavernous nerve endings under magnification; similarly, the proximal nerve end is attached to the distal cavernous nerve endings. The nerve endings can be identified at the time of resection and marked with a stitch through the use of the CaverMap nerve stimulator (Canto et al, 2001). The nerves are attached to the nerve endings with 7-0 polypropylene sutures secured with

microclips. After the procedure, suction drains are placed and directed away from the graft site.

Many questions remain with respect to the need for nerve grafting following wide excision of the neurovascular bundle after radical retropubic prostatectomy (Walsh, 2001). **Davis and colleagues** (2009) **reported a large series of patients undergoing unilateral nerve-sparing procedures with randomization to sural nerve grafting or standard erectile dysfunction therapy. At 2 years, no difference in potency was noted in the two groups (71% in nerve graft group and 67% in the standard group). Bilateral nerve grafting has resulted in a 5-year cumulative recovery of erectile function permitting penetration of 34% and the rate of consistent penetration of 11%** (Secin et al, 2007). **Thus although the techniques of nerve grafting are safe and feasible, the overall benefits appear limited.**

The authors of this chapter do not perform nerve-grafting surgery.

SALVAGE RADICAL PROSTATECTOMY

The goal of primary external beam radiation therapy (intensity-modified or three-dimensional conformal) or primary brachytherapy in the treatment of clinically localized prostate cancer is to eradicate all tumor. Failure to achieve this goal leads to local progression, distant metastasis, and potentially death. The recognition of local recurrence after definitive radiation therapy is complex (American Society of Therapeutic Radiology and Oncology criteria, PSA nadir, PSA bump), yet all would agree that it portends a poor outcome with few options for salvage. This poor prognosis has led to development of several options to salvage cure: cryosurgery (Chapter 105), watchful waiting (Chapter 108), androgen deprivation (Chapter 109), and salvage prostatectomy. **Salvage radical prostatectomy has been used successfully to eradicate locally recurrent cancer after definitive radiotherapy, but complications are common and the effects on overall survival uncertain** (Rogers et al, 1995; Cheng et al, 1998; Garzotto and Wajsman, 1998; Gheiler et al, 1998; Tefilli et al, 1998a, 1998b; reviewed by Chen and Wood, 2003; Stephenson et al, 2004; Ward et al, 2005; Paparel et al, 2009). From the literature, several generalizations can be made:

- The procedure (salvage prostatectomy) is reserved for patients with excellent health and with a life expectancy of more than 15 years.
- Patients must have no evidence of metastatic disease.
- Salvage surgery should be offered only to men who at initial presentation had unequivocally clinically localized prostate cancer.
- Prostate biopsy, histologic grade, clinical examination findings, and serum PSA levels must continue to suggest localized disease.

In summary, candidates for salvage surgery should be unrecognizable from the candidates we would choose for initial therapy with radical retropubic prostatectomy and be highly motivated individuals who understand and accept the potentially higher morbidity associated with salvage surgery.

Scardino and colleagues (Rogers et al, 1995) have reported a large series (N = 80) with long-term outcome data for salvage radical prostatectomy. Early in their series, the estimated blood loss, transfusion requirements, and average length of stay in the hospital were greater than with standard classic radical prostatectomy. Since the mid-1990s, they have reported major improvements in the morbidity associated with this operation. **Whereas rectal injuries occurred in 15% of the first 39 cases, this morbidity is now rare** (Chen and Wood, 2003). **With complete bowel preparation (mechanical and intraluminal antimicrobial) before the operation, rectal injuries, if encountered, can be primarily repaired without altering postoperative recovery. Urinary incontinence rates remain high. Scardino and colleagues reported an estimated 58% with persistent leakage requiring two or more pads per day, and 20% required placement of an artificial urinary sphincter; 27% developed an anastomotic stricture** (Rogers et al, 1995). A summary of the published literature (1985-2000) regarding salvage prostatectomy (Chen and Wood, 2003) demonstrates that the length of hospital stay has dropped from 13 days to 3.2 days, mean estimated blood loss has remained stable around 1000 mL, overall incontinence (stress, total) rates have remained stable at nearly 50% and total incontinence rates have remained stable at 20% to 30%, rectal injury has decreased from 30% to nearly 6%, and bladder neck contracture has remained constant at 20% to 30%. Erectile dysfunction is nearly universal; however, sural nerve grafting (Kim and Seo, 2001; Kim et al, 2001a, 2001b) has been suggested to improve potency after salvage surgery.

Another review of a salvage prostatectomy experience by Stephenson and colleagues (2004) recounted a series of nearly 100 men treated between 1984 and 2003 with either external beam (N = 58) or interstitial (N = 42) radiotherapy. The authors saw a decrease in complication rates (overall from 33% to 13%, rectal injuries from 15% to 2%). They also reported urinary continence rates of 39% totally dry and 86% with one or fewer pad per day. Nearly 20% required an artificial sphincter. The 5-year actuarial recovery of potency rate for this group was 16% (Masterson et al, 2005). Another recent report (Ward et al, 2005) recounted a 30-year experience with salvage retropubic prostatectomy and cystoprostatectomy for radioresistant adenocarcinoma of the prostate. From 1967 to 2003, they found sufficient data to comment on 199 men; 138 were treated with retropubic prostatectomy and 61 with cystoprostatectomy. Average follow-up was 7 years. Rectal injury occurred in 5% of radical retropubic prostatectomies and 10% of cystoprostatectomies. Incontinence was "zero pads" in 43% of the more contemporary cohort. Cancer-specific survival was 65% at 10 years.

Data on oncologic outcomes after salvage radical prostatectomy are limited. Eastham and colleagues report excellent local control and a 45% 5-year recurrence in patients with presurgical biopsies demonstrating a Gleason score of less than 8 (Paparel et al, 2009). However, the overall effect of salvage prostatectomy on prostate cancer–specific mortality remains unclear (Paparel et al, 2009).

The surgical technique for salvage prostatectomy does not differ from that of classic radical prostatectomy. Radiation effects (vasculitis, ischemia, and fibrosis) can make the surgical dissection technically challenging (Chen and Wood, 2003). Special care should be taken in separating the apical region of the prostate, wide dissection of the neurovascular bundles, and dissection of Denonvilliers fascia near the base of the prostate because these regions represent the most common sites for rectal injury.

SUMMARY OF RADICAL RETROPUBIC PROSTATECTOMY

A number of advances have been made in the diagnosis and treatment of localized prostate cancer. Today, more men are diagnosed with curable disease at a younger age. Men are also living longer;

a man 65 to 70 years old has a 50% chance of living for another 15 years. Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it. These are also the patients who will have the best quality of life postoperatively (Walsh, 2000).

Radical Perineal Prostatectomy

This section is included in honor and the memory of Marty Resnick, MD. This slightly modified version of his chapter in *Campbell-Walsh Urology, 9th Edition* reflects his career efforts in the field of urology and his expertise in performance of the radical perineal prostatectomy (RPP).

Hugh Hampton Young described the first RPP for treatment of cancer in 1905. In 1939 Belt and colleagues modified the procedure, and until the description of the radical retropubic approach by Walsh, this approach represented the principal method for treatment of patients with localized prostate malignant disease. Furthermore, Walsh improved on the retropubic technique, demonstrating functional anatomic relationships that reduced intraoperative blood loss and improved outcomes of impotence and urinary continence (Reiner and Walsh, 1979; Walsh and Donker, 1982; Walsh et al, 1983).

Surgical and anatomic techniques of the retropubic prostatectomy were applied to the perineal approach, resulting in potency comparable with that of the early radical retropubic prostatectomy (RRP) results (Weiss et al, 1985; Weldon, 1988; Weldon and Tavel, 1988). **In addition, the perineal approach offers visualization of the urethral dissection and anastomosis, resulting in excellent urinary continence similar to the results achieved through the laparoscopic approach. Finally, RPP demonstrates the proven long-term cancer control of RRP with low morbidity and rapid convalescence** (Sullivan et al, 2000; Guillonneau et al, 2002; Harris, 2003; Lotan et al, 2004; Silverstein et al, 2004).

RADICAL PERINEAL PROSTATECTOMY: SELECTION OF PATIENTS

Like the RRP, RPP is offered to those patients with a life expectancy of more than 10 years who demonstrate a high likelihood of organ-confined disease. A nerve-sparing approach is accomplished for most of these patients, and the decision to excise a neurovascular bundle is usually made intraoperatively on the basis of the adherence of the neurovascular bundle to the prostate or preoperatively on the basis of the biopsy report or results of the DRE. A pre-RPP laparoscopic pelvic lymphadenectomy is deemed unnecessary if the biopsy Gleason score is below 7 and the serum PSA level is less than 10 ng/mL (low- to moderate-risk disease).

In patients with localized cancer, **there are few contraindications to this procedure.** Patients with severe ankylosis of the hips or spine and those with unstable artificial hip replacements may not tolerate the exaggerated lithotomy position. However, **common degenerative disk disease is not a contraindication to positioning.** Some patients, such as those having renal transplantation or those with severe inflammation secondary to placement of synthetic mesh for repair of a hernia or the morbidly obese, who may not be amenable to RRP, typically may undergo

Key Points: Anatomic Radical Retropubic Prostatectomy

- There is no better way to cure cancer that is confined to the prostate than total surgical removal.
- The three goals of the surgeon, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function.
- Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate.
- A fiberoptic headlight and 2.5- to 4.5-power loupes are most useful because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. Magnification can enable the surgeon to exert less traction on the neurovascular bundles and more easily identify the correct plane of dissection.
- Regional anesthesia is associated with less blood loss and a lower frequency of pulmonary emboli.
- If the patient has a well-differentiated to moderately well-differentiated tumor (Gleason grade < 8) and the lymph nodes are normal to palpation, frozen-section analysis is not performed.
- With the recent recognition that branches of the nerves innervating the striated sphincter and cavernous bodies may travel more anteriorly at the apex, an alternative technique involving high anterior release of the neurovascular bundles at the apex before division of the dorsal vein is described. This technique is associated with earlier recovery of sexual function.
- Today, in most men who are candidates for surgery, it is safe to preserve both neurovascular bundles and rarely necessary to excise both of them, thus making cavernous nerve replacement or transplantation unnecessary in most cases.
- The tactile sensation provided by open surgery is so important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. In gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be preserved. With the laparoscopic technique, tactile sensation is muted; with the robot, it is absent.
- Patients requiring acute transfusions for hypotension after radical prostatectomy should be explored to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.
- Thrombophlebitis with pulmonary embolism is the major cause of mortality after radical prostatectomy. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, the use of intermittent compression devices, and early ambulation.
- The authors concluded that complete excision of the seminal vesicle during radical prostatectomy is essential for cancer control.
- Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it.

prostatectomy by the perineal approach (Yiou et al, 1999; Boczko and Melman, 2003). Additionally, a large (>100 g) prostate and a narrow pelvis can cause difficulties with this surgical approach.

PREOPERATIVE CARE/POSITION

A full bowel preparation is administered on the day before surgery on the basis of the surgeon's preference; the patient is instructed to consume polyethylene glycol or administer a Fleet Phospho-Soda enema in the afternoon before surgery. Also, 1 g of neomycin is administered orally at 12:00, 2:00, 4:00, 6:00, 8:00, and 10:00 PM. This bowel preparation allows primary closure of any inadvertent rectal injury at the time of surgery without problem. A sample for blood type and antibody screen is obtained from all patients in the days or hours before surgery, but because blood loss is minimal and transfusion rarely required, a cross-match is unnecessary; preoperative donation and storage of blood by the patient is not required, either.

In the preoperative holding area, antithromboembolic surgical stockings are positioned and the patient is administered a second-generation cephalosporin intravenously. Although perineal prostatectomy lends itself to regional anesthetics such as spinal or epidural anesthesia, most patients receive a general anesthetic. The only specialized instruments needed are curved and straight Lowsley tractors, a self-retaining retractor such as the mini-crescent or Thompson, and a headlight.

After the induction of anesthesia, the patient is positioned supine so that when the leg portion of the operating table is lowered, the buttocks are extended beyond the table edge. Allen stirrups are stationed 2 inches cranially on the rail so that there is ample room for the attachment of the self-retaining retractor. The patient is then placed in an exaggerated lithotomy position with the perineum almost parallel to the floor or in a modified exaggerated lithotomy position with the perineum only slightly elevated (Fig. 102–39). The perineum, anus, and scrotum are shaved, and the abdomen inferior to the umbilicus, penis, scrotum, perineum, anus, and both thighs are painted with povidone-iodine in the standard sterile fashion. After gowning, a sterile towel is sewn from the 9-o'clock to the 3-o'clock position around the anus at the mucocutaneous pigmentation line with silk suture, maintaining a sterile environment. Leg and perineal drapes are placed. The upright of the self-retaining retractor is secured to the table rail on the patient's left while the sterility of the upright is maintained.

EXPOSURE OF THE PROSTATE

A curved Lowsley tractor is placed transurethrally into the bladder and its wings opened. A curvilinear incision is made from a position just medial to the right ischial tuberosity to a position just medial to the left ischial tuberosity. The incision should not extend posteriorly beyond the 3- and 9-o'clock positions relative to the anus. Blunt dissection is employed to open and develop each ischiorectal fossa lateral to the central tendon, and the central tendon is then divided by electrocautery (Fig. 102–40). In the original description by Young, the dissection is carried anteriorly along the external anal sphincter until arriving at the rectourethralis muscle (1905). However, with the Belt approach preferred by the authors, the fibers of the external anal sphincter are dissected and retracted anteriorly with an appendiceal retractor; these fibers are not incised (1939). The longitudinal muscle fibers of the rectum are identified, and gentle traction is placed dorsally on the rectum by a dampened sponge. The plane is developed leading to the rectourethralis muscle, which is formed by fascicles of the rectal muscle, connecting the rectum to the perineal body. It appears as a strap of muscle tenting the rectum ventrally. **Without any traction on the Lowsley tractor, the rectourethralis muscle is divided close to the apex of the prostate with vertically oriented scissors, allowing the rectum to fall dorsally; caution must be exercised to prevent rectal injury at this point of the procedure.** Gentle pressure is then applied on the Lowsley tractor toward the anterior abdominal wall. This maneuver delivers the prostate well into the field of view and allows the blunt, digital dissection of the prostate from the rectum in a cephalad direction until the base of the prostate is identified at the vesicoprostatic junction (Fig. 102–41). Classically, the proper plane is between the anterior and posterior leaves of Denonvilliers fascia.

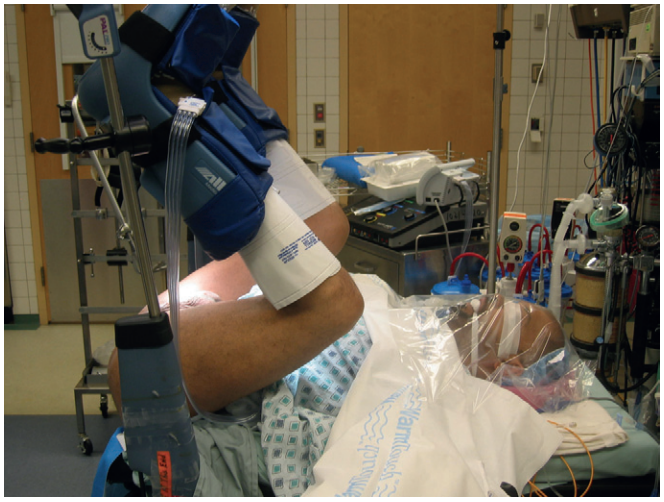

Figure 102–39. The modified exaggerated lithotomy position. The perineum is only slightly elevated and almost at a 90-degree angle with the floor. The legs are positioned at nearly a 75-degree angle with the floor.

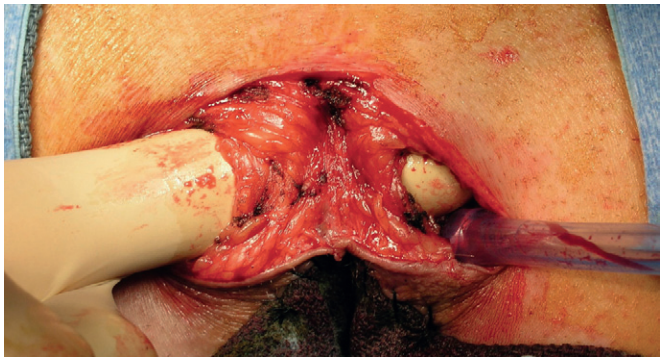

Figure 102–40. Each ischiorectal fossa is dissected bilaterally, and the finger is bluntly brought beneath the central tendon. The central tendon will be divided with electrocautery as traction is maintained with the finger.

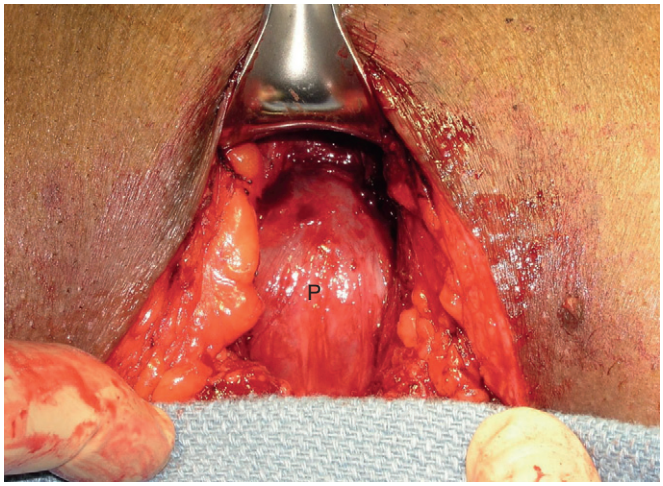

Figure 102–41. The external anal sphincter is retracted anteriorly, and the rectourethralis muscle is divided. The prostate (P) is delivered into the field of view.

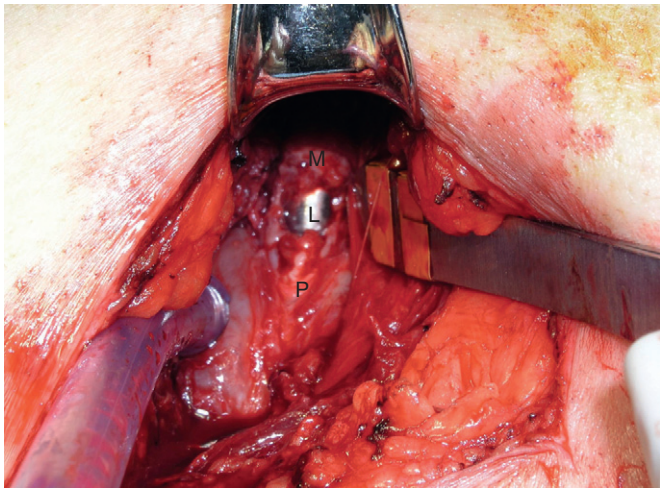

Figure 102–42. The anterior urethra is incised over the curved Lowsley tractor (L) between the membranous urethra (M) and prostate (P).

NERVE-SPARING DISSECTION

Resumed traction on the Lowsley tractor toward the anterior abdominal wall again brings the prostate into the incision. If preservation of the neurovascular bundles is intended, the exposed anterior layer of Denonvilliers fascia is incised vertically in the midline from the vesicoprostatic junction to the apex of the prostate with a No. 15 blade scalpel. **Avoiding use of electrocautery, careful lateral dissection with gentle lateral traction preserves the neurovascular bundles as they course between the layers of Denonvilliers fascia at the posterolateral edge of the prostate. The fascia and enclosed nerves must be sufficiently mobilized to allow eventual extraction of the prostate without stretching or damage of the bundles.**

Attention is then directed toward the prostatic apex and urethra. The Lowsley tractor can be palpated within the urethra, and a right-angled clamp is placed with the open points facing cephalad on either side of the urethra to dissect the neurovascular bundles away from the urethra as they course distally. The No. 15 blade scalpel is again used to incise the posterior aspect of the urethra over the Lowsley tractor (Fig. 102–42). The curved Lowsley tractor is then replaced by a straight Lowsley, and the wings are opened in a vertical fashion. With moderate traction on the Lowsley tractor, the remaining intact anterior aspect of the membranous urethra is sharply transected from the prostatic apex and the anterior prostate is freed to the bladder neck by sharp and blunt dissection.

The self-retaining retractor is attached to the previously placed upright, and blades are placed in the 3-, 9-, and 12-o'clock positions. Dissection is then directed over the anterior prostate from the apex toward the bladder neck. Traction on the Lowsley tractor aids in this portion by bringing the prostate into the incision. **The surgeon must be mindful not to dissect too far ventrally and to touch on the dorsal venous complex.** To sufficiently expose the anterior prostate, the puboprostatic ligaments are encountered and divided with scissors (Fig. 102–43).

The junction of the bladder neck and prostate base is then identified by palpating the wings of the Lowsley tractor. This junction is then further developed with blunt and sharp dissections, preserving the bladder neck. The bladder is entered anteriorly with a scalpel, the Lowsley tractor is removed from the urethra, and a

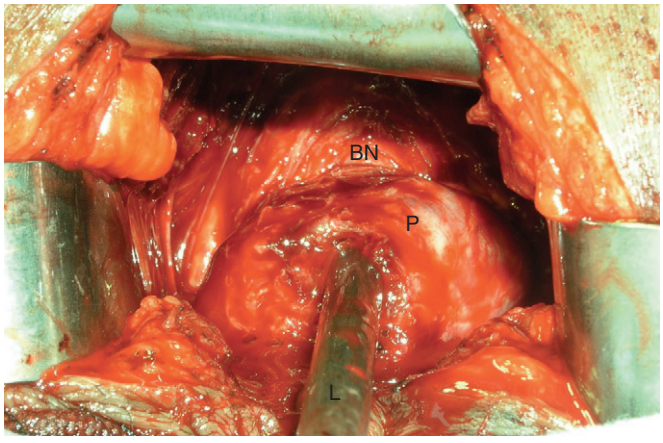

Figure 102–43. The urethra is divided, and the curved Lowsley has been replaced with a straight Lowsley tractor (L). The anterior prostate (P) has been dissected, and the puboprostatic ligaments are divided, exposing the bladder neck (BN).

long right-angled clamp is passed retrograde through the prostatic urethra and bladder neck. A 14-Fr red rubber catheter is then fed into the open right-angled clamp and pulled through the prostatic urethra; the ends are clamped together with a Kelly clamp, making a loop that may be used for manipulation of the specimen (Fig. 102–44). Traction on the catheter further delivers the prostate into the incision, and dissection of the anterior bladder neck is continued circumferentially around the prostate base. Identification of the ureteral orifices is generally unnecessary unless the dissection inadvertently involves the trigone. The lateral attachments and vascular pedicles are found coursing toward the base of the prostate and are dissected, sharply divided between right-angled clamps, and secured with 3-0 absorbable ties. **To preserve the neurovascular bundles, the lateral pedicles should be divided close to the prostate, taking care not to compromise the surgical margin. Electrocautery is avoided during this phase.**

The dissection is continued posteriorly at the bladder neck to separate it completely from the prostate. The red rubber catheter is then removed, and a right-angled clamp is passed along the midline posterior surface of the prostate with tips directed toward

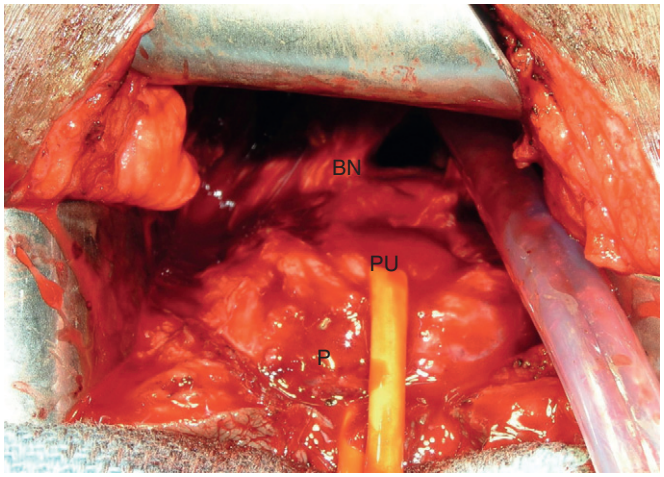

Figure 102–44. The bladder neck (BN) is incised, and a red rubber catheter is placed through the prostatic urethra (PU) and used to hold traction on the prostate (P).

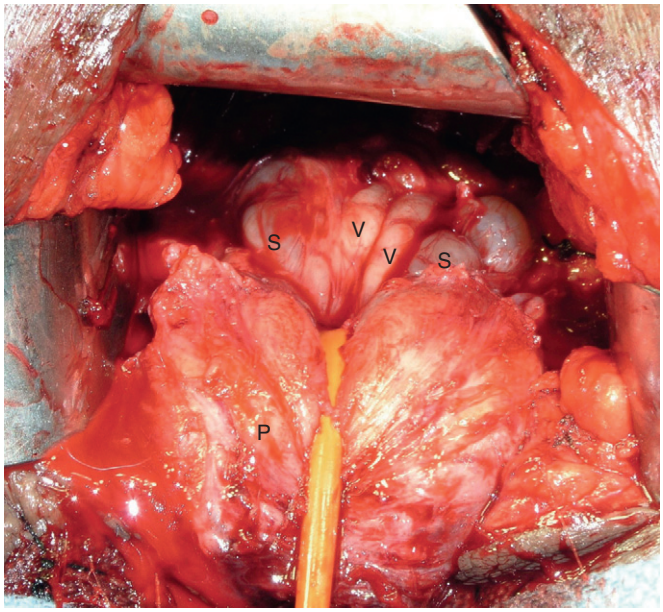

Figure 102–45. The bladder neck is freed from the prostate, and a red rubber catheter is clamped around the entirety of the prostate (P). Further dissection at the prostate base exposes the right and left vas deferens (V) and bilateral seminal vesicles (S).

the base. The 14-Fr red rubber catheter is passed through the open tips of the right-angled clamp and pulled through, and the ends are secured together with a Kelly clamp, making a loop around the whole prostate. Traction can then be applied around the entirety of the prostate toward the incision, and an appendiceal retractor may be placed under the trigone, exposing the vasa deferentia and seminal vesicles (Fig. 102–45). Each vas deferens is grasped with a right-angled clamp, bluntly dissected, and divided with electrocautery. Each seminal vesicle is similarly grasped with a right-angled clamp, bluntly dissected, and divided, ligating the seminal vesicle artery with 3-0 absorbable ties. The complete surgical specimen is thus removed and passed off for pathologic examination.

VESICOURETHRAL ANASTOMOSIS

On occasion, it may be necessary to reconstruct the posterior bladder neck with simple interrupted absorbable suture placed in a tennis racquet fashion. **The ureteral orifices should be identified, and care should be taken to prevent damage to them.**

The retractor placed at the 12-o'clock position is removed, and the red rubber catheter is placed retrograde through the penile urethra and clamped at the level of the glans so that traction can be applied to it while retaining it in the urethra. This catheter is used to identify and provide traction on the membranous urethra, enabling accurate anastomotic suture placement (Fig. 102–46). A 3-0 polyglycolic acid suture is placed from outside the anterior bladder neck at the 12-o'clock position and from inside to outside the membranous urethra at the same position and tied. While the assistant places traction on the red rubber catheter toward the contralateral side, the surgeon places sutures at the 2- and 10-o'clock positions. The red rubber catheter is removed, and a 22-Fr Silastic Foley catheter is carefully passed retrograde from the penile urethra and into the bladder. The 5-mL balloon is inflated with 15 mL of sterile water. Sutures are then placed at the 4-, 6-, and 8-o'clock positions and tied, completing the anastomosis.

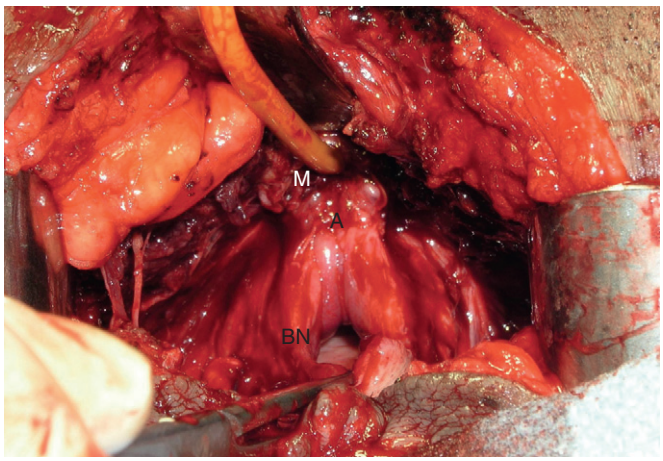

Figure 102–46. The specimen is removed from the field. A red rubber catheter emanates from the membranous urethra (M), and the bladder neck (BN) is open. The anterior aspect of the vesicourethral anastomosis (A) is complete. This exposure is unmatched with any other approach to radical prostatectomy.

Closure

The field is inspected for hemostasis and again for rectal injury. A Penrose drain is positioned near the vesicourethral anastomosis and brought through the incision. The levator ani are reapproximated with 2-0 absorbable sutures, avoiding damage to the neurovascular bundles and Penrose drain. **The central tendon and Colles fascia are reapproximated, respectively, with 2-0 absorbable sutures; care must be exercised to use superficial "bites" posteriorly during this portion of the procedure because the anterior rectal wall is only a short distance away.** The skin is closed with 4-0 absorbable suture interrupted in a vertical mattress fashion. The wound is dressed with a fluffed gauze dressing.

Postoperative Care

Patients are started on a clear liquid diet on the day of surgery and advanced to a regular diet as tolerated. Patients are encouraged to

ambulate routinely beginning the evening of surgery. Lower-extremity sequential compression devices are used while the patient is in bed. **Rectal stimulation, instrumentation, and medication insertion are prohibited.** Furthermore, gentle irrigation of the catheter is performed only when absolutely necessary. The patient is provided oral analgesia and stool softeners. All patients are maintained on a prophylactic oral antibiotic until the catheter is removed. The Penrose drain is typically removed on postoperative day 1, and the urethral catheter is removed in the office 2 to 3 weeks after surgery, although it is recognized that earlier removal is feasible. **Patients are discharged on postoperative day 1 or 2** (Ruiz-Deya et al, 2001; Harris, 2003).

PATHOLOGIC OUTCOMES

RPP demonstrates excellent pathologic outcomes consistent with those of RRP. In a retrospective review, Korman and colleagues (2002) failed to demonstrate a significant difference in the incidence of positive margins between RPP specimens and those of RRP, 22% and 16%, respectively, and each had a 4% incidence of capsular incision. Furthermore, it has been shown that there is no significant difference in the time to PSA failure between patients who underwent RPP with complete excision of the seminal vesicles and those undergoing RRP (Theodorescu et al, 1998). A review of the literature demonstrates an incidence of positive margins of 15% to 44% of radical perineal specimens, with the prostate base being the most likely positive margin (Weldon et al, 1995; Iselin et al, 1999; Lance et al, 2001; Harris, 2003; Gillitzer et al, 2004). In the 20-year experience of Paulson, consisting of 1242 consecutive radical perineal prostatectomies for clinically organ-confined prostate cancer, 18% of patients with organ- or specimen-confined disease died either with or of prostate cancer. After 5 years, PSA failure (defined by PSA level > 0.5 ng/mL) occurred in 8%, 35%, and 65% of men with organ-confined, specimen-confined, and margin-positive disease, respectively. In patients with positive margins, the median time to PSA failure was 2.4 years; however, approximately 20% of patients with positive margins did not demonstrate biochemical failure. Cancer-associated death occurred approximately 10 years after the time of PSA failure (Iselin et al, 1999).

Morbidity

As a result of short operative times and relatively low blood loss, perioperative morbidity is low. Weldon and colleagues (1997) reported that 18% of their perineal prostatectomies experienced adverse events; however, most events were not serious, and no deaths were reported. Anastomotic strictures occur in 1% to 8% and usually within the first 4 months of surgery (Frazier et al, 1992; Levy and Resnick, 1994; Weldon et al, 1997; Gillitzer et al, 2004). Lower-extremity neurapraxia, unique to the perineal approach, is often sensory and reported by Weizer and colleagues (2003) to occur in 25.5% of patients. **However, most series report an incidence of neurapraxia less than 2% and it is transient** (Weldon et al, 1997; Gillitzer et al, 2004). Keller (1999) reported a 0% incidence of neurapraxia in 284 prostatectomies and concluded that an operative time of less than 180 minutes is preventive. In experienced hands, **blood loss typically ranges from 200 to 800 mL and transfusions are necessary in approximately 5% of patients** (Weldon et al, 1997; Lance et al, 2001; Gillitzer et al, 2004). These rates of transfusion are comparable with those of laparoscopic radical prostatectomy (Guillonneau et al, 2002; Rassweiler et al, 2003). Rectal injuries have been reported to occur during 1% to 11% of radical perineal prostatectomies (Parra et al, 1994, 1996; Levy and Resnick, 1994; Lassen and Kearse, 1995; Weldon et al, 1997; Gillitzer et al, 2004). **When rectal injury is recognized at the time of surgery and repaired primarily with a two-layer closure, clinical sequelae are typically avoided.** If it is unrecognized or when it occurs in concert with postoperative urinary extravasation, a rectocutaneous or rectourethral fistula may develop. Like rectal injury, fecal incontinence occurs at a higher rate after RPP than after RRP. Bishoff and colleagues (1998) surveyed 227 patients 12 months after radical prostatectomy and reported that 18% of perineal patients had new onset of fecal incontinence compared with only 5% in the retropubic group. In a prospective longitudinal assessment by Dahm and colleagues (2003), rectal urgency was the most common complaint and symptoms resolved over time; only 2.9% of patients reported involuntary stool leakage by 12 months after RPP. The exposure of the vesicourethral anastomosis generated with the perineal approach results in excellent continence outcomes. In a series of 220 cases, with incontinence defined as daily use of pads, Weldon and colleagues (1997) reported a 95% continence rate within 1 year, with younger age being a significant predictor of improved urinary continence. Yang and colleagues (2004) confirmed these results in a prospective study. **In studies comparing the outcomes of perineal prostatectomy and RRP, urinary continence was either improved by the perineal approach or not significantly different** (Parra et al, 1994; Bishoff et al, 1998; Gray et al, 1999; Sullivan et al, 2000; Lance et al, 2001). To date, studies comparing laparoscopic radical prostatectomy and perineal prostatectomy are not available. **A review of the literature demonstrates potency in 35% to 70% of patients after nerve-sparing RPP** (Lerner et al, 1994; Harris and Thompson, 1996; Weldon et al, 1997; Ruiz-Deya et al, 2001; Harris, 2003; Rabbani, 2000). At 24 months of follow-up, Weldon and colleagues (1997) reported 73% potency in 22 patients who had a bilateral nerve-sparing procedure and 63% potency in 28 patients who had a unilateral bundle preserved, although these results were not statistically different. Lerner and colleagues (1994) demonstrated unassisted potency in 22% of nerve-spared patients and an additional 30% who achieved vaginal penetration with pharmacotherapy.

SUMMARY OF RADICAL PERINEAL PROSTATECTOMY

The use of RPP for the treatment of localized prostate cancer has been facilitated by the emphasis on the identification of prostate cancer at earlier stages. This technique provides cancer control for localized prostate cancer similar to RRP.

Key Points: Radical Perineal Prostatectomy

- There are few contraindications to RPP.
- RPP demonstrates proven long-term cancer control.
- A nerve-sparing approach may be applied to RPP with excellent potency outcomes.
- RPP is renowned for rapid convalescence and overall low morbidity.

Summary

EVOLUTION OF MINIMALLY INVASIVE LAPAROSCOPIC PROSTATECTOMY

Over a century has passed since Hugh Hampton Young (1905) performed the first open prostatectomy for carcinoma through a perineal approach. In 1947, Millin was the first to describe the retropubic approach to radical prostatectomy. In the late 1970s and early 1980s several detailed anatomic studies performed in fetal and adult cadavers provided important insights into the periprostatic anatomy, especially that of the dorsal vein complex (DVC; Reiner and Walsh, 1979), the neurovascular bundle (NVB; Walsh and Donker, 1982), and the striated urethral sphincter (Oelrich, 1980). These observations provided a more anatomic approach to radical prostatectomy with a consequent reduction in operative morbidity. Subsequently, anatomic, nerve-sparing radical prostatectomy has maintained a cardinal role in the management of localized prostate cancer for more than 2 decades.

Schuessler and colleagues (1997) performed the first successful laparoscopic radical prostatectomy (LRP) in 1997. In their series of nine patients, operative duration was lengthy (8 to 11 hours) and the length of stay was 7.3 days on average. Although the authors concluded that cure rates with LRP may be comparable with open surgery, they could not define any significant advantages. As a result, LRP was not immediately widely adopted in the field of urology.

Advances in task-specific surgical instrumentation, optics, digital video equipment, and computer and robotic technology opened a new frontier for minimally invasive laparoscopic prostatectomy. These advances led urologists to revisit LRP, spearheaded by two centers in France that reported on their techniques and early results (Abbou et al, 2000; Guillonneau and Vallancien, 2000). Their stepwise approach to LRP proved to be both reproducible and teachable, although the learning curve remained challenging. Operative times were in a more acceptable 4- to 5-hour range with reported overall positive margin rates of 15% to 28%. Both groups had good continence and potency rates. This work rekindled worldwide interest in LRP, and in the ensuing years surgeons at a number of centers throughout the world acquired the skills and experience to perform LRP. However, advanced laparoscopic skills are necessary to perform a proficient LRP, especially for suturing of the vesicourethral anastomosis.

Computer-assisted surgical devices using mechanical robotic arms were adopted for use with radical prostatectomy in part due to their ability to aid the surgeon in performing the challenging task of laparoscopic suturing. One such device, the da Vinci Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) has become the dominant robotic surgical device in the field of urology. By incorporating sophisticated wristed technology at the terminal ends of the robotic instruments, a surgeon can operate, dissect, and suture with the facility of a human wrist. In addition, a 10× magnified, three-dimensional image is displayed as a result of a specialized stereo endoscope lens and camera, providing the surgeon with an unprecedented view of the operative field and periprostatic anatomy. The first-generation robotic platform, originally launched in the United States in 2000, allows for the surgeon to control three robotic arms simultaneously, two arms for robotic instrumentation and a third arm that controls the stereo endoscope and camera. The newer da Vinci S system, made available in 2006, incorporates high-definition image capability with an additional fourth robotic arm for grasping and retraction. Finally the latest-generation robot, the da Vinci Si HD, which was

launched in 2009, offers two separate surgeon consoles allowing two surgeons to operate simultaneously, providing an opportunity for improved operative efficiency and teaching.

There has been an almost revolutionary introduction of robotic surgery into the surgical management of carcinoma of the prostate. Since its introduction into the United States in 2000, robotic-assisted laparoscopic prostatectomy (RALP) has rapidly grown in popularity with surgeons and patients alike. With rapid dissemination of this robotic platform into large tertiary referral centers and community hospitals throughout the country, it is now estimated that RALP is the dominant surgical approach for radical prostatectomy in the United States. In addition, robotic technology is rapidly expanding throughout centers worldwide.

There have been considerable and ongoing debates about the merits of RALP versus an open surgical approach by either the retropubic or perineal route. Issues with equipment expense, the learning curve for the surgeon and surgical team, and patient-related outcomes remain. **Nonetheless, RALP has virtually replaced LRP in the United States, and the overwhelming majority of new surgeons have adopted RALP as their preferred surgical approach for prostate cancer.** Thus it seems virtually certain that the use of RALP will continue to proliferate.

This chapter highlights some of the surgical advances for both LRP and RALP. Further, technical details for the surgical dissection and currently available data on oncologic, as well as functional outcomes, are presented. Finally, the authors review the role of pelvic lymph node dissection (PLND) in conjunction with minimally invasive approaches to prostatectomy along with technical considerations and potential complications.

PATIENT SELECTION

Indications and Contraindications

The indications for LRP and RALP are identical to that for open surgery (i.e., patients with ≤ clinical stage T2 with no evidence of metastasis either clinically or radiographically [computed tomography (CT) and bone scan]). Absolute contraindications to minimally invasive laparoscopic prostatectomy include uncorrectable bleeding diatheses and the inability to undergo general anesthesia because of severe cardiopulmonary compromise. Patients who have received neoadjuvant hormonal therapy or who have a history of prior complex lower abdominal and pelvic surgery such as partial colectomy, inguinal mesh herniorrhaphy, or prior transurethral resection of the prostate (TURP) pose a greater technical challenge due to distortion of normal anatomy and adhesions but are not an absolute contraindication to LRP and RALP. In those patients with a history of prior laparoscopic extraperitoneal mesh herniorrhaphy, a transperitoneal approach may be preferred over the extraperitoneal approach because dense adhesions in the retropubic space often make attempts at initial access to the space of Retzius challenging.

Morbidly obese patients pose additional challenges due to the potential respiratory compromise encountered when placing these patients in a steep Trendelenburg position, as well as the relatively limited working space and limitations of trocar size and instrumentation length, especially with LRP. Patients with large prostate volumes (e.g., >70 g) are often met with longer operative times, blood loss, and hospital stay than those with smaller glands; however, long-term urinary outcomes appear comparable (Levinson et al, 2008, 2009; Link et al, 2008). Salvage surgery after failure of primary treatment (e.g., radiation, brachytherapy, cryotherapy, high-intensity focused ultrasound) has been successfully reported in properly selected patients but should be approached with caution due to the attendant risks and complications (Kaouk, 2008; Boris et al, 2009). Due to the effects of prior local radiotherapy or ablation, the tissue planes surrounding the prostate and especially between the posterior prostate and anterior rectum are often fibrotic and obliterated, increasing the risk of inadvertent entry into the rectum during salvage surgery. As a result, patients undergoing salvage prostatectomy need to be counseled on the potential risk of rectal injury in addition to the higher incidence of impotence and incontinence as compared with primary surgery. **It is strongly advised that these more complex patient scenarios be avoided in a surgeon's early experience with LRP and RALP; however, these patient features are not by themselves absolute contraindications for a minimally invasive approach to prostatectomy** (Brown et al, 2005a; Erdogru et al, 2005; Singh et al, 2005; Stolzenburg et al, 2005).

INSTRUMENTATION

Instrumentation required for LRP and RALP is dependent on the chosen approach and model of da Vinci system being used (i.e., three- vs. four-arm robot) in the case of RALP. A list of suggested instrumentation for LRP and RALP are listed in Table 103–1. For LRP, the AESOP 3000 robotic arm (Intuitive Surgical, Inc., Sunnyvale, CA) may be used to stabilize and control the laparoscopic lens and camera by hand-held remote control, voice activation, or foot pedal control. Alternatively, a surgical assistant can be used for this purpose. During RALP, the use of the da Vinci S or Si HD system allows the surgeon to control a total of four robotic arms with one being the endoscope as compared with only three robotic arms with the first-generation standard robotic platform. The surgeon generally begins the operation by using a 0-degree stereo endoscope and controlling a grasping forceps in the left robotic arm (such as the Maryland curved bipolar forceps or plasma kinetic dissector) and the curved monopolar scissors in the right robotic arm. The fourth robotic arm controls the ProGrasp forceps (Intuitive Surgical, Inc., Sunnyvale, CA), a large atraumatic blunt grasper for retraction and exposure of tissues. The surgeons then toggle between control of any two of the three working robotic arms at any given time to allow for greater autonomy and to achieve optimal exposure and dissection.

PREOPERATIVE PREPARATION

Bowel Preparation

As with open surgery, a preoperative mechanical bowel preparation may be used. Most commonly, one bottle of citrate of magnesium is taken the day before surgery and the patient's diet is limited to clear liquids. An enema administered the morning of surgery is recommended by some surgeons. A broad-spectrum antibiotic such as cefazolin is administered intravenously 30 minutes before surgery.

Informed Consent

In addition to bleeding, transfusion, and infection, patients undergoing LRP and RALP must be aware of the potential for conversion to open surgery. As with open surgery, patients must be counseled on the risk of impotence, incontinence, incisional hernia, and adjacent organ injury (e.g., ureter, rectum, bladder, small bowel).

Table 103–1.

Suggested Instrumentation for LRP and RALP

Laparoscopic Radical Prostatectomy
AESOP 3000 Robotic arm, if available (Intuitive Surgical, Sunnyvale, CA)
Monopolar electrocautery scissors
Monopolar electrocautery hook device
Bipolar forceps
Ultrasonic shears
Maryland dissector
60-degree and 90-degree fine-tipped (0.8-mm) dissectors for neurovascular bundle preservation
Laparoscopic needle drivers (2)
Suction-irrigation device
10-mm, 0-degree and 30-degree laparoscope lens
Veress needle
5-mm trocars (3)
12-mm trocars (2)
20-Fr van Buren urethral sound
18-Fr urethral catheter
Small and medium-large Hem-o-Lok clips (Teleflex Medical, Research Triangle Park, NC)
0 polyglactin suture (GS21) for dorsal venous complex
2-0 polydioxanone suture for posterior reconstruction
3-0 poliglecaprone (Monocryl) double-armed suture for anastomosis
Robotic-Assisted Laparoscopic Prostatectomy
da Vinci S or Si Surgical System (Intuitive Surgical, Sunnyvale, CA)
Endowrist Maryland bipolar forceps or PK dissector (Intuitive Surgical, Sunnyvale, CA)
Endowrist curved monopolar scissors (Intuitive Surgical, Sunnyvale, CA)
Endowrist ProGrasp forceps (Intuitive Surgical, Sunnyvale, CA)
Endowrist needle drivers (2) (Intuitive Surgical, Sunnyvale, CA)
InSite Vision System with 0-degree and 30-degree lens (Intuitive Surgical, Sunnyvale, CA)
12-mm trocars (2)
8-mm metal robotic trocars (3 if using a fourth robotic arm)
18-Fr urethral catheter
Small and medium-large Hem-o-Lok clips (Teleflex Medical, Research Triangle Park, NC)
0 polydioxanone suture for dorsal venous complex
2-0 polydioxanone suture for posterior reconstruction
3-0 Monocryl double-armed suture for anastomosis

LRP, laparoscopic radical prostatectomy; RALP, robotic-assisted laparoscopic prostatectomy.

The risks of general anesthesia must also be presented to the patient because LRP and RALP cannot be performed under regional anesthesia. In addition, it may be appropriate for the surgeon to discuss his or her overall operative experience with radical prostatectomy and provide a realistic forecast of cancer control, as well as return to normal urinary and sexual function on the basis of each patient's unique characteristics.

Operating Room Personnel

LRP and RALP require that the surgical team including the scrub technician, circulating nurse, and surgical assistant(s) be fully trained and skilled in the instrumentation, operative setup, and technical steps of these minimally invasive techniques. Only one skilled assistant is generally required for these procedures, but a second assistant may be used if available to provide retraction of tissues. The scrub technician is an integral part of the operative team and must be versed in the wide array of laparoscopic and robotic instruments that may be used to accomplish this procedure. **For RALP, it is important for the tableside assistant to have adequate training in basic laparoscopy and the mechanics, setup, and troubleshooting of the robotic system.** Typical operating room equipment and setup for RALP and LRP are shown in Figure 103–1.

Patient Positioning

After induction of general endotracheal anesthesia, the patient is placed in a supine position in steep Trendelenburg with arms tucked and padded at the sides. Sequential compression stocking devices are placed on both legs and activated. The patient's legs are spread apart and supported by spreader bars to allow for access to the rectum and perineum. Alternatively, the patient's legs may be placed in stirrups in the low lithotomy position. The patient is then secured to the table using tape and egg-crate padding. An orogastric tube and urethral catheter are placed to decompress the stomach and bladder, respectively.

Anesthesia Considerations

Both LRP and RALP require general anesthesia. Because the patient's arms are tucked at the side and difficult to access, establishing accurate pulse oximetry, blood pressure cuff placement, and intravenous access is critical before patient positioning. The anesthesiologist must be aware of the potential consequences of CO_2 insufflation and pneumoperitoneum including oliguria and hypercarbia. Prompt adjustments in minute and tidal volumes may be required by the anesthesiologist in the event of rising end-tidal CO_2 levels and hypercarbia (Meininger et al, 2004). Adjustments in CO_2 insufflation pressures may also be required by the surgeon to reduce the risk of continued hypercarbia. Taken together, maintaining good communication between the surgeon and the anesthesia team is important during these procedures.

SURGICAL TECHNIQUE

Robotic-Assisted versus Pure Laparoscopic Approach

Most of the principles and considerations for the surgical dissection are similar regardless of whether a pure laparoscopic or robotic-assisted approach is used. For RALP, the da Vinci Surgical System is a master/slave system with three components: surgical robot (also called the patient side cart), surgeon console, and video cart (Fig. 103–2). For the purpose of this chapter and for simplicity, the technique using the four-arm da Vinci S system is described. The robot is docked at the foot of the operating table between the patient's legs. The tableside assistant is responsible for docking/undocking the robot, suction-irrigation, retraction of tissues, passing sutures into the operative field, and robotic instrument changes. The surgeon is seated at the surgeon console, which provides a superb three-dimensional, 10× magnified, high-definition operative view and allows for the surgeon to have complete control of all camera movements and three additional robotic arms. The surgeon's thumb and index fingers are inserted into master controls that allow natural hand

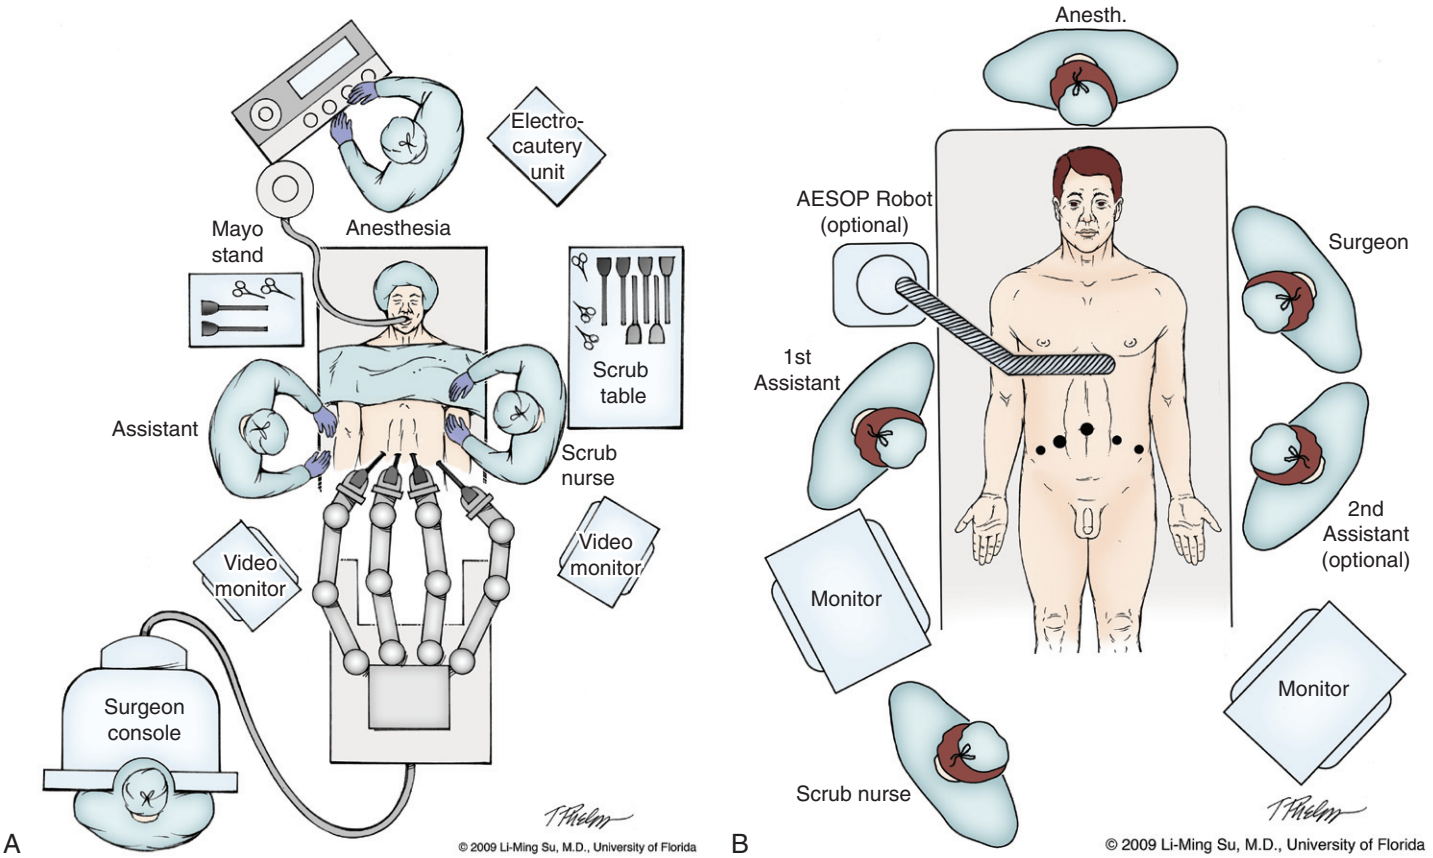

Figure 103–1. Operating room equipment and setup for robotic-assisted **(A)** and pure laparoscopic radical prostatectomy **(B)**. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Figure 103–2. Three components of the da Vinci S Surgical System (Copyright 2009, Intuitive Surgical, Inc.)—the surgeon console, patient side cart, and video cart.

and wrist movements to be precisely replicated by wristed instruments at the terminal ends of the robotic arms in real time.

Highly skilled laparoscopic surgeons may find the robotic technology unnecessary and discover that they are equally as facile with pure laparoscopic suturing and dissection as with the robot (Guillonneau, 2005). **Most surgeons, however, feel that the robotic technology significantly facilitates suturing of the vesicourethral anastomosis and aids in other aspects of the surgical dissection such as achieving the critical angles of dissection required to optimize cavernous nerve preservation.**

Other than setup of the operating room and surgical fields, there is little difference in the surgical technique between LRP and RALP. In general, the following discussion of technique and the pros and cons of various maneuvers and approaches apply to either surgical approach.

Transperitoneal Approach

The most common approach to LRP and RALP is the transperitoneal anterior approach in which following transperitoneal access and insufflation, the space of Retzius is immediately entered and the prostate gland, seminal vesicle, and vasa are approached and dissected from an anterior approach. This is in contrast to the transperitoneal retrovesical approach in which the seminal vesicles and vasa are initially approached and completely dissected behind the bladder near the cul-de-sac. The transperitoneal access and approaches are favored by most surgeons over the extraperitoneal approach due to the greater working space and familiar landmarks of the pelvis and its contents. For the purposes of this chapter, the transperitoneal anterior approach will be primarily described with brief mention about the extraperitoneal approach.

Abdominal Access, Insufflation, and Trocar Placement. For a transperitoneal approach, pneumoperitoneum is established using either a Veress needle inserted at the base of the umbilicus or an open Hasson technique. Following initial trocar placement, CO_2 insufflation pressure in general is maintained between 12 and 15 mm Hg. Secondary trocars are then placed under laparoscopic view. For RALP, an example of a trocar configuration is shown in Figure 103–3A. A 12-mm trocar is initially placed at or slightly above the umbilicus for insertion of the stereo endoscope. In a morbidly obese or very tall patient, infraumbilical camera placement may be preferable. Three 8-mm metal robotic trocars are used by the working robotic arms of the surgeon while the assistant provides retraction, suction, and irrigation and passes clips and sutures via the 12-mm and 5-mm trocars placed along the patient's right side. The surgeon controls camera movement by depressing a foot pedal and using brief, simultaneous arm movements to affect camera positioning and rotation. Endoscopes with either angled (30-degree) or straight-ahead (0-degree) viewing are available and interchangeable at various portions of the procedure. In general, most surgeons use the 0-degree endoscope lens throughout the operation; however, some surgeons prefer to switch to the 30-degree down lens when approaching the bladder neck, NVBs, and apical dissection. Figure 103–3B depicts the trocar configuration for LRP. The surgeon stands at the patient's left side and operates through the two pararectus trocars while one or two assistants use the lateralmost trocars. The endoscope is held and controlled by an AESOP robotic arm or surgical assistant through the umbilical trocar.

Extraperitoneal Approach. For an extraperitoneal approach, a 1.5-cm incision is made at the level of the umbilicus and dissection is carried out down through the anterior rectus sheath. Using blunt finger dissection, a space is created immediately anterior to the posterior rectus sheath and underlying peritoneum. A trocar-mounted balloon dilator device (PDB Balloon, Covidien Autosuture, Mansfield, MA) is inserted into the preperitoneal space anterior to the posterior rectus sheath and advanced down to the pubis along the midline. Using a 0-degree, 10-mm endoscope inserted through the balloon trocar, approximately 500 mL of air is inflated to develop the space of Retzius under laparoscopic view (Fig. 103–4). Secondary trocars are then inserted as described previously under laparoscopic view. The operation then proceeds in the exact manner to that of the transperitoneal anterior approach.

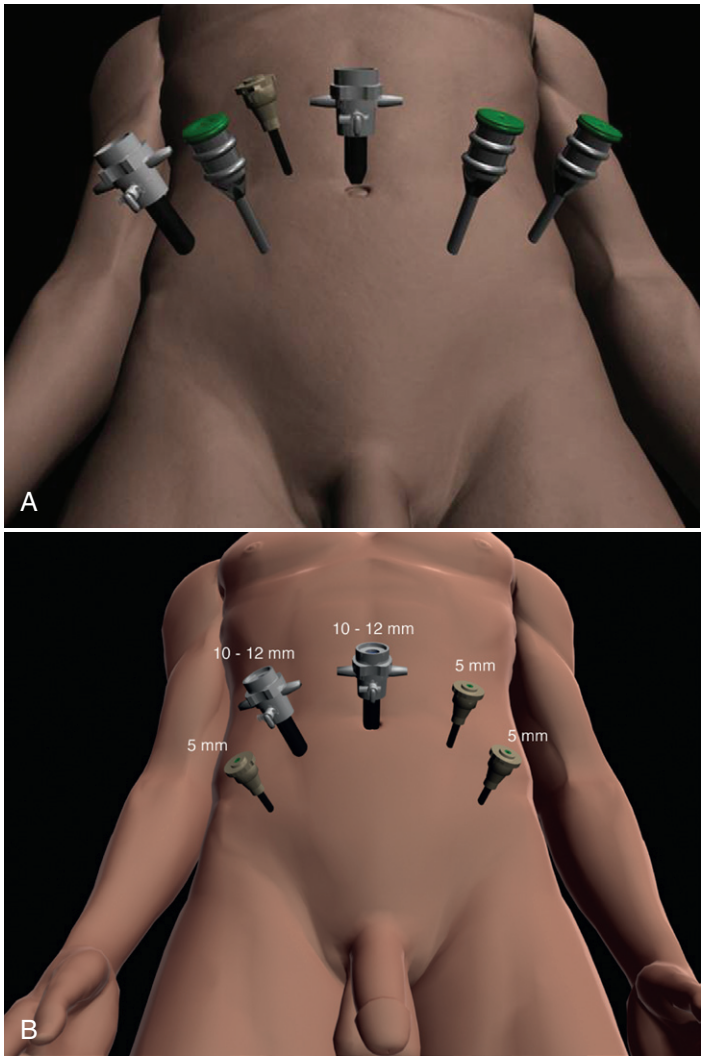

Figure 103–3. Trocar configuration for robotic-assisted laparoscopic prostatectomy **(A)** and laparoscopic radical prostatectomy **(B)**.

Pros and Cons of Extraperitoneal versus Transperitoneal Approach. In a retrospective comparison between extraperitoneal versus transperitoneal LRP, Hoznek and colleagues (2003) found that the mean operative time was shorter with the extraperitoneal approach (169.6 vs. 224.2 minutes, $P < .001$) with the greatest time saved during access to the space of Retzius. They suggested that time to full diet was less with the extraperitoneal versus the transperitoneal LRP approach (1.6 vs. 2.6 days, $P = .002$) because the peritoneum had not been violated and postoperative ileus was minimized. Eden and colleagues (2004) found a statistical significant advantage in operative time, hospital stay, and return of early

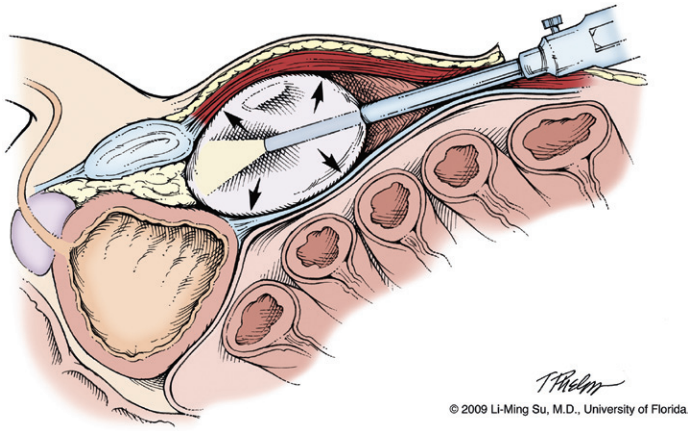

Figure 103–4. Creation of working space for extraperitoneal pure laparoscopic or robotic-assisted radical prostatectomy using a trocar-mounted balloon dilator device. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

continence favoring patients undergoing extraperitoneal versus transperitoneal LRP, postulating that earlier return to urinary control may be secondary to less bladder dissection and, perhaps, less bladder dysfunction as compared with transperitoneal LRP. **Most studies, however, have found little or no difference in operative time and perioperative outcomes between transperitoneal and extraperitoneal approaches** (Cathelineau et al, 2004a; Erdogru et al, 2004; Brown et al, 2005b; Atug et al, 2006).

With an extraperitoneal approach, the simultaneous laparoscopic management of concurrent inguinal hernias using prosthetic mesh is feasible (Stolzenburg et al, 2003). Simultaneous inguinal herniorrhaphy has also been reported during transperitoneal LRP (Allaf et al, 2003); however, proper coverage of the mesh prosthesis is necessary using peritoneal flaps, omentum, or a second absorbable mesh to reduce the risk of direct contact between the mesh and bowel with subsequent fistula. The extraperitoneal technique may be preferable in patients with previous extensive abdominal surgery or morbid obesity. **With the extraperitoneal approach, the peritoneum acts as a natural barrier, minimizing the potential for bowel injury and preventing the bowels from falling into the operative field and obscuring the surgeon's view. Furthermore, this approach helps to confine any urine leak that may occur from the vesicourethral anastomosis within the extraperitoneal space. One limitation with the extraperitoneal approach is the reduced working space as compared with the relatively larger working space of the peritoneal cavity gained with transperitoneal access.** This is especially relevant when a well-meaning assistant attempts to clear the operative field of blood or smoke. Suctioning can evacuate CO_2 gas and rapidly collapse the already limited extraperitoneal working space, thus significantly compromising visualization. A second limitation to the extraperitoneal approach is in patients with a prior history of laparoscopic extraperitoneal mesh herniorrhaphy because the retropubic space is often obliterated, making attempts at extraperitoneal access challenging. Lastly, higher CO_2 absorption has been reported with extraperitoneal versus transperitoneal insufflation, requiring a higher minute volume to compensate for hypercarbia and associated acidosis (Meininger et al, 2004). **Overall, whether to use an extraperitoneal or transperitoneal approach for LRP or RALP is largely a matter of surgeon preference and experience and there is no consistently demonstrated advantage for either approach.**

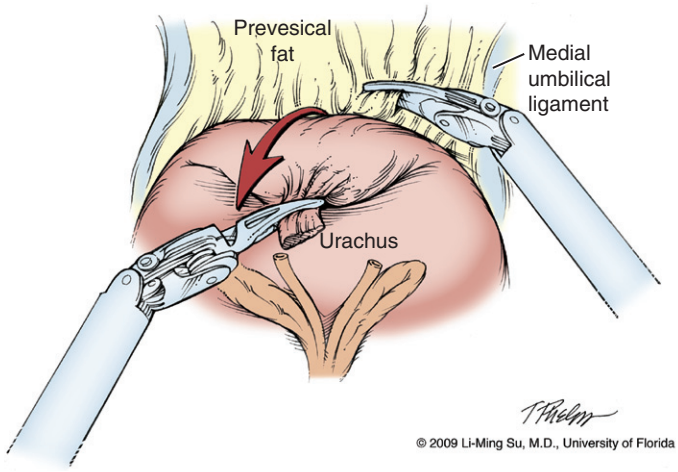

Figure 103–6. Division of urachus and entry into the space of Retzius. Cephalad traction on the urachus with the left hand helps to identify the fatty alveolar tissue immediately anterior to the bladder, which marks the proper plane of dissection. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Developing the Space of Retzius. Following abdominal access and trocar placement for the transperitoneal anterior approach, the pelvic contents are inspected (Fig. 103–5) and adhesions are lysed if present. The initial step is entry and development of the space of Retzius. The bladder is dissected from the anterior abdominal wall by dividing the urachus high above the bladder and incising the peritoneum bilaterally immediately lateral to the medial umbilical ligaments using monopolar electrocautery. The presence of prevesical fatty alveolar tissue confirms the proper plane of dissection. Applying posterior and cephalad traction on the urachus, the retropubic space is rapidly developed with a combination of blunt and sharp dissection along the relatively avascular plane within the space of Retzius (Fig. 103–6). **Lateral dissection of the bladder is carried out down toward the crossing of the median umbilical ligament and vas deferens in order to ensure optimal mobility of the bladder**

and to minimize future tension at the vesicourethral anastomosis. The fat overlying the prostate is removed using sharp dissection and electrocautery as needed, and the superficial branches of the DVC coagulated using bipolar electrocautery.

At this point, visible landmarks include the anterior aspect of the bladder and prostate, puboprostatic ligaments, endopelvic fascia, and pubis (Fig. 103–7). The endopelvic fascia and puboprostatic ligaments are sharply divided, exposing levator muscle fibers attached to the lateral and apical portions of the prostate. These fibers are meticulously and bluntly dissected from the surface of the prostate exposing the deep DVC and urethra at their confluence with the apex of the prostate. Electrocautery is avoided if possible to minimize thermal damage to the external sphincter and nearby NVBs.

Accessory pudendal arteries traveling longitudinally along the anteromedial aspect of the prostate are easily recognized during LRP and RALP. Attempt at preservation of these arteries is important for erectile function because in some men these arteries may be the dominant source of arterial blood supply to the corpora cavernosa (Nehra et al, 2008). These accessory arteries can usually be preserved, although separation of the artery from the prostatic apex can be somewhat challenging. Most commonly, though, careful and meticulous dissection allows enough mobilization of the artery away from the deep DVC and prostatic apex that both good anatomic dissection of the prostatic apex and preservation of the accessory vessel are feasible.

Ligation of the Deep Dorsal Venous Complex. As with open surgery, different methods have been described for control of the DVC. **A common observation, though, is that the profuse bleeding, which is sometimes encountered during open surgery, is not usually problematic because of the tamponade effect on venous bleeding offered by the pneumoperitoneum.** In fact, some techniques involve simple cutting of the DVC with or without the use of electrocautery and placement of a suture only if necessary. Typically, there are one or two small arteries in the DVC. Most described techniques use placement of an absorbable suture for hemostasis before initiation of the surgical dissection of the prostate. During RALP, the Pro-Grasp forceps can be used for fixed cephalad retraction of the prostate and bladder to achieve optimal exposure of the DVC and prostatic apex before DVC ligation. Similar retraction can be applied by the surgical assistant during LRP. The deep DVC is suture ligated using a 0-polydioxanone suture or polyglactin suture as close to the pubis and as far from the prostatic apex as possible (Fig. 103–8). **Securing the DVC as far away from the prostatic apex as possible can help minimize iatrogenic entry into the prostatic apex during later division of the DVC.** The needle is passed beneath the DVC and anterior to the urethra. An alternative method to DVC ligation is the use a laparoscopic linear stapling device, which ligates and divides the DVC all in one step (Ahlering et al, 2004b; Nguyen et al, 2008). Regardless of the method used, it is important to avoid damage to the anterior urethral sphincter muscle from placing the sutures or staples too deep. With most techniques, the DVC is not divided until later in the operation and immediately before prostatic apical dissection and division of the urethra. A back-bleeding suture may be placed along the anterior base of the prostate to help identify the contour of the prostate and to aid in subsequent bladder neck identification and transection.

Bladder Neck Identification and Transection. Proper identification of the bladder neck during RALP and LRP can be initially challenging due to the lack of tactile feedback in delineating the precise margin between the prostate and bladder. **Several maneuvers are helpful in identifying the proper plane of dissection and in minimizing inadvertent entry into the prostate. First, visual identification of the point of transition of the prevesical fat to the anterior prostate can serve as a guide. Second, intermittent and repetitive**

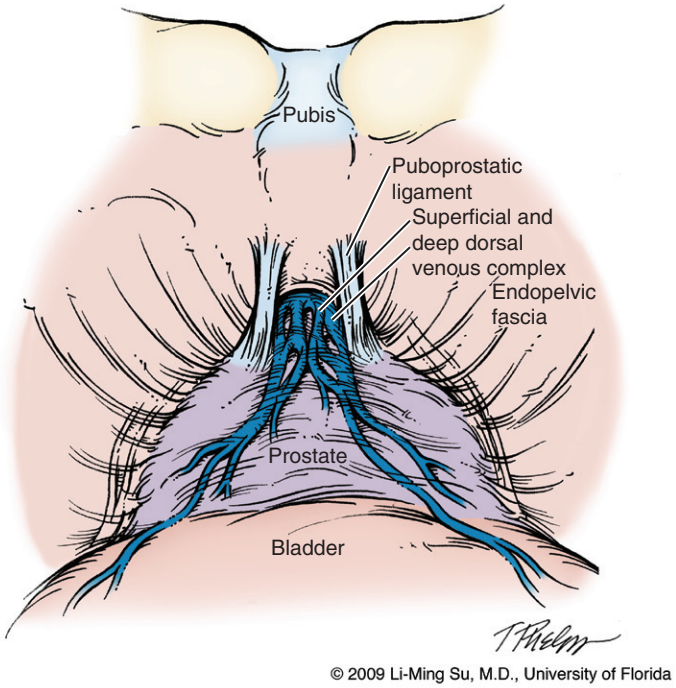

Figure 103–7. Retropubic view of the bladder and prostate following entry into the space of Retzius. The fatty tissue overlying the anterior aspect of the prostate has been removed, exposing the puboprostatic ligaments, superficial and deep dorsal venous complex, and endopelvic fascia. caudal retraction of the urethral catheter balloon can help identify and confirm the transition between bladder neck and prostate. Third, using a forceps to grasp and retract the dome of the bladder in a cephalad direction results in "tenting" of the bladder neck at its attachment to the prostate. Lastly, further confirmation of this margin between the bladder and prostate is made by a bimanual "palpation" or "pinch" of the bladder neck using the tips of two robotic or laparoscopic instruments.

The anterior bladder is divided horizontally using monopolar electrocautery along the midline until the urethral catheter is identified. **The anterior bladder neck incision should not be carried too laterally because branches of the bladder pedicle are often encountered, resulting in unwanted bleeding.** The balloon is decompressed, and the tip of the urethral catheter is brought through the anterior bladder neck opening and lifted anteriorly with the assistant applying counter traction externally at the penile meatus to suspend the prostate.

The posterior bladder neck is inspected for the presence of a median lobe and to locate the ureteral orifices. If a vertical drop-off of the posterior bladder neck mucosa is noted, this would suggest the absence of a median lobe. Alternatively, if a mass effect from a large median lobe is identified, further exposure may be required to visualize beneath the protruding median lobe and identify the posterior bladder neck. The median lobe is lifted anteriorly using either the ProGrasp forceps or the surgical assistant. **The posterior bladder neck is horizontally divided with monopolar electrocautery, staying along the midline to avoid bleeding from the lateral pedicles** (Fig. 103–9). **Dissection is carried out in a 45-degree downward angle to avoid entry into the base of the prostate, as well as creating a buttonhole in the posterior wall of the bladder.** In case of a prior TURP, the bladder neck margin is less evident and often distorted as a result of prior resection and scarring. Careful inspection is made of the posterior bladder neck paying specific attention to the location of the ureteral orifices because they are often found close to the posterior bladder neck margin. Attempt at bladder neck sparing should be avoided in post-TURP and median lobe cases. When in doubt, the posterior bladder neck should be divided slightly more proximally in these particular cases so as to avoid inadvertent entry into the prostate gland.

Dissection of the Seminal Vesicles and Vasa Deferentia. Following bladder neck transection, the seminal vesicles and vasa deferentia are individually identified, dissected, and divided, avoiding electrocautery if possible to prevent damage to the nearby NVB (Fig. 103–10). One unique distinction between the transperitoneal anterior and retrovesical approach is in dissection of the seminal vesicles and vasa deferentia. During a transperitoneal retrovesical approach, the initial step of the operation is complete dissection of the vasa deferentia and seminal vesicles deep within the cul-de-sac. Following abdominal access, the vasa are dissected from lateral to medial toward their confluence at the ejaculatory ducts. The seminal vesicles are found immediately lateral to the vasa and are dissected free from the nearby NVB using hemoclips while avoiding the use of thermal energy (Fig. 103–11). With the dissection of the seminal vesicles and vasa now completed, once the bladder neck is divided from the prostate, these structures are simply grasped and brought through the opening. **This retrovesical approach to the seminal vesicles and vasa deferentia is particularly useful in cases of a median lobe where identification and dissection of these structures by the anterior approach may be more challenging due to the protruding median lobe.**

Development of the Plane between the Prostate and Rectum. Separation of the posterior prostate from the anterior rectal wall is a key surgical maneuver to avoid rectal injury but also to permit adequate identification of the prostatic pedicles and establish the medial border of the NVB. Development of this plane in an antegrade fashion is a

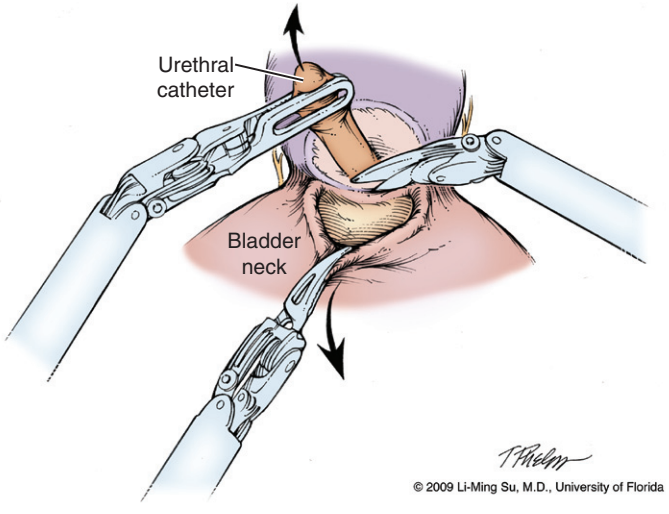

Figure 103–9. Division of the posterior bladder neck. An assistant or ProGrasp forceps is used to grasp and elevate the urethral catheter anteriorly, providing exposure to the posterior bladder neck. Dissection is carried out along the midline, avoiding bleeding from the lateral pedicles. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

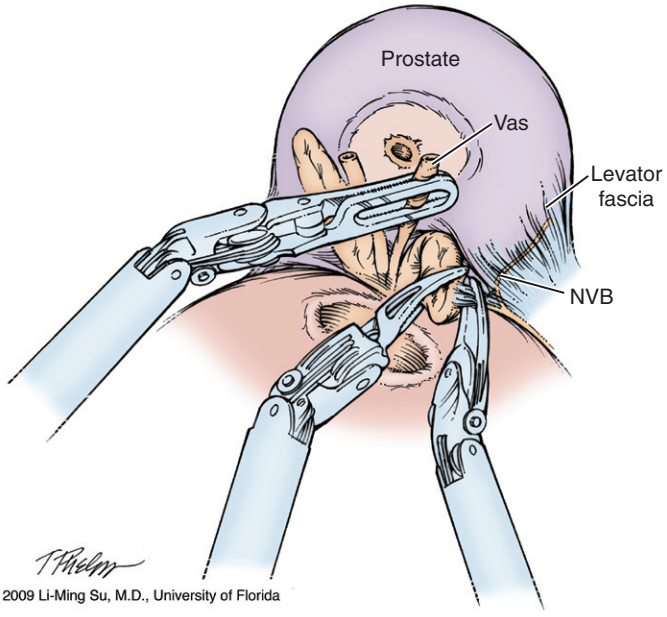

Figure 103–10. Dissection of seminal vesicles and vasa deferentia via the transperitoneal anterior approach. The seminal vesicles and vasa are identified and dissected within the opening created between the posterior bladder neck and prostate following division of the bladder neck. Hemoclips are used in lieu of electrocautery to avoid thermal injury to the nearby neurovascular bundles (NVB). (Copyright Li-Ming Su, MD, University of Florida, 2009.)

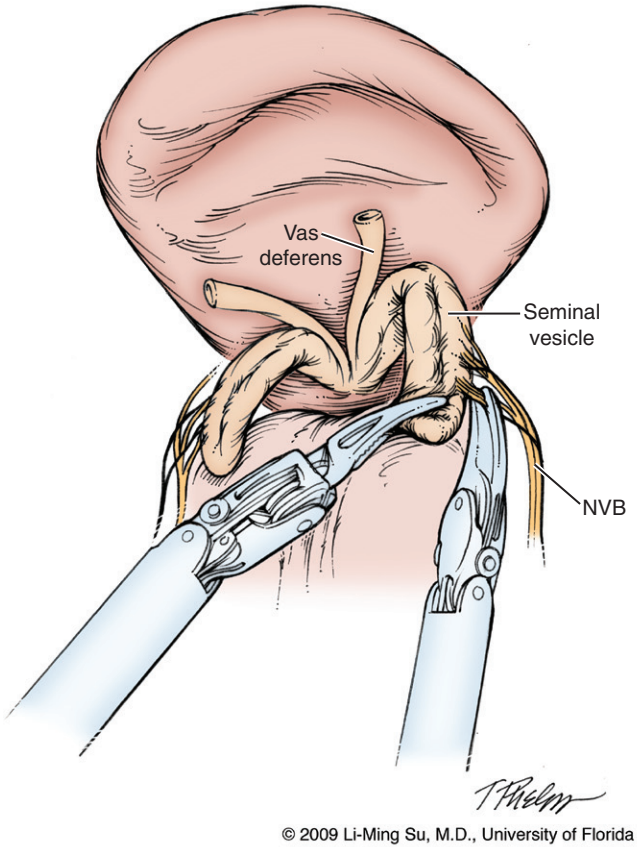

Figure 103–11. Dissection of the seminal vesicles and vasa deferentia via the transperitoneal retrovesical approach. The vasa and seminal vesicles are identified as the initial step in this approach deep within the retrovesical space. The neurovascular bundles (NVB) are dissected off of the seminal vesicles in an antegrade direction from the tip toward the base using hemoclips. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

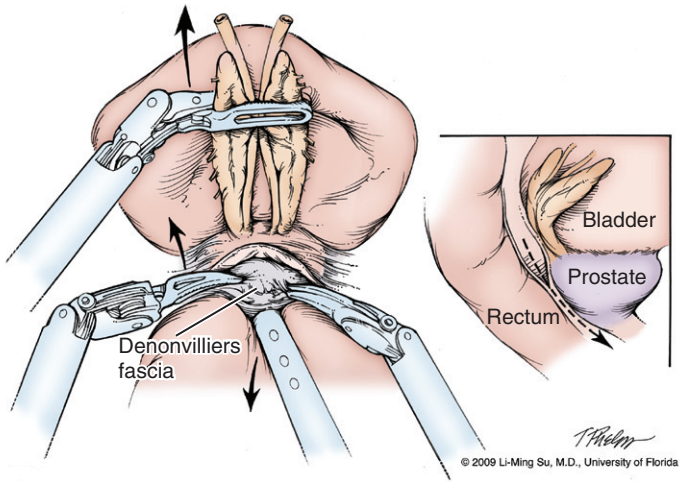

Figure 103–12. Development of the plane between the prostate and rectum. As the assistant or ProGrasp forceps is used to apply anterior traction on the seminal vesicles and vasa deferentia and downward traction on the rectum, a transverse incision is made in Denonvilliers fascia below the seminal vesicles, and blunt dissection is used to develop a plane between the posterior prostate and the rectum. Inset demonstrates the direction of dissection toward the prostatic apex. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

maneuver often unfamiliar to surgeons experienced with open surgery but one that is rapidly adaptable to laparoscopic and robotic approaches. Anterior retraction of the vasa deferentia and seminal vesicles by either a surgical assistant or the robotic ProGrasp forceps helps with identification of the proper plane for the initial dissection (Fig. 103–12).

Denonvilliers fascia is an inferior extension of the peritoneal cul-de-sac that lies between the prostate and rectum. With an intrafascial or interfascial dissection, Denonvilliers fascia can be separated from the posterior prostate by careful blunt and sharp dissection. The separation can be carried all the way to the prostatic apex and laterally to the prostatic pedicle. The proper surgical plane is relatively avascular. **When a wider margin of tissue is desired on the posterior prostate such as in cases of palpable disease, Denonvilliers fascia should be sharply incised just posterior to the junction of the seminal vesicle and the prostate. This allows immediate entry into the anterior perirectal fat plane of dissection. Good visualization can be achieved as the dissection proceeds distally toward the apex staying between Denonvilliers fascia anteriorly and the anterior propria fascia of the rectum posteriorly.**

Substantial bleeding typically suggests that the dissection may be too close to the prostate. If difficulty is encountered in establishing the proper plane of dissection, a new attempt can be directed to one side or the other of the initial entry point. Once the proper plane is entered, the dissection characteristically progresses rather smoothly. The rectal wall should be mobilized far enough laterally that there is sufficient separation for dissection of the NVB and prostatic apex.

Prostatic Pedicle Control. Various methods have been described for control of the prostatic pedicle. Some techniques use pure electrocautery, either monopolar or bipolar. **Because of the propagation of thermal energy through tissue, which may result in damage to the nearby NVB, limitation of the use of electrocautery is advised even in the prostatic pedicle.** Locking polymer Hem-o-Lok clips (Teleflex Medical, Research Triangle Park, NC) are commonly employed, but engagement of the clipping mechanism does require good delineation and thinning of the pedicle tissue so that the clipping mechanism will engage. This is best facilitated by adequate mobilization of the rectum and lateral prostate for identification of the prostatic pedicle. Application of a bulldog clamp to the pedicle with subsequent suturing after the specimen has been removed has also been described (Ahlering et al, 2005; Gill et al, 2005). Regardless of the method used, though, successful division of the prostatic pedicle in the correct anatomic location is an important step in avoiding positive margins and damage to the nearby NVB.

Preservation of the Neurovascular Bundle. Preservation of the periprostatic parasympathetic nerve fibers important for erectile function is one of the key and most difficult maneuvers during radical prostatectomy, regardless of surgical approach. **Increasingly, it is recognized that the periprostatic nerves of significance have a more diffuse and highly variable course than previously believed** (Costello et al, 2004; Takenaka et al, 2004; Lunacek et al, 2005), **but there is a confluence of nerves along the posterolateral prostate commonly termed the NVB.** Nerve tissue extends posteriorly around the prostate, forming a virtual hammock of nerves. In addition, nerve fibers can be identified in the periprostatic tissue along the more anterior portion of the prostate gland, although there is still debate about their relative contribution to erectile function. A well-performed, nerve-sparing radical prostatectomy

takes all of these considerations into account and preserves as much periprostatic nerve tissue as possible.

The superb visualization of the periprostatic tissues with laparoscopic surgery has led to a greater appreciation of the periprostatic fascial layers. Although there is some confusion in the literature regarding the terminology used for the various fascial layers, an extra fascial dissection typically implies dissection laterally between the lateral prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the anterior propria rectal fascia. **An interfascial dissection is carried out laterally between the prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the posterior prostate** (Fig. 103–13). **This is the preferred approach in patients with presumed organ-confined disease because it permits safe preservation of the cavernous nerves without violating the anatomic limits of the prostate gland and capsule.** An intrafascial dissection is between the prostatic capsule and the prostatic fascia and leaves virtually no periprostatic tissue overlying the prostate. Although technically feasible, this approach may lead to a higher incidence of positive margins due to the relatively closer dissection to the prostate gland. Even though these fascial layers as described do have some true integrity for intraoperative identification, it is also well recognized that they can be multilayered.

Damage to the NVB can occur because of direct incision, entrapment in a suture or clip, thermal injury, or traction. Some surgeons advocate release of the NVB from the prostate before mobilization of the specimen to help avoid traction injury. **With the antegrade approach typically used for LRP and RALP, identification and at least partial release of the NVB along the lateral aspect of the prostate before controlling the prostatic pedicle can help drop the nerve tissue away from the gland and permit a more precise placement of sutures, hemoclips, or clamps on the pedicle while preventing inadvertent entrapment of the nerve bundles.** To accomplish this, the levator fascia is first incised sharply along the anteromedial aspect of the midprostate entering into the interfascial plane of dissection (Fig. 103–14). Blunt dissection is carried out along the prostatic fascia in a posterolateral direction, thus partially releasing the lateral NVB and developing a visible NVB groove, which aids in precise hemoclip placement and division of the prostatic pedicle (Fig. 103–15). The ergonomics and scaled motion of the wristed robotic instruments are helpful in achieving this delicate dissection. During LRP, specially designed fine-tipped (0.8-mm) dissectors have been described to aid in NVB dissection and preservation (Su et al, 2004). Some discussion and debate has centered around how far anteriorly on the prostate the interfascial dissection of the nerve bundles should be performed. Whether high release (vs. standard

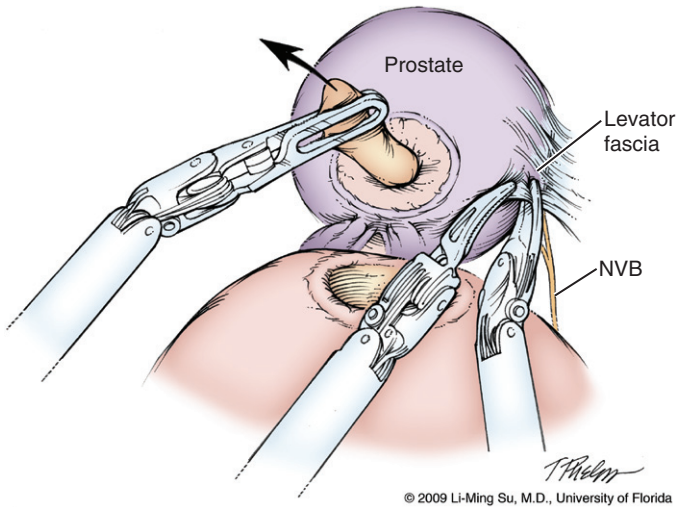

Figure 103–14. Entering into the interfascial plane of dissection for neurovascular bundle (NVB) preservation. The levator fascia is first incised along the anteromedial aspect of the midprostate, allowing entry into the interfascial plane of dissection. Figure 103–13. Cross section of the prostate demonstrating the periprostatic fascial planes with respect to the location of the neurovascular bundles. The *dashed line* indicates the direction of interfascial dissection (i.e., between the levator and prostatic fascia) to accomplish a high anterior release of the neurovascular bundle from the prostate and establish the lateral neurovascular bundle groove. The *solid line* indicates the incision made for a standard release of the neurovascular bundle. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

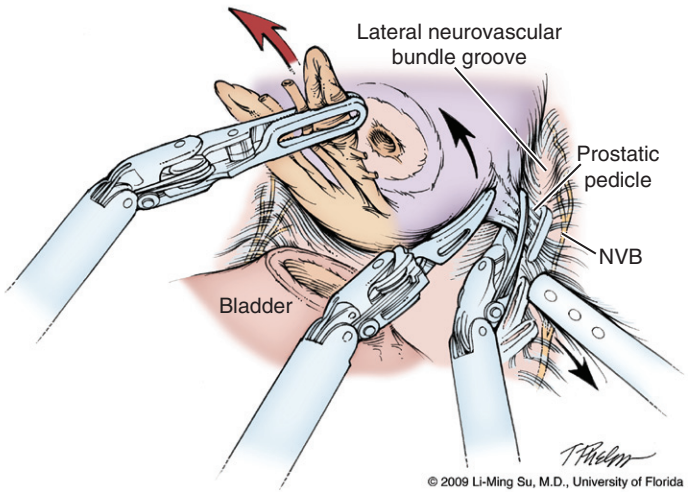

Figure 103–15. Developing the interfascial plane of dissection. Using blunt dissection, the nerve bundle is partially released from the prostate in a posterolateral direction, forming a visible lateral neurovascular bundle groove. This step serves to delineate the prostatic pedicle and course of the nerve bundle and allow for precise placement of hemoclips, while avoiding nerve entrapment. NVB, neurovascular bundle. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

release) preserves important nerves or simply allows for a physical handle to permit more precise, meticulous dissection and preservation of the true cavernous nerves located at the 5- and 7-o'clock positions without direct manipulation of these main nerve fibers is uncertain (see Fig. 103–13). **However, there is a general consensus that thermal energy should be minimized and, ideally, completely avoided during dissection of the NVB. These microscopic postganglionic parasympathetic nerve fibers are highly susceptible to thermal injury as shown in both animal and human studies** (Ong et al, 2004; Ahlering et al, 2005). Bleeding along the NVB is usually relatively minimal and may require no specific hemostatic measures. There may be small arteries or larger veins that require suturing with small tissue bites to avoid entrapment of adjacent nerves. Overdissection of the NVB at the prostatic apex should be avoided.

Patients with extremely large prostate glands (especially those > 100 g) offer a unique challenge during preservation of the NVB. Maneuvering a large prostate gland in the tight confines of the bony pelvis can be challenging, especially during exposure of the prostatic pedicles and NVB. Effective exposure of tissues by the surgical assistant, as well as the fourth robotic arm, is critical and can optimize visualization during prostatic pedicle ligation and NVB preservation.

Apical Dissection. **The prostatic apex is a common location for tumor involvement and the most common site of positive margins with radical prostatectomy.** Further, the steps required for apical dissection are crucial to preservation of erectile function and avoidance of urinary incontinence. The visualization of the operative field and the ability to limit bleeding from the DVC facilitate apical prostatic dissection during LRP and RALP.

Up to this point in the operation, antegrade dissection has permitted complete mobilization of the lateral, base, and posterior prostate, leaving division of the DVC and urethra from the prostatic apex for last. **It is critical to avoid entry into the anterior prostate during division of the DVC because this may result in an iatrogenic positive margin.** Although the previously placed DVC stitch may become dislodged or divided during this step, further sutures to secure the DVC can be easily placed. Also, bleeding from the DVC during attempts at resuturing can be kept to a minimum by transiently increasing the CO_2 insufflation pressure to 20 mm Hg to improve the tamponade effect on venous bleeding. Once the DVC is divided, there should be good visualization of the prostatic apex and its junction with the urethra (Fig. 103–16). **The anatomy of the prostatic apex is variable and should be carefully inspected before division of the urethra. As much urethral length as possible should be maintained, but an overlying anterior lip of prostate must be recognized, as well as posterior extension of prostatic tissue beneath the urethra.** Nevertheless, leaving a small rim of urethra along the prostatic apex may be advisable to reduce the incidence of apical positive margins because this does not appear to have an adverse effect on the return of urinary continence (Borin et al, 2007). Sharp dissection with limited use of electrocautery is preferred during the prostatic apical dissection and division of the urethra so as to prevent thermal injury to the external striated sphincter and nearby NVBs.

Intraoperative Inspection of Prostate. **Upon completely freeing the prostate gland and before entrapment of the specimen, the entire surface of the gland can be inspected laparoscopically to assess the adequacy of resection and integrity of the tissues covering the prostate specimen.** If concern exists regarding a close surgical margin, additional tissue may be excised specific to the location of concern; however, with experience this should rarely be necessary.

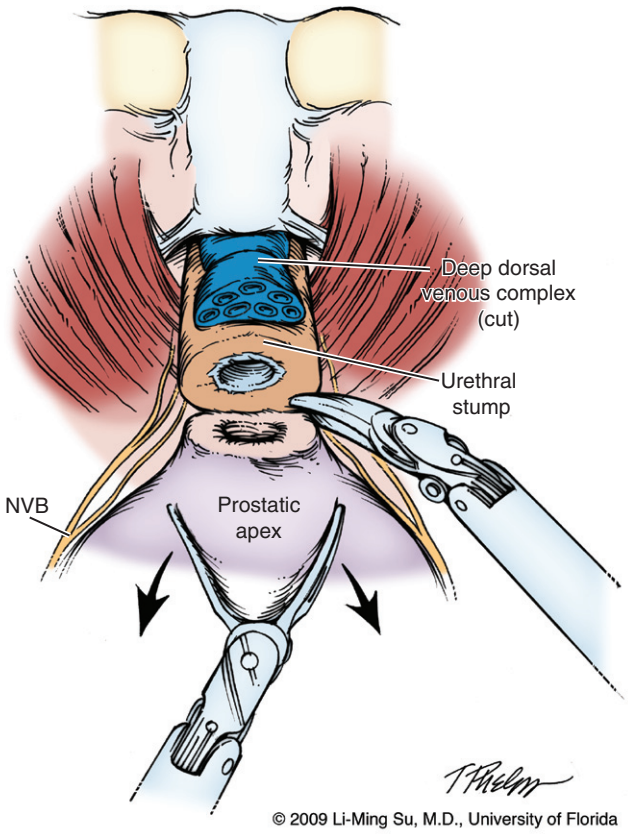

Figure 103–16. Division of urethra. Following division of the deep dorsal venous complex, the anterior and posterior urethra is divided sharply without electrocautery. A small rim of urethra may be safely left on the prostate apex to avoid an iatrogenic positive apical margin. Great care must be taken to avoid damage to the nearby nerve bundles. NVB, neurovascular bundle. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Pelvic Lymphadenectomy. It is generally at this time that pelvic lymphadenectomy takes place because prior mobilization of the bladder allows for excellent exposure of the obturator lymph node region. The extent of pelvic lymphadenectomy remains controversial but can be tailored on the basis of patient-specific risk factors including prostate-specific antigen (PSA), clinical stage, and Gleason score. Technical description of laparoscopic pelvic lymphadenectomy follows later in this chapter.

Entrapment of Specimens. The prostate and pelvic lymph nodes are entrapped within a laparoscopic entrapment sack introduced into the abdomen by the surgical assistant through the 12-mm assistant trocar and stored in the abdomen until completion of the vesicourethral anastomosis.

Bladder Neck Reconstruction. The bladder opening is often slightly larger than the urethral lumen, but a parachuting effect can be achieved during the vesicourethral anastomosis that allows direct approximation of the bladder neck to the urethra. If the bladder neck opening is considerably larger than the urethra, a tennis racquet handle closure can be performed using absorbable suture either posteriorly or anteriorly to allow a better size match with the urethra. **In the event of a large prostate gland, median lobe, or prior TURP, the bladder neck may often be disproportionately larger than the urethra and thus may require extensive reconstruction before performing**

the vesicourethral anastomosis. Often, in these circumstances, the ureteral orifices are located at or near the posterior margin of the bladder neck where they are at risk of injury or obstruction during suturing of the anastomosis. In such cases the ureteral orifices can be imbricated by placing a few interrupted sutures at the 5- and 7-o'clock position along the posterior bladder neck using 3-0 polyglactin or polydioxanone suture. This maneuver can help avoid inadvertent sutures passing through or near the ureteral orifices during the anastomosis while at the same time reduce the size of the bladder neck opening.

Posterior Support of the Vesicourethral Anastomosis. As a result of prostatectomy the posterior supportive layers of the bladder and prostate are divided, including the Denonvilliers fascia and its confluence with the posterior rhabdosphincter. Recent reports of attempts at reconstruction of these posterior supportive structures have suggested improvement in earlier postoperative return of urinary control (Rocco et al, 2007), whereas others have found no significant benefit (Menon et al, 2008). Reconstituting the posterior support to the anastomosis is accomplished by reapproximating the remnant Denonvilliers fascia and posterior bladder neck to the posterior rhabdosphincter beneath the urethra using a running continuous 2-0 poliglecaprone (Monocryl) suture before completion of the vesicourethral anastomosis (Fig. 103–17). Although the exact mechanism remains unclear, suggested mechanisms include re-establishment of the posterior anatomic support to the bladder and urethra improving urethral coaptation during voiding, reduced tension at the vesicourethral anastomosis, and increase in the functional length of the striated urethral sphincteric complex. **Despite the ongoing debate on its effectiveness, many believe that this step at the very least reduces the distance between the bladder neck and urethra, thus facilitating completion of a tension-free vesicourethral anastomosis.** Resuspension of the anastomosis and distal bladder neck to the arcus tendineus is used by some to restore anterior urethral support and preserve the vesicourethral angle (Tewari et al, 2007).

Vesicourethral Anastomosis. With LRP, the vesicourethral anastomosis is one of the most difficult aspects of the procedure due to the challenges of performing laparoscopic suturing. The da Vinci surgical robot greatly facilitates suturing of the anastomosis due to the ergonomics of the wristed robotic instrumentation. Although interrupted sutures may be used for the anastomosis, van Velthoven and colleagues (2003) described a running suture technique, which distributes tension broadly across multiple points along the bladder and urethra. Typically, two separate sutures are tied together at their ends, each 6 to 8 inches in length. The anastomosis between the bladder and urethra begins posteriorly, leaving two needles to run progressively in an anterior direction on either side, finally ending at a single anterior tie. **Dedicated mucosal eversion sutures at the bladder neck, commonly used during radical retropubic prostatectomy (RRP), are seemingly unnecessary with the excellent running mucosa-to-mucosa anastomosis achieved with LRP and RALP.** Multiple sutures are first placed through the urethra and bladder before progressive cinching of the anastomosis by lifting each arm of the suture in an anterior direction (Fig. 103–18). Either an assistant or the robotic ProGrasp forceps can be used to grasp one arm of the suture to maintain tension and approximation of the posterior anastomosis while the surgeon reapproximates the contralateral side of the anastomosis using the second suture. The final urethral catheter is passed under direct vision immediately before completion of the anastomosis and the bladder is irrigated to make certain that there are no anastomotic leaks. Further sutures may be required if a leak is identified.

Delivery of the Specimens and Exiting the Abdomen. Prior to undocking the robot and removal of the specimens, the pelvis and operative field should be carefully reinspected for bleeding under low insufflation pressure (<10 mm Hg). The bowel should be examined closely to make certain that there is no injury resulting from instrument exchanges. The string for the laparoscopic entrapment sack is

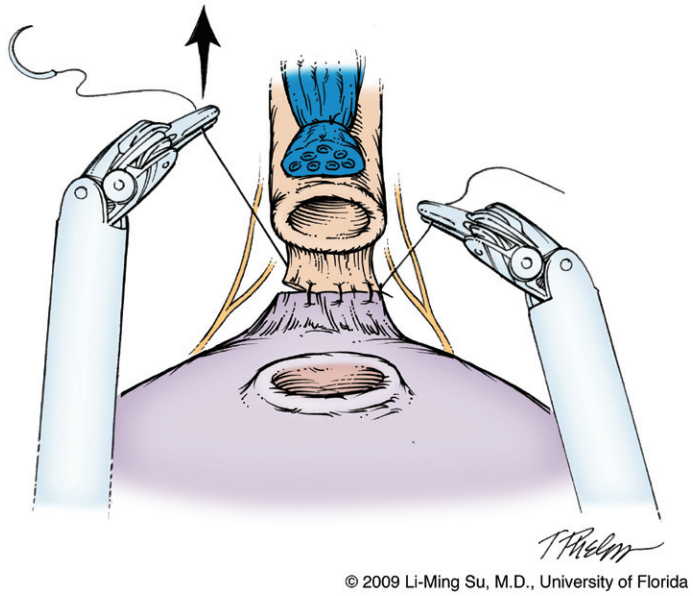

Figure 103–17. Modified Rocco stitch. Posterior support is provided to the vesicourethral anastomosis by reapproximating the remnant Denonvilliers fascia and posterior detrusor along the posterior bladder neck to the posterior rhabdosphincter using a running continuous 2-0 Monocryl suture. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

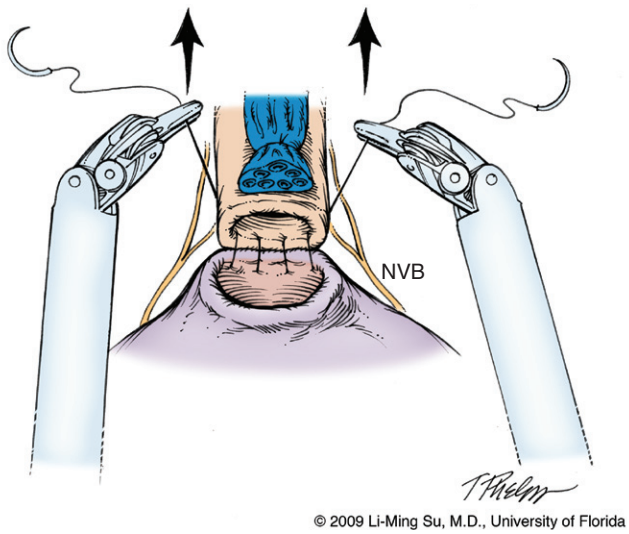

Figure 103–18. Running vesicourethral anastomosis. The posterior anastomosis is reapproximated after preplacing two to three sutures on either side and cinching the sutures by lifting anteriorly. Great care must be taken to avoid incorporating the neurovascular bundles (NVB) when placing sutures within the urethra. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

transferred to the camera port site at the umbilicus and the abdomen is completely desufflated. The specimens within the laparoscopic entrapment sack are extracted intact through extension of the periumbilical trocar site. The fascial defect is then closed by open suture placement, and the skin defects are closed with a subcuticular absorbable suture or a skin adhesive. Closure of the fascial defect for the 5-mm trocar sites is generally not necessary. Due to the potential risk of a trocar site hernia, it is advisable to close the 12-mm trocar sites with a Carter Thomason fascial closure device, especially if a bladed (vs. dilating) trocar is used.

POSTOPERATIVE MANAGEMENT

With the secure and watertight running anastomosis typically achieved, a pelvic drain may not always be necessary. However, a drain may be placed through one of the 8-mm robotic trocar sites and does not require a separate stab wound. The drain may evacuate an unanticipated urine leak or lymphatic fluid collection. Often, though, drainage is minimal and the drain typically can be removed on the first postoperative day. Parenteral narcotic medications may be required for the first 24 hours following surgery but should be used sparingly. Instead, ketorolac may be used in select patients for postoperative pain control.

The duration of time required for the urethral catheter depends to a great extent on the preferred approach of the surgeon, as well as the extent of bladder neck reconstruction. The 2-week period commonly used with open surgery is in general unnecessary if a good running anastomosis is achieved. With 1 week or more of an indwelling urethral catheter, the vast majority of patients are able to void adequately with minimal risk of urinary retention and need for catheter replacement. Performing a cystogram before removal of the catheter is based on surgeon preference. If catheter removal before a week is planned, it may be advisable to obtain a cystogram to ensure that there is no extravasation from the anastomotic site. In cases of a leak, longer duration of the urethral catheter is required to allow for spontaneous healing. Although this may prolong the time to achieve urinary continence, long-term urinary outcomes do not appear to be affected (Patil et al, 2009). Some surgeons are exploring an approach that uses suprapubic catheter drainage of the bladder with a specially designed anastomotic splint rather than a urethral catheter with good initial results (Tewari et al, 2008a).

Even with LRP and RALP, some degree of postoperative ileus occurs. Most patients can tolerate a regular diet within 24 hours of surgery, and hospitalization beyond the first postoperative day is not typically necessary. Patients can characteristically return to their preoperative activities shortly after catheter removal but must avoid strenuous activity.

Key Points: Technique of Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

- Use of a transperitoneal or extraperitoneal approach is based primarily on surgeon preference because there is no demonstrable advantage to either approach.
- The robotic technology facilitates suturing and dissection for surgeons who do not have advanced laparoscopic skills.
- Identification of the precise margin between the bladder neck and prostate can be accomplished by using a set of physical and visual cues.
- Following division of the anterior bladder neck, the presence or absence of a median lobe should be defined before division of the posterior bladder neck.
- Complete mobilization of the plane between the posterior prostate and rectum is an important step in avoiding rectal injury and defining the medial aspect of the neurovascular bundle.
- Use of thermal energy should be minimized during control of the prostatic pedicles and dissection near the neurovascular bundles because thermal energy has been shown to be deleterious to cavernous nerve function in both animal and human studies.
- An interfascial dissection of the neurovascular bundle is preferred in patients with presumed organ-confined cancer.
- An anterior or posterior protruding lip of prostate should be anticipated when dividing the prostatic apex from the urethra so as to avoid an iatrogenic apical positive margin.
- Bladder neck reconstruction may be required if there is a size discrepancy between the bladder neck and urethra, especially in patients with prior TURP, median lobe, or large prostate gland.
- The vesicourethral anastomosis is best accomplished with a running continuous suture.

RESULTS

Published results continue to emerge with regards to midterm outcomes of LRP and RALP both in the United States and abroad, suggesting comparable outcomes with RRP. Most of these reports, however, are case series. No randomized trials have been conducted evaluating laparoscopic and robotic versus open techniques, and retrospective comparisons are limited by disparities in surgeon experience, the influence of patient selection, and nonstandardized methods of outcome assessment.

Perioperative Outcomes

Operative Time. The duration of surgery is typically longer with LRP or RALP compared with open surgery, especially early in the surgeon's experience. In fact, operating times are often used as a surrogate for assessing the "learning curve" with laparoscopic prostatectomy (Herrell and Smith, 2005). As both surgeon and operating team experience is gained, virtually all reported series have documented a substantial decrease in operative times that approach and in some series surpass those for open surgical techniques. At experienced centers of excellence with LRP, operative times less than 3 to 4 hours are common (Turk et al, 2001; Salomon et al, 2004; Stolzenburg, 2008). Similar findings have been observed with RALP. Inexperience of both the console surgeon and the tableside operating team can lead to lengthy procedures initially. Once experience is gained, operative times of less than 3 hours have been reported for the total procedure (Smith, 2004; Badani et al, 2007; Patel et al, 2008).

Postoperative Pain. One of the distinct advantages of laparoscopy for many surgical procedures (e.g., laparoscopic nephrectomy) is its minimally invasive nature resulting in less postoperative pain than comparative open approaches. For radical prostatectomy, however, this advantage seems to be less dramatic because RRP is performed through an infraumbilical muscle-splitting incision. In addition, relatively little pain occurs after radical perineal prostatectomy. Some series have shown decreased pain in patients undergoing either LRP or RALP compared with RRP (Menon et al, 2002; Bhayani et al, 2003). Other reports have

shown no substantial difference in postoperative narcotic use or in patient-reported pain (Webster et al, 2005). **The lack of a significant advantage for laparoscopic prostatectomy is attributable primarily to low pain scores even in the open surgical group.**

Intraoperative Blood Loss. Because most of the blood loss that occurs during radical prostatectomy is from venous sinuses, the tamponade effect from the pneumoperitoneum helps diminish ongoing blood loss during LRP and RALP. **Further, the antegrade approach used during LRP and RALP entails earlier control of the prostatic pedicles and late division of the DVC as compared with RRP, in which the DVC is divided early and the arterial supply to the prostate managed late in the operation.** Thus the potential for ongoing bleeding is reduced during LRP and RALP as compared with open surgery. Both of these factors, as well as the excellent visualization with laparoscopy, account for the minimal blood loss reported in most series. Blood loss of less than a few hundred milliliters is routinely reported (Ficarra et al, 2009).

Perhaps the most meaningful parameter clinically is the proportion of patients requiring transfusion of homologous blood products. Most studies have shown a significant decrease in transfusion requirement for patients undergoing LRP or RALP compared with RRP (Tewari et al, 2003; Ahlering et al, 2004a). Others have shown no statistically significant difference if the transfusion requirement with RRP can be limited to only a few percent of patients (Farnham et al, 2006).

Hospital Stay. Over the past decade, hospital stay after radical prostatectomy has diminished remarkably regardless of the surgical approach. Some centers have reported a length of stay as short as 1 or 2 days after RRP (Holzbeierlein and Smith, 2000). With LRP and RALP, a hospital stay of only 1 day has become routine in many centers. Ileus and inability to tolerate a regular diet are the most common factors limiting early discharge. Pain control does not typically contribute to prolonged length of stay because parenteral narcotics are rarely required. **With early discharge programs for radical perineal and RRP being commonly used at many centers within the United States, no distinct advantage exists for LRP or RALP, although discharge on the first postoperative day may be more easily accomplished routinely with the minimally invasive approaches.**

Functional Outcomes

The complications of radical prostatectomy with the greatest potential for an adverse effect on quality of life are urinary incontinence and erectile dysfunction. Greater surgical experience with radical prostatectomy and refinements in surgical technique have reduced the frequency with which these problems are observed in most radical prostatectomy series from centers of excellence. However, most large population-based studies show substantial rates of erectile dysfunction and incontinence after both RRP and radical perineal prostatectomy (Fowler et al, 1993). Whether laparoscopic or robotic approaches offer improved functional outcomes is still a matter of debate, and comparison of published series is difficult because of differences in patient populations and methods of outcome assessment.

Urinary Incontinence. Urinary incontinence after radical prostatectomy is usually manifested as stress incontinence secondary to intrinsic sphincter deficiency. Although more than 90% of patients ultimately regain good urinary control and do not require pads for incontinence in reports from high-volume centers (Walsh, 1998; Catalona et al, 1999), other studies have shown that a substantial proportion of patients may be bothered by some degree of stress incontinence (Fowler et al, 1993). The exact physiologic mechanisms that contribute to urinary control after radical prostatectomy are not entirely understood and are likely multifactorial. However, surgical technique is undoubtedly a contributing factor (Smith, 2002).

With LRP and RALP, visualization of the prostatic apex is typically superb. The minimal bleeding and magnification of the operative field allow precise dissection of the prostatic apex with limited trauma to the periurethral striated sphincter and genitourinary diaphragm. As mentioned previously, the ability to more reliably accomplish a tension-free, watertight anastomosis under the superior and direct visualization offered by laparoscopic approaches in theory favors LRP and RALP over open surgery. A common observation after radical prostatectomy, regardless of surgical approach, is that urinary incontinence improves substantially within the first 3 to 6 months after surgery and to some extent for another year or more. Therefore the time points at which data on incontinence are collected are highly influential. Differences exist whether the information is gathered by questionnaire, the physician, or an independent third party. Further, even though validated instruments for assessment of incontinence exist, the manner and location in which the data are collected can affect results. Although the method used to evaluate continence in reported series varies, the recovery of urinary continence is excellent at 1 year following LRP and RALP (Table 103–2). More recent reports of techniques that provide both posterior and anterior support to the vesicourethral anastomosis report even further improvements in urinary continence, especially at earlier time points (Tewari et al, 2007).

Erectile Dysfunction. Preservation of erectile function after radical prostatectomy depends on precise and meticulous separation of the cavernous nerves within the NVB from the prostate gland (Walsh and Donker, 1982). The anatomic course of these nerves has been described but can be variable (Costello et al, 2004; Takenaka et al, 2004; Lunacek et al, 2005). Intraoperative localization using nerve stimulation has not been sufficiently accurate for clinical utility (Holzbeierlein et al, 2001). The principles and anatomic dissection for nerve preservation are the same regardless of surgical approach. It is still uncertain whether the magnified image of the operative field afforded by laparoscopy and the precision of the surgical instruments allows more anatomically accurate and less traumatic dissection of the NVBs, resulting in improved postoperative erectile function. As with incontinence, comparison of the published literature is difficult (Salomon et al, 2004). Differences in the method of assessment, definition of potency (e.g., spontaneous erections vs. intercourse), and patient selection complicate comparisons. In addition, the use of adjunctive therapies such as phospho-diesterase-5 inhibitors or vasoactive injections can substantially influence results. Also, in concordance with other nerve injuries, improvement in erectile function is a prolonged process that is ongoing for years after radical prostatectomy. Good results with erectile function after both LRP and RALP have been reported (Table 103–3). **However, there are no published data that allow definitive conclusions about the relative merits of either LRP or RALP in avoiding erectile dysfunction compared with open surgical approaches.** Nevertheless, the avoidance of hemostatic energy sources during NVB preservation and the performance of meticulous interfascial dissection and preservation of the cavernous nerves appear to be critical to optimizing postoperative recovery of potency.

Anatomic studies indicate that the cavernous nerves in the NVB course posterolateral to the prostate and urethra. A technique

during RALP for preservation of more anteromedial periprostatic fascia in addition to the conventional NVB regions has been reported to significantly improve potency outcomes (Menon et al, 2005; Savera et al, 2006). Although some neural tissue can be shown histologically to travel within the anterior and medial periprostatic fascia, the purpose and significance of these nerves and their relative contribution to erectile function remains uncertain. Nevertheless, the concept of optimizing both qualitative and quantitative preservation of nerve fibers traveling within the periprostatic fascial planes irrespective of whether they affect penile erections or urinary continence seems reasonable. In cases where wide excision of the nerve bundles is required, cavernous nerve grafting and nerve advancement have been described; however, the true merits of these techniques remain unclear (Martinez-Salamanca et al, 2007; Zorn et al, 2008).

Oncologic Outcomes

Surgical margin status and biochemical recurrence have generally been used as surrogates for oncologic efficacy following radical prostatectomy.

Surgical Margins. The goal of radical prostatectomy is complete surgical removal of the entire prostate and its investing fascia, as well as the seminal vesicles. Because most adenocarcinomas of the prostate occur in the peripheral zone and approach the capsular margin, surgical technique can influence oncologic outcomes. Proper surgical dissection should allow negative margins with pathologic stage T2 tumors while also permitting complete excision and negative margins for some extracapsular lesions. Efforts to avoid urinary incontinence or erectile dysfunction by dissecting too closely to the prostatic apex or the posterolateral aspect of the prostate can compromise margins, regardless of the surgical approach. Once again, comparison of positive margin rates in reported series is difficult because of patient selection. **Importantly, the method and detail of pathologic analysis of the surgical specimen can be highly influential in assessing surgical margin status.** Some reports have used only biopsies of remaining tissue after removal of the surgical specimen to assess margin status, whereas others rely on step-sectioned routine or whole mount histology. **According to the World Health Organization International Consultation Consensus Committee guidelines established for the pathologic analysis of prostatectomy specimens, whole mount histologic sectioning may miss areas of extraprostatic extension in 7% to 15% of cases and positive margins in up to 12% as compared with specimens analyzed by routine sectioning** (WHO International Consultation on Prediction of Patient Outcome in Prostate Cancer, 2004). This finding is thought to be due to the relatively thicker slices required during sectioning of the prostate for whole mount technique as compared with the serial 3- to 5-mm slices used during routine sectioning.

In most series of LRP and RALP, positive margin percentages decrease with experience (Ahlering et al, 2004b; Salomon et al, 2004; Rassweiler et al, 2005). This implies that inexperience with the surgery accounts for positive margins in some cases. Sometimes, this may be from difficulty in identifying the proper anatomic plane of dissection between the bladder neck and the base of the prostate. The most common site of a positive margin, whether the operation is performed via open or laparoscopic approaches, is the prostatic apex (Touijer et al, 2005). Insufficient removal of prostatic tissue at the apex in an effort to optimize urethral length and avoid incontinence can result in positive margins even with tumors that do not pathologically violate the capsule (i.e., stage pT2). **As mentioned previously in the surgical techniques section of this chapter, adhering to specific surgical principles can help reduce site-specific positive margins at the apex, bladder neck, and posterolateral regions of the prostate.** Published rates of pathologic stage-specific positive margins for LRP or RALP are shown in Table 103–4.

The primary factor that determines the positive margin rate in a given series is patient selection. As discussed earlier, the method and detail of pathologic analysis is also influential. Evaluating positive margin rates from one series to another, then, is not necessarily a comparison of surgical technique. A more accurate technical comparison is analysis of the pathologic results in stage T2 tumors wherein a positive margin implies surgical violation of the prostatic capsule. Even in this circumstance, though, the methodology for pathologic sampling is important. Intrainstitutional comparisons from some studies have shown a reduced rate of positive margins with laparoscopic approaches compared with RRP. **However, comparison of margin status between high-volume centers with operations performed by experienced surgeons has shown no definitive advantage for one surgical approach over the other in achieving negative surgical margins** (Brown et al, 2003; Khan et al, 2005).

LRP, laparoscopic radical prostatectomy; RALP, robotic-assisted laparoscopic prostatectomy.

Biochemical Recurrence. Biochemical recurrence following prostatectomy may perhaps provide a more accurate assessment of oncologic control than margin status. Guillonneau and colleagues reported on their oncologic outcomes with 1000 consecutive LRPs performed over a 4-year period with a median follow-up period of 12 months (Guillonneau et al, 2003b). Their overall actuarial biochemical progression-free survival rate was 90.5% at 3 years. By pathologic stage, the rates were 92% for pT2a, 88% for pT2b, 77% for pT3a, and 44% for pT3b. Pavlovich and colleagues (2008) reported on 528 consecutive LRP patients with a mean follow-up of 13 months. The 3-year, actuarial, biochemical-free survival was 94.5% overall, 98.2% for pT2, and 78.7% for pT3 disease.

With regard to RALP, Badani and colleagues in 2007 reported on their large series of 2766 consecutive RALP patients with a mean follow-up period of 22 months. Their overall 5-year, actuarial, biochemical-free survival was 84% overall, 84% for pT2, and 66% for pT3 patients. It should be noted that their patient population included higher-risk patients than most reported series with a Gleason score of 7 or higher in 64% and a pathologic stage of pT3 or higher in 22% of their patients. In a retrospective comparison of biochemical recurrence between RALP and a contemporary series of RRP performed at a single center, no difference was found between the two groups after controlling for clinical and pathologic features (Schroeck et al, 2008). In the end, longer-term follow-up is required to compare the results of LRP and RALP with results of RRP from established and experienced centers of excellence.

Economic Considerations

Both the duration of surgery and equipment expenses contribute to operating room costs for LRP and RALP, which typically are

higher than those for open approaches (Link et al, 2004; Lotan et al, 2004; Scales et al, 2005). This is particularly true with robotic-assisted surgery. Current purchase cost of a da Vinci S system is approximately $1.65 million with an average cost of $2400 for each multiple-use (10 lives) robotic instrument. For robotic instrumentation, this would translate to approximately $1200 per case for the use of five separate robotic instruments with an additional $325 per case for disposables (sterile robotic drapes and trocar seals).

In the study by Link and colleagues (2004), **the factors that most influenced overall LRP cost in order of importance included operative time, length of hospital stay, and consumable items (e.g., disposable laparoscopic equipment and trocars).** They found that the calculated cost equivalence between RRP and LRP could be met if disposable equipment was eliminated by using reusable items and operative times for LRP were reduced to 3.4 hours. Lotan and colleagues (2004) found that RALP costs were approximately $1155 per case more than RRP if the initial purchase cost of the robot were excluded. In a local cost analysis performed by Scales and colleagues (2005), they found that RALP would be less expensive than RRP in some practice settings in which RALP hospital stay was less than 1.5 days if case volumes increased to 14 cases per week. This study suggested that RALP may be more economically viable in high-volume centers with multispecialty robotic use.

These increased costs may be partially mitigated by shorter hospital stays compared with open surgery. The decrease in expense for hospital stay depends partly on the discharge day for the laparoscopic procedure but also the customary length of stay at a given hospital for open radical prostatectomy. Published reports detailing a length of stay of a week or more for RRP are not in concordance with other contemporary reports wherein patients are discharged on the second or even first postoperative day after radical perineal or RRP (Holzbeierlein and Smith, 2000).

COMPLICATIONS

Complications Related to Patient Positioning

LRP and RALP are typically performed with the patient in a steep exaggerated Trendelenburg position and with the legs in lithotomy position. Careful padding of vulnerable body parts such as the hips, shoulders, knees, and calves is important to prevent pressure injury and neuromuscular complications. Increased intraocular pressure can occur in patients in an exaggerated Trendelenburg position, but in patients undergoing RALP this does not appear to have any apparent clinical long-term consequence. However, there may be an increased risk of corneal abrasion, making it even more important for the anesthesiologist to maintain good eye lubrication and protection.

Vascular and Bowel Injury

Vascular or bowel perforations are rare but can occur during placement of abdominal trocars. In addition, once safe trocar placement is established and the robot is docked, care must be taken to avoid injury along the path of the multiple instruments, which must be interchanged and directed toward the pelvis. The key to avoiding major postoperative complications is prompt recognition and immediate management of injury to bowel or blood vessels. Often, relatively minor injuries can be repaired laparoscopically, although there should be no hesitation to convert to an open approach in the face of a difficult problem.

Open Conversion

Open conversion is rare (<2%) and has been cited in the literature, usually during a surgeon's early experience with LRP or RALP, mainly as a result of failure to progress or uncertainty of dissection planes (Bhayani et al, 2004). With experience, the need for open conversion is rare; however, patients must be properly counseled on this possibility.

Rectal Injury

Rectal injuries, although uncommon during LRP and RALP (0.7% to 2.4%), have been reported and repaired successfully by laparoscopic means (Guillonneau et al, 2003a; Katz et al, 2003; Gonzalgo et al, 2005). Intraoperative recognition and repair of the injury is crucial. Multilayered primary closure and interposition of omentum between the rectum and anastomosis can usually avoid long-term problems, as well as the need for open conversion and intestinal diversion. Inadequate closure or lack of recognition can result in a fistula between the vesicourethral anastomosis and the rectum. If a small rectal injury is suspected but not readily identified, insufflation of air into the rectum using a catheter inserted into the rectum with fluid within the pelvis can often demonstrate small bubbles at the site of the injury.

Thromboembolic Complications

The incidence of thromboembolic complications is low after LRP and RALP (0.5%) likely, in part, due to faster postoperative patient mobilization and Trendelenburg positioning, used for decreasing the venous stasis in the lower extremities as compared with open surgery (Secin et al, 2008). The American Urological Association guidelines do not recommend routine use of prophylactic anticoagulants for laparoscopic procedures unless a patient has known risk factors such as obesity or a prior history of deep venous thrombosis. Nonetheless, because of the known venous stasis and hypercoagulable state that can occur during pelvic surgery in patients with known malignancy, these patients are still at risk for thromboembolic problems. Secin and colleagues (2008) propose the use of heparin only in patients at high risk for venous thromboembolism. Sequential compression stockings are advised during the operative and perioperative period. The presentation of deep venous thrombosis in the lower extremities should prompt a pelvic CT scan or ultrasound to exclude a lymphocele, hematoma, or urinoma that could be compressing the external iliac vein.

Anastomotic Complications

Failure to achieve a watertight closure of the anastomosis can result in urinary extravasation and accumulation of urine even if a pelvic drain is placed. This is even more problematic with a transperitoneal approach because the entire abdominal cavity becomes accessible for urine egress. In such cases a cystogram should be performed to make certain that there is some degree of integrity of the anastomosis. Fluid accumulations may require percutaneous drainage. If complete disruption of the anastomosis has occurred, surgical revision, either laparoscopic or open, is indicated if the problem is recognized in the first few days after surgery. Anastomotic stricture resulting in bladder neck contracture seemingly occurs at a lower rate after LRP and RALP compared

with open surgical approaches, especially in the hands of experienced surgeons. Rates of less than 2% have been reported (Msezane et al, 2008; Webb et al, 2009). This implies that achievement of a watertight anastomosis with good mucosal approximation is the key measure in preventing postoperative bladder neck contracture.

Bleeding and Transfusion

Virtually all published reports have documented a distinct advantage for laparoscopic surgery in diminishing the amount of bleeding that occurs with radical prostatectomy. Transfusion requirements of 2% or less are commonly reported (Ficarra et al, 2009). The tamponade effect of the pneumoperitoneum compresses venous bleeding, and the superb visualization allows prospective identification of bleeding vessels that require hemostasis. However, in addition to the risk of major vascular injury from the surgical dissection or trocar placement, there is the possibility of postoperative bleeding once the pneumoperitoneum is relieved. As mentioned previously, the pelvis and surgical field should be carefully inspected for the presence of bleeding at the end of the operation under low insufflation pressure. Because of the low incidence of postoperative bleeding, though, routine use of topical hemostatic agents along the prostate bed is not generally required.

Equipment Malfunction

The surgeon is highly dependent on sophisticated technology and equipment for performance of LRP and, in particular, RALP. Equipment malfunction, especially with RALP, can create problems that make it difficult to progress with surgery and may result in case cancellation or conversion to pure laparoscopic or even open surgery. Zorn and colleagues (2007a) identified recoverable errors in 0.4% of RALP cases performed at their institution. Lavery and colleagues (2008) found a 0.4% nonrecoverable malfunction rate in their multi-institutional study of high-volume RALP centers. Although extremely rare, patients need to be properly counseled about the possibility of conversion to a pure laparoscopic or open surgical approach in the event of an unrecoverable equipment malfunction.

Key Points: Results and Complications of Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

- Blood loss is minimal in part due to the tamponade effect of the pneumoperitoneum.
- Hospital length of stay is often only 1 day.
- Whether postoperative continence and/or potency are better with laparoscopic and robotic-assisted approaches compared with open surgery in expert hands remains uncertain.
- Surgical margins are comparable with those with open approaches and are partly influenced by patient selection, surgical technique, and experience.
- Higher costs are still a concern, especially with the robotic-assisted approach.
- Thromboembolic events, rectal injury, transfusion, and equipment malfunction are rare events.

LAPAROSCOPIC PELVIC LYMPH NODE DISSECTION

Indications

Currently, PLND is rarely indicated as an independent staging procedure. In some patients with a significant risk for nodal metastasis, such as those with a high Gleason grade tumor, a large tumor volume, or a markedly elevated PSA level, PLND may be useful for staging and selection of therapy before external beam irradiation. Also, staging PLND may have a role in some patients in whom radical perineal prostatectomy is planned. With RRP, LRP, or RALP, it is the usual practice that PLND be performed simultaneously with the radical prostatectomy.

Expert opinion about the role of PLND in patients undergoing surgery for carcinoma of the prostate is evolving. **Current debate centers around the anatomic boundaries for the procedure, the merits of an extended lymph node dissection, and whether there is any meaningful clinical (i.e., therapeutic) benefit to surgical removal of involved nodes.** Most studies show histologic evidence of nodal metastasis in less than 5% of patients with low-risk features in the primary tumor. Consequently, PLND may not be required in these patients.

PLND is generally recommended in patients with intermediate or high-risk parameters of the primary tumor, generally implying a PSA of greater than 10, a large palpable nodule, or a Gleason sum of 7 or greater.

Surgical Technique

In laparoscopic staging PLND, trocar configuration is similar to that of LRP and RALP but only one assistant trocar is generally necessary, if at all. Abdominal access is established, and an incision is made just lateral to the medial umbilical ligament back toward its confluence with the hypogastric artery and down to the pubis (Fig. 103–19). Great care must be taken so as to avoid injury to the nearby ureter. If PLND is performed during LRP or RALP, the dissection is simplified because previous mobilization of the bladder provides excellent exposure of the obturator space. As with an open approach, a key initial step to standard laparoscopic PLND is separation of the nodal packet from the external iliac vein. The lymph node packet is grasped and retracted medially. A relatively avascular plane between the lymph node packet and lateral pelvic sidewall is identified and dissected bluntly using a suction-irrigation device. Dissection is carried out proximally to the iliac bifurcation and distally to the pubis, thus defining the lateral extent of the lymph node packet. By retracting the lymph node packet medially, the precise course of the obturator nerve and vessels can be identified and protected (Fig. 103–20). After securing the distal extent of the lymph node packet, the packet is divided, retracted cranially, and bluntly separated from the obturator vessels and nerve. Hemoclips are used to control lymphatic vessels at the most proximal and distal extent of the dissection (Fig. 103–21). The lymph nodes can usually be removed as a single packet and extracted either through the 12-mm trocar or by placing them in the entrapment sack along with the prostate specimen.

An extended lymph node dissection typically includes nodes categorized as external iliac, obturator, and hypogastric and has a boundary of the genitofemoral nerve laterally, the bladder wall medially, the node of Cloquet distally, and a point 2 cm above the bifurcation of the common iliac artery proximally. Importantly,

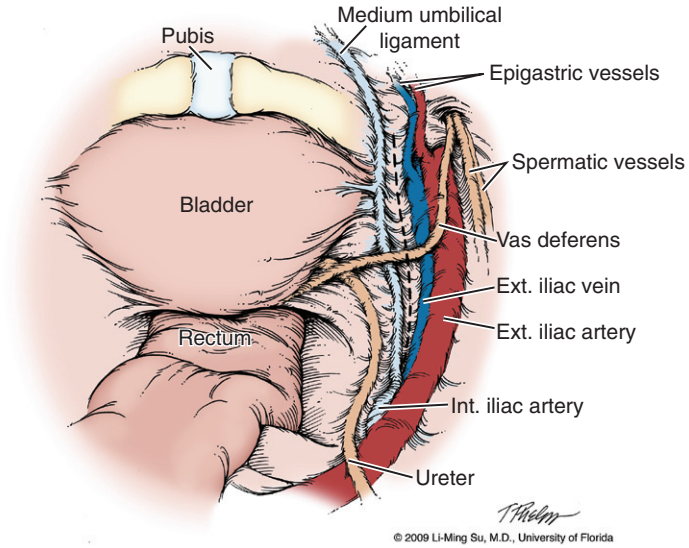

Figure 103–19. Laparoscopic pelvic lymph node dissection. Initial transperitoneal view of the obturator fossa and relevant anatomy. The *dashed line* indicates the longitudinal incision that is made in the peritoneum lateral and parallel to the median umbilical ligament back toward the bifurcation of the iliac vessels in efforts to provide exposure to the obturator fossa and lymph nodes. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

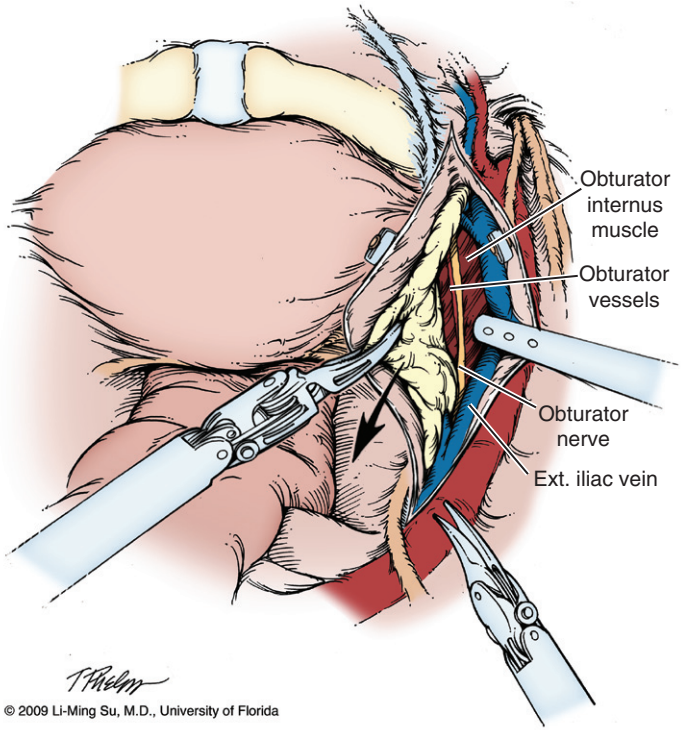

Figure 103–20. Initial dissection of a standard pelvic lymph node template. The vas deferens has been clipped and divided. With medial traction on the lymph node packet, the lateral extent of the dissection is defined using mainly blunt dissection. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

the posterior dissection involves complete skeletonization of the hypogastric artery and its medial branches, as well as the area posterior to the obturator. **Studies show that an extended dissection has a higher diagnostic yield than standard or limited PLND because it recognizes and removes positive lymph nodes more commonly.**

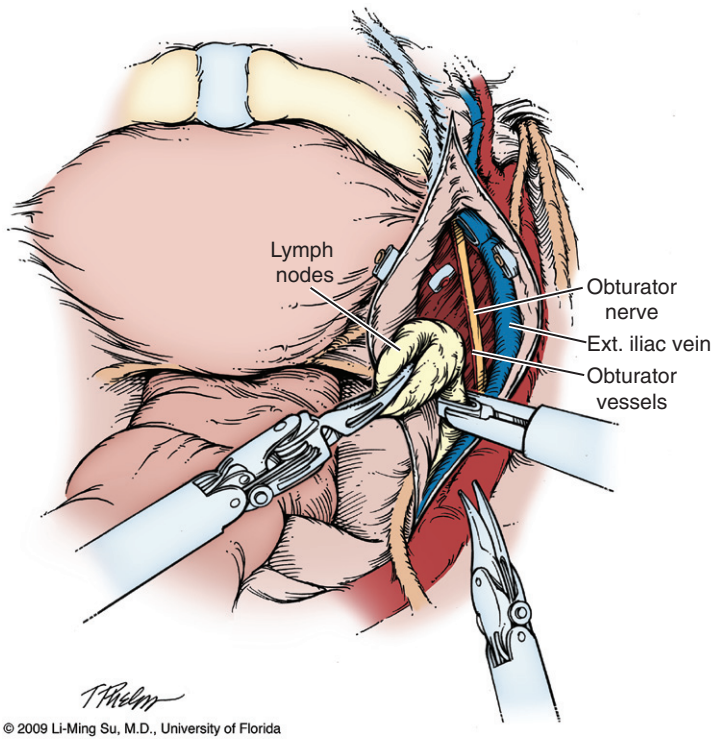

Figure 103–21. Final dissection of a standard pelvic lymph node template. The proximal and distal extent of the lymph node packet are clipped and divided, taking great care to avoid injury to the obturator nerve and vessels, as well as the accessory obturator vein. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Extended lymph node dissection can be performed laparoscopically and robotically. The da Vinci S system allows more proximal angulation of the instruments, and this can significantly facilitate dissection around the bifurcation of the common iliac artery. A thorough dissection adds time to the surgical procedure, but this is true regardless of whether laparoscopic or open surgery is performed. No valid comparative studies exist to support the superiority of open versus laparoscopic PLND. Using lymph node count as a surrogate for adequacy of the dissection is problematic because the method and thoroughness of pathologic evaluation is, perhaps, even more influential than the anatomic extent of the surgical dissection. With careful attention to meticulous dissection, though, all of the fibrous, fatty, and lymphatic tissue within the commonly accepted anatomic boundaries for an extended lymph node dissection can be removed laparoscopically or robotically. Use of clips on identifiable lymphatic channels can minimize the occurrence of a postoperative lymphocele.

Complications of Pelvic Lymph Node Dissection

Because, by definition, PLND requires skeletonization of portions of the common iliac, external iliac, and hypogastric arteries and veins, the possibility of major vascular injury exists. A small venotomy or arteriotomy can be closed laparoscopically with a fine polypropylene (Prolene) suture. A major injury may require rapid conversion to an open approach. However, the incidence of major vascular injury resulting in enough bleeding to require transfusion is well under 1% with PLND.

Transection of the obturator nerve may occur. Direct repair with suturing of the ends of the obturator nerve can restore partial function. Ureteral injury is uncommon, but caution must be observed during the proximal portion of the dissection as the ureter crosses the anterior portion of the common iliac artery.

A transperitoneal approach is not protective against the formation of a lymphocele. Theoretically, the communication with the entire peritoneum would allow distribution and absorption of any lymphatic fluid throughout the peritoneal lining of the abdomen and decrease the risk of lymphocele. Despite this, however, a loculation of lymphatic fluid can occur. Asymptomatic lymphoceles do not necessarily require drainage or treatment. A larger collection can compress the bladder and cause voiding symptoms. Compression of the external iliac vein can predispose the patient to deep vein thrombosis in the lower extremity. Secondary infection of lymphoceles may also occur. In the presence of symptoms or complications from a lymphocele, percutaneous drainage is typically successful. However, lymphatic fluid can reaccumulate, requiring repeat drainage with injection of a sclerosing agent or surgical opening of a window with marsupialization of the lymphocele wall by laparoscopic means.

Key Points: Laparoscopic Pelvic Lymph Node Dissection

- PLND is generally recommended in patients with intermediate or high-risk parameters of the primary tumor, generally implying a PSA of greater than 10, a large palpable nodule, or a Gleason sum of 7 or higher.
- Although an extended PLND may yield a higher lymph node count, debate continues as to the extent of PLND and the clinical benefit of removing cancerous nodes.
- Use of clips on identifiable lymphatic channels can minimize the occurrence of postoperative lymphoceles.
- A transperitoneal approach is not protective against the formation of a lymphocele because loculation of lymphatic fluid can still occur within the peritoneal cavity.
- Symptomatic lymphoceles may require percutaneous or laparoscopic drainage.

SUMMARY

In the past decade, LRP and RALP have become accepted surgical approaches for the management of patients with localized carcinoma of the prostate both in the United States and abroad. As expertise with these procedures is achieved, operative times have diminished. In experienced centers operative times are similar to that of RRP. The robotic-assisted technique provides ergonomic advantages for the surgeon and facilitates suturing and other technical aspects of the operation for surgeons who do not have highly advanced laparoscopic skills.

Comparison of outcomes between reported series is imprecise because of differences in patient selection, methods of collecting and reporting data, and the technique of pathologic sectioning and analysis. However, intraoperative blood loss with LRP and RALP has consistently been reported as minimal and transfusion is required in only a small percentage of patients. Postoperative morbidity and return to activity are both improved compared with open surgery in most reports. Good results with postoperative urinary continence and erectile function are reported with mature LRP and RALP series, although there is still debate about whether these outcomes are superior to open RRP performed by experienced surgeons. Pathologic tumor margins status seems to be comparable between laparoscopic, robotic, and open series overall (Parsons and Bennett, 2008; Ficarra et al, 2009).

Improvements in the available instruments are highly likely to advance even further the technologic capabilities of surgeons performing LRP and RALP. Equipment expense remains a significant issue for some hospitals, and not all may be able to offer this state-of-the-art technology. Nonetheless, there seems to be little doubt that minimally invasive approaches for radical prostatectomy, especially RALP, have become the dominant surgical treatment for localized prostate cancer in the United States and are having continued growth and acceptance worldwide.

Radiation Therapy for Prostate Cancer

Anthony V. D'Amico, MD, PhD ● Juanita M. Crook, MD, FRCPC ● Clair J. Beard, MD ● Theodore L. DeWeese, MD ● Mark Hurwitz, MD ● Irving D. Kaplan, MD

Historical Perspective
Localized Disease
Treatment: Cancer Control and Quality of Life

HISTORICAL PERSPECTIVE

Two major advances in the radiotherapeutic management of adenocarcinoma of the prostate have occurred since the early 1980s. The first advance was the generation of linear accelerators and conformal techniques capable of delivering high doses of radiation deep within the pelvis while simultaneously respecting the normal tissue tolerance of the anterior rectal wall, prostatic urethra, femoral heads, and bladder neck. The second advance occurred when image-guided techniques were introduced for use during the insertion of radioactive sources directly into the prostate gland. Eliminating the former freehand technique has vastly improved the physician's ability to deliver high doses of radiation to the prostate gland while sparing interposed and juxtaposed normal structures. These two advances have increased the therapeutic ratio of radiation therapy (RT) in the management of prostate cancer. Specifically, decreased gastrointestinal toxicity has been documented (Dearnaley et al, 1999), and improved cancer control has been suggested (Pollack et al, 1999).

The physical property that permits the photon radiation generated from a linear accelerator to penetrate deeply and spare normal tissue is the high energy of the beam. As the energy of the beam increases, the beam penetrates deeper before exerting its cytocidal effect. Whereas orthovoltage and ^{60}Co units deposited their maximum dose within 1.25 cm below the skin surface, high-energy linear accelerators deliver the maximum dose of radiation at more than 15 cm below the skin surface. In addition, the use of multiple and conformal fields, as well as intensity-modulated and image-guided radiation therapy (Jani et al, 2003), has minimized the amount of rectum receiving the high-dose radiation volume, leading to lower rates of radiation-induced proctitis (Pollack et al, 1999).

With respect to image guidance and brachytherapy, transrectal ultrasonography (TRUS) has provided an improved monitoring system compared with freehand or fluoroscopically guided radioactive source deposition. Using this image guidance system, geometric feedback on source location within the prostate gland intraoperatively has provided the potential for delivering high doses of radiation within the prostate gland while limiting dose to the prostatic urethra and the anterior rectal wall. The theoretical advantage of brachytherapy is the physical property of rapid dose falloff (a few millimeters) because of the low energy of the radioactive sources used—only 21 and 28 keV for palladium 103 and iodine 125, respectively. This rapid falloff, however, also mandates millimeter precision in the placement of these sources to ensure that the tumor-bearing regions within the prostate gland are not underdosed. These issues are discussed in more detail in the brachytherapy sections.

In brief, the close of the 20th century saw the introduction of three-dimensional, conformal-based, image-guided RT using high-energy radiation beams and image guidance for the placement of permanent radioactive sources into the prostate gland. As discussed in this chapter, these advances in the radiotherapeutic management of adenocarcinoma of the prostate provided the basis for improvement in both quality of life and cancer control.

LOCALIZED DISEASE

Pretreatment Prognostic Factors

Recommendations for the treatment of clinically localized adenocarcinoma of the prostate should be made using the results of evidence-based medicine. The ideal end point on which to make therapeutic decisions is cause-specific survival. At present, follow-up is too short to make statistically meaningful statements regarding cause-specific survival for men diagnosed and treated for clinically localized disease in the prostate-specific antigen (PSA) era as a function of pretreatment prognostic factors and treatment modality. However, pretreatment prognostic factors have established roles in predicting recurrence (PSA, clinical) after external-beam RT (Pisansky et al, 1993; Zietman et al, 1994; Hanks et al, 1995; Lee et al, 1995; Zagars et al, 1995; Pisansky et al, 1997). These pretreatment factors include PSA level, biopsy Gleason grade, and 1992 American Joint Commission on Cancer Staging (AJCC) clinical stage. Combining these three factors has led to a definition of the three risk groups for patients managed with RT who have clinically localized disease. These three risk groups are as follows:

- Low risk: more than 85% 5-year PSA failure-free survival, 1992 AJCC clinical stage T1c-T2a and PSA level of 10 ng/mL or lower, and biopsy Gleason grade of 6 or lower

- Intermediate risk: approximately 50% 5-year PSA failure-free survival, 1992 AJCC clinical stage T2b or PSA higher than 10 but no higher than 20 ng/mL, or biopsy Gleason grade of 7
- High risk: approximately 33% 5-year PSA failure-free survival, 1992 AJCC clinical stage T2c or PSA higher than 20 ng/mL, or biopsy Gleason grade of 8 or more; patients having at least clinical stage T3a disease are grouped with high-risk patients with localized disease

Figure 104–1 shows 5-year actuarial data for 473 patients stratified using the clinical risk groups based on pretreatment PSA, biopsy Gleason grade, and 1992 AJCC clinical stage.

Pretreatment Risk Groups and Prostate Cancer–Specific Mortality

Data (D'Amico et al, 2003) now exist to support the significant association of the pretreatment risk groups and prostate cancer–specific mortality (PCSM) following external-beam radiation as shown in Figure 104–2. Specifically, in a multi-institutional study of 2370 radiation-managed patients, the relative risk of PCSM for patients with high- or intermediate-risk disease compared with low-risk disease was 14.3 (95% confidence interval [CI]: 5.2 to 24.0; $p_{Cox} < .0001$) and 5.6 (95% CI: 2.0 to 9.3; $p_{Cox} = .0012$), respectively. For illustration, Figure 104–3 contains the relative contribution of PCSM and non-PCSM following treatment to all-cause mortality stratified by the patients' age at the time of RT and the pretreatment risk group. These findings have been validated by others at Johns Hopkins (Hernandez et al, 2007) and the Mayo Clinic (Boorjian et al, 2008).

Percentage of Positive Prostate Biopsies and Intermediate-Risk Patients

The fraction of prostate biopsies found to contain prostate cancer is readily available information for all patients with PSA-detected or clinically palpable prostate cancer. The fraction of positive biopsies is obtained by dividing the number of positive cores by the number of cores sampled. Studies investigating the ability of the fraction of positive prostate biopsies × 100 (percentage of positive biopsies) to predict pathologic end points after RT suggest a role for this clinical factor in predicting tumor volume (Terris et al, 1995), extracapsular extension (Badalment et al, 1996; Borirakchanyavat et al, 1997), seminal vesicle invasion (D'Amico et al, 1996), lymph node involvement (Conrad et al, 1998), and percentage of Gleason grade 4 and 5 disease in the radical prostatectomy specimen (Epstein et al, 1994).

The percentage of positive prostate biopsies has been shown to be an independent predictor of time to postoperative PSA failure after controlling for the established prognostic factors (D'Amico et al, 2000b). The percentage of positive prostate biopsies has also been shown to provide information in addition to the known prognostic factors for predicting PSA control after external-beam RT. Specifically, 473 men treated using three-dimensional conformal external-beam RT at the Joint Center for Radiation Therapy between 1989 and 1998 had detected PSA or clinically palpable prostate cancer. Figure 104–1 illustrates the ability of the previously described risk group system (D'Amico et al, 1998b) that was based on pretreatment PSA level, biopsy Gleason grade, and 1992 AJCC clinical stage to stratify patients according to PSA outcome. Specifically, 5 years after RT, 91%, 62%, and 43% of low-, intermediate-, and high-risk patients, respectively, had not experienced PSA failure as defined by the American Society for Therapeutic Radiology and Oncology (ASTRO) consensus panel (Consensus statement, 1997).

Figure 104–4 illustrates the clinically relevant stratification provided by the percentage of positive biopsies in the previously defined intermediate-risk group on the basis of pretreatment PSA level, biopsy Gleason grade, and the 1992 AJCC clinical stage. Specifically, patients in the intermediate-risk subgroups who also had less than 34% of the positive biopsies improved their risk stratification for PSA outcome by one category to low risk. Conversely, patients with more than 50% of the positive biopsies

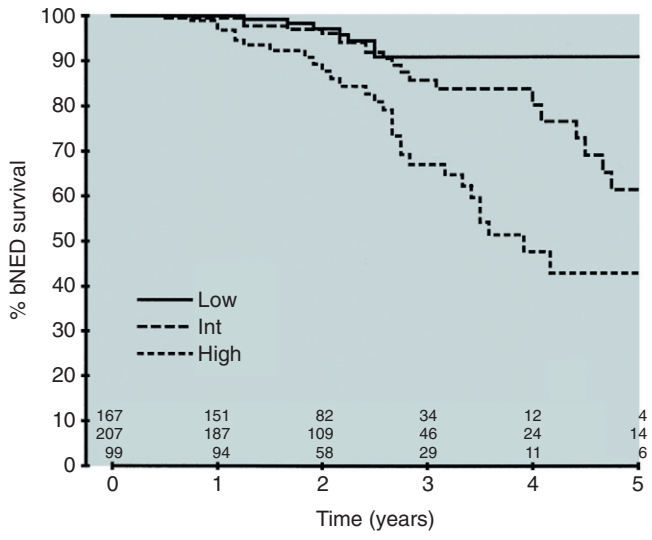

Figure 104–1. Prostate-specific antigen (PSA) failure-free survival stratified by risk group, defined using PSA value, biopsy Gleason grade, and 1992 American Joint Commission on Cancer Staging clinical T stage for 473 patients managed using external-beam radiation therapy. Pairwise, *P* values are as follows: low versus intermediate, *P* = .02; intermediate versus high, *P* = .0004; low versus high, *P* = .0001.

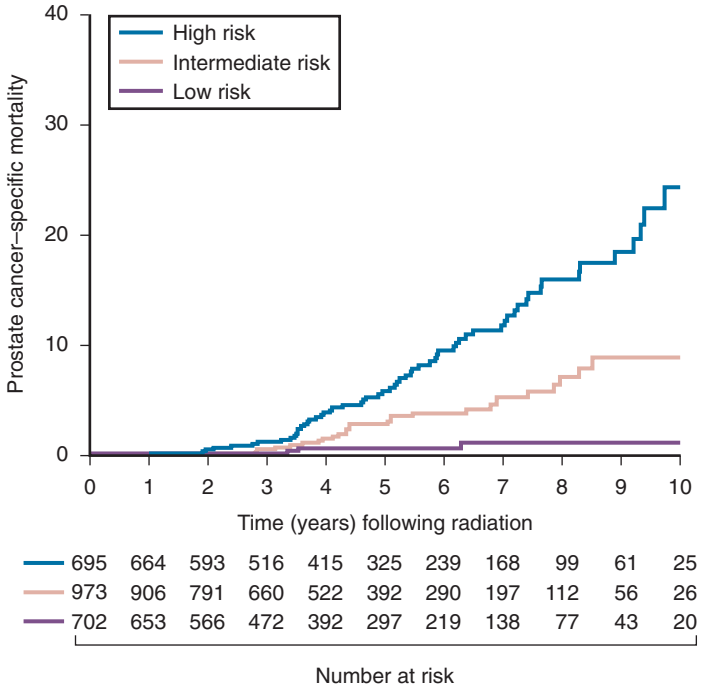

Figure 104–2. Pretreatment risk groups and prostate cancer–specific mortality following external-beam radiation.

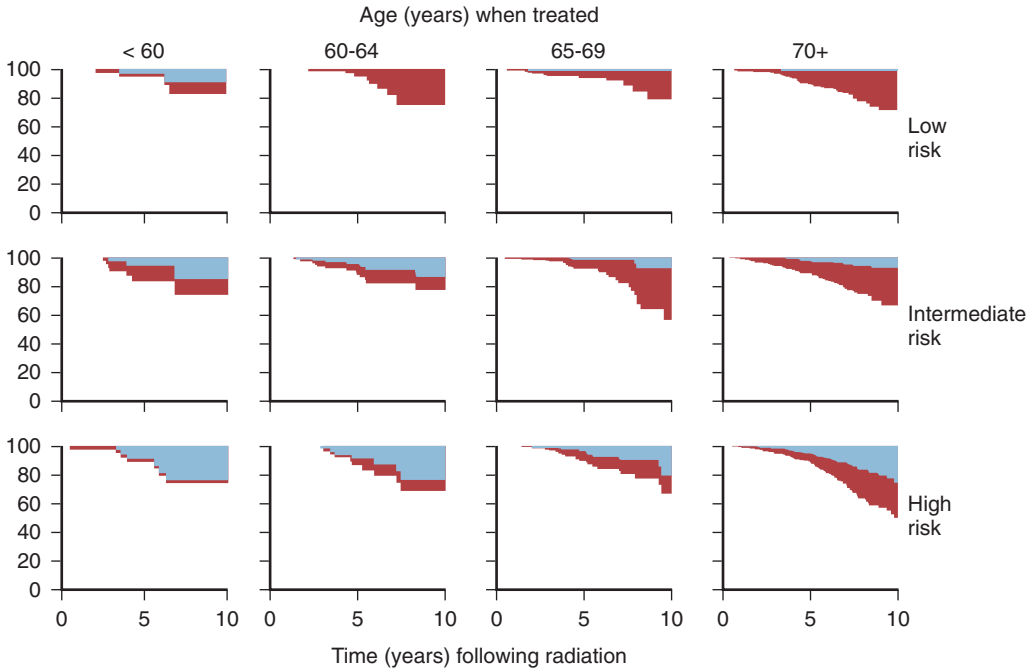

Figure 104–3. Relative contribution of prostate cancer–specific mortality (PCSM) and non-PCSM following treatment to all-cause mortality stratified by the patients' age at the time of radiation therapy and the pretreatment risk group.

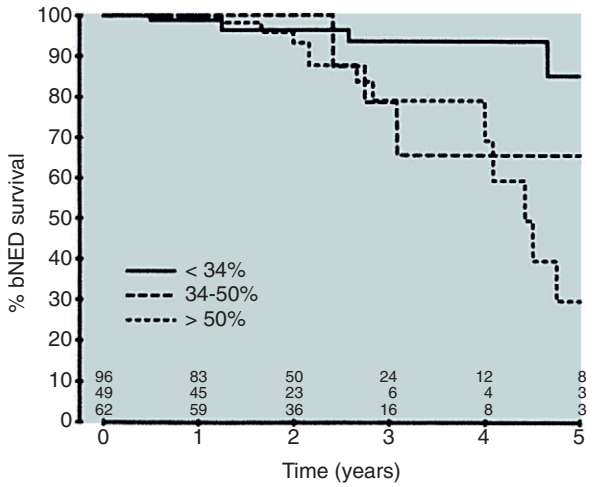

Figure 104–4. Prostate-specific antigen failure-free survival stratified by percentage of positive biopsies for 207 intermediate-risk patients managed using external-beam radiation therapy. Pairwise, *P* values are as follows: 34% versus greater than 34% to 50%, *P* = .02; greater than 34% to 50% versus greater than 50%, *P* = .06; 34% versus greater than 50%, *P* = .002.

performed less well than expected and were comparable with the high-risk patients.

Of particular importance, however, is that the majority of patients (158 of 207 [76%]) in the intermediate-risk group could be classified into either a 30% or an 85% 5-year PSA control high- or low-risk cohort, respectively, using the preoperative prostate biopsy data. Therefore of the 473 study patients, all but 49 (10%) were classified into high- or low-risk groups regarding PSA outcome after RT, using the percentage of positive prostate biopsies, the PSA level, the biopsy Gleason grade, and the 1992 AJCC clinical stage.

Percentage of Positive Prostate Biopsies and Prostate Cancer–Specific Mortality in Low-Risk and Favorable Intermediate-Risk Patients

With longer follow-up, the impact of the percentage of prostate positive biopsies (PPBs) on prostate cancer–specific mortality in low-risk and favorable intermediate-risk patients has become available (D'Amico et al, 2004). Specifically, from a series of 421 patients with low-risk (PSA ≤ 10 ng/mL and biopsy Gleason score ≤ 6) or favorable intermediate-risk (PSA > 10 to 15 ng/mL or biopsy Gleason score 7 but not both factors) disease who underwent three-dimensional conformal radiation therapy (3DCRT) to a median dose of 70.4 Gy, a significant association between PCSM and the percentage of positive prostate biopsies at diagnosis was documented. In particular, the relative risk of PCSM following 3DCRT for patients with 50% or more as compared with less than 50% PPB was 10.4 (95% CI: 1.2 to 87; p_{Cox} = .03), 6.1 (95% CI: 1.3 to 28.6; p_{Cox} = .02), and 12.5 (95% CI: 1.5 to 107; p_{Cox} = .02) in men with a PSA of 10 or less and Gleason score 6 or less, PSA 10 or less and Gleason score 7 or less, and PSA 15 or less and Gleason score 6 or less, respectively. By 5 years after 3DCRT, up to 10% as compared with 2% or less ($p_{log\ rank}$ ≤ .01) of these patients experienced PCSM if they had 50% or more as compared with less than 50% PPB as shown in Figures 104–5, 104–6, and 104–7. For the purpose of illustration, Figure 104–8 contains the relative contributions of PCSM and non-PCSM following treatment to all-cause mortality stratified by the % PPB (<50% vs. 50% or more) and the PSA level and biopsy Gleason score at diagnosis.

Therefore the percentage of positive prostate biopsies should be considered in conjunction with the PSA level, the biopsy Gleason grade, and 1992 AJCC clinical stage at diagnosis when counseling patients with newly diagnosed and clinically localized prostate cancer about both PSA outcome and, more important, the chance of avoiding PCSM after RT.

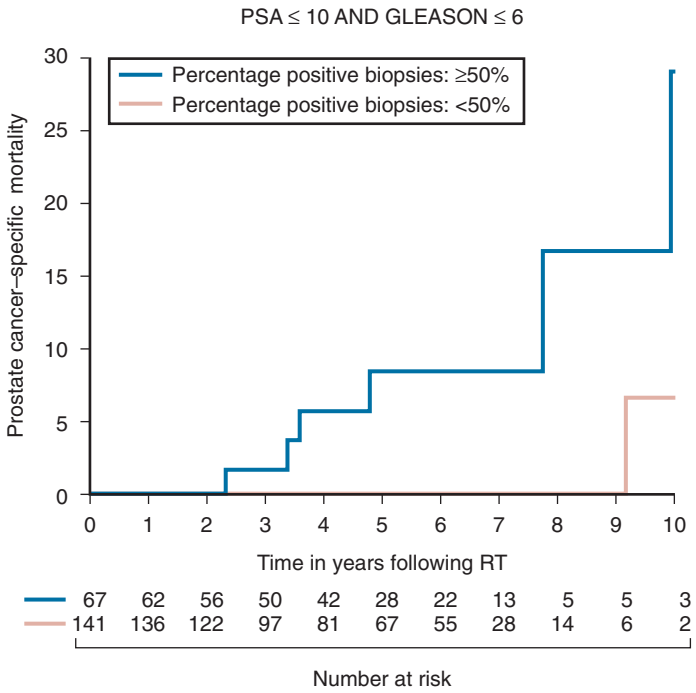

Figure 104–5. Prostate cancer–specific mortality following three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy in men with a prostate-specific antigen (PSA) of 10 or less and Gleason score of 6 or less. RT, radiation therapy.

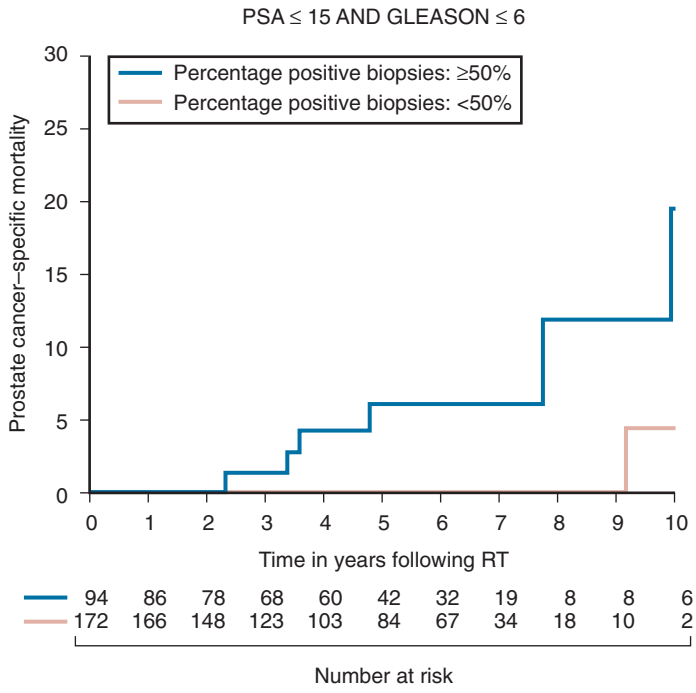

Figure 104–6. Prostate cancer–specific mortality following three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy and a prostate-specific antigen (PSA) of 15 or less and Gleason score of 6 or less, respectively. RT, radiation therapy.

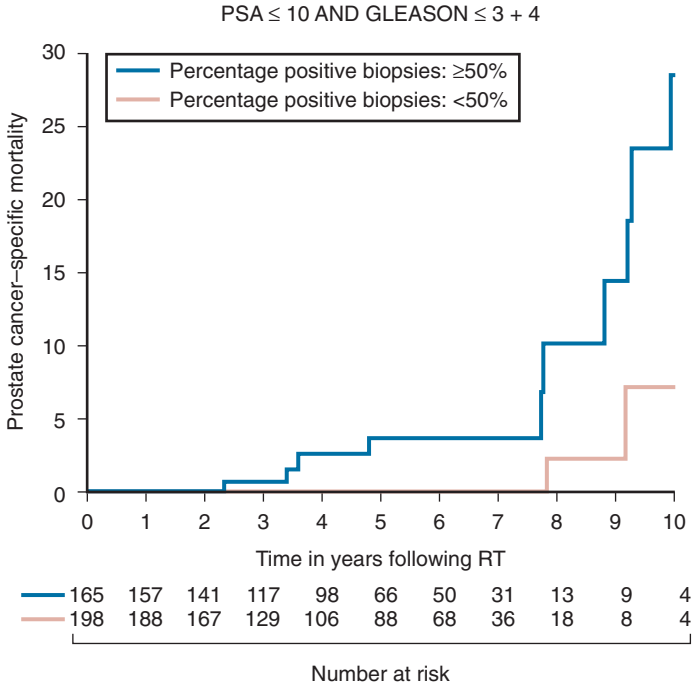

Figure 104–7. Prostate cancer–specific mortality following three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy in men with a prostate-specific antigen (PSA) of 10 or less and Gleason score of 7 or less. RT, radiation therapy.

Pretreatment PSA Velocity and the Risk of Prostate Cancer–Specific Mortality

Studies (D'Amico et al, 2005; Palma et al, 2008) have documented that a pretreatment PSA velocity greater than 2 ng/mL/year is associated with an increased risk of biochemical recurrence, metastasis, and cancer-specific death following treatment with RT or RT and hormonal therapy. In particular, in men with otherwise low-risk disease undergoing external beam RT, a pretreatment PSA velocity greater than 2 ng/mL/year increased the risk of death from prostate cancer x-fold, which translated into 19% [95% CI: 2 to 39%] as compared with 0% of men dying of prostate cancer within 7 years following treatment with RT if the PSA velocity was more than as compared with 2 ng/mL/year or less, respectively. As a result such men planning to undergo RT should be considered for RT and hormonal therapy because of the known survival benefit when adding hormonal therapy to RT in men with locally advanced (Pilepich et al, 1995, 1998, 2001; Bolla et al, 2002) or localized high-risk disease (D'Amico et al, 2008).

Key Points: Pretreatment Prognostic Factors

- Prostate cancer–specific mortality can be estimated on the basis of the pretreatment PSA level, biopsy Gleason score, and clinical T category.
- The percentage of positive prostate biopsies and the pretreatment PSA velocity, particularly when greater than 2 ng/mL/year provides additional information regarding prostate cancer–specific mortality in men with low-risk or favorable intermediate-risk disease.

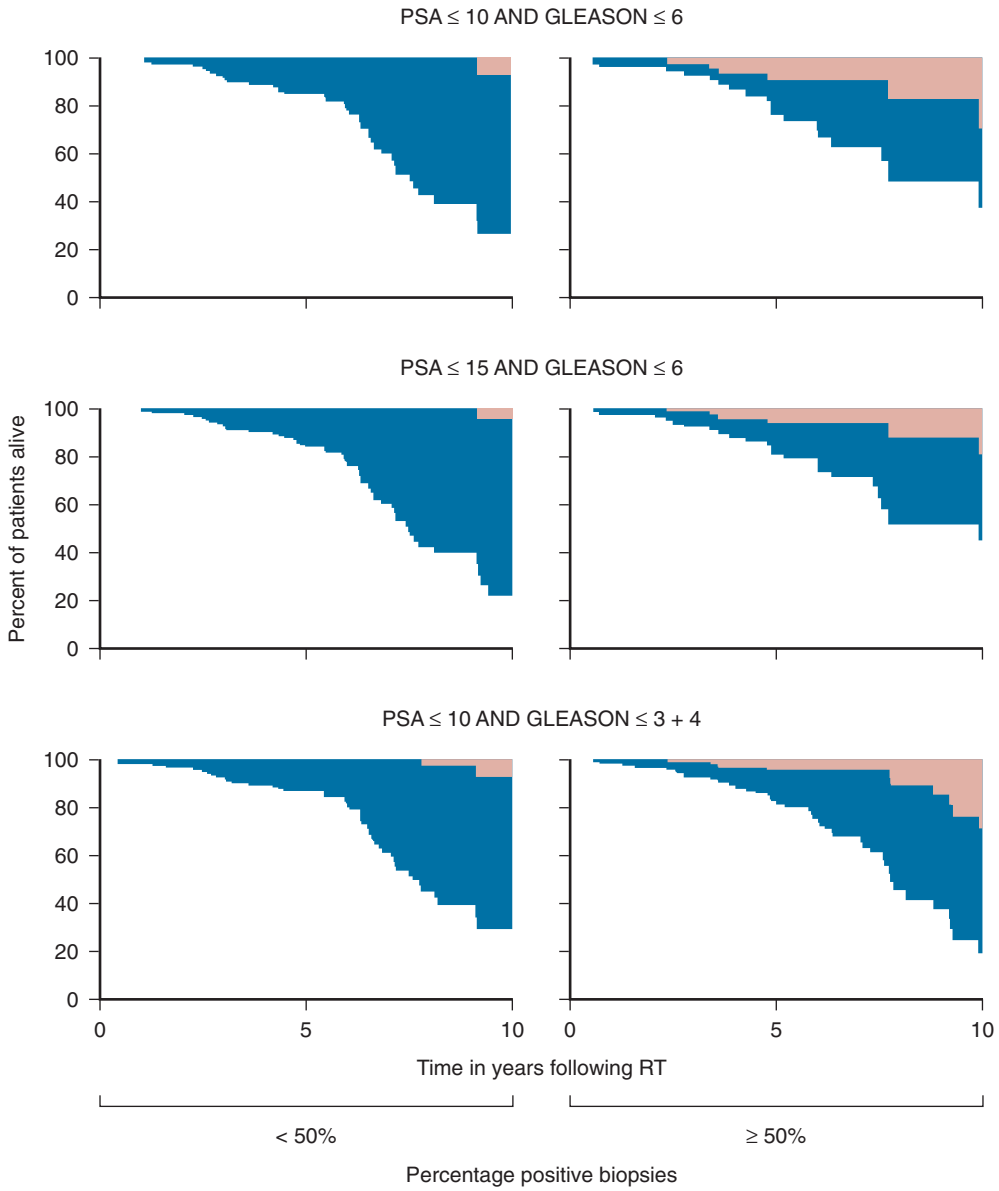

Figure 104–8. Relative contributions of prostate cancer–specific mortality (PCSM) and non-PCSM following treatment to all-cause mortality stratified by the percentage of prostate-positive biopsy (<50% vs. ≥ 50%) and the prostate-specific antigen (PSA) level and biopsy Gleason score at diagnosis. RT, radiation therapy.

Post-Treatment Prognostic Factors

Localized Disease—Evaluating the Response to Radiation

PSA Follow-up—Definition of Failure. Serum PSA has become widely accepted as a surrogate end point for monitoring the success of definitive treatment for localized prostate cancer. However, the definition of biochemical failure after RT remains controversial. Unlike the situation after radical prostatectomy, the patient successfully treated with radiotherapy still has a prostate gland and therefore is not expected to achieve an undetectable PSA reading. However, an "acceptable" PSA level after successful radiotherapy is markedly lower than the range of normal for an age-matched unirradiated population because of marked atrophy and a reduction in the size and number of nonmalignant acini (Grignon and Sakr, 1995).

Ablation of normal prostatic epithelium appears to be dose dependent. In a randomized trial comparing 70 and 78 Gy, Pollack and colleagues (2002b) found that with 78 Gy, 80% of patients achieved a nadir of less than 0.5 ng/mL, compared with 67% who received 70 Gy (P = .02). Although higher nadirs are associated with decreased disease-free survival, it is probably not necessary to ablate all the normal epithelium in order to achieve cure. Five-year freedom from biochemical failure is in the range of 80% to 90% for nadirs less than 0.5 ng/mL (Zincke et al, 1994; Lee et al, 1996; Crook et al, 1998; Critz et al, 1999; Kestin et al, 1999; DeWitt et al, 2003) but drops to 29% to 60% for nadirs of 0.6 to 1.0. However, even for PSA nadirs above 1.0 ng/mL, up to one third of patients remain free of recurrence at 5 years (DeWitt et al, 2003). Nadir PSA is a significant predictor of outcome, but no absolute nadir threshold can or should be used to define cure (DeWitt et al, 2003; Ray et al, 2004).

The 1996 ASTRO Consensus Conference (Consensus statement, 1997) proposed a standardized definition of biochemical failure after radiotherapy. Although there is no distinct PSA threshold that defines successful treatment, PSA stability following the nadir is important. The panel concluded that three consecutive increases in PSA is a reasonable definition of biochemical failure, recommending that the PSA determinations be 3 to 4 months apart in the first 2 years after radiotherapy and every 6 months thereafter. The requirement for three readings and the temporal spacing between the readings are necessary to avoid overcalling failure on the basis of temporary instability related to biologic noise or fluctuations in PSA of benign etiology (Crook et al, 1997a). It must be emphasized that establishing that a patient meets the criteria for biochemical failure is not justification for intervention. However, for the purposes of clinical trials and the reporting of data, a standard definition of failure is required. For these purposes, the date of failure should be backdated to midway between the PSA nadir and the date of the first increase.

Although the ASTRO definition provided uniformity in reporting of results, it is not a perfect solution to the problem of defining biochemical failure after radiotherapy. Waiting for three rises delays the establishment of failure by 18 months or more (Cherullo et al, 2002). This has no consequences for the individual patient because no individual requires intervention before the third rise, which defines the change in status. Furthermore, biochemical failure is not equivalent to clinical failure and is not of itself an indication for additional treatment. However, when reporting results, waiting for three rises and then backdating failure to midway between the nadir and the first rise tends to flatten the tail of the survival curve, underestimating late failures (Coen et al, 2003). Long follow-up minimizes this effect and short follow-up overestimates treatment success (Horwitz et al, 2003) because outcome cannot be predicted when the median follow-up is shorter than the median time to failure. One means of overcoming this shortcoming in the ASTRO definition is to backdate the follow-up time for all patients with one or two PSA rises (Coen et al, 2003; Thames et al, 2003). These patients can be censored (as disease free) midway between their nadir and first rise at the same time as they would be censored as a failure should they go on to have a third rise. In this way, the actuarial calculation does not benefit from extended follow-up for these patients whose status is uncertain. An alternative definition of biochemical failure that is particularly useful when few PSA values are available, as occurs when a patient has been lost to follow-up for a period of time or when PSAs are checked only annually, is any PSA value that is more than 2 ng/mL above the nadir (Coen et al, 2003).

Time to Nadir. Serum PSA declines slowly after completion of radiotherapy. The time to nadir has been shown to be inversely proportional to disease-free survival (Ray et al, 2004). The median time to nadir in patients who remain with no evidence of disease (NED) is 22 to 34 months (Hanlon et al, 2002; Pollack et al, 2002a). In a series of 615 men with a median follow-up of 64 months, Hanlon and colleagues (2002) reported that a lower nadir ($P < .0001$) and longer time to nadir are independent predictors of freedom from distant metastases ($P = .0002$). Lee and colleagues (1996) reported that 75% of men whose PSA reached a nadir in less than 12 months had distant metastases by 5 years as compared with 25% of those whose PSA took more than 12 months to reach a nadir ($P < .001$). Kestin and colleagues (1999) found that 92% of men whose PSA reached a nadir at 36 months or longer remained disease free as compared with 30% of those who reached a nadir in less than 12 months. The slow decline in PSA and the long time to PSA nadir are explained by the fact that, unlike other ablative treatment modalities such as surgery and cryotherapy, radiotherapy does not cause immediate cell death. The double-stranded DNA chromosomal breaks caused by radiotherapy are not immediately fatal but do not permit successful cell reproduction. Postmitotic cell death is not expressed until a cell tries to reproduce. Given the long doubling time of most prostate cancers, a fatally damaged cell may survive 18 to 24 months before unsuccessfully attempting cell division and dying.

Table 104–1.

Failure Pattern According to Level of PSA Nadir, Time to Nadir, and PSA Doubling Time

	PSA NADIR (ng/mL)	TIME TO NADIR (mo)	PSA DOUBLING TIME
NED	0.4-0.5	22-33	NA
Local failure	1.0-2.0	12-18	11-13 mo
Distant failure	>2.0	<12	3-6 mo

NA, not applicable; NED, no evidence of disease; PSA, prostate-specific antigen.

Significance of Nadir Value and Doubling Time. The level of PSA nadir achieved to some extent reflects the type of failure (Table 104–1). The median PSA nadir for NED patients in most series treated with external-beam radiotherapy is 0.4 to 0.5 ng/mL (Zietman et al, 1996; Critz et al, 1999; Crook et al, 2000), whereas for those exhibiting local failure it is often greater than 1.0 ng/mL and for distant failure greater than 2 ng/mL. A study by Hanlon and colleagues (2004) ($n = 615$, follow-up median 64 months) reported that freedom from distant metastases was 96% for a nadir less than 1 ng/mL, 89% for nadirs 1.1 to 2 ng/mL, and 61% for nadirs greater than 2 ng/mL. The postnadir doubling time of the PSA also correlates with the type of failure, with distant failures having shorter PSA doubling times of 3 to 6 months (Zagars et al, 1993; Hancock et al, 1995; Lee et al, 1997) and local failures having longer PSA doubling times of 11 to 13 months (Zagars et al, 1993; Hancock et al, 1995). D'Amico and coauthors (2003) reported that a PSA doubling time of less than 3 months is associated with prostate cancer mortality. Kuban and colleagues (2004) ($n = 4839$) found that PSA doubling time (<10 months vs. >10 months) and time to PSA failure (<2 years vs. >2 years) were the most significant factors in predicting distant metastasis-free survival after PSA failure.

The manner in which PSA nadir and time to nadir reflect the type of failure requires explanation. Three sources of PSA potentially contribute to the nadir: residual benign prostatic epithelium, residual local prostate cancer cells, and subclinical disseminated micrometastases. The longer the time to nadir and the lower the absolute nadir, the more likely it is that only benign prostatic epithelium remains, hence the NED status. A higher radiation dose achieves a more complete ablation of normal epithelium and thus a lower nadir. For patients in whom radiotherapy fails to eradicate all the local tumor, the PSA declines progressively until the rate of growth of the surviving prostate cancer cells is greater than the death rate of those fatally damaged by the radiation, at which point the PSA begins to rise. In the third scenario, subclinical micrometastases continue to grow unchecked despite successful treatment of the primary tumor. This growth rate outstrips the rate of decline in the local tumor population relatively early after treatment, leading to a higher and earlier nadir.

In any multivariate analysis of prognostic factors, if PSA nadir is included in the model with pretreatment PSA, Gleason score, and T stage, it becomes the strongest independent predictor of outcome (Ben-Josef et al, 1998; Crook et al, 1998; Preston et al,

1999). This is not surprising considering the close temporal relationship between the PSA nadir and the definition of biochemical recurrence. Although it is common practice to mix pretreatment prognostic factors in the same multivariate model with postradiotherapy PSA nadir, the latter should more correctly be considered a means of evaluating the response to radiotherapy.

Neoadjuvant Hormones and the Definition of Biochemical Failure. When neoadjuvant androgen deprivation is used before radiotherapy, patients often start radiotherapy with an already undetectable PSA. If the PSA remains undetectable, it is impossible to determine a true nadir or time to nadir. If hormonal therapy is only neoadjuvant or concurrent, or both, rapid recovery of the serum testosterone may cause a temporary increase in PSA shortly after completion of radiotherapy and cessation of hormonal therapy. Subsequently, as the effect of the radiotherapy is expressed, the PSA declines once again. Although complete data from randomized trials are still pending on this point, this secondary nadir probably has the same prognostic significance as PSA nadir in the absence of neoadjuvant hormonal therapy. Adherence to the ASTRO definition of biochemical failure, requiring three successive PSA increases 3 to 4 months apart, usually allows sufficient time for this phenomenon to pass and to avoid incorrectly labeling the patient as a radiotherapy failure.

Benign Bounce Phenomenon. In the presence of residual benign epithelium or before the full effect of radiotherapy has been expressed, PSA may fluctuate or show several consecutive increases. A spike or bounce can be defined as a rise greater than 0.2 ng/mL followed by a durable decline (Merrick et al, 2003b). This phenomenon is especially common after brachytherapy, where it is reported to occur in 24% to 35% of men (Critz et al, 2000; Smathers et al, 2001; Merrick et al, 2002a, 2003b; Reed et al, 2003). Spikes have been reported to be more common in younger men and after implantation with ^{125}I rather than ^{103}Pd (33% vs. 17%) (Merrick et al, 2003a). Spikes can start any time from 9 to 30 months after brachytherapy (Reed et al, 2003) and may reach a maximum PSA value up to 10 ng/mL, although the majority shows a cumulative rise of not more than 2 to 3 ng/mL. Spikes may last as long as 12 to 18 months, and double peaks can be seen. Biopsies performed to investigate the rising PSA may show residual cancer with treatment effect (indeterminate) (Reed et al, 2003). Currently, there is no reliable way to discern whether a rising PSA in the first 3 years after brachytherapy represents treatment failure. Many meet the ASTRO definition of biochemical failure. Only patience and careful follow-up demonstrate the subsequent spontaneous PSA decline to low levels.

Postradiation Therapy Biopsy

Although serum PSA nadir has been widely adopted as a surrogate end point to determine treatment efficacy, it cannot distinguish between local and systemic failure. Postradiotherapy prostate biopsies would seem to be the logical means of evaluating the local effect of radiotherapy. The major issues involve the following:

- Timing of the biopsies with respect to completion of radiotherapy
- Interpretation of indeterminate biopsies that show residual tumor with marked radiation effect and uncertain viability
- The usefulness of markers of cellular proliferation
- The uncertainty imposed by sampling error

Timing. In early reports, little was known about the rate of histologic clearance of irradiated tumor and failures were declared as early as 6 months after completion of radiotherapy (Scardino and Wheeler, 1985). It is now recognized that the time for histologic resolution of tumor parallels the time to serum PSA nadir and for the same reasons. Radiation causes postmitotic cell death, and fatally damaged cells may survive a limited number of cell divisions (Mostofi et al, 1992, 1993). Biopsies taken before histologic resolution is complete show a moderate to marked radiation effect (Crook et al, 1997b). Ultimate viability of these cells cannot be predicted. Crook and colleagues (1995) have determined that the optimal time to biopsy is 30 to 36 months after radiotherapy.

Interpretation. Gleason scoring of irradiated prostate cancer should be performed only if the histologic evidence of radiation effect is absent or minimal. Gleason's original work was based on surgically obtained material that had not been exposed to prior radiotherapy or hormonal therapy. It is based on gland architecture, which is known to be markedly altered by radiotherapy. Inappropriate application of the Gleason scoring system to disintegrating malignant glands showing a marked RT effect (Siders and Lee, 1992; Grignon and Sakr, 1995) results in a false-positive biopsy and perhaps unnecessary "salvage" therapy.

Radiation atypia in benign glands can be severe enough to mimic malignancy (Bostwick et al, 1982; Grignon and Sakr, 1995; Cheng et al, 1999). Anticytokeratin monoclonal antibody for high-molecular-weight keratin labels the basal cell layer of benign glands and therefore helps to distinguish radiation atypia in benign glands from residual tumor where the basal cell layer would be absent (Brawer et al, 1989).

Scoring systems for the degree of radiation effect have been proposed (Dhom and Degro, 1982; Bocking and Auffermann, 1987) on the basis of cytoplasmic and nuclear changes (Table 104–2) and can be helpful in interpreting the significance of residual tumor in the biopsy (Crook et al, 1997a). Their importance is to emphasize the need to differentiate between biopsies showing no or minimal radiation effect and those showing marked treatment effect (Zelefsky et al, 2004). Failure to do so dilutes the prognostic significance of biopsy status and may lead to inappropriate salvage therapy.

Markers of Cellular Proliferation. Immunohistochemical stains for markers of cellular proliferation can also be useful in interpretation of the significance of residual tumor. The two nuclear proteins expressed in proliferating cells for which there is the most clinical experience are proliferative cell nuclear antigen or PCNA (Crook et al, 1994) and Ki-67 (Ljung et al, 1996). PCNA is expressed both at DNA replication for cell division and during cellular repair.

Table 104–2.

Grading Scheme for Cytoplasmic and Nuclear Radiation Effect

(The scores for cytoplasmic and nuclear changes are added together. A score of 5-6 represents marked treatment effect, 3-4 is moderate, and 0-2 minimal.)
Cytoplasmic changes 0 No identifiable RT effect
1 Swelling and microvesicular change
2 Extensive vacuolation, macrovesicular change, and voluminous cytoplasm
3 Indistinct or ruptured cytoplasm
Lipofuscin pigment accumulation
Glands dilated or just single cells with no glandular formation
Nuclear changes 0 No identifiable RT effect
Some swelling or smudging of nuclei but nucleoli still visible
Smudged and distorted chromatin
Nucleoli rare or absent
Large bizarre nuclei
Pyknotic small condensed nuclei

RT, radiation therapy.

It is not formalin stable and is unreliable if the duration of formalin fixation is not closely monitored (Wiatrowska et al, 1997). On the other hand, Ki-67 is expressed exclusively in proliferating cells, reaches a maximum in the mitotic phase, and is formalin stable. Positive immunohistochemical staining for either of these markers in residual tumor is strongly associated with subsequent failure (Crook et al, 2000).

Sampling Error. Although TRUS guidance is recommended for postradiotherapy prostate biopsies to ensure adequate and systematic sampling, TRUS alone is of limited diagnostic use because the increase in fibrosis alters the echogenic characteristics of the irradiated prostate (Crook et al, 1993; Svetec et al, 1998). Surviving malignant cells may be in the form of minimal scattered microscopic foci. False-negative rates approaching 20% have been reported (Crook et al, 2000).

Biochemical freedom from disease, as determined by a nonrising serum PSA, is the accepted surrogate end point in determining treatment outcome and tumor eradication. It does not, however, distinguish between local and systemic failure. Local therapy should be evaluated in terms of local tumor eradication. Local failures can be reduced by treatment refinements such as dose escalation and improvements in treatment planning and delivery. Systemic failures are a problem of selection of patients and a failure to recognize high-risk features that require a combined modality approach to address a potential systemic component. Although postradiotherapy prostate biopsies are fraught with problems of timing, interpretation, and sampling error, they do help to distinguish between local and systemic failures and are a valuable research tool. Clearly viable residual tumor should be in evidence before considering radical local salvage for radiation failure.

Key Points: Post-Treatment Prognostic Factors

- The level of PSA nadir achieved following radiation therapy reflects the pattern of failure. Specifically, a nadir greater than 2 ng/mL is associated with distant failure.
- The PSA doubling time following radiation therapy also predicts the pattern of failure. Specifically, a PSA doubling time of less than 3 months is almost always associated with distant failure.

TREATMENT: CANCER CONTROL AND QUALITY OF LIFE

The question of whether the absence or presence of local control of a treated tumor is related to the subsequent development of metastatic disease was explored experimentally as far back as 1970. Mice with sarcomas of the extremity developed fewer pulmonary metastases if their affected limbs were amputated early in the course of disease (Suit et al, 1970). Given that RT is a local treatment modality, one of the goals of treatment became local control, with the expectation that only patients who achieved such control could be expected to be cured of their cancer. This principle was first examined in prostate cancer in the 1980s, when a relationship between treatment planning technique and cancer control was demonstrated in the Patterns of Care Studies (Leibel et al, 1984; Hanks et al, 1988). Patients' treatment records were reviewed from 163 randomly selected radiation oncology departments located across the United States.

Tumor control was better in patients who received higher doses of radiation to larger fields, at the expense of increased complications. Fully 40% of patients' records indicated departure from current cancer guidelines for diagnostic evaluation and treatment. These studies sparked an intense interest in and ongoing effort to improve outcomes in men with prostate cancer by providing the best treatment planning and delivery systems possible (Leibel et al, 1994).

Although external-beam RT has been used for decades to treat prostate cancer, it is still an evolving specialty. Until the 1970s, radiation oncologists had to treat cancers without precise knowledge of their location within the body. Knowledge of normal anatomy, routes of spread of a particular cancer, and limited information from diagnostic radiology were used for treatment planning (Asbell et al, 1980). Radiation oncologists became adept at designing their portals on the basis of skeletal anatomy. For the treatment of prostate cancer, the radiation portals were centered on the pubic symphysis and femoral heads. One group designed a rotating platform treatment; men with prostate cancer stood on a small mechanical platform that rotated 360 degrees while the radiation beam was aimed at the level of their pants pockets. This was considered advanced for its time.

Later, oncologists learned to use additional tools for treatment planning. The location of the prostate was inferred indirectly by introducing a contrast-filled Foley catheter and rectal tube into the patient. The prostate was assumed to be located in the space between these two organs, as shown in Figure 104–9. As recently as the mid-1980s, this technique was considered state of the art.

With the advent of computed tomography (CT) scanners, a direct method to localize the prostate within the bony pelvis became available, and optimization of radiation with both physical and biologic end points was finally possible (Mohan et al, 1992; Niemierko et al, 1992). Clinicians knew as early as 1980 that they were making significant errors in field placement without CT data, but limitations in computer hardware and software allowed no solution to the problem (Rosenman et al, 1991; Fraass, 1993). Fortunately, the dramatic and rapid improvement in computer availability, lowered costs, improved graphics, and rapid computational power has changed forever the field of radiation oncology. Men with prostate cancer are the direct beneficiaries of the new technologies, and prostate cancer is one disease for which the treatment of today bears little resemblance to that used as recently as the late 1980s (Fraass, 1995).

The 1990s began the era of three-dimensional tumor visualization and treatment planning. For the first time, the internal organs—the prostate and surrounding structures—could be identified with increased precision, and the beam's eye view, a technique allowing visualization of the regional anatomy from the perspective of the beam apertures, enabled the design of plans that could more accurately treat the prostate target while minimizing dose to the surrounding normal tissues. The result is loosely described as conformal radiation therapy (CRT) because the radiation beams conform to the shape of the treatment target (Fraass, 1995). The ability to deliver CRT requires special hardware, software, and training. In the United States, there are approximately 1500 radiation facilities, only 20% of which are associated with a university or residency training program (D'Amico and Hanks, 1999). Today's residency programs all educate their radiation oncology residents in the art of CRT, and each year more practices offer this treatment as a standard therapy.

One of the goals of conformal prostate radiation is to lower the dose to the surrounding normal tissues, such as the rectum and bladder, while simultaneously increasing the dose delivered to the

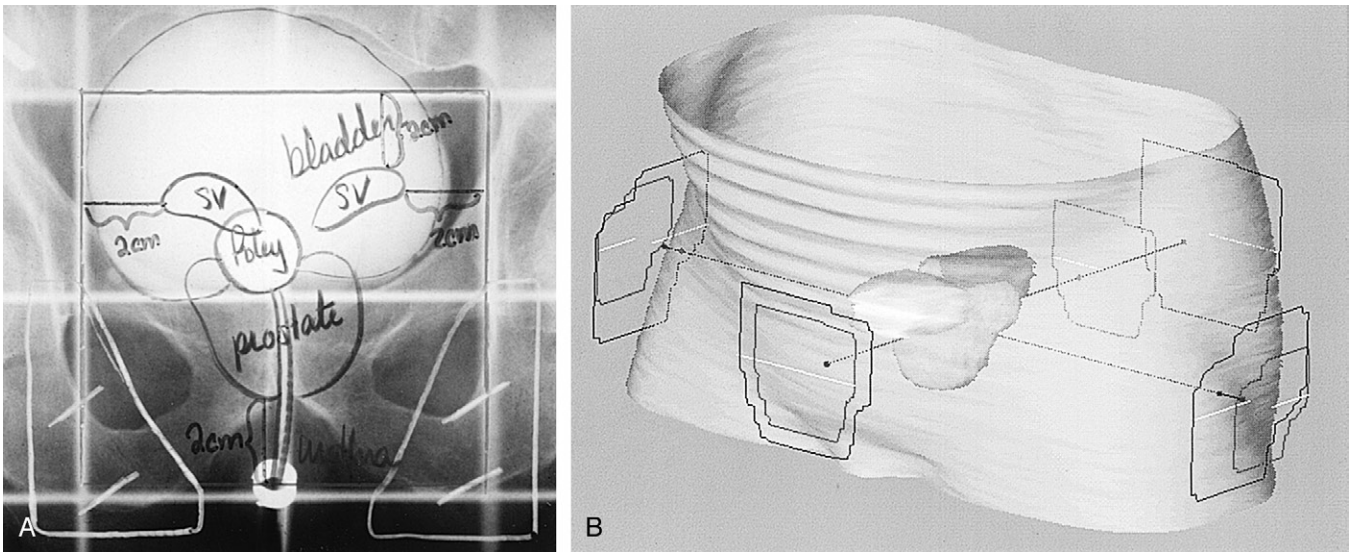

Figure 104–9. **A,** Conventional radiation therapy treatment portal, anterior view. The location of the prostate is inferred from the location of the Foley balloon and from contrast in the bladder, as well as from the location of the wire anal marker. **B,** Conformal radiation therapy portal, anterior view. The fully three-dimensional prostate volume is reconstructed from the planning computed tomography scan.

Table 104–3.

Side Effects in Patients Receiving Radiation Therapy

INSTITUTION AND REFERENCE	NO. OF PATIENTS STUDIED AND RADIATION THERAPY TECHNIQUE	PERCENTAGE WITH MODERATE TO SEVERE INTESTINAL COMPLICATIONS	PERCENTAGE WITH MODERATE TO SEVERE GENITOURINARY COMPLICATIONS
Medical College of Wisconsin (Lawton et al, 1991)	1020 Nonconformal	3.3	7.7
Memorial Sloan-Kettering (Zelefsky et al, 1999a)	743 Conformal 64.8-81 Gy	11.8	13
Fox Chase Cancer Center (Schultheiss et al, 1995)	616 Conformal 68-75 Gy	2.7	3.2
Joint Center for Radiation Therapy (Beard et al, 1998)	354 Nonconformal 66 Gy	2.6	4
University of Michigan Medical Center (Sandler et al, 1995)	721 Conformal 59.4-80.4 Gy	3	N/S
University Hospital Rotterdam (Koper et al, 1999)	266 66 Gy conformal vs. 66 Gy conventional	 19 32	
Royal Marsden Hospital (Dearnaley et al, 1999)	225 64 Gy conformal vs. 64 Gy conventional	 5 15	 20 23

prostate itself (Burman et al, 1991; Niemierko et al, 1992). All radiation oncologists agree that CT data allow more accurate placement of the radiation fields. This was first demonstrated by Pilepich and colleagues (1982), who found a 53% error rate in field placement and portal size in patients simulated without CT data. In theory, better pretreatment visualization and localization of the prostate eliminate the need to enlarge the radiation portal to account for anatomic and geometric uncertainties. It follows that smaller radiation portals allow less irradiation of nontarget structures such as the bladder or rectum. However, some data suggest that the geometric relationships between the prostate and the contiguous normal tissues vary within the same patient owing to physiologic motion of the pelvis in a random fashion that can be difficult to categorize (Ten Haken et al, 1991; Beard et al, 1996; Zelefsky et al, 1999b). The proximity of the prostate to the radiation-sensitive bladder, rectum, neurovascular bundles, and erectile tissue of the penis has always been a concern; patients who undergo external-beam radiation are at risk for gastrointestinal, genitourinary, and sexual side effects. The percentage of patients who experience side effects and the severity of the side effects differ somewhat from series to series, depending on the morbidity scale used and also on whether the assessment is physician based or patient based (Table 104–3) (Pilepich et al, 1987; Lawton et al, 1991; Austin-Seymour et al, 1994; Beard et al, 1997, 1998). In general, prospective patient-based assessments yield higher percentages of patients experiencing side effects, irrespective of the type of treatment studied (Beard et al, 1997; Talcott et al, 1998). If there is still some debate about whether complication rates have decreased as a result of conformal treatment, it is probably because clinicians increased their doses as treatment portals became smaller. Also, although normal tissue complication rates have been established to be related to radiation dose and volume, they

are also influenced by other dosimetric and clinical factors such as coexisting disease in individual patients that cannot be fully controlled or described in clinical studies (Pollack et al, 2003).

Several authors (Sandler et al, 1992, 1995; Leibel et al, 1994; Schultheiss et al, 1995, 1997) have compared the complication rates in their own prostate cancer patients receiving conventional versus conformal radiation. Most authors use the Radiation Therapy Oncology Group (RTOG) late-radiation morbidity scales, as shown in Table 104–4.

A prospective randomized trial was performed in the University Hospital of Rotterdam and the Daniel den Hoed Cancer Center of the Netherlands comparing the effect of 66 Gy delivered by either conventional therapy or CRT in a group of 266 patients (Koper et al, 1999). All patients were evaluated for gastrointestinal and genitourinary outcomes. A statistically significant reduction was seen in the proportion of patients experiencing grade 2 rectal toxicity in the conformal arm of the study (19% vs. 32%) ($P = .02$). Most of the benefit with conformal RT was due to a low incidence of anal side effects (8% compared with 16% experienced by the control group). Interestingly, no difference was seen in the percentages of patients who experienced bladder symptoms, which were minimal in both arms of the trial. A second prospective randomized trial comparing conformal and conventional radiation was performed at the Royal Marsden Hospital (Dearnaley et al, 1999). In that trial, 225 men were randomly assigned to receive 64 Gy of one or the other form of radiation. Only 5% of the conformal group developed grade 2 proctitis and bleeding, compared with 15% of the conventional group ($P = .01$). As in the Dutch study, no difference was seen between the groups in the development of grade 1 or 2 bladder symptoms.

Sexual function after conformal RT has been evaluated by several groups. At the Joint Center for Radiation Therapy and the Dana-Farber Cancer Institute (DFCI), patients participating in a prospective multi-institutional outcomes trial were divided into three groups on the basis of their RT treatment technique (Beard et al, 1997). As shown in Table 104–5, fewer patients reported sexual side effects after treatment with conformal radiation than with small-field or whole-pelvis treatment. None of the values were statistically significant, but this may have been due in part to the small sample size studied.

New data exist on the relationship between dose and morbidity. For prostate cancer, most of the progress has been made in the area of rectal complications. Predictors of bladder complications have yet to be identified, perhaps because they manifest many years after treatment (Gardner et al, 2002). Most "late" rectal complications, however, are seen within 2 years and almost always within 4 years of treatment (Pollack et al, 2002b) and are more easily evaluated. In the M.D. Anderson Cancer Center trial, the

From Beard C, Propert K, Rieker P, et al. Complications after treatment with external-beam irradiation in early-stage prostate cancer patients: a prospective multiinstitutional outcomes study. J Clin Oncol 1997;15:223–9.

5-year freedom from a complication above grade 2 was 26% in the 78-Gy arm and 12% for those in the 70-Gy arm, nicely demonstrating the relationship that can exist between dose and complications. When further analysis was performed to identify factors other than total dose that might be used to predict for rectal toxicity, it was shown that the risk of complications increased from 25% to 46% when the rectal volume exposed to 70 Gy increased from less than 25% to greater than 25% (Pollack et al, 2002a). A more detailed analysis followed and showed that it was the proportion of the rectum receiving greater than 70 Gy that was more significant than the absolute rectal volume (Huang et al, 2002b), but the basic premise remained the same.

Unlike that after radical prostatectomy, sexual dysfunction after RT increases slowly with time (Talcott et al, 1998). Zelefsky and colleagues (1999a) from Memorial Sloan-Kettering Cancer Center reported that 39% of 542 previously potent patients given 64.8 to 81 Gy of conformal radiation became impotent within 5 years of treatment. A retrospective evaluation of 287 men from the University of Chicago yielded similar results, with 53% of previously potent men reporting impotence by 60 months after conformal therapy (Mantz et al, 1999). As with other studies of sexual function after radiation, the men most likely to remain potent after treatment were those with good pretreatment sexual function and little or no comorbid illness and those who did not receive androgen therapy.

Key Point: Treatment—Cancer Control and Quality of Life

- Randomized control trials show a benefit in PSA control for doses of radiation therapy of 78 to 79 Gy as compared with 70 Gy primarily in men with low- or intermediate-risk prostate cancer.

Tumor Control after Conformal Radiation Therapy

Long-term (more than 10 years of follow-up) data after conformal RT are not yet available, but early data have been reported by several centers. Most of these data are measured by freedom from PSA failure.

Zelefsky and colleagues (1998) reported their results for the first 743 men with prostate cancer treated with prospective dose-escalation conformal radiation. Patients were divided into favorable (stage T1 or T2, PSA < 10 ng/mL, Gleason grade < 6), intermediate (having one unfavorable feature), and unfavorable (having two unfavorable features) groups. For these three groups, the 5-year PSA freedom-from-relapse rates were 85%, 65%, and 35%, respectively. Almost identical data were obtained by Fukunaga-Johnson and colleagues (1997) at the University of Michigan. In that series, 707 patients received conformal radiation at doses of up to 80 Gy, with most patients receiving more than 69 Gy. Patients with favorable features (defined as stage T1 or T2, Gleason grade 7, and PSA < 10 ng/mL) enjoyed a 75% 5-year freedom from PSA relapse, compared with a 37% rate in those with unfavorable features (T3 or T4, Gleason grade > 7, or PSA > 10 ng/mL). Researchers at the Fox Chase Cancer Center in Philadelphia modeled the effect of dose levels less than 74 Gy against those greater than 74 Gy using pairs of patients matched by stage, pretreatment PSA level, and Gleason grade (Hanks et al, 1999). When PSA was discounted, delivered dose greater than 74 Gy correlated significantly with freedom from local disease progression and freedom from distant metastases and increased cause-specific and overall survival. The results were still significant for freedom from disease progression and freedom from distant metastases when PSA was included as an independent variable.

Six hundred eighteen patients who received conformal radiation were divided into groups on the basis of their pretreatment tumor characteristics (Gleason grade, clinical stage, and PSA level) and their total radiation dose (76 Gy vs. more than 76 Gy). Six subgroups were created. Patients with favorable tumors (Gleason grade 6, stage T1 or T2a) who also had a PSA less than 10 ng/mL derived no benefit from dose escalation because all patients in this group did well. Patients with unfavorable tumors (Gleason grade 7 to 10, stage T2b or T3) who had a PSA greater than 20 ng/mL also derived no benefit from dose escalation. In this cohort, both arms fared poorly, with freedom-from-relapse rates that were less than 30%. All other patients demonstrated statistically significant improved freedom-from-relapse rates with high-dose conformal treatment, as shown in Figure 104–10.

It has long been understood that increased doses of external RT are associated with better cancer control rates for patients with prostate cancer. For many years, an isocenter dose of 70 Gy was considered the maximum dose that could be safely delivered. With the advent of CRT, several groups looked at higher doses in the setting of a randomized trial. At Massachusetts General Hospital, a trial randomizing between 67.2 Gy (conventional arm) and 75.6 Gy (proton boost arm) was undertaken in patients with locally advanced disease. The study showed a significant increase in local control with the higher dose, with 8-year rates of 19% and 84% (P = .0014) for patients in the high- and low-dose arms, respectively (Shipley et al, 1995). Disease-free survival was also better for a subset of patients with Gleason grade 8 to 10 cancer, but no differences in overall or cancer-specific survival were noted.

A number of CRT and intensity-modulated radiotherapy (IMRT) dose escalation trials are under way or have completed accrual

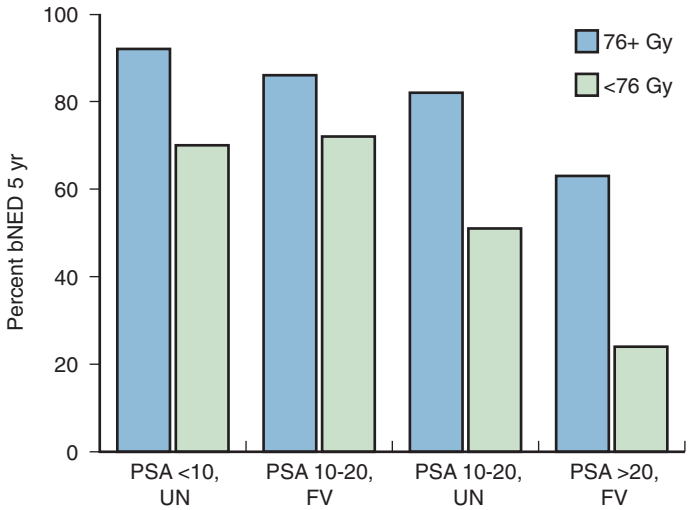

Figure 104–10. The advantage of dose escalation is shown in these dose-response graphs. Patients are divided into groups on the basis of their pretreatment clinical characteristics and the dose of radiation they received. FV, favorable characteristics (Gleason grade 6, stage T1c-T2a); UN, unfavorable characteristics (Gleason grade 7-10, stage T2b-T3). (Modified from Hanks G, Hanlon A, Pinover W, et al. Survival advantage for prostate cancer patients treated with high-dose three-dimensional conformal radiotherapy. Cancer J Sci Am 1999;5:152–8.)

(Pollack), but only the M.D. Anderson Cancer Center trial has reached maturity and been published. In this trial, 301 patients were randomized; 150 received the standard CRT dose of 70 Gy at isocenter, and the other 150 received the higher dose of 78 Gy at isocenter (Pollack et al, 2002b). The 6-year rates of freedom from failure were significantly higher for those randomly assigned to the 78-Gy arm (70% vs. 64%, $P = .03$). The greatest benefit was observed for patients with a pretreatment PSA greater than 10 ng/mL. These intermediate- to high-risk patients had 6-year freedom-from-failure rates of 62% and 43% when treated with 78 and 70 Gy, respectively ($P = .12$). There was also a borderline reduction in distant metastases for patients in this group who received the higher dose (2% vs. 12%, $P = .056$).

Patients who receive conformal radiation, as opposed to conventional radiation, may be treated with higher doses safely. They appear to develop fewer complications and enjoy a decreased risk of tumor recurrence during the first 5 years after treatment. Given the benefit demonstrated by both single-institutional retrospective reviews and prospective randomized trials, conformal radiation has become the standard against which other therapies must be measured. Dose escalation therapy to doses greater than 75 Gy is still experimental, but the early data appear to be highly favorable.

Intensity Modulation

Although CRT was a major technological advance, it represented advancement of treatment planning processes that had been in place since the 1980s. Real progress in the delivery of radiation came with the advent of IMRT. IMRT is an exciting form of conformal RT that uses extremely advanced software, specialized personnel, and hardware adaptations to linear accelerators (Burman et al, 1997). At present, its availability is limited to a small number of radiation centers because of its complexity, but in time it may replace CRT in popularity and availability. The goal of IMRT treatment planning and delivery is to maximize treatment to the target (e.g., the prostate) while minimizing treatment to the surrounding tissues to a degree that is not possible with conformal therapy (Oh et al, 1999).

The term *IMRT* is now applied to a family of methodologies that use different methods of treatment planning and delivery in order to achieve a precise, nonuniform beam fluence (Jani et al, 2003). IMRT uses a new planning approach referred to as inverse treatment planning. This approach gives equal attention to the areas where radiation dose is to be minimized and the areas that are to receive high-dose treatment. Inverse planning uses a mathematic approach to convert a desired dose distribution to the target volume and normal organs into a clinically applicable treatment plan. The planning computer, using a mathematic optimization technique known as simulated annealing, determines the optimized beam arrangement. The second component of IMRT is computer-controlled modulation of the intensity of the radiation beam during treatment. The outcome is a set of radiation beams with changing intensities across the field, as shown in Figure 104–11. With this technology, the prostate can receive a daily dose of 180 cGy, whereas the majority of the adjacent bladder receives less than half of this dose.

An example of an intensity-modulated beam is shown in Figure 104–12. The tight distribution of radiation around the prostate with avoidance of most of the rectum and bladder is seen on inspection of the figure. IMRT for prostate cancer generally uses five or seven radiation ports or fields per day, as shown in Figure 104–13. Prostate cancer is currently the single most common tumor site treated with IMRT worldwide (Guerrero Urbano et al, 2004). When IMRT is compared with CRT in the same patient, using the same prescribed dose, statistically significantly lower doses are delivered to the critical normal tissues: rectum, bladder, and small bowel (Luxton et al, 2004).

Because the risk of rectal and bladder complications is believed to be a continuous function of dose, the lower the proportion of

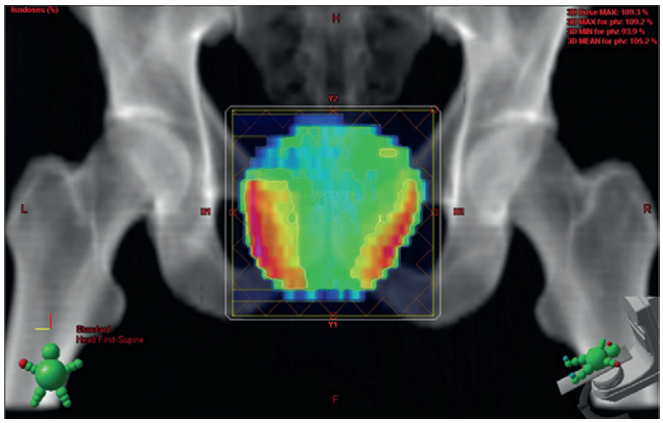

Figure 104–11. Intensity-modulated radiotherapy fluence.

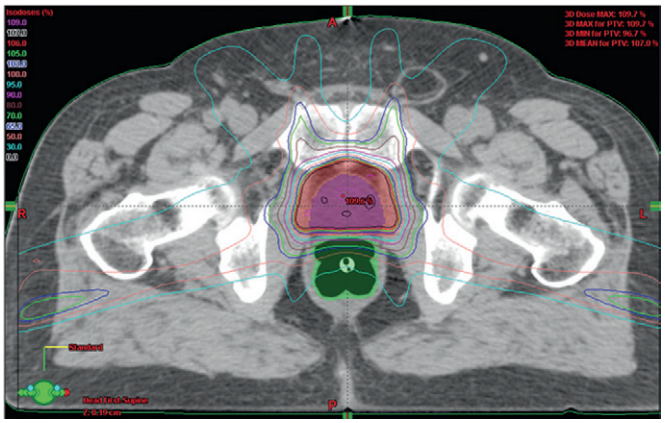

Figure 104–12. New intensity-modulated radiotherapy.

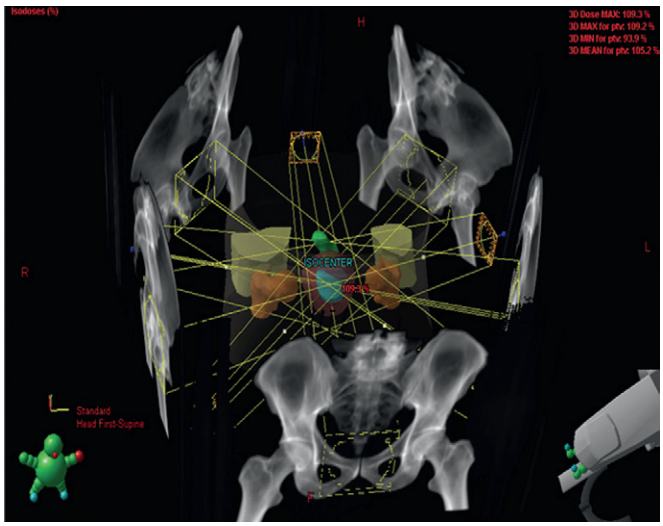

Figure 104–13. Intensity-modulated radiotherapy setup.

these organs that receive high dose, the lower the complication probability, all else being equal. For this reason, radiation oncologists who deliver IMRT choose dose constraints before initiating treatment planning. At the Brigham and Women's Hospital, we limit the volume of rectum that receives more than 65 Gy to 25%. The volume of rectum that receives more than 47 Gy is limited to less than 43%. Although the exact relationship between bladder dose and complication rates has not been established, it is common practice to define constraints for the bladder as well. In general, the goal is to limit less than 25% of the bladder volume to more than 65 Gy and less than 50% of the bladder volume to more than 40 Gy. Each practitioner may have his or her own set of constraints. There is no universally accepted standard.

One of the important considerations for radiation oncologists who treat prostate cancer is the issue of prostate motion. That prostate motion occurs is well documented, both on a day-to-day basis (Ten Haken et al, 1991; Beard et al, 1996) and, to a lesser extent, during the time it takes to deliver a daily radiation treatment (Huang et al, 2002a). Radiation oncologists can either expand the size of the radiation beam to accommodate prostate motion and accept the risk of increased morbidity or, if small fields are to be used, check the location of the prostate each day before delivering radiation. This can be done with a daily ultrasound determination of the prostate location immediately before treatment while the patient is on the treatment table, but this approach is highly operator independent and susceptible to error (Lee et al, 2002). Another option is to introduce radiopaque markers into the prostate under ultrasound guidance and to use a commercially available software program to localize the prostate each day before treatment while the patient is on the treatment table. Neither approach, however, addresses the issue of intrafraction motion. The solution to this problem may be prostate immobilization. At Brigham and Women's Hospital, a balloon immobilization device is introduced through the rectum before treatment planning and each of the first 15 treatments. The balloon is inflated with 60 to 100 cm^3 of air. Inflation of the balloon pins the prostate against the pubic bone. Each day with the patient on the treatment table, positioning films are taken and the fields are set up to the balloon immobilizer. Because the immobilized prostate does not move during treatment, small posterior margins can be used (Fig. 104–14), thus minimizing dose to the rectum. In the first 28 patients studied with this approach at Brigham and Women's Hospital, the use of the balloon immobilizer decreased the percentage of rectum receiving more than 70 Gy from 36% if no balloon was used to 3.5% with 15 immobilized treatments (Sanghani et al, 2004).

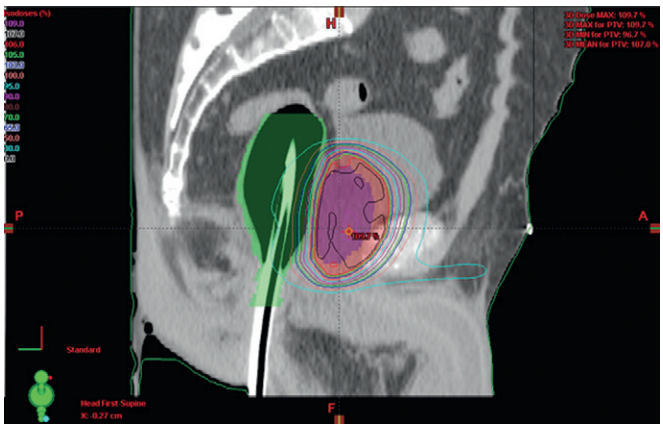

Figure 104–14. Balloon intensity-modulated radiotherapy. (Courtesy of Fred Hacker, PhD, Department of Radiation Oncology, Brigham and Women's Hospital.)

In a retrospective analysis of patients treated in a phase I/II trial, investigators from Memorial Sloan-Kettering Cancer Center reported a reduction in morbidity from 14% at 3 years to 2% after moving from CRT (81 Gy, $n = 189$) to IMRT (81 Gy, $n = 61$) (Zelefsky et al, 2002). Ninety percent of the patients in this study were treated to 81 Gy and 10% to 86.4 Gy, doses never attempted before in prostate cancer patients. After 2 years, only 4.5% of patients had acute grade 2 rectal toxicity and none experienced grade 3 or 4. Late grade 2, 3, and 4 toxicity occurred in 1.5%, 0.1%, and 0% of patients, respectively. One caveat in the interpretation of these data is as follows. Rectal blocks were used and the entire prostate gland with a margin did not receive the prescribed dose. Specifically, prostate tissue in the region of the anterior rectal wall received much lower doses, on the order of 74 to 76 Gy. However, much of the gland was treated to the prescribed dose and the complication rates were low. In a retrospective analysis of 77 patients treated at Baylor College of Medicine, investigators demonstrated a statistically significant difference for both rectal and bladder toxicity ($P < .001$) between the IMRT and CRT groups. These publications created immediate interest in dose escalation and IMRT for prostate cancer.

Published reports suggest that erectile dysfunction after radiation is caused predominantly by vascular damage. More recent data suggest that it is dose to the penile bulb that correlates best with erectile dysfunction after CRT (Roach et al, 2000; Fisch et al, 2001; Merrick et al, 2001). With the interest in dose escalation, there is some concern that post-therapy potency rates will decline (Kao et al, 2004), and preliminary data from Memorial Sloan-Kettering suggest that this may be true (Zelefsky et al, 1999a). In order to maintain or lower the risk of erectile dysfunction after dose escalation, it is necessary to modify existing techniques with this goal in mind. Researchers at the University of Chicago Medical Center undertook a planning exercise in 10 consecutive patients with prostate cancer. They planned each patient with an optimized CRT technique and then replanned each for IMRT, without adding dose constraints for the erectile tissue. IMRT significantly decreased the percentage of the penile bulb receiving 40 Gy ($P < .001$), and the percentage of volume receiving more than 70 Gy was nearly identical for both CRT and IMRT.

A similar modeling study was undertaken by investigators at Fox Chase Cancer Center (Buyyounouski et al, 2004). In this study, the object was to limit the radiation dose to the penile bulb and corpora without increasing radiation dose to the rectum and bladder. Twenty-three patients were studied. The dose to the erectile tissue was easily decreased by 60% (compared with standard CRT) in all patients. Limiting the dose received by erectile tissue to 15 Gy was easily accomplished in 80% of patients but required significant alteration of field arrangement in the other 20%. These investigations provided interesting dosimetric evidence that IMRT allows an increased therapeutic ratio in prostate cancer. However, long-term clinical data to prove this hypothesis are not yet available.

Only a few groups have used IMRT for enough time to report any efficacy data. The group at Memorial Sloan-Kettering has the most experience in the United States with IMRT. As shown in their outcome data, the PSA-relapse-free survival rates were highest after treatment with IMRT when the dose of radiation delivered was greater than 81 Gy (Leibel et al, 2003). The median time to follow-up for these patients was 50 months, but the range was broad (6 to 150 months) and presumably the patients who received the highest doses were also those treated most recently.

Key Point: Intensity Modulation

- IMRT provides the ability to deliver higher doses of radiation with lower rates of rectal bleeding.

Heavy Particle Beams

Since the 1950s, radiation oncologists have used particle beam therapy for their patients with cancer. The common application of particle therapy is with the electron beam, which is created by all modern linear accelerators. Other particles such as protons, neutrons, helium ions, heavy ions (neon, argon, carbon), and negative ions are available as well. These heavy particle beams are difficult to produce and to control but have certain theoretic advantages over conventional x-ray and electron beams. They are more densely destructive in tissue, and the damage they create is less easily repaired by tumor cells. In addition, they travel differently in tissue and exhibit a Bragg peak, which refers to a sharp cutoff in dose at the end of the particle's range in tissue; see Figure 104–15. Beyond this depth, the tissue receives little or no radiation. Thus with appropriate focus and application, it can be easier to spare the normal tissues surrounding the cancerous target.

The most commonly used particles are neutrons and protons. The RTOG sponsored a phase III trial in 1977 (Lawton et al, 1991) in which 91 patients with prostate cancer were randomly assigned to receive treatment with neutrons or conventional radiographs. At 10 years, survival was better in the neutron arm (46%) than in the photon arm (26%). However, the patients were not equally divided between the two arms. Poor prognosticators such as stage D1 disease were more common in the photon arm. A survival difference between the two groups may have been due to this aspect more than to any therapeutic benefit of neutrons per se.

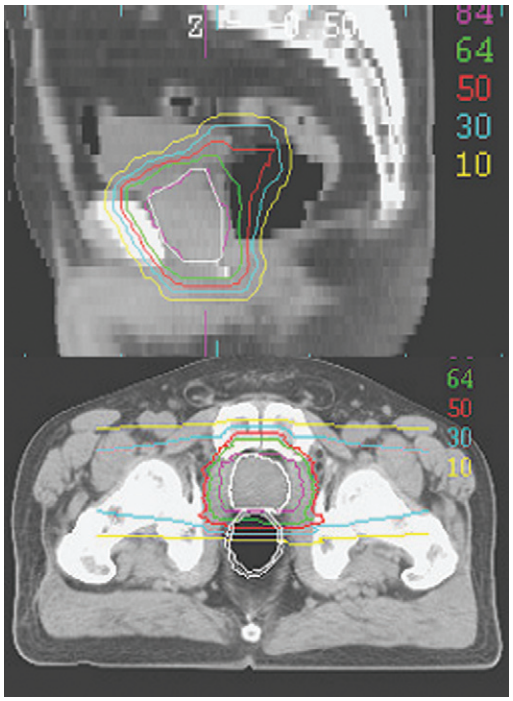

Figure 104–15. Proton beam therapy. (Courtesy of Anthony Zietman, Massachusetts Hospital.)

However, the data were compelling enough to lead the National Cancer Institute to fund the construction of several state-of-the-art neutron beam facilities. Again, trials were undertaken to study the efficacy and morbidity of neutron treatment. Because today's cyclotrons are large and extremely expensive, there are few national facilities using neutron beam treatment for cancer patients. In the mid-1980s, a second prospective randomized trial was undertaken by the RTOG (Russell et al, 1994). One hundred seventy-eight prostate cancer patients were randomly assigned to receive either neutron beam or conventional x-ray treatment (nonconformal). The local control rate was higher for the patients who received neutron therapy than for those who received photons (89% vs. 68%), as was the 5-year rate of freedom from PSA failure (83% vs. 55%). However, survival rates were the same for both arms. Morbidity was higher in patients who received neutron beam treatment and was described as severe in 11% compared with 3% for those who underwent photon irradiation.

In general, acceptance of neutron beam therapy by radiation oncologists has been limited because of the perception that complication rates are high without much gain in tumor control, as well as because of the limited availability and expense associated with neutron production. Nonetheless, efforts are ongoing in neutron beam facilities to improve outcomes using the same computer-driven technologies used in x-ray treatment. A form of conformal neutron beam therapy is now possible in several centers (Forman et al, 1995). At Wayne State University, 300 patients were entered into a phase III trial and randomly assigned to conformal neutron therapy followed by standard CRT or CRT followed by a neutron therapy boost. A statistically significant difference in 5-year disease-free survival was seen for patients treated with neutrons first (93% compared with 73%, $P = .008$) (Forman et al, 2002). Treatment-related morbidity was the same for both groups in this study. A larger retrospective review from the same group of neutron therapy and standard x-ray CRT revealed a statistically significant improvement in 5-year relapse-free survival for the group that received neutrons as any component of their therapy. The effect was most pronounced for high-risk patients who had a 35% 5-year relapse-free survival rate versus 7% in the photon-only group ($P = .0004$). Although these data are provocative, one criticism is that the relapse-free survival in the photon-only group from Wayne State is much lower than that of other series reporting on the same population of patients.

Despite the data from Wayne State, most radiation oncologists believe that neutron beam therapy causes greater normal tissue damage than x-ray photon beam therapy. Investigators from the Catholic University of Louvain, Belgium, used a mailed questionnaire to assess quality-of-life changes in 262 patients who received mixed neutron-photon irradiation. Twenty-two percent of the 230 patients who replied had four or more bowel movements per day. Retaining stool was a problem in 26% of the patients, and only 38% reported full bowel continence. The patients in this trial received neutron beam therapy using equipment that was not conformal. These data were sufficiently concerning to close their program and demonstrate the importance of up-to-date equipment and technology for the delivery of neutron beam therapy.

Proton beams are also used to treat cancer. These charged particles are generated by a linear accelerator, cyclotron, or synchrotron. Each method of manufacturing has strengths and weaknesses, and, to date, it has been difficult to create a simple, cost-effective, and robust system that can be used for cancer treatment. Most proton facilities are located near nuclear physics laboratories, but a free-standing unit does exist at Loma Linda Medical Center in California.

Protons have the same theoretic advantage over conventional x-rays as neutrons (i.e., they are more densely ionizing in tissue and have a sharp dose falloff in tissue; see Fig. 104–14). At Massachusetts General Hospital, clinicians have used a cyclotron housed at Harvard University for the treatment of patients for many years. In the 1980s, a prospective randomized trial was undertaken in men with locally advanced prostate cancer (Shipley et al, 1995). Patients treated with proton beams had a 95% incidence of clinical local control at 5 years, compared with a 64% incidence for those treated with photons. Although no grade 3 to 5 toxicities were reported in either arm of this trial, grade 1 and 2 rectal bleeding rates were higher in the proton group (32% vs. 12%, $P = .002$), as were urethral strictures (19% vs. 8%, $P = .07$). When the group with rectal bleeding was carefully analyzed, a relationship between the volume of rectum treated and the dose of protons given was established and guidelines were developed for future trials (Hartford et al, 1999).

At Loma Linda University Medical Center, 643 patients have received treatment with protons alone or in combination with photons (Rossi, 1999). Eighty-nine percent of early-stage patients (stage T1b or T2b, PSA < 15 ng/mL) achieved 5-year biochemical disease-free survival, as opposed to 68% of those with more advanced tumors. In this series 21% of patients developed minimal radiation proctitis, and severe side effects were seen in less than 1%. Similar results were published in 16 patients from Kobe University of Japan, emphasizing how few new data are available on this form of therapy. In this study, none of the patients evidenced PSA failure within the first 12 months.

The same technical advances that allow delivery of improved photon therapy (conformal radiation) must be used by particle beam specialists. In time, it may be possible to deliver particle beams safely and inexpensively. At present, conformal particle beam treatment units are extremely expensive to construct and operate, and this poses a problem for those interested in particle beam therapy, particularly because, to date, the single-institution results in prostate cancer demonstrate disease control rates that are similar to those seen with conformal radiation.

Key Point: Heavy Particle Beams

- Proton radiation therapy also provides the ability to deliver higher doses of radiation therapy while minimizing rectal bleeding.

Brachytherapy

Brachytherapy ("close" therapy) is the placement of radioactive sources into or near tumors for therapeutic purposes. The discovery of x-rays and the purification of radium in the early 20th century paved the way for the development of this form of therapy. Subsequent technical advances and refinements led to the increasingly accurate techniques currently in use, which are associated with lower cost and morbidity rates. Today, the number of patients undergoing brachytherapy for early-stage prostate cancer has increased dramatically. The CaPSURE database reported an increase in the use of brachytherapy from 3.1% to 12.0% in the past decade (Cooperberg et al, 2004).

Pasteau and Degrais described the temporary placement of radium-containing needles into the prostate through the urethra (Pasteau et al, 1913). During the 1920s, Young (1922) at Johns Hopkins performed prostate brachytherapy using intracavitary radium sources in the bladder, rectum, and urethra "cross-firing" into the prostate (Young, 1922). This technique was refined at Memorial Hospital in New York by Benjamin Stockwell Barrington, who pioneered implanting needles containing radioactive radon gas into the prostate by a transperineal approach. During the 1970s, Whitmore and colleagues (1972) at Memorial Sloan-Kettering in New York performed ^{125}I implantation in patients after they underwent lymph node dissection. The prostate was exposed by the retropubic approach for implantation. However, this "free-hand" technique resulted in suboptimal distribution of seeds and poor dosimetry (Zelefsky et al, 1977).

Holm and colleagues (1983) described closed transperineal implantation with the aid of TRUS. With this approach, the needles used to insert the radioactive seeds could be visualized, with an improvement in the accuracy of seed placement compared with the retropubic approach. Surgical morbidity and cost were reduced. For this procedure, the patient is placed in the high lithotomy position to maximize the transperineal exposure of the prostate. A transrectal ultrasound probe is then inserted and affixed to a mount or stabilizer through a stepping device. A template with a predrilled pattern of parallel holes is attached to the stepper. This permits accurate and reproducible imaging of the prostate throughout the procedure. The template pattern can also be superimposed over the ultrasound image by computer software in the ultrasound device. Seventeen- or 18-gauge needles are inserted through the template into the prostate. The position of the needle can be confirmed on either transverse or parasagittal imaging. The sealed metallic seeds containing the radioactive isotope are deployed as the needle is withdrawn (Figs. 104–16 through 104–19).

Several methods are currently in use for permanent radioactive seed implantation. The method popularized by Blasko and colleagues (1993) in Seattle uses preimplant transrectal ultrasound images to calculate a dosimetric plan. These images are then used in the operating room to determine locations for planned seed placement. Kaplan and colleagues (2000) have described a method in which the dosimetric plan is calculated intraoperatively. Computer programs using sophisticated algorithms to optimize dosimetry have been developed. Stone and Stock (1999) determined the number of seeds to be implanted on the basis of the size of the gland and the nomogram reported by Anderson (1976). The

needles are implanted using the empirical rules defined by Patterson and Parker in the 1930s (Fletcher, 1980). Other methods for seed implantation using CT (Koutrouvelis, 1998) and an intraoperative magnetic resonance imaging (MRI) device (D'Amico et al, 1998a; Saul et al, 2004) have also been described.

High-dose-rate (HDR) brachytherapy techniques for treatment of prostate cancer have been developed. In this procedure, needles are placed through the perineum into the prostate. For treatment planning the prostate is imaged postoperatively, with needles in

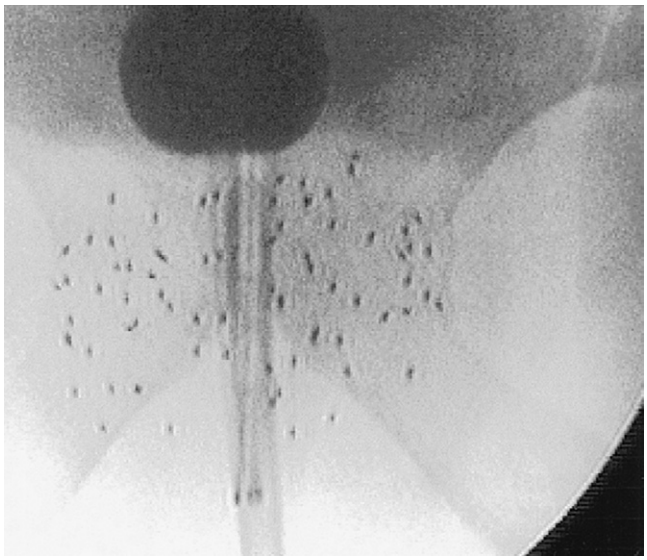

Figure 104–19. Intraoperative fluoroscopic image of the prostate demonstrating the placement of palladium 103 seeds.

place. One- to 10-curie iridium 192 sources in a flexible catheter are inserted remotely into the needles at various positions for variable lengths of time, in the order of seconds to minutes. The radiation dose is delivered in this way over several applications.

Postimplantation CT is performed to determine seed localization and reference the dose to the prostate and other structures of importance (Willins and Wallner, 1997). However, defining prostate volume on CT images is not unambiguous (Lee et al, 2002). Some groups fuse postimplantation MRI images to the CT to better define pelvic anatomy, to improve the accuracy of post-treatment dosimetry (Mizowaki et al, 2002).

Isotopes

There are several choices for isotopes for permanent seed implantation. ^{125}I is the most commonly used isotope. ^{125}I emits low-energy x-rays at 27 keV with a half-life of 59.6 days. The use of ^{103}Pd was introduced in 1986. The radiation from palladium has an energy spectrum similar to that of ^{125}I, with 21 keV x-rays, but with a significantly shorter half-life of 17 days. Therefore higher activity seeds are required for ^{103}Pd versus ^{125}I to deliver a similar tumoricidal dose (i.e., 1.3 to 1.5 mCi per palladium seed vs. 0.4 to 0.5 mCi per iodine seed).

Increasingly, palladium implants are being performed for patients with higher Gleason scores (specifically, Gleason score above 8) or patients receiving an implant boost after external-beam irradiation. This has made retrospective analysis of outcome for different isotopes difficult (Stone and Stock, 1999). However, in single-institution retrospective series that control for presenting prognostic variables, no difference in outcome was observed. Similarly, no difference in cancer control has been reported to date in a prospective trial evaluating isotope selection.

Outcome of Implants

Prostate cancer has a long natural history and generally occurs in a population in which competing mortalities and morbidities are important factors in analyzing outcomes. Because image-guided implantation of the prostate is a relatively new procedure, there are few long-term survival data. Surrogate end points can be used to evaluate its efficacy. However, with the advent of serum PSA determination there has been an improvement in outcome-based

staging, making comparison with results of therapy reported before the PSA era difficult. With the widespread use of PSA and the Gleason system for grading pathology since the late 1980s, there is now 15 years' follow-up after therapy (Sylvester et al, 2004).

Postimplantation Biopsies

Post-treatment biopsies can be used to assess the efficacy of local therapies to control cancer. However, there are several limitations to using this technique in prostate cancer. The typical rate of PSA decline after local prostate irradiation suggests that the complete effect is not observed until 18 months or longer after completion of radiotherapy (Ragde et al, 1998). In addition, there are potential sampling errors and difficulties in interpretation of postirradiation biopsy pathology. Early studies that included in their analyses a significant proportion of higher-stage patients or suboptimal dosimetry show a high proportion of positive post-treatment biopsies (Kuban et al, 1992; Vijverberg et al, 1993). More recent studies with biopsies after treatment for early-stage disease with improved implant quality report a post-treatment positive biopsy rate of 3% to 20%. Table 104–6 summarizes the results of several studies. The clinical significance of a positive post-treatment biopsy, especially when obtained within the first 2 years after RT, is unclear and is not an indicator.

Post-Treatment Prostate-Specific Antigen

Serum PSA is the most useful marker to assess relapse. Experts generally agree that a rising PSA after treatment is a harbinger for eventual clinical recurrence. A rising PSA level after irradiation predicts local or distant relapse, or both, often many years before clinical evidence of recurrence (Kaplan et al, 1993). However, the variability of PSA, especially at low levels, often makes interpretation problematic. In addition, the suppression of PSA with even short courses of antiandrogen therapy can complicate interpretation of results. The definition of treatment failure itself remains controversial. Absolute threshold levels of 0.5 or 1.0 ng/mL after treatment have been suggested as alternative end points (Critz et al, 1996; Borghede et al, 1997). ASTRO proposed that biochemical failure after RT be defined as three consecutive increases in PSA, with the date of failure being the midpoint between PSA nadir and the first of the consecutive rises.

A PSA bounce has been reported in approximately 25% of patients after brachytherapy. This is a temporary rise in PSA followed by a decline in PSA levels at subsequent follow-up (Critz et al, 2000; Stock et al, 2003). This rise in the PSA can be confused with a PSA failure. Patel and colleagues (2004) reported that 11% of patients who experienced a PSA bounce would have met the ASTRO criterion for PSA failure. In addition, Reed and colleagues (2003) reported eight patients who had a positive post-treatment prostate biopsy during a PSA bounce and subsequently remained free from recurrence. Some investigators have reported improved rates of cancer control in patients who experience a PSA bounce (Das et al, 2002; Patel et al, 2004).

Pretreatment prognostic factors such as pretreatment PSA, clinical examination, Gleason score, and percentage of biopsy cores positive have been used to define risk groups in relation to pathologic findings at surgery and freedom from PSA relapse after RT or radical surgery (D'Amico et al, 1998b, 2002; Partin et al, 2001; Kuban et al, 2003). There is no consensus in the definition of these prognostic groupings. However, there is general agreement that "low risk" (defined as a low risk for extracapsular disease at prostatectomy and a high probability of disease-free survival after treatment) includes patients with clinical T1-T2 disease, a Gleason score less than 6, and a pretreatment PSA less than 10 ng/mL (D'Amico et al, 1998b, 2002; Partin et al, 2001; Kuban et al, 2003). Some investigators exclude T2b from the low-risk group (D'Amico et al, 1998b). There is no consensus in the definition of risk groups with an intermediate risk or high risk of failure after local treatment (D'Amico et al, 1998b; Blasko et al, 2002; Kollmeier et al, 2003). The high-risk grouping typically includes patients with multiple high-risk features such as Gleason score greater than 7, PSA above 10 ng/mL, or large palpable tumors. The intermediate group is heterogeneous and includes patients who have features in between low and high risk.

Table 104–7 summarizes the clinical outcomes of permanent implant monotherapy without hormone ablation in several large series using the ASTRO definition for biochemical failure. These studies report on more than 1000 patients treated with permanent implant monotherapy. Although these are retrospective single-institution studies (with the exception of RTOG 98-05), they represent results from a uniform population of patients. These results compare favorably with those of similarly selected patients treated with external-beam irradiation or radical prostatectomy (D'Amico et al, 1998b; Quaranta et al, 2004).

Seed Brachytherapy with External Irradiation

Seed brachytherapy can be used as a boost either before or after external-beam irradiation for prostate cancer. Generally, brachytherapy combined with external-beam irradiation, rather than brachytherapy alone, is used for patients with higher-stage disease. External-beam irradiation is employed in these higher-stage patients to treat the prostate and periprostatic tissues. Typically, a dose of 4500 cGy of external-beam RT is delivered (compared with 7560 to 7920 cGy when external-beam irradiation is used alone). The dose of the implant boost in such combination therapy is generally 60% to 70% of the dose prescribed for patients treated with implant alone. Table 104–8 summarizes the results of several

Table 104–6.

Postimplantation Biopsy Results

AUTHOR	ISOTOPE	RESULTS
Prestidge et al, 1997	^{125}I and ^{103}Pd	201 Postimplantation biopsies—80% negative, 17% indeterminate, 3% positive
Ragde et al, 1997	^{125}I	82% Negative 13% Indeterminate 5% Positive
Stock et al, 1996a	^{125}I and ^{103}Pd	Post-treatment biopsies on patients (T1b-T2c)—26% positive
Stock et al, 2004	9 mo hormonal therapy, external beam with ^{103}Pd boost	4% Post-treatment biopsies at 2 yr in a "high-risk" group
Sharkey et al, 1998	^{103}Pd	11% Positive at 2 yr after implant
Kuban et al, 1992	^{125}I	Biopsy at least 18 mo after implant, negative DRE, 18% positive biopsy
Stone et al, 2004	^{125}I, ^{103}Pd monotherapy or as boost ± hormones	"Low-risk" group, 4.1% positive

DRE, digital rectal examination.

High Dose Rate Boost with External-Beam Irradiation

Martinez phase I prospective trial (Martinez et al, 2002)	58 pts	46 Gy external beam + "Low-dose"	52%	5 yr	Fewer patients with Gleason ≥ 8 and PSA
	149 pts	HDR (≤6.5 Gy × 3 applications) "High-dose" HDR (≤11.5 × 2 applications)	87%	5 yr	>20 ng/mL in "high-risk" group
Galalae prospective phase II trial (Galalae et al, 2002)	46 pts	50 Gy pelvis, 40 Gy prostate	94.7%	5 yr	WHO grading used
	22 pts	2 HDR applications of 15 Gy	93%	8 yr	
	25 pts	PSA < 10 and grade 1-2	67.7	5 yr	
		PSA > 20 and grade 1-2	63.9	8 yr	
		PSA > 20 and grade 3	38%	5 yr	
			32%	8 yr	
Mate et al, 1998		50.4 Gy external beam			Mean follow-up 46 mo
	54 pts	4 HDR applications of 3-4 Gy	93%		
	29 pts	PSA < 10 ng/mL	90%		
	20 pts	PSA 10-20 ng/mL	60%		
		PSA ≥ 20			
Deger et al, 2002		45 Gy external beam	100%	5 yr	
		Two applications of 9-10 Gy	75%	5 yr	
		T1	60%	5 yr

studies employing combined external-beam radiation and implant boost for low-risk-group patients. Potters (1999) and Grado (1998) and their colleagues did not find the addition of external beam to implantation to be statistically significant in a multivariate analysis. The role of external beam with permanent seed brachytherapy versus brachytherapy alone is being investigated in a randomized clinical trial by the RTOG (RTOG trial 02-32).

Assessment of Implant Quality

The goal of prostate brachytherapy is to deliver a homogeneous dose to the prostate while minimizing dose to nearby sensitive normal structures such as the rectum and urethra. Postimplant dosimetry in these dose-limiting regions is important for an assessment of implant quality. The matched peripheral dose is defined as the dose to a volume of an ellipsoid having the calculated volume of the prostate ([height] × [length] × [width] × [pi/6]). However, this dosimetric calculation does not take into account geographic misses and cannot directly calculate point doses to structures such as the urethra, rectum, or prostatic apex. To determine the minimum dose within the prostate and to assess the distribution of volume and dose, three-dimensional reconstruction of the prostate and unambiguous determination of seed location within the prostate are necessary. These factors can be calculated with postimplantation imaging using either CT or MRI (Moreland et al, 1997; Willins and Wallner, 1997; Amdur et al, 1999). The American Brachytherapy Society (ABS) has proposed the D_{90} (the minimal dose covering 90% of the prostate volume) and the V_{100} and V_{150} (the percent volume of the prostate receiving 100% and 150% of the prescribed dose, respectively) as parameters

to assess implant quality (Nag et al, 1999). However, these descriptive parameters may not adequately predict for tumor control, and more sophisticated measures have been proposed.

A significant source of error in these calculations is prostatic edema, which is invariably observed after implantation (Prestidge, 1998; Waterman et al, 1998). Accordingly, Yue and colleagues (1999) suggested that postimplantation scans should be performed 2 weeks after ^{103}Pd and 6 weeks after ^{125}I. However, Taussky and colleagues (2004) analyzed serial postimplantation MRI images and reported that edema effects are minimal and the time to postimplantation scan is not important.

Toxicity

Implant techniques and procedures vary from institution to institution. Variations in these factors are important when assessing rates of treatment toxicity. Implants are currently performed using peripheral loading techniques. With this scheme, there is a greater density of seeds placed in the periphery of the gland than in the center. This ensures a more uniform distribution of dose throughout the gland and minimizes "hot spots" around the urethra. Some investigators completely exclude the transitional zone of the prostate from the treatment volume, significantly reducing the urethral dose (D'Amico et al, 2000a). Other groups intentionally place seeds outside the gland to improve peripheral dose coverage. This increases the dose received by the rectum and the neurovascular bundles. Age, existing comorbid diseases such as peripheral vascular disease or diabetes mellitus, and tobacco use may also predispose to increased toxicity from treatment.

Determining incidence rates and severity of treatment-related morbidity is also dependent on the instrument used and how the information is gathered. The ABS proposed as a minimal set of assessment criteria the International Prostate Symptom Score (IPSS) for assessing urinary function, the International Index of Erectile Function for erectile function, and RTOG toxicity grading criteria for rectal toxicity.

Urinary Toxicity

Brachytherapy after TURP was initially reported to be associated with a significant rate of serious urethral toxicity. Blasko and colleagues (1993) reported that 24% of patients who underwent implantation after TURP developed urinary morbidity, compared with 3% of patients who did not undergo this procedure. However, several more recent reports have demonstrated that men who have undergone prior TURP can be implanted as long as there is adequate tissue remaining to accommodate the seed sources. Most patients who have had a TURP can be safely implanted without an increased risk of urinary retention (Stone et al, 2000).

The IPSS tends to increase significantly immediately after implantation. Subsequently, the score decreases, but it is still significantly elevated at 3 months after treatment (Lee et al, 1999). Gelblum and colleagues (1999) observed that 37% of patients report grade 1 urinary toxicity (defined as symptoms not requiring medical intervention) within the first 60 days after implantation. Zelefsky and colleagues (1999a) reported grade II urinary toxicity (symptoms requiring medical intervention) occurring at a mean duration of 19 months after implantation, with a likelihood of resolution of 68% at 36 months. Continued significant urinary obstruction requiring self-catheterization occurs in 1% to 5% of patients (Grado et al, 1998; Gelblum et al, 1999; Peschel et al, 1999). The use of α blockers before implantation may decrease the severity and duration of urinary symptoms (Merrick et al, 2002b).

Longitudinal studies are being conducted to assess late urinary morbidity. Merrick and colleagues (2003a) reported the results of a survey of 225 patients who reached an average of 5.5 years after brachytherapy and compared their urinary symptoms with those in a cohort of more recently diagnosed patients. No significant difference was seen between the two groups (Merrick et al, 2003a). Stone and Stock (2003) reported a small but significant long-term increase in urinary frequency and weak stream in their series.

Wallner and colleagues (1995) reported the risk of urinary toxicity to be a function of the length of the urethra receiving a high dose. Grade 2 to 3 morbidity was observed when 20 mm + 11 mm of the urethra received more than 400 Gy with ^{125}I implants. Larger prostatic volumes—specifically, glands greater than 60.0 cm^3—were also associated with higher rates of urinary toxicity (Wallner et al, 1995). Terk and colleagues (1998) reported on 251 patients using the IPSS to assess urinary function before and after ^{125}I or ^{103}Pd implantation. Patients with a pretreatment IPSS above 20 demonstrated a 29% risk of developing urinary retention, and a pretreatment score less than 10 was associated with only a 2% risk. Overall, significant postbrachytherapy obstructive symptoms refractory to medical management occur in approximately 2% to 3% of patients. Postbrachytherapy TURP can be performed with a low rate of post-TURP incontinence if care is taken to preserve the urethral blood supply (Flam et al, 2004).

Rectal Toxicity

Minor rectal symptoms secondary to brachytherapy are usually self-limiting. The usual scale to assess rectal toxicity, the RTOG acute and late toxicity scale, is not a sensitive enough measure to report minor changes in rectal function after treatment. Rectal toxicity—specifically, rectal bleeding secondary to radiation proctitis—can be a minor, self-limiting side effect of radiation or a major toxicity requiring surgical intervention such as argon plasma coagulation (Smith et al, 2001) or, in the worst cases, diverting colostomy. The rate of minor rectal bleeding after implant therapy has been reported to be approximately 1% to 4% (Zelefsky et al, 1999a). The incidence of significant rectal complications has been reported to be 0% to 1% (Grado et al, 1998; Zelefsky et al, 1999a). A postimplantation colostomy rate of 0.3% was observed in a study of Medicare claims (Benoit et al, 2000a, 2000b). The rate of rectal complications is correlated with the dose and the length of rectum receiving a high dose. For example, rectal complications have been observed when 17 mm^2 (±5 mm) of the rectal wall received more than 100 Gy (Wallner et al, 1995). Wallner and colleagues (1995) accordingly recommended minimizing the amount of rectum receiving 100 Gy in ^{125}I implants. Merrick and colleagues (2003a) reported that rectal complications were rarely observed when the rectal wall received 85% of the prescribed dose.

Potency

Impotence is defined by the National Institutes of Health (NIH) consensus on erectile dysfunction (ED) as the "inability to attain and maintain a penile erection sufficient to permit satisfactory sexual intercourse" (NIH Consensus Conference, 1993). The cause of implant-related ED is multifactorial. Factors such as underlying small vessel disease, nerve damage, and dose to specific tissues have been implicated in postimplantation ED.

DiBiase and colleagues (2000) reported that dose to the neurovascular bundle was related to development of postbrachytherapy ED. Merrick and colleagues (2001) reported that dose to the penile bulb correlates with rates of ED, although the penile bulb is composed of corpus spongiosum, not corpus cavernosum (Muhall and Yanover, 2001). In any case, potency preservation rates for patients undergoing implantation are superior to those reported for

patients receiving external-beam irradiation or neoadjuvant hormonal therapy, external beam, and brachytherapy boost. Zelefsky (1999c) and Stock (1996b) and their colleagues reported that potency was maintained in 79% of patients undergoing brachytherapy compared with 68% receiving external-beam irradiation. There is continued drop-off in potency with continued follow-up in the past 3 years (Zeitlin et al, 1998). Merrick and colleagues (2002a) reported that 50% of men who were fully potent before brachytherapy maintained potency at 6 years after treatment.

The potency rate has been reported to be 62% in patients receiving combined external beam with an implant boost (Zeitlin et al, 1998). Potters and colleagues (2001) reported a 5-year potency maintenance rate of 76% with brachytherapy monotherapy and 56% with combined external beam and brachytherapy boost. The addition of hormones to external beam and brachytherapy boosted lower potency rates to 52%. Similarly, Stock and Stone (2002) reported that potency was maintained in 43% at 3 years after combined neoadjuvant hormonal therapy with external beam and brachytherapy boost. Age was a significant prognostic factor in a univariate analysis (Merrick et al, 2002a), and the addition of external beam and a history of diabetes mellitus were significant factors in a multivariate analysis (Robinson et al, 2002). In a meta-analysis, the probability of maintaining potency at 1 year after treatment was 76% (69% to 82%) with brachytherapy monotherapy and 60% (48% to 73%) with external beam with brachytherapy boost (Robinson et al, 2002). When the probability of ED was adjusted for age, the difference between prostate brachytherapy and prostatectomy increased (Robinson et al, 2002). Sildenafil citrate and other phosphodiesterase-5 inhibitors have been reported effective in 74% to 81% of patients who avail themselves of oral therapy for ED (Albert et al, 2003; Merrick et al, 2003a; Raina et al, 2003).

High-Dose-Rate Brachytherapy

HDR brachytherapy afterloading techniques have been developed to treat prostate cancer. This procedure uses high-activity ^{192}Ir sources in cables stored in a mobile computer-controlled lead safe. ^{192}Ir emits gamma radiation at 400 keV, which is significantly more penetrating than either ^{125}I or ^{103}Pd. Needles are first implanted transperineally into the prostate under ultrasound guidance. The precise positions of the needles are then determined by CT, and a dosimetric plan is calculated before the radiation is administered. Under computer guidance, the ^{192}Ir sources are transferred to the needles for a predetermined time. A precise dose is administered by varying the dwell times of the source in each needle. Kini and colleagues (1999) reported on 20 HDR treatments delivered in 11 patients. An average of 16 needles was used. Ninety-two percent of the prostatic volume received 100% of the prescribed dose; this is slightly superior to the dosimetry generally achieved during permanent seed implantation (Merrick et al, 1999).

HDR has been used primarily in combination with external-beam irradiation for patients with intermediate- or high-risk features. It is delivered as a boost in two to four applications, either before or after external-beam irradiation. HDR is a new technology, and there is heterogeneity in dose per fraction delivered and techniques employed. Consequently, the reports with the longest follow-up are from phase I dose escalation studies. Dinges and colleagues (1998) reported on 82 patients with a mean pretreatment PSA of 14.0 ng/mL. All patients had pathologic node-negative disease as determined by laparoscopic staging. Two HDR treatments calculated to deliver 9 to 10 Gy were followed by 40 to 45 Gy of external-beam irradiation. Seventy-three percent of patients had negative biopsies at 2 years. Local failure (defined as a positive post-treatment biopsy and a PSA > 1.0 ng/mL) was observed in 21.5% of patients. In a multi-institution report in which different dose fractionation schemes and doses of external beam were used, a 5-year biochemical disease-free survival (ASTRO definition) of 96% was observed in patients with low-risk disease, with 87% and 69% for an intermediate- and high-risk group of 137 and 240 hormonally naïve patients, respectively (Galalae et al, 2004). Table 104–8 summarizes results of trials of HDR delivered as a boost with external-beam irradiation, using the ASTRO definition for biochemical failure.

Early results with HDR used as monotherapy for patients with low-risk prostate cancer have demonstrated acceptable toxicity and early biochemical freedom-from-relapse rates similar to those for permanent seed implants (Grills et al, 2004). Further experience with more patients and longer follow-up is required to assess the efficacy of this approach.

Key Point: Brachytherapy

- Prostate brachytherapy is best performed using intraoperative real-time dosimetry in order to minimize normal tissue complications and maximize tumor control.

Radiation Therapy and Androgen Suppression Therapy

Locally Advanced Prostate Cancer

Among strategies to improve outcome for patients with locally advanced prostate cancer, hormonal manipulation in combination with RT has consistently demonstrated improvement in treatment outcome as compared with standard-dose radiation alone (Pilepich et al, 1995, 1997; Bolla et al, 1997; Vicini et al, 1999). A meta-analysis of both retrospective and prospective trials of androgen deprivation in combination with RT demonstrated near-universal benefit in regard to local/regional control, disease-free survival, and freedom-from-failure survival. However, the ultimate impact on overall and cause-specific survival remains to be fully defined (Vicini et al, 1999). There are now three published cooperative group phase III trials and a single-institution phase III trial reporting advantage in various outcome parameters with the use of androgen deprivation compared with use of radiation alone.

In RTOG 86-10, 456 patients with large (25 cm^3), stage T2B to T4, Nx tumors randomly assigned to 4 months of total androgen suppression with RT given after the first 2 months had improved local control, disease-free survival, and freedom from metastases compared with patients receiving RT alone. At 8 years significant improvements in rates of local control of 42% versus 30%, distant metastases of 34% versus 45%, disease-free survival of 33% versus 21%, biochemical disease-free survival (PSA < 1.5 ng/mL) of 24% versus 10%, and cause-specific mortality of 23% versus 31% were noted with versus without addition of this short course of neoadjuvant androgen suppression. A hypothesis-generating subset analysis indicates that the beneficial effect of short-term androgen ablation appears preferentially in patients with Gleason score 2 to 6. In that population, there is a highly significant improvement in all end points including survival (70% vs. 52%, P = .015) (Pilepich et al, 1995, 1998, 2001).

In European Organization for Research in the Treatment of Cancer (EORTC) 22863, a phase III trial of androgen suppression,

Bolla and colleagues (1997, 1999) reported an overall survival advantage for patients receiving 3 years of goserelin starting at the initiation of RT. Most of the patients in this study had stage T3 disease, and the remainder were eligible owing to high-grade tumors. With median follow-up of 66 months, 5-year clinical disease-free survival was 40% (95% CI 32 to 48) in the radiotherapy-alone group and 74% (67 to 81) in the combined-treatment group ($P = .0001$). Five-year overall survival was 62% (95% CI 52 to 72) and 78% (95% CI 72 to 84), respectively ($P = .0002$), and 5-year specific survival 79% (95% CI 72 to 86) and 94% (95% CI 90 to 98), supporting the use of androgen suppression (Bolla et al, 2002).

The optimal type, timing, and duration of androgen suppression in combination with RT remain to be defined. In RTOG 92-02, patients with stage T2c-T4, N0-1, M0 disease were randomly assigned to 4 months of total androgen suppression with radiation administered after 2 months or the same regimen followed by an additional 2 years of goserelin. A hypothesis-generating subgroup analysis revealed significant improvement in overall survival, 80% versus 69%, and disease-specific survival, 90% versus 78%, in patients with Gleason grade 8 to 10 tumors.

Should Pelvic Lymph Nodes Be Treated?

The question of timing of hormonal therapy and impact of radiation field size was addressed by RTOG 94-13, a four-arm study comparing whole-pelvis versus small-field radiation with 4 months of either neoadjuvant or adjuvant total androgen suppression. Eligible patients had adverse risk factors, with estimated risk of positive-node disease of more than 15%. A difference was initially seen in progression-free survival at 4 years, 54% versus 47% for the whole-pelvis versus prostate-only radiation, respectively ($P = .022$), but no difference was seen in overall survival. However, an update of this study (Lawton, 2007) shows loss of this benefit, so pelvic lymph node treatment can no longer be recommended for all men with high-risk or locally advanced prostate cancer.

Localized Prostate Cancer

Two studies (Denham et al, 2005, D'Amico et al, 2008) have investigated the use of 6 months of combined hormonal blockade and RT versus RT alone. Both show benefits in cancer-specific survival, and one shows an overall survival benefit for men who were randomized to receive RT and 6 months of combined hormonal blockade as compared with RT alone. Specifically, in the study by Denham and colleagues, 802 men with a median PSA of 15 ng/mL and in whom 55% had Gleason score 7 or higher disease and 40% had clinical T3/4 disease, a prolongation in time to prostate cancer death was noted. D'Amico and colleagues (2008) studied 206 men, all with clinical T1/2 disease and followed for a median of 7.6 years. Their median PSA was 11 ng/mL, and 73% had Gleason score 7 or higher disease. Benefits in both overall and cancer-specific survival were noted. Of note, it appeared that the survival benefit may have been limited to only those men with no or minimal comorbid illness.

Key Points: Radiation Therapy and Androgen Suppression Therapy

- Randomized controlled trials have shown a survival benefit for the addition of androgen suppression therapy to external-beam radiation therapy.
- Six months of hormonal therapy compared with 3 years of hormonal therapy provides a survival benefit for men with localized high-risk versus locally advanced prostate cancer, respectively. However, this benefit may only apply to men with no or minimal comorbid disease.

Radiation Therapy for Palliation

Bone Metastases

In genitourinary cancers, bone metastases are a common problem (Abrams et al, 1950; Gilbert and Dagan, 1976). Many therapies are available for bone metastases including surgery, medical management, and radiation. RT can treat most patients with highly effective symptom relief.

The hallmark of osseous metastases is localized pain, which is frequently continuous and unrelenting regardless of the site. The pain caused by bone metastases is not well understood. Some investigators have hypothesized that irritation of the periosteal membrane or release of biologic mediators is responsible for bone pain. The most serious complication of osseous metastases is spinal cord compression, which is discussed later.

Most bone metastases can be diagnosed by physical examination, plain radiographs, and bone scan. CT and MRI are sometimes required if there is suspicion of bone involvement, but x-ray and bone scans are negative if there is soft tissue involvement.

With respect to treatment, reviewing the currently available data from prospective studies has shown overall response rates ranging from 85% to 100% using various treatment schedules (Madsen, 1983; Price et al, 1988; Cole, 1989). A single-fraction regimen (800 cGy × 1) appears to be as effective as other, more protracted regimens but is also associated with increased acute morbidity, particularly to the abdominal organs. A frequently used regimen in the United States is 3000 cGy in 10 divided fractions. This dosage is adequate for most osseous metastases.

Metastasis to a weight-bearing region raises many concerns. A pathologic fracture can be painful and disabling, both functionally and psychologically. Radiographic and clinical factors that warrant consideration of prophylactic surgical fixation include the following:

- An intramedullary lytic lesion equal to or greater than 50% of the cross-sectional diameter of the bone
- A lytic lesion involving a length of cortex equal to or greater than the cross-sectional diameter of the bone or greater than 2.5 cm in axial length (Lane et al, 1980)

These patients should be evaluated by an orthopedic surgeon. If a pathologic fracture has occurred in a weight-bearing region, surgical fixation is required for pain control and to promote adequate healing. In all situations, postoperative radiation is required. Because prostate cancer produces primarily blastic metastases, pathologic fracture is correspondingly infrequent.

Spinal Cord Compression

Spinal cord compression is a medical emergency. Failure to diagnose and treat promptly can lead to significant morbidity including paraplegia and autonomic dysfunction. The predominant symptom of cord compression is pain, which occurs in about 95% of patients (Gilbert et al, 1978). Pain usually precedes a diagnosis of spinal cord compression by about 4 months. Symptoms, however, can progress rapidly to neurologic dysfunction in a matter of hours to days. When a patient has progressed to paraplegia, return of function is infrequent. Therefore early diagnosis and therapy are critical. The diagnostic tool of choice to evaluate spinal cord compression is MRI.

Table 104–9.

Physical Characteristics of Radionuclides Reviewed

RADIONUCLIDE	PHYSICAL HALF-LIFE	BETA ENERGY (MeV)	GAMMA ENERGY (keV)	CHELATE
^{32}P	14.3 days	1.71	0	Orthophosphate
^{89}Sr	50.6 days	1.46	0	Chloride
^{186}Re	90.6 hr	1.07	137	HEDP
^{153}Sm	46.3 hr	0.84	103	EDTMP

EDTMP, ethylenediamine tetramethylene phosphonate; HEDP, hydroxyethylidene diphosphonate.

Table 104–10.

Clinical Efficacy and Toxicity of Radionuclides Reviewed

RADIONUCLIDE	RESPONSE RATE (%)	RESPONSE DURATION (MO)	TOXICITY
^{32}P	60-80	≈5	++
^{89}Sr	60-90	≈6	+
^{186}Re	75-80	1-2	+
^{153}Sm	75-90	2-3	+

Once the diagnosis of spinal cord compression is made, the physician is left with the dilemma of how to treat. There are a few instances in which surgery should be considered as an option before radiation including pathologic fracture with spinal instability or compression of the spinal cord by bone, unknown tissue diagnosis, or history of previous radiation to the same area.

When the diagnosis of cord compression is made or even suspected, all patients should receive steroid therapy. Steroids can decrease vasogenic edema and provide striking analgesic benefit. The loading dose of dexamethasone (Decadron) is 4 to 10 mg, followed by a maintenance dosage of 4 to 24 mg every 6 hours.

Systemic Radionuclide Therapy

The first report on the use of systemic radionuclides for the treatment of bone metastases was published by Pecher in 1942. Tables 104–9 and 104–10 provide a summary of the physical characteristics and the clinical usefulness of the radionuclides discussed.

Clinical Experience with Strontium 89

The efficacy of strontium 89 has been demonstrated in multiple studies (Firusian et al, 1976; Correns et al, 1979; Silberstein and Williams, 1985; Robinson et al, 1987; Tennvall et al, 1988; Montebello and Hartson-Eaton, 1989; Williams and Dillehay, 1989; Laing et al, 1991). Most of these studies involved patients with hormone-refractory prostate cancer. The limited experience in patients with metastatic breast cancer, however, suggests similar efficacy. In one retrospective review, 89% of 28 patients reported moderate or good relief of pain (Robinson et al, 1992).

Toxicity of strontium 89 is mainly hematologic. Platelet depression is dose dependent. Most patients have a 20% to 50% drop in their counts after doses of 3 to 4 mCi (1.5 to 2 MBq/kg).

Key Point: Radiation Therapy for Palliation

- Spinal cord compression, bone metastasis, and pathologic fractures are conditions that require external-beam radiation therapy for palliation.

Gene Therapy for Prostate Cancer

Advances in RT technique have clearly resulted in improved biochemical control of clinically localized prostate cancer (Shipley et al, 1999). Although continued refinement of these techniques will result in further gains, other innovative approaches such as gene therapy may enhance or complement radiation-induced cell killing. In addition, gene therapy may have a role in the management of patients with prostate cancer that is locally recurrent after RT.

A rapid escalation in knowledge of molecular and biologic mechanisms that characterize the cellular response to radiation-induced damage, combined with new molecular biologic techniques, has allowed the possibility of novel genetic therapies. In general, these genetic therapies as applied to prostate cancer can be divided into three major categories: corrective therapy, immunotherapy, and cytolytic/proapoptotic therapy. A brief synopsis of gene therapy as it relates to RT for the treatment of prostate cancer follows.

Corrective Gene Therapy

Corrective gene therapy can generally be thought of as the functional complementation of abnormal or absent genes in a cell. However, the application of p53-corrective gene therapy strategies in combination with RT for the treatment of clinically localized disease remains controversial (Waldman et al, 1997; DeWeese et al, 1998).

Immunotherapy

Defects in major histocompatibility complex class I expression have been noted in 85% of primary prostate cancers and essentially all metastatic tumors (Blades et al, 1995). As with other tumors, these data suggest that evasion of host immunity may be a critical factor in prostate cancer development. Strategies designed to improve tumor antigen presentation to the host immune system are termed *cancer vaccines* and frequently employ targeted expression of cytokines in tumor cells. This approach results in improved cancer cell vaccine antigen presentation and activation of antigen-presenting cells, both of which are necessary to effect a cellular immune response. A number of cytokines have been tested for their efficacy in inducing an antitumor immune response (Dranoff et al, 1993). Granulocyte-macrophage colony-stimulating factor has emerged as the most potent cytokine for activation of antigen processing and presentation by dendritic cells (Cella et al, 1997). When tumor antigens are presented in the context of high-level cytokine expression, cytotoxic T lymphocyte–based antitumor immune responses can be enhanced.

It has been suggested that therapies like radiation can result in the presentation of tumor-associated antigens, which subsequently enhance vaccine-based immunotherapies. One such study using an autochthonous murine model of prostate cancer tested whether

radiation in combination with a granulocyte/macrophage colony-stimulating factor (GM-CSF)-based vaccine could augment the CD4 T cell response (Harris et al, 2008). Although vaccine alone or radiation alone was not capable of priming an antitumor T-cell activation, the combination of radiation with vaccine substantively enhanced antitumor T-cell activation. This effect was dependent on the relative timing of radiation and vaccination. An interesting clinical trial that tested this general concept has also been completed (Gulley et al, 2005). In this phase I study, a PSA-targeted vaccine and radiation were used to treat men with localized prostate cancer. The combination resulted in significant T-cell responses in the majority of treated patients. These studies and others offer the promise of combination therapies that have both local and systemic anticancer potential.

Cytolytic/Proapoptotic Gene Therapy

Cytoreductive approaches to gene therapy that result in cytolytic or apoptotic cell death are generally grouped into three categories: (1) enzyme/prodrugs ("suicide gene" therapy), (2) oncolytics, and (3) cytotoxins. A rational combination of these approaches with a more standard cytotoxic therapy such as RT may provide superior cell killing as a result of nonoverlapping modes of cell death.

Enzyme/Prodrug Gene Therapy

This method of gene therapy relies on the conversion of an inactive prodrug into a toxic drug using an enzyme vectored only to target tumor cells. In this way, active drug is limited to the transduced cells and adjacent surrounding cells. In this therapy, it is critical that the vector have high tumor cell specificity to minimize normal tissue toxicity. Prodrug-activating enzymes employed include those not normally found in humans such as cytosine deaminase, which catalyzes the conversion of nontoxic 5-fluorocytosine to cytotoxic 5-fluorouracil, and herpes simplex virus (HSV)-thymidine kinase, which assists in the conversion of ganciclovir to toxic ganciclovir triphosphate. Even when only a small percentage of cells contain the enzyme, substantial tumor reductions have been noted, given the significant cell death attributed to the bystander effect (Kim et al, 1998). A recently reported study of HSV-thymidine kinase and ganciclovir suicide gene therapy in combination with replication-competent adenovirus and radiation revealed this approach to be safe and associated with frequent negative post-treatment biopsies of the prostate (Freytag et al, 2007).

Oncolytics

Viruses alone can infect and kill tumor cells without insertion of a transgene. Certain viruses have, as part of their normal life cycle, a lytic phase that is lethal to the host cell. In the 1950s, the potential therapeutic activity of this lytic life cycle was documented when cervical cancer was treated with intratumoral injections of wild-type adenovirus with subsequent tumor responses (Smith et al, 1956). Examples of oncolytic viruses that could be used for therapy include adenovirus, vaccinia, Newcastle disease virus, HSV, influenza virus, and mumps virus. Adenoviruses are attractive vectors for gene transfer and therapy for several reasons. They have low pathogenicity for normal tissue, are not tumorigenic, and, when present, result in only mild to moderate clinical symptoms (Anderson, 1998). They can also effect relatively high gene transfer.

The adenovirus exerts its control over host cell growth regulation by a complex set of proteins that facilitate viral replication. A prostate-specific construct has been developed and tested in vitro, in vivo, and in humans. This vector, CN-706, has a minimal promoter enhancer construct of the human PSA gene inserted 5′ of E1A and shows potent PSA selective cytotoxic activity in preclinical testing (Rodriguez et al, 1997). Phase I testing of this virus has been completed in patients with prostate cancer that is locally recurrent after radiation (DeWeese et al, 2000). In this study, the prostate received the oncolytic vector by multiple injections delivered by TRUS-guided transperineal needles. No serious adverse events were noted, and no irreversible grade 3 or any grade 4 toxicities were documented. Preliminary analysis of PSA response found that 4 of 19 patients exhibited more than 50% reduction in PSA from pretreatment values. Viral replication was also documented by electron microscopy of post-treatment biopsy specimens. Strong evidence indicates that radiation can modify adenoviral infectability or gene transfer, or both.

Numerous challenges lie ahead in the development of effective gene therapeutic approaches for prostate cancer. Vector development will continue to be critical in establishing less immunogenic viruses with the capacity to carry large transgenes and with high transduction efficiency. Newer molecular biologic techniques combined with the explosion in genomic information will facilitate development of the next generation of prostate-specific promoters and regulators that will enhance targeted therapy. This new genetic information may also allow individualized gene therapy based on bioassays of newly discovered pretreatment molecular characteristics. Finally, the concept of combined-modality therapy, which has shown success in other tumor sites, will become more standard in prostate cancer management. The combination of gene therapy with conventional therapies such as RT and surgery provides new hope for uniform cure of patients with prostate cancer.

Future Directions

Historically, the principal treatment options for patients with clinically localized prostate cancer have included radical prostatectomy, radiation therapy, and active surveillance or watchful waiting (Middleton et al, 1995). With the exception of radical prostatectomy and watchful waiting (Bill-Axelson et al, 2005), however, randomized, prospective clinical trials comparing the efficacy of primary prostate cancer therapies are lacking. Radical prostatectomy has been perceived as morbid by some, whereas radiation therapy has been criticized for its uncertain efficacy (Scardino and Wheeler, 1988; Kabalin et al, 1989; Fowler et al, 1993; Crook et al, 2000; Potosky et al, 2000, 2004; Zelefsky et al, 2001; Pollack et al, 2002; Penson et al, 2005). Active surveillance is an early option for some patients; however, these patients often proceed with definitive local therapy during longer-term follow-up (Koppie et al, 2000). These and other concerns regarding conventional treatment have fueled an interest, among both patients and physicians, in alternative treatments that are both efficacious and associated with limited treatment-related morbidity.

In fact, cryotherapy—the ablation of tissue by local induction of extremely cold temperatures—has re-emerged as a therapeutic modality that meets these criteria. In 1996 the American Urological Association (AUA) recognized cryotherapy as a therapeutic option for prostate cancer and removed the "investigational" label from this procedure. In late 2008 the AUA released a consensus "Best Practice Statement" on cryosurgical ablation as a treatment option for patients with clinically localized prostate cancer (Babaian et al, 2008). The consensus panel concluded that cryosurgery is an established treatment option for men with newly diagnosed, or radio-recurrent, organ-confined prostate cancer. Moreover, the consensus panel concluded that advances in cryotherapy technology including ultrasonographic ice ball monitoring and use of multipoint thermal sensors have allowed more efficient freezing of the prostate gland while reducing collateral damage to surrounding tissues, notably, the rectum, urethra, and external urinary sphincter (Babaian et al, 2008). **Accordingly, contemporary cryotherapy offers patients a minimally invasive treatment option with low morbidity, minimal blood loss, short hospital stay, good recurrence-free survival, and high rates of negative post-treatment biopsies** (Shinohara et al, 1996; Koppie et al, 1999; Long et al, 2001; Bahn et al, 2002; Donnelly et al, 2002; Han et al, 2003; Prepelica et al, 2005; Cohen et al, 2008; Jones et al, 2008; Pisters et al, 2008).

HISTORY OF CRYOTHERAPY

Human cancers were first managed with cryotherapy in the 19th century when cervical and breast cancers were treated with a salt and ice mixture (Gage, 1998). Although the method was crude, tumor size could be reduced and local tumor control was an attainable goal. In 1961 Cooper and Lee built the first closed cryoprobe system, which circulated liquid nitrogen through a closed metal tube that was placed in contact with the tissue to be treated. This system was used for treating patients with Parkinson disease and other neuromuscular disorders. The first urologic application of prostate cryotherapy was by Gonder and colleagues (1964), who developed probes suitable for transurethral freezing of prostate tissue for benign prostatic hyperplasia and prostate cancer.

As of 2008, four distinct generations of cryotherapy for prostate cancer have been described, highlighting both the progressive evolution of relevant technology and improved patient selection (Table 105–1). During the 1960s and 1970s, early cryosurgeons applied both transurethral and open transperineal approaches in their attempts to eradicate prostate cancer (Gonder et al, 1964). In 1972 Flocks and colleagues described a refined transperineal approach. An incision was made anterior to the rectum, allowing separation of the rectum and prostate and exposure to the most posterolateral aspects of the prostate gland. Freezing was then performed on the surface of the gland and monitored by direct vision. Although the technique compared favorably with treatment modalities such as radical prostatectomy and external-beam radiation therapy (EBRT) with respect to survival, morbidity was significant and included urethral sloughing, rectourethral or urethrocutaneous fistulae, bladder neck obstruction, and urinary

incontinence (Bonney et al, 1982). In 1974 Megalli and colleagues were the first to report a transperineal percutaneous approach using a single 6.3-mm (18-Fr), sharp-tipped liquid nitrogen cryoprobe (Megalli et al, 1974). This cryoprobe was introduced through perineal skin incisions performed on either side of the midline, and its placement was guided by digital palpation. The digitally monitored freezing process was often augmented by a single thermostat placed in the perirectal region. The cryoprobe was typically repositioned to achieve adequate coverage of the prostate, seminal vesicles, and any identifiable extraglandular extension. In an attempt to improve monitoring, Reuter (1972) described the use of a rigid cystoscope, as an adjunct to the rectal index finger, to directly monitor the bladder and ureteral orifices. Unfortunately, the inability, with first-generation cryotherapy, to precisely place cryoprobes and monitor the extent of freezing in real time resulted in the abandonment of the technology until the late 1980s (Gonder et al, 1964; Flocks et al, 1972).

The development and implementation of transrectal ultrasound (TRUS) guidance and urethral warming heralded the second generation of prostate cryotherapy and significantly reduced the number of treatment-related complications. Onik and colleagues (1984) first demonstrated that the frozen area could be visualized ultrasonographically as a well-marginated, hyperechoic rim with acoustic shadowing, and that the leading edge of the growing iceball could be monitored in real time with TRUS imaging (Onik et al, 1988). In the 1990s TRUS technology achieved widespread adoption for the early detection of prostate cancer, and this trend fueled the development of a transperineal, percutaneously introduced, multiple cryoprobe system (Chang et al, 1994). TRUS guidance allowed accurate placement of cryoprobes, real-time monitoring, control of freezing, and visualization of the rectum to protect it from injury. At the same time, the use of urethral warmers with a continuous irrigation system maintains the urethral mucosa above freezing and preserves a thin layer of the mucosa. Urethral warming has been credited with significantly reducing urethral sloughing, stricture formation, and urinary incontinence (Cohen and Miller, 1994; Cohen et al, 1995; Wong et al, 1997; Lee et al, 1999). **Another significant advance for modern prostate cryotherapy was the development of cryogenic systems with multiple cryoprobes.** Multiple, simultaneously controlled cryoprobes achieve a uniform and effective distribution of lethal temperature throughout the iceball, thereby increasing clinical efficacy and reducing the risk of collateral injury. In addition, the availability of multiple cryoprobes provides surgeons with greater flexibility to conform ice formation to each patient's unique anatomy. During this same time period, the **emergence and widespread adoption of the prostate-specific antigen (PSA) assay allowed for better selection of patients and more precise assessment of postcryotherapy cancer control outcomes** (Stamey et al, 1987).

The first modern cryoprobe system was a liquid nitrogen system that supported independent throttle control of five cryoprobes (Accuprobe System, Cryomedical Sciences, Inc., Rockville, MD) that delivered high-efficacy freezing. An advancement of the system over earlier liquid nitrogen systems was refrigeration ("supercooling") of the liquid nitrogen from its usual boiling point at below –195.8° C down to –209° C. This improved efficiency by overcoming problems with nitrogen bubbles forming in the cryoprobe transport tubes or in the cryoprobes, which could unpredictably impede liquid nitrogen cryogen circulation. The first clinical application of such a system in humans was in 63 patients with localized prostate cancer (Onik et al, 1993). Although essential to the successful reintroduction of cryotherapy, liquid systems have intrinsic difficulties in containing, controlling, and circulating liquid nitrogen. **Therefore the hallmark of third-generation cryotherapy was the transition from liquid to gas systems. With this technologic advance, surgeons could now use pressurized gas to both freeze (argon gas) and actively warm (helium gas) tissue via the Joule-Thompson effect. According to the Joule-Thompson effect, different gases undergo unique temperature changes when depressurized according to unique gas coefficients** (Fig. 105–1). In the case of argon gas, this is a constant enthalpy expansion that results in rapid cooling to its boiling point of argon gas (–185.7° C). To accomplish this, high-pressure (3000 psi) ambient temperature argon gas is circulated to the cryoprobe tip, where it expands rapidly as it decreases to room pressure (15 psi). The expanded gases are circulated back to the cryogenic unit through the larger outer lumen of the cryoprobe and the supply hose. The venting of used gas, usually into the room, occurs at the cryogenic machine. The use of helium gas (67° C), which warms up rather than cools when expanded, provided an active defrosting capability that was not available in the second-generation systems, improving the control of iceball formation. It is noteworthy that both argon and helium are inert gases and therefore safe. However, both will displace oxygen from a room and thus adequate air circulation should be maintained within the cryogenic suite.

Importantly, the transition from liquid to gas allowed for the development of ultra-thin, 17-gauge (1.47-mm) cryoprobes, which permitted direct transperineal needle placement through a template without making incisions or using tract dilatation and insertion kits (Fig. 105–2). Another advantage is that gas systems are more compact and easier to use and maneuver within the operating room environment. The introduction of pinpoint thermocouples for systematic temperature monitoring has also substantially contributed to a

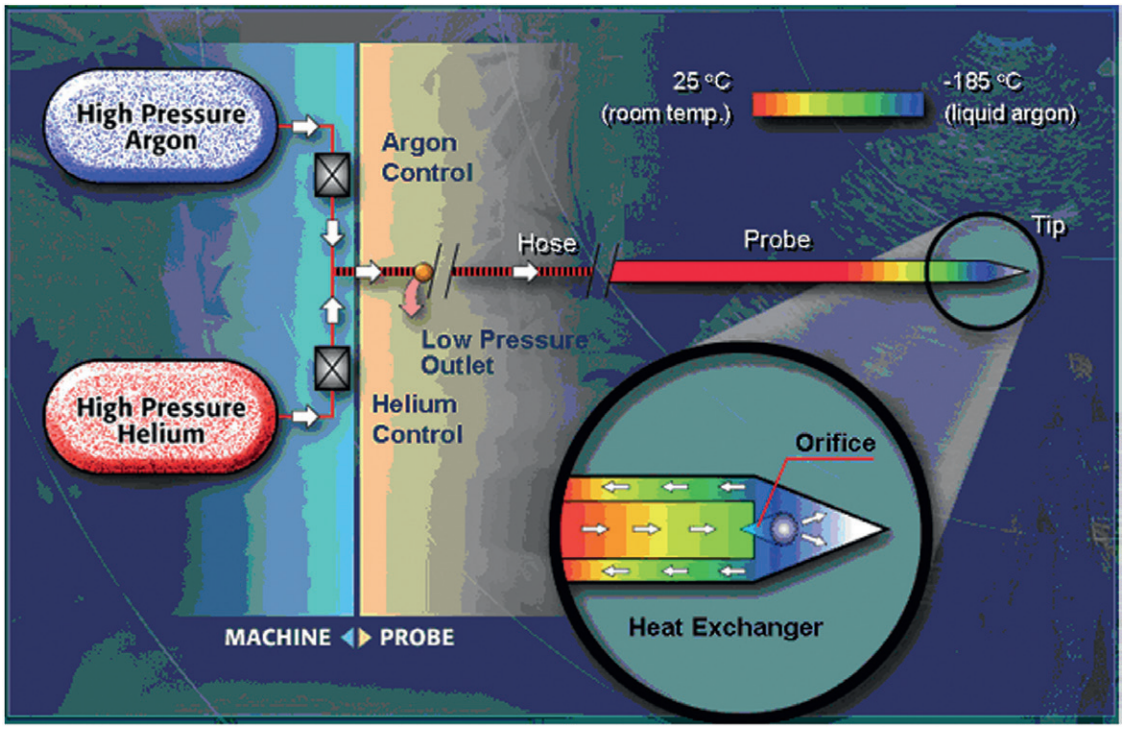

Figure 105–1. Joule-Thompson principle. High-pressure gases enter through the spiraled central port and expand at a narrow terminal port to effect cooling. In accordance with the gas coefficient and the dimension of the nozzle, different gaseous elements generate different thermal exchange events at the area close to the nozzle. Expanded gases return back through the larger, outer lumen and are vented outside the patient into the room. Argon gas is used for cooling (–185.7° C), and helium is used for heating (67° C).

reduction in cryotherapy-associated morbidity. They are used to ensure both that adequately cold temperatures are reached within the prostate and that sensitive adjacent structures, namely, the rectum and external sphincter, are maintained at temperatures warm enough to ensure maintenance of their structural and functional integrity. In addition, the risk of rectal freezing can be lessened by injection of saline solution into Denonvilliers fascia, increasing the space between the prostate and the rectum.

The development of multipoint thermal sensors marked the emergence of fourth-generation prostate cryosurgical technology. With multipoint sensors, surgeons are now able to monitor temperatures along an entire plane (e.g., between the prostate and rectum), rather than at isolated anatomic sites. Although empiric data are not yet available, it is anticipated that the routine utilization of multipoint thermal sensors will further reduce the incidence of postcryotherapy morbidity including both fistulae and urinary incontinence. Fourth-generation technology also involves the use of newly introduced, variable-length cryosurgery probes. The principal advantage of variable-length probes is that they allow surgeons to conform the iceball to the length of the prostate under treatment, thereby obviating the need for a pullback procedure in a majority of cases. Finally, the newest generation of cryosurgical technology also includes computer software that allows surgeons to construct preoperative temperature maps on the basis of theoretic cryoprobe placement (Babaian et al, 2008). With these computer models, surgeons are able to prospectively plan cryoprobe configuration in an attempt to further optimize targeting of diseased tissue, while minimizing damage to adjacent important structures including the rectum, urethra, and external urinary sphincter (Babaian et al, 2008).

CRYOBIOLOGY

Mechanisms of Cell Injury and Death by Cryotherapy

The principles of cryotherapy including the mechanisms of cell injury and cell death have been well studied (Gonder et al, 1964; Gage and Baust, 1998, 2007; Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007) (Table 105–2). Unlike radiation (mitotic arrest) or androgen deprivation (apoptosis), the main mechanism of cryotherapy-produced cytotoxicity is the induction of targeted areas of coagulative necrosis in the prostate gland. **The key factors involved in freezing injury include direct mechanical shock, osmotic shock, and cellular hypoxia.** Mechanisms of action include protein denaturation via dehydration, transfer of water from the intracellular space to the extracellular space, rupture of cell membranes from ice crystal expansion, toxic concentration of cellular constituents, thermal shock from rapid supercooling, slow thawing, vascular stasis, and increased apoptosis (Cooper and Hirose, 1966; Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007).

The extracellular fluid begins to crystallize after reaching a tissue temperature below 0° C. The osmotic pressure of the unfrozen portion of the extracellular fluid compartment increases, causing dehydration of cells to occur due to the shift of water from the intracellular to the extracellular space, which also results in an accumulation of toxins within the cell (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Changes in cellular pH lead to the denaturing of cellular

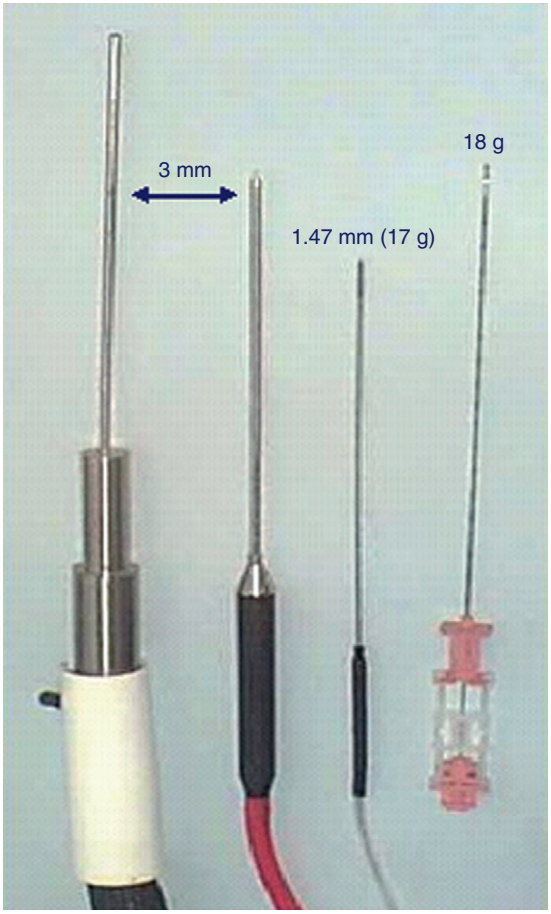

Figure 105–2. Evolution of cryoprobes. Development of third-generation cryotherapy included the transition from liquid nitrogen to gas-driven cryoprobes, which permitted the use of smaller-diameter cryoprobes that allow for direct transperineal probe placement through a brachytherapy-like template, without using tract dilatation and insertion kits.

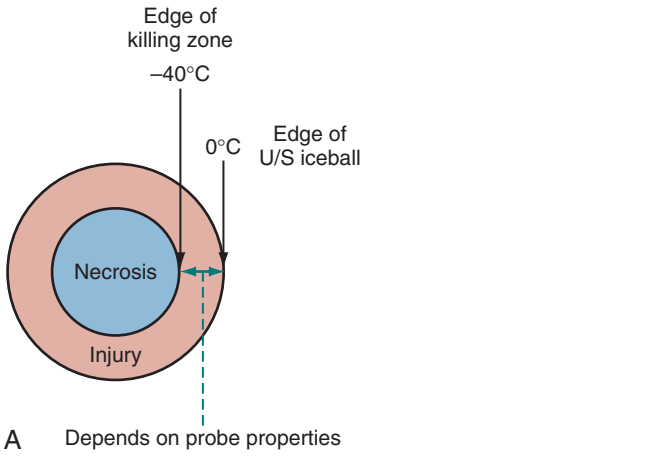
proteins. At a temperature of –15° C, most of the extracellular environment is frozen, which causes trapping of tissue and shearing forces to disrupt cellular structure (i.e., mechanical shock) (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Further decreases in temperature lead to crystallization of water in the intracellular space that mechanically breaks the cellular membrane (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007).

The delayed or indirect destructive effects of cryotherapy continue primarily because of injury to the vasculature, resulting in tissue hypoxia and vascular thrombosis (Hoffman and Bischof, 2002; Chao et al, 2004; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Zacarian and colleagues (1970) reported that at temperatures below –20° C, venules were more susceptible to injury than arterioles. Freezing promotes stasis of blood, leading to thrombosis and subsequent coagulative necrosis of tissue. This process includes local edema with activation of the inflammatory cascade. On thawing, extracellular fluid shifts back into the intracellular space, leading to lysis of both the intracellular organelles and the cell membrane itself. The blood vessels around the targeted tissue initially dilate after thawing, and hyperpermeability of the vessel wall occurs. After a few hours of this hyperemic state, microthrombi form on the damaged vessel wall, leading to regional tissue ischemia (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007).



Apoptosis is recognized as a mechanism of cell death that occurs in both normal tissues and various pathologic conditions. Apoptotic cells are characterized by nonrandom DNA cleavage, blebbing of membranes, phospholipid inversion in the membranes, and caspase activation (Kerr et al, 1994). **Following cryosurgical ablation, apoptotic cells are found primarily in the peripheral zone of the cryogenic lesion outside the killing zone, where the temperature was not sufficiently cold to kill all the cells** (Hollister et al, 1998; Hoffman and Bischof, 2002). In addition, kinetic studies have shown that cells are susceptible to entering the apoptotic state up to 8 hours after rewarming (Yang et al, 2003). The recent finding of apoptosis in cells in the peripheral zone of the cryogenic injury may one day be exploited therapeutically using other proapoptotic stimuli to extend the zone of cell death (Yang et al, 2003; Clarke et al, 2007). Currently, however, the precise role of apoptosis in cryosurgery-induced tissue injury remains incompletely understood (Hoffman and Bischof, 2002; Baust et al, 2004).

In-vivo experiments have suggested that cryodestruction of living tissues can elicit an immunologic response by the host that may itself eradicate cancer cells (Ablin, 1972). Experiments with MRMT-1 mammary adenocarcinoma cells and R3327 prostate adenocarcinoma cells in rats have demonstrated the appearance of tumor immunity by 7 to 10 weeks after cryotherapy that was associated with a decrease in growth of metastatic lesions. However, cryotherapy of the Dunning AT-1 cell line, an androgen-insensitive cell line, in Copenhagen rats was associated with a minimal increase in T-cell counts without an effect on the local tumor growth rate (Hoffmann et al, 2001). **Although the potential for a cryoimmunologic effect against residual prostate cancer cells is intriguing, cryotherapy must still be considered as a local therapy.**

Tissue Response to Freezing

The response of human tissue to freezing injury varies from inflammatory to destructive, depending on the

severity of freezing (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Minor freezing injury features only inflammatory responses, whereas severe freezing injury destroys cells and tissues, which is the prime requirement for treating tumors. The cryogenic lesion is characterized by a central region of uniform coagulation necrosis. Surrounding the central lesion is a peripheral zone that develops several days after freezing (Fig. 105–3). In this region, tissue temperatures ranged 0° C to –0° C, and only partial cell death has occurred (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). The process of wound repair begins in the peripheral zone in the areas in contact with viable tissue; inflammatory cells infiltrate and new blood vessels may grow into the injured tissue. Over the following weeks or months, the dead tissue is slowly replaced by fibroblasts and new collagen formation, yielding a contracted healed area in lieu of the previously ablated tissue.

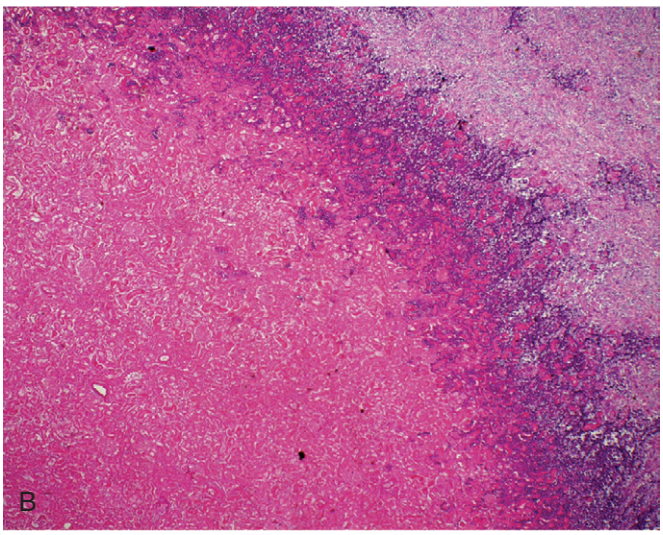


Figure 105–3. **A,** The cryogenic lesion is characterized by a central uniform coagulation necrosis surrounded by a peripheral zone. Tissue temperatures range from 0° C to –40° C in the peripheral zone leading to partial cell death and apoptosis. **B,** Complete necrosis within central portion of scar with rim of sublethal injury was seen after cryotherapy. (Hematoxylin and eosin, reduced from ×80.)

Factors Affecting Tissue Destruction during Cryotherapy

Optimal technical application of cryotherapy requires a thorough understanding of the freeze-thaw cycle and its components (Table 105–3). **The variables that correlate with the likelihood of cell destruction include the cooling rate during freezing, the warming rate during thawing, and the lowest temperature achieved in the tissue** (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007; Babaian et al, 2008). Tatsutani and colleagues (1996) described these effects in an in-vivo prostate cancer cell experiment. In this study, complete cell death was unlikely to occur at temperatures higher than –20° C and temperatures lower than –40°C were required to completely destroy cells (Tatsutani et al, 1996). Moreover, the investigators noted that a faster freezing rate and a slower thawing rate resulted in optimal cellular destruction.

For optimal results, a tissue temperature of –40° C to –50° C, which is lethal for cells, should be produced within the tumor including a safe distance around the tumor (Bischof et al, 1997; Gage and Baust, 1998; Hoffmann and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). In addition to the nadir temperature, the duration of freezing appears to be an important determinant of tissue destruction (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Once the tissue temperature reaches a certain nadir level, more cellular destruction can be achieved by prolonged freezing at this temperature. The target tissue should therefore be held in the frozen state for several minutes to allow time for solute effects, ice crystal formation, and recrystallization effects. When the tissue is held at –15° C to –40° C, biochemical changes and growth of ice crystals are enhanced, increasing the rate of cell death (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). Nonetheless, the optimum duration of freezing is not well defined and may prove to be cell/tissue-type specific (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007).

Slow thawing of the frozen tissue is also a crucial determinant of tissue destruction (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). In fact, the rate of thawing should be as slow as clinically practical. A longer thaw will yield greater cellular damage due to solute effects, ice crystal restructuring (recrystallization), prolonged oxidative stress, and growth of ice crystals (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). The large ice crystals that form during "warming" recrystallization create shearing forces, thereby disrupting the target tissues and

Table 105–3.

Factors Affecting Tissue Destruction during Cryotherapy

Rate of tissue freezing

Nadir tissue temperature
Duration of freezing
Number of freeze-thaw cycles
Existence of heat sinks

promoting cellular death. Repetition of the freeze-thaw cycle is also important (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007; Babaian et al, 2008). The first freeze-thaw cycle increases the thermal conductivity of the tissue caused by cellular breakdown; the second freeze-thaw subjects the tissue to extended physiochemical changes, while passing through damaging thermal conditions for the second time (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). With repetition, the second cycle increases the extent of necrosis up to 80% of the previously frozen volume (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). The second cycle also moves the lethal isotherm close to –20° C, permitting a closer approach to the margins of the prostate without endangering the rectum. The interval between freeze-thaw cycles is also an important factor in tissue injury. A longer thaw time supports complete vasoconstriction of larger blood vessels, continued ice crystal growth, and more extensive osmotic damage. A further delay after thawing, but before the second freeze cycle, leaves the tissue in a hypothermic state and allows time for the microcirculation to fail. In combination, these events provide the targeted tissue with conditions consistent with severe oxidative stress that may ultimately give rise to additive post-thaw cell death (Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007).

In a clinical setting therefore the number of freezing cycles, the lowest temperature achieved, and the existence of any regional "heat sinks" may be important factors relating to cancer destruction. **Double freeze-thaw cycles during cryotherapy for prostate cancer in humans have been associated with lower positive biopsy rates, as well as improved PSA results, when compared with a single freeze-thaw cycle, without an increase in the development of cryotherapy-related morbidities** (Shinohara et al, 1996; Pisters et al, 1997; Wong et al, 1997; Mouraviev and Polascik, 2006; Babaian et al, 2008). Temperature mapping studies performed in patients with localized prostate cancer, who agreed to undergo focal cryotherapy of the prostate before undergoing radical prostatectomy, demonstrated that cryotherapy resulted in a central zone of complete cellular necrosis surrounded by a more peripheral zone of cell damage, and that **two consecutive 10-minute freeze cycles produced a larger area of coagulative necrosis than a single 20-minute freeze** (Larson et al, 2000). Furthermore, a **double freeze at temperatures below –40° C appears to yield more complete tissue necrosis** (Larson et al, 2000). This fact has important clinical implications because the hyperechoic edge of the iceball visualized is 0° C to –2° C, and temperatures as low as –20° C to –40° C are inside this edge (see Fig. 105–3). Therefore the iceball should be extended beyond the edge of the prostate to ensure adequate tissue ablation. Although the available literature supports the use of a minimum of two freeze-thaw cycles (Shinohara et al, 1996; Pisters et al, 1997; Wong et al, 1997; Mouraviev and Polascik, 2006; Babaian et al, 2008), it remains unknown whether additional therapeutic efficacy may be derived from more than two treatment cycles. Finally, cryosurgeons should be aware that large blood vessels may act as heat sinks and highly vascular areas may not achieve target temperatures even though they are completely enclosed in the treatment area.

Recognizing the critical importance of these technical concerns and determinants of tissue destruction, authors of the AUA's Best Practice Statement for prostate cryosurgery recommended that the following procedural requisites be considered in every case (Babaian et al, 2008):

1. Tissue freeze rate: The authors concluded that rapid freezing is more efficacious than slow freezing with respect to cell death (Babaian et al, 2008).
2. Temperature monitoring: The consensus panel strongly recommended the use of thermal couples during cryosurgical ablation, despite the absence of clear scientific evidence to support their use. It is believed that real-time temperature monitoring allows the cryosurgeon to better control the freezing process while at the same time protecting key vital structures (e.g., rectum, urethra) from unintended injury (Babaian et al, 2008).
3. Nadir temperature: On the basis of in-vitro and in-vivo data, the panel recommended attaining intraprostatic temperatures of –40° C or lower whenever possible during cryosurgical ablation. They recognized, however, that prostate cancer may be relatively temperature labile and that lethal temperatures may occur closer to –20° C.
4. Thaw rate: The authors concluded that prostate cancer ablation is more effective with slow (passive) versus rapid (active) tissue thawing. They note, however, that active thawing may not affect thaw rates at the distal edges of the gland (Babaian et al, 2008).
5. Freeze cycles: Members of the panel endorsed the use of a double freeze-thaw cycle during cryosurgical ablation of the prostate. They based this recommendation on experimental and clinical evidence that cancer cells not killed by the first freeze cycle may be stressed to such an extent that a second cycle achieves complete cellular death (Babaian et al, 2008).

TECHNICAL IMPROVEMENTS IN CRYOTHERAPY EQUIPMENT

Transrectal Ultrasound Systems

One of the most significant advances in the application of prostate cryosurgery has been the implementation of real-time, ultrasound-guided placement of the cryoprobes and continuous sonographic monitoring of the freezing process. **Biplanar transrectal ultrasound systems (TRUSs) allow for transverse and longitudinal views of the prostate, and the views are easily interchangeable during the procedure.** Frozen tissue is significantly different from unfrozen tissue in sound impedance, resulting in strong echo reflection at the interface of frozen and normal tissue. Accordingly, **the leading edge of frozen tissue is easily visualized as a bright line** (Fig. 105–4). The tissue inside this leading edge is concealed within the acoustic shadow created by this boundary so that the anterior boundary of the freezing area cannot be monitored (Mouraviev and Polascik, 2006). The refraction and reflection of the sound wave can also overestimate the lateral boundary of the iceball. The use of color Doppler imaging may be helpful for monitoring tissue viability (vascularity) as freezing approaches the rectum. Although not an objective parameter, color Doppler imaging provides some indication about the vascular state between the ice and the rectal mucosa and may therefore potentially provide some information about the likely speed of freezing in this area. Sonography provides no information about the temperature distribution within the ice, nor does it show the extent of freezing at the lateral or anterior aspects of the prostate. Reports of three-dimensional ultrasound during cryosurgery show potential, especially for preoperative planning of a procedure and cryoprobe placement (Chin et al, 1998). In practice, however, these have been relatively slow and

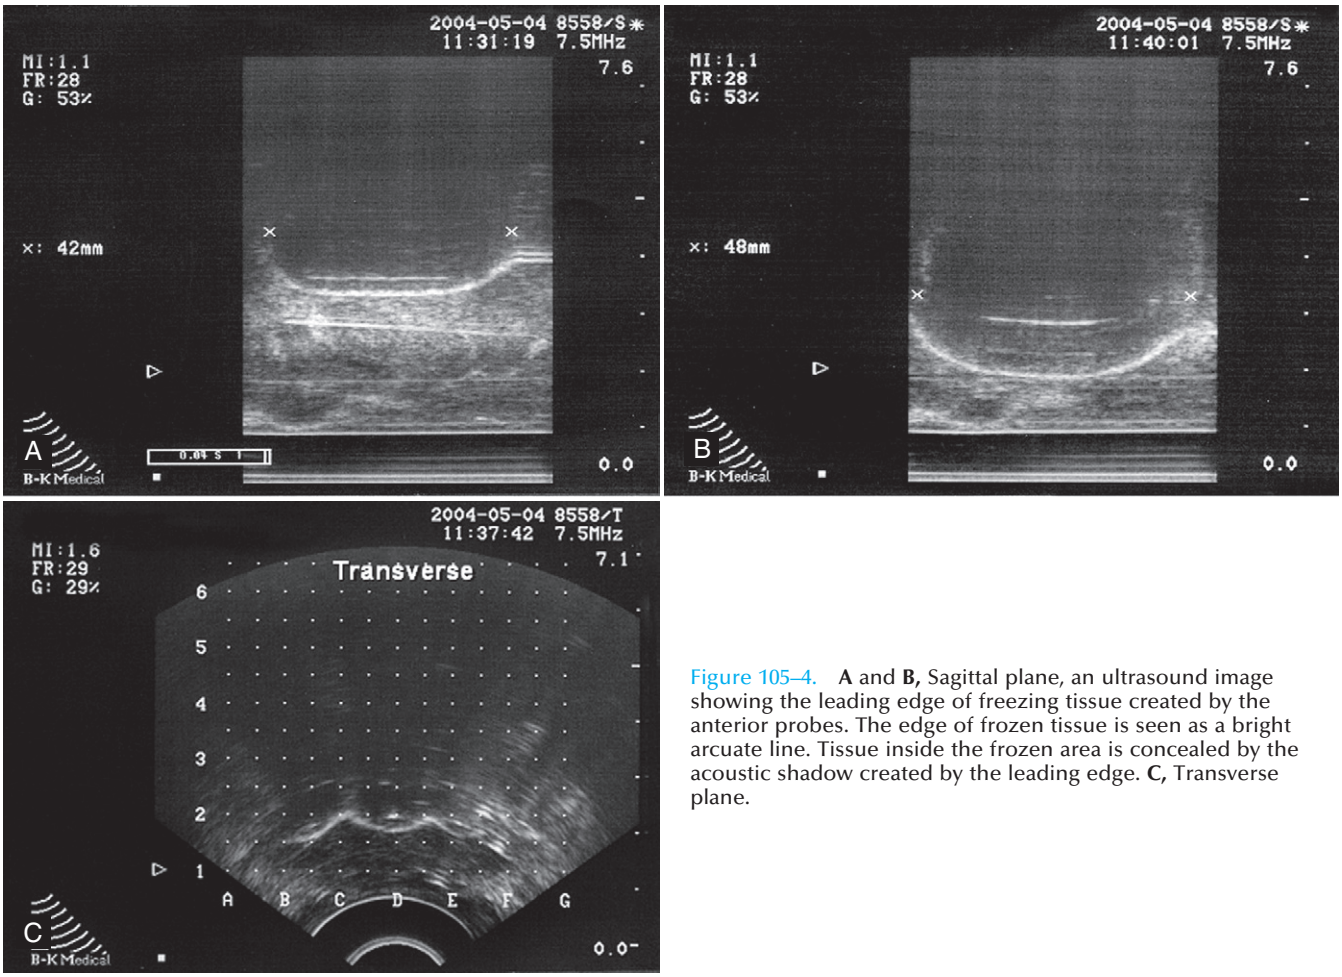

Figure 105–4. **A** and **B,** Sagittal plane, an ultrasound image showing the leading edge of freezing tissue created by the anterior probes. The edge of frozen tissue is seen as a bright arcuate line. Tissue inside the frozen area is concealed by the acoustic shadow created by the leading edge. **C,** Transverse plane.

cumbersome to apply, making their clinical implementation difficult.

Template and Stands

A brachytherapy-like stepper includes a cradle to which the multifrequency biplanar TRUS probe is attached. A brachytherapy-like template drilled with a matrix of holes that will accommodate the cryoprobes is then attached to the holding device (Fig. 105–5). Systems are available with a floor stand or table-mounted device. The brachytherapy-like grid can be adjusted to ensure accuracy with any ultrasound system.

Figure 105–5. Brachytherapy-like template drilled with a matrix of holes to accommodate cryoprobes.

Cryogenic Systems

Liquid nitrogen (–195.8° C) is the coldest practical cryogenic agent and has the greatest freezing capacity, but it cannot be used in probes of less than 3 mm in diameter. The transition from systems circulating liquid nitrogen to gas-driven probes now permits the use of ultra-thin cryoprobes. In accordance with gas coefficient and nozzle dimensions, different gaseous elements generate different thermal exchange events (Joule-Thompson principle). **In clinical practice, argon gas is used for cooling and helium gas is used for heating (thawing).** Third-generation cryotherapy using gas-driven delivery systems and 17-gauge cryoprobes inserted via a direct transperineal route into the prostate without using an insertion kit were first reported in 2000 (Zisman et al, 2000). At present in the United States, there are two available systems for cryosurgical ablation of the prostate. The Precise system (Galil Medical, Plymouth Meeting, PA) uses pressurized argon gas as the source of freezing, and up to twenty-five 17-gauge (1.47-mm) cryoprobes (IceSeeds) can be used to create a conformal

freezing pattern. The iceball created with the IceSeeds is approximately 18 mm in diameter and 27 mm in length. The Precise system also has available the IceRod needles in which a bigger iceball is created (32 mm × 56 mm), thereby facilitating treatment of men with larger prostate glands. The CRYOcare system (Endocare, Inc., Irvine, CA) also uses pressurized argon gas as a cryogen and can freeze up to eight 2.4-mm, vacuum-insulated cryoprobes simultaneously; the iceball created is approximately 33 mm in diameter and 54 mm in length. An important recent advance is the introduction of variable-length cryotherapy probes that tailor the length of the iceball to the length of the prostate. The authors anticipate that, in the future, cryotherapy probes may be further modified to also allow intraoperative tailoring of the iceball width.

Warming Probes

Warming probes can be used to protect tissues and organs from being inadvertently damaged during cryotherapy. Warming probes actively warm by using helium gas, which warms when it expands through the Joule-Thompson principle. In selected cases, warming probes may be used to protect the neurovascular bundles (NVBs) in an attempt to preserve sexual function.

Thermocouples

Because fairly reliable coagulative necrosis can be achieved when temperatures below –40° C are reached in the target tissues (Gage and Baust, 1998; Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007), many surgeons now place thermocouples at the margins of the targeted treatment zones to ensure that cytotoxic temperatures are achieved during freezing. Several studies reported improved PSA recurrence-free rates and postcryotherapy biopsy results with thermocouple monitoring when compared with patients in whom this had not been used (Lee et al, 1997; Wong et al, 1997). In most cases, thermocouples are also used to ensure maintenance of nonablative temperatures within Denonvilliers fascia, the anterior rectal wall, the external sphincter, and/or the neurovascular bundle(s).

Urethral Warming Device

The primary role for the urethral warming device during prostate cryotherapy is to protect the urethra and the external urinary sphincter to minimize urethral sloughing and prevent urinary incontinence. The urethral warmer is a closed double-lumen catheter made of a polyethylene membrane through which saline heated to 43° C is continuously circulated by a water pump at a rate of 350 to 500 mL/min. The first urethral warming system was marketed as a nonsignificant risk device until approximately July 1994. Initial experiences with this system were notable for fairly low rates of urethral sloughing, ranging from 4% to 10% (Onik et al, 1993; Coogan and McKiel, 1995; Wieder et al, 1995). Because of concerns submitted to the U.S. Food and Drug Administration (FDA) surrounding the safety of this particular device, it was taken off the market in mid-1994 for approximately 18 months while it underwent regulatory review. During this time period, numerous investigators reported a sharp increase in postcryotherapy transurethral resection of the prostate (TURP) and overall urethral sloughing rates due to the use of alternative urethral warmers or warming systems that did not have many of the features of the original one (Cohen et al, 1996a, 1996b; Lee et al, 1997). As expected, the safety of the original warmers was confirmed and, since 1996, FDA-approved urethral warming devices have been widely available. Studies directed toward improving catheter design and urethral warming efficacy are ongoing, with the hope that slough rates will decline even further as new devices are marketed. Moreover, because urethral warming catheters necessarily preserve a ring of viable tissue around the urethra, further improvements in the efficiency of these devices may allow surgeons to achieve a tighter treatment margin by reducing the diameter of viable periurethral tissue. This may, in turn, yield improved cancer control following cryosurgical ablation as preserved prostate tissue around the urethra represents a sanctuary site for residual and/or recurrent cancer.

Computerized Planning

Computer-guided systems now provide improved intraoperative treatment planning with a potential for more precise and complete tissue destruction. The thermal distribution is predictable around a cryoprobe and can be modeled using computer simulation (Rewcastle et al, 1998, 2001; Babaian et al, 2008). Similar to the treatment planning strategies used for radiation therapy, it is possible to determine optimal placement of cryoprobes in the prostate to maximize ablation of the prostate while minimizing collateral damage (Sandison, 2002; Babaian et al, 2008). Research and development are focusing on the incorporation of functional and multimodality imaging data, as well as on the development of accurate mathematic models for in-vivo tissue injury response to thermal history (including cryotherapy-induced ischemia) to optimize treatment planning.

PATIENT SELECTION

Primary Cryotherapy

As with other forms of local therapy for prostate cancer, outcomes after cryotherapy correlate with cancer severity including the stage and grade of the primary tumor. In general, **primary cryotherapy is suitable for patients with clinical stage T1c-T3 disease of any tumor grade who are not potent or not interested in maintaining their potency;** in this setting, primary cryosurgical ablation is regarded mainly as an alternative treatment to radiation therapy. The authors believe that radical prostatectomy remains the gold-standard therapy for localized prostate cancer and the preferred treatment in younger patients. For patients with clinical stage T3 disease, primary cryotherapy is more appropriate for smaller-volume disease in which the tumor is likely to be encompassed in the freezing process. Moreover, extensive disease in a periurethral location is a contraindication to primary cryotherapy because use of the urethral warming catheter will preclude complete eradication of disease in this group of patients.

Because of the minimally invasive nature of cryotherapy, it may have specific advantages in select patients with certain comorbidities including those who are poor candidates for radical prostatectomy or radiation therapy (e.g., men with Crohn disease, ulcerative colitis, prior pelvic irradiation or pelvic surgery, cardiac disease, morbid obesity, and/or body habitus unfavorable for radical prostatectomy or radiation therapy). Primary cryotherapy can also be offered to patients who have no evidence of metastatic disease with more than a 10-year life expectancy who, after reviewing available information on prevailing therapeutic options for new diagnoses of prostate cancer, are either unsatisfied with or refuse to undergo radical prostatectomy or radiation therapy. In particular, many patients who are candidates for EBRT may wish to

consider primary cryotherapy because treatment can be administered as a 1-day ambulatory procedure as opposed to 7 to 9 weeks of treatment.

Before proceeding with cryosurgery, patients with a high risk of metastatic disease should undergo imaging, radionuclide bone scan, or cross-sectional imaging of the abdomen and pelvis on the basis of the stage and grade, as well as serum PSA concentrations. Patients at high risk for lymph node metastases may undergo regional lymph node dissection if identification of disease would alter treatment choice. Patients with gross extracapsular extension or seminal vesicle invasion are treated with neoadjuvant hormone therapy to reduce the tumor volume and allow for easier inclusion within the iceball. **If the prostate size exceeds 50 cm^3, complete freezing of the prostate may be difficult and neoadjuvant hormone therapy is indicated to reduce the target volume and allow** uniformly cold temperatures throughout the gland (Bales et al, 1995; Miller et al, 1996; Shinohara et al, 1996; Baust et al, 1997; Cespedes et al, 1997; Pisters et al, 1997; Babaian et al, 2008). There are no data, however, that neoadjuvant or concurrent androgen deprivation therapy influences postcryosurgery cancer control outcomes (Babaian et al, 2008).

Salvage Cryotherapy

Nearly one third of men with newly diagnosed prostate cancer are treated with EBRT and/or brachytherapy as primary therapy each year (Mettlin et al, 1998, 1999). Despite advances in radiation therapy techniques including image-guided and intensity-modulated radiation therapy (IMRT), three-dimensional conformal radiation therapy (3DCRT), and image-guided implantation of electromagnetic sensors to improve treatment planning (Pisansky, 2006), urologists will continue to see men with recurrent prostate cancer following primary radiation therapy (Allen et al, 2007; Nguyen et al, 2007). In fact, depending on failure definitions and initial cancer severity, it estimated that between 20% and 60% of men who undergo initial definitive radiation therapy for prostate cancer may develop a postradiotherapy PSA recurrence (Allen et al, 2007; Nguyen et al, 2007); among this group, local-only failure rates range from 25% to 32% (Touma et al, 2005). Radioresistant or radio-recurrent prostate cancer is typically an aggressive form of localized prostate cancer that represents a serious health risk for patients treated with primary radiation therapy for clinically localized prostate cancer. Many patients with radio-recurrent disease harbor large-volume and/or poorly differentiated tumors at the time of diagnosis (Allen et al, 2007; Nguyen et al, 2007), making it a challenge for salvage therapies to fully eradicate the cancer. Early detection with serum PSA monitoring and prostate needle biopsy after primary radiation therapy may identify residual adenocarcinoma at an earlier stage and increase the likelihood of successful salvage therapy (Allen et al, 2007; Nguyen et al, 2007). The goal of salvage therapy is to provide a treatment option with curative intent that improves local control and possibly affect long-term survival (Babaian et al, 2008).

Radical prostatectomy, cryotherapy, brachytherapy, and radiation therapy are the options available for salvage treatment of radiorecurrent prostate cancer (Touma et al, 2005; Allen et al, 2007; Nguyen et al, 2007). Salvage prostatectomy is associated with significant morbidity and therefore used relatively infrequently, particularly among older men with radio-recurrent prostate cancer (Krupski et al, 2006). Salvage brachytherapy and/or radiation therapy confer the potential for increased rectal and urinary toxicity in a patient who has previously received prostate irradiation (Allen et al, 2007; Nguyen et al, 2007). As a result, patients are often left with the option of either watchful waiting or temporary palliation with hormone deprivation therapy and its attendant toxicity. Notably, recent modifications in the technique of salvage cryotherapy have led to the ability to eradicate radiorecurrent prostate cancer safely and with decreased morbidity (Spiess et al, 2006; Ismail et al, 2007; Ng et al, 2007). However, complications associated with salvage cryotherapy are higher than those associated with primary treatment (Bales et al, 1995; Pisters et al, 1997; Long et al, 1998; Perrotte et al, 1999; Han et al, 2003; Spiess et al 2006; Ismail et al, 2007; Ng et al, 2007).

Only patients with a rising PSA value after radiation, a positive postradiation biopsy, and a negative metastatic survey are candidates for salvage cryotherapy (Mouraviev et al, 2006; Babaian et al, 2008). The authors' practice has been to wait at least 18 to 24 months after radiation therapy and to perform a biopsy of the prostate if the PSA value rises above the nadir level and there are three consecutive rises. Patients with a postradiation PSA greater than 10 ng/mL and/or a PSA doubling time of 16 months or less have been shown to be more likely to have unsuccessful salvage cryotherapy (Spiess et al, 2006; Ng et al, 2007; Babaian et al, 2008). **If a biopsy is undertaken, multiple cores should be obtained and the pathologist needs to be informed that the patient has had previous radiation.** Severe radiation effects with both nuclear and cytoplasmic alterations are seen in many prostatic biopsies and may confound the diagnosis of residual cancer (Cheng et al, 1999). **Given the high prevalence of seminal vesicle involvement in series of patients undergoing salvage radical prostatectomy, consideration should also be given to performing concurrent seminal vesicle biopsies** (Babaian et al, 2008). The incidences of positive biopsy results after primary radiation therapy vary widely in the literature but seem to be higher after EBRT than after brachytherapy (Stone et al, 2000).

Once it has been determined that primary therapy has failed, local recurrences must be distinguished from systemic recurrences. Local failure has been defined as histologically proven active adenocarcinoma on repeat prostate biopsy in the absence of radiographic evidence of metastatic disease. Unfortunately, multiple studies have demonstrated the relative lack of sensitivity and specificity of most radiographic tests including computed tomography (CT), magnetic resonance imaging (MRI), bone scan, and, more recently, monoclonal antibody-labeled nuclear scans for the diagnosis of systemic disease in biochemically recurrent prostate cancer (Albertsen et al, 2000; Sodee et al, 2000). High-resolution MRI with a lymphotropic superparamagnetic nanoparticle imaging agent may offer greater sensitivity for the detection of lymph node metastases; however, this technology is not yet available in clinical practice (Harisinghani et al, 2003; Nguyen et al, 2007). Despite the shortcomings of currently available imaging techniques, these modalities should be applied if recurrence is suspected because the presence of overt metastatic disease may obviate the patient being exposed to unnecessary local therapies. In this setting, pathologic confirmation via prostate biopsy of locally recurrent disease is warranted before consideration of invasive salvage therapies. In rare cases, **there may be a role in performing an open or laparoscopic biopsy of the pelvic lymph nodes because between 20% and 40% of patients will have lymph node metastases** (Rogers et al, 1995; Babaian et al, 2008). Caution is advised for novice laparoscopic surgeons because the dissection of these nodes can be technically challenging owing to potential adherence to the pelvic side wall and external iliac vessels.

Contraindications

Relative contraindications to cryotherapy are similar to those for brachytherapy and include prior TURP with a large tissue defect, significant symptoms of urinary obstruction before treatment, large prostate size, and a history of abdominoperineal resection for rectal cancer, rectal stenosis, or other major rectal pathology (Babaian et al, 2008). Prior TURP is associated with an increased risk for sloughing and urinary retention (Babaian et al, 2008). **Absolute contraindications include fistulae for any reason (including but not limited to inflammatory bowel disease) and previous surgery or trauma to the pelvis (e.g., urethroplasty, open book fracture) that may distort the anatomy of the prostate.** Significant preoperative obstructive symptoms increase the likelihood of postoperative urinary retention. Cryotherapy is not as sensitive to pubic arch interference as brachytherapy because the iceball migrates away from the cryoprobe. In rare cases, pubic arch interference may preclude adequate placement of cryoneedles. In these cases the prostate may be cytoreduced with neoadjuvant hormonal ablation (Babaian et al, 2008).

Combination Treatment

Patients with locally progressive disease despite hormonal ablation may be treated with cryotherapy to prevent urinary obstruction or bleeding (Cohen et al, 1996; Shinohara et al, 1996). Cryotherapy could also be used in combination with radiation therapy to more effectively manage the primary or dominant cancer lesion. Whether such combination therapy will improve cancer-specific outcomes compared with radiation alone or neoadjuvant androgen deprivation in combination with radiation is unknown at this time but merits further evaluation. A study evaluating the feasibility and complications of cryotherapy followed by radical prostatectomy in patients with clinical stage T3 disease demonstrated complete tumor destruction in four of seven patients (Fig. 105–6) (Pisters et al, 1999a). However, all seven patients who underwent radical prostatectomy had significant urinary incontinence requiring the use of pads. Cryotherapy has also been used to treat select patients with ultrasonically visible bulky local recurrences after radical prostatectomy (Siddiqui et al, 2007).

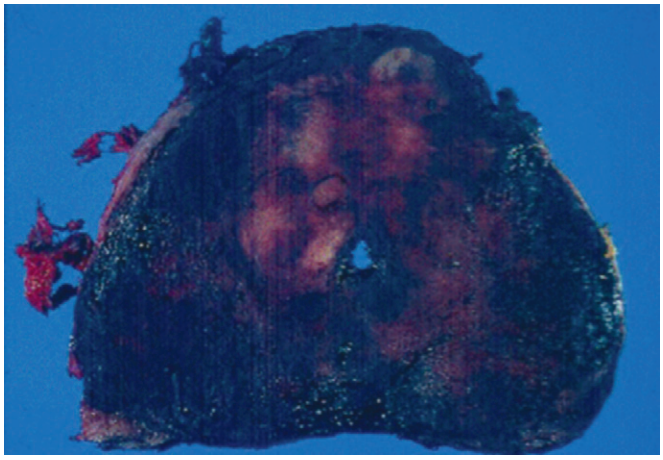

Figure 105–6. Cross section of prostatectomy specimen after two freeze-thaw cycles during cryotherapy of the prostate without the use of a urethral warming catheter. There was no histologic evidence of residual viable prostate cancer (pT0).

SURGICAL TECHNIQUE

Patient Preparation

Patients undergo a light bowel preparation consisting of oral magnesium citrate the day before and a phospho-soda enema the morning of the procedure. After induction of regional or general anesthesia (in the authors' experience, the latter is preferable), the patient is placed in an exaggerated dorsal lithotomy position, which provides excellent transperineal access to the prostate. Sequential compression devices are used preoperatively and during the procedure. A Foley catheter is inserted and clamped to allow the bladder to distend, thereby displacing the intraperitoneal contents.

Transrectal Ultrasound Evaluation

A multifrequency biplanar TRUS probe is inserted in the rectum and secured within the adapting cradle of a brachytherapy-like stepper. The prostate is imaged and its dimensions measured. The aiming grid software is activated and projected on the corresponding TRUS image. The attached probe is lowered posteriorly until either slight resistance is encountered from the posterior rectal wall or the sonographic image of the shiny anterior fibromuscular stroma is lost at 5 MHz. This maneuver opens up the distance between the prostate gland and the rectum, thereby increasing the safety of the procedure by reducing the risk of freezing injury to the anterior rectal wall. Once the necessary adjustments of the TRUS probe are complete, the holding device is fixed in place for the remainder of the case. A brachytherapy-like template, drilled with a matrix of holes to accommodate the cryoprobes, is attached to the holding device (see Fig. 105–5), gently fixed against the perineum, and stabilized with the stepper. The holes in the template are 5 mm apart and correspond to the aiming grid projected on the ultrasound image.

Cryoneedle Placement

At present, techniques for cryoneedle placement vary on the basis of the cryotherapy system employed for a particular case. Irrespective of the system employed, however, knowledge of the isotherm profile (i.e., the temperature range within the iceball) and iceball geometry for a particular cryoneedle is essential to achieving adequate overlap and confluence between adjacent iceballs (Fig. 105–7). Both cryotherapy systems currently on the market allow for direct transperineal placement of cryoprobes using a brachytherapy-like template without the use of insertion or dilation kits (Fig. 105–8). Cryoneedles are inserted under TRUS guidance and positioned in layers so that prostate is adequately covered (Fig. 105–9). Because the iceball progresses longitudinally past the needle tip, the cryoneedles are advanced into the base of the prostate and positioned just caudal to the bladder neck, depending on the cryoprobe-specific iceball geometry. The distance between the most posterior layer of cryoneedles and the prostate capsule also depends on the probe-specific iceball geometry. Given the propensity of prostate cancer to expand through the capsule in locations pierced by the branches of the NVB, lateral needles are placed as indicated to permit extraprostatic freezing and facilitate killing by early shutdown of the arterial supply to the gland. The prostatic urethra is identified by TRUS in both the longitudinal and the transverse views, and each cryoneedle is placed a safe distance away from the urethra. A complete description of specific

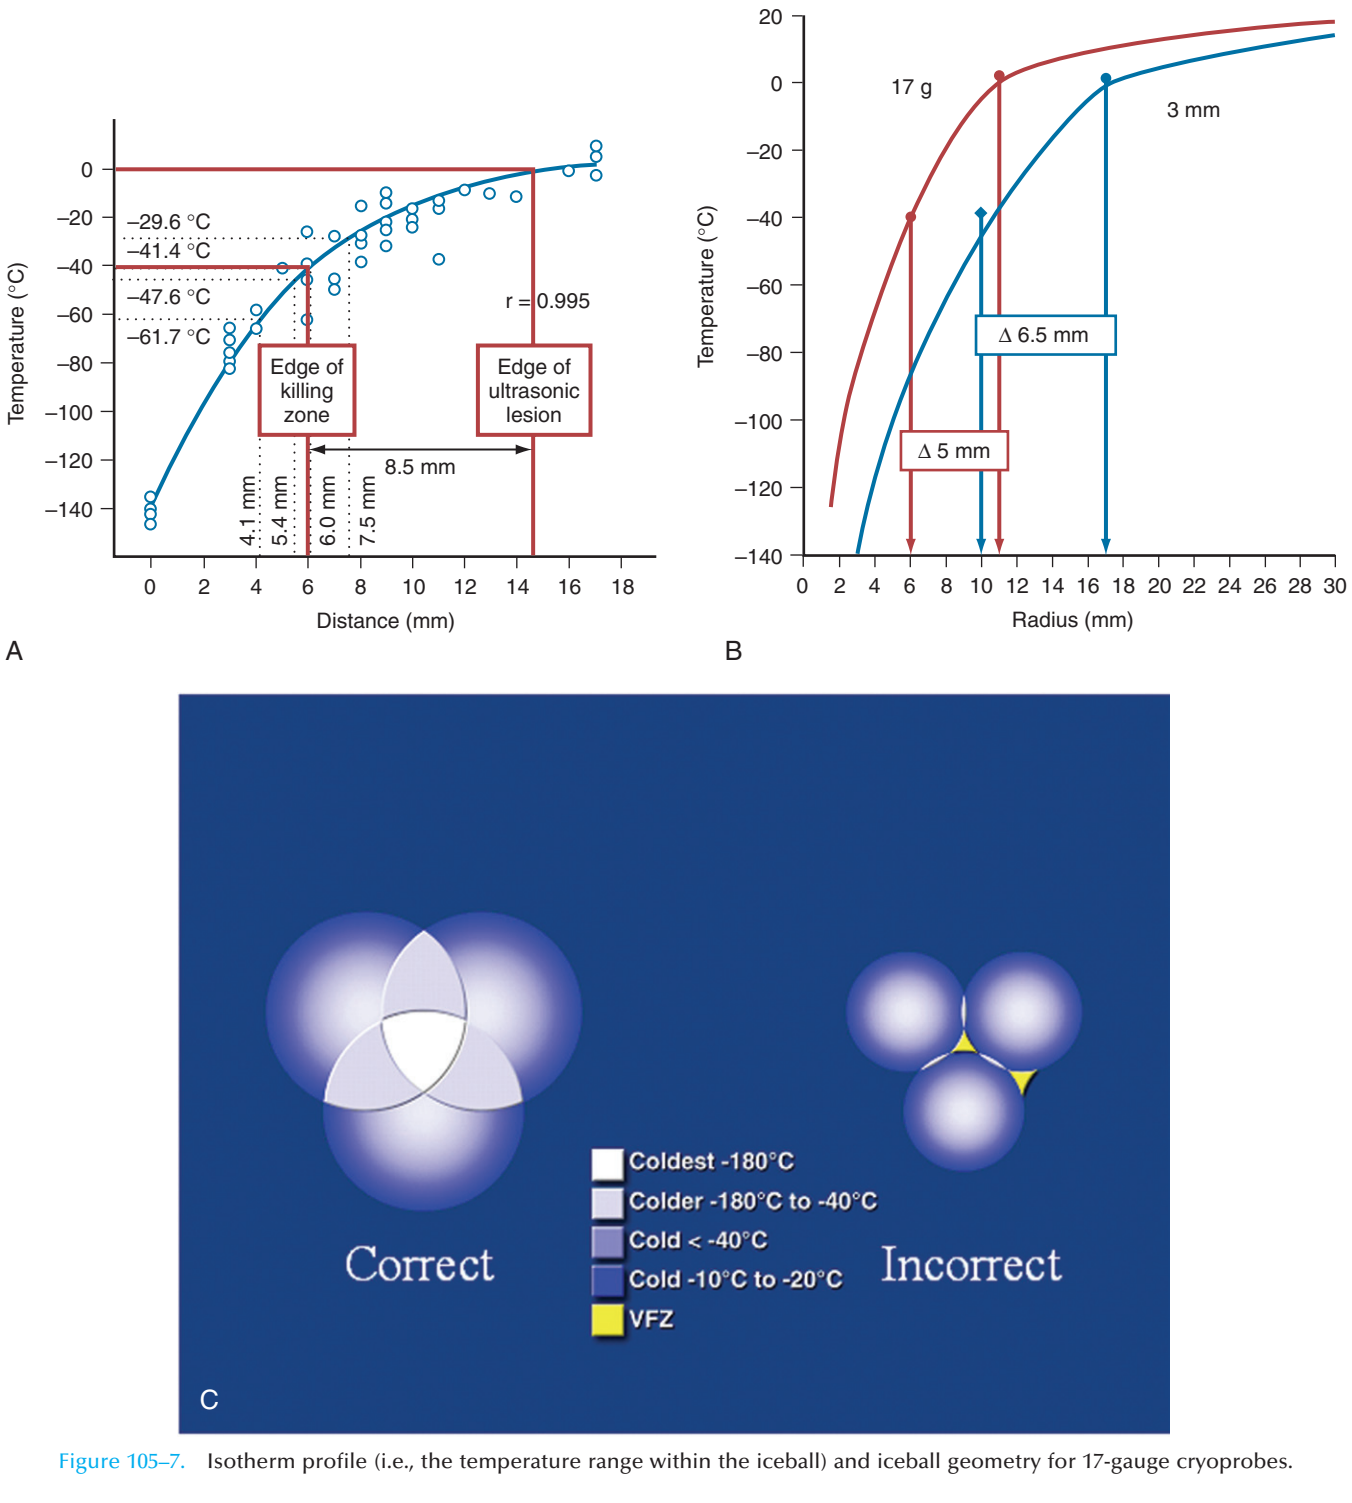

Figure 105–7. Isotherm profile (i.e., the temperature range within the iceball) and iceball geometry for 17-gauge cryoprobes.

techniques using the different cryogenic systems has been reported previously (Zisman et al, 2001; Ellis, 2002).

As described earlier, computerized treatment planning systems are now available. They incorporate serial transverse TRUS images of the prostate to render an individualized plan for optimal cryoprobe positioning (Babaian et al, 2008). However, there are currently no empiric data demonstrating that utilization of computerized treatment planning influences the safety and/or efficacy of cryosurgical ablation.

Thermocouple and Urethral Warmer Placement

Depending on the preference and experience of the surgeon, thermocouples may be placed in the mid gland, at the level of the external sphincter, at each NVB, and in Denonvilliers fascia. Thermocouples placed at the level of the external sphincter and in Denonvilliers fascia are used to minimize the risk of incontinence

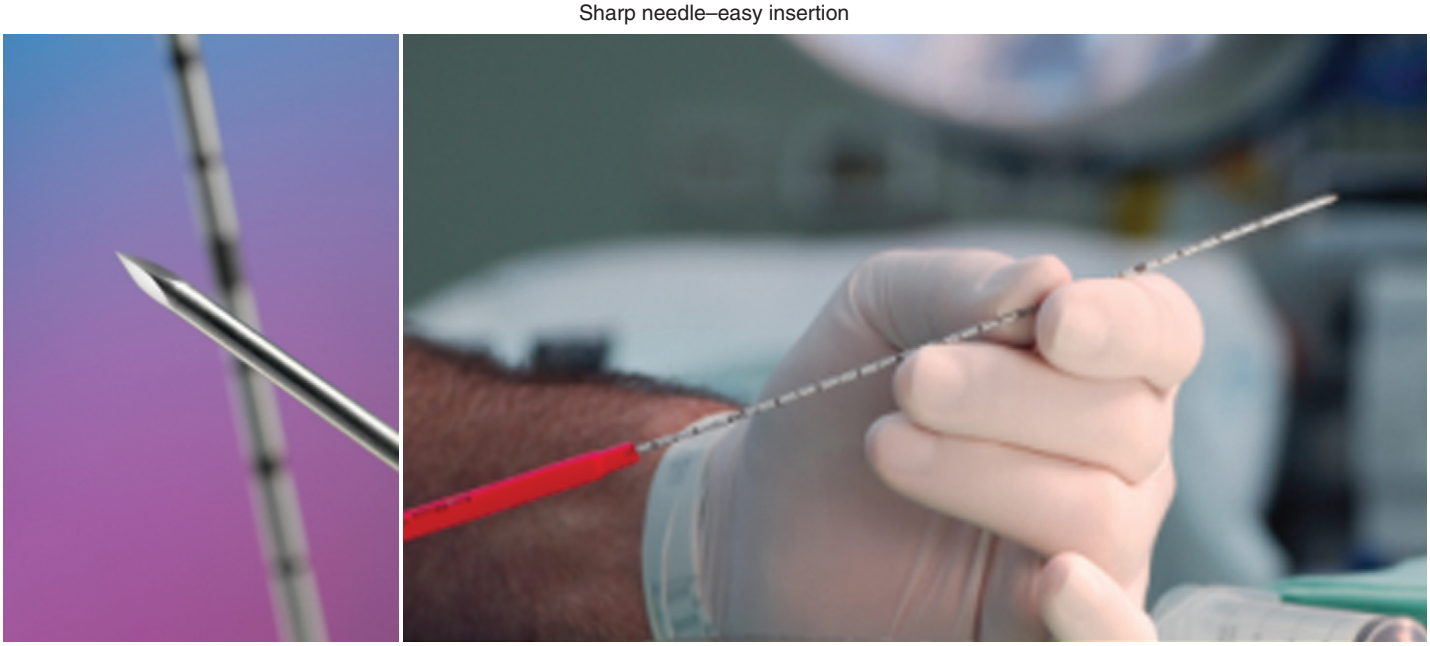

Figure 105–8. Currently available cryotherapy systems include sharp, small-diameter cryoneedles that allow direct transperineal placement using a brachytherapy-like template without the use of insertion or dilation kits.

and rectourethral fistula, respectively, whereas those in the mid gland and NVB ensure that the required temperature of –40° C is reached (Fig. 105–10). When possible, it is recommended that the temperature in the sphincter be maintained above 15° C. Some operators place a thermocouple in the distal apex to ensure adequate freezing at the apex and adequate coverage of the prostate. The use of newly introduced MultiThermal Sensor (MTS) needles, which enable four separate temperature readings from each sensor, has improved significantly the safety of cryosurgical ablation and decreased dramatically the risk of postablation fistulae (Fig. 105–11).

After all the needles have been positioned, the Foley catheter is gently removed. Any difficulty may indicate that a probe is wrongly positioned and potentially piercing the urethra. A meticulous 360-degree examination of the urethra is performed using a flexible cystoscope. If a misplaced probe is visualized in the urethra or a wall hematoma is detected, probe repositioning is indicated to avoid the detrimental outcome of direct urethral freezing or freezing the circulating urethral warmer fluid into a standstill position. The bladder is also inspected to ensure that no misplaced probes have pierced the bladder neck. Once the urethra and the bladder are found to be normal, some cryosurgeons proceed to place a soft 10- to 12-Fr suprapubic catheter under direct vision. On the other hand, some surgeons prefer to conclude the procedure with a 16-Fr Foley catheter left indwelling for a duration of 1 to 10 days. A 0.038-inch super-stiff guidewire is inserted through the working channel of the cystoscope, which is then withdrawn, and a heavily lubricated urethral warming catheter is introduced into the bladder over the guidewire and under sonographic guidance. During the procedure, the bladder is kept nearly full to prevent injury from the rigid tip of the warmer device.

Monitoring of Freezing Process

To maintain TRUS visibility, the freezing is started at the anterior probe layer and continued posteriorly. Using this technique, untreated areas may be visualized and a correcting maneuver may be used. Two freezing cycles are performed. Between the cycles, the prostate may be allowed to thaw passively (≈15 to 20 minutes) or actively (≈7 to 8 minutes) using helium. If the apex-to-base measurement of the prostate is greater than the length of the iceball that the cryoprobe produces, pull-back of the cryoprobes is performed to cover the inadequately treated portion of the gland and two additional freeze-thaw cycles are performed. To ensure adequate cancer treatment, the iceball is often allowed to extend 2 to 4 mm laterally into the periprostatic tissues, beyond the apex, and into the muscularis propria of the rectum posteriorly. In areas of extracapsular cancer extension, greater propagation of the iceball is permitted laterally and, if necessary, an additional cryoprobe may be placed in such areas. When seminal vesicle invasion is present, a cryoprobe may be placed deep into the invaded seminal vesicle. After completion of the last freeze cycle, the urethral warmer is left in place for up to 20 minutes to minimize the risk of urethral sloughing and subsequent urinary retention and irritative voiding symptoms. At this point, a full TRUS image of the prostate is regained and no iceball is seen. Cryoprobes are removed and pressure is applied to the perineum for 2 to 5 minutes. The urethral warmer is gently removed, and a Foley catheter is inserted afterward or, alternatively, the suprapubic catheter is opened if one was inserted before the procedure.

In patients undergoing salvage cryotherapy, previously placed radioactive seeds may cause some confusion because their sonographic appearance is similar to that of the tip of the cryoprobes. This can be overcome by using the sagittal view to assist in placing the cryoprobes. In this view, the length of the cryoprobes can be easily followed. Some degree of fibrosis may be encountered during placement in patients undergoing salvage cryotherapy. The gland may be adherent to the anterior rectal wall due to the previous radiation, diminishing the thickness of the Denonvilliers fascia. If the space between the anterior rectal wall and posterior prostatic capsule is less than 5 mm, it may not be possible to drive the temperature down to

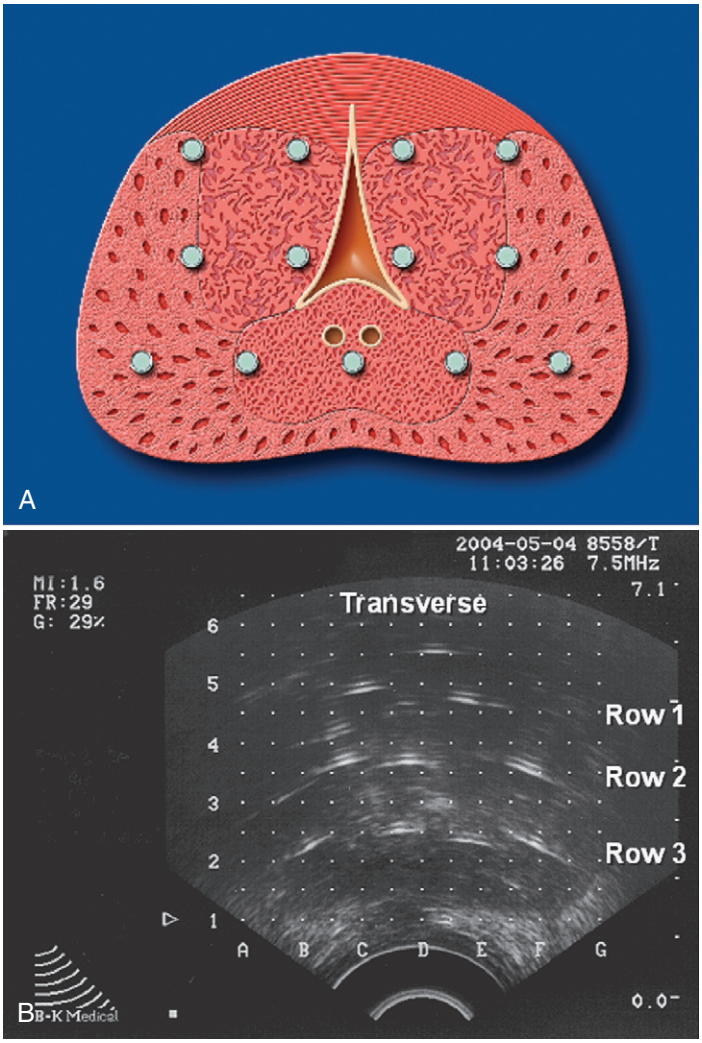

Figure 105–9. **A,** Tranverse template for placement of 17-gauge cryoprobes. **B,** Transverse ultrasound image showing placed cryoprobes in prostate.

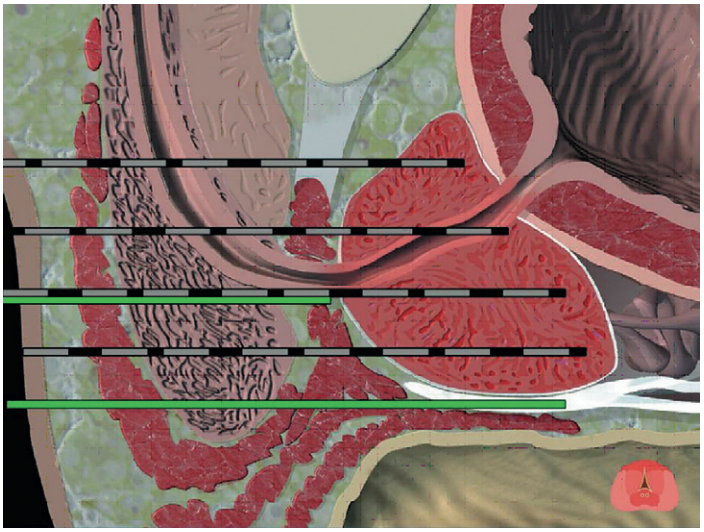

Figure 105–10. Sagittal view of placed cryoprobes *(gray)* and thermocouples *(green)* in prostate. Cryoprobes are placed in layers with the tip at the base of the prostate. Thermocouples are placed at the level of the external sphincter and in Denonvilliers fascia.

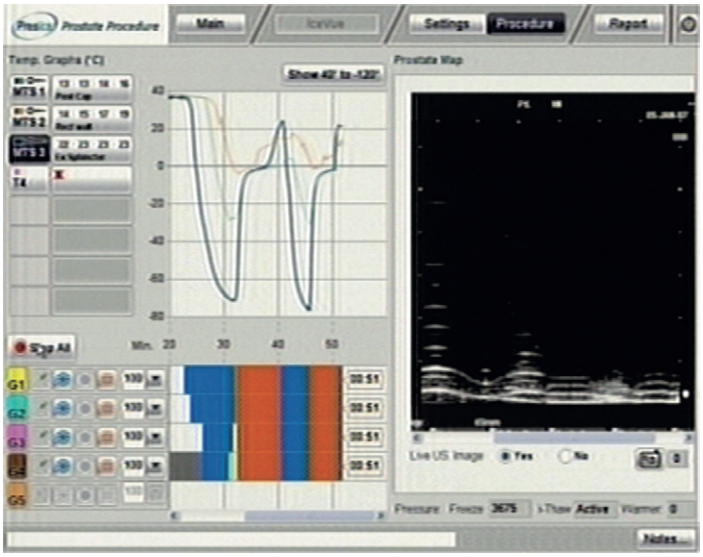

Figure 105–11. Newly introduced multipoint thermal sensors allow simultaneous intraoperative assessment of temperatures in multiple tissue planes (four separate temperature readings are provided from each needle). The availability of MTS needles has improved significantly the safety of cryosurgical ablation and decreased dramatically the risk of postablation rectal fistulae.

–40° C safely, and freezing should be terminated when the leading edge of the iceball has extended just beyond the capsule, even if the target temperature of –40° C is not reached. Injection of saline into the area of Denonvilliers fascia may help increase the distance between the prostate and anterior rectal wall provided the tissue is not too fibrotic to separate. Urologists learning to perform cryotherapy should be aware of these considerations and should maintain a heightened awareness of the potential increased risk of incontinence in previously irradiated patients.

Postoperative Care

Patients are discharged on the same day or on postoperative day 1 with antibiotics (usually a fluoroquinolone), oral analgesics, an α-adrenergic blocker (maintained for at least a month), and a Foley catheter to be removed in 2 to 10 days. If a suprapubic catheter was placed, it is kept open for 72 hours and then closed. The patient documents voiding frequency and volumes, and once normal voiding is regained the suprapubic catheter is removed.

PATIENT FOLLOW-UP

Patients are followed with clinical examinations and serial PSA measurements at 3-month intervals. After the first year, follow-up intervals can be increased to 6 months. Serum PSA levels after cryotherapy may not decrease to undetectable levels owing to the necessary preservation of a thin rim of periurethral prostatic tissue (Babaian et al, 2008). Immediately after the procedure, serum PSA levels rise to a high value due to release of intracellular PSA from cellular necrosis (Leibovici et al, 2005). The PSA nadir is usually achieved in 3 months (Wieder et al, 1995). In truth, however, the PSA nadir level that should be achieved after cryotherapy is not known with certainty, and nadir values have been achieved more than 3 months after cryotherapy. **There is no established definition of biochemical failure after cryotherapy. Investigators have often employed various static PSA cutoffs including 0.3, 0.4, 0.5, and 1 ng/mL** (Greene et al, 1998;

Koppie et al, 1999; Ghafar et al, 2001; Long et al, 2001; Bahn et al, 2002; Han et al, 2003; Chinn et al, 2004; Donnelly et al, 2005; Polascik et al, 2007). More recently, **American Society for Therapeutic Radiology and Oncology (ASTRO) definitions for biochemical failure have been leveraged by cryotherapy investigators including both the traditional ASTRO failure definition of three consecutive PSA rises after the post-treatment nadir and the more recent Phoenix (i.e., PSA nadir plus 2) definition for biochemical recurrence** (Long et al, 2001; Prepelica et al, 2005; Cohen et al, 2008). Given the uncertainty surrounding optimal definitions of biochemical failure following cryosurgical ablation, it is not surprising that establishment of a scientifically based definition for postcryotherapy PSA failure is a priority for clinical investigators working in this area (Jones et al, 2008). Finally, some surgeons perform a prostate biopsy after cryotherapy to assess local control. If biopsies are considered, however, they should not be performed until 6 months or longer after cryotherapy to allow for resolution of most of the acute inflammation.

OUTCOMES AFTER PRIMARY CRYOTHERAPY

Local Control

Prostate biopsy has been performed in patients 6 to 12 months after cryotherapy in several series. **The positive biopsy rate after cryotherapy ranges from 7.7% to 25%** (Shinohara et al, 1996; Connolly et al, 1997; Pisters et al, 1997; Wong et al, 1997). Ellis and colleagues (2007) reported that 17 of 168 (10.1%) men treated with third-generation cryosurgical technology had a positive biopsy at an average of 10 months postablation. In a series with longer-term follow-up, Cohen and colleagues (2008) reported a 10-year negative biopsy rate of 77%. The authors also observed that higher pretreatment PSA levels and clinical T stage were independently associated with an increased risk of positive postcryosurgical biopsy (Cohen et al, 2008). Among nearly 1200 cases included in the Cryo On-Line Data (COLD) Registry, 336 patients underwent post-treatment biopsy. For this group, the positive biopsy rate was 38% (49 of 129) for patients with a documented biochemical recurrence versus only 14.5% (30 of 207) with no clinical evidence for biochemical recurrence (Jones et al, 2008). In fact, data from the COLD Registry highlight the important caveat that rates of local control may vary substantially depending on whether biopsies are performed as part of standard follow-up (i.e., regardless of postcryotherapy PSA levels) or performed only "for cause" in those patients with a rising PSA following cryosurgical ablation. In most series in which surgeons routinely perform postcryotherapy biopsies, positive biopsies are generally reported in less than 10% of patients treated with a double-freeze thaw cycle procedure. As illustrated in the COLD Registry data, however, rates of positive biopsies tend to be higher in series where post-treatment biopsies are performed only "for cause" (Jones et al, 2008). Moreover, the likelihood of a positive biopsy is related to the post-treatment PSA kinetics, with residual cancer noted rarely among patients with a PSA nadir less than 0.5 ng/mL (Greene et al, 1998).

Finally, certain areas of the prostate and/or seminal vesicles have been reported to be more likely sites of treatment failure (Bahn et al, 1995; Shinohara et al, 1997). For instance, Shinohara and colleagues (1997) reported that recurrence was more common in cancers located at the apex (9.5%) and the seminal vesicles (43.8%), in contrast to those located in the mid gland (4.1%) and base (0%).

Biochemical Failure

Biochemical failure rates after primary cryosurgical ablation from several contemporary series are summarized in Table 105–4. Recently, investigators from the multicenter COLD Registry reported pooled biochemical control outcomes for 1198 patients treated with primary cryosurgical ablation at an international collection of academic and community medical centers (Jones et al, 2008). For this cohort, the 5-year actuarial biochemical (i.e., PSA recurrence) disease-free survival was 77.1% on the basis of the traditional ASTRO definition and 72.9% on the basis of the newer Phoenix definition. In risk-stratified analyses (using the D'Amico risk categories), 5-year biochemical disease-free survival rates based on the ASTRO criteria were 84.7% for patients in the low-risk group, 73.4% for moderate-risk patients, and 75.3% for patients in the high-risk group. Using the Phoenix (nadir plus 2) definition, corresponding 5-year biochemical disease-free survival rates were 91.1%, 78.5%, and 62.2% for low-, intermediate-, and high-risk groups, respectively (Jones et al, 2008).

Cohen and colleagues (2008) also recently reported long-term biochemical control outcomes among more than 200 patients treated with cryosurgical ablation of the prostate from 1991 through 1996. On the basis of the Phoenix definition, the authors reported 10-year PSA-recurrence-free survival rates of 80.6%, 74.2%, and 45.5% for low-, intermediate-, and high-risk groups, respectively. In multivariable analyses, the authors noted several variables significantly associated with postcryosurgery biochemical recurrence including patient age, pretreatment PSA, and the postcryosurgery PSA nadir (Cohen et al, 2008). Likewise, Shinohara and colleagues (1997) correlated the rate of biochemical and biopsy failure with the PSA nadir after cryotherapy in 132 patients. Biochemical failure was lowest in patients who achieved PSA nadirs less than 0.1 ng/mL (21%) but was common in those with higher nadir values. Biopsy failure was lowest in those with a PSA nadir less than 0.1 ng/mL (1.5%) and those with a nadir less than 0.4 ng/mL (10%). In contrast, 55% of patients with a PSA nadir greater than 0.5 ng/mL had a positive result at follow-up prostate biopsy. Biochemical and biopsy failure tended to occur within the first 12 months after treatment (96% and 88% of biochemical and biopsy failures, respectively).

In a separate multi-institutional collaborative based on 175 patients treated with third-generation technology at several institutions in the United States, Han and colleagues (2003) reported that 80 (73%) of 110 patients remained with a PSA of less than or equal to 0.4 ng/mL, whereas 42 (76%) of 65 low-risk patients (Gleason ≥ 6, PSA ≤ 10 ng/mL, ≤cT2) remained free from biochemical progression at 1 year (Han et al, 2003). For men with high-risk features (defined as a pretreatment PSA ≥ 10 ng/mL and/or a Gleason score ≥8), Prepelica and colleagues (2005) demonstrated 6-year biochemical disease-free rates of 81.7%, 50%, and 35% according to the ASTRO criteria, PSA less than 4 ng/mL, and PSA less than 1 ng/mL, respectively. **Taken together, results of recent series suggest that, depending on the definition of PSA failure, 5-year biochemical disease-free survival rates following primary cryosurgical ablation range from 60% to 90%, with more favorable cancer control outcomes reported for patients with low- and intermediate-risk cancers** (Koppie et al, 1999; De La Taille et al, 2000; Long et al, 2001; Bahn et al, 2002; Donnelly et al, 2002; Chinn et al, 2004; Prepelica et al, 2005; Ellis et al, 2007;

ASTRO, American Society for Therapeutic Radiology and Oncology.

Polascik et al, 2007; Cohen et al, 2008; Jones et al, 2008). To date, there are no long-term data available regarding metastasis-free or overall survival following cryosurgical ablation of the prostate (Babaian et al, 2008).

Comparison with Other Minimally Invasive Options

Primary cryotherapy has several potential advantages over other local therapies. **Cryotherapy can destroy a biologically heterogeneous population of cancer cells including cell populations that are resistant to radiation therapy and hormonal therapy.** Prostate cryotherapy can also be used to treat more extensive and aggressive tumors than brachytherapy. In particular, the **freezing process can extend beyond the capsule of the prostate, potentially eradicating extracapsular disease in patients with low-volume T3 cancers. Another advantage is that cryotherapy can be repeated with minimal morbidity. To date, however, there are actually little data that directly compare cancer control**

outcomes following cryosurgery versus other therapies for localized prostate cancer.

In 2001 Long and colleagues reported on a 5-year retrospective, multi-institutional pooled analysis of 975 patients who had cryotherapy and compared the results with those in recently published series of brachytherapy and EBRT. The 75 patients who had mainly second-generation cryotherapy had a 5-year biochemical freedom from recurrence of 76% when the PSA threshold was 1 ng/mL; these results were similar to those reported by the combined eight series that used EBRT or brachytherapy. The review also concluded that the 93% rate of impotence for cryotherapy was higher than the 37% to 70% (EBRT) and 10% to 40% (brachytherapy) rates reported by other investigators. Fistula rates were reported as 1% to 9%, 0% to 7%, and 0.5%, respectively, with incontinence rates of 0% to 13%, 0% to 5%, and 7.5%, respectively (Long et al, 2001).

Katz and Rewcastle (2003) also performed a retrospective comparative analysis on the basis of all studies of primary prostate cancer therapies (radical prostatectomy, cryotherapy, brachytherapy, 3DCRT, and EBRT) from 1992 to 2002. They reported rates of 5-year biochemical disease-free survival stratified by risk group. Although biochemical disease-free survival definitions varied across the studies, this analysis was intended only to evaluate trends for the different therapies. For low-risk disease, the 5-year biochemical disease-free survival rates for patients treated with radical prostatectomy, cryotherapy, brachytherapy, 3DCRT, and EBRT were 78% to 98%, 60% to 92%, 78% to 89%, 76% to 87%, and 81% to 86%, respectively (Katz and Rewcastle, 2003). Notably, the durable long-term results (>15-year follow-up) for radical prostatectomy reinforce its role as the gold-standard therapy for localized prostate cancer.

More uncertainty arises, however, in determining the optimal approach for patients with intermediate- and high-risk disease. In the retrospective observational comparison performed by Katz and Rewcastle, the 5-year biochemical disease-free survival rates for patients treated with radical prostatectomy, cryotherapy, brachytherapy, 3DCRT, and EBRT were 60% to 76%, 61% to 89%, 66% to 82%, 51% to 85%, and 26% to 60% for those with intermediate-risk disease and 30% to 61%, 36% to 89%, 0% to 65%, 21% to 43%, and 19% to 25% for those with high-risk disease, respectively (Katz and Rewcastle, 2003). Moreover, the positive biopsy rate after cryotherapy appears to be similar to, if not less than, those observed in series of patients with brachytherapy or EBRT (Babaian et al, 1995; Ljung et al, 1995; Stock et al, 1996; Laverdiere et al, 1997; Ragde et al, 1997, 1998; Crook and Bunting, 1998; Dinges et al, 1998). Taken together, these observational data suggest that cryotherapy may be equivalent to radiotherapy and surgery in terms of efficacy among patients with intermediate- and high-risk prostate cancer.

In contrast to these observational data, however, Chin and colleagues (2008) recently reported results from a small, randomized, controlled trial comparing cancer control outcomes following cryosurgical ablation versus external beam radiotherapy for patients with locally advanced, nonmetastatic prostate cancer. Specifically, patients with clinical stage T2c, T3a, or T3b tumors were randomized to receive 6 months of hormonal therapy along with either cryosurgical ablation or external beam radiotherapy. In terms of cancer control, 64% of patients in the cryosurgery group developed a biochemical recurrence (ASTRO definition) versus only 45% of patients in the external beam radiotherapy arm. Four-year actuarial biochemical disease-free survival also favored EBRT (47%) over cryosurgery (13%) in this group of patients. The investigators concluded that, despite flaws in the trial design and failure to accrue targeted numbers of patients, external beam radiotherapy provides better biochemical control than cryosurgical ablation for patients with locally advanced prostate cancer (Chin et al, 2008).

OUTCOMES AFTER SALVAGE CRYOTHERAPY

Prognostic Factors

Several clinical variables appear to influence the efficacy of salvage cryosurgical ablation. Pisters and colleagues (1999b) were among the first to identify clinical pretreatment factors associated with early treatment failure after salvage cryotherapy. From an analysis of 145 men who underwent salvage cryotherapy, those for whom initial radiation therapy was unsuccessful with a **PSA greater than 10 ng/mL and Gleason score of the recurrent cancer greater than or equal to 9 were unlikely to be successfully salvaged.** Izawa and colleagues (2002) analyzed 131 patients who had received definitive EBRT and subsequent salvage cryotherapy for locally recurrent prostate cancer. This group reported that androgen-independent local recurrences, Gleason score, and preradiation clinical stage were important determinants of disease-specific survival and disease-free survival. **In more contemporary studies, patients with a postradiation PSA greater than 10 ng/mL and/or a PSA doubling time of 16 months or less have been shown to be more likely to develop recurrent cancer following salvage cryosurgical ablation** (Spiess et al, 2006; Ng et al, 2007; Babaian et al, 2008).

Local Control

Estimates of the proportion of men with positive biopsies after salvage cryosurgical ablation are variable but generally range from 15% to 35% in contemporary series of patients treated for radiorecurrent disease (Ng et al, 2007; Pisters et al, 2008). For instance, among 279 salvage cases included in the COLD Registry, 15 of 46 (32.2%) patients who underwent postcryotherapy prostate biopsy were found to have residual cancer. Among those with documented biochemical recurrence, 8 of 15 (53.3%) had a positive biopsy. Ng and colleagues reported a lower positive biopsy rate (16.6%) among their series of 187 patients, most of whom were treated with third-generation cryosurgical technology. In terms of determinants of a positive biopsy after salvage cryosurgery, Izawa and colleagues (2001) reported that patients with initial clinical stage T1-2N0M0 disease and PSA less than 10 ng/mL have a higher rate of negative biopsies after salvage cryotherapy.

Biochemical Failure

The results from several recent salvage cryotherapy series, based on third-generation argon technology, are summarized in Table 105–5 (Han and Belldegrun, 2004; Donnelly et al, 2005; Ismail et al, 2007; Ng et al, 2007; Pisters et al, 2008). In the multicenter study using third-generation 17-gauge cryoprobes, 13 of 18 (72%) patients who had undergone salvage cryotherapy and were followed for at least 12 months remained with a PSA less than or equal to 0.4 ng/mL. Similarly, Katz (2004) reported on a 6-year experience with 67 men who underwent salvage cryotherapy. Multiple thermocouples were used, and all patients received 3 months of hormone deprivation before salvage cryotherapy. On the basis of a PSA cutoff value of more than 1 ng/mL, 72% of patients remained free of biochemical recurrence at 12 months.

Table 105–5.

Recent Salvage Cryotherapy Series: Biochemical Disease-Free Survival and Complications

Series, Year	Donnelly et al, 2005	Han et al, 2003	Ng et al, 2007	Ismail et al, 2007	Pisters et al, 2008
No. Patients	46	29	187	100	279

Impotence	46			86	69

*Median follow-up (range).
†37% with mild to moderate incontinence, 3% with severe incontinence.
LUTS, lower urinary tract symptoms.

More recently, Ismail and colleagues (2007) reported cancer control data for a cohort 100 patients treated with salvage cryosurgical ablation of the prostate between May 2000 and November 2005. With a median follow-up of 33.5 months, the authors observed biochemical recurrence-free survival (defined as PSA < 0.5 ng/mL) for 73%, 45%, and 11% of men with low-, intermediate- and high-risk cancers, respectively. The authors further noted significantly more favorable biochemical recurrence-free survival among those patients with a postablation PSA nadir less than or equal to 0.1 ng/mL (Ismail et al, 2007). Ng and colleagues reported intermediate biochemical failure outcomes among 187 treated with salvage cryosurgical ablation between March 1995 and September 2004. For this cohort, the authors noted that the preablation PSA level was a significant predictor of postsalvage treatment failure. Specifically, for patients with a presalvage PSA level less than or equal to 4 ng/ml, 5-year biochemical recurrence-free survival was 56% and 8-year biochemical recurrence-free survival was 37%. Conversely, for patients with a presalvage PSA greater than or equal to 10 ng/mL, biochemical recurrence-free survival rates were only 14% and 7% at 5 and 8 years, respectively (Ng et al, 2007). Finally, the COLD Registry collaborators reported biochemical cancer control outcomes among 279 patients treated with salvage cryosurgical ablation. The authors specifically observed 5-year biochemical recurrence-free survival rates of 59% and 55%, on the basis of ASTRO and Phoenix criteria, respectively (Pisters et al, 2008). Taken together, these data suggest that salvage cryosurgical ablation of the prostate is associated with biochemical control rates of 50% to 60% at 4 or more years after salvage therapy, with more favorable outcomes observed among patients with lower presalvage PSA levels and postsalvage PSA nadirs (Ismail et al, 2007; Ng et al, 2007; Pisters et al, 2008).

Comparison with Other Salvage Treatments

In addition to cryosurgical ablation, patients with documented local recurrences following initial radiation therapy may also be treated with salvage radical prostatectomy or salvage brachytherapy. Salvage radical prostatectomy has been the most commonly performed curative treatment for clinically localized prostate cancer after radiation therapy, although its use is distinctly uncommon among older men with radio-recurrent prostate cancer (Krupski et al, 2006). This procedure is capable of eradicating the local lesion and providing long-term disease-specific survival (Ward et al, 2005; Allen et al, 2007; Nguyen et al, 2007). Despite the potential for successful extirpation of the cancer, the surgical procedure is complicated by the tissue effects of radiation and is associated with significant side effects (Bianco et al, 2005; Ward et al, 2005; Allen et al, 2007; Nguyen et al, 2007). Radiation results in vascular occlusion with resulting tissue hypoxia, whereas alterations in basement membrane proteins lead to increased fibrosis. Anatomic planes between pelvic organs are often obliterated, with a poorly vascularized bladder and urethra available for surgical reconstruction. As such, there is an increased likelihood of postprostatectomy incontinence and impotence, as well as the possibility of rectal injury, which may necessitate fecal diversion (colostomy) (Bianco et al, 2005; Ward et al, 2005; Allen et al, 2007; Nguyen et al, 2007). Salvage brachytherapy has emerged more recently as a treatment option for men with local-only recurrence following primary external beam radiotherapy, although the total number of cases reported in the literature remains quite small (Allen et al, 2007; Nguyen et al, 2007).

In terms of comparative efficacy, cancer control and morbidity outcomes following salvage cryosurgery, salvage prostatectomy, and salvage brachytherapy have recently been meticulously reviewed by both Nguyen and colleagues (2007) and Allen and colleagues (2007). The authors concluded that because no prospective comparative trials are available, it is currently not possible to determine whether one treatment is superior with respect to biochemical recurrence-free survival or other cancer control outcomes. Generally speaking, 5-year biochemical recurrence-free survival rates following salvage radical prostatectomy (RP) range from 50% to 60% across the various case series reported in the literature (Allen et al, 2007; Nguyen et al, 2007), with perhaps slightly less favorable PSA control rates following salvage cryotherapy and brachytherapy. In a recent study that supports this conclusion, Pisters and colleagues (2009) reported their findings from a retrospective comparison of cancer control outcomes following salvage cryotherapy versus salvage RP among a cohort of patients with presalvage PSA less than 10 ng/mL, postradiation therapy biopsy Gleason score less than 8, and no prior exposure to hormonal therapy. Compared with salvage cryosurgery, salvage RP yielded superior outcomes on the basis of two separate definitions of biochemical failure (PSA > 0.4 ng/mL: salvage cryo 21% vs. salvage RP 61% at 5 years; 2 rises above PSA nadir: salvage cryo 42% vs. salvage RP 66%), as well as superior overall survival at 5 years (salvage cryo 85% vs. salvage RP 95%). Disease-specific

survival at 5 years did not differ by treatment group (salvage cryo 96% vs. salvage RP 98%). Even after adjustment for postradiation therapy biopsy Gleason score and presalvage treatment serum PSA level, salvage RP remained superior to salvage cryosurgery for the biochemical recurrence and overall survival end points. On the basis of these data, the authors concluded that young, healthy patients with recurrent prostate cancer after radiation therapy should consider salvage RP because it may offer superior progression-free survival (Pisters et al, 2009).

Irrespective of the salvage therapy, Nguyen and colleagues reported that the following clinical variables predict a greater likelihood of PSA recurrence-free survival: (1) low-risk tumor (i.e., clinical stage T1c or T2a, PSA < 10 ng/mL, and GS ≤ 6) at the time of original diagnosis; (2) PSA velocity before initial radiation therapy <2 ng/mL per year; (3) time to postradiation PSA failure >3 years; (4) postradiation PSA doubling time >12 months; and (5) negative bone scan and pelvic imaging (Nguyen et al, 2007).

In terms of morbidity, complications appear to be more common following salvage versus primary therapy for all three treatment modalities, with urinary incontinence, erectile dysfunction (ED), urethral/bladder neck stricture, and rectal injury/fistulae representing increasingly infrequent, but still significant, adverse outcomes (Allen et al, 2007; Nguyen et al, 2007; Babaian et al, 2008).

MANAGEMENT OF LOCAL RECURRENCE AFTER CRYOTHERAPY

Repeat Cryotherapy

Treatment options for patients in whom primary cryotherapy has failed are not well documented in the literature but commonly practiced by all users. Repeat cryoablation of the prostate is safe and can be effective for the properly selected candidates with truly localized disease. Bahn and colleagues (2002) reported repeat cryotherapy on 32 patients who had a positive biopsy result after primary cryotherapy. For these patients, biochemical recurrence-free survivals at 63 months after repeat freezing were 68%, 72%, and 91% using a definition of failure of 0.5 ng/mL, 1 ng/mL, and the ASTRO criteria, respectively. A more precise understanding of the efficacy of repeat cryotherapy will require further study in a larger number of patients.

Salvage Radiation Therapy

Although limited data exist, salvage radiation appears to be safe and potentially effective for patients with local recurrence after primary cryotherapy. McDonough and colleagues (2001) treated six patients with biopsy-proven local recurrence after primary cryotherapy with 66 Gy of EBRT. Sixty-six percent of patients were rendered disease free, and two patients developed biochemical failure as defined by ASTRO criteria. No patient developed distant metastasis at a median follow-up of 34 months. Complications included proctitis in two patients. Burton and colleagues (2000) reported outcomes of 49 patients treated with salvage 3DCRT for prostate cancer recurrence after primary cryotherapy. The initial three patients were treated to 50 Gy without severe toxicity. Six patients treated with dose escalation to 55 to 60 Gy did not encounter grade 3 or greater toxicity. Twenty patients were then initially treated to a dose range between 60 and 65 Gy, and another 20 patients then received a dose between 65 and 68.4 Gy. The investigators have since increased their typical total dose, with three patients receiving a dose of 70.2 Gy who were not included in this study because of limited follow-up, but none has experienced a significant increase in acute toxicity. As the total dose was increased, special effort was made to limit the dose to the rectum (as outlined earlier) to decrease the potential morbidity. The PSA nadir was less than 1 ng/mL in 42 patients, greater than 1 ng/mL in 5 patients, and stable in 2 patients. With a median follow-up time of 32 months (range: 12 to 85 months), the overall biochemical control rate was 61%. Only two patients developed subacute morbidity (proctitis and a urethral stricture), and all complications resolved with conservative measures. Additional prospective randomized studies are necessary to better assess the role of salvage radiation therapy in the treatment of these patients.

Salvage Prostatectomy

Grampsas and colleagues (1995) performed a salvage radical prostatectomy in six patients 3 to 10 months after unsuccessful prostate cryotherapy. They reported the presence of marked scarring and adhesions after cryotherapy but were able to avoid injury to the rectum, ureters, or other surrounding structures. The most significant postoperative complications were temporary incontinence and impotence. Future studies are necessary to define cancer control and complications of these various treatment modalities for PSA failure after cryotherapy.

ADJUNCTIVE THERAPY

One potential strategy for improving the efficacy of cryosurgical ablation is to identify adjuvant therapies that can optimize the freezing process in the border zone of the cryogenic region where tissue temperatures often exceed –20° C and therefore may not reach lethal values less than –40° C (Baust et al, 2007). Potential adjunctive therapies described in the literature include irradiation, cytotoxic chemotherapy, and even apoptotic and immunologic promoters (Baust et al, 2007). Each of these has been shown in various preclinical settings to potentially increase the efficacy of cryosurgical ablation (Baust et al, 2007).

For instance, in-vitro experiments have shown that cooled cells have a greater sensitivity to irradiation (Znati et al, 1998). Nevertheless, this has not yet been investigated in a clinical setting and it is unclear what the optimal timing would be for delivering radiation therapy in an adjuvant setting. Many cryotherapy treatments for various cancers already use adjuvant chemotherapy; however, the optimum time and dose for delivery of chemotherapeutic drugs remain uncertain. Drugs that are given during the period of tissue thawing remain concentrated in the frozen tissue for a longer time. Therefore the appropriate cytotoxic drug should probably be delivered systemically during the period of thawing and before the microcirculation fails, generally within approximately 1 hour of the last freeze cycle (Gonder et al, 1964; Gage and Baust, 1998; Hoffman and Bischof, 2002; Baust and Gage, 2005; Baust et al, 2007; Gage and Baust, 2007). An alternative technique may be instillation of the drug locally into the previously frozen tissue, possibly attached to an agent for slow release (Baust et al, 2004; Le Pivert et al, 2004). As adjunctive therapeutic agents, the role of immunologic enhancers should also be considered in future investigations (Baust et al, 2007). Many investigations have been directed at the nature of the immunologic response (Chao et al, 2004). **Despite their promise, however, no therapy has proven beneficial in an adjuvant setting with cryotherapy and none of these strategies is currently ready for clinical application.**

Table 105–6.
Complication Rates of Cryosurgical Ablation (Selected Series)

SERIES, YEAR	NO. PATIENTS	ED (%)	COMPLICATION RATES (%)		
			Fistula	Incontinence	Sloughing/TURP
Han et al, 2003	122	87	0	4.3	5.8
Ellis, 2007	416	49	0	4.0	
Polascik et al, 2007	50	50*	0	3.7	0
Jones et al, 2008	1198	92	0.4	4.8	2.1

*Among men potent preoperatively.
ED, erectile dysfunction; TURP, transurethral resection of the prostate.

COMPLICATIONS

Erectile Dysfunction

ED after cryotherapy of the prostate is common (Table 105–6). Although some series have reported rates ranging from 40% to 47% (Bahn et al, 1995), **more contemporary series report rates between 50% and 90%** (Long et al, 2001; Bahn et al, 2002; Han et al, 2003; Ellis et al, 2007; Polascik et al, 2007; Jones et al, 2008). The high incidence of ED following cryosurgery is likely due to the use of multiple freeze-thaw cycles and extension of the iceball beyond the prostate, into the areas adjacent to the neurovascular bundles. Although some authors have reported that up to 50% of patients regain erectile function 3 to 5 years after cryosurgical ablation (Donnelly et al, 2002; Ellis et al, 2007), the authors of this chapter do not routinely perform cryotherapy in patients interested in maintaining their potency. They currently believe that complete ablation of the NVB is necessary to ensure complete eradication of tissue at the periphery of the prostate gland. Early studies of subtotal and focal cryotherapy report potency rates in the range of 71% to 85%, although subtotal or focal cryoablation should be regarding as investigational until optimal patient selection is determined and long-term oncologic outcomes are available (Lambert et al, 2007; Onik et al, 2007).

Urinary Incontinence

The incidence of incontinence varies among series, probably owing to different definitions of incontinence, and variable use of an effective urethral warming catheter. Generally speaking, long-term urinary incontinence develops in approximately 1% to 10% of patients undergoing contemporary (i.e., third or fourth generation) cryosurgical ablation, with the higher end of this range seen mainly in series of patients undergoing salvage cryosurgery (Mouraviev and Polascik, 2006; Ellis et al, 2007; Ismail et al, 2007; Nguyen et al, 2007; Babaian et al, 2008; Jones et al, 2008; Pisters et al, 2008). The potential causes of postcryotherapy urinary incontinence include sphincter muscle destruction/scarring leading to intrinsic sphincter deficiency, disruption of the pudendal nerve, urethral sloughing, and possibly even detrusor factors such as detrusor instability or overflow incontinence. Prior TURP is an important risk factor for development of de-novo urinary incontinence among patients undergoing cryotherapy (Shinohara et al, 1996). As described previously, the major risk of salvage cryotherapy remains incontinence, although this risk is lower than with salvage radical prostatectomy (Nguyen et al, 2007). Historically, postsalvage cryotherapy urinary incontinence rates ranged from 0% to 83% (Miller et al, 1996; Cespedes et al, 1997; Pisters et al, 1997; Long et al, 2001; Han et al, 2003). More recently, however, the use of urethral warming catheters and an external sphincter thermocouple has decreased urinary incontinence rates to less than 10% to 15% in contemporary salvage cryosurgery series (Ghafar et al, 2001; Han and Belldegrun, 2004; Ismail et al, 2007; Ng et al, 2007; Pisters et al, 2008).

Complications Specific to Cryotherapy

Urethral Sloughing and/or Urethral Stricture

In earlier cryosurgery series, urethral tissue **sloughing occurred in 3.8% to 23% of cases** (Coogan and McKiel, 1995; Wieder et al, 1995; Cohen et al, 1996; Shinohara et al, 1996; Long et al, 1998; Han et al, 2003). With the current refinement of the freezing technique, however, symptomatic sloughing is a minor and infrequent event occurring in less than 5% to 15% of patients (Babaian et al, 2008; Jones et al, 2008). When present, treatment of urethral sloughing consists of antibiotics and adequate urinary drainage. Clean intermittent catheterization may lead to spontaneous tissue dislodgment and should be encouraged as an initial therapeutic maneuver. However, transurethral resection or removal of the necrotic tissue may be required if the condition persists. Urethral stricture is rare following cryotherapy if an effective urethral warming device is used. If extensive tissue sloughing occurs, however, strictures at the bladder neck or the middle of the prostatic urethra may develop and are best treated with either balloon dilation or transurethral incision. In rare cases, calcification of the stricture may also occur, necessitating transurethral resection. The authors cannot overemphasize that the use of an effective urethral warming catheter is essential to minimize the risk of tissue sloughing.

Pelvic and/or Rectal Pain

Pelvic, rectal, and/or perineal pain after the procedure is an event that occurs in anywhere from 0% to 50% of cases (Coogan and McKiel, 1995; Cohen et al, 1996; Shinohara et al, 1996; Long et al, 1998; Han et al, 2003; Ismail et al, 2007; Babaian et al, 2008; Pisters et al, 2008). This complaint has been reported to be more common in older series and especially in previously irradiated patients (Pisters et al, 1997; De La Taille et al, 2000). One explanatory factor for this symptom complex is that periosteum and bone may be frozen by anterior probes placed close to the symphysis pubis, which may lead to osteitis pubis. Seigne and colleagues (1996) reported that 4 (2.7%) of 147 patients undergoing postradiation salvage cryotherapy developed symptomatic osteitis pubis. Generally, such patients are best managed with anti-inflammatory agents, once a urinoma or abscess has been excluded by imaging. Han and colleagues (2003) reported that 3% of patients treated with cryotherapy developed transient

penile numbness, most likely **caused by damage to the dorsal nerve of the penis due to close proximity of the cryoprobe.** This complication generally resolves spontaneously.

Rectourethral Fistula

Rectourethral fistula formation has been reported to occur in 0% to 3% of patients treated with contemporary cryosurgical ablation of the prostate (Cox and Crawford, 1995; Izawa et al, 2000; Ghafar et al, 2001; Long et al, 2001; Han et al, 2003; Babaian et al, 2008; Jones et al, 2008; Pisters et al, 2008). This complication is distinctly more common among patients treated with salvage versus primary cryosurgical ablation (Mouriavev and Polascik, 2006; Babaian et al, 2008; Jones et al, 2008; Pisters et al, 2008). Importantly, however, given the high accuracy of modern-day TRUS combined with temperature monitoring at the anterior rectal wall, the incidence of this dreaded complication is near 0% in contemporary series (Mouriavev and Polascik, 2006; Babaian et al, 2008; Jones et al, 2008; Pisters et al, 2008). **Fistulae may present either early after the procedure or up to several months postoperatively. Watery diarrhea, pneumaturia, or fecaluria should alert the clinician to the possibility of fistula formation.** A voiding urethrogram or CT scan will confirm the diagnosis and location of the fistula. Conservative treatment with Foley catheter drainage is sometimes successful and should be tried initially in patients who underwent primary cryotherapy. Conservative measures are unlikely to be successful in patients treated with postradiation salvage cryotherapy. Early fecal and urinary diversion is an important component of fistula management in these patients. If the fistula tract matures and epithelializes, fulguration may facilitate spontaneous closure. Formal fistula repair should be delayed until the inflammatory process has resolved completely, usually in 4 to 6 months. **A transperineal, posterior, or anterior approach for closure is recommended** (Nyam and Pemberton, 1999; Izawa et al, 2000).

Other Complications

Penile and scrotal swelling, generally self-limited, may occur in the first several weeks after cryosurgical ablation (Babaian et al, 2008). In experienced hands, where the needles are accurately placed with minimal tissue damage, this complication is less common and occurs in less than 5% of patients. Hydronephrosis is a relatively uncommon complication that may manifest from extensive freezing of the bladder neck area or placement of a cryoprobe probe deep into the seminal vesicle leading to freezing of the ureteral orifices or distal ureters (Bales et al, 1995). Small bowel obstruction may occur if the iceball is allowed to extend into the cul-de-sac of the peritoneal cavity (Koppie et al, 1999). Distention of the bladder with normal saline during the procedure and placing patients in a Trendelenburg position if the cul-de-sac is anatomically low generally prevents this complication by moving the peritoneal contents away from the freezing process.

HEALTH-RELATED QUALITY OF LIFE

The importance of assessing health-related quality of life (HRQOL) in evaluating treatment outcomes for patients with prostate cancer is now well established. Moreover, such data are increasingly used by both patients and physicians during the treatment decision-making process. To date, there is a limited but growing literature describing generic and disease-specific HRQOL outcomes after primary or salvage cryosurgical ablation. In one of the first studies, Robinson and colleagues (1999) assessed 69 patients undergoing cryotherapy for localized prostate cancer. Patients were asked to complete the Functional Assessment of Cancer Treatment-Prostate (FACT-P) and the Sexuality Follow-up Questionnaire (SFQ) before treatment and again at 6 weeks and 3, 6, and 12 months afterward. For this cohort, FACT-P scores demonstrated a significant decrease from baseline at 6 weeks postoperatively. Subsequently, FACT-P scores demonstrated a progressive increase during the first postoperative year such that the 12-month FACT-P scores did not differ significantly from those reported at baseline. Conversely, the 12-month SFQ scores remained significantly below baseline, suggesting persistent decrement in sexual HRQOL. Emblematic of this concern is that only 1 of the 46 sexually active participants who were potent before treatment had recovered the ability to have erections sufficient for intercourse at 12 months (Robinson et al, 1999). In a follow-up publication, the authors reported 3-year HRQOL outcomes for the same patient cohort. In general, disease-specific HRQOL remained stable over the subsequent 2 years. Notably, at 3 years post-treatment, 13% of patients had regained erectile function, and an additional 34% of patients were sexually active with the help of aids. All other areas of functioning remained high, and no delayed-onset morbidity was associated with cryotherapy (Robinson et al, 2002).

Perrotte and colleagues (1999) evaluated HRQOL after salvage cryotherapy using a modification of the validated UCLA Prostate Cancer Index (PCI). In this study, treatment without an effective urethral warming catheter was highly associated with urinary incontinence, perineal pain, tissue sloughing, and AUA symptom score greater than 20. ED was higher in the double freeze-thaw cycle group (Perrotte et al, 1999). Importantly, however, this study was performed on patients who had undergone cryotherapy with older-generation technology. Anastasiadis and colleagues (2003) compared HRQOL among 81 patients who underwent primary or salvage cryotherapy. Primary cryotherapy patients fared significantly better regarding physical and social functioning. **The most prominent disease-specific HRQOL concern for both patient groups was sexual dysfunction, followed by urinary symptoms. The latter were significantly more severe in the salvage group.** Incontinence rates were 5.9% and 10% in the primary and salvage groups, respectively. Severe ED was reported in 86% and 90% of the primary and salvage groups, respectively.

Finally, Hubosky and colleagues (2007) recently provided one of the first reports of comprehensive disease-specific HRQOL outcomes for patients treated with third-generation cryosurgical ablation. The median follow-up for this 89-patient cohort was 11 months (range 1 to 32). The authors specifically used the UCLA PCI and American Urologic Association Symptom Index Score to prospectively measure HRQOL evolution following cryosurgical ablation and to compare postcryosurgical HRQOL to that observed for a contemporaneous series of patients treated with permanent interstitial brachytherapy. At 12 months post-therapy, the authors noted that patients treated with cryosurgery had largely returned to their baseline urinary and bowel function; however, both sexual function and bother remained significantly below reported levels of baseline function (Hubosky et al, 2007). Relative to patients treated with brachytherapy (who had better baseline sexual and urinary function), patients who underwent cryosurgical ablation reported less favorable sexual HRQOL during the first postoperative year. In contrast, urinary function was similar between the two groups until 18 months postoperatively, at which time urinary HRQOL became more favorable among cryosurgery patients. The more favorable urinary HRQOL among cryosurgery patients persisted until at least 24 months. On the basis of these data, the

authors concluded that, relative to patients treated with brachytherapy, patients undergoing primary cryosurgical ablation experience fewer irritative and obstructive voiding complaints with their consequent detrimental effects on urinary HRQOL. Moreover, urinary function among patients treated with cryosurgery may improve up to 24 months after treatment (Hubosky et al, 2007).

Taken together, existing studies have started to define the evolution of HRQOL following primary or salvage cryosurgical ablation. Nonetheless, there is much work to be done in this area before the postcryotherapy HRQOL roadmap is defined as precisely for cryotherapy as it is for radical prostatectomy, external beam radiation therapy, and permanent interstitial brachytherapy (Sanda et al, 2008).

COSTS OF CRYOTHERAPY

The cost of care is an increasingly important consideration in the delivery of health care services. Several studies have evaluated the cost of cryotherapy for prostate cancer (Miller et al, 1996; Benoit et al, 1998; Schmidt et al, 1998). Schmidt and colleagues (1998) estimated that the typical cryotherapy-related charges approximate $13,000 including all professional fees and hospital and technical components. This represented roughly half of the typical cost for radical prostatectomy or radiation therapy at their institution during the same time period (Schmidt et al, 1998). Benoit and colleagues (1998) reviewed the costs of 114 cryotherapy cases performed in the same period time as 67 radical prostatectomies. Average hospital costs, excluding physician fees, were significantly lower for cryotherapy ($4150) than for radical prostatectomy ($5660). Much of this difference was explained by the shorter hospital stay for patients undergoing cryoablation (1.1 days vs. 3.4 days for radical prostatectomy). Given the progressively shorter length of stay for patients undergoing RP, it is unknown whether these significant cost differences persist in 2011.

FUTURE DIRECTIONS

Nerve-Sparing Cryoablation

Nerve-sparing cryotherapy represents an attempt to protect a neurovascular bundle (NVB) during cryosurgical ablation by active warming or injection of antifreeze proteins. The feasibility of nerve-sparing cryotherapy by active warming of the NVB has been evaluated in a canine model (Janzen et al, 2005). Cryotherapy was performed using 17-gauge, gas-driven cryoprobes on nine prostate lobes from five dogs. Seven lobes were treated with active warming of the NVB, and two lobes were treated without active warming. All seven prostate lobes treated with active warming demonstrated complete or partial NVB preservation, but four prostate lobes demonstrated adjacent gland preservation (Fig. 105–12). All prostate lobes treated with a double freeze-thaw cycle demonstrated complete and uniform ablation of prostate tissue, whereas one of three prostate lobes treated with a single freeze-thaw cycle demonstrated incomplete ablation of the prostate tissue. Future studies include the feasibility of injecting antifreeze proteins (Jia and Davies, 2002) or saline to protect or separate the NVB. Although promising, the optimal clinical application of nerve-sparing cryosurgical ablation (in the absence of a planned subtotal or focal ablation) remains undetermined. Whereas these results are provocative and intriguing, the authors currently do not recommend nerve-sparing cryotherapy as a mainstream therapy given the current inability to determine accurately the aggressiveness, extent, and spatial distribution of cancer within the prostate.

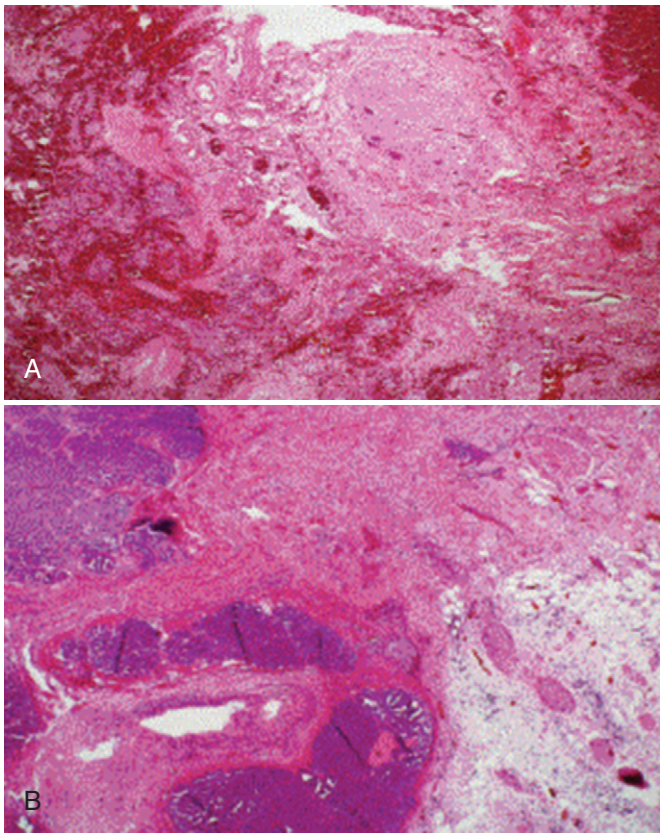

Figure 105–12. Preservation of the neurovascular bundle by active warming. **A,** Preserved nerve adjacent to hemorrhagic necrosis of the prostate. **B,** Presence of viable prostate glands immediately adjacent to a preserved neurovascular bundle.

Subtotal Cryoablation

There is general consensus that widespread early detection efforts have led to potential overdetection and overtreatment of early-stage prostate cancer (Cooperberg et al, 2004; Miller et al, 2006; Eggener et al, 2007). Because radical whole-gland therapy (and its consequent implications for urinary and sexual function) may be more than what is necessary for patients with lower-risk cancers, there is growing interest in the potential development and refinement of subtotal and focal therapies for men with prostate cancer (Eggener et al, 2007). **Subtotal cryotherapy is generally defined as an ablation of less than the entire prostate gland in an attempt to reduce cryotherapy morbidity by sparing one of the neurovascular bundles** (Ward et al, 2009). **Accordingly, the concept of subtotal cryotherapy encompasses both focal cryotherapy (in which just the region of the prostate harboring the index cancer is targeted) and more extensive ablations intended to treat half or even a majority of the prostate gland (i.e., 70% to 80%) while still preserving one NVB** (Fig. 105–13). An example of the latter treatment paradigm is the "hockey-stick" pattern of freezing described by Ward and colleagues (2009). **In general, it is important to recognize that there is as yet no standard treatment volume for patients undergoing subtotal cryosurgery and this critical issue will need to be addressed in future studies.**

Despite the interest in and rationale for subtotal and focal therapy(ies), prostate cancer poses a particular challenge for these techniques because it remains difficult to reliably define the

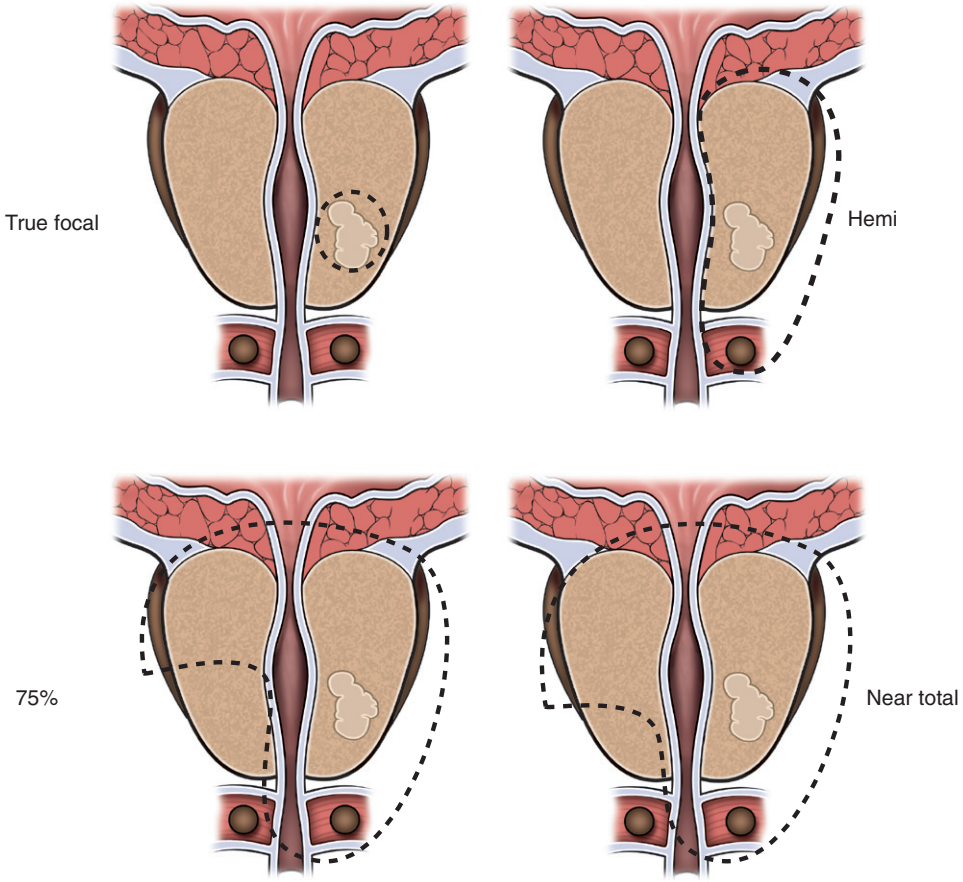

Figure 105–13. Patterns of ablation currently employed for subtotal and focal cryosurgical ablation of the prostate.

location or extent of the local tumor burden (Eggener et al, 2007). It has been shown that prostate cancers are usually multifocal and often include two to five tumor foci per gland (Miller and Cygan, 1994). However, stage migration resulting from widespread PSA screening has led some investigators to question the clinical significance of ancillary multifocal tumors and to ask whether it is possible to predict unifocal cancer, unilateral cancer, or clinically insignificant multifocal prostate cancer preoperatively (Eggener et al, 2007). Emblematic of the growing interest in potential focal therapies is the recent publication from the International Task Force on Prostate Cancer and the Focal Lesion Paradigm, which comprehensively explained the rationale for focal therapy for men with low-risk prostate cancer, potential concerns related to this approach, and recommendations for the further study of this treatment paradigm (Eggener et al, 2007).

An important rationale for focal prostate cancer therapy is that this approach may allow eradication of clinically important tumors while at the same time minimizing injury to adjacent vital structures including the urethra, external urinary sphincter, and neurovascular bundles. In theory, focal prostate cancer therapy could potentially provide excellent cancer treatment while minimizing downstream treatment-related consequences including, most importantly, ED and urinary incontinence. Subtotal or focal cryotherapy involves no manipulation and minimal vascular disruption of the spared NVBs and therefore a reasonable likelihood of preserving sexual function in patients who are potent at the time of ablation. In 2002 Onik and colleagues reported an initial pilot study of nine patients treated with focal, unilateral nerve-sparing cryotherapy. With this technique, they attempted to exploit the advantages of cryotherapy, particularly with respect to excellent treatment of potential extracapsular extension while minimizing the sexual function morbidity associated with whole-gland ablation. At a mean follow-up of 36 months, all nine men had stable PSA levels and the six patients who had post-treatment biopsies had no evidence for residual cancer in the ablation field (Onik et al, 2002). More recently, the authors reported longer-term follow-up on a larger cohort of patients treated with focal cryosurgical ablation between June 1995 and December 2005 (Onik et al, 2007; Onik et al, 2008). In this study the eligibility criteria for focal ablation included cancer confined to one lobe of the prostate and a desire to preserve both continence and potency. Among the 55 patients undergoing focal ablation, 52 (95%) had a stable PSA level at the time of most recent follow-up. The authors reported that the postcryosurgery PSA stabilization was at some fraction of the preoperative PSA level, depending on the extent of the gland ablation. The mean preoperative PSA level for this cohort was 8.3 ng/mL, whereas the mean postoperative PSA was 2.4 ng/mL. Among the four patients noted to have an "unstable" PSA level in the first year post treatment, prostate biopsy revealed that each patient harbored persistent cancer in an untreated portion of the gland. Among 51 patients with normal preoperative erections, 44 (85%) reported maintenance of erections following the focal ablative procedure (Onik et al, 2007). No patients developed de-novo urinary incontinence (Onik et al, 2007).

Lambert and colleagues (2007) reported their experience with subtotal cryosurgical ablation of the prostate among 25 patients with primary unilateral prostate cancer treated from June 2000 to December 2005. The median follow-up for this cohort of patients

was 28 months with a range of 9 to 72 months. In this study, each patient had unilateral, histologically proven prostate cancer meeting the following criteria: (1) Gleason score 6 or Gleason score 7 (3 + 4) prostate cancer that involved only a single lobe of the gland; (2) involvement of only 1 or 2 contiguous biopsy cores; and (3) tumor volume of less than 10% in a 12-core biopsy. The specific procedure involved hemigland ablation of the lobe harboring cancer. The NVB on the treated side was destroyed, while the contralateral NVB was spared. Depending on the definition employed, the authors reported a range of biochemical disease-free survival rates. For instance, using a PSA nadir of less than 1 ng/mL as the definition of biochemical failure, the authors reported 36% biochemical disease-free survival (median follow-up 28 months). Using PSA less than 2 ng/mL or less than 3 ng/mL as the definitions for biochemical control, the PSA recurrence-free survival rates were higher at 48% and 72%, respectively. When the authors applied more liberal definitions (e.g., PSA nadir > 50% lower than the pretreatment PSA level, Phoenix [nadir + 2]), they observed even more favorable biochemical recurrence-free survival outcomes (Lambert et al, 2007). Among seven patients who underwent post-treatment biopsy, three had recurrent cancer including one patient with tumor in the previously ablated lobe. In terms of morbidity, 71% of patients maintained potency and no patients developed postoperative urinary incontinence.

Finally, in a recent study, Eisenberg and Shinahara (2008) reported preliminary results with partial salvage cryoablation of the prostate among men with radio-recurrent prostate cancer. In this series, 19 patients with a unilateral focus of radio-recurrent prostate cancer were treated with hemigland ablation in the salvage setting. The authors reported biochemical recurrence-free survival rates (ASTRO definition) of 89%, 67%, and 50% at 1, 2, and 3 years, respectively. Using the Phoenix criteria, biochemical control rates were 89%, 79%, and 79% at 1, 2, and 3 years, respectively. At 1 year, 1 of 10 (10%) patients undergoing post-treatment biopsy harbored residual cancer. Reported complications in this series were rare and included one case of incontinence, one case of urethral stricture, and one case of urethral ulcer. The authors concluded that, in selected patients with a unilateral focus of radio-recurrent prostate cancer, acceptable oncologic results may be achieved with partial cryoablation of the prostate, while at the same time minimizing postcryotherapy morbidity.

Despite the promising and provocative data that continue to emerge for subtotal (including focal) cryoablation, overall clinical experience is limited and long-term results are largely unavailable (Babaian et al, 2008). Moreover, there is still no precise means to definitively identify histologically and/or biologically unifocal tumors (Eggener et al, 2007). At present therefore the authors believe that subtotal and focal cryotherapy should be considered only in the context of a clinical research protocol. Furthermore, **the authors agree strongly with recommendations from the AUA Best Practices Consensus Panel and the International Task Force on Prostate Cancer and the Focal Lesion Paradigm that the potential application of subtotal or focal cryotherapy be carefully investigated in prospective clinical trials** (Eggener et al, 2007; Babaian et al, 2008).

Technologic Advances for Cryosurgical Ablation

As with all treatments for clinically localized prostate cancer, cryotherapy is being refined. Clinical experience continues to grow, as does an understanding of cryobiology. Patient selection has been better defined, and complication rates have declined. The development of new imaging systems such as interventional MRI (Gilbert et al, 1997) and three-dimensional ultrasound units (Chin et al, 1998) may allow more effective freezing. The use of biologic modifiers such as antifreeze proteins at the time of the procedure is also being investigated and may improve the efficiency of the freezing process (Pham et al, 1999).

A modified technique of active rectal wall protection has been reported to permit deeper freezing of the peripheral zone of the prostate and for longer duration, rendering the procedure safer and more effective (Cytron et al, 2003). Two warming probes are placed in between the prostate and rectal wall to serve as active warming using the thawing mode when temperatures drop to approximately 0° C and as rectal lumen washing with warm water (40° C) when the temperature drops to –8° C to –10° C. This technique enabled a safe generation of an iceball at the peripheral zone of the prostate, which resulted in no rectal injuries and was effective in ablating the prostate gland.

Imaging techniques used in the definition of the extent of disease and in monitoring the process of tissue freezing have improved substantially over the years, and further advances are expected from CT and MRI in the next decade. Both CT and MRI are able to visualize the complete circumference of frozen tissue, as well as demonstrate its internal structure, potentially permitting continuous real-time monitoring of the complete three-dimensional progression of prostate freezing (Rubinsky et al, 1993). CT application is hindered by imaging artifacts created by metal cryoprobes, the physical restriction of the gantry, and the need for continuous radiation for real-time monitoring. CT also cannot directly determine the temperature of completely frozen tissue by objective assessment of tissue density or other parameters (Sandison et al, 1998). In addition to visualizing the entire frozen surface of tissue, magnetic resonance (MR) thermometry can potentially correlate measurable MR signal with the actual temperature of frozen tissue down to the critical level of about –40° C and could assist in objectively monitoring target tissue temperature within the iceball (Daniel et al, 1999; Wansapura et al, 2001). MRI is not ionizing and readily generates three-dimensional imaging. There are also evolving scanner designs that

Key Points: Cryotherapy for Prostate Cancer

- Fourth-generation cryotherapy includes TRUS guidance, pinpoint thermocouples, and the use of a brachytherapy-like template, with argon gas (freeze) and helium gas (thaw). The development of multipoint thermal sensors (MTS), which allow temperature monitoring along an entire tissue plane, marked the emergence of fourth-generation prostate cryosurgical technology.
- Two main mechanisms of cryotherapy-induced cytotoxicity exist: direct cellular toxicity (e.g., ice crystals disrupting cellular membrane) and vascular complications (thrombosis and ischemia).
- A minimum temperature of –40° C must be reached.
- At least two freeze-thaw cycles must be used.
- Long-term PSA follow-up is necessary before cryotherapy can be considered a minimally invasive first-line option, especially in younger men.
- Morbidity is minimal and decreasing with newer-generation technology and increasing cryosurgical experience.
- Subtotal and focal cryotherapy is under investigation.
- Salvage cryotherapy is associated with minimal morbidity and is an alternative to salvage radical prostatectomy.
- Cryotherapy may be repeated.

use a relatively "open" magnet that is easily applicable to intraoperative application. Even without thermometry, both MRI and CT lend themselves to computer integration with mathematic models that can generate real-time three-dimensional thermal maps of tissue freezing (Gilbert et al, 1997; Rewcastle et al, 1998; Jankun et al, 1999). These models can potentially integrate the visualized margin of freezing and a finite number of measurable temperature readings into a volumetric thermal model of frozen tissue. These interpolations could then be overlaid as graphical models on real-time images to create a virtual thermal map of the inside of a frozen prostate. Finally, electrical impedance tomography has also been proposed as a novel method for monitoring the iceball form during cryosurgical ablation (Baust et al, 2007). Although not yet ready for clinical application, this technology introduces low-amplitude AC currents into the body, allowing measurement of electrical potentials on the body surface. These potentials can then be recorded and analyzed to create tomographic images that monitor progression of the iceball (Baust et al, 2007).

chapter 106

High-Intensity Focused Ultrasound for the Treatment of Prostate Cancer

Michael O. Koch, MD

High-Intensity Focused Ultrasound Technology
General Clinical Use of High-Intensity Focused Ultrasound
High-Intensity Focused Ultrasound in Localized Prostate Cancer
Summary

Conventional treatments for localized prostate cancer have been consistently associated with untoward effects on patients' quality of life, primarily urinary incontinence and sexual dysfunction. Although quality of life outcomes have been shown to be minimized when treatment is performed by high-volume surgeons, even the most capable surgeons have significant rates of impotence and urinary incontinence (Begg et al, 2002). The significance of these side effects of therapy is further amplified by the frequently indolent nature of this disease, which may take more than a decade to progress. Thus while the severity of these side effects of therapy may pale in comparison with other cancer surgeries, their overall impact after adjusting for the remaining years of life affected is quite large. Thus there remains a need for therapies that reduce the side effects of prostate cancer therapy while maintaining efficacy.

The application of thermal-based therapies in the treatment of localized prostate cancer has the potential to eliminate many of the treatment-related side effects while maintaining efficacy. Two basic forms of thermal therapy have been developed: cryotherapy, which freezes tissue to destroy it, and HIFU (*H*igh-*I*ntensity *F*ocused *U*ltrasound), which uses focused sound energy to heat tissue to destroy it. HIFU is different from cryotherapy in that the focal zone is extremely discrete with little or no tissue effects in areas immediately adjacent to the treatment zone. In this chapter the author reviews the development of HIFU, the scientific basis for its use in prostate cancer, and the published trials in localized prostate cancer.

HIGH-INTENSITY FOCUSED ULTRASOUND TECHNOLOGY

HIFU uses high-energy ultrasound waves to destroy the tissue at the focal point of a transducer without injuring the intervening tissue. **Strong ultrasound waves in the inaudible sound range and approximately 10,000 times stronger than diagnostic ultrasound are generated by a transducer with a parabolic configuration** (Fig. 106–1). **This parabolic configuration focuses these sound waves into a discrete focal point measuring approximately 3 mm × 3 mm × 11 mm. This focal point is located 3 to 4 cm distant from the transducer, and its size and shape is dependent on the energy emitted by the transducer, the geometric configuration of the transducer, and the characteristics of the tissue. At the focal point of the transducer, ultrasound energy is concentrated, is absorbed by the tissue, and generates temperatures that can exceed 80° C, resulting in coagulative necrosis and the destruction of tissue.**

The procedure is performed by imaging the prostate in the coronal and sagittal planes with a transrectally placed stationary probe. This probe allows both imaging and treatment of the prostate. The treating physician outlines the areas to be treated in both planes (Fig. 106–2). This focal point is then sequentially moved through the tissue to be destroyed by a computer-driven system that moves the parabolic transducer sagittally and coronally until the entire selected area has been coagulated. Treatment of contiguous areas of the prostate consecutively would result in heat build-up within that area of the prostate and the conductive spread of heat and thermal injury of the tissue. Conductive spread of the heat energy would negate the anatomic precision of the treatment, and the primary advantage of HIFU technology is the precise nature of the coagulated treated foci. In order to prevent the conductive spread of thermal energy through the prostate, the computer-controlled transducer is moved throughout the treatment to noncontiguous areas to allow treated areas to cool down. Eventually, all areas are treated as the transducer moves back and forth. **Because of the lack of adjacent tissue damage, HIFU is a repeatable precise technology.**

HIFU results in coagulative necrosis of the treated tissue. In the case of complete prostate ablation with HIFU, the prostate gland retains its general anatomic configuration but shrinks to a small size (≈15 mL) over 3 to 6 months post therapy. Post-HIFU biopsies show fibrosis only.

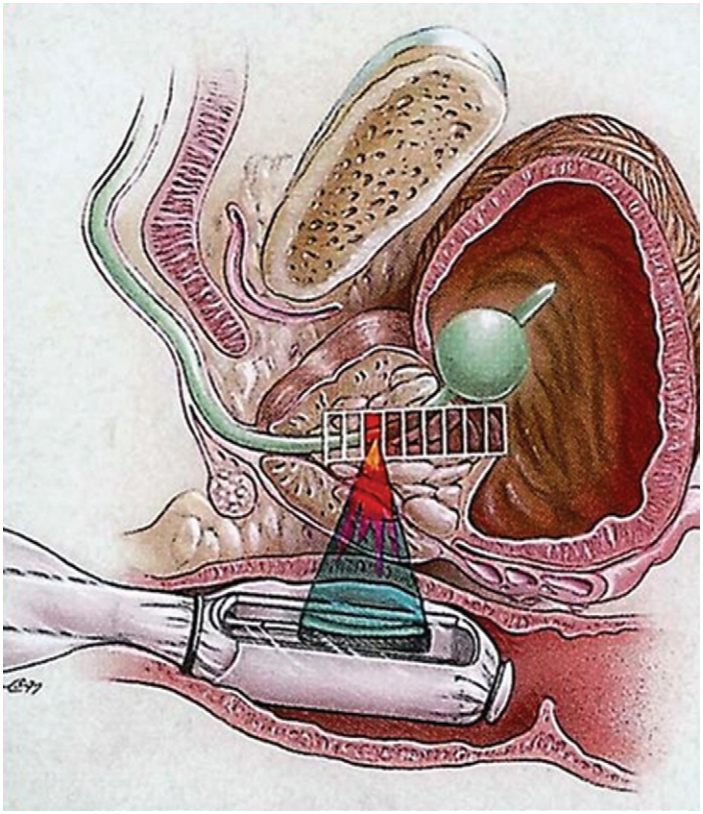

Figure 106–1. High-intensity focused ultrasound schematic shows parabolic dish concentrating sound waves remote from the transducer in a small focal point.

GENERAL CLINICAL USE OF HIGH-INTENSITY FOCUSED ULTRASOUND

This technique was initially investigated in both animals and humans in the 1940s and 1950s to destroy selective regions in the central nervous system (Fry et al, 1954; Fry and Johnson, 1978). It is now recognized that HIFU has the capability of transdermally or transmucosally coagulating and destroying tissue in a variety of conditions that have medical applications including spleen, liver, kidney, breast, uterus, and bone (Vaezy et al, 1997, 1999; Wu et al, 2001).

HIFU has been most well studied in the treatment of prostatic conditions. HIFU was initially tested in experiments in the canine prostate by Gelet and colleagues (1993), Bihrle and colleagues (1994a), and Kincaide and colleagues (1996). The use of the transrectal probe for the treatment of benign prostatic hypertrophy (BPH) in humans was first reported in the mid-1980s at Indiana University and by Madersbacher and colleagues in Vienna (Bihrle et al, 1994a; Madersbacher et al, 1994). HIFU was used to coagulate the periurethral area of the prostate in these series. The most common complication from the HIFU treatment was transient urinary retention, which occurred in 73% of patients. Two subsequent and larger studies have examined the efficacy and safety of the use of HIFU for the treatment of symptomatic BPH (Nakamura et al, 1997; Madersbacher et al, 2000). HIFU has not been widely used for the treatment of symptomatic BPH because of its relatively invasive nature in comparison to other thermal-based modalities such as microwave and radiofrequency ablation. Currently, HIFU does not have U.S. Food and Drug Administration (FDA) approval for the treatment of BPH in the United States. HIFU currently has FDA approval for the treatment of uterine fibroids in the United States.

Two companies are currently producing HIFU devices for the treatment of the prostate. The Ablatherm is produced by EDAP TMS (Lyons, France), and the Sonoblate-500 is produced by Focus Surgery (Indianapolis, IN).

HIGH-INTENSITY FOCUSED ULTRASOUND IN LOCALIZED PROSTATE CANCER

Madersbacher and colleagues (1995) were the first to examine the feasibility of HIFU for the treatment of localized prostate cancer. These investigators treated 29 patients with HIFU therapy immediately before radical prostatectomy using a predecessor of the currently used Sonoblate-500 device. They demonstrated that HIFU resulted in a sharply demarcated lesion with no treatment effects in areas immediately adjacent to the treatment zone. Two of these patients had sharply demarcated cancerous lesions on ultrasound and had this area targeted with HIFU (i.e., partial prostatic treatment). In these patients, no heat damage was noted to the rectum or neurovascular bundle even though HIFU was extended to the prostatic capsule (Fig. 106–3). Beerlage and colleagues (1999) subsequently confirmed these findings using the EDAP device.

HIFU is generally performed under general or regional anesthesia. A high-frequency transducer probe placed in a balloon filled with liquid, either cooled or room temperature, is inserted into the rectum to both serve as an acoustical interface and to cool the rectal wall. There are two transducers on these devices, low-energy transducers (3 to 4 MHz) for imaging and high-energy transducers for treatment. The prostate is imaged in both the sagittal and coronal planes, and the target treatment zone is outlined. With both systems, there is a treatment cycle in which the treatment zone is heated and then a cooling period during which the computer-controlled device moves to the next treatment zone distant from the first. Significant differences in these two devices do exist in terms of prostate imaging, geometric configuration of the treatment zone, tissue penetration, and safeguards. These devices are continually being modified to improve treatment ease, efficacy, and safety.

Gelet and colleagues (1996, 2000) reported on the use of the Ablatherm device in 82 patients with stage T1-2 prostate cancer and subsequently presented comprehensive outcome data in 2000 (Table 106–1). In the latter report, patients with stage T1-2 disease with prostate-specific antigen (PSA) less than 20 ng/mL were considered appropriate candidates for treatment with total prostatic ablation. Forty-six percent were stage T1, 49% were stage T2, and 5% were local failures after definitive external radiotherapy. Neoadjuvant hormonal therapy was administered in 9% of patients. Forty-one percent, 39%, 11%, 7%, and 1% of patients were treated with 1, 2, 3, 4, and 5 HIFU sessions, respectively.

Seventy-eight percent had negative sextant biopsies at 3 and 12 months. Fifty-six percent of patients had a PSA nadir of less than 1 ng/mL. Forty-two patients (51%) had both negative biopsies and a PSA nadir less than 1 ng/mL. Actuarial analysis was also performed on low-risk (PSA < 10 and Gleason < 7) and moderate-risk patients (PSA < 15 and Gleason < 8), and disease-free survival as defined by a PSA less than 1 ng/mL and negative sextant biopsies were 83% and 68% at 5 years, respectively. Mean follow-up for the overall series of patients was 17.6 months (range 3 to 68.5 months).

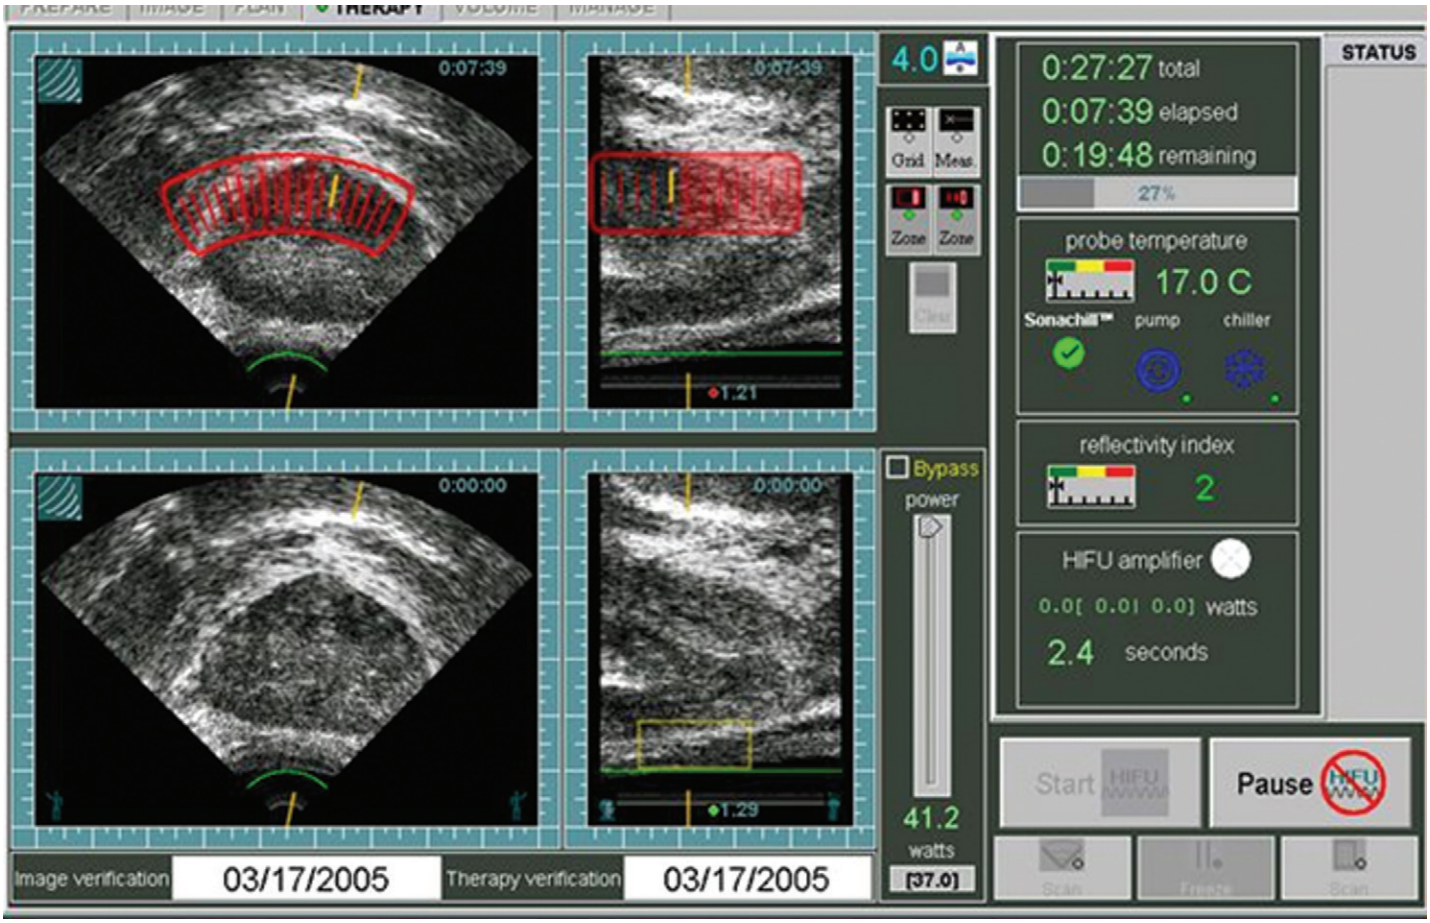

Figure 106–2. Treatment console of the Sonoblate-500 device. The two ultrasound images to the left are the coronal images, and the two images to the right are the sagittal images. The images on the upper part of the screen are the planned treatment area before high-intensity focused ultrasound treatment, and the two images at the bottom are live images during therapy. The right side of the screen reflects the treatment settings and ongoing measurements of rectal wall changes and machine settings.

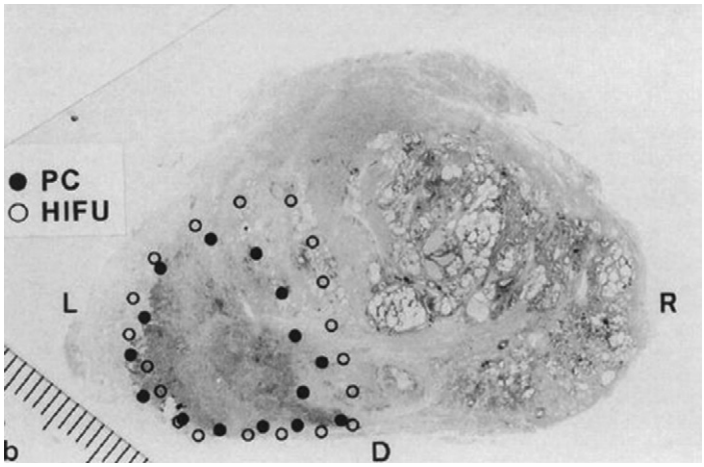

Figure 106–3. This whole mount section of the prostate was from a patient who underwent radical prostatectomy immediately after high-intensity focused ultrasound treatment of the left side of the prostate. Complete coagulative necrosis is noted in the treatment zone with no histologic evidence of tissue injury in areas immediately adjacent to the treatment zone. (From Madersbacher S, Pedevilla M, Vingers L, et al. Effect of high-intensity focused ultrasound on human prostate cancer in vivo. Cancer Res 1995;55:3346–51.)

Mean postoperative catheterization time was 8.5 days. Mean time to PSA nadir was 5 months.

A multi-institutional report on the results of the Ablatherm device was reported in 2003 (Thüroff et al, 2003). This report describes the results of HIFU treatment in 402 patients treated across six sites in Europe. This was a noncontrolled clinical trial in patients considered unsuitable candidates for radical prostatectomy. Thirty-five patients (9%) had undergone previous radiation therapy, and 104 patients (26%) were being treated with some form of hormonal therapy. Patients were stratified into low-, intermediate-, and high-risk groups for efficacy analysis. Efficacy was assessed by sextant biopsy of the prostate and serum PSA.

There were an average number of treatments of 1.47 treatments per patient with 28% of patients requiring two treatment sessions. Post HIFU, 288 patients underwent sextant biopsy and 87% had a negative biopsy; 92%, 86%, and 82% in the low-, intermediate-, and high-risk groups, respectively. Mean nadir PSA in the low-, intermediate-, and high-risk groups was 1.3 ng/mL, 1.4 ng/mL, and 3.1 ng/mL, respectively. Larger prostate volumes were predictive of failure by both biopsy and PSA. Transient urinary retention was the most common complication occurring in all patients and lasting for a median of 5 days (Table 106–2). Prolonged retention was reported in 9% of patients. Although one might predict a high degree of urethral strictures and bladder neck contractures with complete urethral treatment, these were seen in only 3.6% of patients. The most serious complication of this technology was

the development of urethrorectal fistulas, which occurred in five patients (1.2%) before the use of the rectal cooling device. Mild to moderate stress incontinence developed in 11% and 3% of patients, respectively, whereas severe incontinence requiring intervention developed in 1.5% of patients. Finally, impotence was reported in only 35 patients (9%).

The Sonoblate devices have been most extensively studied in Japan. Uchida and colleagues (2002) are the only investigators to report an experience with the Sonoblate-200 device for the treatment of localized prostate cancer. The Sonoblate-200 device uses a 4-MHz power generator, which has different tissue characteristics than the Ablatherm and employs a rectal cooling device. In the initial report, 20 patients were treated with 28 treatments (1.4 treatments per patient). Patients all had localized disease, the average PSA was 9.65 ng/mL, and all had Gleason score 7 or less disease. Four patients (20%) received pretreatment hormonal therapy, and none received post-treatment hormonal therapy. A PSA nadir of less than 0.5 ng/mL, 0.5 to 1 ng/mL, and 1.01 to 2 ng/mL was achieved in 65%, 25%, and 10% of patients, respectively. This same center subsequently published overall 5-year biochemical disease-free rates of 67% (Uchida, 2005). Patients with preoperative PSA less than 10 ng/mL demonstrated 5-year disease-free survivals of 88%.

Contemporary Series

The Sonoblate-500 device has just recently completed the first successful U.S.-based trial on the use of HIFU for the treatment of localized prostate cancer at Indiana University. This trial was structured as a feasibility trial to demonstrate the safety and, to a lesser degree, the efficacy of this technology before petitioning the FDA to allow Focus Surgery to conduct a multi-institutional pivotal trial to examine the true efficacy of this technology. Twenty patients with early-stage prostate cancer (T1-2, ≤Gleason score of 7, and PSA ≤ 10 ng/mL) were treated with this device. Follow-up included a mandatory extended field biopsy (minimum 10 cores) at 6 months post treatment. Success defined as a negative extended field biopsy at 12 months and a PSA nadir less than 1 ng/mL were achieved in 58% of patients overall and in 65% of patients that underwent retreatment when indicated. Transient urinary retention occurred in all patients, and a single patient developed a rectourethral fistula that healed with temporary fecal diversion. One patient developed mild stress incontinence, and potency was not well evaluated. Follow-up beyond 6 months was not reported.

Two series report moderately long-term results with HIFU for localized prostate cancer. Blana and colleagues (2007) reported on a multi-institutional group of patients treated from 1997 through

2001 with early prototypes of the Ablatherm device. This series included 140 patients with moderate- to low-risk prostate cancer; cT1-cT2, PSA less than 15 ng/mL, and Gleason score of 7 or less. Efficacy was based on a prostate biopsy, and the researchers used the ASTRO Phoenix criteria (PSA nadir + rise of 2 ng/mL). Twenty-three patients (16%) received some period of androgen blockade around the time of therapy. In this population of patients, a PSA nadir of less than or equal to 0.5 ng/mL was achieved in 68% of patients and actuarial biochemical-free survival was reported as 77% and 69% at 5 and 7 years, respectively. Biopsies (minimum of six cores) were done on patients between 3 and 6 months post treatment and were negative in 86% of patients. The average follow-up in this series was 6.4 years. Uchida and colleagues (2006a) reported on a 5-year experience with 181 consecutive patients treated with the Sonoblate-500 device. The median follow-up in this series of patients was only 18 months, and in this series 52% of patients were treated with neoadjuvant androgen ablation. Biochemical disease-free survivals using the ASTRO consensus panel criteria were 84%, 80%, and 78% at 1, 3, and 5 years, respectively.

High-Intensity Ultrasound after Radiation Failure

Both HIFU devices have also been tested for use as salvage therapy after radiation failure. Murat and colleagues (2009) reported on the use of HIFU for the treatment of 167 patients after failure of external beam radiotherapy. Ninety-five patients were on androgen ablation therapy before HIFU, but none were continued on it after treatment. Sextant biopsies at 3 months were negative in 73% of patients, and the median PSA nadir was 0.21 ng/mL. Although this follow-up is quite short, 63% of these patients did have Gleason score 7 or higher disease and a median of three positive biopsies cores preoperatively. Although technical modifications over time did reduce treatment-related side effects, 31.5% experienced grade 2 to 3 incontinence, bladder neck stenosis occurred in 15% to 30%, and five patients (3%) developed urethrorectal fistulae.

Zacharakis and colleagues (2008) examined the use of the Sonoblate-500 device in 31 men with recurrent prostate cancer after external beam radiation therapy. Mean follow-up was only 7.4 months. Half of these men achieved a PSA nadir of less than 0.2 ng/mL. Unfortunately again, side effects were common with 36% developing obstruction from urethral sloughing or stricture, 7% developing urinary incontinence, and 6% developing urethrorectal fistulas.

High-Intensity Focused Ultrasound End Points

The accurate assessment and understanding of the efficacy of any technology is highly dependent on the selection of appropriate end points, particularly in the case of prostate cancer where mortality of the disease in the short term is low and alternate end points such as PSA criteria are used. Ganzer and colleagues (2008) examined the use of PSA nadir in predicting ultimate treatment efficacy after HIFU in 103 patients who underwent HIFU at two different centers for the treatment for localized prostate cancer (Ganzer et al, 2008). Treatment failure was defined as PSA nadir + 2 ng/dL, a positive biopsy, or the use of salvage therapy. A PSA nadir of less than or equal 0.2 ng/mL, 0.21 to 1 ng/mL, and greater than 1 ng/mL occurred in 64%, 22%, and 14% of patients, respectively. Failures occurred in 4.5%, 30%, and 100% of these three groups, respectively. Because the median follow-up in this series was only 4.9 years, these failure rates are best-case scenarios with HIFU treatment. Uchida and coworkers reported similar findings with the Sonoblate-500 device (Uchida et al, 2006b). In this series, patients with a PSA nadir of 0.0 to 0.2 ng/mL had an 11% chance of having a positive post-treatment biopsy at 6 months, whereas patients with PSA nadirs of 0.21 to 1 ng/mL and greater than 1 ng/mL had positive biopsy rates of 46% and 48%, respectively. Again, because of the false-positive rates of prostate biopsies and the lack of biopsies at longer follow-up, these figures paint the most optimistic picture of HIFU therapy.

Most series of HIFU therapy for prostate cancer have included some form of prostate biopsy ranging from 4 to 10 cores. Prostate glands do shrink considerably after HIFU therapy, lessening the likelihood of a false-negative biopsy. Nevertheless, that problem still exists and as in the Uchida publication mentioned earlier, most series have not included biopsies after 6 to 12 months.

The most current studies on the use of HIFU are highly flawed by the use of inappropriate PSA end points to assess efficacy. The original ASTRO consensus panel recommendations were that treatment failure *after external beam radiotherapy* should be defined as two consecutive rises in the PSA after the occurrence of the PSA nadir. It specifically stated that this criterion for failure was not appropriate for other forms of radiation, for radiation combined with hormonal therapy, or for cryotherapy (and therefore other thermal-based approaches). In order to improve on this definition and enable radiation oncologists to compare one form of radiation therapy to another and account for the common use of hormonal therapy in these patients, a second consensus panel was formed and reported a new recommendation in 2006. Their consensus was that biochemical failure after radiation be defined as a rise of 2 ng/mL after nadir occurred, the so-called Phoenix criteria (Roach et al, 2006). They specifically addressed the issue of whether the Phoenix criteria were to be interpreted as indicative of cure and chose instead a criteria that predicted likely morbidity from prostate cancer rather eradication of all disease (i.e., treatment success by the Phoenix criteria are not to be considered synonymous with cure). **Moreover, they expressly state that because of the prolonged period of time necessary to demonstrate failure by these criteria, the results of prostate cancer treatment by Phoenix criteria should never be reported more than 2 years less than the median follow-up and that the Phoenix criteria were again inappropriate for thermal-based therapies for prostate cancer.** Unfortunately, these specifics have been overlooked by proponents of HIFU for prostate cancer who report efficacy results that are inappropriately long and scientifically invalid.

Treatment of High-Intensity Focused Ultrasound Failures

Despite the failings of the HIFU trials published thus far, HIFU remains unique compared with other modalities for localized prostate cancer in that it results in much less adjacent tissue damage. This makes it a repeatable technology and thus potentially more salvageable by other techniques when it fails. Stolzenburg and coworkers (2007) reported a series of nine patients who successfully underwent laparoscopic salvage prostatectomy, three of whom were after HIFU failure and the other six of whom were after external beam radiotherapy. Results were generally favorable

and felt to be comparable in the two groups. Pasticier and colleagues (2008) reported a larger group of 45 patients who had local failure after HIFU and were treated either with external beam monotherapy (32 patients) or external beam radiotherapy in combination with androgen ablation (Pasticier et al, 2008). The median total prescribed radiation dose to the prostate in this series was 71 Gy. These investigators noted no additional toxicity compared with patients undergoing primary external beam radiotherapy for prostate cancer. No rectal fistulae occurred, and only 15% of patients experienced new grade 2 urinary incontinence. Oncologic efficacy was not well evaluated in this study.

SUMMARY

It seems clear at this point that HIFU treatment of prostate cancer has the potential to completely eradicate the prostate gland and therefore prostate cancer in some patients. Technical modifications continue to improve the ability to use these modalities effectively and with ever-decreasing morbidity from damage to adjacent structures. These treatments offer potential major advantages over surgical and radiation-based treatment modalities in terms of its lack of invasiveness and its repeatability. However, the available published trials have been severely limited by the concomitant use of hormonal therapy and transurethral prostatectomy, inadequate sampling of the prostate, the lack of long-term follow-up, and most importantly, inappropriate end points. As results are published, the technology continues to evolve. This will make the technology even more difficult to evaluate. At present, this technology is not approved for the treatment of prostate cancer in the United States. Two phase III trials were initiated in 2006-2007 to compare HIFU to cryotherapy for the treatment of prostate cancer. If these trials are successfully completed and results are favorable, this technology may become an important form of treatment for prostate cancer.

Treatment of Locally Advanced Prostate Cancer

Maxwell V. Meng, MD ● Peter R. Carroll, MD, MPH

Definition
Trends in Incidence and Treatment
Natural History
Radical Prostatectomy
Radiation Therapy
Focal Ablative Therapy
Androgen Deprivation and Its Timing
Management of Delayed Sequelae
Clinical Trials

The widespread application of prostate cancer early-detection efforts in the United States has resulted in both an increased number of prostate cancers diagnosed and the earlier identification of these tumors. Despite the stage migration associated with prostate-specific antigen (PSA) testing and the growing number of low-stage and organ-confined tumors, at least 10% of men with newly diagnosed prostate cancer have locally advanced disease (T3NX/+M0). Although this proportion has declined somewhat, it remains significant and has been relatively constant during the past decade. Those men with locally advanced or metastatic prostate cancer at the time of presentation contribute disproportionately to prostate cancer mortality, and improved treatments for such men could have a significant positive impact on overall morbidity and mortality due to this disease.

Currently, no consensus exists regarding the optimal management of locally advanced prostate cancer. Unlike with clinically localized and low-grade prostate cancer, for which comparable and excellent outcomes may be achieved with a variety of interventions, treatment of disease with local or regional spread by any single modality is associated with significant risk of recurrent disease. Ongoing interest in and the development and evaluation of combination therapy, as well as improvements in risk assessment, should improve cancer outcomes while minimizing treatment-related morbidity and adverse impact on quality of life in these patients.

DEFINITION

Traditionally, the identification of patients with locally advanced disease was based on clinical examination (e.g., digital rectal examination) and clear evidence of spread outside of the prostate capsule (clinical stage T3a), involvement of the seminal vesicles (cT3b), or involvement of adjacent organs (cT4) (Greene et al, 2002). However, the contemporary use of PSA has led to the majority of men diagnosed with prostate cancer initially having nonpalpable cancers (cT1c). **Features other than clinical T stage most often contribute to the identification of men with advanced disease and a concomitant increased risk of failure after primary therapy.** Thus improved methods of risk assessment have facilitated categorization of men as "high risk" and involve consideration of variables such as serum PSA level and Gleason score in addition to clinical stage. The subsequent discussion focuses on this broader definition of locally advanced disease, with inclusion of those with regional or lymph node involvement without distant metastasis (T3-4N ±M0).

Contemporary Risk Assessment

Multiple methods are currently available to accurately risk stratify men with prostate cancer (Partin et al, 1997; D'Amico et al, 1999; Tewari et al, 2001; Shariat et al, 2008). The Partin tables were initially constructed in the 1990s and updated in 2001, assisting in the preoperative prediction of final pathologic stage in men with clinically localized prostate cancer undergoing radical prostatectomy (Partin et al, 2001). Although clinical stage, serum PSA level, and Gleason score individually predict pathologic stage and prognosis, the combination of these three variables increases the accuracy of this assessment. These data continue to illustrate that a significant number of men thought to harbor organ-confined tumors have more advanced disease. The ability to assess pathologic stage permits better pretreatment counseling of patients and more appropriate selection of therapy and consideration of those with more advanced disease for novel clinical trials. **The most important pathologic criteria predicting prognosis after radical prostatectomy are Gleason score, surgical margin status, and presence of non-organ-confined disease (e.g., extracapsular extension, seminal vesicle invasion, lymph node involvement).**

In addition, to help predict pathologic stage, biopsy information has been incorporated into models estimating cancer outcomes, primarily PSA- or biochemical-free survival, after treatment. Whereas biochemical-free survival is a frequent end point of current prostate cancer studies, it merely represents an intermediate surrogate outcome variable; further trials and studies are necessary to confirm the utility of biochemical recurrence as a marker for reduced prostate cancer-specific survival after treatment. The

most widely used tools to predict disease recurrence after local therapy are the nomograms developed by Kattan and colleagues (1998, 2000). In all pretreatment nomograms, clinical stage, biopsy Gleason grade, and pretreatment serum PSA level are incorporated to predict the continuous risk of disease progression after definitive local therapy; models for radiation therapy (RT) also include data on use of androgen deprivation (AD), total radiation dose, and combination treatment (i.e., external beam and permanent brachytherapy). The radical prostatectomy nomogram was based on nearly 1000 patients with clinically localized disease (T1c-T3aNXM0); thus this model is not applicable for those men with evidence of seminal vesicle involvement or regional spread.

Key Points: Risk Assessment

- Risk assessment is best performed by a combination of serum PSA level, T stage, cancer grade, and extent of cancer on biopsy.
- Imaging plays a limited role in identifying most patients with high-risk features for whom local therapy may fail.

To simplify risk stratification, men with prostate cancer can be grouped into fewer categories but with maintenance of ability to predict disease behavior and response to intervention. D'Amico and colleagues (1998) defined patients at low, intermediate, and high risk for biochemical failure, still based on pretreatment disease characteristics (clinical stage, PSA value, Gleason score). Recurrence after treatment may be due to unrecognized micrometastatic disease or persistence of locoregional disease. Other variations of simplified risk stratification have been developed and validated, with inclusion of features such as ethnicity and pathologic findings (Moul et al, 2001; Cooperberg et al, 2005). The Cancer of the Prostate Risk Assessment score, ranging from 0 to 10, provides another method to assess risk with each 2-point increase in score doubling the risk of recurrence after prostatectomy. **Although men with "low-risk" disease generally do well and are unlikely to have biochemical recurrence, men in the intermediate- and high-risk groups may have widely discrepant outcomes. Therefore men in these groups benefit from more modern and accurate risk prediction models and nomograms** (Mitchell et al, 2005).

Imaging Modalities

Although observations on traditional gray-scale ultrasonography can identify extraprostatic disease, the general ability to improve cancer staging is limited (Figs. 107–1 and 107–2). Directed biopsy of the seminal vesicles or prostate capsule can be obtained to confirm cT3 disease. Smith and colleagues (1997) found that transrectal ultrasonography did not improve the ability to stage prostate cancer; the area under the curve was .69 and .74 for transrectal ultrasonography in predicting extracapsular extension and seminal vesicle invasion, respectively, compared with .72 and .69 for digital rectal examination, respectively. Salo and colleagues (1987) reported high sensitivity (86%), specificity (94%), positive predictive value (92%), and negative predictive value (89%) of ultrasonography in predicting extracapsular extension in patients undergoing radical prostatectomy. However, more contemporary studies suggest otherwise, with lower sensitivities (23% to 66%), specificities (46% to 86%), positive predictive values (50% to 62%), and negative predictive values (49% to 69%). The inaccuracy of ultrasound staging for prostate cancer is likely to be the result of significant interobserver variability, often subtle signs of extraprostatic spread, and lower-volume tumors currently diagnosed. In general, transrectal ultrasonography understages rather than overstages prostate cancer. Newer ultrasound techniques such as color and power Doppler studies are under investigation to

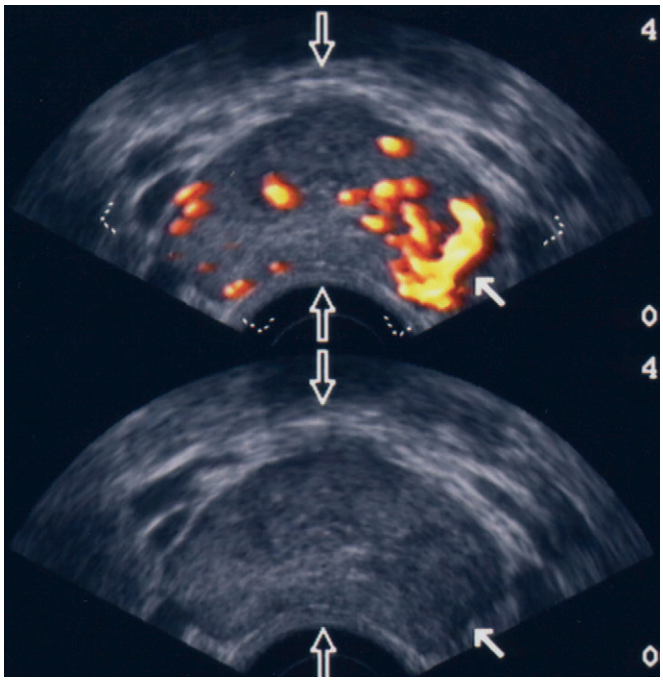

Figure 107–1. Transrectal ultrasound examination demonstrates increased flow on color Doppler study at the left posterior *(upper panel, arrow)* with corresponding hypoechoic area on gray-scale images *(lower panel, arrow)*. Note the left lateral distortion and squaring of the capsule, suggesting extracapsular extension. (Courtesy of Dr. Katsuto Shinohara.)

determine if observations of abnormal blood flow can increase the ability to detect and stage prostate tumors.

Endorectal magnetic resonance imaging (MRI) uses a magnetic coil placed in the rectum to achieve better visualization of the zonal anatomy of the prostate and may delineate subtle distinctions between T2a/b disease and T3 disease (Fig. 107–3). However, use of MRI, alone or in combination with magnetic resonance spectroscopy (MRS), for tumor staging remains controversial. Variable sensitivities (13% to 91%) and specificities (49% to 97%) have been reported for predicting extracapsular extension, in part attributed to variability in interpreting MRI and lack of uniform diagnostic criteria. In a cohort of 336 men with more than three cores involved with cancer, abnormal findings on digital rectal examination, and PSA level higher than 10 ng/mL undergoing radical prostatectomy, the specificity of MRI in predicting pT3 disease was 95% (Cornud et al, 2002). Thus the use of MRI may be best limited to those patients with higher-risk features.

Novel Markers

It is clear that traditional clinical and pathologic parameters are limited in their ability to accurately predict local extent of tumor before treatment. Given the importance of assessing true pathologic stage, novel markers of advanced disease are necessary. Chu and colleagues (2003) used comparative genomic hybridization in primary prostate specimens and identified chromosomal regions potentially useful in discriminating between organ-confined and locally advanced tumors (Table 107–1). Prediction of stage by a model incorporating six aberrations in a stepwise fashion was accurate in 91.1% of cases. Further metabolic, genetic, and proteomic signatures will likely better define and discriminate between organ-confined and non–organ-confined prostate cancer (Ashida et al, 2004; Paris et al, 2004; Mehra et al, 2007; Sreekumar et al, 2009). Chromosomal rearrangements involving the androgen-regulated gene *TMPRSS2* and the *ETS* family genes are associated with higher pathologic stage, whereas the glycine-metabolite sarcosine was more often elevated in metabolomic profiles of men with metastatic prostate cancer.

TRENDS IN INCIDENCE AND TREATMENT

Within the Cancer of the Prostate Strategic Urological Research Endeavor (CaPSURE), **Cooperberg and colleagues (2003) observed a significant decrease in the fraction of men presenting with high-risk disease characteristics, as defined by D'Amico criteria, from 40.9% in 1989-1990 to 14.8% in 2001-2002.** However, alterations in cancer screening and use of PSA are likely to account for this reduction, with significantly fewer men presenting with elevations in PSA level higher than 20 ng/mL (32.8% to 7.2%); indeed, currently, higher Gleason grade defines a larger number of high-risk patients (61.5%). Overall, **the presence of clinically advanced disease (i.e., T3-4) decreased from 11.8% to 3.5%, with a decline from 32.3% to 21.9% in the high-risk group during the observation period.**

In men undergoing radical prostatectomy, the number of men with clinical evidence of locally advanced disease, as defined by clinical stage (T3), has declined from 25.3% in 1987 to 2.8% in 2001 (Ward and Zincke, 2003). Although the use of PSA screening can account for part of this change, the more selective application of surgery and improved techniques of RT may also explain the decline in patients with cT3 disease undergoing prostatectomy. Within reports of men undergoing radical prostatectomy, the fraction of men with pT3 disease has decreased; these are highly selected patients with largely clinically localized disease at the time of treatment (Table 107–2). Roehl and colleagues (2004) reported that pathologically advanced disease decreased from 39% (1983-1991) to 31% (1992-2003). In men undergoing radical prostatectomy alone at the Cleveland Clinic, the overall rate of extracapsular extension declined from 65.8% (1987-1989) to 25.2% (2000-2001), and this trend was true for all clinical stages of tumor (T1c-T2b/c), as well as for pretreatment variables (PSA value, Gleason score).

Key Points: Trends in Incidence and Treatment

- Fewer men are presenting with locally advanced prostate cancer.
- There has been an increase in organ-confined cancers identified after radical prostatectomy.
- There is an increasing use of treatment modalities other than surgery for high-risk prostate cancers.

The National Comprehensive Cancer Network (2004, 2009) provided updated decision trees for men with prostate cancer to aid in treatment selection. High risk of recurrence includes men with clinically advanced disease, both cT3a and cT3b-T4. Bone scans are indicated in these men, as well as in those with PSA greater than 20 ng/mL or Gleason score greater than or equal to 8; pelvic computed tomography (CT) or MRI is also indicated for cT3-T4 or if the calculated probability of lymph node involvement is greater than 20%. In general, radical prostatectomy with pelvic lymphadenectomy is reserved for those high-risk men with low-volume tumors that can be completely excised. The alternative treatment strategy for these men with locally advanced disease and higher risk of biochemical failure is AD therapy combined with RT. The shift in treatment is also reflected within the CaPSURE database (Meng et al, 2005). A total of 6074 men with prostate cancer (clinical stage lower than T3a,N0,M0) was stratified according to risk group, of whom 26% were high risk. Fewer men in this group underwent radical prostatectomy compared with the low-risk cohort, with older age, advanced disease, and increased number of comorbidities significant predictors of treatment (external beam radiation or AD therapy) in multivariate modeling. In addition, more than half of high-risk men receiving radiation therapy also received AD, significantly more than in the low- and intermediate-risk groups ($P < .0001$).

NATURAL HISTORY

Active surveillance, with deferred treatment when necessary, is becoming a viable treatment alternative in men with prostate cancer. Multiple studies have suggested that cancer-specific mortality is low and primarily associated with higher-grade and higher-stage disease. Even in those low-risk cancers, however, an increased and unexpected progression of disease and associated prostate cancer mortality may be seen during an extended period (Johansson et al, 2004). In men with higher-risk disease characteristics, it has been recognized that disease progression occurs more rapidly and that some form of intervention is typically warranted in healthy patients.

Few reports address the specific question of outcome in men with locally advanced cancers merely observed for a prolonged period. Older studies such as that from Nesbit and Plumb (1946) have little relevance to current disease management. Other studies have included only a small number of patients with higher clinical stage. A range of clinical progression (22% to 75%), local progression (22% to 84%), and development of distant metastases (27% to 56%) has been reported during 5 and 10 years of follow-up. **Overall survival is reported from 10% to 92% at 5 years and 14% to 78% at 10 years for patients who harbor cancers of high grade or stage.** The Veterans Administration Cooperative Urological Research Group (VACURG) study reported a 58% overall 5-year survival in 248 men with clinical stage III disease treated with placebo. Comparable survival outcomes were reported within the Medical Research Council study (Adib et al, 1997) randomizing previously untreated patients with locally advanced, nonmetastatic disease ($n = 501$) to early or delayed AD therapy (castration or luteinizing hormone-releasing hormone [LHRH] agonist). The median time to clinical progression and death from prostate cancer in the 244 patients receiving delayed treatment was 10 months and 48 months, respectively.

In the analysis from Chodak and colleagues (1994), grade 3 tumors were significantly associated with disease-specific mortality (risk ratio, 10.04) in men treated conservatively, compared with low-grade (grade 1) cancers. The 10-year disease-specific survival was 87% in men with grade 1 or grade 2 tumor and 34% with grade 3 tumor, with metastasis-free survival of 81% for grade 1, 58% for grade 2, and 25% for grade 3 diseases. Johansson and colleagues (1997) prospectively observed 642 men with prostate cancer diagnosed between 1977 and 1984, with any stage of disease. Of those with clinically localized disease, 11% of men died of prostate cancer with corrected 15-year survival comparable for those who received initial and deferred treatment. Conversely, the corrected 15-year survival was 57% in patients with locally advanced cancer. Approximately half of men had well-differentiated tumors, and only 6% of these men died of prostate cancer. Death from prostate cancer increased with moderately differentiated (17%) and poorly differentiated (56%) disease. These data are summarized in Table 107–3. Albertsen and colleagues (1998) reported the long-term outcomes of watchful waiting in 767 men identified from the Connecticut Tumor Registry with clinically localized prostate cancer (1971-1984). The 15-year cancer-specific mortality in men with Gleason sum 6 was 18% to 30%, compared with the 25% to 59% risk of death from other causes. The chances of death from prostate cancer increased with Gleason score 7 (42% to 70%) and 8 to 10 (60% to 87%). It is likely that a significant proportion

of this cohort had non–organ-confined disease because none of the men underwent PSA testing and therefore probably had more advanced stages of disease compared with contemporary cohorts. In contrast to the report from Johansson and colleagues (2004), the annual mortality rate from low-grade prostate cancer appears to remain stable beyond 15 years after diagnosis (Albertsen et al, 2005) (Fig. 107–4). **Men with high-risk prostate cancer including those with locally advanced disease are at significant risk of disease progression and cancer-specific death if left untreated.**

RADICAL PROSTATECTOMY

The use of radical prostatectomy for management of locally advanced prostate cancer has decreased. In part, the shift in paradigm is due to the recognition that prostatectomy alone is often insufficient. In addition, improved risk assessment has permitted better identification of these patients before treatment. Advances in delivery of RT and recognition that combined modality treatment (e.g., RT and AD) improved outcomes compared with monotherapy have further contributed to the migration away from surgery for high-risk and locally advanced tumors. Nevertheless, radical prostatectomy can cure some men with high-risk disease features, and the addition of adjuvant and combined therapy may further improve outcomes of surgery alone.

Surgery for Clinical Stage T3 Prostate Cancer

Several series report outcomes of radical prostatectomy for clinical stage T3 tumors (Table 107–4). In examining all reports, **overall survival ranges from 64% to 96% at 5 years, 12.5% to 72% at 10 years, and 20% to 51% at 15 years after treatment.** Earlier data reflected less accurate risk assessment and a potentially greater number of patients with unsuspected lymph node metastases and associated earlier progression and death. Less variability exists in more contemporary cohorts, in which the **cancer-specific survival rates are 85% to 92% and 79% to 82% at 5 and 10 years, respectively, regardless of adjuvant therapy.**

Pound and colleagues (1999) found that a reasonable outcome was possible after prostatectomy for clinical stage T3a disease, with a 52% 8-year, recurrence-free survival. Similarly, Ward and Zincke (2003) reported 5- and 10-year cancer-free survival of 60% and 44%, respectively, without application of adjuvant AD. Freedom from local or systemic disease at 5 and 15 years after surgery was 73% and 67%, respectively (Ward et al, 2005). In the 812 patients from the series of Lerner and colleagues (1995), 10-year cancer-specific survival was 80%, with only 31% of men with clinical stage T3 disease dying of prostate cancer 15 years after radical prostatectomy. It is unclear, however, whether surgical intervention improves survival compared with alternative treatment strategies. Another interesting observation from the Mayo Clinic was

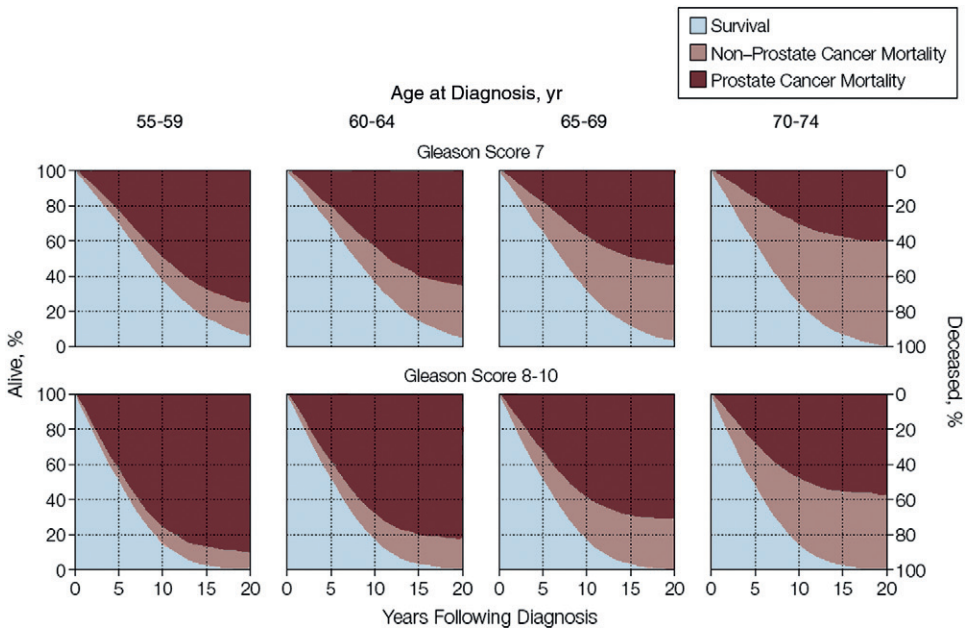

Figure 107–4. Prostate cancer mortality as a factor of Gleason grade and age at diagnosis in men managed conservatively. *Brown-shaded areas* represent proportion of patients dying of prostate cancer. *Light brown-shaded areas* represent death from competing causes. *Light-blue areas* represent proportion of patients alive. §7-year figures.

that clinical *overstaging* was identified in 27% of patients, consistent with other reported rates of 7% to 26%, suggesting that uniformly excluding patients from prostatectomy on the basis of clinical staging may not be appropriate (Ward et al, 2005). Gerber and colleagues (1997) reviewed results in 298 men with clinical stage T3 disease undergoing radical prostatectomy and pelvic lymphadenectomy. Although the overall 10-year cancer-specific survival was 57%, an apparent benefit of radical prostatectomy in some men with locally advanced disease was suggested by the increased survival (70%) in those who actually underwent prostatectomy and lymph node dissection. **Many men with clinical stage T3 disease have regional spread and may not benefit from prostatectomy; however, select patients (e.g., lower-volume disease) may benefit because local control may be achieved in most, and complete cancer excision is possible in some men.**

Biochemical progression after radical prostatectomy is difficult to assess, given the frequent use of adjuvant therapy (e.g., RT or AD). Without the use of secondary treatment, 5-year biochemical relapse is higher than 60% (van den Ouden et al, 1998). In other series with variable use of adjuvant therapy, 5- and 10-year biochemical progression was observed in 42% to 49% and 59% to 62%, respectively. The impact of adjuvant therapy may be minimal with respect to clinical progression (i.e., biopsy-proven local recurrence or objective distant metastasis) after radical prostatectomy. Rates of clinical progression at 5, 10, and 15 years are 12% to 45%, 39% to 49%, and 50% to 71%, respectively.

Outcomes of Prostatectomy for Pathologically Advanced Disease

A significant minority of patients undergoing radical prostatectomy for clinically organ-confined disease will ultimately be found to have *pathologic* evidence of spread outside the prostate. Although these patients may be expected to have progression and survival rates comparable with those of patients with clinically advanced disease, as defined by grade and serum PSA level, those men who present with clinical stage T3 disease are likely to have greater tumor volume, higher grade, and increased likelihood of regional spread. Currently, the majority of men undergoing prostatectomy for pathologically advanced disease are categorized as high risk on the basis of serum PSA value or biopsy Gleason score. Nevertheless, there is overlap in the groups of men undergoing radical prostatectomy for *clinical* stage T3 and *pathologic* stage T3.

As discussed, pathologic stage after radical prostatectomy provides important prognostic information and is a powerful predictor of outcome, considering all clinical and pathologic factors (Fig. 107–5). **The presence of focal and established extracapsular extension increases the rate of clinical progression from 7% for organ-confined disease to 18% and 35%, respectively, at 5 years.** Patients with evidence of seminal vesicle invasion or lymph node metastasis are highly likely to develop clinical progression (86% and 95%, respectively) after radical prostatectomy. In men undergoing radical prostatectomy for clinically organ-confined disease, Hull and colleagues (2002) reported 5-year PSA-free survival of 95%, 76%, 37%, and 18% for men with pathologic organ-confined disease, extracapsular extension, seminal vesicle invasion, and positive lymph nodes, respectively. In multivariate analysis, pathologic parameters increasing the relative risk (RR) for progression included extracapsular extension (RR, 2.17 to 2.72), seminal vesicle involvement (RR, 2.61), and lymph node involvement (RR, 3.31). The presence of a positive surgical margin was associated with the greatest relative risk (4.37; range, 2.90 to 6.58). This reinforces the concept that complete surgical removal of all prostatic tissue, regardless of clinical or pathologic stage, should be accomplished when prostatectomy is undertaken. Even with seminal vesicle invasion, however, men without concomitant lymph node involvement can achieve 15-year cancer-specific survival and biochemical relapse-free rates of 81% and 32%, respectively (Secin et al, 2006).

Biochemical progression after prostatectomy for pathologically advanced tumors depends on the definition applied. Five-year rates of biochemical recurrence have been as high as 65% to 72% when a PSA threshold of 0.2 ng/mL is used; less stringent thresholds such as 0.4 ng/mL may yield recurrence rates of 26% at 5 years and at least 50% at 10 years. Seminal vesicle involvement not only increases the risk of biochemical recurrence but also

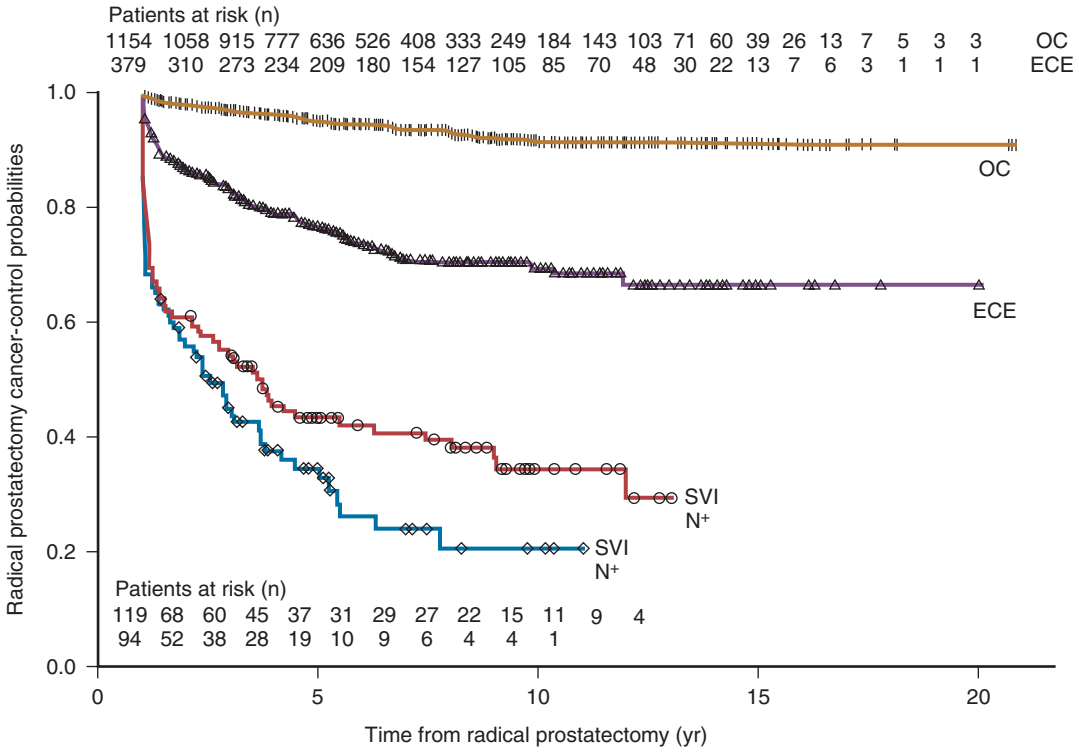

Figure 107–5. Probabilities of cancer control after radical prostatectomy based on pathologic stage. ECE, extracapsular extension; OC, organ confined; SVI, seminal vesicle invasion. (Modified from Bianco FJ Jr, Scardino PT, Eastham JA. Radical prostatectomy: long-term cancer control and recovery of sexual and urinary function ("trifecta"). Urology 2005;66:83–94.)

significantly increases the risk of local recurrence after radical prostatectomy. With prolonged follow-up, Hawkins and colleagues (1995) reported local recurrence in nearly half of patients. This risk appears to be lower in contemporary series of patients because of improved selection of patients for surgery, improved surgical technique, and earlier use of secondary treatment either as adjuvant therapy or at the time of biochemical relapse.

Predictive models have permitted preoperative estimation of PSA-free survival after prostatectomy. Patients with higher biopsy Gleason score and more elevated serum PSA level are at increased risk of failure after surgery. **Overall, the actuarial PSA-free survival after surgery in high-risk men is approximately 50% at 5 to 7 years.** The validity of the Kattan preoperative nomogram was examined in a community-based cohort of patients undergoing radical prostatectomy (Greene et al, 2004). Interestingly, although the overall concordance index (.68) supported the applicability of the tool to a broad spectrum of patients, the nomogram underestimated recurrence in lower-risk men and overestimated recurrence in men at higher calculated risk. Indeed, up to half of men with Gleason sum 8 to 10 or higher PSA level (>20 ng/mL) may achieve prolonged disease-free survival with prostatectomy alone. Further refinements of risk assessment and novel markers will help determine which high-risk men and locally advanced tumors truly benefit from aggressive surgical intervention, either alone or in combination with other therapy.

Neoadjuvant Androgen Deprivation

To improve outcomes of radical prostatectomy in men with locally advanced or high-risk tumors, several investigators have assessed the use of neoadjuvant AD (NAD) before radical prostatectomy. In 1944 Vallet reported performing radical perineal prostatectomy after orchiectomy in a 59-year-old man with prostate cancer. Others reported the use and efficacy of diethylstilbestrol (DES) before surgery. In 1964 Scott evaluated the results of NAD in 31 men who were observed for 10 years. The majority of patients (52%) were alive and free of clinical recurrence. The prospective randomized trials of NAD in patients with stage cT1-T3 prostate cancer before radical prostatectomy are summarized in Table 107–5.

Key Points: Radical Prostatectomy

- Radical prostatectomy alone can result in cancer-free survival in at least half of men at 8 to 10 years despite clinically advanced disease.
- The risk of cancer recurrence after surgery can be quantitated on the basis of pathologic stage, cancer grade, and surgical margin status.
- Neoadjuvant androgen deprivation therapy before radical prostatectomy does not appear to improve cancer-specific or overall survival.

Various measures of outcome have been evaluated in these studies including changes in digital rectal examination (clinical stage), appearance of tumor on imaging, detection of micrometastatic or circulating cancer cells, and pathologic features such as T stage, surgical margin and lymph node status, and histopathologic changes. Ultimately, the utility of AD must be assessed by its impact on disease-specific survival or its current surrogate, biochemical-free survival. It is clear that NAD affects tumor behavior and biology, evaluable by changes in metabolic patterns of atrophy on MRS, lowering of serum PSA level, and histologic atrophy (fibrosis, vacuolization, glandular collapse). Studies have demonstrated that significant reductions in prostate volume (30% to 50%), tumor volume, and PSA level (90%) are consistently noted, with maximal effects occurring during the first 2 months of treatment. However, conflicting results have been reported with respect to pathologic downstaging after NAD in patients with clinical stage T3 cancer. **Overall, only 20% of such patients have organ-confined disease at the time of radical prostatectomy despite clinical downstaging in 32% to 90%.** Schulman and colleagues (2000) described 402 patients with cT2-T3N0M0 tumors randomized to either radical prostatectomy alone or 3 months of total androgen blockade followed by surgery. Pathologic downstaging was seen more frequently in the neoadjuvant group (15%) than in the prostatectomy-alone group (7%; $P < .01$); however, in men with cT3 disease, there was no difference in pathologic downstaging ($P = .18$) and the incidence of lymph node metastases ($P = .36$) in the neoadjuvant and surgery-alone cohorts. Thus whereas clinical downstaging may occur frequently, **pathologic downstaging is significantly less common after NAD, ranging between 8% and 31%.** Most studies do not show decreased seminal vesicle invasion (Table 107–6). Similarly, rates of lymph node metastases are not altered, with the incidence varying between 3.3% and 16% in both the prostatectomy-alone and NAD groups.

Klotz and colleagues (2003) provided long-term follow-up (median, 6 years) of a prospective randomized trial comparing 3 months of NAD before prostatectomy and surgery alone. There was no overall benefit of NAD as measured by biochemical recurrence (34% to 38%), although in the subgroup of men with PSA level above 20 ng/mL, those receiving NAD had greater PSA-free survival (53%) compared with those undergoing prostatectomy alone (35%; $P = .015$). The Southwest Oncology Group (SWOG) Study 9109 was a phase II feasibility study of 16 weeks of goserelin and flutamide before radical prostatectomy in men with T3-T4N0M0 prostate cancer (Powell et al, 2002). Of the 55 patients who underwent prostatectomy, 31% had seminal vesicle invasion and 19% had lymph node metastasis. Organ-confined disease was identified in 67% of cases. At median follow-up of 6.1 years, 5-year progression-free and overall survival estimates were 70% and 90%, respectively. The study demonstrated the feasibility of 4 months of AD before surgery, with acceptable morbidity, and outcomes comparable with RT for this population of patients.

Table 107–6.

Pathologic Findings from Studies of Neoadjuvant Androgen Deprivation (NAD) in Patients with cT1-T3 Prostate Cancer before Radical Prostatectomy

AUTHOR (yr)	NO. PATIENTS	Seminal Vesicle		Lymph Node	
		CONTROL	NAD	CONTROL	NAD
Vailancourt et al (1996)	96	6%	0%		NR
Soloway et al (1995)	282	22%	15%	5.8%	6.3%
Dalkin et al (1996)	56	14%	18%		NR
Aus et al (1998)	122	14.5%	21.8%	16%	5.5%
Meyer et al (1999)	680	16%	17%	16%	14%
Klotz et al (1999)	213	14%	28%*	6.9%	3.3%
Schulman et al (2000)	402	23%	20%	23%	15.%

*$P = .035$.
NR, not reported.

Studies have also examined the incidence of positive surgical margins in those with cT3 disease. Witjes and colleagues (1997) reported similar rates of positive margins in men receiving NAD and those undergoing radical prostatectomy alone (43% and 59%, respectively; $P = .14$). Van Poppel and colleagues (1995) did not find a statistically significant difference between these groups with respect to positive margins—41.3% in the neoadjuvant cohort and 44% in the surgery-alone group. SWOG 9109 reported positive surgical margins in 30% of patients. In contrast, the randomized and nonrandomized studies of NAD in men with lower clinical stage (cT1-T2) clearly demonstrate a reduction in the rate of positive surgical margins. This advantage has not translated into improved long-term PSA-free survival. **For locally advanced tumors (specifically cT3), current data, both retrospective and prospective, do not support a significant benefit of neoadjuvant androgen deprivation before surgery** (Table 107–7).

The apparent lack of benefit of NAD before radical prostatectomy, in men with both lower-stage and locally advanced prostate cancer, may be due to a number of factors. It has been suggested that 3 months of AD may be insufficient to cause an improvement in disease-free survival compared with prostatectomy alone. Meyer and colleagues (1999) followed 680 men treated with radical prostatectomy, of whom 292 received NAD. Although there was no difference in risk of biochemical recurrence between the two groups, patients receiving both LHRH agonist and antiandrogen for more than 3 months had a significantly lower risk of PSA failure than did those treated with surgery alone (hazard rate [HR], 0.52; 95% confidence interval [CI], 0.29 to 0.93). Subsequently, the Canadian Urologic Oncology Group (Gleave et al, 2001) randomized patients with clinically localized disease to either 3 or 8

months of NAD before radical prostatectomy. In the 500 patients with pathologic staging, positive surgical margins were identified in 23% of the 3-month group and 12% of the 8-month group (P = .011); organ-confined disease was found in 68% and 80% of the 3- and 8-month groups, respectively (P = .0019). In addition, the rate of non–specimen-confined or lymph node extension was greater in the 3-month group (25.6%) compared with the 8-month group (12.6%). However, despite evidence of continued biochemical and pathologic regression of the tumor between 3 and 8 months, no significant difference in PSA recurrence rates was observed at 4 years.

Neoadjuvant Chemotherapy and Chemotherapy-Hormone Therapy

The role of chemotherapy in the treatment of prostate cancer has primarily been limited to men with the most advanced disease. Taxanes, alone or in combination with other agents, have proved effective in those with hormone-refractory prostate cancer, with significant PSA declines (>50%) in more than half of patients and measurable disease response in 28% to 75% (Oh, 2004). Mitoxantrone plus low-dose steroids has shown benefit in pain relief compared with steroids alone and is approved for use in hormone-refractory disease (Tannock et al, 1996; Kantoff et al, 1999). On the basis of these observations, interest has increased in earlier use of chemotherapy in high-risk patients or those with locally advanced disease. These studies are summarized in Table 107–8.

Pettaway and colleagues (2000) treated 33 higher-risk patients with a 3-month combination regimen consisting of two 6-week cycles of ketoconazole and doxorubicin alternating with vinblastine and estramustine. In addition, concurrent AD was accomplished with an LHRH agonist and antiandrogen. Lower pathologic stage was found in 18% of patients with cT3 disease, and the overall positive surgical margin rate of only 17% suggests that the regimen may have improved the ability to resect the cancer above that achieved with NAD alone. A second report of chemotherapy and hormone therapy before surgery combined 4 to 6 months of NAD with paclitaxel, estramustine, and carboplatin in patients with androgen-dependent, high-risk prostate cancer (Konety et al, 2004). No patients were downstaged to pT0 after neoadjuvant therapy, and organ-confined disease was reported in 36%, with a 22% positive surgical margin rate. Overall, 45% remain without biochemical relapse, defined as PSA level above 0.05 ng/mL on three occasions, at median follow-up of 29 months, and no patient has had documented local recurrence. At 43 months follow-up, Chi and colleagues (2008) reported a 3% complete pathologic response rate and distant relapse rate of 30% in patients treated with NAD and docetaxel.

Other centers have used chemotherapy without concurrent NAD. At the Cleveland Clinic, 16 patients with locally advanced disease (clinical M0) underwent three cycles of oral estramustine and etoposide and subsequent surgery (Clark et al, 2001). Although grade 3 or grade 4 toxicity was seen in 34% of patients, surgery was not delayed in any individual and surgical outcomes were comparable with those in series of prostatectomy without

neoadjuvant therapy. With a median follow-up of 14 months, 88% were free of disease and the early PSA failures occurred in the two patients with lymph node metastases.

Single-agent docetaxel is well tolerated before radical prostatectomy, with minimal toxicity (Oh et al, 2001; Dreicer et al, 2004). No cases of complete pathologic response were observed, but no lymph node metastases were identified in one series, whereas the other reported 11% with organ-confined disease. Two thirds and 24% of patients, respectively, experienced a more than 50% reduction in PSA level in response to docetaxel alone. Similar observations have been made using a novel nanoparticle-based formulation of paclitaxel, with no complete pathologic responses (Shepard et al, 2009). Combination therapy with mitoxantrone or estramustine has been reported in small numbers, and the use of chemotherapy or novel therapy with surgery requires additional study. Agents described in recent reports include granulocyte macrophage colony-stimulating factor and thalidomide (Garcia et al, 2008), as well as the epidermal growth factor receptor inhibitor gefitinib (Vuky et al, 2009).

Adjuvant Radiation Therapy

Withholding regional or systemic therapy until after the prostate has been removed may (1) prevent delay in time to surgery, (2) reduce operative morbidity, and most importantly (3) identify those men with adverse pathologic features or evidence of residual disease who truly need additional therapy, thereby avoiding overtreatment in those found to have more favorable disease. The selection of appropriate adjuvant therapy remains difficult because knowledge of the ultimate site of failure (discriminating local-regional from distant recurrence) determines the actual type, timing, and efficacy of such intervention.

Until recently, adjuvant RT was not clearly demonstrated to be beneficial after radical prostatectomy; older studies demonstrated no impact on development of distant metastasis or cancer-specific survival, and more recent data show improved biochemical control. Table 107–9 summarizes selected comparative series of adjuvant RT for pathologically advanced disease. In the matched pair analysis of Valicenti and colleagues (1999), early adjuvant RT was administered within 3 to 6 months of surgery with undetectable PSA; control subjects were observed until PSA recurrence. The reduction in risk of PSA relapse was 88% after adjuvant RT with 5-year PSA-free survival of 89%. Anscher and colleagues (1995) provided long-term follow-up (median, 10 years) in 46 patients receiving adjuvant RT after radical prostatectomy for pT3-T4. At 10 and 15 years, overall survival and disease-free survival in the RT groups were 62% and 62% and 55% and 48%, respectively; these were not statistically different from the rates in the group not receiving adjuvant RT. In addition, development of distant metastases was comparable in the two cohorts. Nevertheless, local control was better after adjuvant RT (82% at 15 years) compared with surgery alone (53%).

The use of adjuvant RT is associated with a range of biochemical-free survival, from 50% to 88% at 5 years. This appears to be an improvement (30% to 50%) compared with the results of surgery alone in high-risk patients. Nevertheless, the benefit of adjuvant RT needed to be proven in appropriately designed clinical trials, of which the European Organization for Research in the Treatment of Cancer (EORTC) 22911 (Bolla et al, 2005) and SWOG 8794 (Thompson et al, 2006) have recently been reported. Both studies randomized patients with pathologically advanced disease, defined as extraprostatic extension (pT3) and/or positive surgical margins without lymph node metastasis, to either immediate RT or observation after surgery. In EORTC 22911, immediate RT was associated with improved biochemical relapse-free survival (74% vs. 53% without RT, $P < .001$) at 5 years. Similarly, SWOG 8794, with 10.6 years median follow-up, supported immediate RT with a nearly 50% reduction in biochemical recurrence (35% vs. 64% without RT, $P < .001$) in those with PSA less than 0.4 ng/mL after prostatectomy In addition, adjuvant RT significantly reduced the risk of clinical local recurrence in both trials. SWOG 8794 demonstrated a surprisingly low risk of metastatic disease (16%) in patients with adverse pathologic features that was further reduced with adjuvant RT (7%) (Swanson et al,

2007), as well as improved freedom from subsequent AD. Moreover, both metastasis-free and overall survival were improved with adjuvant RT (HR, 0.71 and 0.72, respectively) (Thompson et al, 2009).

The decision to administer adjuvant RT is often based on various adverse pathologic features, not all of which carry the same prognosis; indeed, SWOG 8794 combined extracapsular extension, seminal vesicle invasion, and positive surgical margin within a single classification. Thus it is difficult to assess the outcomes of adjuvant RT when the populations are composed, variably, of those with positive surgical margins, extracapsular extension, seminal vesicle invasion, or a combination of these features. Those men with positive surgical margins are at an increased risk of biochemical recurrence. A decision analytic model examining this question demonstrated that the benefit may be limited to those with high likelihood of recurrent local, rather than distant, disease; thus initial RT was recommended for patients with low- to intermediate-grade disease without evidence of seminal vesicle invasion (Grossfeld et al, 2000). This report suggested that adjuvant RT should be considered in those with extensive or multiple positive surgical margins. Secondary analyses of EORTC 22911 also support the role of immediate RT in the specific subset with positive surgical margin (Van der Kwast et al, 2007). The treatment benefit of adjuvant RT was primarily seen in patients with positive surgical margins (HR, 0.38, $P < .0001$), whereas no benefit was observed in those with negative margins independent of other risk factors. However, the report from Stephenson and colleagues (2004) suggests that the application of adjuvant RT in a broader group of men may be beneficial; 501 men received salvage RT for biochemical recurrence after radical prostatectomy, and 50% experienced disease progression after treatment at a median follow-up of 45 months. Although higher Gleason score and seminal vesicle invasion were poor prognostic variables in predicting response to salvage RT, selected patients with high-grade disease or other adverse features (e.g., rapid PSA doubling time) could still achieve a durable response. Indeed, more than half of patients with Gleason sum 8 to 10 and positive surgical margins had a PSA nadir of 0.1 ng/mL or less without subsequent rise above this level. **Thus early use of secondary therapy, be it RT or AD, may be beneficial in locally advanced tumors, as well as at the time of biochemical recurrence in select patients.** However, the optimal timing and how these interventions may differentially affect local control, development of distant disease, and survival remains to be determined. Trock and colleagues (2008) reported an improvement in overall survival in patients with pT3 receiving salvage RT, with 5-year overall survival of 98%.

In general, men with seminal vesicle invasion are at significant risk for distant metastasis and may not benefit from local or regional RT; nevertheless, some men with pT3b may have local recurrence alone. Valicenti and colleagues (1998a) identified a group of 53 men undergoing radical prostatectomy with pT3b N0 disease, with 35 achieving undetectable PSA after surgery. The biochemical-free survival (3 years) in the 15 patients receiving adjuvant RT was 86% compared with 48% in the 20 men who were observed ($P = .01$). In EORTC 22911, there was no statistically significant predictive impact of seminal vesicle invasion on the benefit from RT as measured by biochemical progression-free survival, regardless of whether PSA was less than or greater than 0.2 ng/mL after surgery (Van der Kwast et al, 2007). However, even with pT3b disease, there was a benefit of adjuvant RT in patients with positive surgical margins. Men in SWOG 8794 with seminal vesicle invasion receiving RT had improved 10-year biochemical failure-free survival (36% vs. 12% for observation) but no significant improvement in metastasis-free and overall survival. **On the basis of limited data, it appears that men with seminal vesicle invasion who achieve a low PSA level (<0.3 ng/mL) after prostatectomy or have positive surgical margins may be a more favorable group in whom adjuvant RT may be considered. Conversely, those men with more advanced disease never reaching an undetectable PSA level generally constitute a poor prognostic group likely harboring unrecognized lymph node or distant disease.**

Traditionally, adjuvant RT has been delivered in lower doses compared with the dose for salvage therapy, with the range from 45 Gy to more than 60 Gy. Most contemporary series of adjuvant RT report doses greater than 60 Gy. Valicenti and colleagues (1998b) evaluated the dose response in a small number of patients ($n = 52$) receiving adjuvant RT for pT3 N0 disease. The difference in 3-year biochemical-free survival between those treated with less than 61.2 Gy (64%) and more than 61.2 Gy (90%) was statistically significant ($P = .015$), suggesting that higher doses may be necessary. In 27 men with detectable PSA 6 months after prostatectomy, Schild and colleagues (1994) noted that RT doses of 64 Gy or more had improved 30-month freedom from failure (62%) compared with lower RT doses (17%; $P = .03$), supporting the hypothesis of a postoperative RT dose response similar to what has been observed for primary RT in prostate cancer.

Key Points: Adjuvant Radiation Therapy

- Adjuvant radiation therapy improves local control and reduces biochemical relapse in selected patients after radical prostatectomy and likely improves metastasis-free and overall survival.
- The benefit of adjuvant radiation therapy may be greatest in cases of positive surgical margins.
- Improved outcomes of adjuvant radiation therapy are associated with dose escalation.

Adjuvant Androgen Deprivation

Indirect evidence from the Medical Research Council and VACURG trials suggesting a benefit of early AD compared with delayed AD, in men with various stages of prostate cancer, served as the impetus for studying adjuvant AD after radical prostatectomy. In addition, evidence of a benefit of continued AD after therapeutic RT supports a potential role for combined systemic treatment after local therapy in the form of prostatectomy. However, limited clinical data are currently published on this issue in men with locally advanced tumors.

Beyer and colleagues (1993) retrospectively reviewed the outcomes of 86 patients undergoing radical prostatectomy and any form of adjuvant therapy (89% endocrine treatment). In the subset of patients with stage pT3N0 tumors, adjuvant treatment did not demonstrate an advantage with respect to time to progression or survival. Cheng and colleagues (1993) reviewed the Mayo Clinic experience with 1035 patients undergoing radical prostatectomy for pathologic stage C prostate cancer; a significant number ($n = 103$) received adjuvant AD with orchiectomy. Adjuvant therapy of any type (AD or RT) decreased the rate of progression but did not improve cancer-specific or overall survival, with no difference between the two modalities. Prayer-Galetti and

colleagues (2000) presented data of 201 men with pT3 disease receiving adjuvant goserelin, demonstrating a 25.4% improvement in disease-free survival at median follow-up of 5 years (P < .05).

Recent publications provide some evidence supporting a benefit of early AD after radical prostatectomy in high-risk men with locoregional disease spread. Zincke and colleagues (2001) retrospectively reviewed data of men with stage pT3b cancer and found that early, adjuvant AD positively affected time to progression and cancer-specific survival. These findings were true not only with seminal vesicle invasion but also with limited lymph node disease, with a 10-year cause-specific survival of 94% after prostatectomy and adjuvant AD with a single positive lymph node. Similar findings arose from the Eastern Cooperative Oncology Group (ECOG 7887) study randomizing men with nodal metastases after radical prostatectomy (cT1-T2) to immediate (adjuvant) or delayed AD (Messing et al, 1999). At a median follow-up of 11.9 years, men receiving adjuvant AD had improved overall (HR, 1.84), cancer-specific (HR, 4.09), and progression-free survival (HR, 3.42).

RADIATION THERAPY

The contemporary trend is to treat high-risk or locally advanced prostate tumors with methods other than surgery. Although a plethora of studies describe the results of RT for clinical stage C and T3 disease, many were performed before the widespread use of serum PSA determinations for early detection and modern radiation techniques for treatment such as three-dimensional conformal RT, intensity-modulated RT, and irradiation of the whole pelvis in addition to the prostate (Kupelian et al, 2003). In addition, contemporary data suggest that the optimal radiation dose is higher than that used in previous reports. In the treatment of men with locally advanced or high-risk prostate tumors, monotherapy with RT or permanent interstitial brachytherapy is likely to be inadequate. Yet it must be emphasized that the outcome measures with demonstrated benefit of AD and RT compared with RT alone often do not include overall survival. The focus has shifted to improving outcomes by combining RT with AD, often in conjunction with whole-pelvis irradiation (Table 107–10).

Overall survival after RT alone for stage C cancer is approximately 60% to 70% at 5 years and below 50% at 10 years. In high-risk patients, defined by individual parameters alone or in combination, the 5-year progression-free survival rates after RT are typically less than 50%.

Neoadjuvant Androgen Deprivation and Radiation Therapy

The theoretic benefits of AD before RT in men with locally advanced cancers are the ability to reduce target volume and the potential cytotoxic synergy of radiation and hormone manipulation. Several Radiation Therapy Oncology Group (RTOG) trials (75-06, 83-07, 85-19) examined the combination of AD and RT in locally advanced disease, suggesting that the regimen was tolerable and improved local tumor control. On the basis of this

information, RTOG 86-10 was designed to compare short-term AD combined with RT with RT alone (Pilepich et al, 2001; Roach et al, 2008). The phase III trial randomized 471 men with cT2-T4 tumors (surface area > 25 cm^2 on rectal examination) to either goserelin plus flutamide for 2 months before and during external beam RT or RT alone. The 4 months of AD was associated with reduction in distant metastases and improvements in local control, disease-free survival, and cancer-specific mortality. At 10 years, the disease-free survival in the AD plus RT and RT-alone groups was 11% and 3%, respectively ($P < .0001$), whereas cancer-specific mortality was 23% and 36%, respectively ($P = .01$). No difference in overall survival between the two groups (43% AD plus RT vs. 34% RT) was found, although men with lower Gleason sum (2 to 6) appeared to have a survival benefit from combined AD and RT. In men with Gleason sum 7 to 10, no significant improvement was observed from AD with respect to locoregional control or survival. Subsequent analysis of RTOG 86-10 (Chakravarti et al, 2003) revealed that loss of p16 expression on immunohistochemistry was associated with reduced overall survival ($P = .039$), disease-specific survival ($P = .006$), and higher risk of local progression ($P = .0007$) and distant metastasis ($P = .026$); overall survival was not significantly associated ($P = .07$) in multivariate analysis. Other correlative studies of tissue from RTOG 86-10 found that the proliferative marker Ki-67 was significantly associated with distant metastasis and cancer-specific survival but not with overall survival (Li et al, 2004).

Similar observations were made by Laverdiere and colleagues (1997) in a prospective randomized study of 120 men with cT2b-T4 disease. Treatments included (1) external beam RT alone, (2) 3 months of NAD before RT, and (3) 3 months of NAD before RT and 6 months of adjuvant AD. Evidence of residual cancer on prostate biopsy was present in 62%, 30%, and 4% of the treatment arms, respectively, at 12 months and 65%, 28%, and 5% at 24 months. Biochemical-free survival at 12 and 24 months paralleled the biopsy data, with the difference between the neoadjuvant and adjuvant AD groups disappearing at 24 months. These observations not only supported neoadjuvant and concurrent AD with RT but also suggest a benefit of prolonged AD. In a group of men randomized to either 3 or 8 months of NAD before RT, of whom 31% were categorized as high risk, longer NAD did not improve freedom from or pattern of failure; the only benefit of 8 months was improved 5-year disease-free survival (71% vs. 42%) (Crook et al, 2009).

Key Points: Neoadjuvant Androgen Deprivation and Radiation Therapy

- Neoadjuvant and concurrent androgen deprivation appears to be appropriate in high-risk patients undergoing radiation therapy.
- Adjuvant androgen deprivation after radiation therapy may benefit those with very high-risk disease.

Adjuvant Androgen Deprivation and Radiation Therapy

Several prospective studies have assessed the role of adjuvant AD after RT, as well as the appropriate duration of such therapy. RTOG 85-31 (Pilepich et al, 1997; Lawton et al, 2001) randomized 977 patients with T3NXM0 or T1-T2N+M0 prostate cancer to RT and either goserelin, started during the last week of RT, continued indefinitely, or goserelin at the time of relapse (i.e., early or late AD). The groups were matched with respect to disease risk characteristics, and less than 30% had lymph node involvement. Improved local control and biochemical disease-free and metastases-free survival were noted in the adjuvant AD group at 8 years of follow-up, and this advantage was most prominent with Gleason sum 8 to 10. Overall survival was not statistically different at 5 years (75% vs. 72%) and 8 years (49% vs. 42%). In those with high-grade tumors, adjuvant AD improved cancer-specific (90% vs. 78%) and overall (80% vs. 69%) survival at 5 years.

In the EORTC 22863 study (Bolla et al, 1997), men undergoing external beam RT for clinically localized disease (cT1-T2 and grade 3, cT3-T4 any grade) were randomized to RT alone or the addition of goserelin starting at the beginning of treatment and continuing for 3 years. This is the only study to demonstrate an overall survival benefit, with 5-year survival of 79% in the adjuvant AD group and 62% in the RT-alone group ($P = .001$). Disease-free survival was 85% and 48%, respectively, and local control was also improved with AD (97% vs. 79%). Of note, the cohort presented with very high-risk disease, with a median PSA level of 30 ng/mL, and this may account for the relatively low overall survival in the RT-alone cohort.

It does not appear that the method of AD affects the outcome of combined treatment with RT. Granfors and colleagues (1998) randomized men with cT1-T4pN0-3M0 cancer to either external beam RT alone or combined orchiectomy and RT; men treated with RT alone received AD at clinical disease progression. At median follow-up of 9.3 years, clinical progression in the RT-alone and RT-plus-AD patients was 61% and 31%, respectively ($P = .005$). Cancer-specific mortality was not different; overall mortality was 61% and 38%, respectively ($P = .02$). However, in men with negative lymph nodes, there was no significant difference in survival rates, and the poor survival was primarily due to metastatic disease at the time of initial treatment.

A meta-analysis of 2742 men treated for clinically localized prostate cancer within RTOG trials from 1975 to 1992 supports use of adjuvant AD in subsets of patients (Roach et al, 2000). Patients were stratified into four prognostic risk groups, and those in risk group 2 (cT3NX, Gleason 2 to 6; cT1-T2NX, Gleason 7; N+, Gleason 2 to 6) appeared to have improved disease-specific survival with addition of short-term (4 months) AD. In further refining the population of patients, limiting the analysis to men with bulky or cT3 disease alone demonstrated a significant survival advantage.

If adjuvant AD is of benefit, the duration of such therapy remains uncertain. RTOG 92-02 supports the use of long-term AD after initial AD with external beam RT (Hanks et al, 2003). Men with locally advanced tumors (cT2c-T4N0-1M0) received either 4 months of AD (2 months neoadjuvant and 2 months concurrent) with RT or that and 24 additional months of AD. Long-term AD was beneficial in all end points evaluated *except* overall survival, with 5-year rates of both approximately 80%. Subset analysis of men with Gleason sum 8 to 10 noted improved overall survival with 24 months of AD (81%) compared with short-term AD (71%; $P = .044$), as well as improved disease-specific survival; these findings were confirmed during 10-year follow-up (Horwitz et al, 2008). D'Amico and colleagues (2004) described 206 men with clinically localized but higher-risk (PSA ≥ 10 ng/mL, Gleason sum ≥ 7, cT3) prostate cancer randomized to RT alone (70 Gy) or RT with 6 months of AD. Overall and cancer-specific survival rates were improved with AD compared with RT alone. Actuarial 5-year

survival and freedom from salvage AD was 88% and 82%, respectively, after early AD and 78% and 57% with RT alone. **Thus a limited period of AD (2 to 4 months) appears to be appropriate for those men with intermediate-risk cancers; more prolonged AD may be beneficial for those with high-risk disease characteristics including high-stage cancers or men with high pretreatment serum PSA values.**

Other aspects of RT for men with more advanced tumors require clarification including the dose and extent (i.e., prostate only vs. prostate and pelvis) applied. RTOG 94-13 randomized men with an estimated risk of lymph node metastasis of 15% into one of four arms: (1) whole-pelvis RT plus neoadjuvant and concurrent AD, (2) prostate-only RT plus neoadjuvant and concurrent AD, (3) whole-pelvis RT plus adjuvant AD, and (4) prostate-only RT plus adjuvant AD (Roach et al, 2003; Lawton et al, 2007). Initial analysis suggested improved progression-free survival for whole-pelvis compared with prostate-only RT and no difference for the two types of AD. In comparing the four groups after longer follow-up, however, progression-free survival rates were similar, with significant difference only in overall survival among the groups (P = .027). Surprisingly, overall survival was worse in patients receiving whole-pelvis RT plus adjuvant AD compared with all other cohorts.

The differences in RT dose among the various prior and contemporary studies make comparisons of efficacy difficult because emerging data support doses greater than 72 Gy as being more effective (Cheung et al, 2005; Jacob et al, 2005). In addition, the role of combined external beam RT and brachytherapy (both permanent and high-dose rate) needs to be better elucidated. Brachytherapy has generally been used to treat patients with lower-risk features. Its use in those with high-risk disease characteristics, often in combination with AD and external beam RT, has been less well studied. Potters and colleagues (2005) noted a 63% biochemical-free survival in those treated with permanent prostate brachytherapy. A similar outcome has been noted with the use of high-dose-rate intensity-modulated brachytherapy with external beam RT (Demanes et al, 2005). Sylvester and colleagues (2003) treated men with interstitial permanent brachytherapy combined with moderate-dose (45 Gy) neoadjuvant external beam RT. In those with high-risk disease (D'Amico criteria), the 10-year biochemical relapse-free survival was 48%; of note, AD was not used. Stock and colleagues (2004) evaluated a multimodal protocol using neoadjuvant and concomitant AD (9 months total), brachytherapy, and three-dimensional conformal RT in a high-risk cohort. The 5-year biochemical-free survival was 86%, with Gleason sum the only variable associated with PSA failure. Excellent local control was also demonstrated, with no patient harboring cancer on the last post-treatment biopsy.

Radiation Therapy and Chemotherapy

The role of chemotherapy in conjunction with RT is less well studied than that for surgery and chemotherapy. Khil and colleagues (1997) administered estramustine and vinblastine concurrently with RT (total, 65 to 70 Gy) in men with locally advanced disease. Although clinical control was reasonable at 5 years at 81%, only 48% of patients had a PSA level below 4 ng/mL at this time. Zelefsky and colleagues (2000) enrolled 27 patients with high-risk disease (Gleason sum ≥ 8 and PSA > 10 ng/mL; Gleason sum 7 and PSA > 20 ng/mL; cT3N0M0 and PSA > 20 ng/mL; cT4N0M0; cTXN1M0) in a phase II clinical trial of the same agents, with RT at 75.6 Gy. Only modest increase in grade 2 toxicity was noted, and no late grade 3 or grade 4 toxicities were observed. The 2-year biochemical-free survival was 60%. An update reported median time to PSA relapse of 12 months, with 48% of patients receiving no additional therapy, and median time to metastasis had not been reached (Ryan et al, 2004).

An estramustine-based regimen has also been examined with etoposide before and during definitive RT (Ben-Josef et al, 2001). Actuarial disease-free and overall survival was 73% and 88%, respectively, at 3 years. Local control as determined by biopsy was 71% at 18 months. A phase I study examined concurrent docetaxel and RT (70.2 Gy) in 22 men (Kumar et al, 2004). The maximal tolerated dose was determined to be 20 mg/m^2, with diarrhea and dysuria the primary toxic effects. All patients were alive at last follow-up, and 77% had continued biochemical response. These promising results support further study of the combined use of RT and chemotherapeutic agents.

FOCAL ABLATIVE THERAPY

Advances in technology have provided methods to ablate prostate tissue while being minimally invasive. There is renewed interest in primary cryoablation, particularly as focal treatment for localized disease, as well as salvage therapy, while high-intensity focused ultrasound (HIFU) appears promising. The ability to treat local disease within the prostate by these modalities may play a role even in men with locally advanced disease, most likely in combination with AD or other systemic therapy.

Cryoablation

Several series have been reported regarding primary cryoablation of the prostate and include many men with high-risk disease (Ahmed et al, 2009). Among 975 men undergoing cryoablation, 41% were high risk and 24% were cT3 in the report from Long and colleagues (2001). At median follow-up of 24 months, the 5-year actuarial biochemical-free survival, defined as PSA less than 1 ng/mL, was 41%. A similar PSA outcome (35%) using the same definition was observed in another group of men with PSA greater than or equal to 10 ng/mL and/or Gleason sum greater than or equal to 8 undergoing primary cryoablation (Prepelica et al, 2005). However, use of more stringent PSA cutoff values may result in significantly worse outcomes, with 2-year rates of biochemical failure higher than 80% if thresholds of 0.5 or 0.2 ng/mL are applied (El Hayek et al, 2008). Chin and colleagues (2008) randomized men with clinical stage T2c-T3 to 6 months of AD and either cryoablation or RT at 66 Gy. At mean follow-up of 37 months, there were no differences in disease-specific (95% to 97%) and overall survival (87%), but cryoablation was associated with shorter PSA-free survival (28 months vs. 41 months) and higher biochemical failure (87% vs. 53%).

High-Intensity Focused Ultrasound

The role of HIFU continues to be elucidated, particularly in men with locally advanced prostate cancer. The limited existing data are confounded by frequent omission of risk stratification and common use of AD to reduce prostate size. At 1-year follow-up, 30 men with locally advanced or high-risk disease receiving AD plus HIFU had reasonable local control, with PSA less than 0.3 ng/mL and negative sextant biopsies in 90%; no patient had clinical disease progression (Ficarra et al, 2006). A larger series from Sumitomo and colleagues (2008) compared men receiving HIFU with and without NAD and without subsequent adjuvant

therapy. In the 29% with D'Amico high-risk cancers, NAD reduced both positive biopsy rate and biochemical failure. Three-year disease-free survival was independently affected by stage cT2c or higher (HR, 2.34) and lack of NAD (HR, 2.19) in multivariable analysis. Parallel to studies of RT, outcomes of local treatment using HIFU may be improved when combined with NAD, primarily in men with intermediate- and high-risk disease characteristics.

ANDROGEN DEPRIVATION AND ITS TIMING

The VACURG and Medical Research Council trials suggest a benefit to early application of AD in men with locally advanced prostate cancer. The first VACURG study randomized 1050 patients with stage III disease and 853 patients with stage IV disease to placebo, 5 mg of DES, orchiectomy plus placebo, or orchiectomy plus 5 mg of DES. All three AD arms had significantly less progression than the placebo group had, but this did not translate into an overall survival benefit. The inability to demonstrate a survival benefit cannot be completely attributed to the increased cardiovascular deaths within the DES groups because survival in the orchiectomy plus placebo group was not significantly different from that in the placebo-alone group. The second VACURG study randomized 1506 men with stage III and stage IV disease to placebo or one of three doses of DES (0.2 mg, 1 mg, 5 mg). DES at 1 mg and 5 mg delayed progression of stage III disease, and patients receiving 1 mg had improved overall survival. However, the 5-mg dose of DES again resulted in increased cardiovascular death. Subsequent analysis suggested that immediate estrogen therapy was most beneficial in patients younger than 75 years with high-grade tumors (Gleason sum 7 to 10). The third VACURG study supported that only a subset of men with prostate cancer benefit from early AD. In men with stage II disease, 5-year survival with placebo and 1 mg of DES was 48% and 75%, respectively. **Taken together, the VACURG data provide evidence of benefit for early AD with respect to disease progression and potential survival only in subsets of men with more aggressive disease** (Byar, 1973; Byar and Corle, 1988). **The studies also clearly show that alternatives to estrogen should be used, given the cardiovascular toxicity associated with higher doses of DES.** The current ability to better monitor disease progression, with use of PSA kinetics and imaging modalities, may improve the outcomes of delayed AD by better determining when institution of AD is necessary.

The Medical Research Council also evaluated the issue of early versus delayed AD (orchiectomy or LHRH agonist) in 938 patients with prostate cancer, of whom 501 had locally advanced disease. The majority of deaths (67%) were attributed to prostate cancer. Cancer-specific mortality was 55% in the early AD group and 43% in the deferred group ($P = .001$). Overall survival was also improved in the immediate AD arm ($P = .02$). The reduction in prostate cancer death was primarily due to patients with M0 disease. This study also provides important data for comparison to other forms of treatment. Median time to death due to prostate cancer (cT3 M0) was 90 months, comparing favorably to EORTC 22863, in which median time was not reached after 65.7 months. Similarly, median overall survival in the Medical Research Council study was 64 months but not reached in EORTC 22864 (56.7 months of follow-up). Thus the apparent beneficial effects of combined AD and RT may be due in part to AD alone with uncertain incremental advantage of RT. The recent results from SPCG-7/SFUO-3 suggest an important role of RT, in addition to AD, in men with locally advanced disease (78% cT3) (Widmark et al, 2009). Men were randomized to either total AD followed by continuous flutamide or endocrine therapy combined with RT. At median follow-up of 7.6 years, both prostate cancer-specific and overall mortality were decreased in the group receiving AD plus RT (RR, 0.44 and 0.68, respectively), and PSA recurrence was higher in men receiving AD alone (75%) compared with the RT group (26%). Despite limitations including the unconventional endocrine regimen and open study design, use of RT and potentially other local treatment modalities appears warranted in men with locally advanced prostate cancer.

Studer and colleagues (2004) evaluated the timing of AD in a study randomizing 197 asymptomatic men with prostate cancer to either immediate or deferred subcapsular orchiectomy; of note, patients were either unsuitable for or unwilling to undergo surgery or RT. A significant fraction of the cohort had higher-risk features, with clinical stage T3 or higher in 67% and median serum PSA level above 46 ng/mL. Of the 92 men in the deferred treatment arm, 42% never required AD; the majority died of causes unrelated to prostate cancer. The median time to deferred AD was 3.2 years, the most common indication being skeletal metastases (45%) and ureteral obstruction (25%). Although overall survival was not different between the immediate and deferred groups ($P = .96$), a trend toward improved cancer-specific survival was noted in those men receiving immediate AD, with a hazard rate for death from prostate cancer of 0.63 ($P = .09$).

To minimize adverse impact on quality of life, antiandrogen therapy alone has been proposed as an alternative to orchiectomy or LHRH agonists. Iversen and colleagues (2004) reported on the effects of 150 mg of bicalutamide in men with localized or locally advanced prostate cancer, the majority of whom were untreated initially (81%). At median 5.3 years of follow-up, survival in those with locally advanced disease was improved with bicalutamide compared with placebo (HR, 0.68). Overall, risk of disease progression was reduced by 43%, with the greatest benefit in locally advanced tumors (HR, 0.4). The combined analysis of the three Early Prostate Cancer bicalutamide trials ($n = 8113$) confirmed improved progression-free survival in the bicalutamide group (Wirth et al, 2004a). Overall survival was not different between the treatment and placebo arms in each trial, but men with locally advanced disease receiving bicalutamide alone (i.e., no surgery or RT) appeared to have improved survival. Although apparently promising in men with high-risk tumors, bicalutamide at 150 mg must be approached cautiously, both in men deferring local therapy and after definitive treatment. In analysis of the Early Prostate Cancer data (median follow-up of 5.4 years), men with localized prostate cancer receiving bicalutamide as primary therapy had an increased risk of death (HR, 1.23; 95% CI, 1.00 to 1.50) compared with surveillance alone. Immediate high-dose bicalutamide is not currently appropriate in men with low risk of disease progression, and potentially adverse effects should be sought in higher-risk patients with extended follow-up.

Wirth and colleagues (2004b) tested adjuvant flutamide (750 mg) after radical prostatectomy in men with pT3-T4N0 disease. Recurrence-free survival, defined as a single PSA value above 5 ng/mL or two PSA values above 2 ng/mL, was improved with flutamide (HR, 0.51) at median follow-up of 6.1 years; however, overall survival was comparable (HR, 1.04). Significant toxicity was associated with flutamide and accounted for nearly half of withdrawals from the treatment arm.

Key Points: Androgen Deprivation

- Early androgen deprivation may improve survival.
- Alternative methods of androgen manipulation (antiandrogen, intermittent) remain investigational.

Intermittent Androgen Deprivation

Another approach to minimizing AD-related morbidity is the intermittent application of androgen suppression. Forty-nine patients (28 with cT3-T4N0M0) were treated with total AD until the PSA level was less than 4.0 ng/mL between 24 and 32 weeks, after which treatment was withheld after 36 weeks (Sato et al, 2004). PSA level was monitored and treatment was recommended when the PSA level reached either pretreatment level (when it was <15 ng/mL) or 15 ng/mL (when the initial PSA level was higher than that). During median follow-up of 126.1 weeks, mean time off treatment during cycles 1, 2, and 3 was 46.1, 36.9, and 23.3 weeks, respectively. No symptomatic or clinical disease was reported in the nonmetastatic subgroup, and PSA failure was observed in 3 (11%) of these patients, with all patients alive at last evaluation. The optimal timing of intermittent AD for reduction of patient morbidity and disease-specific end points remains to be determined.

Quality of Life

The early institution of AD in men with prostate cancer, whether it is localized or locally advanced, must be balanced against the known side effects and long-term morbidity. Only recently has the impact of AD been appreciated and reported on bone events, cognitive function, and quality of life. In comparing bicalutamide (150 mg) and castration with locally advanced but nonmetastatic disease, both sexual interest and physical capacity were better with bicalutamide monotherapy (Iversen et al, 2000). Although hot flashes were more common with castration, a trend toward reduced quality of life was associated with bicalutamide including higher incidence of gynecomastia, breast pain, and asthenia. In the study of intermittent AD from Sato and colleagues (2004), many quality of life domains were improved during off-treatment cycles including potency and social and family well-being.

The multimodal approach with AD and RT may increase the relative toxicity compared with each intervention alone. Schultheiss and colleagues (1997) reported that NAD was correlated with later gastrointestinal and genitourinary (grade 2 or higher) morbidity. Another study found that adjuvant AD after RT predicted for late grade 2 to grade 4 rectal toxicity (Sanguineti et al, 2002). Within RTOG 86-10, potency after RT with or without AD was similar at 81% and 74%, respectively. Chen and colleagues (2001) also found that the addition of AD did not further contribute to decline in sexual function after RT. Zelefsky and colleagues (1999) evaluated predictors of late toxicity in men treated with three-dimensional conformal radiotherapy. Although the 5-year actuarial likelihood of gastrointestinal and urinary toxicities was low (<10% overall), use of NAD was an independent predictor ($P = .01$) of post-treatment erectile dysfunction. The incidence of rectal morbidity and sexual dysfunction may be related to duration of AD longer than 6 or 9 months.

The benefits of adjuvant AD plus RT for locally advanced prostate cancer, both short and long term, appeared to outweigh the associated side effects in a number-needed-to-treat analysis (Jani et al, 2003). A model that compared treatment options while incorporating benefit and complications was constructed, and data from randomized trials of RT with or without AD for cT2c-T4 N0-1 were input into the calculation. Even considering the increased incidence of side effects of long-term AD, this approach appeared to be better than short-term AD for virtually all end points evaluated.

Given concerns regarding AD and impact on body mass index, lipid profile, diabetes, and cardiovascular disease, Efstathiou and colleagues (2009) assessed the relationship between AD and cardiovascular events within RTOG 85-31. Adjuvant AD (median duration 4.2 years) was not associated with increased cardiovascular mortality. Additional evidence from RTOG 86-10 suggests that short-term NAD also does not increase the risk of fatal cardiac events.

MANAGEMENT OF DELAYED SEQUELAE

The direct comparison of prostatectomy and RT in the treatment of locally advanced prostate cancer is challenging and primarily based on historical studies. Even with the addition of neoadjuvant and adjuvant systemic therapy, leaving the prostate gland in situ poses potential problems. First, effective local control of some high-risk cancers may influence survival. Second, local recurrence may lead to the need for additional treatment of the prostate. At 10 years, local recurrence rates after RT for cT3 or stage C range from 24% to 74%. Holzman and colleagues (1991) reported that 36% of patients required transurethral resection of the prostate because of urinary obstruction after RT alone, without AD. Other morbidity included hydronephrosis (20%) and incontinence (13%). An older report (Tomlinson et al, 1977) also demonstrated significant local complications of stage C prostate cancer with nonextirpative interventions—infection (80%), bladder outlet obstruction (75%), gross hematuria (45%), and ureteral obstruction (40%). Systemic therapy in the form of AD may not prevent local progression or reduce need for palliative intervention. Despite orchiectomy for bladder outlet obstruction, 31% of men with locally advanced disease required transurethral prostate resection because of persistent voiding dysfunction after 60 days. Similarly, in 277 patients with cT2-T4 randomized to orchiectomy, RT, or both, rates of local disease control were comparable (Fellows et al, 1992). Studer and colleagues (2004) demonstrated that AD alone, whether it is instituted early or late, does not prevent local morbidity. More than half of the men in their study required transurethral resection of the prostate. In addition, delayed institution of AD was necessary because of ureteral obstruction (25%), anticipation of local complications (10%), and rectal infiltration (4%).

Quality of life is an increasingly important end point for prostate cancer. However, the impact of untreated local tumor progression or the various treatment modalities for locally advanced disease on quality of life outcomes is poorly characterized. Rosenfeld and colleagues (2004) examined the relationship between cancer stage and quality of life in 341 ambulatory men with prostate cancer. Instruments used included the Functional Assessment of Cancer Therapy (FACT), urinary function subscale of the UCLA Prostate Cancer Index, and Hospital Anxiety and Depression Scale (HADS). The stage of prostate cancer was significantly associated with most FACT scales—increasing stage was negatively correlated with nearly every FACT subscale score; the observation persisted in multivariate models, accounting for covariates such as comorbidity and time since diagnosis. Interestingly, stage was more strongly associated with physical domains of health-related quality

Table 107–11.

Current Phase III Clinical Trials in Locally Advanced/High-Risk Prostate Cancer

STUDY	ELIGIBILITY CRITERIA	TREATMENTS
Radical Prostatectomy		
NEOADJUVANT		
CALGB 90203	Clinically localized, ≤60% 5-yr disease free, Gleason 8-10	Surgery alone vs. estramustine/docetaxel
ADJUVANT		
SWOG 9921	Gleason 8-10, pT3b-4, PSA > 20 ng/mL, N1, Gleason 7 and + margin	AD (2 yr) vs. AD + mitoxantrone/prednisone
VA Study 553	pT3b-4, pT3a and Gleason ≥7, pT2 and Gleason 8-10 and + margin, PSA > 20 ng/mL	Surveillance vs. docetaxel/prednisone
SPCG 12	pT3a and Gleason ≥4+3, pT2 and + margin and Gleason ≥4+3, pT3b and Gleason ≥7	Surveillance vs. docetaxel
NCT 00667069	>pT2 or R1 N0/x and PSA ≤0.1 ng/mL	Immediate vs. delayed RT + triptorelin
MRC PR 10	After radical prostatectomy with PSA ≤0.2 ng/mL: pT3-4, Gleason 7-10, preoperative PSA ≥10 ng/mL, + margin	Immediate vs. delayed RT RT vs. RT + 6 mo AD vs. RT + 24 mo AD
External Beam Radiation Therapy		
NEOADJUVANT		
RTOG 9910	Gleason 2-6 and PSA 10-100 ng/mL, Gleason 7 and PSA < 20 ng/mL, cT1 and Gleason 8-10 and PSA < 20 ng/mL	8 wk NAD vs. 28 wk NAD
CAN-NCIC-PR12	≥T3a, Gleason ≥ 8, PSA > 20 ng/mL	NAD + docetaxel vs. NAD
ADJUVANT		
RTOG 9902	Gleason ≥ 7 and PSA 20-100 ng/mL, ≥cT2 and Gleason ≥ 8 and PSA < 100 ng/mL	AD vs. AD + estramustine/etoposide/paclitaxel
NCT 116142	cT1-T2a and PSA < 10 ng/mL or Gleason ≥4+3 or PSA velocity >2 ng/mL/yr, cT2c-4 and tertiary Gleason 5 or T3b or Gleason ≥3+4 with ≥50% cores positive	AD vs. AD + docetaxel
RTOG 0521	Gleason ≥ 9 and PSA ≤ 150 ng/mL, Gleason 8 and PSA < 20 ng/mL and ≥cT2, Gleason 7 or 8 and PSA 20-150 ng/mL	AD vs. AD + docetaxel/prednisone
SPCG 13	cT2 and Gleason 4+3 and PSA 10-70 ng/mL, cT2 and Gleason 8-10 and PSA < 70 ng/mL, cT3	AD vs. AD + docetaxel
Androgen Deprivation		
CAN-NCIC-PR3	cT3-4N0/M0, cT2 and PSA > 40 ng/mL, cT2 and PSA > 20 ng/mL and Gleason ≥ 8	AD alone vs. additional pelvic RT
NCT 00055731	Gleason > 7, cT3-4, N1, PSA > 20 ng/mL	AD vs. AD + docetaxel/estramustine

of life and there was no association with psychologic symptoms as measured by HADS.

Berg and colleagues (2007) treated high-risk patients with RT monotherapy and characterized quality of life using validated instruments. Although mean scores for bowel function were similar to those for a normative control population, bowel bother and diarrhea were greater after RT. Patients who had clinical progression or required AD reported worse sexual, urinary, and social function, and more sleeping problems and exhibited great declines in all domains over time. Data from CaPSURE (Wu et al, 2008) also suggest that men with high-risk cancer are likely to suffer negative effects beyond cancer outcomes. Use of AD with both surgery and RT was associated with a loss of sexual function that improved within 9 months, whereas the combination of external beam RT and brachytherapy resulted in continuous worsening of urinary function and bother.

Additional evidence from SWOG 8794 supports an adverse impact of multimodal therapy on quality of life (Moinpour et al, 2008). Men receiving adjuvant RT reported worse bowel and urinary function, but not erectile function, compared with surgery alone. Although symptom distress was significantly worse for the adjuvant RT group, likely correlating with bowel and urinary problems, there were no differences in other general measures of health-related quality of life, whereas global health-related quality of life was initially worse but continuously improved over time after adjuvant RT.

CLINICAL TRIALS

Given that outcomes of therapy are not optimal for those men with high-risk disease features, patients who present with such cancers should be considered for enrollment in novel clinical trials (http://clinicaltrials.gov/). Table 107–11 summarizes phase III clinical trials for high-risk or locally advanced prostate cancer, some of which have completed accrual; others are ongoing. The resulting data should answer some of the current questions regarding the optimal type and timing of traditional combination treatment, as well as the role of chemotherapy in men with locally advanced and high-risk prostate cancer.

Clinical Trial Considerations

Summary

No tumor marker has had as great an impact on the diagnosis, management, and treatment of a disease as prostate-specific antigen (PSA) has had on prostate cancer. PSA assessments are used during every phase of the disease—screening and early detection, determining extent of local disease, defining the probability of disease control after surgery or radiation therapy, and indicating whether a patient is responding to treatment, be it local or systemic.

Perhaps the most controversial and problematic aspect of PSA monitoring is that it has created a new "clinical state" to characterize patients whose sole manifestation of disease recurrence after definitive local therapy is a detectable and increasing PSA value, in the absence of detectable disease according to the currently available imaging modalities. Based on the estimated probability of relapse after surgery or radiation therapy, upward of 50,000 American men fall into this category (Moul, 2000). Unfortunately, the management of these patients remains controversial because the course of the disease is highly variable and there are no completed prospective randomized studies that directly address the questions of when therapy should be initiated, should treatment should be systemic or local, and whether an intervention prolongs life.

Within the clinical spectrum of men with a rising PSA value are (1) those in whom the rising PSA value reflects persistent or recurrent disease in the prostate or prostate bed, (2) those in whom the rising PSA value is a harbinger of detectable metastases, and (3) those with both local and systemic disease. Within the category of those with systemic disease are men who are at high risk of developing symptoms of or dying of their cancer. Such patients may well benefit from the early administration of systemic treatments to prevent metastases, to preserve quality of life, to delay the complications of osseous lesions, and to prolong survival. In other patients with systemic involvement the disease will follow a more indolent clinical course for which observation may be appropriate because the risk of developing metastases or symptoms, or of dying of the disease, may be very low during their life expectancy (Pound et al, 1999; Antonarakis et al, 2009). For these individuals, side effects from treatment may be worse than the anticipated morbidity of the cancer itself, exposing men to unnecessary toxicities. Some patients fall within these two extremes and warrant neither observation nor systemic treatments but rather additional therapy directed at the prostate or prostate bed.

Given this spectrum of disease, accurate methods of determining the clinical risk represented by a rising PSA value are critical to developing rational treatment strategies. Such clinical risks include the development of systemic rather than local disease, developing metastases, or dying of a prostate cancer–related cause. **In turn, evaluation of these risks will determine whether the cancer can potentially be eliminated by additional local therapy, and whether systemic therapy is likely to prevent a clinically significant event such as detectable metastases on imaging or death from disease. In both scenarios the therapeutic question is how to balance the need for therapy with the anticipated decrease in quality of life associated with treatment.**

A critical issue for patients is the anxiety associated with knowing that the cancer is "progressing." Men are diagnosed with and treated for prostate cancer earlier than ever, yet the symptoms most experience are related more to therapy than cancer. The clinical dilemma facing both the patient and the physician is how to balance the anxiety provoked by the rising PSA against the

paucity of objective data regarding who would benefit from treatment and what the tangible benefits might be from such interventions. In this discussion a framework is provided to assess the prognosis of patients in the state of a rising PSA (Scher and Heller, 2000) so that a rational risk-adapted approach can be implemented. This is done with the recognition that the tools for both prognostication and treatment continue to evolve and at present must be considered works in progress.

WHEN DOES A PATIENT OCCUPY THE CLINICAL STATE OF A RISING PSA VALUE?

Prostate Cancer: A States-Based Model

Prostate cancer presents a wide clinical spectrum from localized to metastatic and asymptomatic to symptomatic and is driven by a range of biologic factors that often change as the disease evolves. These variable disease manifestations can be segregated into patient groups, represented as easily recognizable clinical states that have shared clinical needs and treatment goals (Fig. 108–1) (Scher and Heller, 2000). Common treatment aims for patients with localized disease are eradication of the disease along with preservation of potency, continence, bladder and rectal integrity, and other quality-of-life measures. Patients with newly diagnosed metastatic disease have the treatment goal of maintaining disease control and prolonging hormonal sensitivity while minimizing the impact of hormones and other treatment strategies on quality of life and bone integrity. For patients with disease that is progressing despite androgen deprivation, the most acute issues are prolonging life and finding treatment strategies to mitigate the effects of an increasing burden of disease, such as pain, neurologic compromise, fatigue, hematologic disorders, and bone fracture.

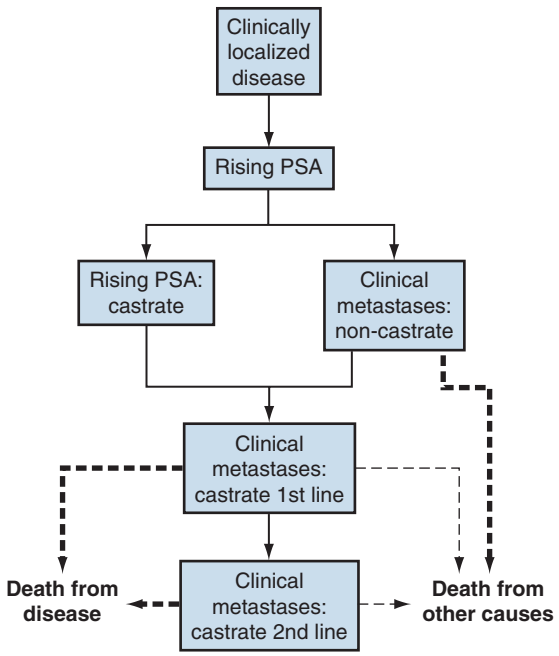

Figure 108–1. Prostate cancer can be considered as a series of clinical states. Each state defines a discrete set of patient characteristics, clinical needs, and treatment aims and therefore is a practical means of distinguishing patient populations and developing clinical trials. Prognostic models are developed on a state-by-state basis to risk-stratify patients in each state. PSA, prostate-specific antigen. (Modified from Scher HI, Heller G. Clinical states in prostate cancer: towards a dynamic model of disease progression. Urology 2000;55:323–7.)

Defining the Clinical State of a Rising PSA Value

Determining when a patient has entered the clinical state known as a "rising PSA" depends on the primary therapy the patient has received and the sensitivity of the assay used to measure his PSA level. By consensus, this clinical state does not include patients with localized disease who are being observed expectantly with "watchful waiting" or "deferred therapy." It also does not include patients who are receiving androgen deprivation in lieu of definitive treatment. As with many issues relating to prostate cancer there is no single uniform definition for "biochemical relapse." **A patient who has undergone a prostatectomy should have no (or minimal) remaining normal, viable, PSA-producing nonmalignant prostate tissue. In contrast, patients who have received external-beam radiation therapy or brachytherapy, whether alone or in combination, have an intact, although irradiated, gland with nonmalignant prostate epithelial cells that will produce low levels of PSA that are not indicative of treatment failure.** In addition, not all PSA assays have the same degree of sensitivity, so a patient's PSA level may be reported as undetectable in one laboratory but detectable at another. A further confounder is that PSA production can vary with testosterone levels. Patients who have undergone neoadjuvant or adjuvant hormonal strategies in conjunction with their local therapy may have variable rates of treatment failure on the basis of testosterone recovery rates. In general, testosterone levels return to baseline within 3 to 6 months after cessation of short-term gonadotropin-releasing hormone analogue treatment, but the recovery can be quite prolonged in individual patients (Padula et al, 2002; Gulley et al, 2005). Age, length of androgen deprivation, and even the type of gonadotropin-releasing hormone analogue therapy used will all impact the rate of biochemical failure (Lukka et al, 2001).

Radical Prostatectomy

As noted, post-prostatectomy patients may have very low levels of PSA that can represent benign prostate tissue at the surgical margin, and as a result there is debate as to what precise level of PSA definitively represents postsurgical treatment failure. The American Urological Association (AUA) Guideline Update Panel examined 319 publications reporting on patients with biochemical relapse, revealing that 166 different definitions were applied to these various studies. The most commonly used cut point was greater than 0.2 ng/mL. The panel recommended using a cut point of greater than or equal to 0.2 ng/mL, with a second confirmatory level of greater than 0.2 ng/mL, to define surgical failure (Cookson et al, 2007), although some authors have recognized that low levels such as 0.01 to 0.07 ng/mL can also represent failure (Amling et al, 2001; Gretzer et al, 2002; Han et al, 2003). It is important to be mindful that the detection of a single abnormal PSA level does not, in and of itself, necessarily indicate that a clinically significant event has occurred, and the presence of a rising PSA level alone does not necessarily imply that a patient will develop symptoms or die of his disease. A recent analysis of 3125 patients treated at Memorial Sloan-Kettering Cancer Center (MSKCC) demonstrated that the best cut point to predict the probability of metastatic

progression was greater than 0.4 ng/mL, followed by another rise (Stephenson et al, 2006). For clinical trial purposes, current consensus guidelines from the Prostate-Specific Antigen Working Group (Scher et al, 2004) recommend that a patient's disease is considered to have progressed after a radical prostatectomy if the PSA value is greater than or equal to 0.4 ng/mL 8 weeks or more after the procedure and rises on a subsequent measurement. Eight weeks is ample time to allow PSA levels to clear, given a half-life of 2 to 3 days (Oesterling, 1991). The "date of failure" is the date that the PSA level is first detectable.

Radiation Therapy

Biochemical failure after radiation therapy was traditionally defined by the American Society for Therapeutic Radiation Oncology (ASTRO) as three consecutive PSA rises, optimally separated by 3 months between measurements, beginning at least 2 years after the start of radiation therapy, with the time of failure as the midpoint between the nadir and the first confirmed rise, or any rise significant enough to trigger therapy (Consensus statement, 1997). Such a definition, however, has not been wholly satisfactory even to its authors. The guidelines did not adequately account for recovering testosterone levels in patients who had received neoadjuvant or adjuvant hormones, for transient post-treatment elevations in PSA (so-called "bounces") that do not represent disease relapse, for small serial rises in PSA that do not represent treatment failure, or for circumstances in which recurrent disease is not manifest in the form of strictly consecutive rises. In addition, bias was introduced by backdating the time of progression, given its sensitivity to the length and rigor of follow-up. To address these issues, new guidelines, termed the ASTRO Phoenix Criteria, were issued. These criteria recommend that biochemical failure be defined as a PSA rise of 2 ng/mL above the post-treatment nadir, whether or not the patient received hormonal therapy in conjunction with radiation therapy. The date at which that level was reached would be the date of relapse, and the practice of backdating would be abandoned. For patients who undergo salvage therapies such as with hormones, prostatectomy, or cryotherapy, failure would be declared not at the time of biochemical relapse but instead at the time of a positive biopsy or when salvage therapy was initiated. The consensus guidelines allowed, however, that the traditional ASTRO definitions were permissible if a patient underwent only external-beam radiation therapy or brachytherapy, provided that adequate follow-up was given and reported (Roach et al, 2006).

RADIOGRAPHIC AND OTHER TESTS TO DETERMINE WHETHER THE RISING PSA VALUE SIGNIFIES LOCALIZED DISEASE, METASTATIC DISEASE, OR BOTH

One of the most difficult aspects of formulating a treatment plan for the patient with a rising PSA level is determining whether it represents locally persistent disease or nonlocalized systemic disease or both. The stakes of such a decision are high. Treating every patient who has undergone a prostatectomy with salvage radiation therapy exposes patients with systemic disease to unnecessary radiation therapy and the risk, albeit low, of proctitis, cystitis, and a reduced likelihood of maintaining or preserving erectile function. On the other hand, with careful patient selection, salvage radiation therapy has the potential to eliminate the disease completely. **Current methods of detecting disease, whether in the prostatectomy bed, an irradiated gland, or metastatic sites such as bone or lymph nodes, are usually of very limited value.** Moreover, the finding of local disease on an imaging study does not exclude a systemic component, which explains in part why radiation therapy to the prostate bed, or salvage surgery after radiation therapy, is not curative for many patients (Laufer et al, 2000; Leventis et al, 2001).

Bone Scintigraphy and Computed Tomography

By definition, the finding of overt radiographic metastases on an imaging study signifies that a patient is no longer in the clinical state of rising PSA but rather has metastatic disease (see Fig. 108–1). Nevertheless, to ensure that patients do indeed have a rising PSA level in the absence of radiographically evident metastases, a staging evaluation should be undertaken. However, bone scintigraphy and computed tomography (CT) of the abdomen and pelvis, the traditional modalities utilized, are of limited value because they are insensitive at detecting early metastatic disease.

Bone scintigraphy will only detect metastatic disease that interferes with normal osteoblast/osteoclast interactions to produce abnormal bone deposition. Areas of marrow involvement that do not impact bone metabolism will remain undetected. Frequently, patients present to their clinician years before bone scintigraphy is likely to be positive. There is no single PSA value that predicts for scan positivity, although in most series PSAs will be well above 20 to 30 ng/mL before bone scintigraphy reflects metastatic disease (Cher et al, 1998). Even when bone scintigraphy is positive, tracer uptake in areas of trauma, infection, or inflammation can easily be mistaken for metastatic disease. More recently, a nomogram was developed to predict the likelihood of a positive scan. The nomogram included parameters that describe PSA kinetics—the PSA slope (odds ratio [OR], 2.71; $P = .03$) and PSA velocity (OR, 0.93; $P = .003$)—as well as the trigger PSA or current PSA value (OR, 1.022; $P < .001$). The concordance index for predicting the bone scan result was 0.93 (Dotan et al, 2005).

Another model has been generated from the CaPSURE database, a national registry of over 13,000 patients treated in more than 40 urology practices in the United States. Of 7311 patients treated with definitive local therapy from 1990 to 2004, 1551 experienced biochemical recurrence (using the traditional ASTRO definition for postirradiation patients and a cutoff of 0.2 ng/mL for postprostatectomy patients). Of the 292 patients who had imaging studies and adequate PSA data, trigger PSA (≥5 ng/mL) and PSA doubling time (PSADT) (<10 months) predicted positive imaging results (which included both bone scintigraphy and CT) with a high concordance index (c-adj 0.84) in a multivariate model (Choueiri et al, 2008).

CT is also suboptimal for the detection of metastasis not only because it has a lower limit of detection of 0.5 cm but also because the scans are nonspecific, making it difficult to distinguish scar tissue or fibrosis from tumor (Moul et al, 2001b).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) using an endorectal coil and a pelvic-specific acquisition methodology can reveal sites of recurrent disease in and around the prostate bed and bladder. In a preliminary study of endorectal MRI this modality correctly identified 39 of 41 patients (95%) thought to have locally recurrent

disease on the basis of a positive biopsy, reduction in PSA level after radiation therapy, or serial MR images that demonstrated an increase in local disease in the fossa. **Endorectal MRI may be able to identify sites of disease that would otherwise not be sampled by routine blind biopsies of the prostate bed and therefore may be useful for identifying areas suggestive of locally recurrent disease or for guiding biopsies** (Sella et al, 2004). In a prospective study of men who had undergone a prostatectomy, endorectal MRI detected locally recurrent disease in all 31 men with clinical evidence of locally recurrent disease, as confirmed by biopsy. Taking together these true positives with nine true negatives found in the study, the investigators considered the sensitivity and specificity of the modality to be 100% (Tatli et al, 2006). This modality, however, may well be more appropriate for the patient who has undergone a prostatectomy rather than radiation therapy, because of treatment-related changes in the latter group.

Positron Emission Therapy

Positron emission tomography (PET) is another area actively under investigation for identifying occult metastatic or locally recurrent disease. Because fluorodeoxyglucose (FDG) is excreted through the kidneys, detection of nodal and locally recurrent disease, even in highly controlled patient populations with known progressive metastatic disease, can be challenging. In one study of 43 patients with definitively established progressive metastatic disease, patients were scanned both with FDG PET imaging as well as standard bone scintigraphy. Of the 1720 bones examined, the PET and bone scans were concordant in 1600 bones (93%) in terms of reflecting the presence or absence of metastatic disease. Of the 121 bones in which there was metastatic disease on the PET but not the bone scan, 84 (80%) ultimately became positive on the bone scan, suggesting that PET can detect disease earlier than bone scintigraphy in many patients (Meirelles et al, 2010).

Schoder and colleagues (2005) used FDG-PET to examine patients with prostate cancer with a rising PSA level. Images were interpreted using a composite, though unvalidated, reference: a positive biopsy, decrease in PSA value after irradiation to the primary site, development of a detectable lesion in the primary site on follow-up conventional imaging studies, and increase in lesion size on follow-up imaging or concurrent other imaging studies within 90 days of PET. A positive FDG-PET was found to correlate with these standards in 31% of cases. Positive cases were more likely to be found in patients with higher PSA values (>9.5 ng/mL), and the probability of a positive scan correlated with PSADT (Schoder et al, 2005). In a retrospective study Chang and colleagues (2003) examined 24 patients with a rising PSA level; PET findings were correlated with pathologic evaluation from a lymph node dissection, the gold standard for disease confirmation. At the sites of pathologically proven metastases, increased FDG uptake suggestive of metastatic disease was found in 12 of 16 patients (75%) (Chang et al, 2003).

Although there have been few well-controlled prospective studies of FDG-PET there are concerns about the ability of FDG to detect local and early metastatic disease, prompting investigations of newer PET modalities. Prostate cancer is associated with upregulated choline kinase activity and increased choline uptake. Choline is a component of phosphatidylcholine, which is a class of phospholipids and a major component of biologic membranes. Choline can be labeled with either carbon-11 ([^{11}C]choline) or fluorine-18 ([^{18}F]fluorocholine). In a prospective study, Scattoni and colleagues (2007) assessed 25 patients with PSA relapse and no evidence of local disease or bone metastases on conventional imaging who were imaged with [^{11}C]choline-PET/CT and then underwent pelvic lymph node dissection. [^{11}C]choline-PET/CT showed abnormal uptake in lymph nodes in 21 patients, 19 of whom had nodal metastases confirmed by histopathology. By comparison, CT or MRI revealed abnormal lymph nodes in 12 patients (Scattoni et al, 2007). Rinnab and colleagues (2007) retrospectively evaluated [^{11}C]choline-PET/CT detection of nodal recurrence in 50 patients in the presence of a rising PSA value. The overall sensitivity of PET/CT was 95% and specificity was 40%. Fluorinated choline (FCH) is also being studied because it has the advantage of a half-life of 110 minutes versus a half-life of only 20 minutes with [^{11}C] choline (DeGrado et al, 2001a, 2001b, 2002; Hara et al, 2002; Cimitan et al, 2006).

Another PET tracer under investigation is [^{11}C]acetate, because a high concentration of [^{11}C]acetate in primary and metastatic lesions has been seen in prostate cancer (Oyama et al, 2002). An advantage of [^{11}C]acetate is that it is not excreted by the kidneys, making it easier to visualize pelvic disease. In a preliminary study, uptake of [^{11}C]acetate and [^{11}C]choline radiotracers appeared similar (Kotzerke et al, 2003). Other preliminary studies suggest that radiolabeled acetate may detect locally recurrent disease, although all of these studies have been small and have had heterogeneous end points and populations (Sandblom et al, 2006). **At this time, PET should be considered investigational, and a positive PET should not be considered definitive proof that a patient has either metastatic or locally persistent disease.**

Antibody-Based Imaging

ProstaScint is the only imaging agent approved by the U.S. Food and Drug Administration (FDA) to detect occult metastatic disease in patients with early prostate cancer. It also is indicated for patients with a rising PSA and a negative or equivocal standard metastatic evaluation when there is a high clinical suspicion of metastatic disease. The basis of this scan is a murine antibody, 7E11, that is combined with indium-111 to target the internal domain of prostate-specific membrane antigen (PSMA), a transmembrane type II glycoprotein found on normal prostate tissue and prostate cancers (Israeli et al, 1993, 1994). However, anti-PSMA antibodies also are taken up in the gut, liver, kidney, and other normal tissues. ProstaScint scanning is associated with a significant number of false-positive and false-negative results, in part related to these areas of uptake (Sartor and McLeod, 2001) in part owing to inflammation and even in part owing to vascular sludge (Hinkle et al, 1998). The specificity of the test may be increased if the images obtained are fused with MRI (Schettino et al, 2004).

Biopsies and Clinical Decision Making

Many clinicians opt to sample palpable abnormalities in the prostate bed in a postprostatectomy patient. Indeed, even radiographic findings that are suggestive of locally recurrent or locally persistent disease may warrant pathologic confirmation. **Biopsy specimens that reveal locally persistent disease may prompt a decision to choose salvage radiation therapy or systemic therapy for at least local control of palpable tumor masses. However, most patients will not have palpable lesions, and most patients will not have evidence of locally recurrent disease. The yield of blind biopsies in the prostate bed is usually low, tends not to affect**

clinical decision making, poorly predicts for the efficacy of salvage radiation therapy, and should not be considered a standard of care (Leventis et al, 2001; Scher et al, 2004).

By contrast, performing a biopsy to prove locally persistent disease in the prostate after external-beam radiation therapy is essential before recommending that a patient receive a salvage radical prostatectomy, cryosurgery (Izawa et al, 2002), brachytherapy (Beyer 1999), or intraprostatic biologic or cytotoxic treatment. Because the risk of false-positive biopsy findings declines 2 years after the completion of radiation therapy, clinicians should wait at least that long before opting for biopsy.

MODELS TO PREDICT LOCAL VERSUS SYSTEMIC RECURRENCE AND TO PREDICT SURVIVAL

For the overwhelming majority of patients, biochemical relapse occurs far earlier than the development of radiographically evident findings or findings on physical examination or by biopsy. Given the limitations of these diagnostic studies, the focus of the clinician should be on using the PSA as a predictor of whether the patient will develop overt metastases, symptoms, or a high risk of death from disease. With such prognostic tools of clinical events the need for treatment can be determined and consideration can be given to what options are available and their likelihood of success in controlling the disease or, preferentially, eliminating it completely (Beekman et al, 2005).

Many prognostic and predictive models have been reported. Some use determinants that reflect the disease at the time of initial diagnosis and treatment, others at the time of relapse, whereas others center on PSA kinetics after the disease has definitively relapsed biochemically. All of the models "work" in defining what they are designed to predict. Indeed, clinicians are often at a loss to decide which of several models to use in predicting a key clinical event. Multiple models now exist to predict the likelihood of a patient transitioning to the clinical state of a rising PSA value (D'Amico et al, 1998; Zelefsky et al, 1998; Moul et al, 2001a), the likelihood that a surgically removed tumor would have a specific pathologic stage according to pretreatment clinical features such as PSA or Gleason score (Partin et al, 1993, 2001; Roach, 1993, 1996), and the likelihood a patient with localized disease would achieve a given median survival (Roach et al, 2000; Vollmer and Humphrey, 2001; D'Amico et al, 2002; Sandler et al, 2000). Nomograms also have been developed that combine many of these prognostic determinants, treat them as continuous variables in multivariate models, and allow specific predictions of an outcome for a patient with given clinical features (Kattan et al, 2000).

The models that have specific relevance to patients in the clinical state of a rising PSA value fall into several categories and are summarized in Table 108–1.

Predicting Local versus Systemic Relapse

The first question the clinician evaluating a patient with a rising PSA value must address is where is the disease? In general, low pretreatment PSA levels, lower-grade tumors, low clinical or pathologic staging, late time from definitive local therapy to PSA relapse, and long PSADTs generally indicate a low likelihood of developing distant radiographically apparent metastases (Pound et al, 1999). Such patients can have durable remissions after salvage radiation therapy to the prostate bed (Moul, 2000; Leventis et al, 2001). Another modeling strategy is to examine patients who have successfully been "cured" using salvage radiation therapy and extrapolate from those data which features predict for exclusively locally recurrent disease. Features such as negative/close margins ($P = .03$), absence of extracapsular extension ($P < .01$), and presence of seminal vesicle invasion ($P < .01$) have been shown to predict for successful salvage radiation therapy (Katz et al, 2003). One multivariate model, derived from a retrospective examination of a multi-institutional database of patients who underwent salvage radiation therapy, showed that predictors of progression following salvage radiation therapy were Gleason score of 8 to 10 (hazard ratio [HR], 2.6; 95% CI, 1.7 to 4.1; $P < .001$), pre-radiotherapy PSA level greater than 2.0 ng/mL (HR, 2.3; 95% CI, 1.7 to 3.2; $P < .001$), negative surgical margins (HR, 1.9; 95% CI, 1.4 to 2.5; $P < .001$), PSADT of 10 months or less (HR, 1.7; 95% CI, 1.2 to 2.2; $P = .001$), and seminal vesicle invasion (HR, 1.4; 95% CI, 1.1 to 1.9; $P = .02$) (Stephenson et al, 2004).

A subsequent report by Stephenson and colleagues (2007), which included a larger group of patients (1540) from 17 tertiary care centers who were observed over a median of 53 months, validated the accuracy of the previous model. In the updated model the same cut points yielded a clinical outcome within 10% of the original model. Based on these data a nomogram predicting the 6-year progression-free probability was constructed. The trigger PSA for radiation therapy was found to be highly predictive of progression-free probability because patients with a trigger PSA of 0.5 ng/mL or lower had nearly double the likelihood of remaining disease free than those treated at higher PSA levels (26% vs. 48%). Other predictive factors were Gleason grade, doubling time, margin status, neoadjuvant hormonal treatment, and nodal status (Stephenson et al, 2007).

A second model examined 368 patients treated at multiple Mayo Clinic locations. This model again confirms that trigger PSA, doubling time, and pathologic staging are prognostic of a patient remaining disease free after salvage radiation therapy and that seminal vesicle involvement, Gleason score 8 to 10, and pre-radiotherapy PSA (treated as a continuous variable) are predictors of treatment failure (Buskirk et al, 2006).

In a third model, derived from 211 patients, factors predictive of biochemical failure included a PSADT of less than 12 months (HR, 3.88; $P = .032$), seminal vesical invasion in the surgical specimen (HR, 3.22; $P = .08$), pathologic grade (HR, 1.58; $P = .23$), and the PSA value at the time of salvage radiotherapy (HR, 1.29; $P = .04$) (Ward et al, 2004).

At what point should the odds of "predicted" success or failure justify recommending treatment is controversial, with the recognition that external-beam radiation therapy can, under the appropriate circumstances, offer at least a potential for disease eradication.

Risk of Developing Metastatic Disease

A corollary to distinguishing between which patients will benefit from salvage radiation therapy and which have micrometastatic disease is to model the risk and timing of developing radiographically evident metastases. Pound and colleagues (1999) observed a cohort of men who underwent radical prostatectomy, had biochemical relapse, and were observed without therapy until symptomatic or metastases

Table 108–1.

Models to Predict Clinically Significant Events in Patients with a Rising PSA Value after Definitive Local Therapy

STUDY	NO. PATIENTS	EVENT PREDICTED	Prognostic Variables				
			PSADT	MARGIN	GLEASON	PSA	OTHER
Leventis et al, 2001	49	Biochemical relapse-free survival after salvage RT	Treated as continuous, HR 0.30 (0.11-0.83; $P = .02$)	NA	NA	Pre-RT PSA treated as continuous, HR 3.22 (1.16-8.93, $P = .025$)	NA
Stephenson et al, 2004 (updated and validated in Stephenson et al, 2007)	501	PSA progression after salvage RT	≤10 mo, HR 1.7 (1.2-2.2; $P = .001$)	Negative margin HR 1.9 (1.4-2.5, $P < .001$)	Gleason 8-10, HR 2.6 (1.7-4.1; $P < .001$)	Pre-RT PSA > 2, HR 2.3 (1.7-3.2; $P < .001$)	SVI, HR 1.4 (1.1-1.9; $P = .02$)
Ward et al, 2004	211	PSA progression after salvage RT	≤12 mo, HR (3.88; $P = .032$)	SVI, HR (3.22; $P = .023$)	Pathologic grade (HR 1.58; $P = .023$)	2-fold increase (HR 1.29; $P = .04$)	NA
Pound et al, 1999	5079	Metastasis-free survival	≤10 mo, poor prognosis (Gleason ≤ 7 only)	NA	Gleason 8-10, poor prognosis	NA	≤2 years to biochemical failure, poor prognosis
Zagars and Pollack, 1997	841	Metastasis-free survival	≤8 mo, poor prognosis	NA	NA	NA	NA
Roberts et al, 2001	587	Metastasis-free survival	<0.5 yr, RR 62; 0.5-0.9 year; RR 9.1; 1-9.9 yr, RR 4.1	NA	NA	NA	NA
Zelefsky et al, 2005	381 (all patients)	Metastasis-free survival	Continuous, HR 0.59 (0.49-0.71); $P = .001$	NA	Gleason 7-10, HR 1.0 (1.2-3.3; $P = .007$)	NA	NA
Zelefsky et al, 2005	229 (no neoadjuvant ADT)	Metastasis-free survival	Continuous, HR 0.54 (0.41-0.70)	NA	Gleason 7-10, HR 2.7 (1.4-5.2; $P = .002$)	NA	T3 or T4, HR 2.0 (1.2-3.6; $P = .01$)
Kwan et al, 2004	1786	Overall survival (disease-specific survival is also included)	NA	NA	Grouped by overall risk category, $P < .001$	Any evidence of biochemical failure, $P < .001$; absolute PSA level, $P = .168$	T stage, $P = .033$ PSA
Lee et al, 1997	151	Disease-specific survival and overall survival	NA	NA	$P = .004$ (disease specific) or .03 (overall)	NA	NA
Sandler et al, 2000	154	Cause-specific survival	Relative PSA rise and log of slope of rise ($P < .001$ and .007)	NA	NA	NA	NA
D'Amico et al, 2002	94	Cause-specific death and all-cause death	≤12 mo ($P = .03$ cause specific; $P = .05$ all causes)	NA	NA	NA	NA
D'Amico et al, 2003	1451	Cause-specific mortality	<3 mo, HR 19.6 (12.5-30.9)	NA	NA	NA	PSADT ≥3 mo (continuous) HR 0.78 (0.74-0.82)
Trock et al, 2008	635	Cancer-specific mortality	<6 mo, HR 0.36 ($P < .001$)	Not significant	8-10 HR 1.77, $P = .003$	Trigger PSA of 2 ng/mL, HR 0.27	NA

ADT, androgen-deprivation therapy; HR, hazard ratio; NA, not applicable (either not analyzed or not statistically significant in a multivariate model); PSA, prostate-specific antigen; PSADT, prostate-specific antigen doubling time; RR, relative risk; RT, radiation therapy; SVI, seminal vesicle invasion.

were found radiographically. As one would anticipate, high-grade disease, short time to biochemical relapse (≤2 years vs. >2 years), and a PSADT of less than 10 months versus 10 months or more predicted for a shorter time to radiographic progression. An updated analysis has been presented based on 8801 men who underwent prostatectomies, in 774 of whom the disease biochemically relapsed, and who were observed for a median of 8 years. In this updated cohort, patients could be stratified by doubling times of less than 3, 3 to 9, 9 to 15, and 5 or more months, by Gleason score (≥8 vs. <8), and by time to relapse (>3 vs. ≤ 3 years). Median time to metastatic disease was 10 years for the entire group, but, underscoring the heterogeneity of this disease state, those with the shortest doubling times developed metastatic disease at a median of 1 year (95% CI, 0 to 1 year), whereas those with a 15-month or more doubling time did not develop metastases for 10 years (95% CI, 9 to 15 years) after biochemical relapse (Antonarakis et al, 2009).

In numerous studies, PSADT is the dominant factor used to assess the risk of developing metastasis-free survival (Roberts et al, 2001; Valicenti et al, 2006). In one study, a PSADT of 6 months or less was associated with a 5-year progression-free survival of 64% versus 93% of patients who had a longer PSADT (Roberts et al, 2001). In the Mayo Clinic series, metastases were detected at 5 and 10 years, respectively, in 10% and 29% of patients with a PSADT of 12 months or less versus 0% and 17% for those with a longer PSADT. The estimation was based on a total of 23 metastatic events representing 10% (23 of 211) of the population studied (Ward et al, 2004). In a series of 1650 patients treated with external-beam radiation therapy at MSKCC, 381 (23%) developed biochemical recurrence, of whom 98 (26%) developed distant metastases at an incidence of 10%, 21%, and 29% at 1, 3, and 5 years, respectively. In a multivariate competing-risk regression model, PSADT ($P < .001$), clinical T stage ($P = .001$), and Gleason score ($P = .007$) from the time of diagnosis were the only independent variables that predicted for distant metastases. At 3 years, patients with a PSADT of 0 to 3, 3 to 6, 6 to 12, and 12 months or more had a frequency of metastasis of 49%, 41%, 20%, and 7%, respectively ($P < .001$), at a relative risk of 7.0-, 6.6-, and 2.8-fold higher than those with a more than 12-month doubling time. The median follow-up time was 92 months from the completion of radiation therapy.

Concerns regarding the use of PSADT are that at present there is no consensus regarding the optimal number of PSA values that should be used, the time interval over which they should be determined, whether these values need to be consecutive, and whether these values should be separated by a minimum period of time. Complicating the issue further is that PSA values can fluctuate independent of treatment. Most calculations are based on a first-order kinetics assumption that

$$PSA(t) = PSA(0)e^{at}$$

where "a" is the relative velocity of PSA. Published reports are inconsistent, but in the authors' experience a minimum of 3 (ideally 4 or 5) measurements are required. Given this, upwards of one third of the PSA profiles in this patient population follow higher-order kinetics; therefore the equation does not represent the kinetics for upwards of 30% of patients (Carter et al, 1992; Patel et al, 1997). Higher-order mathematical methods may better describe the PSA profiles for these men.

Another confounder in calculating PSADT is the effect of neoadjuvant or adjuvant hormonal therapy administered during radiation therapy. Rapid testosterone recovery may induce a rapid PSA rise, which may not reflect disease kinetics. Such a patient may not be at a significant risk of developing metastatic disease despite a seemingly rapid doubling time, because if he was observed long enough for the testosterone level to stabilize the rate of rise in PSA level could plateau or at least slow.

Risk of Disease-Specific and All-Cause Risk of Death

Data exist that demonstrate an association between PSADT and disease-specific survival after radiation therapy (Lee et al, 1997; Zagars and Pollack,1997; Sandler et al, 2000; D'Amico et al, 2002, 2003a, 2003b) and between a post-treatment PSADT and time to prostate cancer–specific mortality and all-cause mortality (all P[Cox] < .001). These data are illustrated in Figure 108–2. In this, the hazard ratio for death from prostate cancer for a patient with a PSADT of less than 3 months after surgery or radiation therapy was 19.6, with a 95% CI of 12.5 to 30.9 (D'Amico et al, 2003b, 2004b). **It is therefore reasonable to incorporate PSADT when considering whether any salvage strategy is worth applying, whether systemic therapy is more appropriate, and whether such systemic options should be applied early or should be deferred.**

In what is perhaps the largest series, Freedland and colleagues (2005) evaluated 5096 patients who underwent surgery at an urban tertiary care hospital between 1982 and 2000, with a mean and median follow-up of 6 and 5 years, respectively. Of these, 979 (19%) developed a biochemical recurrence and 379 (7.6%) who were deemed to have systemic as opposed to local progression had a minimum of two PSA values to estimate the doubling times. Sixty-six patients (1.3% of the entire group) died of prostate cancer during follow-up. Overall, 6% had a doubling time of less than 3 months and 15% of less than 6 months. Considering the entire cohort, the 5-, 10-, and 15-year cause-specific survival from the time of biochemical recurrence was 93% (95% CI, 90% to 96%), 73% (95% CI, 66% to 79%), and 55% (95% CI, 41% to 67%), respectively. Patients were stratified into high-risk and low-risk categories using the Gleason score from the radical prostatectomy specimen, time from surgery to PSA relapse, and PSADT. In one example, the median survival of the 23 patients with a PSADT of less than 3 months was 6 years; for the 15 patients with a PSADT of less than 3 months, biochemical recurrence of 3 years or less, and pathologic Gleason score of 8 to 10, the median survival was only 3 years. This contrasted to a 100% 15-year cause-specific survival for those with a PSADT of 15 months or more and a biochemical recurrence of more than 3 years after surgery. Using different combinations of these same variables, cohorts of patients with 15-year survivals ranging from 94% to less than 1% could be derived.

In an attempt to define what factors at the time of surgery might independently predict for developing a rapid PSADT after biochemical relapse, Teeter and colleagues (2008) examined data from 856 men listed in the Shared Equal Access Regional Cancer Hospital Database. PSA (OR, 2.20; 95% CI, 1.52 to 3.19), Gleason score greater than or equal to 8 (OR, 4.70; 95% CI, 2.11 to 10.43) or 7 (OR, 2.11; 95% CI, 1.09 to 4.08), and stage pT3a or worse disease (OR, 2.08; 95% CI, 1.48 to 3.91) were all predictors of developing a PSADT of 9 months or less.

These analyses share certain limitations: they were retrospective; the imaging modalities used to detect disease were not the same, nor were they performed at fixed intervals; and the numbers of events on which the models are based were often quite small.

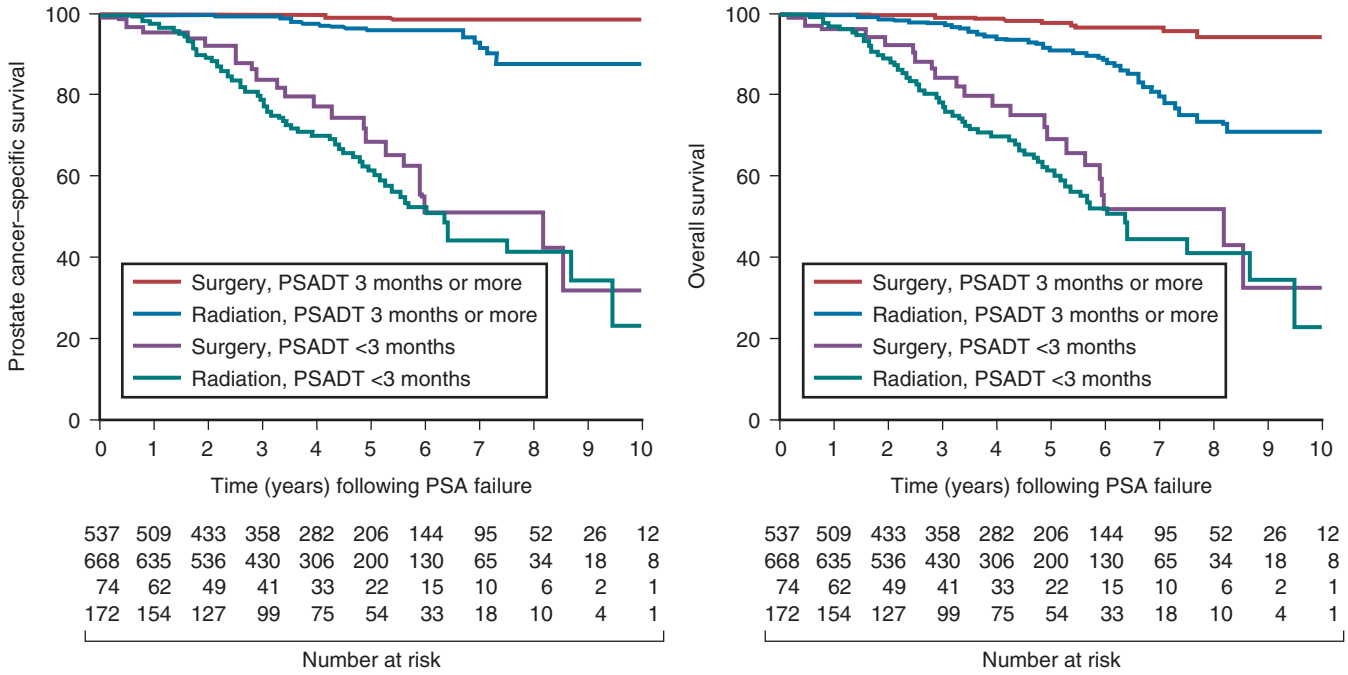

Figure 108–2. Prostate-specific antigen doubling time (PSADT) can be used to predict disease-specific *(left)* or all-cause *(right)* mortality for patients who have a rising PSA. In the model shown, patients are stratified on the basis of primary therapy and PSADT. Such models exist to predict for developing radiographically evident metastases as well and are crucial for rational clinical decision making and clinical trial design. (From D'Amico AV, Moul JW, Carroll PR, et al. Surrogate end point for prostate cancer–specific mortality after radical prostatectomy or radiation therapy. J Natl Cancer Inst 2003;95[18]:1376–83.)

Consequently, the confidence limits around the estimated survival probabilities are large. Despite these limitations the models, and in particular the PSADTs, do provide prognostic information. They do not, however, represent surrogate markers for metastatic progression or survival because they were not derived from prospective randomized comparisons in which a beneficial effect of treatment was shown.

TREATMENT STRATEGIES FOR THE PATIENT WITH A RISING PSA VALUE

It is essential to recognize that treatments given to patients with a low risk of a clinically significant event can be harmful in ways not traditionally assessed in clinical trials. In fact, few studies have systematically and prospectively assessed the compromises in patients' cognitive function and emotional well-being, overall quality of life, sexual health, cardiovascular risk, or bone integrity as primary end points. Those studies that have been performed suggest that hormonal therapy can be detrimental in all of these areas (Herr and O'Sullivan, 2000; Berruti et al, 2002; Green et al, 2004; Shahinian et al, 2005; Keating et al, 2006; Saigal et al, 2007; Tsai et al, 2007).

These potential drawbacks of hormonal therapy must be at the forefront of practitioners' minds when making decisions about this patient population, given that there are no prospective randomized data comparing any hormonal approach against no treatment for this group of patients. **Deferring treatment, especially for low-risk patients, may indeed be in the patient's interest, difficult as it may be for both patient and clinician to observe the patient's disease "progress" by a rising marker.** Indeed, the American Society of Clinical Oncology Clinical Practice Guidelines formally argue against an "early" treatment policy, with the caveat that patients preferentially should be entered into clinical trials (Loblaw et al, 2004, 2007).

Adding to this conundrum is that clinicians have no data regarding the optimal PSA value at which to initiate treatment, even for patients who are at high risk of suffering or dying of their disease. Some practitioners have advocated that androgen deprivation be started at the time of biochemical relapse, or at arbitrarily established thresholds, such as when the PSA level reaches 10 or 20 ng/mL. Such thresholds are based on data indicating that the risk of developing radiographically evident metastases increases as the PSA level rises. However, guidelines based on absolute PSA levels generally do not account for the rate of PSA level rise, Gleason score, or pretreatment PSA level, all of which have been shown, as described earlier, to be important prognosticators of time to metastatic disease, progression-free survival, and overall survival. Therefore, contemporary models that determine an individual patient's risk of metastatic progression and death from disease should be used as the basis for risk assessment in this population. What level of risk is tolerable in a given time frame is a decision to be made after a thorough discussion between the patient and his physician.

Neither clinicians nor patients, however, are immune to the impact of a significant body of literature suggesting that early hormonal therapy has the potential to confer a survival advantage in selected patients relative to hormonal therapy that has been deferred until metastases are radiographically evident. Most are randomized trials of androgen deprivation applied before, during, and after radiation therapy for variable amounts of time (from 6 months to continuously), which show improvements in disease-free and overall survival compared with either no hormonal therapy or hormonal therapy that has been deferred until diagnosis of metastatic disease (Lawton et al, 2001; Bolla et al, 2002; Pilepich et al, 2003, 2005; D'Amico et al, 2004a, 2008; Horwitz et al, 2008).

Table 108–2.

Prospective Randomized Studies of Deferred Versus Early Hormones*

STUDY	NO. PATIENTS	STAGE	THERAPY	FOLLOW-UP (yr)	OVERALL SURVIVAL (%)
RTOG 85-31 (Pilepich et al, 2005)	977	T3 or any T/N1	None vs. goserelin indefinitely	8	39 vs. 49; $P = .002$
EORTC 22863 (Bolla et al, 2002)	415	T1-2 (WHO grade 3)/ N1-N2 or T3-4/N0-1/M0	None vs. goserelin × 3 yrs	5	62 vs. 78; $P = .0002$
D'Amico et al, 2008	206	T1b-T2b + unfavorable risk factor	None vs. LH-RH/ flutamide	8	HR 1.8; $P = .01$
Messing et al, 1999, 2003, 2006	98	Node + after RRP	Goserelin or orchiectomy vs. observation	12	64 vs. 45; $P = .001$ (HR 1.84; $P = .04$)
EORTC 30891 (Studer et al, 2006)	985	T0-4N0-2M0	Immediate vs. deferred ADT	8	48 vs. 43; HR 1.25 (noninferiority $P > .1$)

*None addresses the rising prostate-specific antigen population directly, but using the results of these trials and the models in Table 108–1 can help the clinician decide whether a given patient would benefit from early hormonal therapy.

ADT, androgen-deprivation therapy; HR, hazard ratio; LH-RH, luteinizing hormone–releasing hormone; RRP, radical retropubic prostatectomy.

These trials are summarized in Table 108–2. Most of these trials are underpowered and do not consider recent trials supporting a deferred or intermittent therapy approach. In addition, the problem with using these trials as a basis for deciding on early hormonal therapy for patients with a rising PSA level is that patients with localized disease are not directly comparable to patients whose treatments have failed and who are now at risk of developing radiographically apparent metastases as the next point in the natural history of their disease.

As a result, one cannot assume that patients with a rising PSA value will derive the same benefits demonstrated in trials with patients occupying other clinical states. Hence, to the strictest and most orthodox adherents of evidence-based medicine, the standard of care for these patients should be observation or registration to a clinical trial. Such practitioners argue that there are no clinical data to demonstrate that hormones applied at biochemical relapse make patients live longer than hormones applied at the time of metastatic disease and that early hormonal therapy subjects such patients to a risk of impotence, gynecomastia, depression, weight gain, osteoporosis, fatigue, anemia, or other hormone-related disorders, with no proven benefit.

Some practitioners have treated these patients with antiandrogen monotherapy, based on results of the Early Prostate Cancer trial. In this series of studies, 8113 men with T1-4, Any N, M0 disease (although eligibility mandated N0 status in one study) were randomized to receive either 150 mg of bicalutamide or placebo in addition to standard care, which was either surgery, radiation, or observation. No difference in survival between the two study arms was seen in the overall population (HR, 1.03; 95% CI, 0.92 to 1.15; $P = 0.582$), although the patients with localized disease on observation appeared to have a survival decrement if they received bicalutamide (HR, 1.23; 95% CI, 1 to 1.5; $P = .05$) (Iversen et al, 2004; Wirth et al, 2004; McLeod et al, 2006). The use, however, of a non–testosterone-lowering form of androgen deprivation as adjuvant or primary therapy cannot be extrapolated to using testosterone-lowering therapy in a group of patients with a rising PSA level whose primary tumors have been treated. Single-agent bicalutamide has been studied in patients with either metastatic or locally advanced disease in two trials, but again neither study directly addressed the population at hand (Boccardo et al, 2002; Tyrrell et al, 2006).

Moul and colleagues (2004) retrospectively examined data collected from the Center for Prostate Disease Research Multicenter National Database (a Department of Defense program) on 1352 patients who had undergone a prostatectomy in the PSA era and who had experienced biochemical relapse. Various PSA cut points relative to when these patients were started on androgen deprivation therapy were examined, as were Gleason scores and other prognostic indicators. Interestingly, initiating hormonal therapy early did not appear to impact time to metastatic disease, which was the primary end point examined, in the overall population studied. On the other hand, time to metastatic disease was delayed in patients with Gleason score 8 to 10 tumors and those with PSADTs of 12 months or less (HR, 2.12; $P = .01$) if hormones were started at a PSA level of 5 ng/mL or less as opposed to 10 ng/mL or less. Unfortunately, these data do not inform the clinician as to whether early hormones in this population prolong survival but the data strongly suggest that the clinician should carefully select the patients he or she ultimately subjects to such therapy.

Once the decision is made to administer treatment the questions that arise are the same as those relating to the use of hormonal therapy in patients with clinical metastases (Wirth et al, 2004): Can intermittent hormones mitigate the side effects of androgen deprivation and improve the period of time of sensitivity to androgen withdrawal? Is total androgen blockade superior to orchiectomy or gonadotropin-releasing hormone monotherapy? Does high-dose bicalutamide prolong overall survival or shorten it (as in patients with localized disease)? These questions are the source of great discussion and debate. A recently completed phase III trial has done much to establish intermittent hormonal therapy as a standard of care in the rising PSA population (Klotz et al, 2011). In this study, men with a rising PSA >3 ng/mL who biochemically relapsed in excess of 1 year after radiation therapy were randomized to either intermittent hormones or continuous androgen deprivation. The primary endpoint was demonstrating noninferiority of the two arms in regard to overall survival, with secondary endpoints of time to castration-resistant disease, quality of life, and various endocrinologic parameters. A total of 1386 patients were randomized, with a median follow-up of 6.9 years. The two arms did indeed have no significant difference in overall survival (HR, 1.02 with a P for noninferiorrity of .009). Time to castration resistance was improved in the intermittent hormonal therapy arm (HR, 0.80; $P = .024$), and while more deaths from disease were seen in the intermittent hormones arm, there were fewer unrelated deaths in the intermittent arm as well. This trial therefore allows the clinician to consider intermittent hormones to be a standard, if not the standard, of care in the rising PSA population.

CLINICAL CONSIDERATIONS REGARDING LOCAL TREATMENTS

Patients who have demonstrable disease in the prostate bed may be considered for salvage radiation therapy and/or hormonal therapy specifically for the purposes of local control (rather than cure) and for preservation of pelvic functionality. Although there is uncertainty as to when these symptoms might occur, patients with local tumor masses are at risk for bowel and urinary obstruction, pain, and bleeding, and the avoidance of these events is critical to preserving quality of life. Whether this is best achieved with androgen deprivation alone is uncertain.

Patients who are anticipated to survive longer than the median duration of androgen deprivation (which generally is no longer than 2 years) may fare better with salvage radiation therapy in addition to or instead of hormonal therapy. In one analysis of 42 patients with a rising PSA level after prostatectomy with palpable cancer on digital rectal examination, patients who underwent salvage radiation therapy had a median rate of remaining free of recurrent local disease of 94%, despite the fact that only 27% of patients were free of biochemical progression (Macdonald et al, 2003).

In another investigation of 35 patients with locally recurrent disease that was clinically evident by biopsy or physical examination, the 8-year clinical relapse-free survival rate was 80% (vander Kooy et al, 1997). Although patients with clinically evident locally recurrent disease may have a worse overall prognosis than patients with a rising PSA alone (in one study, median survival was 78% vs. 96%, respectively; $P = .02$) (Macdonald et al, 2004), salvage radiation therapy may be an important tool in preserving quality of life.

However, the majority of patients in this clinical state will not have clinically evident disease in conjunction with a rise in PSA value. It is for these patients that models were developed to help assess the likelihood of durable PSA control after salvage radiation therapy. In the model of Stephenson and colleagues (2007) favorable outcomes were associated with long PSADTs and lower Gleason scores. In addition, a low PSA level at the start of radiation therapy ("trigger PSA") was associated with a favorable outcome, because 48% of patients who had a trigger PSA of 0.5 ng/mL had a 6-year progression-free survival, compared with 26% for those treated with higher trigger PSA values. Finally, late time to relapse (>2 years) and positive surgical margins were favorable prognostic indicators.

In contrast, 635 men who experienced biochemical relapse after radical prostatectomy and received salvage radiation therapy at Johns Hopkins Hospital were retrospectively analyzed by Trock and colleagues (2008) for disease-specific survival. In the overall population studied, patients who underwent salvage radiation therapy were significantly less likely to die of prostate cancer at 5 and 10 years than those who did not (0.96 and 0.86 vs. 0.88 and 0.62, respectively, $P < .001$), regardless of whether hormones were used with the radiation therapy. Many of the elements of this model disagree with those of the model of Stephenson and colleagues. In the analysis of Trock and colleagues, patients with short PSADTs (<6 months) who had salvage radiation therapy died at a significantly lower rate than their counterparts who did not receive salvage therapy, with a reduction in risk of prostate cancer–specific mortality of more than 75%. Men with longer PSADTs appeared not to benefit from salvage radiation therapy. In addition, receiving radiation therapy within 2 years of surgery and at a trigger PSA level of 2 ng/mL or less predicted for longer disease-specific survival. It should be noted that the models of Stephenson and Trock and their colleagues differ in end points—the former used progression-free survival whereas the latter used disease-specific survival—and the databases differ as well; nonetheless, contrasting these analyses gives the clinician pause and generates uncertainty as to who should be referred for salvage radiation therapy. It is the authors' practice to err on the side of potentially increasing survival by over-referring patients for radiation therapy rather than under-referring them. Certainly, however, the health status of the patient and the potential for rectal and urinary toxicities should lessen the temptation to simply refer all patients for salvage radiation therapy.

CLINICAL TRIAL CONSIDERATIONS

Patients and Agents

The rate of referrals to trials of neoadjuvant and adjuvant therapy has historically been low, in spite of the possibility that systemic therapy may be more effective in the earliest stages of the disease. Systemic therapy that confers only modest benefits in the latest phases of disease has been shown, in colorectal, thoracic, and breast malignancies, to be more effective in patients with early disease and is now the standard of care in those malignancies. But despite the fact that the response proportions with chemotherapy in prostate cancer are equivalent to or exceed those of the diseases just cited, neoadjuvant and adjuvant trials in prostate cancer have been slow to accrue, owing to both physician and patient reluctance to join such studies.

By contrast, patients who have a rising PSA level are ideal candidates for a clinical trial. They are highly motivated to join studies, especially when they see by the rising marker that they have unequivocally experienced relapse; and their risk of developing metastases and dying of their disease can be estimated with relative accuracy. In particular, high-risk patients, who may develop metastatic disease within a few years of presentation and die of their disease within a decade, are frequently eager to aggressively pursue early treatments, as may be their physicians. Given that there is no true standard of care for patients in this clinical state and there have been no definitive studies demonstrating that either the type or timing of hormonal therapies impacts survival, patients should most appropriately be referred to a clinical trial for treatment.

Patients can be divided into three groups based on prognosis: low-risk patients are unlikely to develop metastases or symptoms or die of their disease and should be managed expectantly; intermediate-risk patients receive androgen deprivation or can be considered for investigational approaches designed to slow the disease to the point where the patient dies of other causes (tantamount to cure); and high-risk patients (those with PSADTs of ≤9 months) can be considered for androgen deprivation or, ideally, enrolled in a clinical trial.

A significant challenge for the treating urologist or oncologist, or even the clinical investigator, is matching the right therapy with the appropriate patient population. Decades of research on the biology underlying prostate cancer tumorigenesis, growth, and resistance to treatment has increased the number and types of compounds available for evaluation. This presents to both

patients and physicians the dilemma of having too many choices. These choices include vaccine-based approaches, which aim to stimulate an immunologic response that results in an antitumor effect, and classes of agents being tested that target the metastatic cascade or the bone microenvironment. Pathways that impact angiogenesis, growth, differentiation, and apoptosis are also under study.

High-risk patients both medically warrant and will accept therapies with higher treatment burdens and side effect profiles, in hopes of disease eradication rather than control. In the spring of 2004, docetaxel was approved by the FDA for the treatment of patients with metastatic prostate cancer that was progressing in spite of castrate levels of testosterone. This approval was supported by a 20% to 25% reduction in the risk of death of such patients registered to two separate clinical trials, TAX327 and SWOG9916, relative to the previous chemotherapy standard of care: mitoxantrone and prednisone. Given the limited prognosis of such patients, this risk reduction translated into only a modest overall survival benefit of 2 to 3 months (Petrylak et al, 2004; Tannock et al, 2004). The overall survival benefit is commensurate with taxane-based and other treatments in patients with advanced solid tumors that are already refractory to previous systemic therapy (Nabholtz et al, 1999; Saltz et al, 2000; Shepherd et al, 2000). There are numerous examples in oncology in which seemingly modest survival benefits in advanced disease translate into increased cure rates when applied early. It is the authors' view that patients with unfavorable PSA kinetics who are at high risk of developing metastases or dying of their disease are a group who not only need systemic therapy but are also most likely to benefit from it.

Currently, the only phase 3 clinical trial to address the needs of high-risk postprostatectomy patients with a rising PSA value is TAX3503, which targets patients with a PSADT of 9 months or less, correlating to a metastasis-free survival of 4 to 5 years and overall survival of 9 to 10 years. Patients are randomized to 18 months of androgen deprivation, either alone or with 10 cycles of docetaxel. The primary end point is progression-free survival and is powered to demonstrate the hypothesis that progression-free survival can be improved from 50% to 65% for a minimum 36 months after the beginning of treatment. Progression-free survival is defined as no detectable PSA in the context of testosterone levels having recovered to noncastrate levels. Controlling for testosterone levels is novel, ensures that patients are not declared to be disease free during the period in which they were simply responding to hormones, and was integral to regulatory acceptance that such patients were indeed truly free of evidence of disease. This trial is nearly entirely accrued at the time of this writing.

Outcome Measures for the Patient with a Rising PSA Value

There are several useful end points for trials in this clinical state. The most immediate of these is the post-therapy change in PSA. The attraction of measuring serial PSA levels is that these assays can be obtained simply and frequently, with minimal inconvenience to the patient. The definition of a favorable post-treatment PSA alteration will depend on the type of agent tested. Examples of such changes are seen in Figure 108–3. Rapid post-treatment PSA declines, with or without escape, are seen with hormonal therapy and chemotherapy (see Fig. 108–3A and B). An example of a study using such end points is a phase 2 study of docetaxel, estramustine, and androgen deprivation for patients with a rising PSA value and no metastases after surgery or irradiation. A complete response was considered to be a post-treatment PSA decline below the assay's level of detectability. The primary end point was time to biochemical progression, with a variable definition depending on whether the patient underwent surgery or radiation therapy as his primary treatment (Taplin et al, 2006). Similarly, TAX3503, discussed earlier, compares androgen deprivation therapy with and without docetaxel in postprostatectomy patients with high-risk doubling times and utilizes as a primary end point duration of time that a patient's PSA value achieves a nadir of no measurable amount, with a confirmed detectable PSA level representing a treatment failure.

In "broken arrow" post-treatment PSA alterations (see Fig. 108–3C, D, F, and G) such changes might be seen in static agents, biologic therapy, or immune agents, with either immediate effects (see Fig. 108–3C) or delayed effects (see Fig. 109–3D). The clinical significance of these post-treatment PSA alterations, however, is entirely unknown. As a result, such changes are a difficult yardstick by which to assess whether a drug should be advanced to phase 3 trials or abandoned. PSA kinetics can be particularly vexing in this context, because simply measuring the PSA level on a regular fixed basis on study can result in an altered rate of rise relative to pretreatment PSA kinetics measured by the schedules typical in routine clinical practice, even if a patient is not receiving active therapy. In one randomized study comparing treatment with a biologic agent versus a placebo in 106 patients, 40% of men in the placebo group and 38% of men in the treatment group had a post-treatment PSADT greater than or equal to 150% of the baseline PSADT (Smith et al, 2004).

Because of these vagaries and the lack of prospective, validated data associating a post-treatment PSA alteration with clinical outcome, PSA-based end points are not surrogates for survival. A surrogate end point is an outcome variable that can substitute for a definitive end point and does not directly alter the treatment effect. Several investigators have proposed that post-therapy PSA changes be used as surrogates for clinical benefits, such as time to metastases or prostate cancer–specific mortality in different clinical states (D'Amico et al, 2003b, 2004b; Kelloff et al, 2004). **The demonstration of an association does not equate with surrogacy, and a large proportion of the association between PSA-based metrics and clinical outcomes has yet to be unexplained.** An additional consideration is that surrogacy cannot be "proven" in the absence of a prospective randomized trial that demonstrates the superiority of one regimen over another. **It is therefore both unsurprising and appropriate that post-therapy PSA changes have not been adopted by the FDA as an intermediate end point that can be used for an accelerated approval in this patient group.**

Other outcome measures independent of PSA, such as metastasis-free survival, delaying the onset of symptoms, or death from disease, must be considered in the context of the risk/reward ratio of intervention versus no intervention. Trials with an end point of clinical progression may be problematic because patients will not remain on observation until the clinically significant event occurs if the PSA value continues to rise, making the risk-reward ratio difficult to quantitate. In practice, the proportion of patients who remain on study without metastatic disease, who receive secondary therapy before the end point of metastatic disease, and who develop metastatic disease should be recorded separately. Finally, assessing quality of life is essential, particularly when the morbidity of the therapy may outweigh the survival benefit and

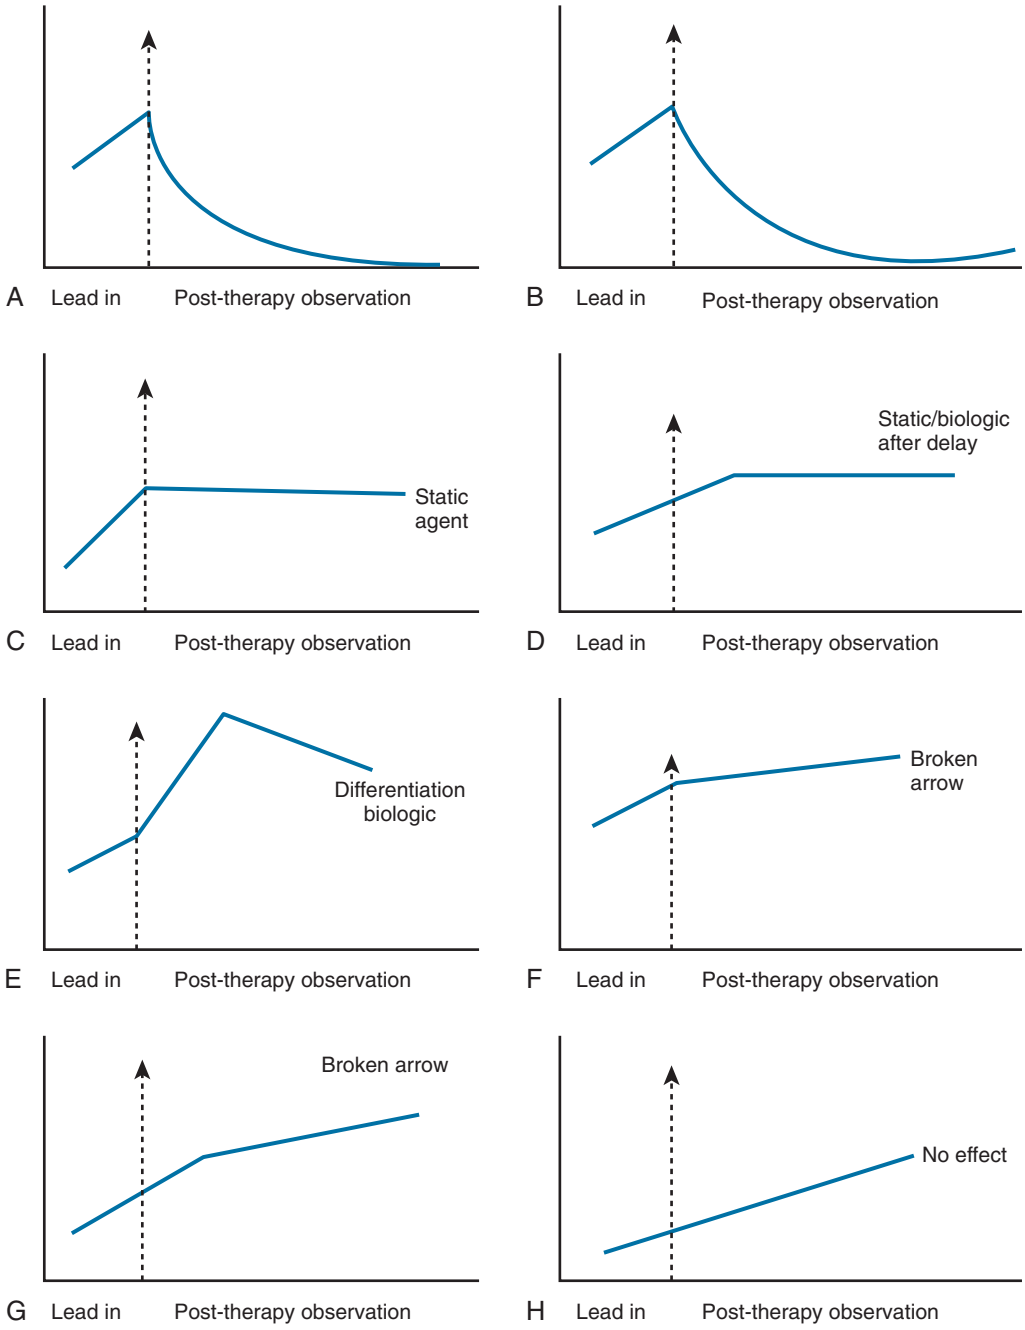

Figure 108–3. **A** to **H**, End points in clinical trials of the rising prostate-specific antigen (PSA) population vary by the type of agent being tested, as shown. The end point must match the mechanism of the drug, although no post-treatment PSA alteration should be used to presume that a clinical benefit has been demonstrated. (From Scher HI, Eisenberger M, D'Amico AV, et al. Eligibility and outcomes reporting guidelines for clinical trials for patients in the state of a rising prostate-specific antigen: recommendations from the Prostate-Specific Antigen Working Group. J Clin Oncol 2004;22[3]:537–56.)

the therapy is administered early in the disease process. Symptom-induced distress, sense of well-being, and self-assessed quality of life should be evaluated, using utilities that yield a quality-adjusted survival time metric or a sensitive measure of symptom frequency, intensity, and duration. A complete discussion of these issues can be found in a recent consensus report by experts in the field (Scher et al, 2004).

SUMMARY

The widespread implementation of PSA screening has created a new disease state, which now includes a group of patients with prostate cancer that is second in size only to those with localized disease. The state of rising PSA value is unique in that patients are characterized by an absence of symptoms, radiographic findings,

Key Points

- The clinical state of rising PSA level defines the second largest group of prostate cancer patients.
- This clinical state refers to biochemical failure after definitive local therapy, in the absence of findings of metastatic disease on standard imaging studies. It does not include patients treated with hormones alone and no definitive treatment to the primary tumor.
- The value of the PSA that defines biochemical failure is contingent on the type of primary therapy (surgery vs. irradiation), the testosterone recovery rate after neoadjuvant or adjuvant hormone therapy, and the sensitivity of the PSA assay used.
- Prognostic models can and should be used to determine the likelihood that a rising PSA level signifies local or systemic recurrence. Therapeutic decision making should be guided accordingly.
- Prognostic models can and should be used to stratify patients for metastasis-free survival, disease-specific survival, and overall survival. Decisions about the timing and type of systemic therapy applied should be guided accordingly.
- Although there are many different models, most have shown that PSADT and Gleason score are highly prognostic for clinical outcome.
- There is no standard of care for patients who occupy this clinical state. Clinical trials are highly appropriate for these patients and generally use risk-adapted strategies to match patients who face a given clinical risk with treatments of appropriate intensity and mechanism of action. Indirect and highly derivative data suggest that early androgen deprivation may be of benefit to high-risk patients.
- Trial designs for these patients, who have no measurable disease and who face highly variable clinical risks, are unique. Efforts to standardize the elements of these studies are under way and have been published as a consensus report.

or pathologic findings—standard measures of treatment effects. Although there is no definitive standard of care for these patients, risk-stratifying models can be used to distinguish patients who are at high risk of developing metastatic disease or of death. The PSADT is one of the most common elements for stratifying patients. High-risk patients should be treated on clinical trials and in the absence of such should be considered for androgen-ablative therapies. A wide range of new therapies are available for testing, from traditional cytotoxic drugs to novel agents that target specific pathways. Alternatively, patients whose predicted risk of metastatic disease is low may benefit from local salvage therapies.

HISTORIC OVERVIEW

The response of prostate cancer to androgen ablation is among the most reproducible, durable, and profound of any systemic therapy for a solid tumor. The early and frequent descriptions of immediate relief of bone pain from metastatic prostate cancer after castration do not diminish the marvel of observing this phenomenon first hand. As is the case with many paradigm-shifting observations, endocrine therapy was based on a simple hypothesis. Described as a "biological syllogism," the idea had a major premise—"In many instances a malignant prostatic tumor is an overgrowth of adult epithelial cells," a minor premise—"All known types of adult prostatic epithelium undergo atrophy when androgen hormones are greatly reduced in amount," and a conclusion—"Therefore, significant improvements should occur in the clinical condition of patients with far advanced prostate cancer subjected to castration" (Huggins, 1947).

It had been known for at least a century that prostatic epithelium undergoes atrophy after castration (Hunter, 1840). The breakthough in Huggin's hypothesis was the recognition that benign prostatic epithelium and prostate carcinoma were biochemically analogous and they would respond in a similar fashion to androgen ablation. Emphasizing the importance of basic observations—"The evidence for the facts which represent the premises was obtained entirely in the laboratory" (Huggins, 1944)—studies on acid phosphatase provided the crucial link between benign and malignant prostate cells. Large amounts of acid phosphatase were found in the prostate glands of men and monkeys (Kutscher and Benjamin, 1935) and in primary and metastatic prostate cancer (Gutman et al, 1936), and the levels increased with androgen administration (Gutman and Gutman, 1938a). Serum levels of acid phosphatase were increased in men with disseminated prostate cancer (Barringer and Woodard, 1938; Gutman and Gutuman, 1938b). With localization of the enzyme to prostatic epithelial cells and primary and metastatic prostatic cancer cells (Gomori, 1939), the stage was set for Charles Huggins, R. E. Stevens, and Clarence V. Hodges to test the hypothesis in men with prostate cancer.

Despite negative results of castration in two men with prostate cancer reported by Young (1936), a series of 21 consecutive patients with locally advanced or metastatic prostate cancer underwent surgical castration at the University of Chicago. "A noticeable improvement occurred in the clinical status of all but three patients" with weight gain, resolution of anemia, and improvement in pain (Huggins et al, 1941). Other reported consequences of castration—a large appetite for food, loss of sexual desire and penile erections, and hot flashes—remain the common side effect profile of androgen ablation therapy today. **Although this report was the first to describe the benefits of androgen ablation in the treatment of prostate cancer it also created a new disease state: androgen-refractory prostate cancer.**

In considering these "failure cases" (Huggins, 1942), it was found that those with small testes at the time of castration had a poor prognosis, the first description of a more ominous prostate cancer arising in the hypogonadal man. After castration, rises in the levels of urinary 17-ketosteroids, a major metabolite of the adrenal gland, led to the hypothesis that adrenal androgens contributed to subsequent disease progression. The first reports of bilateral adrenalectomies for the treatment of castration-resistant disease (Huggins and Scott, 1945) are described later in a somewhat defensive manner (Scott, 1954), owing, perhaps, to the lack of response and high perioperative mortality. Hypophysectomy and pituitary irradiation (Murphy and Schwippert, 1951) were also investigated. Unfortunately the benefits of surgical castration were soon equaled by the tenacity and inevitable progression of androgen independence, a state still synonymous with the lethal form of the disease. Even in accepting the Nobel Prize for this work in 1966, Charles Huggins admitted "Despite regressions of great magnitude, it is obvious that there are many failures of endocrine therapy to control the disease" (Huggins, 1972).

Direct ablation of the source of androgen, like surgical castration, is only one of the perturbations of the hypothalamic-pituitary-gonadal axis developed to treat prostate cancer. **The first central inhibition of the axis exploited the potent negative feedback of estrogen on luteinizing hormone (LH) secretion: it is now known that estradiol is a 1000-fold more potent at suppressing LH and follicle-stimulating hormone (FSH) secretion by the pituitary compared with testosterone** (Swerdloff and Walsh, 1973). The effects of estrogen on the male phenotype, namely, regression of androgen-sensitive tissues, have been exploited, historically, to produce the effects of castration without surgical removal of the testes. For example, capons (neutered roosters) were produced by placing estrogen pellets in the neck of the bird rather than by castration (Scott, 1954). Among the various estrogenic compounds diethylstilbestrol (DES) has been most widely studied and used. Early studies indicating improved survival in men treated with both surgical castration and continuous DES (Nesbit and Baum, 1951) have not held up under further scrutiny, but the equivalence of DES compared with castration has. Indeed, given the effectiveness of the considerably less expensive estrogenic compounds it is unfortunate the associated cardiovascular toxicity has limited their widespread use.

The first isolation of luteinizing hormone–releasing hormone (LH-RH) by Schally and colleagues (1971, 1992) required the hypothalami of 165,000 pigs to obtain 800 μg of the 10 amino acid peptide. This 1977 Nobel Prize–winning work led to the development of synthetic LH-RH analogues, peptides generated by substituting D-amino acid residues at certain locations in the natural compound, creating both LH-RH agonists and LH-RH antagonists. **After an initial surge in LH release (and testosterone levels) in response to LH-RH agonists the loss of phasic pituitary stimulation results in plummeting LH levels. In the absence of LH, Leydig cell production of testosterone drops to castrate levels.** Initially, the clinical utility of these agents was hampered by their short half-lives, requiring daily injections to maintain suppression of the hypothalamic-pituitary axis. The generation of long-acting depot preparations, lasting several months, has established LH-RH agonists as the dominant treatment in hormone therapy for prostate cancer. Recently, direct LH-RH antagonists have been developed for clinical use. Lacking agonist action, these agents do produce the surge in LH and testosterone. It is interesting that both classes of compounds were developed within a few years of the discovery of LH-RH and yet it took decades to develop clinically useful agents.

Moving beyond strategies targeting the hypothalamic-pituitary axis, interruption of ligand-receptor interaction with antiandrogenic compounds is another way to reduce androgen action in prostate cancer. **All antiandrogens inhibit androgen action by binding to the androgen receptor in a competitive fashion and are classified as either steroidal or nonsteroidal.** The steroidal antiandrogen cyproterone acetate is a derivative of 17-hydroxyprogesterone and suppresses LH release (and testosterone production) through its central progestational inhibitory effects. Therefore steroidal antiandrogens block androgen action at the cellular level and also reduce circulating testosterone levels, leading to the classic side effects of the hypogonadal state such as loss of libido and erectile dysfunction. On the other hand, **the nonsteroidal antiandrogens have no antigonadotropic effects and simply block androgen receptors, including those in the hypothalamic-pituitary axis. By blocking the normal inhibiting feedback of testosterone the antiandrogens produce a paradoxic increase in LH and testosterone.** Although this maintenance of testosterone preserves potency, the peripheral conversion of this excessive testosterone to estrogen can lead to painful gynecomastia.

MOLECULAR BIOLOGY OF ANDROGEN AXIS

The androgen receptor (AR) is a member of the nuclear receptor superfamily, which includes the sex steroids (androgen, estrogen, progestin), adrenal steroids (mineralocorticoids, glucocorticoids), thyroid hormones, vitamin D, and retinoids. These receptors act as ligand-inducible transcription factors, meaning that they cause transcription of target genes within specific cells after ligands (e.g., testosterone) bind to them. **All current forms of androgen-deprivation therapy (ADT) function by reducing the ability of androgen to activate the AR, whether through lowering levels of androgen or by blocking AR binding** (Fig. 109–1). Therefore the AR is not directly affected by ADT, leading many to hypothesize that castration-resistant prostate cancer is a result of reactivation of AR-mediated pathways.

There are a variety of molecular mechanisms implicated in this process of androgen independence (Fig. 109–2). First, the AR pathway can become hypersensitive through a variety of molecular alterations and be activated by even lower levels of androgen (Linja et al, 2004). In androgen-refractory tumors, approximately one third of patients will show evidence of *AR* gene amplification, meaning many more copies of the *AR* gene are present (Koivisto et al, 1997; Linja et al, 2001). Second, the promiscuity of the AR for ligands other than androgen has been widely recognized. Mutations of the *AR* gene can also increase receptor activity (Tilley et al, 1996; Gottlieb et al, 1998; Taplin et al, 1999; Marcelli et al, 2000; Balk, 2002). Third, in an outlaw AR model, growth factor peptides, such as epithelial growth factor and insulin-like growth factor type 1 increase AR transcriptional activity in the absence of androgen (Culig et al, 1994). The cytokine interleukin-6 can activate AR, as can protein kinases A and C (Nazareth and Weigel, 1996; Lin et al, 2001). If these ligands can reactivate AR signaling in the absence of androgen, then prostate cancer can still progress in the castrate state. Increased expression of AR coregulators, proteins involved in the complex that binds to DNA, has been found in hormone-refractory prostate cancer, suggesting autonomous activation of the pathway (Yeh et al, 1999; Fujimoto et al, 2001; Gregory et al, 2001). Fourth, in a bypass AR model, activation of parallel or alternative survival pathways allows otherwise androgen-dependent prostate cancer cells to survive in the absence of androgen (Feldman and Feldman, 2001). Finally, in a lurker cell model, a small population of possible epithelial stem cells is preexistent in the prostate and androgen deprivation selects for the outgrowth of these androgen-independent cells. Rather than an acquired alteration, this model suggests an inherent quality of the prostate gland.

Even when prostate cancer progresses despite castrate levels of androgen it is rarely resistant to androgen action. In 87% of patients with androgen-refractory prostate cancer, the administration of exogenous androgen results in symptomatic tumor flare (Fowler and Whitmore, 1982). Therefore the term *androgen independent* is not completely precise: such a cancer is no longer dependent on androgen (and thus may be considered independent), but since it remains responsive to androgen it is not wholly independent of the influence of androgen. The term *androgen refractory* is more precise, indicating a disease state in which the cancer is able to progress in the absence of androgen but is neutral about a

Drug Class	Drugs	Site of Action	Mechanism of Action	Comments/Risks
Gondatropin-Releasing Hormone (GnRH) Agonists	Leuprolide Goserelin	Anterior Pituitary Gland	Decreases Release of LH Through Down-regulation of GnRH Receptors	Testosterone Surge
GnRH Antagonists	Abarelix*	Anterior Pituitary Gland	Directly Inhibits GnRH Receptors	Anaphylaxis
Adrenal Ablating Drugs	Ketoconazole	Adrenal Gland	Decreases Androgen Synthesis From Steroid Precursors Through Inhibition of Cytochrome P450 Enzymes	Administration Requires Steroid Supplementation to Prevent Adrenal Insufficiency
Androgen Receptor Antagonists	Flutamide Bicalutamide Nilutamide	Prostate Gland	Inhibits Androgen Receptor Ligand-Binding Domain Through Competitive Binding	Gynecomastia, Increased Liver Transaminases, and Mastodynia
5α-Reductase Inhibitors	Finasteride	Prostate Gland	Decreases Conversion of Testosterone to DHT Through Inhibition of 5α-Reductase	No Defined Role in Standard Care of Prostate Cancer

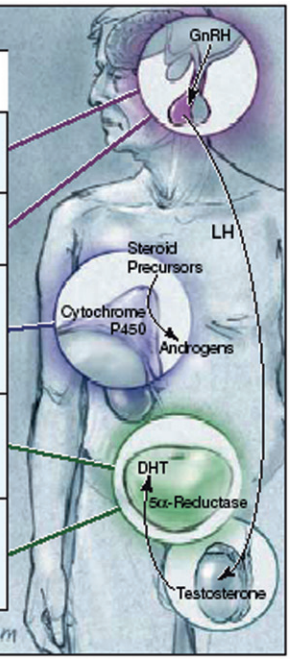

Figure 109–1. Hormonal interventions and endocrine axis in prostate cancer. DHT, dihydrotestosterone; LH, luteinizing hormone. *Abarelix is no longer available for new patients in the United States. (From Sharifi N, Gulley JL, Dahut WL. Androgen deprivation therapy for prostate cancer. JAMA 2005;294:238–44.)

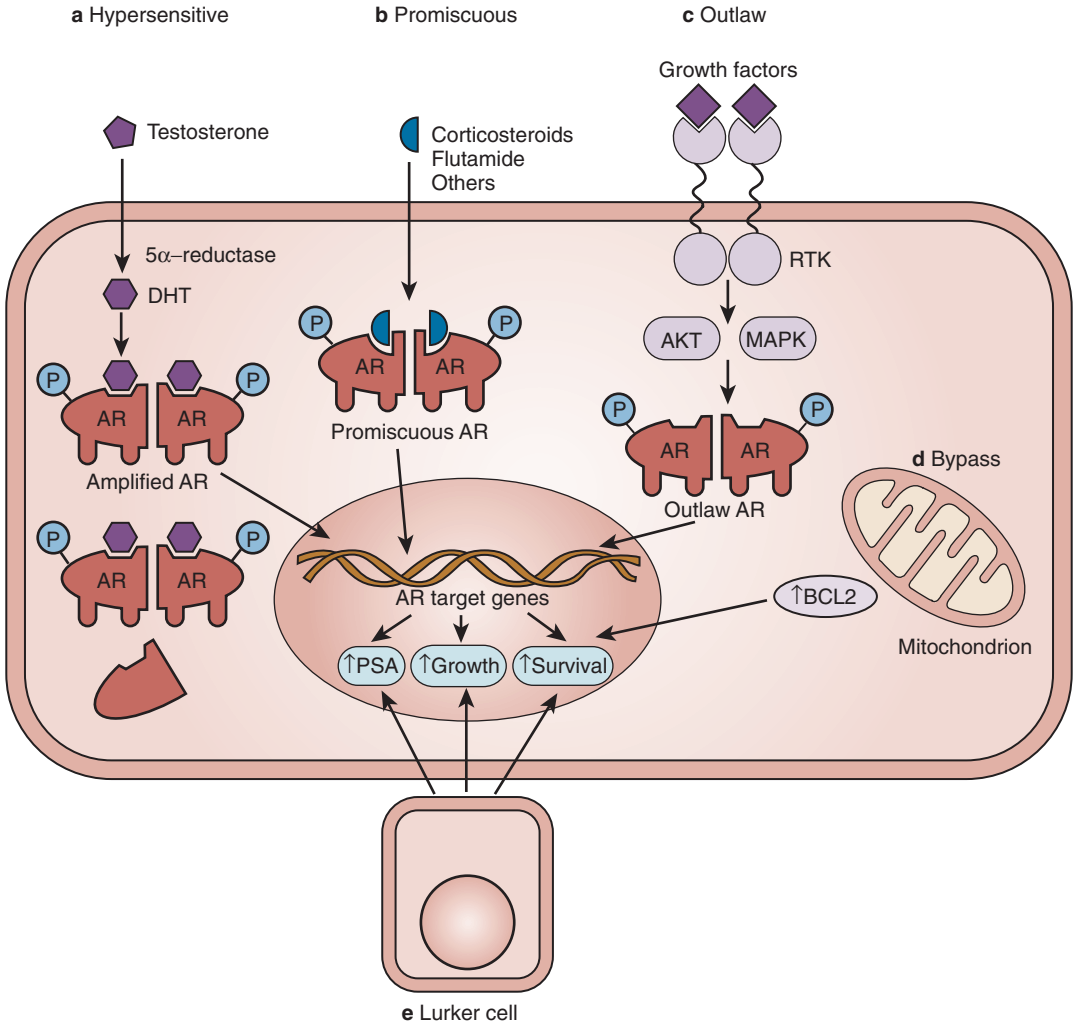

Figure 109–2. Five *(a to e)* possible pathways to androgen independence. AR, androgen receptor, DHT, dihydrotestosterone; MAPK, mitogen-activated protein kinase; P, phosphorylated; PSA, prostate-specific antigen; RTK, receptor tyrosine kinase. (From Feldman BJ, Feldman D. The development of androgen-independent prostate cancer. Nat Rev Cancer 2001;1:34–45.)

Table 109–1.

Major Circulating Androgens

SOURCE	ANDROGEN	AMOUNT PRODUCED PER DAY (mg)	RELATIVE POTENCY	RELATIVE POTENCY/ AMOUNT PRODUCED
Testes	Testosterone	6.6	100	15.2
Testes and peripheral tissues	Dihydrotestosterone	0.3	160-190	533-633
Adrenal	Androstenedione	1.4	39	27.9
Adrenal	Dehydroepiandrosterone	29	15	0.5

			Cetrorelix
			Abarelix
			Degarelix

DES, diethylstilbestrol; LH, luteinizing hormone; LH-RH, luteinizing hormone–releasing hormone.

responsive to androgen. Likewise, the word "hormone" is quite broad and includes the host factors defining the field of endocrinology. Therefore the term *hormone independent* is vague, as evident from the therapeutic response to secondary hormonal manipulation, estrogens, and glucocorticoids; and androgen-refractory prostate cancer is not actually independent of hormone action. The terms *hormone independent* and *hormone refractory* should be reserved for the rare cancers that are completely non-responsive to any hormonal agent (Chang et al, 2005). **Although hormone refractory prostate cancer is widely used to describe a state of progressive disease despite androgen-deprivation therapy, the term *castration-resistant prostate cancer* is more clinically precise and relevant** (Scher et al, 2004, 2008).

SOURCES OF ANDROGEN

Testosterone is the major circulating androgen, with 90% produced by the testes. Over half of testosterone is bound to sex-binding globulin and 40% is bound to albumin. Only 3% of testosterone remains unbound, and this is the functionally active form of the hormone. After passive diffusion through the cell membrane into the cytoplasm, testosterone undergoes conversion to dihydrotestosterone (DHT) through the action of the enzyme 5α-reductase. Although the relative potency of testosterone and DHT are similar (as defined by the ability to cause half-maximal response in a prostate regrowth model), if the conversion of testosterone to DHT is blocked by the 5α-reductase inhibitor finasteride, 13-fold more testosterone is required for the same effect (Wright et al, 1999). Both testosterone and DHT exert their biologic effects by binding to the AR in the cytoplasm, promoting the association of AR coregulators. The complex then translocates to the nucleus and binds to androgen response elements in the promoter regions of target genes (Heinlein and Chang, 2004).

Androgens produced by the adrenal gland—androstenedione and dehydroepiandrosterone—are stimulated by adrenocorticotropic hormone (ACTH) released by the pituitary gland in response to corticotropic-releasing factor (CRF). Adrenal androgens negatively feed back on ACTH secretion: cortisol acts as the feedback signal. **Adrenal androgens are relatively weak compared with testosterone and DHT and are almost entirely bound to albumin** (Table 109–1). Adrenal androgens remain normal in men who have undergone orchiectomy (Walsh and Siiteri, 1975), and adrenal androgens are insufficient to maintain prostatic epithelium in such men.

MECHANISMS OF ANDROGEN AXIS BLOCKADE

There are four therapeutic approaches for androgen axis blockade in current clinical use: (1) ablation of androgen sources, (2) inhibiting androgen synthesis, (3) antiandrogens, and (4) inhibition of LH-RH and/or LH release (Table 109–2).

Ablation of Androgen Sources

Bilateral orchiectomy quickly reduces circulating testosterone levels to less than 50 ng/dL, which, based on this procedure, is considered the castrate range. Within 24 hours of surgical castration, testosterone levels are reduced by greater than 90% (Maatman et al, 1985). **The Veterans Administration Cooperative Urological Research Group (VACURG) conducted a series of larger clinical trials, demonstrating the clinical effectiveness of surgical castration in reducing pain and performance status in men with advanced disease** (Veterans Adminstration, 1967; Byar, 1973; Byar and Corle, 1988).

Scrotal (Simple) Orchiectomy

A straightforward outpatient procedure, the simple scrotal orchiectomy, can be performed with the patient under local anesthesia. At the level of the external ring, each spermatic cord is grasped and infiltrated with 10 mL of 1% lidocaine without epinephrine. This cord block can be performed before the formal skin preparation and draping. After infiltration of the skin overlying the median raphe with 1% lidocaine, a 6- to 8-cm incision is made directly over the median raphe. After the skin incision, electrocautery is used exclusively to transect the other tissue layers, reducing the risk of scrotal hematoma formation. The incision is directed into one hemiscrotum where the tunica vaginalis is divided and the testis delivered through the wound. The cord is mobilized above the testis but below the level of the external ring. After dividing the cord structures into two or three equal components, the cord is ligated with nonabsorbable sutures. The author prefers double ligating the proximal cord with two sutures, one of which is a suture ligature. The cord is transected relatively close to the ligatures, to limit the amount of nonviable tissue distal to the ligature. Care is taken to examine for any bleeding, because a scrotal hematoma after scrotal orchiectomy can be dramatically large. The identical procedure is performed on the contralateral side. The dartos is then reapproximated in the midline, closing each semiscrotal incision at the same time in one layer. The skin is closed with interrupted absorbable sutures. Drains are not used for clean scrotal wounds. Scrotal supports are used for the first several days after surgery and ice is applied for symptomatic relief.

Subcapsular orchiectomy has been advocated as a technique of ADT that avoids the psychologic consequences of an empty scrotum (Desmond et al, 1988). **Because this approach relies on the complete removal of all intratesticular tissue and Leydig cells it is more dependent on technique than a simple orchiectomy to achieve ADT. In a properly performed operation, however, the hormonal and cancer responses are indistinguishable from a simple, complete orchiectomy** (Zhang et al, 1996).

Antiandrogens

Cyproterone Acetate

The classic steroidal antiandrogen with direct AR blocking effects, cyproterone acetate, also rapidly lowers testosterone levels to 70% to 80% through its progestational central inhibition (Jacobi et al, 1980; Goldenberg and Bruchovsky, 1991; Barradell and Faulds, 1994). An oral agent, the recommended dose is 100 mg, two to three times per day. Side effects are consistent with the hypogonadal state and include loss of libido, erectile dysfunction, and lassitude. **Severe cardiovascular complications can occur in up to 10% of patients, limiting the use of this agent** (deVoogt et al, 1986). Gynecomastia occurs in less than 20% of men. Rare cases of fulminate hepatotoxicity have been reported (Parys et al, 1991). Cyproterone acetate has been used at doses of 50 to 100 mg/day for the treatment of hot flashes (Goldenberg and Bruchovsky, 1991).

Nonsteroidal Antiandrogens

By blocking the testosterone feedback centrally the nonsteroidal antiandrogens cause LH and testosterone levels to increase. Testosterone levels reach about 1.5 times the normal levels of hormonally intact men (Neri, 1977). This allows antiandrogen activity without inducing hypogonadism: potency therefore can be preserved (Brufsky et al, 1997). However, in clinical trials specifically examining erectile functioning and sexual activity in men on flutamide monotherapy, long-term preservation of those domains was only 20%, not much different than men undergoing surgical castration (Schröder et al, 2000). The peripheral aromatization of increased testosterone to estradiol has been demonstrated after antiandrogen administration (Knuth, 1984), leading to the widely recognized gynecomastia and mastodynia associated with these agents. **Gastrointestinal toxicity, and most notably diarrhea, is more common with flutamide than the other nonsteroidal antiandrogens** (Han and Nelson, 2000). **Liver toxicity, ranging from reversible hepatitis to fulminate hepatic failure, is associated with all nonsteroidal antiandrogens and requires periodic monitoring of liver function tests** (Lund and Rasmussen, 1988; Wysowski et al, 1993; Dawson et al, 1997; Thole et al, 2004).

Antiandrogen Withdrawal Phenomenon

Patients treated with a combination of an antiandrogen and an LH-RH agonist can experience a decline in the prostate-specific antigen (PSA) value and even objective responses with the withdrawal of the antiandrogen from the combination. Based on this response, it appears the antiandrogen is actually exerting agonistic activity on prostate cancer cells. This phenomenon, first described with flutamide (Kelly and Scher, 1993), has now been demonstrated with all antiandrogens, including cyproterone acetate, as well as with DES and progestational agents (Kelly et al, 1997). Declines in PSA are seen within 4 weeks with flutamide withdrawal and within 6 weeks with bicalutamide and nilutamide withdrawal (Nieh, 1995). **Between 15% and 30% of patients may have PSA level declines of greater than 50% after antiandrogen withdrawal with a median duration of 3.5 to 5 months** (Scher and Kelly, 1993; Small and Srinivas, 1995). Objective, measurable tumor responses are observed less commonly. Overall survival has not been shown to be increased in those demonstrating the antiandrogen withdrawal phenomenon compared with those who have not (Small and Srinivas, 1995). Clinical trial designs of novel agents must take this phenomenon into consideration, given the possible confounding effects (Scher and Kelly, 1993). Prospective criteria to predict who will demonstrate this response have not been established, but it has been recognized that those with rapid PSA responses after androgen ablation have higher rates of antiandrogen withdrawal phenomenon.

It has been postulated that mutations in the AR may underlie this phenomenon, allowing the antiandrogen to behave as an activator of the AR (Taplin et al, 1995). The widely used prostate cancer cell line LNCaP expresses an AR with a specific point mutation that causes cell proliferation in the presence of hydroxyflutamide; the identical mutation was found in human tumor samples from patients who had remarkable declines in PSA levels after antiandrogen withdrawal (Suzuki et al, 1996). Similar point mutations in the AR have been described for bicalutamide to act as an agonist (Hara et al, 2003), with the structural basis of this mutation resolved by x-ray crystallography demonstrating the ability of bicalutamide to bind to the mutant AR in a fashion similar to DHT to the wild-type AR (Bohl et al, 2005).

Flutamide

A nonsteroidal antiandrogen, flutamide was the first "pure" antiandrogen (Neri et al, 1967). Because of the short half-life (6 hours) of the active metabolite, 2-hydroxyflutamide, this oral agent is given in a dose of 250 mg three times a day. Elimination of

hydroxyflutamide is via renal excretion. Unlike the steroidal antiandrogens there are no associated side effects of fluid retention or thromboembolism (Dalaere and Van Thillo, 1991). In a randomized, double-blind study comparing flutamide to DES (3 mg/day) in metastatic prostate cancer, overall survival was significantly shorter with flutamide (28.5 months) compared with DES (43.2 months) (Chang et al, 1996).

Bicalutamide

A nonsteroidal antiandrogen with a long serum half-life (6 days), bicalutamide has a once-per-day dosing schedule and therefore likely better compliance. It is the most potent of the nonsteroidal antiandrogens (Kolvenbag and Nash, 1999) and the best tolerated (Kolvenbag and Blackledge, 1996; Schellhammer and Davis, 2004; Fradet, 2004). The pharmacokinetics of bicalutamide are not affected by age, renal insufficiency, or moderate hepatic impairment (Mahler et al, 1998). The R-isomer of bicalutamide has about a 30-fold higher binding affinity to the AR compared with the S-isomer and functionally processes the antiandrogen activity (Mukherjee et al, 1996). As with the other antiandrogens, bicalutamide is associated with maintenance of serum testosterone levels: in the majority of patients these remain within the normal range (Denis and Mahler, 1996; Tay et al, 2004).

Bicalutamide as monotherapy has been most extensively studied and, as with flutamide monotherapy's inferiority to DES, bicalutamide monotherapy at a 50-mg/day dose was inferior to castration in survival of men with metastatic disease (Kaisary et al, 1995; Bales and Chodak, 1996; Kolvenbag and Nash, 1999). **At higher dose of 150 mg/day, however, bicalutamide monotherapy appears to have equivalent efficacy to medical or surgical castration** (Tyrrell et al, 1998; Iversen et al, 2000; Anderson, 2003; Iversen et al, 2004; Wirth et al, 2004, 2005; McLeod et al, 2005) in men with metastatic or locally advanced disease. In these large phase 3 studies, bicalutamide monotherapy (150 mg/day) had significantly better quality of life in the domains of sexual interest and physical capacity (Iversen, 2003). There was, however, a high rate of gynecomastia (66.2%) and breast pain (72.8%) (Iversen, 2003). Of more concern, **in men with low-risk, localized prostate cancer, bicalutamide was associated with significantly worse overall survival compared with those on "watchful waiting"** (see later).

Nilutamide

The plasma half-life of nilutamide is 56 hours, and elimination is via hepatic clearance employing the cytochrome P450 system. Because steady-state plasma levels are achieved in 14 days on once-daily dosing (Creaven et al, 1991), dosing recommendations are a single 300-mg daily dose for the first month of treatment followed by a single 150-mg daily dose (Mahler et al, 1998). **About one fourth of men on nilutamide therapy will note a delayed adaptation to darkness after exposure to bright illumination** (Creaven et al, 1991). Nilutamide is also associated with interstitial pneumonitis in approximately 1% of patients, which can progress to pulmonary fibrosis (Pfitzenmeyer et al, 1992). The early effects are usually reversible with cessation of nilutamide. In a small study there was a suggestion of a role for nilutamide as an effective secondary hormonal agent (Desai et al, 2001).

MDV3100

This small molecule is an AR antagonist, but, unlike bicalutamide, MDV3100 inhibits AR function by blocking nuclear translocation and DNA binding and has no agonist activity when AR is overexpressed. It is being evaluated in phase 1/2 clinical trials in men with castration-resistant prostate cancer. Early results indicate the PSA level declines in the majority of patients (Scher et al, 2008).

Inhibition of LH-RH

LH-RH Agonists

The LH-RH agonists exploit the desensitization of LH-RH receptors in the anterior pituitary after chronic exposure to LH-RH, thereby shutting down the production of LH and, ultimately, testosterone. **The clinical utility of the current LH-RH agonists is based on the creation of analogues of native LH-RH by amino acid substitutions, particularly position 6 in the peptide, increasing their potency and half-lives** (Table 109–3). Pharmacologic depot preparations and osmotic pump devices allow dosing to extend from 28 days to 1 year, respectively (Table 109–4) (Ahmann et al, 1987). **In a review of 24 trials, involving more than 6600 patients, survival after therapy with an LH-RH agonist was equivalent to that of orchiectomy** (Seidenfeld et al, 2000).

The initial exposure to more potent agonists of LH-RH results in a flare of LH and testosterone levels (Waxman et al, 1985). **This phenomenon is seen with all available LH-RH preparations and can result in a severe, life-threatening exacerbation of symptoms.** The flare, associated with up to a 10-fold increase in LH, may last for 10 to 20 days (Weckerman and Harzmann, 2004). Fortunately, **the coadministration of an antiandrogen functionally blocks the increased levels of testosterone** (Labrie et al, 1987; Kuhn et al, 1989; Schultz and Senge, 1990). Although it had been argued that the administration of the antiandrogen should precede the administration of the LH-RH agonist by a week, others have found no differences in PSA levels with the simultaneous administration of both agents (Tsushima et al, 2001). Given the predictable length

IM, intramuscular; SC, subcutaneous.

of the flare phenomenon, antiandrogen coadministration is required for only 21 to 28 days.

LH-RH Antagonists

The LH-RH antagonists bind immediately and competitively to the LH-RH receptors in the pituitary, reducing LH concentrations by 84% within 24 hours of administration (Weckerman et al, 2004). **The direct antagonistic activity eliminates the LH and testosterone flare, which is the major therapeutic advantage of these agents: there is no need for antiandrogen coadministration.** Hormonally naive patients with impending spinal cord compression or severe bone pain for whom surgical castration is not appropriate may uniquely benefit from this class of agents: clinical response has been observed with the LH-RH antagonist cetrorelix (Gonzalez-Barcena et al, 1995).

In clinical trials of the LH-RH antagonist abarelix, testosterone levels dropped very quickly, with 34.5%, 60.5%, and 98.1% of men chemically castrated at 2, 4, and 28 days, respectively (Tomera et al, 2001). Compared with an LH-RH agonist and an antiandrogen, abarelix monotherapy was equally effective in achieving castrate levels of testosterone (Trachtenberg et al, 2002). Ninety-percent of men with symptomatic prostate cancer treated in an open-label fashion had improvements in pain and/or disease-related problems (Koch et al, 2003).

Many of the first- and second-generation antagonists induced significant histamine-mediated side effects, complications not as often observed in third- and fourth-generation agents (Weckerman et al, 2004). Nevertheless, **severe allergic reactions can occur with abarelix, even after previously uneventful treatment** (Koch et al, 2003). Abarelix is approved in the United States for the treatment of advanced prostate cancer in patients who cannot take other hormonal therapies and have refused surgical castration. Given the rare but serious allergic reactions, patients must be monitored for at least 30 minutes after administration.

FSH levels are only partially suppressed by LH-RH agonists and are significantly elevated after surgical castration given the loss of inhibitory feedback. LH-RH antagonists reduce both LH and FSH levels. In an androgen-insensitive prostate cancer xenograft model, cetrorelix significantly reduced tumor growth (Lamharzi et al, 1998), suggesting other factors stimulate tumor growth. In men with disease progression after surgical castration, treatment with abarelix reduced FSH levels by nearly 90% but did not meet criteria for PSA response (Beer et al, 2004a).

A new LH-RH antagonist, degarelix, has completed phase 2 and phase 3 studies in prostate cancer (Gittelman et al, 2008; Klotz et al, 2008). **Unlike with abarelix there were no systemic allergic reactions with degarelix.** In the phase 3 study, degarelix was compared with leuprolide: at 1 year of treatment degarelix was not inferior to leuprolide, and, based on this result, it has been approved for use in the United States.

Inhibition of Androgen Synthesis

Aminoglutethimide

Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone, an early step in steroidogenesis (Cash et al, 1967; Blankenstein and Bakker, 1985). **Given its inhibition of a very proximal step in adrenal function, aminoglutethimide blocks production of aldosterone and cortisol. As the medical version of a total adrenalectomy, the use of this agent requires replacement of cortisone and fludrocortisone.** Side effects include anorexia, nausea, rash, lethargy, vertigo, hypothyroidism, and nystagmus. Clinical responses have been observed in a subset of patients with androgen-refractory prostate cancer treated with aminoglutethimide plus cortisone (Sanford et al, 1976; Ponder et al, 1984). In the PSA era, 37% of patients had greater than a 50% decline in the PSA level with treatment with aminoglutethimide (1000 mg/day) and hydrocortisone acetate (40 mg/day), with median response times lasting 9 months (Kruit et al, 2004).

Ketoconazole

An orally active, broad-spectrum azole antifungal agent, ketoconazole interferes with two cytochrome P450–dependent pathways: by inhibiting 14-methylation the conversion lanosterol to cholesterol is blocked, and it also blocks 17,20-desmolase, impacting on the conversion of C21 to C19 steroids. Based on the observation that some patients taking the drug developed gynecomastia, investigations on its effects on steroid synthesis demonstrated loss of adrenal steroid synthesis (Pont et al, 1982b) and testosterone synthesis by Leydig cells (Pont et al, 1982a). The effects were rapid, with testosterone levels dropping to the castrate level within 4 hours of administration in some cases (Trachtenberg et al, 1983); the effects were also immediately reversible, indicating dosing must be continuous to maintain low testosterone levels (400 mg every 8 hours).

Early experience with ketoconazole in the treatment of prostate cancer showed this agent to be tolerable, durable, and effective (Trachtenberg and Pont, 1984) and was palliative for those who had failed first-line androgen-ablation therapy (Pont, 1987). **Although effective in rapidly bringing testosterone levels into the castrate range, with continuous treatment with ketoconazole in the otherwise hormonally intact individual (no other surgical or chemical ADT), testosterone levels begin to rise and can reach low-normal ranges within 5 months of therapy** (Vanuytsel et al, 1987). Therefore currently, ketoconazole is used for men with castration-resistant prostate cancer, often as the first or second agent in so-called secondary hormonal manipulation (Small et al, 2004). In addition to gynecomastia (caused by alterations in testosterone-estradiol ratios [Pont et al, 1985]),

ketoconazole is associated with lethargy, weakness, hepatic dysfunction, visual disturbance, and nausea (Wilkinson and Chodak, 2004; Scholz et al, 2005). Because of the adrenal suppression, ketoconazole is usually given with hydrocortisone (20 mg twice daily). Patients with higher levels of the adrenal androgen androstenedione had a improved survival in response to ketoconazole compared with those with lower levels, suggesting ketoconazole is less effective in patients with low levels of androgen at baseline (Ryan et al, 2007).

Abiraterone

Unlike the less potent ketoconazole, which inhibits several cytochrome P pathways, abiraterone is a potent, selective and irreversible inhibitor of cytochrome P17, a key enzyme in androgen synthesis (Chan et al, 1996). Specifically, abiraterone inhibits 17α-hydrolase, resulting in excess synthesis of aldosterone and its precursors and causing a suppression of cortisol with a compensatory rise in ACTH. Abiraterone also inhibits C17,20-lyase, resulting in suppression of testosterone to levels of less than 1 ng/mL (significantly < 50 ng/ml, castrate levels) (O'Donnell et al, 2004; Attard et al, 2005). Based on the hypothesis that castration-resistant prostate cancer remains driven by low levels of androgens, abiraterone is undergoing clinical testing in this state of disease. In a phase 1 clinical trial, abiraterone was well tolerated, with toxicities associated with the expected effects of mineralocorticoid excess, namely, hypertension, hypokalemia, and lower-extremity edema (Attard et al, 2008). Declines in PSA level and measurable tumor response were observed and supported by preliminary phase 2 results (de Bono et al, 2008). Phase 3 studies are underway.

RESPONSE TO ANDROGEN BLOCKADE

After the initiation of ADT the vast majority of prostate cancer patients will show some evidence of clinical response: the magnitude and rapidity of that response remain the best predictors of its durability. Assuming ADT effectively targets the androgen-sensitive population of prostate cancer cells, an incomplete or sluggish response is evidence of a significant androgen-refractory population. Early in the clinical use of PSA as a biomarker of prostate cancer it was recognized that declines in PSA could predict response (Hudson et al, 1989; Aria et al, 1990; Cooper et al; 1990). For example, **patients who had more than an 80% drop of PSA within 1 month of initiating ADT had a significantly longer disease-free progression rate** (Aria et al; 1990). Likewise, the nadir PSA predicted the progression-free interval (Matzkin et al, 1992; Benaim et al, 2002a), as did pretreatment testosterone levels (Imamoto et al, 2001). **A rise in PSA level, which is evidence of the emergence of castration-resistant disease, preceded bone metastatic progression by several months, with a mean lead time of 7.3 months** (Cooper et al, 1990; Miller et al, 1992).

More recent studies of PSA response to ADT have confirmed and amplified those observations. The odds ratio for progressing to castration-resistant progression with 24 months of starting ADT was almost 15 times higher for patients who did not achieve an undetectable PSA level (Benaim et al, 2002a). For each unit increase in Gleason score, the cumulative hazard of castration-resistant progression was nearly 70% (Benaim et al, 2002b). In one cohort of Asian men the nadir PSA was the most accurate predictor of disease progression and was independently prognostic of survival; achieving a PSA level of 1.1 ng/mL or less at 6 months after initiating ADT was the most sensitive and specific predictor of progression at 2 years (Kwak et al, 2002). **In men with newly diagnosed metastatic prostate cancer (stage D2) started on ADT the absolute PSA level after 7 months of ADT was a strong, independent predictor of survival** (Hussain et al, 2006). Median survival of men achieving a PSA level less than or equal to 0.2 ng/mL was 75 months, compared with 13 months for men whose nadir was more than 4 ng/mL (Fig. 109–3). Considering the kinetics of PSA rise before ADT compared with

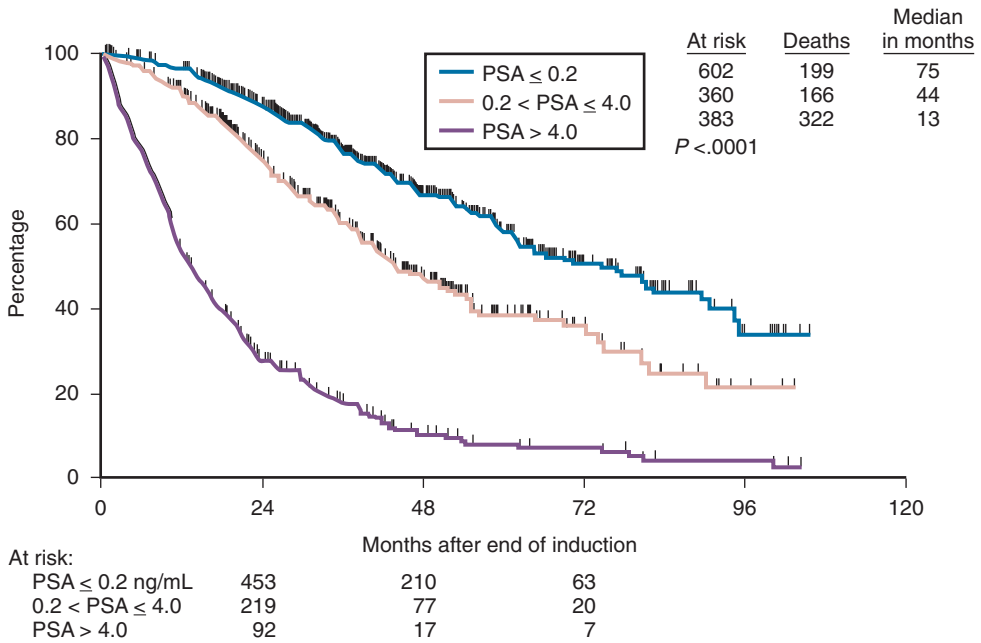

Figure 109–3. Overall survival by prostate-specific antigen (PSA, ng/mL) status at the end of induction with androgen-deprivation therapy. (From Hussain M, Tangen CM, Higano C, et al. Absolute prostate-specific antigen value after androgen deprivation is a strong independent predictor of survival in new metastatic prostate cancer: data from Southwest Oncology Group Trial 9346 (INT-0162). J Clin Oncol 2006;24:3984–90.)

the rate of PSA decline after ADT also predicted outcome, specifically prostate cancer–specific mortality (D'Amico et al, 2005). If the pre-ADT PSA rise was rapid and the decline after ADT was slow the cancer-specific mortality was significantly worse compared with those with slow rises in PSA before ADT and rapid declines after ADT (D'Amico et al, 2004a, 2004b).

Almost without exception those no longer responding to ADT (androgen-refractory) remain on ADT. Therefore factors influencing survival in that disease state should be considered in this discussion. In most cases, available data are based on pre- or post-treatment responses to other systemic treatments (Galsky and Kelly, 2003). Consistently predictive variables (by both univariate and multivariate analysis) of survival in this state include performance status; serum lactate dehydrogenase (LDH), serum alkaline phosphatase, and hemoglobin levels; and PSA response to secondary therapy (Smalez et al, 2002). The survival of men treated on seven sequential chemotherapy protocols at one institution provided an early experience in developing predictive measures (Kelly et al, 1993). A 50% decline in PSA value in response to chemotherapy was one of the most significant variables predicting survival. A nomogram, based on a larger groups of patients, finds the presence of visceral disease, Gleason score, performance status, baseline PSA value, LDH and alkaline phosphatase levels, and hemoglobin level were useful in modeling prognosis (Smalez et al, 2002; Halabi et al, 2003).

GENERAL COMPLICATIONS OF ANDROGEN ABLATION

Osteoporosis

The increased number of men being placed on androgen ablation therapy much earlier in the course of their disease allows the chronic manifestations of the hypogonadal state to emerge. **Widespread androgen ablation therapy applied to an increasing aging population, already predisposed to loss of bone mineral density (BMD), has created an epidemic of osteopenia and osteoporosis.** Fragile bones increase the risk of skeletal fracture. **More than half of men meet the BMD criteria for osteopenia or osteoporosis—defined as more than 2.5 standard deviations below an age-specific reference mean—before the initiation of ADT** (Wei et al, 1999; Conde et al, 2004). The longer a man remains on ADT, the greater the risk of fracture (Daniell et al, 2000; Krupski et al, 2004). After 5 years on ADT, 19.4% of men experienced fractures compared with 12.6% of controls (Shahinian et al, 2005): over 15 years, cumulative incidence of fractures was 40%, compared with 19% in noncastrate controls (Melton et al, 2003). **It has been estimated that 4 years of ADT will place the average man in the osteopenic range** (Wei et al, 1999). Prostate cancer was associated with an increased odds ratio (95% confidence intervals) for hip fractures of 3.7 (3.1 to 4.4) in a large Danish population-based study (Abrahamsen et al, 2007). Rarely discussed even 10 years ago, skeletal health is now becoming a major concern of patients and their physicians (Chen et al, 2002).

Treatment of osteoporosis begins with recognition. BMD of the hip, as measured by dual-energy x-ray absorptiometry, should be considered on all men who are anticipated to be on long-term ADT (Bae and Stein, 2004; Diamond et al, 2004). Smoking cessation, weight-bearing exercise, and vitamin D and calcium supplementation can help improve BMD. **Daily supplementation of calcium and vitamin D is recommended by the National Institutes of Health at doses of 1200 to 1500 mg/day and 400 IU/day, respectively** (Michaelson et al, 2008). Supplementation decreases the incidence of nonvertebral fractures in men and women older than 65 years of age (Dawson-Hughes et al, 1997). Prevention of osteoporosis in men receiving ADT has been demonstrated in controlled studies using the bisphosphonate pamidronate (Smith et al, 2001). **In a randomized prospective study, once-weekly oral alendronate reversed bone loss associated with ADT and improved bone density; this benefit continued with ongoing treatment, suggesting chronic treatment is beneficial** (Greenspan et al, 2007, 2008). BMD also increased in men on ADT using the considerably more potent bisphosphonate zoledronic acid (Smith et al, 2003a). Bisphosphonate therapy should be considered in any man with evidence of osteopenia or osteoporosis (Bae and Stein, 2004). Transdermal estradiol also increases BMD in men with prostate cancer (Ockrim et al, 2004). Not surprisingly, serum testosterone and estradiol levels were much lower on men receiving LH-RH agonists compared with those on nonsteroidal antiandrogen therapy; interestingly, markers of bone turnover were significantly higher in men taking LH-RH agonists compared with those on nonsteroidal antiandrogen therapy, suggesting the nonsteroidal antiandrogens may help maintain BMD (Smith et al, 2003b).

Hot Flashes

For more than 100 years, hot flashes (also called hot flushes, vasomotor symptoms) have been recognized as a side effect of androgen ablation: in 1896 Cabot mentioned "uncomfortable flushes of heat, similar to those experienced by women at the time of menopause" in men undergoing castration for prostatic enlargement (Cabot, 1896; Stearns, 2004). **Described as a subjective feeling of warmth in the upper torso and head followed by objective perspiration, hot flashes are not life threatening but are among the most common side effects of androgen ablation, affecting between 50% and 80% of patients** (Moyad, 2002; Spetz et al, 2003; Nishiyama et al, 2004). Occurring both spontaneously and precipitated by changes in body position, ingestion of hot liquids, or changes in environmental temperature, the exact etiology of hot flashes remains undefined. Among the proposed mechanisms include increases in hypothalamic adrenergic concentrations and alterations in β-endorphins and calcitonin gene–related peptides acting on the thermoregulatory center in the hypothalamus (Yuzurihara et al, 2003). Hot flashes generally decrease both in frequency and intensity over time but often persist in some men (Holzbeierlein et al, 2004).

Treatment of hot flashes should be reserved for those who find them bothersome. Just as hot flashes are a consequence of alterations in the hormonal milieu the mainstay of treatment has been based on efforts to influence that milieu (Kouriefs et al, 2001). In a double-blind, placebo-controlled, crossover study, the progestational agent megestrol acetate (20 mg, twice per day) significantly reduced the frequency of hot flashes (Loprinzi et al, 1994). The dose can be reduced to 5 mg twice daily, which may help reduce the appetite-stimulating effect of this agent. The efficacy of cyproterone acetate is based on its progestational effects (Cervenakov et al, 2000). Dosing should start at 50 mg/day and be titrated to 300 mg/day. Estrogenic compounds, such as low-dose DES and transdermal estradiol, appear to be the most effective treatment, with up to 90% partial or complete

resolution of symptoms (0; Smith, 1994; Gerber et al, 2000). With estrogen compounds, however, the cure may be worse than the disease; painful gynecomastia and thromboembolic effects have limited the utility of this approach. Clonidine, a centrally acting α agonist that decreases vascular reactivity, has been used with mixed results: in a placebo-controlled study, transdermal clonidine did not significant decrease hot flashes (Loprinzi et al, 1994). Antidepressant agents, particularly the selective serotonin reuptake inhibitor venlafaxine (12.5 mg, twice daily), have reduced hot flashes in more than 50% of men (Quella et al, 1999; Loprinzi et al, 2004). In a phase 3 randomized, double-blind, placebo-controlled trial, the antiseizure agent gabapentin decreased hot flashes to a moderate degree (Loprinzi et al, 2009).

Sexual Dysfunction (Erectile Dysfunction and Loss of Libido)

The effects of ADT on sexual function are profound, as first described by Huggins and associates (1941): "Sexual desire and penile erections were absent in all cases following castration." **Loss of sexual functioning is not inevitable, however, with up to 20% of men on ADT able to maintain some sexual activity** (Rousseau et al, 1988; Clark et al, 2001). Specifically, between 10% and 17% of men undergoing ADT can maintain an erection adequate for intercourse (Tomic, 1983; Potosky et al, 2001). **Libido is more severely compromised, with approximately 5% of men maintaining a high level of sexual interest with ADT** (Potosky et al, 2001). Sexual desire is inversely related to the duration of androgen deprivation (Basaria et al, 2002). Loss of penile volume, penile length, nocturnal penile tumescence, and, for those undergoing medical ADT, testicular volume is common (Marumo et al, 1999; Higano, 2003).

Treatment for loss of libido is extremely difficult—if not impossible—for those on ADT. Likewise, medical treatments, such as oral phosphodiesterase type 5 inhibitors, or local treatments, such as intracavernosal injections of alprostadil, can still be effective in selected patients but may not be used over the long term. If there is any fairness in the negative effects of ADT on sexual function it is the decline in both libido and erectile functioning: despite no erections or desire, the majority of patients have little to no problem with their lack of sexual functioning (Potosky et al, 2001).

Cognitive Function

There is a strong suggestion that ADT is linked to subtle but significant cognitive declines in men with prostate cancer (Nelson et al, 2008). In both men and women the hypogonadal state is associated with declines in cognitive functioning (Gouchie and Kimura, 1991; Sherwin and Tulandi, 1996). Testosterone supplementation improves verbal fluency (Alexander et al, 1998) whereas other controlled studies have found no effect of such supplementation on memory (Sih et al, 1997). In one small study, men with prostate cancer randomized to ADT performed worse in cognitive studies compared with men with prostate cancer under surveillance (Green et al, 2002); the declines were associated with tasks requiring complex information processing (Green et al, 2004). Compared with tests for other cognitive domains, tests for spatial ability uniquely declined in men on intermittent hormone therapy (Cherrier et al, 2003). In men on neoadjuvant ADT before radiotherapy, cognitive functioning declined (Jenkins et al, 2005). Unfortunately, the studies examining the effects of ADT on cognitive functioning have been small and underpowered. Not surprisingly, given many side effects of ADT, quality of life worsens, specifically in men receiving flutamide in addition to castration, compared with placebo, in the domain of emotional functioning (Moinpour et al, 1998). A short course of ADT (36 weeks) increased depression and anxiety scores on formal neuropsychologic evaluations (Almeida et al, 2004); major depressive disorder was prevalent in 12.8% of men on ADT, 8 times greater than the national rate and 32 times the rate of men older than 65 years of age (Pirl et al, 2002). Finally, psychologic distress accounted for approximately one third of declines in fatigue severity scale in men undergoing ADT (Stone et al, 2000).

Changes in Body Habitus

A loss of muscle mass and increase in percent fat body mass are common in men undergoing ADT, and these changes are most pronounced with the initiation of ADT (van Londen et al, 2008). **After 1 year of ADT the mean overall weight increases from 1.8% to 3.8%, which translates into about 5 lb for a 200-lb man** (Smith et al, 2002; Berruti et al, 2002; Smith, 2004). One study found weight increased a median of 6 kg (13.2 lbs), with a range of 3 to 15 kg (6.6 to 33 lb) (Higano et al, 1996). Because lean body mass usually decreases by the same magnitude, the weight gain is largely due to an increase in fat mass (Levy et al, 2008). The average increase in fat mass ranges from 9.4% to 23.8% (Berruti et al, 2002; Smith et al, 2002; Smith, 2004). As noted by Huggins and colleagues (1941), ADT is associated with an increase in appetite and a low testosterone level is associated with increased insulin levels and abdominal girth (Seidell et al, 1990).

The Cancer Prevention Studies I and II (1959-1972 and 1982-1996, respectively) were large population-based studies of obesity and the risk of cancer mortality. In both studies the risk of death from prostate cancer in obese men was 34% (study I) and 36% (study II) when compared with men of normal weight (Rodriguez et al, 2001; Calle et al, 2003). Furthermore, men older than the age of 65 who engaged in vigorous exercise more than 3 hours per week had a 70% reduction in prostate-cancer specific death (Giovannucci et al, 2005). The body composition changes associated with ADT may portend a worse prognosis for men with prostate cancer. Regular vigorous exercise may help patients limit the accumulation of fat and even prevent prostate cancer progression.

Diabetes and Metabolic Syndrome

Given the changes in body habitus, it is not surprising that metabolic syndrome, a clustering of specific cardiovascular disease risk factors related to insulin resistance, is present in more than 50% of men undergoing long-term ADT (Braga-Basaria et al, 2006). Unlike classic metabolic syndrome, however, characterized by visceral fat accumulation, ADT preferentially increased subcutaneous fat: furthermore, high-density lipoprotein cholesterol concentrations were increased (Smith et al, 2008a). Short-term ADT affected serum lipid and hemoglobin A1c independent of statin therapy (Yannucci et al, 2006). In a small but carefully controlled prospective study, ADT significantly decreased insulin sensitivity in men with prostate cancer (Smith et al, 2006). These findings were supported by a larger observational study (73,196 men with prostate cancer) in which there was a significant risk of developing diabetes with ADT (Keating et al, 2006). In a subset analysis of a phase 3 trial of the selective estrogen-receptor modulator toremifene for

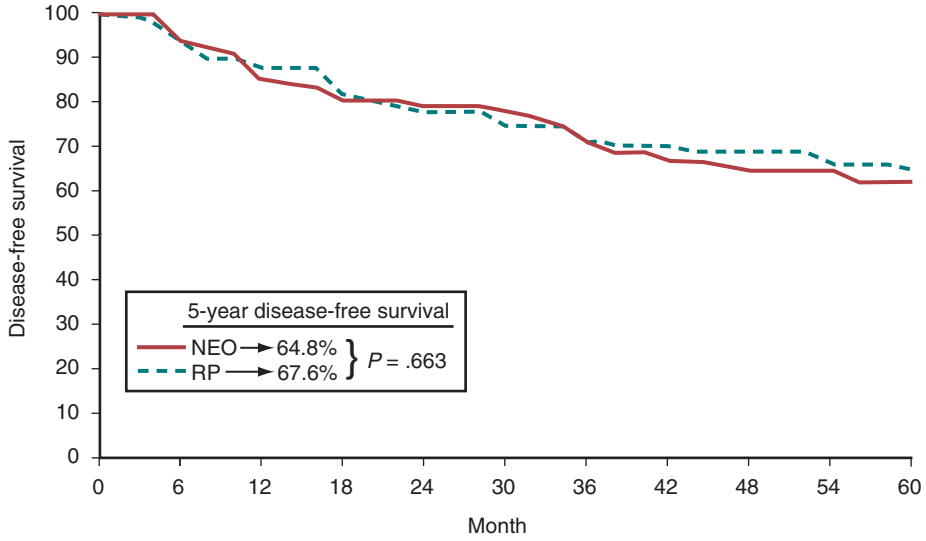

Figure 109–4. Biochemical failure rate in prostatectomy only (RP) and neoadjuvant androgen ablation plus prostatectomy (NEO) groups. (From Soloway MS, Pareek K, Sharifi R, et al. Neoadjuvant androgen ablation before radical prostatectomy in cT2bNxM0 prostate cancer: 5-year results. J Urol 2002;167:112–6.)

the prevention of osteoporosis in men undergoing ADT, placebo-treated patients had increases in low-density lipoprotein cholesterol and triglycerides, which were significantly decreased with toremifene (Smith et al, 2008b).

Cardiovascular Morbidity and Mortality

Given the generally adverse effects of ADT on body habitus, glucose metabolism, and lipid profiles, it is not surprising that studies have found that ADT is associated with increased cardiovascular morbidity and mortality. The effects appear to be most pronounced in men with lower-risk prostate cancer treated with ADT. In a large (22,816 subjects), population-based registry, newly diagnosed prostate cancer patients who received ADT for at least 1 year had a 20% higher risk of cardiovascular morbidity compared with similar men who did not receive ADT (Fig. 109–4) (Saigal et al, 2007). In men older than the age of 65 undergoing radical prostatectomy who also received ADT, the cumulative incidence of cardiovascular death was 5.5% over 5 years compared with 2.0% in those not receiving ADT (Tsai et al, 2007). On the other hand, in men with locally advanced prostate cancer treated with radiation therapy and ADT there was not an increase in cardiovascular mortality compared with men receiving radiation therapy alone (Efstathiou et al, 2008).

Gynecomastia

Depending on the agents used in ADT, alterations in breast tissue are common. **Gynecomastia, an increase in breast tissue, and mastodynia, or breast tenderness, may occur together or independently.** Estrogenic compounds, such as DES, induce gynecomastia in 40% of patients (Smith, 1996). Likewise, **the peripheral conversion of testosterone to estradiol associated with the antiandrogens induces gynecomastia at high rates: 66.3% of men taking 150 mg bicalutamide developed gynecomastia and 72.7% developed mastodynia.**

Prophylactic radiation therapy (10 Gy) has been used to prevent or reduce painful gynecomastia (Payne et al, 2002) as a result of DES or antiandrogen therapy. Radiation has no benefit once gynecomastia has begun. Liposuction and subcutaneous mastectomy have been used to treat established gynecomastia (Higano, 2003). The selective estrogen receptor modulator tamoxifen has been used to treat mastodynia (Serels and Melmann, 1998).

Anemia

The anemia associated with ADT is normochromic, normocytic, and very common: 90% of men receiving combined androgen blockade experienced declines in hemoglobin concentration of at least 10% (Strum et al, 1997). Although anemia can be further complicated by tumor growth in the marrow space, compromising hematopoiesis, even in men with nonmetastatic prostate cancer experience anemia with ADT (Choo et al, 2005). Unfortunately, anemia (defined as hemoglobin < 12 g/dL) is associated with a shorter survival in those anemic before initiation of ADT (Beer et al, 2004b). Declines in hemoglobin begin within 1 month of ADT initiation (Strum et al, 1997) and continue for 24 months (Choo et al, 2005). Compensatory mechanisms limit the symptomatic effects of anemia to a small subset (13%) of men (Strum et al, 1997).

The etiology of anemia is thought to be secondary to lack of testosterone stimulation of erythroid precursors and a decrease in erythropoietin production. In an animal model, however, erythropoietin levels increased after ADT (Voegeli et al, 2005). Whatever the etiology, clinically, patients respond to recombinant human erythropoietin. The anemia is reversible after stopping ADT but may take up to a year (Strum et al, 1997).

COMBINATION THERAPY

The advent of nonsurgical, reversible hormone therapy coupled with its profound effects on prostate cancer have led to a broad investigation of the combination of ADT with nearly every other treatment applied at prostate cancer. In some cases, most notably external-beam radiotherapy, the combination clearly improves the

outcomes: in others, most notably radical prostatectomy, there is no obvious benefit.

With Radical Prostatectomy

In nonrandomized clinical trials of ADT before radical prostatectomy the effects on the final surgical specimen were dramatic. Positive surgical margin rates fell from nearly 50% in hormonal intact patients to 15% in ADT patients (Lee et al, 1997). Glands with no evidence of malignancy (P0) were not uncommon. There was a nonsignificant trend toward improved biochemical outcome with neoadjuvant ADT. Based on these findings and a perception that neoadjuvant ADT reduced blood loss and rendered the procedure easier to perform, randomized prospective studies of 3 months of ADT following by radical retropubic prostatectomy were compared with radical retropubic prostatectomy alone (Witjes et al, 1997; Soloway et al, 2002; Klotz et al, 2003) (Table 109–5). **In both short (15 month mean follow-up) and longer (4 to 7 years) follow-up there was no significant difference in PSA progression between the groups** (see Fig. 109–4). The lack of improved biochemical recurrence in these three, randomized, prospective trials using 3 months of neoadjuvant ADT before RRP argues strongly that this combination is not indicated in the treatment of prostate cancer. Studies comparing longer term (8 months) to 3 months of ADT are underway, but at a 3-year interim analysis there is no difference in biochemical recurrence between the groups (Gleave et al, 2003).

With Radiation Therapy

Unlike the lack of long-term improved cancer-specific progression with the combination of ADT and radical prostatectomy there have been several phase 3 clinical trials that have shown a benefit with the combination of ADT and external-beam radiation therapy in overall survival, cancer-specific survival, or freedom from disease progression. The benefit appears to be in men with locally advanced disease and/or those with high-grade, high-risk disease.

A phase 3 study comparing radiation therapy alone to the combination of radiation therapy and orchiectomy in men undergoing pelvic lymph node dissection was closed owing to high frequency of progression in those receiving only radiation therapy (Granfors et al, 1998). A report at 9.3 years of median follow-up, based on 91 men randomized in this study demonstrated a significant difference in clinical progression (61% vs. 31%), overall mortality (61% vs. 38%), and prostate cancer–specific mortality (44% vs. 27%), after treatment by radiation therapy alone versus radiation therapy and orchiectomy, respectively (Granfors et al, 1998). This observation was supported by another study, randomizing men with locally advanced prostate cancer to radiation therapy alone versus radiation therapy combined with goserelin for 3 years (Bolla et al, 1997). The significant disease-free and overall survival advantage of the combination was confirmed at a long-term analysis of the trial (Fig. 109–5) (Bolla et al, 2002). **Clearly, in locally**

Phase 3 Randomized, Prospective Trials Comparing Primary Radiation Therapy (RT) Alone to a Combination with Androgen-Deprivation Therapy (ADT), or 3 versus 8 Months of ADT with Radiation Therapy

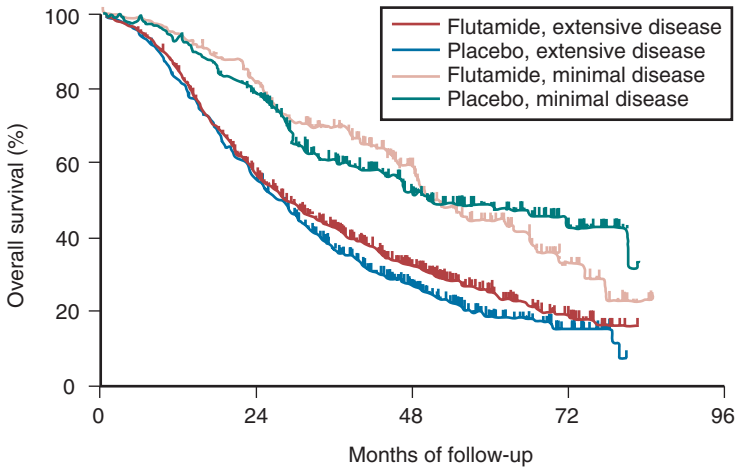
TRIAL (SOURCE)	TREATMENT ARMS	NO. PATIENTS	5-YEAR OVERALL SURVIVAL	5-YEAR CANCER-SPECIFIC SURVIVAL	5-YEAR PSA PROGRESSION
EORTC 22863 (Bolla et al, 1997, 2002)	Goserelin 3 yr vs. none	208 vs. 207	78% vs. 62%	94% vs. 79%	76% vs. 45%
RTOG 85-31 (Pilepich et al, 1997, 2005; Lawton et al, 2001)	Goserelin lifetime adjuvant vs. none until relapse	477 vs. 468	75% vs. 71%*	91% vs. 87%*	54% vs. 21%
RTOG 86-10 (Pilepich et al, 2001; Shipley et al, 2002)	Goserelin + flutamide 4 mo (2 mo neoadjuvant, 2 mo concurrent) vs. none	226 vs. 230	72% vs. 68%†	85% vs. 80%	28% vs. 10%
RTOG 92-02 (Hanks et al, 2003)	Goserelin 2 yr adjuvant vs. none	761 vs. 753	80% vs. 78.5%†	91.2% vs. 94.6%	28% vs. 55.5%
DFCI 95096 (D'Amico et al, 2004)	Goserelin or leuprolide + flutamide 6 mo vs. none	102 vs. 104	88% vs. 78%		
Granfors et al, 2006‡	Orchiectomy vs. none	45 vs. 46			
Canadian Multicenter (Crook et al, 2009)	Goserelin + flutamide 3 mo vs. 8 mo, neoadjuvant	184 vs. 194	81% vs. 79%†	94% vs. 93%†	58% vs. 65%†

*The 5-year overall survival and cancer-specific survival differences between the two study arms were not significant. At 10 years of follow-up, however, the combination of adjuvant goserelin and RT compared with RT alone was significantly different: for overall survival, 49% vs. 39%, respectively; for cancer-specific survival, 84% vs. 78%, respectively.

†Difference not significant.

‡During 14 to 19 years of follow-up, 87% of subjects in RT-only arm and 76% of those in the RT + orchiectomy arm died (log rank $P = .03$); prostate cancer mortality was 57% and 35%, respectively (log rank $P = .02$).

PSA, prostate-specific antigen.



advanced, high-risk disease the combination of radiation therapy with ADT is certainly better than radiation therapy alone. A number of trials have been designed to address the timing of ADT (length, neoadjuvant, adjuvant) (Crook et al, 2004): some of the results are summarized in Table 109–6 and in several review articles (D'Amico, 2002; Lawton, 2003). Changes in the dose and field of the external-beam radiation therapy make direct study to study comparisons difficult: unlike the uniformity of radical prostatectomy (complete ablation of the prostate), the optimum irradiation technique remains undefined.

Combined Androgen Blockade

Among all the efforts to improve the efficacy of ADT, none has been as widely studied as combinations of the various forms of hormone therapy, particularly if mechanistically nonredundant. For example, ablation of the source of androgen (castration) coupled with inhibition of LH-RH with DES was one of the first combinations studied clinically to suggest improved survival (Nesbit and Baum, 1951); on closer scrutiny in the first VACURG trial the survival advantage of this combination was lost (Blackard et al, 1973). Likewise, an early experience with an LH-RH analogue and an antiandrogen in 30 patients suggested improved outcomes compared with standard treatment (Labrie et al, 1983); **on extensive scrutiny in a meta-analysis of 27 prospective, randomized, international clinical trials of the combination of an antiandrogen with either castration or an LH-RH agonist the collective result was clinically insignificant** (Prostate Cancer Trialists' Collaborative Group, 2000).

The concept of adding an antiandrogen to surgical castration or LH-RH agonists is based on the idea that, after the elimination of testicular androgens through surgical or medical castration, adrenal androgens still contribute to prostate cancer progression (Labrie et al, 1988; Miyamoto et al, 1998; Miyamoto and Chang, 2000). The fact that serum testosterone does not drop to zero after surgical or medical castration is clear evidence for additional sources of androgen (Geller, 1985; Sandlow et al, 1988). The idea of trying to eliminate all sources of endogenous androgen in treating prostate cancer is not new: bilateral surgical adrenalectomy was performed with failure far outweighing success (Huggins, 1945). Also referred to, somewhat presumptuously, as total androgen blockade or maximum androgen blockade—as if such a state is actually achieved—the term *combined androgen blockade* is more appropriate. **The antiandrogens are nonspecific in blocking the binding of androgens to the AR: both testicular and adrenal androgens are affected. In concept, the approach is sensible and some clinical trials showed prolonged survival in patients treated with combined androgen blockade with advanced prostate cancer compared with standard ADT** (Crawford et al, 1989; Dijkman et al, 1997; Denis et al, 1998).

One study showing a survival advantage to combined androgen blockade compared the antiandrogen flutamide (250 mg, three times per day) in combination with daily leuprolide—a formulation not currently used—to placebo plus daily leuprolide in men with metastatic prostate cancer (Crawford et al, 1989). The combination therapy resulted in a significantly longer progression-free survival and longer overall median survival (35.6 vs. 28.3 months) when compared with the placebo-treated controls. In a hypothesis generating subset analysis, the authors found those with minimal metastatic disease (defined as the absence of metastases in the skull, ribs, long bones, and non-nodal soft tissue) enjoyed the largest survival benefit compared with similarly defined men receiving placebo. Another positive study compared orchiectomy plus the antiandrogen nilutamide to orchiectomy plus placebo

No. of patients at risk					
Flutamide, extensive disease	556	310	120	20	0
Placebo, extensive disease	539	295	101	16	0
Flutamide, minimal disease	141	115	58	13	0
Placebo, minimal disease	146	114	51	16	0

Figure 109–6. Overall survival among eligible patients with follow-up, according to treatment assignment and extent of disease: orchiectomy plus placebo versus orchiectomy plus flutamide. (From Eisenberger MA, Blumenstein BA, Crawford ED, et al. Bilateral orchiectomy with or without flutamide for metastatic prostate cancer. N Engl J Med 1998;339:1036–42.)

(Dijkman et al, 1997): at 8.5 years of follow-up the combined androgen blockade group had significantly longer median time to progression (21.2 vs. 14.7 months) and higher overall survival (37 vs. 29.8 months). Finally, a study of depot goserelin combined with flutamide was compared with orchiectomy and showed increased survival in the combined androgen blockade group (Denis et al, 1998).

Against the backdrop of these positive studies are a host of randomized trials showing no significant survival advantage for combined androgen blockade. A landmark randomized clinical trial comparing surgical castration alone to surgical castration combined with flutamide in men with metastatic prostate cancer showed no significant survival advantage for those undergoing combined therapy (Eisenberger et al, 1998). **Unlike the previous study suggesting an advantage of combined androgen blockade in men with minimal metastatic disease, stratifying outcome by disease burden (defined prospectively) was not significant** (Fig. 109–6).

In a clinical trial, when the variability in a possible outcome is large and the effect being studied may be small, confidence in the interpretation of the result is dependent on the size of the study. When several studies testing the same idea in presumably the same patient population demonstrate both positive and negative results, concerns about the existence of a real treatment effect increase. Such is the case with many of the studies of combined androgen blockade: when the study consists of only a few hundred men or is based on subset analysis of a larger study there is a risk that chance and not an antiandrogen drive the survival outcomes. Those favoring a role of combined androgen blockade in prostate cancer management point to the selected studies supporting their point of view, only to be met by those against combined androgen blockade who bring forth the negative studies that support their point of view.

Fortunately, the idea of combined androgen blockade has been very extensively studied: since the early 1980s, 27 randomized studies including 8275 men have been conducted, providing the basis for a meta-analysis comparing combined androgen blockade to standard ADT (Prostate Cancer Trialists' Collaborative Group, 2000). In these studies, 88% of patients had metastatic disease; the remainder had locally advanced disease. Interestingly, **in studies recording specific cause of death, 20% died of causes other than prostate cancer: not everyone with metastatic prostate cancer die of their disease.** In this meta-analysis the 5-year survival with combined androgen blockade was 25.4% compared with 23.4% with standard ADT, a nonsignificant gain in favor of ADT of 1.8% (Fig. 109–7). Studies including the steroidal antiandrogen cyproterone acetate had a slightly worse outcome of the combined androgen blockade study arms (5-year survival of 15.4% vs. 18.1% for ADT alone), suggesting increased non–prostate cancer deaths in those receiving cyproterone acetate. **When studies examining the outcomes of the nonsteroidal antiandrogens flutamide or nilutamide were considered independent of those with cyproterone acetate, the 5-year survival improved from 24.7% (standard ADT) to 27.6% for combined androgen blockade. This 2.9% improvement was significant, but the meta-analysis had a 0% to 5% range of uncertainty about the true size of the benefit.**

TIMING OF THERAPY

The timing of the initiation of ADT, although not as extensively studied as combined androgen blockade (CAB), remains one of the

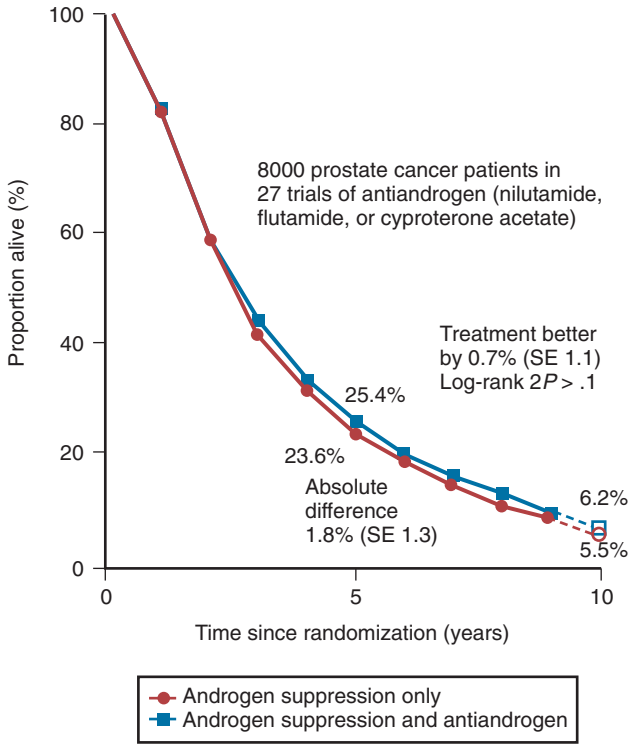


Figure 109–7. Meta-analysis of maximal androgen blockade versus testicular androgen suppression alone in 27 randomized trials and 8275 patients, with an average follow-up of about 5 years. Overall survival curves are for all men irrespective of the antiandrogen used. (From Prostate Cancer Trialists' Collaborative Group. Maximum androgen blockade in advanced prostate cancer: an overview of randomized trials. Lancet 2000;255:1491–8.)

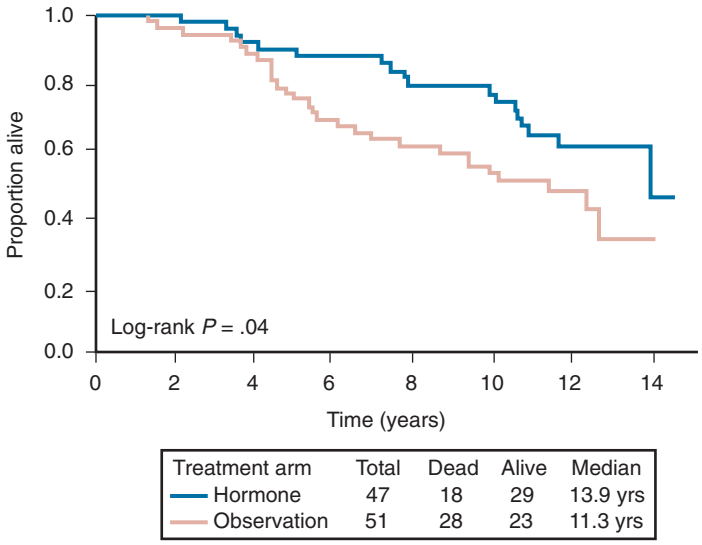
most contested areas of prostate cancer management. The spectrum of opinions range from ADT initiation at the first sign of primary prostate cancer failure (early) to ADT initiation only with objective evidence of distant metastatic disease (late) (Reese, 2000; Walsh et al, 2001; Loblaw et al, 2004; Miyamoto et al, 2004; Sharifi et al, 2005). Unfortunately, the clinical data to support the various perspectives are limited and it is not uncommon for proponents of a particular opinion to extrapolate data from one clinical state to another for which data do not exist. **There is no question that early ADT delays biochemical and clinical disease progression, but the effects of early ADT on survival remain unclear** (Ryan and Small, 2005). Likewise there is no question that ADT is indicated in symptomatic, metastatic disease. For the sake of this discussion ADT will be considered continuous, from initiation until death; intermittent ADT will be discussed in a subsequent section. Additionally, the focus of this discussion is on overall and prostate cancer–specific survival resulting from ADT.

It is useful to consider some facts about ADT and prostate cancer progression. First, the natural history of prostate cancer progression, even in the hormonally intact individual, is protracted. In a cohort of 304 men with a biochemical recurrence after radical prostatectomy, the median time from recurrence to metastasis was 8 years and from metastasis to death it was 5 years (Pound et al, 1999). In updates of this study the median time to prostate cancer–specific mortality had, initially, not been reached after 16 years of follow-up but was subsequently found to be 168 months (14 years) (Freedland et al, 2005; Makarov et al, 2008). Therefore, even in the absence of ADT, men with progressive prostate cancer live for a long time. **Second, despite dramatic clinical responses, men undergoing ADT will either die of a non–prostate cancer cause (estimated at 20% based on the combined androgen blockade meta-analysis) or will eventually demonstrate evidence of castration-resistant disease and die of prostate cancer.** In the randomized prospective study of orchiectomy with or without the antiandrogen flutamide, only 7% of men were still alive at 10 years after the initiation of ADT (Tangen et al, 2003). In a study using a 5% national random sample of Medicare beneficiaries undergoing ADT for prostate cancer, the median overall survival after the initiation of ADT was 4.4 years and after 8 years only 4.5% of the population was still alive (Krupski et al, 2004). **Third, ADT is not an innocuous therapy: beyond the quality of life side effects discussed earlier, in a global sense men on ADT age more rapidly; the natural extension of more rapid aging is earlier death.** Therefore the long natural history of prostate cancer progression coupled with the inevitability of its progression after ADT initiation in a population with a growing risk of death from all causes should temper enthusiasm to indiscriminately apply this therapy to all men with progressive prostate cancer.

The questions about the timing of ADT are not new. In 1973 the results of a large (more than 1900 men) study performed by the then Veterans Administration of early versus late hormonal therapy were reported (Byar, 1973). **In men with metastatic disease, death from prostate cancer occurred in 48% of men treated early versus 47% of men treated late. In men with locally advanced disease, death from prostate cancer occurred in 14% of men treated early versus 17% of patients treated late.** The lack of a survival benefit in men treated early coupled with the known side effects of therapy support the recommendations that hormonal therapy should be instituted in men with symptomatic disease. Since that time, several randomized studies have applied ADT at different times in the natural history of prostate cancer; the results of those studies must be considered within the context of when ADT is used and the circumstances of the study.



Immediate versus Delayed Androgen-Deprivation Therapy in Clinically Localized Disease

In the bicalutamide Early Prostate Cancer (EPC) program, men were randomized to bicalutamide 150 mg or placebo in addition to standard for care (See et al, 2003). End points of these trials include overall survival, progression-free survival, and tolerability. **In the subset of men with clinically localized disease the overall survival was significantly worse in those undergoing ADT with 150 mg bicalutamide compared with placebo** (Iversen, 2004). No specific cause for this decline in overall survival with ADT was identified, but it appeared to be the result of increased deaths from non–prostate cancer causes for those on bicalutamide. It is unlikely the excessive death rate in the bicalutamide study arm in those with clinically localized disease will lose significance with longer follow-up.

In a community-based cohort study (Prostate Cancer Outcomes Study), men with localized prostate cancer treated with primary ADT within 1 year of diagnosis had a 91% cancer-specific survival but only a 66% overall survival at 5 years (Graff et al, 2007). A larger study of 19,271 men 66 years or older with localized prostate

cancer who did not receive definitive local therapy found that primary ADT was associated with lower 10-year prostate cancer-specific survival compared with those on conservative management (Lu-Yao et al, 2008). Although this finding could be the result of more aggressive prostate cancers requiring immediate primary ADT, there was no increase in 10-year overall survival with primary ADT. The authors conclude "primary ADT is not associated with improved survival in the majority of elderly men with localized prostate cancer when compared with conservative management" (Lu-Yao et al, 2008). Finally, in a retrospective, matched cohort study of adjuvant ADT (within 90 days of node-negative, radical prostatectomy) compared with those who did not have ADT there was a 3% improved prostate cancer–specific survival (98% vs. 95%, respectively, $P = .009$) but no improvement in overall survival (83% in both groups) (Siddiqui et al, 2008).

These observations are important for several reasons. First, these observations resoundingly answer the claim that "ADT can't hurt, so why not use it early." **In the EPC study, men *without* ADT had significantly better survival.** Second, when ADT is applied in situations when the risk of death from prostate cancer is already low, demonstration of a prostate cancer–specific survival benefit from that therapy will be very difficult. If ADT itself increases overall mortality compared with no ADT, then a demonstration of a prostate cancer–specific benefit will be nearly impossible. Third, men with localized, low-risk prostate cancer should not be treated with ADT without first being informed of these findings. Avoidance of prostate cancer progression and death may come at the expense of a higher overall death rate. These data support the hypothesis that the more rapid aging associated with ADT will bring men with low-risk prostate cancer more quickly to their deaths.

Treatment arm	Total	Dead	Alive	Median
Hormone	47	18	29	13.9 yrs
Observation	51	28	23	11.3 yrs

Figure 109–8. Long-term overall survival of man randomized to immediate hormone therapy compared with observation after radical prostatectomy with pelvic lymphadenectomy in men with node-positive prostate cancer: at median 11.9 year follow-up, overall survival in the immediate hormone therapy group was 64% (30/47) compared with 45% (23/51) in the observation group ($P = .04$, log-rank). (From Messing EM, Manola J, Yao J, et al. Immediate versus deferred androgen deprivation treatment in patients with node-positive prostate cancer after radical prostatectomy and pelvic lymphadenectomy. Lancet Oncol 2006;7:472–9.)

Immediate versus Delayed ADT in Lymph Node Metastatic Prostate Cancer

A randomized prospective study of immediate ADT compared with delayed ADT was performed in men with histologic evidence of metastatic prostate cancer in regional lymph nodes after radical prostatectomy by the Eastern Cooperative Oncology Group (ECOG). At the time of the initial report, **at 7.1 years of median follow-up, overall survival significantly ($P < .02$) favored the immediate ADT group compared with the delayed ADT group: in the immediate ADT group, only 3 of the 7 deaths were due to prostate cancer compared with 16 of the 18 cancer-specific deaths in the delayed ADT group** (Messing et al, 1999). In an updated report, median overall survival was significantly longer in the immediate ADT compared with the delayed ADT group, 13.9 versus 11.3 years, respectively (Fig. 109–8) (Messing et al, 2003, 2004). Eight of 18 men in the immediate ADT group died of prostate cancer compared with 25 of 28 in the delayed ADT group. Given the previous discussion of the increased non–prostate cancer death rate with 150 mg bicalutamide, it is interesting that there have been proportionally more non–prostate cancer deaths in the immediate ADT group (55%) compared with the delayed therapy group (11%). Nevertheless, **based on this randomized, prospective trial, there appears to be a benefit to immediate ADT in those with histologic evidence of lymph node metastases at the time of radical prostatectomy.**

There have been several criticisms of this study (Eisenberger and Walsh, 1999). First, the study was designed to enroll 240 patients yet only enrolled 100. When a large difference in outcome is found in a small study there is a risk of a type I error (assuming a treatment has an effect when in reality it does not). There was no evidence for an imbalanced randomization, but unrecognized prognostic factors can influence outcomes in smaller studies. Second, Gleason grading was not centralized and the absence of a correlation between histologic grade and survival suggests an imbalance may exist. This concern was partially addressed by a central pathologic review in a blinded fashion of a subset (51%) of the initial specimens. Based on this reanalysis there was no significant difference in outcomes by treatment arm. Third, those on delayed ADT experienced disease progression and death from prostate cancer that was much more rapid than would have been expected from contemporary series of node-positive patients (Zincke et al, 1992; deKernion et al, 1990; Cadeddu et al, 1997). In contrast to the ECOG study, an observational study of 731 men with node-positive prostate cancer after radical prostatectomy between 1991 and 1999 found no significant difference in overall survival in those who received adjuvant ADT (within 120 days of surgery, $n = 209$) compared with those who did not (Wong et al, 2008).

The magnitude of the difference observed in the ECOG study has not been in seen in larger similar, but not identical, patient populations. A European Organization for the Research and Treatment of Cancer (EORTC) trial of immediate versus delayed ADT in pN1-3M0 patients without local treatment of the primary tumor was performed in 302 patients, of which 115 were randomized to delayed ADT and 119 to immediate ADT (Schröder et al, 2004). At a median follow-up of 13 years, the median overall survival on immediate ADT was 7.6 years (95% CI, 6.3 to 8.3 years) versus 6.1 years (95% CI, 5.7 to 7.3 years) in the delayed ADT group. The 10-year cumulative incidence of death from prostate cancer was 55.6% in the delayed ADT group versus 52.1% in

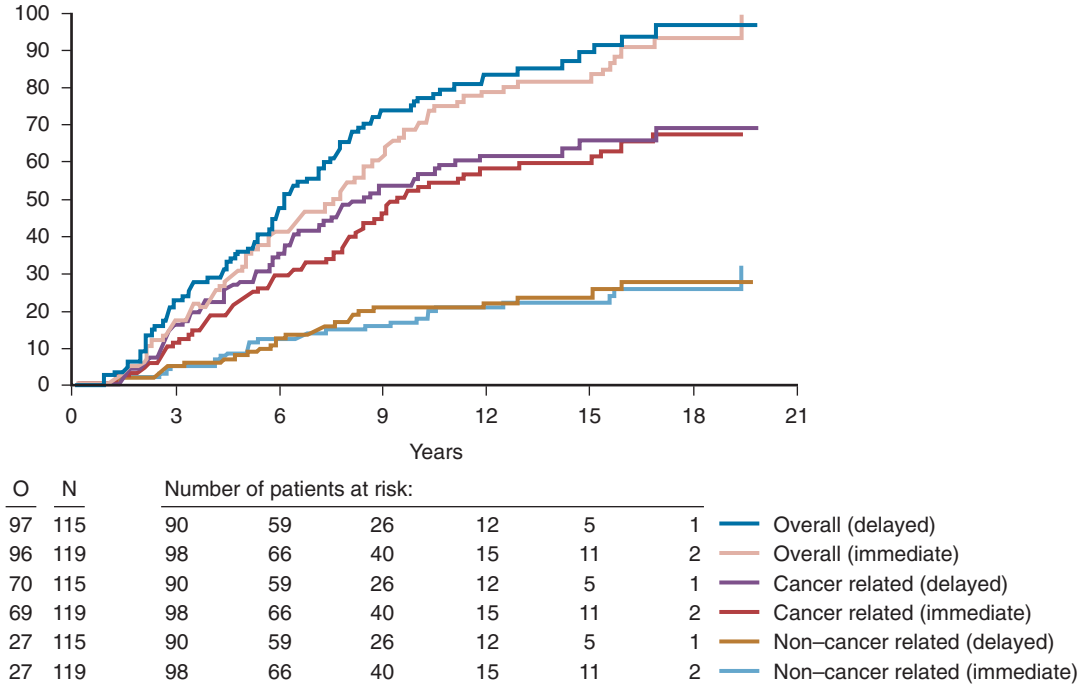


Figure 109–9. Overall mortality, cancer-related mortality, and non–cancer-related mortality in early versus delayed androgen-deprivation therapy in men with T2-T3pN1-3M0 prostate cancer without local treatment of the primary tumor. (From Schröder FH, Kurth KH, Fossa SD, et al. Early versus delayed endocrine treatment of T2-T3 pN1-3 M0 prostate cancer without local treatment of the primary tumor: final results of European Organisation for the Research and Treatment of Cancer Protocol 30846 after 13 years of follow-up [a randomized controlled trial]. Eur Urol 2009;55[1]:14–22.)

the immediate ADT group (Schröder et al, 2009) (Fig. 109–9). **Based on these data, 20.8 patients would need to be treated with immediate ADT to spare one life at 5 years and 28.6 would need to be treated to spare one life at 10 years.**

Immediate versus Delayed ADT in Locally Advanced, Asymptomatic Metastatic Disease or Disease Not Suitable to Local Treatment

A trial of immediate versus delayed ADT in men with locally advanced or asymptomatic prostate cancer was conducted by the Medical Research Council (MRC) Prostate Cancer Working Group Investigators Group (1997). A total of 934 men were included (500 M0, 261 M1, and 173 Mx), with 469 randomized to immediate ADT and 465 randomized to delayed ADT. **As originally reported there was a significant survival advantage in the M0 group; on longer follow-up the overall survival advantage is not significant** (Kirk, 2004). Overall, men in the delayed ADT arm died significantly more often from prostate cancer and had significantly more symptoms related to disease progression. Based on these data the benefits of immediate ADT would seem to support its use.

There have been many criticisms of the MRC trial. First, 6% (29/465) of men in the delayed ADT arm "died from prostate cancer before treatment could be started," meaning they died without ever receiving ADT. Delayed ADT is not the same as no ADT. Second, 173 of subjects included in the study were not staged (Mx). When nearly one in five men could have been incorrectly randomized, the impact on the study's outcome could be significant. Third, almost 10% of men in the delayed group were treated only when they had developed spinal cord compression or pathologic fractures. The emergency implementation of hormonal therapy is a rare event in patients followed closely; it certainly should not occur in 10% of patients. Finally, the lack of a standardized follow-up protocol—follow-up and management were otherwise according to the participating clinician's normal practice—may provide meaningful "real world" result but likely introduces major deviations from rigorous clinical trial design.

Because the majority of men in the MRC study have died (92.5% in immediate ADT, 93.6% in delayed ADT), the data are now mature and unlikely to change significantly in the future (Kirk, 2004). **Time to death from prostate cancer remains significantly in favor of the immediate ADT group (P = .019), whereas time to death from any cause is not significantly different between the groups (P = .0914).** The total difference in prostate cancer–specific deaths was 46 men: 241 died of prostate cancer in the immediate ADT study arm, 287 in the delayed ADT arm (Kirk, 2004); the impact of the 29 men in the delayed ADT group who never received ADT on this result is unknown but could reasonably be considered significant. Unlike the increased overall mortality for immediate ADT found in the EPC study of bicalutamide 150 mg for localized, low-risk disease, no similar increase was observed in immediate ADT in the MRC study of a higher-risk cohort.

Immediate versus delayed ADT was studied in another group (n = 935) of men not suitable for local treatment (refused local treatment, had decreased life expectancy, advanced local tumor stage and/or severe comorbidities) (Studer et al, 2006). Unlike the MRC study, immediate ADT resulted in a significant, albeit small improvement in overall survival but no difference in prostate cancer–specific mortality or overall symptom-free survival. Interestingly, **in the delayed ADT study arm, 25.6% died without ever needing treatment.**

Immediate versus Delayed ADT: Integrating the Data

With the emerging data from ongoing clinical trials and the recently published results of new studies, it is possible to consider the timing of ADT from the perspective of the natural history of the disease.

1. **There is no survival benefit to immediate ADT in low-risk, localized prostate cancer.** In fact, from the perspective of overall survival, men treated in this fashion do significantly worse than those spared ADT in this setting.
2. **In locally advanced, asymptomatic metastatic and clinically present but undefined prostate cancer treated in a community setting with limited disease monitoring, immediate ADT results in significantly better prostate cancer–specific survival but not better overall survival. On the other hand, in men deemed not suitable for local treatment, immediate ADT improved overall survival but not prostate cancer–specific survival.**
3. **In node-positive disease without primary treatment there is no significant advantage to immediate ADT, although on balance there is a 1.5-year median survival advantage. In node-positive disease with radical prostatectomy there is a significant survival advantage favoring immediate ADT, with a 2.6-year difference in median overall survival.**

In Figure 109–10, conceived and developed by Iversen, one can see the relative gain and loss in survival from adjuvant ADT based on the stage of the disease. In low-risk disease the toxicity of ADT exceeds any prostate cancer–specific benefit, so there is an overall net loss in survival. For locally advanced disease, particularly in combination with local treatment directed at the primary tumor, ADT provides a net gain in survival. As the disease progresses the inevitability of castration-resistant progression and prostate cancer-specific death limits the magnitude of the nonetheless real benefit of ADT. **Because life is more than simply survival, discussions about ADT should include the expected impact on quality of life.**

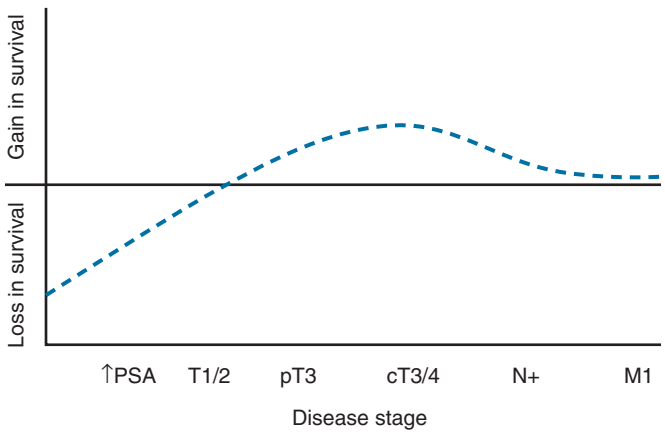

Figure 109–10. Based on available clinical trial data, the hypothetical gain or loss in overall survival based on the time in the natural history of the disease that ADT is instituted, as demonstrated by the *dotted line*. (Concept and figure courtesy of P. Iversen.)

ECONOMIC CONSIDERATIONS

In the United States, the cost of drug therapy for ADT (LH-RH agonists) in the Medicare Program was $761 million in 1997 and rose to $1.2 billion in 2003 (Holtgrewe et al, 2000; Shahinian et al, 2006). Indeed, in 2003, LH-RH agonists were the second highest Medicare Part B expenditure. This expense is not unique to the United States: in 1997, the annual cost of these agents in Sweden was $17 million and in Germany the annual cost was $142 million. In a study of 96 men undergoing ADT for prostate cancer over a 10-year period the cost of LH-RH agonists ranged from greater than 10.7 to 3.2 times the cost of bilateral orchiectomy and the cost of combined androgen blockade was 17.3 to 20.9 times greater (Mariani et al, 2001). **Clearly the cost of ADT, as currently being delivered, is extraordinary.**

Although DES is associated with increased cardiovascular toxicity, from a strictly cost point of view, it is the least expensive form of ADT, particularly at the 1-mg/day dose, with no prophylactic breast irradiation (Mariani et al, 2001). **There is no significant survival advantage of LH-RH agonists over orchiectomy, so from an economic perspective LH-RH agonists would only be more cost effective than orchiectomy if a patient only lived for a few months after initiation of ADT. The 3-month formulations of leuprolide acetate and goserelin become more expensive than orchiectomy on the administration of a second 3-month depot;** specifically, the break-even rate for leuprolide acetate is 4.2 months and that of goserelin is 5.3 months compared with orchiectomy (Mariani et al, 2001).

Combined androgen blockade is the most expensive form of ADT. Although there is no significant benefit of this treatment over orchiectomy alone (Eisenberger et al, 1998), some patients may experience a large benefit. Assuming a cost-effectiveness threshold of $100,000—meaning the expense of combined androgen blockade minus the expense of orchiectomy—for each quality of life year, combined androgen blockade would need to decrease the risk of disease progression by 20% compared with orchiectomy to be considered cost effective (Seidenfeld et al, 1999). **The earlier medical ADT is initiated, the more expensive it becomes: in models examining the cost-effectiveness, ADT was most cost effective if initiated after patients became symptomatic from prostate cancer metastases** (Bayoumi et al, 2000). In this model, LH-RH agonists, nonsteroidal antiandrogens or combined androgen blockade, had higher costs and lower quality-adjusted survival than orchiectomy.

If orchiectomy is just as effective and so much less expensive, why is it not more widely used? In two studies that offered orchiectomy versus medical therapy for ADT, 70% of patients chose medical therapy (Iversen et al, 1998). Clearly, patients (and physicians) choose medical ADT for reasons other than efficacy or expense. Indeed, the use of ADT in all-stage prostate cancer has increased significantly between 1989 to 2001: for example, primary ADT rose from 32.8% to 48.2% in men with high-risk disease (Cooperberg et al, 2003). **Avoiding the largely psychologic quality of life issues unique to orchiectomy (disfigurement, permanence) comes at an expense that would seem disproportionate to the risk, and yet society has chosen to accept this expense.**

Perhaps most sobering about the costs of ADT is the significant variability with which ADT is used by urologists. In a study of 61,717 American men with prostate cancer from 1992 until 1999,

the total variance in the use of ADT attributable to the urologist was approximately 21%, which was significantly more than that attributable to tumor characteristics (approximately 9%) or patient characteristics (approximately 4%). In other words, "the urologist who sees the patient may be a more important determinant of whether that patient will receive androgen deprivation than the characteristics of the tumor (e.g., stage or grade) or the patient (e.g., age and comorbidity)" (Shahinian et al, 2006). The challenge for urologists is to offer this expensive form of treatment to those who need it and to avoid ADT in those who do not (Schellhammer, 2006).

THE FUTURE OF HORMONE THERAPY

Intermittent Androgen-Deprivation Therapy

The use of intermittent ADT is being studied in at least seven large randomized phase 3 clinical trials (Boccon-Gibod et al, 2007). The rationale for intermittent ADT is based on two complementary ideas. First, in preclinical animal models (Shionogi breast cancer tumor, LNCaP prostate cancer tumor) exposure to androgen deprivation on a intermittent, rather than continuous, basis lengthened the time to the emergence of androgen-refractory cancer growth (Akakura et al, 1993; Sato et al, 1996). Because androgen-refractory prostate cancer is synonymous with lethal prostate cancer, any manipulation of the hormonal milieu that can delay progression into this state would be welcomed. Second, many patients (and their physicians) have increasingly questioned the real benefit of continuous ADT, given the profound and often debilitating side effects associated with its use. With readily reversible ADT, recovery of normal testosterone levels should occur when androgen ablation is stopped. In theory, the quality of life side effects of ADT on intermittent treatment should be some fraction of those side effects when ADT is used continuously.

There are several reasons to await the results of the randomized trials of intermittent ADT before it is adopted as a standard treatment for advanced prostate cancer (Bhandari et al, 2005). **There is no evidence cycling androgen levels in men with prostate cancer will delay the emergence of androgen-refractory disease:** indeed, preclinical models using the Shionogi tumor strongly predicted neoadjuvant ADT would benefit men undergoing radical prostatectomy (Gleave et al, 1997) and yet the clinical trials resoundingly rejected this hypothesis. One could make a compelling argument why return of normal androgen levels associated with intermittent ADT would actually accelerate cancer progression, recalling the 87% tumor flare associated with testosterone administration (Fowler et al, 1982) or the exacerbations of symptoms with initial use of LH-RH agonists (Waxman et al, 1985). Quality of life should improve, but at what cost? The studies of intermittent ADT may bring the balance between quantity and quality of life into fuller view but not necessarily into clearly focus. Finally, based on a lack of adequate initial response to ADT, men with the most advanced prostate cancer (high PSA [mean 834 ng/mL], high alkaline phosphatase level, more frequent T4 stage, poorly differentiated tumors, and more than five skeletal metastases) are much less likely to be eligible for intermittent ADT (Salonen et al, 2008).

Key Points

- Androgen deprivation is one of the most effective therapies against any solid tumor; unfortunately, with time almost all prostate cancers will become androgen refractory.
- All current forms of androgen-deprivation therapy (ADT) function by either lower levels of circulating androgens or blocking the binding of androgen to the androgen receptor.
- All most all androgen-refractory prostate cancer remains sensitive to androgen; therefore ADT should be continued in castration-resistant disease.
- Relative to testosterone and dihydrotestosterone, the adrenal androgens are weak.
- There are four general forms of ADT: (1) ablation of androgen sources; (2) inhibition of androgen synthesis; (3) antiandrogens; and (4) inhibition of LH-RH and/or LH.
- Bilateral orchiectomy reduces testosterone by 90% within 24 hours of surgery.
- Nonsteroidal antiandrogens cause LH and testosterone levels to increase.
- Serious liver toxicity is a possible side effect of all antiandrogens.
- Antiandrogens can act agonistic on some tumors; antiandrogen withdrawal results in PSA declines in 15% to 30% of patients.
- Bicalutamide 150 mg monotherapy appears to have equivalent efficacy to medical or surgical castration for locally advanced or metastatic prostate cancer.
- All LH-RH agonists induce a testosterone increase on initial exposure. Coadministration of an antiandrogen functionally blocks the effects of testosterone.
- The magnitude and rapidity of the initial response to ADT are strong predictors of the durability of that response.
- The side effects of ADT include osteoporosis, hot flashes, sexual dysfunction, cognitive function alterations, changes in body habitus, gynecomastia, and anemia. These side effects can be progressive but are responsive to other treatments.
- There is no evidence 3 months of neoadjuvant ADT before radical prostatectomy improves biochemical outcomes.
- There is considerable evidence that ADT combined with external-beam radiation therapy improves overall survival, cancer-specific survival, and freedom from disease progression. The optimal timing and duration of ADT in this combination remains undefined.
- Based on a large meta-analysis of many clinical trials, combined androgen blockade with nonsteroidal antiandrogens provides about a 3% survival benefit at 5 years compared with standard ADT.
- The natural history of prostate cancer progression is protracted. Many men with evidence of disease will never require ADT.
- The use of ADT in low-risk, localized prostate cancer significantly increases overall (non–prostate cancer) mortality.
- In lymph node metastatic prostate cancer ADT improves overall survival if the primary tumor is removed but has no significant effect if the primary tumor is not removed.

Clinical Considerations
Cytotoxic Chemotherapy
Palliative Management
Novel Approaches
Conclusions

During the past several decades, endocrine manipulations developed to inhibit hormone-dependent prostate cancer growth and differentiation have constituted the basic strategy for the systemic control of prostate cancer. **Suppression of gonadal testosterone is the central principle of androgen-deprivation therapy (ADT), and this represents one of the most effective systemic palliative treatments known for solid tumors. Although it is extremely effective initially, virtually all patients eventually develop clinical evidence of treatment resistance. The outcomes with endocrine therapy have not changed significantly during the past few decades. Progression-free and overall survival figures of patients with metastatic disease with various methods of ADT have ranged from 12 to 20 months and 24 to 36 months, respectively** (Leuprolide Study Group, 1984; Crawford et al, 1989; Denis et al, 1993; Eisenberger et al, 1998). **Whereas somewhat longer survival times are reported in the more recent studies, this is most likely due to a "lead time" effect observed in contemporary populations of patients. The development of hormone resistance (i.e., cancer progression despite castrate levels of serum testosterone) is virtually a universal issue that affects all patients treated with ADT. Undoubtedly, further improvement in the outcome of patients with metastatic castration-resistant prostate cancer (CRPC) rests on the use of nonhormonal approaches that can effectively control the growth of the disease.**

During recent years, clinical investigations testing nonhormonal approaches have shown that systemic chemotherapy improves survival and quality of life in patients with castration-resistant (i.e., hormone-refractory) disease. Advances in the understanding of the biology of prostate cancer and characterization of key molecular pathways have added an important new dimension for treatment and the opportunity to design disease-specific targeted treatment approaches. Evolving data suggest that targeted approaches may play an important role in treatment of prostate cancer that may improve the outcome of our patients.

Progress in cell and molecular biology during the past decade has also enhanced our understanding of the mechanisms involved in the progression of prostate cancer, and this may provide the opportunity for rational planning of the appropriate timing of systemic therapeutic intervention with the objective of preventing or delaying progression of disease to lethal proportions. **Cancer cells demonstrating the castration-refractory phenotype can be identified during early stages of development of prostate cancer. Somatic alterations of the androgen receptor are frequently observed in patients with evidence of disease progression after androgen deprivation. It has also been demonstrated that during cancer progression, in the absence of androgens, a molecularly altered androgen receptor can still undergo ligand-dependent activation by other hormones such as estrogens and progestational agents and non–ligand-dependent activation by growth factors and cytokines** (Feldman and Feldman, 2001; Gelmann, 2002; Nelson WG et al, 2003). **The observation that the androgen receptor can still be activated even after long-term gonadal ablation suggests that it continues to play an important role in prostate cancer growth and may indeed be a reasonable target for treatment in patients with androgen-independent disease.**

In the presence of androgens, prostatic cancer growth is based on a cell proliferation rate that exceeds that of cell death (Isaacs et al, 1992). Androgen ablation primarily affects the cell death rate by inducing a swift apoptotic cascade. **As the tumor progresses the threshold of apoptosis progressively rises to a point at which cell proliferation exceeds cell death** (Berges et al, 1995). This results in the accumulation of endocrine-independent cells that eventually dominate the biologic behavior of prostate cancer in late stages.

Preclinical data suggest that the relatively low growth fraction expressed by adenocarcinoma of the prostate (compared with other common tumor types) may be a determining factor to explain the relative insensitivity to conventional cytotoxic chemotherapy. The proliferation rate of prostate cancer cells, which is directly proportional to the growth fraction, appears to increase with tumor progression especially after androgen ablation. Cell proliferation antigens, such as Ki-67 expressed by cycling cells (Cattoretti et al, 1992), may have important prognostic and therapeutic implications because most conventional cytotoxic chemotherapeutic agents available are usually more effective

in tumors with high proliferative rates such as lymphomas, small cell lung carcinomas, and germ cell tumors of the testis.

Changes in differentiation pathways in prostate cancer have been increasingly emphasized, particularly in the form of neuroendocrine/anaplastic cells (diSant'Agnese, 1995). Evolving experience with cytotoxic chemotherapy suggests that this aggressive clinical entity may be responsive to treatment regimens frequently employed for comparable tumors at other sites with similar phenotypic characteristics, such as small cell carcinoma of the lung. There is strong evidence to support the relationship between prostate cancer growth and various peptide growth factors (Djakiew et al, 1991; Steiner, 1993; Hofer et al, 1995; Sherwood et al, 1998; Kaplan et al, 1999; Nelson WG et al, 2003). Peptide growth factors may also exert their effects through the activation of the androgen receptor. Androgens are capable of inducing stromal production of various growth factors that could replace the androgen requirements for cell growth and differentiation (Lee, 1996). In addition, cytokines released primarily by stromal cells, such as interleukin-6, may also be important in the pathogenesis of prostate cancer. Indeed, small molecule inhibitors and other modalities of treatment (e.g., monoclonal antibodies) are being actively designed to target intracellular pathways associated with the expression of various growth factors and their receptors. Such strategies have involved inhibition of receptor tyrosine kinase activity and other intracellular molecular pathways of signal transduction as well as other critical pathways of cell growth and survival.

CLINICAL CONSIDERATIONS

Disease Assessment and Treatment Selection

Conventional staging criteria, such as the TNM staging system, do not describe the extent of disease beyond a simple anatomic classification. Treatment practices result in the creation of different disease states as described by Scher and colleagues (2008). **This system allows classification of patients in a more clinically applicable fashion and is increasingly being used throughout the literature.** Figure 110–1 **illustrates the natural history of prostate cancer relative to treatment practices and identifies the various paradigms according to the response status to different therapies.** Throughout this chapter prognostic and therapeutic considerations are largely based on the concepts proposed by this classification. A complete disease evaluation is required to estimate the outcome and to make therapeutic decisions. Critical baseline components include extent of disease, mode and site of progression (rising prostate-specific antigen [PSA] level alone, new bone metastasis, visceral and nodal metastasis), presence or absence of symptoms, and response to prior endocrine treatment. Regular monitoring with serial bone scintiscans and serum PSA levels during hormone treatment provides important information in patients demonstrating evidence of disease progression while they are receiving hormone therapy. Table 110–1 describes the postprogression survival of patients with distant metastatic disease who demonstrated progression of disease while on hormone therapy in a large prospective trial (Eisenberger et al, 1995). The data shown in this table illustrate the broad range in postprogression survival according to the mode of progression (PSA only vs. bone scintiscan progression) and according to the extent of bone metastases. This observation highlights the importance of establishing precisely the predominant mode of progression in these patients and underlines the need for serial determinations of all laboratory, clinical, and radiologic data. It also provides critical information for the interpretation of subsequent clinical trials with regard to time-dependent outcomes, such as time to disease progression and survival. Usually the first manifestation of disease progression after hormone therapy is a rising serum PSA level. In patients with metastatic disease, a rise in serum PSA level precedes evidence of advancing disease in the bone scintiscan, and during this time patients may remain relatively asymptomatic (Eisenberger et al, 1995). Routine evaluation of serum testosterone levels may provide important information for the choice of treatment. This is especially important when there are reasons to suspect treatment noncompliance

Table 110–1.

Metastatic Castration-Resistant Prostate Cancer: Survival According to Mode of Progression

MODE OF PROGRESSION	MINIMAL DISEASE, MEDIAN SURVIVAL	EXTENSIVE DISEASE, MEDIAN SURVIVAL
PSA only	40 months	18 months
PSA + bone scintiscan	23 months	11 months

Data from Eisenberger M, Crawford E, McLeod D, et al. The prognostic significance of prostate specific antigen in stage D2 prostate cancer: interim evaluation of Intergroup 0105. Proc Am Soc Clin Oncol 1995;14:abstract 613.

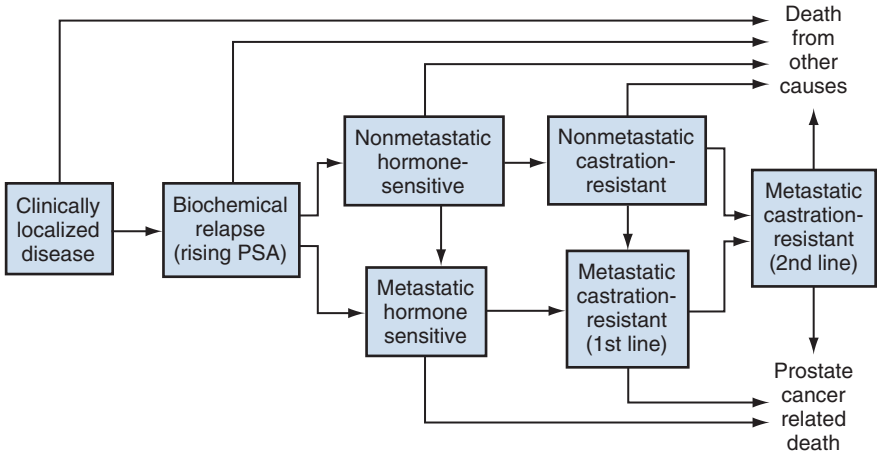

Figure 110–1. Prostate cancer clinical states. PSA, prostate-specific antigen. (Modified from Scher HI, Halabi S, Tannock I, et al. Design and end points of clinical trials for patients with progressive prostate cancer and castrate levels of testosterone: recommendations of the Prostate Cancer Clinical Trials Working Group. J Clin Oncol 2008;26:1148–59.)

or if the choice of prior treatment involved regimens known not to result in a sustained suppression of serum testosterone to castrate levels (e.g., monotherapy with nonsteroidal antiandrogens, low-dose estrogens, or 5α-reductase inhibitors).

For several years it has been postulated that discontinuation of androgen suppression in nonorchiectomized patients may adversely influence the outcome of disease in terms of progression and survival (Taylor et al, 1993). **Similarly, it has been shown that administration of exogenous testosterone and its derivatives may indeed produce a significant clinical flare that results in severe pain and neurologic, urologic, and coagulation complications in a small proportion of patients** (Fowler and Whitmore, 1981; Manni et al, 1988). **In a retrospective analysis of 205 patients with castration-resistant disease treated with chemotherapy, various prognostic variables including orchiectomy were evaluated by Hussain and associates** (1994). **A multivariate analysis failed to indicate a significant correlation between prior orchiectomy and improved time to disease progression and survival. In these patients all medical forms of androgen deprivation were discontinued at least 4 weeks before initiation of chemotherapy and, contrary to that suggested by Taylor and colleagues** (1993), **this did not significantly affect outcomes. Until this issue is resolved the general consensus is to maintain all patients on luteinizing hormone–releasing hormone (LH-RH) agonists indefinitely, even during the course of chemotherapy.**

Another important management aspect relates to antiandrogen withdrawal effects (Scher and Kelly, 1993; Small and Srinivas, 1995; Small et al, 2004). **Discontinuation of antiandrogens (both steroidal and nonsteroidal) can result in short-term clinical responses expressed by decreases in PSA levels, symptomatic benefits, and, less frequently, objective improvements in soft tissue and bone metastasis in a small proportion of patients.** Because of this, it has been recommended that in patients treated with antiandrogens in combination with other forms of androgen deprivation (e.g., LH-RH agonists) the first step should involve the discontinuation of these agents and careful observation including serial monitoring of PSA levels for a period of 4 to 8 weeks before embarking on the next therapeutic maneuver.

The next step is to determine which modality of treatment should be employed first, either administration of second-line hormonal manipulation or cytotoxic chemotherapy. There is an increasing body of data on second-line endocrine therapies suggesting that there may be a role for this approach before institution of chemotherapy (Small and Vogelzang, 1997; Small et al, 2004; Ryan 2006; Ang et al, 2009). Although initial response rates range between 20% and 60%, the median duration of such responses is short ranging, between 2 and 4 months. Agents that have been reported to produce some benefit in this setting include diethylstilbestrol (Smith et al, 1986), aminoglutethimide (Sartor and Myers, 1995), ketoconazole (Small et al, 2004), as well as corticosteroids (Storlie et al, 1995). **In view of the potential higher toxicity profile associated with cytotoxic chemotherapy, a sequential hormonal approach may be a reasonable alternative for those patients with relatively limited metastatic disease who remain asymptomatic at the time of disease progression (e.g., rising serum PSA value without other clinical manifestations).**

Another important consideration is the initial clinical assessment of the potential biologic behavior of these tumors. **Evolving data evaluating the role of PSA dynamics suggest that the PSA doubling time (PSADT) predicts for the rapidity of bone scintiscan progression and survival** (D'Amico et al, 2005; Armstrong et al, 2007; Robinson et al, 2008). **Patients with PSADTs shorter than 3 months have a particularly rapid clinical course and should be considered for more aggressive management approaches.** In addition, poorly differentiated and anaplastic/neuroendocrine tumors usually have a low likelihood of significant and durable responses to androgen deprivation. The anaplastic/neuroendocrine phenotype is rare and requires special therapeutic considerations. It has been suggested that systematic biopsies of disease sites in patients with clinically aggressive disease and relatively low serum PSA levels may demonstrate evidence of a neuroendocrine component by immunostaining, which may be of prognostic and therapeutic significance (see later). The usefulness of systematic biopsies in all patients with extensive metastasis and relatively low PSA levels, however, needs to be better defined before routine clinical application.

Nonmetastatic Castration-Resistant Disease

The extraordinary stage migration that has affected all stages of prostate cancer has profoundly modified the spectrum of clinical presentation of patients with castration-resistant disease. An increasing number of patients now begin androgen deprivation at very early stages of their disease course, often at the first sign of a rising PSA, before clinical and radiologic evidence of metastasis is present. This group of patients, termed the M0 (nonmetastatic) castrate-resistant subset, is now seen in increasing proportions in the clinic. Given the changes in treatment practices with early initiation of androgen deprivation, it is conceivable that these numbers will continue to increase. At this time data on the natural history of these patients are evolving.

A number of clinical trials using second-line hormonal manipulations and noncytotoxic interventions (bone-targeted treatments) focusing on time to development of bone metastasis are providing some useful information. A report of 201 patients from a prospective clinical trial comparing the effects of the bisphosphonate zoledronate and placebo in biochemically progressing (M0), castrate-resistant disease suggests that the time to bone scintiscan positivity may be very long. At 2 years, only 33% of these patients had evidence of bone metastasis, with a median time to bone metastasis in this group of 30 months. The baseline PSA level (>10 ng/mL) and the PSA velocity independently predicted time to bone metastasis and survival (Smith et al, 2005). In a retrospective review of a similar group of patients prescribed ADT before the development of metastatic disease the median time to clinical metastasis was 9 months. The pretreatment PSA level and the PSA nadir on ADT predicted this outcome (Dotan et al, 2005). The wide difference observed with these two reports (30 months vs. 9 months for time to bone scan metastasis) underscores the heterogeneity of this group of patients and the need for careful prospective evaluation. Their outcome is dependent on various factors, among which are pre-ADT characteristics (pretreatment PSA level, PSADT, initial stage, Gleason score), as well as response to hormonal treatment. The rate of progression may be estimated by PSA constructs such as PSADT and PSA velocity.

At present there is no consensus on the most appropriate management for these patients, although the sequential endocrine approach is the most commonly employed therapeutic modality.

A trial investigating the relative efficacy of a second-line endocrine manipulation versus a docetaxel-based chemotherapy regimen in nonmetastatic disease was closed prematurely because of poor accrual. More data are needed to characterize the natural history and to define the best treatment approach of the M0 castrate subset, which represents an important evolving new paradigm.

Metastatic Castration-Resistant Disease

Patients with metastatic CRPC represent a heterogeneous group with respect to their clinical status at the time of disease progression (Fig. 110–2). **Metastatic adenocarcinoma of the prostate has an overwhelming predilection to involve the bone.** Although the explanation for this unique metastatic pattern has not been completely elucidated it probably reflects the combination of various biologic factors starting at the time of metastatic spread. Circulating prostatic adenocarcinoma cells are arrested in the cortical and medullary bone spaces, where they subsequently adhere to bone surfaces through specific receptors for moieties such as integrins, collagens, laminin, and other bone-derived proteins. Cell growth is subsequently promoted by various factors such as hormones, growth factors, and stromal-epithelial biologic interactions, most of which operate in the bone marrow. Expansion of tumor from the bone may cause pain, compression, or pathologic fractures, and extensive bone marrow replacement may cause impairment in hematologic function.
